ASM HANDBOOK®

VOLUME

6

WELDING BRAZING AND SOLDERING

ASM INTERNATIONAL®

WELDING, BRAZING, AND SOLDERING WAS PUBLISHED IN 1993 AS VOLUME 6 OF THE ASM HANDBOOK. THE VOLUME WAS PREPARED UNDER THE DIRECTION OF THE ASM HANDBOOK COMMITTEE.

VOLUME CHAIRMEN

THE VOLUME CHAIRMEN WERE DAVID LEROY OLSON, THOMAS A. SIEWERT, STEPHEN LIU, AND GLEN R. EDWARDS.

AUTHORS

- **LAMET** UFRGS
- **BRUNO L. ALIA**
- **RICHARD L. ALLEY** AMERICAN WELDING SOCIETY
- **WILLIAM R. APBLETT, JR.**
- **WILLIAM A. BAESLACK III** THE OHIO STATE UNIVERSITY
- **WILLIAM BALLIS** COLUMBIA GAS OF OHIO
- **CLIFF C. BAMPTON** ROCKWELL INTERNATIONAL SCIENCE CENTER
- **PROBAL BANERJEE** AUBURN UNIVERSITY
- **JOHN G. BANKER** EXPLOSIVE FABRICATORS INC.
- **ROBERT G. BARTIFAY** ALUMINUM COMPANY OF AMERICA
- **ROY I. BATISTA**
- **ROY E. BEAL** AMALGAMATED TECHNOLOGIES INC.
- **RAYMOND E. BOHLMANN** MCDONNELL AIRCRAFT COMPANY
- **SÉRGIO D. BRANDI** ESCOLA POLITECNICA DA USP
- **JOHN A. BROOKS** SANDIA NATIONAL LABORATORIES
- **DONALD W. BUCHOLZ** IBM FEDERAL SYSTEMS CORPORATION
- **PAUL BURGARDT** EG&G ROCKY FLATS PLANT
- **ROGER A. BUSHEY** THE ESAB GROUP INC.
- **CHRIS CABLE** FEIN POWER TOOL
- **RICHARD D. CAMPBELL** JOINING SERVICES INC.
- **HOWARD CARY** HOBART BROTHERS COMPANY
- **HARVEY CASTNER** EDISON WELDING INSTITUTE
- **ALLEN CEDILOTE** INDUSTRIAL TESTING LABORATORY SERVICES
- **HARRY A. CHAMBERS** TRW NELSON STUD WELDING
- **C. CHRIS CHEN** MICROALLOYING INTERNATIONAL INC.
- **SHAOFENG CHEN** AUBURN UNIVERSITY
- **SHAO-PING CHEN** LOS ALAMOS NATIONAL LABORATORY
- **BRYAN A. CHIN** AUBURN UNIVERSITY
- **MICHAEL J. CIESLAK** SANDIA NATIONAL LABORATORIES
- **RODGER E. COOK** THE WILKINSON COMPANY
- **STEPHEN A. COUGHLIN** ACF INDUSTRIES INC.
- **MARK COWELL** METCAL INC.
- **RICHARD S. CREMISIO** RESCORP INTERNATIONAL INC.
- **CARL E. CROSS**
- **CRAIG DALLAM** THE LINCOLN ELECTRIC COMPANY
- **BRIAN DAMKROGER** SANDIA NATIONAL LABORATORIES
- **JOSEPH R. DAVIS** DAVIS AND ASSOCIATES

- **JANET DEVINE** SONOBOND ULTRASONICS
- **PAUL B. DICKERSON**
- **RAY DIXON** LOS ALAMOS NATIONAL LABORATORY
- **SUE DUNKERTON** THE WELDING INSTITUTE
- **KEVIN DUNN** TEXAS INSTRUMENTS INC.
- **CHUCK DVORAK** UNI-HYDRO, INC.
- **JIM DVORAK** UNI-HYDRO, INC.
- **ROBERT J. DYBAS** GENERAL ELECTRIC COMPANY
- **THOMAS W. EAGAR** MASSACHUSETTS INSTITUTE OF TECHNOLOGY
- **GLEN R. EDWARDS** COLORADO SCHOOL OF MINES
- **GRAHAM R. EDWARDS** THE WELDING INSTITUTE
- **W.H. ELLIOTT, JR.** OAK RIDGE NATIONAL LABORATORY
- **JOHN W. ELMER** LAWRENCE LIVERMORE NATIONAL LABORATORY
- **STEVEN C. ERNST** EASTMAN CHEMICAL COMPANY
- **WILLIAM FARRELL** FERRANTI-SCIAKY COMPANY
- **JOEL G. FELDSTEIN** FOSTER WHEELER ENERGY CORPORATION
- **DAVID A. FLEMING** COLORADO SCHOOL OF MINES
- **JAMES A. FORSTER** TEXAS INSTRUMENTS INC.
- **MICHAEL D. FREDERICKSON** ELECTRONICS MANUFACTURING PRODUCTIVITY FACILITY
- **EDWARD FRIEDMAN** WESTINGHOUSE ELECTRIC CORPORATION
- **R.H. FROST** COLORADO SCHOOL OF MINES
- **CHARLES E. FUERSTENAU** LUCAS-MILHAUPT INC.
- **EDWARD B. GEMPLER**
- **STANLEY S. GLICKSTEIN** WESTINGHOUSE ELECTRIC CORPORATION
- **JOHN A. GOLDAK** CARLETON UNIVERSITY
- **ROBIN GORDON** EDISON WELDING INSTITUTE
- **JERRY E. GOULD** EDISON WELDING INSTITUTE
- **JOHN B. GREAVES, JR.** ELECTRONICS MANUFACTURING PRODUCTIVITY FACILITY
- **F. JAMES GRIST**
- **JOHN F. GRUBB** ALLEGHENY LUDLUM STEEL
- **MAOSHI GU** CARLETON UNIVERSITY
- **IAN D. HARRIS** EDISON WELDING INSTITUTE
- **L.J. HART-SMITH** DOUGLAS AIRCRAFT COMPANY
- **DAN HAUSER** EDISON WELDING INSTITUTE
- **C.R. HEIPLE** METALLURGICAL CONSULTANT
- **HERBERT HERMAN** STATE UNIVERSITY OF NEW YORK
- **G. KEN HICKEN** SANDIA NATIONAL LABORATORIES
- **EVAN B. HINSHAW** INCO ALLOYS INTERNATIONAL INC.
- **D. BRUCE HOLLIDAY** WESTINGHOUSE MARINE DIVISION
- **S. IBARRA** AMOCO CORPORATION
- **J. ERNESTO INDACOCHEA** UNIVERSITY OF ILLINOIS AT CHICAGO
- **SUNIL JHA** TEXAS INSTRUMENTS INC.
- **JERALD E. JONES** COLORADO SCHOOL OF MINES

FOREWORD

COVERAGE OF JOINING TECHNOLOGIES IN THE *ASM HANDBOOK* HAS GROWN DRAMATICALLY OVER THE YEARS. A SHORT CHAPTER ON WELDING--EQUAL IN SIZE TO ABOUT 5 PAGES OF TODAY'S *ASM HANDBOOK*--APPEARED IN THE 1933 EDITION OF THE *NATIONAL METALS HANDBOOK* PUBLISHED BY THE AMERICAN SOCIETY OF STEEL TREATERS, ASM'S PREDECESSOR. THAT MATERIAL WAS EXPANDED TO 13 PAGES IN THE CLASSIC 1948 EDITION OF *METALS HANDBOOK*. THE FIRST FULL VOLUME ON WELDING AND BRAZING IN THE SERIES APPEARED IN 1971, WITH PUBLICATION OF VOLUME 6 OF THE 8TH EDITION OF *METALS HANDBOOK*. VOLUME 6 OF THE 9TH EDITION, PUBLISHED IN 1983, WAS EXPANDED TO INCLUDE COVERAGE OF SOLDERING.

THE NEW VOLUME 6 OF THE *ASM HANDBOOK* BUILDS ON THE PROUD TRADITION ESTABLISHED BY THESE PREVIOUS VOLUMES, BUT IT ALSO REPRESENTS A BOLD NEW STEP FOR THE SERIES. THE HANDBOOK HAS NOT ONLY BEEN REVISED, BUT ALSO ENTIRELY

REFORMATTED TO MEET THE NEEDS OF TODAY'S MATERIALS COMMUNITY. OVER 90% OF THE ARTICLES IN THIS VOLUME ARE BRAND-NEW, AND THE REMAINDER HAVE BEEN SUBSTANTIALLY REVISED. MORE SPACE HAS BEEN DEVOTED TO COVERAGE OF SOLID-STATE WELDING PROCESSES, MATERIALS SELECTION FOR JOINED ASSEMBLIES, WELDING IN SPECIAL ENVIRONMENTS, QUALITY CONTROL, AND MODELING OF JOINING PROCESSES, TO NAME BUT A FEW. INFORMATION ALSO HAS BEEN ADDED FOR THE FIRST TIME ABOUT JOINING OF SELECTED NONMETALLIC MATERIALS.

WHILE A DELIBERATE ATTEMPT HAS BEEN MADE TO INCREASE THE AMOUNT OF CUTTING-EDGE INFORMATION PROVIDED, THE ORGANIZERS HAVE WORKED HARD TO ENSURE THAT THE HEART OF THE BOOK REMAINS PRACTICAL INFORMATION ABOUT JOINING PROCESSES, APPLICATIONS, AND MATERIALS WELDABILITY--THE TYPE OF INFORMATION THAT IS THE HALLMARK OF THE *ASM HANDBOOK* SERIES.

PUTTING TOGETHER A VOLUME OF THIS MAGNITUDE IS AN ENORMOUS EFFORT AND COULD NOT HAVE BEEN ACCOMPLISHED WITHOUT THE DEDICATED AND TIRELESS EFFORTS OF THE VOLUME CHAIRPERSONS: DAVID L. OLSON, THOMAS A. SIEWERT, STEPHEN LIU, AND GLEN R. EDWARDS. SPECIAL THANKS ARE ALSO DUE TO THE SECTION CHAIRPERSONS, TO THE MEMBERS OF THE ASM HANDBOOK COMMITTEE, AND TO THE ASM EDITORIAL STAFF. WE ARE ESPECIALLY GRATEFUL TO THE OVER 400 AUTHORS AND REVIEWERS WHO HAVE CONTRIBUTED THEIR TIME AND EXPERTISE IN ORDER TO MAKE THIS HANDBOOK A TRULY OUTSTANDING INFORMATION RESOURCE.

EDWARD H. KOTTCAMP, JR.
PRESIDENT
ASM INTERNATIONAL

EDWARD L. LANGER
MANAGING DIRECTOR
ASM INTERNATIONAL

PREFACE

THE *ASM HANDBOOK,* VOLUME 6, *WELDING, BRAZING, AND SOLDERING,* HAS BEEN ORGANIZED INTO A UNIQUE FORMAT THAT WE BELIEVE WILL PROVIDE HANDBOOK USERS WITH READY ACCESS TO NEEDED MATERIALS-ORIENTED JOINING INFORMATION AT A MINIMAL LEVEL OF FRUSTRATION AND STUDY TIME. WHEN WE DEVELOPED THE ORGANIZATIONAL STRUCTURE FOR THIS VOLUME, WE RECOGNIZED THAT ENGINEERS, TECHNICIANS, RESEARCHERS, DESIGNERS, STUDENTS, AND TEACHERS DO NOT SEEK OUT JOINING INFORMATION WITH THE SAME LEVEL OF UNDERSTANDING, OR WITH THE SAME NEEDS. THEREFORE, WE ESTABLISHED DISTINCT SECTIONS THAT WERE INTENDED TO MEET THE SPECIFIC NEEDS OF PARTICULAR USERS.

THE EXPERIENCED JOINING SPECIALIST CAN TURN TO THE SECTION "CONSUMABLE SELECTION, PROCEDURE DEVELOPMENT, AND PRACTICE CONSIDERATIONS" AND FIND DETAILED JOINING MATERIALS DATA ON A WELL-DEFINED PROBLEM. THIS HANDBOOK ALSO PROVIDES GUIDANCE FOR THOSE WHO NOT ONLY MUST SPECIFY THE JOINING PRACTICE, BUT ALSO THE MATERIALS TO BE JOINED. THE SECTION "MATERIALS SELECTION FOR JOINED ASSEMBLIES" CONTAINS COMPREHENSIVE INFORMATION ABOUT THE PROPERTIES, APPLICATIONS, AND WELDABILITIES OF THE MAJOR CLASSES OF STRUCTURAL MATERIALS. TOGETHER, THESE TWO MAJOR SECTIONS OF THE HANDBOOK SHOULD PROVIDE AN ENGINEER ASSIGNED A LOOSELY DEFINED DESIGN PROBLEM WITH THE MEANS TO MAKE INTELLIGENT CHOICES FOR COMPLETING AN ASSEMBLY.

FREQUENTLY, TECHNOLOGISTS ARE CALLED UPON TO INITIATE AND ADOPT WELDING PROCESSES WITHOUT IN-DEPTH KNOWLEDGE OF THESE PROCESSES OR THE SCIENTIFIC

PRINCIPLES THAT IMPACT THE PROPERTIES AND PERFORMANCE OF WELDMENTS. THE SECTIONS "FUNDAMENTALS OF JOINING" AND "JOINING PROCESSES" ARE DESIGNED TO MEET THE NEEDS OF THESE USERS, OR ANYONE WHO NEEDS BASIC BACKGROUND INFORMATION ABOUT JOINING PROCESSES AND PRINCIPLES.

WELDING, BRAZING, AND SOLDERING ARE TRULY INTERDISCIPLINARY ENTERPRISES; NO INDIVIDUAL CAN BE EXPECTED TO BE AN EXPERT IN ALL ASPECTS OF THESE TECHNOLOGIES. THEREFORE, WE HAVE ATTEMPTED TO PROVIDE A HANDBOOK THAT CAN BE USED AS A COMPREHENSIVE REFERENCE BY ANYONE NEEDING MATERIALS-RELATED JOINING INFORMATION.

MANY COLLEAGUES AND FRIENDS CONTRIBUTED THEIR TIME AND EXPERTISE TO THIS HANDBOOK, AND WE ARE VERY GRATEFUL FOR THEIR EFFORTS. WE WOULD ALSO LIKE TO EXPRESS OUR THANKS TO THE AMERICAN WELDING SOCIETY FOR THEIR COOPERATION AND ASSISTANCE IN THIS ENDEAVOR.

Energy Sources Used for Fusion Welding

Thomas W. Eagar, Massachusetts Institute of Technology

Introduction

WELDING AND JOINING processes are essential for the development of virtually every manufactured product. However, these processes often appear to consume greater fractions of the product cost and to create more of the production difficulties than might be expected. There are a number of reasons that explain this situation.

First, welding and joining are multifaceted, both in terms of process variations (such as fastening, adhesive bonding, soldering, brazing, arc welding, diffusion bonding, and resistance welding) and in the disciplines needed for problem solving (such as mechanics, materials science, physics, chemistry, and electronics). An engineer with unusually broad and deep training is required to bring these disciplines together and to apply them effectively to a variety of processes.

Second, welding or joining difficulties usually occur far into the manufacturing process, where the relative value of scrapped parts is high.

Third, a very large percentage of product failures occur at joints because they are usually located at the highest stress points of an assembly and are therefore the weakest parts of that assembly. Careful attention to the joining processes can produce great rewards in manufacturing economy and product reliability.

The Section "Fusion Welding Processes" in this Volume provides details about equipment and systems for the major fusion welding processes. The purpose of this Section of the Volume is to discuss the fundamentals of fusion welding processes, with an emphasis on the underlying scientific principles.

Because there are many fusion welding processes, one of the greatest difficulties for the manufacturing engineer is to determine which process will produce acceptable properties at the lowest cost. There are no simple answers. Any change in the part geometry, material, value of the end product, or size of the production run, as well as the availability of joining equipment, can influence the choice of joining method. For small lots of complex parts, fastening may be preferable to welding, whereas for long production runs, welds can be stronger and less expensive.

The perfect joint is indistinguishable from the material surrounding it. Although some processes, such as diffusion bonding, can achieve results that are very close to this ideal, they are either expensive or restricted to use with just a few materials. There is no universal process that performs adequately on all materials in all geometries. Nevertheless, virtually any material can be joined in some way, although joint properties equal to those of the bulk material cannot always be achieved.

The economics of joining a material may limit its usefulness. For example, aluminum is used extensively in aircraft manufacturing and can be joined by using adhesives or fasteners, or by welding. However, none of these processes has proven economical enough to allow the extensive replacement of steel by aluminum in the frames of automobiles. An increased use of composites in aircrafts is limited by an inability to achieve adequate joint strength.

It is essential that the manufacturing engineer work with the designer from the point of product conception to ensure that compatible materials, processes, and properties are selected for the final assembly. Often, the designer leaves the problem of joining the parts to the manufacturing engineer. This can cause an escalation in cost and a decrease in reliability. If the design has been planned carefully and the parts have been produced accurately, the joining process becomes much easier and cheaper, and both the quality and reliability of the product are enhanced.

Generally, any two solids will bond if their surfaces are brought into intimate contact. One factor that generally inhibits this contact is surface contamination. Any freshly produced surface exposed to the atmosphere will absorb oxygen, water vapor, carbon dioxide, and hydrocarbons very rapidly. If it is assumed that each molecule that hits the surface will be absorbed, then the time-pressure value to produce a monolayer of contamination is approximately 0.001 Pa · s (10^{-8} atm · s). For example, at a pressure of 1 Pa (10^{-5} atm), the contamination time is 10^{-3} s, whereas at 0.1 MPa (1 atm), it is only 10×10^{-9} s.

In fusion welding, intimate interfacial contact is achieved by interposing a liquid of substantially similar composition as the base metal. If the surface contamination is soluble, then it is dissolved in the liquid. If it is insoluble, then it will float away from the liquid-solid interface.

Energy Sources Used for Fusion Welding

Thomas W. Eagar, Massachusetts Institute of Technology

Energy-Source Intensity

One distinguishing feature of all fusion welding processes is the intensity of the heat source used to melt the liquid. Virtually every concentrated heat source has been applied to the welding process. However, many of the characteristics of each type of heat source are determined by its intensity. For example, when considering a planar heat source diffusing into a very thick slab, the surface temperature will be a function of both the surface power density and the time.

Figure 1 shows how this temperature will vary on steel with power densities that range from 400 to 8000 W/cm^2. At the lower value, it takes 2 min to melt the surface. If that heat source were a point on the flat surface, then the heat flow would be divergent and might not melt the steel. Rather, the solid metal would be able to conduct away the heat as fast as it was being introduced. It is generally found that heat-source power densities of approximately 1000 W/cm^2 are necessary to melt most metals.

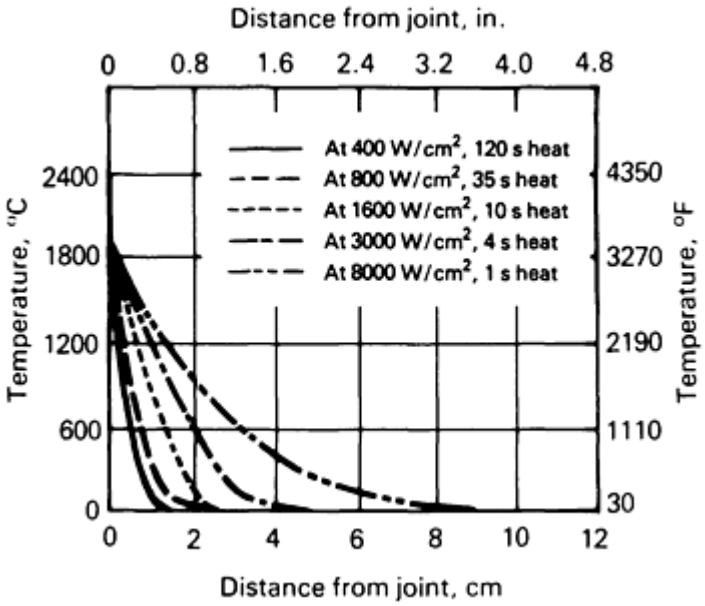

FIG. 1 TEMPERATURE DISTRIBUTION AFTER A SPECIFIC HEATING TIME IN A THICK STEEL PLATE HEATED

UNIFORMLY ON ONE SURFACE AS A FUNCTION OF APPLIED HEAT INTENSITY; INITIAL TEMPERATURE OF PLATE IS 25 °C (77 °F)

At the other end of the power-density spectrum, heat intensities of 10^6 or 10^7 W/cm^2 will vaporize most metals within a few microsecond. At levels above these values, all of the solid that interacts with the heat source will be vaporized, and no fusion welding can occur. Thus, the heat sources for all fusion welding processes should have power densities between approximately 0.001 and 1 MW/cm^2. This power-density spectrum is shown in Fig. 2, along with the points at which common joining processes are employed.

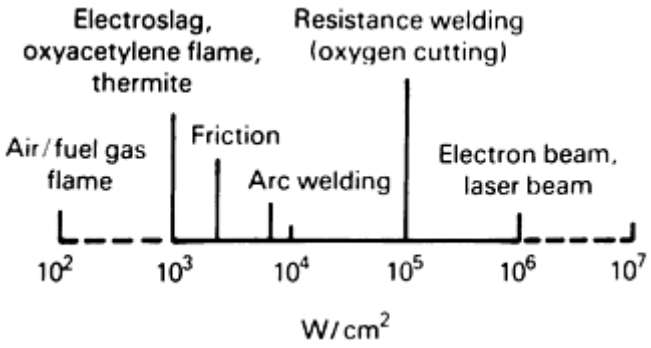

FIG. 2 SPECTRUM OF PRACTICAL HEAT INTENSITIES USED FOR FUSION WELDING

The fact that power density is inversely related to the interaction time of the heat source on the material is evident in Fig. 1. Because this represents a transient heat conduction problem, one can expect the heat to diffuse into the steel to a depth that increases as the square root of time, that is, from the Einstein equation:

$$X \sim \sqrt{a\,t} \qquad \textbf{(EQ 1)}$$

where x is the distance that the heat diffuses into the solid, in centimeters: α is the thermal diffusivity of the solid, in cm^2/s; and t is the time in seconds. Tables 1 and 2 give the thermal diffusivities of common elements and common alloys, respectively.

TABLE 1 THERMAL DIFFUSIVITIES OF COMMON ELEMENTS FROM 20 TO 100 °C (68 TO 212 °F)

For the planar heat source on a steel surface, as represented by Fig. 1, the time in seconds to produce melting on the surface, t_m, is given by:

$$T_M = (5000/\text{H.I.})^2 \qquad \textbf{(EQ 2)}$$

where H.I. is the net heat intensity (in W/cm^2) transferred to the workpiece.

Equation 2 provides a rough estimate of the time required to produce melting, and is based upon the thermal diffusivity of steel. Materials with higher thermal diffusivities--or the use of a local point heat source rather than a planar heat source--will increase the time to produce melting by a factor of up to two to five times. On the other hand, thin materials tend to heat more quickly.

If the time to melting is considered to be a characteristic interaction time, t_I, then the graph shown in Fig. 3 can be generated. Heat sources with power densities that are of the order of 1000 W/cm^2, such as oxyacetylene flames or electro-slag welding, require interaction times of 25 s with steel, whereas laser and electron beams, at 1 MW/cm^2, need interaction times on the order of only 25 μs. If this interaction time is divided into the heat-source diameter, d_H, then a maximum travel speed, V_{max}, is obtained for the welding process (Fig. 4).

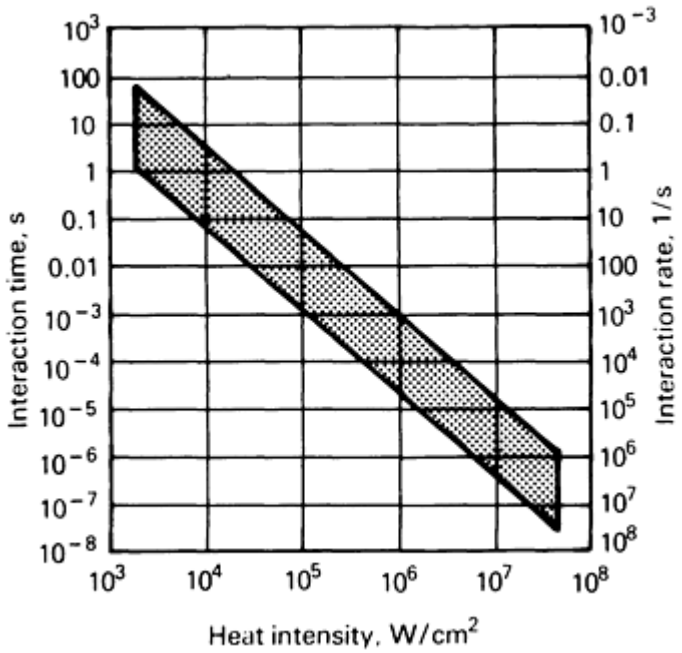

FIG. 3 TYPICAL WELD POOL-HEAT SOURCE INTERACTION TIMES AS FUNCTION OF HEAT-SOURCE INTENSITY.

MATERIALS WITH A HIGH THERMAL DIFFUSIVITY, SUCH AS COPPER OR ALUMINUM, WOULD LIE NEAR THE TOP OF THIS BAND, WHEREAS STEELS, NICKEL ALLOYS, OR TITANIUM WOULD LIE IN THE MIDDLE. URANIUM AND CERAMICS, WITH VERY LOW THERMAL DIFFUSIVITIES, WOULD LIE NEAR THE BOTTOM OF THE BAND.

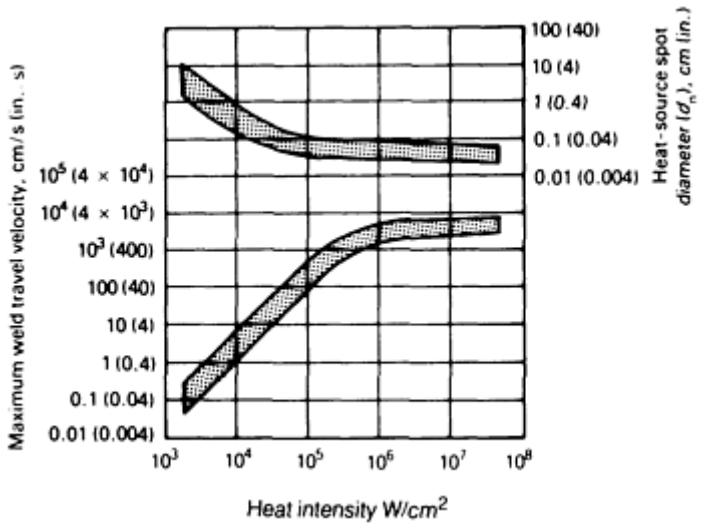

FIG. 4 MAXIMUM WELD TRAVEL VELOCITY AS A FUNCTION OF HEAT-SOURCE INTENSITY BASED ON TYPICAL HEAT-SOURCE SPOT DIAMETERS

The reason why welders begin their training with the oxyacetylene process should be clear: it is inherently slow and does not require rapid response time in order to control the size of the weld puddle. Greater skill is needed to control the more-rapid fluctuations in arc processes. The weld pool created by the high-heat-intensity processes, such as laser-beam and electron-beam welding, cannot be humanly controlled and must therefore be automated. This need to automate leads to increased capital costs. On an approximate basis, the W/cm^2 of a process can be substituted with the dollar cost of the capital equipment. With reference to Fig. 2, the cost of oxyacetylene welding equipment is nearly $1000, whereas a fully automated laser-beam or electron-beam system can cost $1 million. Note that the capital cost includes only the energy source, control system, fixturing, and materials handling equipment. It does not include operating maintenance or inspection costs, which can vary widely depending on the specific application.

For constant total power, a decrease in the spot size will produce a squared increase in the heat intensity. This is one of the reasons why the spot size decreases with increasing heat intensity (Fig. 4). It is easier to make the spot smaller than it is to increase the power rating of the equipment. In addition, only a small volume of material usually needs to be melted. If the spot size were kept constant and the input power were squared in order to obtain higher densities, then the volume of fused metal would increase dramatically, with no beneficial effect.

However, a decreasing spot size, coupled with a decreased interaction time at higher power densities, compounds the problem of controlling the higher-heat-intensity process. A shorter interaction time means that the sensors and controllers necessary for automation must operate at higher frequencies. The smaller spot size means that the positioning of the heat source must be even more precise, that is, on the order of the heat-source diameter, d_H. The control frequency must be greater than the travel velocity divided by the diameter of the heat source. For processes that operate near the maximum travel velocity, this is the inverse of the process interaction time, t_I (Fig. 3).

Thus, not only must the high-heat-intensity processes be automated because of an inherently high travel speed, but the fixturing requirements become greater, and the control systems and sensors must have ever-higher frequency responses. These factors lead to increased costs, which is one reason that the very productive laser-beam and electron-beam welding processes have not found wider use. The approximate productivity of selected welding processes, expressed as length of weld produced per second, to the relative capital cost of equipment is shown in Fig. 5.

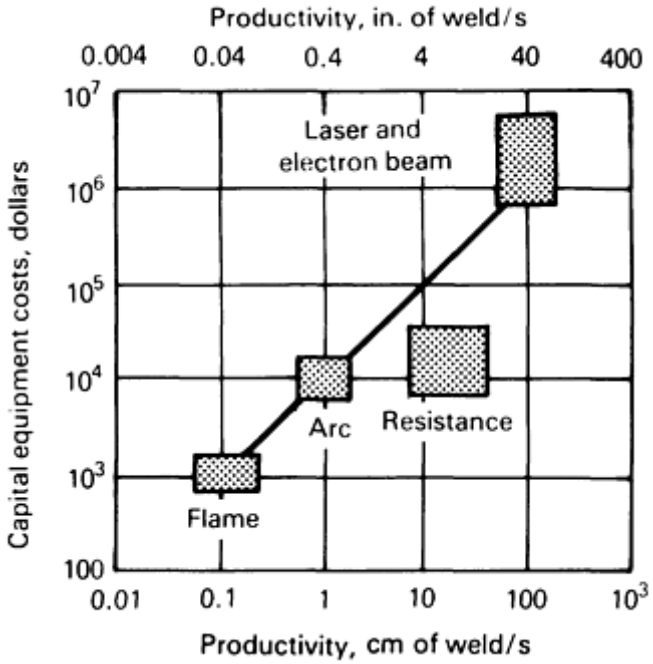

FIG. 5 APPROXIMATE RELATIONSHIP BETWEEN CAPITAL COST OF WELDING EQUIPMENT AND SPEED AT WHICH SHEET METAL JOINTS CAN BE PRODUCED

Another important welding process parameter that is related to the power density of the heat source is the width of the heat-affected zone (HAZ). This zone is adjacent to the weld metal and is not melted itself but is structurally changed because of the heat of welding. Using the Einstein equation, the HAZ width can be estimated from the process interaction time and the thermal diffusivity of the material. This is shown in Fig. 6, with one slight modification. At levels above approximately 10^4 W/cm^2, the HAZ width becomes roughly constant. This is due to the fact that the HAZ grows during the heating stage at power densities that are below 10^4 W/cm^2, but at higher power densities it grows during the cooling cycle. Thus, at low power densities, the HAZ width is controlled by the interaction time, whereas at high power densities, it is independent of the heat-source interaction time. In the latter case, the HAZ width grows during the cooling cycle as the heat of fusion is removed from the weld metal, and is proportional to the fusion zone width.

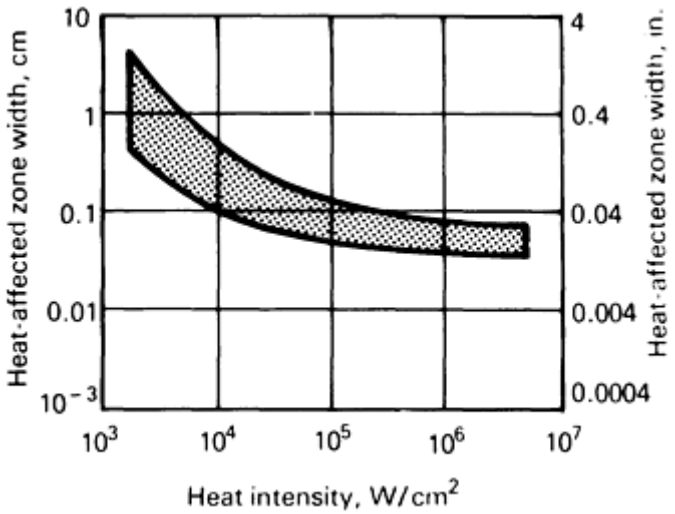

FIG. 6 RANGE OF WELD HAZ WIDTHS AS FUNCTION OF HEAT-SOURCE INTENSITY

The change of slope in Fig. 6 also represents the heat intensity at which the heat utilization efficiency of the process changes. At high heat intensities, nearly all of the heat is used to melt the material and little is wasted in preheating the surroundings. As heat intensity decreases, this efficiency is reduced. For arc welding, as little as half of the heat generated may enter the plate, and only 40% of this heat is used to fuse the metal. For oxyacetylene welding, the heat entering the metal may be 10% or less of the total heat, and the heat necessary to fuse the metal may be less than 2% of the total heat.

A final point is that the heat intensity also controls the depth-to-width ratio of the molten pool. This value can vary from 0.1 in low-heat-intensity processes to more than 10 in high-heat-intensity processes.

It should now be evident that all fusion welding processes can be characterized generally by heat-source intensity. The properties of any new heat source can be estimated readily from the figures in this article. Nonetheless, it is useful to more fully understand each of the common welding heat sources, such as flames, arcs, laser beams, electron beams, and electrical resistance. These are described in separate articles in the Section "Fusion Welding Processes" in this Volume.

Heat Flow in Fusion Welding

Chon L. Tsai and Chin M. Tso, The Ohio State University

Introduction

DURING FUSION WELDING, the thermal cycles produced by the moving heat source cause physical state changes, metallurgical phase transformation, and transient thermal stress and metal movement. After welding is completed, the finished product may contain physical discontinuities that are due to excessively rapid solidification, or adverse microstructures that are due to inappropriate cooling, or residual stress and distortion that are due to the existence of incompatible plastic strains.

In order to analyze these problems, this article presents an analysis of welding heat flow, focusing on the heat flow in the fusion welding process. The primary objective of welding heat flow modeling is to provide a mathematical tool for thermal data analysis, design iterations, or the systematic investigation of the thermal characteristics of any welding parameters. Exact comparisons with experimental measurements may not be feasible, unless some calibration through the experimental verification procedure is conducted.

Welding Thermal Process. A physical model of the welding system is shown in Fig. 1. The welding heat source moves at a constant speed along a straight path. The end result, after either initiating or terminating the heat source, is the formation of a transient thermal state in the weldment. At some point after heat-source initiation but before termination, the temperature distribution is stationary, or in thermal equilibrium, with respect to the moving coordinates. The origin of the moving coordinates coincides with the center of the heat source. The intense welding heat melts the metal and forms a molten pool. Some of the heat is conducted into the base metal and some is lost from either the arc column or the metal surface to the environment surrounding the plate. Three metallurgical zones are formed in the plate upon completion of the thermal cycle: the weld-metal (WM) zone, the heated-affected zone (HAZ), and the base-metal (BM) zone. The peak temperature and the subsequent cooling rates determine the HAZ structures, whereas the thermal gradients, the solidification rates, and the cooling rates at the liquid-solid pool boundary determine the solidification structure of the WM zone. The size and flow direction of the pool determines the amount of dilution and weld penetration. The material response in the temperature range near melting temperatures is primarily responsible for the metallurgical changes.

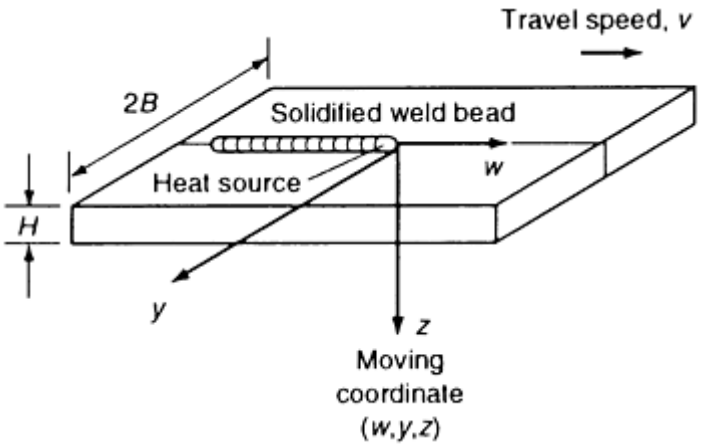

FIG. 1 SCHEMATIC OF THE WELDING THERMAL MODEL

Two thermal states, quasi-stationary and transient, are associated with the welding process. The transient thermal response occurs during the source initiation and termination stages of welding, the latter of which is of greater metallurgical interest. Hot cracking usually begins in the transient zone, because of the nonequilibrium solidification of the base material. A crack that forms in the source-initiation stage may propagate along the weld if the solidification strains sufficiently multiply in the wake of the welding heat source. During source termination, the weld pool solidifies several times faster than the weld metal in the quasi-stationary state. Cracks usually appear in the weld crater and may propagate along the weld. Another dominant transient phenomenon occurs when a short repair weld is made to a weldment. Rapid cooling results in a brittle HAZ structure and either causes cracking problems or creates a site for fatigue-crack initiation.

The quasi-stationary thermal state represents a steady thermal response of the weldment in respect to the moving heat source. The majority of the thermal expansion and shrinkage in the base material occurs during the quasi-stationary thermal cycles. Residual stress and weld distortion are the thermal stress and strain that remain in the weldment after completion of the thermal cycle.

Relation to Welding Engineering Problems. To model and analyze the thermal process, an understanding of thermally induced welding problems is important. A simplified modeling scheme, with adequate assumptions for specific problems, is possible for practical applications without using complex mathematical manipulations. The relationship between the thermal behavior of weldments and the metallurgy, control, and distortion associated with welding is summarized below.

Welding Metallurgy. As already noted, defective metallurgical structures in the HAZ and cracking in the WM usually occur under the transient thermal condition. Therefore, a transient thermal model is needed to analyze cracking and embrittlement problems.

To evaluate the various welding conditions for process qualification, the quasi-stationary thermal responses of the weld material need to be analyzed. The minimum required amount of welding heat input within the allowable welding speed range must be determined in order to avoid rapid solidification and cooling of the weldment Preheating may be necessary if the proper thermal conditions cannot be obtained under the specified welding procedure. A quasi-stationary thermal model is adequate for this type of analysis.

Hot cracking results from the combined effects of strain and metallurgy. The strain effect results from weld-metal displacement at near-melting temperatures, because of solidification shrinkage and weldment restraint. The metallurgical effect relates to the segregation of alloying elements and the formation of the eutectic during the high nonequilibrium solidification process. Using metallurgical theories, it is possible to determine the chemical segregation, the amounts and distributions of the eutectic, the magnitudes and directions of grain growth, and the weld-metal displacement at high temperatures. Using the heating and cooling rates, as well as the retention period predicted by modeling and analysis, hot-cracking tendencies can be determined. To analyze these tendencies, it is important to employ a more accurate numerical model that considers finite welding heat distribution, latent heat, and surface heat loss.

Welding Control. In-process welding control has been studied recently. Many of the investigations are aimed at developing sensing and control hardware. However, a link between weld-pool geometry and weld quality has not been fully established. A transient heat-flow analysis needs to be used to correlate the melted surface, which is considered to be the primary control variable, to the weld thermal response in a time domain.

Welding Distortion The temperature history and distortion caused by the welding thermal process creates nonlinear thermal strains in the weldment. Thermal stresses are induced if any incompatible strains exist in the weld. Plastic strains are formed when the thermal stresses are higher than the material yield stress. Incompatible plastic strains accumulate over the thermal process and result in residual stress and distortion of the final weldment. The material response in the lower temperature range during the cooling cycle is responsible for the residual stresses and weldment distortion. For this type of analysis, the temperature field away from the welding heat source is needed for the modeling of the heating and cooling cycle during and after welding. A quasi-stationary thermal model with a concentrated moving heat source can predict, with reasonable accuracy, the temperature information for the subsequent stress and distortion analysis.

Literature Review. Many investigators have analytically, numerically, and experimentally studied welding heat-flow modeling and analysis (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18). The majority of the studies were concerned with the quasi-stationary thermal state. Lance and Martin (Ref 1), Rosenthal and Schmerber (Ref 2) and Rykalin (Ref 3) independently obtained an analytical temperature solution for the quasi-stationary state using a point or line heat source moving along a straight line on a semi-infinite body. A solution for plates of finite thickness was later obtained by many investigators using the imaged heat source method (Ref 3, 4). Tsai (Ref 5) developed an analytical solution for a model that incorporated a welding heat source with a skewed Gaussian distribution and finite plate thickness. It was later called the "finite source theory" (Ref 6).

With the advancement of computer technology and the development of numerical techniques like the finite-difference and finite-element methods, more exact welding thermal models were studied and additional phenomena were considered, including nonlinear thermal properties, finite heat-source distributions, latent heat, and various joint geometries. Tsai (Ref 5), Pavelic (Ref 7), Kou (Ref 8), Kogan (Ref 9), and Brody (Ref 10) studied the simulation of the welding process using the finite-difference scheme. Hibbitt and Marcal (Ref 11), Friedman (Ref 12), and Paley (Ref 13) made some progress in welding simulation using the finite-element method.

Analytical solutions for transient welding heat flow in a plate were first studied by Naka (Ref 14), Rykalin (Ref 3), and Masubuchi and Kusuda (Ref 15) in the 1940s and 1950s. A point or line heat source, constant thermal properties, and adiabatic boundary conditions were assumed. Later, Tsai (Ref 16) extended the analytical solution to incorporate Gaussian heat distribution using the principle of superposition. The solution was used to investigate the effect of pulsed conditions on weld-pool formation and solidification without the consideration of latent heat and nonlinear thermal properties.

The analysis of the transient thermal behavior of weldments using numerical methods has been the focus of several investigations since 1980. Friedman (Ref 17) discussed the finite-element approach to the general transient thermal analysis of the welding process. Brody (Ref 10) developed a two-dimensional transient heat flow model using a finite-difference scheme and a simulated pulsed-current gas-tungsten arc welding process (GTAW). Tsai and Fan (Ref 18) modeled the two-dimensional transient welding heat flow using a finite-element scheme to study the transient welding thermal behavior of the weldment.

General Approach. The various modeling and analysis schemes summarized above can be used to investigate the thermal process of different welding applications. With adequate assumptions, analytical solutions for the simplified model can be used to analyze welding problems that show a linear response to the heat source if the solutions are properly calibrated by experimental tests. Numerical solutions that incorporate nonlinear thermal characteristics of weldments are usually required for investigating the weld-pool growth or solidification behavior. Numerical solutions can also be necessary for metallurgical studies in the weld HAZ if the rapid cooling phenomenon is significant under an adverse welding environment, such as welding under water.

Thermally related welding problems can be categorized as:

- SOLIDIFICATION RATES IN THE WELD POOL
- COOLING RATES IN THE HAZ AND ITS VICINITY
- THERMAL STRAINS IN THE GENERAL DOMAIN OF THE WELDMENT

The domain of concern in the weld pool solidification is within the molten pool area, in which the arc (or other heat source) phenomena and the liquid stirring effect are significant. A convective heat-transfer model with a moving boundary at the melting temperature is needed to study the first category, and numerical schemes are usually required, as well.

The HAZ is always bounded on one side by the liquid-solid interface during welding. This inner-boundary condition is the solidus temperature of the material. The liquid weld pool might be eliminated from thermal modeling if the interface could be identified. A conduction heat-transfer model would be sufficient for the analysis of the HAZ. Numerical methods are often employed and very accurate results can be obtained.

The thermal strains caused by welding thermal cycles are caused by the nonlinear temperature distribution in the general domain of the weldment. Because the temperature in the material near the welding heat source is high, very little stress can be accumulated from the thermal strains. This is due to low rigidity, that is, small modulus of elasticity and low yield strength. The domain for thermal strain study is less sensitive to the arc and fluid-flow phenomena and needs only a relatively simple thermal model. Analytical solutions with minor manipulations often provide satisfactory results.

In this article, only the analytical heat-flow solutions and their practical applications are addressed. The numerical conduction solutions and the convective models for fluid flow in a molten weld pool are not presented.

Heat Flow in Fusion Welding

Chon L. Tsai and Chin M. Tso, The Ohio State University

Mathematical Formulations

Conduction Equation. A diagram of the welding thermal model is shown in Fig. 1. The origin of the moving coordinates (*w,x,z*) is fixed at the center of the welding heat source. The coordinates move with the source at the same speed. The conduction equation for heat flow in the weldments is:

$$\nabla.(l\nabla q) + rC_p v\frac{\partial q}{\partial w} + \dot{Q} = rC_p v\frac{\partial q}{\partial t} \qquad \textbf{(EQ 1)}$$

The initial condition is:

$$\theta = \theta_0, \text{ AT } T = 0 \qquad \textbf{(EQ 2)}$$

and the general boundary condition is:

$$l\frac{\partial q}{\partial w}I_w + \frac{\partial q}{\partial y}I_y + \frac{\partial q}{\partial z}I_z - \dot{q} + h(q - q_\infty) = 0 \qquad \textbf{(EQ 3)}$$

where ∇ is a differential operator; θ is the temperature; $\theta\ \infty$ is the environmental temperature; θ_0 is the initial temperature; λ is thermal conductivity; ρ is density; C_p is specific heat h is the surface heat-loss coefficient; l_w, l_y, and l_z are the direction cosines of the boundary surface; Q is the volumetric heat source, t is time, and v is welding speed.

The volumetric heat source represents the Joule heating in the weldment that is due to the electric current flow within that conducting medium. The total energy of such heating in welding is usually minimal, compared to the arc heat input. The majority of the energy is concentrated in a very small volume beneath the arc (Ref 5). In other words, a very high energy density generation exists in the weld pool, and it may have a significant effect on transient pool growth and solidification.

Heat-Source Formulation. The direction cosines on the surface that receive the heat flux from the welding source (z = 0) are $l_w = l_y = 0$ and $l_z = -1$. Within the significant heat-input area (to be defined later in this section), the heat loss coefficient, h, is zero.

The distribution of the welding heat flux on the weldment surface can be characterized, in a general form, by a skewed Gaussian function (Ref 19):

$$\dot{q}(r,w) = \dot{q}_0 \exp\left(-Cr^2 - \frac{bv}{2k}w\right) \qquad \textbf{(EQ 4)}$$

where β is a weight constant, κ is the thermal diffusivity of the base material, C is a shape constant, $\dot{q}$ is heat flux as a function of (*r*, *w*), $\dot{q}_0$ is heat flux at the source center, *r* is the radial coordinate from the source center, and *v* is welding speed.

The weight constant, β, indicates the significance of the welding travel speed. A normal distribution of the welding heat flux is obtained if the weight constant is zero.

In general, the total energy input to the weldment, which is a fraction of the total welding power generated by the welding machine, is the sum of the concentrated heat and the diffused heat (Ref 20). The concentrated heat is carried by the core of the energy transmission medium, for example, the arc plasma column. The diffused heat reaches the weld surface by radiation and convection energy transport from the core surface. The heat-flux distribution is a function of the proportional values between these two types of energy. The fraction of the total welding power reaching the weldment indicates the heating efficiency of the welding process, and the fraction percentage is defined as welding heat efficiency, η.

The shape constant, C, can be obtained in terms of the core diameter, *D*, and the concentration factor, *F*. The concentration factor is defined as the ratio of the concentrated heat to the net energy reaching the weldment. The core diameter can be assumed to be the diameter of the plasma column in the arc welding process. The concentration factor and welding heat efficiency are not fully understood and have been subjected to manipulation during the mathematical analyses in order to obtain a better correlation with the experimental data.

Assuming a normal heat-flux model, two concentrations are required to determine the shape constant and the heat flux at the source center, $\dot{q}_0$. By integrating Eq 4 over the core heat area and the entire heat input domain ($r = 0 \rightarrow \infty$), the shape factor can be determined by dividing the two integrals. The heat flux at the source center can then be determined from the second integral. The two constants are expressed as:

$$C = \frac{4l_{arc}[1/(1-F)]}{D^2} \qquad \textbf{(EQ 5)}$$

where l_{arc} is the length of the arc plasma column.

$$\frac{\dot{q}_0}{\dot{Q}} = \frac{C}{p} \qquad \textbf{(EQ 6)}$$

In the case of arc welding,

$$\frac{\dot{q}_0}{hEI} = \frac{C}{p} \qquad \textbf{(EQ 7)}$$

where *E* is the welding arc voltage and *I* is the welding current.

For practical purposes, the welding heat source can be considered to be restricted within a circle of radius r_a, where the heat flux drops to 1/100 of the center flux $\dot{q}_0$. The radius of the significant heat input area can be written as:

$$r_a = \left(\frac{I_{arc}100}{C}\right)^{0.5} \qquad \textbf{(EQ 8)}$$

Surface Heat Loss. The heat-loss coefficient, *h*, represents both radiation and convection heat loss from the boundary surfaces outside the significant heat input area. The formulation for both heat-loss mechanisms can be written as the radiation heat-loss coefficient (in air):

$$H_{RAD} = \varepsilon\sigma(\theta_w + \infty)(\theta_W{}^2 - \theta\infty^2)) \qquad \textbf{(EQ 9)}$$

or the natural convection heat-loss coefficient (in air):

$$H_{AC} = 0.00042\frac{q_W - q_\infty}{B} \qquad \textbf{(EQ 10)}$$

or the convection heat-loss coefficient (in water):

$$H_{CW} = 0.442(\theta_W - \theta\infty)^{0.25} \qquad \textbf{(EQ 11)}$$

where ε is emissivity, σ is the Stefan-Boltzmann constant, θ_w is the surface temperature, θ ∞, is the environmental temperature, and *B* is the characteristic surface dimension.

Natural convection is dominant at a temperature below 550 °C (1020 °F), whereas radiation becomes more important at temperatures above this level. The total heat-loss coefficient is the sum of Eq 9 and 10. The characteristic surface dimension is the effective distance from the source beyond which the temperature rises insignificantly during welding. The characteristic dimension for steel is about 150 mm (6 in.) (Ref 5). In underwater welding, heat losses are primarily due to heat transfer from the surface to the moving water environment. This motion is created by the rising gas column in the arc area (Ref 21).

For an insulated surface, no heat transfer into or out of the surface is assumed. The temperature gradient normal to the surface is zero, and can be represented by:

$$N \cdot \nabla q = 0 \qquad \textbf{(EQ 12)}$$

where *n* is a unit vector normal to the surface and equals $(l_w{}^2 + l_y{}^2 + l_z{}^2)^{0.5}$.

Other Boundary Conditions. There are several other possible boundary conditions in welding heat-flow modeling that depend on the assumptions used for model simplification. One is the condition at infinity:

$$q = q_\infty \text{ or } \lim_{r\to\infty}\frac{\partial q}{\partial r} = 0 \qquad \textbf{(EQ 13)}$$

Another is the condition near the heat source. In the case of a line source for a thin plate:

$$-2p\,l\,\mathrm{H}\lim_{r\to\infty} r\frac{\partial q}{\partial r} = h\,EI \qquad \textbf{(EQ 14)}$$

In the case of a point source for a thick plate:

$$-2p\,l\lim_{r\to\infty} r^2\frac{\partial q}{\partial r} = h\,EI \qquad \textbf{(EQ 15)}$$

In the case of a finite source for a thick plate:

$$N \cdot (-\lambda\nabla\theta) = \dot{q}\,;\; R \le R_A \qquad \textbf{(EQ 16)}$$

Another is represented by the conditions at the solid-liquid interface:

$$\theta_1 = \theta_S = \theta_M \qquad \textbf{(EQ 17)}$$

$$\text{n.}(l\nabla q)_s - n(l\nabla q)_1 = \pm r_s L\frac{ds}{dt} \qquad \textbf{(EQ 18)}$$

where + indicates the melting process and - indicates the solidification process. The subscripts s and l indicate the temperature and the properties in a solid and liquid, respectively. The *n* is a normal vector on the boundary surface or interface, r_a is the radius of the heat-input area, *L* is the latent heat of the base material, and the subscript m represents the melting temperature of the base material.

Engineering Solutions and Empirical Correlation

General Solutions. The general (analytical) heat-flow solutions for fusion welding can be categorized by those appropriate for a thick plate, a thin plate, or a plate with finite thickness. In most cases, the boundary surfaces (except for the heat-input area) are assumed to be adiabatic, and the thermal properties are independent of temperature. The various metallurgical zones in the weldment are assumed to be homogeneous, and the thermal model is linear.

The solutions give the temperature for a specific point if the welding velocity, *v*, voltage, *E*, and current, *I*, as well as the physical properties of the plate material (ρ, λ, C_p) and the welding heat efficiency, η, are known. This specific point is defined by *r* and *w* in:

$$r = \sqrt{w^2 + y^2 + z^2} \qquad \textbf{(EQ 19)}$$

where $w = x - vt$. The heat-flow solutions are not accurate at points near the welding arc, because a point source or line source is assumed for thick and thin plates, respectively.

To approximate the transient temperature changes at the start and end of a weld, Fig. 2 shows a global coordinate system (*x,y,z*), the origin of which is fixed at the source initiation, where t_0 is the welding time and t_1 is the time after the welding heat-source termination. The temperature solutions at t_0 and t_1 are the temperature changes at the start and end of the weld, respectively.

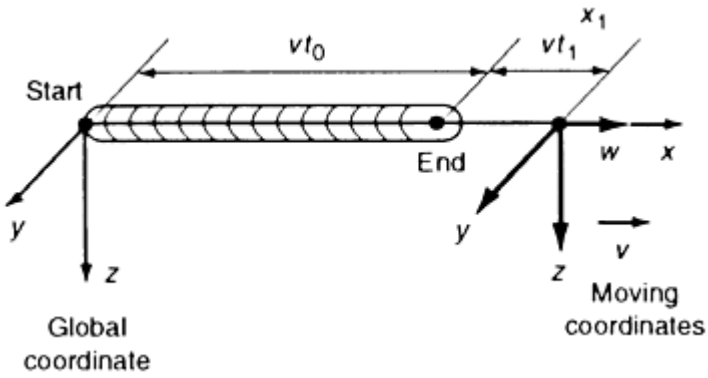

FIG. 2 GLOBAL AND MOVING COORDINATE SYSTEMS FOR WELDING HEAT CONDUCTION.

The temperature solution for thick plate at the arc start location is:

$$q - q_0 = \frac{h\,EI}{2p\,l\,vt_o} \qquad \textbf{(EQ 20)}$$

The quasi-stationary temperature distribution is:

$$q - q_0 = \frac{h\,EI}{2p\,l\,r}\exp\left[\frac{-v(w+r)}{2k}\right] \qquad \textbf{(EQ 21)}$$

At the arc termination location, the solution is:

$$q - q_0 = \frac{h\,EI}{2p\,l\,vt_1} \qquad \textbf{(EQ 22)}$$

The temperature solution for thin plate at the arc start location is:

$$q - q_0 = \frac{h\,EI}{2p\,l\,H}\exp\frac{v^2t_o}{2k}k_o\frac{v^2t_o}{2k} \qquad \textbf{(EQ 23)}$$

The quasi-stationary temperature distribution is:

$$q - q_0 = \frac{h\,EI}{2p\,l\,H}\exp\frac{-vw}{2k}k_o\frac{vr}{2k} \qquad \textbf{(EQ 24)}$$

For the arc termination location, the solution is:

$$q - q_0 = \frac{h\,EI}{2p\,l\,H}\exp\frac{v^2t_1}{2k}k_o\left(\frac{v^2t_1}{2k}\right) \qquad \textbf{(EQ 25)}$$

where K_0 is the modified Bessel function of the second kind of zeroth order and $\eta\,EI$ is the welding heat input rate.

Temperature for Plate With Finite Thickness. The image method enables the investigator to superimpose the solutions for an infinitely thick plate, the source of which is placed on imaginary surfaces until the proper boundary

conditions on the plate surfaces are obtained. This method is based on the premise that if a solution satisfies the governing equation and the boundary conditions, then it must be not only a correct solution, but the only solution (that is, the uniqueness of solution premise).

Using the image method, the solution for plates of finite thickness with a adiabatic surfaces can be modified from the respective temperature solutions described previously.

Let $f_0(w,y,z,t)$ be the initial solution for an infinitely thick plate. The temperature solution for a finite thick plate can be obtained by super imposing the imaginary solutions $f_{mn}(w,y_m, z_n, t)$ and $f'_{mn}(w,y'_m, z'_n, t)$ to the initial solution, and this can be written in a general form as:

$$q - q_0 = -f_0(w, y, z, f) + \sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\left[f_{mn}(w, y_m, z_m, t] + f'_{mn}(w, y'_m, Z_m t)\right] \qquad \textbf{(EQ 26)}$$

where $y_m = 2mB - y$; $y'_m = 2mB + y$; $z_n = 2nH - z$; and $z'_n = 2nH + z$, in which B is the half width and H is the thickness of the plate. The subscripts m and n are integers that vary from zero to infinity.

For a plate with sufficient width, the subscript m is zero. The solution will coverage and reach the correct adiabatic surface condition in six to ten superposition steps, depending on the thickness of the plate. The two-dimensional solution (that is, thin plate) is generally used for any solution that requires more than ten superposition steps.

Equation 26 can be expressed as:

$$q - q_0 = -\frac{h\,EI\exp\left(\frac{-vw}{2k}\right)}{2p\,l}\left\{\frac{\exp\left(\frac{-vr}{2k}\right)}{r} + \sum_{n=1}^{\infty}\left[\frac{\exp\left(\frac{-vr_{2n}}{2k}\right)}{r_{2n}} + \right]\frac{\exp\left(\frac{-vr_{2n+1}}{2k}\right)}{r_{2n-1}}\right\} \qquad \textbf{(EQ 27)}$$

where

$$R_{2N} = W^2 + Y^2 + (2NH - Z)^2 \text{ AND}$$
$$R_{2N+1} = W^2 + Y^2 + (2NH + Z)^2 \qquad \textbf{(EQ 28)}$$

Cooling Rate. Frequently, it is desirable to know the cooling rate experienced at some location in a weldment to enable a prediction of the metallurgical structure in that area. A general methodology by which cooling rate equations are obtained from the temperature-distribution equations is discussed below.

Recall that the moving coordinate w is defined by $w = x - vt$. Using this definition, it is easily shown that:

$$\frac{\partial w}{\partial t} = -v \qquad \textbf{(EQ 29)}$$

Using the chain rule, the cooling-rate equation is:

$$\frac{\partial q}{\partial t} = -v\frac{\partial q}{\partial w} \qquad \textbf{(EQ 30)}$$

Because the temperature-distribution equations are a function of w and r, the cooling-rate equations can be obtained by differentiating the temperature-distribution equations with respect to w and multiplying by $-v$.

The cooling rate is defined as the slope of a tangent line drawn on the temperature-time curve. Because the cooling rate changes with temperature, when one speaks of a cooling rate, the specific temperature, θ_c, at which it occurs must also be

given. In a weldment, the variable of interest is the cooling rate at the critical temperature that ultimately defines what type of metallurgical structure will result (if the material is heat treatable). For steels, this critical temperature is the "nose" of the continuous cooling-transformation (CCT) curve. At this temperature, the cooling rate determines if upper transformation products (pearlite, upper bainite) or lower transformation products (martensite, lower bainite) will form. For many steels, this critical temperature ranges from approximately 200 to 540 °C (400 to 1000 °F).

The cooling rate in a weldment is also a function of location. In order to find a cooling-rate equation, the particular location in the weldment that is of interest must be defined. The resulting cooling-rate equation will be applicable only to that location.

The differentiation, $\partial\theta/\partial w$, of either Eq 21 or 27, which is required to obtain the cooling-rate expression, will result in a function of *w* and *r*. The variable *r* can be written in terms of *w* if the location of interest is defined by a given set of values of *y* and *z*. This relationship for *r*, once formulated, can then be substituted into $\partial\theta/\partial w$, the result being a function of *w* alone.

To determine *w* corresponding to the critical temperature, θ_c, a temperature-distribution equation is required (Eq 21 or 27). The aforementioned *r*-*w* relationship and temperature distribution equation (Eq 21 or 27) where θ is equal to θ_c, critical temperature, are used to determine *w*. Then *w* is substituted into the $d\theta/dw$ expression obtained previously. The end result will be an equation that defines the cooling rate for a particular location in the weldment, and, being a function of the critical temperature, the welding conditions and thermal conductivity of the base material.

To determine the cooling rate in a thick plate along the weld centerline (that is $y = 0$) for a particular critical temperature, the cooling-rate equation can be reduced to:

$$\frac{\partial q}{\partial t} = \frac{2p\,l\,v\left(q_c - q_0\right)^2}{h\,EI} \qquad \textbf{(EQ 31)}$$

This equation has been used to predict weld cooling rates in shop practices. Cooling rate is inversely (that is, $\dot{Q}/V$) and is proportional to thermal conductivity and the critical temperature at which the cooling rate needs to be evaluated.

On the basis of experimental results, a cooling-rate equation was developed for the HAZ of low-carbon steel weldments (Ref 25). This equation considers the combined effects of plate thickness, *H*, preheating temperature, θ_0, and welding conditions, and is given as:

$$\left.\frac{\partial q}{\partial t}\right|_{HAZ} = 0.35\left\{\left(\frac{q_c - q_0}{I/v}\right)^{1.7}\left[1 + \frac{2}{p}\tan^{-1}\left(\frac{H - H_o}{a}\right)\right]\right\}^{0.8} \qquad \textbf{(EQ 32)}$$

The variables α and H_0 depend on the critical temperature of interest. Several values are given in Table 1.

TABLE 1 SELECTED CRITICAL TEMPERATURE AND CORRESPONDING VALUES FOR α AND H_0

CRITICAL TEMPERATURE, θ_C		**H_0**		**α**	
°C	**°F**	**mm**	**in.**	**mm**	**in.**
700	1290	9.9	0.39	2.0	0.08
540	1000	14.2	0.56	4.1	0.16
300	570	19.8	0.78	9.9	0.39

The units used in Eq 32 are important, because the same units that were used in developing the equation must be employed in its application. The plate thickness, *H*, must be given in inches, and the travel speed, *v*, must be given in in./min. The temperatures θ_c and θ_0 must be given in °C, and the welding current, *I*, must be given in amperes. Using the

correct units, the application of Eq 32 will result in a predicted cooling rate (°C/s) for the HAZ of a low-carbon steel weldment.

For low-carbon steels welded by the shielded metal arc welding (SMAW), gas-metal arc welding (GMAW), and submerged arc welding (SAW) processes, an empirical equation has been developed that correlates the weld-metal cooling rate at 538 °C (1000 °F) with a 95 to 150 °C (200 to 300 °F) preheat, the weld nugget area (Ref 26):

$$°C/s = \left(\frac{2012}{\textit{nugget}\ \text{area}} \right)^{1.119} \qquad \textbf{(EQ 33)}$$

where the nugget area is in mm^2. For low-carbon steels, an empirical chart for determining nugget area for a given welding condition (Fig. 3) also has been developed (Ref 27). The straight line drawn to connect the current and travel speed intersects the nugget area at the calculated value. Welding voltage controls weld bead shape.

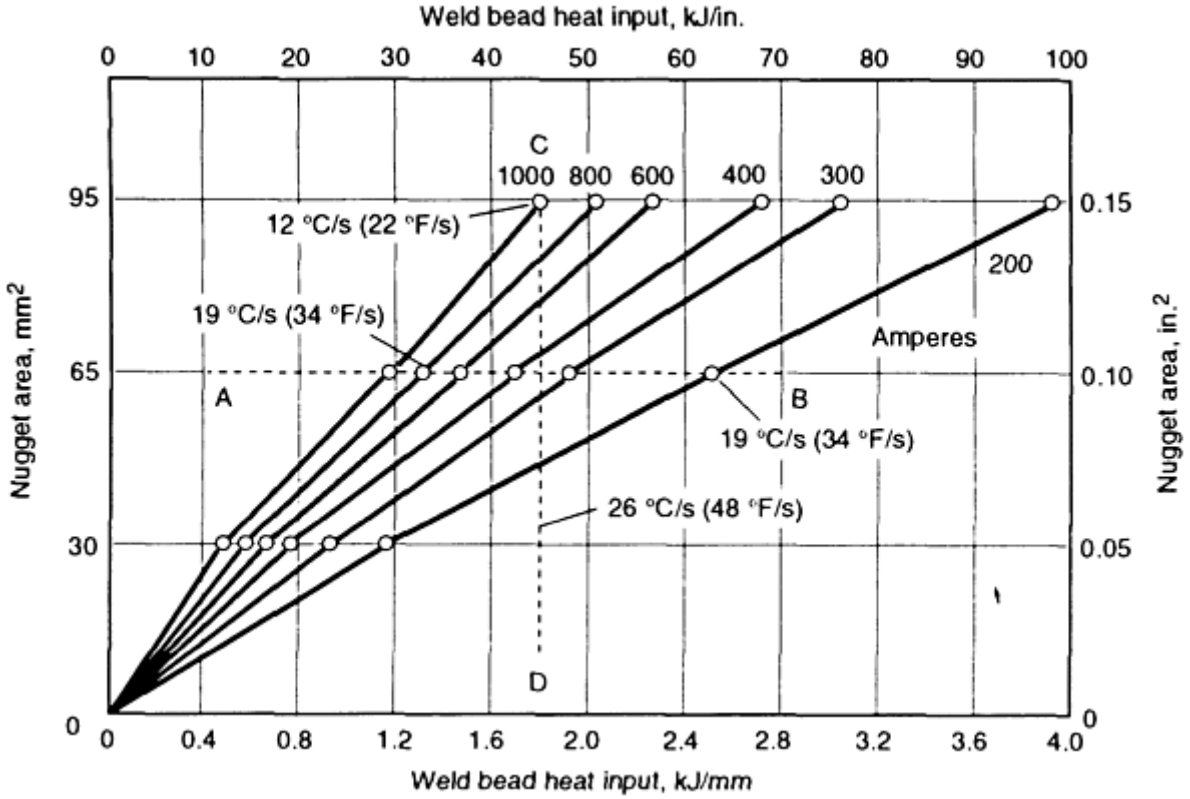

FIG. 3 RELATION BETWEEN NUGGET AREA, HEAT INPUT, AND CURRENT

Peak Temperature. An equation to determine the peak-temperature in a weldment at a given distance *y* from the weld centerline would enable the prediction of HAZ sizes, as well as weld bead widths. The general concept of obtaining a peak-temperature equation, as well as some results that have been obtained, are discussed below.

Consider Fig. 4 and note that the maximum, or peak, temperature is given when $\partial\theta/\partial t = 0$. For the thick-plate model, the cooling rate can be obtained by differentiating Eq 21 and multiplying by -*v*:

$$\frac{\partial q}{\partial t} = -v\frac{\partial q}{\partial w} = \frac{-vhEI}{2p\,l\,r}\exp\left[\frac{-v(w+r)}{2k}\right] x \left[\frac{-w}{r^2} - \frac{v}{2k}\left(1+\frac{w}{r}\right)\right] \qquad \textbf{(EQ 34)}$$

Clearly, the only way that $\partial\theta/\partial t$ can be equal to zero is if

$$\frac{-w}{r^2} - \frac{v}{2k}\left(1 + \frac{w}{r} = 0\right) \qquad \textbf{(EQ 35)}$$

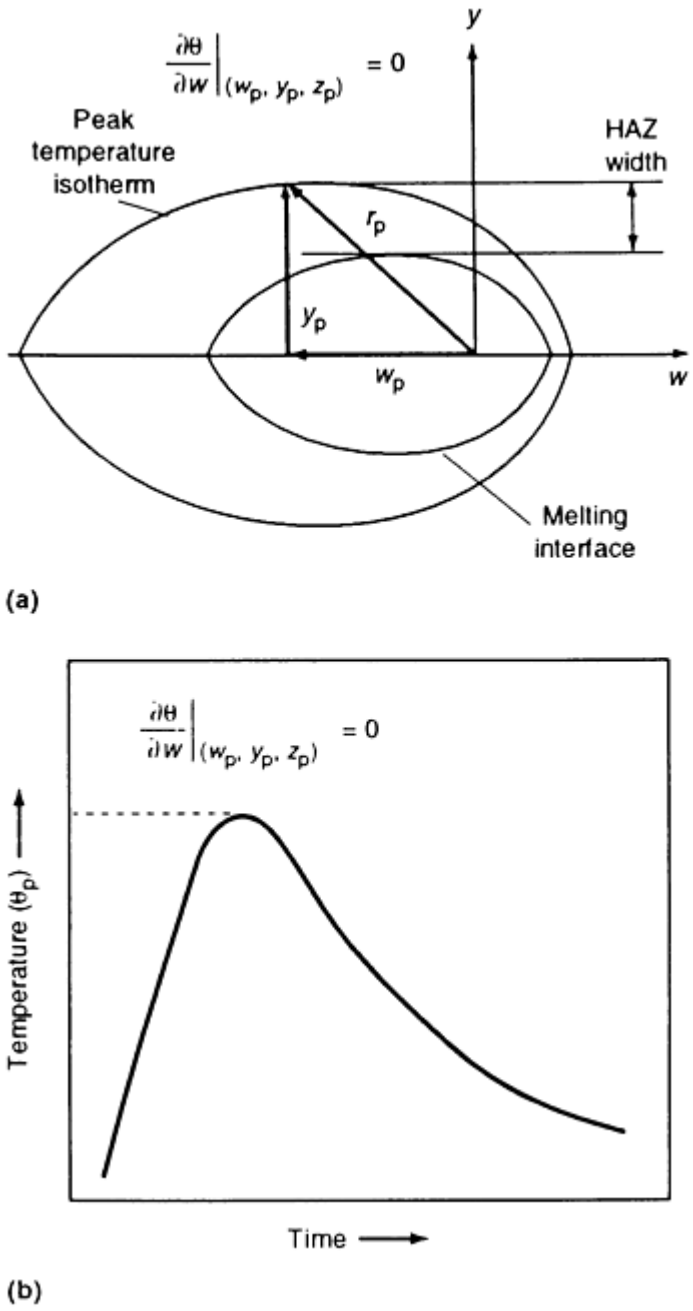

FIG. 4 SCHEMATIC SHOWING PEAK TEMPERATURE AT (W_P, Y_P, Z_P) WITH W_P TO BE DETERMINED FOR A GIVEN PEAK TEMPERATURE VALUE FOR A GIVEN (Y_P, Z_P) LOCATION. (A) ISOTHERMS. (B) TEMPERATURE HISTORY

Equation 35 describes the relationship that must exist between the two location variables, *r* and *w*, for the temperature at the point to be equal to the peak temperature. If this expression were to be substituted into the temperature distribution equation for thick plates (Eq 21) and solved for *w* and *r* (two equations and two unknowns), then the location of the peak temperature could be determined in terms of *w* and *r*. The location given by *r* and *w* would be easily converted to *y* and *z* as:

$$R^2 = W^2 + Y^2 + Z^2 \qquad \textbf{(EQ 36)}$$

Such a solution for r and w is not explicitly possible, however, because the equations for r and w that result are not explicit. Consequently, iterative techniques are required, resulting in a solution that is both cumbersome and time-consuming.

One method of obtaining a simpler thick-plate peak-temperature equation is to assume that the heat input is from an instantaneous line on the surface of the plate, rather than from a moving point source (that is, $v \to \infty$). This allows the elimination of the time dependency in the peak-temperature evaluation. Using this assumption, the temperature distribution is given by:

$$q - q_0 = \frac{h\,EI}{2p\,l\,t}\exp\left(\frac{r^2}{4kt}\right) \qquad \textbf{(EQ 37)}$$

Again, to find the peak-temperature location, $\partial\,\theta/\,\partial\,t$ is set equal to zero and the equation is solved for r. The result is:

$$\frac{r^2}{4kt} = 1 \qquad \textbf{(EQ 38)}$$

Substituting Eq 38 into Eq 37 yields the peak-temperature expression:

$$\frac{1}{q - q_0} = \left(\frac{e\,r\,C_p p\,r^2}{2}\right) / \left(\frac{h\,EI}{v}\right) \qquad \textbf{(EQ 39)}$$

It has been found that Eq 39 gives results that are too high, but that the slope of $1/(\theta_p - \theta_0)$ versus r^2 is accurate. To rectify this situation, Eq 39 is forced to fit experimental results by specifying a known temperature/location condition. When this is done, Eq 39 becomes:

$$\frac{1}{q_p - q_0} = \left(\frac{[e\,r\,C_p p\,(r^2 - r_t^2)]/2}{\left(\frac{h\,EI}{v}\right)}\right) + \frac{1}{q_r - q_0} \qquad \textbf{(EQ 40)}$$

where θ_r and r_r are the reference temperature and distance. If the peak temperature (θ_p) evaluation is restricted to locations on the plate surface ($z = 0$), and if the reference temperature and distance are assumed to be the melting temperature and the distance from the weld centerline to the fusion boundary (one half of the weld bead width), then Eq 40 can be written as:

$$\frac{1}{q_p - q_0} = \left(\frac{\frac{e\,r\,C_p p\,(y^2 - \left(\frac{d}{2}\right)^2}{2}}{\left(\frac{h\,EI}{v}\right)}\right) + \frac{1}{q_m - q_0} \qquad \textbf{(EQ 41)}$$

where θ_m is the melting temperature and d is the weld bead width. This equation gives the peak temperature θ_p in a thick plate at a distance y from the weld centerline.

Solidification Rate. The weld solidification structure can be determined by using the constitutional supercooling criterion. Three thermal parameters that influence the solidification structure are temperature gradient normal to the solid-liquid interface, G (°C/cm), solidification rate of the interface, R (cm/s), and cooling rate at the interface, $d\theta/dt$ at melting temperature (°C/s and equal to the product of GR). The microstructure may change from being planar to being cellular, a columnar dendrite, or an equiaxial structure if the G/R ratio becomes smaller. The dendrite arm spacing will decrease as the cooling rate increases. The solidification structure becomes refined at higher cooling rates.

At a quasi-steady state, the weld pool solidifies at a rate that is equal to the component of the electrode travel speed normal to the solid-liquid interface. Therefore, the solidification rate varies along the solid-liquid interface from the electrode travel speed, at the weld trailing edge, to zero, at the maximum pool width. The temperature gradient and the cooling rate at the solid-liquid interface can be determined from Eq 21, 24, and 27.

Modified Temperature Solution. The temperature solutions have a singularity at the center of the heat source. This singularity causes the predicted temperatures to be inaccurate in the area surrounding the heat source. However, a condition exists in which the peak temperature along the weld bead edge, that is, the solid-liquid interface location at the maximum pool width, is the melting temperature of the material. Using this temperature condition as a boundary condition for the temperature solutions, Eq 21 and 24 can be modified as shown below for thin plate:

$$q - q_0 = B_z \exp\left(\frac{-vw}{2k}\right) K_0\left(\frac{-vr}{2k}\right) \qquad \textbf{(EQ 42)}$$

where B_z is a heat input constant to be determined from the weld bead width, *d*.

$$B_z = \frac{q_m - q_0 \exp(vr_B / 2k)\left[\dfrac{K_0(vr_B / 2k)}{K_1(vr_B / 2k)}\right]}{K_0(vr_B / 2k)} \qquad \textbf{(EQ 43)}$$

with a bead width of:

$$d = 2r_B \left\{1 - \left[\frac{K_0(vr_B / 2k)}{K_1(vr_B / 2k)}\right]^2\right\}^{0.5} \qquad \textbf{(EQ 44)}$$

and for thick plate:

$$q_m - q_0 = B_z \exp\left[\frac{-v(w+r)}{2k}\right] / r \qquad \textbf{(EQ 45)}$$

$$B_z = (q_m - q_0) r_B \exp\left(\frac{-vr_B}{2k}\right)\left[\frac{1}{1+(2k / vr_B)} - 1\right] \qquad \textbf{(EQ 46)}$$

with a bead width of:

$$d = 2r_B \left[1 - \frac{1}{1+(2k / vr_B)}\right]^{0.5} \qquad \textbf{(EQ 47)}$$

The welding heat input, *Q*, is replaced by the weld bead width.

A Practical Application of Heat Flow Equations (Ref 22). The thermal condition in and near the weld metal must be established to control the metallurgical events in welding. The particular items of interests are the:

- DISTRIBUTION OF PEAK TEMPERATURE IN THE HAZ
- COOLING RATES IN THE WELD METAL AND IN THE HAZ
- SOLIDIFICATION RATE OF THE WELD METAL

Although the following discussion primarily focuses on manual are welding, certain general statements are applicable to all welding processes.

Peak Temperatures. The distribution of peak temperatures in the base metal adjacent to the weld is given by (Ref 23):

$$\frac{1}{T_p - T_0} = \frac{4.13 r C_p t Y}{H_{met}} + \frac{1}{T_m - T_0} \qquad \textbf{(EQ 48)}$$

where T_p is the peak temperature (°C) at distance Y (mm) from the weld fusion boundary, T_0 is the initial temperature (°C), T_m is the melting temperature (°C), H_{net} is the net energy input equal to $\eta EI/v$ (J/s · mm), ρ is the density of the material (g/mm^3), C_p is the specific heat of solid metal (J/g · °C), and t is the thickness of the base metal (mm).

Equation 48 can be used in order to determine the:

- PEAK TEMPERATURES AT SPECIFIC LOCATIONS IN THE HAZ
- WIDTH OF THE HAZ
- EFFECT OF PREHEAT ON THE WIDTH OF THE HAZ

In addition, determination of the peak temperature at specific locations in the HAZ and the width of the HAZ can be obtained by the procedure described from Eq 34, 35, 36, 37, 38, 39, 40, and 41.

Cooling Rate. Because the cooling rate varies with position and time, its calculation requires the careful specification of conditions. The most useful method is to determine the cooling rate on the weld centerline at the instant when the metal passes through a particular temperature of interest, T_c. At a temperature well below melting, the cooling rate in the weld and in its immediate HAZ is substantially independent of position. For carbon and low-alloy steels, T_c is the temperature near the pearlite "nose" temperature on the time-temperature transformation (TTT) diagram. The value of T_c = 550 °C (1020 °F) is satisfactory for most steels, although not critical.

The cooling rate for thick plate (Ref 23) is:

$$R = \frac{2\pi l (T_c - T_0)^2}{H_{met}} \qquad \textbf{(EQ 49)}$$

Equation 49 is comparable to Eq 31, which was obtained by the procedure described in the section "Cooling Rate" in this article. Adams (Ref 24) has developed a cooling rate equation for thin plate along the centerline from Eq 24.

The cooling rate for thin plate (Ref 24) is:

$$R = 2\pi l r C_p \left(\frac{t}{H_{met}} \right)^2 + (T_c - T_0)^3 \qquad \textbf{(EQ 50)}$$

where R is the cooling rate (°C/s) at a point on the weld centerline at just that moment when the point is cooling past the T_c, and λ is the thermal conductivity of the metal (J/mm · s · °C).

The dimensionless quantity t , called the "relative plate thickness," can be used to determine whether the plate is thick or thin:

$$t = t\sqrt{\frac{r C_p (T_c - T_0)}{H_{met}}} \qquad \textbf{(EQ 51)}$$

The thick-plate equation applies when t is greater than 0.75, and the thin-plate equation applies when t is less than that value.

Equations 49 and 50 are used to determine the cooling rate along the centerline for thick plate and thin plate, respectively. If one is interested in the cooling rate at the location at distance y (in mm) from the centerline, iterative techniques should be used to solve the cooling rate. First, w and r can be obtained by iteration of the simultaneous equation, which consists of Eq 21 or 27, where θ equals θ_c and $r^2 = w^2 + y^2$, where y is given. Then substitute w and r into the differentiation, $\partial\theta/\partial t = -v\partial\theta/\partial w$, from the temperature from Eq 21 or 27. The result will be the cooling rate for thick or thin plate located at y distance from the centerline:

$$\frac{\partial q}{\partial t}_{qc}$$

In addition, the cooling rate for HAZ of low-carbon steel weldments can be obtained from Eq 32 directly.

The solidification rate can have a significant effect on metallurgical structure, properties, response to heat treatment, and soundness. The solidification time, S_t, of weld metal, measured in seconds, is:

$$S_t = \frac{LH_{net}}{2p\,l\,C_p(T_m - T_o)^2} \qquad \textbf{(EQ 52)}$$

where L is the heat of fusion (J/mm^3).

Example 1: Welding of 5 mm (0.2 in.) Thick Low-Carbon Steels.

The thermal properties needed for heat flow analysis are assumed to be:

MELTING TEMPERATURE (T_M), °C (°F)	1510 (2750)
AUSTENIZATION TEMPERATURE, °C (°F)	730 (1350)
THERMAL CONDUCTIVITY (λ), W/M · K (J/MM · S · °C)	11.7 (0.028)
VOLUMETRIC SPECIFIC HEAT (ρC_P), J/MM^3 · °C	0.0044
HEAT OF FUSION (L), J/MM^3	2

The welding condition is assumed to be:

CURRENT (I), A	200
ARC VOLTAGE (E), V	20
TRAVEL SPEED (V), MM/S (IN./S)	5 (0.2)
PREHEAT (T_0), °C (°F)	25 (77)
HEAT-TRANSFER EFFICIENCY (η)	0.9
NET ENERGY INPUT, H_{NET}, J/MM (KJ/IN.)	720 (18.3)

Calculation of the HAZ Width. The value of Y at T_p = 730 °C (1345 °F) must be determined from Eq 48:

$$\frac{1}{730-25} = \frac{4.13(0.0044)5Y_z}{720}\frac{1}{1510-25} \qquad \textbf{(EQ 53)}$$

resulting in a value for Y_z (the width of the HAZ) of 5.9 mm (0.24 in.).

In addition, the HAZ width can be obtained by the procedure described in Eq 34, 35, 36, 37, 38, 39, 40, and 41. By substituting $w = w_p$, $r = r_p$, $y = y_p$, and $z = 0$ (on surface) into Eq 35 and 36, we obtain:

$$\frac{-w_p}{r_p^2} - \frac{v}{2k}\left(1 + \frac{w_p}{r_p}\right) = 0 \qquad \textbf{(EQ 54)}$$

$$r_p^2 = w_p^2 + y_p^2 \qquad \textbf{(EQ 55)}$$

The substitution of Eq 55 in Eq 54 yields:

$$\frac{-w_p}{w_p^2 + y_p^2} = \frac{v}{2k} 1 + \frac{w_p}{\sqrt{w_p^2 + y_p^2}} \qquad \textbf{(EQ 56)}$$

Inserting v = 5 mm/s, $\kappa = \lambda/\rho c_p = 0.028/0.004$ into Eq 56:

$$\frac{-w_p}{w_p^2 + y_p^2} = 0.3831 + \frac{w_p}{\sqrt{w_p^2 + y_p^2}} \qquad \textbf{(EQ 57)}$$

w_p and y_p should satisfy Eq 57.

From the temperature distribution equation (Eq 21) and E = 10V, I = 200 A, η= 0.9, λ= 0.028, θ_p = 730 °C, θ_0 = 25 °C, v = 5 mm/s, $\kappa = \lambda/\rho c_p = 0.028/0.044$:

$$730 - 25 = \frac{0.9x20x200/5}{2p\,x0.028r_p} x \exp\left[\frac{-5(w_p + r_p)}{2x0.028/0.0044}\right] \qquad \textbf{(EQ 58)}$$

$$-1.76 + \mathrm{LN}R_P = -0.393\,(W_P + R_P) \qquad \textbf{(EQ 59)}$$

Solving Eq 21 using the above values, by iteration:

- ASSUME R_P = 3.4 AND PUT THIS VALUE OF R_P INTO EQ 59 TO OBTAIN W_P = -2.036. SUBSTITUTE R_P = 3.4 AND W_P = -2.036 INTO EQ 55 AND SOLVE FOR Y_P: Y_P = 2.7. SUBSTITUTE Y_P AND W_P INTO EQ 56: THE LEFT SIDE OF EQ 56 = 0.176; THE RIGHT SIDE OF EQ 56 = 0.158. THE RESULTS DO NOT SATISFY EQ 56.
- ASSUME R_P = 3.5 AND PUT THIS VALUE OF R_P INTO EQ 59 TO OBTAIN W_P = -2.2. SUBSTITUTE R_P = 3.5 AND W_P = -2.2 INTO EQ 55 AND SOLVE FOR Y_P: Y_P = 2.72. SUBSTITUTE Y_P AND W_P INTO EQ 56: THE LEFT SIDE OF EQ 56 = 0.179; THE RIGHT SIDE OF EQ 56 = 0.146. THE RESULTS DO NOT SATISFY EQ 56.
- ASSUME R_P = 3.3 AND PUT THIS VALUE OF R_P INTO EQ 59 TO OBTAIN W_P = -1.86. SUBSTITUTE R_P = 3.3 AND W_P = -1.86 INTO EQ 55 AND SOLVE FOR Y_P: Y_P = 2.726. SUBSTITUTE Y_P AND W_P INTO EQ 56: THE LEFT SIDE OF EQ 56 = 0.170; THE RIGHT SIDE OF EQ 56 = 0.171. EQUATION 56 IS NOW SATISFIED.

The full HAZ width equals $2y_p = 2 \times 2.726 = 5.5$ mm. Comparing this result, 5.5 mm, with the result obtained with Eq 48 (that is, 5.9 mm), we know that Eq 48 can be used to obtain accurate results when calculating HAZ width and peak temperature.

Effect of Tempering Temperature on Quenched and Tempered (Q&T) Steels. If the plate had been quenched and then tempered to 430 °C (810 °F), then any region heated above that temperature will have been "over-tempered" and may exhibit modified properties. It would then be reasonable to consider the modified zone as being "heat affected," with its outer extremity located where T_p = 430 °C (810 °F):

$$\frac{1}{430-25}=\frac{4.13(0.0044)5Y_z}{720}+\frac{1}{1510-25} \qquad \textbf{(EQ 60)}$$

resulting in a value for Y_z of 14.2 mm (0.568 in.).

Effect of Preheating Temperature on Q&T Steels. Assume that the Q&T steel described above was preheated to a temperature, T_0, of 200 °C (390 °F):

$$\frac{1}{430-200}=\frac{4.13(0.0044)5Y_z}{720}+\frac{1}{1510-200} \qquad \textbf{(EQ 61)}$$

resulting in a value for Y_z of 28.4 mm > 14.2 mm (1.14 > 0.568 in.). Therefore, increasing the preheating temperature will increase the value of Y_z.

Effect of Energy Input on Q&T Steels. Assume that the energy input into the Q&T steel (without preheating) increases 50% (that is, 1.08 kJ/mm, or 27.4 kJ/in.):

$$\frac{1}{430-200}=\frac{4.13(0.0044)5Y_z}{1080}+\frac{1}{1510-25} \qquad \textbf{(EQ 62)}$$

resulting in a value for Y_z of 21.3 mm > 14.2 mm (0.839 > 0.568 in.). Therefore, increasing the energy input will increase the value of Y_z.

Example 2: Welding of 6 mm (0.24 in.) Thick Low-Carbon Steels.

The thermal properties needed for heat-flow analysis are assumed to be:

MELTING TEMPERATURE (T_M), °C (°F)	1510 (2750)
AUSTENIZATION TEMPERATURE, °C (°F)	730 (1346)
THERMAL CONDUCTIVITY (l), W/M · K (J/MM · S · °C)	11.7 (0.028)
VOLUMETRIC SPECIFIC HEAT (r C_P), J/MM^3 · °C	0.0044
HEAT OF FUSION (L), J/MM^3	2

The welding condition is assumed to be:

CURRENT (I), A	**300**
ARC VOLTAGE (E), V	**25**
PREHEAT (T_0), °C (°F)	**25 (77)**
HEAT-TRANSFER EFFICIENCY (η)	**0.9**

Critical Cooling Rate at 550 °C (1020 °F) (T_c). A critical cooling rate exists for each steel composition. If the actual cooling rate in the weld metal exceeds this critical value, then hard martensitic structures may develop in the HAZ, and there is a great risk of cracking under the influence of thermal stresses in the presence of hydrogen.

The best way to determine the critical cooling rate is to make a series of bead-on-plate weld passes in which all parameters, except the arc travel speed, are held constant. After the hardness tests on the weld passes deposited at travel speeds of 6, 7, 8, 9 and 10 mm/s (0.23, 0.28, 0.32, 0.35, and 0.39 in./s), it was found that at the latter two travel speeds, the weld HAZ had the highest hardness. Therefore, the critical cooling rate was encountered at a travel speed of approximately 8 mm/s (0.32 in.s). At this speed, the net energy input is:

$$H_{net} = \frac{25(300)0.9}{8} = 8.43.75 J/mm \qquad \textbf{(EQ 63)}$$

From Eq 51, the relative plate thickness is:

$$t = 6\sqrt{\frac{0.0044(550-25)}{843.75}} = 0.31 \qquad \textbf{(EQ 64)}$$

Because t is less than 0.75, the thin-plate equation (Eq 50) applies:

$$\frac{R}{2p\,l} = 0.0044\left(\frac{6}{843.75}\right)^2 (550-25)^3 = 32.2 \qquad \textbf{(EQ 65)}$$

resulting in R being equal to $2\pi(0.028)32.2$, which is equal to 5.7 °C/s (10.3 °F/s). This value is the maximum safe cooling rate for this steel and the actual cooling rate cannot exceed this value.

Preheating Temperature Requirement. Although the critical cooling rate cannot be exceeded, in the actual welding operation a preheat can be used to reduce the cooling rate to 5.7 °C/s (10.3 °F/s).

Assume that the welding condition is:

CURRENT (I), A	250
ARC VOLTAGE (E), V	25
HEAT-TRANSFER EFFICIENCY (η)	0.9
TRAVEL VELOCITY (V), MM/S (IN./S)	7 (0.3)
PLATE THICKNESS (T), MM (IN.)	9 (0.4)

The energy heat input, H_{net}, is:

$$H_{net} = \frac{25(250)0.9}{7} = 804 J/mm \qquad \textbf{(EQ 66)}$$

Assuming that the thin-plate equation (Eq 50) applies:

$$\left(\frac{R}{2p\,l}\right)_{max} = 32.2 = 0.0044\left(\frac{9}{804}\right)^2 (550-T_0)^3 \qquad \textbf{(EQ 67)}$$

resulting in a T_0 of 162 °C (325 °F).

The relative plate thickness should be checked:

$$t = 9\sqrt{\frac{0.0044(550-162)}{804}} = 0.41 \qquad \textbf{(EQ 68)}$$

Because t is less than 0.75, the thin-plate equation does apply. If the initial plate temperature is raised either to or above 162 °C (325 °F), then the cooling rate will not exceed 5.7 °C/s (10.3 °F/s).

Effect of Joint Thickness. If the plate thickness increases from 9 to 25 mm (0.36 to 1 in.), but there is the same level of energy input, then the calculation of the initial plate temperature would be as follows. First, using the thin-plate equation (Eq 50):

$$\left(\frac{R}{2pl}\right)_{\max} = 32.2 = 0.0044\left(\frac{25}{804}\right)^2 (550-T_0)^3 \qquad \textbf{(EQ 69)}$$

resulting in a value for T_0 of 354 °C (670 °F).

The relative plate thickness, t, should be checked:

$$t = 25\sqrt{\frac{0.0044(550-354)}{804}} = 0.82 \qquad \textbf{(EQ 70)}$$

Because t is greater than 0.75, the use of the thin-plate equation is inadequate. Using the thick-plate equation (Eq 49):

$$32.2 = \frac{(550-T_0)^2}{804} \qquad \textbf{(EQ 71)}$$

resulting in a value for T_0 of 389 °C (730 °F).

The relative plate thickness should be checked:

$$t = 25\sqrt{\frac{0.0044(550-389)}{804}} = 0.74 \qquad \textbf{(EQ 72)}$$

Although t is less than, but near to, 0.75, using the thin-plate equation is adequate. Therefore, the initial temperature should be raised to 389 °C (730 °F) to avoid exceeding the cooling rate of 5.7 °C/s (10.3 °F).

Now, if the plate thickness increases to 50 mm (2 in.), but there is the same level of energy input, then the thick-plate equation (Eq 49) applies and, again, the value for T_0 is 389 °C (730 °F).

The relative plate thickness should be checked:

$$t = 50\sqrt{\frac{0.0044(550-389)}{804}} = 1,48 \qquad \textbf{(EQ 73)}$$

Because t is greater than 0.75, the use of the thick-plate equation is adequate.

Under some welding conditions, it is not necessary to reduce the cooling rate by using a preheat. For example, if the plate thickness is 5 mm (0.2 in.) and there is the same level of energy input:

$$\left(\frac{R}{2p\,l}\right)_{\max} = 32.2 = 0.0044\left(\frac{5}{804}\right)^2 (550 - T_0)^3 \qquad \textbf{(EQ 74)}$$

resulting in a value for T_0 of -24 °C (-11 °F). Therefore, using a preheat is unnecessary.

Fillet-Welded "T" Joints. For a weld with a higher number of paths, as occurs in fillet-welded "T" joints, it is sometime necessary to modify the cooling-rate equation, because the cooling of a weld depends on the available paths for conducting heat into the surrounding cold base metal.

When joining 9 mm (0.35 in.) thick plate, where H_{net} = 804 J/mm (20.4 kJ/in.), and when there are three legs instead of two, the cooling-rate equation is modified by reducing the effective energy input by a factor of $\frac{2}{3}$:

$$H_{NET} = \frac{2}{3}\,(804) = 536 \text{ J/MM} \qquad \textbf{(EQ 75)}$$

Using the thin-plate equation (Eq 50):

$$\left(\frac{R}{2p\,l}\right)_{\max} = 32.2 = 0.0044\left(\frac{9}{536}\right)^2 (550 - T_0)^3 \qquad \textbf{(EQ 76)}$$

resulting in a value for T_0 of 254 °C (490 °F).

The relative plate thickness should be checked:

$$t = 9\sqrt{\frac{0.0044(550 - 254)}{536}} = 0,44 \qquad \textbf{(EQ 77)}$$

Because t is less than 0.75, using the thin-plate equation is adequate. Therefore, a higher preheat temperature is more necessary than a butt weld because of the enhanced cooling.

Example 3: Cooling Rate for the Location at Distance *y* (in cm) from the Centerline.

For a steel plate of 25 mm (1 in.) thickness, (*t*), the welding condition is assumed to be:

HEAT INPUT (ηEI), KW (CAL/S)	7.5 (1800)
TRAVEL SPEED (V), CM/S (IN./S)	0.1 (0.04)
PREHEAT (T_0), °C (°F)	20 (68)
NET ENERGY INPUT (H_{NET}), CAL/CM	18,000

The thermal properties needed for heat flow analysis are assumed to be:

MELTING TEMPERATURE (T_M), °C (°F)	1400 (2550)
THERMAL CONDUCTIVITY (λ), W/M · K (CAL_{IT}/CM · S · °C)	43.1 (0.103)
SPECIFIC HEAT (C_P), J/KG · C (BTU/LB · °F)	473 (0.113)
DENSITY (ρ), G/CM^3 (LB/$IN.^3$)	7.8 (0.28)

Assume that one is interested in the critical cooling rate at the location on the surface (z = 0) at distance y = 2 cm from the centerline at the instant when the metal passes through the specific temperature of 615 °C (1140 °F). Initially, the relative plate thickness should be checked. From Eq 51, the relative plate thickness (using English units) is:

$$t = 25\sqrt{\frac{7.8x0.113(615-20}{18,000}} = 4,267$$

Because t is greater than 0.75, this plate can be treated as a thick plate. From Eq 78, cooling rate for thick plate at the location where the variables are w and r and at critical temperature $\theta = \theta_c$ is:

$$\frac{\partial q}{\partial t} = -v\frac{\partial q}{\partial w} = \frac{-vhEI}{2p\,l\,r}\exp\left[\frac{-v(w+r)}{2k}\right]x\left[\frac{-w}{r^2} - \frac{v}{2k}\left(1+\frac{w}{r}\right)\right] \qquad \textbf{(EQ 78)}$$

To solve Eq 78, we need to calculate the value of w and r first. From Eq 21, the temperature distribution of thick plate, and Eq 36 where z = 0, we can get:

$$q - q_0 = \frac{hEI}{2p\,l\,r}\exp\left(\frac{-v(w+r)}{2k}\right) \qquad \textbf{(EQ 79)}$$

and $r=\sqrt{w^2+y^2}$

By substituting the welding condition and material properties into Eq 21, Eq 36, and $r = \sqrt{w^2+y^2}$, we can obtain the following simultaneous equations:

$$615-20 = \frac{1800}{22p\,x0.103r}\exp\left[\frac{-0.1(w+r)}{2x0.117}\right]$$

and $r=\sqrt{w^2+4}$

The value of w and r can be solved by using iteration techniques to solve the above simultaneous equation. The result is that w = -3 cm and r = 3.606 cm.

Substituting w and r into Eq 78:

$$\frac{\partial q}{\partial t}_{qC} = -v\frac{\partial q}{\partial w} = \frac{-0.1x1800}{2p\,x0.103x3.606}x\exp\left[\frac{-0.1(-3+3.606}{2x0.117}\right]x\left[\frac{-(-3)}{3.606^2} - \frac{0.1}{2x0.117}\left(1+\frac{-3}{3.606}\right)\right]$$

Therefore:

$$\left.\frac{\partial q}{\partial t}\right|_{qC} = -9.78°C/s$$

From Eq 49 we can calculate the cooling rate along the centerline at the same temperature (615 °C, or 1140 °F):

$$R = \frac{2p\,x0.103(615-20)^2}{18,000} = 12.7°C/s$$

Also from Eq 32, we can calculate the cooling rate in the heat-affected zone at a temperature of 615 °C (1140 °F):

$$\frac{\partial q}{\partial t}_{qC=615} = 0.35\left\{\left[\frac{615-20}{336/2.362}\right]^{1.7} x\left[1+\frac{2}{p}\tan^{-1}\left(\frac{0.9843-0.486}{0.125}\right)\right]\right\}^{0.8} = 4°C/s$$

Therefore, at the same temperature, the cooling rate at the centerline is greater than the cooling rate at the location a distance *y* from the centerline. In addition, the cooling rate of the heat-affected zone is less than the cooling rate in the weld pool at the same temperature.

Example 4: Solidification Rate.

A weld pass of 800 J/mm (20.3 kJ/in.) in net energy input is deposited on a steel plate. The initial temperature is 25 °C (75 °F). The solidification time would be:

$$S_t = \frac{2(800)}{2p\,(0.028)(0.0044)(1510-25)^2} = 0.94(s) \qquad \textbf{(EQ 80)}$$

Parametric Effects

To show the effects of material property and welding condition on the temperature distribution of weldments, the welding of 304 stainless steel, low-carbon steel, and aluminum are simulated for three different welding speeds: 1.0, 5.0, and 8.0 mm/s (0.04, 0.02, and 0.03 in./s). The thermal conductivity and thermal diffusivity of 304 stainless steel are 26 W/m · K (0.062 cal/cm · s · °C) and 4.6 mm^2/s (0.007 $in.^2/s$), respectively. For low-carbon steel, the respective values are 50 W/m K (0.12 cal/cm s °C) and 7.5 mm^2/s (0.012 $in.^2/s$), whereas for aluminum, the respective values are 347 W/m K (0.93 cal/cm · s · °C) and 80 mm^2 (0.12 $in.^2/s$). The heat input per unit weld length was kept constant, 4.2 kJ/s (1 kcal/s), for all cases. The parametric results are described below.

Effect of Material Type. Figures 5(a), 5(b), and 5(c) depict the effect of thermal properties on isotemperature contours for a heat input of 4.2 kJ/s (1 kcal/s) and travel speeds of 1.0, 5.0, and 8.0 mm/s (0.04, 0.02, and 0.3 in./s). The temperature spreads over a larger area and causes a larger weld pool (larger weld bead) for low-conductivity material. The isotemperature contours also elongate more toward the back of the arc for low-conductivity material. For aluminum, a larger heat input would be required to obtain the same weld size as the stainless steel weldment.

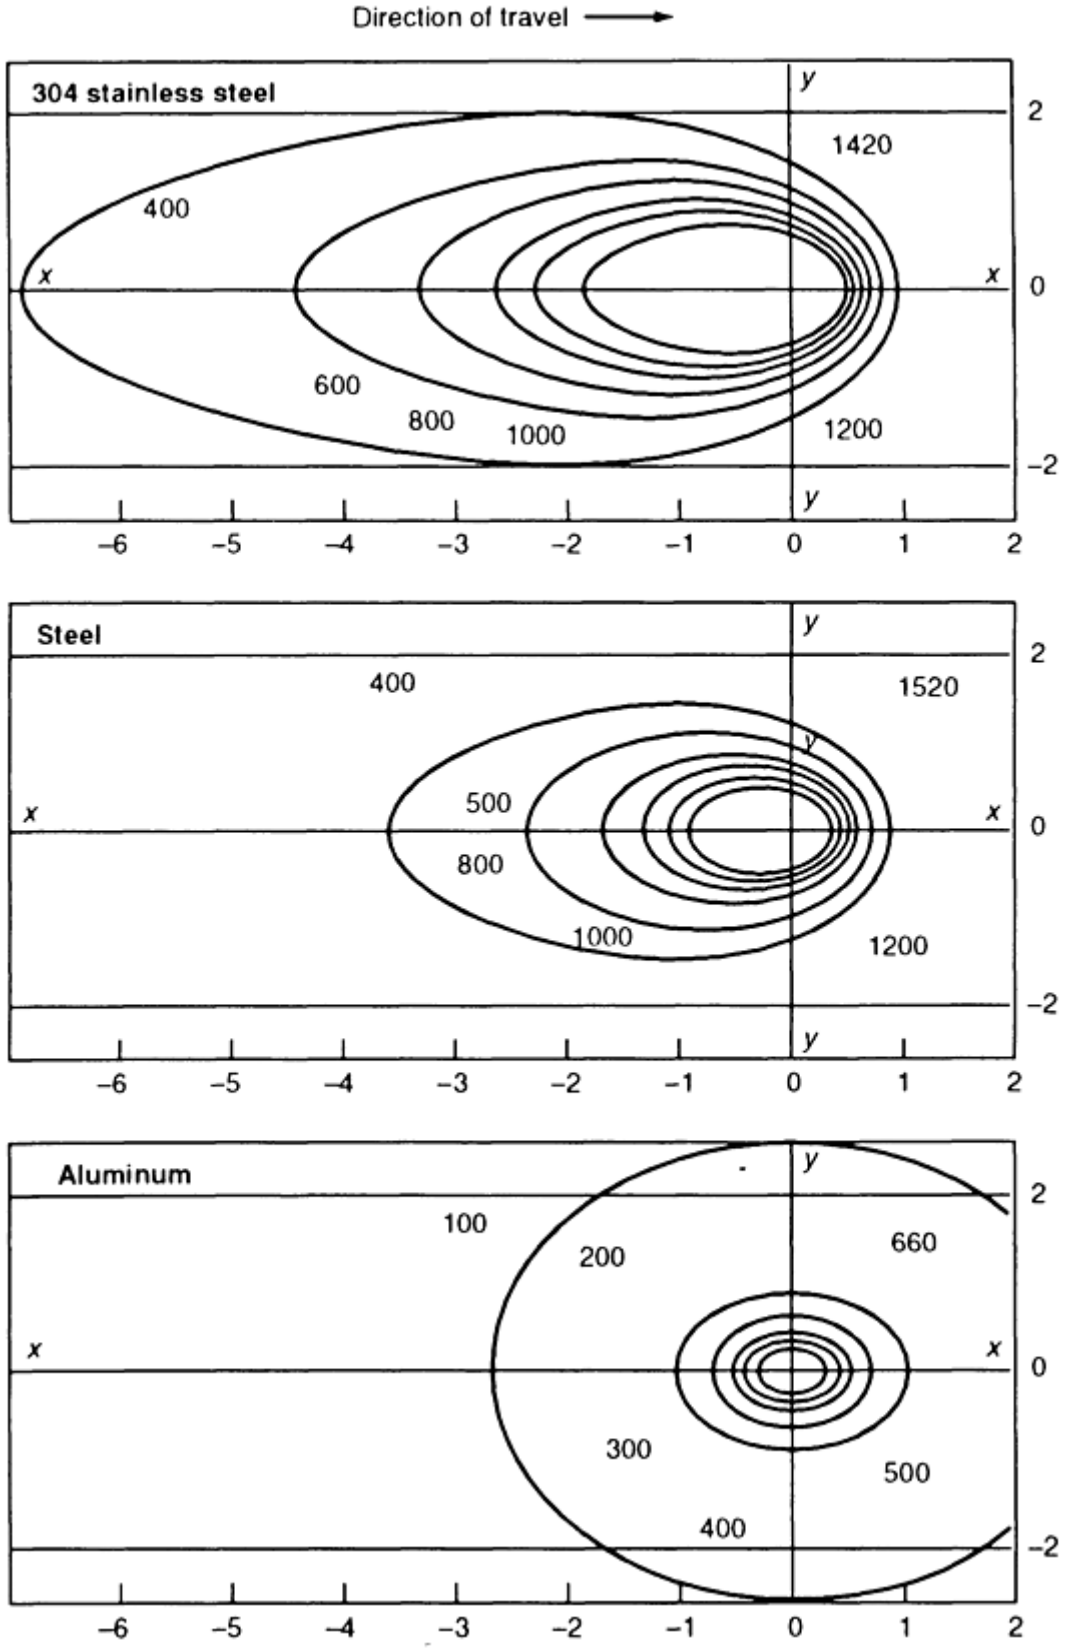

FIG. 5(A) EFFECT OF THERMAL PROPERTY ON ISOTEMPERATURE CONTOURS FOR A HEAT INPUT OF 4.2 KJ/S (1000 CAL/S) AT A WELDING SPEED, *V*, OF 1 MM/S (0.04 IN./S) AND THE RESPECTIVE THERMAL CONDUCTIVITIES OF EACH MATERIAL (REFER TO TEXT FOR VALUES). VALUES FOR *X* AND *Y* ARE GIVEN IN CM, AND TEMPERATURES ARE GIVEN IN °C.

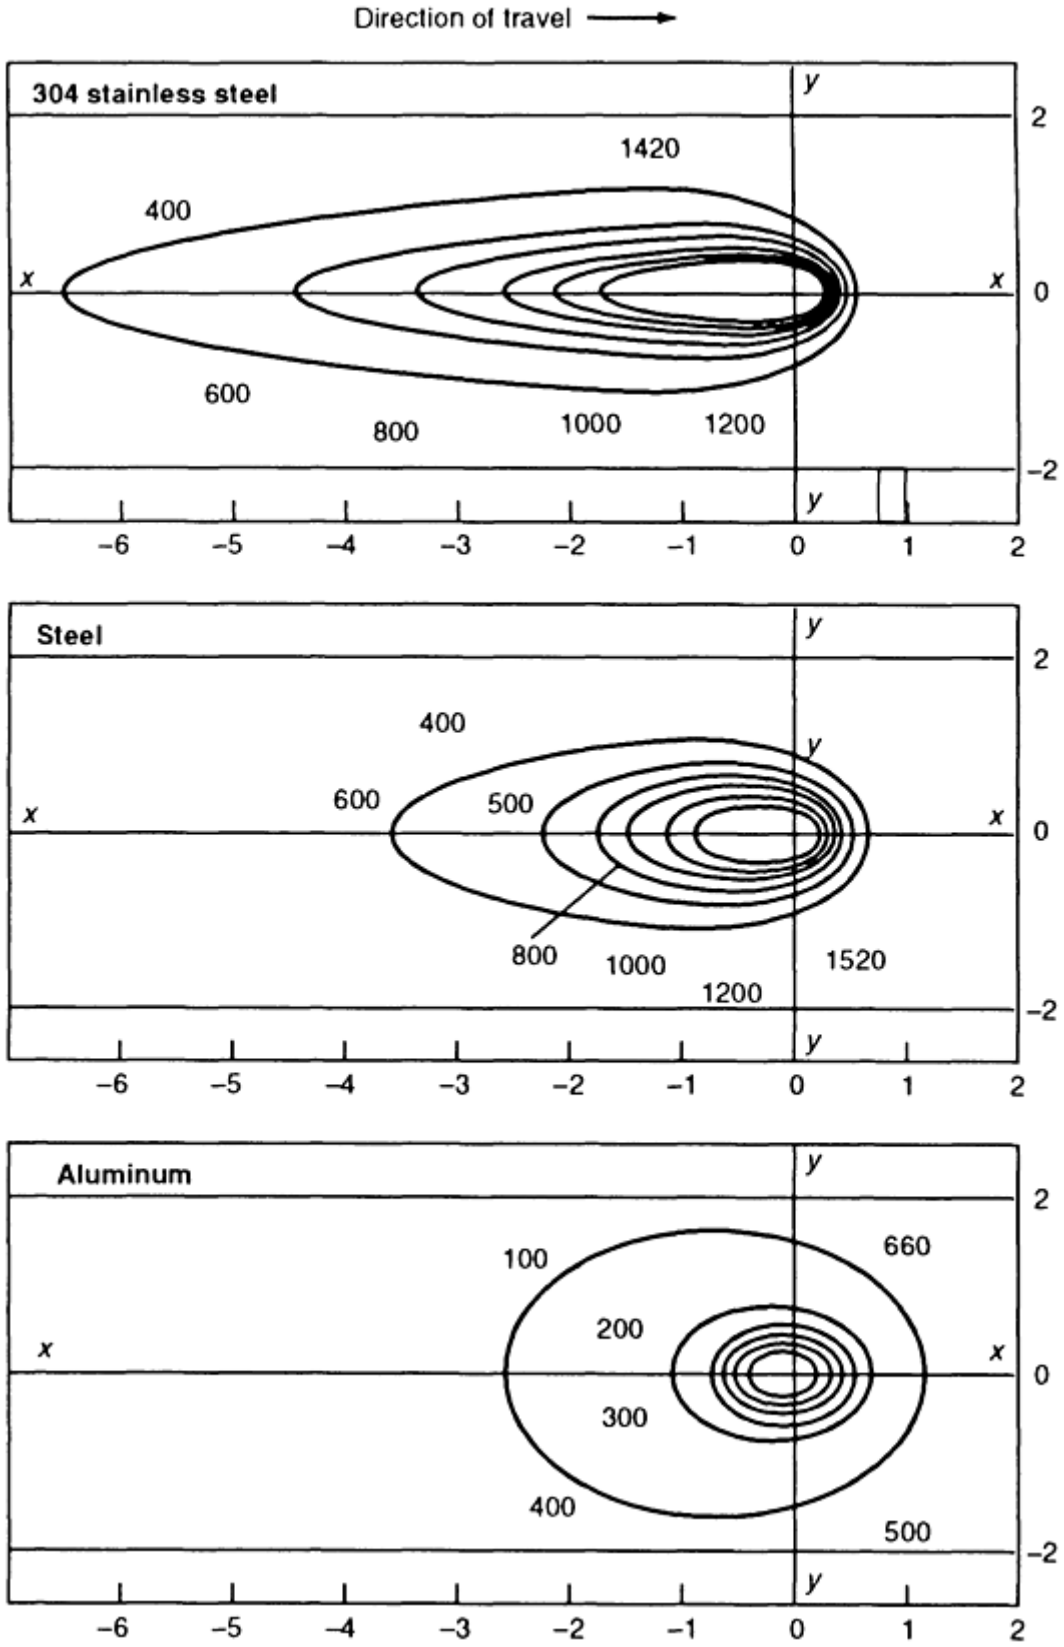

FIG. 5(B) EFFECT OF THERMAL PROPERTY ON ISOTEMPERATURE CONTOURS FOR A HEAT INPUT OF 4.2 KJ/S (1000 CAL/S) AT A WELDING SPEED, *V*, OF 5 MM/S (0.02 IN./S) AND THE RESPECTIVE THERMAL CONDUCTIVITIES OF EACH MATERIAL (REFER TO TEXT FOR VALUES). VALUES FOR *X* AND *Y* ARE GIVEN IN CM, AND TEMPERATURES ARE GIVEN IN °C.

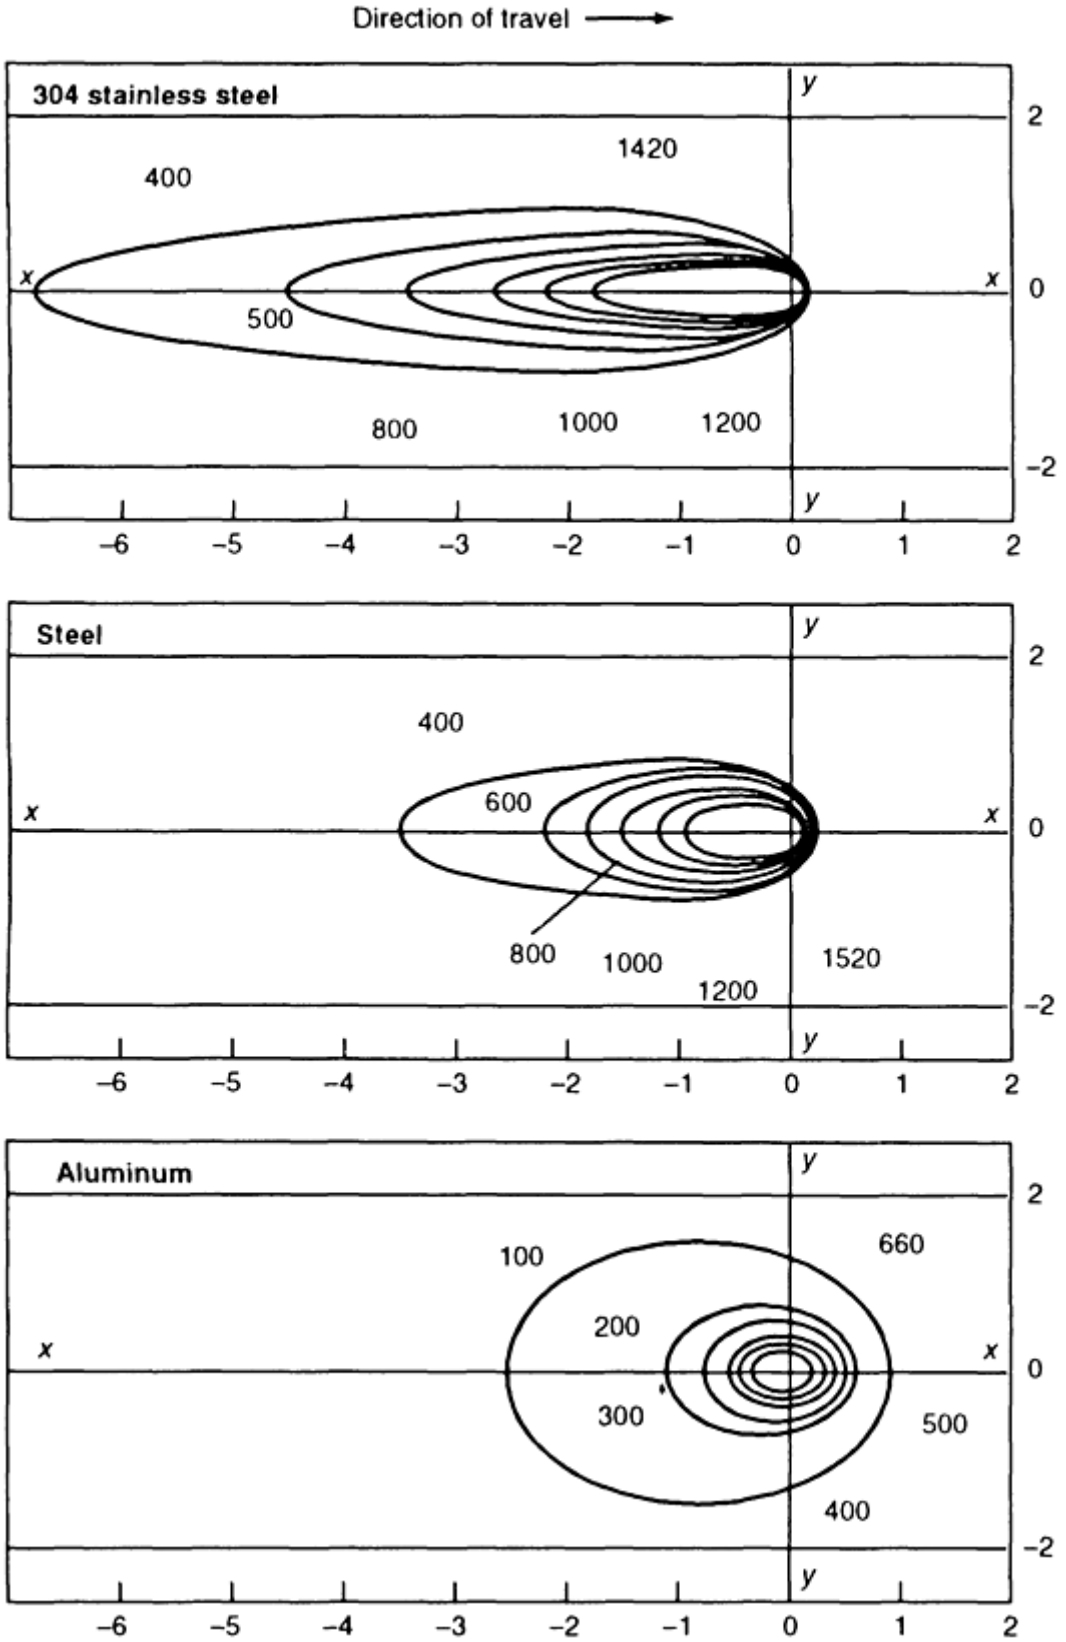

FIG. 5(C) EFFECT OF THERMAL PROPERTY ON ISOTEMPERATURE CONTOURS FOR A HEAT INPUT OF 4.2 KJ/S (1000 CAL/S) AT A WELDING SPEED, *V*, OF 8 MM/S (0.3 IN./S) AND THE RESPECTIVE THERMAL CONDUCTIVITIES OF EACH MATERIAL (REFER TO TEXT FOR VALUES). VALUES FOR *X* AND *Y* ARE GIVEN IN CM, AND TEMPERATURES ARE GIVEN IN °C.

Welding Speed. Figures 6(a), 6(b), and 6(c) show the effect of welding speed on isotemperature contours. When the travel speed increases, the weld size decreases and the isotemperature contours are more elongated toward the back of the arc. Larger heat inputs would be required for faster travel speeds in order to obtain the same weld size.

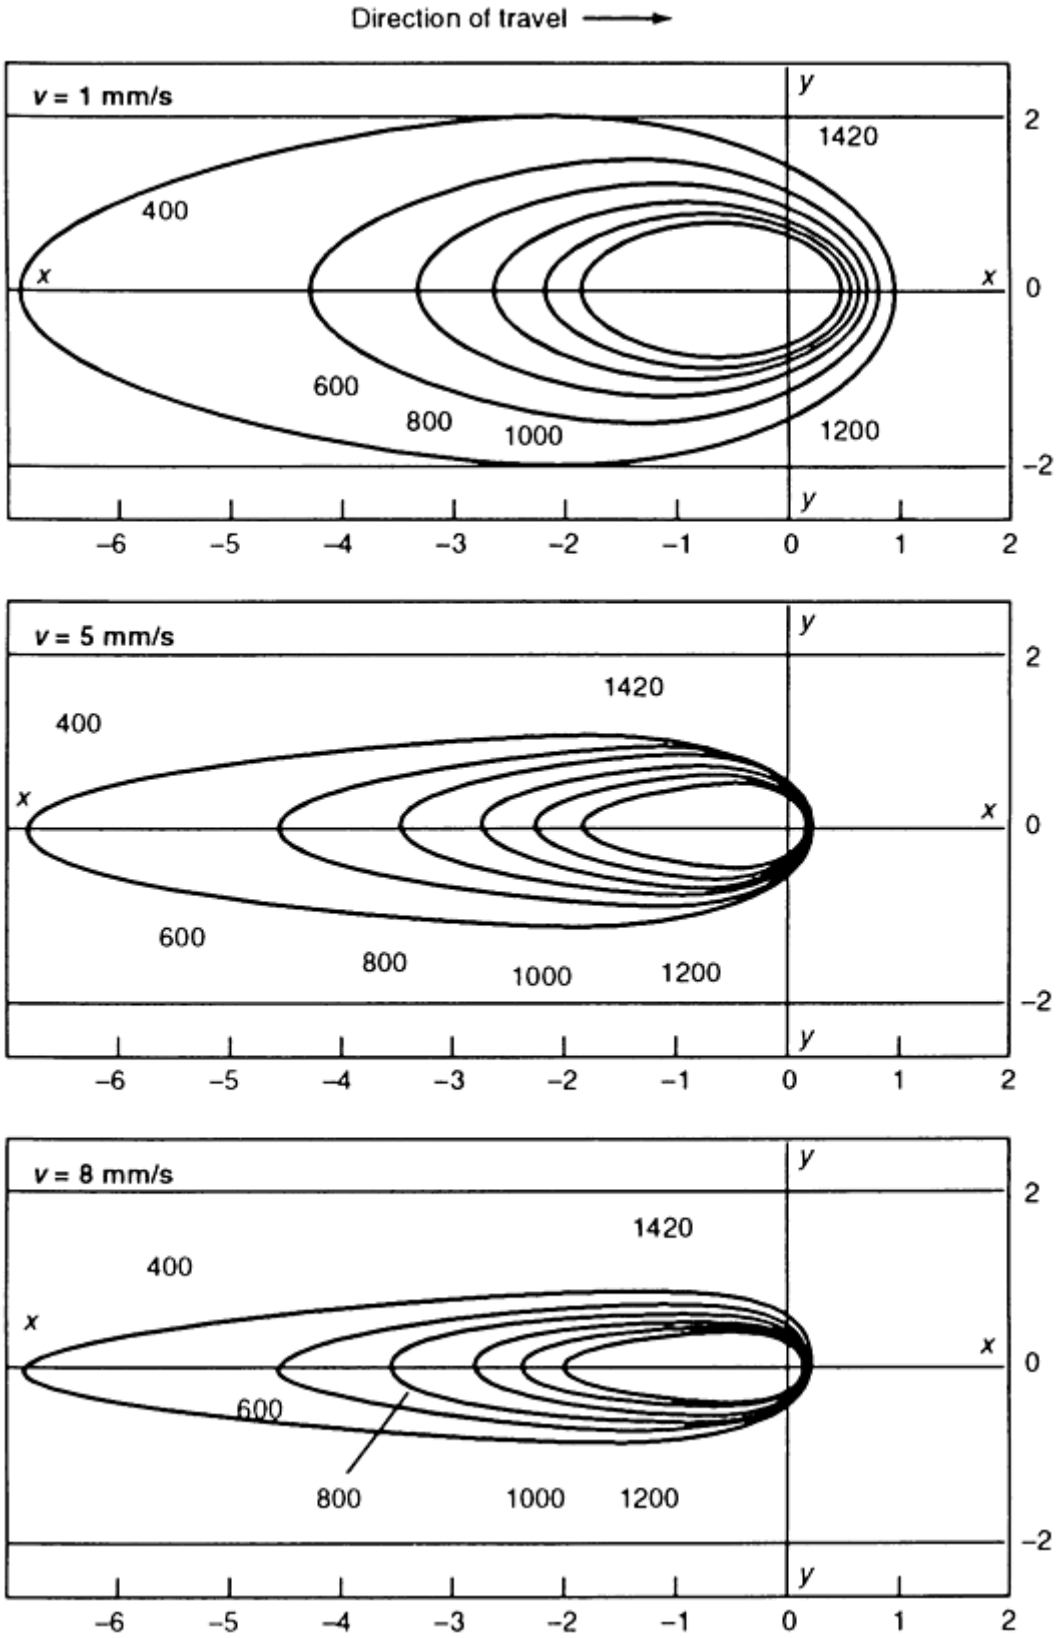

FIG. 6(A) EFFECT OF WELDING SPEED, *V*, ON ISOTEMPERATURE CONTOURS OF 304 STAINLESS STEEL FOR 4.2 KJ/S (1000 CAL/S) HEAT INPUT

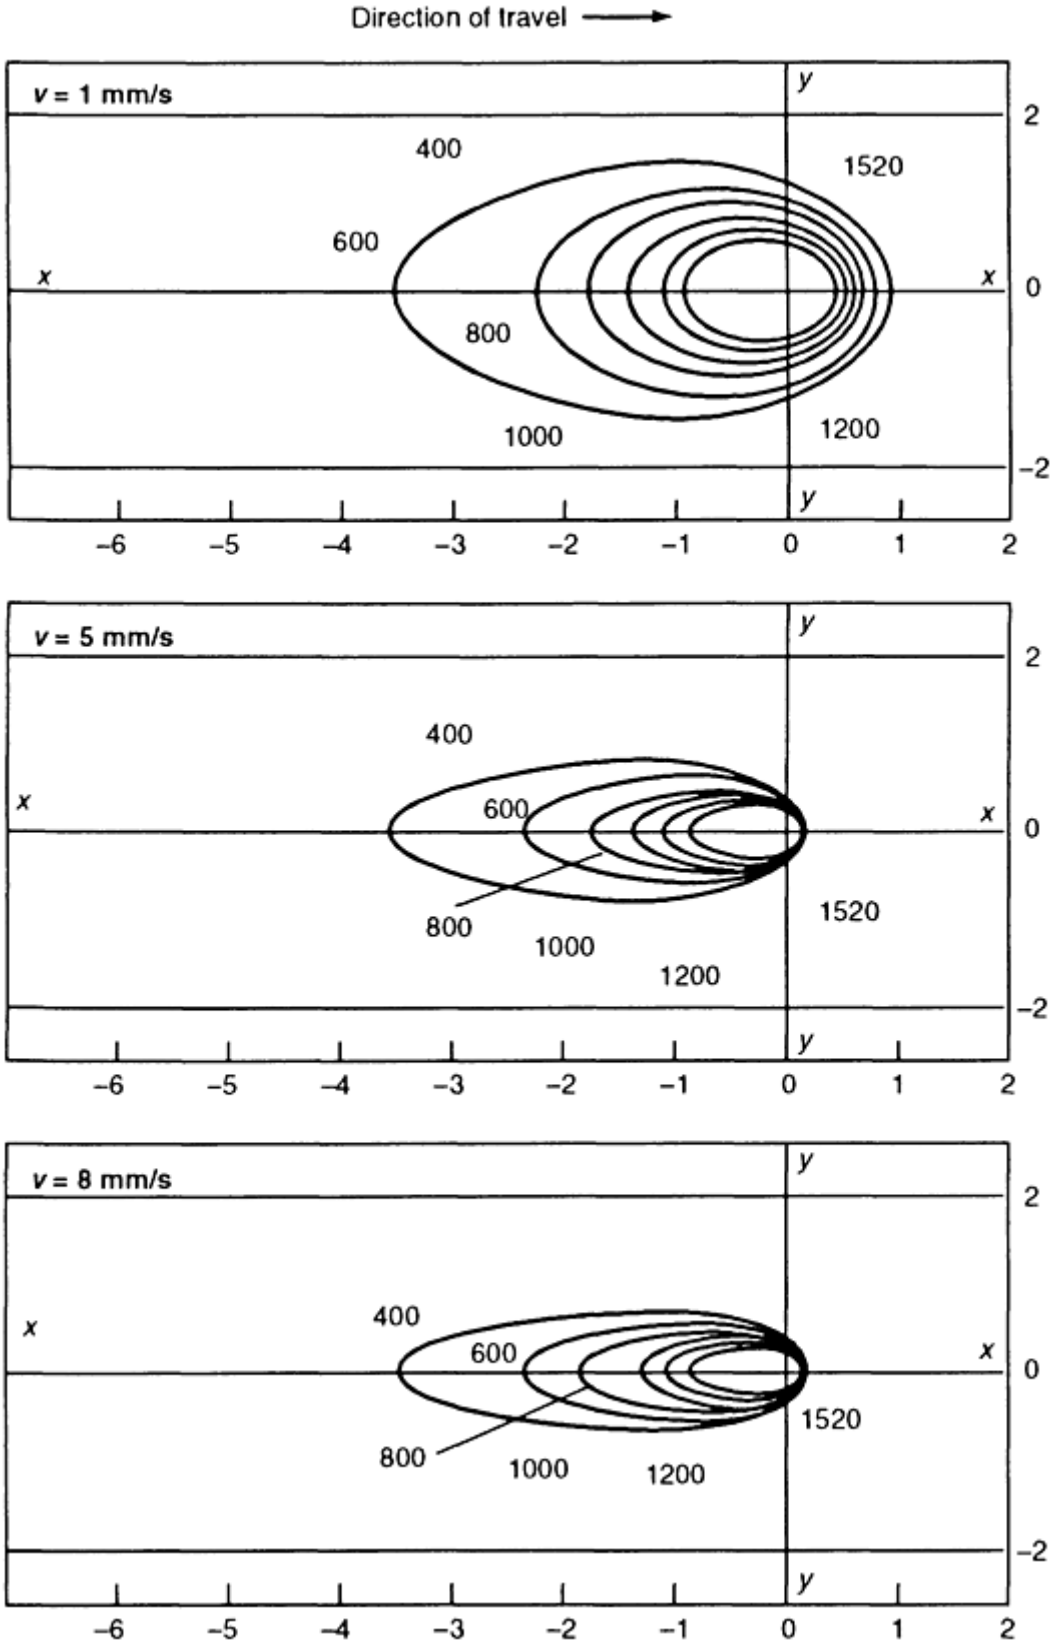

FIG. 6(B) EFFECT OF WELDING SPEED, *V*, ON ISOTEMPERATURE CONTOURS OF LOW-CARBON STEEL FOR 4.2 KJ/S (1000 CAL/S) HEAT INPUT

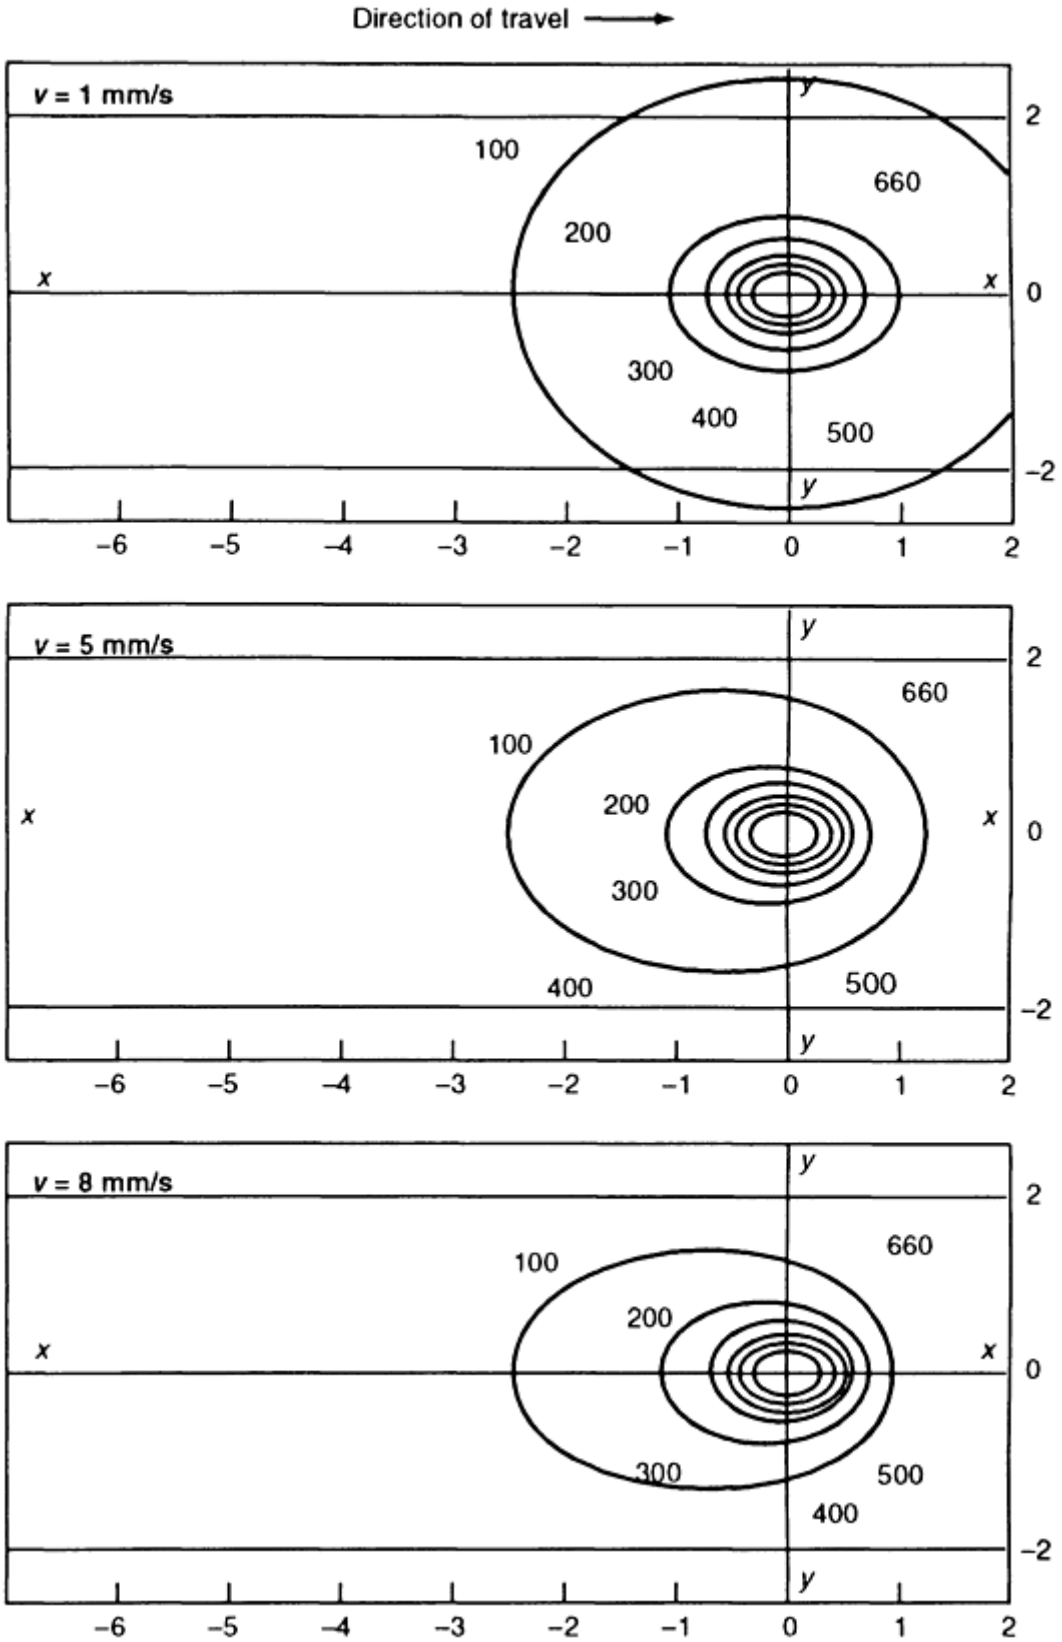

FIG. 6(C) EFFECT OF WELDING SPEED, *V*, ON ISOTEMPERATURE CONTOURS OF ALUMINUM FOR 4.2 KJ/S (1000 CAL/S) HEAT INPUT

Figure 7 shows the effect of welding heat input on the peak temperature at two locations, 6.4 mm ($\frac{1}{4}$ in.) and 13 mm ($\frac{1}{2}$ in.) from the weld centerline. (The material simulated in this illustration is low-carbon steel plate with a large thickness.) Within the practical range of welding conditions for the GMAW process of low-carbon steels, the peak temperature at both locations increases linearly, as the welding current increases, and decreases exponentially, with the travel speed. To increase welding current proportionally with travel speed for a constant heat input per unit weld length (that is. $\dot{Q}/V$ = constant), the peak temperature at two locations increases with the travel speed, which implies a larger weld size resulting from higher heat input. The welding current has a more significant effect on peak temperature than does the travel speed. However, the increase in peak temperature is more dominant at the 6.4 mm ($\frac{1}{4}$ in.) location. The influence of proportional increase in welding current and travel speed on peak temperature diminishes as the distance from the weld centerline increase and when the travel speed becomes high.

Fluid Flow Phenomena During Welding

C.R. Heiple and P. Burgardt, EG&G Rocky Flats

Introduction

MOLTEN WELD POOLS are dynamic. Liquid in the weld pool in acted on by several strong forces, which can result in high-velocity fluid motion. Fluid flow velocities exceeding 1 m/s (3.3 ft/s) have been observed in gas tungsten arc (GTA) welds under ordinary welding conditions, and higher velocities have been measured in submerged arc welds. Fluid flow is important because it affects weld shape and is related to the formation of a variety of weld defects. Moving liquid transports heat and often dominates heat transport in the weld pool. Because heat transport by mass flow depends on the

direction and speed of fluid motion, weld pool shape can differ dramatically from that predicted by conductive heat flow. Temperature gradients are also altered by fluid flow, which can affect weld microstructure. A number of defects in GTA welds have been attributed to fluid flow or changes in fluid flow, including lack of penetration, top bead roughness, humped beads, finger penetration, and undercutting. Instabilities in the liquid film around the keyhole in electron beam and laser welds are responsible for the uneven penetration (spiking) characteristic of these types of welds.

Mass Transport in the Arc

High-velocity gas motion occurs in and around the arc during welding. The gas motion is partially due to cover gas flow, but, more importantly, it is driven by electromagnetic forces associated with the arc itself. In gas metal arc (GMA) welds, liquid filler metal is also being transferred through the arc from the electrode to the workpiece. Both the mode and velocity of metal transfer have major effects on weld pool shape. Mass transport in and around the arc is important in GTA welding (GTAW) and even more so in GMA welding (GMAW); a detailed description of this phenomenon can be found in the articles on arc physics and metal transfer and weld behavior in this Volume. Only the effects of this transport on the weld pool will be discussed in this article.

Fluid Flow Phenomena During Welding

C.R. Heiple and P. Burgardt, EG&G Rocky Flats

Gas Tungsten Arc Welding

Most experimental and theoretical work on weld pool fluid flow and its effects has been directed toward GTAW. The motivation for much of this work was the observation of dramatically different weld pool shapes for GTA welds made using identical welding parameters on different heats of the same material with the same nominal composition. An extreme example of weld shape variability is shown in Fig. 1. Early observations of variable weld shape (often referred to as variable penetration) were not only an intellectual puzzle but also an indication of a growing practical problem. Gas tungsten arc welding is commonly used for high-precision, high-quality automated welding applications, where reproducibility of weld shape or penetration is critical.

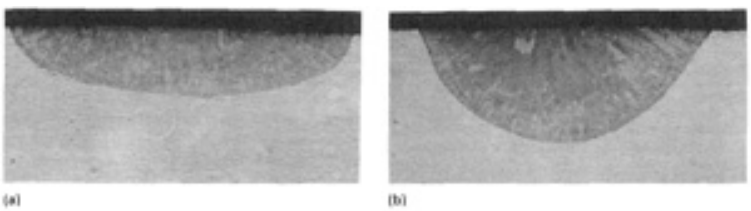

FIG. 1 PARTIAL-PENETRATION GTA WELDS MADE UNDER THE SAME WELDING CONDITIONS ON TWO HEATS OF TYPE 304L STAINLESS STEEL HAVING THE SAME NOMINAL COMPOSITION. (A) 3 PPM S, *D*/*W* = 0.2. (B) 160 PPM S, *D*/*W* = 0.40. 9×

The possibility that fluid flow in the weld pool could alter weld shape has been recognized for many years. For example, in 1965 Christensen *et al.* (Ref 1) proposed that convection is partially responsible for deviations in weld pool shapes from those predicted by conduction solutions. The forces driving fluid flow in GTA weld pools have also been long known. The four primary driving forces are surface tension gradients, electromagnetic or Lorentz forces, buoyancy forces, and aerodynamic drag forces caused by passage of the arc plasma over the weld pool surface.

Surface-Tension-Driven Fluid Flow Model. Surface tension gradients were first proposed by Ishizake *et al.* (Ref 2) as potential driving forces for weld pool fluid flow. Surface-tension-driven fluid flow was first described by Thomson (Ref 3) in 1855, but the phenomenon is commonly called Marangoni convection from the work of Carlo Marangoni (Ref 4).

In 1982, Heiple and Roper (Ref 5) proposed that surface tension gradients are commonly the dominant forces driving fluid flow in GTA welds and that these gradients could be drastically altered by very small concentrations of certain trace elements. Surface tension gradients exist on a weld pool surface because the surface tension is temperature dependent, and there are large temperature gradients on a weld pool surface. For pure metals and many alloys, the surface tension decreases as temperature increases; that is, the surface tension temperature coefficient is negative. For weld pools in such materials, the surface tension will be greatest on the coolest part of the pool surface at the edge and lowest on the hottest part under the arc near the center of the pool. Such a surface tension gradient produces outward surface fluid flow, as shown schematically in Fig. 2(a). This fluid flow pattern transfers heat efficiently from the hottest part of the weld pool (near the center) to the edge and produces a relatively wide and shallow weld.

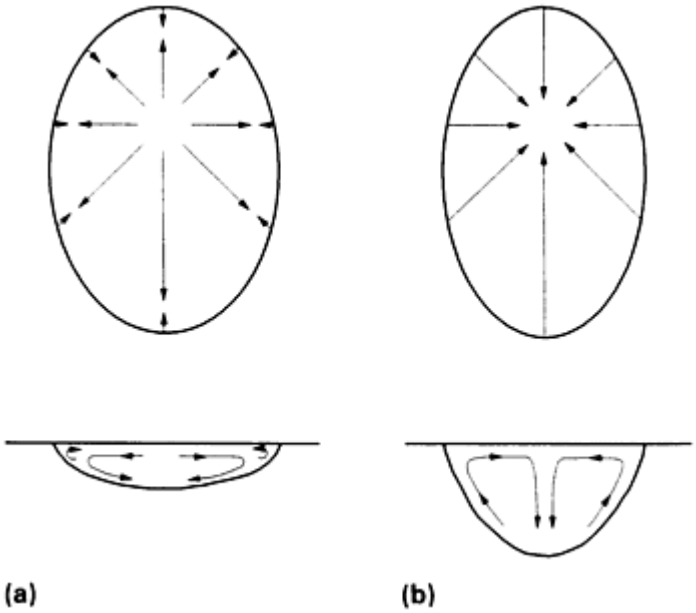

FIG. 2 SCHEMATIC SHOWING SURFACE FLUID FLOW (TOP) AND SUBSURFACE FLUID FLOW (BOTTOM) IN THE WELD POOL. (A) NEGATIVE SURFACE TENSION TEMPERATURE COEFFICIENT (PURE MATERIAL). (B) POSITIVE SURFACE TENSION TEMPERATURE COEFFICIENT (SURFACE-ACTIVE ELEMENTS PRESENT)

Certain elements are surface active in molten metals; that is, they segregate to the surface of the solvent liquid metal and lower the magnitude of the surface tension, often drastically. Small concentrations of surface-active additions can also change the temperature dependence of the surface tension of the solvent metal or alloy so that, for a limited range of temperature above the melting point, the surface tension increases with increasing temperature. With a positive surface tension temperature coefficient, the surface tension will be highest near the center of the weld pool. Such a surface tension gradient will produce fluid flow inward along the surface of the weld pool and then down, as indicated schematically in Fig. 2(b). This fluid flow pattern transfers heat efficiently to the bottom of the weld pool and produces a relatively deep, narrow weld.

Experimental Observations. This physical model was developed and verified with a series of experiments in which stainless steel base metal was doped with low concentrations of various elements and the effect of the doping on weld pool shape measured. High-speed motion pictures of the weld pool surface suggested the fluid flow patterns indicated in Fig. 2. The addition of sulfur, oxygen, selenium, and tellurium to stainless steel in low concentrations (less than 150 ppm) was shown to substantially increase GTA weld depth-to-width ratio (d/w). All these elements are known to be highly surface active in liquid iron. Measurements of the temperature dependence of the surface tension for steels with different GTA weld penetration characteristics produced an impressive correlation between a positive surface tension temperature coefficient arising from surface-active impurities and high d/w ratio welds (Fig. 3).

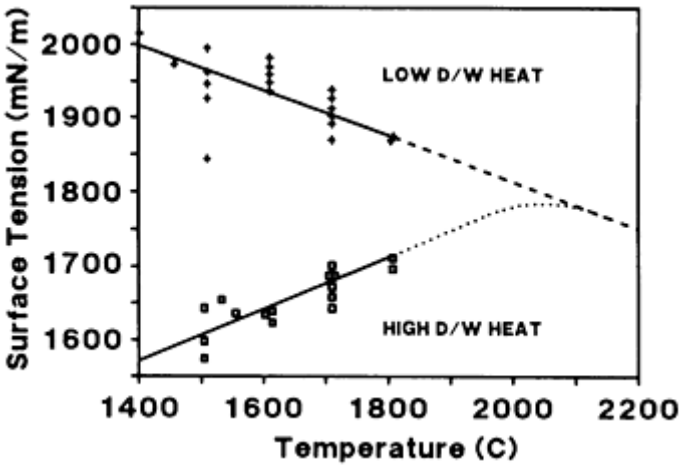

FIG. 3 PLOT OF SURFACE TENSION VERSUS TEMPERATURE FOR TWO LIQUID STEELS. THE DATA LABELED "HIGH *D/W* HEAT" ARE FROM MATERIAL HAVING APPROXIMATELY 160 PPM MORE SULFUR THAN THE MATERIAL LABELED "LOW *D/W* HEAT." THE DASHED LINES INDICATE THE EXPECTED BEHAVIOR OF THE SURFACE TENSION ABOVE THE MAXIMUM TEMPERATURE STUDIED. SOURCE: REF 6

When additions were made to the weld pool of elements known to react with surface-active elements already present in the steel to form compounds that are not surface active, the GTA weld *d*/*w* ratio decreased. Aluminum reacts with oxygen and produced wider, shallower welds in 21-6-9 stainless steel. Cerium reacts with both sulfur and oxygen and also produced lower *d*/*w* ratio welds. The effects of trace elements on weld shape have also been observed in a number of other alloys. These observations are summarized in Table 1.

TABLE 1 EFFECT OF TRACE ELEMENT IMPURITIES ON GTA WELD PENETRATION OF SELECTED ALLOYS

ALLOY SYSTEM	TRACE ELEMENT IMPURITY	
	INCREASES WELD PENETRATION	DECREASES WELD PENETRATION
ZIRCALOY-2	CHLORINE	. . .
IRON-BASE ALLOYS STAINLESS STEELS 304, 316, 21-6-9 JBK-75 AISI 8630 2.5CR-1MO	SULFUR, OXYGEN, SELENIUM(A), TELLURIUM(A)	CALCIUM, ALUMINUM, CERIUM(A), LANTHANUM(A), SILICON(B), TITANIUM(B)
NICKEL-BASE ALLOYS INCONEL 600, 718	SULFUR	OXYGEN

(A) UNCOMMON IMPURITIES

(B) EFFECT NEGLIGIBLE OR UNCERTAIN

The simple physical model illustrated in Fig. 2 has been remarkably successful in qualitatively explaining trace element effects. For example, changing GTA welding conditions alters the magnitude and distribution of arc energy input to the weld, which in turn changes temperature gradients on the weld pool surface. From Fig. 2, a change in welding conditions that makes the center of the weld hotter, such as increasing current, should drive the existing fluid flow pattern more strongly. As shown in Fig. 4, increasing current improves the *d/w* ratio of steel doped with surface-active elements and reduces it for high-purity base metal. If the center of the weld becomes so hot that there is a region where the temperature coefficient of the surface tension is no longer positive, then the fluid flow pattern necessary for deep penetration is disrupted and the *d/w* ratio decreases. This effect is seen at high currents in Fig. 4. Similar results have been obtained for other welding parameters. The surface temperature at which the change from positive to negative surface tension

temperature coefficient occurs for stainless steel is estimated by extrapolation in Fig. 3 to be about 2050 °C (3720 °F). Detailed thermodynamic calculations of the temperature dependence of the surface tension of iron-sulfur alloys predict that the transition from positive to negative $d\gamma/dT$ will occur at 2032 °C (3690 °F) for the high-sulfur alloy in Fig. 3. Recent spectrographic weld pool temperature measurements and numerical simulations have indicated that this temperature can be exceeded in stainless steel GTA weld pools under normal welding conditions.

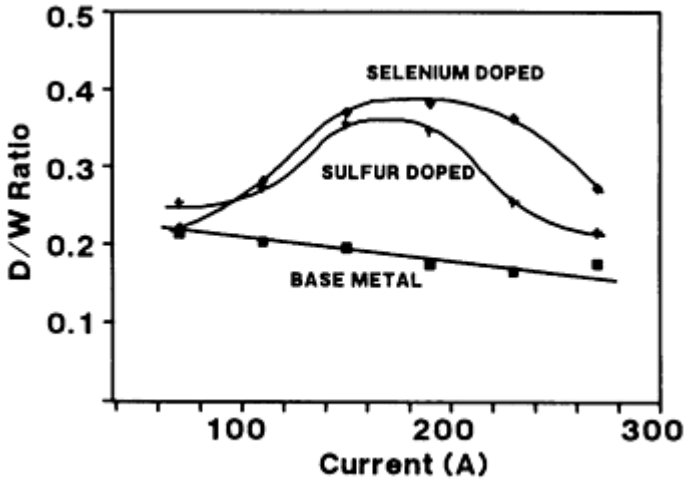

FIG. 4 PLOT OF WELD *D/W* RATIO VERSUS WELD CURRENT FOR THE STARTING BASE METAL (TYPE 304 STAINLESS STEEL WITH VERY LOW RESIDUAL IMPURITY CONTENT) AS WELL AS FOR ZONES DOPED WITH SULFUR AND SELENIUM. SOURCE: REF 7

The surface-tension-driven fluid flow model should be applicable to non-arc processes, provided the energy input distribution is similar to a GTA arc. This condition is satisfied for conduction-mode electron beam and laser welds. Dramatic increases in weld d/w ratio in selenium-doped zones in stainless steel have been observed for both traveling laser and electron beam conduction-mode welds. The weld shape changes were similar to those observed for GTA welds.

Conduction-mode electron beam welds can also be used to demonstrate that variations in weld shape with changes in welding parameters, as illustrated in Fig. 4, are not a result of some complex arc/weld pool interaction. One of the results of an investigation of the effect of changes in beam focus on weld shape in electron beam welds on low- and high-sulfur materials is shown in Fig. 5. The high-sulfur material exhibits a maximum in d/w ratio with increasing power density at a moderate power density away from sharp focus, which is analogous to that shown with increasing current in Fig. 4. (The low- and high-sulfur stainless steels have deep and nearly identical penetration near sharp focus. Near sharp focus, where the power density is high, penetration is by a keyhole mechanism in which average penetration is unrelated to surface-tension-driven fluid flow.) Measurements of the electron beam power-density distribution verified that there were no anomalous changes in the beam, such as a beam width maximum, with increasing peak power density. The d/w ratio maximum away from sharp focus is therefore proposed to originate from exactly the same mechanism as for increasing current with GTA welds.

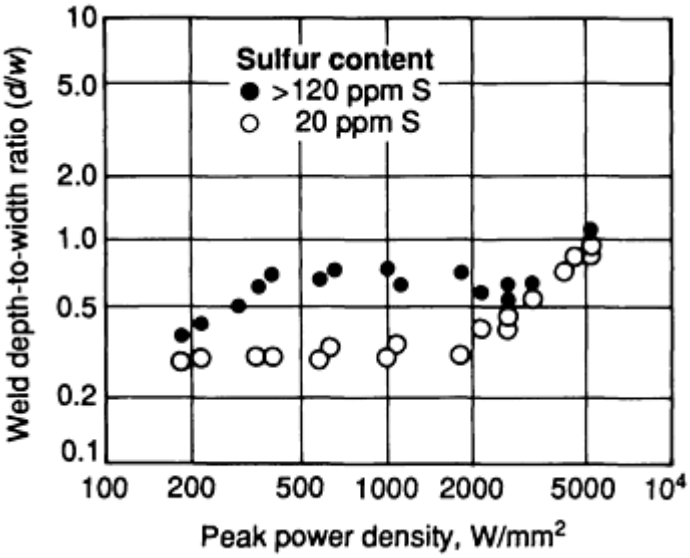

FIG. 5 PLOT OF ELECTRON BEAM WELD POOL RATIO (*D*/*W*) VERSUS ELECTRON BEAM POWER DENSITY FOR LOW-SULFUR (20 PPM) AND HIGH-SULFUR (>120 PPM) TYPE 304L STAINLESS STEEL. KEYHOLE FORMATION BEGINS AT ABOUT 2 × 10^3 W/MM^2.

Measurements of electron beam power distribution were made as a function of beam focus and were used to calculate the beam power density at the *d*/*w* maximum. The power density was also calculated at the *d*/*w* maximum for GTA welds. Calculation of weld pool surface temperatures using a traveling distributed heat source model showed the central surface temperatures to be essentially identical at the *d*/*w* maxima for the electron beam and GTA processes. The calculated surface temperatures using the traveling distributed heat source conduction approximation are much too high because, as indicated previously, most of the heat transport in the weld pool is by mass flow rather than by conduction. Nevertheless, the equality of the calculated weld pool peak temperatures at the *d*/*w* maxima provides strong confirmation that the mechanism responsible for the presence of the maximum in weld *d*/*w* with increasing input power density is independent of heat source and is not a result of an arc phenomenon.

A final example of the success of the fluid flow model in explaining GTA welding phenomena is provided by butt welding together two steels with large differences in weld penetration characteristics. The weld pool is not centered over the joint; rather, it is displaced toward the material with low *d*/*w* behavior (Ref 8), as indicated schematically in Fig. 6. The low *d*/*w* material has a low concentration of surface-active impurities and therefore a high surface tension. Thus, there is a net surface tension gradient across the weld pool toward the low *d*/*w* material, producing the fluid flow pattern and weld cross section indicated in Fig. 6. The actual fluid flow pattern is certain to be more complicated than that illustrated.

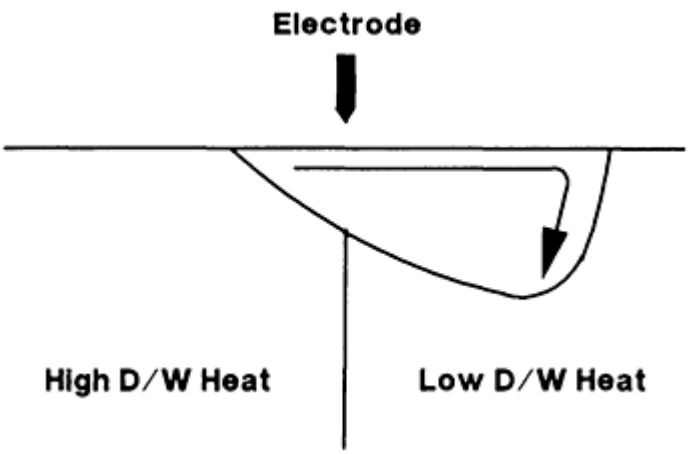

FIG. 6 SCHEMATIC SHOWING TYPICAL FLUID FLOW GENERATED WHEN BUTT WELDING TWO HEATS OF MATERIAL WITH DIFFERENT PENETRATION CHARACTERISTICS. SOURCE: REF 8

Numerical Simulations. Direct measurement of weld pool fluid flow is very difficult. Surface flow has been studied by observing the motion on the surface of slag or intentionally added particles, as has bulk flow in transparent liquid/solid systems using simulated welding heat sources. There are a number of numerical calculations of weld pool fluid flow and shape, the most comprehensive of which appears to be that of Zacharia *et al.* (Ref 9). These numerical fluid flow simulations agree in broad terms with the physical model illustrated in Fig. 2; however, they differ in detail with Fig. 2 and with one another. One result of the analysis of Zacharia is that the weld pool surface temperature reached in stationary welds exceeds that in traveling welds. Trace element effects should therefore be less pronounced in stationary welds, because a larger portion of the pool surface is above the temperature range where a positive surface tension temperature coefficient exists. This prediction is in agreement with experimental observations.

Interactions. Experiments in which low concentrations of various elements have been added to the base metal have demonstrated clear changes in weld pool shape. However, when weld *d*/*w* ratio is plotted versus chemical analysis for numerous heats of material, considerable scatter is observed. A comparison of weld *d*/*w* ratio in a standard weldability test versus sulfur content for about 200 lots of steel is shown in Fig. 7. There is a clear trend of increasing *d*/*w* with increasing sulfur, but the variability for a given sulfur content is substantial. Some of this variability is associated with imprecision in chemical analysis for sulfur and some with variations in oxygen content. However, it appears that much of the variability is related to interactions of the surface-active elements sulfur and oxygen with other components of the steel. Calcium is known to react with oxygen and, to a lesser extent, with sulfur to form stable compounds unlikely to be surface active. Aluminum and silicon also react with oxygen to form stable compounds. Thus, the amount of sulfur and oxygen available for segregation to the weld pool surface is a complicated function of the total weld pool chemistry.

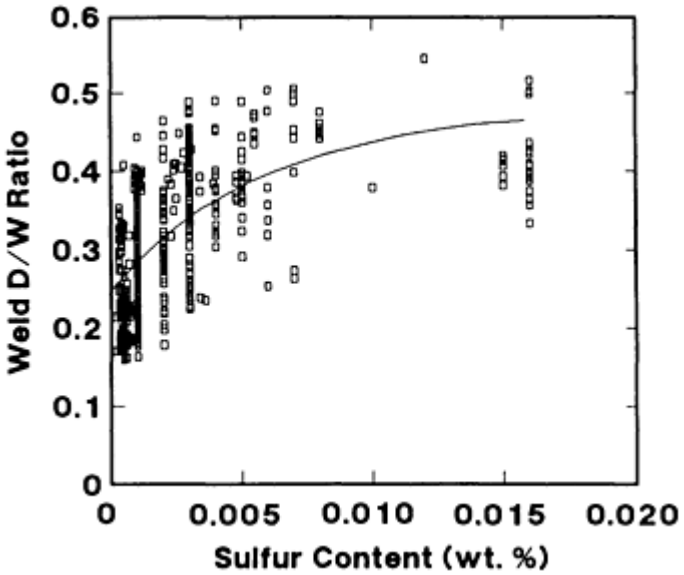

FIG. 7 PLOT OF WELD *D*/*W* RATIO VERSUS SULFUR CONTENT FOR APPROXIMATELY 200 HEATS OF TYPE 304L STAINLESS STEEL. EACH POINT IS AN AVERAGE OF MULTIPLE SULFUR ANALYSES AND WELD *D*/*W* RATIO MEASUREMENTS. IF SINGLE VALUES ARE USED, THE SCATTER IS GREATER. SOURCE: REF 10

There is an additional complication, illustrated in Fig. 8. When oxygen is added to the shielding gas, weld *d*/*w* ratio increases, passes through a maximum, and then declines with increasing oxygen content. Similar effects are seen with SO_2 additions. The surface of welds made with torch gas concentrations above the *d*/*w* maximum are heavily oxidized. A possible explanation for the decreasing *d*/*w* ratios at higher oxygen concentrations is that a liquid oxide film (slag) is formed on the weld pool surface, altering the surface tension gradients.

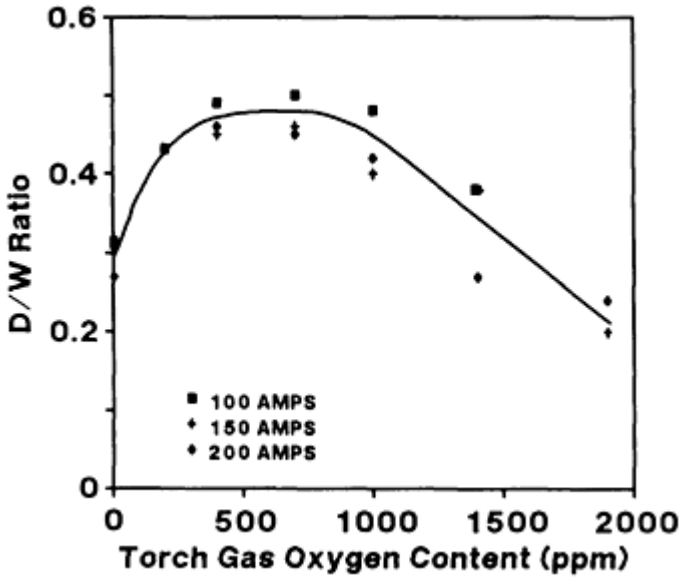

FIG. 8 PLOT OF WELD *D*/*W* RATIO VERSUS OXYGEN CONCENTRATION IN THE TORCH GAS FOR GTA BEAD-ON-PLATE WELDS ON 21-6-9 STAINLESS STEEL. SOURCE: REF 11

Oxygen can be added to the weld pool in other ways. Oxidizing the plate surface prior to welding adds oxygen to the weld pool and increases the weld *d*/*w* ratio. Wire brushing and grit blasting an originally clean surface increases both the surface oxide thickness and the surface area, thereby adding oxygen to the weld pool. The *d*/*w* ratio of JBK-75 stainless steel (a modification of ASTM A-286) GTA welds as a function of amount of wire brushing is similar in form to Fig. 8. Welds on plate brushed beyond the weld *d*/*w* maximum had extensive slag on the weld surface. The weld *d*/*w* ratio on JBK-75 stainless steel appears to be particularly sensitive to oxygen additions. Similar wire-brushing experiments on type 304 stainless steel showed smaller effects.

Although the origin of the difference in sensitivity between JBK-75 and type 304 is not known, one possibility is indicated by surface tension measurements on iron-silicon alloys in contact with carbon dioxide. The effect of CO_2 on the surface tension was a strong function of silicon content. For low-silicon alloys, the surface tension dropped sharply when contacted with CO_2. For alloys with more than 1.2% Si, the surface tension increased when contacted with CO_2. The different behavior was attributed to differences in slag formation on the liquid metal surface. Thus, silicon appears to interfere with the ability of oxygen to produce a positive surface tension temperature coefficient on liquid iron. The JBK-75 stainless steel used in the wire-brushing experiments contained only 0.06% Si, and the 21-6-9 used for the torch gas experiment (Fig. 8) contained only 0.16% Si. Type 304 stainless steel typically contains more than 0.5% Si. Thus, the high sensitivity of JBK-75 to oxygen additions may be related to its unusually low silicon content. Reports in the literature on the effect of oxygen on GTA weld penetration have been somewhat variable; differences in weld pool silicon content may be partially responsible for this variability.

Effects of High Current. Electromagnetic (Lorentz) stirring of the weld pool becomes more important at higher currents. The direction of the Lorentz force produces the deep penetration fluid flow pattern indicated in Fig. 2(b). At sufficiently high current, the Lorentz force dominates other forces that drive fluid flow, and the effects of trace elements become less important. In addition, the plasma jet becomes stronger with increasing current and at high enough currents produces a significant depression of the weld pool surface. The plasma jet forces are resisted by surface tension forces on the weld pool. Halmoy (Ref 12) has shown that for a traveling weld the radial pressure gradient from the plasma jet tends to transport liquid from the front to the rear of the weld (Fig. 9). For a sufficiently strong pressure gradient, p_B, the liquid level under the arc may be pushed down to the bottom of the pool, as shown in Fig. 9(c). High-speed motion pictures of the effect of sulfur additions on weld pool fluid flow in 21-6-9 stainless steel showed behavior similar to that in Fig. 9(c) after large sulfur additions. Sulfur additions substantially reduce the weld pool surface tension and thereby increase the effect of the plasma jet.

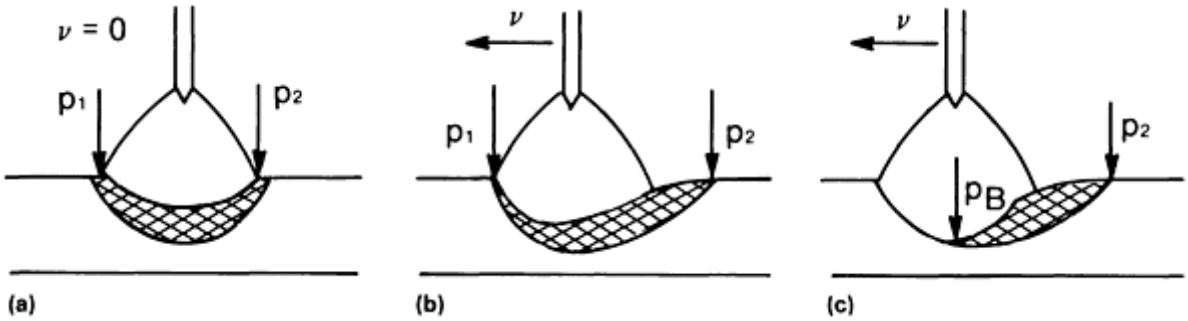

FIG. 9 EFFECT OF ARC PRESSURE ON THE WELD POOL FOR STATIONARY AND TRAVELING WELDS. (A) *V* = 0. (B) *V* > 0, WITH WEAK RADIAL PRESSURE GRADIENT, P_1. (C) *V* > 0, WITH STRONG RADIAL PRESSURE GRADIENT, P_B. SOURCE: REF 12

In addition, a surface depression almost certainly changes the energy distribution input to the weld pool by the arc compared with a flat weld pool surface. Finally, under some high-current conditions, a vortex has been observed near the center of weld pools.

Strategies for Controlling Poor and Variable Penetration. A number of techniques have been developed to reduce penetration variability and improve penetration. Sometimes the weld pool shift illustrated in Fig. 6, which occurs when heats with different penetration characteristics are welded together, can be minimized by very tight heat sinking. The sensitivity of weld shape to trace element differences is a function of welding parameters, as illustrated in Fig. 4 for current; thus, combinations of welding parameters can be chosen that minimize heat-to-heat penetration variability. For wire-fed joints, some joint designs are more tolerant of penetration variability than others. For example, joints with thinner, wider lands are less sensitive than narrower grooves with thicker lands.

Material control by selection or specification is another approach. It was originally anticipated that stainless steels with less than 20 ppm S would have poor, but consistent, penetration. However, the data illustrated in Fig. 7 demonstrate that penetration variability is substantial even at these very low sulfur levels. Stainless steels with more than about 100 ppm S generally have consistently good penetration. A related approach is to test incoming material for welding characteristics and then select material with desired welding behavior for critical applications.

Finally, the weld pool can be doped with enough surface-active elements to ensure good penetration. Sulfur and oxygen are the most practical dopants for ferrous alloys. The addition of oxygen or sulfur dioxide to the torch shielding gas has been shown to improve penetration and reduce penetration variability; however, this approach presents several practical problems. Oxygen can also be added to the weld pool by oxidizing the weld joint or by otherwise increasing the oxygen content of the weld groove surface--by wire brushing, for example. Probably the most useful approach is to dope the weld pool in the wire-fed joints by using a special filler wire. A group of defense contractors had a special heat of type 380L stainless steel produced with a sulfur content in the range of 100 to 150 ppm. The heat was then converted into weld wire. Welds made with this wire on a variety of stainless steel base metals have exhibited consistent and good penetration.

Deep-Penetration Electron Beam and Laser Welds

Keyhole Formation. A fundamental difference between arc heat sources and electron or laser beam heat sources is that electron and laser beams are capable of delivering heat over a small area at much higher power densities. As the power density of the welding heat source is increased, the peak surface temperature of the weld pool rises. For many metals, vapor pressure rises nearly exponentially with temperature and becomes appreciable (above 4000 Pa, or 30 torr, for an electron beam operating in a vacuum) near 0.8 T_b, where T_b is the material boiling point in degrees Kelvin. As the surface temperature approaches this value, the liquid surface under the power source is depressed by the vapor pressure. As the liquid moves away from the power source, the surface is depressed and a cavity is formed. This is the basic theory of keyhole formation by an electron or laser beam.

Fluid Flow in the Keyhole. The keyhole is a cavity having roughly the size and shape of the beam; that is, it is usually approximately cylindrical. Fluid flow in the thin layer around the cavity plays a major role in determining the behavior of deep-penetration, keyhole-mode electron beam and laser welds. The first flow required for a traveling weld is transport of metal melted at the front wall of the cavity to the rear (where it eventually solidifies). Because of the weld geometry, this liquid must move around the keyhole cavity as a thin, high-velocity layer on the walls of the cavity. The dominant driving force for this motion appears to be surface tension gradients. As in GTAW, these gradients arise because the surface tension is temperature dependent and there is a substantial temperature difference between the front and rear of the cavity.

Calculations of the fluid flow have been performed by Wei and Giedt (Ref 13). Their calculations for pure iron predict that liquid metal is moved from the front to the rear of a sharp focus keyhole in a film that is about 0.02 mm (0.0008 in.) thick and is moving at a velocity of about 250 mm/s (10 in./s). The fluid is driven by a temperature difference of about 400 °C (720 °F). These results are only nominal values from the calculations, but they change little with the assumptions used and are representative of electron beam welds in general.

There is an interesting potential problem with this model. As discussed previously, the surface tension temperature coefficient, $d\gamma/dT$, can be positive over a limited temperature range in steels and some other alloys if surface-active impurities are present in sufficient quantity. If $d\gamma/dT$ is positive, then it would appear that molten metal would not be transported around the cavity. The likely resolution of this difficulty is that the liquid dwells slightly longer in the front of the cavity and is heated by the beam above the temperature at which a transition to negative $d\gamma/dT$ occurs. Some perturbation of the normal fluid flow may occur under these circumstances. Effects of such a perturbation on weld characteristics appear to be uncommon. The only available evidence for such an effect comes from electron beam welds performed on a heat of type 304 stainless steel with very low residual impurity content, except for about 340 ppm S. These welds had very high porosity compared with identical welds in other heats of material.

Instability in Keyhole Fluid Flow. In addition to the steady-state flow of liquid around the keyhole, significant instability in the fluid motion has been seen. For example, Mara *et al.* (Ref 14) used side-view, self-illuminated X-ray films to show that the beam locations shifts between full penetration and nearly zero penetration in an irregular fashion. High-speed X-ray photographs show that the variable penetration is caused by a lump of metal that sags into the keyhole from high up on the cavity rear wall. The sequence of events that creates weld penetration irregularity was analyzed by Tong and Giedt (Ref 15) and is illustrated schematically in Fig. 10. First, the beam forms a keyhole and produces a lump of very hot displaced metal at the top rear of the traveling cavity (Fig. 10a). After some period of time, the weld reaches the full penetration allowed by heat flow (Fig. 10b). The lump of displaced metal is unstable and eventually falls into the cavity, partially filling it. The beam must now drill through this additional material. The sequence (a) to (c) in Fig. 10 occurs repeatedly, but irregularly, and produces weld penetration variability. When particularly severe, the irregular penetration is called spiking. Spiking also leads to a tendency for voids to become trapped in the root of the weld.

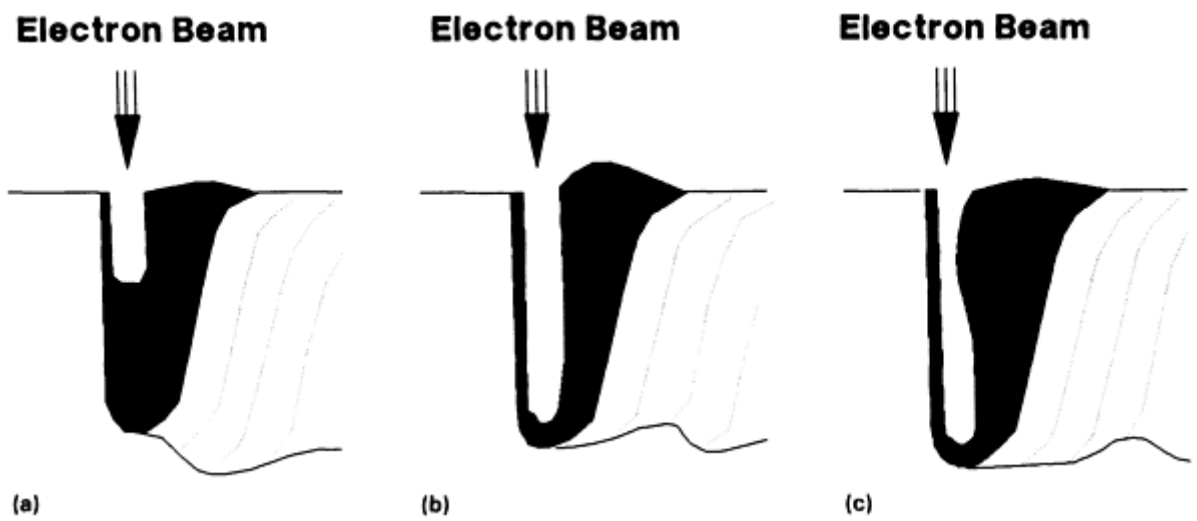

FIG. 10 SCHEMATIC SHOWING KEYHOLE INSTABILITY. (A) KEYHOLE IS FORMED BY HEAT GENERATED BY ELECTRON BEAM. (B) MAXIMUM PENETRATION THAT CAN BE PRODUCED BY HEAT FLOW. (C) LIQUID COOLS, CAUSING IMPENDING COLLAPSE OF DISPLACED METAL. THE KEYHOLE IS FILLED BY A LUMP OF COOLING MATERIAL AT THE END OF (C), WHICH RETURNS THE KEYHOLE TO CONDITION (A) TO RESTART THE SEQUENCE.

A mathematical model that is the basis for understanding this keyhole instability was developed by Giedt *et al.* (Ref 13, 15). Stability of the keyhole is basically a balance between vapor pressure, which keeps the cavity open, and surface tension, which tries to close the cavity. Vapor pressure and surface tension are both functions of temperature. Vapor pressure increases nearly exponentially with temperature for many materials, while surface tension generally decreases slowly with temperature. Because there is a substantial temperature gradient from the top to the bottom of the keyhole, both vapor pressure and surface tension vary with depth in the keyhole. Direct measurements of cavity wall temperatures for electron beam welds indicate that the temperature at the top is nearly equal to the melting temperature, while the temperature at the bottom is high enough that the vapor pressure there is large. In type 304 stainless steel, the temperature at the bottom of the cavity is about 2200 °C (1200 °F). The data indicate that the temperature profile is insensitive to welding variables and is determined primarily by material properties, that is, by the temperature where the vapor pressure exceeds about 1330 Pa (10 torr).

Based on temperature measurements of a typical keyhole, the vapor pressure decreases approximately exponentially with height from the bottom of the keyhole and approaches zero at the top of the keyhole. The vapor pressure is balanced primarily by surface tension. For pure iron and many other materials, the surface tension decreases approximately linearly with temperature. Thus, the inward surface tension pressure increases slowly from the bottom to the top of the keyhole. The balance of vapor pressure and surface tension is such that the cavity is stable near the bottom, where the vapor pressure tending to expand the cavity exceeds the surface tension tending to collapse it. At the top, the cavity is unstable because the surface tension tending to collapse it exceeds the vapor pressure tending to expand it. Thus, the cavity will always tend to be filled by liquid originating from above some height *H* in the keyhole, the pressure crossover height. This cavity filling produces weld penetration irregularity. Weld penetration irregularity is a consequence of the nature of the keyhole in deep-penetration welding and will not generally be solved by simple equipment or material modifications.

Penetration irregularity is usually less severe if *H* (as measured from the top) is a small fraction of the keyhole depth. In such cases the volume of the lump is small, and liquid tends to flow into the cavity relatively smoothly. If *H* is a large fraction of the keyhole depth, then the liquid lump has a relatively large volume and, when it falls into the keyhole at irregular times, it nearly fills the cavity and produces large penetration variations.

Gas Metal Arc Welding

Fluid flow certainly occurs in GMA weld pools, but reports on the details of its nature and effects are quite limited. In the spray transfer mode, the impact of the stream of droplets from the electrode on the weld pool forms a substantial depression or crater. This is the mechanism responsible for the typical fingerlike penetration observed with argon as the torch gas. Thus, the depth of penetration is primarily dependent on the momentum of the stream of droplets. A plot of penetration versus the momentum of the droplet stream shows an excellent correlation (Fig. 11). Because the major force driving the droplets toward the weld is drag from the plasma jet, the kinematic viscosity (density times viscosity) of the shielding gas is important. For example, argon has a substantially higher kinematic viscosity than helium, so argon drives the droplet stream more effectively, resulting in a deeper, narrower penetration finger than with helium torch gas. The strength of the plasma jet can also be altered by changing the ambient pressure. For GMA welds on aluminum. Amson and Salter (Ref 17) saw a steady decrease in penetration with pressure until at 13,300 Pa (100 torr) there was essentially no penetration at all. Another way to modify the penetration depth is to spread the stream of droplets over the surface of the weld. This can be accomplished by applying a varying transverse magnetic field.

Fluid Flow Phenomena During Welding

C.R. Heiple and P. Burgardt, EG&G Rocky Flats

Submerged Arc Welding

Currents commonly employed in submerged arc welding (SAW) are much higher than those used in GTAW or GMAW. Submerged arc welding currents often exceed 1000 A. Thus, the electromagnetic or Lorentz force combined with the tendency of the radial pressure gradient in the moving cavity to transport liquid to the rear of the cavity (Fig. 9) are likely the dominant forces driving fluid flow. The generally accepted flow pattern is indicated schematically in Fig. 12. A cavity is formed at the front of the moving weld pool by arc pressure and by the momentum of drops from the rapidly melting electrode. Metal that is melted at the front of the pool flows underneath and on either side of the cavity. At the rear of the pool, the flow reverses and metal flows back toward the cavity along and near the surface. Flow velocities can be very high; Eichhorn and Engel (Ref 19) measured 4 m/s (13 ft/s) at 720 A. The flow pattern was derived from observations of motion of marker elements, added to the weld pool, as determined from subsequent metallographic sections, and from the motion of radioactive tracer additions. The general features illustrated in Fig. 12 appear to be supported by X-ray fluoroscopy observations. Major perturbations in the indicated fluid flow have been demonstrated, including reversal of the flow direction. These perturbations have been associated with weld defects.

Transfer of Heat and Mass to the Base Metal in Gas-Metal Arc Welding

Herschel B. Smartt, Idaho National Engineering Laboratory

Introduction

HEAT AND MASS TRANSFER in arc welding is normally studied from the standpoint of the weld pool and heat-affected zone (HAZ); however, it is also instructive to examine heat and mass transfer from the arc to the base metal. This article describes the latter topic in terms of the gas-metal arc welding (GMAW) process and provides practical information related to the development of welding procedures and the general operation of the process.

Welding procedures emphasize control of parameters such as electrode speed (or current), voltage, welding speed, contact tube-to-base metal distance, as well as current pulse parameters for out-of-position welding. It is therefore easy to overlook the fact that the process is simply a source of heat and mass inputs to the weldment. Melting of the base metal, dilution of the filler metal, solidification of the weld bead, microstructural development in the weld bead and HAZ, and thermomechanical distortion and residual stresses all follow from the heat and mass inputs. The conventional parameters identified above arc variables that control the heat and mass inputs. An example of the relationship between the conventional parameters of electrode speed and welding speed to heat and mass transferred to the weldment is shown in Fig. 1 for certain conditions, as applied to the welding of thick-section steel.

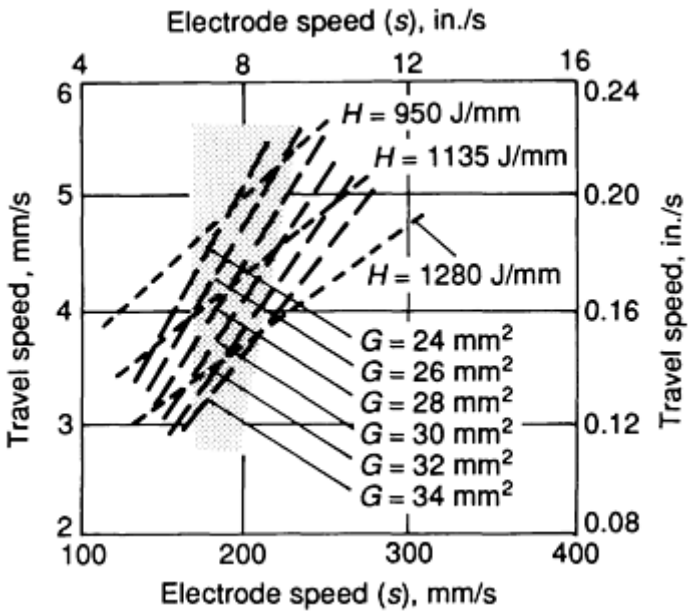

FIG. 1 PLOT OF WELDING SPEED VERSUS ELECTRODE SPEED AS FUNCTION OF HEAT TRANSFER PER LENGTH OF WELD, *H,* AND MASS TRANSFER EXPRESSED IN TERMS OF REINFORCEMENT, *G.* POWER SUPPLY OPEN-CIRCUIT VOLTAGE, E_0, IS 32 V; CONTACT TUBE-TO-BASE METAL DISTANCE, C_T, IS 15.9 MM (0.625 IN.). Transfer of Heat and Mass to the Base Metal in Gas-Metal Arc Welding

Herschel B. Smartt, Idaho National Engineering Laboratory

Heat Transfer

The total transfer of heat, *H,* (neglecting preheating) from the GMAW process to the weldment per unit time is given by:

$$H = \eta EI \qquad \textbf{(EQ 1)}$$

where E is voltage, I is current, and η is the heat-transfer efficiency. The rate at which heat is transferred to the weldment per unit length of weld is given by:

$$H = \frac{h\,EI}{R} \qquad \textbf{(EQ 2)}$$

where R is welding speed. Calorimeter-based heat-transfer experiments reveal that the heat-transfer efficiency for welding thick-section steel is nominally 80 to 90%, as indicated in Fig. 2. The total heat-transfer efficiency is altered somewhat by changing other parameters. For example, it increases slightly as the power supply open-circuit voltage is decreased (for a silicon controlled rectifier regulated power supply and it increases slightly with increasing contact tube-to-base metal distance. However, 85% is a reasonable estimate for most conditions.

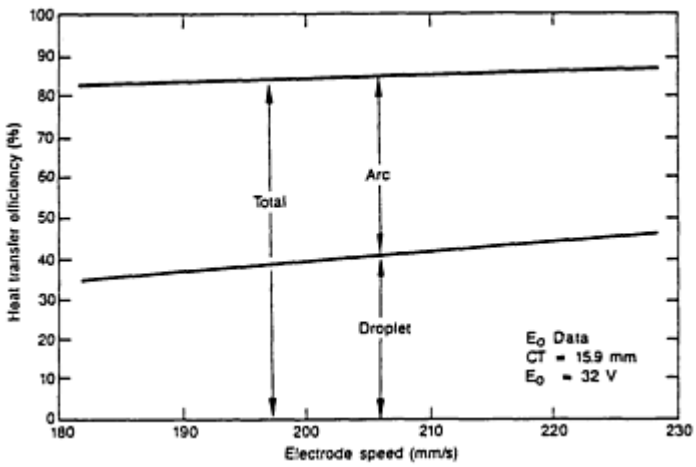

FIG. 2 PLOT OF HEAT-TRANSFER EFFICIENCY TO BASE METAL VERSUS ELECTRODE-SPEED FOR 0.89 MM (0.035 IN.) DIAMETER STEEL ELECTRODE IN AN AR-2% O_2 SHIELD GAS. TOTAL HEAT-TRANSFER EFFICIENCY

Partitioning of Heat Transfer. In the GMAW process, the molten droplets of electrode material carry a significant portion of the total heat transferred to the weld pool. This is seen in calorimetry experiments (Fig. 2), where the total heat-transfer efficiency of the GMAW process is partitioned into those portions associated with transfer by the arc and by the molten droplets. At low electrode speeds, about 60% of the total heat transferred is associated with the arc. As electrode speed increases, the fraction of total heat transferred associated with the droplets increases, reaching nominally 50% at current levels in excess of about 220 A (that is, at about 230 mm/s, or 9.1 in./s, electrode speed) for the conditions used.

Mass Transfer

Droplet Transfer Modes. Although the International Institute of Welding (IIW) lists eight distinct metal transfer modes (Ref 3), the modes commonly used in U.S. welding practice are globular, spray, streaming, rotating, and short circuiting. The mode terms "drop" and "repelled" used by the IIW are often referred to as "globular," and the mode term "projected" is generally referred to as "spray." The globular, spray, streaming, and short-circuiting transfer modes are shown in Fig. 3, 4, 5, 6.

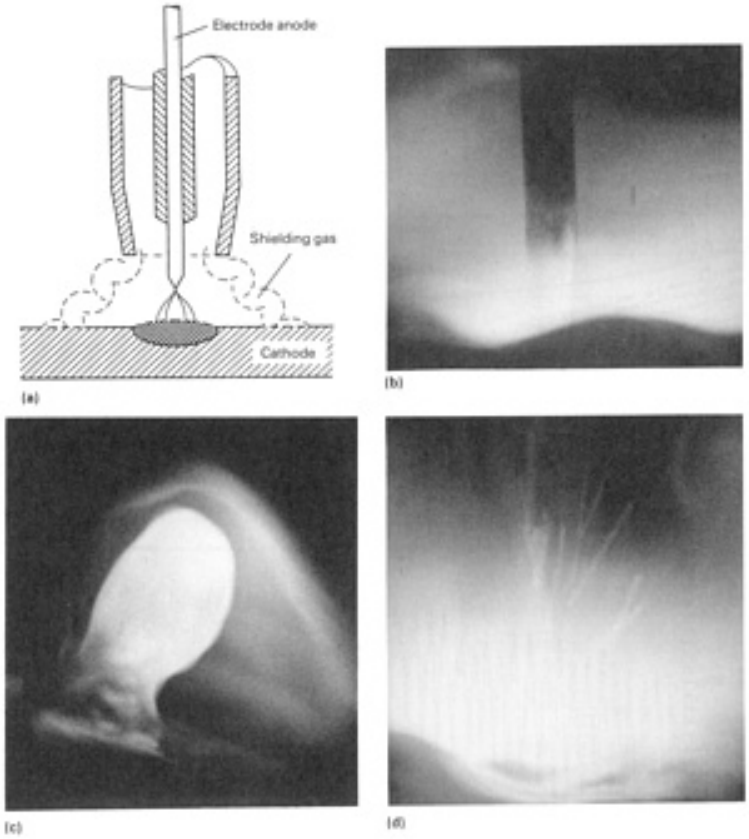

FIG. 6 SHORT-CIRCUITING TRANSFER MODE IN GAS-METAL ARC WELDING OF STEEL. (A) SCHEMATIC SHOWING TRANSFER OF ELECTRODE MATERIAL BY SURFACE TENSION OF WELD POOL ONTO CATHODE BASE METAL. (B) HIGH-SPEED PHOTOGRAPH OF MATERIAL TRANSFER WHEN ARC LENGTH IS VERY SHORT. (C) HIGH-SPEED PHOTOGRAPH OF CYCLIC SHORTING OF ARC BY THE ELECTRODE DURING METAL TRANSFER TO WELD POOL. (D) HIGH-SPEED PHOTOGRAPH OF VIOLENT ARC REIGNITION WITH ASSOCIATED SPATTER

When all other parameters are held constant, the metal transfer mode at the lowest wire feed speed (and associated current level) is globular. As wire speed (and therefore current) increases, the mode changes rapidly from globular to spray. With an additional increase in wire speed (and current), spray transfer becomes streaming transfer. Figure 7 shows the droplet sizes during the transition from globular to spray to streaming transfer for direct and pulsed current welding. If an adequately high current, contact tube-to-base metal distance, and voltage exist, then rotating transfer, wherein the lower part of the electrode becomes molten over a considerable length and rotates in a helical spiral under the influence of the magnetic field surrounding the arc, can occur. As it rotates, a controlled stream of droplets is transferred from the electrode tube to the weld pool over a relatively wide area. Additional increases in wire feed/current at low voltage shorten the arc length and, eventually, the wire stubs into the weld pool. In addition, with appropriate conditions (for example, carbon dioxide, argon-carbon dioxide mixtures, and helium-based shielding gases), droplets can be transferred directly, by surface tension forces, after contact of the drop with the weld pool, a condition called short-circuiting transfer.

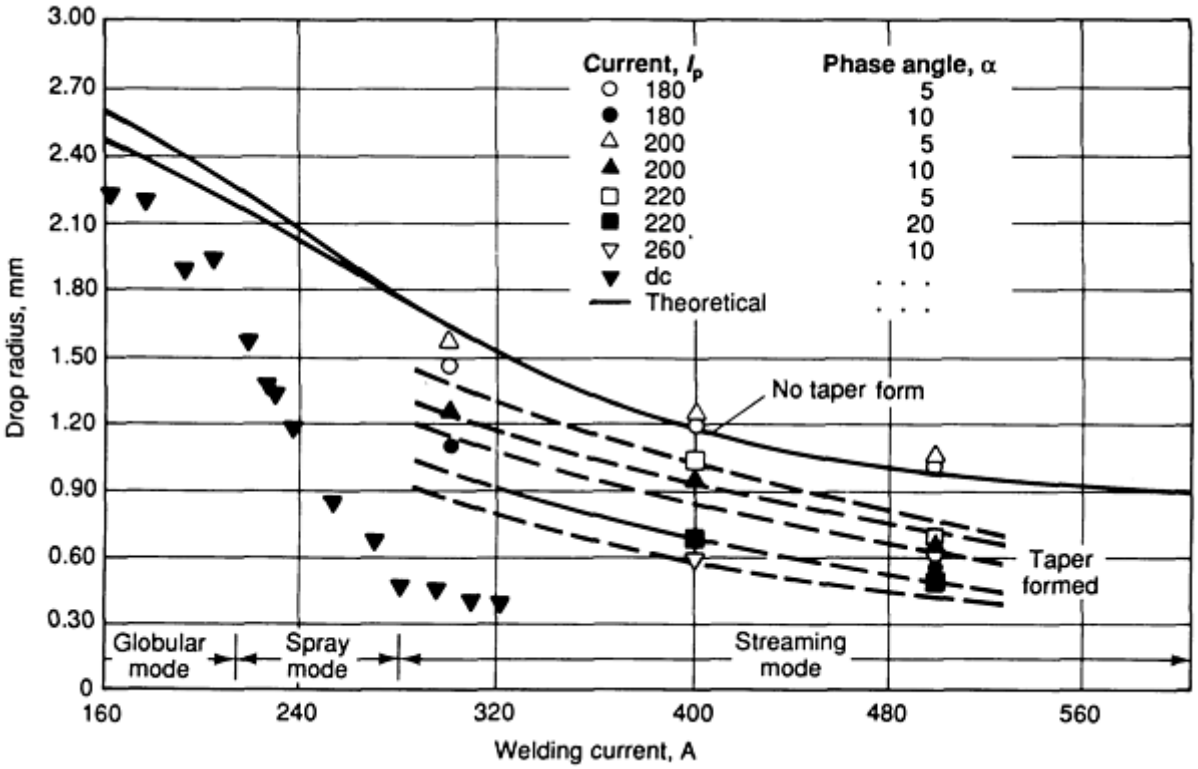

FIG. 7 DROPLET SIZES ATTAINABLE UNDER SELECTED CURRENT PULSING CONDITIONS IN GAS-METAL ARC WELDING OF STEEL. SOURCE: REF 4

In practical applications, the optimum transfer mode depends in part on the thickness of the base metal being welded. For example, very thin sections (in all positions) require the short-circuiting mode (with low current levels and appropriate settings of voltage and other operating parameters, including shielding gas composition). Thicker sections show best results with spray or streaming transfer. These transfer modes also produce high heat input, maximum penetration, and a high deposition rate. In welding steel, they are generally limited to welding that occurs in the flat position and the horizontal fillet position, except when pulsed current is used. Rotating transfer can be used in a deep groove in thick-section material. One- and two-pass heavy fillet welds are also a major area of application for this process variation.

Globular transfer (Fig. 3) involves a droplet that, generally, is much larger in diameter than the electrode wire. Globular transfer can involve a transfer rate of about 1 to 10 drops/s, and the arc has a soft, rounded appearance. Droplet detachment and transfer are mainly due to the gravitational force, which limits globular transfer to in-position welding. For spray transfer (Fig. 4), droplet and electrode diameters are roughly equivalent.

Spray transfer can involve 100 drops/s, and the arc noticeably contracts, or "stiffens." Drops usually travel in-line down the center of the arc, but several drops may be in flight at the same instant.

In streaming transfer (Fig. 5), a well-developed liquid column extends from the solid electrode down into the arc and breaks into small droplets before contacting the weld pool (see the discussion on spatter below). Streaming transfer can involve 1000 drops/s, and the arc has a characteristic "cone" shape, as shown in Fig. 5.

In short-circuiting transfer, the arc is very short (Fig. 6a). During metal transfer, the undetached molten droplet contacts the weld pool, shorting out the arc (Fig. 6b), which then extinguishes. Surface tension plays an important role in transferring the drop to the weld pool, but detachment of the drop from the electrode is due to electromagnetic pinch forces. Reignition of the arc is violent (Fig. 6c), resulting in considerable scatter.

As seen in Fig. 7, the transition from one mode to another actually involves continuous variations in droplet size. Because the product of droplet volume and transfer rate equals the electrode melting rate (in appropriate dimensions), there is also a continuous variation in droplet transfer rate. Detailed experimental studies have shown that rapid, cyclic transition from globular to spray to globular, and so on, occurs in the transition region between globular and spray transfer (Ref 5).

Although it is generally not possible for the welder to see droplet transfer events in the spray and streaming transfer modes (except under ideal conditions for spray transfer), the arc shape changes and associated changes in electrical and acoustic noise allow a trained welder to readily identify all of the transfer modes. The section "Electrical and Acoustic Signals" in this article describes this event more fully.

Weld Reinforcement. Assuming that mass is conserved as welding occurs, the transverse cross-sectional area of the weld bead added to the weldment for a single weld pass, which is called the reinforcement, *G*, is given by:

$$G = \frac{S}{R}\frac{p d^2}{4} \qquad \textbf{(EQ 3)}$$

where *S* is electrode speed, *R* is welding speed, and *d* is electrode diameter. For the spray and streaming transfer modes, the assumption that mass is conserved is reasonably good. However, because short circuiting and other conditions generate considerably spatter, the actual reinforcement will be slightly less than the value calculated by Eq 3.

Droplet Velocity and Temperature. In spray and streaming transfer, the droplets are accelerated rapidly through the arc to the weld pool. Velocities of 1 m/s (40 in./s) are typical, increasing with voltage (Fig. 8). Calorimetry-based experimental results indicate that steel droplets can reach temperatures of approximately 2600 K (4220 °F) (Ref 2). This explains why the droplets transport one-half of the total heat transferred to the base metal.

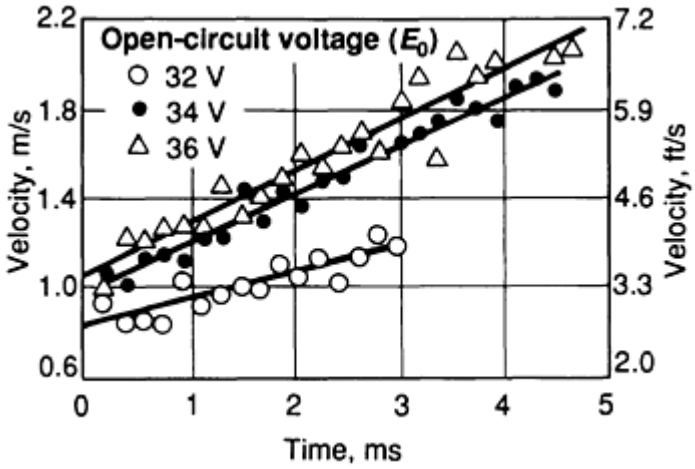

FIG. 8 DROPLET VELOCITIES FOR SPRAY TRANSFER IN GAS-METAL ARC WELDING OF STEEL AT THREE DIFFERENT OPEN-CIRCUIT VOLTAGES. SOURCE: REF 5

A result of the activity of molten electrode droplets in heat transfer to the base metal is that they also play an important role in convective heat transport in the weld pool and, thus, in weld penetration (Ref 6). This can be seen in Fig. 9, a transverse cross section of a gas-metal arc bead-on-plate weld on carbon steel. The region of deep penetration in the center of the weld bead is associated with the heat convected to the lower portion of the weld pool by the entering droplets.

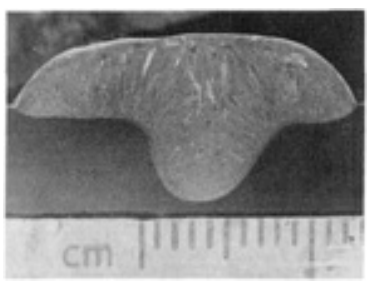

FIG. 9 TRANSVERSE CROSS SECTION OF GAS-METAL ARC BEAD-ON-PLATE WELD IN CARBON STEEL TO SHOW DEEP PENETRATION IN THE WELD BEAD CENTER GENERATED BY MOLTEN ELECTRODE DROPLETS

Electrical and Acoustic Signals. As the droplets of molten metal detach from the electrode, an almost instantaneous change occurs in the electrode extension, which results in a sudden, although small, change in the electrical resistance between the contact tube and the base metal. The results are spikes in the secondary circuit voltage and welding current, accompanied by pressure changes in the arc. Thus, both electrical and acoustic noise (Fig. 10) are generated by the GMAW process and are characteristic of the droplet transfer mode. The waveforms for globular transfer show prominent spikes associated with individual droplet transfer events. This can also be seen in Fig. 11, a plot of the computer-digitized current for a weld on carbon steel, where a change from globular to spray transfer has occurred at about 8 s into the weld. The power spectra of the current changes dramatically for the two transfer modes (Fig. 12), leading to a means of detecting transfer mode during welding.

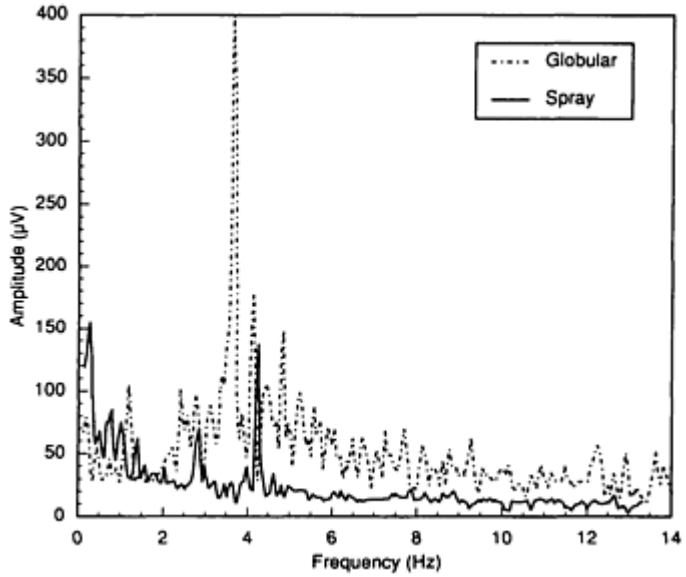

FIG. 12 WELDING CURRENT POWER SPECTRA FOR GLOBULAR TRANSFER AND SPRAY TRANSFER MODES DURING GAS-METAL ARC WELDING OF STEEL. SOURCE: REF 1

Several specific techniques have been identified (Ref 8) for detecting the mode of metal transfer: Fourier transform, standard deviation, peak ratios, and integrated amplitude of the current and voltage signal. In a similar manner, spatter, lack of shielding gas, and contact tube wear can also be detected. Similar power spectra changes also occur in the secondary circuit voltage and acoustic noise. The change in acoustic noise allows the aural detection of the transfer mode. An experienced welder can readily hear, for example, the difference between globular and spray transfer.

Contact of the molten droplet with the weld pool, while the droplet is still attached to the electrode, also results in a sudden change in electrical resistance. This is important, because spatter is generally produced when this electrode-to-

weld pool contact breaks. (Spatter can also be produced by rapid expansion of gas bubbles in the electrode as it melts.) The resulting electrical and acoustic noise can be used to detect that spatter is being produced.

Procedure Development

The preceding discussion leads to a logical approach toward selecting welding parameters during the development of welding procedures. First, given a nominal power supply open-circuit voltage and contact tube-to-base metal distance, the electrode speed can be set to determine the welding current. It can be shown that:

$$S = \frac{4hGI}{Hpd^2}(E_0 + HI) \qquad \textbf{(EQ 4)}$$

where E_0 is the power supply open-circuit voltage. It is assumed that the proper selection of electrode type and shielding gas have been made, and that the electrode diameter is appropriate for the application.

Second, the open-circuit voltage is adjusted to give either an acceptable arc length or electrode extension. The objective is to prevent either burnback (transfer of the arc to the contact tube) or spatter caused by shorting of the molten electrode droplets with the weld pool prior to detachment from the electrode. Fine adjustment of voltage may be necessary to obtain a clean start of the process, thus avoiding a short period of spatter or globular transfer following arc ignition. The combination of current and voltage for a given contact tube-to-base metal distance determines the droplet transfer mode.

Third, the welding current determines the melting rate of the electrode. The electrode melting rate (M_{rp}) is a quadratic function of current (Ref 9):

$$M_{rp} = (C_1 + C_2 A)I + C_3 \frac{LI^2}{A^2} \qquad \textbf{(EQ 5)}$$

where A is the cross-sectional area of the electrode and C_1, C_2, C_3, and i are constants.

Another researcher (Ref 10) defines M_{rp} by:

$$M_{rp} = C_4 I + C_5 \frac{LI^2}{A} \qquad \textbf{(EQ 6)}$$

where C_4 and C_5 are constants.

Given a desired melting rate, the welding travel speed is set to obtain the desired weld bead reinforcement. The current, voltage, and weld travel speed have all now been set, thus determining the heat input per length of weld ($H = \eta EI/R$).

It should be noted that it is actually possible to independently vary heat input and mass input (in terms of weld bead reinforcement) to the weld, over at least a small range. This is shown in Fig. 13, where the same data presented in Fig. 1 are replotted in terms of reinforcement as a function of heat input per length of weld.

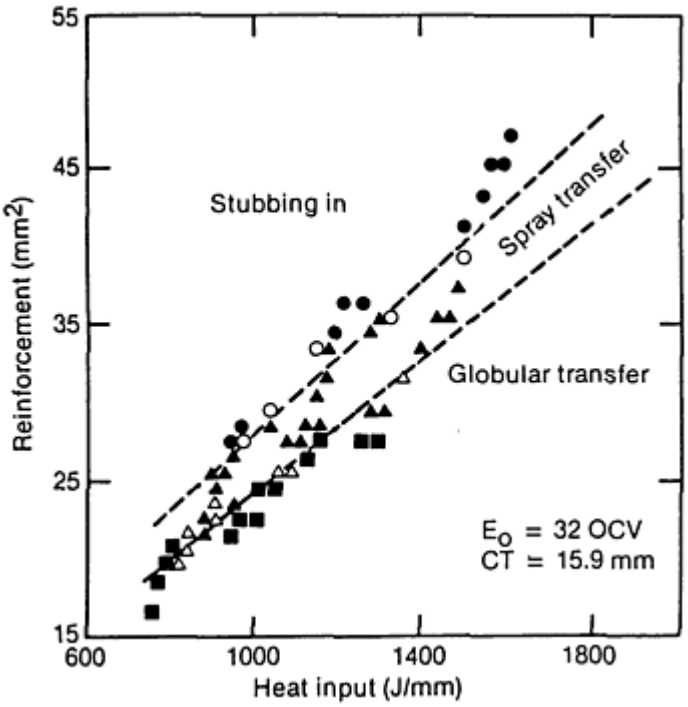

FIG. 13 PLOT OF REINFORCEMENT VERSUS HEAT INPUT TO SHOW PARAMETERS THAT FAVOR SPRAY TRANSFER MODE FOR GAS-METAL ARC WELDING OF STEEL. POWER SUPPLY OPEN-CIRCUIT VOLTAGE, E_0, IS 32 V; CONTACT TUBE-TO-BASE METAL DISTANCE, C_T, IS 15.9 MM (0.625 IN.).

The above discussion on procedure development ignores second-order effects, such as the dependence of arc length on weld travel speed. It should also be realized that several iterations through the steps defined above may be required for final parameter determination. Proper power supply settings must be used, and code requirements must be met.

Arc Physics of Gas-Tungsten Arc Welding

J.F. Key, EG&G Idaho, Inc.

Introduction

THE GAS-TUNGSTEN ARC WELDING (GTAW) process is performed using a welding arc between a nonconsumable tungsten-base electrode and the workpieces to be joined. C.E. Jackson defined a welding arc as "a sustained electrical discharge through a high-temperature conducting plasma producing sufficient thermal energy so as to be useful for the joining of metals by fusion." This definition is a good foundation for the discussion that follows.

The physics of GTAW are fundamental to all arc processes and are more straightforward, because the complications of materials (for example, filler and flux) transferred through and interacting with the arc can be avoided. Geometrically, the arc discharge in GTAW is between a rod-shaped tungsten electrode and a planar-shaped electrode, that is, the workpiece.

Pure tungsten electrodes are less expensive and, possibly, more environmentally compatible than those with rare earth or other oxide additions. They are used for lower-specification welds, where tungsten contamination that is caused by the molten electrode surface can be tolerated. They are also used for alternating current (ac) welding of aluminum, copper, magnesium, and thin sections of low-alloy and stainless steels.

Analysis of the arc discharge is separated into electrode regions and the arc column. The electrode regions are confined to very small distances from the electrode surfaces, have very high electrical and thermal fields, and have much higher current density, because of the contraction of the arc to a small spot. As a result, electrode regions for both the cathode and the anode are difficult to analyze by diagnostic measurements and theoretical computation. This situation must be remedied for a thorough understanding of the process, because the process parameters control the arc discharge at the cathode, with the anode serving as the connection to ground. The arc column, on the other hand, is relatively easy to analyze, but is important primarily as a means to deduce arc characteristics at the electrodes.

Polarity. The GTAW process generally utilizes a direct current (dc) arc, where the tungsten electrode has a negative polarity. The tungsten electrode thus becomes the cathode and the workpiece becomes the anode. The polarity is called straight polarity, or direct current electrode negative (DCEN).

Reverse polarity, or direct current electrode positive (DCEP), is literally the reverse of DCEN. The workpiece is the cathode and the tungsten electrode serves as the anode. Because most heat is generated at the anode in the GTAW process, DCEP is used for welding certain thin-section, low melting point materials when DCEN would be likely to cause excessive penetration or burn-through.

Either alternating current or DCEP is used for removing an oxide film from the surface of the weld pool or workpiece. The oxide film promotes emission during the half-cycle (ac) when the workpiece is negative polarity. As the oxide is depleted, the emission moves to a new location that has a high enough oxide content to sustain the discharge of electrons. The arc root or cathode spot where the emission occurs is highly mobile in ac or DCEP and, as a result, the arc is much less stable than in DCEN.

Gas Shielding. In all cases, the arc and both electrodes are shielding by gas, usually an inert gas or a gas mixture. Argon and argon-helium mixtures are used most often, although argon-hydrogen mixtures are used for some applications. The GTAW process may simply utilize the arc to fuse the workpieces together without the addition of filler materials (autogenous) or filler may be added to the molten pool to fill grooves in thicker weldments. A reasonable understanding of welding arc fundamentals and the GTAW process requires a more thorough discussion of the electrode regions of the arc and the arc column.

Arc Physics of Gas-Tungsten Arc Welding

J.F. Key, EG&G Idaho, Inc.

Electrode Regions and Arc Column

The cathode and anode are similar in several respects. Both exhibit a voltage drop caused by a space charge that covers a very thin region over their surfaces, and the arc is significantly contracted on the surfaces. Figure 1 shows that the total arc voltage is partitioned between the electrode drops and arc column. The relative magnitude of these drops depends on welding parameters and electrode material.

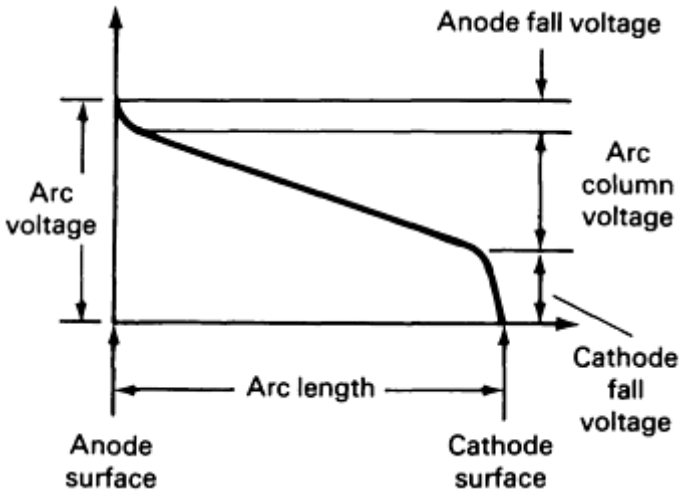

FIG. 1 PLOT OF RELATIVE ARC VOLTAGE DISTRIBUTION VERSUS RELATIVE ARC LENGTH BETWEEN ELECTRODES

The arc discharge requires a flow of electrons from the cathode through the arc column to the anode, regardless of polarity or whether ac or dc is used. Two cases of electron discharge at the cathode will be discussed: thermionic emission and nonthermionic emission, also called cold cathode, or field emission.

Thermionic emission results from joule heating (resistance) of the cathode by the imposed welding current until the electron energy at the cathode tip exceeds the work function (energy required to strip off an electron). This case applies to the general case of DCEN, where the tungsten electrode is the emitter, or cathode. Pure tungsten electrodes have to be heated to their melting point to achieve thermionic emission. Once molten, the equilibrium tip shape becomes a hemisphere, and a stable arc results from uniform emission over this surface. Thoria (ThO_2), zirconia (ZrO_2), or ceria (CeO_2) are added to pure tungsten in amounts up to 2.2 wt% ThO_2, 0.4 wt% ZrO_2, or 3.0 wt% CeO_2 to lower the work function, which results in thermionic emission at lower temperatures and avoids melting the cathode tip. These electrodes typically have a ground conical tip, and thermionic emission is localized to a cathode spot. Thermionic emission creates a cloud of electrons, called a space charge, around the cathode. If a second electrode at a higher potential is nearby (the workpiece, in this case), then the electrons will flow to it, thus establishing the arc.

Nonthermionic, or field, emission creates an electron discharge with a very high electric field, typically exceeding 10^9 V/m. This intense electric field literary pulls electrons out of a relatively cold or unheated cathode. This would not appear to be applicable to welding until one considers that for reverse polarity or DCEP, a condensation of positive ions from the arc column can build up in a very thin (1 nm, or 0.04 μin.) layer over the cathode surface, creating a very high localized electric field even though the cathode voltage drop may only amount to several volts.

An oxide layer, which is always present on the cathode surface in an actual weld, facilitates the discharge with a source of lower work function electrons. When the oxide layer is very thin (on the order of one atom layer), emission occurs via a tunneling mechanism through the film to an emitting site. Thicker oxide films exhibit locally conducting spots at the end of filamentary channels through the oxide. Large currents flow in these channels, which are on the order of 100 nm (4 μin.) in diameter and have lifetimes of 0.001 to 1 μs.

The cathode cleaning action, which is one of the principal reasons to use DCEP or ac, results from stripping away the oxide film at the emitting sites by very small and intense jets of metal vapor and debris. It becomes obvious that a practical implication of the short lifetime of these cathode spots is a generally unstable arc that is due to the necessity of continual movement of the cathode spot to undepleted regions of oxide film. Arc instability is undesirable and DCEP or ac is only used when cathodic cleaning or the minimizing of heat input to the workpiece is a higher priority than optimizing weld bead shape and location.

Anode. Welding process parameters (for example, current and voltage) control the arc discharge at the cathode. Although the electron flow enters the anode through the anode spot and constitutes 85% of the energy going into the weld pool, thus making current density the single most important welding parameter that determines pool shape, events at the anode can

only be controlled indirectly by controlling the cathode. Anode spot stability does depend somewhat on shielding gas composition and the shape of the anode (that is, weld groove).

Current density and heat input measurements at the anode have been made to better understand how process parameters that are largely controlling events at the cathode will, in turn, influence the shape and melting rate of the weld pool. The relative contributions of heat transfer to the workpiece, in terms of the GTAW process, are shown in Fig. 2.

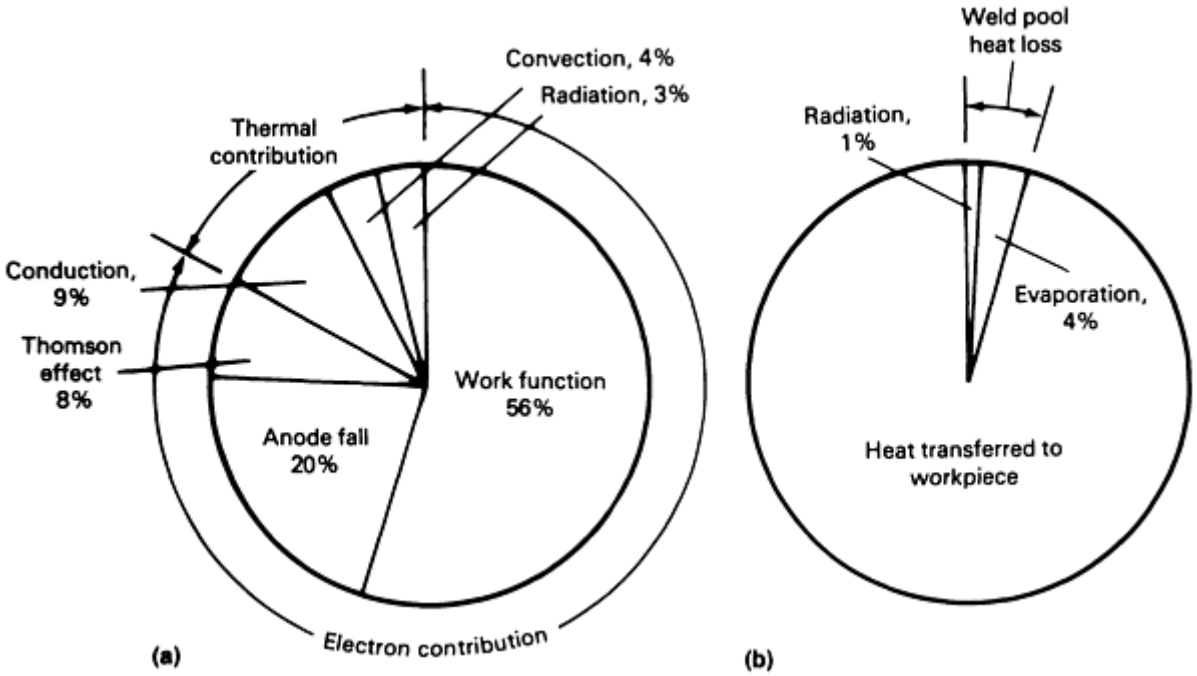

FIG. 2 RELATIVE HEAT TRANSFER CONTRIBUTIONS TO WORKPIECE WITH GTAW. (A) CONTRIBUTION OF INDIVIDUAL PARAMETERS TO ANODE HEAT INPUT. (B) HEAT OUTPUT AT CATHODE (WORKPIECE) RELATIVE TO WELD POOL HEAT LOSS

The Thomson effect represents the energy lost by electrons as they move from higher to lower temperatures. The sum of work function, Thomson effect, and anode fall gives an electron contribution to heat transfer of approximately 84%. The remaining 16% is due to thermal effects (that is, conduction, convection, and radiation). There are small heat losses from the pool that are due to evaporation of metal ions and radiation. Figure 3 shows that the energy distribution for this particular case approaches a Gaussian distribution (that is, normal distribution curve). High helium contents in the shielding gas have produced data that are typically better fit by a Lorentzian curve, indicating a narrower current density distribution (that is, a more-contracted arc at the anode spot).

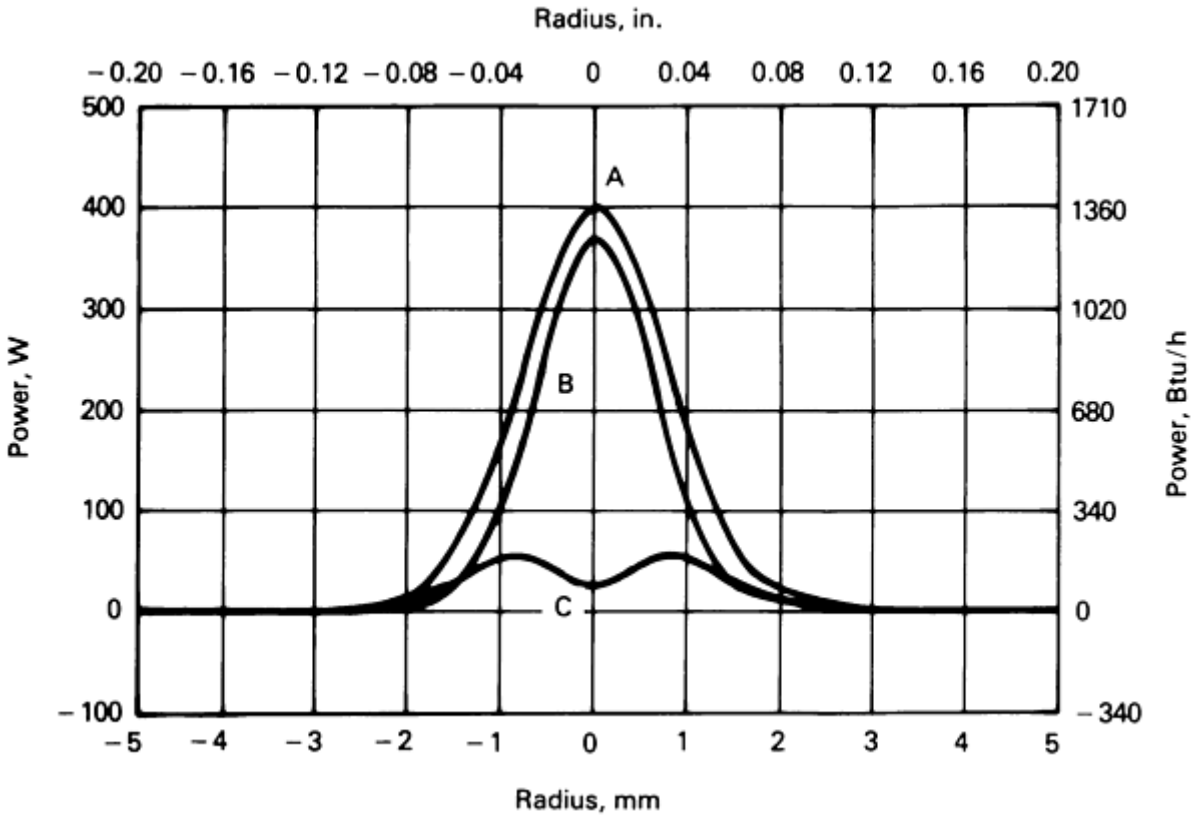

FIG. 3 PLOT OF ELECTRON AND THERMAL CONTRIBUTIONS TO HEAT TRANSFER. A, TOTAL ARC POWER (STANDARD DEVIATION, *s* , OF 0.8 MM, OR 0.031 IN.); B, ELECTRON CONTRIBUTION (σ = 0.7 MM OR 0.028 IN.); C, THERMAL CONTRIBUTION. WELD PARAMETERS: CURRENT, 10 A; VOLTAGE, 10 V; TIME, 10 S; SHIELDING GAS, ARGON; ELECTRODE ANGLE, 30°

Arc efficiency, in addition to those variables that have an effect on it, is an extremely important term in the heat transfer analysis of welding. It gives the percentage of heat dissipated in the arc that actually is captured by the workpieces and is available for melting. Arc efficiency, as a function of all GTAW welding parameters and many materials, has been determined experimentally and found to be nominally 75%. The variables having the greatest effect on arc efficiency are arc voltage and anode material. For those variables, the effect is usually no more than ±5%. Other parameters have a negligible effect.

Arc Column. The electron discharge between the electrodes partially ionizes the shielding gas in its path, thus making the arc column a conductor, or plasma. Overall, the arc column is neutral and is composed of electrons, positive gas and possibly metal ions, and neutral gas atoms.

Ironically, fundamental measurements of arc properties are most easily made in the arc column, although the actual effect of these properties on the electrode region of an actual weld must still be inferred. Nevertheless, it is useful to understand fundamentals of the arc that relate essential welding variables (for example, current, voltage, electrode gap, choice of shielding gas, and electrode shape) to arc temperature, current density distribution, and gas flow structure at the anode surface.

Effect of Cathode Tip Shape. For the general case of straight polarity, DCEN, the tip of the tungsten alloy cathode is ground to a point and then truncated somewhat to prevent the sharp tip from burning off and contaminating the weld. The included angle of the cone and the diameter of the truncation under some welding conditions have a significant effect on weld pool shape. Figure 4 shows examples of the effect of these two parameters on weld pool shape.

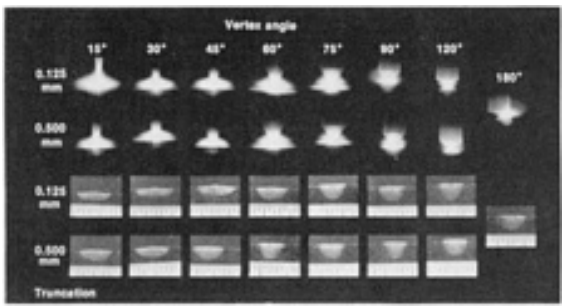

FIG. 4 FUSION ZONE PROFILE FOR SPOT-ON-PLATE WELDS AS A FUNCTION OF ELECTRODE TIP GEOMETRY USING 100% AR AS A SHIELDING GAS. WELD PARAMETERS: CURRENT, 150 A; DURATION, 2 S

For a stationary spot-on-plate weld shielded by pure argon, the weld depth-to-width ratio increased with an increasing vertex angle up to 90° and with an increasing truncation diameter. The arc became less "bell shaped" and more "ball shaped" as the vertex angle or truncation diameter increased. These results should be a valid indication of the effect of cathode tip shape for pulsed current welding, which produces a series of overlapping spot welds.

A study of bead-on-plate welds (Fig. 5) made with constant current and velocity indicated a similar but less pronounced trend. These conditions produce a tear-drop molten pool shape when viewed from above, compared to circular shape for spot or pulsed current welding. Fluid and heat flow within the pool is less uniform front-to-rear in a tear-drop-shaped pool and probably has a greater influence on pool shape than electrode tip shape.

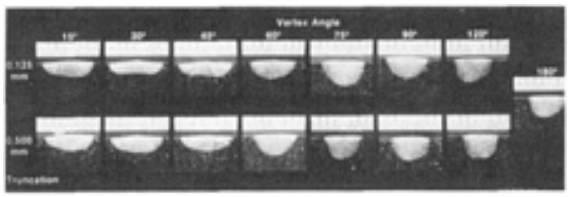

FIG. 5 FUSION ZONE PROFILE FOR BEAD-ON-PLATE WELDS AS A FUNCTION OF ELECTRODE TIP GEOMETRY USING 100% AR AS A SHIELDING GAS. WELD PARAMETERS: CURRENT, 150 A; WELDING SPEED, 3 MM/S (0.12 IN./S)

When the arc is used in a weld groove, the relative shapes of the cathode tip and the anode groove become more important. The arc discharge from the cathode will seek a path to ground with the lowest electrical resistance. For a stable arc properly centered in the groove (for example, a root pass), the shortest path to ground should be between the cathode tip and the bottom of the groove (Fig. 6). This will require the cathode vertex angle to be somewhat less than the included angle of the groove and/or a sufficiently wide groove to ensure that the shortest path to ground is from the cathode tip to the groove bottom and not, for example, from the electrode shoulder to the groove wall, as the case would be with a 90° electrode in a 10° narrow groove. Welding in a groove places a higher priority on arc stability and location than on maximum penetration.

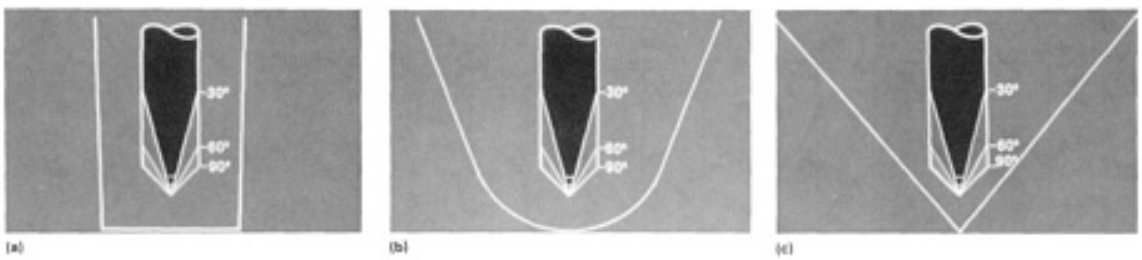

FIG. 6 EFFECTS OF ELECTRODE TIP GEOMETRY ON THE PATH LENGTH TO GROUND IN WELD GROOVES OF VARIOUS SHAPES. (A) 75° V-GROOVE. (B) 40° U-GROOVE. (C) 10° NARROW GROOVE

To understand the effects of tip shape, temperature distributions in the plasma were measured. Figure 7 shows that as the cathode vertex angle increases, the plasma radius of the arc column increases at mid-gap and becomes more constricted near the anode. The quantitative interpretation of these results requires theoretical modeling, which has yet to be completed.

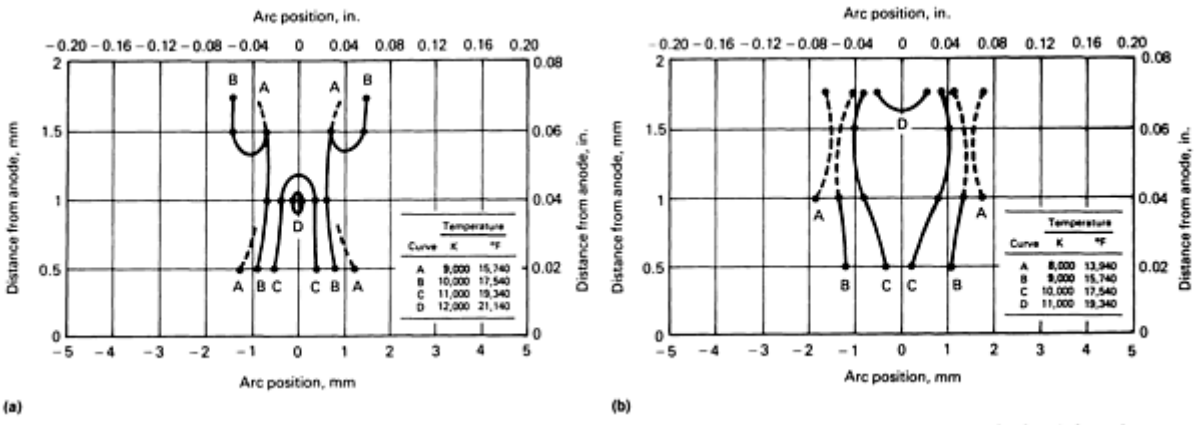

FIG. 7 EFFECT OF VERTEX ANGLE ON GTAW ARC COLUMN TEMPERATURE DISTRIBUTION WITH 100% AR USED AS SHIELDING GAS. (A) 30° ELECTRODE VERTEX ANGLE. (B) 90° ELECTRODE VERTEX ANGLE. WELDING CURRENT, 150 A

Effect of Shielding Gas Composition. The GTAW process typically uses either an inert gas, such as argon, or an inert gas mixture, such as argon and helium, to shield the arc and the weld from atmospheric contamination. Occasionally, a slightly reactive gas mixture, such as argon with up to 15 vol% H_2, is used. (The 15 vol% limit is based on safety considerations.) Shielding gas composition has a rather strong effect on arc temperature distribution and, under certain conditions, a significant effect on weld pool shape.

Figure 8 shows how shielding gas affects arc voltage. The curves would all be displaced downward for shorter arc lengths, but the relative positions would be maintained. Figure 9 shows the effects of both cathode vertex angle and shielding gas composition on weld pool shape for spot-on-plate welds. Increasing additions of helium to argon show a remarkable increase in penetration when using a 30° vertex angle. However, the effect is much less evident when using a 90° vertex angle.

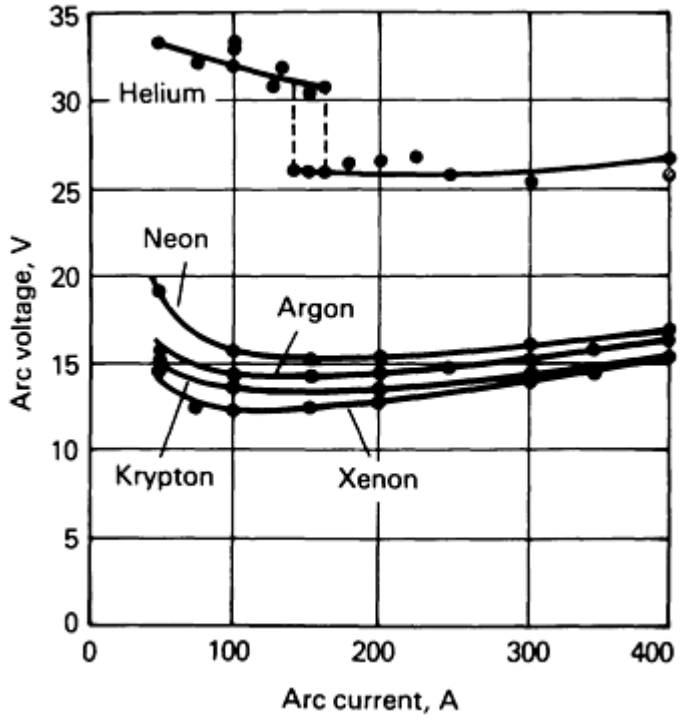

FIG. 8 PLOT OF ARC VOLTAGE VERSUS ARC CURRENT FOR SELECTED INERT SHIELDING GASES. WELDING PARAMETERS: ANODE, TITANIUM; CATHODE, TUNGSTEN; POLARITY, DCEN; ARC LENGTH, 12.7 MM (0.050 IN.)

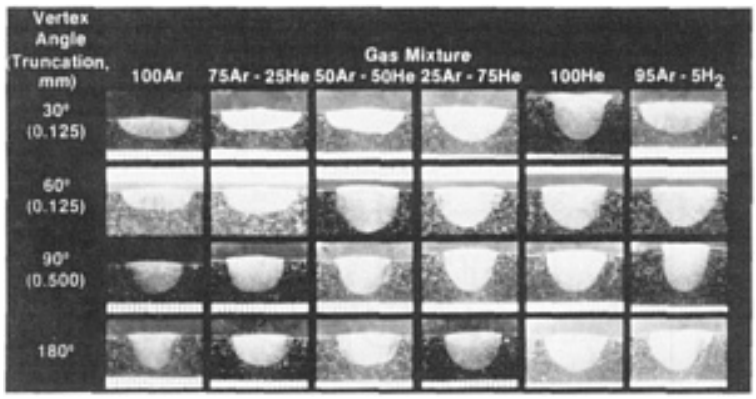

FIG. 9 EFFECT OF ELECTRODE TIP GEOMETRY AND SHIELDING GAS COMPOSITION ON WELD POOL SHAPE FOR SPOT-ON-PLATE WELDS. WELDING PARAMETERS: CURRENT, 150 A; DURATION, 2 S

To understand these phenomena, arc temperature distributions for a variety of shielding gases and mixtures, electrode shapes, current, arc voltages (electrode gaps), and anode materials have been measured in order to clarify welding arc fundamentals. Welding arcs are composed of electrons, positive gas ions, and neutral gas atoms. Some measurement techniques give the temperature of one species (electrons), whereas other techniques give the temperature of another species (neutral atoms). If the arc is in local thermodynamic equilibrium (LTE), all techniques should give the same temperature.

Although the assumption of LTE used to be considered completely valid, contemporary investigations have suggested that this is not always the case and that some of the older measurements may be somewhat in error. Absolute values of arc temperature are only needed to establish boundary conditions for detailed arc modeling of temperature-dependent properties. What is of more importance to the welding engineer or technologist is the relative effect of essential variables

on heat input to the workpiece. Arc temperature measurement is one useful indication of how these variables affect the arc.

When compared to Fig. 7(a), Fig. 10 shows that large additions of helium to argon decrease peak temperatures slightly and increase the plasma diameter in the plasma column. The arc appears to become a broader and more isothermal heat source. The lower peak temperature is reasonable, because a combination of the high ionization potential of helium and relatively low currents of welding arcs gives an arc column that is only slightly ionized. Figure 7 showed that a large vertex angle had a similar, but less pronounced, effect on arc temperature when adding helium to the shielding gas (that is, the axial peak temperature decreased and the plasma diameter increased).

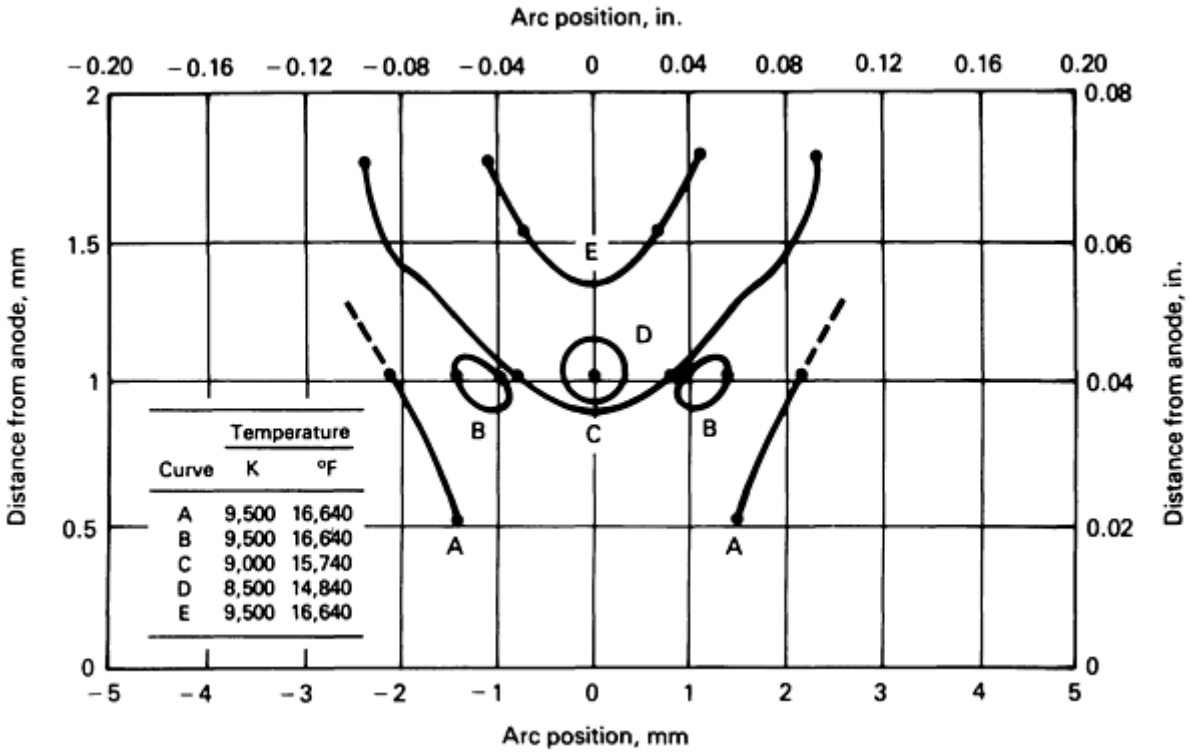

FIG. 10 PLOT OF GTAW ARC COLUMN TEMPERATURE DISTRIBUTION AS A FUNCTION OF ANODE DISTANCE AND ARC POSITION. WELDING PARAMETERS: ELECTRODE VERTEX ANGLE, 30°; CURRENT, 150 A; SHIELDING GAS, 10AR-90HE

Figure 11 shows that doubling the current from 150 to 300 A produces an increase in plasma diameter (that is, that portion of the arc above approximately 8000 K, or 13,900 °F). This effect occurs regardless of the shielding gas composition.

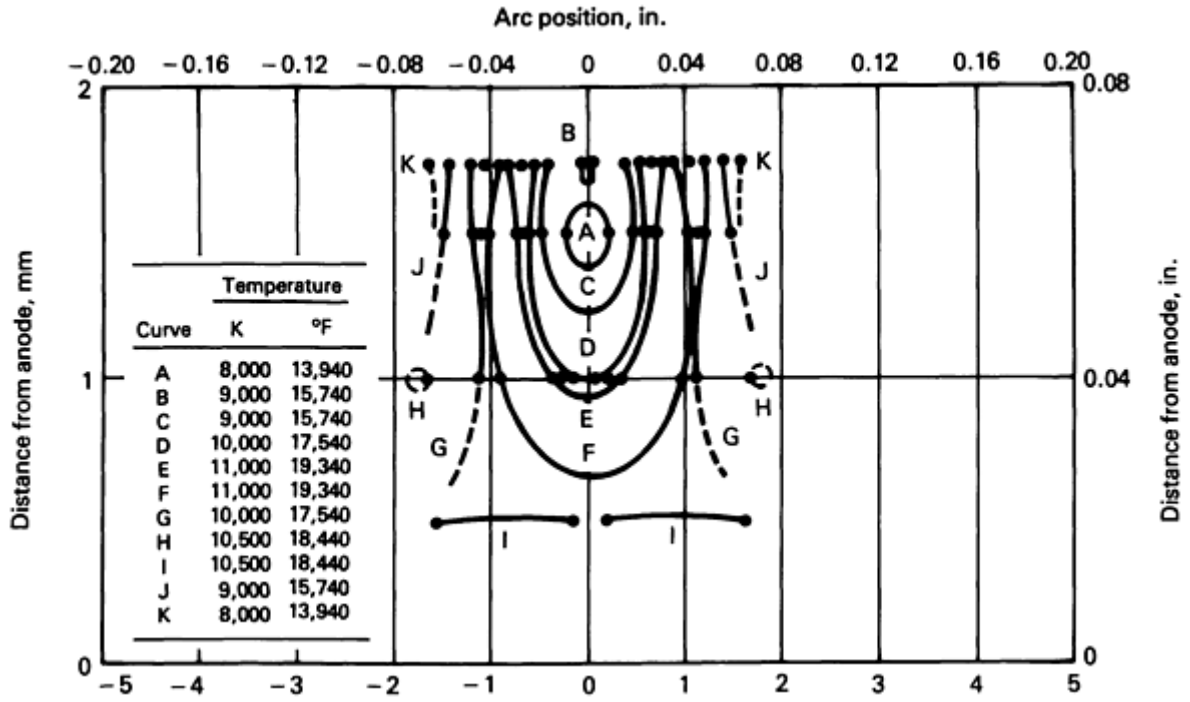

FIG. 11 PLOT OF GTAW ARC COLUMN TEMPERATURE DISTRIBUTION RELATIVE TO ANODE DISTANCE AND ARC POSITION. WELDING PARAMETERS: ELECTRODE VERTEX ANGLE, 30°; CURRENT, 300 A; SHIELDING GAS, 100% AR

The arc length or gap between the electrodes is yet another process parameter that must be considered, especially for mechanized welding, where it can be kept reasonably constant. Because arc length is proportional to arc voltage, longer arcs have higher arc voltages and consume more energy for the same current. However, this increased energy is generally lost through radiation to the environment surrounding the weld and does not effectively supply additional heat to the workpieces. Mechanized welding generally utilizes rather short arc lengths (2 to 3 mm, or 0.08 to 0.12 in.), whereas manual welding uses a longer arc length. Unfortunately, relationships that establish a direct correlation between the temperature distribution in the arc column and the weld pool shape still have not been established, primarily because weld pool shape depends on other factors, such as compositionally dependent molten metal properties.

Flow Structure. Shielding gas is used to displace reactive gases in the atmosphere from the vicinity of the weld. Inert gases are preferred for the GTAW process, because they minimize unwanted gas-metal reactions with the workpieces. A uniform laminar flow of gas from the gas cup would be ideal and, in fact, is usually achieved as long as there is no welding arc. However, the arc discharge rapidly heats the gas in the arc column, and thermal expansion causes plasma jets. The lower temperature near the cathode tip in Fig. 11 is an indication of a jet pumping in cooler gas. This becomes an important factor at high currents, because these jets can depress the surface of the weld pool and alter heat transfer to it. The rapid gas expansion can cause the flow to deviate from laminar and, in extreme cases, the flow can become turbulent. Turbulence tends to mix atmospheric contaminants into the arc, often where they can do the most harm: at the surface of the molten weld pool. Holographic interferometry and Schlieren photography have been used to characterize gas flow.

Figures 12, 13, and 14 show examples of laminar and turbulent flow. The flow from a commercial-design gas cup for three current levels is shown in Fig. 12. Laminar flow occurs where the fringes are generally straight and parallel. Turbulent flow is indicated by very wavy or circular fringes. Increasing current tends to make the laminar region somewhat broader and thicker, effectively increasing the area shielded from atmospheric contamination.

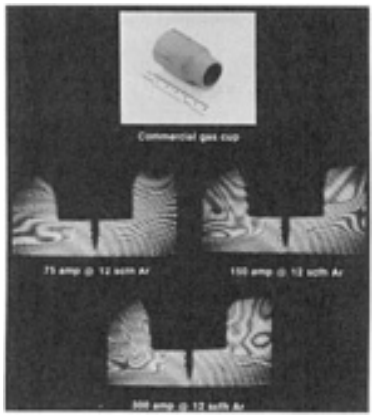

FIG. 12 EFFECT OF GEOMETRY ON COMMERCIAL GAS CUP LAMINAR AND TURBULENT FLOW AS DETECTED BY REAL-TIME HOLOGRAPHIC INTERFEROMETRY

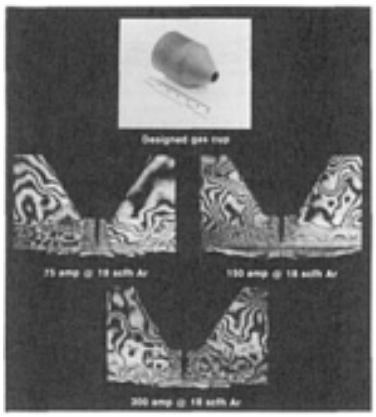

FIG. 13 EFFECT OF GEOMETRY ON CONVERGING CONE CUP LAMINAR AND TURBULENT FLOW AS DETECTED BY REAL-TIME HOLOGRAPHIC INTERFEROMETRY

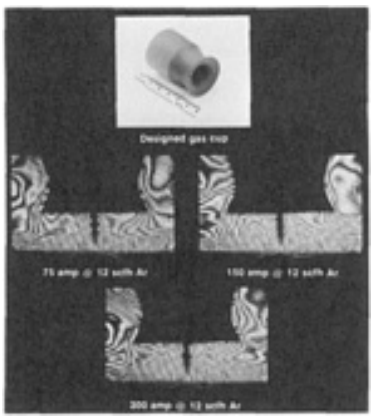

FIG. 14 EFFECT OF GEOMETRY ON VENTURI GAS CUP LAMINAR AND TURBULENT FLOW AS DETECTED BY REAL-TIME HOLOGRAPHIC INTERFEROMETRY

Figures 13 and 14 result from experiments with gas cup shapes that were designed to improve shielding. Figure 13 shows that a converging cone would be a very poor choice for the GTAW process, as indicated by the very small area of laminar flow and the extreme turbulence in the surrounding region.

Figure 14 is a venturi shape, which provides a large laminar flow region for all current levels and excellent shielding. This design may be somewhat better than commercial designs, but weld contamination studies should be conducted to verify this possibility.

Power Sources for Welding

F. James Grist, Miller Electric Manufacturing Company, Inc.; William Farrell and Glen S. Lawrence, Ferranti Sciaky

Introduction

POWER SOURCES are apparatuses that are used to supply current and voltages that are suitable for particular welding processes. This article describes power sources for arc welding, resistance welding, and electron-beam welding.

Power Sources for Welding

F. James Grist, Miller Electric Manufacturing Company, Inc.; William Farrell and Glen S. Lawrence, Ferranti Sciaky

Arc Welding Power Sources

Arc welding requires that an electric arc be established between an electrode and the workpiece to produce the heat needed for melting the base plate. Because utility energy is not delivered at the proper voltage and current, it must be converted to the required levels by the welding power source.

Arc power sources convert the customary 240 or 480 V alternating current (ac) utility power to a range from 20 to 80 V and simultaneously increase the current proportionately. Galvanic isolation is also provided from the utility line voltage to ensure operator safety. Motor- or engine-driven welding generators are wound to deliver the correct voltage and current

directly; therefore, no transformer is necessary. Actual arc voltage is established by factors other than the power source (for example, electrode type, base-metal type, shielding gas, and standoff distance).

Ratings and Standards

The National Electrical Manufacturers Association (NEMA) categorizes arc welding power sources into three classes on the basis of duty cycle:

- CLASS I: RATED OUTPUT AT 60, 80, OR 100% DUTY CYCLE
- CLASS II: RATED OUTPUT AT 30, 40, OR 50% DUTY CYCLE
- CLASS III: RATED OUTPUT AT 20% DUTY CYCLE

Duty cycle is the ratio of arc time to total time based on a 10 min averaging period. A 60% machine will deliver 6 min of arc time and 4 min off time without overheating. In Fig. 1, curve A shows a NEMA class I (60%) 300 A rated machine that is capable of a maximum 375 A at reduced duty cycle (38%) and 232 A at 100% (continuous). Curve B represents a NEMA class II (50%) 250 A machine with a continuous duty of 176 A. Curve C represents an engine-driven machine rated at 225 A and 20% duty. It does not offer output in excess of its rating, because of a horsepower limitation of the engine.

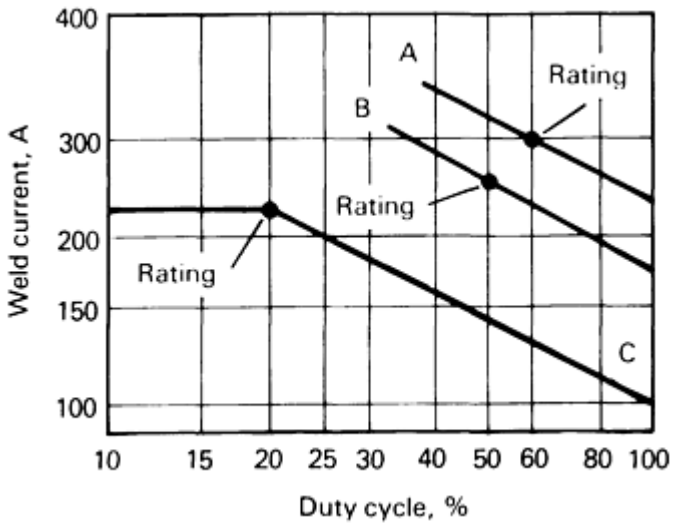

FIG. 1 SELECTED DUTY CYCLE CURVES. A, 300 A, 60% MACHINE; B, 250 A, 50% MACHINE; C, 225 A, 20% ENGINE-DRIVEN MACHINE WITH HORSEPOWER LIMITATION

NEMA requires most machines to produce a maximum of 125% of rated output current. No minimum current is specified, but 10% (of rating) is typical. Load voltage, *E*, for class I and II machines is defined by:

$$E = 20 + 0.04I \qquad \textbf{(EQ 1)}$$

where *I* is the current in amperes, below 600 A. Above 600 A, the rated load voltage remains at 44 V. Power sources intended for gas-tungsten arc welding (GTAW) service are defined by:

$$E_{GTAW} = 13 + 0.012I \qquad \textbf{(EQ 2)}$$

Class III machines are constant-current types limited to 20% duty cycle.

Efficiencies (that is, ratios of power output to power input) of 68% for line-frequency machines and 88% for inverters are typical. Line current draw can be reduced in certain machines by the addition of power factor correcting capacitors connected to the primary winding.

Input (line) voltages shown on the manufacturer nameplate are often multivoltage by means of tap changing for 200, 230, 460, or 575 V. Designed primarily for 60 Hz power, most systems will operate at 50 Hz, with minor changes in output. Input voltages for 50 Hz systems are typically 220, 380, and 415 V. Usual service conditions are temperature that range from 0 to 40 °C (32 to 105 °F) and altitudes of up to 1000 m (3300 ft). (Altitude is a factor because of fuel-air mixtures.)

The power source nameplate must include the following specifications:

- MANUFACTURER
- NEMA CLASS (I, II, OR III) AND DUTY CYCLE
- MAXIMUM OPEN-CIRCUIT VOLTAGE
- NUMBER OF PHASES
- MAXIMUM SPEED (IN REVOLUTIONS PER MINUTE) AT NO LOAD (ROTATING EQUIPMENT)
- RATED LOAD (IN VOLTS)
- RATED LOAD (IN AMPERES)
- FREQUENCY (OR FREQUENCIES) IN HERTZ
- INPUT VOLTAGE(S)

The National Electric Code (NEC) requires that a main disconnect switch be provided for each installed welding machine. Manufacturer installation instructions list the kVA and kW rating and recommend the correct fuse and conductor size. Local codes may differ from NEC requirements.

Proper grounding is a necessary safety consideration. Machines equipped with high-frequency arc stabilizers must be correctly grounded to prevent electromagnetic interference (EMI) to nearby equipment. The installer certifies (to the Federal Communications Commission) that the machine has been grounded according to manufacturer instructions. Most power sources are forced-air cooled by internal fans. Thermal sensors will interrupt output if airflow is impeded.

Power Source Selection

Because no single power source is right for all welding situations, it is necessary to know the processes to be used before selecting the best power source. Table 1 gives the more-common processes that use constant-current and constant-voltage power sources.

TABLE 1 SELECTION OF POWER SOURCE RELATIVE TO WELDING PROCESS TO BE EMPLOYED

WELDING PROCESS	POWER SOURCE	
	CONSTANT CURRENT	CONSTANT VOLTAGE
SHIELDED METAL ARC WELDING (SMAW)	•	. . .
GAS-TUNGSTEN ARC WELDING (GTAW)	•	. . .
GAS-METAL ARC WELDING (GMAW)	. . .	•
PULSED GAS-METAL ARC WELDING (GMAW-P)	•	. . .
FLUX-CORED ARC WELDING (FCAW)	. . .	•
SUBMERGED ARC WELDING (SAW)	. . .	•
ELECTROGAS WELDING (EGW)	•	•
ELECTROSLAG WELDING (ESW)	. . .	•
PLASMA ARC WELDING (PAW)	•	. . .

PLASMA ARC CUTTING (PAC)	•	. . .

Alternating current power sources for shielded metal arc welding (SMAW) and submerged arc welding (SAW) can be as simple as a single transformer (Fig. 2a). Low-voltage machines with open-circuit voltages of 50 V or less are transformer types. Output alternating current reflects the sinusoidal waveform of the utility input line (Fig. 3a).

FIG. 3 TYPICAL AC WELDING CURRENT WAVEFORMS. (A) SINE WAVE ALTERNATING CURRENT, SIMPLE TRANSFORMER WELDER. (B) MODIFIED SINE WAVE OBTAINED FROM MAGNETIC AMPLIFIER-TYPE WELDER. (C) SQUARE WAVE, LINE FREQUENCY, AND BALANCED DWELL. (D) SQUARE WAVE WITH UNBALANCED DWELLS, EP VERSUS EN. (E) VARIABLE-POLARITY AC WITH DWELL, AMPLITUDE, AND FREQUENCY ALL ADJUSTABLE

Magnetically controlled equipment (that is, a saturable reactor or magnetic amplifier) used for GTAW delivers a modified sinewave output (Fig. 3b). There is a risk of electrode (tungsten) migration to the workpiece if peak current greatly exceeds the average value. This technology exhibits moderate response.

Newer technologies deliver a square wave output at line frequency (Fig. 3c). A square wave eliminates peaking and provides a rapid transition through zero, which is important to cyclic reignition of the arc. Thyristors are employed in concert with magnetic cores to generate the square current waveform. Adjustable imbalance permits the operator to control the ratio of electrode positive (EP) to electrode negative (EN) current by dwell extension (Fig. 3d).

Direct current power sources can be classified as being constant-current sources or constant-voltage sources.

Constant-Current Sources. For the SMAW process, a family of "drooping" volt-ampere (V-A) curves (A, B, and C) is provided in Fig. 4(a). Often, a current boost or "dig" characteristic is made available (curve D in Fig. 4a). A burst of extra current during the brief period of metal transfer shorting tends to alleviate sticking during keyhole welding or when weaving or whipping the electrode, especially with the more-globular transfer electrodes.

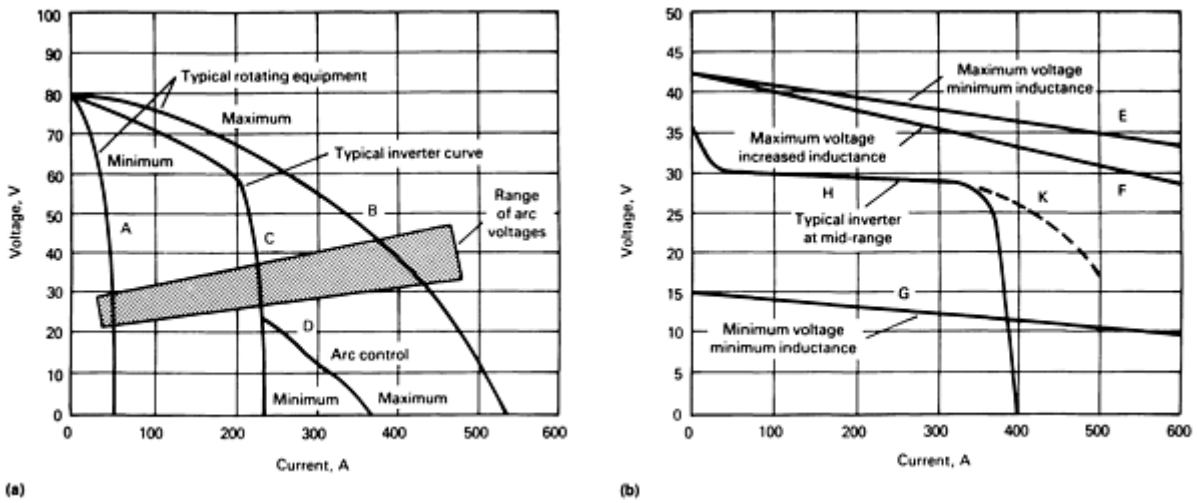

FIG. 4 VOLT-AMPERE CURVES OF TYPICAL DC POWER SOURCES. (A) CONSTANT-CURRENT SOURCE. (B) CONSTANT-VOLTAGE SOURCE

Power sources for dc GTAW processes are generally more critically constant-current than are the SMAW "stick droopers." Ripple content is lower and current regulation is tighter. Inverter types customarily regulate to ±1% or ±1 A, whichever is larger. Remote foot control is essential to ensure that both hands are free for manipulation. Response time need not be fast, except for pulsed programs. Programmable and pulse-capable units permit the automation of complex current profiles.

Power sources for GTAW processes include a high-frequency arc starting device that impresses a high radio frequency (RF) voltage on the electrode. This energy "jumps the gap" from the electrode to the workpiece, ionizing the shielding gas, and permits establishment of an arc. Thus, the electrode need not touch the workpiece.

Constant-Voltage Sources. Power sources intended for gas-metal arc welding (GMAW) exhibit a relatively flat V-A curve, as shown in Fig. 4(b) (curves E, F, and G). The self-correcting characteristic of GMAW regulates the electrode burn-off rate. As the wire feed rate is increased, additional current will be drawn, but terminal voltage will remain

essentially constant. Voltage feedback techniques are used in solid-state designs to hold long-term output close to a set value.

In the short-circuiting GMAW process, for example, drops of metal are transferred to the base metal through a pinch-off routine during a period of short circuiting of the electrode to the workpiece. Shorting time and arc time are determined by power source dynamics.

Source Characteristics

Whether utility fed or motor driven, all welding power sources have a characteristic that indicates their dynamic and steady-state response. In early machines, source characteristics were optimized for a single process and were relatively unchangeable. More recent designs can be programmed for a variety of characteristics that include multiple weld processes.

The welding arc process is a dynamic, fast-changing load, exhibiting short circuits (if shorting, then no arc) at high currents and momentary voltages from near zero to over 50 V. Changes occur in milliseconds, particularly when metal transfer takes place. The ability of the power source to respond properly to rapidly changing conditions at the arc is critical to good performance. Modern technology invariably includes a closed-loop feedback circuit in the control system.

Open-Circuit Voltage (OCV). When no load is connected to the output terminals of a welding power source, the voltage that appears at the terminals is at its maximum. A high OCV value generally aids in arc starting and stability. In transformer-type power sources. OCV is established by the incoming utility line voltage and the transformer primary-to-secondary turns ratio. The output winding turns, the flux, and the angular velocity (rev/min) will establish the OCV in generators.

In manual welding, the maximum OCV is 80 V_{rms} for machines with more than 10% ripple, or 100 V OCV for a ripple content of less than 10%. Power sources intended for automatic welding only are permitted 100 V OCV. The percentage ripple voltage is the ratio of rms ripple to average pulsating dc, expressed as:

$$\%ripple = \frac{V_{\max} - V_{\min}}{V_{rms}} \qquad \textbf{(EQ 3)}$$

Static V-A Curves. Two terms are commonly used to define the characteristics of a power source for welding: static output and dynamic response. Static characteristics are set forth by the manufacturer as a series of V-A curves (Fig. 4). The slope of the static V-A curve is the ratio of load voltage change to the change in load current, expressed in V/100 A. It indicates the achievable envelope of output limits, including the highest voltage the machine will support at a given current, and the highest current that can be drawn at a given voltage.

Dynamic Response. The static V-A curves discussed above do not take into account the dynamic interplay between the power source and the process. Instantaneous response of the power source to step changes in load voltage is important to welding performance. This is especially true in the case of certain GMAW processes, where the response to a metal transfer short circuit is instrumental in bead formation and the reduction of spatter generation.

Methods of Control or Electrical Conversation. Power source control methods are a key factor in the rate of current rise (d*I*/d*t*). Either increased reactance in the ac circuitry or inductance in the dc portion will slow the rate of rise (and fall) of current during changes at the arc. Some equipment incorporates an adjustment to select the proper number of turns for a given welding condition (with silicon-controlled rectifiers [SCR] and transistor controls, these characteristics can be synthesized). Because there is no industry-accepted method to quantify the dynamics, the user must obtain a power source with a satisfactory range of adjustment.

Another consideration is the frequency response of the power source, that is, its ability to "follow" a fast command signal, such as a pulse program. Magnetically based machines are generally not fast enough to faithfully reproduce a pulsed GMAW control signal and deliver it at high currents to the weld. When a better response is required, inverter-based SCR, transistorized sources with a high-frequency response are preferred.

Droopers. A constant-current, a drooper, power source displays V-A curves such as those in Fig.(a) (curves A and C). A considerable negative slope is evident. The internal impedance of the power source is said to be high. Large variations in

the arc (load) voltage (for example, below 40 V) do not appreciably affect the selected current. Droopers are noted for their use in the SMAW process, where the operator sets current to establish a suitable burn-off rate for the selected electrode. Manipulation, that is, shortening or lengthening the arc, does not greatly affect the arc current.

However, if welding is conducted on a flatter V-A curve (see curve B in Fig. 3a), then electrode manipulation may change the current considerably. Thus, the operator gains more local control of the current through eye-hand coordination. Increasing the arc length by "pulling back" on the electrode causes the operating point to shift up slightly in terms of voltage, but decrease considerably in terms of current.

Open-circuit voltage can be field adjusted in generator types, which provides the operator with a great degree of control through electrode manipulation. Skilled operators use this flexibility to their advantage when performing difficult out-of-position welds.

Constant-Voltage Sources. Equipment designed for constant-voltage processes will display a "stiff," nearly horizontal V-A curve (curve E, F, and G in Fig. 4b). The open-circuit voltage is 43 V for curve F. When serving a 300 A load, it falls to 35 V. This is expressed as:

$$\frac{(43-35)}{300A} = \frac{8V}{300A} = \frac{2.6V}{100A} \qquad \textbf{(EQ 4)}$$

Curve H of Fig. 4(b) is representative of an inverter source in the constant-voltage mode. When set to 30 V, the electronic regulation system keeps the output very constant out to 300 A under a static (resistive) load, beyond which it falls abruptly to 0 V at 400 A. Curve K in Fig. 4(b) represents an extended output that may be available on a short-term (dynamic) basis from inverters.

The term "constant" is taken to mean relatively constant. Some droop in voltage is permitted, and is even preferred in certain welding situations. Load current at a given voltage is responsive to the rate at which a consumable electrode is fed into the arc. The designer ensures that terminal voltage is maintained during heavy loads by providing tight coupling between the primary and secondary windings of the transformer, or by providing electronic regulation systems, or both.

Movable Magnetic Cores. Welding power must be delivered to the arc under complete control of the operator. In the simplest form, conversion to the lower voltage and selection of current are incorporated into a single, special welding transformer. Movable coils (varying the coupling between primary and secondary windings) and moving iron shunts provide stepless adjustment of the output (Fig. 2a).

Saturable Reactors. In heavy industrial equipment, control is imparted by saturable reactors. These reactors comprise laminated iron core assemblies fitted with power and control windings. A small control current varies the effective magnetic permeability of the iron core and controls flux to the power winding. Considerable gain is obtained. Typically, 5 A of control will command several hundred amperes of welding current. Both ac and dc outputs are available. Direct current output is obtained by the addition of secondary rectifiers. By combining rectifier diodes with self-saturating magnetic cores, a wider range is obtained, referred to as magamp control.

Alternating current and ac/dc power sources are manufactured in sizes that range from 180 A Class III "farm welders" to units designed for industrial use and rated in hundreds of amps. Principal attributes are low cost and simplicity. Alternating current is specified wherever arc blow is a concern. It is also preferred for welding aluminum. Direct current machines are favored for most SMAW and GTAW processes, and for essentially all GMAW processes.

Silicon-Controlled Rectifiers. In addition to the transformer taps, moving coils, moving shunts, and saturable reactors mentioned earlier, there are a number of other means by which output can be controlled. Thyristors, commonly known a SCRs, are frequently employed as control elements, replacing magnetic cores.

The SCR is similar to a rectifying diode, but is equipped with an additional gating element. With properly phased low-power gate signals, a configuration of SCRs will deliver hundreds of amperes of current.

The output of such a phase-controlled arrangement (Fig. 2b) can be tailored to perform as a stiff (that is, flat slope) constant-voltage source or as a drooping constant-current source through closed-loop feedback controls. When designed for three-phase operation, the dc output ripple frequency is either three times the line frequency (using three SCRs) or six

times, using six SCRs. Output ripple is "smoothed" with an appropriate inductor. Single-phase versions display the ripple of twice the line frequency and require a larger output inductor, *L*.

Because welding current is analog in nature, it has traditionally been adjusted with analog circuitry via rheostats and potentiometers. Recent advances allow digital control with microprocessors and dedicated software; tight-tolerance repeatability is the driving force.

Inverters. Inverter welding power sources are smaller and more efficient, and they offer better performance than their line-frequency counterparts. The size and weight of iron-core components are reduced when operating at higher frequencies (Fig. 5).

FIG. 5 300 A RATED CONVENTIONAL LINE-FREQUENCY POWER SOURCE (RIGHT) AND INVERTER POWER SOURCE WITH SAME RATING (LEFT). COURTESY OF MILLER ELECTRIC MANUFACTURING COMPANY, INC.

With reference to the inverted shown in Fig. 2(c), the incoming utility line directly feeds a rectifier for conversion to direct current, which powers an inverter stage operating in the range from 2 to 100 kHz. Various topologies include forward, buck, series capacitor, and series resonant inverters.

Control methods employ either pulse width modulation (PWM) or frequency modulation (FM). A variety of semiconductors are used as switching elements, including transistors (for example, field-effect transistors [FETs] and insulated-gate bipolar transistors [IGBTs]).

The transformer, which is often designed of ferrite core material, operates at high frequencies without introducing high losses. The turns ratio determines welding voltage, usually 80 V_{rms} ac at the secondary winding. A second rectifier converts it back to dc for welding. A small output inductor is required to smooth the high-frequency ripple.

Inverters have the greatest application where portability or advanced performance is required. Fast response permits current with fast transitions, low overshoot, and faithful reproduction of pulse programs.

Variable Polarity. High-technology power sources permit adjustment of the ac waveform to vary the ratio of EP to EN current and terms of both width and amplitude (Fig. 3e). Among these are switched dc types, wherein two dc constant-current power sources are alternately switched on and off, and arc current is of one polarity and then the other polarity. Almost unlimited frequencies can be generated, with rapid zero crossings.

Cycloconverter power sources constitute a family that uses three-phase inputs to generate low-frequency ac for the GTAW process. Through careful selection of specific portions of each line-frequency cycle, a pseudo square wave is assembled at a frequency lower than line frequency.

Rotating Equipment. For a variety of reasons, rotating generators and alternators are often used to supply welding power. In what is known as a motor-generator (M-G) set, an electric motor (Fig. 2d) drives the shaft of a generator, which also isolates weld power from the input utility power. The flywheel effect of the M-G set ensures stable output.

Where no electric utility power is readily available, engine-driven equipment can supply welding power (Fig. 2e). Gasoline and diesel fuels predominate. Both air- and water-cooled prime movers are available. Some include an auxiliary air compressor for air tool use.

Generators produce direct current. A wire-wound armature spins in a frame arranged with electromagnetic field poles. The armature windings cut through these fields cyclically, generating ac. This is collected by commutator, that is, copper segments fitted to the armature shaft and equipped with fixed carbon brushes. The commutator serves as a "mechanical rectifier," converting the armature currents to dc. Both the OCV and current can be user adjusted, providing good control of the V-A slopes. The output is relatively pure dc, with very little ripple content. Engine speed is governor controlled.

Most generators provide constant-current output for SMAW and GTAW processes, but adapters are often available for constant-voltage operation in the GMAW process. Auxiliary power for lights, tools, and so on derived from auxiliary stator windings.

Alternators (that is, ac generators) produce alternating current, as the name implies (Fig. 2e). A spinning rotor winding is charged with direct current obtained from the exciter and applied through slip rings, creating a rotating magnetic field. No commutator is required. The rotating field cuts through a surrounding stator assembly, the windings of which collectively produce alternating current, either single phase or three phase, as designed. In single-phase designs, the resulting current can be used for ac welding.

Output selection is provided in course ranges with reactor taps (Fig. 6), and fine adjustment is provided by rheostat-controlled current in the revolving field windings. Engine speeds are generally either 1800 or 3600 rev/min, corresponding with four-people and two-pole alternators, respectively. Some alternators eliminate the revolving field winding by employing rotating permanent magnets. If direct current is required, a static (silicon diode) rectifier is included. The combination is referred to as a dc generator-rectifier.

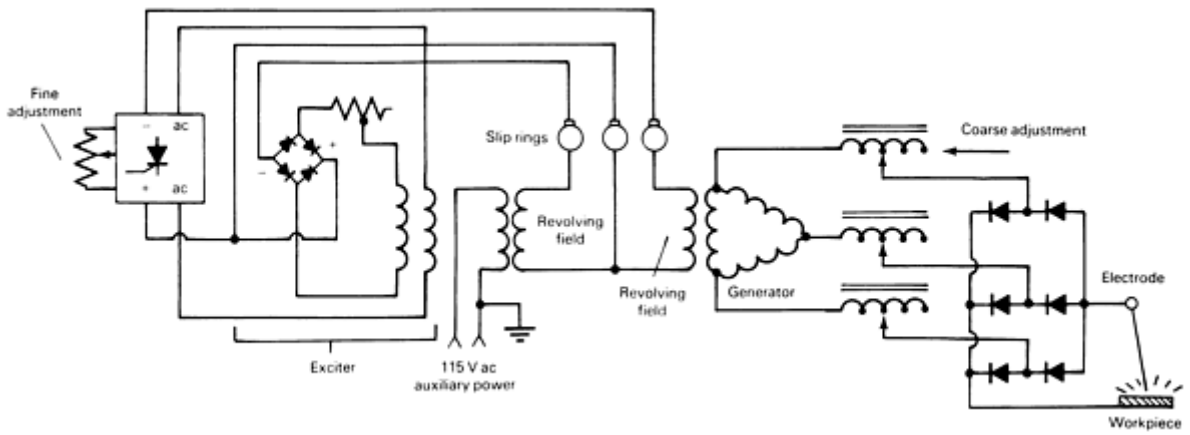

FIG. 6 SCHEMATIC SHOWING TYPICAL ENGINE-DRIVEN WELDING POWER SOURCE

The recent evolution to solid-state controls has raised the performance level of engine-driven machines. Accessories include remote controls, idle devices to reduce engine speed when not welding, battery charging capabilities, and high-frequency arc igniters.

Pulsed Power Supplies

Pulsed GTAW and GMAW processes require a power source with the ability to deliver precisely shaped current pulses superimposed on a lower background (arc-sustaining) level. In addition to thyristors in phase control, inverters are also used to generate pulses and are especially versatile for such applications. Add-on "pulse formers" have also been designed for attachment for conventional dc welding power sources.

Pulse Repetition Rates (PRR). For the GTAW process, PRRs (the number of times per second that a pulse is transmitted) are relatively low (typically, 1 to 10 PRR). Fast rise times are not essential. However, in the GMAW pulse

process, repetition rates typically range from 100 to 200 PRR. Rise (and fall) times must be short (50 to 500 μs) and overshoot must be low to preserve pulse fidelity.

The mean current of a train of rectangular pulses is given by:

$$I_{AV} = FT_P(I_P - I_B) + I_B \qquad \textbf{(EQ 5)}$$

where I_{av} is the average current, I_B is the background current, I_P is pulse peak current, f is frequency, and T_P is pulse width.

From Eq. 5, with background current, pulse width, and peak current selected, the average current will be proportional to frequency. Increasing and decreasing pulse frequency in proportion to wire feed speed will balance the current with the burn-off rate of the electrode, maintaining the proper arc length for the GMAW process. Individual droplet size will remain essentially constant.

Some pulse power sources generate pulses at line frequency or multiples thereof and stabilize the process by adjusting the power envelope of each pulse. (In a refined development, designated "one-knob control," the operator need only select a wire and gas type; pulse parameters are established by algorithms in the controller. As wire feed speed is adjusted, all other functions "track.")

Synergic Pulsed GMAW. A step higher in technology results in synergic pulsed GMAW. Inverters (Fig. 2c) and secondary switchers (Fig. 2f) ensure process stability by controlling melting rate through modulation of pulse shape and frequency. The relationship between digitally monitored wire feed speed and pulsation parameters is managed by microprocessor look-up tables and similar control strategies. The power source is simply required to exhibit fast response and high peak current capability.

Multiple Operator Power Sources

On large job sites with a number of arcs, a multiple operator (MO) power source can serve several operators. Diversity of use suggests that all arcs will not be operating simultaneously and that a 0.25 factor is typical. Accordingly, a single, large, 76 V constant potential power source can supply up to 20 SMAW operators. Each operator is equipped with a resistor "grid" to adjust arc current to his particular needs.

An alternative MO concept provides individual magamp control modules (typically, eight) fed from a single, large, multiwinding transformer. Each operator can select his preferred polarity and current. Modules can be connected in parallel for greater output.

Power Sources for Welding

Resistance Welding Power Sources

The function of the power source for resistance welding (RW) is to deliver a predetermined amplitude of current to the welding electrodes that are clamping the workpiece. Current flows from the power source to one electrode, through the workpiece to the opposing electrode, and returns to the power source. The electrodes concentrate current into a small, usually circular area. The flow of this constricted current generates heat, concentrated largely at the interface(s) of the workpiece details to be joined.

Heat Input. The rate of heating must be sufficiently intense to cause local electrode/workpiece interface melting. The opposed electrodes apply a pressure and, when sufficient melting has been achieved, the current is interrupted. Electrode force is maintained while the molten metal solidifies, producing a sound, strong weld.

If both the local resistance of the workpiece and the welding current magnitude were constant, then the total quantity of heat, Q, developed in the workpiece would be given (in joules) by:

$$Q = I^2 RT \qquad \textbf{(EQ 6)}$$

where I is the effective value of current in amperes, R is the resistance of the workpiece in ohms, and t is the duration of flow of current in seconds.

However, the resistance is not constant. Contact resistances decrease in magnitude and the bulk resistance of the work column increases as its temperature rises. Furthermore, resistance variations of the workpiece may cause variations in the current amplitude, depending on the nature of the power source. Under these circumstances, the total quantity of heat, Q, is given by:

$$Q = \sum_{0}^{t} i^2 r.dt \qquad \textbf{(EQ 7)}$$

where i is the instantaneous value of current expressed as a function of time and r is the instantaneous resistance that is changing with time.

Equipment Selection. The design of resistance welding machines resembles that of a "C" frame press (Fig. 7). The power source transformer secondary winding is connected to the electrodes on cantilevered arms, one of which provides for adjustable electrode force. Throat depth is the distance from the frame to the electrodes. Throat gap is the vertical distance between the two parallel secondary conductors. The total area of the secondary circuit (throat depth times throat gap) exerts a profound influence on output performance. Any increase in inductance, whether due to geometry or magnetic materials within the secondary, will degrade performance and lower the power factor.

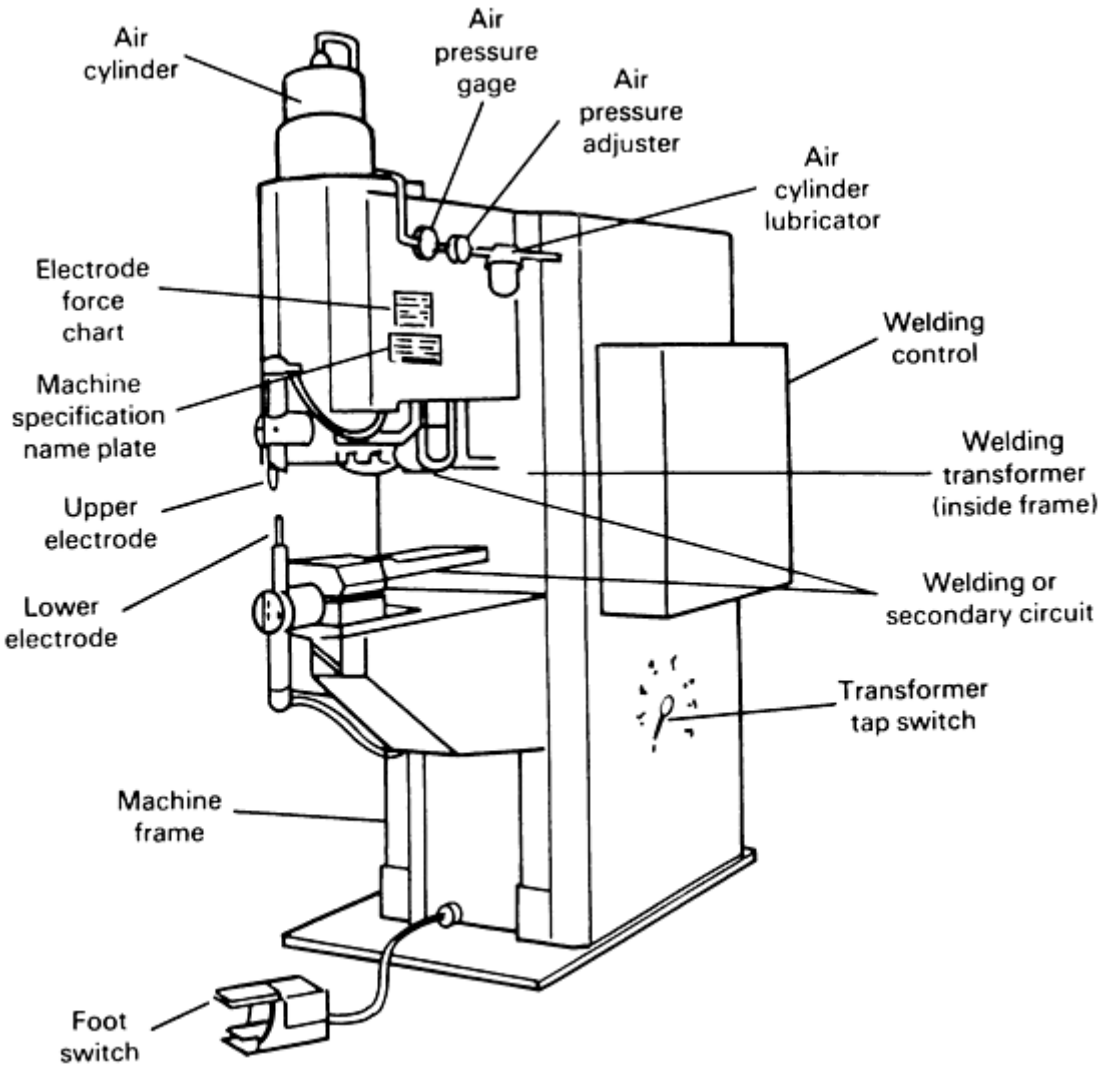

FIG. 7 SCHEMATIC SHOWING PRIMARY COMPONENTS OF A RESISTANCE WELDING MACHINE

The input to resistance welding power sources is usually 230 or 460 V utility power delivering single-phase or three-phase alternating current at 60 Hz. All systems require transformers to step down the line voltage to a relatively low value, with a proportional increase in current. The simplest systems consist of a transformer connected to single-phase power. More advanced sources produce a dc welding current through rectification.

Rectification Systems. In primary rectification systems, a special three-phase transformer is designed with a very large iron core. Each dc pulse is limited in duration and each is reversed in polarity to prevent saturation of the core. In the majority of applications, a weld is produced by a single impulse of direct current. For heavy gages, pulsation welding is used. A series of dc impulses of alternating polarity is separated by "cool time." The result is a very low frequency alternating current. Hence, the term frequency converter is commonly applied to this type of power source. Figure 8 shows a three-phase half-wave primary rectified power source.

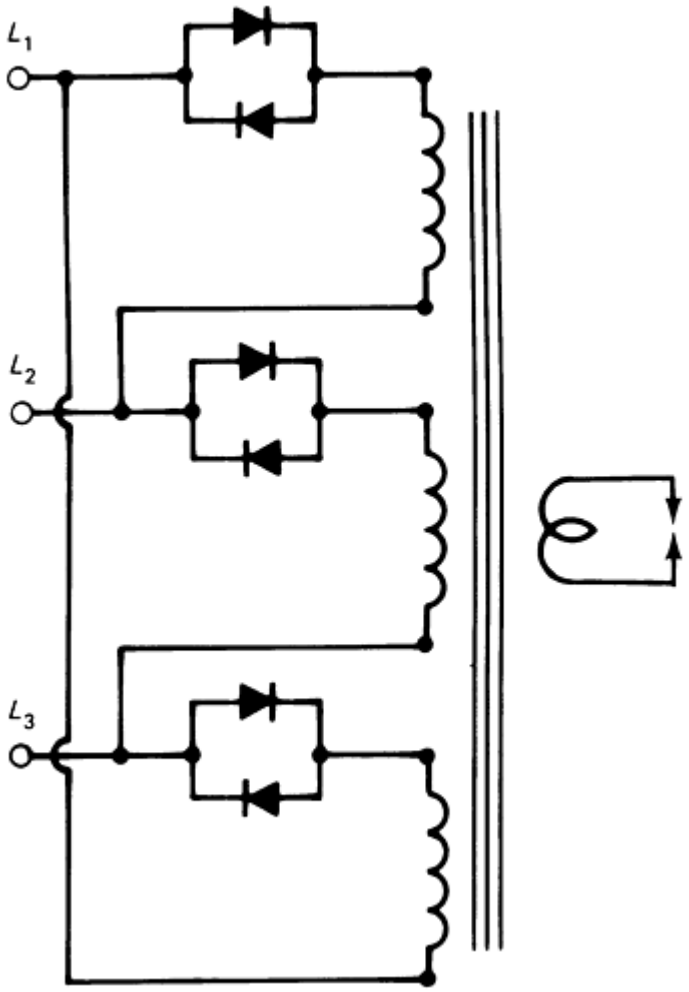

FIG. 8 CIRCUIT DIAGRAM OF THREE-PLATE HALF-WAVE RESISTANCE WELDING POWER SOURCE WITH PRIMARY RECTIFICATION

Secondary rectification systems are available in single-phase full-wave, three-phase half-wave, and three-phase full-wave forms; the latter is most commonly utilized. Three-phase full-wave systems consist of three single-phase transformers, with rectifiers connected to the secondary windings (Fig. 9). With this system, current pulse time is limited only by thermal considerations and polarity is fixed.

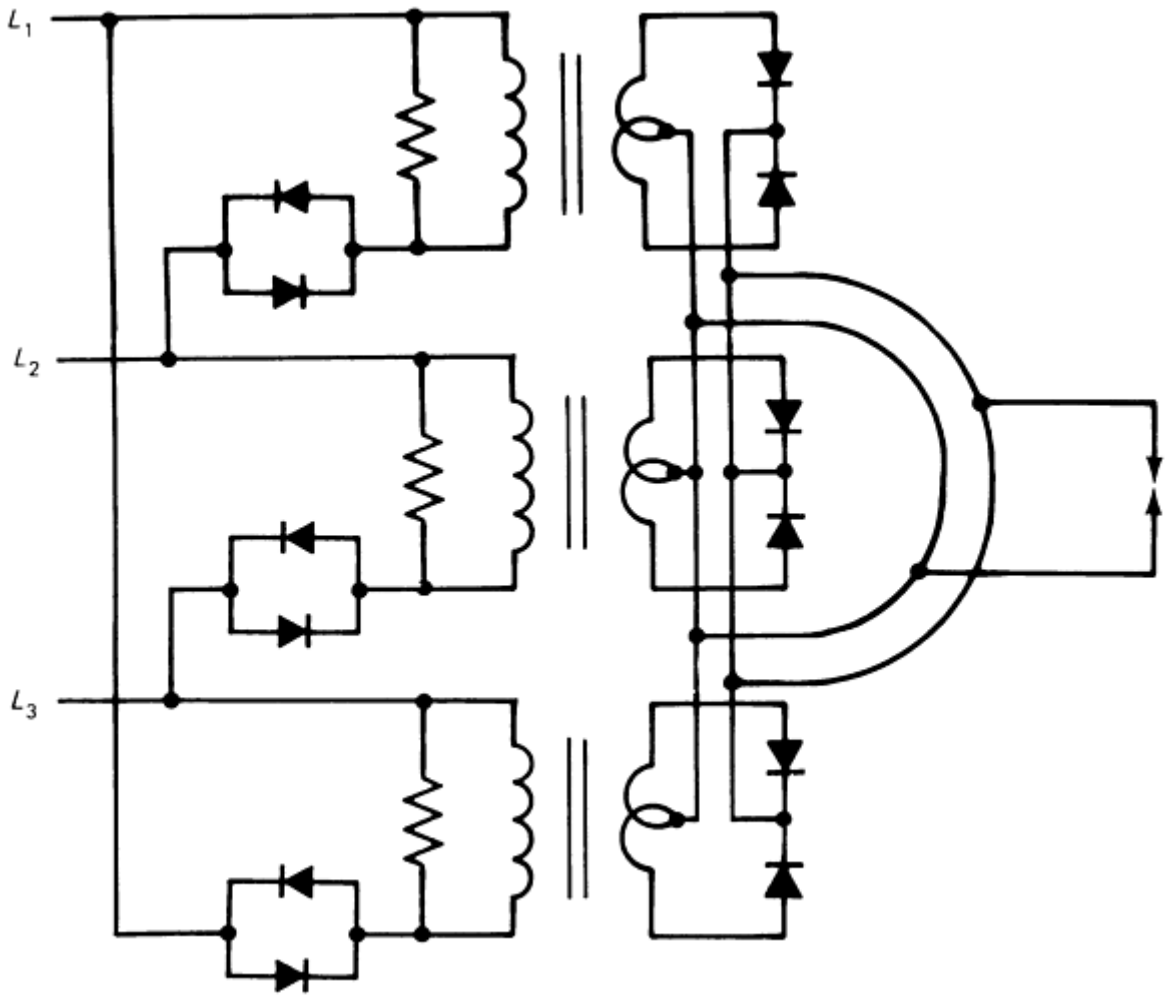

FIG. 9 CIRCUIT DIAGRAM OF THREE-PHASE FULL-WAVE RESISTANCE WELDING POWER SOURCE WITH SECONDARY RECTIFICATION

The energy efficiency of a resistance welder depends on the efficiency of delivered energy at the electrodes. Energy is dissipated in the form of heat, because of resistance in the conductors. The current, *I*, which produces the heat of welding, is simply the secondary voltage divided by the total machine impedance, *Z*, plus that of the weld:

$$i = \frac{E}{Z} \qquad \textbf{(EQ 8)}$$

where *Z* is the vector sum of the resistance and the reactance:

$$Z = \sqrt{R^2 + X^2} = \sqrt{R^2 + (wL)^2} \qquad \textbf{(EQ 9)}$$

where *R* is the total resistance of the circuit and $X = \omega L$ is the total reactance of the circuit (where ωequals $2\pi f$ and *L* is the inductance).

Resistance welders designed for single-phase utility power are lowest in investment cost, but highest in energy cost. The high-magnitude alternating current results in large inductive losses and a low power factor. Three-phase primary rectification and three-phase full-wave secondary rectification power sources reduce the power demand to about one half and operate at a higher power factor.

The rapidly pulsing weld zone temperature inherent with a single-phase source is least desirable from a welding standpoint. In addition, copper electrodes suffer from clamping impact, force, and heat, causing the occurrence of "mushrooming," which lowers current density.

Mushrooming also reduces resistance in the current path. Welding current will increase, because current is controlled indirectly in resistance welding machines by adjusting secondary voltage (that is, advancing or retarding the firing angle). From Eq 8, a decrease in impedance causes an increase in the current. Therefore, all resistance in the work path influences the current magnitude produced by a given secondary voltage. This influence is small if total system impedance is high, but significant if the system impedance is low.

A three-phase primary rectification system exhibits the greatest degree of this self-compensating effect, followed to a somewhat lesser degree by the three-phase secondary rectification category.

Finally, a thermoelectric effect is associated with passing current from a copper alloy electrode to a workpiece of a given material. This phenomenon is important when welding aluminum or magnesium alloys with a single impulse. Reversing the current polarity for each successive weld, an inherent characteristic of the three-phase primary rectification system, provides the maximum electrode life between dressings.

Duty Cycle. Resistance welding is inherently an intermittent process with a series of very short current periods followed by "off" or "cool" periods. Therefore, this type of power source is rated on a 50% duty cycle and a 1 min integrating period. The relationship between kVA rating at 50% duty cycle and kVA demand at actual duty cycle is as follows:

$$KVA_{50\%} = KVA_{Demand}\sqrt{2.(D.C.)} \qquad \textbf{(EQ 10)}$$

where D.C. is the duty cycle in %, entered in the form of a decimal. Duty cycle is defined by:

$$D.C. = \frac{N.T}{60.f} \qquad \textbf{(EQ 11)}$$

where N is the number of welds per minute, T is the weld time in cycles, and f is the frequency in hertz.

Heat Controls. Resistance welds are short and are measured in cycles. Because timing is very important, digital microprocessor controls abound. Electrochemical contactors have been replaced by SCRs or ignitrons connected in inverse parallel to handle the high currents. Coarse heat adjustment is accomplished by transformer tap switch setting, and fine adjustment is achieved through phase shifting, with digital circuitry providing the highest repeat accuracy.

Additional information on resistance welding is available in the Section "Joining Processes" in this Volume.

Power Sources for Welding

Electron-Beam Welding Power Sources

Electron-beam welding (EBW) requires a variety of power supplies in two categories: those that generate and control beam position and those that control beam power. The outputs of various power supplies are coordinated by a machine control system.

Beam Position and Intensity. Beam position arrangements for alignment, deflection, and focus are dominated by magnetic devices in electron-beam welders. Because the magnetic field effect on the beam (the magnetomotive force) is directly proportional to the current in the windings of the device, these power supplies are typically current regulated.

$$MMF = N \cdot I \qquad \textbf{(EQ 12)}$$

where N is the number of turns in the coil and I is the current in the coil. The desired current value is programmed by potentiometer, computer, or function generator.

A second factor regarding the effectiveness of magnetic devices is the velocity of the electrons in the beam, as determined by the accelerating voltage. At the voltages used in EBW (typically, 50 to 150 kV), relativistic effects must be considered. In situations where the beam potential is changing, but it is desired to have the effect of the magnetic devices be constant, then the effective magnetic excitation, k, must be constant:

$$K^2 = \frac{(N.I)^2}{V^*} \qquad \textbf{(EQ 13)}$$

where NI is the magnetomotive force and V^* is the relativistic voltage. The relativistic voltage can be expressed in volts as:

$$V^* = V + (0.9785 \times 10^{-6})V^2 \qquad \textbf{(EQ 14)}$$

Sensors monitor the beam potential generated by the high-voltage (HV) supply and correct the control signal to the magnetic device power supply. Thus, the action of the device can be held constant as beam potential changes.

This correction can be achieved by using computer software or an analog circuit. Such correction is often called square root compensation, because of the relationship indicated in Eq 13.

Alignment coils are used for slight corrections to the x and y positions of the beam as it enters the magnetic focusing coil. Power supplies for these devices are typically potentiometer programmed by the operator in an alignment procedure. These supplies are characterized by a high degree of long-term stability, with minimal need for dynamic response. Selected installations employ alternate means for achieving alignment.

The magnetic focus coil acts very much as a glass focusing lens would for optics. It takes a divergent electron beam and converges it at a more distant point along the beam axis. The beam focus point from the magnetic lens is roughly inversely proportional to the square of the lens excitation:

$$f \propto \frac{V^*}{(N.I)^2} \qquad \textbf{(EQ 15)}$$

The magnetic lens supply is usually controlled by computer output in order to coordinate beam focus with the weld program. Manual control (operator offset) and square root compensation are also usually provided. These supplies are of high stability and moderate dynamic response.

The deflection coil moves the beam along the x and y axes to position the beam over the surface of the workpiece. Deflection rates can range from dc to high audio frequencies. Thus, the deflection supply is a high-quality current-regulated stereo amplifier.

Amplifier input controls allow computer input for coordinated movements of the part and beam, function generator inputs for beam deflection patterns (rasters, and so on), and dc offsets to patterns. These are highly stable current-regulated coils drivers with wide dynamic response.

High-Voltage Control. The electron beam is generated in an electron gun (resembling a diode or triode of cylindrical symmetry) that generates a paraxial flow of electrons. The power in an electron beam comes from the high-voltage supply that generates the large voltage difference between the anode and cathode of the gun. Electrons are emitted from the cathode and, accelerated by the voltage, fall to the anode. The beam passes through a central aperture in the anode and drifts through various alignment, focus, and deflection elements to strike the workpiece (Fig. 10). Both the workpiece and the anode are typically at ground potential, whereas the cathode is highly negative.

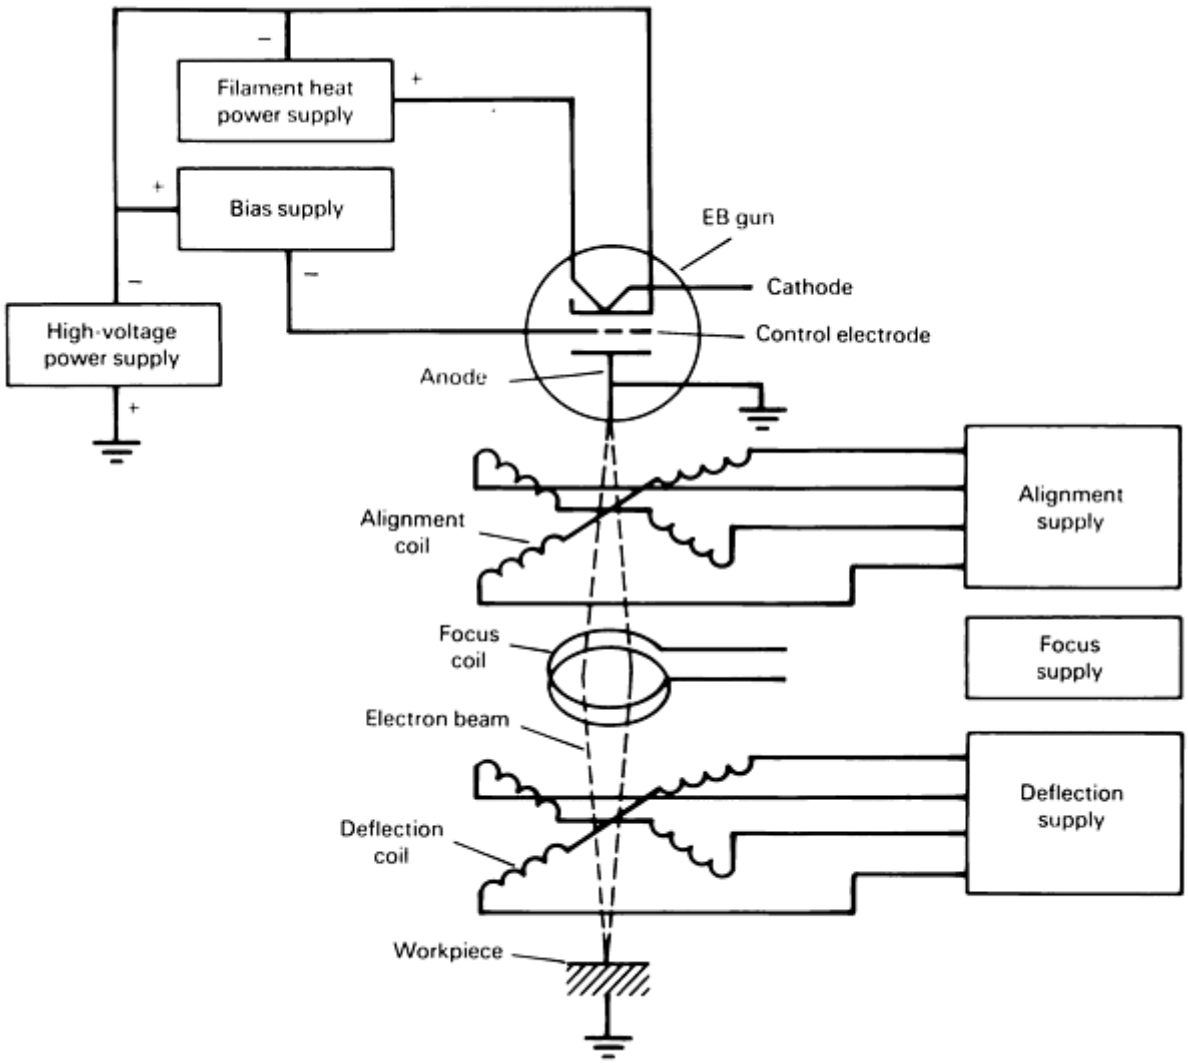

FIG. 10 SIX INDIVIDUAL POWER SUPPLIES THAT CONTROL POSITION AND INTENSITY OF THE BEAM IN EBW PROCESS

Control and regulation of the high voltage is usually done on the input to the high-voltage transformer/rectifier oil-filled tank. The input control installations range from motor-driven variable autotransformers, motor-alternators with field controls, SCR switching or phase control, to power MOSFET (metal-oxide semiconductor field-effect transistor) and IGBT devices in various switch mode regulators.

In a three-phase input unit, a standard technique is to place the switching control in the primary neutral conductor of the HV transformer (Fig. 11). The secondary circuitry is three-phase or six-phase, full-wave rectified, and filtered.

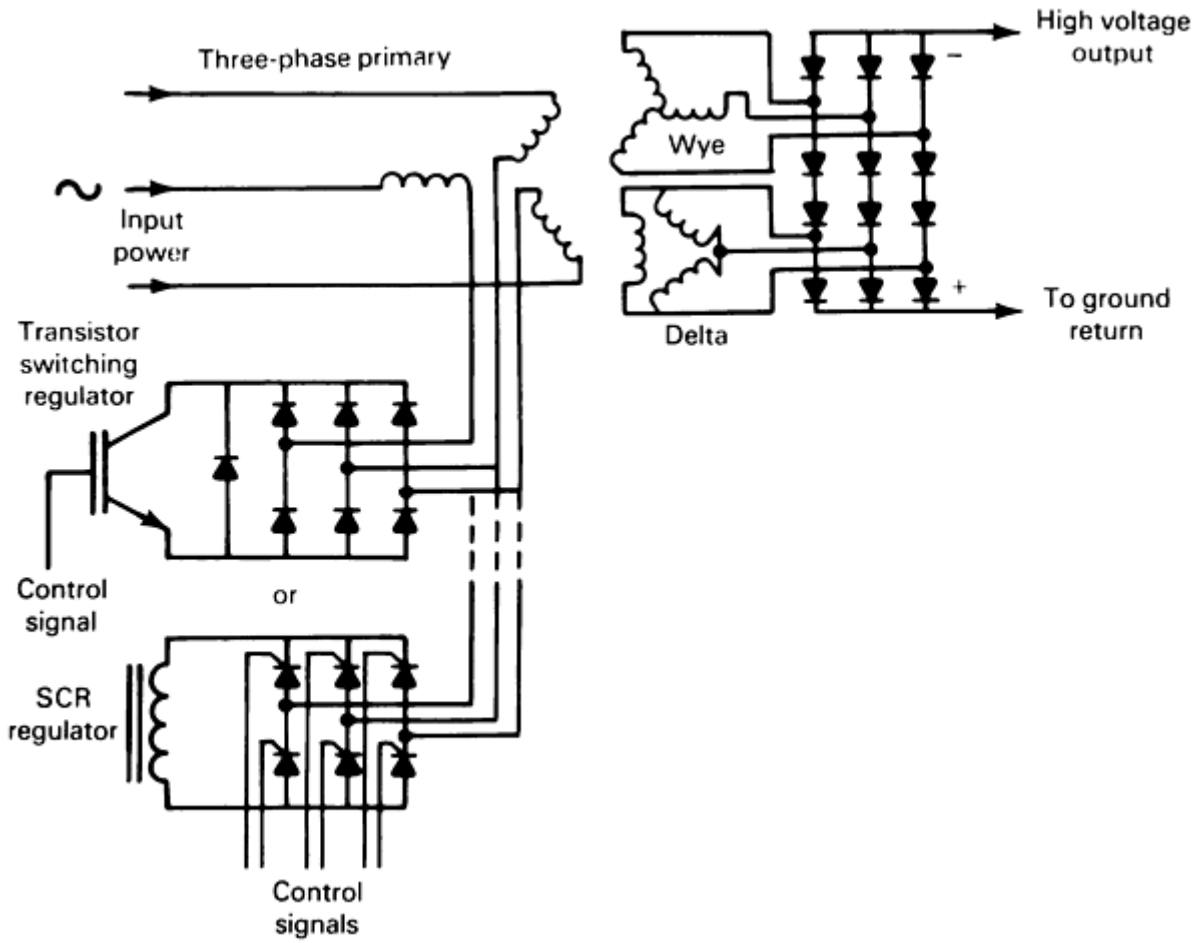

FIG. 11 CIRCUIT DIAGRAM OF A HIGH-VOLTAGE CONTROL IN NEUTRAL IN A THREE-PHASE INPUT UNIT

In an alternate arrangement, line voltage is converted to dc, which powers an inverter to produce high-frequency single-phase input to the high-voltage transformer. Control can be provided either by regulating the level of the dc supply or by controlling the inverter pulse width or frequency. The HV transformer can be a conventional step-up unit or a voltage multiplier. These supplies can be characterized as voltage regulated and input controlled, with a moderate response rate.

Thermionic Emission. The cathode heating unit provides the energy to raise the cathode to thermionic electron emission temperatures. This is usually a dc source. For beam-heated cathodes, discharge-heated cathodes, and others, it may be more complicated, to a point of supplying power to a second miniature gun.

In a space-charge limited electron beam, the cathode temperature must be held high enough that temperature-limited emission (Eq 16) is greater than space-charge limited flow (Eq 17):

$$I_P = AT^2 E^{-ef/kt} \qquad \textbf{(EQ 16)}$$

$$I_P = K(V_P + m V_G)^{3/2} \qquad \textbf{(EQ 17)}$$

In Eq 16 and 17, I_p is beam current, V_p is accelerating voltage, A is Dushman's constant, V_g is bias voltage, and T is temperature.

The bias supply provides voltage to the control electrode and regulates the magnitude of the beam current. Bias supplies can be input controlled with ground-level sensing of beam current on the return of the HV supply, or the beam can be sensed and regulated at high voltage using optical isolation (Fig. 12).

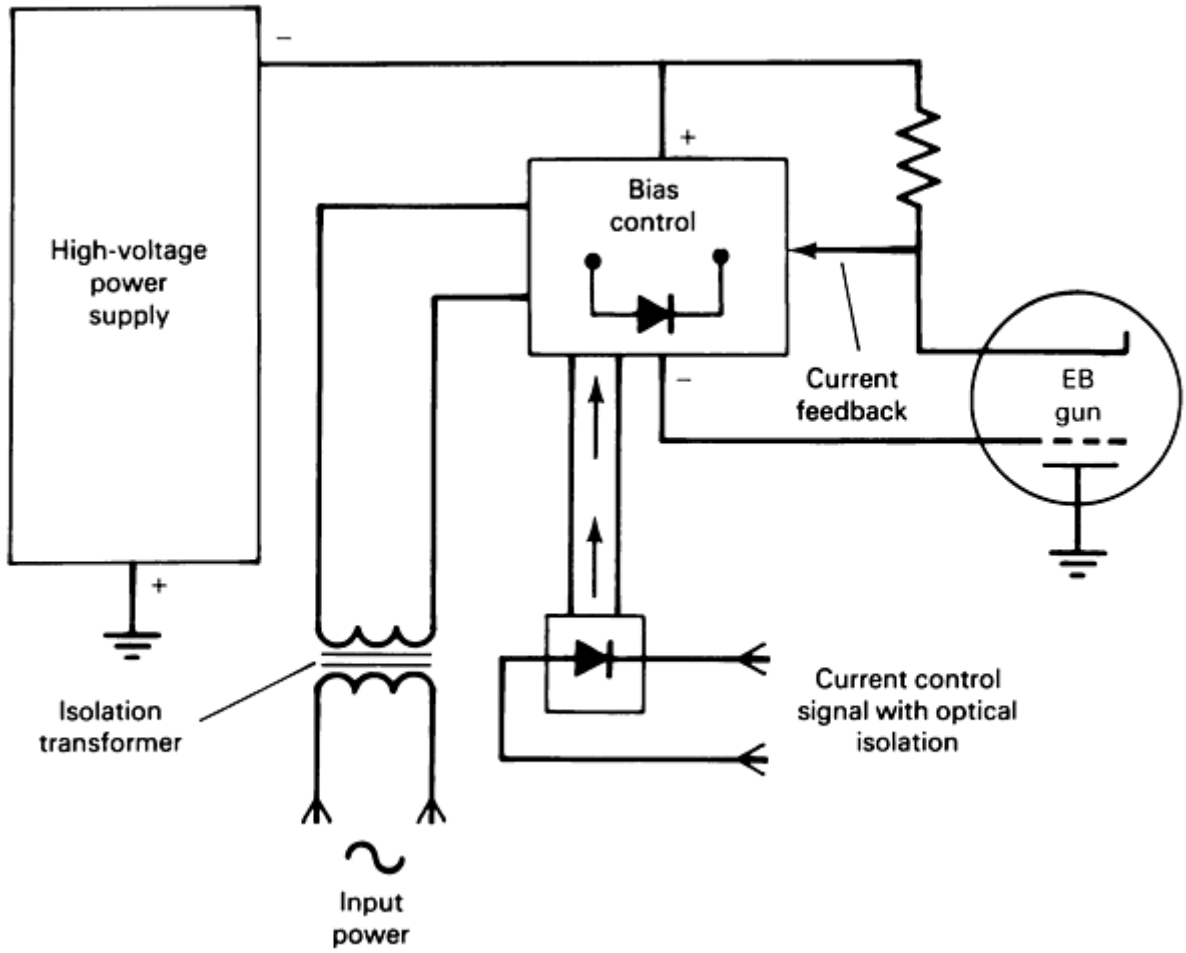

FIG. 12 CURRENT FEEDBACK AND BIAS CONTROL AT HIGH-VOLTAGE POTENTIAL

Ground-level sensing systems tend to use high-frequency inputs from linear amplifiers or switch mode inverters in order to achieve response on the order of a millisecond. Submillisecond response bias supplies are achieved by sensing and controlling the beam current at the high-voltage output. Because bias voltage is in the low kV range, vacuum tubes are used for output control.

Additional information on electron-beam welding is available in the article "Electron-Beam Welding" in this Volume.

Fundamentals of Weld Solidification

Harvey D. Solomon, General Electric Company

Introduction

OF ALL PHASE TRANSFORMATIONS, few have been more widely observed and studied than the transformation of a liquid to a solid (that is, solidification). The process of solidification is the same in all cases, whether it is the freezing of water on a windshield or in a freezer, or the solidification of metal in a casting or in the weld that joins two solids.

The process is controlled by the free energy of the liquid phase, G_l, relative to that of the solid, G_s. This is depicted in Fig. 1, which shows the behavior of a pure (single component) material. Above the freezing temperature, T_f, the liquid phase has the lower free energy and is therefore stable, but below T_f, the solid is the stable phase. At T_f, both phases are in equilibrium, that is, $G_l = G_s$.

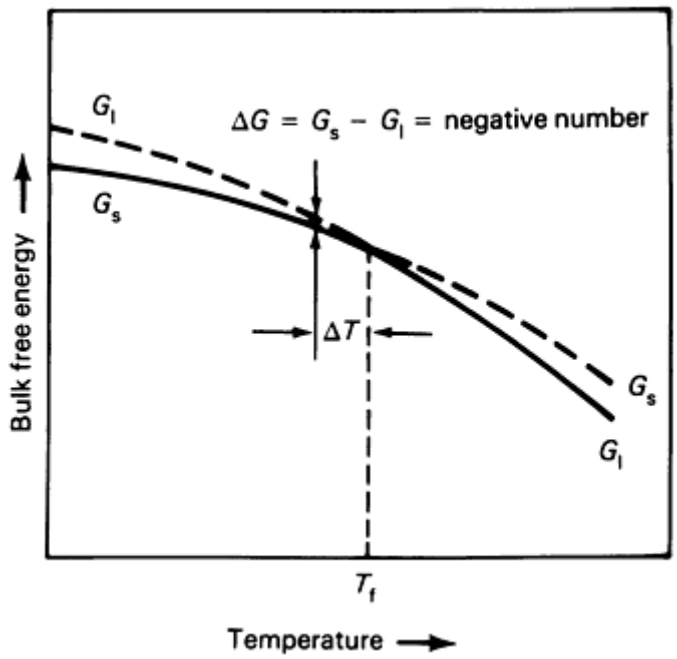

FIG. 1 TEMPERATURE DEPENDENCE OF BULK FREE ENERGY OF THE LIQUID AND SOLID PHASES IN SINGLE-COMPONENT SYSTEM. THE SOLID LINE PORTION AND THE DASHED LINE PORTION OF EACH G_L, AND G_S CURVE INDICATE THE STABLE AND UNSTABLE PHASES, RESPECTIVELY, OF THE FREE ENERGY ON EITHER SIDE OF T_F. SOURCE: REF 1

In the transition from one phase to another, the change in free energy, ΔG, is the difference in free energy of the product and the reactant. This free energy change can be expressed in terms of the enthalpy and the entropy changes, that is, for the transformation of a liquid to a solid during freezing:

$$\Delta G = G_S - G_L = (H_S - H_L) - T(S_S - S_L) = \Delta H - T\Delta S \qquad \textbf{(EQ 1)}$$

At the freezing temperature, T_f, $\Delta G = G_s - G_l = 0$, because the free energy of the two phases is the same, and $\Delta H = T_f \Delta S$, It is necessary to cool below T_f for solidification, because at T_f both the solid and liquid phases are present and in equilibrium. Below T_f, ΔG is not equal to zero (Fig. 1 shows that $G_s < G_l$) and is given by Eq 1 with $T = T'$, where $T' < T_f$.

Because the ΔH and ΔS are not strong functions of temperatures, they can be assumed to be temperature independent. Therefore, at any temperature, $\Delta H = \Delta H_f$ and $\Delta S = \Delta S_f$, where ΔH_f and ΔS_f are the values of the enthalpy and the entropy changes for the equilibrium reactions at T_f (that is, the latent heat of fusion and the entropy change on fusion, respectively). Combining these enthalpy and entropy expressions, the fact that $\Delta H = T_f \Delta S$, and Eq 1, then at T', one obtains:

$$\Delta G = (\Delta H_F / T_F)(T_F - T') \qquad \textbf{(EQ 2)}$$

where ΔH_f, the latent heat of fusion, is negative. Hence, in agreement with Fig. 1, ΔG is negative. The greater the amount of undercooling (supercooling) below T_f ($T_f - T'$), then the greater the thermodynamic driving force for solidification.

However, even when the conditions of Eq 2 are met, the liquid does not spontaneously transform to the solid below T_f. Rather, small amounts of solid nucleate and grow to produce complete solidification. Nucleation creates a new surface, that is, the surface between the solid and the liquid. The energy per unit are of this surface is the surface tension, γ, which is always positive. For solidification to occur, the increase in energy associated with the surface energy must be balanced by a greater decrease in the free energy of the solid relative to that of the liquid. This requires undercooling, as shown by Eq 2.

There are three ways in which a solid can form: homogeneous nucleation, heterogeneous nucleation, and epitaxial growth. Homogeneous nucleation occurs when there is no foreign body (mold wall, solid particle in the melt, etc.) on which to form the solid. Figure 2 shows the balance of the surface tension and the bulk free energy per unit volume, ΔG_v, as a function of the size of the nucleus that forms during homogeneous nucleation. The ΔG_v, value is just ΔG (as given by Eq 2) divided by the molar volume of the solid, V_s.

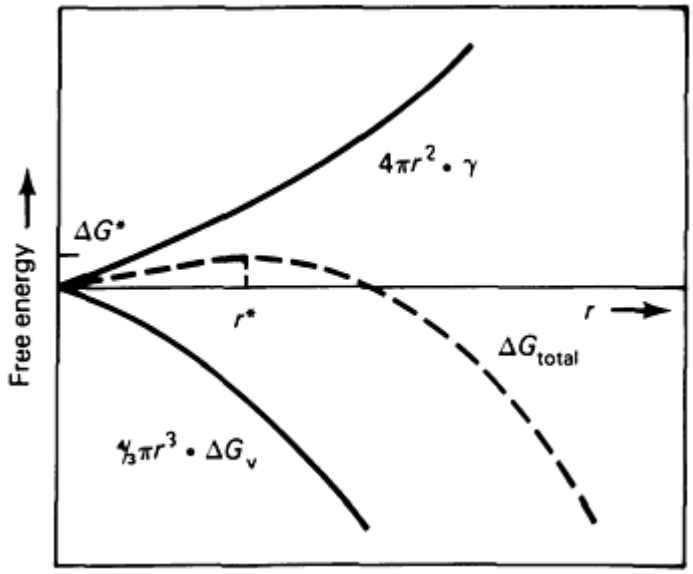

FIG. 2 FREE ENERGY OF FORMATION OF A NUCLEUS AS FUNCTION OF ITS RADIUS. SOURCE: REF 1

For a spherical nucleus of radius greater than r_c, the volume free energy decrease outweighs the increase in energy that is due to the surface energy, and the nucleus is stable. At $r = r^*$, the net energy is a maximum, but if additional atoms are added to the nucleus, then the energy decreases. The value r^* is thus the radius at which the spherical nucleus is just stable, because as additional atoms are added, the energy is decreased. The value r^* is given by:

$$R^* = -2\gamma/\Delta G_V \qquad \textbf{(EQ 3)}$$

which is a positive number, because ΔG_v is negative. Substituting into Eq 2, one gets:

$$R^* = -2\,\gamma T_F V_S/\Delta H_F(T_F - T) \qquad \textbf{(EQ 4)}$$

The r^* is positive because ΔH_f is negative and, for undercooling, $(T_f - T)$ is positive. This equation is a general expression relating the radius of curvature of a surface and the degree of undercooling that is required for solidification of that surface. The greater the degree of undercooling, the smaller the radius of curvature that is stable. This equation will be considered again when nonplanar solidification is discussed.

Nucleation requires a thermal energy either equal to or greater than ΔG^* in order for a spherical nucleus of radius r^* to form. The ΔG^* value is the activation energy, which, as Fig. 2 shows, is a positive quantity. The greater the degree of undercooling, the more negative the free energy, the less positive the ΔG^* value, and the greater the rate of nucleation of the solid. For homogeneous nucleation, ΔG^* is given by:

$$\Delta G^* = (16/3)(\pi\,\gamma^3 T_F^2 V_S^2)/(\Delta H_F^2 \Delta T^2) \qquad \textbf{(EQ 5)}$$

where $\Delta T = T_f - T$.

Heterogeneous nucleation develops when the solid forms on a foreign body. Now, the interaction of the nucleus and the foreign body must be considered. This interaction is defined in terms of the wetting angle between the nucleus and foreign body. The activation energy for heterogeneous nucleation is given by:

$$\Delta G^* = \frac{4p}{3}\frac{g^3 T_f^2 V_s^2}{\Delta H_f^2 \Delta T^2}(2 - 3\cos q + \cos^3 q) \qquad \textbf{(EQ 6)}$$

The angle is 180° if there is no wetting, and Eq 6 reduces to Eq 5, that is, with no wetting, there can only be homogeneous nucleation. With a wetting angle of 90°, ΔG^* is one half the value given by Eq 5. Instead of requiring a spherical nucleus of radius r^*, a hemispherical nucleus of the same radius is necessary, which requires one half the number of atoms and one half the activation energy. This is the sort of nucleation that develops in a casting, where the mold wall acts as the foreign body.

When the wetting angle is zero, Eq 6 shows that the activation energy is zero. This is the case for epitaxial growth on a substrate, where epitaxial derives from the Greek *epi*, upon, and *taxis*, to arrange, that is, to arrange upon. In effect, no new surface is being formed. Atoms are just being added to the substrate, thereby extending it. The important point is that no activation energy nor undercooling is required to add atoms onto an existing substrate. This is the situation that develops when a liquid solidifies on a substrate of the same material or one that is similar in composition and structure, as in the solidification of a weld.

Fundamentals of Weld Solidification

Harvey D. Solomon, General Electric Company

Comparison of Casting and Welding Solidification

A weld can be thought of as a miniature casting. The fundamentals of weld solidification are the same as those of a casting, but with different boundary conditions. These differences and their effects are described below.

First, by its very nature, a sound weld *must* attach to the metals being joined, whereas a casting *must not* adhere to the mold wall. To achieve this, the mold is treated to prevent adherence, whereas the joint to be welded is prepared to promote adherence. The practical result of this preparation is that there is generally excellent heat transfer through a weld joint, but relatively poor heat transfer through the mold, because oxides are often used as mold materials or for mold coatings (the molten metal will not wet the oxide and therefore cannot adhere to it).

Second, heat is continually being added to the weld pool as it travels, whereas no heat is added to a casting after the pour, except for possibly modest heating of the mold. The practical result of this and of the first consideration described above is that the temperature of the casting is relatively uniform. In contrast, a very large temperature gradient develops in a weld. The center of a weld pool reaches a very high temperature (typically, 2000 to 2500 °C, or 3630 to 4530 °F), which is limited by the vaporization of the weld metal. At the sides of the weld pool, where solidification is taking place, the temperature is the solidification temperature, which is typically about 1000 °C (1800 °F) less than the temperature at the center on the weld pool. Thus, a positive temperature gradient is developed in a weld (that is, measured from the fusion line of the weld, the temperature increases going into the molten material). A casting will typically supercool to below the solidification temperature. Solidification will first develop by heterogeneous nucleation at the mold wall. The latent heat and the poor heat transfer through the mold wall will then cause a temperature rise at the mold wall. Thus, a small negative temperature gradient can develop briefly in a casting. The nature of this gradient is important, because it

promotes nonplanar solidification (to be discussed below) in the casting, whereas the positive gradient that develops in a weld helps to limit nonplanar solidification.

Third, solidification is developed at the mold wall of a casting by heterogeneous nucleation, whereas epitaxial growth develops at the weld fusion line. Thus, some supercooling is required for the casting, but only a vanishingly small degree of supercooling is required for the weld. (As was discussed, epitaxial growth requires no supercooling, but some slight degree of undercooling is required to shift the reaction from an equilibrium between the solid and liquid, to all solid.) This undercooling in a weld would typically be *less* than 1 °C (1.8 °F). In contrast, in castings when there is a lack of effective nuclei for hetergeneous nucleation, undercoolings of 100 °C (180 °F) or more are possible. In general, however, the undercooling in castings is typically only on the order of a few degrees centigrade.

Fourth, the generally larger volume of a casting, relative to that of a weld, and the poorer heat transfer makes the cooling rate and the solidification rate much lower for castings than for welds.

Fifth, as a casting solidifies, the volume of the remaining liquid decreases. Thus, the shape of the molten pool is continually changing. In a weld, the weld pool shape is generally kept constant as it travels (if the heat input and section geometry are constant).

Sixth, because of the stirring action of the arc and the action of Marongoni surface tension gradient induced convection forces, there is good mixing of the molten weld pool. In contrast, there is comparatively little mixing of the molten material of a casting.

As discussed in the section "Solidification of Alloy Welds (Constitutional Supercooling)" in this article, all of these factors influence the nature of weld solidification, relative to what is observed in a casting.

Solidification of Alloy Welds (Constitutional Supercooling)

The solidification of an alloy is much more complex than that of a pure metal, whether in a weld pool or in a casting. Figure 3 shows a simple binary isomorphous phase diagram. The temperatures of the liquidus and solidus lines of Fig. 3 can be approximated by straight lines (for a limited temperature range). (The liquidus defines the temperature above which only liquid is present and the solidus the temperature below which only solid is present. The liquidus and solidus lines bound the two-phase liquid plus solid region.) The liquidus line is given by:

$$T_L = T_{MA} + M_L C_L \qquad \textbf{(EQ 7)}$$

where T_{mA} is the melting point of pure A, M_L is the slope of the liquidus, and C_L is the composition of the liquid at T_L. The solidus is described by a similar expression.

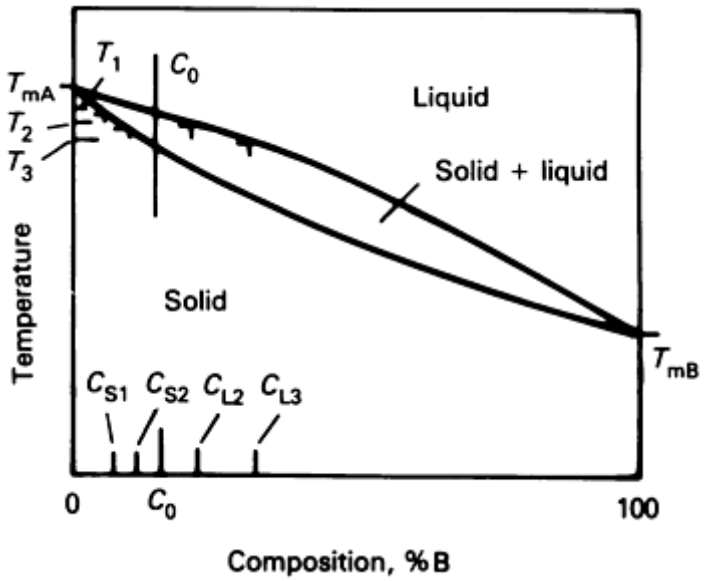

FIG. 3 BINARY ISOMORPHOUS PHASE DIAGRAM SHOWING THE LIQUID AND SOLID COMPOSITIONS AT SELECTED TEMPERATURES

Another important quantity that can be estimated from the phase diagram is the distribution coefficient, *K,* which is defined as:

$$K = C_S/C_L \qquad \textbf{(EQ 8)}$$

where C_S and C_L are the solidus and liquidus compositions, respectively, defined by equilibrium tie lines. Assuming that the solidus and liquidus lines are straight lines means that *K* is not a function of temperature. In general, the liquidus and solidus lines are curved, so that in actuality, *K* is a function of temperature. For simplicity, this curvature will be neglected and, instead, limited temperature ranges where *K* can correctly be assumed to be a constant will be considered. The use of a distribution coefficient defined by equilibrium tie lines implies that equilibrium exists between the liquid and the solid at the solid-liquid interface. This equilibrium need not exist elsewhere. Figure 3 and the following discussion are based on a *K* value of less than 1 and a negative M_L value. The following discussion is also true for diagrams where *K* is greater than 1 and M_L is positive.

The distribution coefficient defines how the solute is distributed or partitioned between the solidifying solid and the remaining liquid. The slope of the liquidus line and the distribution coefficient are important in defining the composition gradient that develops when alloys solidify. In general, the distribution coefficient, *K,* is a function of temperature, but as already noted, to simplify the analysis, it will be assumed that over a limited temperature range, it is a constant.

An equilibrium phase diagram, such as that of Fig. 3, assumes that equilibrium is maintained in all of the solid and liquid and that there are no composition gradients in the solid or liquid. It defines the equilibrium solid and liquid compositions at any temperature. Figure 3 shows that the solidification of an alloy of composition C_0 will begin when the temperature is reduced below T_1. If equilibrium is maintained, then solidification will be complete when the temperature is reduced below T_3. A two-phase mixture of solid plus liquid will be present between T_1 and T_3, with the relative amount of each phase given by the lever rule:

$$\%_{liquid} = \left(\frac{C_0 - C_{s2}}{C_{1.2} - C_{s2}} \right) 100\% \qquad \textbf{(EQ 9)}$$

at T_2. The free energy curves corresponding to this equilibrium are much more complex than those of Fig. 1, which is relevant for a pure material.

The equilibrium predicted by Fig. 3 is never realized in practice, because it would require an infinitely slow cooling rate. When considering castings, it is generally assumed that the equilibrium predicted by the phase diagram is maintained at the solid-liquid interface, but that no composition change occurs in the solid as the temperature is lowered. At T_1, a solid of composition C_{S1} forms. C_{S1} is equal to $C_{L1}K$, and because at the liquidus $C_{L1} = C_0$ the $C_{S1} = C_0K$. When the temperature drops to T_2, the solid that forms has a composition of C_{S2}, and so on. A composition gradient is thus developed in the solid. As the solid forms, solute is rejected into the liquid, and it is assumed that this solute is mixed into the liquid, raising its composition to that predicted by the phase diagram. This occurs even though the mixing action in a casting is relatively poor, because the cooling rate is generally low enough to provide enough time to allow for the required solute redistribution by diffusion in the liquid. As a result, no gradient is developed in the liquid. The composition of the solid at the solid-liquid interface is still given by the equilibrium phase diagram. However, the previously formed solid is deficient in solute. As a consequence, complete solidification does not occur at T_3. Further cooling is required, with solidification being completed only when the *average* solid composition is C_0.

The boundary conditions for a weld are somewhat different from those of a casting. The composition gradient that develops in the solid is assumed to be the same as that which forms in a casting, but the behavior of the liquid is assumed to be different. The mixing of the melt is greater than that developed in a casting, but the cooling rate is much higher. Thus, the solute that is rejected as the solid forms is not completely mixed into the liquid. Rather, the bulk liquid remains at the initial composition, C_0, with a solute gradient formed in the liquid near the solid-liquid interface. At the liquids, T_1, the solid that forms has a composition of $C_{S1} = C_0K$. At T_2, the solid composition is C_{S2}. As with castings, it is assumed that the solid-liquid equilibrium predicted by the equilibrium phase diagram is maintained at the solid-liquid interface. Therefore, the liquid in equilibrium with this solid is $C_{L2} = C_{S2}/K$. However, the lack of complete mixing means that the bulk liquid remains at C_0, and that a composition gradient forms directly ahead of the solid-liquid interface. This composition gradient is illustrated in Fig. 4, which shows the composition gradient developed by unidirectional solidification and the temperature gradient driving this solidification. The solidification is modeled by assuming that a bar is being unidirectionally solidified, but this approach is applicable to solidification in general.

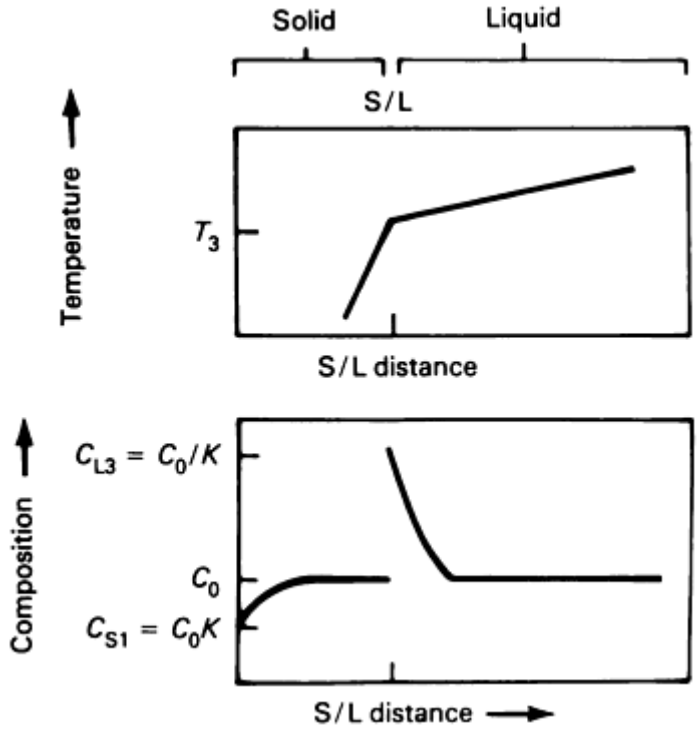

FIG. 4 INITIAL STAGE OF DIRECTIONAL SOLIDIFICATION OF A BAR, SHOWING THE TEMPERATURE PROFILE DRIVING THE SOLIDIFICATION AND THE COMPOSITION PROFILE ESTABLISHED FOR AN ALLOY WITH A SOLUTE CONTENT OF C_0. SOURCE: REF 4

At temperature T_3, the solid that forms has a composition of C_0. The solid that is forming now has the same composition as the bulk liquid. Thus, an equilibrium situation exists. Solidification can now continue *without* having to further reduce the temperature. For castings, however, the composition gradient in the solid and complete mixing of the solute into the

liquid leaves the liquid still present at T_3, thereby reducing the liquidus temperature. This means that, in a casting, the temperature must be lowered even more before further solidification can take place.

Figure 4 shows the situation *during* weld solidification, whereas Fig. 5 shows the composition when solidification is complete. For most of the solidification, the solid forms at C_0. The exceptions are at the start and at the end of solidification. The first solid that forms does so with a solute composition of C_{S1}, which the phase diagram shows is less than C_0. A composition gradient develops until temperature is lowered to T_3, when the solid composition reaches C_0 and an equilibrium is reached between the solid being formed and the composition of the bulk liquid. At the end of solidification, there is an increase in the solute content. This occurs to accommodate the solute buildup at the solid-liquid interface. At the end of the solidification, there is no longer any *bulk* liquid at C_0. The solute that is ahead of the solid-liquid interface raises the composition of the remaining liquid as it is rejected into this final small volume of liquid. This obviates the assumed boundary condition (a lack of mixing of the solute into the bulk liquid), and the situation becomes more like that of a casting (complete mixing in this small liquid volume). The final liquid composition of this final transient is the terminal composition predicted by the phase diagram, that is, the final liquid is driven to the composition of the lowest melting point. In the case of the simple binary isomorphous diagram used for this example, this is pure B. For a simple binary eutectic, it would be the eutectic composition.

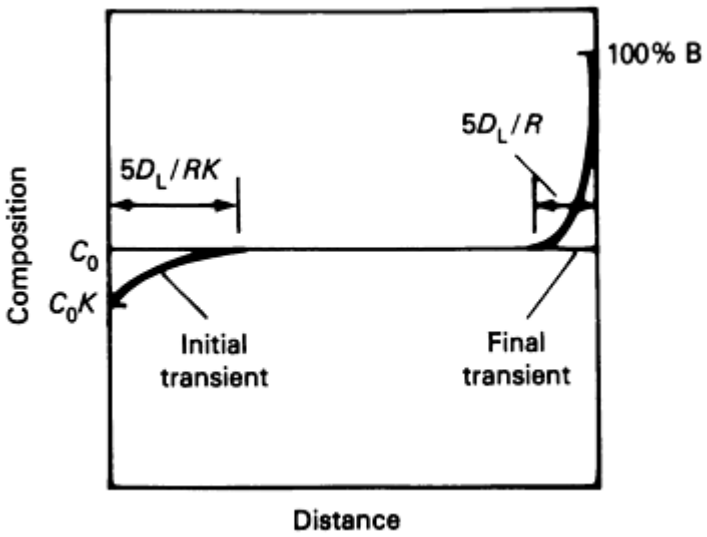

FIG. 5 FINAL COMPOSITION PROFILES FOR THE UNIDIRECTIONAL SOLIDIFIED BAR SHOWN IN FIG. 4. THE INITIAL AND FINAL TRANSIENT ARE SHOWN FOR $K < 1$. R, RATE OF SOLIDIFICATION; D_L, DIFFUSION RATE OF THE SOLUTE IN THE LIQUID. SOURCE: REF 4

The profile of the liquid composition gradient that is ahead of the solid-liquid interface is given by:

$$C_L = C_A e^{-[RX_L / D_L]} + C_0 \qquad \textbf{(EQ 10)}$$

where R is the rate of solidification. D_L, is the diffusion rate of the solute in the liquid, C_a is the increase in the composition of the liquid at the solid-liquid interface (relative to C_0), and X_L is the distance into the liquid that is ahead of the solid-liquid interface. The liquid at the solid-liquid interface has a composition of C_{L3}, which is in equilibrium with $C_{S3} = C_0$. Therefore, $C_{L3} = C_0/K$. The enrichment of the solute in the liquid, C_a, is thus $(C_0/K) - C_0$ or $C_0(1 - K)/K$. The distribution coefficient, K, is thus an important variable in determining the composition profile in the liquid and, as will be shown, in determining the nature of the solidified microstructure.

Substituting Eq 10 into Eq 7, one gets the expression describing the temperature variation of the liquidus that is ahead of the solid-liquid interface, namely:

$$T_L = T_{MA} + M_L C_A e^{-[RX_L / D_L]} + M_L C_0 \qquad \textbf{(EQ 11)}$$

Figure 6 illustrates this liquidus profile, along with three possible temperature gradients that could actually exist in the liquid. They are all positive, reflecting the positive gradient that develops in a weld. Gradient A is greater than the slope of the liquidus at the solid-liquid interface, but those of B and C are not. The slope of the liquidus can be found by differentiating Eq 11 at $X_L = 0$, that is, at the solid-liquid interface. For the temperature gradient to be less than this slope, the gradient G must be:

$$G < M_L R C_0 (K - 1)/D_L K \qquad \textbf{(EQ 12)}$$

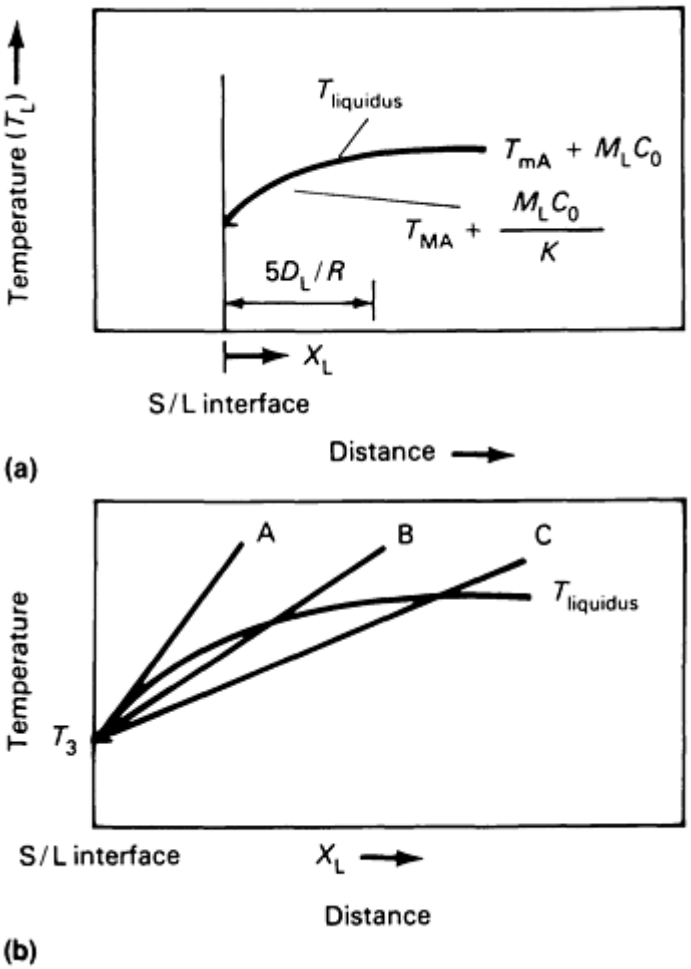

FIG. 6 LIQUIDUS PROFILE OF A SOLID-LIQUID INTERFACE. (A) LIQUIDUS PROFILE FOR STEADY-STATE CONSTITUTIONAL SUPERCOOLING. (B) THREE LIQUIDUS TEMPERATURE GRADIENTS (CURVES A, B, AND C) COMPARED TO THE LIQUIDUS PROFILE. SOURCE: REF 6

Equation 12 is important because it describes the temperature gradient required for constitutional supercooling (Ref 3, 4, 5). The establishment of the composition gradient in the liquid that is ahead of the solid-liquid interface produces a variation in the temperature of the liquidus. For curves B and C, this has allowed the actual temperature to be below the liquidus (that is, supercooling has developed, even though the temperature of the bulk liquid is above the bulk liquidus temperature). This is constitutional supercooling, and as will be shown, this promotes nonplanar solidification, even though there is a positive temperature gradient. The liquidus profile shown in Fig. 6 is correlated with the propensity for hot cracking. The greater the temperature difference between that of the solid-liquid interface and that of the bulk liquid, the greater the tendency for hot cracking. This is discussed in more detail in the article "Cracking Phenomena Associated with Welding" in this Volume.

The constitutional supercooling model for describing weld solidification is presented because it qualitatively describes the evolution of different microstructures (described in the section "Development of Weld Microstructures" in this article). Many newer nonequilibrium approaches to solidification give better quantitative results. These approaches will be

discussed in the section "Nonequilibrium Effects: High-Rate Weld Solidification and Composition Banding" in this article.

Development of Weld Microstructures

Nonplanar solidification develops when a protrusion moves ahead of the rest of the solid-liquid interface and continues to grow in a stable manner. This increases the surface area. The stable radius is given by Eq 4, which shows that the protrusion must move into a supercooled region in order to be stable. This is possible in a casting, because a negative temperature gradient is developed (that is, the temperature decreases from the solid-liquid interface into the liquid). In a pure material (single-component system), the positive temperature gradient that is established in the liquid of a weld prevents this nonplanar growth. In an alloy, however, constitutional supercooling allows nonplanar solidification in a weld, even with a positive temperature gradient.

The lower the gradient, *G*, (compare curve C with curve B in Fig. 6), the greater the degree of constitutional supercooling. This is illustrated in Fig. 7, which shows several temperature gradients (Fig. 7f) compared to the variation in the liquidus and the nature of the solid-liquid interface (Ref 5, 6, 7). For a curve a, the temperature gradient is steeper than the liquidus temperature curve and only planar solidification is possible. For curve b, there is a shallower gradient and the solid-liquid interface can move by cellular growth. The gradient is successively lower for c and d, which allows larger protrusions and the development of cellular dendritic and columnar dendritic growth. At curve e, the gradient is so shallow and the resulting liquidus temperature is so far above the actual temperature in the liquid that equiaxed dendrites can form ahead of the solid-liquid interface.

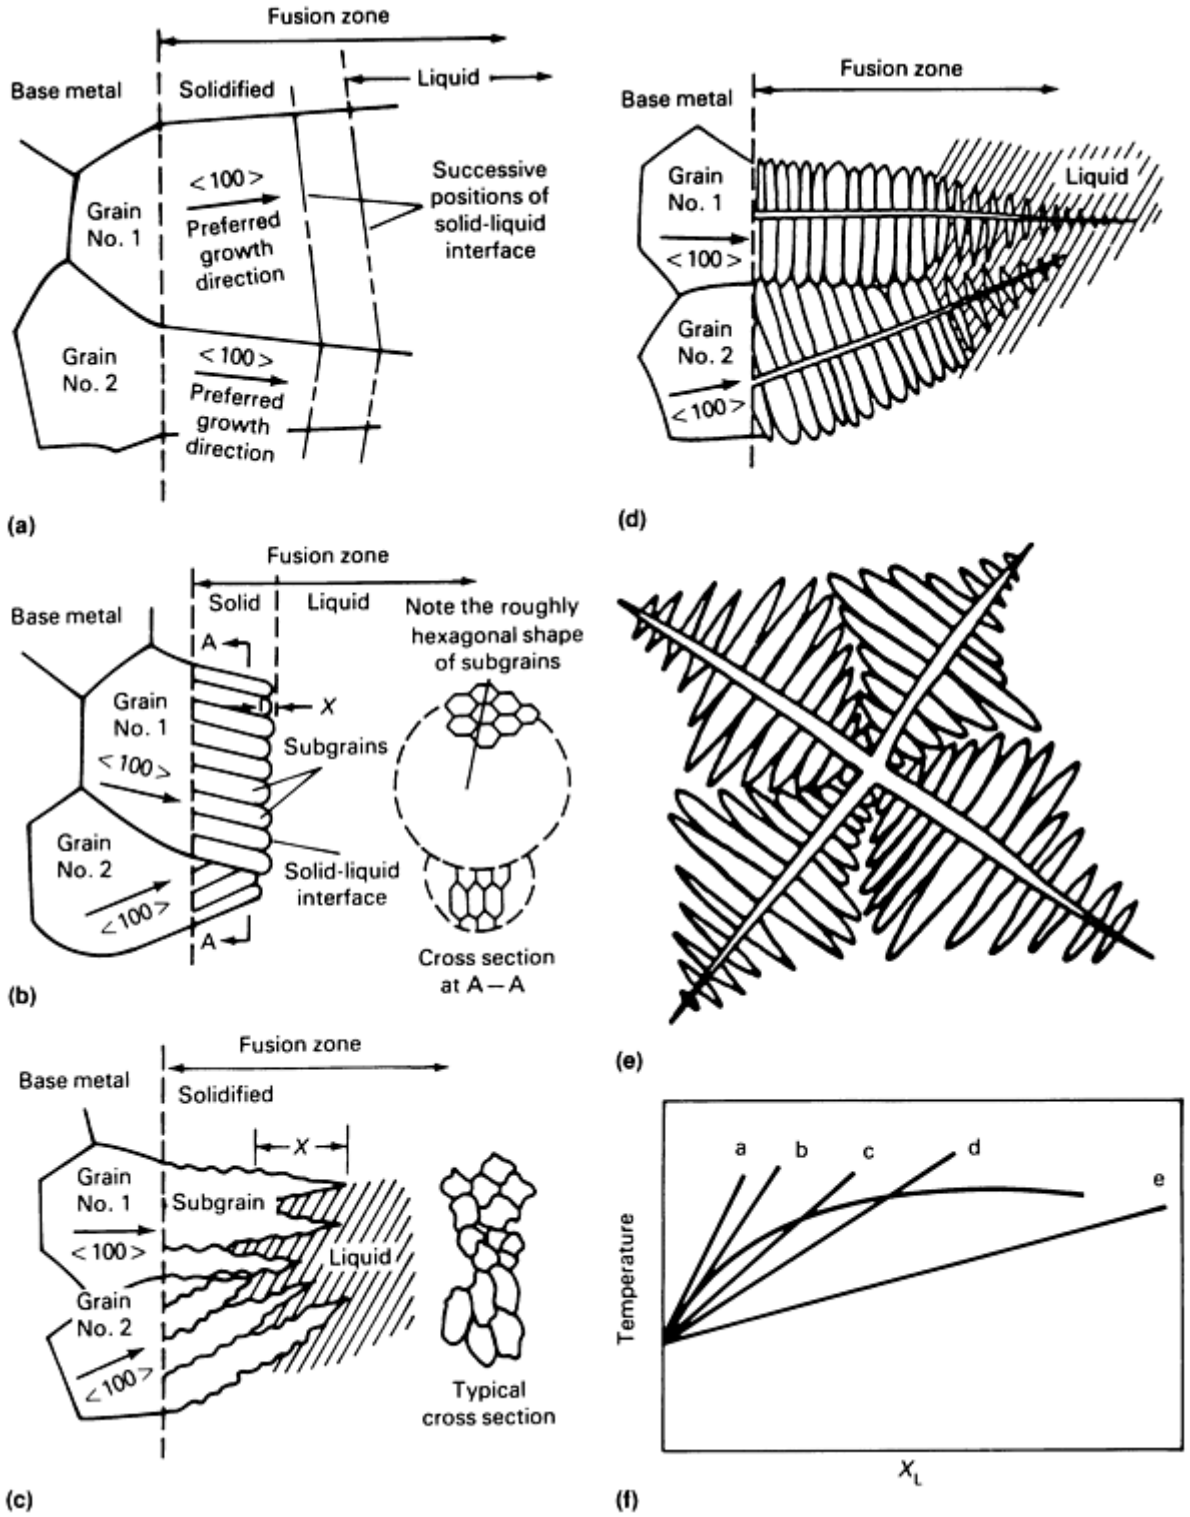

FIG. 7 SCHEMATICS SHOWING MICROSTRUCTURE OF SOLID-LIQUID INTERFACE FOR DIFFERENT MODES OF SOLIDIFICATION AND THE TEMPERATURE GRADIENTS THAT GENERATE EACH OF DIFFERENT MODES. (A) PLANAR GROWTH. Figure 8, which is based on experimental observations, relates the gradient, solidification rate, and composition to the type of structure developed (Ref 5, 6, 7). The basis for this figure lies in Eq 12. If R is moved to the left side of Eq 12, then the right side contains only material variables. For a given alloy system (where D_L, M_L, and K are fixed), the greater the C_0, the greater the tendency for constitutional super-cooling and nonplanar solidification. Equation 12 predicts that the

smaller the G/R, the more nonplanar the solidification. Figure 8 shows that, experimentally, the correlation is with $G/\sqrt{R}$, rather than G/R.

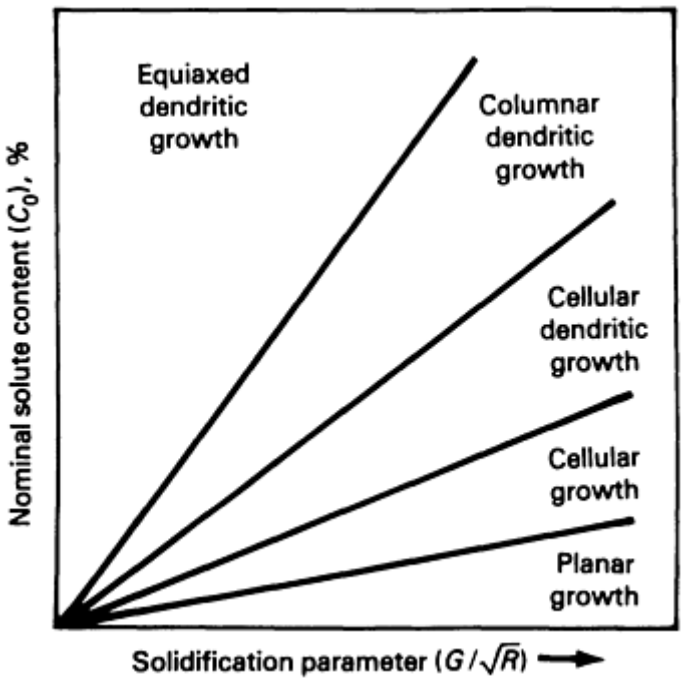

FIG. 8 PLOT OF SOLUTE CONTENT VERSUS SOLIDIFICATION PARAMETER TO SHOW THE NATURE OF SOLIDIFICATION. SOURCE: REF 6

As the dendrite, or columnar grain, grows into the liquid, it should follow the behavior shown in Fig. 5. (As will be discussed in the section "Nonequilibrium Effects: High-Rate Weld Solidification and Composition Banding" in this article, the experimentally determined compositions do not always exactly agree with that predicted by Fig. 5.) The center of each cell or dendrite behaves like the initial transient, that is, the solute content is low. The regions between the cells or dendrites behave like the final transients, that is, they are enriched in solute. This is illustrated schematically in Fig. 9. Cellular growth occurs for a smaller C_0 and/or for a larger $G/\sqrt{R}$ than that for dendritic growth (see Fig. 8).

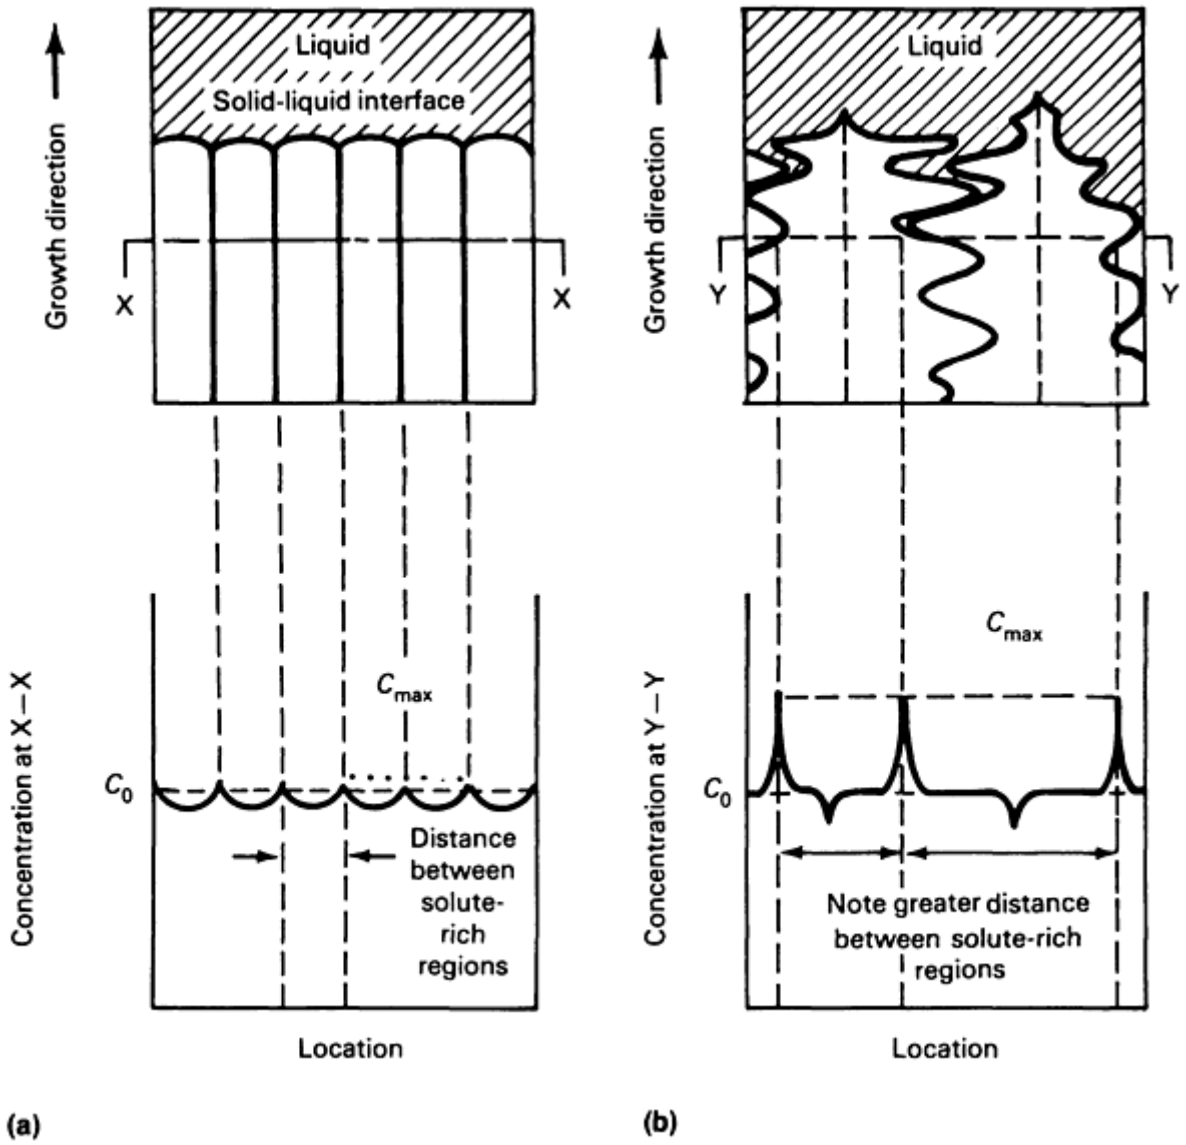

FIG. 9 SCHEMATIC SHOWING SOLUTE DISTRIBUTION AT THE DENDRITE OR CELL CORE AND IN THE INTERCELLULAR OR INTERDENDRITIC REGIONS. (A) CELLULAR GROWTH. (B) DENDRITIC GROWTH. SOURCE: REF 8

The constitutional cooling described by Fig. 4, 5, 6, 7, 8, and 9 occurs on a very fine scale. Solving Eq 10 shows that the solute composition that is ahead of the solid-liquid interface will decrease to almost C_0 when $X_L = 5D_L/R$. For a typical liquid diffusion rate of 5×10^{-5} cm^2/s (5×10^{-8} ft^2/s) and a solidification rate of 5 mm/s (0.2 in./s), the liquid composition drops to C_0 within about 5 μm (200 μin.). In the initial transient, the distance over which the solid composition increases to C_0 is given by $5D_L/RK$. Thus, for $K < 1$, this distance is greater than the region in the liquid just ahead of the solid-liquid interface. This is illustrated in Fig. 5. This difference is also important in defining the extent of the final transient, which is of the order of the length of the zone in the liquid where the composition drops to C_0. The length of the initial transient is thus $1/K$ larger than that of the final transient. The length of the solute-poor cell or dendrite core is thus $1/K$ larger than that of the solute-rich intercellular or interdendritic regions.

The solute-rich region between the cells or dendrites has a lower freezing temperature than that of the cellular or dendritic core. Thus, it is possible to have liquid films between impinging cells or dendrites. These films cannot support the thermally induced shrinkage stress that develops during solidification, and hot cracking can develop (see the article "Cracking Phenomena Associated with Welding" in this Volume). The hot cracking produced by nonplanar solidification can be minimized by reducing C_0 (that is, by using purer materials) and/or by increasing $G/\sqrt{R}$ (see Fig. 8).

The temperature gradient in the liquid, G, is *inversely* proportional to the heat input, Q, which is given by:

$$Q = FEI/V \qquad \textbf{(EQ 13)}$$

where f is the efficiency of the welding process, E is the arc voltage, I is the arc current, and V is the welding torch velocity. Thus, G can be increased by decreasing either the arc voltage or arc current, or by increasing the torch velocity. The influence of the velocity is counterbalanced by the fact that the solidification rate, R, is proportional to V (see the section "Effect of Welding Rate on Weld Pool Shape and Microstructure" in this article). Thus, increasing V increases R, which tends to increase the degree of constitutional supercooling.

Effect of Welding Rate on Weld Pool Shape and Microstructure

The velocity of the welding torch affects not only the rate of solidification, but the shape of the weld pool and the propensity to develop centerline hot cracks. The shape of the weld pool is dictated by the velocity, V, at which the welding torch moves and by the rate at which heat can be removed at the solid-liquid interface. To keep a constant shape, the rate of new melting must be exactly balanced by the solidification rate. On the average, this solidification occurs normal to the solid-liquid interface, because this is the direction of the maximum temperature gradient and, thus, the direction of the maximum heat removal. Simple geometry requires that for the weld pool shape to remain constant, the solidification rate, R, must be related to the torch velocity by:

$$R = V \cos f \qquad \textbf{(EQ 14)}$$

where f is the angle between the normal to the solid-liquid interface and the direction of motion of the torch (Fig. 10). At the back of the weld pool, where $f = 0$, $R = V$. If this were not so, then the weld pool would be elongating or shortening. At the side of the weld pool, where $f = 90°$, $R = 0$. If this were not the case, then the weld pool would be decreasing in diameter. With a constant weld pool shape, solidification at the side of the weld pool occurs as the region adjacent to where $f = 90°$ sweeps by, rather than by the motion normal to the weld pool velocity.

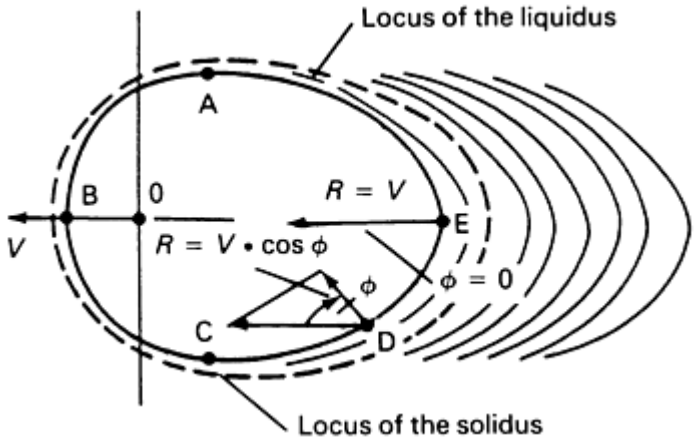

FIG. 10 SCHEMATIC OF A MOVING WELD POOL SHOWING THE RELATIONSHIP BETWEEN VELOCITY OF TRAVEL OF WELDING TORCH, *V*, AND THE RATE OF SOLIDIFICATION, *R*, AT SELECTED POINTS ALONG WELD POOL BOUNDARY. SOURCE: REF 9

Equation 14 predicts that *R* will vary around the weld pool. Figure 8 shows that as *R* varies, so does the microstructure. The result of these two effects is a variation of the microstructure around the weld pool (Ref 7). Planar solidification is to be expected at the sides of the weld pool, with the extent of the nonplanar solidification increasing towards the center of the weld pool. This is shown schematically in Fig. 11.

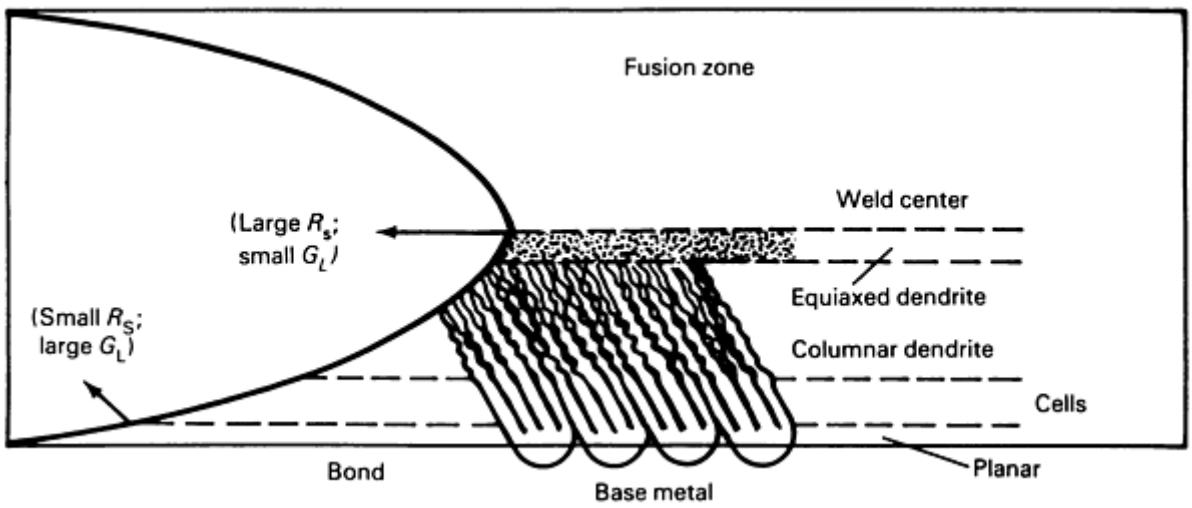

FIG. 11 SCHEMATIC SHOWING VARIATION OF MICROSTRUCTURES IN RESPONSE TO VARIATION OF THE SOLIDIFICATION RATE AROUND THE WELD POOL. SOURCE: REF 7

The coarseness of the nonplanar structure is also a function of *R.* The dendrite tip radius varies inversely with the square root of *R.* Not only does the dendrite tip radius become smaller as *R* increases, the dendrite arm spacing does also, although the exact form of the dependency is more complex. The same general inverse dependency with *R* is also true for the cell spacing when the solidification is cellular.

The ability of the solid-liquid interface to move at a velocity, *V*, depends on two factors: the maximum solidification rate, which is a function of the crystallographic orientation of the solid at the point in question, and the ability of the temperature gradient in the solid to remove the heat and establish the appropriate temperature for solidification to proceed. Consider first the influence of the orientation of the solid grain at the solid-liquid interface. For body-centered

cubic (bcc) and face-centered cubic (fcc) metals, the preferred growth direction for epitaxial solidification is the <100> direction. For hexagonal close-packed (hcp) metals, the preferred growth direction is <10**1**0>.

The planar growth of grains oriented with this direction normal to the solid-liquid interface is favored. This is illustrated in Fig. 12. Grains with the preferred orientation will grow at the expense of adjacent grains that are less favorably oriented (Ref 8, 9, 10, 11, 12). Because dendrites follow the same preferred growth directions, those with the proper orientation will be favored. The requirement for a constant weld pool size becomes somewhat more complex when the effect of crystallographic orientation is considered (Fig. 12). Equation 14 can be modified to become:

$$R' = V \cos f / \cos (f' - f) \qquad \textbf{(EQ 15)}$$

where R' is the growth rate in the preferred direction required to maintain a constant weld pool shape and f' is the angle between R' and V, and $(f' - f)$ is the angle between the local preferred growth direction and R, which is normal to the solid-liquid interface.

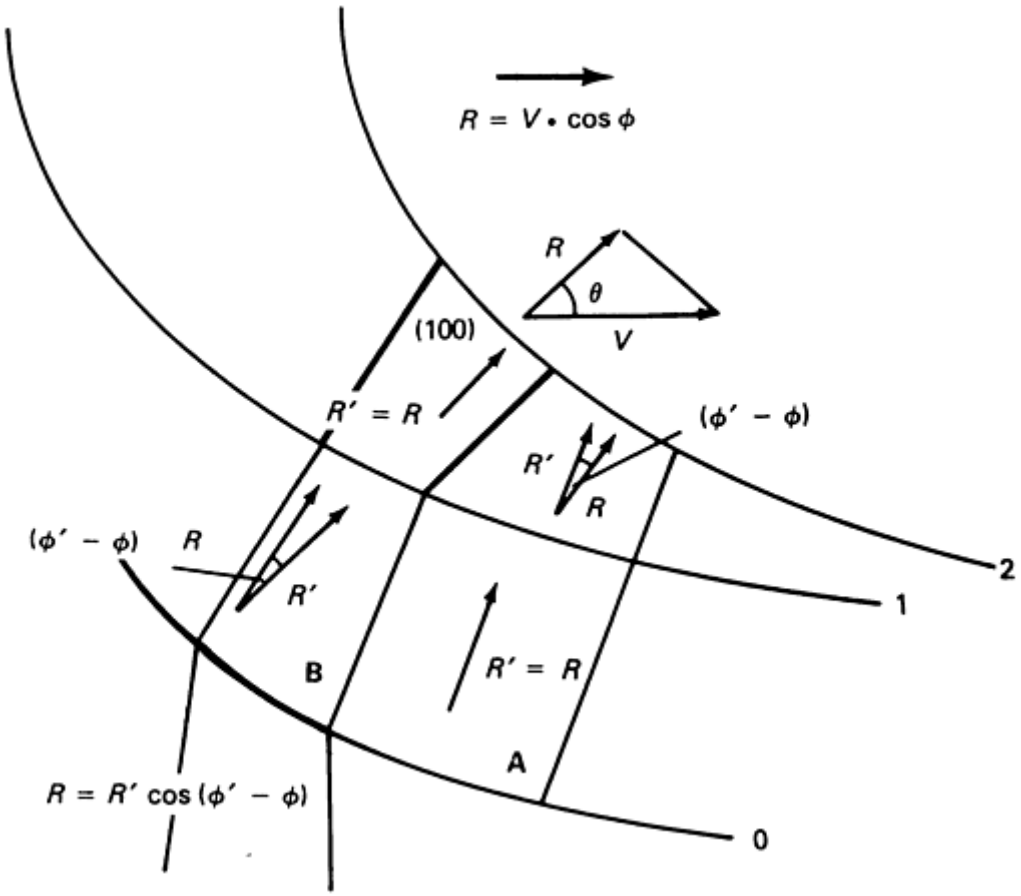

FIG. 12 SCHEMATIC SHOWING MOVEMENT OF A CURVED SOLID-LIQUID INTERFACE FOR SEVERAL GRAINS (A AND B), AND THE CHANGE IN THE RAPID GROWTH DIRECTION RELATIVE TO THE INTERFACE POSITION.

Figure 12 shows the situation at successive positions of the weld pool as it moves in the direction of V. The situation for the weld moving from position 1 to position 2 is shown. The weld pool is assumed to be elliptical in shape, so that at any point (except at the very back of the weld pool where $f = 0$) as the pool moves, the angle between R (or R') and V changes. If an adjacent grain becomes oriented such that R' becomes normal to the solid-liquid interface [that is, so that $(f' - f)$ is equal to zero], it will become most favored and will grow at the expense of adjacent grains. In Fig. 12, between positions 0 and 1, grain A is more favorably oriented than grain B. The reverse is true between positions 1 and 2. Figure 12 uses only a few widely spaced positions, but in reality there is a continuum of such positions.

Competitive growth causes grains to try to rotate into the direction of *V*. Figure 13(a) shows how the grains rotate in an elliptical weld pool. Dendrites will also try to rotate into the *R* direction, although the grains or dendrites do not actually rotate. Rather, the growth shifts to the most favored <100> (or <1010>) direction of the six present in the fcc, bcc, or hcp lattices. As grains are edged out by more favorably oriented grains, they get smaller and eventually can disappear. The solute that they were rejecting is spread out as this competitive process favors and disfavors different grains. Those grains or dendrites that eventually grow into the *V* direction will reject their solute into the weld pool, which gradually becomes solute enriched, contributing to possible crater cracking when the weld terminates. To combat this, the weld power should be gradually decreased in order to maintain a steep temperature gradient (minimizing the degree of constitutional supercooling). The use of a runoff weld tab could also be considered.

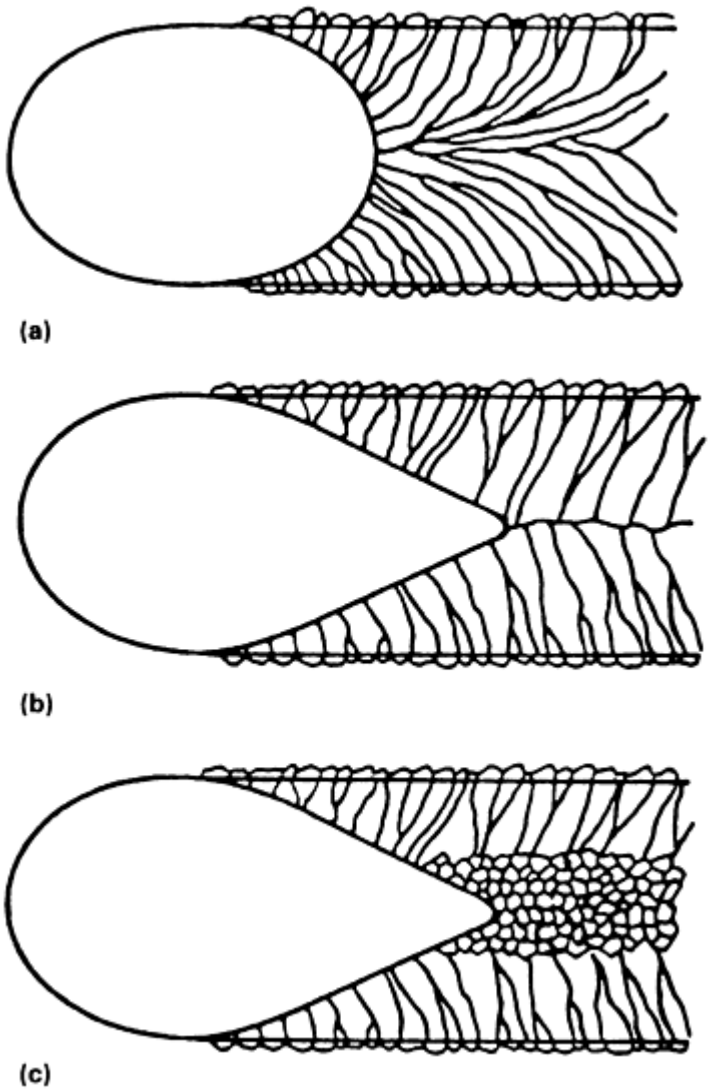

FIG. 13 SCHEMATIC SHOWING EFFECT OF HEAT INPUT AND WELDING SPEED VARIATIONS ON WELD GRAIN STRUCTURE. (A) LOW HEAT INPUT AND LOW WELDING SPEED, PRODUCING AN ELLIPTICAL WELD POOL. (B) HIGH HEAT INPUT AND HIGH WELDING SPEED, PRODUCING A TEAR-DROP-SHAPED WELD POOL. HERE, THE HEAT INPUT AND WELDING SPEED ARE NOT YET SUFFICIENT TO CAUSE HETEROGENEOUS NUCLEATION AT THE WELD POOL CENTERLINE. (C) HIGH HEAT INPUT AND HIGH WELDING SPEED, WITH HETEROGENEOUS NUCLEATION AT THE WELD POOL CENTERLINE. SOURCE: REF 13

The second factor to consider is the ability to extract heat at the solid-liquid interface. Heat is extracted by the temperature gradient of the solid. This gradient is a minimum at the back of the weld pool, where the temperature of the solid is the highest. Unfortunately, this is exactly where the solidification rate must be a maximum to keep up with *V*. The temperature gradient is a maximum at the side of the weld pool, where the least heat extraction is required, because here $R = 0$. As long as the maximum possible solidification rate, R_{max}, is equal to or greate than *V*, the weld pool can maintain an elliptical shape. If *V* is increased above R_{max}, then the solidification rate at the back of the weld pool cannot keep up, and

the weld pool elongates. Increasing V decreases the heat input, which shrinks the weld pool volume. With the weld elongating, this means that the diameter must decrease as the pool elongates. This causes the weld to take on a tear-drop shape, as shown in Fig. 13(b). The angle at the back of the weld pool will decrease until f_{critical} is reached. f_{critical} is given by:

$$f_{\text{CRITICAL}} = \text{COS}^{-1}\,(R_{\text{MAX}}/V) \qquad \textbf{(EQ 16)}$$

R_{max} is controlled by the thermal conductivity of the solid, the geometry of the part being welded (primarily the thickness), and the preferred direction growth rate.

When there is a shift to a tear-drop weld pool, the grain (or dendrite) rotation is limited to f_{critical}. When this situation is attained (Fig. 13b), the grains (or dendrites) will all grow together at the center of the weld pool. The solute that is being rejected into the terminal transient will build up at the centerline, which can lead to centerline cracking. This cracking is caused by the lower solidification temperature of this solute-rick centerline region. As the surrounding material solidifies, stresses are developed that cannot be supported by the liquid centerline material, causing centerline cracking. The obvious remedy is to reduce the welding rate, although this has a production rate penalty.

Figure 13(b) typifies what is to be expected from a pure material or one with a low solute content. In the case of alloys or in cases when the solute content is high, Fig. 8 predicts that when R is increased, not only does the weld pool become tear-drop shaped, but the nature of the structure changes, as shown in Fig. 11. If R is large enough, equiaxed grains can develop from heterogenous nucleation in the supercooled centerline material (Fig. 13c). Such behavior has indeed been observed in aluminum alloys (Ref 13, 14, 15). Figure 14 shows actual weld microstructures corresponding to the schematic structures of Fig. 13.

Nonequilibrium Effects: High-Rate Weld Solidification and Composition Banding

As has been noted, while the constitutional supercooling model (described in previous sections of this article) gives valuable insights into the establishment of nonplanar structures, it does not necessarily give an exact depiction of the composition gradient develop within the dendrites or cells that may form and within the interdendritic or intercellular regions. This has been shown by Brooks and Baskes (Ref 16) in their study of gas-tungsten arc and electron-beam aluminum-copper and iron-niobium welds. For the aluminum-copper welds, the cell core compositions were about 2 to 3 times the KC_0 value expected for the first material to solidify (see Fig. 5) and almost 4 times KC_0 for the iron-niobium welds. This discrepancy was ascribed to the undercooling because of the curvature at the cell tip (see Eq 4), which is not considered in the constitutional supercooling model. Tip undercooling decreases the temperature at which the solidification occurs and, as Fig. 3 shows, increases the composition of the solid that is forming.

No initial transient of the sort shown in Fig. 5 was observed. This was explained by using the lower solidification rate at the side of a cell, rather than that at the dendrite tip in the calculation of the size of the initial transient. This increases the length of the transient (which is inversely proportional to the solidification rate, R) and eliminates the sharp composition variation of the initial transient shown in Fig. 5. Brooks and Baskes also incorporated postsolidification solid-state diffusion of solute (following the approach of Brody and Flemings, which is given in Ref 17) to explain the composition gradients that they measured. Such diffusion is also not considered in the conventional constitutional supercooling model.

In addition, the classical theory of constitutional supercooling, as described by Eq 10, 11, and 12, does not take into account the temperature gradient that develops in the solid, the thermal conductivity of the solid and the liquid, and, most importantly, the surface tension of the solid-liquid interface. These factors are considered in interface stability models (Ref 18, 19, 20, 21, 22, 23, 24, 25, 26), which describe the breakdown of a planar solid-liquid interface in terms of the stability of nonplanar perturbations. The importance of these models is that they explain the observed transition from nonplanar solidification *back* to planar solidification when the solidification rate is increased to very high levels.

As has already been shown, at low solidification rates there can be a transition from planar to nonplanar solidification, as described by constitutional supercooling (as shown in Fig. 8). As the solidification rate is increased, the radius of curvature and spacing of the dendrite arms will decrease, as does the cell spacing. What eventually occurs, at very high solidification rates, is that the very small radius that is required is not supportable, because of the increased surface energy. The stability models predict that there will be a solidification rate (the limiting stability rate) beyond which there will be a transition *back* to planar solidification. Figure 15 shows the calculated dendrite tip radius as a function of velocity of the solid-liquid interface. The increase in R at high rates defines the limiting stability rate.

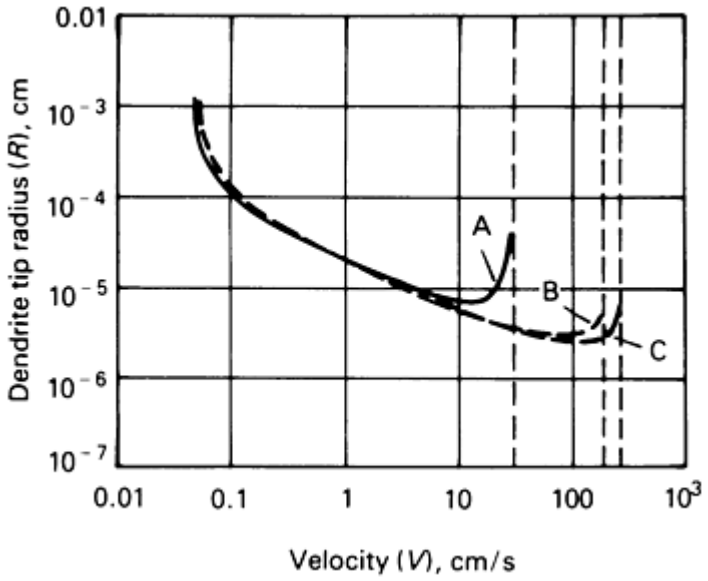

FIG. 15 PLOT OF DENDRITE TIP RADIUS, *R*, VERSUS VELOCITY, *V*, OF THE SOLID-LIQUID INTERFACE FOR AN AG-5% CU COMPOSITION WITH TEMPERATURE GRADIENT, *G*, OF 10^5 K/CM (5×10^5 °F/IN). CURVE A HAS $D_L(T)$ AND $K(V)$ WITH K_E AND M_L AS CONSTANTS; CURVE B, D_L (T) WITH K_E AND M_L AS CONSTANTS; CURVE C, WITH D_L, K_E, AND M_L AS CONSTANTS. THE VELOCITY WHERE THE TIP RADIUS INCREASES IS THE STABILITY LIMIT. THE CALCULATIONS ARE MADE USING THE CONVENTIONAL STABILITY LIMIT APPROACH, WITH THE ADDITION OF A TEMPERATURE-DEPENDENT DIFFUSION COEFFICIENT, AND WITH THE ADDITION OF BOTH A TEMPERATURE-DEPENDENT DIFFUSION COEFFICIENT AND A VELOCITY-DEPENDENT PARTITION COEFFICIENT. SOURCE: REF 21

Each of the three curves in Fig. 15 illustrates different assumptions. The right-most curve shows the result using the approach of Mullins and Sekerka (Ref 18), who developed the original interface stability model. Here, the solute diffusion rate in the liquid, D_L, the equilibrium distribution coefficient, K, and the liquidus slope, M_L, are all assumed to be constants. The middle curve takes into account the fact that the diffusion coefficient is temperature dependent. (Increasing the degree of undercooling that is due to rapid solidification decreases both the solute diffusion rate and the limiting velocity.) The left-most curve not only considers the temperature dependence of the diffusion coefficient, but also takes into account a dependency of the distribution coefficient on the solidification rate.

The preceding discussions have utilized the distribution coefficient, K, determined from equilibrium phase diagrams. At high solidification rates, this equilibrium is not achieved at the solid-liquid interface. Rather, K is a function of the solidification rate. One of several different expressions for the variation of K with V is given by (Ref 23):

$$K = [K_E + (V A_0/D_L)] / [1 + (VA_0/D_L)] \qquad \textbf{(EQ 17)}$$

where K_e is the equilibrium distribution coefficient (K in Eq 8 and 12), and a_0 is a distance that is related to the interatomic spacing. Different models use different definitions for a_0 and different functional relationships, but give similar results. When $V > D/a_0$, K will approach 1. For $D = 5 \times 10^{-5}$ cm^2/s, or 5×10^{-8} ft^2/s (a typical value for liquid diffusion), and $a_0 = 5 \times 10^{-8}$ cm, or 2.0×10^{-8} in., K will approach 1 for $V > 10^3$ cm/s, or 4×10^2 in./s. With $K = 1$, there is no partition of the solute, no constitutional supercooling, and the solidification will be planar for a positive temperature gradient. Figure 15 shows that the limiting velocity, as predicted by the stability model, is quite a bit lower than 10^3 cm/s (4×10^2 in./s). Thus, the reestablishment of planar solidification is not just the result of K approaching unity. Rather, it is due to the lack of the stability of nonplanar protrusions, which is influenced by this change in K. This development of planar solidification is important because it can arise in electron-beam and laser welds, and because the development of planar solidification lessens the tendency for hot cracking.

Figure 15 shows the results of calculations, whereas Fig. 16 shows the results of actual observations made on silver-copper electron-beam scans (passes of the electron beam). These results are in general agreement with the predictions of Fig. 15. Figure 16 shows the compositional dependence of the transition to segregation-free planar solidification. It is

analogous to Fig. 8, which describes the transition from planar to nonplanar solidification that occurs at lower solidification rates. Figure 16 also shows that just below the limiting solidification rate, a banded structure can develop. This banding develops at a constant solidification rate and is due to instabilities at the solid-liquid interface.

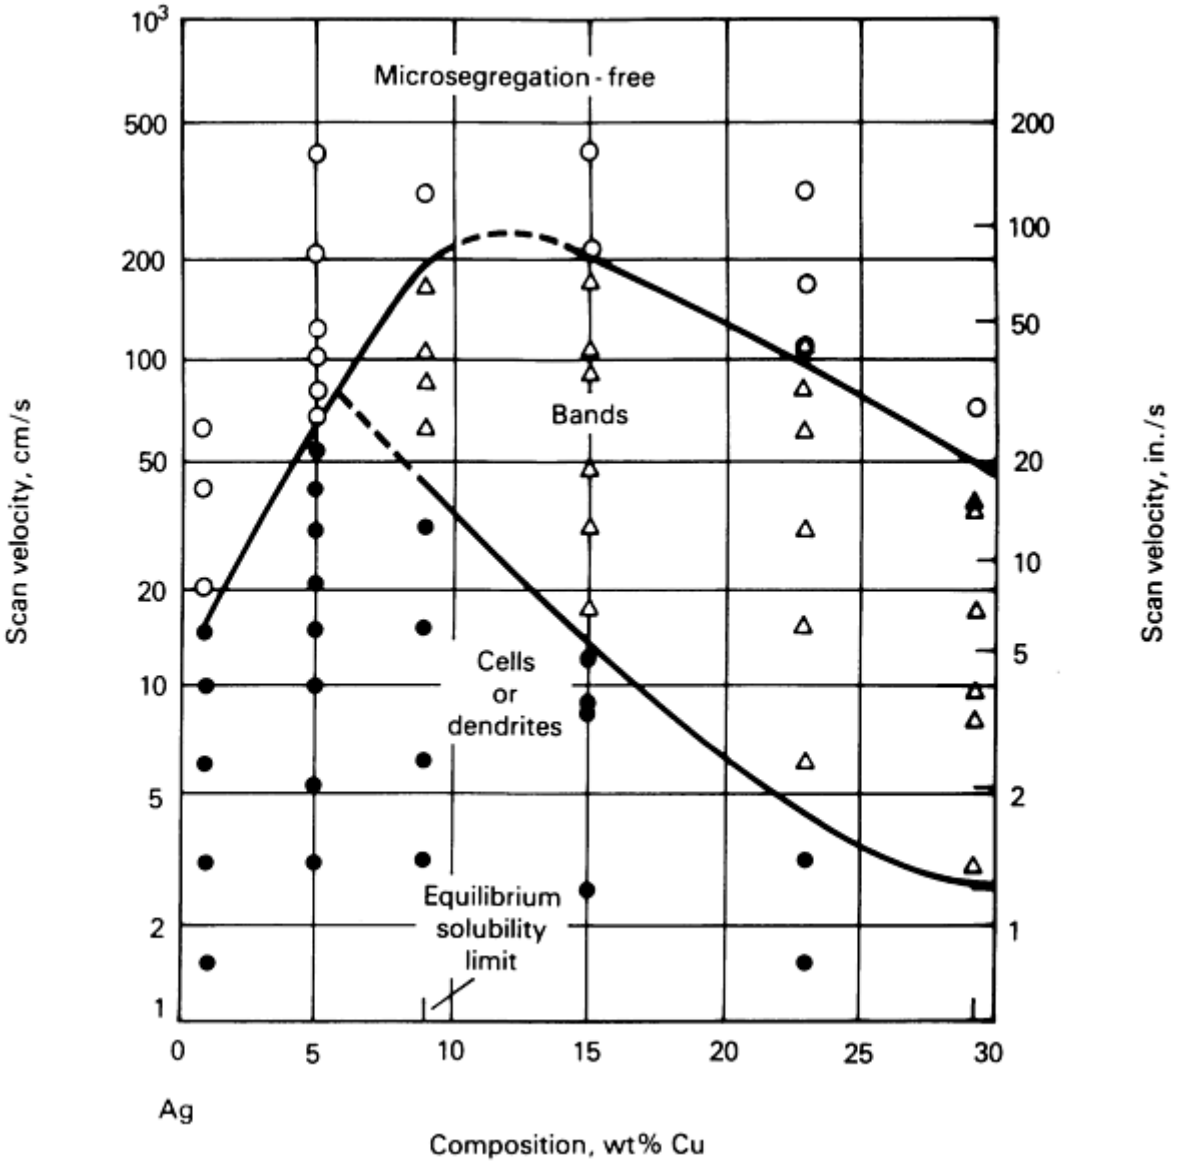

FIG. 16 OBSERVED MICROSTRUCTURES IN SILVER-COPPER ALLOYS AS A FUNCTION OF THE SCAN VELOCITY (BEAM TRANSLATION VELOCITY) FOR ELECTRON-BEAM WELDS. OPEN CIRCLES DENOTE MICROSEGREGATION-FREE STRUCTURE; CLOSED CIRCLES, A STRUCTURE CONSISTING OF CELLS OR DENDRITES; AND OPEN TRIANGLES, THE DEVELOPMENT OF A BANDED STRUCTURE. SOURCE: REF 24

A more common type of banding is associated with the ripples observed on the surface of most welds. Variations in the welding power will cause variations in the solidification rate. If the power decreases, then the solidification rate will increase. More solute will be incorporated into the solid and a solute-rich band will be created (for $K < 1$ and where M_L is negative). The reverse is true for an increase in the power (that is, the solidification rate will decrease), and this will cause a solute-poor band to form (for $K < 1$ and where M_L is negative). These power fluctuations can be deliberate, as in pulsed welding, or can result from unavoidable instabilities in the welding power supplies or fluctuations in primary voltage, mechanical (travel) motion, and so on. Solute banding and surface rippling are illustrated in Fig. 17.

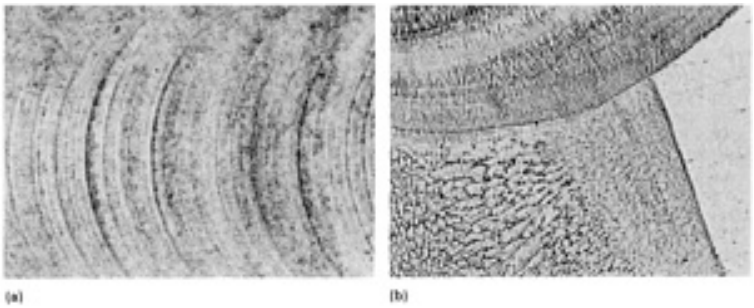

FIG. 17 SOLUTE BANDING AND SURFACE RIPPLING IN WELD BEADS. (A) SURFACE RIPPLES IN A TUNGSTEN-INERT GAS WELD MADE WITH AL-5SI FILLER. 6×. (B) SULFUR AND PHOSPHORUS SOLUTE BANDING AT THE FUSION BOUNDARY OF A MANUAL ARC WELD IN CARBON-MANGANESE STEEL. 26×. COURTESY OF THE WELDING INSTITUTE

Variations in the welding speed can also cause banding, as can the waves associated with the weld pool circulation, which can also influence the solidification rate. Special alternating magnetic fields have been used to supplement the surface tension forces, the usual electromagnetic forces, and the arc pressure and buoyancy forces, all of which affect the weld pool circulation (Ref 27). The aim is to induce interface fragmentation and cause grain refinement.

The solidified structure can also be influenced by several other factors, in addition to variations in the rate of movement of the solid-liquid interface (Ref 27). Inoculants have been used to nucleate equiaxed grains by heterogeneous nucleation on the inoculant particles. Ferro-titanium, ferro-niobium, titanium carbide, and titanium nitride have been used as grain refiners in steels. Zirconium and titanium have also been used as inoculants for aluminum. The effectiveness of inoculants depends not only on the type of inoculants used, but on the size of the inoculant particles, the method of introduction (where in the weld pool it is added), and welding conditions.

Arc motion and vibrations have also been used to suppress columnar growth and to produce a finer grain size (Ref 27). The effectiveness of arc vibration on the as-solidified grain size of an Al-2.5% Mg weld is illustrated in Fig. 18. The effectiveness of this approach depends on the frequency and amplitude of the arc motion, the heat input, arc length, and sheet thickness. In general, the greater the amplitude of vibration, the less the frequency required for grain refinement (Ref 28).

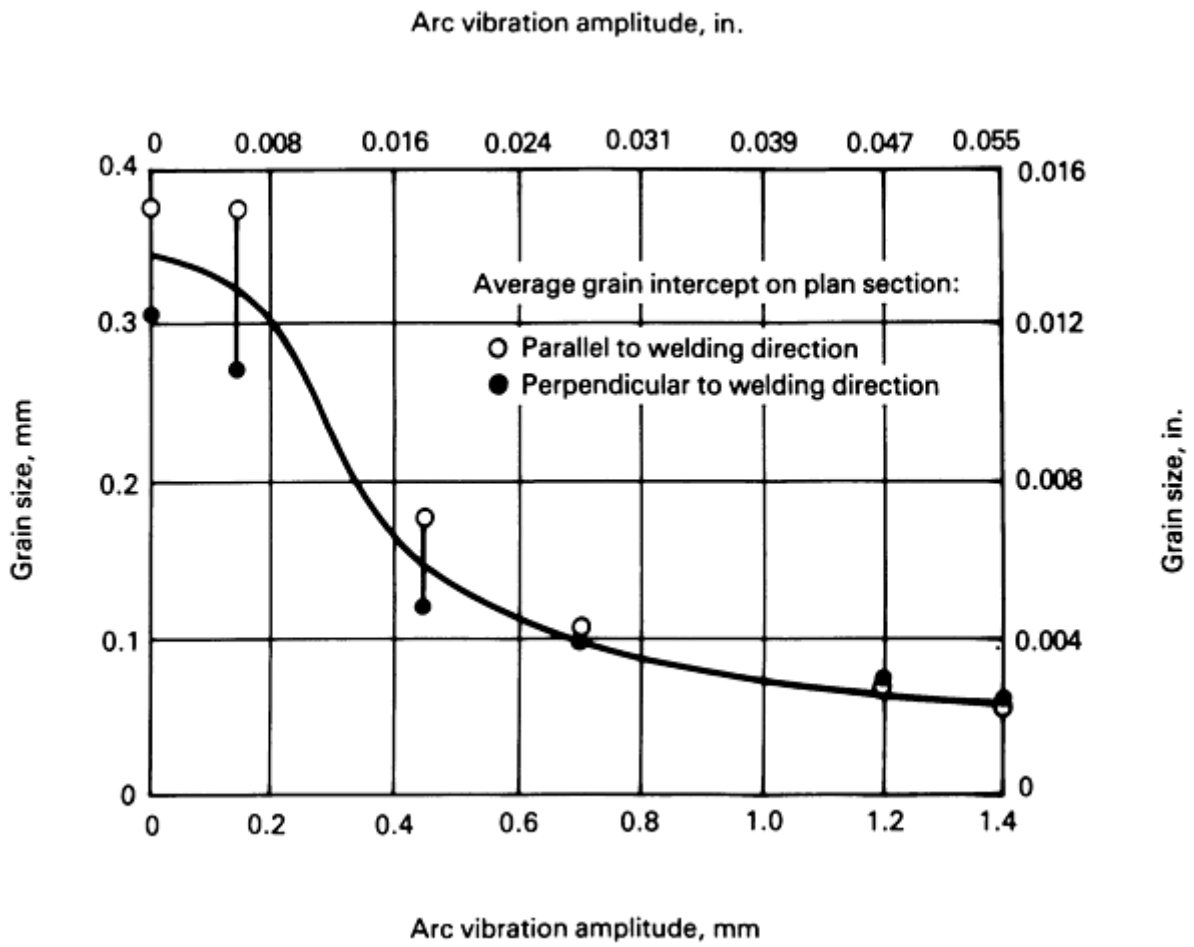

FIG. 18 PLOT OF GRAIN SIZE VERSUS ARC VIBRATION AMPLITUDE FOR AL-2.5MG WELD. WELD PARAMETERS: WELDING CURRENT, 150 A; WELDING SPEED, 200 MM/MIN (50 IN./MIN); ARC GAP, 2.4 MM (0.094 IN.); ARC VIBRATION FREQUENCY, 10 HZ. SOURCE: REF 27

Campbell (Ref 28) has developed frequency-amplitude maps that define several physical effects associated with the use of vibrations (that is, peak pressures generated, development of shearing stresses, power densities, laminar flow around dendrite arms, and the development of standing waves). These factors affect microstructural features, such as grain size, amount of microsegregation, and the development of porosity. For a given frequency of vibration, increasing the amplitude of vibration can cause a refinement of the grain size (Fig. 18), reduce microsegregation, and, unfortunately, increase the degree of porosity that is caused by vibration-induced cavitation. Vibrations can also cause splatter of the liquid weld metal; coarsen intragranular features, such as the secondary dendrite arm spacing; and promote hot tearing. Great care must therefore be taken when using vibratory motion and when determining the optimum amplitude and frequency of vibration.

Variations in the arc current can also help to refine the weld microstructure. Ultrasonic vibration of the weld pool has also been found to be effective in some cases. These vibrations have been added through the filler wire and through the use of water-cooled copper probes (in large weld pools, such as those developed in electro-slag welding). In some cases, variations in the nature of the weld pool circulation have also been found to be effective in refining the weld structure. The desire to produce a fine-grained equiaxed weld structure is driven by the improved mechanical properties and lessened hot cracking that this structure provides.

Torch weaving (Ref 29) (that is, moving the arc in a sinusoidal rather than linear fashion) has been used to break up the linear nature of the weld and to prevent hot cracks from propagating along the weld. A weld made with torch weaving is shown in Fig. 19. This weaved weld structure prevents cracks from running the length of the weld, but adds to the cost of the weld by decreasing the linear travel speed.

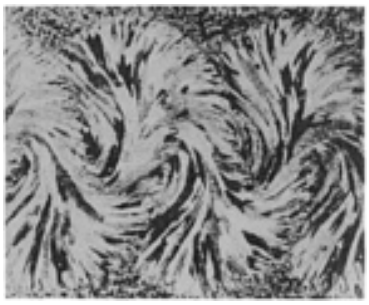

FIG. 19 TYPICAL GRAIN STRUCTURE OBTAINED WHEN TORCH WEAVING IS USED TO WELD ALUMINUM ALLOY 2014. WELD PARAMETERS: TRANSVERSE ARC FREQUENCY OSCILLATION, 1.0 HZ; AMPLITUDE OF OSCILLATION, 1.5 MM (0.059 IN.). SOURCE: REF 13, 30

Our understanding of weld solidification owes much to the more extensive study of the solidification of castings. The reader should refer to that subject area for a more in-depth treatment of solidification in general. However, it should be remembered that the boundary conditions for weld solidification and for that of a casting are not the same. Therefore, care must be taken in applying all that has been learned from casting metallurgy to the metallurgy of welds.

Nature and Behavior of Fluxes Used for Welding

D.L. Olson, S. Liu, R.H. Frost, G.R. Edwards, and D.A. Fleming, Colorado School of Mines

Introduction

FLUXES are added to the welding environment to improve arc stability, to provide a slag, to add alloying elements, and to refine the weld pool (Ref 1, 2). Different ingredients in the flux system will provide the process with different pyrometallurgical characteristics and thus different weld metal properties (Ref 3, 4).

The slag that forms during welding covers the hot weld metal and protects it from the atmosphere. Welding slag consists of the glass-forming components of the flux, as well as inclusions that form in the weld pool, coalesce, rise, and become incorporated into the slag.

The need to improve flux formulation to achieve optimal weld metal composition, and ultimately improve the properties of weldments, has led to fundamental studies of weld pyrochemistry. Understanding the thermodynamic and kinetic factors that are prevalent at the electrode, in the arc column, and in the weld pool, has led to more precise prediction of the final weld metal composition (Ref 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15).

Nature and Behavior of Fluxes Used for Welding

D.L. Olson, S. Liu, R.H. Frost, G.R. Edwards, and D.A. Fleming, Colorado School of Mines

---

Equilibrium Parameters

Equilibrium is not achieved during welding, because of the very large temperature and density gradients, the short reaction times, and the large electric currents. Despite these expected departures from equilibrium, thermodynamic considerations can be used as a guide for constraining chemical reactions and mechanisms involved in welding (Ref 5, 7, 9). A common approach is to assume that extremely high temperatures and high surface-to-volume ratios allow thermodynamic equilibrium to be locally attained, in spite of the short reaction times available.

Further complicating the issue is the dependence on welding parameters of the chemical partitioning between the slag and the weld metal (Ref 3, 7). This dependence suggests that the pyrometallurgical reactions involved are influenced by the processes that occur at the electrode tip. As a specific example, the welding parameters affect metal-droplet size, which in turn alters the chemical kinetics. Nonetheless, thermodynamics will reveal the direction taken by the chemical reactions (but will not accurately predict weld metal composition).

The effective slag-metal reaction temperature has been estimated (by pyrochemical analysis of slag-metal compositions) to be approximately 1900 °C (3450 °F), a temperature intermediate between that of the hot spot at the arc root (2300 °C or 4170 °F) and the melting point of iron (1500 °C or 2730 °F). Thus, during the droplet lifetime, the average temperature is effectively 1900 °C (2730 °F). During this period, oxygen from the hot spot reactions is distributed throughout the droplet, and that oxygen reacts with the metallic elements to form oxides; these products of oxidation pass into the slag, and the slag-metal reactions tend toward equilibrium. Estimates of the time for which the molten slag and molten metal are in contact range from 3 to 8 s. During the process, the gaseous phase in the arc cavity contacts the metal for an estimated 0.5 to 1.0 s.

Effect of Oxygen

The most important chemical reagent in controlling weld metal composition, and thus microstructure and properties, is oxygen (Ref 3, 4, 14, 16, 17, 18, 19). Oxygen directly reacts with alloying elements to alter their effective role by:

- REDUCING HARDENABILITY
- PROMOTING POROSITY
- PRODUCING INCLUSIONS.

All three effects are significant to weld quality.

Oxygen is introduced into the weld pool at high temperatures by:

- THE PRESENCE OF OXIDE FLUXES THAT DISSOCIATE IN THE ARC
- THE SLAG-METAL REACTIONS IN THE WELD POOL
- THE OXIDES ON THE SURFACE OF BAKED METALLIC POWDERS MIXED WITH FLUX OR ON ELECTRODE
- THE ASPIRATION OF ATMOSPHERE (AIR) INTO THE ARC.

Shielding gas may contain oxidizing reagents; a common gas is 75Ar-25CO_2 or 100% CO_2. As a 100 to 1000 ppm, depending on the type of welding consumable used.

The weld metal oxygen measured directly at the molten electrode tip has been reported to be as high as 1400 ppm. Individual droplets have been found to contain as much as 2000 ppm O_2. There are two views concerning the genesis of the high oxygen content. One suggests that pyrochemical or electrochemical reactions (or both) provide oxygen to the electrode tip, and then further oxidation occurs within the droplet as it passes through the arc. The other view is that the high oxygen levels of the droplet represent the maximum buildup of oxygen in the electrode prior to detachment, with limited reaction during flight across the arc to the weld pool. In either case, high oxygen concentrations are introduced into the weld pool by the welding process.

At the melting point, the solubility of oxygen in pure liquid iron is approximately 1600 ppm at 100 kPa (1 atm) pressure. During solidification, solubility decreases to about 860 ppm at 1500 °C (2730 °F) in δ-Fe. Most of the alloying elements present in liquid steel reduce oxygen solubility through deoxidation equilibria. Steelmaking processes typically yield analytical oxygen levels ranging from 70 to 100 ppm. Welds typically pick up oxygen to levels of several hundred ppm, then deoxidize to oxygen levels of around 200 to 300 ppm. Deoxidation of the weld metal occurs in two separate steps, the first being the primary deoxidation of the weld pool (Ref 6). Secondary deoxidation occurs during solidification as solute concentrations increase within the intercellular or interdendritic regions. The secondary deoxidation will either form very small inclusions or will coat the interdendritically trapped primary inclusions.

The high oxygen concentrations added to the weld pool by the metal droplets significantly affect deoxidation. Figure 1 shows experimentally measured soluble oxygen concentrations for various deoxidants (solid lines), along with deoxidation curves predicted by the solubility products (broken lines). The experimental deviation is caused by interactions of the deoxidant with other alloy elements. If the oxygen and metallic element concentrations resulting from the welding process exceed the equilibrium concentration for a specific reaction, inclusions will result. The ability to form a specific inclusion will correspond directly to the position of the weld pool composition relative to the activity plot for this inclusion. Thus, the thermodynamic order for the formation of primary oxides would be: Al_2O_3 > Ti_2O_3 > SiO_2 > Cr_2O_4 > MnO.

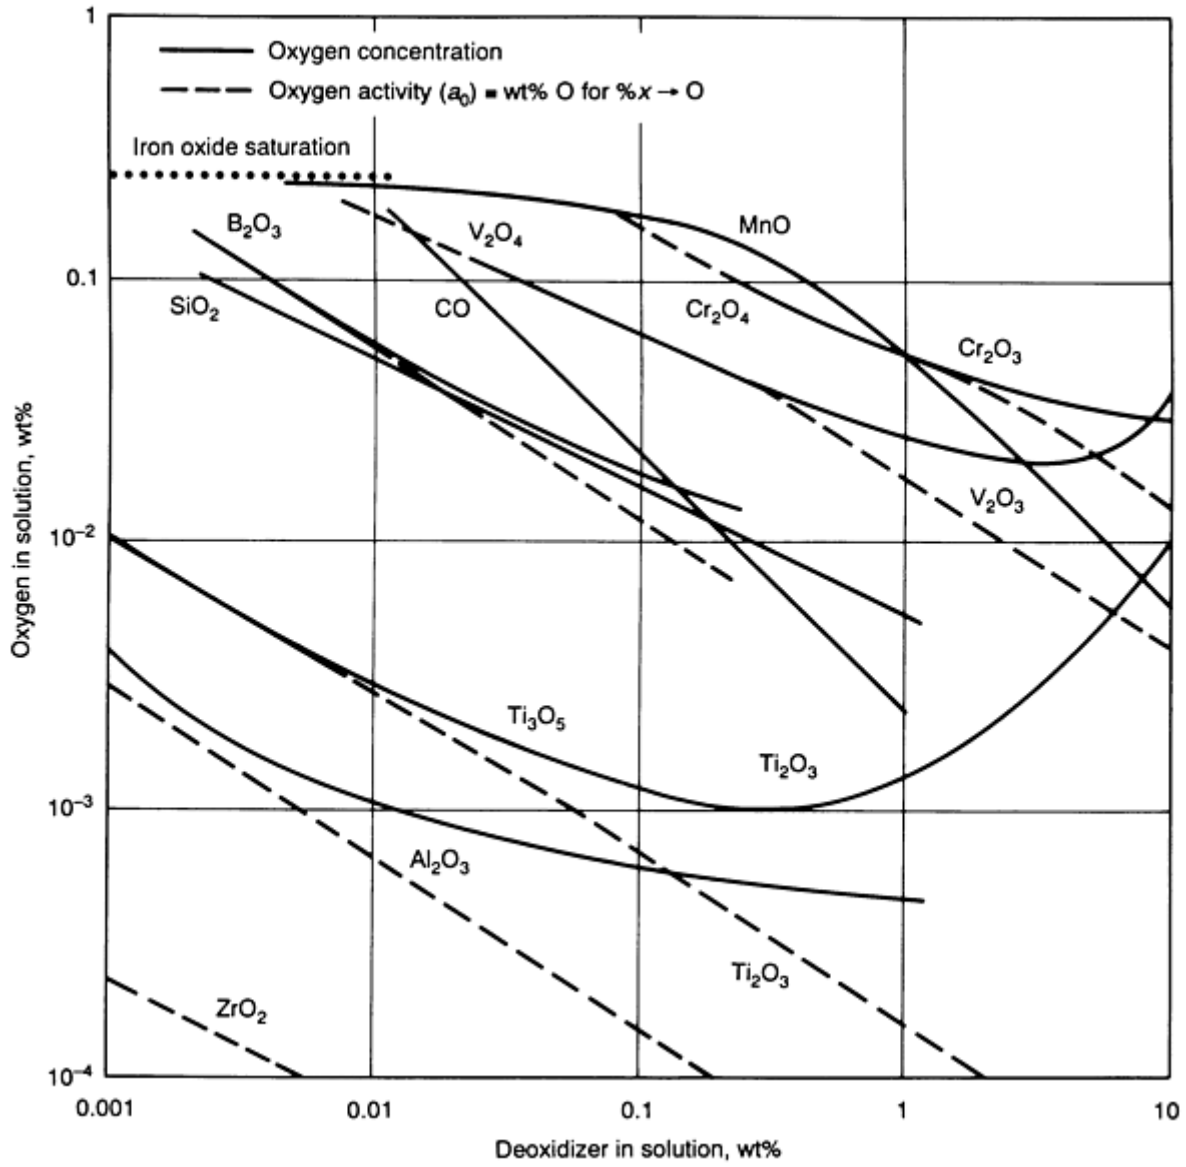

FIG. 1 DEOXIDATION EQUILIBRIA IN LIQUID IRON ALLOYS AT 1600 °C (2910 °F). THE BROKEN LINES SHOW DEOXIDATION EQUILIBRIA PREDICTED BY SOLUBILITY PRODUCT CALCULATIONS. THE SOLID LINES SHOW EXPERIMENTALLY DETERMINED SOLUBLE OXYGEN CONCENTRATIONS FOR VARIOUS DEOXIDANTS. THE EXPERIMENTAL DEVIATION IS CAUSED BY VARIATIONS IN THE ACTIVITY COEFFICIENTS WITH INCREASING DEOXIDANT CONCENTRATION. SOURCE: REF 20

Inclusion Formation. Inclusions form as a result of reactions between metallic alloy elements and nonmetallic tramp elements, or by mechanical entrapment of nonmetallic slag or refractory particles. Inclusions may include:

- OXIDES
- SULFIDES
- NITRIDES
- CARBIDES
- OTHER COMPOUNDS
- MULTIPLE PHASES

Among these, oxides and complex oxides occur most frequently in the size range known to influence weld metal microstructure.

Using only thermodynamic considerations in the analysis of slag-metal reactions, the following reactions may be considered as the ones that describe inclusion formation:

$$X\ \underline{M}\ + Y\ \underline{O}\ = (M_XO_Y) \qquad \textbf{(EQ 1)}$$

where the underlining of a component M ($\underline{M}$) and the component O ($\underline{O}$) indicate that M and O, respectively, are dissolved in the metal, and:

$$X\ \underline{M}\ + Y(FEO) = (M_XO_Y) + YFE \qquad \textbf{(EQ 2)}$$

The equilibrium constants (K_1 and K_2) for the above two reactions are:

$$K_1 = \frac{(A_{M_xO_y})}{[a_M]^x[a_o]^y} \qquad \textbf{(EQ 3)}$$

where a_i is the activity, a function of the concentration, for component *i*, and:

$$K_2 = \frac{(A_{M_xO_y})}{[a_M]^x[a_{FeO}]^y} \qquad \textbf{(EQ 4)}$$

Equilibrium compositions for the weld deposit can be estimated with Eq 1, 2, 3, and 4 and can be used to predict trends for the weld pool pyrochemical reactions. The actual compositions may, however, differ from the calculated values due to alloying-element partitioning during cellular or dendritic solidification, commonly observed in steel weldments.

During solidification of a weld metal, solute elements segregate to the liquid at the solid/liquid interface, and the solute concentrations can reach high levels in the interdendritic regions, as suggested in Fig. 2. Neglecting solid diffusion, the solute composition in the liquid at the solid/liquid interface can be modeled (Ref 6) by the nonequilibrium lever rule, or Scheil Equation:

$$C_L = C_0F_L^{K-1} \qquad \textbf{(EQ 5)}$$

where C_0 is the bulk concentration in the weld pool, C_L is the solute concentration in the liquid at the interface, and *k* is the equilibrium partition ratio.

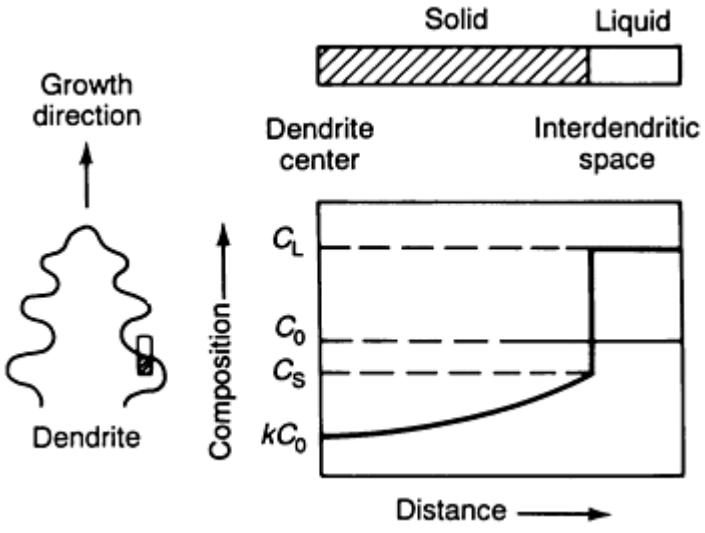

FIG. 2 SCHEMATIC SHOWING THE SOLID AND LIQUID COMPOSITION PROFILES MODELED BY EQ 5 BASED ON THE ASSUMPTION THAT THERE IS COMPLETE LIQUID DIFFUSION AND NO SOLID DIFFUSION. C_0, THE INITIAL ALLOY COMPOSITION; K, THE PARTITION RATIO OF THE SOLID TO LIQUID COMPOSITIONS ON THE EQUILIBRIUM PHASE DIAGRAM; KC_0, THE INITIAL COMPOSITION OF THE SOLID; AND C_S AND C_L, THE SOLID AND LIQUID COMPOSITIONS, RESPECTIVELY, AT THE SOLIDIFICATION INTERFACE. SOURCE: REF 4

The equilibrium partition ratio, *k*, controls the direction and the extent of segregation. For most alloy elements in steel, the partition ratio is less than one, and the element segregates to the interdendritic liquid.

Consider the deoxidation equilibrium as represented by the dissolution reaction for a complex oxide:

$$M_XN_YO_Z = X\ \underline{M}\ + Y\ \underline{N}\ + Z\ \underline{O} \qquad \textbf{(EQ 6)}$$

The free energy change associated with the dissolution of the $M_xN_yO_z$ can be written as:

$$\Delta G = \Delta G^\circ + RT \ln \frac{[M]^x[N]^y[O]^Z}{[M_xN_yO_z]} \qquad \textbf{(EQ 7)}$$

where [M], [N], and [O] are the solute activities in the liquid; and *x*, *y*, and *z* are the stoichiometric constants from Eq 6. The value $[M_xN_yO_z]$ is the activity for the specific inclusion and can be assumed to have the value of one.

The ratio of the activities of the reactants to that of the oxide can be termed the activity quotient (*Q*):

$$Q = \frac{[M]^x[N]^y[O]^Z}{[M_xN_yO_z]} \qquad \textbf{(EQ 8)}$$

With Eq 5 representing the extent of segregation, the solute activities in the interdendritic liquid can be written as:

$$[M]=[\gamma_M][M_O]f_L^{k_M-1} \qquad \textbf{(EQ 9A)}$$

$$[N]=[\gamma_N][N_0]f_L^{k_N-1} \qquad \textbf{(EQ 9B)}$$

$$[O] = [\gamma_O][O_0]f_L^{k_O-1} \qquad \textbf{(EQ 9C)}$$

In Eq 9a, 9b, and 9c, $[M_O]$, $[N_O]$, and $[O_O]$ are the bulk concentrations of M, N, and O in the melt; and $[\gamma_M]$, $[\gamma_N]$, and $[\gamma_O]$ are the activity coefficients for the solutes.

Substituting Eq 9a, 9b, and 9c into Eq 8 gives the free energy as a function of the remaining liquid fraction:

$$\Delta G = \Delta G^\circ + RT \ln \frac{[\gamma_M M_O f_L^{k_M-1}]^x [\gamma_N N_O f_L^{k_N-1}]^y [\gamma_O O_O f_L^{k_O-1}]^z}{[M_xN_yO_z]} \qquad \textbf{(EQ 10)}$$

Equation 10 expresses the free energy driving force for oxide dissolution. The first term on the right side, ΔG, represents equilibrium conditions. The second term represents the departure from equilibrium caused by changes in reactant concentrations or by segregation during solidification.

At equilibrium, the free energy driving force, ΔG, is zero, and the equilibrium concentrations can be found by equating the two terms on the right-hand side of Eq 10. At equilibrium, the activity quotient becomes the equilibrium constant, K_{eq}:

$$\Delta G^\circ = -RT \ln \frac{[M]^x[N]^y[O]^z}{[M_xN_yO_z]} = -RT \ln K_{eq} \qquad \textbf{(EQ 11)}$$

Inclusion precipitation is possible when the concentrations of oxygen and deoxidants exceed the equilibrium values for a particular oxide. This condition can be expressed with the ratio of the activity quotient to the equilibrium coefficient:

$$\text{Precipitation index} = \frac{Q}{K_{eq}} \qquad \textbf{(EQ 12)}$$

A precipitation index less than unity indicates that the concentrations of oxygen and deoxidants are below the equilibrium value, and the precipitation of the inclusions will not occur. A value greater than 1.0 indicates that concentrations are sufficiently high for precipitation according to the methodology described above. The compounds Al_2O_3, Ti_2O_3, and SiO_2 are some of the oxides that will form in a low-carbon low-alloy steel weld. Multiple reactions can occur, and different oxides may appear in the same weld when more than one of these deoxidizers is present.

Metal Transferability During Pyrochemical Reactions. The final weld metal concentration for a particular element is made up of contributions from the filler wire, flux, and base metal; however, losses caused by the welding process vary for each element.

Delta Quantity. The nominal composition of each weld can be calculated considering just the dilution effect of the filler wire and base metal. The extent of loss or transfer of a specific element can be evaluated by a quantity, which expresses the difference between the analytical and the nominal composition. These quantities, designated delta quantity in this article, indicate the effect of the flux on element transfer during welding. A positive delta quantity indicates an elemental transfer from the flux to the weld metal. A negative delta quantity suggests an elemental loss from the weld pool to the slag. A null delta quantity for a specific element suggests an apparent equilibrium condition, in which the flux and slag content for that element are the same. Flux compositions with null delta-quantity behavior have been used to make equilibrium calculations and thus achieve a better understanding of the chemical reactions involved in welding (Ref 8). Investigators have also quantified elemental transfer by measuring similar neutral points (null delta quantity) for various flux systems and have developed a thermodynamic model capable of predicting neutral points for some slag systems (Ref 10).

Arc Stabilizers. Arc welding fluxes are compositionally more complex than fluxes used in other metallurgical processes, such as steelmaking. Many of the additions to the flux are not designed to assist weld metal refinement. Some additions are present to promote arc stability, generate plasma and protective gases, control viscosity, support out-of-position welding, and promote slag detachability.

The welding arc requires an inert or chemically reducing plasma and shielding gas that can be easily ionized. Additions must be made to the flux to achieve the necessary current-carrying capacity and to maintain arc stability. Specific additions will be necessary for the various modes of current (direct current, dc, or alternating current, ac) and polarity.

Alkali metal, zirconium, and titanium additions to the arc affect the ionization process and the ease with which the welding is reinitiated (reinitiation is required 50 to 60 times per second with ac welding). These additions come to the welding flux as feldspar (alkali aluminum silicates), rutile, lithium carbonate, titanium aluminate, and potassium oxalate, and they play an especially important role when welding either in the dc electrode negative (DCEN) mode or in the alternate current (ac) mode. Arc stabilizers are also important in high-speed welding when the cathode and anode spots are less stable. These additions are part of the AWS classification of electrodes, as seen by the fourth digit (E XXX $\underline{X}$) in the classification standard for steel electrodes for shielded metal arc welding (SMAW) given in Table 1. The electrodes designed to perform with ac mode or in the DCEN mode current have been specified as containing high titania or alkali metal (potassium or sodium) additions. Special additions such as Li_2O have been used to achieve multipurpose results--for example, reducing the viscosity while increasing the arc stability.

TABLE 1 AWS CLASSIFICATION OF SELECTED SMAW ELECTRODES FOR WELDING MILD AND LOW-ALLOY STEELS

ELECTRODE DESIGNATION	CURRENT AND POLARITY[(A)]	PENETRATION	ARC STABILIZERS	% FE
EXX10	DCEP	DEEP	HIGH CELLULOSE-NA	0-10
EXXX1	AC, DCEP	DEEP	HIGH CELLULOSE-K	0
EXXX2	AC, DCEN	MEDIUM	HIGH RUTILE-NA	0-10
EXXX3	AC, DCEP, DCEN	LIGHT	HIGH RUTILE-K	0-10

Changes in Flux Composition With Delta Quantity. Figure 3 shows a transfer of manganese for welds made with SiO_2-TiO_2-CaO-$1Na_2O$ flux at constant SiO_2 content in the flux. These values vary widely, depending on other alloy concentrations. The data imply that manganese is almost always lost to the slag, and that the activity of manganese varies considerably with changes in the amount of titania in the flux. Manganese is very important to weld metal hardenability and must be closely controlled to obtain the optimum weld microstructure. Controlling the weld metal manganese concentration in the titania-containing flux systems would require strict compositional control of the welding flux to ensure the correct manganese concentration in the weld metal.

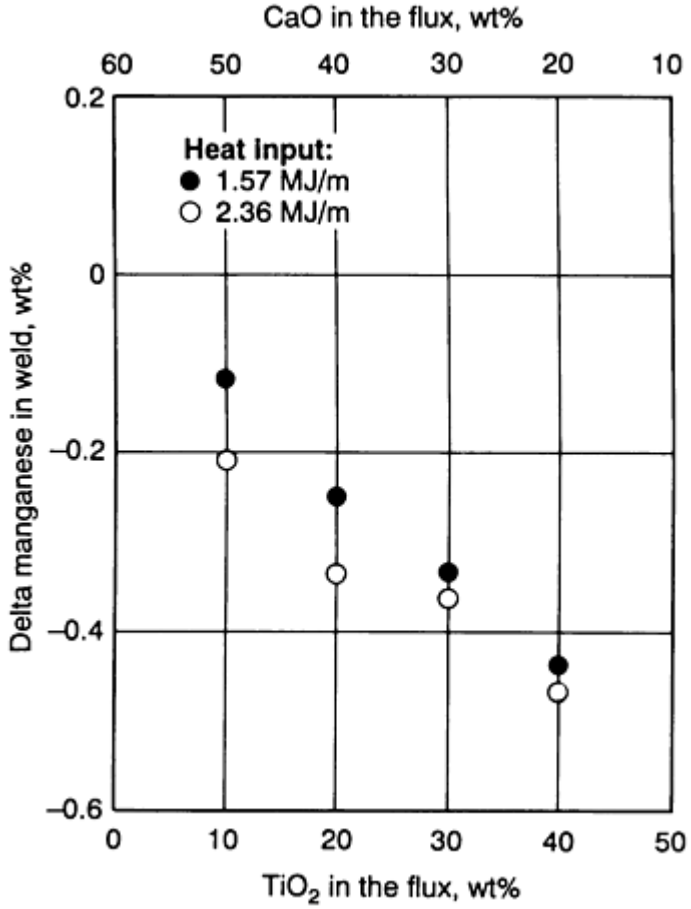

FIG. 3 PLOT OF CHANGES IN MANGANESE CONTENT IN THE WELD VERSUS THE VARIATION IN FLUX COMPOSITION AS A FUNCTION OF TWO-HEAT INPUTS. THE SIO_2 CONTENT WAS MAINTAINED AT 40% THROUGHOUT THE FLUX-CORED ARC WELDING PROCESS. SOURCE: REF 21

In the same system, the delta titanium showed a constant increase with increasing titania content of the flux (Fig. 4). Because of the large amounts of titania in the flux, it is not surprising that the welds show positive compositional deviations for titanium. These results also suggest that control of the weld metal titanium content will require tight control of the limits of the TiO_2 content of the flux.

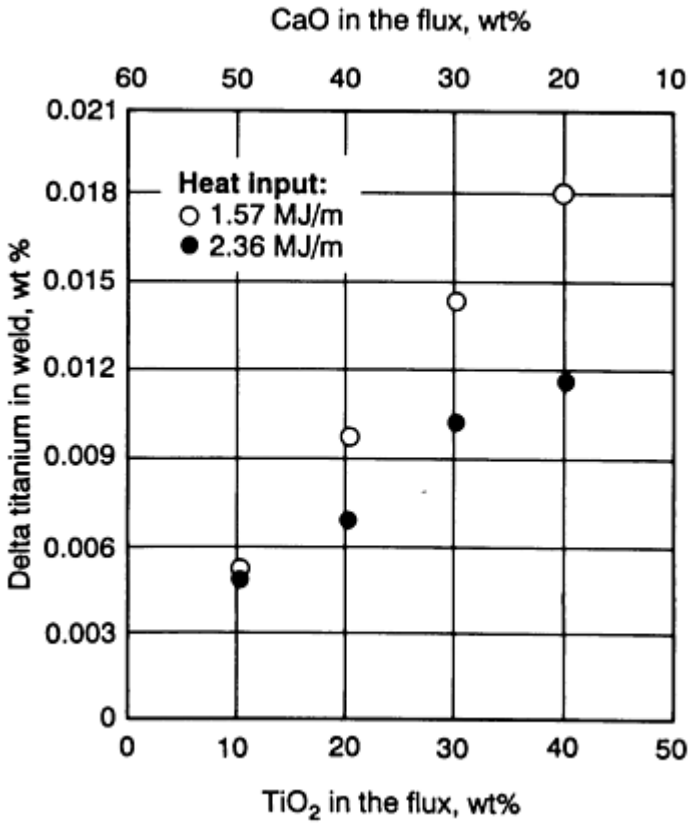

FIG. 4 PLOT OF CHANGES IN TITANIUM CONTENT IN THE WELD VERSUS THE VARIATION IN FLUX COMPOSITION AS A FUNCTION OF TWO HEAT INPUTS. THE SIO_2 CONTENT WAS MAINTAINED AT 40% THROUGHOUT THE FLUX-CORED ARC WELDING PROCESS. SOURCE: REF 21

If the delta quantity changes rapidly with flux composition, it may be difficult to maintain specific weld metal composition, microstructure, and properties with variation in flux composition. The magnitude of the delta quantity for specific elements is most often not as serious a concern as a rapid change in the delta quantity with variations in flux chemistry and welding parameters. The magnitude of the delta quantity can be adjusted by altering the alloy content of the welding wire or the amount of ferro-additions to the flux. Thus, a suitable combination of wire, flux, and welding parameters should achieve negligibly small delta quantities of major alloying elements.

Shielding Gas. When the shielding gas that protects the weld pool comes from the flux, it is necessary to understand the decomposition of specific flux components. Two common shielding gas atmospheres from flux dissociation are hydrogen and CO/CO_2. The hydrogen gas can be produced by the decomposition of cellulose (wood flour or similar hydrocarbons). A CO/CO_2 atmosphere results from the decomposition of carbonates such as limestone ($CaCO_3$) or dolomite [$CaMg(CO_3)_2$]. The CO/CO_2 atmosphere can be balanced to provide a reducing (and thus protective) atmosphere.

At high temperatures, CO_2 or CO will react with carbon to achieve equilibrium, which requires the presence of CO and CO_2. It is the relative amounts of CO and CO_2 that determine the reducing/oxidizing nature of the arc environment. The CO/CO_2 ratio also determines the recovery of specific alloying elements. Typical plasma atmospheres for both hydrogen-type and low-hydrogen-type electrodes are given in Table 2.

TABLE 2 GAS COMPOSITION OF WELDING ARC OBTAINED FROM SPECIFIC TYPES OF WELDING ELECTRODES

AWS DESIGNATION	TYPE	COMPOSITION, WT%			
		H_2O	H_2	CO_2	CO
6010	CELLULOSIC	16	41	3	40

6015	BASIC	2	2	19	77

Source: Ref 15

In submerged arc welding, the covering flux also produces the protective shielding gas and plasma. Other gaseous phases, including flourine-bearing components, are also part of the plasma.

The effect of arc environment (for example, amounts of CO and CO_2) on weld metal chemistry control for hyperbaric welding with a basic electrode is shown in Fig. 5. The high-pressure welding allows evaluation of the CO reaction. Considering the CO reaction:

$$C + O = CO \qquad \textbf{(EQ 13)}$$

the law of mass action gives:

$$k = \frac{P_{CO}}{[C][O]} \qquad \textbf{(EQ 14)}$$

where [C] and [O] are the weld metal carbon and oxygen contents, respectively. At equilibrium the partial pressure of CO is directly related to the total pressure by Dalton's Law.

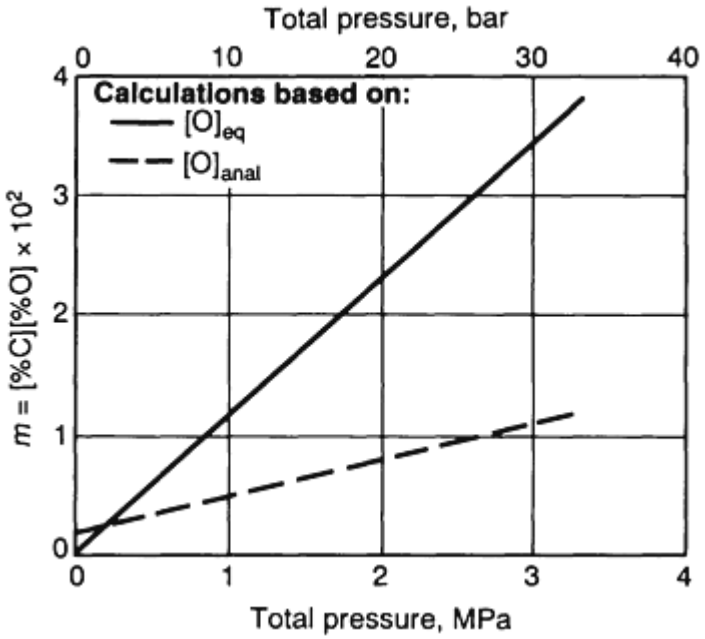

FIG. 5 EFFECT OF PRESSURE ON THE PRODUCT *M* = [%C][%O] FOR HYPERBARIC WELDING WITH A BASIC ELECTRODE. SOURCE: REF 12

In Fig. 5, two lines are indicated. The solid line plots the product of the weld metal oxygen and carbon as a function of total pressure when the analytical weld metal oxygen concentration, $[\%O]_{anal}$, was used. The broken line indicates a similar relationship; however, in this case, the weld metal oxygen concentration has been corrected for the displacement of oxygen because of the formation of manganese silicate inclusions during welding and its transport to the slag. The equilibrium oxygen content, $[\%O]_{eq}$, in the liquid steel at high temperatures is then given by the following expression:

$$[\%O]_{eq} = [\%O]_{anal} + \frac{32}{28}\Delta[\%Si] + \frac{16}{55}\Delta[\%Mn] \quad \textbf{(EQ 15)}$$

where Δ[%Si] and Δ[%Mn] represent the difference between the expected compositions of these elements (from knowledge of initial consumables and base plate compositions as well as dilution) and the actual compositions measured. The linearity of these lines in Fig. 5 is evidence of the strong influence of the CO reaction in arc welding.

The evidence of water reaction control for some electrodes (for example, cellulosic electrodes) can be seen in Fig. 6. With an increase in the degree of oxidation of the deposited metal, the weld metal hydrogen content decreases (Ref 22). The relationship between weld metal oxygen and hydrogen contents as seen in Fig. 6 is consistent with the functional form expected from the law of mass action for a H_2O reaction. It is apparent that with increasing weld metal oxygen content there is a significant reduction in weld metal hydrogen. The hydrogen content of the deposited metal can be reduced by increasing the $CaCO_3$ content of the coating. With the ever-increasing requirements of weld-deposit properties and the increasing need for higher productivity, pyrochemistry will play an important role for flux formulation and weld-property prediction.

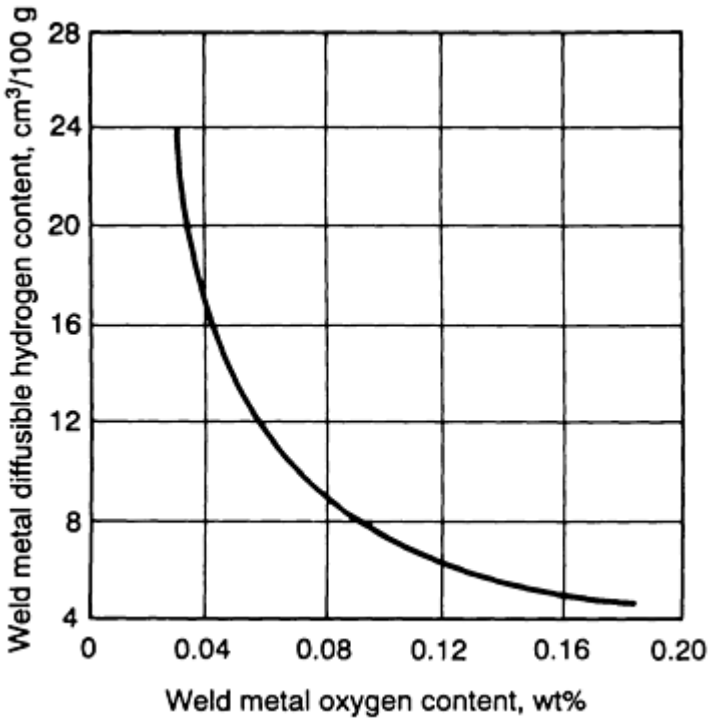

FIG. 6 PLOT OF WELD METAL OXYGEN CONTENT VERSUS WELD METAL HYDROGEN CONTENT WHEN WELDING WITH ELECTRODES THAT CONTAIN CHROMIUM AND NIOBIUM IN THEIR COATINGS. SOURCE: REF 22

Basicity Index

As indicated in the section "Metal Transferability During Pyrochemical Reactions" in this article, the transfer of alloying elements during welding depends strongly on the physical and chemical properties of the flux. The ability to correlate flux properties with weld metal chemical compositions and properties is essential to understand the interactions between weld metal and flux.

Because of the incomplete understanding of the thermodynamic properties of slags, the empirical concept of basicity has been applied to predict flux and weld properties. A basicity index, *BI,* for welding has been proposed:

$$BI = \frac{CaO + CaF_2 + MgO + K_2O + Na_2O + Li_2O + 1/2(MnO + FeO)}{SiO_2 + \frac{1}{2}(Al_2O_3 + TiO_2 + ZrO_2)} \quad \textbf{(EQ 16)}$$

where the chemical components are given in wt%. When the basicity index for a given flux is less than one, the flux is considered acidic. A flux with a *BI* between 1.0 and 1.2 can be classified as neutral. A flux with a *BI* greater than 1.2 is considered basic.

In general, the higher the basicity, the cleaner the weld with respect to nonmetallic inclusions (that is, lower weld metal oxygen content) (Ref 23). Figure 7 illustrates the correlation between weld metal oxygen and the basicity index for some flux systems. The weld metal oxygen content drops significantly as the *BI* is increased to 1.2 and then remains relatively constant at about 250 ppm O. The correlation between weld metal oxygen, which is an indication of weld metal toughness, and basicity is acceptable for some welding flux systems, especially those that are primarily based on CaO, MgO, and SiO_2. However, Eq 16 cannot be used to correlate the strength and toughness of welds made with high flux concentrations of Al_2O_3, TiO_2, ZrO_2, MnO, FeO, and CaF_2. Although numerous basicity formulas have been considered, none has been flexible enough to deal with high amphoteric oxide contents. There is still some concern over utilizing this index (which was primarily conceived by steelmakers for evaluating sulfur refinement) for predicting weld metal oxygen, or for use as a general criterion for weld metal quality (Ref 7). Additionally, the *BI* does not consider the physical properties of the fluxes, nor does it explain the kinetics of the flux-metal reactions.

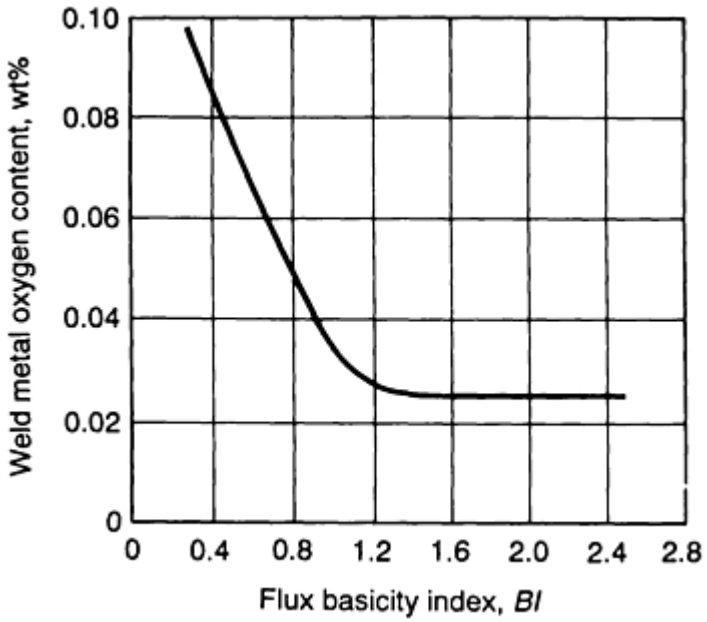

FIG. 7 EFFECT OF WELD METAL OXYGEN CONTENT ON FLUX BASICITY INDEX WHEN USING THE SUBMERGED ARC WELDING PROCESS. SOURCE: REF 23

Basicity index has been used by the welding industry as a measure of expected weld metal cleanliness and mechanical properties. Consequently, manufacturers of welding consumables have classified and advertised their fluxes with this index. It is believed that high basicity means high toughness, a quality of great interest to the engineer, while an acidic flux means excellent slag behavior, a characteristic of interest to the welder attempting to improve weld bead morphology and deposition rate. Table 3 classifies the various coating formulations for SMAW electrodes using the descriptors of cellulosic, basic, acid, and rutile (alternating current stabilizer and slag former).

TABLE 3 ELECTRODE COATING FORMULATIONS OF SELECTED SMAW ELECTRODES

Electrode		Coating formulation[(a)]										Comments
Type	AWS designation	Rutile	Cellulose	Quartz	Carbonates	Ferromanganese	Organics	Iron ore-manganese ore	Calcium carbonate	Complex silicates	Fluorspar	Ferroalloys	
Cellulosic	6010	20-60	10-50	15-30	0-15	5-10	. . .	. . .	. . .	. . .	. . .	. . .	Cellulose promotes gas shielding in the arc region. Hydrogen increases heat at weld. High hydrogen content (30-200 ppm). Deep penetration, fast cooling weld
Rutile	6012 6013	40-60 20-40	. . . . . .	15-25 15-25	0-15 5-25	10-12 1.4-14	2-6 0-5	. . . . . .	. . . . . .	. . . . . .	. . . . . .	. . . . . .	Slags mainly for slag shielding relatively high hydrogen content (15-30 ppm). High inclusion content in weld deposit
Acid-ore[(a)]	6020	. . .	. . .	X	X	X	. . .	X	. . .	X	. . .	. . .	Relatively high hydrogen content. High slag content in weld metal
Basic	7015	0-10	. . .	0-5	. . .	. . .	. . .	. . .	20-50	. . .	20-40	5-10	Relatively low hydrogen levels ($\leqslant$ 10 ppm), hence commonly used in welding low-alloy construction steels. Electrodes should be kept dry. Low inclusion content in weld deposit

Pyrochemical Kinetics During Welding

The ability of a flux to refine as well as protect the weld pool is related to the mass transport processes in the flux. The flux should melt approximately 200 °C (360 °F) below that of the alloy for proper flux coverage and for protection of the weld deposit. One of the most important physical properties of a flux is its slag viscosity, which not only governs the way the slag flows and covers the molten weld pool but also strongly affects the transport processes involved in pore removal, deoxidation, and retention of alloying additions. The chemical processing and refining by the flux to achieve a weld deposit with low concentrations of oxygen and sulfur and optimal concentration of hardenability agents (carbon, manganese, chromium, molybdenum, nickel, and so on) may not be achieved unless slag viscosity is also adequate. The viscosity is strongly temperature-dependent, so the use of various heat inputs during welding may require different flux compositions to produce the matching slag viscosity. For simple ionic melts, the viscosity has been shown to follow an Arrhenius-type temperature dependence:

$$\eta = \eta_0 \exp\left(\frac{E_\eta}{RT}\right) \qquad \textbf{(EQ 17)}$$

where ηis the viscosity, η_0 is a system constant, $E\eta$ is the viscous activation energy, RT is the gas constant, and T is the temperature.

For polymeric melts, Eq 17 often does not hold true. It has been shown that in certain cases a modified equation can be used:

$$\eta = \eta_0 \exp\left[\frac{E_\eta}{R(T - T_0)}\right] \qquad \textbf{(EQ 18)}$$

where T_0 is a constant for a given flux composition. The presence of entrapped particulates tends to increase the slag viscosity. Slag viscosity is also affected by composition. The compositional dependence is commonly reported by considering $E\eta$ to be a function of composition at constant temperature.

The slag must be fluid enough so that it flows and covers the molten weld pool but must be viscous enough so that it does not run away from the molten metal and flow in front of the arc, leading to possible overlapping by the weld metal. (For overhead welding, surface tension becomes a primary factor because fluidity reduces coverage [opposite gravitational vector].) It has been reported that if the manganese silicate flux viscosity at 1450 °C (2640 °F) is above 0.7 Pa · s (7 P), a definite increase in weld surface pocking will occur. Pock marks have been associated with easily reducible oxides in the flux, which contribute oxygen to the weld pool. The weld pool reacts with carbon to form carbon monoxide, which cannot be transported through a high-viscosity flux and is trapped at the liquid-metal/flux interface. The result is a weld metal surface blemished by surface defects or pocks. Because viscosity is sensitive to temperature and thus heat input, pocking can be the evidence that a flux formulated for high-current welding is being used at too low a current or too great a travel speed. The viscosity of most welding fluxes at 1400 °C (2550 °F) is in the range of 0.2 to 0.7 Pa · s (2 to 7 P).

Slag viscosity also affects the shape of the weld deposit and must be carefully controlled when covered electrodes are used out of position. The higher the slag viscosity, the greater the weld penetration in submerged arc welding. However, this benefit must be balanced, because if the viscosity is too high, the gaseous products cannot escape the weld pool, resulting in unacceptable porosity. This condition can be monitored by observing the density of pores trapped in the underside of the detached slag. Detached slags manifesting a honeycomb structure suggest a severe weld metal porosity problem. This condition usually means that a given flux has experienced an insufficient heat input for the effective transport of gas through the slag.

Alloy Modification

Other additions to the welding consumables are required to make alloy additions to the weld pool, usually in the form of powder metal or ferro-additions (Ref 1). Often the composition of the wire that makes up the rod for the shielded metal arc electrode from a specific manufacturer is the same, regardless of the alloy to be welded. Alloying is achieved by

powder metal additions to the flux coating. Manganese, silicon, chromium, niobium, and other alloying additions are adjusted in the weld pool by ferroalloy powder additions. Specially prepared alloy additions of Fe-50Si, Fe-80Mn, Fe-60Mn-30Si, and others are used. One concern in formulating electrodes using ferro-additions is the alloying element recovery (that is, the amount of the element that is transferred across the arc and into the weld deposit). Values for the recovery of typical elements in steel welding are given in Table 4. The metal losses are either to the slag or to the fume.

TABLE 4 RECOVERY OF ELEMENTS FROM SELECTED ELECTRODE COVERINGS

ALLOY ELEMENT	FORM OF MATERIAL IN ELECTRODE COVERING	APPROXIMATE RECOVERY OF ELEMENT, WT%
ALUMINUM	FERROALUMINUM	20
BORON	FERROBORON	2

Slipping and Binding Agents. In the case of SMAW electrodes, slipping agents are also added to the green flux formulation to improve the extrudability of the flux onto the rod (Ref 1). Glycerin, china clay, kaolin, talc, bentonite, and mica have all been used as slipping agents. Binding agents can be classified into two types. The first type comprises binders that bond the flux components to the rod without introducing a hydrogen source. These low-hydrogen binders include sodium silicate and potassium silicate. The second type of binding agent does function as a hydrogen source. The binders used for high-hydrogen electrodes can be organic in nature and include gum arabic, sugar, dextrine, and other specialized synthetic organic binders.

Slag Formation. Slag, a mixture of glass and crystalline structure, must solidify on the already solidified weld deposit to protect the surface from oxidation during cooling. Specific physical properties are required of the slag. It must melt below the melting temperature of steel (~ 1450 °C, or 2640 °F), must have a density significantly less than steel to reduce slag entrapment in the weld deposit, must possess the proper viscosity in the temperature range of 1450 to 1550 °C (2640 to 2820 °F), and must easily detach from the weld deposit after welding.

Silicates, aluminates, and titanates are all primary slag formers. The high-valence cations of these compounds produce a bonding network that can promote glass formation. Most electrodes produce silicate or titanate slag. Silicates of such elements as manganese produce very workable glass deposits, but also produce weld deposits that are relatively high in weld metal oxygen content. These fluxes are said to range from acidic to neutral. The titanate and aluminate fluxes produce more rigid and stable oxide covers. The result is a lower concentration of weld metal oxygen, but a higher-viscosity slag. Aluminates and calcium-bearing compounds are common additions to basic fluxes for the submerged arc welding of high-toughness linepipe steels. Minerals used for slag formation include:

- RUTILE
- POTASSIUM TITANATE
- ILMENITE
- ALUMINA
- SILICA FLOUR

- IRON POWDER
- FLUORSPAR
- FELDSPAR
- MANGANESE DIOXIDE

Asbestos (up to 50%) was used as a slag former, but has been phased out by welding consumable manufacturers.

Slag detachability is a serious productivity concern for steel fabricators. The relative ease of slag detachability influences the economic advantages of flux-related welding processes. Residual slag on the weld deposit promotes slag stringers in multipass weldments, limits the effective use of narrow-gap flux-related welding processes, and may reduce the corrosion resistance of the weldment. Welding flux formulators have modified flux compositions to alleviate or reduce this hindrance (Ref 25).

Poor slag removal has been reported to occur when the flux contains fluorite. Slags containing spinels generally have been found to attach tenaciously to the weld deposit. Slags with cordierite and $(Cr,Mn,Mg)O \cdot (Cr,Mn,Al)_2O_3$ type spinel phases have been reported to be difficult to remove from stainless steel weldments. It has also been reported to be difficult to remove from stainless steel weldments. It has also been reported that if $(CaO)_2SiO_2$, Cr_2TiO_5, and $FeTiO_5$ are present, the slag readily detaches from the weld deposit (Ref 25). The compositional range for acceptable slag detachability has been reported for the $CaO \cdot CaF_2 \cdot SiO_2$ system and the $CaO \cdot TiO_2 \cdot SiO_2$ system. Easier slag removal has also been related to deoxidation with aluminum instead of titanium. Increasing the Al_2O_3 content in the flux has demonstrated improved detachability (Ref 25).

Differences in the coefficient of thermal expansion between the slag and the weld are also important.

Types of Fluxes

Producing a weld deposit with high mechanical integrity and with high productivity requires many physical and chemical occurrences in the welding arc. These occurrences are achieved in flux-related arc welding processes by the careful formulation of the welding flux. The welding flux must:

- STABILIZE ARC AND CONTROL ARC RESISTIVITY
- PROVIDE SLAG WITH PROPER MELTING TEMPERATURE
- PROVIDE LOW-DENSITY SLAG
- PERMIT USE OF DIFFERENT TYPES OF CURRENT AND POLARITY
- ADD ALLOYING ELEMENTS
- REFINE THE WELD POOL (DEOXIDATION AND DESULFURIZATION)
- PROVIDE PROPER VISCOSITY FOR OUT-OF-POSITION WELDING
- PROMOTE SLAG DETACHABILITY
- PRODUCE SMOOTH WELD CONTOUR

- REDUCE SPATTER AND FUME

It is apparent, after considering the large number of necessary requirements, that a welding flux must be carefully and deliberately formulated to achieve an optimized performance.

A number of different arc welding processes depend on welding fluxes. Each of these processes requires a different formulation.

SMAW Fluxes. The typical constituents and their functions in electrode coatings for the SMAW process are given in Table 5. It should be noted that the flux ingredients are based on additions of refined minerals of the earth. Natural minerals offer an economical method of keeping welding consumables at a reasonable cost. Table 6 presents the elemental content of these minerals. Table 7 gives the typical chemical compositions for flux coatings for three different SMAW electrodes.

(A) AFTER BAKING.

Flux-cored arc welding (FCAW) uses a hollow wire filled with flux reagents and ferro-additions. The two types of flux-cored electrodes are carbon-dioxide-shielded flux-cored electrodes and self-shielded flux-cored electrodes (Ref 26). Table 8 gives typical compositions for the three types of carbon-dioxide-shielded cored electrodes. Table 9 gives the typical compositions for the four types of self-shielded flux-cored electrodes.

Submerged Arc Welding (SAW). In the SAW process, the flux drops from a hopper onto the work such that the welding arc is submerged beneath the granular flux, producing an arc cavity that contains metal vapors, silicon monoxide, manganese oxide, gaseous fluorides, and other higher-vapor-pressure components of the flux. This arc welding process has been recognized as one that produces very little, if any, fume. Submerged arc welding is limited mainly to the flat or

horizontal position, and requires significant setup time. It is very successful in manufacturing numerous similar parts, such as producing welded steel pipe.

Submerged arc fluxes are made in three different forms:

- *BONDED FLUXES* MIX NONMETALLIC AND FERRO-ADDITIONS WITH A LOW-TEMPERATURE BINDER INTO MIXTURES OF SMALL PARTICLES.
- *AGGLOMERATED FLUXES* ARE SIMILAR TO THE BONDED FLUXES EXCEPT THAT A CERAMIC GLASS BINDER, CURED AT HIGH TEMPERATURE, IS USED.
- *FUSED FLUXES* ARE MADE BY POURING A HOMOGENEOUS GLASS MIXTURE OF THE PROPER FLUX COMPOSITION INTO WATER, RESULTING IN A FRIT.

Generally speaking, changing from bonded to agglomerated to fused fluxes improves control of the weld metal composition, especially with respect to such impurities as hydrogen and oxygen.

There are seven types of submerged arc fluxes (Table 10). Flux classification according to basicity is the result of observed correlations between weld metal oxygen concentration and flux composition. Table 11 gives some typical compositions for SAW fluxes.

TABLE 10 FLUXES USED FOR SAW APPLICATIONS

FLUX TYPE	CONSTITUENTS	BASICITY	FLUX FORM	ADVANTAGES	LIMITATIONS	COMMENTS
MANGANESE SILICATE	MNO + SIO_2 > 50%	ACID	FUSED	MODERATE STRENGTH; TOLERANT TO RUST; FAST WELDING SPEEDS; HIGH HEAT INPUT; GOOD STORAGE	LIMITED USE FOR MULTIPASS WELDING; USE WHERE NO TOUGHNESS REQUIREMENT; HIGH WELD METAL OXYGEN; INCREASE IN SILICON ON WELDING; LOW IN CARBON	ASSOCIATED MANGANESE GAIN; MAXIMUM CURRENT, 1100 A; HIGHER WELDING SPEEDS
CALCIUM-HIGH SILICA	CAO + MGO + SIO_2 > 60%	ACID	AGGLOMERATED, FUSED	HIGH WELDING CURRENT; TOLERANT TO RUST	POOR WELD TOUGHNESS; USE WHERE NO TOUGHNESS REQUIREMENT; HIGH WELD METAL OXYGEN	DIFFER IN SILICON GAIN; SOME CAPABLE OF 2500 A; WIRES WITH HIGH MANGANESE
CALCIUM SILICATE-NEUTRAL	CAO + MGO + SIO_2 > 60%	NEUTRAL	AGGLOMERATED, FUSED	MODERATE STRENGTH AND TOUGHNESS; ALL CURRENT TYPES; TOLERANT TO RUST; SINGLE- OR MULTIPLE-PASS WELD	. . .	. . .
CALCIUM SILICATE-LOW SILICA	CAO + MGO + SIO_2 > 60%	BASIC	AGGLOMERATED, FUSED	GOOD TOUGHNESS WITH MEDIUM STRENGTH; FAST WELDING SPEEDS; LESS CHANGE IN COMPOSITION AND LOWER OXYGEN	NOT TOLERANT TO RUST; NOT USED FOR MULTIWIRE WELDING	. . .
ALUMINATE	AL_2O_3 + CAO +	BASIC	AGGLOMERATED	GOOD STRENGTH	NOT TOLERANT TO	USUALLY

BASIC	MGO > 45%; AL_2O_3 > 20%			AND TOUGHNESS IN MULTIPASS WELDS; NO CHANGE IN CARBON; LOSS OF SULFUR AND SILICON	RUST, LIMITED TO DC ELECTRODE POSITIVE	MANGANESE GAIN; MAXIMUM CURRENT 1200 A; GOOD MECHANICAL PROPERTIES
ALUMINA	BAUXITE BASE	NEUTRAL	AGGLOMERATED, FUSED	LESS CHANGE IN WELD COMPOSITION AND LOWER OXYGEN THAN FOR ACID TYPE; MODERATE TO FAST WELDING SPEEDS	. . .	. . .
BASIC FLUORIDE	CAO + MGO + MNO + CAF_2 > 50%; $SIO_2 \leqslant$22%; $CAF_2 \leqslant$15%	BASIC	AGGLOMERATED, FUSED	VERY LOW OXYGEN; MODERATE TO GOOD LOW-TEMPERATURE TOUGHNESS	MAY PRESENT PROBLEMS OF SLAG DETACHABILITY; MAY PRESENT PROBLEM OF MOISTURE PICKUP	CAN BE USED WITH ALL WIRES, PREFERABLE DC WELDING; VERY GOOD WELD PROPERTIES

TABLE 11 TYPICAL COMPOSITIONS OF SMAW FLUXES

FLUX	COMPOSITION, WT%									BASICITY INDEX (*BI*)

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Introduction

THE SHIELDING GAS used in a welding process has a significant influence on the overall performance of the welding system. Its primary function is to protect the molten metal from atmospheric nitrogen and oxygen as the weld pool is being formed. The shielding gas also promotes a stable arc and uniform metal transfer. In gas-metal arc welding (GMAW) and flux-cored arc welding (FCAW), the gas used has a substantial influence on the form of metal transfer during welding. This, in turn, affects the efficiency, quality, and overall operator acceptance of the welding operation.

The shielding gas interacts with the base material and with the filler material, if any, to produce the basic strength, toughness, and corrosion resistance of the weld. It can also affect the weld bead shape and the penetration pattern.

Understanding the basic properties of a shielding gas will aid in the selection of the right shielding gas or gases for a welding application. Use of the best gas blend will improve the quality and may reduce the overall cost of the welding operation as well.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Basic Properties of a Shielding Gas

The "controlled electrical discharge" known as the welding arc is formed and sustained by the establishment of a conductive medium called the arc plasma. This plasma consists of ionized gas, molten metals, slags, vapors, and gaseous atoms and molecules. The formation and structure of the arc plasma is dependent on the properties of the shielding gases used for welding. Table 1 lists the basic properties of gases used for welding (Ref 1).

TABLE 1 PROPERTIES OF SHIELDING GASES USED FOR WELDING

GAS	CHEMICAL SYMBOL	MOLECULAR WEIGHT	SPECIFIC GRAVITY(A)	DENSITY		IONIZATION POTENTIAL	
				g/ft^3	g/l	aj(b)	eV
ARGON	AR	39.95	1.38	0.1114	1.784	2.52	15.7

The ionization potential is the energy, expressed in electron volts, necessary to remove an electron from a gas atom--making it an ion, or an electrically charged gas atom. All other factors held constant, the value of the ionization potential decreases as the molecular weight of the gas increases. Arc starting and arc stability are greatly influenced by the ionization potentials of the component shielding gases used in welding process. A gas with a low ionization potential,

such as argon, can atoms into ions easily. Helium, with its significantly higher ionization potential, produces a harder to start, less stable arc.

Although other factors are involved in sustaining the plasma, the respective energy levels required to ionize these gases must be maintained; as a consequence, the arc voltage is directly influenced. For equivalent arc lengths and welding currents, the voltage obtained with helium is appreciably higher than is with argon. This translates into more available heat input to the base material with helium than with argon.

The thermal conductivity of a gas is a measure of how well it is able to conduct heat. It influences the radial heat loss from the center to the periphery of the arc column as well as heat transfer between the plasma and the liquid metal. Argon, which has a low thermal conductivity, produces an arc that has two zones: a narrow hot core and a considerably cooler outer zone. The penetration profile of the weld fusion area then exhibits a narrow "finger" at the root and a wider top. A gas with a high thermal conductivity conducts heat outward from the core; this results in a wider, hotter arc core. This type of heat distribution occurs with helium, argon-hydrogen, and argon-carbon dioxide blends; it gives a more even distribution of heat to the work surface and produces a wider fusion area.

Dissociation and Recombination. Shielding gases such as carbon dioxide, hydrogen, and oxygen are multiatom molecules. When heated to high temperatures within the arc plasma, these gases break down, or dissociate, into their component atoms. They are then at least partially ionized, producing free electrons and current flow. As the dissociated gas comes into contact with the relatively cool work surface, the atoms recombine and release heat at that point. This heat of recombination causes multiatomic gases to behave as if they have a higher thermal conductivity, similar to that of helium. Dissociation and recombination do not occur with gases, such as argon, that consist of a single atom. Thus, at the same arc temperature, the heat generated at the work surface can be considerably greater with gases such as carbon dioxide and hydrogen.

Reactivity/Oxidation Potential. The oxidizing nature of the shielding gas affects both welding performance and the properties of the resultant weld deposit. Argon and helium are completely nonreactive, or inert, and thus have no direct chemical affect on the weld metal. Oxidizing or active gases, such as CO_2 and oxygen, will react with elements in the filler metal or baseplate and will form a slag on the surface of the weld deposit. The loss of elements, such as manganese and silicon, from steel can affect the quality and cost of the weldment produced. Both weld strength and toughness generally decline as the oxidizing nature of the shielding gas increases.

Additions of reactive gases such as oxygen or carbon dioxide enhance the stability of the arc and affect the type of metal transfer obtained. Metal droplet size is decreased, and the number of droplets transferred per unit time increases as the level of oxygen in the shielding gas increases. Oxygen reduces the molten weld bead surface tension, promoting better bead wetting and higher welding travel speeds. Small additions of CO_2 work in a similar manner.

The surface tension between the molten metal and its surrounding atmosphere has a pronounced influence on bead shape. If the surface energy is high, a convex, irregular bead will result. Low values promote flatter beads with minimal susceptibility for undercutting.

Pure argon is generally associated with high interfacial energy, producing a sluggish weld puddle and high, crowned bead. The addition of a small amount of a reactive gas, such as oxygen, lowers this surface tension and promote fluidity and better wetting of the base material; it does this without creating excessive oxidation of the weld metal.

Gas Purity. Some metals, such as carbon steel and copper, have a relatively high tolerance for contaminants in the shielding gas; others, such as aluminum and magnesium, are fairly sensitive to particular contaminants. Still others, such as titanium and zirconium, have an extremely low tolerance for any foreign constituent in the shielding gas.

Depending on the metal being welded and the welding process used, very small quantities of gas impurities can significantly affect welding speed, weld surface appearance, weld bead solidification, and porosity levels. The effects of any given impurity are wide ranging, but weld quality and eventual fitness for purpose are major areas of concern.

There is always a possibility that the gas, as delivered, is contaminated; however, it is far more likely that impurities will enters somewhere between the supply and the end-use points. For this reason, property designed piping systems and high-quality hose are recommended for use with welding shielding gases. Typical industry minimum purity levels for welding gases are listed in Table 2 (Ref 2).

TABLE 2 TYPICAL GASES PURITY AND MOISTURE CONTENT OF SHIELDING

GAS	PRODUCT STATE	MINIMUM PURITY, %	MAXIMUM MOISTURE, PPM(A)	APPROXIMATE DEW POINT AT MAXIMUM MOISTURE CONTENT	
				°C	°F

(A) MOISTURE SPECIFICATIONS ARE MEASURED AT FULL CYLINDER PRESSURE, THE PRESSURE AT WHICH THE CYLINDER IS ANALYZED.

Gas density is the weight of the gas per unit volume. Density is one of the chief factors that influence shielding gas effectiveness. Basically, gases heavier than air, such as argon and carbon dioxide, require lower flow rates in use than do the lighter gases, such as helium, to ensure adequate protection of the weld puddle.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Characteristics of the Components of a Shielding Gas Blend

To obtain a shielding gas that is suited to a specific application, a mix of gases is generally needed. Each basic gas contributes certain characteristics to the performance of the overall mix. Some gas blends have relatively specific areas of application and limited operating ranges; others can be used on many materials under a variety of welding conditions. Each component of the blend brings with it properties that are supplemented by the others to produce an enhanced level of performance.

Argon is inert or unreactive with respect to the materials present in the welding electrode. With its low ionization potential, argon promotes easy arc starting and stable arc operation. Its lower thermal conductivity promotes the development of axial "spray" transfer in certain forms of GMAW. It is also used in applications where base material distortion must be controlled or where good gap-bridging ability is required.

Helium. Unlike argon, helium is lighter than air and has a low density. Like argon, it is chemically inert and does not react with other elements or compounds. Because of its high thermal conductivity and high ionization potential, more heat is transferred to the base material, thus enhancing the penetration characteristics of the arc. In many applications, it also allows higher weld travel speeds to be obtained. Because of its higher cost, helium is frequently combined with argon or argon mixtures to enhance the overall performance of the blend while minimizing its cost.

Oxygen combines with almost all known elements except rare and inert gases; it vigorously support combustion. Small amounts of oxygen are added to some inert mixtures to improve the stability of the welding arc developed as well as to increase the fluidity of the weld puddle.

In the spray-transfer mode of GMAW, small additions of oxygen enhance the range over which this spatterless form of welding can be performed. The droplet size decreases and the number of drops transferred per unit time increases as oxygen is added to the blend.

Carbon dioxide is a reactive gas that is commonly used alone in certain types of GMAW. Oxidation of the base material and any filler electrode occurs readily. Carbon dioxide is added to argon blends to improve are stability, enhance penetration, and improve weld puddle flow characteristics. The higher thermal conductivity of carbon dioxide (because of the dissociation and recombination of its component parts) transfer more heat to the base material than does argon alone. A broader penetration pattern versus argon is obtained; however, base material distortion and lack of gap-bridging ability are possible problems.

Hydrogen is the lightest known element and is a flammable gas. Explosive mixtures can be formed when certain concentration of hydrogen are mixed with oxygen or air. It is added to inert gases to increase the heat input to the base material or for operations involving cutting and gouging. Because some materials are especially sensitive to hydrogen-related contamination, its use is generally limited to special applications, such as the joining of stainless steels, and to plasma are cutting and gouging.

Nitrogen is generally considered to be inert except at high temperatures. At arc welding temperatures, it will react with some metals (e.g., aluminum, magnesium, steel, and titanium), so it is not used as a primary shielding gas. It can be used with other gases for some welding applications (e.g., copper) and is also widely used in plasma cutting.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Shielding Gas Selection

In most welding applications, more than one shielding gas or gas blend can be used successfully. For example, there is no one optimal gas blend for joining carbon steels, but a considerable array of mixes are available depending on the specific requirements of the application. For some processes, such as gas-tungsten arc welding (GTAW) and plasma arc welding (PAW), the choices may be somewhat limited by the nature of the electrodes used and the materials being welded. However, for applications involving GMAW, a multitude of blends can be selected from when carbon steels are being joined. Determination of the best blend depends on a number of specific job-related needs.

Accuracy of Gas Blends

The accuracy with which gases are blended is a function of the way in which they are supplied. If the source of the gas is a high-pressure cylinder, the following generally applies:

1. ±10% RELATIVE, MINOR COMPONENT (REF 3)

2. ±0.5% ABSOLUTE FOR CONCENTRATIONS UP TO 5%; ±10% RELATIVE FOR CONCENTRATIONS BETWEEN 5 AND 50% (REF 4)

For example, the mix accuracy of an Ar-2O_2 blend would be Ar/1.8-2.2O_2 (method 1) or Ar/1.5-2.5O_2 (method 2). A blend of Ar-25CO_2 would yield Ar/22.5-27.5CO_2 by their method of calculation.

When gas cylinders are properly filled with the appropriate blend, the components of that mixture will not separate unless the temperature of the environment is reduced far below normal working temperatures. If the gases are supplied from a liquid source, such as a bulk tank, the accuracy of the blend is a function of the mixing equipment used, but most likely falls within the ±10% minor component range.

Shielding Gases for GMAW

By far, the largest number of gas blends have been developed for GMAW, especially for joining carbon steel. These can be roughly divided into four categories: pure gases, argon-oxygen mixes, argon/carbon dioxide mixes, and three-part gas blends composed of either argon, helium, oxygen, carbon dioxide, or hydrogen. Table 3 contains suggestions for shielding gas selection based on material type, thickness, and mode of metal transfer.

TABLE 3 RECOMMENDED SHIELDING GAS SELECTION FOR GMAW

MATERIAL	THICKNESS		TRANSFER MODE	RECOMMENDED SHIELDING GAS	ADVANTAGES AND LIMITATIONS
	MM	IN.			
CARBON STEEL	<2.0	<0.080	SHORT CIRCUITING	AR-25CO_2 AR-15CO_2 AR-8CO_2	GOOD PENETRATION AND DISTORTION CONTROL TO REDUCE POTENTIAL BURNTHROUGH
	2.0-3.2	0.080-0.125	SHORT CIRCUITING	AR-8CO_2 AR-15CO_2 AR-25CO_2	HIGHER DEPOSITION RATES WITHOUT BURNTHROUGH: MINIMUM DISTORTION AND SPATTER; GOOD PUDDLE CONTROL FOR OUT-OF-POSITION WELDING
	>3.2	>0.125	SHORT CIRCUITING	AR-15CO_2 AR-25CO_2 CO_2	HIGH WELDING SPEEDS, GOOD PENETRATION AND PUDDLE CONTROL; APPLICABLE LOT OUT-OF-POSITION WELDS
			GLOBULAR	AR-25CO_2 CO_2	SUITABLE FOR HIGH-CURRENT AND HIGH-SPEED WELDING; DEEP PENETRATION AND FAST TRAVEL SPEEDS, BUT WITH GREATER BURNTHROUGH POTENTIAL
			CONVENTIONAL SPRAY ARC	AR-1O_2 AR-2O_2 AR-5CO_2	GOOD ARC STABILITY; PRODUCES A MORE FLUID PUDDLE AS O_2

				AR-8CO_2 AR-10CO_2 AR-15CO_2 AR-CO_2-O_2 BLENDS	INCREASES; GOOD COALESCENCE AND BEAD CONTOUR, GOOD WELD APPEARANCE AND PUDDLE CONTROL
			PULSED SPRAY	ARGON-5CO_2 AR-HE-CO_2 BLENDS AR-CO_2-O_2 BLENDS	USED FOR BOTH GAGE AND OUT-OF-POSITION WELDMENTS; ACHIEVES GOOD PULSED SPRAY STABILITY OVER A WIDE RANGE OF ARC CHARACTERISTICS AND DEPOSITION RANGES
ALLOY STEEL	ALL SIZES		SHORT CIRCUITING	AR-8CO_2 AR-15CO_2 AR-CO_2-O_2 BLEND	HIGH WELDING SPEEDS; GOOD PENETRATION AND PUDDLE CONTROL; APPLICABLE FOR OUT-OF-POSITION WELDS; SUITABLE FOR HIGH-CURRENT AND HIGH-SPEED WELDING
			SPRAY ARC (HIGH-CURRENT DENSITY AND ROTATIONAL)	AR-2O_2 AR-5O_2 AR-CO_2-O_2 BLENDS AR-HE-CO_2 BLENDS	REDUCES UNDERCUTTING; HIGHER DEPOSITION RATES AND IMPROVED BEAD WETTING; DEEP PENETRATION AND GOOD MECHANICAL PROPERTIES
			PULSED SPRAY	AR-5CO_2 AR-8CO_2 AR-2O_2	USED FOR BOTH LIGHT-GAGE AND HEAVY OUT-OF-POSITION WELDMENTS; ACHIEVES GOOD PULSED SPRAY STABILITY OVER A WIDE RANGE OF ARC CHARACTERISTICS AND DEPOSITION RANGES
STAINLESS STEEL, COPPER, NICKEL, AND CU-NI ALLOYS	ALL SIZES		SHORT-CIRCUITING TRANSFER	AR-HE-CO_2 BLENDS HE-AR-CO_2 BLENDS AR-1O_2 AR-2O_2	LOW CO_2 CONTENTS IN HELIUM MIX MINIMIZE CARBON PICKUP, WHICH CAN CAUSE INTERGRANULAR CORROSION WITH SOME ALLOYS; HELIUM IMPROVES WETTING ACTION; CO_2 CONTENTS >5% SHOULD BE USED WITH CAUTION ON

					SOME ALLOYS; APPLICABLE FOR ALL POSITION WELDING
			SPRAY ARC	AR-HE-CO_2 BLENDS AR-1O_2 AR-2O_2	GOOD ARC STABILITY; PRODUCES A FLUID BUT CONTROLLABLE WELD PUDDLE; GOOD COALESCENCE AND BEAD CONTOUR; MINIMIZES UNDERCUTTING ON HEAVIER THICKNESSES
			PULSED SPRAY	AR-HE-CO_2BLENDS AR-1O_2 AR-2O_2	USED FOR BOTH LIGHT-GAGE AND HEAVY OUT-OF-POSITION WELDMENTS; ACHIEVES GOOD PULSED SPRAY STABILITY OVER A WIDE RANGE OF ARC CHARACTERISTICS AND DEPOSITION RANGES
ALUMINUM, TITANIUM, AND OTHER REACTIVE METALS	≤ 13	$\leq \frac{1}{2}$	SPRAY ARC	ARGON	BEST METAL TRANSFER, ARC STABILITY, AND PLATE CLEANING; LITTLE OR NO SPATTER; REMOVES OXIDES WHEN USED WITH DCEP (REVERSE POLARITY)
			SPRAY ARC	75HE-25AR 50HE-50AR	HIGH HEAT INPUT; PRODUCES FLUID PUDDLE, FLAT BEAD CONTOUR, AND DEEP PENETRATION; MINIMIZES POROSITY
	>13	$> \frac{1}{2}$	SPRAY ARC	HELIUM 50HE-25AR	HIGH HEAT INPUT; GOOD FOR MECHANIZED WELDING AND OVERHEAD; APPLICABLE TO HEAVY SECTION WELDING
			PULSED SPRAY	ARGON	GOOD WETTING; GOOD PUDDLE CONTROL

Argon. Pure argon is generally used on nonferrous base metal, such as aluminum, nickel, copper, and magnesium alloys, and on reactive metals, such as titanium. Argon provides excellent arc stability, penetration, and bead profile when joining these materials. Its low ionization potential results in easy arc starting. Argon produces a constricted arc column with high current density, which concentrates the arc energy over a small area; deep, fingerlike penetration results.

Carbon Dioxide. A reactive gas, carbon dioxide is generally used only for joining carbon steel. It is readily available and relatively inexpensive. Because CO_2 will not support spray transfer, deposition efficiency is lower and spatter and fume

levels are higher than with argon blends. Weld bead surfaces are more oxidized and irregular in shape. The higher ionization potential of CO_2 and its characteristic dissociation upon heating provide greater weld fusion and penetration while still achieving acceptable mechanical properties.

Helium. Because of its higher thermal conductivity, helium can provide additional heat input to the base material while still maintaining an inert atmosphere. Wetting action, depth of fusion, and travel speed can be improved over comparable argon levels. This advantage is most frequently utilized in the welding of heavier sections of aluminum, magnesium, and copper alloys.

Argon-Oxygen. The addition of a small amount of oxygen to a argon greatly stabilizes the welding arc, increases the filler metal droplet rate, lowers the spray transition current, and influences bead shape. The weld pool is more fluid and stays molten longer, allowing the metal to flow out toward the edges of the weld (Fig. 1a).

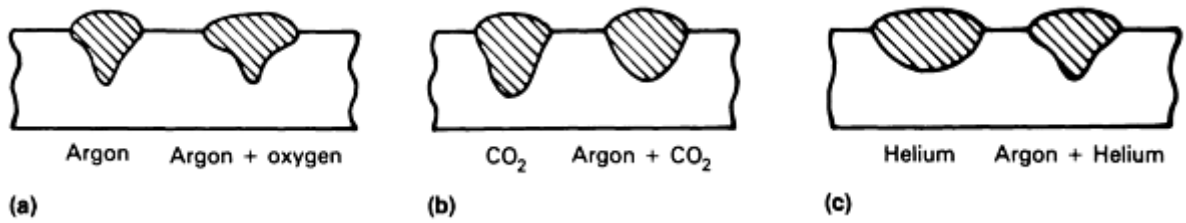

FIG. 1 EFFECT OF SHIELDING GAS BLENDS ON WELD PROFILE USING DIRECT CURRENT ELECTRODE POSITIVE (DCEP). (A) ARGON VERSUS ARGON-OXYGEN. (B) CARBON DIOXIDE VERSUS ARGON/CARBON DIOXIDE. (C) HELIUM VERSUS ARGON-HELIUM. SOURCE: REF 5

The most common blends contain 1, 2, 5, or 8% O_2 in argon. Increasing oxygen improves arc stability and makes higher travel speeds possible by enhanced puddle fluidity. Some increased alloy loss and a greater chance of undercut occur as the oxygen level is increased, especially beyond 5%.

Argon/carbon dioxide blends are primarily used for carbon and low-alloy steels and have limited use for stainless steels. The addition of CO_2 to argon produces results similar to the addition of oxygen, but is also broadens the penetration pattern as the CO_2 content is increased (Fig. 1b). Above a range of 18 to 20% CO_2, spraylike transfer can no longer be obtained; short-circuiting/globular transfer with somewhat increased spatter levels is found from this point up to approximately 50% CO_2 in argon.

The most common blends for spray transfer are argon plus 5, 8, 10, or 13 to 18% CO_2. With increased CO_2 content, the more fluid weld puddle permits higher weld travel speeds.

Mixes with higher carbon dioxide levels can also be used for short-circuiting transfer--commonly, argon plus 20 or 25% CO_2. Mixtures in this range provide an optimum droplet frequency for minimum spatter when small-diameter (0.9 and 1.2 mm, or 0.035 and 0.045 in.) wire is used.

Argon-Helium. Helium is often mixed with argon to obtain the advantages of both gases. These blends are primarily used for nonferrous base materials, such as aluminum, copper, and nickel alloys. Helium increases the heat input to the base material and thus is used for joining thick, thermally conductive plates. As the helium percentage increases, the arc voltage, spatter, and weld width-to-depth ratio increase (Fig. 1c).

The most common blends contain 25, 50, or 75% He in argon. The highest percentage of helium is used for joining thick (>50 mm, or 2 in.) plate material, especially aluminum and copper. Higher travel speeds can be obtained using helium-enhanced blends.

Argon/Oxygen/Carbon Dioxide. Mixtures containing three gas components are versatile because of their ability to operate in short-circuiting, globular, and spray-transfer modes. These blends are generally proprietary, and manufacturers' recommendations should be followed for their proper use. Blends of argon, carbon dioxide, and oxygen are generally used to join carbon and alloy steels.

Argon/Helium/Carbon Dioxide. Helium and carbon dioxide additions to argon increase the heat input to the base metal, which improves wetting, puddle fluidity, and weld bead profile. With helium plus CO_2 additions less than 40%, good spray transfer is obtained for carbon and low-alloy steel welding. Some increase in tolerance of base material surface contamination is also noted.

When the helium content exceeds 50 to 60%, transfer is restricted to short-circuiting and globular. Blends in which the CO_2 content is relatively low ($\leq 5\%$) are generally used for the joining of stainless steels without any loss in corrosion resistance.

Argon/Carbon Dioxide/Hydrogen. Three-part blends of this design are intended for the joining of austenitic stainless in the spray or short-circuiting transfer modes. Because of the addition of hydrogen, these blends should not be used for carbon steel. The carbon dioxide and hydrogen increase the heat input to the base material and improve bead shape characteristics, as well as promote higher welding travel speeds.

Shielding Gas Selection for FCAW

Carbon Dioxide. The majority of large-diameter (>1.6 mm, or $\frac{1}{16}$ in.) wires that use a shielding gas use carbon dioxide. Some smaller diameter wires are formulated to operate in 100% CO_2. The arcs are generally stable and provide a globular transfer over the usable operating range. Good performance over rust and mill scale on the plate surface is obtained with these large-diameter wires and CO_2 shielding.

Argon/Carbon Dioxide. A significant number of small-diameter (≤ 1.6 mm, or $\frac{1}{16}$ in.) cored wires are shielded with the blends of argon with 15 to 50% CO_2. These blends provide better out-of-position weld puddle control versus that of CO_2. To obtain the best performance from a particular cored wire, check the manufacturer's product literature for the recommended gas blend.

Shielding Gas Selection for GTAW

Argon. The most commonly used gas for GTAW, argon exhibits low thermal conductivity, which produces a narrow, constricted arc column; this allows greater variations in arc length with minimal influence on arc power or weld bead shape. Its low ionization potential provides good arc starting characteristics and good arc stability using the direct current electrode negative (DCEN) power connection plus superior arc cleaning action and bead appearance when ac power is used. Argon is the most commonly selected gas for DCEN welding of most materials and ac manual welding of aluminum.

Helium. The high thermal conductivity and ionization potential of helium make it suitable for the high-current joining of heavy sections of heat-conductive materials such as aluminum. Helium increases the penetration of the weld as well as its width. It also allows the use of higher weld travel speeds.

Argon-Helium. Blends of argon and helium are selected to increase the heat input to the base material while maintaining favorable arc stability and superior arc starting characteristics. Blends of 25, 50, and 75% He in argon are commonly used.

Argon-Hydrogen. Hydrogen is added to argon to enhance its thermal properties. The slightly reducing atmosphere improves weld puddle wetting and reduces some surface oxides to produce a cleaner weld surface. To minimize problems associated with arc starting, additions of hydrogen are generally limited to 5 to 15%. These blends are primarily used to join some stainless steels, nickel, and nickel alloys. These mixtures should not be used to join alloy steels; delayed weld cracking may result.

Argon/2-5H_2 is used in manual welding applications on materials thicker than 1.6 mm ($\frac{1}{16}$ in.). Additions of 10 to 15% H_2 are used in mechanized applications, such as those found in the manufacture of stainless steel tubing.

Caution: Special safety precautions are required when mixing argon and hydrogen. Do not attempt to mix argon and hydrogen from separate cylinders. Always purchase ready-mixed hydrogen blends from a qualified supplier.

Shielding Gas Selection for PAW

The physical configuration of the PAW system requires the use of two gases: a "plasma" or orifice gas and a shielding gas. The primary role of the plasma gas, which exits the torch through the center orifice, is to control arc characteristics and shield the electrode. The shielding gas, introduced around the periphery of the arc, shields or protects the weld area. In many applications, the shielding gas is also partially ionized to enhance the performance of the plasma gas.

Low-Current (<100 A) PAW. Argon is the preferred plasma gas for low-current PAW because of its low ionization potential, which ensures easy and reliable arc starting. Argon-hellium mixtures are used for some applications requiring higher heat inputs. The choice of the shielding gas depends on the type and thickness of the base material. Recommendations can be found in Table 4.

TABLE 4 RECOMMENDED GUIDELINES FOR SELECTING PAW SHIELDING GASES

MATERIAL	THICKNESS		MODE OF PENETRATION	
	MM	IN.	KEYHOLE TECHNIQUE[C]	MELT-IN TECHNIQUE[D]

Source: Ref 6, 7

(A) GAS SELECTIONS SHOWN ARE FOR SHIELDING GAS ONLY. ORIFICE GAS IN ALL CASES IS ARGON.

(B) GAS SELECTIONS SHOWN ARE FOR BOTH THE ORIFICE AND SHIELDING GAS.

(C) PROPERLY BALANCED GAS FLOW RATES PRODUCE COMPLETE JOINT PENETRATION BY FORMING A SMALL WELD POOL WITH A HOLE PENETRATING COMPLETELY THROUGH THE BASE METAL. AS THE PLASMA TORCH IS MOVED, METAL MELTED BY THE ARC IS FORCED TO FLOW AROUND THE PLASMA STEAM PRODUCING THE "KEYHOLE" TO THE REAR WHERE THE WELD POOL IS FORMED AND SOLIDIFIED.

(D) CONVENTIONAL FUSION WELDING SIMILAR TO THAT DONE WITH GTAW.

High-Current ([ges]100 A) PAW. The choice of gas used for high-current PAW also depends on the material to be welded. In almost all cases, the shielding gas is the same as the orifice gas. Again, argon is suitable for welding all metals, but it does not necessarily produce optimum results. Depending on the welding mode used (keyhole or melt-in), the optimum gas blend will vary. Table 4 lists gases recommended on the basis of materials joined.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Influence of Shielding Gas on Weld Mechanical Properties

The mechanical properties of a weld are dependent on specific characteristics of the shielding gas. When the gas blend is totally inert, the effects are less pronounced and are derived more indirectly. In this case, the shielding gas affects penetration and solidification, which can influence the microstructure of the resulting weld.

When the shielding gas contains active components, such as oxygen or carbon dioxide, the influence is direct and more substantial. The oxygen potential of the shielding gas influences the amount of surface slag, the fume emission rate, the fluidity of the weld puddle, and the mechanical properties (both strength and toughness) of the weld metal. A number of empirical formulas have been developed to estimate the oxygen potential of a gas blend (Ref 8); the differences lie in their treatment of the CO_2 component of the gas mix. Because parameters other than gas composition can affect the

oxygen level of the weld metal (e.g., welding speed), most of the recently developed formulas are also welding parameter and material specific. Their importance centers on how the oxidation potential is linked to elemental loss of silicon and manganese in the weld metal, to weld metal oxygen content, and to weld mechanical properties.

Because a relatively complex relationship exists between the loss of alloying elements, the composition of the shielding gas, and the mechanical properties of the resulting weld metal it is difficult to select an optimum gas blend that will work well with all types of wires. This influence is most noticeable in the gas metal-arc welding of carbon steel. Figure 2 (Ref 8) and Table 5 (Ref 9) illustrate the effect of the shielding gas on impact strength and tensile strength. In general, as the oxidation potential of the shielding gas increases, the toughness and the tensile strength of the weld deposit decrease. Because of their lower oxidizing gas content, argon blends will generally produce weld properties superior to those obtained by shielding with CO_2 only. There appears to be an "optimum" oxygen content, as too low an oxygen level can also be detrimental to toughness.

TABLE 5 EFFECT OF SHIELDING GAS ON CARBON, MANGANESE, AND SILICON LOSSES AND ON WELD STRENGTH VALUES

SHIELDING GAS[A]	ULTIMATE TENSILE STRENGTH		YIELD STRENGTH		ELONGATION, %	WELD METAL COMPOSITION, %[B]

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Shielding Gas and Fume Generation

The shielding gas used in solid and flux-cored wire welding affects the rate at which fumes are produced during welding, as well as the composition of the fumes. The type of shielding gas also affects the composition of the pollutant gases in the welding area. The fumes and gases generated in some welding applications impact on health and safety; therefore, it is important for the user to review the Material Safety Data Sheets and precautionary labeling provided by the manufacturers and suppliers of welding consumables. Welding safety and health information can be also be found in this Handbook and in ANSI Z49.1, "Safety in Welding and Cutting."

Fume generation rates are generally highest when CO_2 shielding is used. Inert gas blends containing CO_2 produce higher fume levels than those containing only oxygen additions. For solid wire welding at the same weld metal deposition rate, argon blends typically generate significantly less fumes than when CO_2 only is used (Ref 10, 11, 12). Figure 3 (Ref 13) illustrates the dependence of the fume generation rate on shielding gas composition as a function of current level in GMAW. Similar trends can be seen when using gas-shielded flux-cored wires.

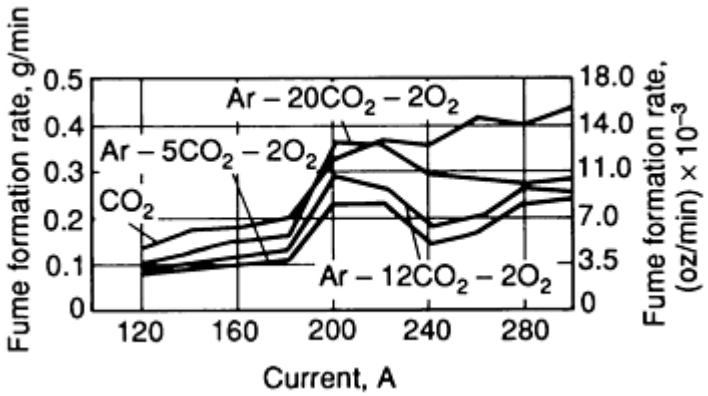

FIG. 3 PLOT OF FUME FORMATION RATE VERSUS CURRENT FOR MILD STEEL SOLID WIRE USING SELECTED SHIELDING GASES. SOURCE: REF 13

Pollutant gases must be considered when arc welding. The gases of greatest interest arc carbon monoxide, ozone, and nitrogen oxides. When CO_2 is used for shielding in confined spaces, CO can be a potential problem. Ozone can be a concern when high-energy gas-shielded welding is conducted, particularly on aluminum and stainless steel plate. It is produced in the immediate arc area as well as in the surrounding environment. Oxides of nitrogen can be present in some plasma welding and cutting applications (Ref 14).

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Self-Shielded Flux-Cored Arc Welding

The self-shielded flux-cored wire welding process employs a continuous wire electrode that requires no external shielding. These cored wires generate protective shielding gases from components in the core material similar to those found in coated electrodes. The unique feature of this class of consumables is that they rely only partly on the exclusion of air from the molten electrode and weld pool to produce a quality deposit. In addition to deoxidizers, they contain denitriders to react with nitrogen that may be entrained in the molten metal. The less a given consumable relies on shielding and the more it relies on "killing" to control nitrogen and produce sound weld metal, the less that consumable will be affected by cross air currents and side winds.

Through careful control of welding parameters and the proper balance of core constituents, good-quality weld metal can be obtained under poor welding conditions. Self-shielded flux-cored wires are especially suited to welding outdoors, where it is difficult to provide acceptable external gas shielding. Both light- and heavy-gage materials have been successfully joined with these electrodes.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

Introduction

SOLID-STATE TRANSFORMATIONS occurring in a weld are highly nonequilibrium in nature and differ distinctly from those experienced during casting, thermomechanical processing, and heat treatment. This discussion will primarily focus on the welding metallurgy of fusion welding of steels and attempt to highlight the fundamental principles that form the basis of many of the recent developments in steels and consumables for welding. Accordingly, examples are largely drawn from the well-known and relatively well-studied case of ferritic steel weldments to illustrate the special physical metallurgical considerations brought about by the weld thermal cycles and by the welding environment. Because of space limitations, only a very brief discussion is included on welds in other alloy systems such as stainless steels and aluminum-base, nickel-base, and titanium-base alloys. For detailed information on how the principles explained in the first part of this article (using steel weldments as an example) are applicable to other materials, the reader is referred to the Sections where individual alloy systems are discussed (see "Selection of Stainless Steels," "Selection of Nonferrous Low-Temperature Materials," "Selection of Nonferrous High-Temperature Materials," and "Selection of Nonferrous Corrosion-Resistant Materials" in this Volume).

A concise method of describing the transformation behavior of a steel is by a continuous cooling transformation (CCT) diagram (Fig. 1). However, a conventional CCT diagram such as the one shown in Fig. 1 cannot be used to accurately describe the transformation behavior in a weldment of the same material because weld thermal cycles are very different from those used for generating conventional CCT diagrams.

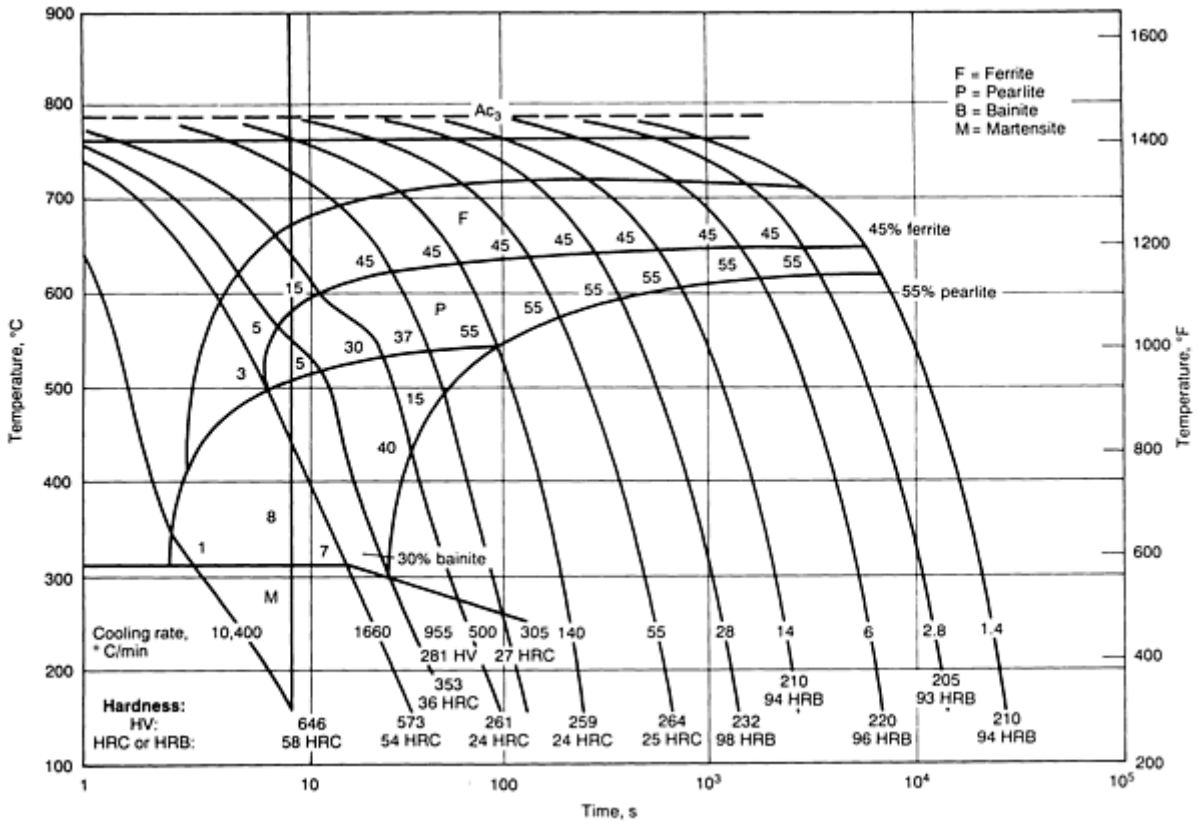

FIG. 1 CONVENTIONAL CCT DIAGRAM FOR AISI 1541 (0.39C-1.56MN-0.21SI-0.24S-0.010P) PLAIN CARBON STEEL WITH ASTM NUMBER 8 GRAIN SIZE AND AUSTENITIZATION AT 980 °C (1800 °F). FOR EACH OF THE COOLING CURVES IN THE PLOT (GIVEN IN TERMS OF °C/MIN), THE TRANSFORMATION START AND END TEMPERATURES GIVEN BY THE CCT CURVES, THE AMOUNT OF EACH TRANSFORMATION PRODUCT, AND THE HARDNESS OF THE FINAL STRUCTURE ARE SHOWN. AC_3, 788 °C (1450 °F); AC_1, 716 °C (1321 °F). F, FERRITE; P, PEARLITE; B, BAINITE; M, MARTENSITE. SOURCE: REF 1

Special Factors Affecting Transformation Behavior in a Weldment

Several aspects of the weld thermal cycle and weld segregation should be considered because of their effect on the transformation upon cooling:

- PEAK TEMPERATURES REACHED IN THE HEAT-AFFECTED ZONE (HAZ) CAN BE VERY MUCH HIGHER THAN THE AC_3 TEMPERATURE (THAT IS, THE TEMPERATURE AT WHICH TRANSFORMATION OF FERRITE TO AUSTENITE IS COMPLETED DURING HEATING). THE HEATING RATES ARE VERY HIGH, AND THE TIMES SPENT AT HIGH TEMPERATURE ARE ONLY OF THE ORDER OF A FEW SECONDS.
- THE TEMPERATURE GRADIENT IN THE HAZ IS VERY STEEP, AND THIS COMPLICATES THE PROBLEM OF STUDYING IN *IN SITU* TRANSFORMATIONS IN THE HAZ DURING WELDING (REF 2).
- DURING SOLIDIFICATION OF THE WELD METAL, ALLOYING AND IMPURITY ELEMENTS TEND TO SEGREGATE EXTENSIVELY TO THE INTERDENDRITIC OR INTERCELLULAR REGIONS UNDER THE CONDITIONS OF RAPID COOLING. ALSO, THE PICKUP OF ELEMENTS LIKE OXYGEN BY THE MOLTEN WELD POOL LEADS TO THE ENTRAPMENT OF OXIDE INCLUSIONS IN THE SOLIDIFIED WELD. THESE INCLUSIONS THEN SERVE AS HETEROGENEOUS NUCLEATION SITES AND CAN SUBSTANTIALLY INFLUENCE THE KINETICS OF SUBSEQUENT SOLID STATE TRANSFORMATIONS. ACCORDINGLY, THE WELD METAL TRANSFORMATION BEHAVIOR IS QUITE DIFFERENT FROM THAT OF THE BASE METAL, EVEN THOUGH THE NOMINAL CHEMICAL COMPOSITION HAS NOT BEEN SIGNIFICANTLY CHANGED BY THE WELDING PROCESS (REF 3). MOST OF THE CCT DIAGRAMS (APPLICABLE TO THE WELD METAL) HAVE BEEN GENERATED BY REHEATING THE AS-DEPOSITED WELD METAL (REF 4). ONE OF THE LIMITATIONS OF THESE DIAGRAMS IS THAT THEY ARE STRICTLY APPLICABLE ONLY TO THE HIGH-TEMPERATURE REHEATED ZONE OF MULTIPASS WELDS, BECAUSE THE INITIAL MICROSTRUCTURE AT HIGH TEMPERATURES IS NOT CHARACTERISTIC OF THAT DEVELOPED FROM THE LIQUID PHASE.
- WELDING MAY BE CARRIED OUT IN SEVERAL PASSES, AND THIS MAY RESULT IN THE SUPERPOSITION OF SEVERAL DIFFERENT HEATING AND COOLING CYCLES AT ONE POINT, EACH OF THESE CYCLES HAVING THE CHARACTERISTICS NOTED ABOVE.
- SOLIDIFICATION OF THE WELD METAL IS ACCOMPANIED BY SHRINKAGE, AND THE ANISOTHERMAL CONDITIONS ALREADY EMPHASIZED CAUSE DEFORMATION. THE THERMAL CYCLES ARE THEREFORE ACTING ON METAL THAT IS SUBJECTED TO MECHANICAL STRESSES AT THE SAME TIME.

The essential differences between weld thermal cycles and then thermal cycles used for generating a conventional CCT diagram are summarized in Fig. 2. Figure 2(a) shows thermal cycles which involve a slow heating rate, soak at a temperature just above the Ac_3 temperature, and various constant cooling rates. Instead of a constant cooling rate, some investigators (Ref 5) have used cooling curves according to Newton's law of cooling:

$$T \propto E^{-T} \qquad \textbf{(EQ 1)}$$

where T is the temperature and t is the time. Others have used cooling curves corresponding to the mid-radial position of cylindrical bars of different diameters when cooled in air or when quenched in different media. The weld thermal cycles shown in Fig. 2(b) are very different, and this is why a conventional CCT diagram can give only an approximate idea of the transformation behavior in the HAZ of a weldment.

HAZ of a Single-Pass Weld

Peak Temperature-Cooling Time Diagrams. The gradient in microstructure than can be obtained in a single-pass weld is shown in Fig. 3. High peak temperatures in the HAZ just adjacent to the fusion line cause coarsening of the austenite (γ) grains, and this in turn increases the hardenability of this region compared to other regions. Because each of the subzones shown in Fig. 3 occurs in a small volume, it is difficult to study the transformation behavior of individual regions by *in situ* methods (Ref 2). It is more convenient to obtain information about the microstructural and property changes in the HAZ by weld simulation (Ref 6, 7). A thermal cycle simulator (TCS) is used to reproduce the thermal cycle corresponding to a point in the HAZ in a large volume (usually a specimen has the Charpy test specimen dimensions). It is possible to program the required thermal cycle in the TCS so that the peak temperature and the cooling rate can be varied independently. It is thus possible to obtain information about the microstructural changes in the HAZ for a wide range of welding parameters.

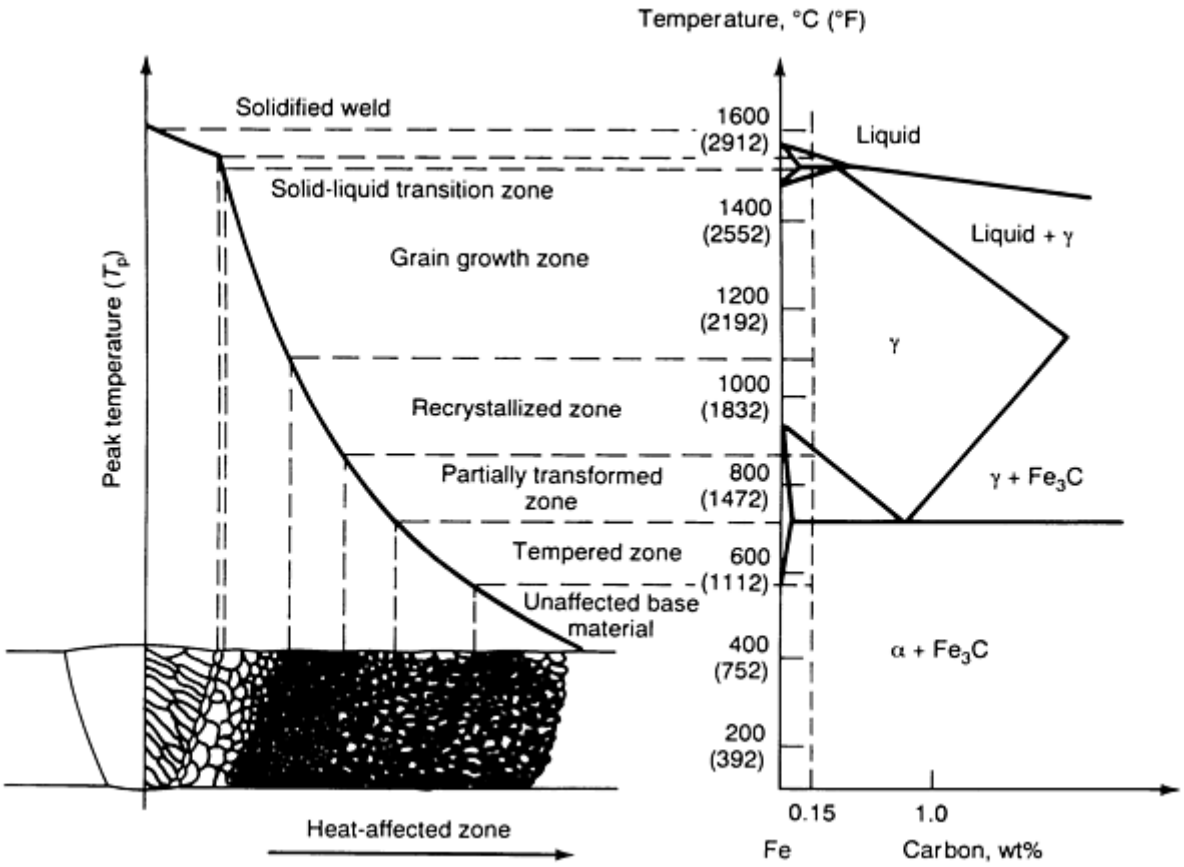

FIG. 3 SCHEMATIC SHOWING VARIOUS SUBZONES THAT CAN FORM IN THE HAZ OF A CARBON STEEL CONTAINING 0.15% C. SOURCE: REF 6

Figure 4 shows how a change in the peak temperature of the thermal cycle affects the CCT characteristics of a steel. The well-known effect of a larger γ grain size (due to a higher peak temperature) in increasing the hardenability of the steel is seen. To present the information about the CCT behavior for a number of peak temperatures (see Fig. 2b and 3), it is more convenient to adopt the scheme shown in Fig. 5. In this peak temperature-cooling time (PTCT) diagram (Ref 8, 9), each point represents a weld thermal cycle with a peak temperature, T_p, given by the ordinate and the cooling time, $\Delta t_{8\text{-}5}$ (that is, required for cooling from 800 to 500 °C, or 1470 to 930 °F), given by the abscissa. A microstructural constituent or a combination of two or more constituents is shown to occur over an area in the diagram. The upward slope in the boundary between two areas is consistent with the information presented earlier in Fig. 4 that the hardenability increases with an increase in the peak temperature of the thermal cycle. Hardness and C_v transition temperatures are also shown in the diagram corresponding to different thermal cycles.

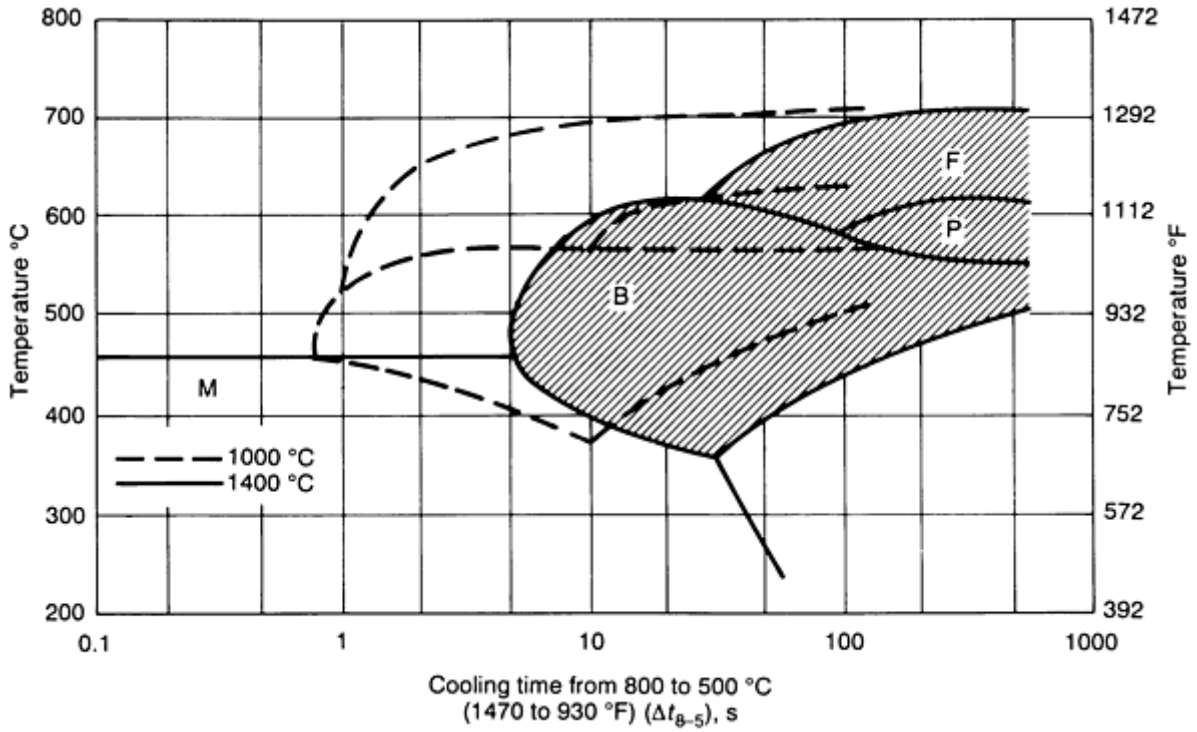

FIG. 4 EFFECT OF A CHANGE IN THE PEAK TEMPERATURE OF THE WELD THERMAL CYCLE (FROM 1000 TO 1400 °C, OR 1830 TO 2550 °F) ON THE CCT CHARACTERISTICS. M, MARTENSITE; B, BAINITE; P, PEARLITE; F, FERRITE. SOURCE: REF 8

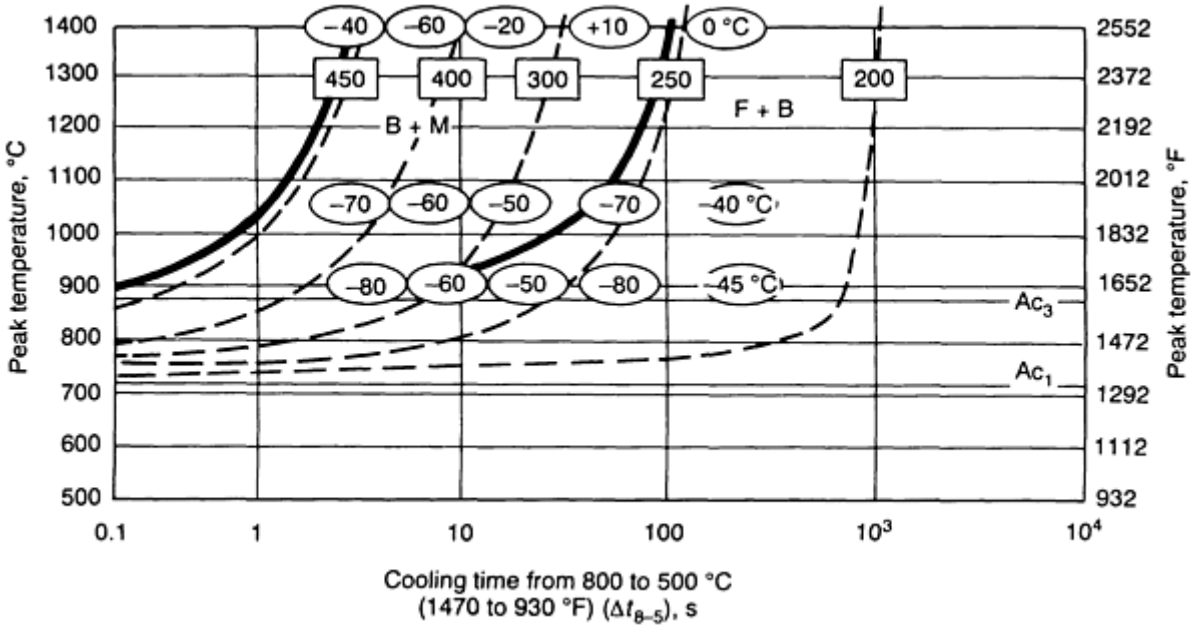

FIG. 5 TYPICAL PEAK TEMPERATURE VERSUS COOLING TIME DIAGRAM, SHOWING THE EFFECTS OF THESE PARAMETERS OF A WELD THERMAL CYCLE ON THE FINAL TRANSFORMATION PRODUCTS, ON HARDNESS, AND CHARPY V-NOTCH IMPACT ENERGY. FIGURES IN SQUARES INDICATE THE HARDNESS (30 HV); FIGURES IN OVALS INDICATE THE 21 J (16 FT · LBF) TRANSITION TEMPERATURES FOR CHARPY V-NOTCH IMPACT SPECIMENS SUBJECTED TO A SPECIFIC THERMAL CYCLE. SOURCE: REF 9

It may appear strange that the CCT diagram shown in Fig. 4 is plotted with $\Delta t_{8\text{-}5}$ as the abscissa instead of time as in Fig. 1. Historically, the practice of thinking in terms of a cooling time began when a need was recognized (Ref 5) to compare the CCT behavior of specimens subjected to different types of cooling curves--Jominy specimens; cylindrical bars cooled in air, water, or oil; dilatometer specimens cooled at a constant or a Newtonian rate; and so on. Initially, the cooling rate at 704 °C (1300 °F) was used as a criterion to judge the equivalency of these specimens in terms of microstructure and hardness. Because transformation takes place at lower temperatures in many steels, the half cooling time (Ref 5) was found to be a better equivalency criterion. The half cooling time was defined as the time to cool from Ac_3 to a temperature that lies midway between Ac_3 and room temperature. For the sake of general applicability, this was later modified to the $\Delta t_{8\text{-}5}$ criterion, and CCT diagrams began to be plotted with $\Delta t_{8\text{-}5}$ as the abscissa. It must be noted that using $\Delta t_{8\text{-}5}$ as an equivalency criterion is just an expedient solution that does not have strict theoretical justification (refer, for example, to the additivity principle in Ref 5).

A special significance of using $\Delta t_{8\text{-}5}$ as the abscissa in Fig. 5 is that it is almost constant (for T_p > 900 °C, or 1650 °F) in the whole of the HAZ. This can be seen from Ref 6, where the expressions given for $\Delta t_{8\text{-}5}$ do not contain the distance from the weld centerline as a factor. The derivation of these expressions is based on the assumption that the time to cool to 800 °C (1470 °F) is far greater than the time to reach the peak temperature, so the $\Delta t_{8\text{-}5}$ can be taken to be the same for the whole of the weld and the HAZ. This can be intuitively rationalized by observing that the thermal cycles in Fig. 2(b) are such that the curves are approximately parallel below 800 °C (1470 °F). The constancy of $\Delta t_{8\text{-}5}$ in the HAZ means that the gradient in microstructure (in terms of the final transformation products from austenite) is mainly due to a variation in the peak temperature. By drawing a vertical line in Fig. 5 at a value of $\Delta t_{8\text{-}5}$ corresponding to a given heat input and preheating temperature, it is possible to get information about the type of microstructural gradient in the HAZ. An idea of property changes like hardness and toughness can also be obtained from Fig. 5.

A fairly satisfactory correlation between real welds and simulation studies has been observed with respect to microstructure and property measurements. However, it has frequently been observed that the maximum prior to austenite grain size in real welds is less than that in corresponding simulation specimens (Ref 2, 6, 7). It is believed that this is due to the growth of large grains in the HAZ of real welds being hindered by the adjacent smaller grains. The constraint arises from the fact that grain growth in real welds is in some sense directional, occurring from the fusion line toward lower temperatures, while under the simulation condition the austenite grains can grow in all directions.

The above discussion shows that the PTCT diagram (along with property measurements, as in Fig. 5) can alert the user to the possibility of local brittle zones in actual weldments, and that any error in the property being assessed will be on the conservative side.

While the expressions for $\Delta t_{8\text{-}5}$ given Ref 6 (to determine the point at which a vertical line is to be drawn in the PTCT diagram) are reasonably accurate, those for T_p may be grossly in error because they are derived from a model with many simplistic assumptions (Ref 10, 11). For this reason, although an idea of the type of microstructural gradient in the HAZ can be obtained from the PTCT diagram, it is not possible to calculate the width of each region using simple closed form solutions of the type given in Ref 6 (derived from Rosenthal's equations). Moreover, T_p and $\Delta t_{8\text{-}5}$ are alone not enough to completely characterize a weld thermal cycle. To improve the accuracy of simulation, it would be necessary to program the thermal cycle with heating rates and the shape of the thermal cycle at higher temperatures, as in the HAZ of real welds. The significance of these additional factors is discussed below.

Continuous Heating Transformation Diagrams. The heating rate in many welding processes can be very high. The implication is that considerable superheating may be required for the transformation to austenite on heating. That is, the Ac_1 and Ac_3 temperatures will be raised with an increase in the heating rate (Ref 11). This is seen in Fig. 6, a continuous heating transformation (CHT) diagram, which is analogous to a CCT diagram. It is seen that grain growth begins only after the carbides have dissolved and after a homogeneous austenite (with respect to the distribution of carbon, at least) is formed.

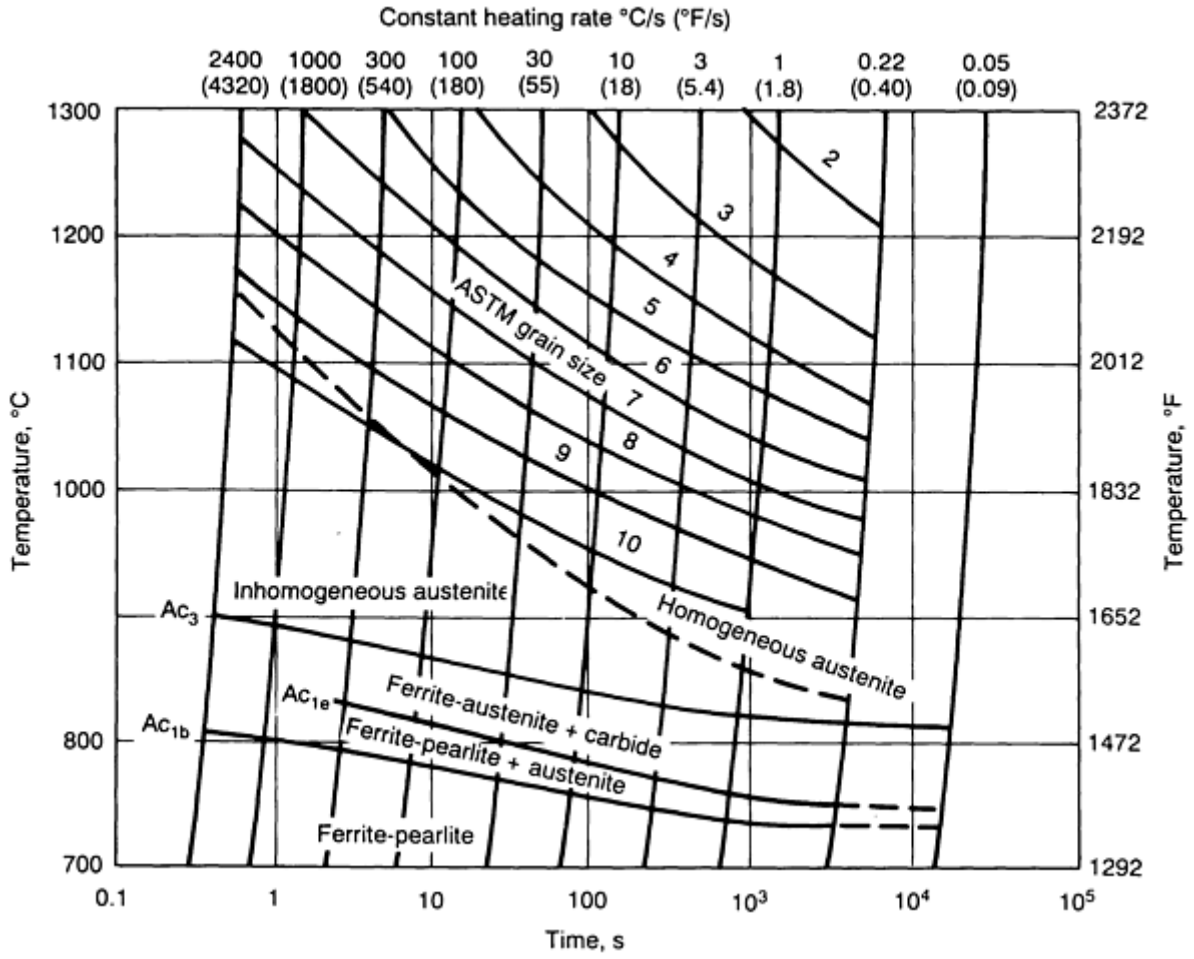

FIG. 6 CONTINUOUS HEATING TRANSFORMATION DIAGRAM FOR 34CRMO4STEEL. IN THE REGION OF HOMOGENEOUS AUSTENITE THERE ARE LINES OF CONSTANT AUSTENITE GRAIN SIZE (ASTM NUMBERS). BECAUSE OF THE MEASURING PROCEDURE, THE DIAGRAMS CAN ONLY BE INTERPRETED ALONG LINES OF CONSTANT HEATING RATE. TO SHOW THE HEATING TIME MORE CLEARLY, A TIME SCALE IS ADDED. SOURCE: REF 12

Precipitate Stability and Grain Boundary Pinning. In the last three decades, there has been a surge in the development of microalloyed or high-strength low-alloy (HSLA) steels (base metals). Almost the entire thrust behind this effort has been to tailor the thermomechanical processing of these steels to produce a fine grain size (Ref 13). Previously, higher strength was obtained by alloying the steel sufficiently to increase the hardenability and then heat treating to obtain a tempered martensitic structure. The higher carbon equivalent (Ref 6, 14) in these alloy steels led to an increased susceptibility to cold cracking or hydrogen-induced cracking. In the microalloyed steels, however, alloying additions are kept to a minimum, and higher strength is achieved primarily by a reduction in the grain size and by precipitation strengthening. A reduction in grain size is the only known method of increasing the strength and toughness at the same time. Because strengthening is obtained by other means, both carbon and carbon equivalent can be decreased to significantly reduce the susceptibility to cold cracking in these new HSLA steels (Fig. 7).

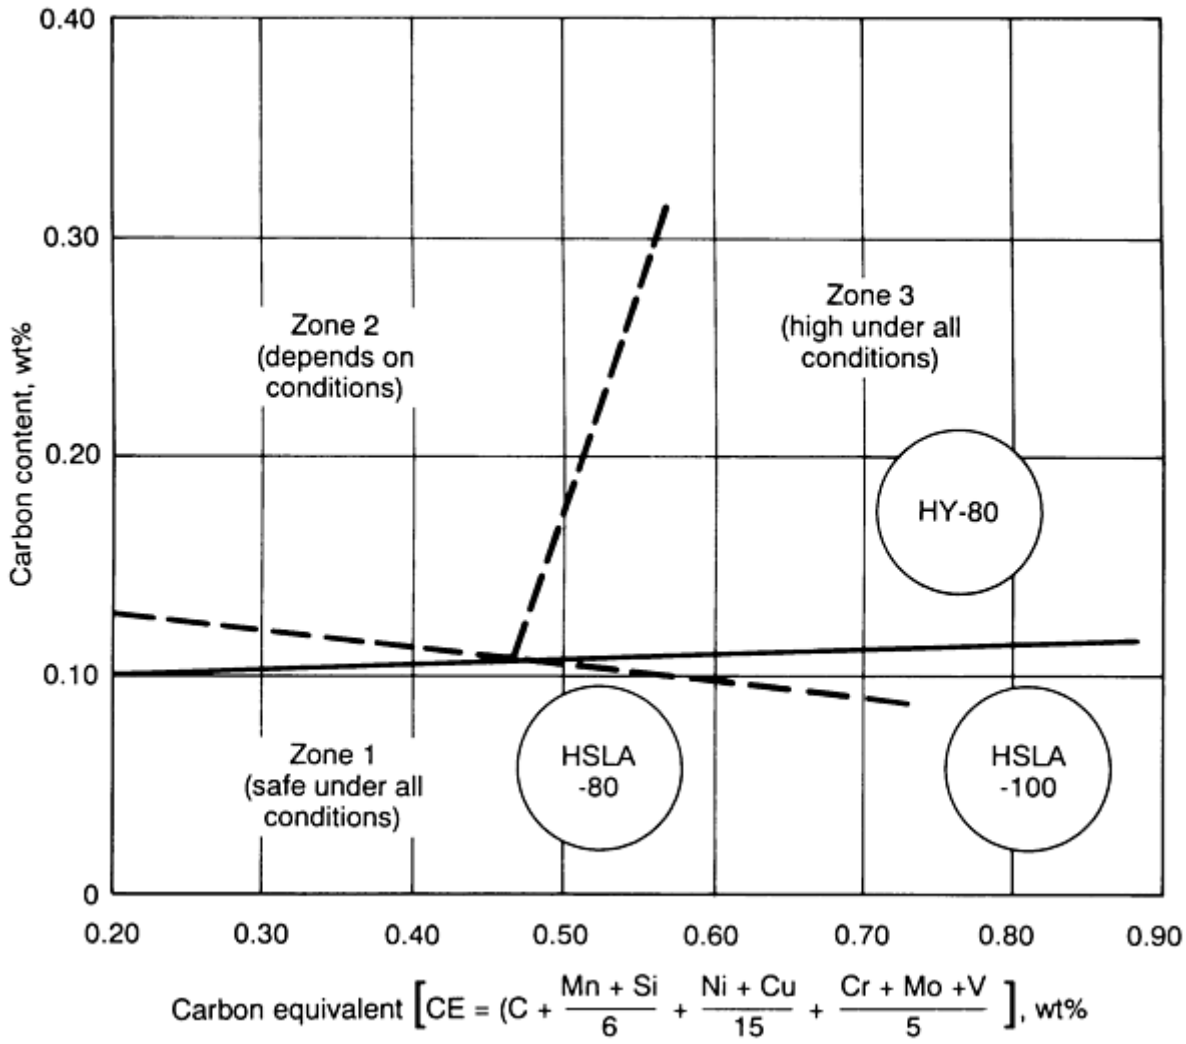

FIG. 7 EFFECT OF STEEL COMPOSITION (HY-80, HSLA-80, HSLA-100) ON THE SUSCEPTIBILITY TO COLD CRACKING IN THE HAZ. SOURCE: REF 13

A fine ferrite grain size in these steels is best achieved (after thermomechanical processing) by obtaining a fine austenite grain size before the γ-α transformation (Ref 13). To realize this goal, it is essential that microalloy additions such as niobium, vanadium, titanium, and aluminum are present so that the fine precipitate particles they form with nitrogen, carbon, or oxygen can "pin" the austenite grain boundaries and inhibit grain coarsening. The pinning effect arises from the fact that when a short length of grain boundary is replaced by a precipitate particle, the effective grain boundary energy is lowered. When the grain boundary attempts to migrate away from the particles, the local energy increases and a drag is exerted on the boundary by the particles.

In the HAZs of welds in these microalloyed steels, it is not possible to get the same optimum microstructure and microalloy precipitation obtained in the parent material by controlled thermomechanical processing. Because peak temperatures are much higher in the HAZ, the precipitate particles coarsen and dissolve, resulting in reduced pinning forces and therefore coarser austenite grains. This effect can be minimized by having precipitate particles that do not dissolve, even at higher temperatures. An idea of the stability of precipitate particles can be obtained from the plot shown in Fig. 8. It is seen that TiN has maximum stability, and this has been used to advantage in many steel. The other carbides and nitrides are not as effective as titanium nitride in limiting the extent of grain coarsening; they play a bigger role during thermomechanical processing (Ref 13).

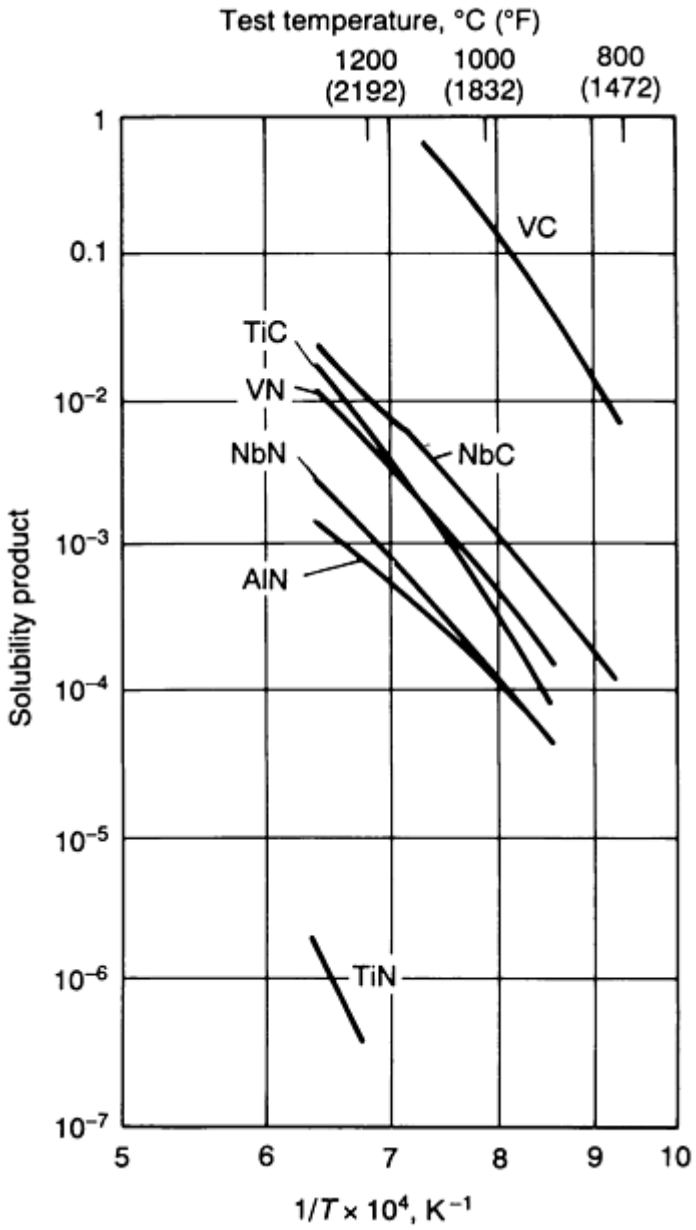

FIG. 8 SOLUBILITY PRODUCTS OF CARBIDES AND NITRIDES AS A FUNCTION OF TEMPERATURE. SOURCE: REF 15

Figure 9 shows how a high volume fraction of fine precipitate particles is needed to maximize the pinning effect. It also shows that heating to high temperatures increases the size of the particles, by a process known as Ostwald ripening (Ref 6), and decreases their volume fraction due to dissolution. This means that it is only possible to limit, and not to totally stop, grain coarsening in the HAZ, especially in high heat input welds. This inevitable grain coarsening is actually used to advantage in titanium, oxide steels (see the section "Titanium Oxide Steels" in this article).

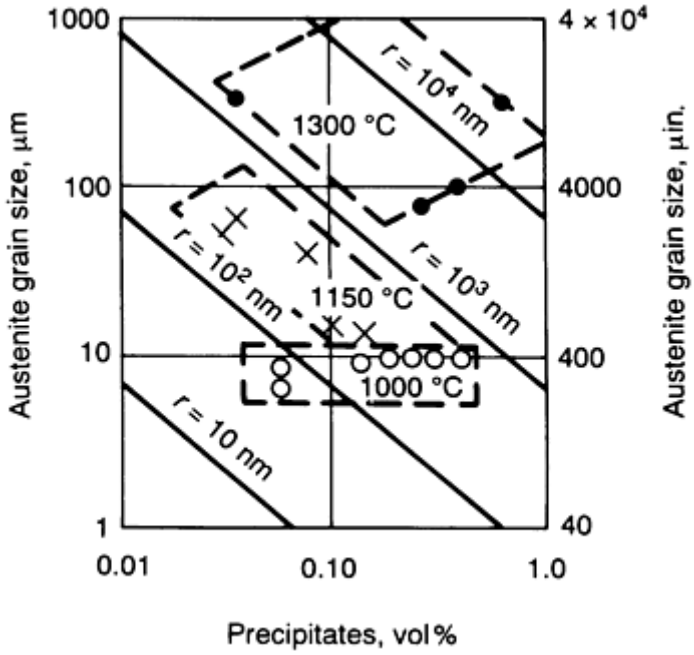

FIG. 9 EFFECT OF PARTICLE RADIUS, *R,* AND AMOUNT OF PRECIPITATE ON AUSTENITE GRAIN SIZE. SOURCE: REF 16

Unmixed and Partially Melted Zones in a Weldment. It is common to think of a single-pass weld as consisting of two zones: weld metal and HAZ. Careful metallographic examination has shown that a weld can in fact be divided into four regions (Fig. 10):

- *THE COMPOSITE ZONE,* IN WHICH A VOLUME OF BASE METAL MELTED BY THE SUPERHEATED FILLER METAL EXPERIENCES COMPLETE MIXING TO PRODUCE AN ALLOY WITH NOMINAL COMPOSITION INTERMEDIATE BETWEEN THAT OF THE BASE METAL AND THAT OF THE FILLER METAL.
- *THE UNMIXED ZONE,* WHICH FORMS FROM THE STAGNANT MOLTEN BOUNDARY LAYER REGION (ABOUT 100 TO 1000 μM, OR 0.004 TO 0.040 IN., THICK) AT THE OUTER EXTREMITIES OF THE COMPOSITE REGION. BECAUSE NO MECHANICAL MIXING WITH THE FILLER METAL OCCURS HERE, THE COMPOSITION OF THE METAL IN THIS REGION IS IDENTICAL TO THAT OF THE BASE METAL, EXCEPT FOR MINOR CHANGES PRODUCED BY DIFFUSION.
- *THE PARTIALLY MELTED ZONE,* WHICH IS A REGION AT THE FUSION BOUNDARY WHERE THE PEAK TEMPERATURES FALL BETWEEN THE LIQUIDUS AND SOLIDUS SO THAT MELTING IS INCOMPLETE.
- *THE TRUE HEAT-AFFECTED ZONE,* WHICH IS THAT PORTION OF THE BASE METAL WHERE ALL MICROSTRUCTURAL CHANGES INDUCED BY WELDING OCCUR IN THE SOLID STATE.

Special metallographic procedures are needed to reveal the existence of these special zones, as shown in Fig. 11.

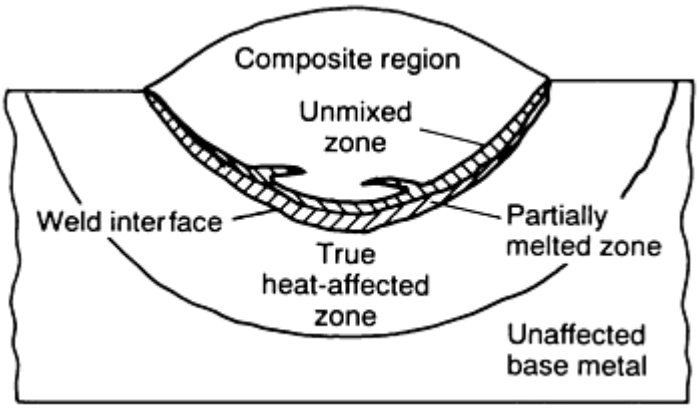

FIG. 10 SCHEMATIC SHOWING THE DIFFERENT DISCRETE REGIONS PRESENT IN A SINGLE-PASS WELD. SOURCE: REF 17

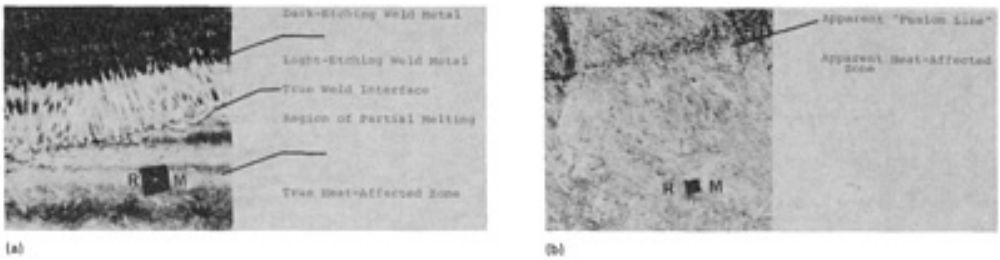

FIG. 11 SPECIAL METALLOGRAPHIC PROCEDURES SHOW THE MICROSTRUCTURE OF DISCRETE REGIONS (SEE FIG. 10) IN AN HY-80 WELD. (A) MICROSTRUCTURE OBTAINED NEAR A REFERENCE MARK (INDICATED BY "RM") USING A TWO-STAGE NITAL AND SODIUM BISULFITE PROCEDURE. (B) MICROSTRUCTURE AT IDENTICAL LOCATION REPOLISHED AND ETCHED WITH NITAL ONLY. TWO-STAGE PROCEDURE SHOWS MUCH GREATER DETAIL. SOURCE: REF 17

The width of the partially melted zone can be extended by a phenomenon known as constitutional liquation (Ref 18), whereby melting can occur even when the peak temperature is less than the solidus temperature. This can be understood by referring to a phase diagram for a simple binary system A and B (Fig. 12). Consider an alloy of composition C. Its equilibrium structures at temperatures T_1, T_2, T_3 and T_4 are α+ β, α, α, and L + α, respectively (Fig. 12a). On heating from room temperature to T_3 and holding at this temperature for a long time, the βparticles will dissolve and give a homogeneous α of composition C. However, under conditions of rapid heating in the HAZ, the dissolution of β will give rise to a solute concentration gradient around each particle, as shown in Fig. 12(b). In the region surrounding each particle, the concentration of the solute B will correspond to that of liquid because, as the phase diagram shows, a liquid phase must exist between α and β at T_3. This phenomenon of localized melting due to a nonequilibrium distribution of phases during rapid heating is called constitutional liquation.

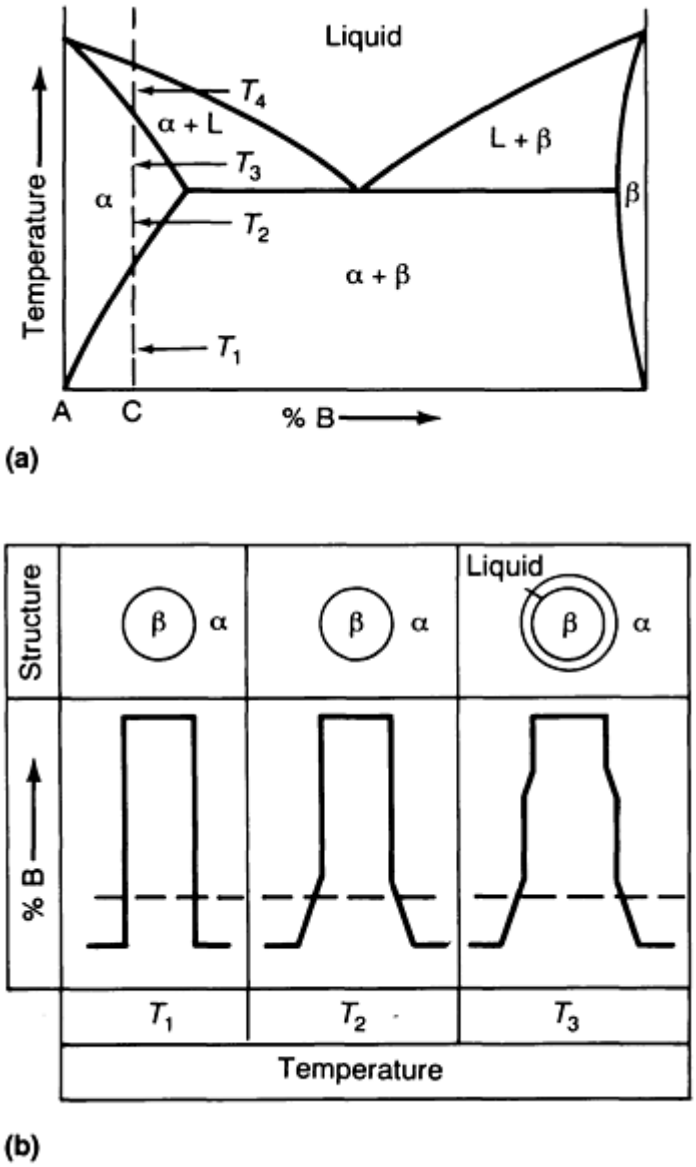

FIG. 12 EXTENSION OF PARTIALLY MELTED ZONE BY CONSTITUTIONAL LIQUATION. (A) PHASE DIAGRAM FOR A SIMPLE BINARY ALLOY. (B) STRUCTURES AND DISTRIBUTION OF CONSTITUENT B IN ALLOY C AT THREE TEMPERATURES SHOWN IN (A) WHEN RAPID HEATING IS APPLIED. SOURCE: REF 19

The partially melted zone is the region where liquation cracks have been known to occur in maraging steels, austenitic stainless steels, heat-treatable aluminum alloys, and nickel-base superalloys. It can also be a site where hydrogen-induced cracking is initiated (Ref 17), because it can act as a pipeline for the diffusion of hydrogen picked up by the molten weld metal and also because of the higher hardenability at these segregated regions.

While the phenomenon of constitutional liquation is usually discussed in connection with liquation cracking of aluminum- and nickel-base alloys (Ref 14, 18, 19), a more dramatic example can actually be found in the case of cast iron welds (Ref 20). Figure 13 shows the micro structure of the HAZ in a cast iron weld deposited using a "quench welding" technique (Ref 21). This procedure involves welding without any preheat by intermittently depositing a series of small stringer beads and strictly maintaining the interpass temperature below about 80 °C (175 °F). The idea is to limit the size of the hard and brittle white iron colonies forming by constitutional liquation around the graphite nodules and to see that they do not interconnect. By contrast, a procedure involving a preheat of about 200 °C (390 °F) can prevent the formation of martensite but not the formation of ledeburite (the structure of white iron). Because ledeburite forms at higher temperatures than martensite (≈1100 °C, or 2010 °F), a much higher preheat temperature of about 600 °C (1110 °F) is required to significantly reduce the cooling rate at the higher temperatures, thereby preventing the formation of white iron. This high level of preheat is impractical. While cast iron appears to have been successfully welded with preheats of

about 200 °C (390 °F), it has sometimes been found that weld repair is most effective using the quench welding technique, by which it is possible to limit both the amount of ledeburite formed and the width of the HAZ.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

Fusion Zone of a Single-Pass Weld

Transformations in Single-Pass Weld Metal. It is usually not necessary to select a filler metal that has exactly the same composition as the base metal; it is more important that the weld metal has the same strength and other properties (such as toughness or corrosion resistance). Because these properties are governed by the microstructure, it is important to understand the influence of different factors on phase transformations in the weld metal. But first, for a meaningful communication of the different features in a microstructure, the various phases and microconstituents must be identified using a system of nomenclature that is both widely accepted and well understood. In wrought steels, this need has been satisfied to a large degree by the Dubé scheme (Ref 22) for classifying the different morphologies of ferrite, as shown in Fig. 14. Similarly, confusion and controversy in the terminology for describing the microstructures in ferritic steel weld metals have been largely resolved by the classification scheme shown in Fig. 15. This scheme (Ref 23) was the result of several collaborative exercises undertaken under the auspices of the International Institute of Welding (IIW). Typical micrographs illustrating some of the microstructural constituents are shown in Fig. 16.

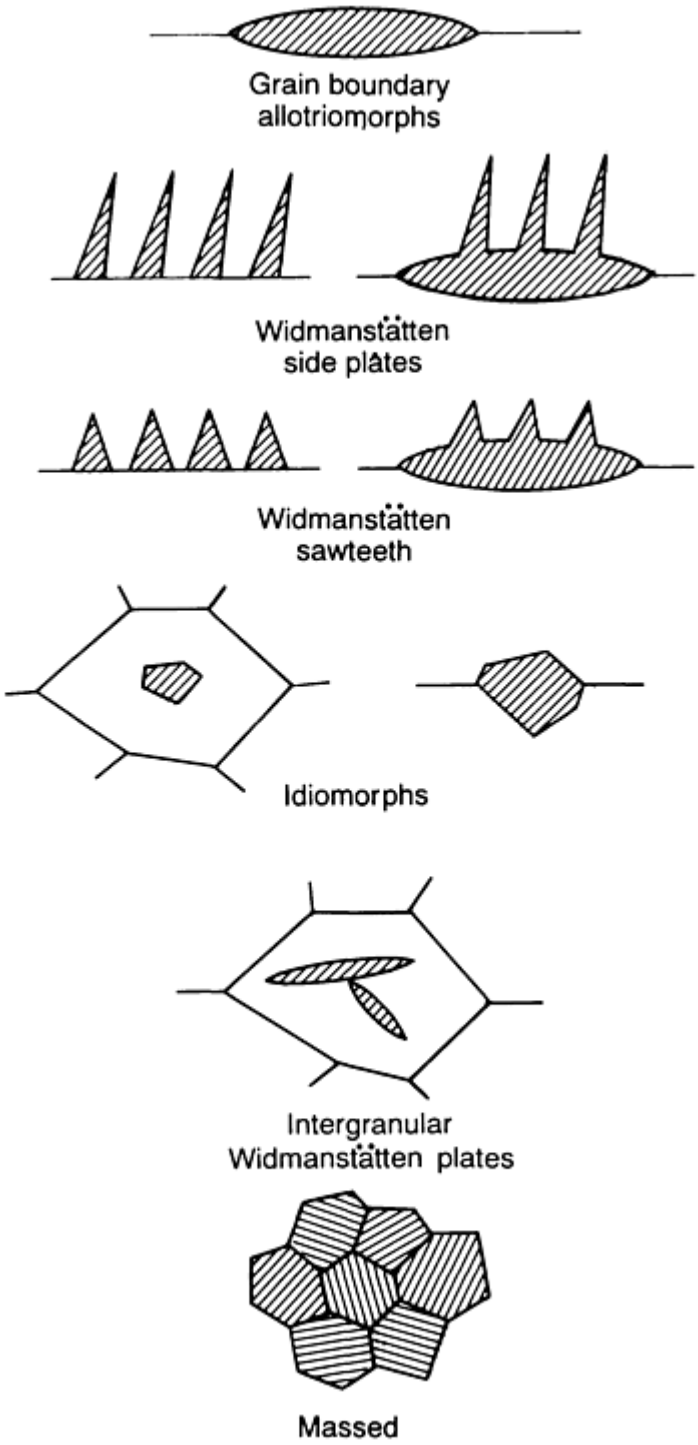

FIG. 14 SCHEMATICS SHOWING THE DUBÉ CLASSIFICATION OF FERRITE MORPHOLOGIES. SOURCE: REF 22

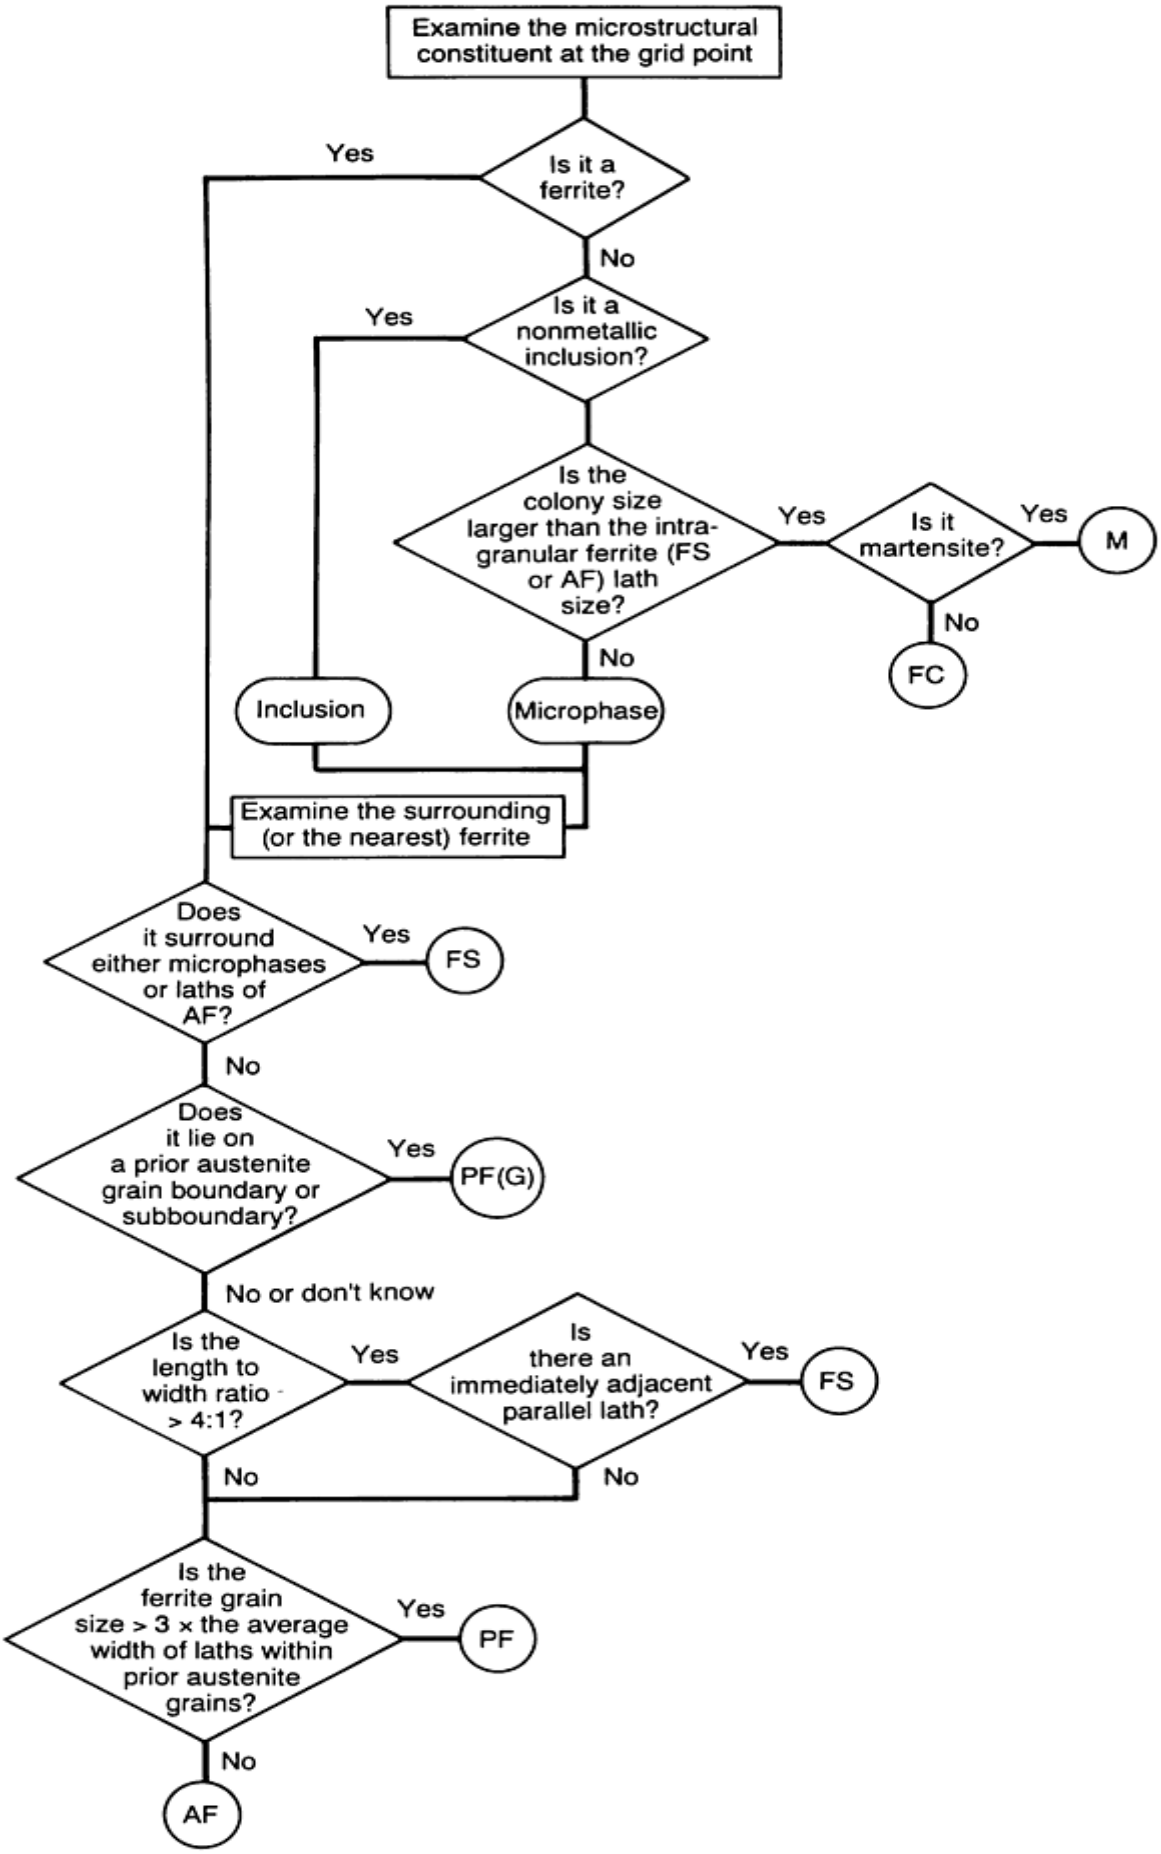

Examine the microstructural constituent at the grid point
Is it a ferrite?
Yes
No
Is it a nonmetallic inclusion?
Yes
Is the colony size larger than the intra-granular ferrite (FS or AF) lath size?
Yes
Is it martensite?
Yes
M
No
FC
No
Inclusion
Microphase
Examine the surrounding (or the nearest) ferrite
Does it surround either microphases or laths of AF?
Yes
FS
No
Does it lie on a prior austenite grain boundary or subboundary?
Yes
PF(G)
No or don't know
Is the length to width ratio > 4:1?
Yes
Is there an immediately adjacent parallel lath?
Yes
FS
No
No
Is the ferrite grain size > 3 × the average width of laths within prior austenite grains?
Yes
PF
No
AF

CATEGORY	ABBREVIATION
PRIMARY FERRITE	PF
GRAIN BOUNDARY FERRITE	PF(G)
INTRAGRANULAR POLYGONAL FERRITE	PF(I)
FERRITE WITH SECOND PHASE	FS
FERRITE WITH NONALIGNED SECOND PHASE	FS(NA)
FERRITE WITH ALIGNED SECOND PHASE	FS(A)

SOURCE: REF 3

The transformation behavior in ferritic steel weld metals is best understood by first noting that ferrite is nucleated heterogeneously and that for all practical purposes, it is necessary to consider the competitive nucleation behavior only at grain boundaries and at inclusions. Figure 17 shows that inclusions have to be larger than a certain size (0.2 to 0.5 μm, or 8 to 20 μin., the typical size range of most weld metal inclusions) for their potency as nucleation sites to reach a maximum. It also shows that nucleation of ferrite is always energetically more favorable at grain boundaries than at inclusions. Based on additional considerations, like thermal contraction strains and lattice matching at inclusion-austenite-

ferrite interfaces (not taken into account to get the results in Fig. 17), a discussion of why certain inclusions are more potent nucleation sites than others is found in Ref 3, 24, and 25.

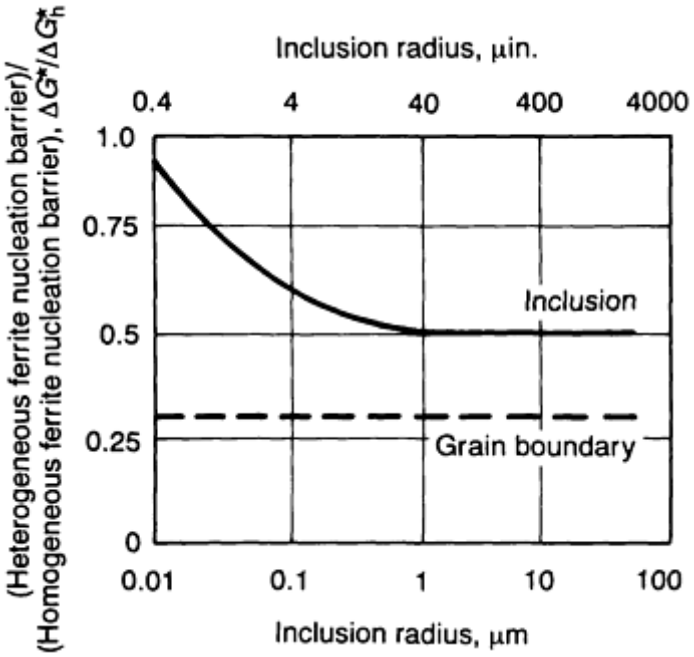

FIG. 17 EFFECT OF PARTICLE RADIUS ON ENERGY BARRIER TO FERRITE NUCLEATION AT INCLUSIONS, ΔG^* (HETEROGENEOUS), NORMALIZED RELATIVE TO THE HOMOGENEOUS NUCLEATION BARRIER, ΔG^*_H (HOMOGENEOUS). CORRESPONDING ENERGY BARRIER TO NUCLEATION OF FERRITE AT AUSTENITE GRAIN BOUNDARIES IS INDICATED BY HORIZONTAL BROKEN LINE. SOURCE: REF 6

Broadly, the major factors affecting transformation behavior in ferritic steel weld metals are alloy composition, weld heat input (by its effect on γ grain size and $\Delta t_{8\text{-}5}$), oxygen content (that is, the inclusion content), and the nature of segregation in the weld metal. A typical weld CCT diagram is shown in Fig. 18. For the cooling curve shown in the figure, the first phase that forms is allotriomorphic ferrite, or grain boundary ferrite in the IIW scheme. The term "allotriomorphic" means a "particle of a phase that does not have a regular external shape" and in the present context means that ferrite grows on the grain boundary surfaces and does not have a regular faceted shape reflecting the symmetry of its internal crystalline structure. At lower temperatures, the mobility of the curved or random γ/α-allotriomorph boundaries decreases, and Widmanstätten side plates (ferrite side plates in the IIW scheme) form. Growth of these side plates is rapid because carbon is efficiently redistributed to the sides of the growing tips, thus avoiding solute pile-up problems. In addition, substitutional atoms do not diffuse during the growth of Widmanstätten ferrite.

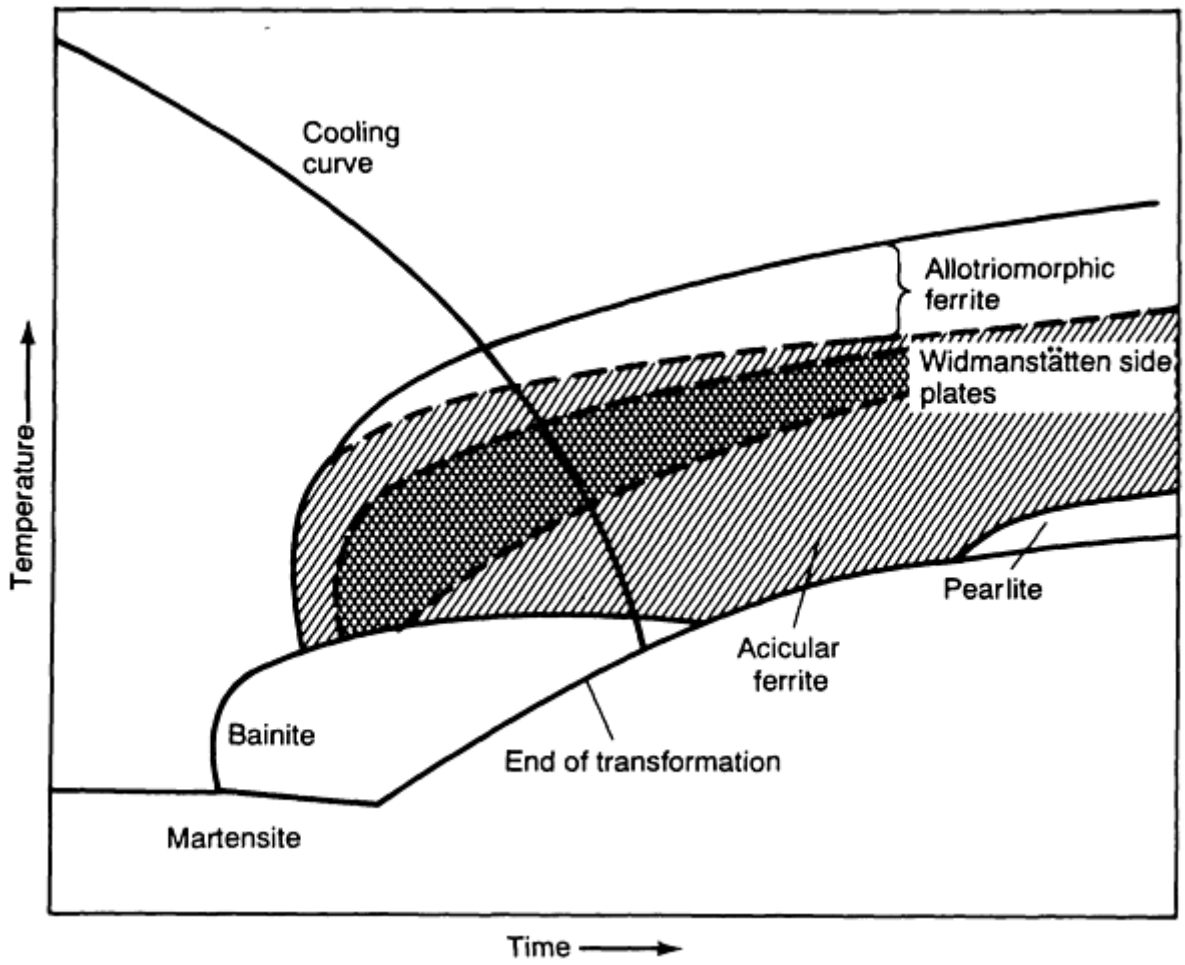

FIG. 18 SCHEMATIC OF WELD CCT DIAGRAM SHOWING SELECTED MICROSTRUCTURES

After all the grain boundary sites are saturated with allotriomorphic or Widmanstätten ferrite and their growth rate is not sufficient to extend to the interior of the grains, the nucleation of ferrite at inclusions within the γ grains becomes competitive. Acicular ferrite forms, a structure resulting from ferrite laths growing in different directions from inclusions and from laths already nucleated. Upon impingement, high-angle grain boundaries and a very fine dispersion of microphases are obtained between ferrite laths. "Microphases" in this context means the transformation structures resulting from the carbon-enriched regions between the ferrite laths and could be the martensite-austenite constituent, bainite, or pearlite (see the section "HAZ in Multipass Weldments" in this article). An example of the microstructure of acicular ferrite is shown in Fig. 19. Acicular ferrite does not figure in the Dubé scheme because it is rarely observed in wrought steels. When the cooling rate is higher or when the inclusion content is very low, bainite can be nucleated directly at the γ grain boundaries. Bainite can form as upper or lower bainite; the difference between the two is illustrated in Fig. 20. Examination with transmission electron microscopy (TEM) is usually required for a firm identification of the type of bainite formed. In the case of the highest cooling rates, martensite is obtained.

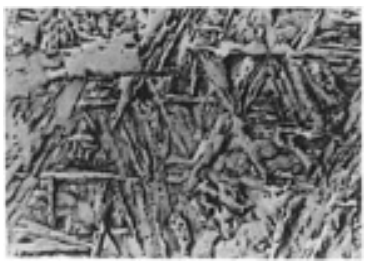

FIG. 19 SCANNING ELECTRON MICROGRAPH SHOWING MORPHOLOGY OF ACICULAR FERRITE. SOURCE: REF 24

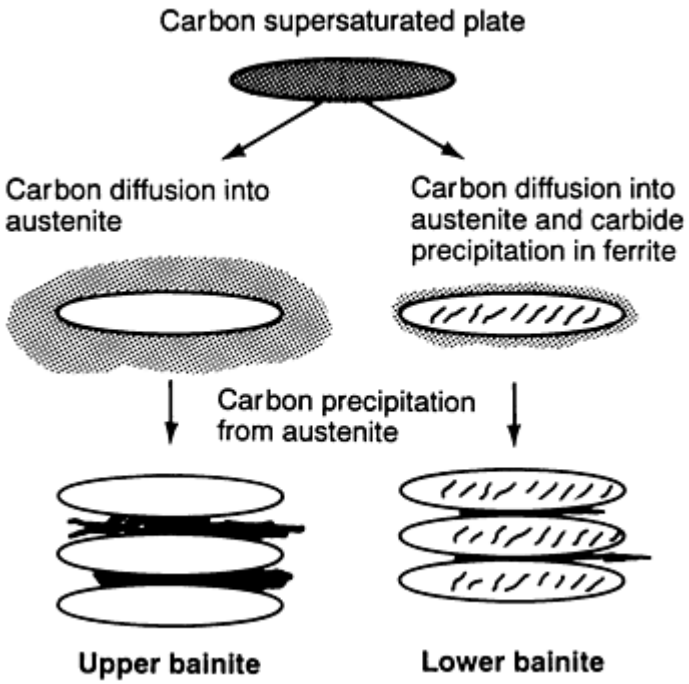

FIG. 20 SCHEMATIC SHOWING THE DIFFERENCES IN THE TRANSFORMATION MECHANISM FOR UPPER AND LOWER BAINITE AND THE EFFECT OF THESE MECHANISMS ON THE FINAL MORPHOLOGY. SOURCE: REF 24

Figure 21 shows the effect of alloying additions, $\Delta t_{8\text{-}5}$, oxygen content, and the γ grain size on the sequence and relative amounts of allotriomorphic ferrite, Widmanstätten ferrite, and bainite in the weld metal. Broadly, the trends shown can be understood in terms of the wellknown observation that an increase in γ grain size, a decrease in inclusion content, and an increase in alloying additions will shift the CCT curves to lower temperatures and to longer times. While Fig. 21 can generally be interpreted by assuming that the individual factors act independently of each other, the transition from (b) to (a) with an increase in the inclusion content must be understood in terms of its effect of the γ grain size. It has been observed that the γ grain size decreases with an increase in the inclusion content, and this has been explained by the higher magnitude of pinning forces at higher inclusion contents (Ref 25). The smaller grain size implies a greater grain boundary surface area, and this increases the amount of grain boundary ferrite and sideplate structures formed at the expense of acicular ferrite in Fig. 21(a). The role of the initial formation or non-formation of allotriomorphic ferrite at γ grain boundaries in bringing about the transition from Fig. 21(b) to Fig. 21(c) in Fig. 21 is discussed in the next section of this article.

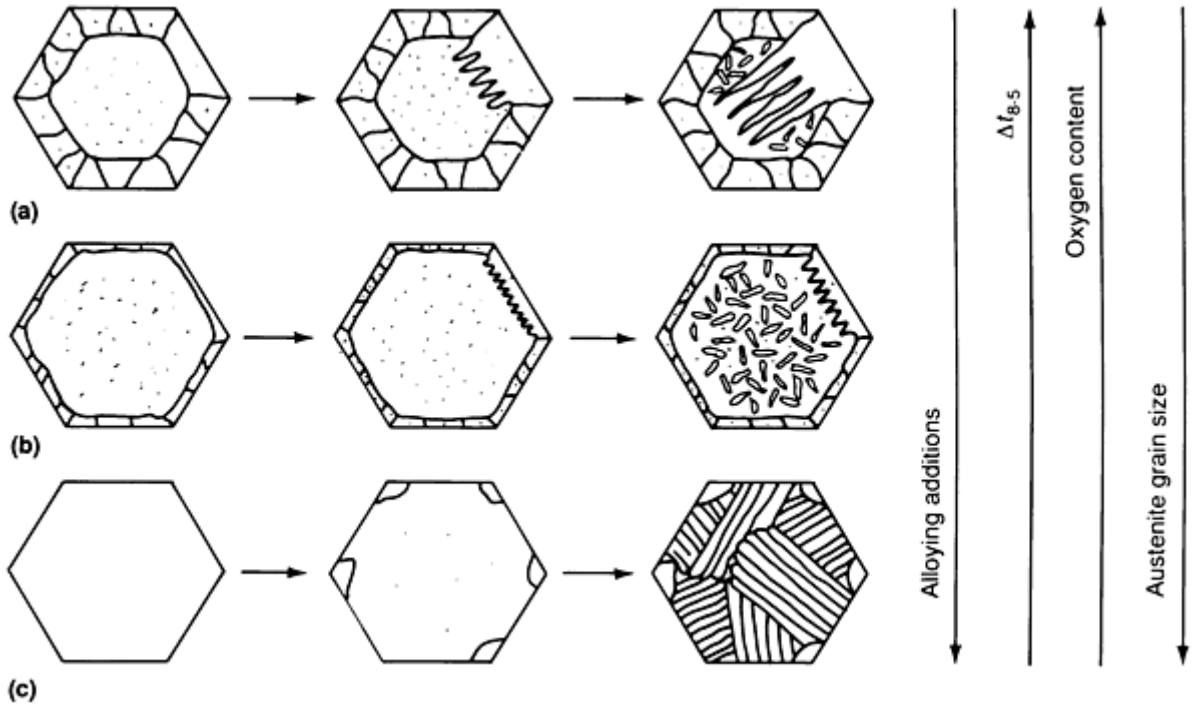

FIG. 21 SCHEMATIC SHOWING THE EFFECT OF ALLOY COMPOSITION, $\Delta T_{8\text{-}5}$, OXYGEN CONTENT, AND γ GRAIN SIZE ON THE DEVELOPMENT OF MICROSTRUCTURE IN FERRITIC STEEL WELD METALS. THE HEXAGONS REPRESENT CROSS SECTIONS OF COLUMNAR γ GRAINS. (A) THE GRAIN BOUNDARIES BECOME DECORATED FIRST WITH A UNIFORM, POLYCRYSTALLINE LAYER OF ALLOTRIOMORPHIC FERRITE, FOLLOWED BY FORMATION OF WIDMANSTÄTTEN FERRITE, AND THEN BY FORMATION OF ACICULAR FERRITE. (B) THE GROWTH RATE OF WIDMANSTÄTTEN FERRITE IS NOT SUFFICIENTLY HIGH TO EXTEND ENTIRELY ACROSS γ GRAINS. NUCLEATION OF FERRITE AT INCLUSIONS WITHIN THE γ GRAINS LEADS TO AN INCREASE IN THE AMOUNT OF ACICULAR FERRITE WHEN COMPARED WITH CASE (A). (C) THE HIGHER ALLOY CONTENT OR THE HIGHER COOLING RATE SUPPRESSES THE FORMATION OF ALLOTRIOMORPHIC FERRITE. THIS LEAVES THE γ GRAIN BOUNDARIES FREE TO NUCLEATE UPPER BAINITE. SOURCE: REF 24

Although the IIW classification is the result of a consensus viewpoint, some researchers (Ref 24) still feel that it places an exaggerated emphasis on morphological features observed with the light microscope. They believe that it is more important that the terminology reflect the mechanism of transformation. For example, it can be difficult to differentiate between Widmanstätten ferrite and upper bainite when using the light microscope, and both are identified as FS in the IIW classification. For a more fundamental understanding and to clearly interpret the trends in microstructural development, it is essential to make a distinction between the two. In addition, the subclassification of grain boundary ferrite in the IIW classification is not unequivocal in its meaning--it could refer to ferrite that forms by diffusion, Widmanstätten ferrite, or the ferrite in upper bainite. By contrast, the term "allotriomorphic ferrite" clearly identifies the mechanism by which it is formed. On the other hand, the IIW classification is easy to use and allows a more detailed identification, either by judgment or by further TEM examination, for example, to determine whether FS is FS(SP) or FS(UB). At least, it decreases the tendency for a wrong identification of the transformation mechanism with insufficient data. For a microstructure-toughness correlation, it is sufficient to characterize the morphological features.

Relating Weld Metal Toughness to the Microstructure. A good insight into the subject of toughness in ferrite steel weld metal is obtained by examining the data shown in Fig. 22. It is seen from Fig. 22(a) that the upper-shelf Charpy V-notch (CVN) energy monotonically decreases with an increase in oxygen content. In the upper-shelf temperature region, ductile fracture occurs by a process of microvoid coalescence, and because microvoids are initiated at the inclusion-matrix interface, the upper-shelf impact energy decreases with an increase in the inclusion content. By contrast, from Fig. 22(b) it is seen that an optimum inclusion content is required to obtain the lowest CVN transition temperature. The transition temperature is mainly governed by cleavage fracture, and this in turn depends on how effectively a propagating cleavage crack is forced to change direction as it traverses the microstructure. At low inclusion contents, an upper bainitic structure is obtained, and this consists of parallel platelets of ferrite (in a single packet) growing from the grain boundary surfaces. With an optimum inclusion content, a predominantly acicular ferrite structure is obtained, and here the adjacent

ferrite platelets tend to radiate in many different directions from inclusion nucleation site. At higher inclusion contents, the amount of ferrite sideplate structures increases, again having nearly parallel ferrite platelets. The highest toughness (that is, the lowest transition temperature) is obtained only in the "chaotic" microstructure of acicular ferrite because it has the smallest effective ferrite grain size.

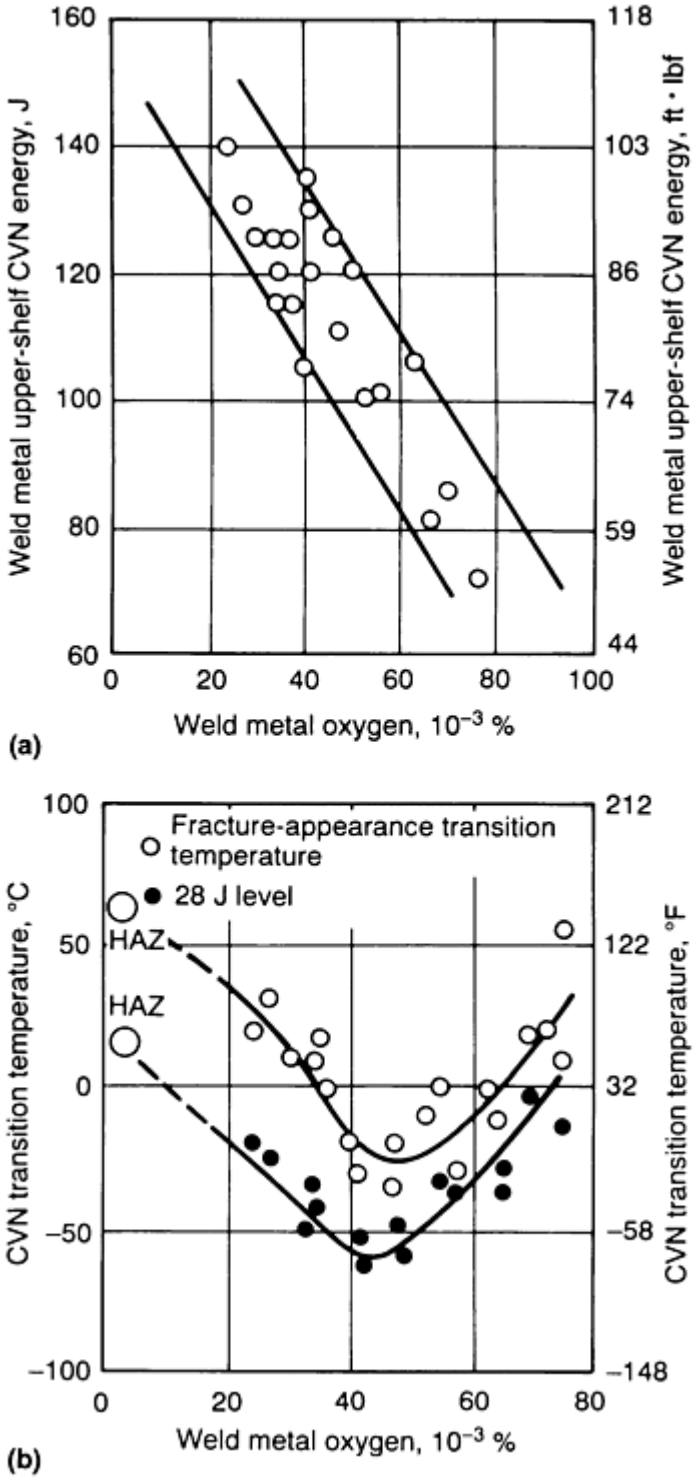

FIG. 22 TYPICAL VARIATION OF SELECTED WELD METAL PROPERTIES WITH OXYGEN CONTENT IN FERRITIC STEEL WELD METALS. (A) PLOT OF CHARPY V-NOTCH (CVN) IMPACT TEST UPPER-SHELF ENERGY VERSUS OXYGEN CONTENT. (B) PLOT OF CVN TRANSITION TEMPERATURE VERSUS OXYGEN CONTENT. SOURCE: REF 26

In recognition of the latter fact, most of the work in consumables development in the recent past has concentrated on increasing the amount of acicular ferrite in the microstructure. In line with the trends shown in Fig. 21(a) and 21(b), it has been found that decreasing the amount of grain boundary ferrite and ferrite sideplate structures increases the acicular ferrite content. This is shown more clearly in Fig. 23.

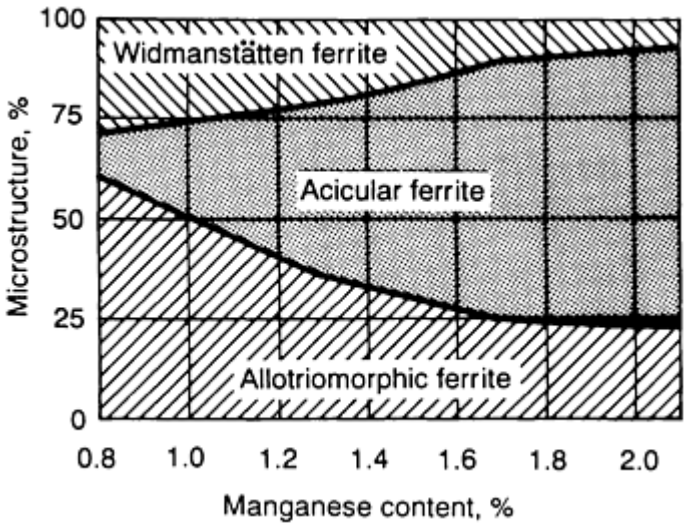

FIG. 23 EFFECT OF MANGANESE CONTENT OF WELD METAL ON THE RELATIVE AMOUNTS OF THE MICROSTRUCTURAL CONSTITUENTS PRESENT. CARBON CONTENT MAINTAINED AT 0.03%. SOURCE: REF 27

Recent work (Ref 24, 25, 27), however, has shown that a 100% acicular ferritic structure is neither desirable nor, in most cases, achievable. Figure 24 shows that the impact toughness peaks at about 70% acicular ferrite and then falls. This was attributed to the formation of segregated bands of brittle microphases in the alloy compositions giving the highest acicular ferrite contents. Moreover, when the alloying additions are increased still further, the transformation behavior becomes such that allotriomorphic ferrite formation is totally suppressed, leaving the γ grain boundaries free to nucleate upper bainite at lower temperatures (see Fig. 21c). It appears that a small layer of allotriomorphic ferrite is essential to obtain high acicular ferrite contents. When it forms, it saturates the γ grain boundary sites, and bainite nucleation at the γ/α-allotriomorphic interface is inhibited by the high carbon content there as a result of its rejection from the ferrite (Ref 24). Conditions are then favorable for intragranular nucleation at inclusion sites and thus the formation of acicular ferrite.

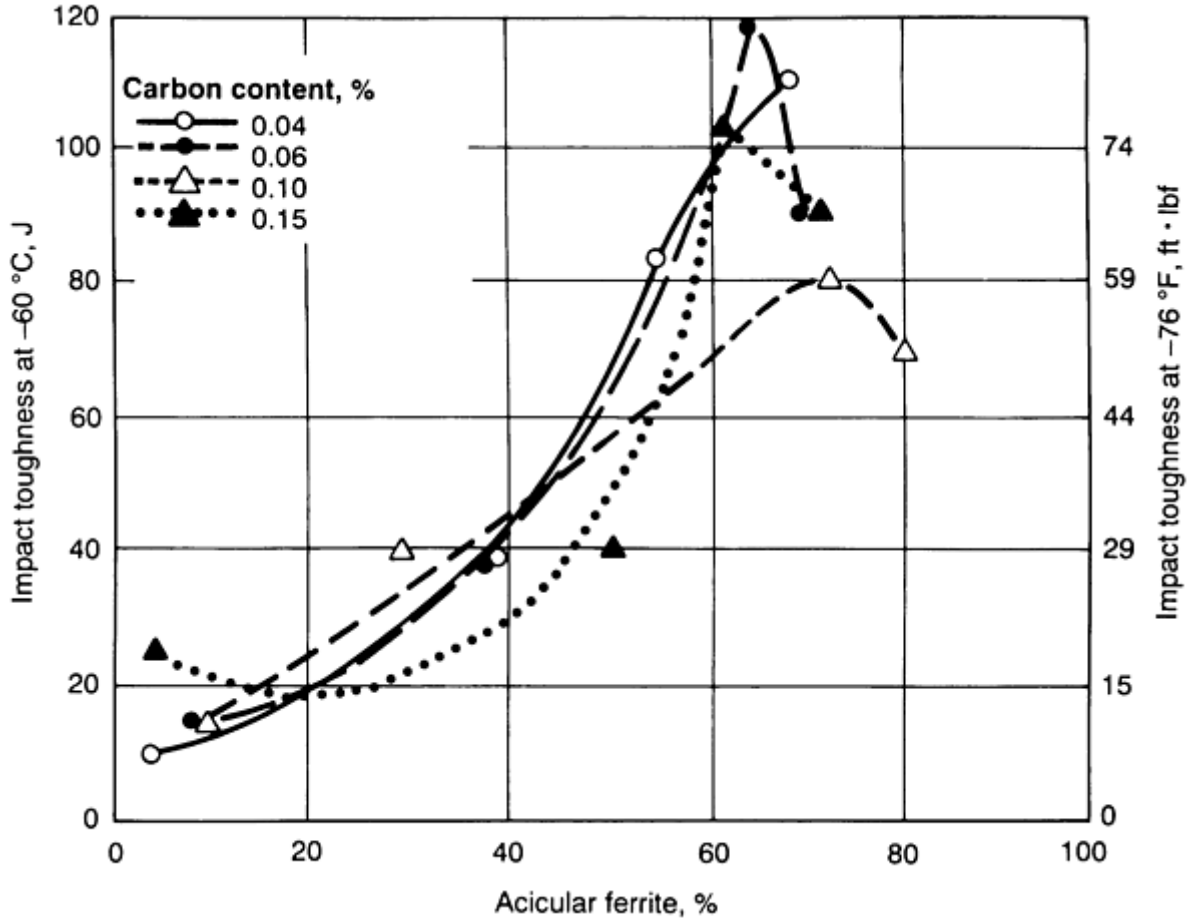

FIG. 24 PLOT OF IMPACT ENERGY VERSUS ACICULAR FERRITE CONTENT FOR SELECTED CARBON CONTENTS AT -60 °C (-78 °F). SOURCE: REF 27

For the welding of steels with yield strengths less than 600 MPa (85 ksi), it has been possible to develop weld metals with matching strength and toughness by having high acicular ferrite contents in them. A yield strength of about 600 MPa (85 ksi) seems to be the ceiling for weld metals based on acicular ferrite. Attempting to obtain additional strength by additional alloying to increase the amount of solid solution hardening and precipitation hardening in fact only results in increasing amounts of martensite and bainite. These structures are associated with a lower toughness. This has been observed in the case of HSLA-100 steels, for example, where attempts to get a matching strength in the weld metal have resulted in a drop in toughness (Ref 25, 28). Work on consumables development for high-strength steels is still in progress to match the base metal in strength and toughness (Ref 25, 28). However, current thinking appears to favor resorting to a slightly undermatching weld metal (in terms of strength) so that the already available lower-strength, high-toughness, consumables having high acicular ferrite contents (Ref 29) can be used. These weld metal compositions have the additional benefit of requiring less stringent measures for avoiding hydrogen-induced cracking.

Titanium Oxide Steels. In the discussion of the role of pinning by precipitate particles (for example, TiN) in limiting grain growth in the HAZ (in the section "Precipitate Stability and Grain Boundary Pinning" in this article), it was pointed out that at high heat inputs the particles dissolve and are not able to prevent coarse γ grains from forming. The low toughness in these coarse-grained regions is of some concern. The fact that a coarse γ grain size will lead to a higher acicular ferrite content (see Fig. 21b) with improved toughness has been used to advantage in the development of titanium-oxide-containing steels (Ref 30, 31). Ti_2O_3 is more stable than titanium nitride and does not dissolve, even at the highest heat inputs. The undissolved, Ti_2O_3 particles do not stop grain growth, but their survival after the heating cycle means that they can be effective in nucleating acicular ferrite within the coarse γ grains. The precise reasons why they are more effective than other undissolved inclusions, such as Al_2O_3 in nucleating acicular ferrite are not well understood (Ref 24). The improved HAZ microstructure and toughness obtained with titanium oxide steels over titanium nitride steels at high heat inputs are shown in Fig. 25 and 26, respectively.

Effect of Transformations on Transient Weld Stresses. The effect of transformations on weld stresses (and vice versa) is best illustrated by introducing an apparently little-known proposal (Ref 32) about the use of a duplex austenite-martensite weld metal for welding high-strength steels. First, to prepare the background, the way in which transient stresses develop in a weld and the effect of transformations on weld stresses will be discussed.

Four uniaxial specimens using an HAZ simulation technique, the manner in which residual stress is accumulated during a weld thermal cycle was investigated (Ref 33), and the results are shown in Fig. 27. Initially, when a material is austenite at high temperature, its yield strength is low and only a small tensile stress can develop. On cooling, the tensile stress increases. When a phase transformation occurs, the resulting volume expansion opposes the contraction due to cooling and decreases the stress. Once the transformation is complete, the tensile stress increases again. As seen in Fig. 27, if the transformation occurs at a lower temperature (for example, in the case of 9Cr1Mo or 12CrMo steels), the magnitude of the final residual stress is less. The dotted line in the plot shows the expected variation for a material with an austenite-martensite structure. The greater the amount of martensite, the lower the final residual stress.

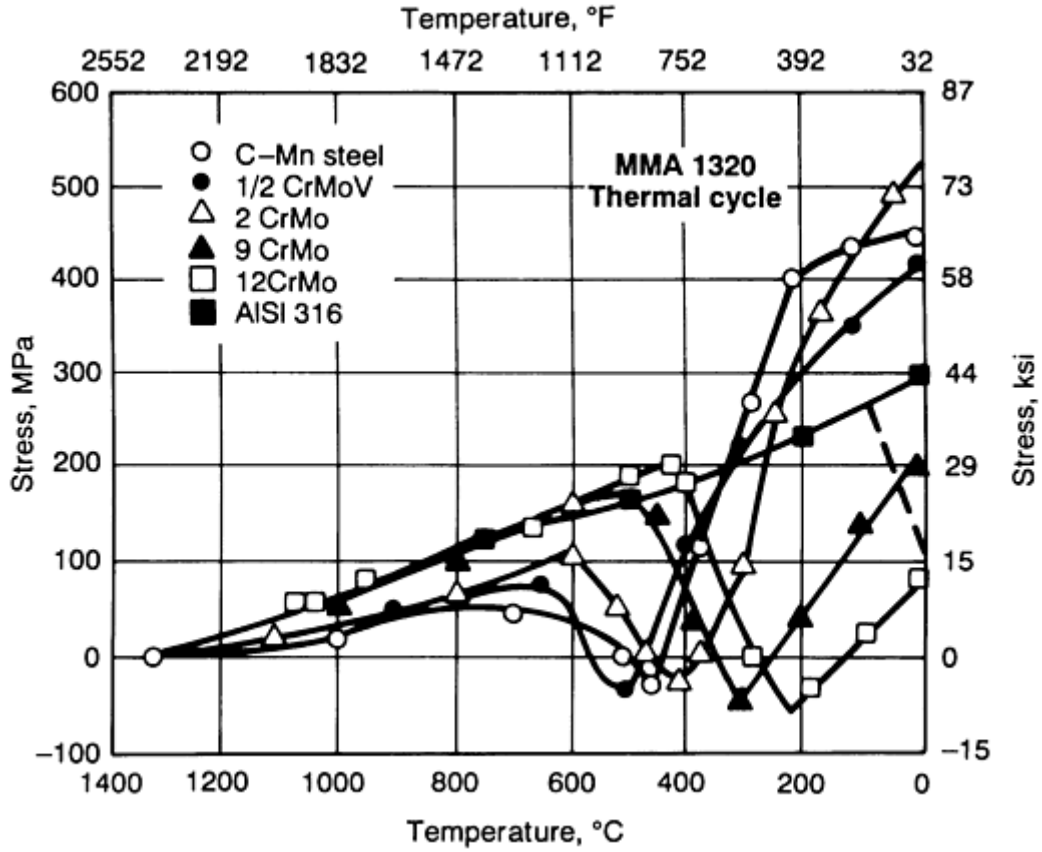

FIG. 27 STRESS ACCUMULATED DURING COOLING UNDER RESTRAINT FOR SELECTED STEELS. THE DOTTED LINE SHOWS THE EXPECTED VARIATION IN STRESS FOR A DUPLEX AUSTENITE-MARTENSITE WELD METAL WHERE TRANSFORMATION BELOW ABOUT 100 °C (212 °F) GREATLY REDUCES THE FINAL STRESS. (MMA 1320 INDICATES THE PEAK TEMPERATURE OF THE SIMULATED WELD THERMAL CYCLE AND CORRESPONDS TO THE TEMPERATURE AT THE START OF THE COOLING CYCLE.) SOURCE: REF 33

As discussed in the section "Weld Metal Toughness Relative to the Microstructure" in this article, the main problems in the welding of high-strength steels (with yield strengths of 600 to 1000 MPa, or 85 to 145 ksi) are hydrogen-induced cracking (HIC) and low toughness in the weld metal. Both problems can be addressed (in principle at least) by the use of a duplex austenite-martensite weld metal. Austenite can contribute by increasing the toughness and by minimizing the risk for HIC (Ref 14). The role of martensite will be to increase the strength and to decrease the final residual tensile stress, which also makes conditions less favorable for HIC. An additional benefit will be that the higher tensile residual stress in the weld metal before martensite forms will induce the transformations in the HAZ to occur at a slightly higher temperature, by Le Chatelier's principle (Ref 34), and thereby cause a microstructure less susceptible to HIC to form in the HAZ. The results of this effect are shown in Fig. 28, where it is seen that a tensile stress in the 500 to 300 °C (930 to 570 °F) temperature range on a ferrite-pearlite weld increased the stresses for failure (Ref 35).

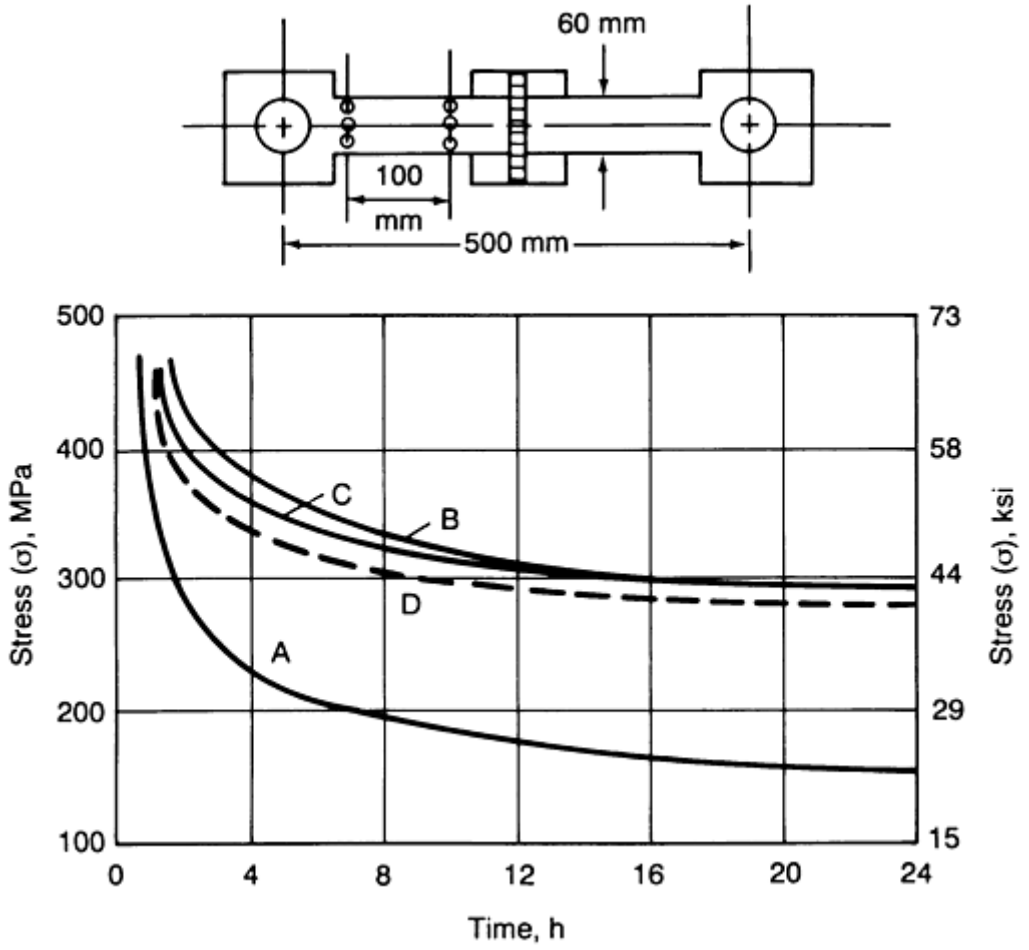

FIG. 28 DELAYED FRACTURE CURVES FOR TENSILE TESTS ON WELDED JOINTS IN 35KH3N3M (A RUSSIAN SPECIFICATION) STEEL. A, FERRITIC-PEARLITIC WELD; B, BAINITIC-MARTENSITIC WELD; C, AUSTENITIC WELD; D, FERRITIC-PEARLITIC WELD PLUS DEFORMATION AT 500 TO 300 °C (930 TO 570 °F). THE SCHEMATIC SHOWS THE SPECIMEN DIMENSIONS FOR THE DELAYED FRACTURE TENSILE TESTS ON WELDED JOINTS. SOURCE: REF 35

It must be mentioned that the idea of using an austenite-martensite weld metal represents a considerable departure from conventional thinking. For example, for certain overlaying applications of stainless steel deposits on low-alloy steel, an overalloyed electrode like E310 or E312 is preferred to E309. Even though the weld metal composition with any of the three electrodes would be acceptable, the use of overalloyed electrodes will minimize the width of the martensitic layer in the unmixed zone at the weld-HAZ interface (Ref 36). By contrast, an austenite-martensite weld metal implies that the choice of consumable will have to be such that the width of the martensitic layer will increase. However, because the proposal is meant for the recently developed high-strength steels that have a low carbon content, only a low-carbon martensite will form, which will not be that harmful. The benefits already discussed could override conventional concerns about having martensite in the weld metal in this case.

To sum up, even though the idea of using an austenite-martensite weld metal for high-strength steels does not seem to have been taken up for serious investigation so far, it has been included here because it is a nice way of illustrating the principles discussed. In addition, it shows that a fundamental knowledge of different effects on phase transformations can lead to unconventional solutions to practical problems.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

HAZ in Multipass Weldments

In the HAZ of a single-pass weld, the grain-coarsened zone (GC HAZ) is normally the region having the lowest toughness. Turning to a multipass weld, Fig. 29 (compare with Fig. 3) shows how the GC HAZ can be modified by subsequent passes and can be categorized into four regions, depending on the reheating temperature (Ref 37):

- SUBCRITICALLY REHEATED GRAIN-COARSENED (SCGC) ZONE, THE ZONE REHEATED BELOW AC_1
- INTERCRITICALLY REHEATED GRAIN-COARSENED (ICGC) ZONE, THE ZONE REHEATED BETWEEN AC_1 AND AC_3
- SUPERCRITICALLY REHEATED GRAIN-REFINED (SCGR) ZONE, THE ZONE REHEATED ABOVE AC_3 AND BELOW ABOUT 1200 °C (2190 °F)
- UNALTERED GRAIN-COARSENED (UAGC) ZONE, THE ZONE THAT IS NOT REHEATED ABOVE ABOUT 200 °C (390 °F) OR THE ZONE THAT IS AGAIN REHEATED ABOVE ABOUT 1200 °C (2190 °F)

Figure 30 shows how the crack tip opening displacement (CTOD) value of simulated specimens varies with the peak temperature of the second thermal cycle, T_{p2} (T_{p1} = 1400 °C, or 2550 °F). It is seen that the ICGC, UAGC, and SCGC regions have CTOD values less than about 0.1 mm (0.004 in.). Similar low values have been obtained by locating the crack tip in the CTOD tests at corresponding locations in the HAZ of actual multipass weldments. These low toughness regions are commonly known as local brittle zones (LBZs).

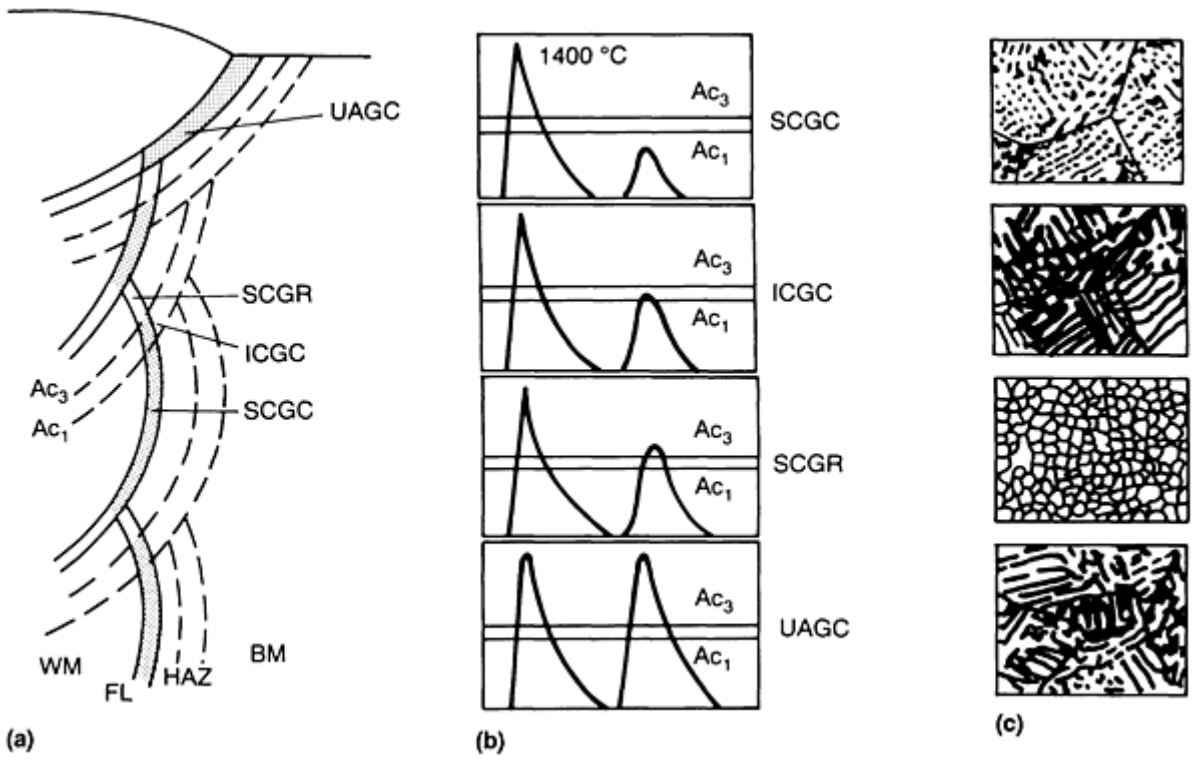

FIG. 29 SCHEMATIC SHOWING THE DIFFERENT SUBZONES THAT CAN FORM IN THE COARSE-GRAINED REGION OF THE HAZ IN A MULTIPASS WELD. (A) POSITION OF SUBZONES RELATIVE TO BASE METAL (BM) AND WELD METAL (WM). (B) PLOT OF THERMAL CYCLES RELATIVE TO AC_3 AND AC_1. (C) MICROSTRUCTURES AT THE DIFFERENT ZONES. FL REFERS TO THE FUSION LINE. SEE TEXT FOR DETAILS. SOURCE: REF 37

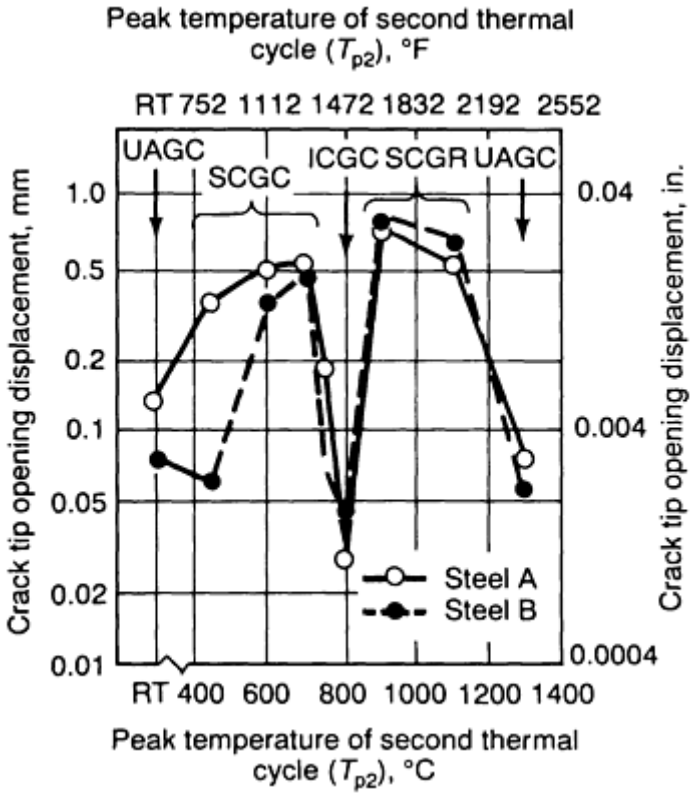

FIG. 30 PLOT OF CRACK TIP OPENING DISPLACEMENT VERSUS PEAK TEMPERATURE OF THE SECOND THERMAL CYCLE FOR SIMULATED SPECIMENS SUBJECTED TO A DOUBLE THERMAL CYCLE. (T_{P1} = 1400 °C = 2550 °F; $\Delta T_{8\text{-}5}$ = 20 S). THE HAZ ZONES (FIG. 29) CORRESPONDING TO THE SIMULATION TRIALS ARE ALSO SHOWN IN THE FIGURE. SOURCE: REF 37

The low CTOD values have been obtained only in tests on modern structural steels, whereas no actual structural failure attributable to the LBZs has been reported so far (Ref 38). Because the structural significance of the low toughness test results is still largely unresolved, the present conservative strategies are to choose a steel whose tendency to form LBZs is less or to choose a welding procedure by which the size of the LBZs can be reduced.

The ICGC HAZ usually has a lower toughness than the SCGC or UAGC regions, even though all of them have nearly the same γ grain size. This is due to the higher amount of highcarbon martensite-austenite (M-A) constituent in the ICGC HAZ. When the GC HAZ is reheated to a temperature between Ac_1 and Ac_3, austenite is nucleated at the high carbon areas. Upon cooling, these local high-carbon areas can transform to give twinned martensite with every thin regions of retained austenite in between. (See Ref 39 for detailed metallographic procedures for identifying the M-A constituent.) The carbon content in the M-A islands can range from about 0.3 to 0.5% C. The significance of this is that, for a given nominal carbon content in the steel, the volume fraction of the M-A constituent will be much higher than if most of the carbon formed carbides (by the lever rule). This will increase the number of crack nucleation sites and thereby contribute to the inferior toughness of ICGC HAZ. As is to be expected, the volume fraction of the M-A constituent also depends on the hardenability of the steel, which in turn depends on the alloying content. It has been shown that if the development of pearlitic microphases could be promoted instead of the development of M-A, by decreasing the alloy content, the toughness of the ICGC HAZ could be improved (Ref 40). However, this would have penalties in terms of achievement of parent plate strength. A more feasible solution would be to inhibit grain growth in the HAZ.

The multipass welding procedure can alternatively be controlled to limit the size of the LBZs. Figure 31 shows how this can be done with a tandem three-wire high current gas-metal arc welding procedure by adjusting the distance between the three arcs. Special "temper-bead" procedures (Ref 42) have been developed for controlling the microstructure in the HAZ, and a need for these procedures arises in the following way. Low-alloy steel weldments for critical applications (for example, pressure vessels) require a postweld heat treatment (PWHT) in a furnace. This is done to temper the hard regions in the HAZ and to relieve residual stresses. If repairs become necessary on site after the component has been in service, PWHT is usually not feasible. The heat of the arc can then be used to achieve the tempering function of PWHT

by suitable spatial positioning and sequencing of the individual passes. Grain refinement in he HAZ is also sought to increase the toughness and thereby offset the harmful effects of residual stresses that would remain in the absence of PWHT.

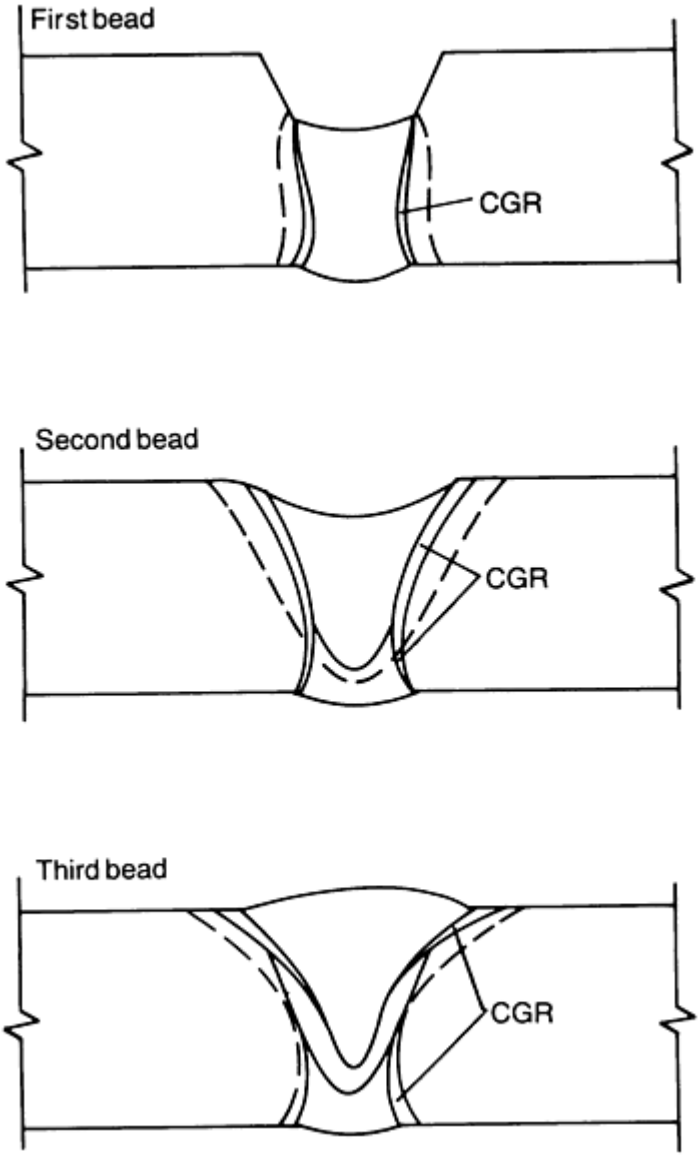

FIG. 31 SCHEMATIC SHOWING THAT THE HAZ ISOTHERMS AND THE SIZE AND LOCATION OF THE COARSE-GRAINED REGION (CGR) CAN BE CONTROLLED IN A TANDEM THREE-WIRE HIGH CURRENT GAS-METAL ARC WELDING PROCEDURE. GRAIN REFINEMENT OF COARSE-GRAINED REGIONS INITIALLY FORMED IS OBTAINED BY OPTIMIZING THE DISTANCES BETWEEN THE THREE ARCS. SOURCE: REF 41

An example of a two-layer temper bead procedure is shown in Fig. 32. The heat inputs of the first and second layer are carefully controlled, so that the heat from the second layer is used to refine the coarse-grained region in the HAZ of the base metal due to the first layer. This ideas can be extended one step further by using a pulsed gas-tungsten arc welding procedure whereby a given pulse in a pulsed weldment can be used to successively refine and temper the preceding pulse pitch regions (Ref 11). The degree of microstructural refinement depends primarily on the welding speed and pulsing frequency, and these parameters can be controlled with great precision. By contrast, an important variable to be controlled in the temper-bead procedure is the weld deposit height, and it is difficult to exercise the same degree of control on this. For this reason, it is argued that the maximum possible control on the microstructural changes in the repair weldment is possible with the pulsing procedure.

Fusion Zone in Multipass Weldments

In the weld metal of a multipass weld, reheating effects will lead to a gradient in microstructure similar to the case of the HAZ. However, instead of a detailed classification, the multipass weld metal is usually considered to consist of just two regions (Fig. 33):

- *AS-DEPOSITED OR PRIMARY REGION,* WHERE THE MICROSTRUCTURE DEVELOPS AS THE WELD COOLS FROM THE LIQUID PHASE TO AMBIENT TEMPERATURE
- *REHEATED OR SECONDARY REGION,* WHERE REGIONS WITH THE ORIGINAL PRIMARY MICROSTRUCTURE ARE REHEATED TO TEMPERATURES ABOVE THE AC_1 TEMPERATURE. THE TEMPERED REGIONS WHICH ARE REHEATED TO SLIGHTLY LOWER TEMPERATURES ARE ALSO GENERALLY CONSIDERED TO BELONG TO THIS CATEGORY

The properties of the weld metal depend on the relative area or volume fractions of the two regions, which in turn depend on the welding procedure, so the properties are procedure-specific. Hence arises the need for welding procedure qualification as per codes and standards in addition to the qualification of consumables (for which is standard procedure is specified).

Stainless Steels

It has long been known that solidification cracking can be avoided in austenitic stainless steel welds by having a small concentration of ferrite in them. Recent work has shown, however, that residual ferrite content at room temperature is no

more than a symptom and that it is really the solidification mode (whether the weld metal solidifies as primary austenite or ferrite) that is the deciding criterion (Ref 43). It has been found that susceptibility to solidification cracking is least for a primary ferrite solidification mode (more specifically, when the solidification mode corresponds to the types shown in Fig. 34c and 34d). It is believed that low-melting-point liquid phases (formed by the segregation of impurities like sulfur and phosphorus, for example) solidifying in the intercellular regions do not wet the δ-γ interphase boundaries as easily as they would δ-δ or γ-γ boundaries. In the ferritic-austenitic solidification mode (Fig. 34c and 34d), the δ-γ interphase boundary area is greater at temperatures just below the nominal solidus temperature, and this is the reason for a greater resistance to solidification cracking.

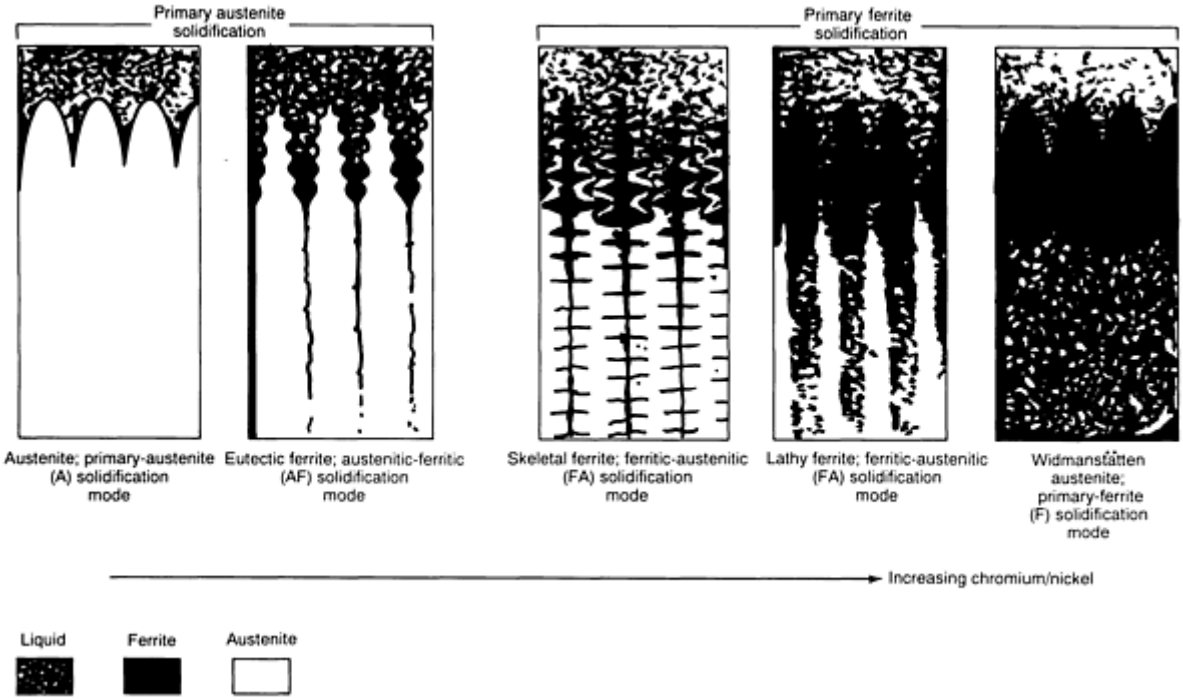

FIG. 34 SCHEMATIC SHOWING SOLIDIFICATION AND TRANSFORMATION BEHAVIOR RESULTING IN A RANGE OF FERRITE MORPHOLOGIES IN AUSTENITIC STAINLESS STEEL WELDS. SOURCE: REF 43

Information about the solidification mode can be obtained from the chemical composition of the weld metal by referring to the WRC-1992 diagram (Fig. 35). It has been found that this diagram is more accurate than the Schaeffler (for duplex stainless steel welds) and Delong (for 300 series austenitic steel welds) diagrams developed earlier. All of these diagrams are strictly applicable only for the cooling rates obtained in manual metal arc (MMA) welding because the data for establishing the statistical correlations have been taken from MMA welds. The dotted lines in Fig. 35 are the demarcation lines between the different solidification modes shown (that is, A, AF, FA, and F) corresponding to the types in Fig. 34(a), 34(b), 34(c), 34(d), and 34(e), respectively. The AF-FA boundary in Fig. 35 (which, as discussed earlier, corresponds to the onset of cracking) intersects the iso-ferrite number lines at an angle. This is consistent with the findings of several investigators that the minimum ferrite content necessary to avoid hot cracking is different for different weld metal compositions (that is, for weld metals deposited with E 316, E 308L, E 309, and so on).

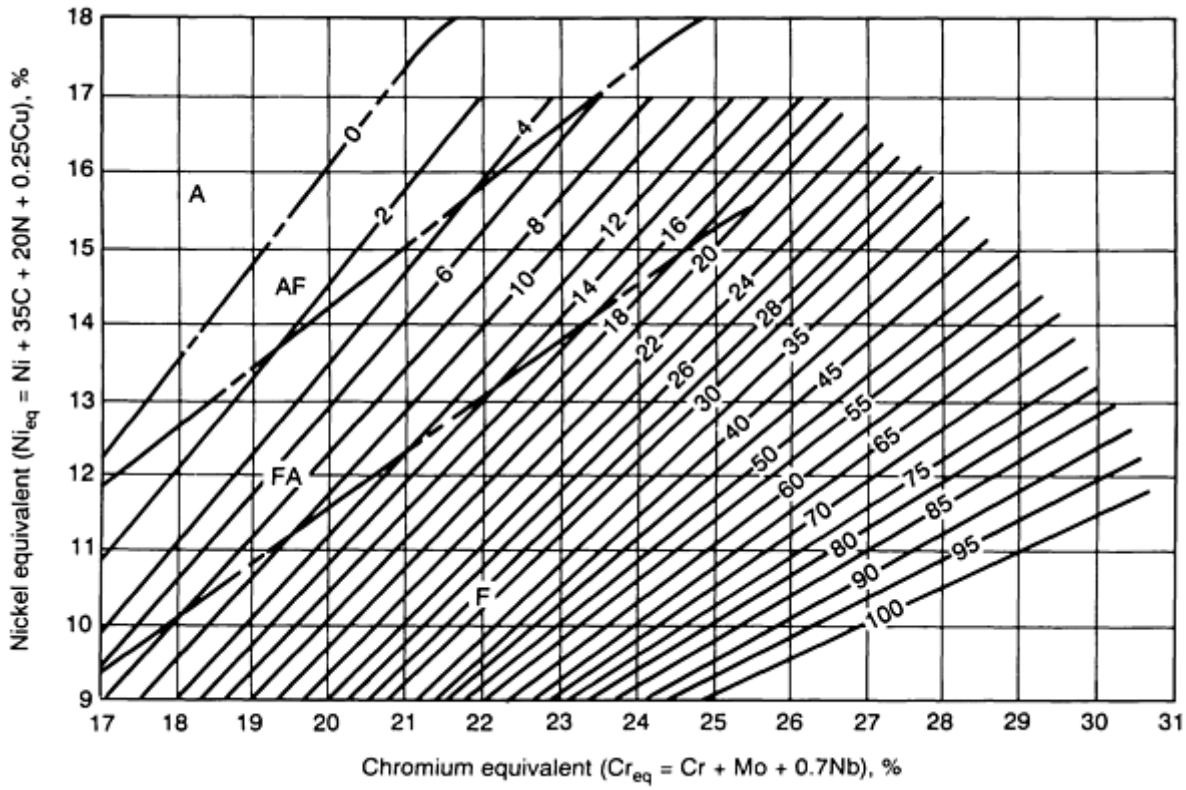

FIG. 35 WRC-1992 DIAGRAM PREDICTING FERRITE CONTENT IN STAINLESS STEELS. FERRITE CONTENT IS GIVEN BY THE FERRITE NUMBER (FN), WHERE 100 FN IS APPROXIMATELY EQUAL TO 65 VOL% FERRITE. BOUNDARIES DENOTING A CHANGE IN SOLIDIFICATION MODE (A, AF, FA AND F PER FIG. 34) ARE ALSO SHOWN (INDICATED BY DOTTED LINES). SOURCE: REF 45

It is a fortunate coincidence that the coefficients in the Cr_{eq} and Ni_{eq} expressions (see Fig. 35), which have been obtained by statistical fitting methods, result in satisfactory correlations with both the solidification mode and the ferrite number (a precisely measurable quantity that is roughly proportional to the actual volume percentage of ferrite at room temperature) (Ref 44). Indeed, it has been found that the same Cr_{eq} and Ni_{eq} expressions (that is, with the same elements and coefficients) are not able to satisfactorily fix the locations of the martensite and martensite-austenite phase fields seen in the lower left region of the Schaeffler diagram. For this reason, such regions of Cr_{eq} and Ni_{eq} are excluded in the WRC-1992 diagram.

A discussion of weld decay due to sensitization and knife line attack in the HAZ of austenitic stainless steels can be found in Ref 14 and 46.

Aluminum Alloys

The main problems in the welding of heat-treatable aluminum alloys are liquation cracking in the partially melted zone (see the section "Unmixed and Partially Melted Zones in a Weldment" in this article) and softening in the HAZ (Ref 14, 47). The latter means that the weld joint strength can be reduced. Reasons for the softening can be understood by referring to Fig. 36. The parent material is assumed to be a 2000- or 6000-series aluminum alloy, artificially aged to contain the metastable phase of θ' (in aluminum-copper alloys), S' (in aluminum-copper-magnesium alloys), or β' (in aluminum-magnesium-silicon alloys). A very fine dispersion of precipitate particles is obtained in the parent material by a solution heat treatment followed by aging, and this is the reason for the high strength in the materials. Figure 36(b) shows that a gradient in hardness is obtained in the HAZ immediately after welding. At location 1, the high peak temperature causes the precipitate particles to go into solution, and the cooling rate is too high for reprecipitation. At locations 2 and 3, the precipitate particles partially dissolve and coarsen. After postweld artificial aging, fine precipitate particles are again formed at location 1, causing the hardness to increase to the parent material level. However, at locations 2 and 3, only a lower hardness can be obtained because of the formation of coarse precipitate particles. For increasing weld heat inputs, the width of the softened zone increases. A good discussion of how the above phenomenon can be modeled is found in Ref 48.

Nickel-Base Superalloys

Nickel-base superalloys have a very high creep resistance, making them attractive for critical high-temperature applications such as gas turbines. Yet it is this very characteristic that gives rise to the problem of strain age cracking in the weld HAZ (Ref 14, 19, 49). The high-temperature creep strength in the parent materials is obtained by forming fine precipitates of γ' (Ni_3(Al, Ti)) or γ" (Ni_3Nb) in them. In the region of the weld HAZ subjected to high peak temperatures, these precipitates dissolve, similar to the case of aluminum alloys. After welding, the weldments are again solution heat-treated and aged (note the difference between aluminum alloys and the nickel-base superalloys in this respect). The purposes of this treatment are to obtain the same uniform and fine precipitation in the weld as in the parent material and to relieve the weld residual stresses.

Normally (for example, in the case of low-alloy or carbon steel welds), PWHT in a furnace relieves the residual stresses because the yield stress at the PWHT temperature is very low. A residual stress greater than the yield stress cannot be supported, and stress relief is brought about by a process of creep and plastic deformation. This process is difficult in nickel-base superalloy weldments, however, because of their high creep strength and low creep ductility. Reprecipitation in the solutionized regions of the HAZ (during the heating-up to the PWHT temperature) strengthens the matrix and does not allow any creep or plastic deformation (necessary for the relief of residual stress) to take place. Cracking can occur in this condition at the grain boundaries in the grain-coarsened region of the HAZ. Cracks initiated here have been known to run far into the base material. This problem is very difficult to solve, and the best solution has been found to be to switch over to materials such as Inconel 718 alloy that are inherently less susceptible to cracking, even though their creep strength is somewhat lower. Inconel 718 alloy contains γ" precipitate, and the slow kinetics of precipitation in this alloy allow substantial stress relief to be achieved before precipitation increases the creep strength in the HAZ.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

Titanium Alloys

Titanium alloys find use in aerospace applications, pressure vessels, and so on because of their high strength-to-weight ratio, high corrosion resistance, and high fracture toughness. Pure titanium has two allotropic forms: low-temperature hexagonal close-packed (hcp) α-phase and elevated-temperature body-centered cubic (bcc) β-phase. Various alloying elements tend to preferentially stabilize one or the other of these phases. As a result, titanium alloys are generally classified as α, α+ β, metastable β, and β alloys (Fig. 37).

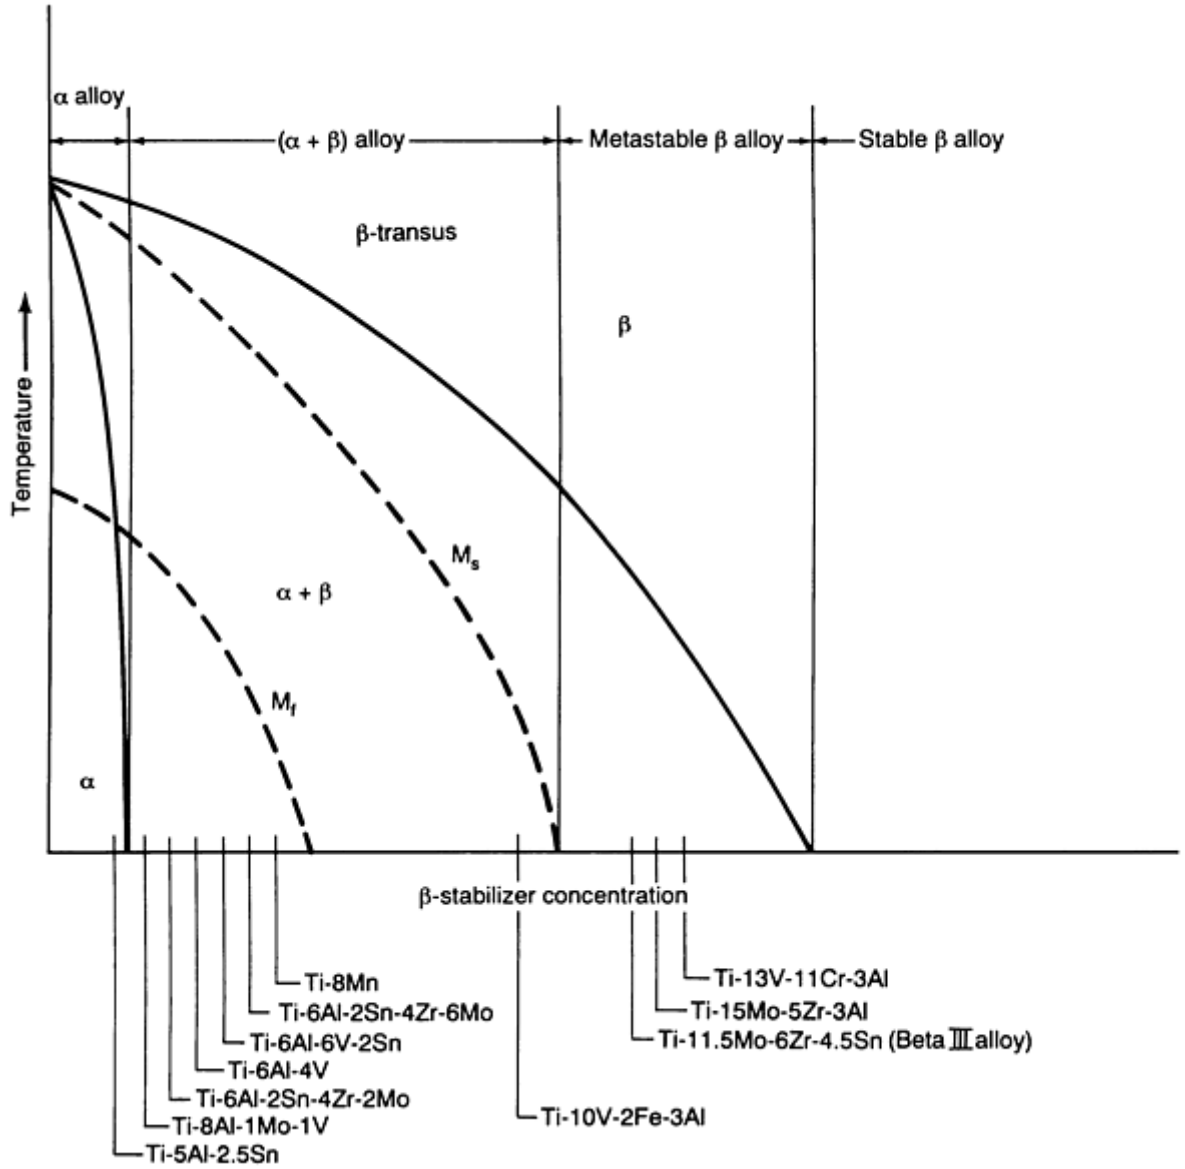

FIG. 37 HYPOTHETICAL β ISOMORPHOUS PHASE DIAGRAM THAT SHOWS RELATION BETWEEN β -STABILIZER SOLUTE CONTENT AND TITANIUM ALLOY FAMILY DESCRIPTION. SELECTED COMMON ALLOYS ARE LISTED ALONG THE *X*-AXIS OF THE DIAGRAM BASED ON THEIR COMPOSITIONS. SOURCE: REF 50

The α-alloys are not heat-treatable (that is, a significant increase in strength and toughness cannot be obtained by heat treatment), and they have the lowest strength of the four titanium alloy families. Interestingly enough, these alloys are thus considered to have excellent weldability. What this means in practice is that there is no significant degradation in the properties of the weld and HAZ with regard to the parent material due to the weld thermal cycles. Also, the β ↔ α transformation in the weld and near HAZ means that the extent of grain coarsening will not be so high as in other single-phase materials in which no phase transformation occurs upon heating or cooling, such as stabilized ferritic stainless steels (Ref 51), pure aluminum, and so on.

In the α+ β alloys, a higher strength is obtained with a higher volume fraction of the β phase, which in turn is obtained with a higher β -stabilizing alloy content (Fig. 37). The effect of cooling rate on the phase transformations in two α+ β alloys is shown schematically in Fig. 38. As in the case of steels, it is seen that the β ↔ αtransformation can occur either by nucleation and growth at slower cooling rates or martensitically at higher cooling rates. The martensitic product in the lean α+ β alloys has an hcp crystal structure (designated as α') or an orthorhombic one (designated as α") in the β-stabilized α+ β alloys. It is seen that the C-curve for the β ↔ intergranular α transformation is shifted to the right for alloys with increasing β-stabilizing alloy content, while that for the allotriomorphic α (more commonly referred to as GB

α) is relatively insensitive to alloy concentration (Ref 52). As a result, alloys that are fairly rich in β-stabilizing additions exhibit a stronger tendency to form a continuous network of GB α than do leaner α + β alloys.

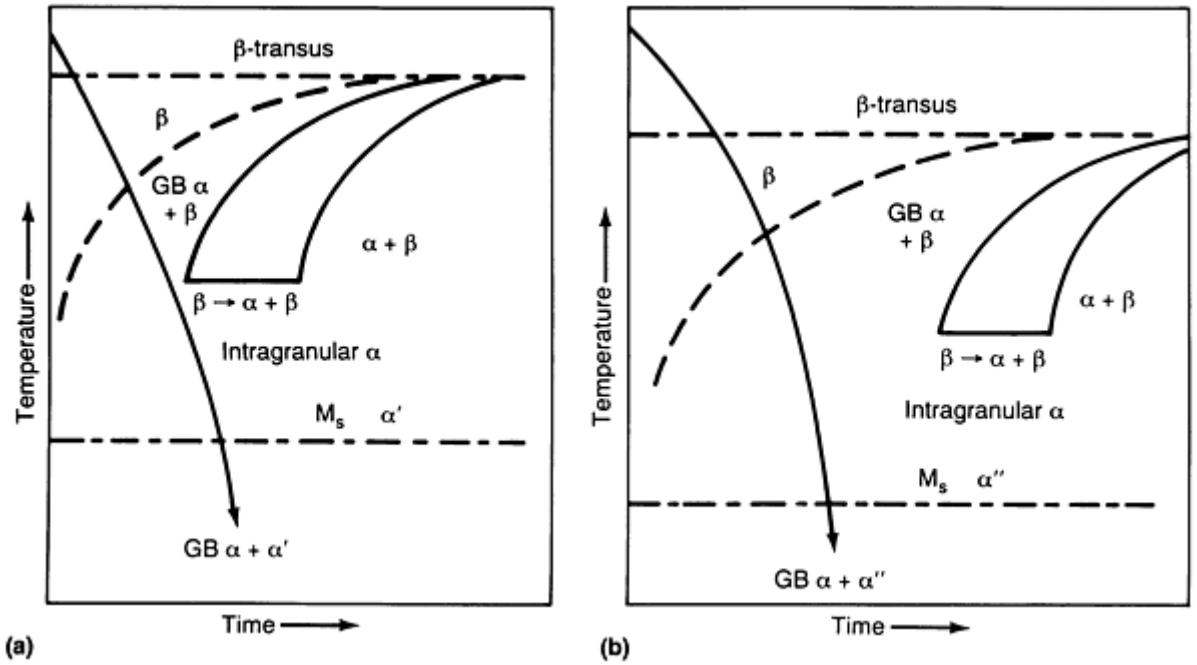

FIG. 38 SCHEMATIC CCT DIAGRAMS FOR TWO α + β TITANIUM ALLOYS WITH DIFFERENT β -STABILIZER SOLUTE CONTENTS. (A) LEAN α + β ALLOY (FOR EXAMPLE, TI-6AL-4V). (B) α + β ALLOY (FOR EXAMPLE, CORONA 5 [TI-4.5AL-5MO-1.5CR]) RICHER IN β -STABILIZING SOLUTE CONTENT

The morphology of the α and β phases in the α + β base materials is strongly dependent on thermomechanical processing (TMP) and heat treatment, which are performed either in the β-phase field or in the two-phase α + β phase field. When TMP is done in the α+ β phase field, the α that forms on cooling is continuously deformed. After recrystallization, a near-equiaxed α structure is obtained after this α + β processing. Very little GB α is formed because deformation introduces sufficient alternate heterogeneous nucleation sites in the form of dislocations. On the other hand, if TMP is done above the β-transus temperature (β-processing) and cooled, α forms at grain boundaries (giving GB α) and in the interior of grains as a Widmanstätten structure (also referred to as an acicular, lenticular, or basketweave structure). The microstructure in the weld and the near HAZ is closer to that obtained after β-processing.

Figure 39 shows the effect of α + β processing and β-processing on the strength and toughness of α + β alloys with increasing β-stabilizing alloy content. At the lower strength levels obtained with a lower β-stabilizing alloy content (because of a lower volume fraction of β-phase present), the finer Widmanstätten structure obtained after β-processing has a higher toughness than the coarser structure obtained by α + β processing. At higher strength levels, the trend reverses with the α + β processed structure having a higher toughness. This result can be understood in terms of the strength differences between GB α and the interior of the prior β grains (Fig. 40). At lower strengths, when the grain interiors are relatively weak, the crack tip plastic zone is distributed between the GB α and the grain interiors. However, as the α-phase precipitates are refined by lower aging temperatures, as in the case of the metastable β alloys, the grain interiors are strengthened considerably. Under such circumstances, the cracks are essentially constrained to follow the GB α layer. This results in a contraction of the plastic zone, a reduction in the crack tip opening displacement for crack extension, and an attendant drop in the toughness.

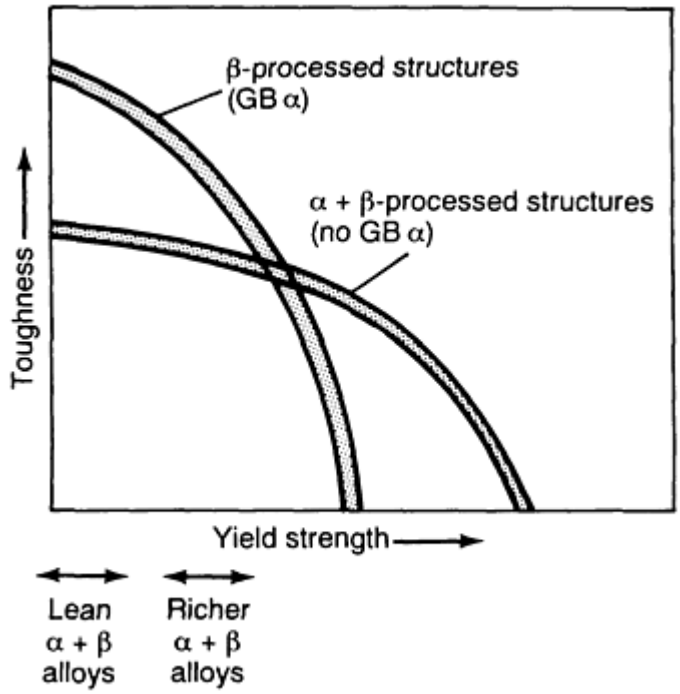

FIG. 39 SCHEMATIC PLOT OF TOUGHNESS VERSUS YIELD STRENGTH FOR α + β AND β-PROCESSED STRUCTURES. APPROXIMATE LOCATIONS OF LEAN (FOR EXAMPLE, TI-6AL-4V) AND RICHER β STABILIZED α + β ALLOYS (FOR EXAMPLE, CORONA 5 [TI-4.5AL-5MO-1.5CR]) ARE SHOWN. SOURCE: REF 52

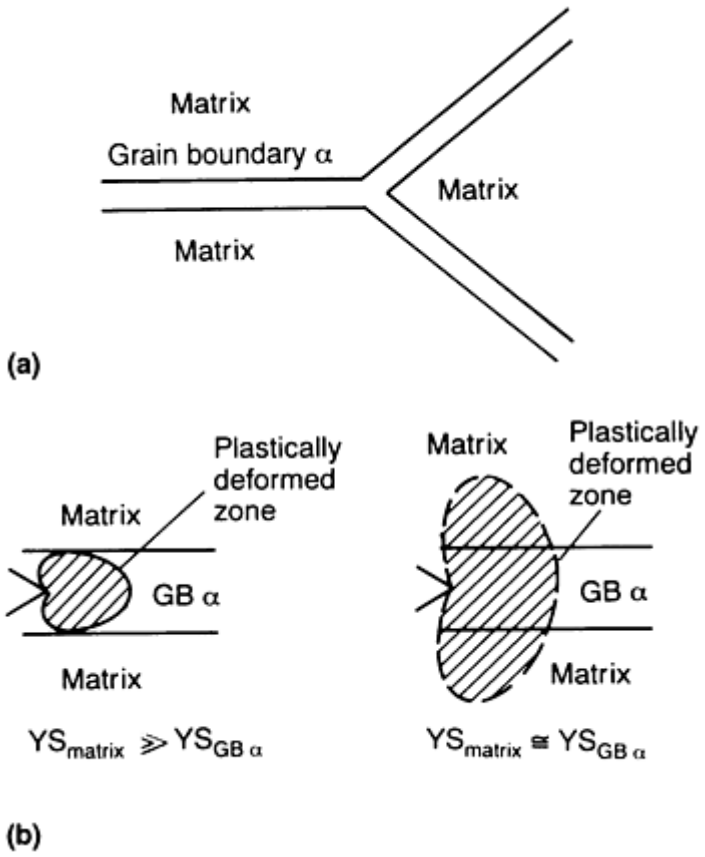

FIG. 40 SCHEMATIC SHOWING THE EFFECT OF THE RELATIVE STRENGTHS OF GB α AND MATRIX ON THE

PLASTIC ZONE SIZE. (A) GB α LOCATION RELATIVE TO MATRIX. (B) EFFECT OF PLASTIC ZONE SIZE ON YIELD STRENGTHS OF MATRIX AND GB α. SOURCE: REF 52

The microstructures in the weld metal and the near HAZ (the region where the peak temperature exceeds the β-transus temperature) resemble those obtained after β-processing. This means that it is easier to get a matching toughness in the weld metal at the lower strength levels referred to in Fig. 39. Even this is made somewhat difficult by the coarser β grain size in the weld and HAZ. Grain coarsening in the HAZ induces coarse β grains to form in the weld also, because solidification in the weld metal occurs by epitaxial growth from the HAZ. The extent of grain coarsening is such that it is not uncommon to find a single columnar β grain traversing the entire thickness in gas-tungsten arc welds on thin sheet (Ref 53). If high energy density welding processes are used (for example, electron-beam welding or laser-beam welding), it is possible to limit the extent of β grain coarsening. However, the high cooling rates in the weld and HAZ will mean that a martensitic structure will be obtained.

To obtain adequate ductility and toughness, PWHT will have to be done at temperatures close to the β-transus temperature. This can be a problem because the low strength at these temperatures can cause sagging in large welded structures, and complex fixturing will be necessary to maintain dimensional tolerances. It can also be expensive, because inert gas shielding is required for almost the entire time of PWHT (it is assumed in the present discussion that adequate care is taken to maintain proper shielding during welding). Moreover, it can be difficult to increase the ductility in the weld metal and HAZ to a level equal to that in an α+ β processed base material (Fig. 41). The trends seen in Fig. 39 and 41 can be understood by noting that crack nucleation is more difficult in an equaixed structure (because the strain concentration effects are less) and that the plastic zone sizes are bigger (Table 1). This results in a higher tensile ductility. However, because crack propagation follows a less tortuous path, the toughness is lower. The reverse is true for a Widmanstätten structure (referred to as a lenticular structure in Table 1). Table 1 explains the apparently strange observation in titanium alloys that a structure having a high strength and toughness is not necessarily the one having a high tensile ductility. The implication of this for weldments is that for many applications it may be more important to optimize the welding and PWHT procedure with respect to the toughness than with respect to the ductility.

TABLE 1 EFFECT OF MORPHOLOGICAL FEATURES OF THE MICROSTRUCTURE ON CRACK NUCLEATION AND PROPAGATION IN α + β TITANIUM ALLOYS

Note: Voids initiated at the α -β interfaces are shown as black regions. Source: Ref 54

Structure	Crack nucleation	Crack growth	Tensile ductility as a function of plastic zone size	Toughness as a function of crack propagation
Lenticular (Widmanstätten)	Easy	Difficult	 Low ductility	 High toughness
Globular (equiaxed)	Difficult	Easy	 High ductility	 Low toughness

The morphology of the α and β phases in the α + β base materials is strongly dependent on thermomechanical processing (TMP) and heat treatment, which are performed either in the β-phase field or in the two-phase α+ β phase field. When TMP is done in the α+ β phase field, the α that forms on cooling is continuously deformed. After recrystallization, a near-equiaxed α structure is obtained after this α + β processing. Very little GB α is formed because deformation introduces sufficient alternate heterogeneous nucleation sites in the form of dislocations. On the other hand, if TMP is done above the β-transus temperature (β-processing) and cooled, α forms at grain boundaries (giving GB α) and in the interior of grains as a Widmanstätten structure (also referred to as an acicular, lenticular, or basketweave structure). The microstructure in the weld and the near HAZ is closer to that obtained after β-processing.

Figure 39 shows the effect of α + β processing and β-processing on the strength and toughness of α + β alloys with increasing β-stabilizing alloy content. At the lower strength levels obtained with a lower β-stabilizing alloy content (because of a lower volume fraction of β-phase present), the finer Widmanstätten structure obtained after β-processing has a higher toughness than the coarser structure obtained by α + β processing. At higher strength levels, the trend reverses with the α + β processed structure having a higher toughness. This result can be understood in terms of the strength differences between GB α and the interior of the prior β grains (Fig. 40). At lower strengths, when the grain interiors are relatively weak, the crack tip plastic zone is distributed between the GB α and the grain interiors. However, as the α-phase precipitates are refined by lower aging temperatures, as in the case of the metastable β alloys, the grain interiors are strengthened considerably. Under such circumstances, the cracks are essentially constrained to follow the GB α layer. This results in a contraction of the plastic zone, a reduction in the crack tip opening displacement for crack extension, and an attendant drop in the toughness.

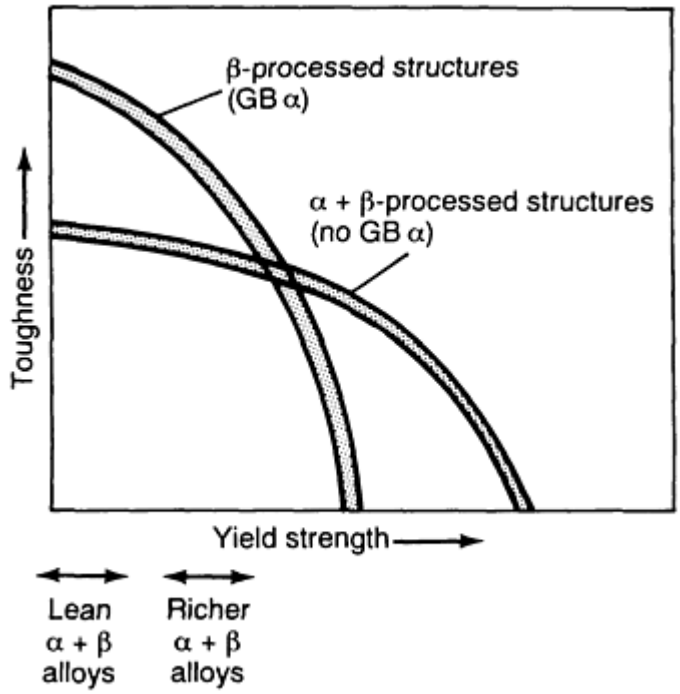

FIG. 39 SCHEMATIC PLOT OF TOUGHNESS VERSUS YIELD STRENGTH FOR α + β AND β -PROCESSED STRUCTURES. APPROXIMATE LOCATIONS OF LEAN (FOR EXAMPLE, TI-6AL-4V) AND RICHER β STABILIZED α + β ALLOYS (FOR EXAMPLE, CORONA 5 [TI-4.5AL-5MO-1.5CR]) ARE SHOWN. SOURCE: REF 52

STRENGTHS OF MATRIX AND GB α. SOURCE: REF 52

The microstructures in the weld metal and the near HAZ (the region where the peak temperature exceeds the β-transus temperature) resemble those obtained after β-processing. This means that it is easier to get a matching toughness in the weld metal at the lower strength levels referred to in Fig. 39. Even this is made somewhat difficult by the coarser β grain size in the weld and HAZ. Grain coarsening in the HAZ induces coarse β grains to form in the weld also, because solidification in the weld metal occurs by epitaxial growth from the HAZ. The extent of grain coarsening is such that it is not uncommon to find a single columnar β grain traversing the entire thickness in gas-tungsten arc welds on thin sheet (Ref 53). If high energy density welding processes are used (for example, electron-beam welding or laser-beam welding), it is possible to limit the extent of β grain coarsening. However, the high cooling rates in the weld and HAZ will mean that a martensitic structure will be obtained.

To obtain adequate ductility and toughness, PWHT will have to be done at temperatures close to the β-transus temperature. This can be a problem because the low strength at these temperatures can cause sagging in large welded structures, and complex fixturing will be necessary to maintain dimensional tolerances. It can also be expensive, because inert gas shielding is required for almost the entire time of PWHT (it is assumed in the present discussion that adequate care is taken to maintain proper shielding during welding). Moreover, it can be difficult to increase the ductility in the weld metal and HAZ to a level equal to that in an α + β processed base material (Fig. 41). The trends seen in Fig. 39 and 41 can be understood by noting that crack nucleation is more difficult in an equaixed structure (because the strain concentration effects are less) and that the plastic zone sizes are bigger (Table 1). This results in a higher tensile ductility. However, because crack propagation follows a less tortuous path, the toughness is lower. The reverse is true for a Widmanstätten structure (referred to as a lenticular structure in Table 1). Table 1 explains the apparently strange observation in titanium alloys that a structure having a high strength and toughness is not necessarily the one having a high tensile ductility. The implication of this for weldments is that for many applications it may be more important to optimize the welding and PWHT procedure with respect to the toughness than with respect to the ductility.

TABLE 1 EFFECT OF MORPHOLOGICAL FEATURES OF THE MICROSTRUCTURE ON CRACK NUCLEATION AND PROPAGATION IN α+ β TITANIUM ALLOYS

Note: Voids initiated at the α-β interfaces are shown as black regions. Source: Ref 54

Structure	Crack nucleation	Crack growth	Tensile ductility as a function of plastic zone size	Toughness as a function of crack propagation
Lenticular (Widmanstätten)	Easy	Difficult	 Low ductility	 High toughness
Globular (equiaxed)	Difficult	Easy	 High ductility	 Low toughness

Note: Voids initiated at the α-β interfaces are shown as black regions. Source: Ref 54

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Introduction

THE FORMATION OF DEFECTS in materials that have been fusion welded is a major concern in the design of welded assemblies. Four types of defects in particular have been the focus of much attention because of the magnitude of their impact on product quality. These defects, all of which manifest themselves as cracks, are characteristic of phenomena that occur at certain temperature intervals specific to a given alloy. Colloquially, these four defect types are known as hot cracks, heat-affected zone (HAZ) microfissures, cold cracks, and lamellar tearing.

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Solidification Cracking (Hot Cracking)

Hot cracks are solidification cracks that occur in the fusion zone near the end of solidification. Simplistically, they result from the inability of the semisolid material to accommodate the thermal shrinkage strains associated with weld solidification and cooling. Cracks then form at susceptible sites to relieves the accumulating strain. Susceptible sites are interfaces, such as solidification grain boundaries and interdendritic regions, that are at least partially wetted.

Figure 1 is a photomicrograph of a metallographic section showing the appearance of a typical solidification crack in a fusion weld. Note the intergranular nature of the crack path. Figure 2 shows the surface morphology of a solidification crack, reflecting the nearly solidified nature of the interface at the time of failure. Note the smooth dendritic appearance of this surface.

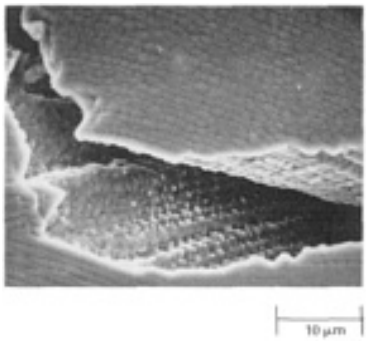

FIG. 1 SOLIDIFICATION CRACK IN A PULSED ND:YAG LASER WELD JOINING HASTELLOY C-276 TO 17-4 PH STAINLESS STEEL. YAG, YTTRIUM-ALUMINUM-GARNET

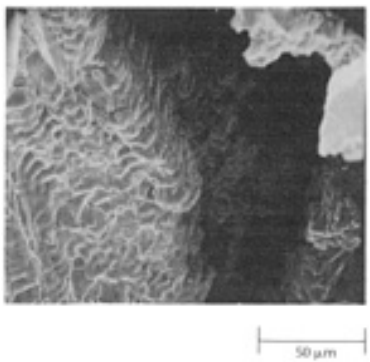

FIG. 2 SURFACE OF A SOLIDIFICATION CRACK IN AN ALLOY 214 VARESTRAINT TEST SPECIMEN

Solidification cracking requires both a sufficient amount of mechanical restraint (strain) and a susceptible microstructure. Knowledge regarding the development of shrinkage strains at the microstructural scale of a solidifying dendrite is still quite limited, making it nearly impossible to quantify *a priori* the amount of local strain required to initiate solidification cracks. Furthermore, the rate at which the strain is applied can influence the ability of an alloy to survive the solidification process without cracking. At temperatures near their melting points, metal alloys can readily dissipate applied loads by time-dependent deformation processes (i.e., creep processes). At high rates of applied stress, both the fusion zone and the HAZ have limited time to accommodate this mechanical imposition. Under conditions of rapid solidification and cooling, the rate of strain accumulation is rapid, leading to an increased cracking susceptibility. Inherently, then, requisite strains for solidification cracking are more likely to be experienced with welding processes that promote rapid solidification and cooling.

Because of the limited quantitative understanding of strain development in a solidifying weld, the practical approach taken to minimize the mechanical factor is to reduce the overall weld restraint through judicious joint design and appropriate choice of welding parameters. A simple way to minimize the restraint on a solidifying weld joint is to keep the joint gap to a minimum by designing hardware with good fit-up. Another approach, particularly attractive for small parts, is to design the weld joint as a standing edge. Welding parameters can have a profound influence on the occurrence of solidification cracking. The natural tendency to use high-speed welding to improve productivity can have detrimental effects. Formation of a teardrop-shaped weld pool, which may occur as the weld travel speed increases, can result in centerline solidification cracks. The solidification pattern associated with this type of weld pool is such that solidifying grains meet at the weld centerline, forming a particularly susceptible site for solidification crack initiation.

The manner in which a fusion weld is terminated can also influence cracking behavior. In a closure weld, simply extinguishing the power can result in the formation of "crater cracks" as the final weld pool rapidly solidifies in on itself. A common method used to minimize this problem is to ramp down the power slowly, either while the workpiece remains stationary or as it continues to travel a short length under the heat source. In some cases, the use of a runoff tab as a site for weld termination may be appropriate.

The extent to which special joint designs or precisely controlled welding parameters can be used to produce welds without solidification cracks is specific for a given alloy. Alloys that are microstructurally susceptible to cracking will necessarily have a more limited set of joint designs and processing parameters around which defect-free welds can be produced.

Alloys with a wide solidification temperature range are more susceptible to solidification cracking than alloys that solidify over a narrow temperature range. Simply described, this is because accumulated thermal strain is proportional to the temperature range over which a material solidifies. This temperature range is determined primarily by chemical composition. For many binary alloy systems and a few ternary alloy systems, the equilibrium solidification (or melting) temperature range has been established in phase diagram studies. For the vast majority of commercial alloys, however, these data are not precisely known.

Borland (Ref 1, 2) attempted to establish a general quantitative method for comparing the effects of various alloying elements on the melting temperature range of a given solvent element. Figure 3 shows a schematic binary alloy phase diagram having linear liquidus and solidus boundaries. For an alloy of composition C_0, T_L is the liquidus composition and T_S is the solidus composition, where the alloy would be completely solidified under conditions of equilibrium cooling. T_M is the invariant melting temperature of the solvent element. The slope of the liquidus is m_L, and the slope of the solidus is m_S. The equilibrium distribution coefficient, k, is defined as the ratio of the composition of the solid, C_S, to the composition of the liquid, C_L, at a given temperature (i.e., $k = C_S/C_L|_T$). For a linear liquidus and solidus, this value is constant and also equal to m_L/m_S.

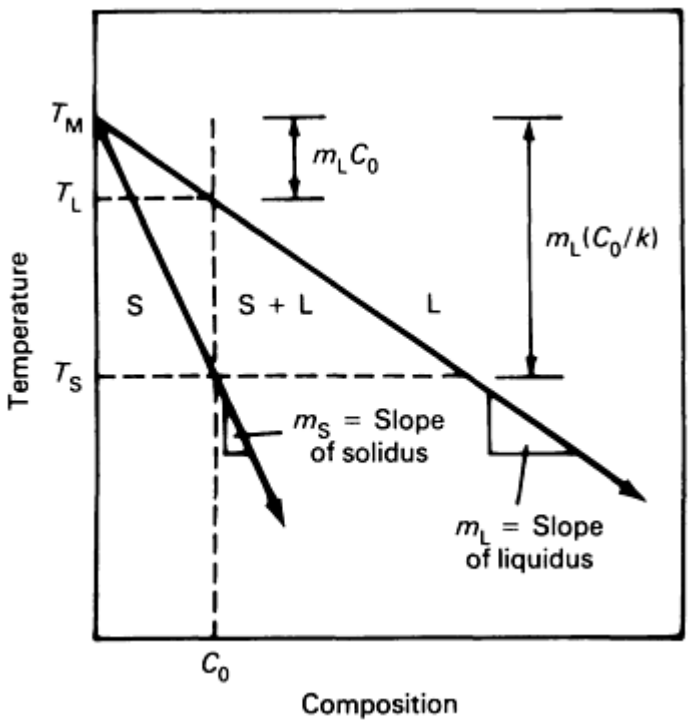

FIG. 3 HYPOTHETICAL BINARY ALLOY PHASE DIAGRAM SHOWING KEY PARAMETERS REQUIRED TO DERIVE THE RELATIVE POTENCY FACTOR (RPF)

With these terms thus defined, a derivation of the relative potency factor (RPF), after Borland (Ref 2), follows:

$$T_L = T_M - M_L C_0 \quad \textbf{(EQ 1)}$$

$$T_S = T_M - M_S C_0 \quad \textbf{(EQ 2)}$$

However, $m_S = m_L/k$:

$$T_s = T_M - \frac{M_L}{K} C_o \quad \textbf{(EQ 3)}$$

Then:

$$T_L - T_S = \frac{m_L C_o (K-1)}{K} \quad \textbf{(EQ 4)}$$

The RPF, always a positive number, is defined as the change in melting temperature ranger per weight percent of solute added, or:

$$RPF = \frac{T1 - Ts}{C_o} = \frac{M_L (k-1)}{K} \quad \textbf{(EQ 5)}$$

where for $k < 1$, $m_L < 0$; and for $k > 1$,$m_L > 0$. The larger the RPF, the wider the melting temperature range and the higher the solidification cracking susceptibility. The final form of Eq 5 indicates that as k becomes very small (indicating a high level of microsegregation), the solidification cracking sensitivity increases. Similarly, as the magnitude of m_L increases (that is, becomes more highly negative), indicating a rapid decrease in liquidus with alloying concentration, the cracking propensity also increases.

Table 1 lists RPF values for various alloying elements in binary iron (Ref 2), nickel-base alloys (Ref 3), and aluminum alloys. It is clear that certain alloying elements, such as sulfur, phosphorus, and boron, are detrimental to the weldability of these alloy systems. This has been borne out by field experience.

TABLE 1 RELATIVE POTENCY FACTORS FOR SELECTED ALLOYING ELEMENTS IN BINARY IRON, NICKEL, AND ALUMINUM SYSTEMS

SYSTEM	RPF FOR:										
	Al	**B**	**C**	**Co**	**Mn**	**Nb**	**Ni**	**P**	**S**	**Si**	**Ti**
BINARY IRON	1.5	. . .	322	0.3	26.2	28.8	2.9	121	925	1.8	13.8
BINARY NICKEL	1.7	22700	330	. . .	0.7	. . .	. . .	556	244000	11	5.4

	Cu	**Li**	**Mg**	**Si**	**Zn**
BINARY ALUMINUM	16.6	9.0	8.0	42.4	2.3

Source: Ref 2, 3

Although the exact derivation of the RPF is specific to a very simple binary system solidifying under equilibrium conditions, the methodology provides general insight that can be applied to commercial alloys. The association of cracking susceptibility with solidification temperature range has implications for alloy design and primary melt processing. An extended melting/solidification temperature range can be the result of either intentional alloying or impurities present after refining.

An example (Ref 4) of the application of Borland's concepts to the solidification cracking propensity of a commercial alloy system involves alloy 625. This alloy is derived from the ternary Ni-Cr-Mo system, a very common base system for alloys designed to survive aggressive corrosive or high-temperature environments. A factorially designed set of alloys was produced to identify the effects of the alloying elements niobium, silicon, and carbon on the temperature range of

two-phase coexistence of liquid and solid (equilibrium melting/solidification temperature range) and on solidification cracking susceptibility.

Solidification cracking susceptibility was measured with the varestraint test, using the maximum crack length (MCL) parameter as the quantitative measurement (Ref 5). The melting temperature ranges of these same alloys were measured using differential thermal analysis (DTA). Table 2 lists the compositions of the alloys examined.

The results of the varestraint testing are shown in Fig. 4. These data clearly show that the alloys that contain intentionally alloyed niobium (alloys 5 to 8) are more susceptible to solidification cracking (larger MCL) than niobium-free alloys (1 to 4). Furthermore, the alloy with no intentionally alloyed carbon, silicon, or niobium (alloy 1) is the least susceptible to cracking.

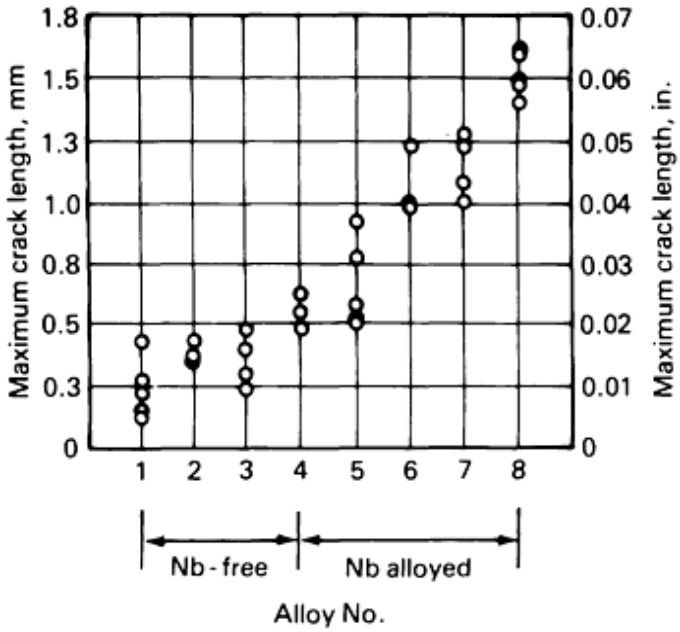

FIG. 4 MAXIMUM CRACK LENGTH DATA OBTAINED FROM VARESTRAINT TEST FOR ALLOY 625 WELDABILITY STUDY

The results of the DTA testing are given in Table 3. Listed are the liquidus (T_L), solidus (T_S), and melting temperature range (ΔT) data obtained from multiple tests. The baseline ΔT of an alloy without intentionally alloyed carbon, silicon,

and niobium (alloy 1) is 26.5 °C (79.7 °F). Increases in ΔT are observed when carbon or silicon is added (alloys 2 and 3) at levels that would be considered high for commercial alloys. When niobium is added (alloy 5) at a level that would be considered nominal for alloy 625 (~3.6 wt%), the melting temperature range effectively doubles to 55.3 °C (131.5 °F). Additions of carbon and silicon to the high-niobium alloys (alloys 6 to 8) further increase this value.

The correlation of cracking susceptibility with melting temperature range is shown in Fig. 5. Linear regression analysis performed on the data set resulted in the following functional relationship:

$$MCL = 0.00087(\Delta T) - 0.015 \qquad \textbf{(EQ 6)}$$

The incomplete statistical correlation ($R^2 = 0.86$) suggests that other factors are necessarily involved.

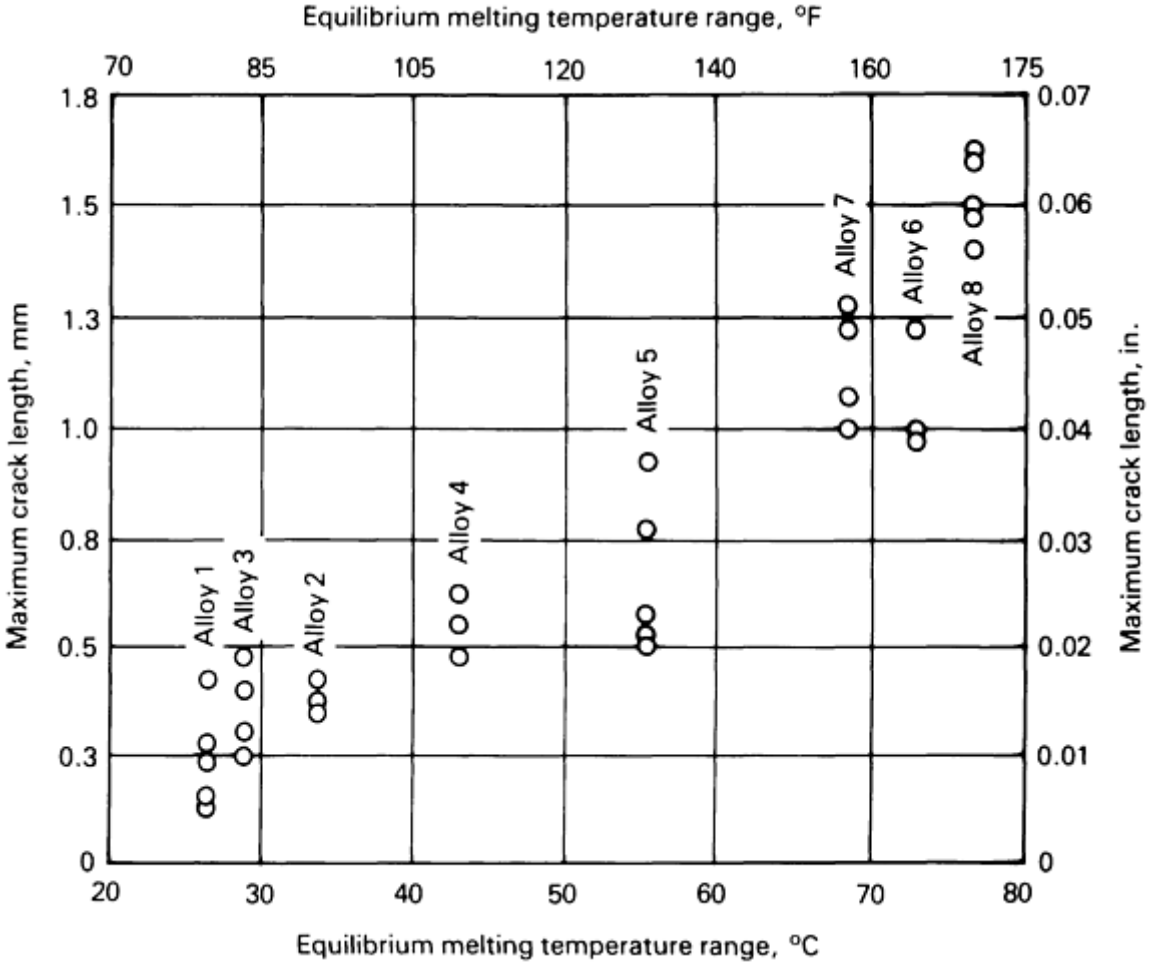

FIG. 5 RELATIONSHIP BETWEEN MAXIMUM CRACK LENGTH AND EQUILIBRIUM MELTING TEMPERATURE RANGE IN ALLOY 625 WELDABILITY STUDY

The solidification behavior of fusion welds is nonequilibrium in nature and may result in an extension of the solidification temperature range significantly beyond that measured under "equilibrium" conditions. Indeed, the niobium-bearing alloys terminate weld solidification below the equilibrium solidus with the formation of nonequilibrium eutecticlike constituents involving niobium carbides and Laves-type phases. Nonetheless, it is clear from an engineering perspective that Borland's concepts are valid enough to allow the establishment of a useful alloy ranking system from a solidification cracking perspective.

In addition to the effect of melting temperature range. Borland realized that the distribution of liquid along solidifying grain boundaries plays an important role in determining the solidification cracking susceptibility on an alloy (Ref 1). If the terminal solidification liquid easily wets the solidifying grain boundary (that is, has a low solid/liquid surface tension), it will tend to be spread out over a wider area, easing separation of the grains under a mechanical imposition. Conversely, if the liquid does not readily wet these boundaries, it will be more localized, creating a smaller area of liquid-solid contact and more solid-solid bridging, resulting in a more robust mechanical structure with increased cracking resistance. Elements such as sulfur and boron have been suggested as providing this surfactant property to terminal solidification liquids in iron and nickel alloys. Manganese may serve to increase the surface tension of terminal solidification fluids.

Figure 6 shows the results (Ref 6) of varestraint testing on two heats of Cabot alloy 214, a Ni-16Cr-4.5Al-2.5Fe alloy designed for use in high-temperature environments. The two alloys differ primarily in their boron content. With no boron intentionally added (0.0002 wt%), the alloy is extremely resistant to solidification cracking. With boron intentionally added at a level of 0.003 wt%, the solidification cracking propensity is much greater. Figures 7 and 8 are surface images of pulsed Nd:YAG laser welds made on the two alloys. Extensive cracking is evident in the high-boron alloy. Figure 7(b) is a good example of the extensive terminal "crater cracking" discussed above.

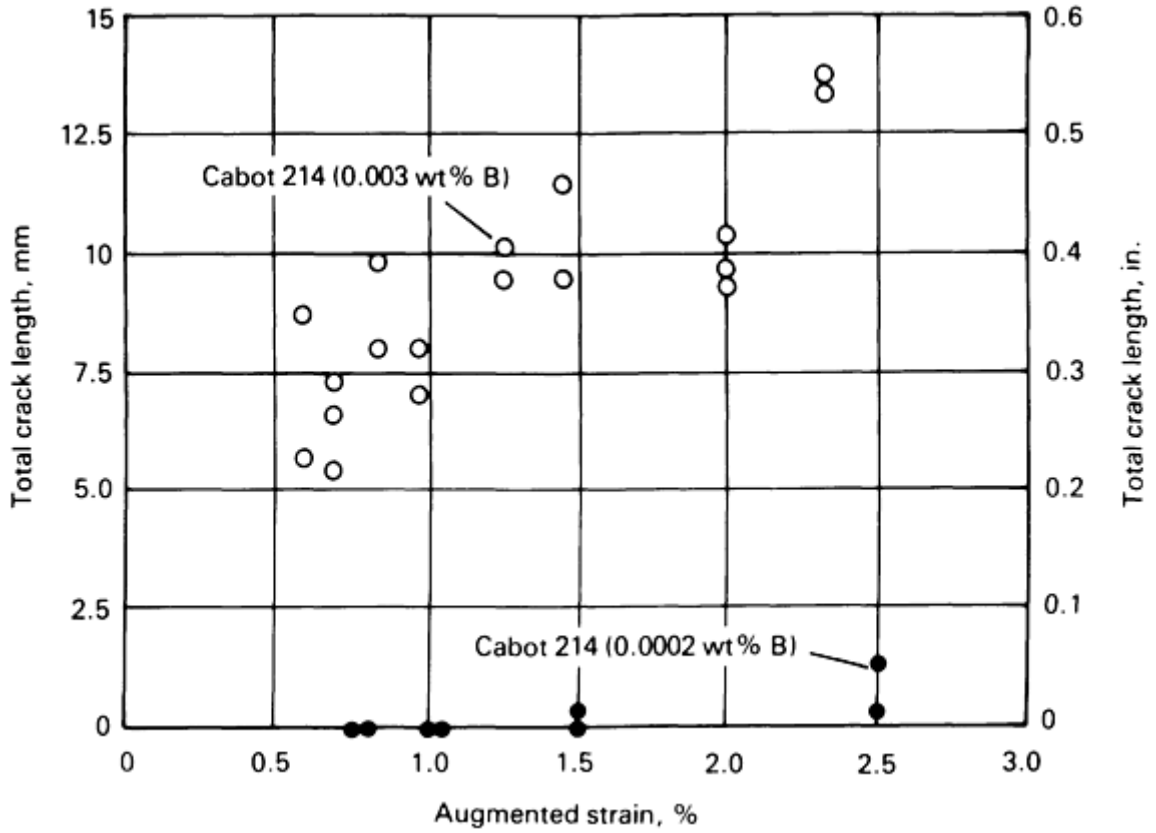

FIG. 6 VARESTRAINT TEST WELDABILITY DATA FOR CABOT ALLOY 214 WITH VARYING BORON CONCENTRATIONS

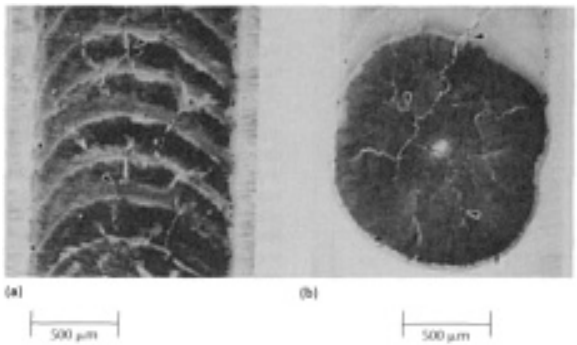

FIG. 7 SEM SURFACE IMAGE OF PULSED ND:YAG LASER WELDS IN HIGH-BORON ALLOY 214. (A) SOLIDIFICATION CRACKING. (B) CRATER CRACKING

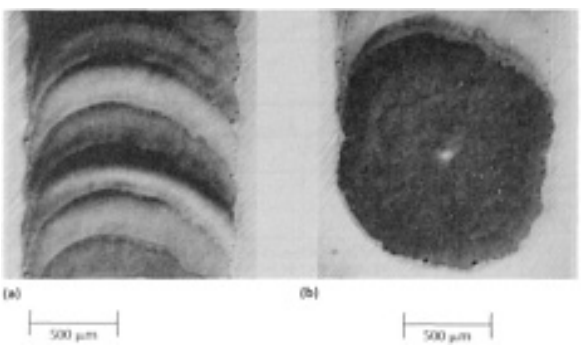

FIG. 8 SEM SURFACE IMAGE OF PULSED ND:YAG LASER WELDS IN LOW-BORON CONTENT ALLOY 214. (A) SOLIDIFICATION CRACKING. (B) CRATER CRACKING

Figures 9 and 10 summarize parameters that affect hot cracking in the weld metal and in the base metal HAZ, respectively. For most alloys that are highly susceptible to solidification cracking, filler metals of different composition have been developed to minimize the cracking that accompanies fusion welding.

Heat-Affected-Zone Cracks

Microfissures are cracks that occur in the area of partial melting and the HAZ adjacent to the fusion line. Because no material can be purified to the state where it solidifies truly as an invariant, all materials have a temperature region of stable two-phase coexistence of solid and liquid. In fusion welding, this manifests itself in the formation of a zone of

partial melting at temperatures below the alloy liquidus. The extent of this zone may be enlarged by the presence of chemical inhomogeneity in a material. Local chemical variations will result in local variations in the melting point. Segregation of specific alloying elements to grain boundaries may cause a reduction in the melting temperatures of these areas.

Many microfissures form in a manner somewhat analogous to the formation of solidification cracks in that susceptible sites, generally grain boundaries that intersect the fusion zone, are wetted with liquid from one of various sources. shrinkage strains accumulating as the weld pool advances past the liquated boundary can develop to a level sufficient to cause boundary separation (i.e., cracking). Figure 11 is a photomicrograph of an HAZ microfissure in a cast austenitic stainless steel (this crack also extends into the fusion zone as a solidification crack). Cast microstructures are highly inhomogeneous, raising the possibility of extensive partial melting. Note the melting associated with interdendritic constituents in Fig. 11.

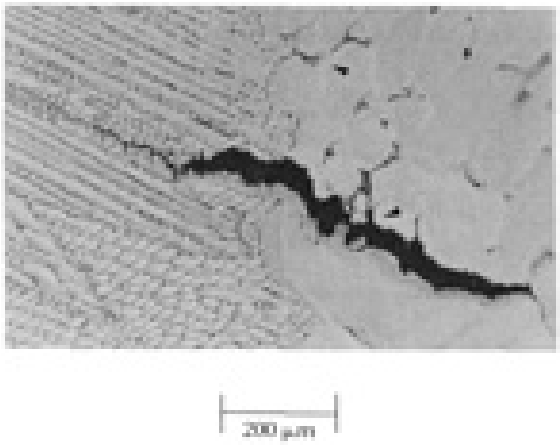

FIG. 11 HAZ MICROFISSURE IN A CAST STAINLESS STEEL. NOTE EXTENSIVE REGION OF PARTIAL MELTING.

Castings represent a special case of inhomogeneity on a continuous scale. Chemical inhomogeneities in wrought products are more discrete, generally involving minor phase particles. In many cases, these minor phases arise from thermomechanical processing of alloys well below the solidus, where the solubility for specific alloying elements can be lower. Because of the potential for extremely rapid rates of heating and cooling (especially heating) in the HAZ of fusion welds, it is entirely possible that minor phases not thermodynamically stable under equilibrium conditions may continue to exist at near-solidus temperatures. Under these conditions, the minor phases may interact with the matrix to form a liquid product. This reaction, often referred to as constitutional liquation (Ref 7), can provide the liquid required to wet grain boundaries producing a microstructure that may be susceptible to cracking.

Hot ductility testing is a common method of assessing the susceptibility of an alloy to this form of cracking. In this test, a laboratory-scale specimen is subjected to a thermal cycle representative of what the material would experience in the HAZ during fusion welding. At various temperatures during both the heating and cooling portions of the cycle, samples are strained to failure. The ductility response (usually expressed in terms of reduction of area) as the alloy progresses through the thermal cycle simulates the response of the alloy to an actual welding situation. In particular, the ability of the material to reestablish ductility after experiencing the peak temperature is a critical measure of sensitivity to this form of cracking.

Figures 12(a) and 12(b) show the hot ductility response of two heats of Cabot alloy 214 containing two different concentrations of boron. The return of ductility in the low-boron alloy after cooling from a peak temperature of 1345 °C (2453 °F) indicates that this alloy should be virtually immune to this form of cracking, as weldability tests confirmed (Ref 6). The high-boron heat showed no appreciable recovery of ductility until a temperature approximately 250 °C (450 °F) below the thermal peak temperature. This alloy should be quite susceptible to this form of cracking, as weldability tests also confirmed (Ref 6). Figure 13 is a fractograph of a hot ductility test specimen from the high-boron alloy taken from the sample strained at 1150 °C (2102 °F) on cooling from the peak temperature. The smooth, intergranular appearance is characteristic of this type of cracking. Although the presence of a liquid phase along this fracture surface could not be

unequivocally established by fractographic techniques, it was noted that the failure occurred at an exceedingly low load (Ref 6), consistent with the presence of a liquid film.

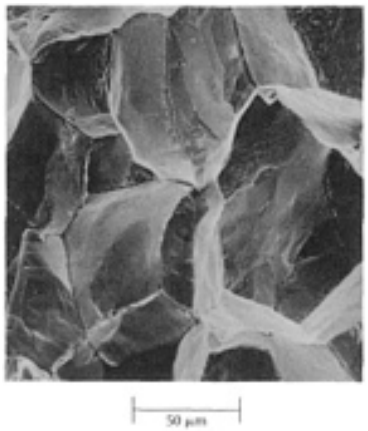

FIG. 13 FRACTURE SURFACE OF A HOT DUCTILITY SAMPLE OF HIGH-BORON ALLOY 214 TESTED AT 1150 °C (2100 °F) ON COOLING FROM 1345 °C (2455 °F)

The presence of a liquid is not essential to the formation of HAZ cracks, as they may occur at temperatures well below the solidus. Poor ductility inherent in certain materials, such as intermetallics, can lead to solid-state failure during welding if the thermal stresses associated with the weld thermal cycle exceed the local tensile strength.

Cracks may also occur in alloys that undergo polymorphic transformations during the weld thermal cycle. The act of fusion welding subjects the fusion zone and the HAZ to temperatures above those normally encountered during prior deformation processing. The resultant HAZ microstructure may be substantially different from that of the base material. In the case of martensitic-type transformations, there is often a relatively large, discontinuous change in the molar volume occurring very rapidly with decreasing temperature below the M_s. If that event causes a local shrinkage, then large, localized tensile stresses can develop. If the newly transformations microstructure has limited ductility (not uncommon in shear transformations or in transformations that result in ordered structures), the likelihood of cracks forming at susceptible sites, such as grain boundaries, matrix/minor phase interfaces, and slip band intersections, is increased.

Reheat cracking, also referred to as stress-relief of strain-age cracking, is another defect type observed in certain alloys that undergo precipitation reactions. Historically observed in several nickel-base superalloys and creep-resistant steels, this type of defect manifests itself during postweld heat treatment, generally as intergranular HAZ cracks.

Postweld heat treatment is often a recommended practice for high-strength thick-section welded steels, where reduction of residual stresses developed as a result of welding is desired. In the case of welded nickel-base superalloys, postweld heat treatment is used both to relieve residual stresses and to achieve optimum mechanical properties through precipitation-hardening reactions.

In alloys that undergo precipitation reactions, the rate at which the alloy strengthens may greatly exceed the rate at which residual stresses are thermally diminished. This can be especially true in the case of heavy-section welds or in alloys with relatively poor thermal conductivity. (That is, before the alloy can reach the temperature at which residual stresses begin to be eliminated, it has aged and lost ductility relative to its as-welded state.) At this new lower level of ductility, the residual stresses present may induce cracks to eliminate the accumulated strain energy.

In principle, the problem of reheat cracking could be largely eliminated if the rate of heating through the precipitation temperature range was rapid enough to prevent precipitate formation. However, extremely rapid rates of heating in welded hardware would likely lead to problems such as excessive distortion; therefore, improved alloys (e.g., alloy 718 among the nickel-base superalloys) have been developed in which the kinetics of precipitate formation have been sufficiently retarded to allow for successful postweld heat treatment.

Dealing with HAZ cracks, however they might form, is generally more difficult than attending to the problem of solidification cracking. Modifying the composition in the HAZ through the addition of consumables is not a viable option. Prior heat treatment may allow the production of a less susceptible starting microstructure, but this option generally is quite limited. Optimization of weld process parameters to minimize the extent of tensile stress and strain development should always be considered, as should optimizing weld joint design as discussed above.

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Hydrogen-Induced Cracking (Cold Cracking)

Cold cracks are defects that form as the result of the contamination of the weld microstructure by hydrogen. Whereas solidification cracking and HAZ cracking occur during or soon after the actual welding process, hydrogen-induced cracking is usually a delayed phenomenon, occurring possibly weeks or even months after the welding operation. The temperature at which these defects tend to form ranges from -50 to 150 °C (-60 to 300 °F) in steels. The fracture is either intergranular or transgranular cleavage.

As with other forms of cracking, hydrogen-induced cracking involves both a requisite microstructure and a threshold level of stress. It also involves a critical level of hydrogen, which is alloy and microstructure dependent.

In the case of ideal weld processing, hydrogen-induced cracking would be at most a minor welding engineering concern. However, excluding hydrogen from structures during welding is exceedingly difficult. Although the primary source of hydrogen in weld metal is considered to be the disassociation of water vapor in the arc and absorption of gaseous or ionized hydrogen into the liquid, other sources are also available. All organic compounds contain hydrogen in their

molecular structure, and all may be broken down in the intense thermal environment of a welding heat source. Organic compounds are ubiquitous in the welding environment, from lubricants in assembly areas to body oils on the hands of welding operators. Plated hardware may also contain high levels of residual hydrogen.

The mechanism of hydrogen-induced crack formation is still being investigated. An early hypothesis, involving the buildup of hydrogen gas pressure in voids, is now generally discredited. Currently, the most widely accepted model involves the presence of preexisting defect sites in the material--small cracks or discontinuities caused by minor phase particles or inclusions. In the presence of existing stress, these sites may develop high local areas of biaxial or triaxial tensile stress. Hydrogen diffuses preferentially to these sites of dilated lattice structure. As the local hydrogen concentration increases, the cohesive energy and stress of the lattice decrease. When the cohesive stress falls below the local intensified stress level, fracture occurs spontaneously. Hydrogen then evolves in the crack volume, and the process is repeated. This model of hydrogen-induced cracking is consistent with the relatively slow and discontinuous nature of the process.

In steels, where the problem of hydrogen-induced cracking is extremely significant, cracking susceptibility has been correlated both with material hardness and strength, and with specific microstructure. Higher-strength steels are more susceptible to hydrogen-induced cracking than low-strength steels. Steels that transform martensitically are particularly susceptible, especially the higher-carbon alloys with twinned martensitic structures. The desire to avoid martensite formation has driven the development of high-strength structural steels for welded applications.

Production of the newer high-strength low-alloy (HSLA) steels uses a variety of precisely controlled alloying additions (for example, aluminum, titanium, vanadium, and niobium) along with meticulous thermomechanical processing to develop a very fine-grained ferrite microstructure possessing substantial strength and fracture toughness with a high degree of resistance to hydrogen-induced cracking. The form of the ferrite produced during transformation on cooling from the austenite phase field is also critical, with acicular ferrite resulting in improved properties compared with grain-boundary, polygonal, or Widmanstätten ferrite. Acicular ferrite is often nucleated on minor phase particles, such as specific oxides or borides. Acknowledgement of the beneficial effect of certain oxides in providing sites for acicular ferrite nucleation in modern steels is in sharp contrast to steel design of earlier decades, when elimination of oxygen to the greatest extent possible was considered essential to the development of optimal fracture behavior.

A useful concept for understanding the susceptibility of carbon and alloy steels to hydrogen-induced cracking is the carbon equivalent (CE), an empirical relationship that attempts to reduce the number of significant compositional variables affecting the weldability of steels into a single quantity. Several carbon equivalent relationships have been developed for different classes of steels. An example is:

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%Cr + \%Mo + \%V}{5} + \frac{\%Si + \%Ni + \%Cu}{15} \qquad \textbf{(EQ 7)}$$

From a metallurgical perspective, the carbon equivalent can be related to the development of hydrogen-sensitive microstructures. That is, as the carbon equivalent increases, microstructures are evolved during cooling through the transformation temperature range that are increasingly more susceptible to hydrogen-induced cracking. At high carbon equivalent values, martensitic structures can be expected.

Carbon equivalent formulas are usually developed from large databases of critical hydrogen concentrations and weld joint restraints that will result in hydrogen-induced cracking in the steels under consideration. At various levels of carbon equivalent, certain weld preheat requirements are often established. In the example of Eq 7, when the carbon equivalent exceeds 0.35%, preheats are recommended to minimize susceptibility to hydrogen cracking. At higher levels of carbon equivalent, both preheats and postheats may be required.

Most structural carbon and low-alloy steels that may be susceptible to hydrogen-induced cracking transform from austenite during cooling through the temperature range of 800 to 500 °C (1470 to 930 °F). The length of time a steel spends in this temperature range during cooling will establish its microstructure and hence its cracking sensitivity. This time segment is generally referred to as $t_{8/5}$ (in seconds). To maximize cracking resistance, a microstructure free of untempered martensite is desired.

Using a specifically developed carbon equivalent, Yurioka (Ref 8) formulated a relationship to establish the critical $t_{8/5}$ for a martensite-free HAZ in low-carbon alloy steels. The carbon equivalent is defined as:

$$CE = \%C^* + \frac{\%Mn}{3.6} + \frac{\%Cu}{20} + \frac{\%Ni}{9} + \frac{\%Cr}{5} + \frac{\%Mo}{4} \qquad \textbf{(EQ 8)}$$

where %C* = %C for C $\leq$ 0.3% and %C* = %C/6 + 0.25 for %C > 0.3%. The critical time length in seconds, $t_{8/5}$, for the avoidance of martensitic transformation is given as:

$$\text{LOG } t_{8/5} = 2.69\ CE^* + 0.321 \qquad \textbf{(EQ 9)}$$

When this quantity is known, welding parameters and preheat temperature for the given thickness of material being welded can be established to produce cooling rates that avoid formation of a martensitic constituent in the HAZ.

The use of preheating and postheating to minimize the susceptibility to hydrogen-induced cracking is an accepted welding procedure for many steels. Preheating controls the cooling rate through the transformation temperature range; a higher base metal temperature in a slower cooling rate through the transformation temperature range and thus a larger $\tau_{8/5}$. Thicker sections often require preheating because of the greater heat-sinking capability of a thick section, for which a given set of welding parameters will produce a faster cooling rate and a smaller $t_{8/5}$. Preheating may also reduce the level of residual stress in the welded assembly.

There are, of course, practical limits to the use of preheating. Excessively high base metal temperatures can make welding difficult, especially manual welding. A high preheat temperature will result in the flattening of temperature gradients, increasing the spatial extent of and the time spent in the austenite phase field. This may result in excessive grain growth in the HAZ, which can lead to a loss of fracture toughness independent of hydrogen content. Preheat temperatures up to 150 °C (300 °F) are not uncommon for low-alloy steels and may increase up to 425 °C (800 °F) for higher-carbon equivalent martensitic steels.

Several benefits can be realized by postheating. At high enough temperatures (550 to 600 °C, or 1020 to 1110 °F), postheating can diminish residual stresses present in the as-welded structure. Microstructural modifications such as tempering can also occur, producing a microstructure less susceptible to hydrogen-induced cracking. Finally, the higher temperature may allow hydrogen to diffuse into the bulk of the structure or even to the surface, where it may recombine and exit as a gas. In either case, the level of hydrogen concentration may be reduced below that required to initiate cracks.

The following guidelines should be followed to minimize the occurrence of hydrogen-induced cracking. For a given level of required strength, the steel with the lowest carbon equivalent should be considered. Low-hydrogen welding practice should be followed. This involves elimination of possible sources of hydrogen by using ultrahigh-purity gases and moisture-free gas lines and by baking coated electrodes following the manufacturer's recommendations to ensure removal of nascent water. Finally, preheating and postheating requirements should be followed assiduously. Figures 14 and 15 summarize the causes and cures of hydrogen-induced cracking in the weld metal and in the base metal, respectively.

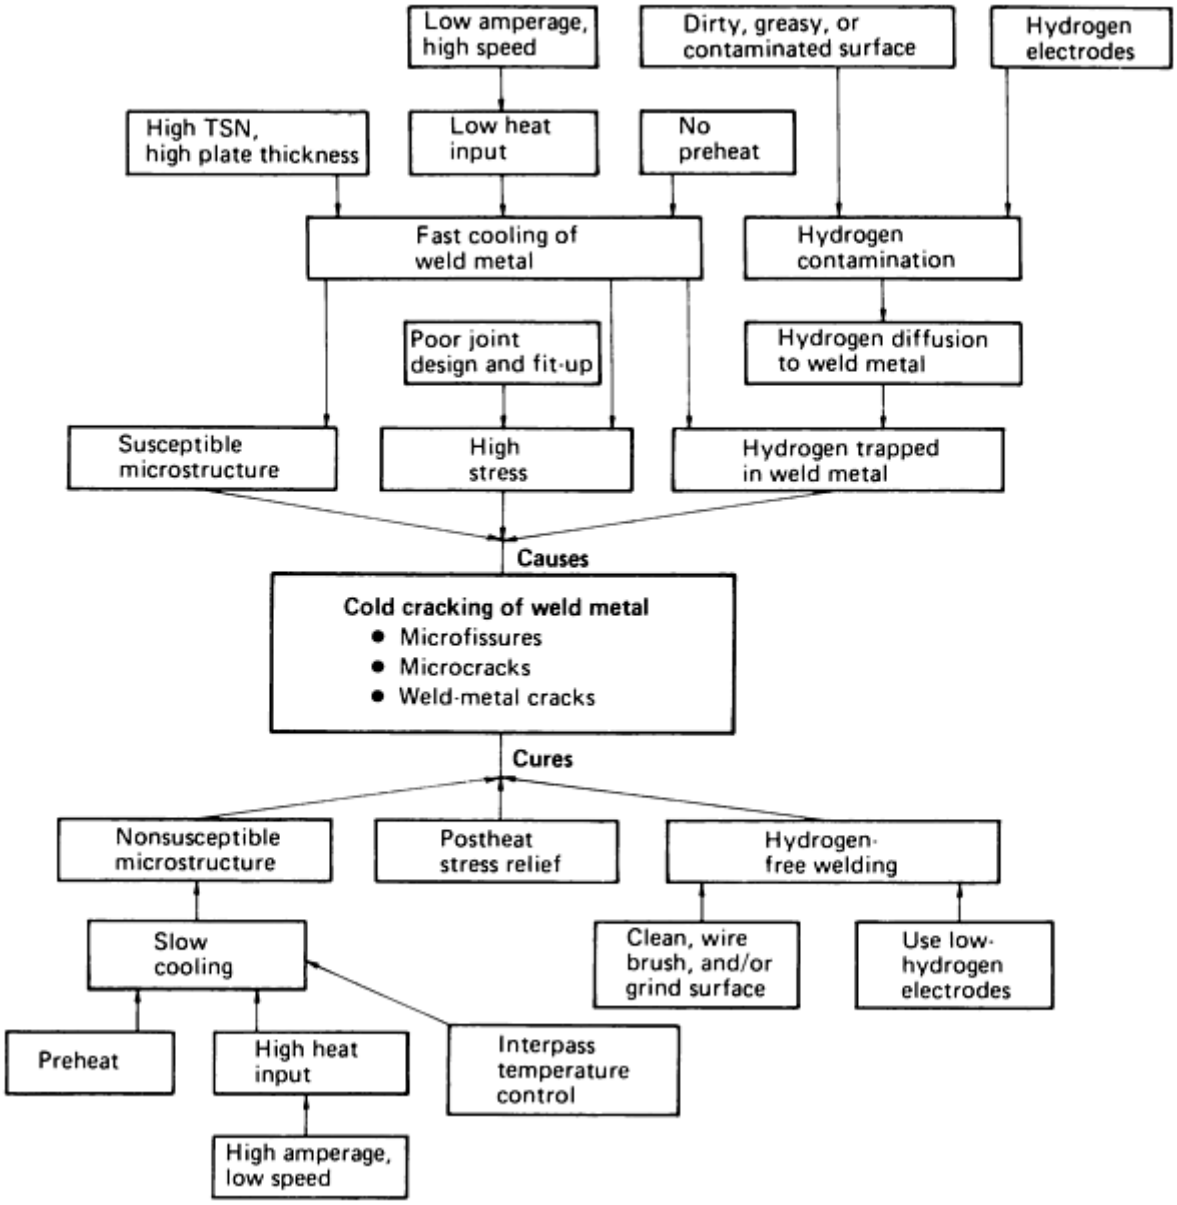

FIG. 14 CAUSES AND CURES OF HYDROGEN-INDUCED CRACKING IN WELD METAL. THERMAL SEVERITY NUMBER (TSN), WHICH IS FOUR TIMES THE TOTAL PLATE THICKNESS CAPABLE OF REMOVING HEAT FROM THE JOINT, IS A MEASURE OF THE ABILITY OF THE MEMBER TO SERVE AS A HEAT SINK.

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Lamellar Tearing (Ref 9)

Lamellar tearing is cracking that occurs beneath welds. It is found in rolled steel plate weldments. The tearing always lies within the base metal, generally outside the HAZ and parallel to the weld fusion boundary. The problem is caused by welds that subject the base metal to tensile loads in the *z*, or through, direction of the rolled steel. Occasionally the tearing comes to the surface of the metal, but more commonly remains under the weld (Fig. 16) and is detectable only by ultrasonic testing. Lamellar tearing occurs when three conditions are simultaneously present:

- STRAINS DEVELOP IN THE THROUGH DIRECTION OF THE PLATE. THEY ARE CAUSED BY WELD METAL SHRINKAGE IN THE JOINT AND CAN BE INCREASED BY RESIDUAL STRESSES AND BY LOADING.
- THE WELD ORIENTATION IS SUCH THAT THE STRESS ACTS THROUGH THE JOINT ACROSS THE PLATE THICKNESS (THE *Z* DIRECTION). THE FUSION LINE BENEATH THE WELD IS ROUGHLY PARALLEL TO THE LAMELLAR SEPARATION.
- THE MATERIAL HAS POOR DUCTILITY IN THE *Z* DIRECTION.

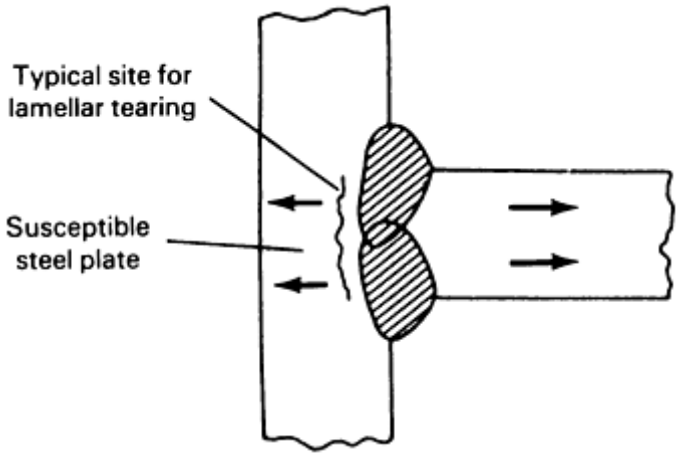

FIG. 16 TYPICAL LOCATION FOR LAMELLAR TEARING IN A T-JOINT

Lamellar tearing can occur during flame cutting and cold shearing operations. Low material strength in the *z* direction is the primary cause, with stress in that direction initiating the tearing. Thermal heating and stresses from weld shrinking create the fracture. Lamellar tearing can take place shortly after welding or occasionally months later. Thicker, higher-strength materials appear to be more susceptible. However, the phenomenon affects only a very small percentage of steel plates, as all three of the above conditions rarely occur in combination.

The problem can be avoided by proper attention to joint details. In T-joints (Fig. 16), double-fillet welds appear to be less susceptible than full-penetration welds. Also, balanced welds on both sides of the joint appear to present less risk than large, single-sided welds. In corner joints, common in box columns, lamellar tearing can be readily detected on the exposed edge of the plate (Fig. 17a). The problem can be overcome by placing the bevel for the joint on the edge of the plate that would exhibit the tearing rather than on the other plate (Fig. 17b). Butt joints rarely exhibit lamellar tearing, because weld shrinkage does not set up a tensile stress in the thickness direction of the plates.

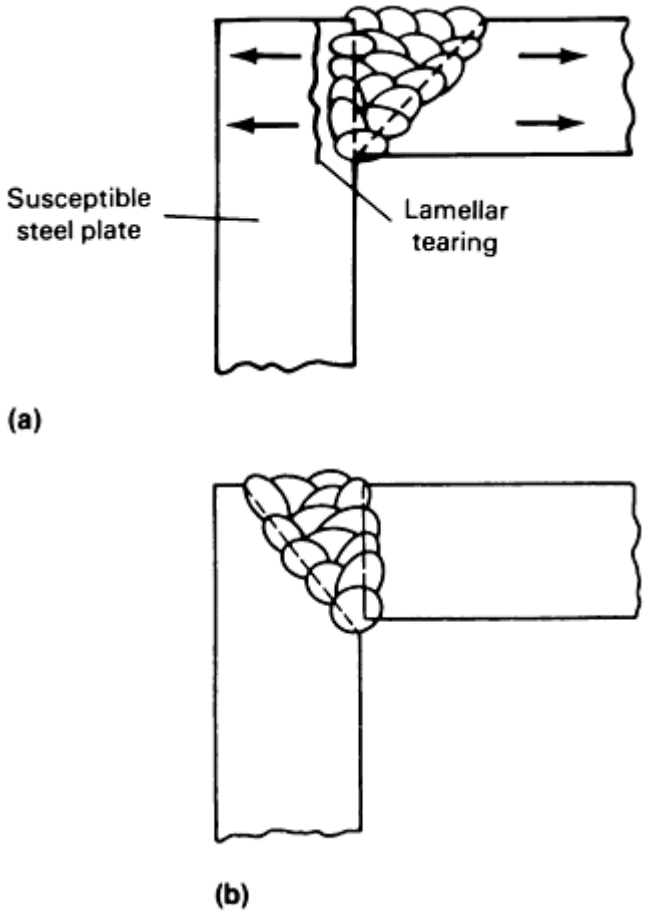

FIG. 17 CORNER JOINT. (A) LAMELLAR TEARING SURFACES AT THE EXPOSED PLATE EDGE. (B) REDESIGNED JOINT

Arc welding processes with high heat input are less likely to create lamellar tearing, perhaps because of the fewer number of applications of heat and the lesser number of shrinkage cycles involved in making a weld. Also, filler metal with lower yield strength and high ductility appears to lessen the possibility of tearing. Preheating does not appear to be particularly advantageous, nor does stress relieving. The "buttering" technique of laying one or more layers of low-strength, high-ductility weld metal deposit on the surface of the plate stressed in the *z* direction will reduce the possibility of lamellar tearing. However, this is an extreme solution and should be used only as a last resort.

Characterization of Welds

Craig B. Dallam, The Lincoln Electric Company; Brian K. Damkroger, Sandia National Laboratories

Introduction

WELDS CAN BE CHARACTERIZED according to a number of criteria, including the welding process used, size, shape, mechanical properties, chemical composition, and a number of others. The appropriate methods of characterization depend on the weld's function and the particular set of properties required for the application. In some instances, the ability of a weld to function successfully can be addressed by characterizing the size or shape of the weld. An example of this is where factors related to the welding procedure, such as inadequate weld size, convexity of the bead, or lack of penetration, may cause a weld to fail. In other cases, it is important to characterize metallurgical factors such as weld metal composition and microstructure. Examples might include welds for which the goal is to avoid failures due to inadequate strength, ductility, toughness, or corrosion resistance. In general, the goals of weld characterization are to assess the ability of a weld to successfully perform its function, to thoroughly document a weld and welding procedure that have been demonstrated to be adequate, or to determine why a weld failed.

In the first part of this article, characterization of welds will be treated as a sequence of procedures, each more involved than the last and concerned with a finer scale of detail. Initially, non-destructive characterization procedures will be the focus. The first level of characterization involves information that may be obtained by direct visual inspection and measurement of the weld. A discussion of nondestructive evaluation follows. This encompasses techniques used to characterize the locations and structure of internal and surface defects, including radiography, ultrasonic testing, and liquid penetrant inspection.

The next group of characterization procedures discussed are destructive, requiring the removal of specimens from the weld. The first of these is macrostructural characterization of a sectioned weld, including features such as number of passes; weld bead size, shape, and homogeneity; and the orientation of beads in a multipass weld. Macroscopic characterization is followed by microstructural analysis, including microsegregation, grain size and structure, the phase makeup of the weld, and compositional analysis.

The third component of weld characterization is the measurement of mechanical and corrosion properties. The goal of any weld is to create a structure that can meet all the demands of its service environment. In many cases, the best way of assessing the performance of a weld is to establish its mechanical properties. In addition to a number of standard material tests, many mechanical tests are directed specifically at determining a weld's capabilities. Examples of mechanical properties typically characterized for welds include yield and tensile strength, ductility, hardness, and impact or fracture toughness. Corrosion testing is often employed in situations where a welding operation is performed on a corrosion-

resistant material, or in a structure exposed to a hostile environment. Although absolute corrosion performance is important, a major concern is to ensure that a weld and its heat-affected zone (HAZ) are cathodic to the surrounding metal.

Following the discussion of the characterization procedures, the second part of this article will give examples of how two particular welds were characterized according to these procedures.

Nondestructive Characterization Techniques

Externally Observed Macroscopic Features. Several factors associated with the production and performance of welds are macroscopic and easily observed. The most obvious of these are the size, shape, and general appearance of the weld. To a large extent, these parameters depend on the geometry of the weld joint and the welding process selected. Figure 1 shows schematic representations of fillet, lap, butt, and groove welds, in which a number of features (defined in Table 1) are labeled.

TABLE 1 NONMENCLATURE FOR FILLET, LAP, BUTT, AND GROOVE WELDS

FEATURE	DEFINITION
FACE	EXPOSED SURFACE OF A WELD ON THE SIDE FROM WHICH THE WELDING WAS PERFORMED
ROOT	POINTS, AS SHOWN IN CROSS SECTION, AT WHICH THE BACK OF THE WELD INTERSECTS THE BASE METAL SURFACE
LEG	SHORTEST DISTANCE FROM ROOT TO TOE IN A FILLET WELD
TOE	JUNCTION BETWEEN THE WELD FACE AND THE BASE METAL
THROAT	SHORTEST DISTANCE FROM ROOT TO FACE IN A FILLET WELD
PENETRATION	DEPTH A GROOVE WELD EXTENDS INTO THE ROOT OF A JOINT, MEASURED ON THE CENTERLINE OF A ROOT CROSS SECTION
REINFORCEMENT	WELD METAL IN EXCESS OF THE SPECIFIED WELD SIZE
FACE REINFORCEMENT	REINFORCEMENT AT THE SIDE OF THE WELD FROM WHICH WELDING WAS PERFORMED
SIZE (GROOVE WELD)	JOINT PENETRATION (DEPTH OF ROOT PREPARATION) PLUS THE ROOT PENETRATION (WHEN SPECIFIED)
SIZE (FILLET WELD)	LEG OF THE LARGEST ISOSCELES RIGHT TRIANGLE THAT CAN BE INSCRIBED WITHIN THE FILLET WELD CROSS SECTION

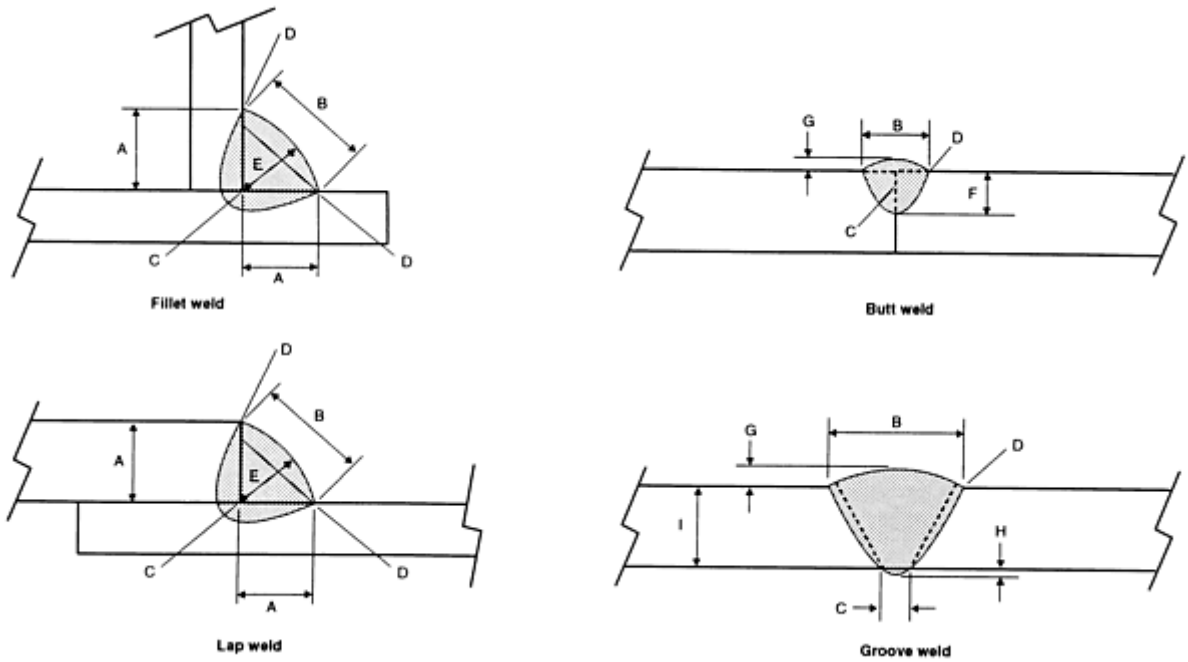

FIG. 1 SCHEMATICS SHOWING PARAMETERS OF COMMONLY USED JOINT GEOMETRIES. A, LEG; A', SMALLER LEG SIZE (EQUAL TO SIZE OF WELD); B, FACE, C, ROOT; D, TOE; E, THROAT; F, PENETRATION (EQUAL TO SIZE OF WELD); G, FACE REINFORCEMENT; H, ROOT REINFORCEMENT; I, SIZE OF WELD

Methods of Characterization. The primary tools used in the external macrocharacterization of a weld are the unaided eye and a hand lens. A number of macrocharacterization parameters (for example, weld location, size, shape, and general uniformity) can be assessed by visual inspection. Figure 2 shows top-view macrographs of two welds that illustrate several of these considerations. In many cases, the presence of gross defects such as hot cracking or porosity may also be detected by visual inspection and a top-view photograph. Additional examples of factors included in overall weld bead appearance include distortion, discoloration due to inadequate shielding or excessive heat, undercut, excessive crater size, and uneven bead width. In fillet welds, a number of performance aspects can be affected by the relative geometry of the joint. Fillet gages can be used to determine the size of a weld, the curvature of the face, and the length of the weld legs.

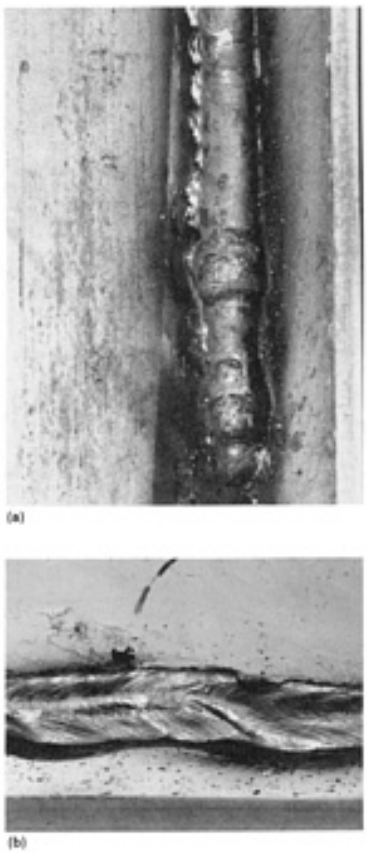

FIG. 2 MACROGRAPHS SHOWING TOP VIEW OF FILLET WELDS. (A) VERTICAL WELD IN TYPE 304L STAINLESS STEEL (NOTE CONVEXITY OF BEAD AND NONUNIFORM REGIONS). (B) HORIZONTAL E 7024 WELD (NOTE WELD PLACEMENT AND LACK OF UNIFORMITY)

General Considerations. Most types of welds will be evaluated with respect to specific macrocharacteristics deemed to be either desirable or undesirable. However, a number of general considerations apply to most types of welds. These include:

- *SIZE:* THE SIZE OF THE WELD SHOULD BE APPROPRIATE FOR THE PART (AS AN EXAMPLE, A GENERAL RULE FOR FILLET WELDS IS THAT THE RATIO OF LEG SIZE/PLATE THICKNESS SHOULD BE BETWEEN 3:4 AND 1:1.
- *LOCATION:* AN INCORRECTLY LOCATED BUTT WELD MAY NOT ALLOW THE PART TO FUNCTION CORRECTLY. A LESS EXTREME EXAMPLE IS A FILLET WELD WITH UNEQUAL LEG LENGTHS, LEADING TO AN UNEVEN STRESS DISTRIBUTION AND PERHAPS LAMELLAR TEARING.
- *UNIFORMITY:* DISTORTION, THE PROBABILITY OF SLAG ENTRAPMENT ON MULTIPASS WELDS, AND UNIFORMITY OF LOAD-CARRYING ABILITY ALL DEPEND ON THE RELATIVE UNIFORMITY OF THE WELD.
- *DEFECTS:* IDEALLY, A WELD SHOULD BE FREE OF MACROSCOPIC DEFECTS. COMMON DEFECTS INCLUDE UNDERCUTTING, LACK OF FUSION, PINHOLE POROSITY, AND SLAG ENTRAPMENT.
- *FACE SHAPE:* A WELD SHOULD HAVE A RELATIVELY FLAT FACE. IF THE WELD IS TOO CONVEX, STRESS WILL BE CONCENTRATED ALONG THE TOE OF THE WELD. CONVERSELY, A HIGHLY CONCAVE WELD FACE WILL RESULT IN LOCALLY HIGH STRESSES IN THE THROAT REGION OF THE WELD.

Defects. The presence of surface or internal defects can degrade the performance of a weld that may appear to be sound in a cursory examination. The causes and means of preventing defects are covered in Ref 2, 3, and 4. Typical defects found in welds include:

- POROSITY
- UNDERCUT
- OVERLAP
- LACK OF PENETRATION
- LACK OF FUSION
- SHRINKAGE VOIDS
- CRATER CRACKING
- MELT-THROUGH OR BURN-THROUGH
- SUBSOLIDUS OR HOT CRACKING
- INCLUSIONS DUE TO ENTRAPPED SLAG, TUNGSTEN ELECTRODE PIECES, OR DEFECTS PRESENT IN THE STARTING MATERIAL

A number of techniques are widely used to assess the presence of surface and subsurface defects in welds. The most common of these are liquid penetrant inspection for surface cracks, magnetic particle inspection, x-ray radiography, and ultrasonic inspection. Penetrant inspection involves the application of an indicator fluid that has a surface tension sufficiently low to be drawn into surface cracks too small to be detected visually. The excess dye or fluorescent material is then removed from the surface, but it remains in and highlights the cracks when a developer is applied. Figure 3 shows cracks in a flux-cored are weld highlighted by dye penetrant inspection. Table 2 lists the characteristics of several types of nondestructive inspection techniques. Additional information is available in the article "Inspection of Welded Joints" in this Volume.

TABLE 2 GUIDELINES FOR SELECTING TECHNIQUES

Technique	Equipment Requirements	Defects Detected	Advantages	Limitations	Comments
liquid-penetrant or fluorescent-penetrant inspection	fluorescent or visible penetration liquids and developers; ultraviolet light for fluorescent dyes	defects open to the surface only; good for leak detection	detects small surface imperfections; easy application; inexpensive; use on magnetic or nonmagnetic material; low cost	time-consuming; not permanent	used on root pass of highly critical pipe welds; indications may be misleading on poorly prepared surfaces
magnetic particle inspection	wet or dry iron particles, or fluorescent; special power source; ultraviolet light for fluorescent dyes	surface and near-surface discontinuities: cracks, porosity, slag	indicates discontinuities not visible to the naked eye; useful for checking edges before welding; no size limitations	for magnetic materials; surface roughness may distort magnetic field; not permanent	test from two perpendicular directions to detect any indications parallel to one set of magnetic lines
radiographic inspection	x-ray or γ ray; film processing and viewing equipment	most internal discontinuities and flaws; limited by direction of discontinuity	provides permanent record of surface and internal flaws; applicable to any alloy	usually not suitable for fillet weld inspection; film exposure and processing	popular technique for sub-surface inspection

				critical; slow and expensive	
ultrasonic inspection	ultrasonic units and probes; reference patterns	can locate all internal flaws located by other methods, as well as small flaws	extremely sensitive; complex weldments restrict usage; can be used on all materials	highly skilled interpretor required; not permanent	required by some specifications and codes

Source: Ref 5

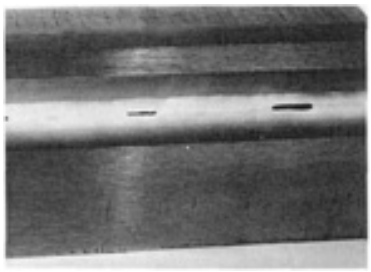

FIG. 3 SURFACE CRACKS IN A FLUX-CORED ARC WELD HIGHLIGHTED BY DYE PENETRANT INSPECTION

X-ray radiography is used to detect internal defects such as porosity or inclusions: these defects show up because of the difference in x-ray absorption between the matrix and defect materials. Although a number of factors affect the resolution level of radiographic techniques (Ref 5, 6), the minimum size of defects considered in AWS specifications is 0.4 mm (0.0156 in.). In practice, this refers to slag entrapment and large inclusions that were present in the starting material. Defect structures are usually quantified by comparison with an existing standard, of which several exist. An example of such a standard is American Petroleum Institute (API) 1104 (Ref 7), a pipeline welding specification. The API 1104 standard includes criteria for acceptance of steel welds based on a number of defects, including inadequate penetration, incomplete fusion, internal concavity, burn-through, slag inclusions, and porosity. For example, one section of API 1104 can be summarized as follows:

> Slag inclusions--50 mm (2 in.) maximum length for elongated slag inclusions, 50 mm (2 in.) limit per 305 mm (12 in.) of weld, 1.6 mm ($\frac{1}{16}$ in.) width limit per elongated slag inclusion. Isolated slag inclusions, 13 mm ($\frac{1}{2}$ in.) per 305 mm (12 in.) of weld, width greater than 3.2 mm ($\frac{1}{8}$ in.), 105 mm ($4\frac{1}{8}$ in.) isolated slag inclusions per 305 mm (12 in.) of weld. Aggregate length of isolated slag inclusion indications may not exceed two times the thinner of the nominal wall thickness and the width may not exceed one-half the thinner of the wall thicknesses joined.

Other examples include ASTM E 390 (Ref 8), which contains reference radiographs for steel welds and the *Structural Welding Code* (Ref 9), which includes a group of radiographic plates showing defect patterns for rounded inclusions corresponding to grade 1 and grade 2 quality levels. Several industries and product categories have applicable specifications and standards. A number of these are given in Ref 5.

Ultrasonic testing can also be used to locate internal defects, including porosity and inclusions. Ultrasonic testing involves transmitting mechanical vibrations through a piece of metal and analyzing both reflected and transmitted vibrations. Vibrations interact with discontinuities in the media through which they are passing, so the operator can detect voids, inclusions, and other internal interfaces. Table 2 includes ultrasonic testing, and Ref 5 lists a number of example specifications and detailed references.

Characterization of Welds

Craig B. Dallam, The Lincoln Electric Company; Brian K. Damkroger, Sandia National Laboratories

Internal Characterization Requiring Destructive Procedures

This section briefly covers macrostructural and microstructural characterization and compositional analysis. These procedures are usually based on a cross section of the weld, referred to as a transverse section. The transverse section may be supplemented by the top-view photograph, the longitudinal section, and the normal section (Fig. 4). In particular, the top-view photograph will depict the general appearance of the weld, illustrating surface irregularities, spatter, or macroscopic defects such as hot cracking or porosity.

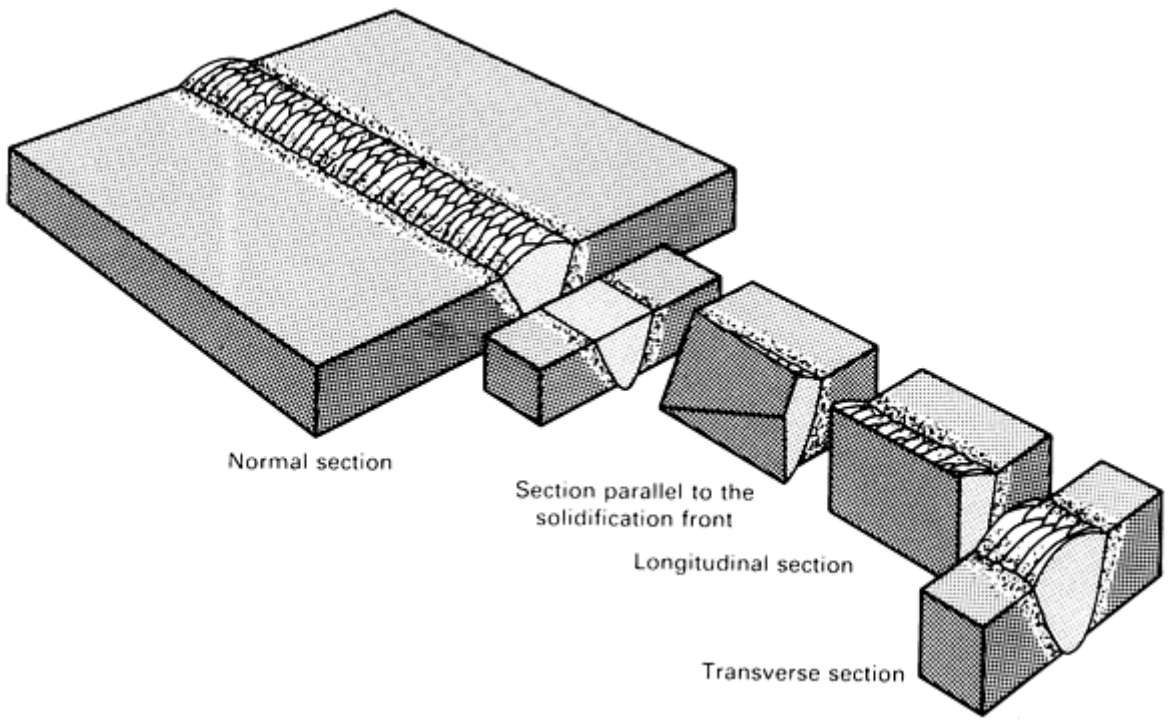

FIG. 4 TYPICAL SECTIONS USED IN THE METALLOGRAPHIC EXAMINATION OF WELDED JOINTS

Weld Macrostructure

Figures 5(a) and 5(b) show transverse sections of two welds, a submerged arc weld made on a 25 mm (1 in.) thick ASTM A 36 steel and a flux-cored weld made on a 50 mm (2 in.) thick ASTM A 537 steel. Readily apparent features include the number of passes and number of layers, fusion zone area, weld aspect ratio, extent of penetration, face width, and the reinforcement and curvature of the top bead. A transverse macrosection will also show any gross porosity or large inclusions present in a weld and the extent of the HAZ. It is important to note that quantitative measurements of weld features made based on a transverse section will be accurate only if the section is properly done. Potential errors, sectioning procedures, and sample preparation techniques are discussed in Ref 10.

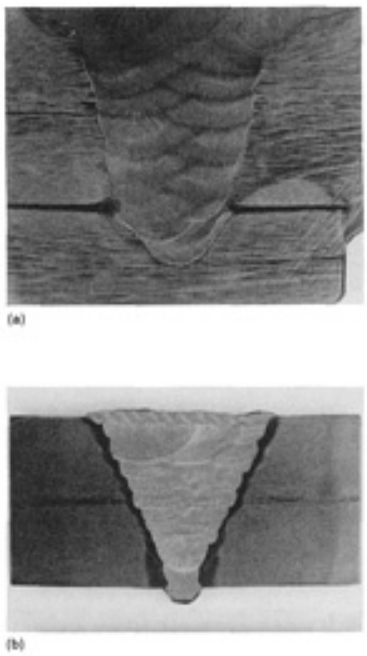

FIG. 5 TYPICAL MULTIPASS ARC WELDS IN STEELS USED IN STRUCTURAL APPLICATIONS. (A) SUBMERGED ARC WELD ON A 25 MM (1 IN.) THICK A 36 STRUCTURAL STEEL; THE MUSHROOM SHAPE OF THE LAST BEAD IS TYPICAL OF WELDS PRODUCED BY THIS PROCESS. (B) FLUX-CORED ARC WELD ON A 50 MM (2 IN.) THICK A 537 STEEL USED IN PRESSURE VESSEL AND STRUCTURE APPLICATIONS (THE LAST LAYER WAS MADE WITH SEVERAL SMALL PASSES TO IMPROVE MECHANICAL PROPERTIES)

Weld Microstructure

In many cases, it is important to examine and characterize the weldment microstructure and to understand its formation and effects on properties. This is the case when the materials and processes involved are not well characterized, so specifications have not been established. Other problems arise where the potential exists for the formation of detrimental microconstituents and/or where the consequences of weld failure are severe. Welding of high-strength or brittle materials are typical examples.

The microstructure of a weld consists of three regions: a fusion zone (material that has been melted); a heat affected zone (material that was not melted, but whose microstructure has been altered); and the base metal. These three regions can be seen in the transverse section shown in Fig. 5(b). Weld microstructures are examined using standard specimen removal and preparation techniques, with some concessions made for their inhomogeneous nature (Ref 10). Similarly, the parameters used to characterize the weld microstructures, such as grain size, grain morphology, and the amount of the various phases or microconstituents present, are those used to characterize monolithic materials. The equipment, procedures, and techniques used are well described in Ref 10.

Special importance may be attached to one or more specific features of a weld microstructure. An example is the classification of ferrite and carbide microconstituents in a low-ally steel weld. The various morphologies included in a characterization of a low-alloy steel weld are listed in Table 3. In these welds, a large amount of acicular ferrite is associated with high toughness levels, whereas martensitic or bainitic microstructures have much lower toughness levels. Bainite and martensite are also associated with higher effective cooling rates, so decreasing the weld metal manganese content, or reducing the cooling rate with increased heat input or preheat, will increase the amount of acicular ferrite and improve weld metal toughness.

TABLE 3 DESCRIPTION OF FERRITE/CARBIDE MICROCONSTITUENTS IN LOW-CARBON STEEL WELDS

Microconstituent	Description
Primary ferrite	
Grain boundry ferrite	Proeutectoid ferrite that grows along the prior austenite grain boundaries. It is equiaxed or polygonal, and it may occur in veins
Intragranular polygonal ferrite	Polygonal ferrite that is not associated with the prior austenite grain boundaries. Much larger than the average width of the surrounding acicular ferrite laths
Ferrite with second phase	
With aligned second phase	Parallel ferrite laths. Further classifications are widmanstätten ferrite and upper/lower bainite
With nonaligned second phase	Ferrite that completely surrounds either equiaxed, randomly distributed microphases, or solitary ferrite laths
Ferrite/carbide aggregate	Fine ferrite/carbide structures, including pearlite
Acicular ferrite	Small nonaligned ferrite grains found within prior austenite grains
Martensite	Martensite colony larger than adjacent ferrite laths

Microstructural characterization of welds has two purposes: to evaluate the microstructure with respect to properties and to relate the microstructure to the process used. The ultimate goal is to optimize the process to produce the most desirable microstructure. In general, the effects of a process and parameters on microstructure are due to the compositional and thermal effects. The compositional effects are largely limited to the fusion zone and will be discussed in the next section. Thermal cycles affect both the fusion zone and HAZ. Microstructural development in the HAZ has been the subject of much study, and a number of computational tools have been developed specifically for the prediction of HAZ microstructures (Ref 11).

Composition of a Weld

The composition of a weld will have a significant effect on its performance, contributing to both the mechanical and corrosion properties of the weld. In some instances, the effects can be drastic, such as sensitization of stainless steel or changing the ductile-to-brittle transition temperature of ferritic steels by an amount sufficient to cause brittle failure under normal use. In a number of cases, particular elements will govern the propensity toward certain defects or behavior. For example, a low-alloy steel weld with a carbon equivalent of over 0.4% is considered to be a high-carbon deposit, and it is treated differently than a low-carbon weld. Similarly, deposit silicon levels in excess of approximately 0.4% are often associated with a defect called "hollow bead," where the root pass in a pipe weld made with a cellulosic electrode has a continuous pore. In general, care must be taken to either minimize the compositional changes associated with welding or to factor the composition and property changes into the design.

Factors Affecting Weld Composition. The composition of a weld is affected by the base metal composition, the composition of any filler metal used (and dilution between the two), reactions with flux or shielding gas, and any material losses associated with the process. These factors are, in turn, largely controlled by the welding setup, process selection, parameters, and stability. The Schaeffler diagram (Ref 12) for stainless steels is an example of composition being controlled by dilution. The weld metal composition and microstructure are predicted based on the "ferrite stabilizer" and the "austenite stabilizer" content of the base metal, the nickel equivalent and chromium equivalent of the filler metal, and the level of dilution. The microstructure will be predicted as martensitic, ferritic, or austenitic, and the level of ferrite in the weldment will be estimated. In these welds, ferrite numbers below 4 indicate microstructures in which low-melting-

point compounds may be formed at the grain boundaries, and the welds can be prone to hot cracking. Conversely, welds with ferrite numbers above 10 have reduced corrosion resistance and can be susceptible to the formation of σ phase at high temperatures (Ref 13). The Schaeffler diagram has been revised many times for adaptation to different alloy modifications. An example is the inclusion of nitrogen in the nickel equivalent. Many stainless steels often contain small amounts of nitrogen, and in fact some stainless steels are deliberately strengthened with nitrogen additions. Other modifications include copper in the nickel equivalent and vanadium and aluminum in the chromium equivalent (Ref 14). Additional information is available in the Section "Selection of Stainless Steels" and in the article "Welding of Stainless Steels" in this Volume.

An example of the effect of flux on weld metal composition is seen when low-carbon steel is welded with E6010 and E7018 electrodes, using identical parameters. Although the core wire composition of the two electrodes is identical, the E6010 electrode will produce a deposit with approximately 0.15 to 0.25% Si, and the E7018 electrode will produce a deposit with 0.5 to 0.6% Si. An example of a procedure-related effect is seen when the arc length is changed for welds made with an E7018 electrode. Arc length changes can alter the silicon content from 0.3 to 0.6%, and they can alter the manganese content from 0.8 to 1.3%.

Measurement Techniques and Procedures. The usual techniques for compositional analysis of metallic samples can be used on welds and are covered in Ref 15. However, some considerations must be made when dealing with welds, because of their inhomogeneity. The most commonly used method for compositional analysis of welds is optical emission spectroscopy, where a spot of material (typically 6 mm, or $\frac{1}{4}$ in., in diameter) is ablated off the surface of the specimen and the light emissions are analyzed. In many welds, a spot this size will encompass several passes in a multipass weld, and it will perhaps encompass weld metal, HAZ, and base metal in a single-pass weld. An average composition over this large an area may not address local effects, for example, sensitization of stainless steel.

Welds are prone to both macrosegregation and microsegregation, and the properties may be governed by the composition in a very local region. A thorough characterization of welds requires techniques with sufficient spatial resolution to characterize their inhomogeneity. Scanning electron microscopy with wavelength or energy dispersive x-ray analysis systems, electron microprobes, and x-ray fluorescence techniques are often employed. Often, a number of closely spaced analyses are made along a line traversing a weld. This data may then be coupled with a similar microhardness traverse and microstructural analyses to characterize the variation across the weld. Thorough treatments of a number of microanalytical techniques are contained in Ref 16.

Mechanical Testing

A number of mechanical properties are used to characterize welds, including strength, ductility, hardness, and toughness. In general, the same samples and procedures are used in other areas of metallurgy (Ref 17). However, a prominent concern regarding the mechanical performance of welds is the direct comparison with base material. The goal is to ensure that the weld is not the weakest component of a structure, or if it is, to compensate for this in the design.

Strength. Yield and tensile strength are measured for all-weld-metal specimens using a standard tensile test (Ref 18), but with specimens removed from test plates welded according to AWS-specified procedures (Ref 19). These tests form the basis for the assignment of yield and ultimate strength values to welds made using a specific electrode and according to a set procedure. Additional tests are sometimes performed to compare the base metal and weld metal strengths. An example of this type of test is the transverse tensile test, in which the specimen is removed from the weld so that the loading axis is perpendicular to the weld bead and the weld reinforcement is left intact. The goal of this test is to verify that overload failure will occur in the base metal rather than in the weld metal or HAZ.

Ductility is another critical weld property. In addition to defects, many welding processes can produce hard, brittle microstructures. The standard measures of ductility--percent reduction in area and percent elongation--are obtained in a uniaxial tensile test. Another test often specified for welds is a bend test (face bends, roof bends, and side bends). In this test, a strip of material containing a weld is deformed around a specified radius and its surface is examined. The criteria for success or failure are the number and size of defects seen on the outer surface of the bend. An example of bend test criteria is the AWS *Structural Welding Code* (Ref 9), which calls for bending around a 19 mm (0.75 in.) radius for materials with yield strengths less than or equal to 345 MPa (50 ksi), a 25 mm (1 in.) radius for 345 to 620 MPa (50 to 90 ksi) materials, and a 32 mm (1.25 in.) radius for materials with yield strengths greater than or equal to 620 MPa (90 ksi).

Hardness. One common use of hardness values in weld specifications is as a check for the formation of microstructures that might have low ductility and toughness and thus are prone to cracking. For example, in pipeline steels, the formation of martensite in the HAZ is a cause for concern because of the potential for cracking. This is addressed by specifying maximum values for microhardness traverses across several sections of the weld. Hardness values are also used as an indicator of susceptibility to some forms of stress-corrosion cracking.

Toughness is the ability of a material to absorb energy during fracture. There are two approaches to toughness testing: impact toughness testing and fracture mechanics testing.

Impact Toughness Testing. To test impact toughness, a sample of specified geometry is subjected to an impact load, and the amount of energy absorbed during fracture is recorded. Usually the specimen is oriented so that the notch and expected plane of fracture run longitudinally through the weld metal. Charpy tests do not measure an inherent material property, but they result in a relative measure of impact toughness between materials. A very common use of the Charpy test is to determine a material's ductile-to-brittle transition temperature by performing tests at several different temperatures. AWS A5.1 (Ref 19) gives minimum Charpy impact values, at several temperatures, for welds made on carbon steel using a number of different electrodes.

Fracture Mechanics Testing. The second type of toughness testing is based on fracture mechanics, and it can use either linear elastic or elastic-plastic methodologies. Although elastic-plastic behavior (J_{Ic}) is becoming of interest in some cases, the bulk of fracture mechanics testing is based on linear elastic considerations. These tests, using specimens and procedures given in ASTM E 399 (Ref 20), are used to measure a material's fracture toughness (K_{Ic}), which is a material property. In the case of welding, fracture toughness is usually expressed using a value for crack tip opening displacement (Ref 21). Fracture toughness testing has only recently begun gaining acceptance as applicable to welds. The major shortcomings of this approach include the complexity and cost of testing and the wide variability in fracture toughness values for weld metal, due largely to the inhomogeneous nature of welds and residual stress effects.

Characterization of Welds

Craig B. Dallam, The Lincoln Electric Company; Brian K. Damkroger, Sandia National Laboratories

Weld Characterization Examples

In this section, two weld will be analyzed to serve as examples of techniques discussed thus far in this article. The first of these welds is a multipass shielded metal arc weld/flux-cored arc weld made on pipe steel for an industrial application. This type of weld would typically be made in great quantity. In practice, it would be characterized largely on the basis of its external appearance, perhaps supplemented by nondestructive testing. The initial characterization of a weld and procedure, however, would be based on chemical composition and mechanical properties. Primary concerns are whether the weld being examined is representative of a normal weld of this type and can thus be reasonably well described based on the materials, process, and specifications involved in its production. The bulk of the actual characterization of such a weld would be done during the development and certification of the initial process to determine its suitability for the intended application.

The second example is a weld used for a very specific application. This weld is a butt weld made on Ti-6Al-4V, with a tantalum shim inserted between the base metal sections. Among the requirements for this weld are that it have microstructural and property homogeneity and stability at elevated temperatures and that it be cathodic to the base metal under unusual and extremely severe environmental conditions. In this case, the concerns center less on the eventual application and more on building a thorough database regarding the metallurgical and microstructural characteristics of the weld.

Example 1: Multipass Weld in a 1.07 m (42 in.) Diameter X-65 Pipe.

This weld is a circumferential weld on a 12.7 mm (0.50 in.) thick, 1.07 m (42 in.) diameter X-65 pipe. The X-65 materials is designated by API as a pipe steel with at least 448 MPa (65 ksi) yield strength and 566 MPa (82 ksi) tensile strength. This type of weld is typical for a large oil or gas pipeline. However, for this example, procedures were deliberately selected to produce a weld with a range of defects. These procedures, given by Table 4, are not representative of standard practice.

TABLE 4 PARAMETERS (NOT STANDARD PROCEDURE) USED TO OBTAIN MULTIPASS WELD IN 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

PROCESS	PASS NO.	ELECTRODE	DIAMETER		WIRE FEED		CURRENT, A	VOLTAGE, V	TRAVEL SPEED

Additional specifications include: 12.7 mm (0.50 in.) wall thickness; 1.59 mm (0.0625 in.) land; 1.59 mm (0.0625 in.) gap; 60° bevel in groove; vertical down position; preheat and interpass temperature of 150 °C (300 °F)

Visual Observation. The weld was initially characterized by visual observation. From the top of the joint, the size and uniformity of the weld and undercut can be observed (Fig. 6a). From the underside, spatter, lack of penetration, and internal undercut can be seen (Fig. 6b).

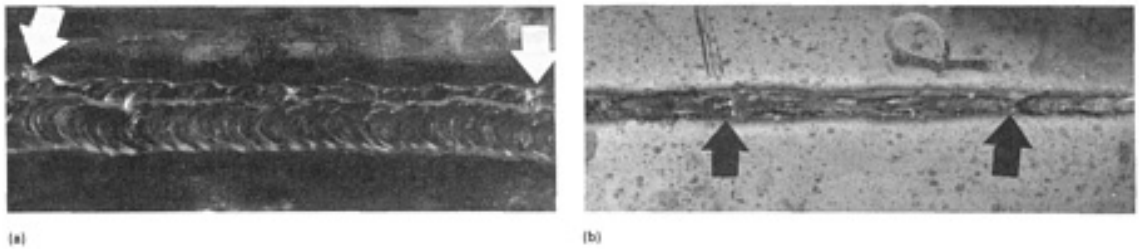

FIG. 6 DEFECTS IN A MULTIPASS WELD MADE ON A 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE. (A) EXTERIOR VIEW SHOWING LACK OF UNIFORMITY (RIGHT ARROW) AND UNDERCUT (LEFT ARROW). (B) INTERIOR VIEW SHOWING LACK OF PENETRATION (RIGHT ARROW) AND BURN-THROUGH (LEFT ARROW)

Nondestructive evaluation was then used to examine the weld for internal and surface defects. Slag entrapment and lack of fusion are typical internal defects for this type of weld, and they can be seen in the radiograph shown in Fig. 7. Figure 7 also shows the external defects noted during visual observation. In addition to nondestructive evaluation, other tests that highlight defects (for example, "nick-break" tests and face or root bend tests) can be run, but these were not used in this case. Similarly, ultrasonic testing, magnetic particle testing, and penetrant testing were not used in this characterization.

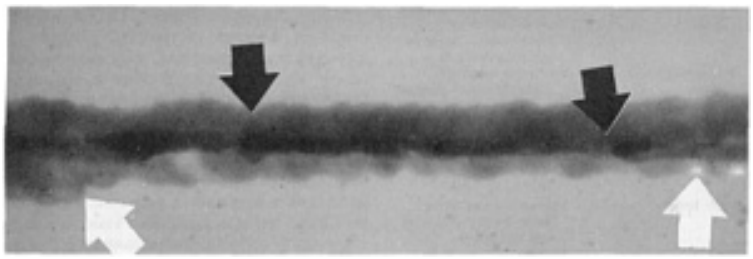

FIG. 7 RADIOGRAPH SHOWING POSITIVE IMAGE OF MACROSCOPICALLY VISIBLE DEFECTS IN THE X-65 PIPE STEEL OF FIG. 6. SEE FIG. 6 FOR DESIGNATION OF SPECIFIC DEFECTS.

Weld Macrostructure. Destructive evaluation begins by removing a transverse section from the weld and preparing it for metallographic examination (Fig. 8). The welding pass sequence (that is, number and size of passes, number of passes per layer, amount of penetration, and extent of HAZ) is apparent. In addition, any gross defects present in the sectioning plane are visible. In this example, nine passes were made, three layers with one pass and three with two passes. Figure 8 also shows four small pores, one each in the third, fourth, sixth, and ninth passes. In this case, the porosity was induced by deliberately varying the electrode stickout.

FIG. 8 TRAVERSE SECTION OF THE X-65 PIPE STEEL SHOWN IN FIG. 6 AND 7. PORES IN PASSES 3, 4, 6, AND

8 WERE CAUSED BY INTENTIONALLY VARYING THE ELECTRODE STICKOUT.

Weld Metal Composition. Compositional analysis of the weld was performed at this point. For this application, the bulk, or average, composition of the weld is of the most interest. The bulk composition of the weld was measured using an emission spectrometer, and the results are given in Table 5. The interstitial content of the weld is also of interest, and the levels of oxygen and nitrogen were measured with dedicated instruments. The oxygen level of the weld was found to be 110 ppm and the nitrogen level, 330 ppm. For some welds, techniques can be used to map compositional variations within the weld. In this case, the bulk composition, measured at the weld center, is considered adequate to characterize the weld.

TABLE 5 BULK COMPOSITION OF WELD IN 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

Weld Microstructure. The transverse section was also used for examination and characterization of the microstructure of the weld. Figure 9 shows micrographs of different regions of the weld. Figure 9(a) shows weld metal that has not been reheated by successive passes. Figure 9(b) shows weld metal that has been reheated and has a finer structure than the non-reheated weld metal. Figure 9(c) shows a location in the HAZ that closely resembles the structure seen in the reheat zone. The important parameters to characterize for this type of weld are the percentage of reheat zone, the relative amount of various microconstituents, and the average grain size. In the example weld, the weld metal is approximately 80% reheat zone. In the non-reheated zone (Fig. 9a), quantitative microstructural analysis showed that the structure consisted of 20% grain boundary ferrite, 20% intergranular polygonal ferrite, 16% acicular ferrite, 32% ferrite with an aligned second phase, and 12% ferrite with a nonaligned second phase. No martensite or ferrite-carbide aggregate was found.

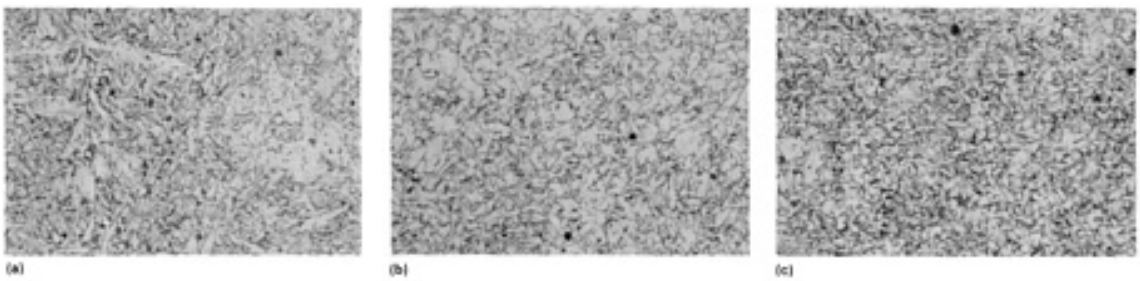

FIG. 9 MICROSTRUCTURE OBTAINED IN SELECTED REGIONS OF THE TRAVERSE SECTION OF THE X-65 PIPE STEEL OF FIG. 8. (A) NON-REHEATED WELD METAL. (B) REHEATED WELD METAL. (C) HEAT-AFFECTED ZONE. ALL 250×

Mechanical Testing. Following the characterization of the microstructure, specimens were removed and used for mechanical testing. For this application, the pertinent mechanical tests are tension tests (transverse and all-weld-metal), Charpy impact tests, fracture toughness tests, and a microhardness traverse. A transverse tensile test is primarily used to ensure that the welded joint is not the weak link in the final structure. In this case, a 305 × 32 mm (12.0 × 1.25 in.) specimen was removed from the pipe, the long axis perpendicular to the weld bead. The specimen was loaded to 247 kN (27.8 tonf) and failed in the base metal. Based on a weld cross-sectional area of 5.08 cm^2 (0.787 $in.^2$), a minimum weld tensile strength was calculated as 487 MPa (70.6 ksi).

An all-weld-metal tensile test was run using a specimen removed from the bead so that its loading axis was parallel to the weld direction. In this case, the weld was aged prior to testing, with the heat treatment being 48 h at 104 °C (220 °F). The results of the tensile test are shown in Fig. 10. The yield strength was found to be 520 MPa (75.4 ksi), the ultimate strength 594 MPa (86.1 ksi), and the percent elongation 30%. With respect to a typical vendor specification for this type of weld, these values indicate that the weld is adequate.

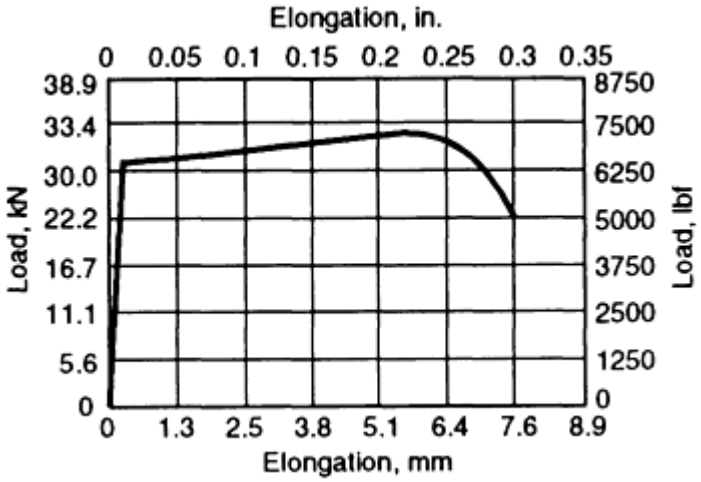

FIG. 10 PLOT OF LOAD VERSUS ELONGATION FOR ALL-WELD-METAL TENSILE TEST OF A 6.4 MM (0.25 IN.) DIAMETER SPECIMEN TAKEN FROM THE 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

Charpy V-notch impact specimens were removed from the weld as shown in Fig. 11. For this type of application, tests are usually run at only one temperature, dictated by a specification and/or past experience. For a full characterization, however, tests will be run over a broad enough range to clearly establish the upper- and lower-shelf energy levels and to identify the ductile-to-brittle transition temperature (DBTT). For this example, tests were run at several temperatures, and the results are shown in Fig. 12. This figure clearly shows that the upper shelf energy is approximately 200 J (150 ft · lbf), the lower shelf 2 J (1.5 ft · lbf), and the DBTT -10 °C (14 °F).

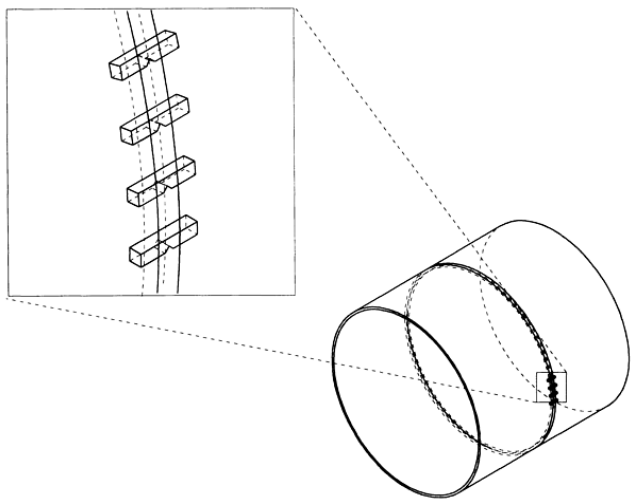

FIG. 11 SCHEMATIC SHOWING LOCATION AND ORIENTATION OF CHARPY V-NOTCH SPECIMENS TAKEN FROM THE 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE. ALTHOUGH INSET SHOWS WIDELY SPACED SAMPLES FOR THE SAKE OF CLARITY, ACTUAL SAMPLES REMOVED ARE TYPICALLY ADJACENT TO ONE ANOTHER.

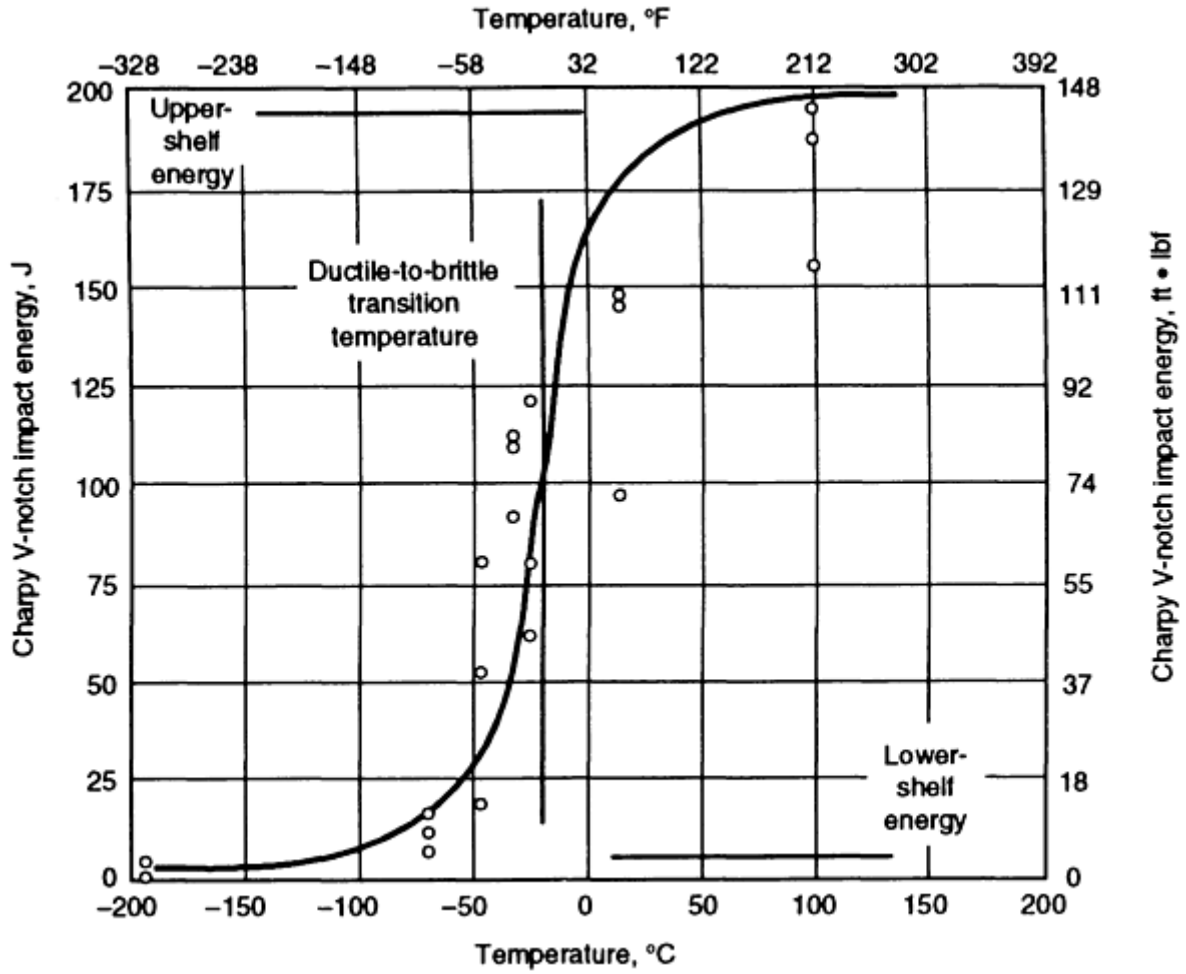

FIG. 12 CHARPY V-NOTCH IMPACT ENERGY TEST RESULTS USED TO OBTAIN DUCTILE-TO-BRITTLE TRANSITION TEMPERATURE (-10 °C, OR 14 °F) FOR THE 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

Fracture toughness specimens were removed from the weld in an orientation similar to that of the Charpy specimens. As with Charpy tests, fracture toughness specifications usually require a certain value at a given temperature, usually the minimum service temperature. Crack tip opening displacement tests were conducted at -45 °C (-50 °F) on three specimens removed from the example weld. The results were found to vary from 0.137 to 0.322 mm (0.005 to 0.013 in.), with the average being 0.229 mm (0.009 in.). Figure 13 shows the fracture surface of one of the test specimens, on which the ductile fracture mode and overload zone can be clearly seen.

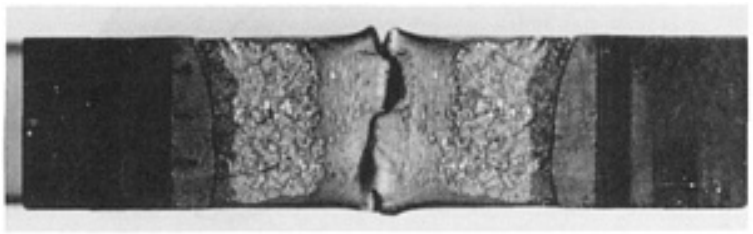

FIG. 13 MACROGRAPH OF THE FRACTURE SURFACE OF A CRACK TIP OPENING DISPLACEMENT TEST SPECIMEN REMOVED FROM THE 1.07 M (42 IN.) X-65 STEEL PIPE. THE REGIONS OF THE SURFACE SHOWN CORRESPOND WITH THE NOTCH, PRECRACK, STABLE CRACK GROWTH, FAST FRACTURE, AND OVERLOAD ZONES.

In addition to the previous mechanical tests, microhardness testing is often used for this type of weld. The primary purpose of microhardness testing is to check for the presence of martensite in the HAZ. Figure 14 shows a schematic of the example weld and the location and values of several microhardness tests. In this case, none of the values exceeded 240 HV, the level associated with the presence of martensite.

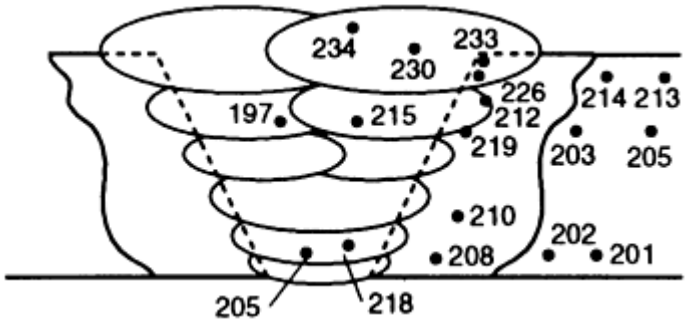

FIG. 14 MICROHARDNESS READINGS (LOCATION IN MULTI-PASS WELD INDICATED BY DOTS) BELOW 240 HV INDICATING THAT NO MARTENSITE STRUCTURE IS PRESENT IN THE 1.07 M (42 IN.) X-65 STEEL PIPE

Typically, this type of pipe weld is characterized with respect to stress-corrosion cracking resistance. In addition, testing is often performed to characterize the HAZ toughness.

Example 2: Welding of 2.5 mm (0.100 in.) Thick Ti-6Al-4V Sheet using a 0.127 mm (0.005 in.) Thick Tantalum Shim.

Figure 15 shows a transverse section of a butt weld, where the base metal is 2.5 mm (0.100 in.) thick Ti-6Al-4V and a 0.127 mm (0.005 in.) thick tantalum shim has been placed in the joint. This weld geometry was used in a study of the effect of dilution on the microstructures and properties of dissimilar metal welds of titanium to refractory metals. The questions to be answered in the characterization of this weld were:

- HOW UNIFORMLY WOULD THE TANTALUM BE DISTRIBUTED IN THE WELD POOL?
- HOW ACCURATELY COULD THE COMPOSITION OF THE WELD POOL BE PREDICTED BASED ON DILUTION CALCULATIONS?
- WHAT PHASES AND MICROCONSTITUENTS ARE PRESENT IN THE WELD METAL?
- WHAT ARE THE MECHANICAL PROPERTIES OF THE WELD METAL?

In addition, a number of very application-specific corrosion and elevated-temperature tests were performed on the dissimilar metal welds. In contrast with the pipe weld of the first example, the primary tools used in this characterization were macrostructural examination, compositional mapping, x-ray diffraction, tension testing of all weld metal specimens, and microhardness traverses.

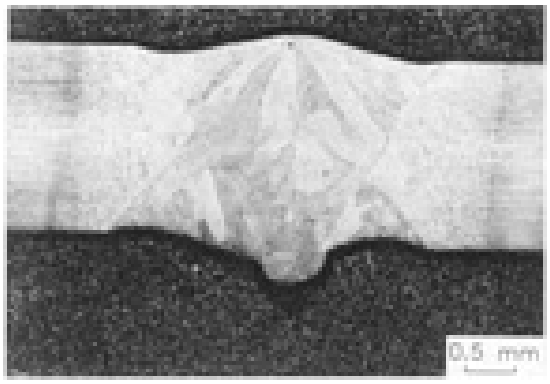

FIG. 15 MICROGRAPH OF TRANSVERSE SECTION OF AN ELECTRON-BEAM WELDED BUTT WELD JOINING 2.5 MM (0.100 IN.) THICK TI-6AL-4V SHEET USING A 0.127 MM (0.005 IN.) THICK TANTALUM SHIM PLACED IN THE JOINT. KROLL'S REAGENT WAS USED AS ETCHANT.

Weld Macrostructure. The weld shown in Fig. 15 was made with the electron-beam welding process, using sharp focus, 100 kV power, 16 to 25 mA current, and a travel speed of 12.7 mm/s (30 in./min). As can be seen in the transverse section, a full penetration weld was achieved using one pass from each side of the weld. The transverse section also shows that no obvious discontinuities exist in the weld pool and that the weld metal microstructure is fairly uniform. Figure 15 also suggests that the tantalum shim was completely melted.

Weld Metal Composition. An initial examination of the weld metal composition was performed to help assess the uniformity of the weld macrostructure. Figure 16 shows tantalum, titanium, vanadium, and aluminum elemental scan lines traversing the weld. These data were generated using a scanning electron microscope with energy-dispersive spectroscopy capability, and they confirm that the elements in question are uniformly distributed throughout the weld pool. Based on these analyses and the macrostructural characterization, it was determined that this combination of welding processes and parameters was successful in producing a full-penetration weld and a macroscopically homogeneous and defect-free weld pool.

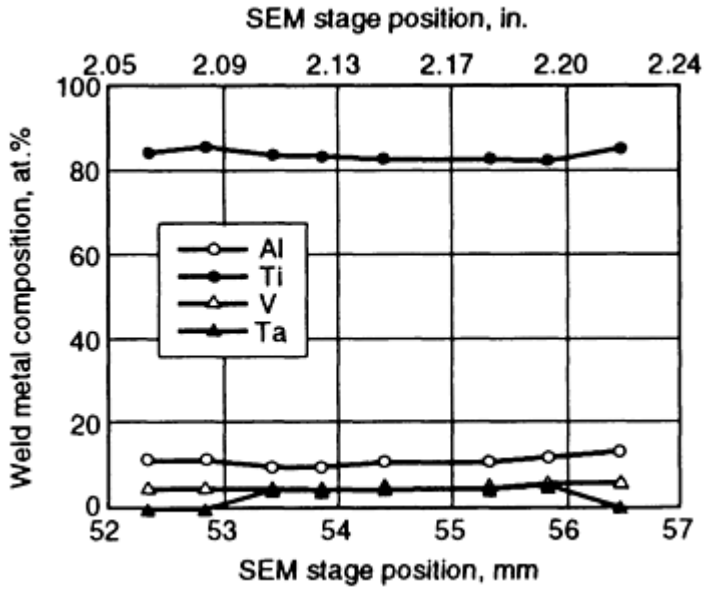

FIG. 16 ELEMENTAL LINE SCANS OF TITANIUM, ALUMINUM, VANADIUM, AND TANTALUM SPANNING THE HAZ AND FUSION ZONE OF THE 2.5 MM (0.100 IN.) THICK TI-6AL-4V SHEET WELDED USING A 0.127 MM (0.005 IN.) THICK TANTALUM SHIM.

The properties of titanium alloys can be strongly affected by the phases present in the microstructure, which are largely controlled by the weld metal composition. In this example, aluminum stabilizes the hexagonal close-packed (hcp) α and/or α' phases, and vanadium and tantalum, the body-centered cubic (bcc) β phase. In titanium alloys, the composition can be expressed as an electron/atom (*e*/*a*) ratio, which allows the phase stabilization effects of different elements to be combined. Table 6 lists the calculated (based on dilution) and measured compositions of the weld. This table shows that the measured and calculated compositions agree reasonably well. The measured aluminum values are somewhat lower than the calculations predict, perhaps due to some loss of aluminum during the welding process. Of most interest is that the measured and calculated *e*/*a* ratios are 3.96 to 3.98. This compositional range indicates that the weld metal microstructure should be α', a hexagonal martensite structure associated with good mechanical properties (Ref 20).

TABLE 6 COMPOSITION OF TI-6AL-4V RELATIVE TO THAT OF TI-6AL-4V PLUS TANTALUM WELD METAL

SAMPLE	COMPOSITION, AT.%				
	Ti	V	Al	Ta	*E/A* RATIO
TI-6AL-4V	86.2	3.6	10.2	. . .	3.93
TI-6AL-4V WELDED TO TA SHIM:					
CALCULATED	83.9	3.5	9.9	2.7	3.96
MEASURED	83.0	3.9	9.5	3.6	3.98

Weld Microstructure. The microstructure of the weld was analyzed using optical microscopy, transmission electron microscopy, and x-ray diffraction. Of particular interest were the structure of any martensitic phase present and the possible existence of ω, an ordered phase that can severely embrittle the material. The composition of the weld metal suggests that the structure will be α' hexagonal martensite. Figure 17 shows an optical micrograph of the fusion zone. Examination of Fig. 17 and comparison with Ti-6Al-4V (no tantalum shim) welds further suggest that the weld metal microstructure is α'. This was further supported by x-ray diffraction and TEM data. Figure 18 shows an x-ray diffraction trace for the weld metal. Aside from peaks from the specimen-mounting material, only peaks associated with a hexagonal structure were detected.

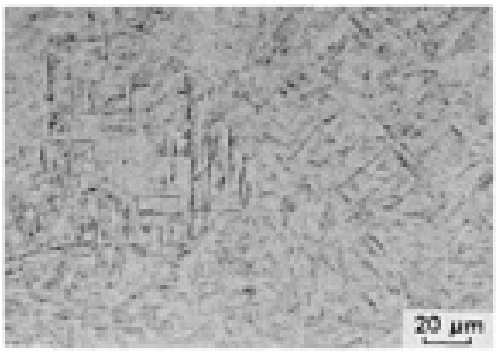

FIG. 17 OPTICAL MICROGRAPH OF FUSION ZONE OBTAINED WITH THE TI-6AL-4V SHEET WELDED USING A TANTALUM SHIM. KROLL'S REAGENT WAS USED AS THE ETCHANT. MICROSTRUCTURE CONSISTS OF WIDMANSTÄTTEN α+ β AND α' MARTENSITE.

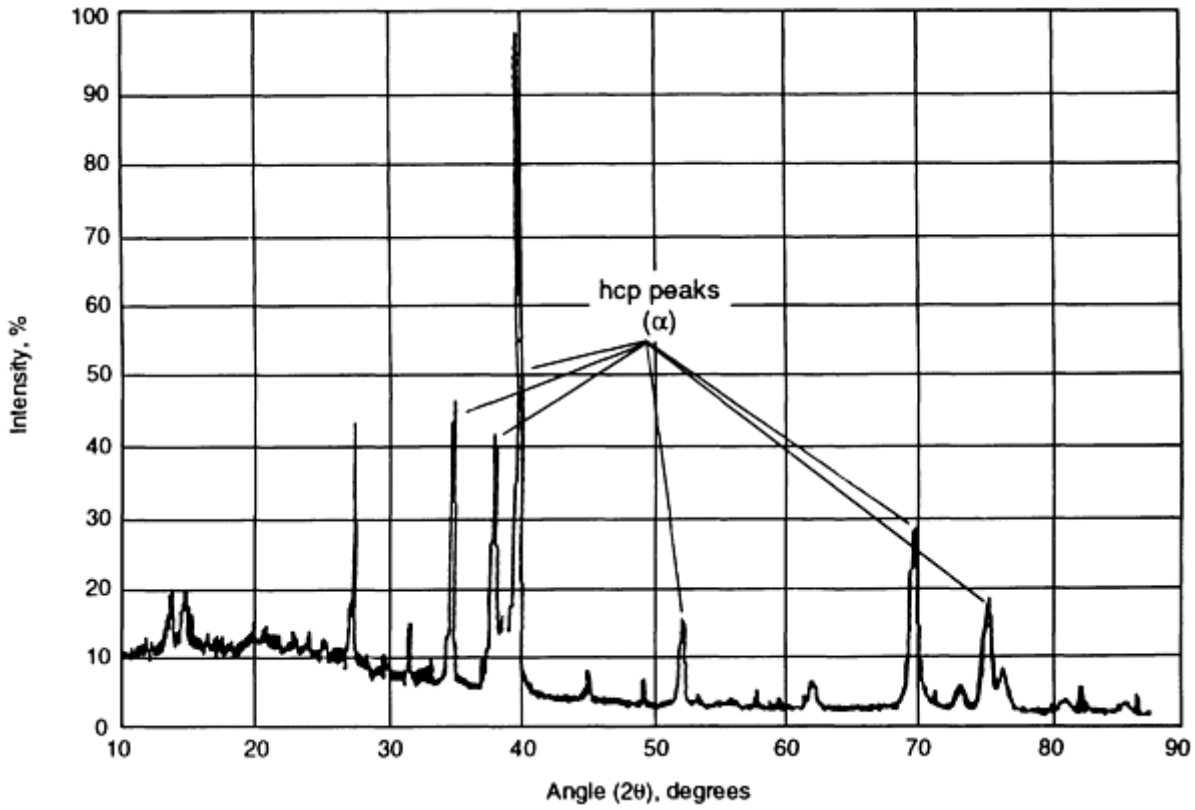

FIG. 18 X-RAY DIFFRACTION TRACE OF FUSION ZONE IN TI-6AL-4V SHEET WELDED USING A TANTALUM SHIM, SHOWING PEAKS THAT IDENTIFY HEXAGONAL STRUCTURES

Based on the compositional analysis, diffraction results, and microstructural analysis, the weld metal can be characterized as α' hexagonal martensite. By comparison with Ti-6Al-4V base metal and (no shim) weld metal, it was determined that the weld metal could be treated as a slightly more heavily stabilized variant of Ti-6Al-4V. This analysis allowed its properties and performance to be reasonably predicted.

Mechanical Testing. Microhardness traverses and all-weld-metal tension tests were performed on this weld. Figure 19 shows the results of two microhardness traverses, one across the second pass only, and one across the middle of the weld where the two passes overlap. Both traces are very similar, and the hardness is fairly constant across the fusion zone. These data confirm that the weld metal is relatively homogeneous. The hardness of the fusion zone is slightly higher than that of the base metal, as would be expected because of the martensitic structure and slightly higher β-stabilizer content.

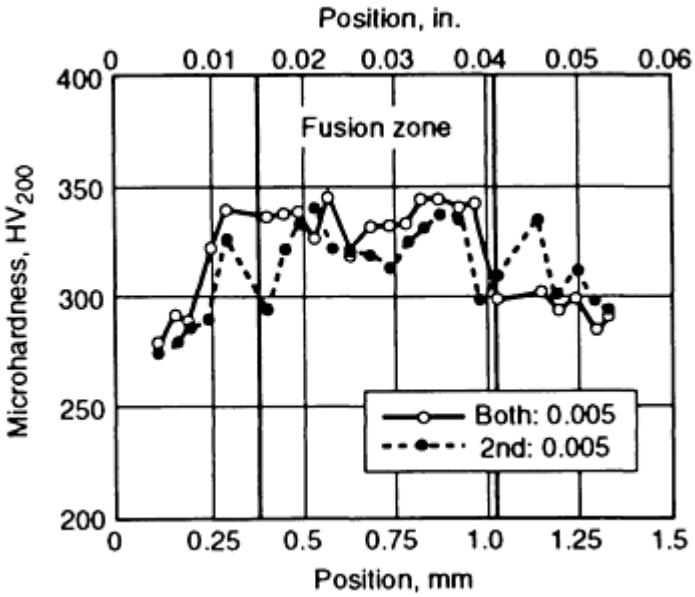

FIG. 19 MICROHARDNESS TRAVERSE DATA IN TWO LOCATIONS FOR THE TI-6AL-4V SHEET WELDED USING A TANTALUM SHIM. DATA LABELED "2ND" REFER TO TRAVERSE OVER SECOND PASS OF WELD ONLY. DATA LABELED "BOTH" INDICATE TRAVERSE ACROSS CENTER OF WELD WHERE TWO PASSES OVERLAP (SEE FIG. 15).

The tensile testing further confirmed that the weld metal could be considered to be a more heavily stabilized variant of Ti-6Al-4V. Table 7 compares the results of tensile tests performed on a baseline Ti-6Al-4V (no shim) weld with those of tests performed on the example weld. As the data show, the tantalum-containing weld had slightly higher strength and lower ductility than the baseline weld. Again these data are consistent with a slightly higher β-stabilizer content. However, the differences were not as great as in the microhardness testing, because in the case of the tensile tests, both structures were α' martensite.

TABLE 7 TENSILE PROPERTIES OF BASELINE TI-6AL-4V WELD COMPARED TO TI-6AL-4V WELDED USING TANTALUM SHIM

SAMPLE	YIELD STRENGTH		ULTIMATE TENSILE STRENGTH		YOUNG'S MODULUS		MAXIMUM STRAIN, %
	MPA	KSI	MPA	KSI	GPA	10^6 PSI

(A) REPLICANTS OF TI-6AL-4V WELDED TO TANTALUM SHIM

Test Results. The goal of the Ti-6Al-4V/tantalum dissimilar metal weld study was to thoroughly characterize the homogeneity, structure, and properties of the weld, relative to a baseline Ti-6Al-4V weld, and to determine the effect of the tantalum additions. The study showed that the tantalum shim could be completely melted using the chosen welding procedure and that a uniform weld bead could be produced. The compositional and microstructural analyses showed that the weld was very similar to the baseline weld. The tantalum-alloyed weld metal appeared to be consistent with standard principles regarding titanium alloy compositions and structure, and it was what would be expected in a weld made on slightly more heavily alloyed material. The mechanical test results confirmed this interpretation as well. In total, the

characterization showed that this weld could be made and that its properties could be predicted and/or interpreted accurately as an extrapolation of the baseline weld.

Characterization Objectives. A number of characterization techniques have been briefly discussed with respect to their application to welds. Examples 1 and 2 show that the choice and emphasis of the characterization procedure are largely determined by the intended application of the weld and the goals to be accomplished by the characterization. Each of the procedures in Examples 1 and 2 are discussed in great detail in the cited references. Additional information is available in the Section "Joint Evaluation and Quality Control" in this Volume and in Ref 16, 17, and 22

Introduction to Brazing and Soldering

Melvin M. Schwartz, Sikorsky Aircraft

Introduction

BRAZING AND SOLDERING require the application of a number of scientific and engineering skills to produce joints of satisfactory quality and reliability. Brazing employs higher temperatures than soldering, but the fundamental concepts are similar, particularly with respect to metallurgy and surface chemistry (Table 1). However, joint design, materials to be joined, filler metal and flux selection, heating methods, and joint preparation can vary widely between the two processes. Economic considerations involving filler metal and process technology are also varied, particularly in relation to automated techniques and inspection and testing. Brazing and soldering are performed in many industries, from exotic applications in the electronics and aerospace field to everyday plumbing applications.

TABLE 1 COMPARISON OF SOLDERING, BRAZING, AND WELDING

Parameter	**Process**		
	Soldering	**Brazing**	**Welding**
Joint formed	Mechanical	Metallurgical	Metallurgical
Filler metal melt temperature, °c (°f)	<450 (<840)	>450 (>840)[(a)]	>450 (>840)[(b)]
Base metal	Does not melt	Does not melt	. . .
Fluxes used to protect and to assist in wetting of base-metal surfaces	Required	Optional	Optional
Typical heat sources	Soldering iron; ultrasonics; resistance; oven	Furnace; chemical reaction; induction; torch; infared	Plasma; electron beam; tungsten and submerged arc; resistance; laser
Tendency to warp or burn	Atypical	Atypical	Potential distortion and warpage of base-metal likely
Residual stresses	. . .	. . .	Likely around weld area

(A) LESS THAN MELTING POINT OF BASE METAL.

Introduction to Brazing and Soldering

Melvin M. Schwartz, Sikorsky Aircraft

Brazing

Many products are assembled from two or more individual components that are often permanently joined to produce structurally sound assemblies. Joining methods include various fasteners, interference-type joints, adhesives, and, for the highest-integrity joints, the many techniques classified under welding. Brazing, although fundamentally indifferent from welding, is one such technique.

Early metalworkers, stimulated by a desire to produce structures that were difficult or impossible to build using methods then in existence, realized that it was possible to fill the joint between two metal pieces with molten metal and allow it to solidify. These artisans soon learned by experience that, in order to achieve adherence, the metals to be joined and the brazing filler metal had to be kept free of oxides and the filler metal had to have a lower melting point, and, furthermore, that a given filler metal would not necessarily adhere to all metals. From these basic requirements, brazing grew into a craft whose practitioners were well versed in what to do and what not to do in order to produce sound joints.

Just as the technique of brazing developed empirically, so did the lower-melting point filler metals. Workers first used lead and tin solders as well as silver and copper-arsenic ores, which were readily available and had low melting points. Later, the alloy brass was developed and found to be more desirable for joining copper, silver, and steel structures, because it provided higher-strength joints and could withstand higher temperatures.

Early silversmiths, probably wanting to produce white solder joints for aesthetic reasons, melted brass and silver together and found it to have an even lower melting point than brass, good adherence, and better corrosion resistance. Although innumerable combinations of silver, copper, and zinc subsequently evolved, primarily to meet melting-point requirements, these silver-brass, brass, and lead-tin alloys were essentially the only brazing and soldering filler materials available for generations.

Advantages of Brazing. Brazing has many distinct advantages, including the following:

- ECONOMICAL FABRICATION OF COMPLEX AND MULTI-COMPONENT ASSEMBLIES
- SIMPLE METHOD TO OBTAIN EXTENSIVE JOINT AREA OR JOINT LENGTH
- JOINT TEMPERATURE CAPABILITY APPROACHING THAT OF BASE METAL
- EXCELLENT STRESS DISTRIBUTION AND HEAT-TRANSFER PROPERTIES
- ABILITY TO PRESERVE PROTECTIVE METAL COATING OR CLADDING
- ABILITY TO JOIN CAST MATERIALS TO WROUGHT METALS
- ABILITY TO JOIN NONMETALS TO METALS
- ABILITY TO JOIN METAL THICKNESSES THAT VARY WIDELY IN SIZE
- ABILITY TO JOIN DISSIMILAR METALS
- ABILITY TO JOIN POROUS METAL COMPONENTS
- ABILITY TO FABRICATE LARGE ASSEMBLIES IN A STRESS-FREE CONDITION
- ABILITY TO PRESERVE SPECIAL METALLURGICAL CHARACTERISTICS OF METALS
- ABILITY TO JOIN FIBER- AND DISPERSION-STRENGTHENED COMPOSITES
- CAPABILITY FOR PRECISION PRODUCTION TOLERANCE
- REPRODUCIBLE AND RELIABLE QUALITY CONTROL TECHNIQUES

Strong, uniform, leakproof joints can be made rapidly, inexpensively, and even simultaneously. Joints that are inaccessible and parts that may not be joinable at all by other methods often can be joined by brazing. Complicated assemblies comprising thick and thin sections, odd shapes, and differing wrought and cast alloys can be turned into

integral components by a single trip through a brazing furnace or a dip pot. Metal as thin as 0.01 mm (0.0004 in.) and as thick as 150 mm (6 in.) can be brazed.

Brazed joint strength is high. The nature of the interatomic (metallic) bond is such that even a simple joint, when properly designed and made, will have strength equal to or greater than that of the as-brazed parent metal. The natural shapes of brazing fillets are excellent. The meniscus surface formed by the fillet metal as it curves across corners and adjoining sections is ideally shaped to resist fatigue. (It should be noted that in brazed joints using eutectic-type filler metal, fillets often contain an excessive amount of brittle intermetallic compounds. In fact, fillets are 5 to 10 times thicker than the joint and thus have a much higher volume of the liquid phase from which these brittle phases crystallize. Therefore, crack nucleation often originates in fillets.)

Complex shapes with greatly varied sections can be brazed with little distortion, and precise joining is comparatively simple. Unlike welding, in which the application of intense heat to small areas acts to move the parts out of alignment and introduces residual stresses, brazing involves fairly even heating and thus part alignment is easier.

Limitations of Brazing. A brazed joint is not a homologous body but rather is heterogeneous, composed of different phases with differing physical and chemical properties. In the simplest case, it consists of the base metal parts to be joined and the added filler metal. However, partial dissolution of the base metal, combined with diffusion processes, can change the composition and therefore the chemical and physical properties of the boundary zone formed at the interface between base metal and filler metal and often of the entire joint. Thus, in addition to the two different materials present in the simplest example given above, a complicated transitional or even completely different zone must be considered.

In determining the strength of such heterogeneous joints, the simplified concepts of elasticity and plasticity theory--valid for a homogeneous metallic body where imposed stresses are uniformly transmitted from one surface or space element to the adjacent ones--no longer apply. In a brazed joint formed of several materials with different characteristics of deformation resistance and deformation speed, the stresses caused by externally applied loads are nonuniformly distributed.

Mechanics of Brazing. Brazing involves a limited dissolution or plastic deformation of the base metal (Ref 1). Brazing comprises a group of joining processes in which coalescence is produced by heating to a suitable temperature above 450 °C (840 °F) and by using a ferrous or nonferrous filler metal that must have a liquidus temperature above 450 °C (840 °F) and below the solidus temperature(s) of the base metal(s). The filler metal is distributed between the closely fitted surfaces of the joint. Brazing is distinguished from soldering in that soldering employs a filler metal having a liquidus below 450 °C (840 °F) (Table 1).

Brazing proceeds through four distinct steps:

- THE ASSEMBLY OR THE REGION OF THE PARTS TO BE JOINED IS HEATED TO A TEMPERATURE OF AT LEAST 450 °C (840 °F).
- THE ASSEMBLED PARTS AND BRAZING FILLER METAL REACH A TEMPERATURE HIGH ENOUGH TO MELT THE FILLER METAL (FOIL, WIRE, PASTE, PLATINGS, ETC.) BUT NOT THE PARTS.
- THE MOLTEN FILLER METAL, HELD IN THE JOINT BY SURFACE TENSION, SPREADS INTO THE JOINT AND WETS THE BASE METAL SURFACES.
- THE PARTS ARE COOLED TO SOLIDITY, OR "FREEZE," THE FILLER METAL, WHICH IS HELD IN THE JOINT BY CAPILLARY ATTRACTION AND ANCHORS THE PARTS TOGETHER BY METALLURGICAL REACTION AND ATOMIC BONDING.

Brazing Versus Other Welding Processes. The mere fact that brazing does not involve any substantial melting of the base metals offers several advantages over other welding processes. It is generally possible to maintain closer assembly tolerances and to produce a cosmetically neater joint without costly secondary operations. Even more important, however, is that brazing makes it possible to join dissimilar metals (or metals to ceramics) that, because of metallurgical incompatibilities, cannot be joined by traditional fusion welding processes. If the base metals do not have to be melted to be joined, it does not matter that they have widely different melting points. Therefore, steel can be brazed to copper as easily as to another steel.

Brazing also generally produces less thermally induced distortion, or warping, than fusion welding. An entire part can be brought up to the same brazing temperature, thereby preventing the kind of localized heating that causes distortion in welding.

Finally, and perhaps most important to the manufacturing engineer, brazing readily lends itself to mass production techniques. It is relatively easy to automate, because the application of heat does not have to be localized, as in fusion welding, and the application of filler metal is less critical. In fact, given the proper clearance conditions and heat, a brazed joint tends to "make itself" and is not dependent on operator skill, as are most fusion welding processes.

Automation is also simplified by the fact that there are many means of applying heat to the joint, including torches, furnaces, induction coils, electrical resistance, and dipping. Several joints in one assembly often can be produced in one multiple-braze operation during one heating cycle, further enhancing production automation.

As noted in Table 1, essentially no melting of the base metal occurs in brazing; however, the temperatures involved can affect the properties of the metals being joined. For example, base metals whose mechanical properties were obtained by cold working may soften or undergo grain growth if the brazing temperature is above their recrystallization temperatures. Mechanical properties obtained by heat treatment may be altered by the heat of brazing. On the other hand, materials in the annealed condition are usually not altered by brazing.

As with other welding processes, brazing produces a heat-affected zone (HAZ) with a strongly altered microstructure due to intensive mutual mass transfer between base metal and filler metal. The width of this zone varies with the heating process used. In torch and induction brazing, for example, only a localized zone is heated; in france and dip brazing, the entire part is subjected to the brazing temperature. As a rule, the HAZ produced during brazing is wider and less sharply defined than those resulting from other fusion-related processes.

Several elements of the brazing process must be understood in order to produce satisfactory brazed joints:

- FILLER METAL FLOW
- BASE METAL CHARACTERISTICS
- FILLER METAL CHARACTERISTICS
- SURFACE PREPARATION
- JOINT DESIGN AND CLEARANCE
- TEMPERATURE AND TIME
- RATE AND SOURCE OF HEATING

Each of these topics is discussed in detail in the article "Fundamentals of Brazing" in this Volume.

Introduction to Brazing and Soldering

Melvin M. Schwartz, Sikorsky Aircraft

Soldering

Like brazing and other joining processes, soldering involves several fields of science, including mechanics, chemistry, and metallurgy. Soldering is a simple operation (Ref 2), consisting of the relative placement of the parts to be joined, wetting the surfaces with molten solder, and allowing the solder to cool until it has solidified.

Soldering in the field of electronics is in many respects different from soldering in other branches of industry. Although the physical principles of all soldering (and brazing) processes are the same, the features specific to their use in electronics are so numerous that it is possible to speak of soldering in electronics as a separate subject.

Soldering Versus Other Joining Technologies. Soldering has several clear advantages over competitive joining techniques, such as welding or bonding with conductive adhesives:

- THE SOLDER JOINT FORMS ITSELF BY THE NATURE OF THE FLOW, WETTING, AND SUBSEQUENT CRYSTALLIZATION PROCESS, EVEN WHEN THE HEAT AND THE SOLDER ARE NOT DIRECTED PRECISELY TO THE PLACES TO BE SOLDERED. BECAUSE SOLDER DOES NOT ADHERE TO INSULATING MATERIALS, IT OFTEN CAN BE APPLIED IN EXCESS QUANTITIES, IN CONTRAST TO CONDUCTIVE ADHESIVES. THE SOLDERING TEMPERATURE IS RELATIVELY LOW, SO THERE IS NO NEED FOR THE HEAT TO BE APPLIED LOCALLY AS IN WELDING.
- SOLDERING ALLOWS CONSIDERABLE FREEDOM IN THE DIMENSIONING OF JOINTS, SO THAT IT IS POSSIBLE TO OBTAIN GOOD RESULTS EVEN IF A VARIETY OF COMPONENTS ARE USED ON THE SAME PRODUCT.
- THE SOLDERED CONNECTIONS CAN BE DISCONNECTED IF NECESSARY, THUS FACILITATING REPAIR.
- THE EQUIPMENT FOR BOTH MANUAL SOLDERING AND MACHINE SOLDERING IS RELATIVELY SIMPLE.
- THE SOLDERING PROCESS CAN BE EASILY AUTOMATED, OFFERING THE POSSIBILITY OF IN-LINE ARRANGEMENTS OF SOLDERING MACHINES WITH OTHER EQUIPMENT.

Mass soldering by wave, drag, or dip machines has been the preferred method for making high-quality, reliable connections for many decades. Despite the appearance of new connecting systems, it still retains this position. Correctly controlled, soldering is one of the least expensive methods for fabricating electrical connections. Incorrectly controlled, it can be one of the most costly processes--not because of the initial cost, but because of the many far-reaching effects of poor workmanship.

Chronology of Soldering. Soldering is not a new process (Ref 2). It probably dates to the Bronze Age, when some metalworker discovered the affinity of a tin-lead mixture for a clean copper surface. As recorded in the writings of Pliny, the Romans used 60Sn-40Pb mixture to solder their lead water pipes.

During the late 19th and early 20th centuries, a great deal of work was devoted to the development and improvement of the soldering process and to the determination of the fundamental principles involved. Examination of the books, papers, and especially the patents of the era shows that soldering as a science was clearly understood long before the start of the electronics industry. There has certainly been a great improvement in the materials and machines used in the process, but the basics have changed little since the early part of this century.

Soldering in the electronics field has undergone many dramatic changes since the first radios were built. Between the 1920s and the 1940s, all interconnections were made using the point-to-point wiring method, and the solder joints were made using soldering irons. After World War II (Ref 3, 4), the demand for consumer electronics began to increase, and by the 1950s a mass market had developed. To meet this demand, the first mass soldering technique, dip soldering, was used with boards that were the precursors of printed wiring boards (PWBs). By the late 1950s, wave soldering had been developed in England and soon thereafter reached the United States. This development was necessitated by the introduction of PWBs. Wave soldering continued to be the method of choice through the 1980s and is still widely used.

The development and maturation of the multi-layer PWB and the first major effort toward miniaturization occurred in the 1970s. The dual inline integrated circuit package replaced many discrete components. By the early 1980s, the pressure to increase component densities had grown to such a degree that a new technique for attachment was needed, and surface mounting was developed. Surface mount technology in turn required new ways to make solder joints, prompting the development of vapor phase, infrared, hot gas, and other reflow soldering techniques.

Soldering remains the attachment method of choice in the evolving electronics industry. It is the only metallurgical joining technique suitable for the mass manufacture of electronic and electrical interconnections within the temperature restrictions of electronic components and substrates.

Solder Metals. The solder metal business has changed dramatically, having moved from merely producing wire to producing bulk, preform, and paste in order to meet the needs of soldering techniques. Solder can be applied in several ways (Ref 2, 3):

- A MIXTURE OF SOLDER POWDER AND FLUX, KNOWN AS SOLDER PASTE (REF 5), CAN BE APPLIED TO THE JOINTS BY SCREENING, STENCILING, OR USING ONE OF THE MACHINES THAT APPLIES DOTS OF THE PASTE BY A SIMPLE PNEUMATIC SYSTEM. THIS METHOD IS ESPECIALLY USEFUL WHERE SURFACE-MOUNTED COMPONENTS ARE TO BE SOLDERED AND CANNOT BE PASSED THROUGH THE SOLDER WAVE.
- PARTS CAN BE PRETINNED, THAT IS, COATED WITH A LAYER OF SOLDER BY FLUXING AND DIPPING INTO A BATH OF THE MOLTEN METAL.
- SOLDER CAN BE OBTAINED IN THE SHAPE OF RINGS, WASHERS, OR TUBES, WHICH ARE PLACED ON OR ADJACENT TO THE PARTS TO BE JOINED. THESE SOLDER PREFORMS CAN BE OBTAINED WITH OR WITHOUT A FLUX COATING.

The two latter methods of providing solder for the joint are used in many areas of the electronics industry where machine soldering is not possible. Tiny solder rings are placed over long wire wrap pins on a mother board, where the gold plating of the pins in the wrapping area must not be coated with solder. Solder washers are fitted under bolts that must be soldered to a ground plane. Wires and tinned before soldering into a pretinned wiring lug. The possibilities are seemingly limitless (Ref 6).

Solder filler metals have also changed. The first electronic soldering was done with the 50Sn-50Pb solder material used by plumbers. By the 1950s, the choice of materials had switched to eutectic tin-lead solders to counter the problems created by a vibrating wave solder machine conveyor. Today a wide range of filler materials is used in the electronics industry. With the spread of electronics technology into every facet of life, the environmental and materials demands have grown substantially, requiring the use of such specialized materials as indium and gold-tin fillers.

Flux technology has also evolved (Ref 3, 5). As a result of the restraints of military and government specifications, the emphasis has been on the addition of new flux types rather than on the replacement of old ones. Extensive work has been done with organic acids, which enlarge the processing windows. Other categories include synthetic activated materials, which are non-rosin fluorocarbon solvent-removable types, and low solids fluxes for surface mounting that can be used instead of the classic fully activated rosin formulations.

Other materials, such as adhesives for the surface mounting of components intended for wave soldering, are new to soldering technology. These materials must be specially designed to avoid interference with the soldering process, yet must remain intact through the solvent action of fluxes and, often, flux removal.

Mass Soldering. With the introduction of mass soldering techniques (Ref 1, 6), the issue of solderability has become one of the major interest. Mass production processes are not as tolerant as the hand soldering process. In addition, modern components cannot withstand as much heat, as for example, a tube socket. Lower soldering temperatures and less mechanical working have made it necessary to attain the highest solderability to ensure a metallurgically sound and reliably solder joint.

Machine or mass soldering (Ref 2, 4, 6) can make thousands of joints in a few seconds, providing the electrical connections and simultaneously mechanically fastening the components. No other process has yet been developed that can so economically interconnect electronic circuitry.

Wave Soldering. From the original concept of hand dipping boards came the idea of pumping solder through a slot or nozzle to form a wave, or mound, of constantly moving, dross-free metal through which the board could be passed. This offered several advantages: the surface of the solder was always clean and did not require skimming, the pumping action maintained an even temperature, and the raised wave provided an easy form for adding a conveyor system for automatic movement of the board over the solder.

Once the idea of the solder wave had been born, it was logical to use a similar method to apply the flux, and the basic soldering machine appeared. These original machines were quite crude, consisting of individual modules with a freestanding conveyor (often added by the user) placed over them. There was little attempt to integrate the parts into one system, and the smoke and fumes were left to escape into the factory exhaust, aided by a makeshift canopy hung over the machine.

Much work was done on the development of the actual wave in an attempt to improve the speed of soldering and to reduce the incidence of shorts and icicles. The solder weir, the double wave, and the cascade all experienced brief popularity. The cascade wave, which consists of several waves in series, was one of the more interesting of these developments. It was used with an inclined conveyor and was the basis of machines built for in-house use by several manufacturers. However, it never achieved great popularity.

Another development was the use of ultrasonics to form a wave, with the intention of causing cavitation at the joint of avoiding the use of flux, or at least reducing the activity required. Some experimental machines were built, but the cost was excessive, the soldering results were no better than those produced with the conventional pumped wave, and the power of the ultrasonic energy had to be so high that the matching horns used to energize the pot were quickly eroded away. With the advent of the semiconductor, ulrasonics were found to cause occasional damage to the devices. Today the main use for ultrasonics in the soldering industry is to be found in the pots used for tinning components prior to assembly. This era also saw the introduction of oil into the solder wave. This idea worked extremely well and has been a feature of some soldering machines for many years (Fig. 1) (Ref 2, 3, 4, 5, 6, 7).

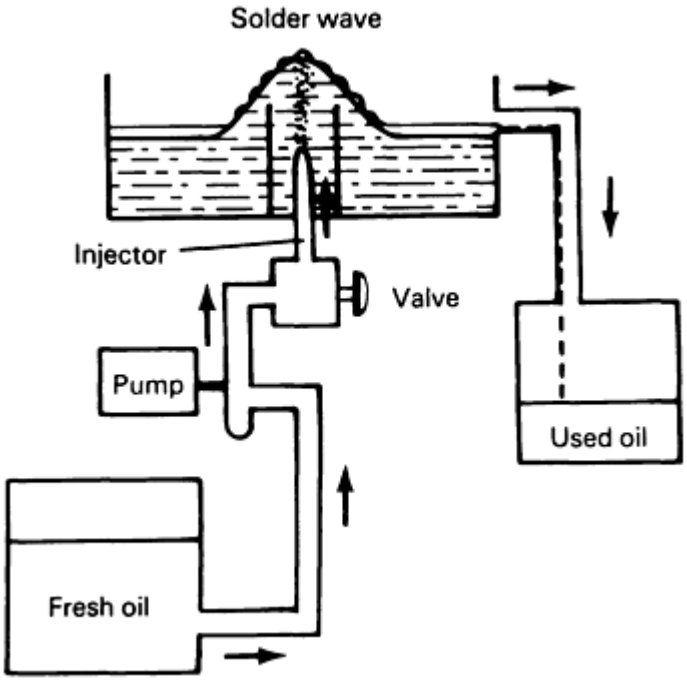

FIG. 1 SCHEMATIC SHOWING SIMPLE OIL INJECTION OF A SOLDER WAVE

Drag Soldering. In a totally different direction, the static solder bath soldering process, or drag soldering, was developed, and machines were designed using this principle (Fig. 2). These machines have been developed to a high level of sophistication, initially in Europe and Japan and later in the United States. As has often been the case in the growth of the soldering machine industry, initial developments were prompted because of patent restrictions that at the time prevented the free use of the more conventional solder wave. These restrictions have often proved beneficial to the industry by forcing creative thinking that has eventually resulted in improved products (Ref 2, 3, 4, 5, 6).

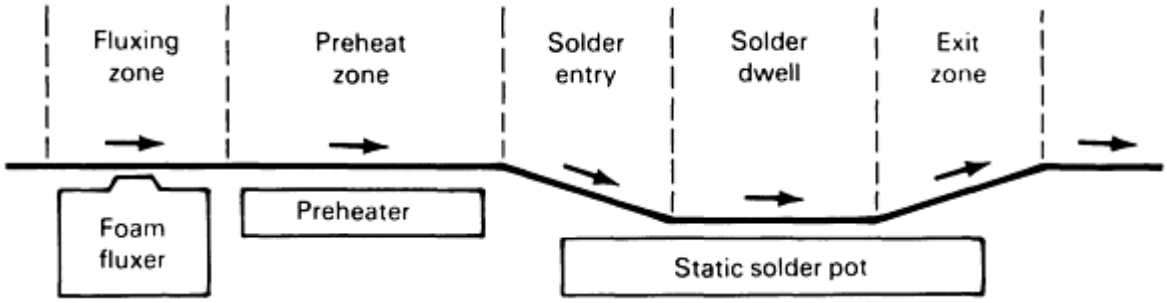

FIG. 2 SCHEMATIC SHOWING SEQUENCE OF OPERATIONS FOR A DRAG SOLDERING MACHINE

Current Technology. Today machines are available from many different manufacturers, each with its own particular features. These machines have various levels of sophistication and capability, ranging from small laboratory units to high-production systems, often complete with in-line cleaning and assembly and return conveyors. Machines in use today are generally self-contained, with a high degree of control, optional auxiliary systems, and exhaust venting. Coming onto the market are systems with computer-controlled operation and setup, which practically eliminate human error from the machine soldering process.

Soldering processes have evolved dramatically since the introduction of mass soldering techniques. Wave machines have become highly specialized, especially since the introduction of surface-mount technology. Reflow techniques (Ref 8), which were once limited to hybrid technology and leaded flatpacks, have grown remarkably. Vapor phase, infrared, and hot gas soldering equipment have initiated a new process of evolution.

The performance of a solder joint in its service environment is a strong consideration in modern electronics. Many applications, such as jet engines, dishwashers, and automobiles, impose a repeated cyclic thermal cycle on the equipment. This produces thermomechanical strains, which result in fatigue or creep failure if the joint design is poor or if life predictions have been incorrectly calculated. Each situation must be carefully analyzed and the correct design employed for the equipment to fulfill its intended service life.

Thermally induced fatigue and creep failures, virtually unknown in the 1950s but common today, are illustrative of the added stresses and strains placed on joints. It should be emphasized that miniaturization of electronic parts, particularly current paths, results in a dramatic increase in current density, which generates strong thermal and mechanical shocks upon switching. Proper design can minimize these strains and make the joints more highly producible. Design has become even more critical with the introduction of surface-mount technology.

Quality Control. Once a joint is made, its quality must be assessed through inspection. Advanced technology has produced some electronic assembly designs that are impossible to inspect visually, and an entire group of automated inspection tools has thus evolved. These tools include radiography, infrared signature, and two- or three-dimensional vision systems. Most of these are aided with very sophisticated computer software. The role of inspection, which historically was to locate those joints that needed rework, is changing along with the technology. Inspection is now used as a process-control audit to locate those portions of the process that need improvement or should returned to a position within the control limits. Therefore, the emphasis has shifted from merely shipping an acceptable product to manufacturing it correctly the first time.

Future Trends. Several other technologies and materials for soldering are being developed and tested (Ref 2, 3, 4, 5). One process that is becoming widely used is condensation, or vapor phase, soldering. In this process, the vapor from a liquid with a high-temperature boiling point is allowed to condense on the items to be soldered and, in giving up the latent heat of vaporization, quickly and evenly raises their temperature and produces a sound soldered joint. The method is simple, clean, and extremely well controlled. It requires-special equipment, and, of course, the parts are all exposed to the same temperature.

In another method, the parts are dipped into an oil heated above the melting point of the solder. Peanut oil can be used, although several excellent synthetic products are available. Here again, the component parts are subjected to the same temperature as the joint. This is a messy process, and the parts must be cleaned after soldering to remove the oil.

Infrared heating is a useful method for producing the temperature necessary for soldering. The shorter wavelengths can be focused onto very small areas, allowing selective heating of the joints to be soldered, without subjecting nearby components to the soldering temperature. Equipment and tooling are expensive if complex assemblies have to be soldered, and the relative emissivity of the joint metals and the adjacent materials can cause processing problems. For example, the base laminate of a PWB can be burned before the joint to be soldered has even reached the soldering temperature. This process thus requires very careful control.

Resistance heating can be used for soldering in two ways. The first method passes a current through the parts of the joint, causing their temperature to rise by virtue of the resistance existing in the joint structure. This is not a very controllable process and is primarily used for less critical applications on large connections. The second method passes a current through a wire that is shaped to touch the parts to be heated. Despite the lack of precise control, the process is often used to solder the leads on surface-mounted components.

Lasers have been used to provide the heat for soldering, although this is not yet a common method. A laser can provide a very high-energy, small-area beam, and heating is therefore extremely fast, localized, and limited only by the ability of the joint materials to absorb this energy. However, the shiny metal surfaces in the joint reflect most of the energy of the commonly used lasers, and coupling the laser and the joint is a major problem. The soldering flux is often used as a coupling medium. When correctly set up, laser soldering offers a fast, clean method of making joints. The cost of the equipment is quite high.

Since 1980, significant improvements and innovations in the soldering arena with respect to materials, equipment, and processes have occurred. However, two main tasks remain: developing environmentally friendly solder materials and establishing failure-free solder joint technology (Ref 2, 3, 4, 6, 7, 8).

For solders and soldering, two issues that are directly related to environmental concerns are the replacement of chlorofluorocarbon (CFCs) as the primary cleaning agent for electronic assemblies and the feasibility of using alternatives to lead-containing solders. For electronic assembly solders (Ref 4), in addition to using CFC substitutes and other solvents (e.g., hydrocarbon-based systems), aqueous cleaning and "no-clean" setups are two viable solutions.

The other task to be accomplished is the development of failure-free solder joint technology. Strengthened solder materials are expected to possess the properties that impede the occurrence of undesirable metallurgical phenomena during their service life under various in-circuit and external conditions, particularly temperature and induced stresses. Three approaches are being examined: macroscopic blends of selected fillers in a tin-rich matrix (composite solder), microscopic incorporation of doping additives to tin-rich base material, and atomic-level interaction. Preliminary experiments have been carried out to accomplish the first approach. Figure 3 demonstrates the increased yield strength of the 63Sn-37Pb composite solder with various amounts of filler (Ref 9).

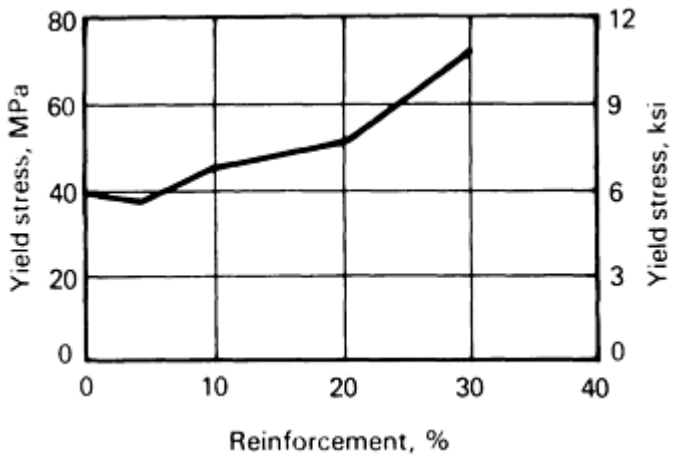

FIG. 3 EFFECT OF FILLER REINFORCEMENT ON THE YIELD STRENGTH OF 63SN-37PB COMPOSITE SOLDER. SOURCE: REF 9

The intrinsic properties of the new materials are expected to possess the following characteristics, while maintaining thermal and electrical conductivities:

- STABLE MICROSTRUCTURE
- INCREASED THERMAL AND MECHANICAL FATIGUE RESISTANCE
- HIGH CREEP RESISTANCE
- DECREASED THERMAL EXPANSION COEFFICIENT

These aggregate characteristics constitute the "strengthened" solder materials that are able to withstand harsher application conditions. The reduced thermal expansion coefficient of these new solders is expected to be more compatible with that of state-of-the-art electronic components and with ceramic substrates.

With respect to quality, solder joints have historically been judged by visual criteria. However, due to the nature of solder materials and the effect of the solder joint-forming process on appearance, many serviceable solder joints are often rejected, while other potentially questionable joints are accepted to carry out critical missions. This not only adds to manufacturing costs, but can also jeopardize service performance. Strengthened solder joints are expected to relieve the necessity of on-line inspection and rework while also reducing manufacturing costs and enhancing life span and tolerance of harsh service conditions in many military applications.

Fundamentals of Brazing

Mel M. Schwartz, Sikorsky Aircraft

Introduction

BRAZING is a process for joining solid metals in close proximity by introducing a liquid metal that melts above 450 °C (840 °F). A sound brazed joint generally results when an appropriate filler alloy is selected, the parent metal surfaces are clean and remain clean during heating to the flow temperature of the brazing alloy, and a suitable joint design is used. Like the other joining processes, brazing encompasses a variety of scientific disciplines (for example, mechanics, physics, and chemistry).

Recently, the demands of more-sophisticated structures have forced technicians and engineers to encourage metal producers to apply their metallurgical knowledge to produce brazing filler metals that meet more-specific needs. To ensure the production of good brazed joints, the technicians and engineers also had to appeal to mechanical engineers for improved joint design, to chemical engineers for solutions to corrosion problems, and to metallurgists and ceramists for proper material selection.

Brazing has been embraced by the engineering community and has now reached a very successful plateau within the joining field. This has come about because of the:

- DEVELOPMENT OF NEW TYPES OF BRAZING FILLER METALS (RAPID SOLIDIFICATION AMORPHOUS FOILS AND TITANIUM-ADDED FILLER METALS FOR CERAMIC JOINING
- AVAILABILITY OF NEW FORMS AND SHAPES OF FILLER METALS
- INTRODUCTION OF AUTOMATION THAT HAS BROUGHT BRAZING PROCESSES TO THE FOREFRONT IN HIGH-PRODUCTION SITUATIONS
- INCREASED USE OF FURNACE BRAZING IN A VACUUM, AS WELL AS ACTIVE AND INERT-GAS ATMOSPHERES

Since the early 1980s, other developments, such as aluminum-clad foils for fluxless aluminum brazing, copper-nickel-titanium filler metals for brazing titanium and some of its alloys, cadmium-free silver filler metals, and vacuum-grade metal brazing foils, have evolved to be used in production applications.

Fundamentals of Brazing

Mel M. Schwartz, Sikorsky Aircraft

Physical Principles

Capillary flow is the dominant physical phenomenon that ensures good brazements when both faying surfaces to be joined are wet by the molten filter metal. The joint must be properly spaced to permit efficient capillary action and coalescence. More specifically, capillarity is a result of the relative attraction of the molecules of the liquid to each other and to those of the solid. In actual practice, brazing filler metal flow characteristics are also influenced by dynamic considerations involving fluidity, viscosity, vapor pressure, gravity, and, especially, by the effects of any metallurgical reasons between the filler metal and the base metal.

Capillary attraction makes the brazing of leak-tight joints a simple proposition. In a properly designed joint, the molten brazing filler metal is normally drawn completely through the joint area without any voids gaps when processed in a protective atmosphere. Solidified joints will remain intact and gas will remain tight under heavy pressures, even when the joint is subjected to shock or vibrational type of loading. Capillary attraction is also the physical force that governs the action of a liquid against solid surfaces in small, confined areas.

The phenomena of wetting and spreading are very important to the formation of brazed joints. Other significant factors that also must be considered include the condition of the solid surface in terms of the presence of oxide films and their effects on wetting and spreading, surface roughness, alloying with between the brazing filler metal and base metal, and the extent to which alloying is affected by the thermodynamic properties of the brazing atmosphere. A number of studies (Ref 1, 2) have been conducted on surface activation, contact angle, equilibrium, and surface energies. Some of these alloy systems have a finite contact angle that is thermodynamically unstable, because the solid-vapor surface energy exceeds the sum of the liquid-solid surface energies, that is, an alloy system in which thermodynamics would predict complete spreading. In actual fact, spreading may or may not occur in this type of alloy system, and the rate of spreading can be markedly dependent on surface chemistry.

Wetting is, perhaps, best explained by the following example. If a solid is immersed in a liquid bath and wetting occurs, then a thin continuous layer of liquid adheres to the solid when it is removed from the liquid (Fig. 1). Technically, the force of adhesion between the solid and liquid (during the wetting process) is greater than the cohesive force of the liquid. In practical terms, with respect to brazing, wetting implies that the liquid brazing filler metal spreads on the solid base metal, instead of balling up on its surface. It has been demonstrated that wetting actually depends on a slight surface alloying of the base metal with the brazing filler metal. Lead, for example, does not alloy with iron and will not wet it. Tin, on the other hand, does form an alloy with iron, and, therefore, a tin-lead solder will wet steel.

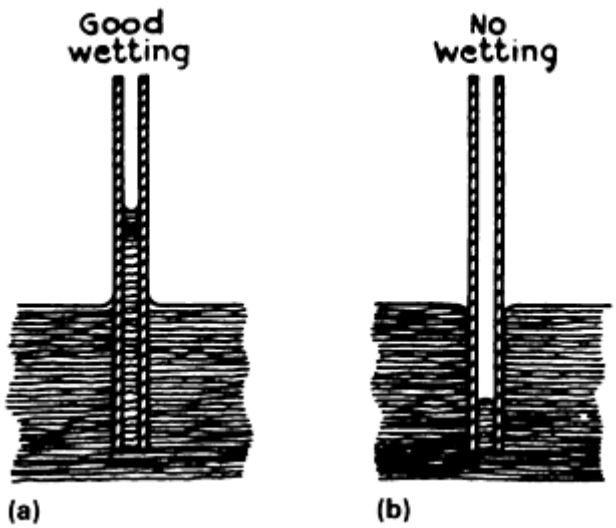

FIG. 1 SCHEMATIC SHOWING PRINCIPLE OF CAPILLARY ATTRACTION FOR SELECTED LIQUIDS WHEN THE LIQUID IS SANDWICHED BETWEEN TWO CLEAN GLASS PLATES. (A) WHEN IMMERSED IN WATER OR INK, A COLUMN WILL RISE BETWEEN THE PLATES BECAUSE OF WETTING. (B) WHEN THE PLATES ARE IMMERSED IN MERCURY, NO WETTING OCCURS AND THE COLUMN IS DEPRESSED. IF PARAFFIN PLATES ARE USED IN PLACE OF THE GLASS PLATES, IMMERSION OF THE PLATES IN MERCURY WILL PRODUCE WETTING.

A comprehensive theory of the wetting or spreading of liquids on solid surfaces and a complete and detailed derivation of the quantitative relationships are presented by Harkins (Ref 3) and Schwartz (Ref 4).

Experimentally, it has been observed that liquids placed on solid surfaces usually do not completely wet, but, rather, remain as a drop that has a definite contact angle between the liquid and solid phases (Ref 5). This condition is illustrated in Fig. 2. The Young and Dupré equation (Eq 1) permits the determination of change in surface free energy, ΔF, accompanying a small change in solid surface covered, ΔA (Ref 5). Thus,

$$\frac{\partial F}{\partial A}_{p,T} = g_{LV} + g_{SL} - g_{SV} \qquad \textbf{(EQ 1)}$$

where γ_{LV} is the liquid-vapor surface energy, γ_{SL} is the solid-liquid surface energy, and γ_{SV} is the solid-vapor surface energy.

$$\Delta F = \Delta A\,(\gamma_{SL} - \gamma_{SV}) + \Delta A \gamma_{LV}\,\mathrm{COS}\,(\theta - \Delta\theta) \qquad \textbf{(EQ 2)}$$

At equilibrium,

$$\lim_{\Delta A \to \Delta 0} \frac{\Delta F}{\Delta A} = 0 \qquad \textbf{(EQ 3)}$$

and

$$\gamma_{SL} - \gamma_{SV} + \gamma_{LV}\,\mathrm{COS}\,\theta = 0 \qquad \textbf{(EQ 4)}$$

or

$$\gamma_{SL} = \gamma_{SV} - \gamma_{LV}\,\mathrm{COS}\,\theta \qquad \textbf{(EQ 5)}$$

In Eq 4 and 5, it can be seen that θ is greater than 90° (1.6 rad) when γ_{SL} is larger than γ_{SV}, as shown in Fig. 3, and the liquid drop tends to spheroidize.

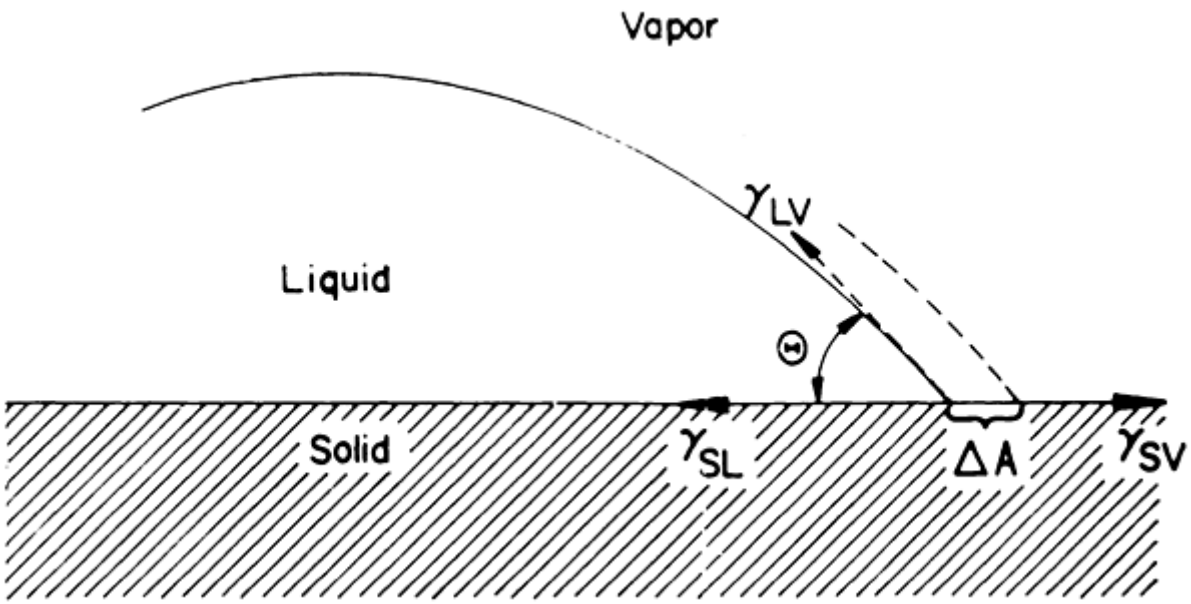

FIG. 2 SESSILE DROP LOCATED ON A SURFACE AND DIRECTIONS OF VECTORS OF THE SURFACE ENERGIES FOR THE SYSTEM

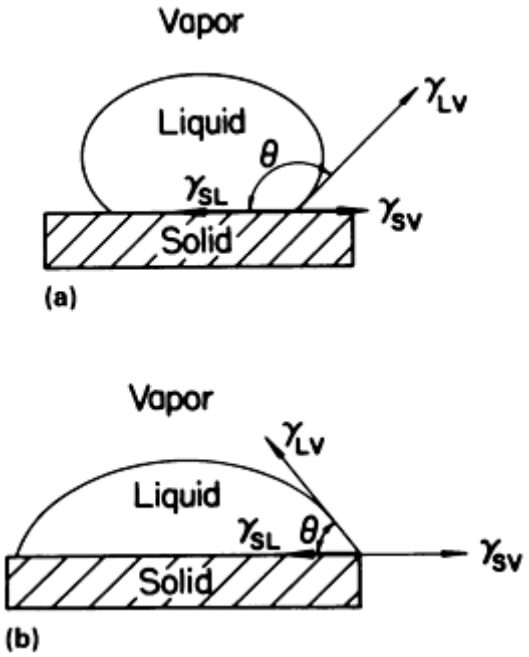

FIG. 3 EFFECT OF INTERFACIAL ENERGIES ON SESSILE DROPS. (A) NO WETTING TAKES PLACE WHEN CONTACT ANGLE IS > 90°. (B) WETTING OCCURS WHEN CONTACT ANGLE IS < 90°.

The contact angle, θ, is less than 90° (1.6 rad) when the reverse is true, as shown at right in Fig. 3, and the liquid drop flattens out and wets the solid. If the balance in such that θ is zero (0 rad) and greater wetting is desired, θ should be as small as possible so that cos θ approaches unity and the liquid spreads over the solid surface.

These considerations show the importance of surface energies in brazing. If brazing filler metal is to successfully form a joint, it must wet the solid material. The surface-energy balance must be such that the contact angle is less than 90° (1.6 rad). The energy equation shows that if θ is to be less than 90° (1.6 rad) (cos θ > 0), then γ_{SV} must be greater than γ_{SL}. This is demonstrated in Table 1, which gives contact-angle measurements of several liquid metals on beryllium at various test temperatures in argon and vacuum.

Although during the testing period minor fluctuations in angle were noted, the overall tendency was for the contact angles to decrease with increasing time at test temperature. This behavior is reflected in the data presented in Table 2. The fluctuations can be attributed to alloying effects, because as alloying progresses, composition and temperature variations change the interfacial energies.

(A) AVERAGE OF TWO TESTS.

(B) ONE TEST ONLY

These data provide a means of comparing the wettability of beryllium by various liquids. If one assumes wettability for contact angles less than 90° and nonwetting for angles greater than 90°, then these data permit qualitative separation of the systems into two classes: those with contact angles less than 90°, and those with contact angles greater than 90°. Gold, Pd-2.1Be, and Ti-6Be were found to wet beryllium at both temperatures. The latter two brazing filler metals, as well as silver and gold, did not wet when tested in argon atmospheres at the lower temperature. However, it was found that an increase of 50 °C (90 °F) resulted in wetting. Aluminum exhibited a nonwetting behavior at both temperatures and in both atmospheres. Copper was nonwetting at both temperatures in vacuum, but underwent extensive alloying with the solid

beryllium at these temperatures in argon. From these data it appears that the binary alloys have the greatest tendency to wet beryllium (Ref 6).

Surface-energy calculations have been performed on beryllium-base metals brazed with Al, Zr-5Be, and Ti-6Be filler metals. The calculated spreading coefficient were negative for all system test conditions, except with Ti-6Be. Negative spreading coefficients indicated a very definite trend. The greater the system wettability, as indicated by lower contact angles and liquid-vapor surface tensions, the greater the numerical magnitude of the spreading coefficient.

Of the three systems used, Ti-6Be was observed to provide the best wetting of beryllium, followed by Zr-5Be. Although no basic significance can be given to the absolute values of the calculated surface-tension properties, they are useful in indicating the relative tendencies for these liquids to wet beryllium.

The above observations indicate that some liquid-metal systems will wet beryllium, whereas some system that should wet it do not, in actual practice. The problem is more complex than it seems at first.

Recent work in Japan (Ref 7) and the United States (Ref 8) has shown that the effects of the base-metal/filler-metal reaction on the wetting of silicon nitride (Si_3N_4) and titanium-added active filler metals vary with reaction-layer thickness and morphology, as well as with the composition of the reaction layer. Several results of thermodynamic studies on the formation of the compound by the interfacial reaction are reported (Ref 7, 9). Moreover, kinetic studies (Ref 7) were also performed to achieve a quantitative understanding of the formation of the reaction layer.

It can be concluded that wetting is the ability of the molten brazing filler metal to adhere to the surface of a metal in the solid state and, when cooled below its solidus temperature, to make a strong bond with that metal. Wetting is a function not only of the nature of the brazing filler metal (Table 3), but of the degree of interaction between materials (ceramics, and so on) to be joined. There is considerable evidence that in order to wet well, a molten metal must be capable of dissolving, or alloying with, some of the metal on which it flows.

Wetting is only one facet of the brazing process. Another factor that affects wetting is the cleanliness of the surface to be wetted. Oxide layers inhibit wetting and spreading, as do grease, dirt, and other contaminants that prevent good contact between the brazing filler metal and the base metal. One of the functions of a flux the oxide layer on the joint area and thereby expose clean base metal.

Good wetting and spreading of the liquid filler metal on the base metal are necessary in brazing because the mechanics of the process demand that the filler metal be brought smoothly, rapidly, and continuously to the joint opening. If the conditions within the capillary space of the joint do not promote good wetting, then the filler metal will not be drawn into the space by capillary attraction.

Kim *et al.* (Ref 10) investigated the wettability and reactivity of pressureless sintered Si_3N_4 with powdered copper-titanium filler metal using sessile drop tests conducted in a vacuum where Si_3N_4 was bonded to itself and joint strength was evaluated by shear testing. The wettability of Si_3N_4 on copper-titanium base filler metals was improved greatly by adding up to 50 wt% titanium. However, the reaction-layer thickness was increased up to 10% and, thereafter, decreased up to 50 wt%.

Wettability improved with the increment of titanium concentration, and no linear proportionality was found between the reaction and the wettability. As titanium concentration increased, a continuous thin layer tended to form at the interface and markedly improved wettability.

The thickness of the reaction layer was not in proportion to the titanium concentration. For a copper-titanium filler metal with a low titanium concentration (less than 5 wt%), the initial reaction layer tended to form discontinuously, whereas the reaction layer thickness increased with titanium concentration. On the contrary, in the filler metal with a high titanium concentration (15 wt%) the reaction-layer thickness decreased as titanium concentration increased because a continuous thin reaction layer tended to form (Ref 10).

The shear strength of the Si_3N_4-Si_3N_4 joint using copper-titanium filler metal is influenced by reaction-layer thickness and morphology. Strength increased with the increment of titanium concentration, and was accompanied by improved wettability, because the tendency of the continuous thin reaction layer to form increased.

With the development of new steels, Keller *et al.* (Ref 11) undertook an extensive study of the wettability of commercial braze filler metals on type 304 stainless steel, the most common of the austenitic stainless steels; type 316 stainless steel, which is often substituted for type 304 when increased corrosion resistance is desired; and 21-6-9, a new high-manganese stainless steel that is an attractive alternative to types 304 or 316 for certain applications. Because the 21-6-9 steel has a very stable austenitic structure, it is attractive for cryogenic applications (Ref 12).

Because high wettability means that the thermocapillary attraction that fills the braze joint is strong, wettability is an important component of braze performance. The wettability index (WI) developed by Feduska (Ref 13) is used as the measure of wettability. The WI is defined as the area covered by the braze metal filler times the cosine of the contact angle between the braze and the base metal. Therefore, the higher the WI, the better the braze filler metal wets the base metal. It should be emphasized that the WI, as defined, is a relative measure, and depends on the volume of filler metal used (Table 4).

The WIs for each braze filler metal at each temperature on type 316 stainless steel, type 304L stainless steel, and 21-6-9 stainless steel are provided in Table 4. Wetting indices greater than 0.05 are indicative of good performance during brazing, whereas WI values greater than 0.10 are indicative of excellent performance during brazing (Ref 13).

A comparison of the WI of the braze filler metals on the three stainless steels revealed these trends:

- FILLER METALS GENERALLY WET TYPE 316 STAINLESS STEEL BETTER THAN TYPE 304 STAINLESS STEEL AND GENERALLY WET TYPE 316 STAINLESS BETTER THAN 21-6-9 STAINLESS.
- THE DEGREE OF WETTING OF MOST BRAZE FILLER METALS ON 21-6-9 STAINLESS WAS EQUAL TO OR BETTER THAN IT WAS ON TYPE 304 STAINLESS (REF 12).
- THE IMPROVED WETTABILITY OF BRAZE FILLER METALS ON TYPE 316 STAINLESS IS BELIEVED TO BE DUE TO THE PRESENCE OF MOLYBDENUM IN THE SURFACE OXIDE, WHEREAS THE ENHANCED WETTING ON 21-6-9 STAINLESS VERSUS TYPE 304 STAINLESS IS BELIEVED TO BE DUE TO THE HIGHER MANGANESE CONTENT OF THE SURFACE OXIDE.

Essentially, the successful joining of components by the brazing process depends on the selected brazing filler metal having a melting point above 450 °C (840 °F) and wetting the base metal without melting it. Furthermore, the joint must be designed to ensure that the mating surfaces of the components are parallel and close enough together to cause capillary attraction.

Mel M. Schwartz, Sikorsky Aircraft

Elements of the Brazing Process

An engineer must consider reliability and cost when designing the braze joint. Joint strength, fatigue resistance, corrosion susceptibility, and high-temperature stability are additional concerns that determine the selection of joint design, braze filler materials, and processing parameters.

A careful and intelligent appraisal of the following elements is required in order to produce satisfactory brazed joints:

- FILLER-METAL FLOW
- BASE-METAL CHARACTERISTICS
- FILLER-METAL CHARACTERISTICS
- SURFACE PREPARATION
- JOINT DESIGN AND CLEARANCE
- TEMPERATURE AND TIME
- RATE AND SOURCE OF HEATING
- PROTECTION BY AN ATMOSPHERE OR FLUX

Filler-Metal Flow. As mentioned previously, wetting is only one important facet of the brazing process. A low contact angle, which implies wetting, is also necessary, but is not a sufficient condition itself for flow. Viscosity is also important. Brazing filler metals with narrow melting ranges that are close to the eutectic composition generally have lower viscosities than those with wide melting ranges. Thus, a high surface tension of liquid filler metal, a low contact angle, and low viscosity are all desirable.

Flowability is the property of a brazing filler metal that determines the distance it will travel away from its original position, because of the action of capillary forces. To flow well, a filler metal must not gain an appreciable increase in its liquidus temperature even though its composition is altered by the addition of the metal it has dissolved. This is important because the brazing operation is carried out at temperatures just above the liquidus of the filler metal.

The composition and surface energy of liquids and solids are assumed to remain constant. In real systems, however, these interactions occur (Ref 14):

- ALLOY FORMATION BETWEEN LIQUID AND BASE METAL
- DIFFUSION OF BASE METAL INTO BRAZING FILLER METAL
- DIFFUSION OF FILLER METAL INTO GRAINS OF BASE METAL
- PENETRATION OF FILLER METAL ALONG GRAIN BOUNDARIES
- FORMATION OF INTERMETALLIC COMPOUNDS

In practice, interactions are usually minimized by selecting the proper brazing filler metal; keeping the brazing temperature as low as possible, but high enough to produce flow; and keeping the time of brazing temperature short and cooling the brazed joint as quickly as possible without causing cracking or distortion. When diffusion brazing is desired, higher brazing temperatures and longer times at brazing temperatures are employed.

Base-Metal Characteristics. The base metal has a prime effect on joint strength. A high-strength base metal produces joints of greater strength than those made with softer base metals (other factors being equal). When hardenable metals are brazed, joint strength becomes less predictable. This is because more-complex metallurgical reactions between hardenable base metals and the brazing filler metals are involved. These reactions can cause changes in the base-metal hardenability and can create residual stresses (Ref 15).

In cases where different materials make up the assembly and gaps may open or close as heating proceeds to the joining temperature, the coefficient of thermal expansion becomes vitally important.

Several metallurgical phenomena influence the behavior of brazed joints and, in some instances, necessitate special procedures. These base-metal effects include alloying by brazing filler; carbide precipitation; stress cracking; hydrogen, sulfur, and phosphorus embrittlement; and oxidation stability.

The extent of interaction varies greatly, depending on compositions (base metal and brazing filler metal) and thermal cycles. There is always some interaction, except in cases of mutual insolubility.

The strength of the base metal has a profound effect on the strength of the brazed joint. Therefore, this property must be carefully considered when designing the joint to have specific properties. Some base metals also are easier to braze than others, particularly by specific brazing processes.

Filler-Metal Characteristics. The second material involved in joint structures is the brazing filler metal. Unfortunately, it cannot be chosen to provide a specific joint strength. Actually, strong joints can be brazed with almost any good commercial brazing filler metal if correct brazing methods and joint design are implemented.

Necessary characteristics of brazing filler metals are:

- PROPER FLUIDITY AT BRAZING TEMPERATURES TO ENSURE FLOW BY CAPILLARY ACTION AND TO PROVIDE FULL ALLOY DISTRIBUTION
- STABILITY TO AVOID PREMATURE RELEASE OF LOW-MELTING-POINT ELEMENTS IN THE BRAZING FILLER METAL
- ABILITY TO WET THE BASE-METAL JOINT SURFACE
- LOW VOLATILIZATION OF ALLOYING ELEMENTS OF THE BRAZING FILLER METAL AT BRAZING TEMPERATURES
- ABILITY TO ALLOY OR COMBINE WITH THE BASE METAL TO FORM AN ALLOY WITH A HIGHER MELTING TEMPERATURE
- CONTROL OF WASHING OR CONTROL OF EROSION BETWEEN THE BRAZING FILLER METAL AND THE BASE METAL WITHIN THE LIMITS REQUIRED FOR THE BRAZING OPERATION

It should be noted that the strength of the brazed joint is not directly related to the method of filler-metal melting. For example, if constructional metals are produced by vacuum melting, then there is a definite relationship between the vacuum-melting practice and the final strength of the ingot, bar, or rolled sheet. With a brazing filler metal, however, joint strength is dependent on joint design, brazing temperature, amount of brazing filler metal applied, location and method of application, heating rate, and many other factors that constitute the brazing technique.

The degree to which brazing filler metal interacts with and penetrates the base metal during brazing depends on the intensity of mutual diffusion processes that occur between both those materials. In applications that require strong joints for high-temperature, high-stress service conditions (such as turbine rotor assemblies and jet-engine components), it is generally wise to specify a brazing filler metal that has high diffusion and solution properties with the base metal. When the assembly is constructed of extremely thin base metals (as in honeycomb structures and some heat exchangers), good practice entails specifying a brazing filler metal that contains elements with a low-diffusion characteristic relative to the base metal being used. Diffusion, a normal part of the metallurgical process, can contribute to good brazed joints when brazing, for example, high-temperature metals with nickel-base brazing filler metals.

Brazing Temperature. When choosing a brazing filler metal, the first selection criterion is the brazing temperature. Some brazing-temperature ranges are given in Table 5. Very few brazing filler metals possess narrow melting ranges. Brazing filler metals in which the solidus and liquidus temperatures are close together do not usually exhibit a strong tendency to coexist as a mixture of liquid and solid phases or to liquate. They flow readily and should be used with small joint clearances. As the solidus and liquidus temperatures diverge, the tendency to liquate increases, requiring greater precautions in brazing filler metal application. The mixture of solid and liquid metal can aid gap filling.

MG-AL-ZN	585-615	1085-1139

The necessity for the brazing filler metal to melt below the solidus of the base metal is just one of several factors that affect its selection. It may be necessary for the brazing filler metal to melt below the temperature at which parts to be brazed lose strength or above the temperature at which oxides are reduced or dissociated. Joining may have to be carried out above the solution-treatment temperature of the base metal, or at a structure refining temperature, or below the remelt temperature of a brazing filler metal used previously in the production of a brazed subassembly.

Liquidation. During melting, the composition of the liquid and solid filler metal phases changes as the temperature increases from the solidus to the liquidus point. If the portion that melts first is allowed to flow out, then the remaining solid phases have higher melting points than the original composition and may never melt, remaining behind as a residue, or "skull." Filler metals with narrow melting ranges do not tend to separate, but flow quite freely in joints of extremely narrow clearance as long as the solution and diffusion rates of the filler metal with the base metal are low (as in aluminum brazing, the use of silver filler metal on copper, and so on). The rapid heating of filler metals with wide melting ranges or their application to the joint after the base metal reaches brazing temperature will minimize the separation, or liquation. However, liquation cannot be entirely eliminated and wide-melting-range filler metals, which tend to have more sluggish flow, will require wider joint clearances and will form larger fillets at the joint extremities. A few brazing filler metals become sufficiently fluid below the actual liquidus temperature, and satisfactory joints are achieved, even though the liquidus temperature has not been reached.

When sluggish behavior is needed, such as in filling large gaps, brazing can be accomplished within the melting range of the filler metal. However, the brazing temperature is usually 10 to 93 °C (20 to 170 °F) above the liquidus of the filler metal. The actual temperature required to produce a good joint filling is influenced by factors such as heating rate, brazing environment (atmosphere or flux), thickness of parts, thermal conductivity of the metals being joined, and type of joint to be made.

Large-scale mechanical properties of brazing filler metals can be a guideline for their suitability (in terms of strength, oxidation resistance, and so on) for use in different capillary joining applications. However, designers cannot use the mechanical properties of brazed assemblies that are related to different joint configurations brazed at given cycles of time and temperatures.

The placement of the brazing filler metal is an important design consideration, not only because the joint must be accessible to the method chosen, but because, in automatic heating setups, the filler metal must be retained in its location until molten. Brazing filler metals are available in different forms (Table 6) and filler-metal selection may depend on which form is suitable for a particular joint design.

Several general rules apply in the filler-metal placement. Wherever possible, the filler metal should be placed on the most slowly heated part of the assembly in order to ensure complete melting. Although brazing is independent of gravity, gravity can be used to assist filler-metal flow, particularly for those filler metals having wide ranges between their solidus and liquidus temperatures. Brazing filler metals can be chosen to fill wide gaps or to flow through joint configurations where the gap may vary, for example, around a corner. Unless movement between the components being joined is unimportant or can be corrected manually (through self-jigging or by using fixtures after the filler metal is molten), the filler metal should be placed outside the joint and allowed to flow into it. It should not be placed between the joint members. If erosion of thin members is possible, then the brazing filler metal should be placed on the heavier sections, which heat up more slowly, so that flow proceeds toward the thin sections. Apart from suiting the placement method selected for the joint, the form chosen for the brazing filler metal may be needed to accurately gage the amount applied, not just for economy and reproducibility, but to regulate and maintain joint properties and configuration.

Surface Preparation. A clean, oxide-free surface is imperative to ensure uniform quality and sound brazed joints. All grease, oil, dirt, and oxides must be carefully removed from the base and filler metals before brazing, because only then can uniform capillary attraction be obtained. Brazing should be done as soon as possible after the material has been cleaned. The length of time that the cleaning remains effective depends on the metals involved, atmospheric conditions, storage and handling practices, and other factors. Cleaning operations are commonly categorized as being either chemical or mechanical. Chemical cleaning is the most effective means of removing all traces of oil or grease. Trichloroethylene and trisodium phosphate are the usual cleaning agents employed. Oxides and scale that cannot be eliminated by these cleaners should be removed by other chemical means.

The selection of the chemical cleaning agent depends on the nature of the contaminant, the base metal, the surface condition, and the joint design. Regardless of the nature of the cleaning agent or the cleaning method used, it is important that all residue or surface film be adequately rinsed from the cleaned parts to prevent the formation of other equally undesirable films on the faying surfaces.

Objectionable surface conditions can be removed by mechanical means, such as grinding, filing, wire brushing, or any form of machining, provided that joint clearances are not disturbed. When grinding the surfaces of the parts to be brazed, care should be exercised to ensure that the coolant is clean and free from impurities to avoid grinding these impurities into the finished surfaces.

When faying surfaces of parts to be brazed are prepared by blasting techniques, several factors should be considered. There are two purposes behind the blasting of parts to be brazed. One is to remove any oxide film and the other is to roughen the mating surfaces in order to increase capillary attraction of the brazing filler metal. The blasting material must be clean and must not leave any deposit on the surfaces to be joined that restricts filler-metal flow or impairs brazing. The particles of the blasting material should be angular rather than spherical, so that the blasted parts are lightly roughened, rather than peened, after the scale is removed. The operation should not distort or otherwise harm delicate parts. Vapor blasting and similar wet blasting methods require care, because of the possibility of surface contamination.

Mechanical cleaning may be adequate, in which case it should be permitted (by the design) during manufacture. In those cases that require chemical cleaning, the cleaning operation may be followed by protective electroplating, which necessitates access to the faying surface by the liquids involved.

Another surface protection technique is the use of solid and liquid brazing fluxes. At temperatures up to about 1000 °C (1830 °F), fluxes often provide the easiest method of maintaining or producing surface cleanliness. In such cases, the design must not only permit easy ingress of the flux, but should allow the filler metal to wash it through the joint. Above 1000 °C (1830 °F), the flux residues can be difficult to remove, and surface cleaning can be accompanied by brazing in furnaces with protective atmospheres. However, the design must permit the gas to penetrate the joint.

In addition to cleanliness and freedom from oxides, another important factor in determining the ease and evenness of brazing filler metal flow is surface roughness. Generally, a liquid that wets a smooth surface will wet a rough one even more. A rough surface will modify filler-metal flow from laminar to turbulent, prolonging flow time and increasing the possibility of alloying and other interactions. Surfaces often are not truly planar, and, in some instances, surface roughening will improve the uniformity of the joint clearance. A rough surface features a series of crests and troughs that produce turbulent flow. These irregularities on the surface simulate grips to prevent the flow of the filler metal.

Conversely, there may be a requirement that brazing filler metal not flow onto some surfaces. Stop-off materials will often avoid flow, but the design must permit easy application of the stop-off material without contaminating the surfaces to be joined.

Self-fluxing filler metals, in a suitably protective environment such as vacuum, may provide the essential surface wetting.

Joint Design and Clearance. A brazed joint is not a homogeneous body. Rather, it is a heterogeneous area that is composed of different phases with different physical and chemical properties. In the simplest case, it consists of the base-metal parts to be joined and the added brazing filler metal. However, dissimilar materials must also be considered.

Small clearances are used because the smaller the clearance, the easier it is for capillarity to distribute the brazing filler metal throughout the joint area and the less likely it is that voids or shrinkage cavities will form as the brazing filler metal solidifies. The optimum joints are those in which the entire joint area is wetted and filled by the brazing filler metal. Typically, brazing clearances that range from 0.03 to 0.08 mm (0.001 to 0.003 in.) are designed for the best capillary action and greatest joint strength.

Because brazing relies on capillary attraction, the design of a point must provide an unobstructed and unbroken capillary path to enable the escape of flux, if used, as well as allow the brazing filler metal into the joint. In cases where filler metal is added to a joint by hand, such as by feeding in a rod or wire, the joint entry must be visible and accessible.

Some of the more-important factors influencing joint design are the required strength and corrosion resistance, the necessary electrical and thermal conductivity, the materials to be joined, the mode of application of the brazing filler metal, and the postjoining inspection needs.

Consideration also should be given to the ductility of the base metal, the stress distribution in the joint, and the relative movements of the two surfaces during joining, which may introduce distortion in dimensions of the work to be brazed.

Viscosity, surface tension, and specific gravity of the brazing filler metal are not the only factors that determine the gap-filling capability of a given filler metal. Joint strength increases as joint gap decreases, down to a minimum. Table 7 gives the allowable joint clearances for various filler-metal systems. Other factors that influence optimum joint gap with a specific brazing filler metal are joint length, brazing temperature, and base-metal/filler-metal metallurgical reactions.

TABLE 7 RECOMMENDED GAP FOR SELECTED BRAZE FILLER METALS

BRAZING FILLER-METAL SYSTEM	JOINT CLEARANCE	
	mm	in.

NI-CR ALLOYS(B)	0.03-0.61	0.001-0.024
PD ALLOYS	0.03-0.10	0.001-0.004

(A) IF JOINT LENGTH IS LESS THAN 6 MM (0.240 IN.), GAP IS 0.12 TO 0.75 MM (0.005 TO 0.030 IN.). IF JOINT LENGTH EXCEEDS 6 MM (0.240 IN.), GAP IS 0.25 TO 0.60 MM (0.010 TO 0.24 IN.).

(B) MANY DIFFERENT NICKEL BRAZING FILLER METALS ARE AVAILABLE, AND JOINT GAP REQUIREMENTS MAY VARY GREATLY FROM ONE FILLER METAL TO ANOTHER

It is important to remember that an assembly expands during heating and that the joint gap can either widen or close by the time the brazing filler metal starts to melt and move. It is desirable to design the joint to expose the solidifying filler metal to compressive, rather than tensile, stress. This is much more important in brazing than in soldering, because brazing temperatures are higher, increasing the total thermal expansion. With cylindrical joints, the components with the larger coefficient of expansion should be on the outside, whenever possible.

Joint clearance is probably one of the most significant factors in vacuum brazing operations. Naturally, it receives special consideration when joint are designed at room temperature. Actually, joint clearance is not the same at all phases of brazing. It will have one value before brazing, another value at the brazing temperature, and still another value after brazing, especially if there has been a substantial interaction between the brazing filler metal and the base metal. To avoid confusion, it has become general practice to specify joint clearance as the value at room temperature before brazing.

The recommended joint clearances given in Table 7 are based on joints that have members of similar metals and equal mass. When dissimilar metals and/or metals of widely differing masses are joined by brazing, special problems arise. These problems necessitate specialized selection of brazing filler metals. Furthermore, the most suitable joint clearance for the specific job must be carefully determined. Thus, clearances given in Table 7 are the clearances that must be attained at the brazing temperature.

Although there are many kinds of brazed joints, the selection of joint type is not as complicated as it may seem, because butt and lap joints are the two fundamental types used. All other types, such as the scarf joint, are modifications of these two. The scarf joint of the scarf angle. It approaches the lap joint at the other extreme of the scarf angle.

Selection of joint type is influenced by the configuration of the parts, as well as by joint strength and other service requirements, such as electrical conductivity, pressure tightness, and appearance. Also influential in the selection of joint type are fabrication techniques, production quantities, and methods of feeding brazing filler metal. Lap joints are generally preferred for brazing operations, particularly when it is important that the joints be at least as strong as the weaker member. For maximum strength, lap-joint length should equal three to four times the thickness of the thinner member.

Temperature and Time. The temperature of the brazing filler metal has an important effect on the wetting and alloying action, which increases with increasing temperature. The temperature must be above the melting point of the brazing filler metal and below the melting point of the parent metal. Within this range, a brazing temperature that is most satisfactory overall is generally selected.

Usually, low brazing temperatures are preferred in order to economize on the heat energy required, minimize the heat effect on the base metal (annealing, grain growth, or warpage, for example), minimize base-metal/filler-metal interactions, and increase the life of fixtures, jigs, or other tools.

Higher brazing temperatures may be desirable so as to:

- ENABLE THE USE OF A HIGHER-MELTING, BUT MORE ECONOMICAL, BRAZING FILLER METAL
- COMBINE ANNEALING, STRESS RELIEF, OR HEAT TREATMENT OF THE BASE METAL WITH BRAZING
- PERMIT SUBSEQUENT PROCESSING AT ELEVATED TEMPERATURES
- PROMOTE BASE-METAL/FILLER-METAL INTERACTIONS IN ORDER TO CHANGE THE

COMPOSITION OF THE BRAZING FILLER METAL (THIS TECHNIQUE IS USUALLY USED TO INCREASE THE REMELT TEMPERATURE AND DUCTILITY OF THE JOINT)

- EFFECTIVELY REMOVE SURFACE CONTAMINANTS AND OXIDES WITHIN PROTECTIVE ATMOSPHERES BRAZING (ALSO APPLIES TO PURE DRY HYDROGEN, TO ARGON, AND TO VACUUM)
- AVOID STRESS CRACKING

The time at brazing temperature also affects the wetting action. If the brazing filler metal has a tendency to creep, the distance generally increases with time. The alloying action between filler metal and parent metal is, of course, a function of temperature, time, and quantity of filler metal. For production work, temperature, time, and quantity of filler metal are generally kept at a minimum, consistent with good quality, where diffusion is not required.

Heating Methods

The numerous heating methods available for brazing often represent constraints on the designer or engineer when selecting the best type of capillary joint (Table 8). However, because effective capillary joining requires the efficient transfer of heat from the heat source into the joint, one cannot braze a 0.025 mm (0.001 in.) diam wire to a 2.3 kg (5.1 lb) lump of copper with a small torch.

TABLE 8 RELATIVE RATING OF SELECTED BRAZING PROCESS HEATING METHODS

METHOD	CHARACTERISTICS[(A)]

The size and value of individual assemblies, the numbers required, and the required rate of production will influence the selection of heating method. Other factors that also must be considered include the rate of heating, differential thermal gradients, and both external and internal cooling rates. These factors vary tremendously with different methods of heating, and their effects on dimensional stability, distortion, and joint structure must be considered.

Manual torch brazing is the method most frequently used for repairs, one-of-a-kind brazing jobs, and short production runs, as an alternative to fusion welding. Any joint that can be accessed by a torch and brought to brazing temperature (by the torch alone or in conjunction with auxiliary heating) can be readily brazed by this technique.

Although any flame-producing device can be used for torch brazing, commercial applications are accomplished with the same type of torch, controls, and gases used for torch fusion welding. Conversion to brazing merely requires changes in torch nozzles and goggle lenses.

The torch brazing technique is relatively simple and can be mastered by the mechanically adept in a short time. Those already experienced in torch welding and the brazing of other metals generally encounter little difficulty learning torch brazing.

Depending on the temperature and heat required, all commercial gas mixtures can be used to fuel the torch: oxyacetylene, oxyhydrogen, oxy-natural gas, acetylene and air, hydrogen and air, propane, methane, and natural gas and air. Oxyacetylene and oxy-natural gas are the mixtures most often used commercially and are preferred in that order. Flame adjustment is very important. Generally, a slightly reducing flame is desirable in order to preserve part surfaces from oxidation.

The oxyacetylene combination produces the highest temperature. The other gases are cooler and their flames have relatively lower intensity. Thus, they are easier to use and are applied advantageously to light-gage material.

Manual torch brazing is particularly useful on assemblies with sections of unequal mass. As warranted by the rate of production, machine operations can be set up using one or more torches equipped with single or multiple flame tips. The machine can be designed to move either the work or the torches.

Torch brazing can be rather easily automated with appropriate gas supplies, indexing fixtures, and cycle controls. Usually, such systems involve multiple-station rotary indexing tables. The part is fed into a holding fixture at the first station and is then indexed to one or more preheating stations, depending on the heating time required. A brazing station is next, followed by a cooling station and an ejection station (see Fig. 4).

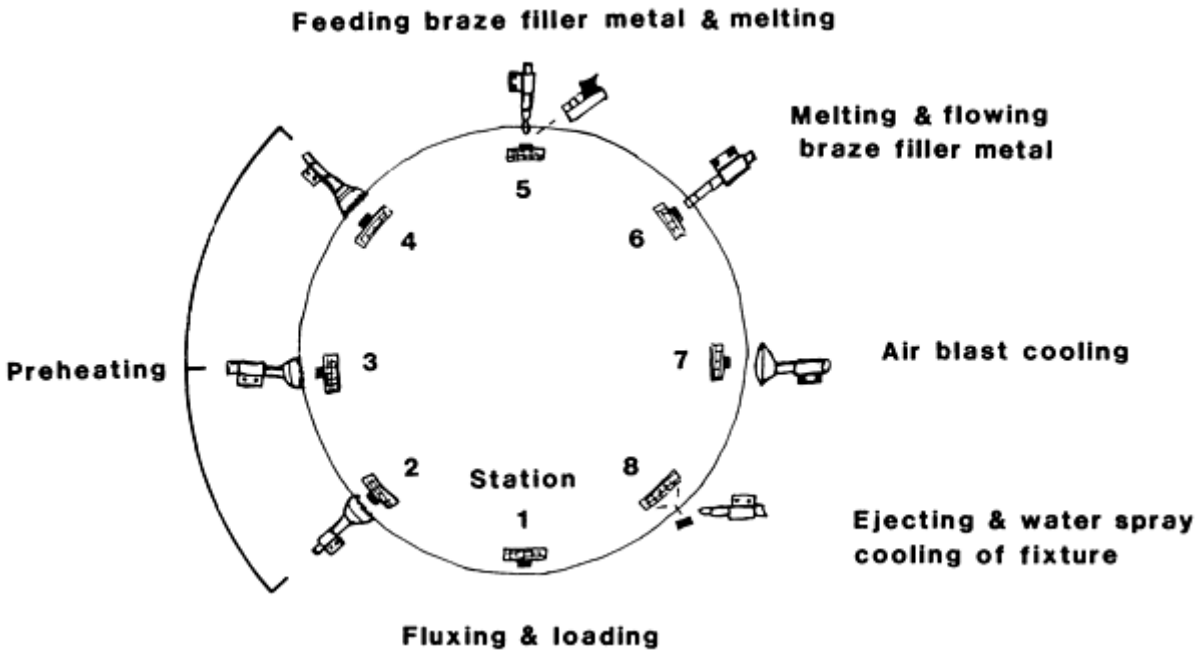

FIG. 4 SCHEMATIC OF AN EIGHT-STATION AUTOMATIC TORCH BRAZING OPERATION THAT PRODUCES MAGNET ARMATURE ASSEMBLIES (230 PIECES/H) USED AS STRIKING MEMBERS OF A PRINTING MACHINE

Additional information is available in the article "Torch Brazing" in this Volume.

Furnace brazing is popular because of its comparatively low equipment cost, furnace adaptability, and minimal required jigging. Furnace brazing is a low-cost process relative to other processes such as torch brazing, induction brazing, or salt-bath brazing when high-volume production output is a primary factor. Secondary factors include tooling requirements, fluxing, and cleaning requirements. With many brazing assemblies, the weight of the parts alone is sufficient to hold them together. Other configurations require only one or two rectangular fixturing blocks of metal.

Four basic types of furnaces are used:

- BATCH, WITH EITHER AIR OR CONTROLLED ATMOSPHERE (FIG. 5)
- CONTINUOUS, WITH EITHER AIR OR CONTROLLED ATMOSPHERE (FIG. 6)
- RETORT, WITH CONTROLLED ATMOSPHERE
- VACUUM

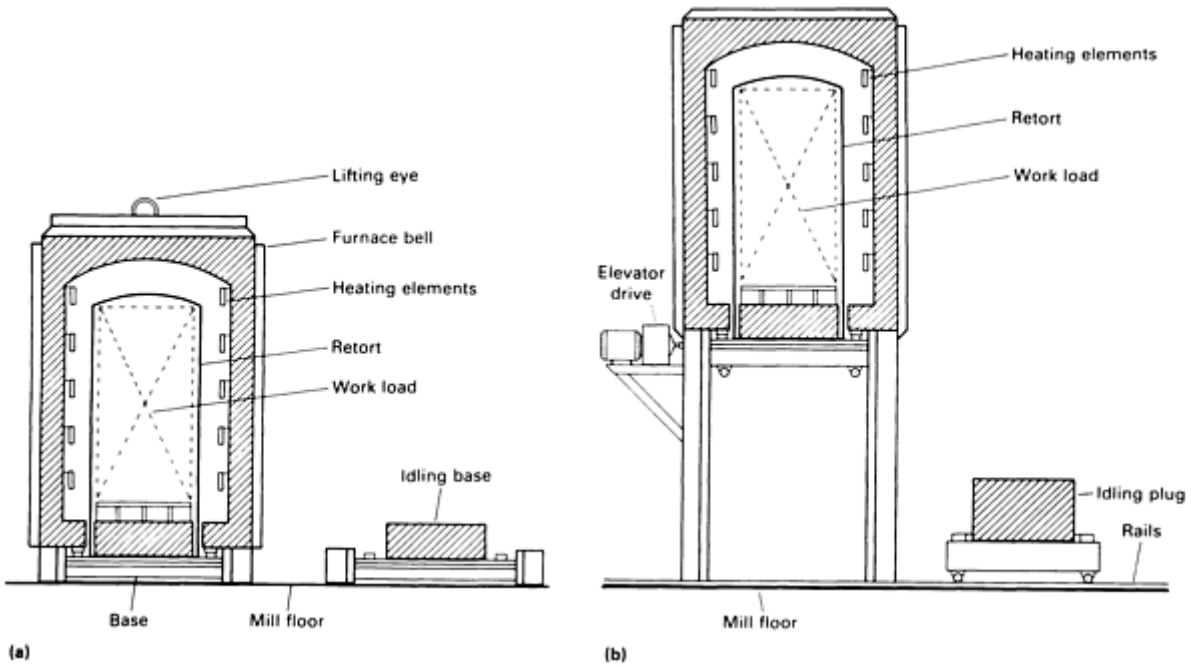

FIG. 5 BATCH-TYPE BRAZING FURNACES. (A) BELL FURNACE. (B) ELEVATOR FURNACE

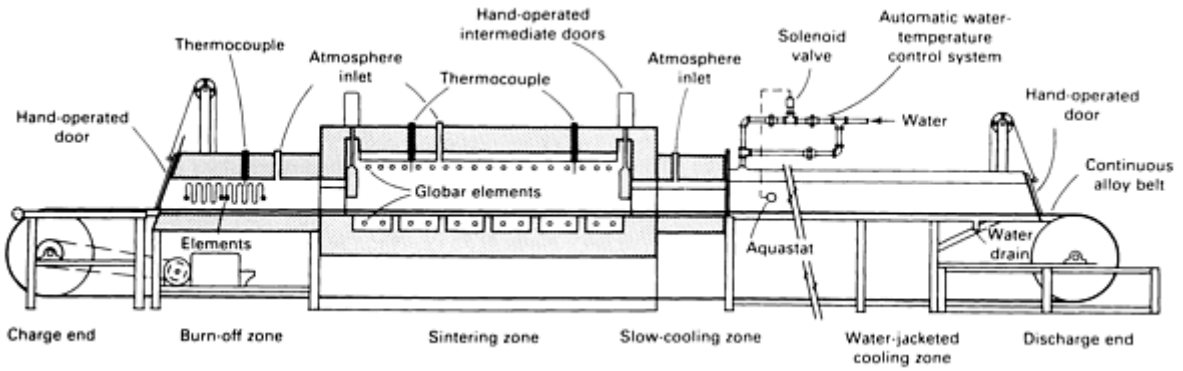

FIG. 6 CONTINUOUS-TYPE BRAZING FURNACE WITH WATER-JACKETED COOLING CHAMBER FOR USE IN AIR OR CONTROLLED ATMOSPHERES

Furnace brazing is used extensively where the parts to be brazed can be assembled with the brazing filler metal preplaced near or in the joint. Furnace brazing is particularly applicable for high-production applications in which continuous

conveyor-type furnaces are used. For medium-production work, batch-type furnaces are best. Regardless of furnace type, heating is usually produced by electrical resistance, although other types of fuel can be used in muffle-type furnaces.

The parts should be self jigged or fixtured and assembled, with brazing filler metal preplaced near or in the joint. Fluxing is used, except in cases where a reducing atmosphere, such as hydrogen, and either exothermic or endothermic combusted gas can be introduced into the furnace. Sometimes, both flux and a reducing atmosphere are necessary. Pure and dry inert gases, such as argon and helium, are used to obtain special atmosphere properties. Fluxes should never be used when furnace brazing with a vacuum atmosphere.

When continuous-type furnaces are used (Ref 16, 17), several different temperature zones can be set up to provide the proper preheating, brazing, and cooling temperatures. The speed through a conveyor-type furnace must be controlled to provide the appropriate time at the brazing temperature. It is also necessary to properly support the assembly so that it does not move while traveling on the belt (Ref 18).

A large volume of furnace brazing is performed in a vacuum atmosphere, which prevents oxidation during the heating cycle and eliminates the need for flux (Ref 19) (Fig. 7). Vacuum brazing has found wide application in the aerospace and nuclear fields, where reactive metals are joined or where entrapped fluxes would not be tolerable. Vacuum brazing does not allow as wide a choice of brazing filler metals as does atmosphere brazing (Ref 20, 21).

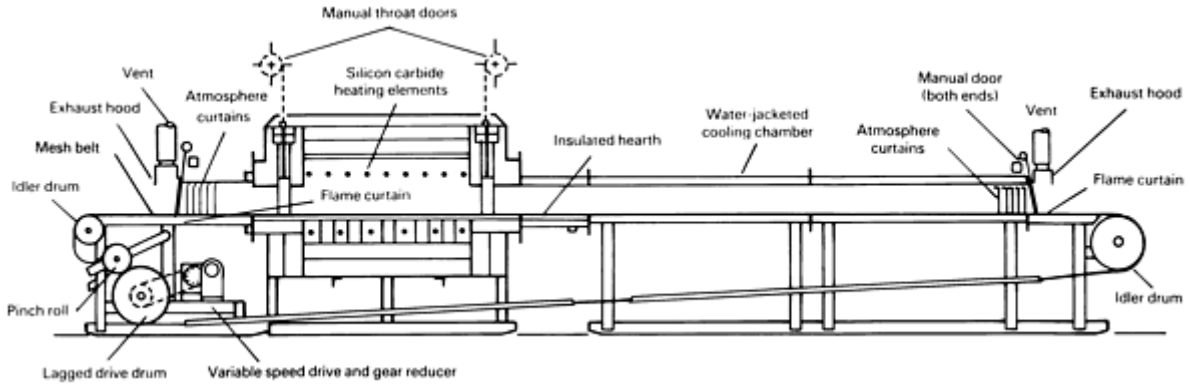

FIG. 7 HIGH-VACUUM BOTTOM-LOADING VACUUM FURNACE FOR MEDIUM-PRODUCTION APPLICATIONS

In most cases, vacuum furnaces are heated by electrical resistance heaters in a numbers of different forms. The overall time of a vacuum brazing operation is usually much longer than that of other batch brazing techniques and involves typing up expensive equipment for long periods to process comparatively small workloads. However, most of the metals on which vacuum brazing excels are also costly, the use of a process that permits material economics through fabrication while ensuring the necessary joint properties often can be justified (Ref 22, 23, 24).

Detailed information is available in the article "Furnace Brazing" in this Volume.

Induction Brazing. The high-frequency induction heating method for brazing is clean and rapid, lends itself to close control of temperature and location, and requires little operator skill.

The workpiece is placed in or near a coil carrying alternating current (ac), which induces the heating current in the desired area (Fig. 8). The coils, which are water cooled, are designed specifically for each part. Therefore, heating efficiency relies on establishing the best coil design and power frequency for each application. In most cases, the coils provide heat only to the joint area.

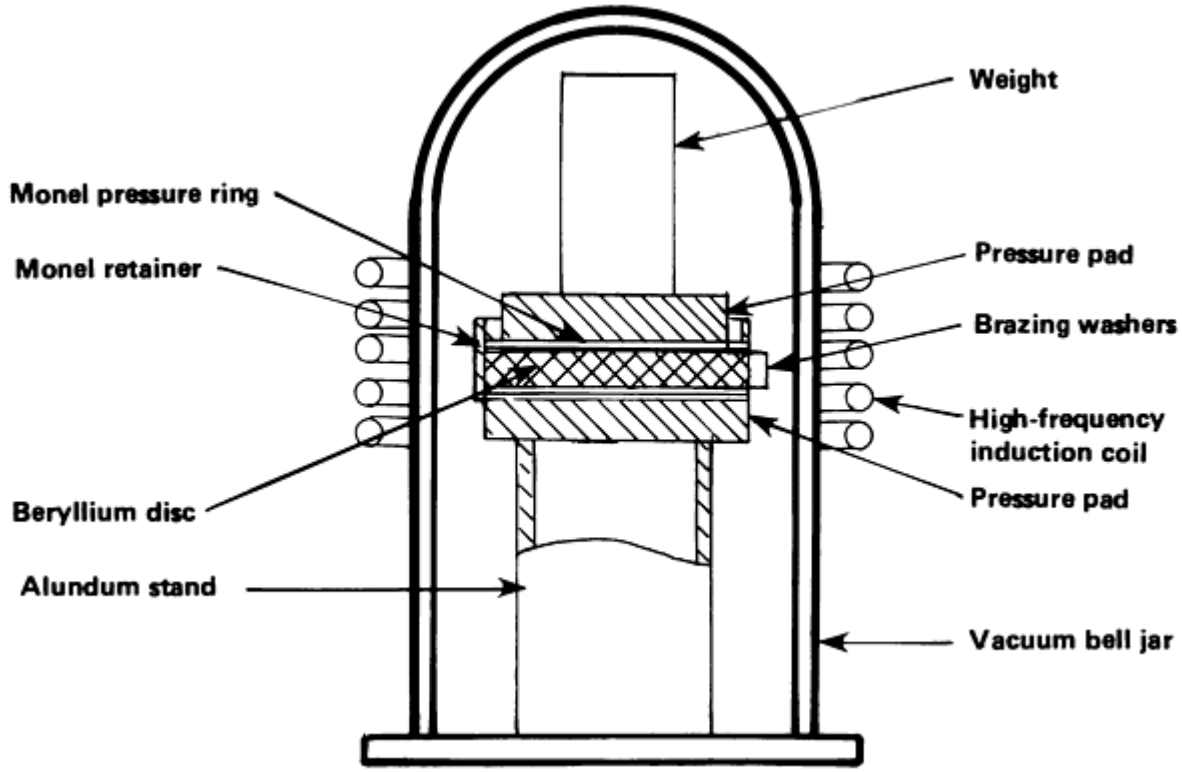

FIG. 8 INDUCTION HEATING APPARATUS USED TO VACUUM BRAZE BERYLLIUM AND MONEL COMPONENTS

The capability to heat selectively enables the induction method to be used when the nature of the brazement demands localized brazing.

There are several types of high-frequency sources to supply power to induction coils, each with a different range of frequencies:

- MOTOR GENERATORS (5 TO 10 KHZ)
- SPARK-GAP OSCILLATORS (20 TO 30 KHZ)
- VACUUM-TUBE OSCILLATORS (20 TO 5000 KHZ)
- SOLID-STATE POWER SUPPLIES (VARIABLE HZ)

The frequency of the power source determines the type of heat that will be induced in the part: high-frequency sources produce "skin" heating, whereas lower-frequency sources provide heating in thicker areas. The brazing heat usually develops within 10 to 60 s.

Induction brazing is well suited for mass production. Mechanized brazing lines for moving assemblies to and from the coils are very common. Brazing filler metals is normally preplaced in the joint, and the brazing can be done in air with the use of a flux, in an inert atmosphere, or in a vacuum atmosphere. The rapid heating rates available with induction heating are a major advantage when using brazing filler metals that tend to vaporize or segregate. The heating cycle for induction brazing is invariably automated, even when manual loading of assemblies is used.

Additional information is available in the article "Induction Brazing" in this Volume.

Dip brazing involves immersion of assembled parts into a suitable molten bath to effect brazing. The bath can be molten brazing filler metal, molten chemical flux, or molten chemical salts. The molten material is contained in a "pot" furnace heated by oil, gas, or electricity. In some instances, electrical-resistance heaters are used in the bath (Fig. 9). In the first type of bath, the parts being joined are held together and immersed in flux-covered molten filler metal, which flows into

the joints when the parts reach the bath temperature. The flux cleans the workpiece as it is introduced and protects the brazing filler metal by preventing oxidation and the loss of volatile elements from the bath.

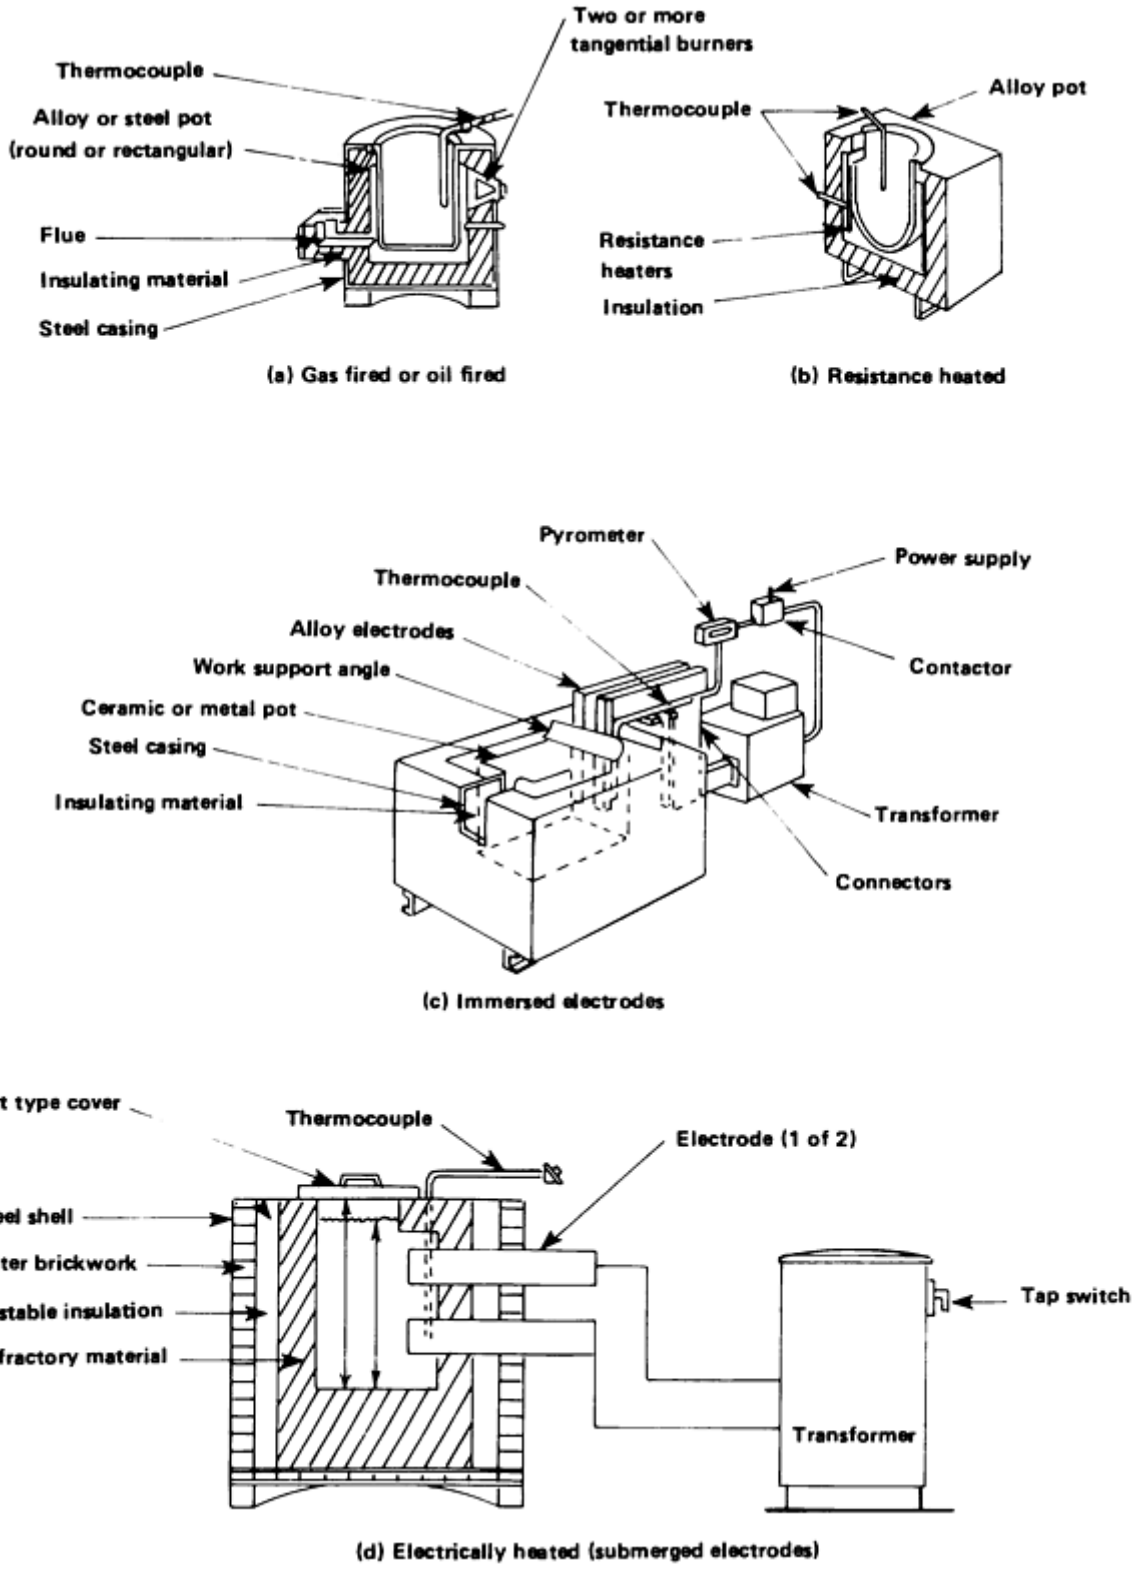

FIG. 9 EXTERNALLY AND INTERNALLY HEATED FURNACES USED FOR DIP BRAZING APPLICATIONS

The pot, or crucible, used in the molten-metal method is usually made of graphite. Jigging to maintain alignment is generally necessary. Because of the difficulties of heating and containing metals at high temperatures, filler metals that

require a brazing temperature above 1000 °C (1830 °F) are rarely used. Therefore, the choice of brazing filler metal is restricted to straight brasses and silver-base filler metals.

In the molten-flux method, the brazing filler metal is located in or near the joints and is heated to the required temperature by immersion in a bath of molten flux. Molten salt bath brazing has a greater scope than any other single brazing process. It can be used on as wide a range of parent metals as torch brazing, but is not subject to the same maximum temperature limitations. Unfortunately, it is an inflexible process. The type of salt used for a particular application depends on the ease with which the parent-metal surface oxides can be removed and on the temperature required for brazing.

The molten-flux method is used extensively for brazing aluminum and its alloys. The flux bath provides excellent protection against metal reoxidation, which can occur quite easily with aluminum.

The dip brazing method generally causes less distortion than torch brazing, because of its uniform heating. However, it may require relatively complex tooling and is therefore best used in medium- to high-production runs. This process is particularly well suited for small- to medium-sized parts with multiple hidden joints.

Detailed information is available in the article "Dip Brazing" in this Volume.

Resistance brazing is most applicable to relatively simple joints in metals that have high electrical conductivity. In this process, the workpieces are heated locally. Brazing filler metal that is preplaced between the workpieces is melted by the heat obtained from its resistance to the flow of electric current through the electrodes and the work. Usually, the heating current, which is normally ac, is passed through the joint itself. The joint becomes part of an electrical circuit, and the brazing heat is generated by the resistance at the joint.

Equipment is the same as that used for resistance welding, and the pressure needed for establishing electrical contact across the joint is ordinarily applied through the electrodes. The electrode pressure also in the usual means for providing the tight fit needed for capillary behavior in the joint. The component parts are generally held between copper or carbon-graphite electrodes.

The flux that is used must be conductive. Normally, fluxes are insulators when cool and dry, but are conductive when wet. The process is generally used for low-volume production in joining electrical contacts, related electrical elements, copper commutator segments, stainless steel tube to fittings, and so on.

Additional information is available in the article "Resistance Brazing" in this Volume.

Infrared (Quartz) Brazing. The development of high-intensity quartz lamps and the availability of suitable reflectors have made the infrared heat technique commercially important for brazing. Infrared heat is radiant heat that is obtained with the sources having energy frequency below the red rays in the light spectrum. Although there is some visible light with every "black" source, heating is principally done by the invisible radiation. Heat sources (lamps) capable of delivering up to 5000 W of radiant energy are commercially available. The lamps do not need to follow the contour of the part in order to hear the joint area, even though the heat input varies inversely as the square of the distance from the source, unless reflectors are used to concentrate the heat.

Lamps are often arranged in a toaster-like configuration, with parts traveling between two banks of lamps (Fig. 10). Infrared brazing can concentrate large amounts of heat in small areas, which can be advantageous in certain applications. Infrared brazing setups are generally not as fast as induction brazing, but the equipment is less expensive.

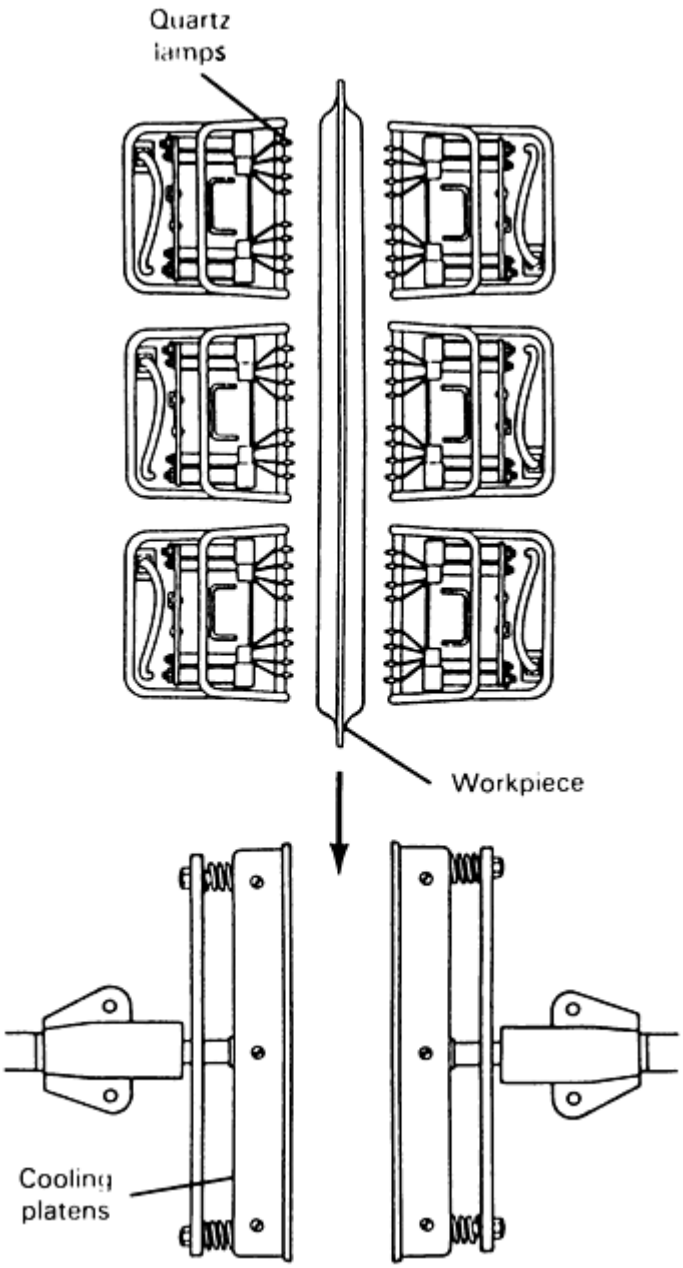

FIG. 10 WORKPIECE SUBJECTED TO INFRARED BRAZING PROCESS PRIOR TO BEING MOVED TO COOLING PLATENS

Exothermic brazing is a special process, but is rarely used because there are more-economical production methods. In this process, the heat required to melt and flow the brazing filler metal is produced by a solid-state exothermic chemical reaction, which is defined as any reaction between two or more reactants that involves the free energy of the system. Although nature provides countless numbers of these reactions, only the solid-state or nearly solid-state metal/metal-oxide reactions are suitable for use in exothermic brazing units.

Additional information is available in the article "Exothermic Brazing" in this Volume.

Electron-beam and laser brazing have been used in a limited number of applications. A laser can be used when a very small localized area of heat is required, such as for brazing small carbide tips on printer heads for electronic printers. The electron beam can be used for brazing by defocusing the beam to provide a wider area of heating. Because this is done in a vacuum, fluxes cannot be used and the brazing filler metal must be selected so that there is little or no vaporization during brazing.

Microwave Brazing. One of the newest heating methods to be developed is the use of microwaves. This technique is being used to join ceramics in high-temperature, corrosion-resistant, and high-performance applications. These applications require complex ceramics parts with strong, durable joints (Ref 25, 26).

The technique uses a single-mode microwave cavity. An iris controls the percent of microwaves reflected in the cavity, and a plunger adjusts the frequency. Together, they focus microwaves on the joint. The major advantage of this technique in terms of ceramic parts is that the entire part does not have to be heated in order to make a joint. Reheating finished ceramic parts can subject them to thermal stresses and cause cracking, which weakens the part. With microwave joining, only the interface between the pieces is heated. The technique is faster than conventional joining, which requires long times to heat ceramics uniformly. Large pieces, can, in principle, be joined at a lower cost.

One disadvantage of microwave joining is that commercial equipment is only produced by a few companies, mostly for research and development purposes.

Some microwave units feature 2.45 GHz single-mode or controlled multimode operation. Their cavity is designed to provide controlled-mode patterns that can focus high-energy microwave fields to heat a part only where it is needed, such as at a joint. The joint or part can be heated up to 2200 °C (3990 °F). Researchers have joined 92% Al_2O_3 ceramic parts in a 6 GHz single-mode microwave cavity at various temperatures and times. The bending strength of this joint gradually increased from the solidus temperature of 1400 °C (2550 °F) and reached a peak of 420 MPa (60 ksi) at about 1750 °C (3180 °F).

Braze welding is a joining process in which a filler metal is melted and deposited in a specific joint configuration, and a metallurgical bond is obtained by a wetting action that is often accompanied by some degree of diffusion with the base metals. Braze welding requires heating and melting of the filler metal that has a melting (liquidus) temperature above 450 °C (840 °F).

Stringent fit-up is not critical, because the filler metal is deposited in grooves and spaces and flows into gaps wider than those used for brazing. Fabricators use braze welding as a low-temperature substitute for oxyfuel welding or as a low-cost substitute for brazing. Joint designs for braze welding are the same as for oxyfuel welding (OFW). Braze welding has been used to join cast iron, steels, copper, nickel, and nickel alloys.

Compared to conventional fusion-welding processes, braze welding requires less heat input, permits higher travel speeds, and causes less distortion. Deposited filler metal is soft and ductile, providing good machinability, and residual stresses are low. The process joins brittle cast irons without extensive preheating.

Although most braze welding initially used an OFW torch, copper filler metal brazing rod, and a suitable flux, present applications use carbon arc welding (CAW), gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), or plasma arc welding (PAW) without flux in the manual, semiautomatic, or automatic modes to economically bond and deposit the filler metal in the braze weld joints. OFW is, however, still widely used in machinery repair applications. Filler metal selection, proper wetting and compatibility with the base metals, and shielding from air are important to the effective use of the process with any suitable heating method.

A wide variety of parts can be braze welded using typical weld joint designs. Groove, fillet, and edge welds can be used to join simple and complex assemblies made from sheet, plate, pipe, tubing, rods, bars, castings, and forgings. Sharp corners that are easily overheated and may become points of stress concentrations should be avoided. To obtain good strength, an adequate bond area is required between filler metal and the base metal. Weld groove geometry should provide an adequate groove face area, so that the joint will not fail along the interfaces. Proper joint design selection will produce deposited filler-metal strengths that may meet or exceed the minimum base-metal tensile strengths. Because of the inert shielding gas, electrical arc methods have fewer included flux compounds and oxides at the faying surfaces. The result is higher joint strength and improved corrosion resistance. Original surfaces are restored by overlayments and subsequent machining.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Introduction

THE SHIELDING GAS used in a welding process has a significant influence on the overall performance of the welding system. Its primary function is to protect the molten metal from atmospheric nitrogen and oxygen as the weld pool is being formed. The shielding gas also promotes a stable arc and uniform metal transfer. In gas-metal arc welding (GMAW) and flux-cored arc welding (FCAW), the gas used has a substantial influence on the form of metal transfer during welding. This, in turn, affects the efficiency, quality, and overall operator acceptance of the welding operation.

The shielding gas interacts with the base material and with the filler material, if any, to produce the basic strength, toughness, and corrosion resistance of the weld. It can also affect the weld bead shape and the penetration pattern.

Understanding the basic properties of a shielding gas will aid in the selection of the right shielding gas or gases for a welding application. Use of the best gas blend will improve the quality and may reduce the overall cost of the welding operation as well.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Basic Properties of a Shielding Gas

The "controlled electrical discharge" known as the welding arc is formed and sustained by the establishment of a conductive medium called the arc plasma. This plasma consists of ionized gas, molten metals, slags, vapors, and gaseous atoms and molecules. The formation and structure of the arc plasma is dependent on the properties of the shielding gases used for welding. Table 1 lists the basic properties of gases used for welding (Ref 1).

TABLE 1 PROPERTIES OF SHIELDING GASES USED FOR WELDING

GAS	CHEMICAL SYMBOL	MOLECULAR WEIGHT	SPECIFIC GRAVITY(A)	DENSITY		IONIZATION POTENTIAL	
				g/ft^3	g/l	aj(b)	eV
ARGON	AR	39.95	1.38	0.1114	1.784	2.52	15.7

The ionization potential is the energy, expressed in electron volts, necessary to remove an electron from a gas atom--making it an ion, or an electrically charged gas atom. All other factors held constant, the value of the ionization potential decreases as the molecular weight of the gas increases. Arc starting and arc stability are greatly influenced by the ionization potentials of the component shielding gases used in welding process. A gas with a low ionization potential,

such as argon, can atoms into ions easily. Helium, with its significantly higher ionization potential, produces a harder to start, less stable arc.

Although other factors are involved in sustaining the plasma, the respective energy levels required to ionize these gases must be maintained; as a consequence, the arc voltage is directly influenced. For equivalent arc lengths and welding currents, the voltage obtained with helium is appreciably higher than is with argon. This translates into more available heat input to the base material with helium than with argon.

The thermal conductivity of a gas is a measure of how well it is able to conduct heat. It influences the radial heat loss from the center to the periphery of the arc column as well as heat transfer between the plasma and the liquid metal. Argon, which has a low thermal conductivity, produces an arc that has two zones: a narrow hot core and a considerably cooler outer zone. The penetration profile of the weld fusion area then exhibits a narrow "finger" at the root and a wider top. A gas with a high thermal conductivity conducts heat outward from the core; this results in a wider, hotter arc core. This type of heat distribution occurs with helium, argon-hydrogen, and argon-carbon dioxide blends; it gives a more even distribution of heat to the work surface and produces a wider fusion area.

Dissociation and Recombination. Shielding gases such as carbon dioxide, hydrogen, and oxygen are multiatom molecules. When heated to high temperatures within the arc plasma, these gases break down, or dissociate, into their component atoms. They are then at least partially ionized, producing free electrons and current flow. As the dissociated gas comes into contact with the relatively cool work surface, the atoms recombine and release heat at that point. This heat of recombination causes multiatomic gases to behave as if they have a higher thermal conductivity, similar to that of helium. Dissociation and recombination do not occur with gases, such as argon, that consist of a single atom. Thus, at the same arc temperature, the heat generated at the work surface can be considerably greater with gases such as carbon dioxide and hydrogen.

Reactivity/Oxidation Potential. The oxidizing nature of the shielding gas affects both welding performance and the properties of the resultant weld deposit. Argon and helium are completely nonreactive, or inert, and thus have no direct chemical affect on the weld metal. Oxidizing or active gases, such as CO_2 and oxygen, will react with elements in the filler metal or baseplate and will form a slag on the surface of the weld deposit. The loss of elements, such as manganese and silicon, from steel can affect the quality and cost of the weldment produced. Both weld strength and toughness generally decline as the oxidizing nature of the shielding gas increases.

Additions of reactive gases such as oxygen or carbon dioxide enhance the stability of the arc and affect the type of metal transfer obtained. Metal droplet size is decreased, and the number of droplets transferred per unit time increases as the level of oxygen in the shielding gas increases. Oxygen reduces the molten weld bead surface tension, promoting better bead wetting and higher welding travel speeds. Small additions of CO_2 work in a similar manner.

The surface tension between the molten metal and its surrounding atmosphere has a pronounced influence on bead shape. If the surface energy is high, a convex, irregular bead will result. Low values promote flatter beads with minimal susceptibility for undercutting.

Pure argon is generally associated with high interfacial energy, producing a sluggish weld puddle and high, crowned bead. The addition of a small amount of a reactive gas, such as oxygen, lowers this surface tension and promote fluidity and better wetting of the base material; it does this without creating excessive oxidation of the weld metal.

Gas Purity. Some metals, such as carbon steel and copper, have a relatively high tolerance for contaminants in the shielding gas; others, such as aluminum and magnesium, are fairly sensitive to particular contaminants. Still others, such as titanium and zirconium, have an extremely low tolerance for any foreign constituent in the shielding gas.

Depending on the metal being welded and the welding process used, very small quantities of gas impurities can significantly affect welding speed, weld surface appearance, weld bead solidification, and porosity levels. The effects of any given impurity are wide ranging, but weld quality and eventual fitness for purpose are major areas of concern.

There is always a possibility that the gas, as delivered, is contaminated; however, it is far more likely that impurities will enters somewhere between the supply and the end-use points. For this reason, property designed piping systems and high-quality hose are recommended for use with welding shielding gases. Typical industry minimum purity levels for welding gases are listed in Table 2 (Ref 2).

TABLE 2 TYPICAL GASES PURITY AND MOISTURE CONTENT OF SHIELDING

(A) MOISTURE SPECIFICATIONS ARE MEASURED AT FULL CYLINDER PRESSURE, THE PRESSURE AT WHICH THE CYLINDER IS ANALYZED.

Gas density is the weight of the gas per unit volume. Density is one of the chief factors that influence shielding gas effectiveness. Basically, gases heavier than air, such as argon and carbon dioxide, require lower flow rates in use than do the lighter gases, such as helium, to ensure adequate protection of the weld puddle.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Characteristics of the Components of a Shielding Gas Blend

To obtain a shielding gas that is suited to a specific application, a mix of gases is generally needed. Each basic gas contributes certain characteristics to the performance of the overall mix. Some gas blends have relatively specific areas of application and limited operating ranges; others can be used on many materials under a variety of welding conditions. Each component of the blend brings with it properties that are supplemented by the others to produce an enhanced level of performance.

Argon is inert or unreactive with respect to the materials present in the welding electrode. With its low ionization potential, argon promotes easy arc starting and stable arc operation. Its lower thermal conductivity promotes the development of axial "spray" transfer in certain forms of GMAW. It is also used in applications where base material distortion must be controlled or where good gap-bridging ability is required.

Helium. Unlike argon, helium is lighter than air and has a low density. Like argon, it is chemically inert and does not react with other elements or compounds. Because of its high thermal conductivity and high ionization potential, more heat is transferred to the base material, thus enhancing the penetration characteristics of the arc. In many applications, it also allows higher weld travel speeds to be obtained. Because of its higher cost, helium is frequently combined with argon or argon mixtures to enhance the overall performance of the blend while minimizing its cost.

Oxygen combines with almost all known elements except rare and inert gases; it vigorously support combustion. Small amounts of oxygen are added to some inert mixtures to improve the stability of the welding arc developed as well as to increase the fluidity of the weld puddle.

In the spray-transfer mode of GMAW, small additions of oxygen enhance the range over which this spatterless form of welding can be performed. The droplet size decreases and the number of drops transferred per unit time increases as oxygen is added to the blend.

Carbon dioxide is a reactive gas that is commonly used alone in certain types of GMAW. Oxidation of the base material and any filler electrode occurs readily. Carbon dioxide is added to argon blends to improve are stability, enhance penetration, and improve weld puddle flow characteristics. The higher thermal conductivity of carbon dioxide (because of the dissociation and recombination of its component parts) transfer more heat to the base material than does argon alone. A broader penetration pattern versus argon is obtained; however, base material distortion and lack of gap-bridging ability are possible problems.

Hydrogen is the lightest known element and is a flammable gas. Explosive mixtures can be formed when certain concentration of hydrogen are mixed with oxygen or air. It is added to inert gases to increase the heat input to the base material or for operations involving cutting and gouging. Because some materials are especially sensitive to hydrogen-related contamination, its use is generally limited to special applications, such as the joining of stainless steels, and to plasma are cutting and gouging.

Nitrogen is generally considered to be inert except at high temperatures. At arc welding temperatures, it will react with some metals (e.g., aluminum, magnesium, steel, and titanium), so it is not used as a primary shielding gas. It can be used with other gases for some welding applications (e.g., copper) and is also widely used in plasma cutting.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Shielding Gas Selection

In most welding applications, more than one shielding gas or gas blend can be used successfully. For example, there is no one optimal gas blend for joining carbon steels, but a considerable array of mixes are available depending on the specific requirements of the application. For some processes, such as gas-tungsten arc welding (GTAW) and plasma arc welding (PAW), the choices may be somewhat limited by the nature of the electrodes used and the materials being welded. However, for applications involving GMAW, a multitude of blends can be selected from when carbon steels are being joined. Determination of the best blend depends on a number of specific job-related needs.

Accuracy of Gas Blends

The accuracy with which gases are blended is a function of the way in which they are supplied. If the source of the gas is a high-pressure cylinder, the following generally applies:

1. ±10% RELATIVE, MINOR COMPONENT (REF 3)

2. ±0.5% ABSOLUTE FOR CONCENTRATIONS UP TO 5%; ±10% RELATIVE FOR CONCENTRATIONS BETWEEN 5 AND 50% (REF 4)

For example, the mix accuracy of an Ar-2O_2 blend would be Ar/1.8-2.2O_2 (method 1) or Ar/1.5-2.5O_2 (method 2). A blend of Ar-25CO_2 would yield Ar/22.5-27.5CO_2 by their method of calculation.

When gas cylinders are properly filled with the appropriate blend, the components of that mixture will not separate unless the temperature of the environment is reduced far below normal working temperatures. If the gases are supplied from a liquid source, such as a bulk tank, the accuracy of the blend is a function of the mixing equipment used, but most likely falls within the ±10% minor component range.

Shielding Gases for GMAW

By far, the largest number of gas blends have been developed for GMAW, especially for joining carbon steel. These can be roughly divided into four categories: pure gases, argon-oxygen mixes, argon/carbon dioxide mixes, and three-part gas blends composed of either argon, helium, oxygen, carbon dioxide, or hydrogen. Table 3 contains suggestions for shielding gas selection based on material type, thickness, and mode of metal transfer.

TABLE 3 RECOMMENDED SHIELDING GAS SELECTION FOR GMAW

MATERIAL	THICKNESS		TRANSFER MODE	RECOMMENDED SHIELDING GAS	ADVANTAGES AND LIMITATIONS
	MM	IN.			
CARBON STEEL	<2.0	<0.080	SHORT CIRCUITING	AR-25CO_2 AR-15CO_2 AR-8CO_2	GOOD PENETRATION AND DISTORTION CONTROL TO REDUCE POTENTIAL BURNTHROUGH
	2.0-3.2	0.080-0.125	SHORT CIRCUITING	AR-8CO_2 AR-15CO_2 AR-25CO_2	HIGHER DEPOSITION RATES WITHOUT BURNTHROUGH: MINIMUM DISTORTION AND SPATTER; GOOD PUDDLE CONTROL FOR OUT-OF-POSITION WELDING
	>3.2	>0.125	SHORT CIRCUITING	AR-15CO_2 AR-25CO_2 CO_2	HIGH WELDING SPEEDS, GOOD PENETRATION AND PUDDLE CONTROL; APPLICABLE LOT OUT-OF-POSITION WELDS
			GLOBULAR	AR-25CO_2 CO_2	SUITABLE FOR HIGH-CURRENT AND HIGH-SPEED WELDING; DEEP PENETRATION AND FAST TRAVEL SPEEDS, BUT WITH GREATER BURNTHROUGH POTENTIAL
			CONVENTIONAL SPRAY ARC	AR-1O_2 AR-2O_2 AR-5CO_2	GOOD ARC STABILITY; PRODUCES A MORE FLUID PUDDLE AS O_2

				AR-8CO_2 AR-10CO_2 AR-15CO_2 AR-CO_2-O_2 BLENDS	INCREASES; GOOD COALESCENCE AND BEAD CONTOUR, GOOD WELD APPEARANCE AND PUDDLE CONTROL
			PULSED SPRAY	ARGON-5CO_2 AR-HE-CO_2 BLENDS AR-CO_2-O_2 BLENDS	USED FOR BOTH GAGE AND OUT-OF-POSITION WELDMENTS; ACHIEVES GOOD PULSED SPRAY STABILITY OVER A WIDE RANGE OF ARC CHARACTERISTICS AND DEPOSITION RANGES
ALLOY STEEL	ALL SIZES		SHORT CIRCUITING	AR-8CO_2 AR-15CO_2 AR-CO_2-O_2 BLEND	HIGH WELDING SPEEDS; GOOD PENETRATION AND PUDDLE CONTROL; APPLICABLE FOR OUT-OF-POSITION WELDS; SUITABLE FOR HIGH-CURRENT AND HIGH-SPEED WELDING
			SPRAY ARC (HIGH-CURRENT DENSITY AND ROTATIONAL)	AR-2O_2 AR-5O_2 AR-CO_2-O_2 BLENDS AR-HE-CO_2 BLENDS	REDUCES UNDERCUTTING; HIGHER DEPOSITION RATES AND IMPROVED BEAD WETTING; DEEP PENETRATION AND GOOD MECHANICAL PROPERTIES
			PULSED SPRAY	AR-5CO_2 AR-8CO_2 AR-2O_2	USED FOR BOTH LIGHT-GAGE AND HEAVY OUT-OF-POSITION WELDMENTS; ACHIEVES GOOD PULSED SPRAY STABILITY OVER A WIDE RANGE OF ARC CHARACTERISTICS AND DEPOSITION RANGES
STAINLESS STEEL, COPPER, NICKEL, AND CU-NI ALLOYS	ALL SIZES		SHORT-CIRCUITING TRANSFER	AR-HE-CO_2 BLENDS HE-AR-CO_2 BLENDS AR-1O_2 AR-2O_2	LOW CO_2 CONTENTS IN HELIUM MIX MINIMIZE CARBON PICKUP, WHICH CAN CAUSE INTERGRANULAR CORROSION WITH SOME ALLOYS; HELIUM IMPROVES WETTING ACTION; CO_2 CONTENTS >5% SHOULD BE USED WITH CAUTION ON

					SOME ALLOYS; APPLICABLE FOR ALL POSITION WELDING
			SPRAY ARC	AR-HE-CO_2 BLENDS AR-1O_2 AR-2O_2	GOOD ARC STABILITY; PRODUCES A FLUID BUT CONTROLLABLE WELD PUDDLE; GOOD COALESCENCE AND BEAD CONTOUR; MINIMIZES UNDERCUTTING ON HEAVIER THICKNESSES
			PULSED SPRAY	AR-HE-CO_2BLENDS AR-1O_2 AR-2O_2	USED FOR BOTH LIGHT-GAGE AND HEAVY OUT-OF-POSITION WELDMENTS; ACHIEVES GOOD PULSED SPRAY STABILITY OVER A WIDE RANGE OF ARC CHARACTERISTICS AND DEPOSITION RANGES
ALUMINUM, TITANIUM, AND OTHER REACTIVE METALS	≤ 13	$\leq \frac{1}{2}$	SPRAY ARC	ARGON	BEST METAL TRANSFER, ARC STABILITY, AND PLATE CLEANING; LITTLE OR NO SPATTER; REMOVES OXIDES WHEN USED WITH DCEP (REVERSE POLARITY)
			SPRAY ARC	75HE-25AR 50HE-50AR	HIGH HEAT INPUT; PRODUCES FLUID PUDDLE, FLAT BEAD CONTOUR, AND DEEP PENETRATION; MINIMIZES POROSITY
	>13	$> \frac{1}{2}$	SPRAY ARC	HELIUM 50HE-25AR	HIGH HEAT INPUT; GOOD FOR MECHANIZED WELDING AND OVERHEAD; APPLICABLE TO HEAVY SECTION WELDING
			PULSED SPRAY	ARGON	GOOD WETTING; GOOD PUDDLE CONTROL

Argon. Pure argon is generally used on nonferrous base metal, such as aluminum, nickel, copper, and magnesium alloys, and on reactive metals, such as titanium. Argon provides excellent arc stability, penetration, and bead profile when joining these materials. Its low ionization potential results in easy arc starting. Argon produces a constricted arc column with high current density, which concentrates the arc energy over a small area; deep, fingerlike penetration results.

Carbon Dioxide. A reactive gas, carbon dioxide is generally used only for joining carbon steel. It is readily available and relatively inexpensive. Because CO_2 will not support spray transfer, deposition efficiency is lower and spatter and fume

levels are higher than with argon blends. Weld bead surfaces are more oxidized and irregular in shape. The higher ionization potential of CO_2 and its characteristic dissociation upon heating provide greater weld fusion and penetration while still achieving acceptable mechanical properties.

Helium. Because of its higher thermal conductivity, helium can provide additional heat input to the base material while still maintaining an inert atmosphere. Wetting action, depth of fusion, and travel speed can be improved over comparable argon levels. This advantage is most frequently utilized in the welding of heavier sections of aluminum, magnesium, and copper alloys.

Argon-Oxygen. The addition of a small amount of oxygen to a argon greatly stabilizes the welding arc, increases the filler metal droplet rate, lowers the spray transition current, and influences bead shape. The weld pool is more fluid and stays molten longer, allowing the metal to flow out toward the edges of the weld (Fig. 1a).

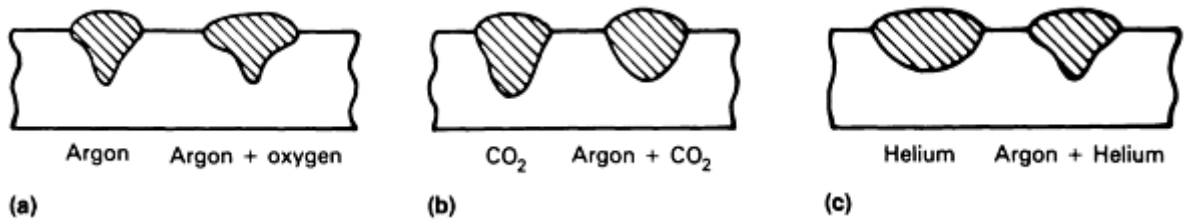

FIG. 1 EFFECT OF SHIELDING GAS BLENDS ON WELD PROFILE USING DIRECT CURRENT ELECTRODE POSITIVE (DCEP). (A) ARGON VERSUS ARGON-OXYGEN. (B) CARBON DIOXIDE VERSUS ARGON/CARBON DIOXIDE. (C) HELIUM VERSUS ARGON-HELIUM. SOURCE: REF 5

The most common blends contain 1, 2, 5, or 8% O_2 in argon. Increasing oxygen improves arc stability and makes higher travel speeds possible by enhanced puddle fluidity. Some increased alloy loss and a greater chance of undercut occur as the oxygen level is increased, especially beyond 5%.

Argon/carbon dioxide blends are primarily used for carbon and low-alloy steels and have limited use for stainless steels. The addition of CO_2 to argon produces results similar to the addition of oxygen, but is also broadens the penetration pattern as the CO_2 content is increased (Fig. 1b). Above a range of 18 to 20% CO_2, spraylike transfer can no longer be obtained; short-circuiting/globular transfer with somewhat increased spatter levels is found from this point up to approximately 50% CO_2 in argon.

The most common blends for spray transfer are argon plus 5, 8, 10, or 13 to 18% CO_2. With increased CO_2 content, the more fluid weld puddle permits higher weld travel speeds.

Mixes with higher carbon dioxide levels can also be used for short-circuiting transfer--commonly, argon plus 20 or 25% CO_2. Mixtures in this range provide an optimum droplet frequency for minimum spatter when small-diameter (0.9 and 1.2 mm, or 0.035 and 0.045 in.) wire is used.

Argon-Helium. Helium is often mixed with argon to obtain the advantages of both gases. These blends are primarily used for nonferrous base materials, such as aluminum, copper, and nickel alloys. Helium increases the heat input to the base material and thus is used for joining thick, thermally conductive plates. As the helium percentage increases, the arc voltage, spatter, and weld width-to-depth ratio increase (Fig. 1c).

The most common blends contain 25, 50, or 75% He in argon. The highest percentage of helium is used for joining thick (>50 mm, or 2 in.) plate material, especially aluminum and copper. Higher travel speeds can be obtained using helium-enhanced blends.

Argon/Oxygen/Carbon Dioxide. Mixtures containing three gas components are versatile because of their ability to operate in short-circuiting, globular, and spray-transfer modes. These blends are generally proprietary, and manufacturers' recommendations should be followed for their proper use. Blends of argon, carbon dioxide, and oxygen are generally used to join carbon and alloy steels.

Argon/Helium/Carbon Dioxide. Helium and carbon dioxide additions to argon increase the heat input to the base metal, which improves wetting, puddle fluidity, and weld bead profile. With helium plus CO_2 additions less than 40%, good spray transfer is obtained for carbon and low-alloy steel welding. Some increase in tolerance of base material surface contamination is also noted.

When the helium content exceeds 50 to 60%, transfer is restricted to short-circuiting and globular. Blends in which the CO_2 content is relatively low ($\leq 5\%$) are generally used for the joining of stainless steels without any loss in corrosion resistance.

Argon/Carbon Dioxide/Hydrogen. Three-part blends of this design are intended for the joining of austenitic stainless in the spray or short-circuiting transfer modes. Because of the addition of hydrogen, these blends should not be used for carbon steel. The carbon dioxide and hydrogen increase the heat input to the base material and improve bead shape characteristics, as well as promote higher welding travel speeds.

Shielding Gas Selection for FCAW

Carbon Dioxide. The majority of large-diameter (>1.6 mm, or $\frac{1}{16}$ in.) wires that use a shielding gas use carbon dioxide. Some smaller diameter wires are formulated to operate in 100% CO_2. The arcs are generally stable and provide a globular transfer over the usable operating range. Good performance over rust and mill scale on the plate surface is obtained with these large-diameter wires and CO_2 shielding.

Argon/Carbon Dioxide. A significant number of small-diameter (≤ 1.6 mm, or $\frac{1}{16}$ in.) cored wires are shielded with the blends of argon with 15 to 50% CO_2. These blends provide better out-of-position weld puddle control versus that of CO_2. To obtain the best performance from a particular cored wire, check the manufacturer's product literature for the recommended gas blend.

Shielding Gas Selection for GTAW

Argon. The most commonly used gas for GTAW, argon exhibits low thermal conductivity, which produces a narrow, constricted arc column; this allows greater variations in arc length with minimal influence on arc power or weld bead shape. Its low ionization potential provides good arc starting characteristics and good arc stability using the direct current electrode negative (DCEN) power connection plus superior arc cleaning action and bead appearance when ac power is used. Argon is the most commonly selected gas for DCEN welding of most materials and ac manual welding of aluminum.

Helium. The high thermal conductivity and ionization potential of helium make it suitable for the high-current joining of heavy sections of heat-conductive materials such as aluminum. Helium increases the penetration of the weld as well as its width. It also allows the use of higher weld travel speeds.

Argon-Helium. Blends of argon and helium are selected to increase the heat input to the base material while maintaining favorable arc stability and superior arc starting characteristics. Blends of 25, 50, and 75% He in argon are commonly used.

Argon-Hydrogen. Hydrogen is added to argon to enhance its thermal properties. The slightly reducing atmosphere improves weld puddle wetting and reduces some surface oxides to produce a cleaner weld surface. To minimize problems associated with arc starting, additions of hydrogen are generally limited to 5 to 15%. These blends are primarily used to join some stainless steels, nickel, and nickel alloys. These mixtures should not be used to join alloy steels; delayed weld cracking may result.

Argon/2-5H_2 is used in manual welding applications on materials thicker than 1.6 mm ($\frac{1}{16}$ in.). Additions of 10 to 15% H_2 are used in mechanized applications, such as those found in the manufacture of stainless steel tubing.

Caution: Special safety precautions are required when mixing argon and hydrogen. Do not attempt to mix argon and hydrogen from separate cylinders. Always purchase ready-mixed hydrogen blends from a qualified supplier.

Shielding Gas Selection for PAW

The physical configuration of the PAW system requires the use of two gases: a "plasma" or orifice gas and a shielding gas. The primary role of the plasma gas, which exits the torch through the center orifice, is to control arc characteristics and shield the electrode. The shielding gas, introduced around the periphery of the arc, shields or protects the weld area. In many applications, the shielding gas is also partially ionized to enhance the performance of the plasma gas.

Low-Current (<100 A) PAW. Argon is the preferred plasma gas for low-current PAW because of its low ionization potential, which ensures easy and reliable arc starting. Argon-hellium mixtures are used for some applications requiring higher heat inputs. The choice of the shielding gas depends on the type and thickness of the base material. Recommendations can be found in Table 4.

TABLE 4 RECOMMENDED GUIDELINES FOR SELECTING PAW SHIELDING GASES

MATERIAL	THICKNESS		MODE OF PENETRATION	
	MM	IN.	KEYHOLE TECHNIQUE[C]	MELT-IN TECHNIQUE[D]

Source: Ref 6, 7

(A) GAS SELECTIONS SHOWN ARE FOR SHIELDING GAS ONLY. ORIFICE GAS IN ALL CASES IS ARGON.

(B) GAS SELECTIONS SHOWN ARE FOR BOTH THE ORIFICE AND SHIELDING GAS.

(C) PROPERLY BALANCED GAS FLOW RATES PRODUCE COMPLETE JOINT PENETRATION BY FORMING A SMALL WELD POOL WITH A HOLE PENETRATING COMPLETELY THROUGH THE BASE METAL. AS THE PLASMA TORCH IS MOVED, METAL MELTED BY THE ARC IS FORCED TO FLOW AROUND THE PLASMA STEAM PRODUCING THE "KEYHOLE" TO THE REAR WHERE THE WELD POOL IS FORMED AND SOLIDIFIED.

(D) CONVENTIONAL FUSION WELDING SIMILAR TO THAT DONE WITH GTAW.

High-Current ([ges]100 A) PAW. The choice of gas used for high-current PAW also depends on the material to be welded. In almost all cases, the shielding gas is the same as the orifice gas. Again, argon is suitable for welding all metals, but it does not necessarily produce optimum results. Depending on the welding mode used (keyhole or melt-in), the optimum gas blend will vary. Table 4 lists gases recommended on the basis of materials joined.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Influence of Shielding Gas on Weld Mechanical Properties

The mechanical properties of a weld are dependent on specific characteristics of the shielding gas. When the gas blend is totally inert, the effects are less pronounced and are derived more indirectly. In this case, the shielding gas affects penetration and solidification, which can influence the microstructure of the resulting weld.

When the shielding gas contains active components, such as oxygen or carbon dioxide, the influence is direct and more substantial. The oxygen potential of the shielding gas influences the amount of surface slag, the fume emission rate, the fluidity of the weld puddle, and the mechanical properties (both strength and toughness) of the weld metal. A number of empirical formulas have been developed to estimate the oxygen potential of a gas blend (Ref 8); the differences lie in their treatment of the CO_2 component of the gas mix. Because parameters other than gas composition can affect the

oxygen level of the weld metal (e.g., welding speed), most of the recently developed formulas are also welding parameter and material specific. Their importance centers on how the oxidation potential is linked to elemental loss of silicon and manganese in the weld metal, to weld metal oxygen content, and to weld mechanical properties.

Because a relatively complex relationship exists between the loss of alloying elements, the composition of the shielding gas, and the mechanical properties of the resulting weld metal it is difficult to select an optimum gas blend that will work well with all types of wires. This influence is most noticeable in the gas metal-arc welding of carbon steel. Figure 2 (Ref 8) and Table 5 (Ref 9) illustrate the effect of the shielding gas on impact strength and tensile strength. In general, as the oxidation potential of the shielding gas increases, the toughness and the tensile strength of the weld deposit decrease. Because of their lower oxidizing gas content, argon blends will generally produce weld properties superior to those obtained by shielding with CO_2 only. There appears to be an "optimum" oxygen content, as too low an oxygen level can also be detrimental to toughness.

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Shielding Gas and Fume Generation

The shielding gas used in solid and flux-cored wire welding affects the rate at which fumes are produced during welding, as well as the composition of the fumes. The type of shielding gas also affects the composition of the pollutant gases in the welding area. The fumes and gases generated in some welding applications impact on health and safety; therefore, it is important for the user to review the Material Safety Data Sheets and precautionary labeling provided by the manufacturers and suppliers of welding consumables. Welding safety and health information can be also be found in this Handbook and in ANSI Z49.1, "Safety in Welding and Cutting."

Fume generation rates are generally highest when CO_2 shielding is used. Inert gas blends containing CO_2 produce higher fume levels than those containing only oxygen additions. For solid wire welding at the same weld metal deposition rate, argon blends typically generate significantly less fumes than when CO_2 only is used (Ref 10, 11, 12). Figure 3 (Ref 13) illustrates the dependence of the fume generation rate on shielding gas composition as a function of current level in GMAW. Similar trends can be seen when using gas-shielded flux-cored wires.

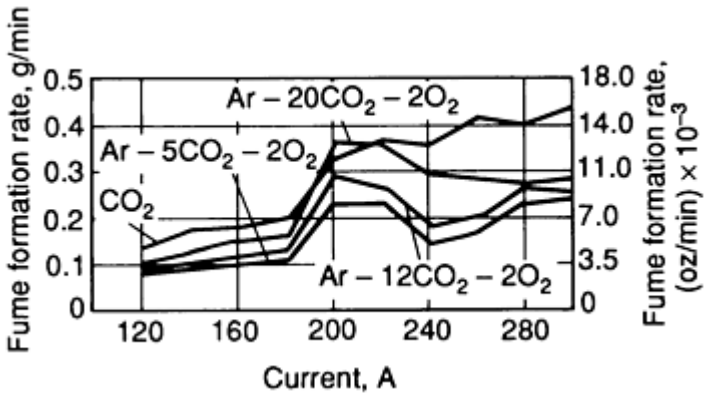

FIG. 3 PLOT OF FUME FORMATION RATE VERSUS CURRENT FOR MILD STEEL SOLID WIRE USING SELECTED SHIELDING GASES. SOURCE: REF 13

Pollutant gases must be considered when arc welding. The gases of greatest interest arc carbon monoxide, ozone, and nitrogen oxides. When CO_2 is used for shielding in confined spaces, CO can be a potential problem. Ozone can be a concern when high-energy gas-shielded welding is conducted, particularly on aluminum and stainless steel plate. It is produced in the immediate arc area as well as in the surrounding environment. Oxides of nitrogen can be present in some plasma welding and cutting applications (Ref 14).

Shielding Gases for Welding

Kevin A. Lyttle, Praxair, Inc.

Self-Shielded Flux-Cored Arc Welding

The self-shielded flux-cored wire welding process employs a continuous wire electrode that requires no external shielding. These cored wires generate protective shielding gases from components in the core material similar to those found in coated electrodes. The unique feature of this class of consumables is that they rely only partly on the exclusion of air from the molten electrode and weld pool to produce a quality deposit. In addition to deoxidizers, they contain denitriders to react with nitrogen that may be entrained in the molten metal. The less a given consumable relies on shielding and the more it relies on "killing" to control nitrogen and produce sound weld metal, the less that consumable will be affected by cross air currents and side winds.

Through careful control of welding parameters and the proper balance of core constituents, good-quality weld metal can be obtained under poor welding conditions. Self-shielded flux-cored wires are especially suited to welding outdoors, where it is difficult to provide acceptable external gas shielding. Both light- and heavy-gage materials have been successfully joined with these electrodes.

Shielding Gases for Welding

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

Introduction

SOLID-STATE TRANSFORMATIONS occurring in a weld are highly nonequilibrium in nature and differ distinctly from those experienced during casting, thermomechanical processing, and heat treatment. This discussion will primarily focus on the welding metallurgy of fusion welding of steels and attempt to highlight the fundamental principles that form the basis of many of the recent developments in steels and consumables for welding. Accordingly, examples are largely drawn from the well-known and relatively well-studied case of ferritic steel weldments to illustrate the special physical metallurgical considerations brought about by the weld thermal cycles and by the welding environment. Because of space limitations, only a very brief discussion is included on welds in other alloy systems such as stainless steels and aluminum-base, nickel-base, and titanium-base alloys. For detailed information on how the principles explained in the first part of this article (using steel weldments as an example) are applicable to other materials, the reader is referred to the Sections where individual alloy systems are discussed (see "Selection of Stainless Steels," "Selection of Nonferrous Low-Temperature Materials," "Selection of Nonferrous High-Temperature Materials," and "Selection of Nonferrous Corrosion-Resistant Materials" in this Volume).

A concise method of describing the transformation behavior of a steel is by a continuous cooling transformation (CCT) diagram (Fig. 1). However, a conventional CCT diagram such as the one shown in Fig. 1 cannot be used to accurately describe the transformation behavior in a weldment of the same material because weld thermal cycles are very different from those used for generating conventional CCT diagrams.

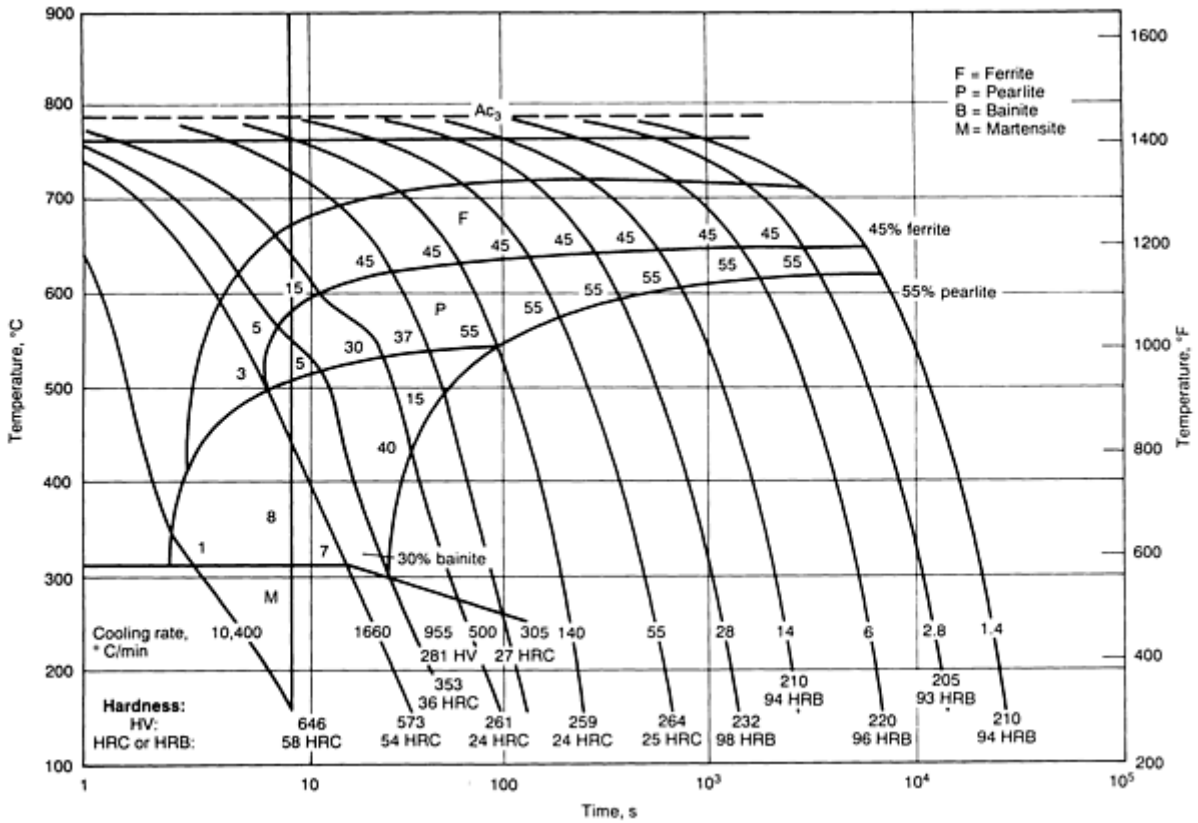

FIG. 1 CONVENTIONAL CCT DIAGRAM FOR AISI 1541 (0.39C-1.56MN-0.21SI-0.24S-0.010P) PLAIN CARBON STEEL WITH ASTM NUMBER 8 GRAIN SIZE AND AUSTENITIZATION AT 980 °C (1800 °F). FOR EACH OF THE COOLING CURVES IN THE PLOT (GIVEN IN TERMS OF °C/MIN), THE TRANSFORMATION START AND END TEMPERATURES GIVEN BY THE CCT CURVES, THE AMOUNT OF EACH TRANSFORMATION PRODUCT, AND THE HARDNESS OF THE FINAL STRUCTURE ARE SHOWN. AC_3, 788 °C (1450 °F); AC_1, 716 °C (1321 °F). F, FERRITE; P, PEARLITE; B, BAINITE; M, MARTENSITE. SOURCE: REF 1

Special Factors Affecting Transformation Behavior in a Weldment

Several aspects of the weld thermal cycle and weld segregation should be considered because of their effect on the transformation upon cooling:

- PEAK TEMPERATURES REACHED IN THE HEAT-AFFECTED ZONE (HAZ) CAN BE VERY MUCH HIGHER THAN THE AC_3 TEMPERATURE (THAT IS, THE TEMPERATURE AT WHICH TRANSFORMATION OF FERRITE TO AUSTENITE IS COMPLETED DURING HEATING). THE HEATING RATES ARE VERY HIGH, AND THE TIMES SPENT AT HIGH TEMPERATURE ARE ONLY OF THE ORDER OF A FEW SECONDS.
- THE TEMPERATURE GRADIENT IN THE HAZ IS VERY STEEP, AND THIS COMPLICATES THE PROBLEM OF STUDYING IN *IN SITU* TRANSFORMATIONS IN THE HAZ DURING WELDING (REF 2).
- DURING SOLIDIFICATION OF THE WELD METAL, ALLOYING AND IMPURITY ELEMENTS TEND TO SEGREGATE EXTENSIVELY TO THE INTERDENDRITIC OR INTERCELLULAR REGIONS UNDER THE CONDITIONS OF RAPID COOLING. ALSO, THE PICKUP OF ELEMENTS LIKE OXYGEN BY THE MOLTEN WELD POOL LEADS TO THE ENTRAPMENT OF OXIDE INCLUSIONS IN THE SOLIDIFIED WELD. THESE INCLUSIONS THEN SERVE AS HETEROGENEOUS NUCLEATION SITES AND CAN SUBSTANTIALLY INFLUENCE THE KINETICS OF SUBSEQUENT SOLID STATE TRANSFORMATIONS. ACCORDINGLY, THE WELD METAL TRANSFORMATION BEHAVIOR IS QUITE DIFFERENT FROM THAT OF THE BASE METAL, EVEN THOUGH THE NOMINAL CHEMICAL COMPOSITION HAS NOT BEEN SIGNIFICANTLY CHANGED BY THE WELDING PROCESS (REF 3). MOST OF THE CCT DIAGRAMS (APPLICABLE TO THE WELD METAL) HAVE BEEN GENERATED BY REHEATING THE AS-DEPOSITED WELD METAL (REF 4). ONE OF THE LIMITATIONS OF THESE DIAGRAMS IS THAT THEY ARE STRICTLY APPLICABLE ONLY TO THE HIGH-TEMPERATURE REHEATED ZONE OF MULTIPASS WELDS, BECAUSE THE INITIAL MICROSTRUCTURE AT HIGH TEMPERATURES IS NOT CHARACTERISTIC OF THAT DEVELOPED FROM THE LIQUID PHASE.
- WELDING MAY BE CARRIED OUT IN SEVERAL PASSES, AND THIS MAY RESULT IN THE SUPERPOSITION OF SEVERAL DIFFERENT HEATING AND COOLING CYCLES AT ONE POINT, EACH OF THESE CYCLES HAVING THE CHARACTERISTICS NOTED ABOVE.
- SOLIDIFICATION OF THE WELD METAL IS ACCOMPANIED BY SHRINKAGE, AND THE ANISOTHERMAL CONDITIONS ALREADY EMPHASIZED CAUSE DEFORMATION. THE THERMAL CYCLES ARE THEREFORE ACTING ON METAL THAT IS SUBJECTED TO MECHANICAL STRESSES AT THE SAME TIME.

The essential differences between weld thermal cycles and then thermal cycles used for generating a conventional CCT diagram are summarized in Fig. 2. Figure 2(a) shows thermal cycles which involve a slow heating rate, soak at a temperature just above the Ac_3 temperature, and various constant cooling rates. Instead of a constant cooling rate, some investigators (Ref 5) have used cooling curves according to Newton's law of cooling:

$$T \propto E^{-T} \qquad \textbf{(EQ 1)}$$

where T is the temperature and t is the time. Others have used cooling curves corresponding to the mid-radial position of cylindrical bars of different diameters when cooled in air or when quenched in different media. The weld thermal cycles shown in Fig. 2(b) are very different, and this is why a conventional CCT diagram can give only an approximate idea of the transformation behavior in the HAZ of a weldment.

HAZ of a Single-Pass Weld

Peak Temperature-Cooling Time Diagrams. The gradient in microstructure than can be obtained in a single-pass weld is shown in Fig. 3. High peak temperatures in the HAZ just adjacent to the fusion line cause coarsening of the austenite (γ) grains, and this in turn increases the hardenability of this region compared to other regions. Because each of the subzones shown in Fig. 3 occurs in a small volume, it is difficult to study the transformation behavior of individual regions by *in situ* methods (Ref 2). It is more convenient to obtain information about the microstructural and property changes in the HAZ by weld simulation (Ref 6, 7). A thermal cycle simulator (TCS) is used to reproduce the thermal cycle corresponding to a point in the HAZ in a large volume (usually a specimen has the Charpy test specimen dimensions). It is possible to program the required thermal cycle in the TCS so that the peak temperature and the cooling rate can be varied independently. It is thus possible to obtain information about the microstructural changes in the HAZ for a wide range of welding parameters.

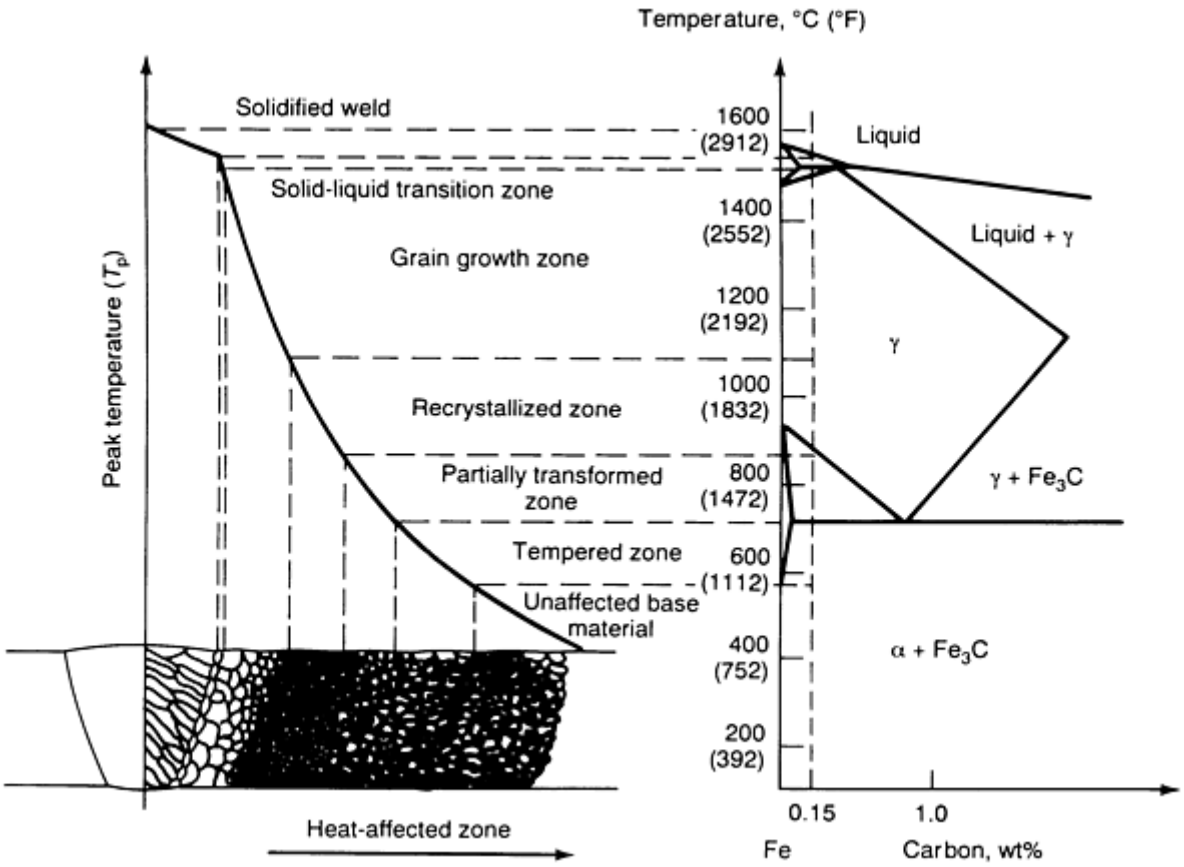

FIG. 3 SCHEMATIC SHOWING VARIOUS SUBZONES THAT CAN FORM IN THE HAZ OF A CARBON STEEL CONTAINING 0.15% C. SOURCE: REF 6

Figure 4 shows how a change in the peak temperature of the thermal cycle affects the CCT characteristics of a steel. The well-known effect of a larger γ grain size (due to a higher peak temperature) in increasing the hardenability of the steel is seen. To present the information about the CCT behavior for a number of peak temperatures (see Fig. 2b and 3), it is more convenient to adopt the scheme shown in Fig. 5. In this peak temperature-cooling time (PTCT) diagram (Ref 8, 9), each point represents a weld thermal cycle with a peak temperature, T_p, given by the ordinate and the cooling time, $\Delta t_{8\text{-}5}$ (that is, required for cooling from 800 to 500 °C, or 1470 to 930 °F), given by the abscissa. A microstructural constituent or a combination of two or more constituents is shown to occur over an area in the diagram. The upward slope in the boundary between two areas is consistent with the information presented earlier in Fig. 4 that the hardenability increases with an increase in the peak temperature of the thermal cycle. Hardness and C_v transition temperatures are also shown in the diagram corresponding to different thermal cycles.

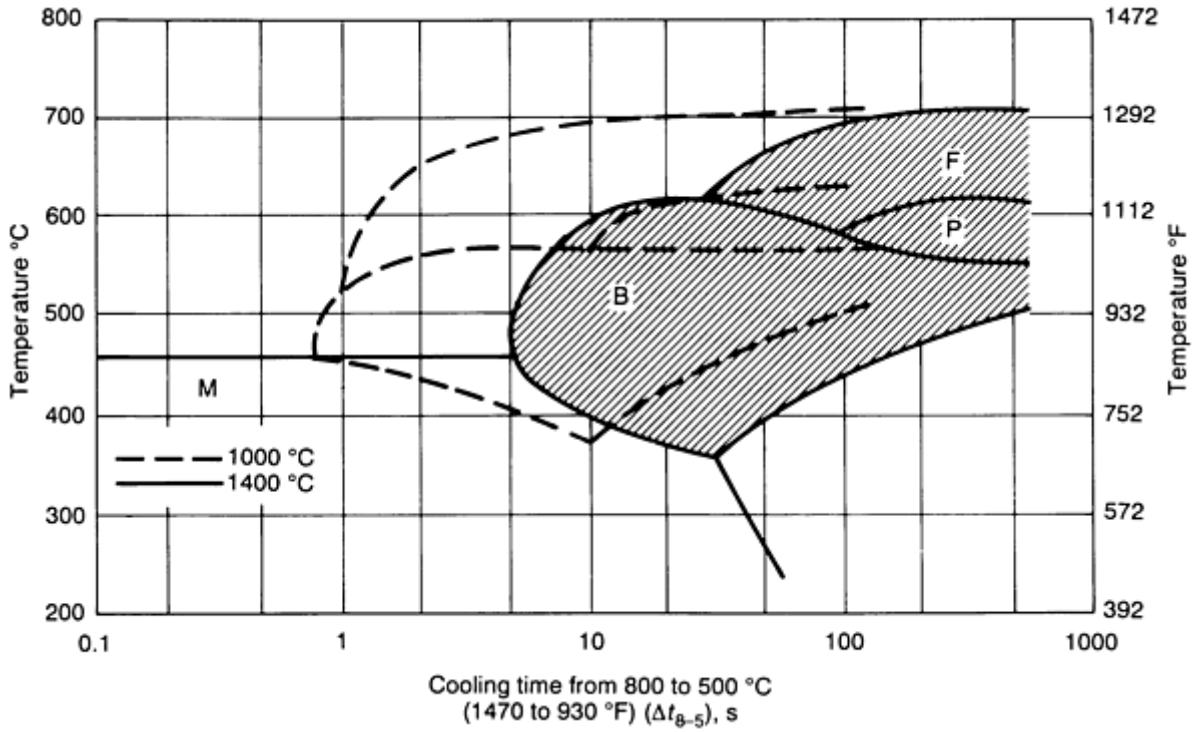

FIG. 4 EFFECT OF A CHANGE IN THE PEAK TEMPERATURE OF THE WELD THERMAL CYCLE (FROM 1000 TO 1400 °C, OR 1830 TO 2550 °F) ON THE CCT CHARACTERISTICS. M, MARTENSITE; B, BAINITE; P, PEARLITE; F, FERRITE. SOURCE: REF 8

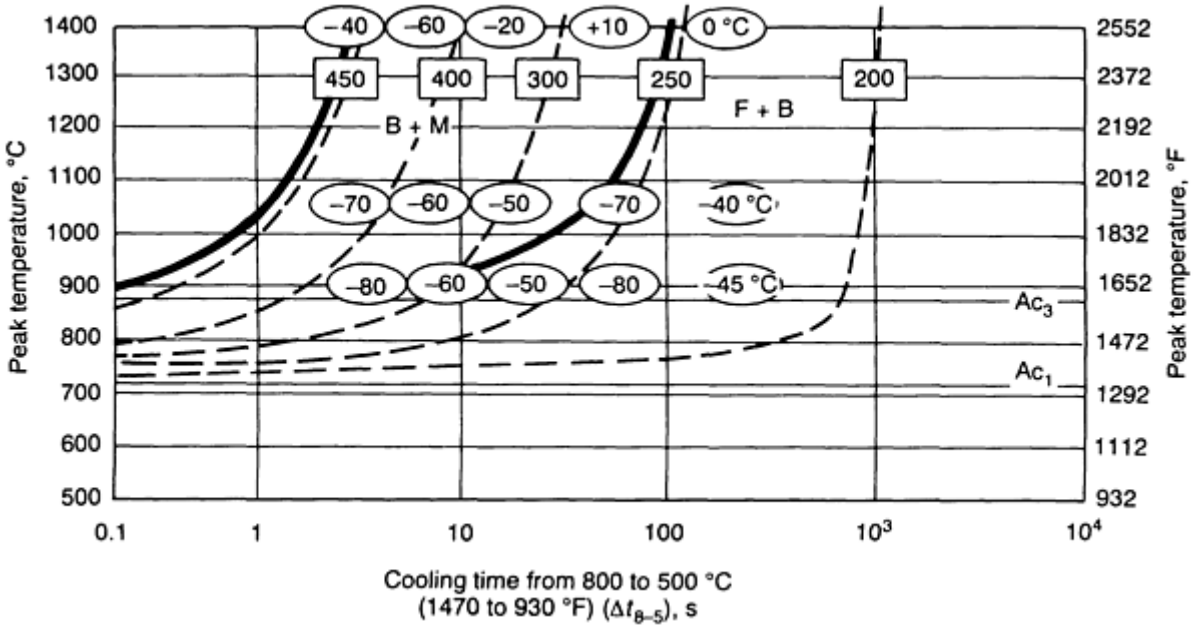

FIG. 5 TYPICAL PEAK TEMPERATURE VERSUS COOLING TIME DIAGRAM, SHOWING THE EFFECTS OF THESE PARAMETERS OF A WELD THERMAL CYCLE ON THE FINAL TRANSFORMATION PRODUCTS, ON HARDNESS, AND CHARPY V-NOTCH IMPACT ENERGY. M, MARTENSITE; B, BAINITE; F, FERRITE. FIGURES IN SQUARES INDICATE THE HARDNESS (30 HV); FIGURES IN OVALS INDICATE THE 21 J (16 FT · LBF) TRANSITION TEMPERATURES FOR CHARPY V-NOTCH IMPACT SPECIMENS SUBJECTED TO A SPECIFIC THERMAL CYCLE. SOURCE: REF 9

It may appear strange that the CCT diagram shown in Fig. 4 is plotted with $\Delta t_{8\text{-}5}$ as the abscissa instead of time as in Fig. 1. Historically, the practice of thinking in terms of a cooling time began when a need was recognized (Ref 5) to compare the CCT behavior of specimens subjected to different types of cooling curves--Jominy specimens; cylindrical bars cooled in air, water, or oil; dilatometer specimens cooled at a constant or a Newtonian rate; and so on. Initially, the cooling rate at 704 °C (1300 °F) was used as a criterion to judge the equivalency of these specimens in terms of microstructure and hardness. Because transformation takes place at lower temperatures in many steels, the half cooling time (Ref 5) was found to be a better equivalency criterion. The half cooling time was defined as the time to cool from Ac_3 to a temperature that lies midway between Ac_3 and room temperature. For the sake of general applicability, this was later modified to the $\Delta t_{8\text{-}5}$ criterion, and CCT diagrams began to be plotted with $\Delta t_{8\text{-}5}$ as the abscissa. It must be noted that using $\Delta t_{8\text{-}5}$ as an equivalency criterion is just an expedient solution that does not have strict theoretical justification (refer, for example, to the additivity principle in Ref 5).

A special significance of using $\Delta t_{8\text{-}5}$ as the abscissa in Fig. 5 is that it is almost constant (for T_p > 900 °C, or 1650 °F) in the whole of the HAZ. This can be seen from Ref 6, where the expressions given for $\Delta t_{8\text{-}5}$ do not contain the distance from the weld centerline as a factor. The derivation of these expressions is based on the assumption that the time to cool to 800 °C (1470 °F) is far greater than the time to reach the peak temperature, so the $\Delta t_{8\text{-}5}$ can be taken to be the same for the whole of the weld and the HAZ. This can be intuitively rationalized by observing that the thermal cycles in Fig. 2(b) are such that the curves are approximately parallel below 800 °C (1470 °F). The constancy of $\Delta t_{8\text{-}5}$ in the HAZ means that the gradient in microstructure (in terms of the final transformation products from austenite) is mainly due to a variation in the peak temperature. By drawing a vertical line in Fig. 5 at a value of $\Delta t_{8\text{-}5}$ corresponding to a given heat input and preheating temperature, it is possible to get information about the type of microstructural gradient in the HAZ. An idea of property changes like hardness and toughness can also be obtained from Fig. 5.

A fairly satisfactory correlation between real welds and simulation studies has been observed with respect to microstructure and property measurements. However, it has frequently been observed that the maximum prior to austenite grain size in real welds is less than that in corresponding simulation specimens (Ref 2, 6, 7). It is believed that this is due to the growth of large grains in the HAZ of real welds being hindered by the adjacent smaller grains. The constraint arises from the fact that grain growth in real welds is in some sense directional, occurring from the fusion line toward lower temperatures, while under the simulation condition the austenite grains can grow in all directions.

The above discussion shows that the PTCT diagram (along with property measurements, as in Fig. 5) can alert the user to the possibility of local brittle zones in actual weldments, and that any error in the property being assessed will be on the conservative side.

While the expressions for $\Delta t_{8\text{-}5}$ given Ref 6 (to determine the point at which a vertical line is to be drawn in the PTCT diagram) are reasonably accurate, those for T_p may be grossly in error because they are derived from a model with many simplistic assumptions (Ref 10, 11). For this reason, although an idea of the type of microstructural gradient in the HAZ can be obtained from the PTCT diagram, it is not possible to calculate the width of each region using simple closed form solutions of the type given in Ref 6 (derived from Rosenthal's equations). Moreover, T_p and $\Delta t_{8\text{-}5}$ are alone not enough to completely characterize a weld thermal cycle. To improve the accuracy of simulation, it would be necessary to program the thermal cycle with heating rates and the shape of the thermal cycle at higher temperatures, as in the HAZ of real welds. The significance of these additional factors is discussed below.

Continuous Heating Transformation Diagrams. The heating rate in many welding processes can be very high. The implication is that considerable superheating may be required for the transformation to austenite on heating. That is, the Ac_1 and Ac_3 temperatures will be raised with an increase in the heating rate (Ref 11). This is seen in Fig. 6, a continuous heating transformation (CHT) diagram, which is analogous to a CCT diagram. It is seen that grain growth begins only after the carbides have dissolved and after a homogeneous austenite (with respect to the distribution of carbon, at least) is formed.

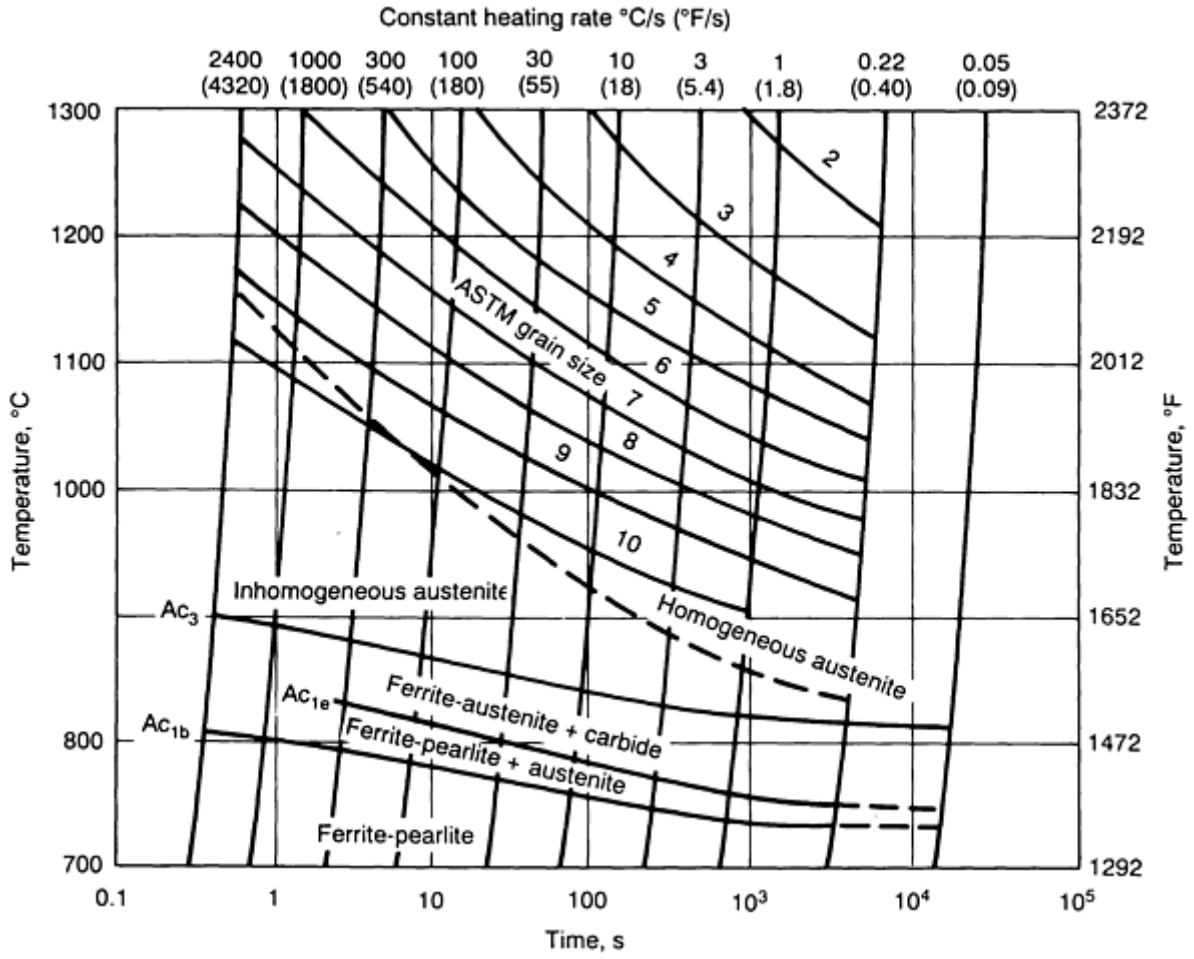

FIG. 6 CONTINUOUS HEATING TRANSFORMATION DIAGRAM FOR 34CRMO4STEEL. IN THE REGION OF HOMOGENEOUS AUSTENITE THERE ARE LINES OF CONSTANT AUSTENITE GRAIN SIZE (ASTM NUMBERS). BECAUSE OF THE MEASURING PROCEDURE, THE DIAGRAMS CAN ONLY BE INTERPRETED ALONG LINES OF CONSTANT HEATING RATE. TO SHOW THE HEATING TIME MORE CLEARLY, A TIME SCALE IS ADDED. SOURCE: REF 12

Precipitate Stability and Grain Boundary Pinning. In the last three decades, there has been a surge in the development of microalloyed or high-strength low-alloy (HSLA) steels (base metals). Almost the entire thrust behind this effort has been to tailor the thermomechanical processing of these steels to produce a fine grain size (Ref 13). Previously, higher strength was obtained by alloying the steel sufficiently to increase the hardenability and then heat treating to obtain a tempered martensitic structure. The higher carbon equivalent (Ref 6, 14) in these alloy steels led to an increased susceptibility to cold cracking or hydrogen-induced cracking. In the microalloyed steels, however, alloying additions are kept to a minimum, and higher strength is achieved primarily by a reduction in the grain size and by precipitation strengthening. A reduction in grain size is the only known method of increasing the strength and toughness at the same time. Because strengthening is obtained by other means, both carbon and carbon equivalent can be decreased to significantly reduce the susceptibility to cold cracking in these new HSLA steels (Fig. 7).

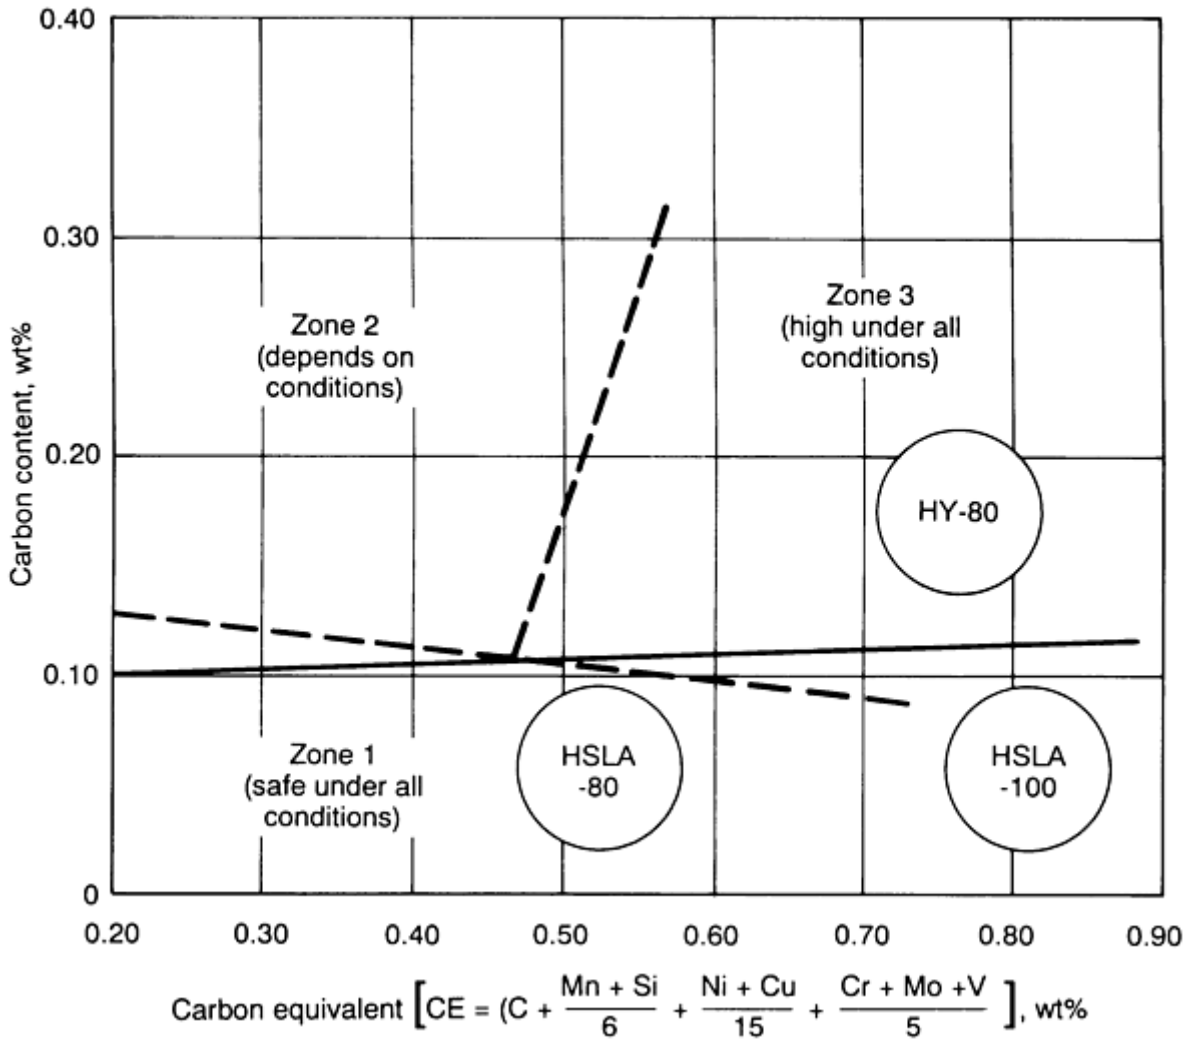

FIG. 7 EFFECT OF STEEL COMPOSITION (HY-80, HSLA-80, HSLA-100) ON THE SUSCEPTIBILITY TO COLD CRACKING IN THE HAZ. SOURCE: REF 13

A fine ferrite grain size in these steels is best achieved (after thermomechanical processing) by obtaining a fine austenite grain size before the γ-α transformation (Ref 13). To realize this goal, it is essential that microalloy additions such as niobium, vanadium, titanium, and aluminum are present so that the fine precipitate particles they form with nitrogen, carbon, or oxygen can "pin" the austenite grain boundaries and inhibit grain coarsening. The pinning effect arises from the fact that when a short length of grain boundary is replaced by a precipitate particle, the effective grain boundary energy is lowered. When the grain boundary attempts to migrate away from the particles, the local energy increases and a drag is exerted on the boundary by the particles.

In the HAZs of welds in these microalloyed steels, it is not possible to get the same optimum microstructure and microalloy precipitation obtained in the parent material by controlled thermomechanical processing. Because peak temperatures are much higher in the HAZ, the precipitate particles coarsen and dissolve, resulting in reduced pinning forces and therefore coarser austenite grains. This effect can be minimized by having precipitate particles that do not dissolve, even at higher temperatures. An idea of the stability of precipitate particles can be obtained from the plot shown in Fig. 8. It is seen that TiN has maximum stability, and this has been used to advantage in many steel. The other carbides and nitrides are not as effective as titanium nitride in limiting the extent of grain coarsening; they play a bigger role during thermomechanical processing (Ref 13).

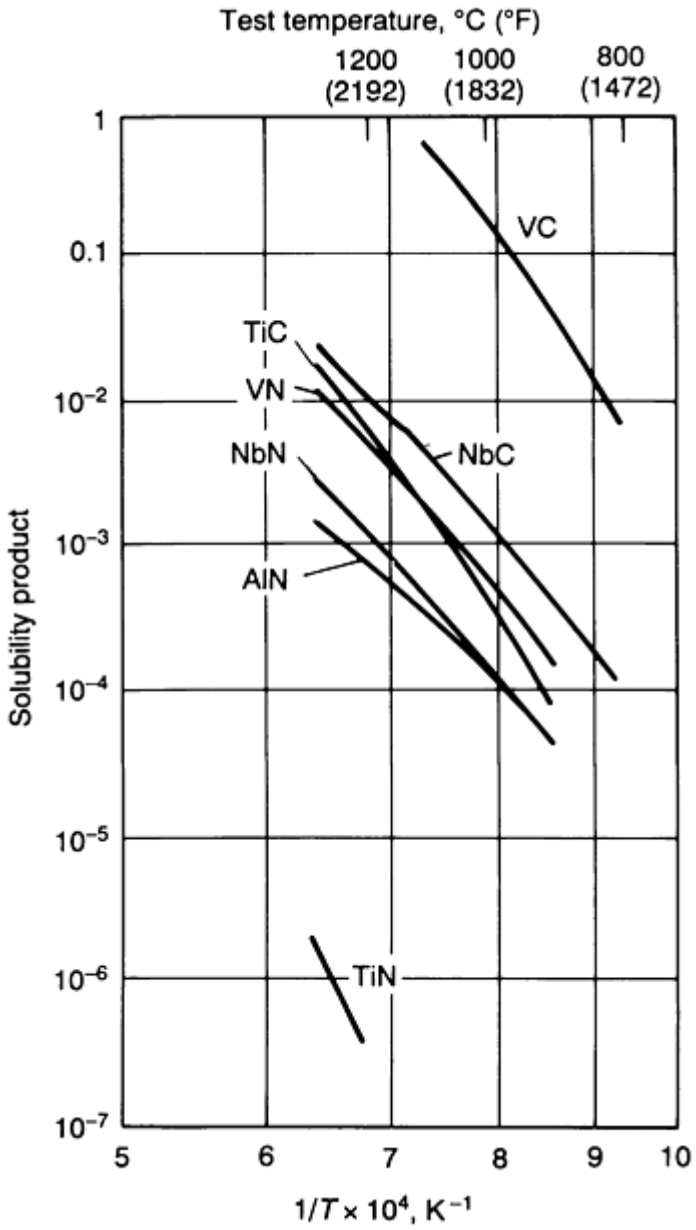

FIG. 8 SOLUBILITY PRODUCTS OF CARBIDES AND NITRIDES AS A FUNCTION OF TEMPERATURE. SOURCE: REF 15

Figure 9 shows how a high volume fraction of fine precipitate particles is needed to maximize the pinning effect. It also shows that heating to high temperatures increases the size of the particles, by a process known as Ostwald ripening (Ref 6), and decreases their volume fraction due to dissolution. This means that it is only possible to limit, and not to totally stop, grain coarsening in the HAZ, especially in high heat input welds. This inevitable grain coarsening is actually used to advantage in titanium, oxide steels (see the section "Titanium Oxide Steels" in this article).

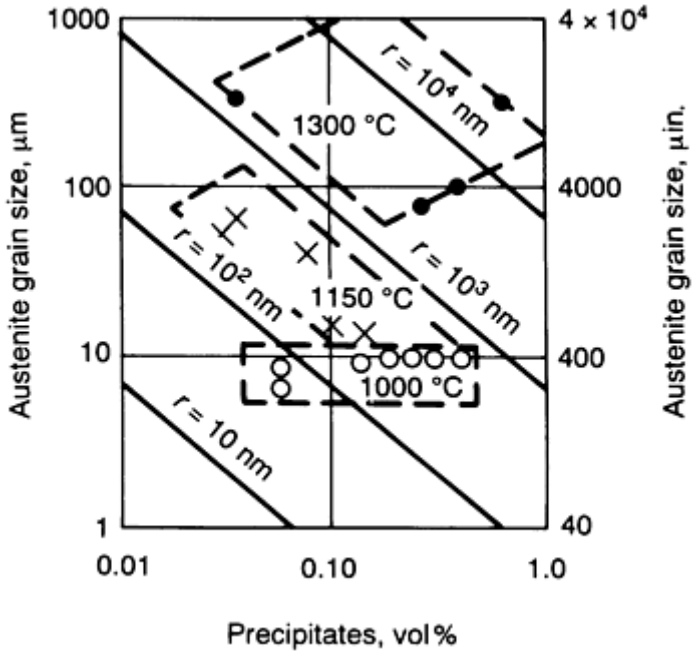

FIG. 9 EFFECT OF PARTICLE RADIUS, *R,* AND AMOUNT OF PRECIPITATE ON AUSTENITE GRAIN SIZE. SOURCE: REF 16

Unmixed and Partially Melted Zones in a Weldment. It is common to think of a single-pass weld as consisting of two zones: weld metal and HAZ. Careful metallographic examination has shown that a weld can in fact be divided into four regions (Fig. 10):

- *THE COMPOSITE ZONE,* IN WHICH A VOLUME OF BASE METAL MELTED BY THE SUPERHEATED FILLER METAL EXPERIENCES COMPLETE MIXING TO PRODUCE AN ALLOY WITH NOMINAL COMPOSITION INTERMEDIATE BETWEEN THAT OF THE BASE METAL AND THAT OF THE FILLER METAL.
- *THE UNMIXED ZONE,* WHICH FORMS FROM THE STAGNANT MOLTEN BOUNDARY LAYER REGION (ABOUT 100 TO 1000 μM, OR 0.004 TO 0.040 IN., THICK) AT THE OUTER EXTREMITIES OF THE COMPOSITE REGION. BECAUSE NO MECHANICAL MIXING WITH THE FILLER METAL OCCURS HERE, THE COMPOSITION OF THE METAL IN THIS REGION IS IDENTICAL TO THAT OF THE BASE METAL, EXCEPT FOR MINOR CHANGES PRODUCED BY DIFFUSION.
- *THE PARTIALLY MELTED ZONE,* WHICH IS A REGION AT THE FUSION BOUNDARY WHERE THE PEAK TEMPERATURES FALL BETWEEN THE LIQUIDUS AND SOLIDUS SO THAT MELTING IS INCOMPLETE.
- *THE TRUE HEAT-AFFECTED ZONE,* WHICH IS THAT PORTION OF THE BASE METAL WHERE ALL MICROSTRUCTURAL CHANGES INDUCED BY WELDING OCCUR IN THE SOLID STATE.

Special metallographic procedures are needed to reveal the existence of these special zones, as shown in Fig. 11.

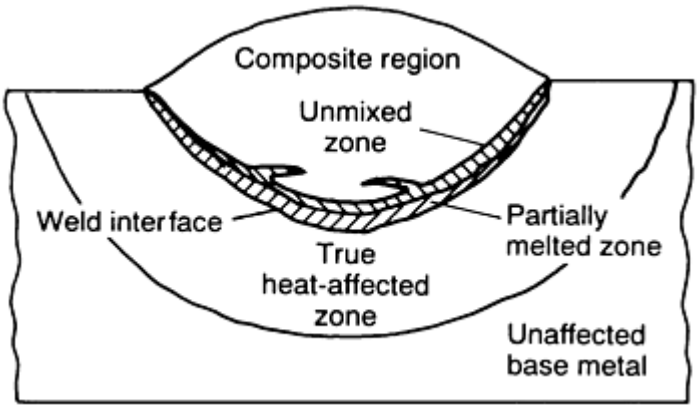

FIG. 10 SCHEMATIC SHOWING THE DIFFERENT DISCRETE REGIONS PRESENT IN A SINGLE-PASS WELD. SOURCE: REF 17

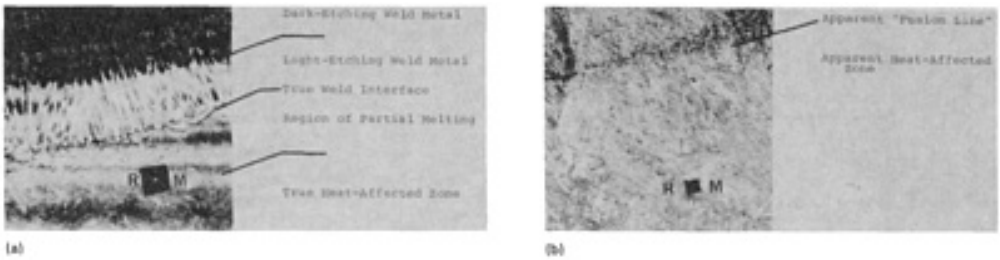

FIG. 11 SPECIAL METALLOGRAPHIC PROCEDURES SHOW THE MICROSTRUCTURE OF DISCRETE REGIONS (SEE FIG. 10) IN AN HY-80 WELD. (A) MICROSTRUCTURE OBTAINED NEAR A REFERENCE MARK (INDICATED BY "RM") USING A TWO-STAGE NITAL AND SODIUM BISULFITE PROCEDURE. (B) MICROSTRUCTURE AT IDENTICAL LOCATION REPOLISHED AND ETCHED WITH NITAL ONLY. TWO-STAGE PROCEDURE SHOWS MUCH GREATER DETAIL. SOURCE: REF 17

The width of the partially melted zone can be extended by a phenomenon known as constitutional liquation (Ref 18), whereby melting can occur even when the peak temperature is less than the solidus temperature. This can be understood by referring to a phase diagram for a simple binary system A and B (Fig. 12). Consider an alloy of composition C. Its equilibrium structures at temperatures T_1, T_2, T_3 and T_4 are α+ β, α, α, and L + α, respectively (Fig. 12a). On heating from room temperature to T_3 and holding at this temperature for a long time, the βparticles will dissolve and give a homogeneous α of composition C. However, under conditions of rapid heating in the HAZ, the dissolution of β will give rise to a solute concentration gradient around each particle, as shown in Fig. 12(b). In the region surrounding each particle, the concentration of the solute B will correspond to that of liquid because, as the phase diagram shows, a liquid phase must exist between α and β at T_3. This phenomenon of localized melting due to a nonequilibrium distribution of phases during rapid heating is called constitutional liquation.

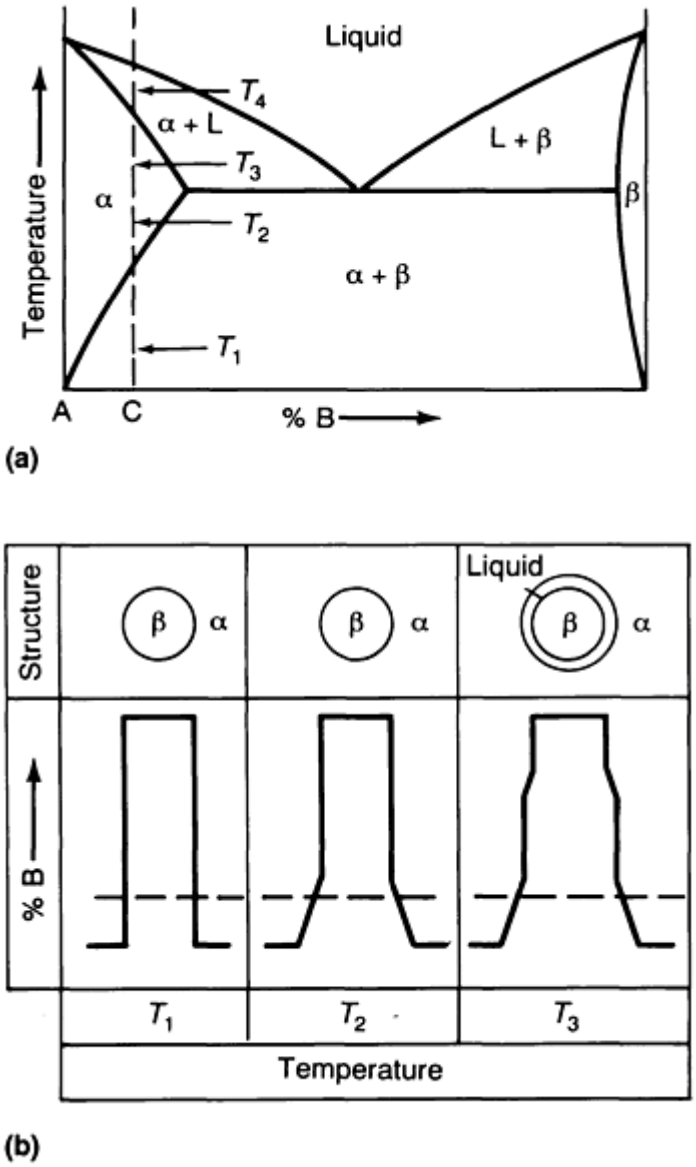

FIG. 12 EXTENSION OF PARTIALLY MELTED ZONE BY CONSTITUTIONAL LIQUATION. (A) PHASE DIAGRAM FOR A SIMPLE BINARY ALLOY. (B) STRUCTURES AND DISTRIBUTION OF CONSTITUENT B IN ALLOY C AT THREE TEMPERATURES SHOWN IN (A) WHEN RAPID HEATING IS APPLIED. SOURCE: REF 19

The partially melted zone is the region where liquation cracks have been known to occur in maraging steels, austenitic stainless steels, heat-treatable aluminum alloys, and nickel-base superalloys. It can also be a site where hydrogen-induced cracking is initiated (Ref 17), because it can act as a pipeline for the diffusion of hydrogen picked up by the molten weld metal and also because of the higher hardenability at these segregated regions.

While the phenomenon of constitutional liquation is usually discussed in connection with liquation cracking of aluminum- and nickel-base alloys (Ref 14, 18, 19), a more dramatic example can actually be found in the case of cast iron welds (Ref 20). Figure 13 shows the micro structure of the HAZ in a cast iron weld deposited using a "quench welding" technique (Ref 21). This procedure involves welding without any preheat by intermittently depositing a series of small stringer beads and strictly maintaining the interpass temperature below about 80 °C (175 °F). The idea is to limit the size of the hard and brittle white iron colonies forming by constitutional liquation around the graphite nodules and to see that they do not interconnect. By contrast, a procedure involving a preheat of about 200 °C (390 °F) can prevent the formation of martensite but not the formation of ledeburite (the structure of white iron). Because ledeburite forms at higher temperatures than martensite (≈1100 °C, or 2010 °F), a much higher preheat temperature of about 600 °C (1110 °F) is required to significantly reduce the cooling rate at the higher temperatures, thereby preventing the formation of white iron. This high level of preheat is impractical. While cast iron appears to have been successfully welded with preheats of

about 200 °C (390 °F), it has sometimes been found that weld repair is most effective using the quench welding technique, by which it is possible to limit both the amount of ledeburite formed and the width of the HAZ.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

Fusion Zone of a Single-Pass Weld

Transformations in Single-Pass Weld Metal. It is usually not necessary to select a filler metal that has exactly the same composition as the base metal; it is more important that the weld metal has the same strength and other properties (such as toughness or corrosion resistance). Because these properties are governed by the microstructure, it is important to understand the influence of different factors on phase transformations in the weld metal. But first, for a meaningful communication of the different features in a microstructure, the various phases and microconstituents must be identified using a system of nomenclature that is both widely accepted and well understood. In wrought steels, this need has been satisfied to a large degree by the Dubé scheme (Ref 22) for classifying the different morphologies of ferrite, as shown in Fig. 14. Similarly, confusion and controversy in the terminology for describing the microstructures in ferritic steel weld metals have been largely resolved by the classification scheme shown in Fig. 15. This scheme (Ref 23) was the result of several collaborative exercises undertaken under the auspices of the International Institute of Welding (IIW). Typical micrographs illustrating some of the microstructural constituents are shown in Fig. 16.

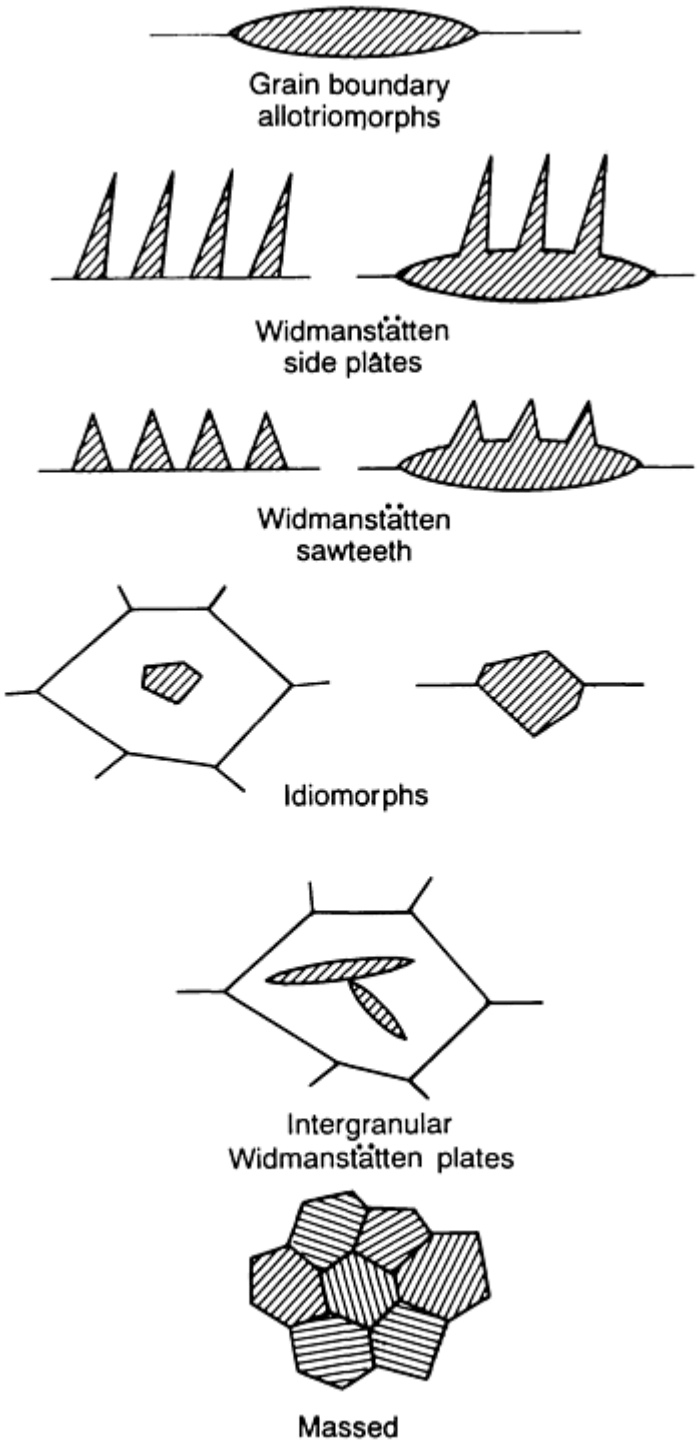

FIG. 14 SCHEMATICS SHOWING THE DUBÉ CLASSIFICATION OF FERRITE MORPHOLOGIES. SOURCE: REF 22

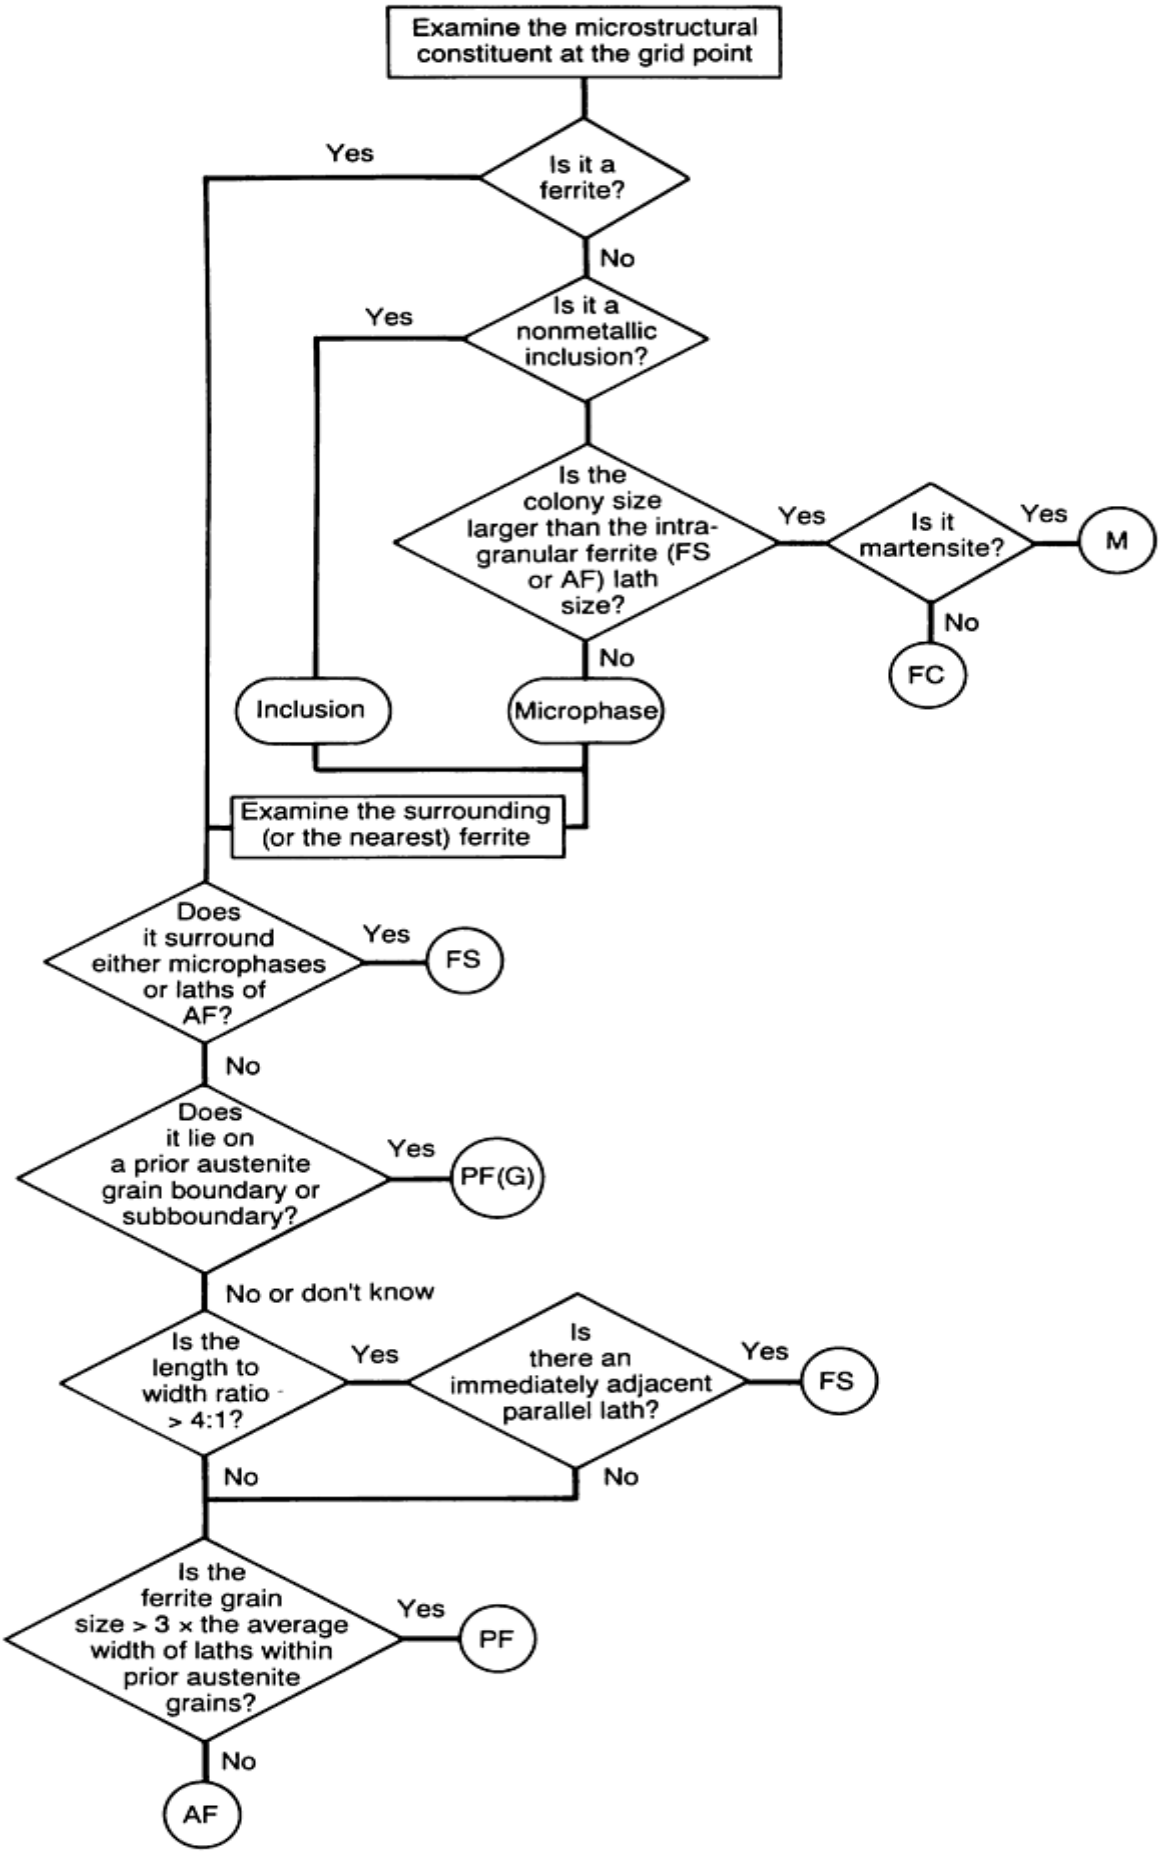

Examine the microstructural constituent at the grid point
Is it a ferrite?
Yes
No
Is it a nonmetallic inclusion?
Yes
Is the colony size larger than the intra-granular ferrite (FS or AF) lath size?
Yes
Is it martensite?
Yes
M
No
FC
No
Inclusion
Microphase
Examine the surrounding (or the nearest) ferrite
Does it surround either microphases or laths of AF?
Yes
FS
No
Does it lie on a prior austenite grain boundary or subboundary?
Yes
PF(G)
No or don't know
Is the length to width ratio > 4:1?
Yes
Is there an immediately adjacent parallel lath?
Yes
FS
No
No
Is the ferrite grain size > 3 × the average width of laths within prior austenite grains?
Yes
PF
No
AF

CATEGORY	ABBREVIATION
PRIMARY FERRITE	PF
GRAIN BOUNDARY FERRITE	PF(G)
INTRAGRANULAR POLYGONAL FERRITE	PF(I)
FERRITE WITH SECOND PHASE	FS
FERRITE WITH NONALIGNED SECOND PHASE	FS(NA)
FERRITE WITH ALIGNED SECOND PHASE	FS(A)
FERRITE SIDE PLATES	FS(SP)
BAINITE	FS(B)
UPPER BAINITE	FS(UB)
LOWER BAINITE	FS(LB)
ACICULAR FERRITE	AF
FERRITE-CARBIDE AGGREGATE	FC
PEARLITE	FC(P)
MARTENSITE	M
LATH MARTENSITE	M(L)
TWIN MARTENSITE	M(T)

SOURCE: REF 3

The transformation behavior in ferritic steel weld metals is best understood by first noting that ferrite is nucleated heterogeneously and that for all practical purposes, it is necessary to consider the competitive nucleation behavior only at grain boundaries and at inclusions. Figure 17 shows that inclusions have to be larger than a certain size (0.2 to 0.5 μm, or 8 to 20 μin., the typical size range of most weld metal inclusions) for their potency as nucleation sites to reach a maximum. It also shows that nucleation of ferrite is always energetically more favorable at grain boundaries than at inclusions. Based on additional considerations, like thermal contraction strains and lattice matching at inclusion-austenite-

ferrite interfaces (not taken into account to get the results in Fig. 17), a discussion of why certain inclusions are more potent nucleation sites than others is found in Ref 3, 24, and 25.

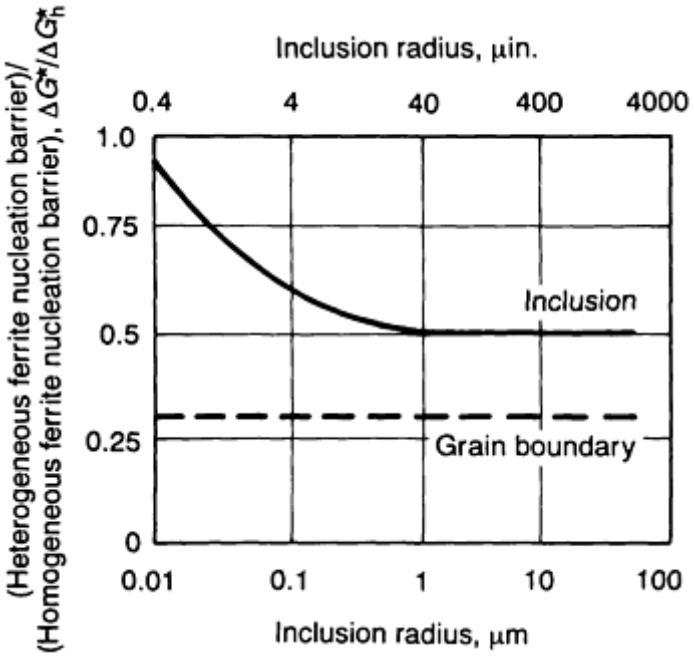

FIG. 17 EFFECT OF PARTICLE RADIUS ON ENERGY BARRIER TO FERRITE NUCLEATION AT INCLUSIONS, ΔG^* (HETEROGENEOUS), NORMALIZED RELATIVE TO THE HOMOGENEOUS NUCLEATION BARRIER, ΔG^*_H (HOMOGENEOUS). CORRESPONDING ENERGY BARRIER TO NUCLEATION OF FERRITE AT AUSTENITE GRAIN BOUNDARIES IS INDICATED BY HORIZONTAL BROKEN LINE. SOURCE: REF 6

Broadly, the major factors affecting transformation behavior in ferritic steel weld metals are alloy composition, weld heat input (by its effect on γ grain size and $\Delta t_{8\text{-}5}$), oxygen content (that is, the inclusion content), and the nature of segregation in the weld metal. A typical weld CCT diagram is shown in Fig. 18. For the cooling curve shown in the figure, the first phase that forms is allotriomorphic ferrite, or grain boundary ferrite in the IIW scheme. The term "allotriomorphic" means a "particle of a phase that does not have a regular external shape" and in the present context means that ferrite grows on the grain boundary surfaces and does not have a regular faceted shape reflecting the symmetry of its internal crystalline structure. At lower temperatures, the mobility of the curved or random γ/α-allotriomorph boundaries decreases, and Widmanstätten side plates (ferrite side plates in the IIW scheme) form. Growth of these side plates is rapid because carbon is efficiently redistributed to the sides of the growing tips, thus avoiding solute pile-up problems. In addition, substitutional atoms do not diffuse during the growth of Widmanstätten ferrite.

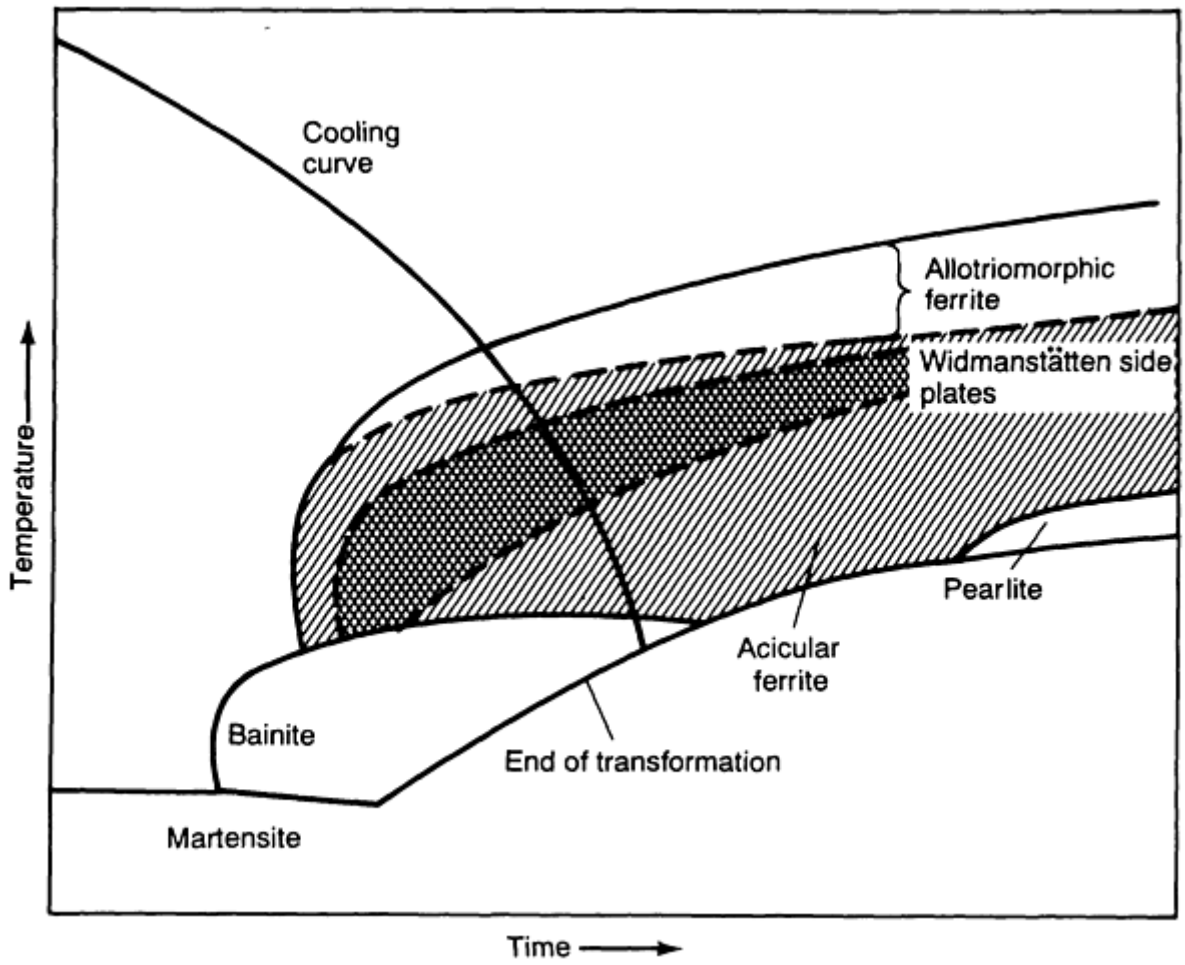

FIG. 18 SCHEMATIC OF WELD CCT DIAGRAM SHOWING SELECTED MICROSTRUCTURES

After all the grain boundary sites are saturated with allotriomorphic or Widmanstätten ferrite and their growth rate is not sufficient to extend to the interior of the grains, the nucleation of ferrite at inclusions within the γ grains becomes competitive. Acicular ferrite forms, a structure resulting from ferrite laths growing in different directions from inclusions and from laths already nucleated. Upon impingement, high-angle grain boundaries and a very fine dispersion of microphases are obtained between ferrite laths. "Microphases" in this context means the transformation structures resulting from the carbon-enriched regions between the ferrite laths and could be the martensite-austenite constituent, bainite, or pearlite (see the section "HAZ in Multipass Weldments" in this article). An example of the microstructure of acicular ferrite is shown in Fig. 19. Acicular ferrite does not figure in the Dubé scheme because it is rarely observed in wrought steels. When the cooling rate is higher or when the inclusion content is very low, bainite can be nucleated directly at the γ grain boundaries. Bainite can form as upper or lower bainite; the difference between the two is illustrated in Fig. 20. Examination with transmission electron microscopy (TEM) is usually required for a firm identification of the type of bainite formed. In the case of the highest cooling rates, martensite is obtained.

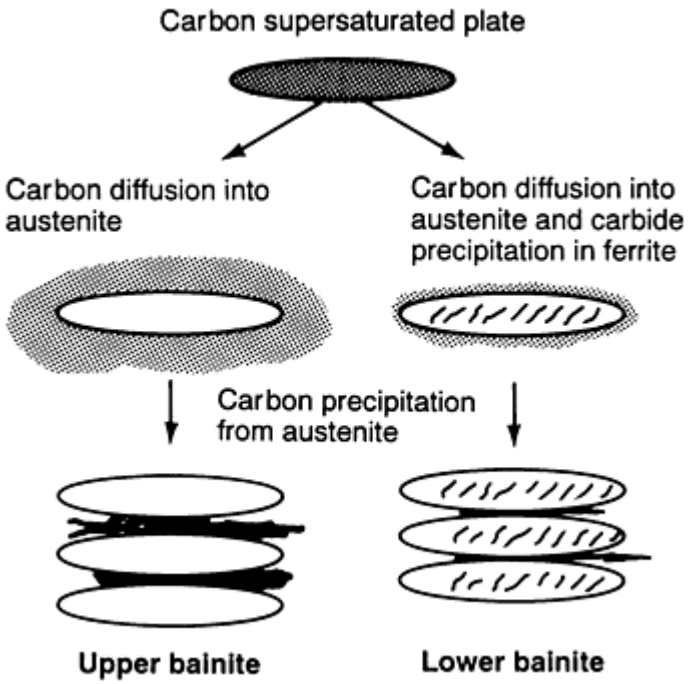

FIG. 20 SCHEMATIC SHOWING THE DIFFERENCES IN THE TRANSFORMATION MECHANISM FOR UPPER AND LOWER BAINITE AND THE EFFECT OF THESE MECHANISMS ON THE FINAL MORPHOLOGY. SOURCE: REF 24

Figure 21 shows the effect of alloying additions, $\Delta t_{8\text{-}5}$, oxygen content, and the γ grain size on the sequence and relative amounts of allotriomorphic ferrite, Widmanstätten ferrite, and bainite in the weld metal. Broadly, the trends shown can be understood in terms of the wellknown observation that an increase in γ grain size, a decrease in inclusion content, and an increase in alloying additions will shift the CCT curves to lower temperatures and to longer times. While Fig. 21 can generally be interpreted by assuming that the individual factors act independently of each other, the transition from (b) to (a) with an increase in the inclusion content must be understood in terms of its effect of the γ grain size. It has been observed that the γ grain size decreases with an increase in the inclusion content, and this has been explained by the higher magnitude of pinning forces at higher inclusion contents (Ref 25). The smaller grain size implies a greater grain boundary surface area, and this increases the amount of grain boundary ferrite and sideplate structures formed at the expense of acicular ferrite in Fig. 21(a). The role of the initial formation or non-formation of allotriomorphic ferrite at γ grain boundaries in bringing about the transition from Fig. 21(b) to Fig. 21(c) in Fig. 21 is discussed in the next section of this article.

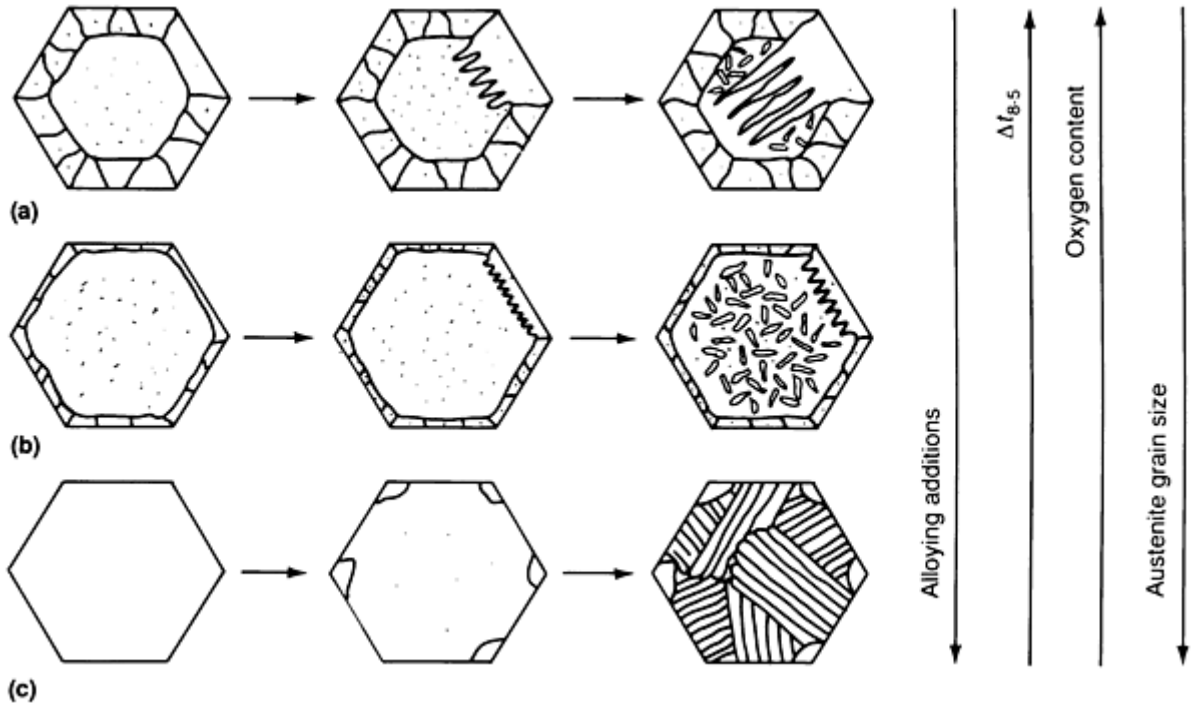

FIG. 21 SCHEMATIC SHOWING THE EFFECT OF ALLOY COMPOSITION, $\Delta T_{8\text{-}5}$, OXYGEN CONTENT, AND γ GRAIN SIZE ON THE DEVELOPMENT OF MICROSTRUCTURE IN FERRITIC STEEL WELD METALS. THE HEXAGONS REPRESENT CROSS SECTIONS OF COLUMNAR γ GRAINS. (A) THE GRAIN BOUNDARIES BECOME DECORATED FIRST WITH A UNIFORM, POLYCRYSTALLINE LAYER OF ALLOTRIOMORPHIC FERRITE, FOLLOWED BY FORMATION OF WIDMANSTÄTTEN FERRITE, AND THEN BY FORMATION OF ACICULAR FERRITE. (B) THE GROWTH RATE OF WIDMANSTÄTTEN FERRITE IS NOT SUFFICIENTLY HIGH TO EXTEND ENTIRELY ACROSS γ GRAINS. NUCLEATION OF FERRITE AT INCLUSIONS WITHIN THE γ GRAINS LEADS TO AN INCREASE IN THE AMOUNT OF ACICULAR FERRITE WHEN COMPARED WITH CASE (A). (C) THE HIGHER ALLOY CONTENT OR THE HIGHER COOLING RATE SUPPRESSES THE FORMATION OF ALLOTRIOMORPHIC FERRITE. THIS LEAVES THE γ GRAIN BOUNDARIES FREE TO NUCLEATE UPPER BAINITE. SOURCE: REF 24

Although the IIW classification is the result of a consensus viewpoint, some researchers (Ref 24) still feel that it places an exaggerated emphasis on morphological features observed with the light microscope. They believe that it is more important that the terminology reflect the mechanism of transformation. For example, it can be difficult to differentiate between Widmanstätten ferrite and upper bainite when using the light microscope, and both are identified as FS in the IIW classification. For a more fundamental understanding and to clearly interpret the trends in microstructural development, it is essential to make a distinction between the two. In addition, the subclassification of grain boundary ferrite in the IIW classification is not unequivocal in its meaning--it could refer to ferrite that forms by diffusion, Widmanstätten ferrite, or the ferrite in upper bainite. By contrast, the term "allotriomorphic ferrite" clearly identifies the mechanism by which it is formed. On the other hand, the IIW classification is easy to use and allows a more detailed identification, either by judgment or by further TEM examination, for example, to determine whether FS is FS(SP) or FS(UB). At least, it decreases the tendency for a wrong identification of the transformation mechanism with insufficient data. For a microstructure-toughness correlation, it is sufficient to characterize the morphological features.

Relating Weld Metal Toughness to the Microstructure. A good insight into the subject of toughness in ferrite steel weld metal is obtained by examining the data shown in Fig. 22. It is seen from Fig. 22(a) that the upper-shelf Charpy V-notch (CVN) energy monotonically decreases with an increase in oxygen content. In the upper-shelf temperature region, ductile fracture occurs by a process of microvoid coalescence, and because microvoids are initiated at the inclusion-matrix interface, the upper-shelf impact energy decreases with an increase in the inclusion content. By contrast, from Fig. 22(b) it is seen that an optimum inclusion content is required to obtain the lowest CVN transition temperature. The transition temperature is mainly governed by cleavage fracture, and this in turn depends on how effectively a propagating cleavage crack is forced to change direction as it traverses the microstructure. At low inclusion contents, an upper bainitic structure is obtained, and this consists of parallel platelets of ferrite (in a single packet) growing from the grain boundary surfaces. With an optimum inclusion content, a predominantly acicular ferrite structure is obtained, and here the adjacent

ferrite platelets tend to radiate in many different directions from inclusion nucleation site. At higher inclusion contents, the amount of ferrite sideplate structures increases, again having nearly parallel ferrite platelets. The highest toughness (that is, the lowest transition temperature) is obtained only in the "chaotic" microstructure of acicular ferrite because it has the smallest effective ferrite grain size.

In recognition of the latter fact, most of the work in consumables development in the recent past has concentrated on increasing the amount of acicular ferrite in the microstructure. In line with the trends shown in Fig. 21(a) and 21(b), it has been found that decreasing the amount of grain boundary ferrite and ferrite sideplate structures increases the acicular ferrite content. This is shown more clearly in Fig. 23.

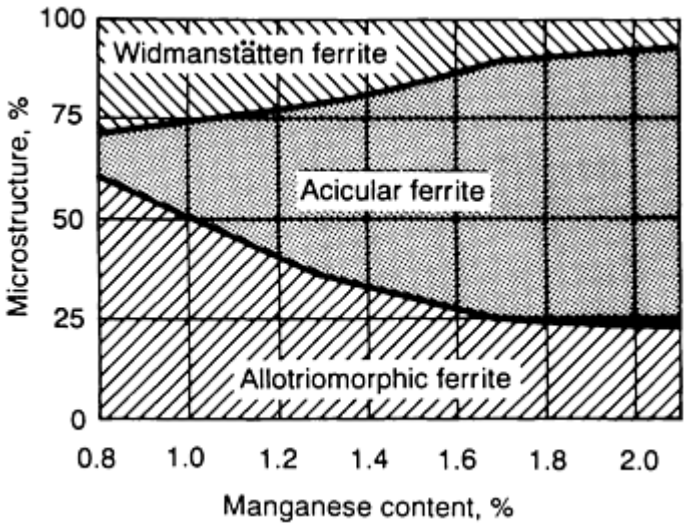

FIG. 23 EFFECT OF MANGANESE CONTENT OF WELD METAL ON THE RELATIVE AMOUNTS OF THE MICROSTRUCTURAL CONSTITUENTS PRESENT. CARBON CONTENT MAINTAINED AT 0.03%. SOURCE: REF 27

Recent work (Ref 24, 25, 27), however, has shown that a 100% acicular ferritic structure is neither desirable nor, in most cases, achievable. Figure 24 shows that the impact toughness peaks at about 70% acicular ferrite and then falls. This was attributed to the formation of segregated bands of brittle microphases in the alloy compositions giving the highest acicular ferrite contents. Moreover, when the alloying additions are increased still further, the transformation behavior becomes such that allotriomorphic ferrite formation is totally suppressed, leaving the γ grain boundaries free to nucleate upper bainite at lower temperatures (see Fig. 21c). It appears that a small layer of allotriomorphic ferrite is essential to obtain high acicular ferrite contents. When it forms, it saturates the γ grain boundary sites, and bainite nucleation at the γ/α-allotriomorphic interface is inhibited by the high carbon content there as a result of its rejection from the ferrite (Ref 24). Conditions are then favorable for intragranular nucleation at inclusion sites and thus the formation of acicular ferrite.

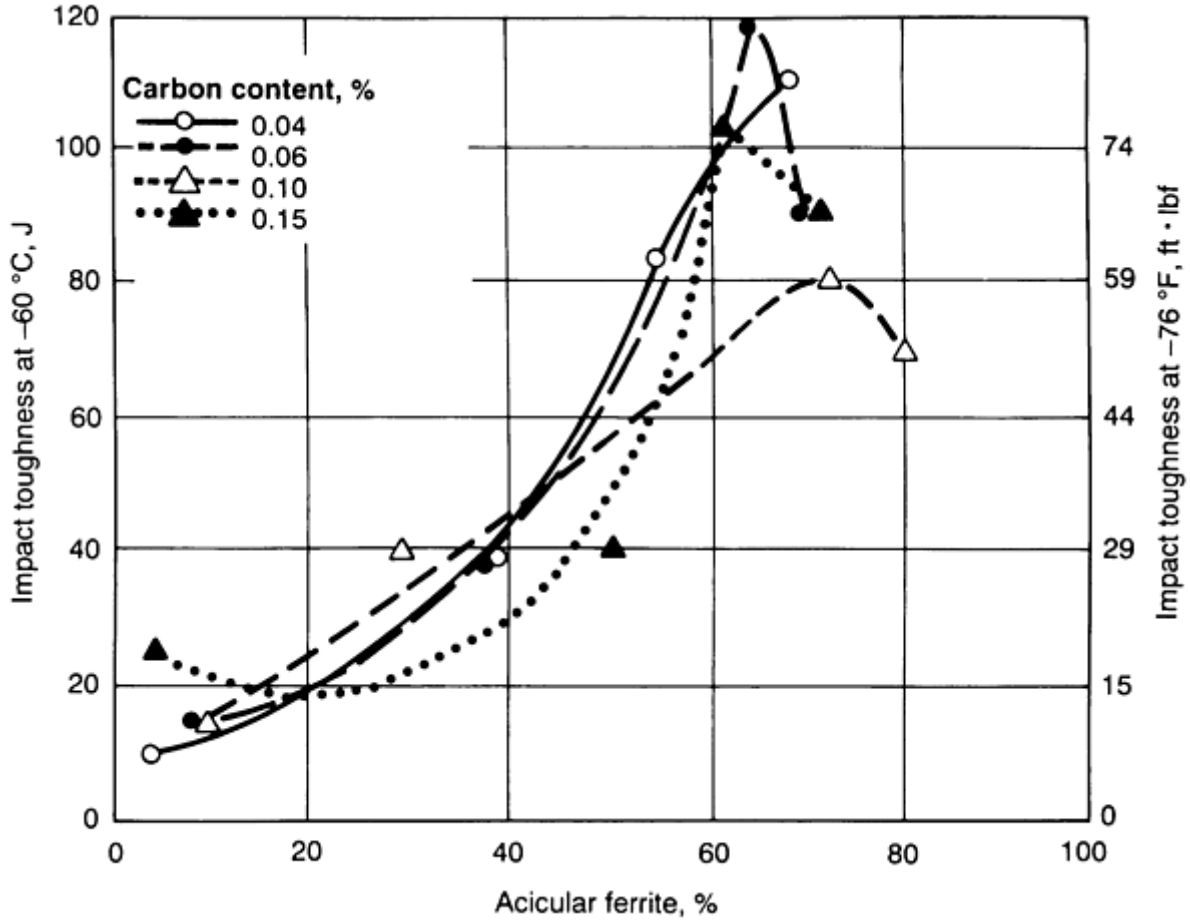

FIG. 24 PLOT OF IMPACT ENERGY VERSUS ACICULAR FERRITE CONTENT FOR SELECTED CARBON CONTENTS AT -60 °C (-78 °F). SOURCE: REF 27

For the welding of steels with yield strengths less than 600 MPa (85 ksi), it has been possible to develop weld metals with matching strength and toughness by having high acicular ferrite contents in them. A yield strength of about 600 MPa (85 ksi) seems to be the ceiling for weld metals based on acicular ferrite. Attempting to obtain additional strength by additional alloying to increase the amount of solid solution hardening and precipitation hardening in fact only results in increasing amounts of martensite and bainite. These structures are associated with a lower toughness. This has been observed in the case of HSLA-100 steels, for example, where attempts to get a matching strength in the weld metal have resulted in a drop in toughness (Ref 25, 28). Work on consumables development for high-strength steels is still in progress to match the base metal in strength and toughness (Ref 25, 28). However, current thinking appears to favor resorting to a slightly undermatching weld metal (in terms of strength) so that the already available lower-strength, high-toughness, consumables having high acicular ferrite contents (Ref 29) can be used. These weld metal compositions have the additional benefit of requiring less stringent measures for avoiding hydrogen-induced cracking.

Titanium Oxide Steels. In the discussion of the role of pinning by precipitate particles (for example, TiN) in limiting grain growth in the HAZ (in the section "Precipitate Stability and Grain Boundary Pinning" in this article), it was pointed out that at high heat inputs the particles dissolve and are not able to prevent coarse γ grains from forming. The low toughness in these coarse-grained regions is of some concern. The fact that a coarse γ grain size will lead to a higher acicular ferrite content (see Fig. 21b) with improved toughness has been used to advantage in the development of titanium-oxide-containing steels (Ref 30, 31). Ti_2O_3 is more stable than titanium nitride and does not dissolve, even at the highest heat inputs. The undissolved, Ti_2O_3 particles do not stop grain growth, but their survival after the heating cycle means that they can be effective in nucleating acicular ferrite within the coarse γ grains. The precise reasons why they are more effective than other undissolved inclusions, such as Al_2O_3 in nucleating acicular ferrite are not well understood (Ref 24). The improved HAZ microstructure and toughness obtained with titanium oxide steels over titanium nitride steels at high heat inputs are shown in Fig. 25 and 26, respectively.

Effect of Transformations on Transient Weld Stresses. The effect of transformations on weld stresses (and vice versa) is best illustrated by introducing an apparently little-known proposal (Ref 32) about the use of a duplex austenite-martensite weld metal for welding high-strength steels. First, to prepare the background, the way in which transient stresses develop in a weld and the effect of transformations on weld stresses will be discussed.

Four uniaxial specimens using an HAZ simulation technique, the manner in which residual stress is accumulated during a weld thermal cycle was investigated (Ref 33), and the results are shown in Fig. 27. Initially, when a material is austenite at high temperature, its yield strength is low and only a small tensile stress can develop. On cooling, the tensile stress increases. When a phase transformation occurs, the resulting volume expansion opposes the contraction due to cooling and decreases the stress. Once the transformation is complete, the tensile stress increases again. As seen in Fig. 27, if the transformation occurs at a lower temperature (for example, in the case of 9Cr1Mo or 12CrMo steels), the magnitude of the final residual stress is less. The dotted line in the plot shows the expected variation for a material with an austenite-martensite structure. The greater the amount of martensite, the lower the final residual stress.

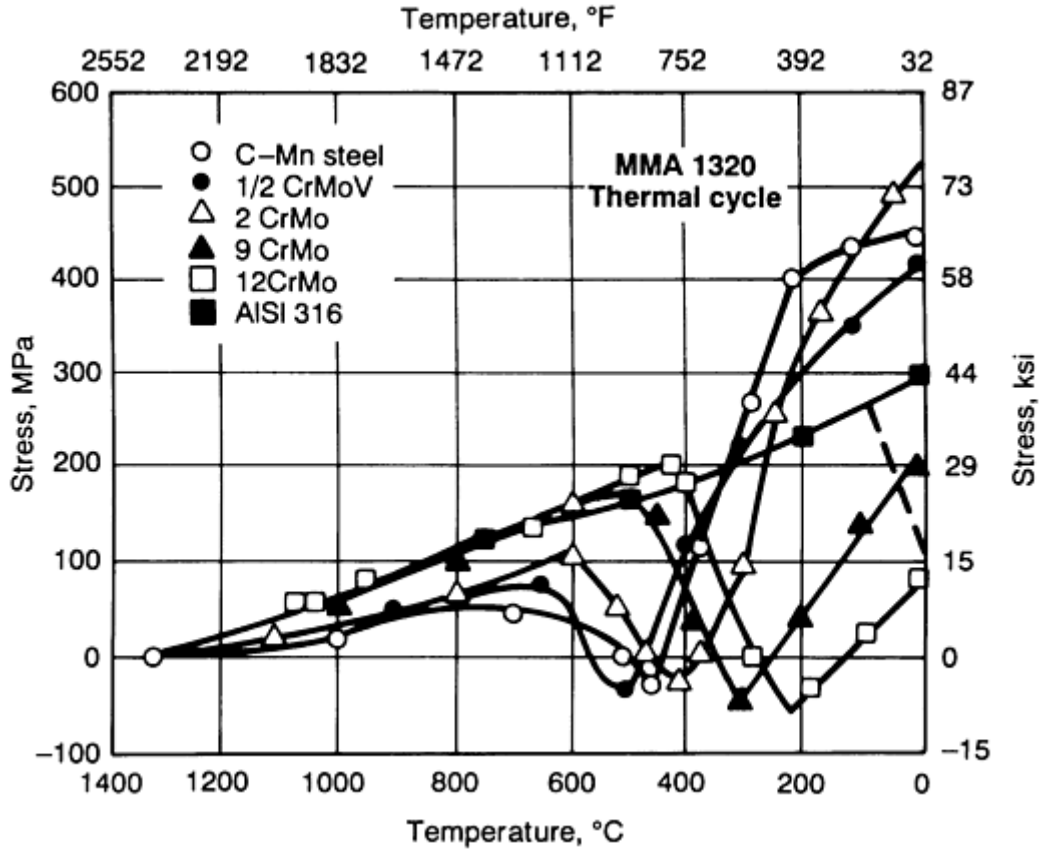

FIG. 27 STRESS ACCUMULATED DURING COOLING UNDER RESTRAINT FOR SELECTED STEELS. THE DOTTED LINE SHOWS THE EXPECTED VARIATION IN STRESS FOR A DUPLEX AUSTENITE-MARTENSITE WELD METAL WHERE TRANSFORMATION BELOW ABOUT 100 °C (212 °F) GREATLY REDUCES THE FINAL STRESS. (MMA 1320 INDICATES THE PEAK TEMPERATURE OF THE SIMULATED WELD THERMAL CYCLE AND CORRESPONDS TO THE TEMPERATURE AT THE START OF THE COOLING CYCLE.) SOURCE: REF 33

As discussed in the section "Weld Metal Toughness Relative to the Microstructure" in this article, the main problems in the welding of high-strength steels (with yield strengths of 600 to 1000 MPa, or 85 to 145 ksi) are hydrogen-induced cracking (HIC) and low toughness in the weld metal. Both problems can be addressed (in principle at least) by the use of a duplex austenite-martensite weld metal. Austenite can contribute by increasing the toughness and by minimizing the risk for HIC (Ref 14). The role of martensite will be to increase the strength and to decrease the final residual tensile stress, which also makes conditions less favorable for HIC. An additional benefit will be that the higher tensile residual stress in the weld metal before martensite forms will induce the transformations in the HAZ to occur at a slightly higher temperature, by Le Chatelier's principle (Ref 34), and thereby cause a microstructure less susceptible to HIC to form in the HAZ. The results of this effect are shown in Fig. 28, where it is seen that a tensile stress in the 500 to 300 °C (930 to 570 °F) temperature range on a ferrite-pearlite weld increased the stresses for failure (Ref 35).

THE SCHEMATIC SHOWS THE SPECIMEN DIMENSIONS FOR THE DELAYED FRACTURE TENSILE TESTS ON WELDED JOINTS. SOURCE: REF 35

It must be mentioned that the idea of using an austenite-martensite weld metal represents a considerable departure from conventional thinking. For example, for certain overlaying applications of stainless steel deposits on low-alloy steel, an overalloyed electrode like E310 or E312 is preferred to E309. Even though the weld metal composition with any of the three electrodes would be acceptable, the use of overalloyed electrodes will minimize the width of the martensitic layer in the unmixed zone at the weld-HAZ interface (Ref 36). By contrast, an austenite-martensite weld metal implies that the choice of consumable will have to be such that the width of the martensitic layer will increase. However, because the proposal is meant for the recently developed high-strength steels that have a low carbon content, only a low-carbon martensite will form, which will not be that harmful. The benefits already discussed could override conventional concerns about having martensite in the weld metal in this case.

To sum up, even though the idea of using an austenite-martensite weld metal for high-strength steels does not seem to have been taken up for serious investigation so far, it has been included here because it is a nice way of illustrating the principles discussed. In addition, it shows that a fundamental knowledge of different effects on phase transformations can lead to unconventional solutions to practical problems.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

HAZ in Multipass Weldments

In the HAZ of a single-pass weld, the grain-coarsened zone (GC HAZ) is normally the region having the lowest toughness. Turning to a multipass weld, Fig. 29 (compare with Fig. 3) shows how the GC HAZ can be modified by subsequent passes and can be categorized into four regions, depending on the reheating temperature (Ref 37):

- SUBCRITICALLY REHEATED GRAIN-COARSENED (SCGC) ZONE, THE ZONE REHEATED BELOW AC_1
- INTERCRITICALLY REHEATED GRAIN-COARSENED (ICGC) ZONE, THE ZONE REHEATED BETWEEN AC_1 AND AC_3
- SUPERCRITICALLY REHEATED GRAIN-REFINED (SCGR) ZONE, THE ZONE REHEATED ABOVE AC_3 AND BELOW ABOUT 1200 °C (2190 °F)
- UNALTERED GRAIN-COARSENED (UAGC) ZONE, THE ZONE THAT IS NOT REHEATED ABOVE ABOUT 200 °C (390 °F) OR THE ZONE THAT IS AGAIN REHEATED ABOVE ABOUT 1200 °C (2190 °F)

Figure 30 shows how the crack tip opening displacement (CTOD) value of simulated specimens varies with the peak temperature of the second thermal cycle, T_{p2} (T_{p1} = 1400 °C, or 2550 °F). It is seen that the ICGC, UAGC, and SCGC regions have CTOD values less than about 0.1 mm (0.004 in.). Similar low values have been obtained by locating the crack tip in the CTOD tests at corresponding locations in the HAZ of actual multipass weldments. These low toughness regions are commonly known as local brittle zones (LBZs).

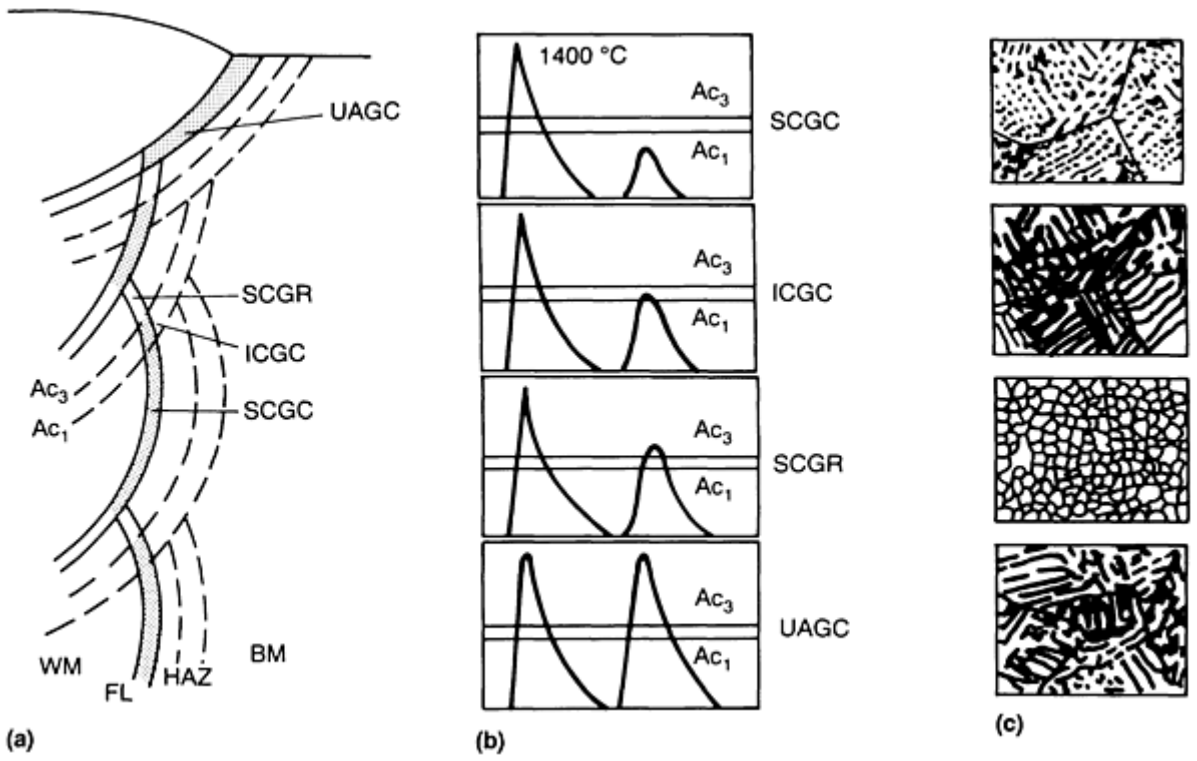

FIG. 29 SCHEMATIC SHOWING THE DIFFERENT SUBZONES THAT CAN FORM IN THE COARSE-GRAINED REGION OF THE HAZ IN A MULTIPASS WELD. (A) POSITION OF SUBZONES RELATIVE TO BASE METAL (BM) AND WELD METAL (WM). (B) PLOT OF THERMAL CYCLES RELATIVE TO AC_3 AND AC_1. (C) MICROSTRUCTURES AT THE DIFFERENT ZONES. FL REFERS TO THE FUSION LINE. SEE TEXT FOR DETAILS. SOURCE: REF 37

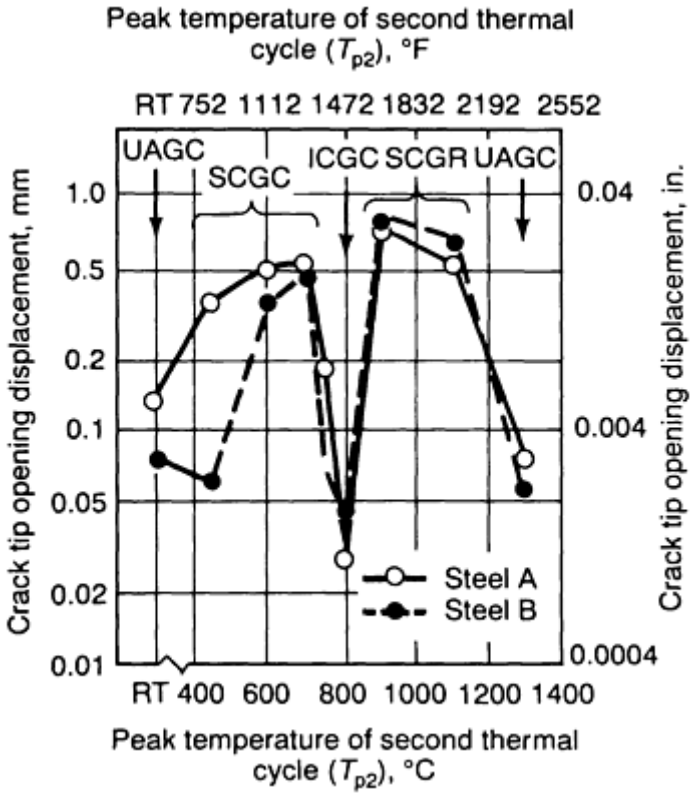

FIG. 30 PLOT OF CRACK TIP OPENING DISPLACEMENT VERSUS PEAK TEMPERATURE OF THE SECOND THERMAL CYCLE FOR SIMULATED SPECIMENS SUBJECTED TO A DOUBLE THERMAL CYCLE. (T_{P1} = 1400 °C = 2550 °F; $\Delta T_{8\text{-}5}$ = 20 S). THE HAZ ZONES (FIG. 29) CORRESPONDING TO THE SIMULATION TRIALS ARE ALSO SHOWN IN THE FIGURE. SOURCE: REF 37

The low CTOD values have been obtained only in tests on modern structural steels, whereas no actual structural failure attributable to the LBZs has been reported so far (Ref 38). Because the structural significance of the low toughness test results is still largely unresolved, the present conservative strategies are to choose a steel whose tendency to form LBZs is less or to choose a welding procedure by which the size of the LBZs can be reduced.

The ICGC HAZ usually has a lower toughness than the SCGC or UAGC regions, even though all of them have nearly the same γ grain size. This is due to the higher amount of highcarbon martensite-austenite (M-A) constituent in the ICGC HAZ. When the GC HAZ is reheated to a temperature between Ac_1 and Ac_3, austenite is nucleated at the high carbon areas. Upon cooling, these local high-carbon areas can transform to give twinned martensite with every thin regions of retained austenite in between. (See Ref 39 for detailed metallographic procedures for identifying the M-A constituent.) The carbon content in the M-A islands can range from about 0.3 to 0.5% C. The significance of this is that, for a given nominal carbon content in the steel, the volume fraction of the M-A constituent will be much higher than if most of the carbon formed carbides (by the lever rule). This will increase the number of crack nucleation sites and thereby contribute to the inferior toughness of ICGC HAZ. As is to be expected, the volume fraction of the M-A constituent also depends on the hardenability of the steel, which in turn depends on the alloying content. It has been shown that if the development of pearlitic microphases could be promoted instead of the development of M-A, by decreasing the alloy content, the toughness of the ICGC HAZ could be improved (Ref 40). However, this would have penalties in terms of achievement of parent plate strength. A more feasible solution would be to inhibit grain growth in the HAZ.

The multipass welding procedure can alternatively be controlled to limit the size of the LBZs. Figure 31 shows how this can be done with a tandem three-wire high current gas-metal arc welding procedure by adjusting the distance between the three arcs. Special "temper-bead" procedures (Ref 42) have been developed for controlling the microstructure in the HAZ, and a need for these procedures arises in the following way. Low-alloy steel weldments for critical applications (for example, pressure vessels) require a postweld heat treatment (PWHT) in a furnace. This is done to temper the hard regions in the HAZ and to relieve residual stresses. If repairs become necessary on site after the component has been in service, PWHT is usually not feasible. The heat of the arc can then be used to achieve the tempering function of PWHT

by suitable spatial positioning and sequencing of the individual passes. Grain refinement in he HAZ is also sought to increase the toughness and thereby offset the harmful effects of residual stresses that would remain in the absence of PWHT.

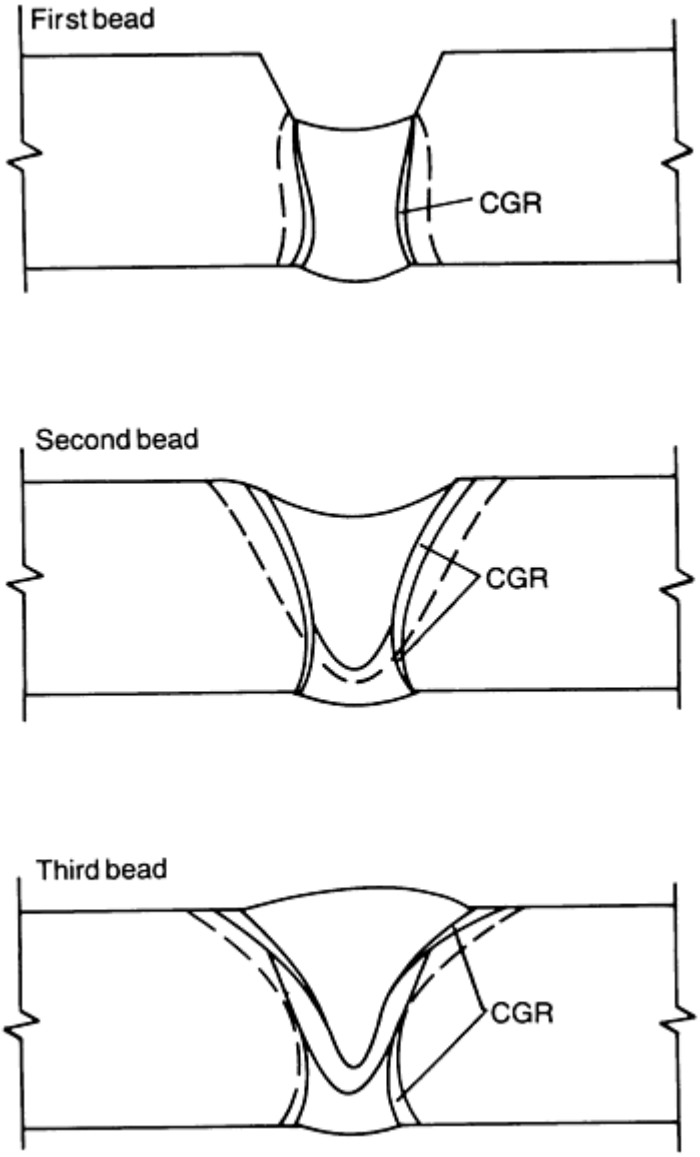

FIG. 31 SCHEMATIC SHOWING THAT THE HAZ ISOTHERMS AND THE SIZE AND LOCATION OF THE COARSE-GRAINED REGION (CGR) CAN BE CONTROLLED IN A TANDEM THREE-WIRE HIGH CURRENT GAS-METAL ARC WELDING PROCEDURE. GRAIN REFINEMENT OF COARSE-GRAINED REGIONS INITIALLY FORMED IS OBTAINED BY OPTIMIZING THE DISTANCES BETWEEN THE THREE ARCS. SOURCE: REF 41

An example of a two-layer temper bead procedure is shown in Fig. 32. The heat inputs of the first and second layer are carefully controlled, so that the heat from the second layer is used to refine the coarse-grained region in the HAZ of the base metal due to the first layer. This ideas can be extended one step further by using a pulsed gas-tungsten arc welding procedure whereby a given pulse in a pulsed weldment can be used to successively refine and temper the preceding pulse pitch regions (Ref 11). The degree of microstructural refinement depends primarily on the welding speed and pulsing frequency, and these parameters can be controlled with great precision. By contrast, an important variable to be controlled in the temper-bead procedure is the weld deposit height, and it is difficult to exercise the same degree of control on this. For this reason, it is argued that the maximum possible control on the microstructural changes in the repair weldment is possible with the pulsing procedure.

Fusion Zone in Multipass Weldments

In the weld metal of a multipass weld, reheating effects will lead to a gradient in microstructure similar to the case of the HAZ. However, instead of a detailed classification, the multipass weld metal is usually considered to consist of just two regions (Fig. 33):

- *AS-DEPOSITED OR PRIMARY REGION,* WHERE THE MICROSTRUCTURE DEVELOPS AS THE WELD COOLS FROM THE LIQUID PHASE TO AMBIENT TEMPERATURE
- *REHEATED OR SECONDARY REGION,* WHERE REGIONS WITH THE ORIGINAL PRIMARY MICROSTRUCTURE ARE REHEATED TO TEMPERATURES ABOVE THE AC_1 TEMPERATURE. THE TEMPERED REGIONS WHICH ARE REHEATED TO SLIGHTLY LOWER TEMPERATURES ARE ALSO GENERALLY CONSIDERED TO BELONG TO THIS CATEGORY

The properties of the weld metal depend on the relative area or volume fractions of the two regions, which in turn depend on the welding procedure, so the properties are procedure-specific. Hence arises the need for welding procedure qualification as per codes and standards in addition to the qualification of consumables (for which is standard procedure is specified).

Stainless Steels

It has long been known that solidification cracking can be avoided in austenitic stainless steel welds by having a small concentration of ferrite in them. Recent work has shown, however, that residual ferrite content at room temperature is no

more than a symptom and that it is really the solidification mode (whether the weld metal solidifies as primary austenite or ferrite) that is the deciding criterion (Ref 43). It has been found that susceptibility to solidification cracking is least for a primary ferrite solidification mode (more specifically, when the solidification mode corresponds to the types shown in Fig. 34c and 34d). It is believed that low-melting-point liquid phases (formed by the segregation of impurities like sulfur and phosphorus, for example) solidifying in the intercellular regions do not wet the δ-γ interphase boundaries as easily as they would δ-δ or γ-γ boundaries. In the ferritic-austenitic solidification mode (Fig. 34c and 34d), the δ-γ interphase boundary area is greater at temperatures just below the nominal solidus temperature, and this is the reason for a greater resistance to solidification cracking.

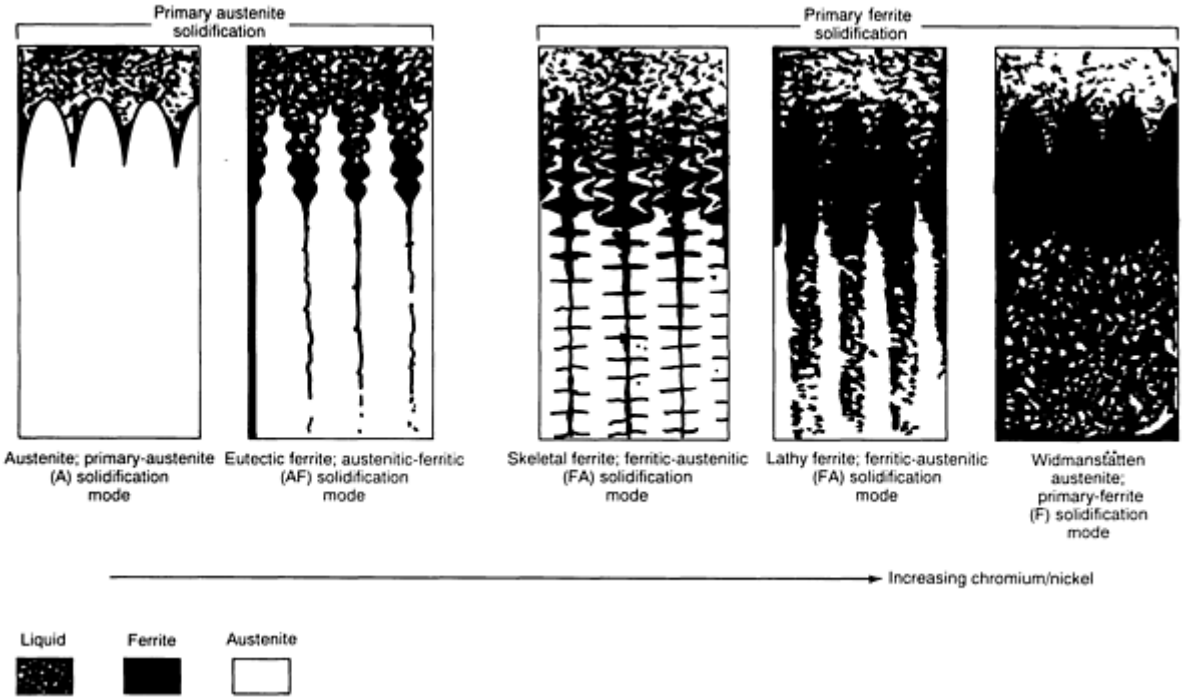

FIG. 34 SCHEMATIC SHOWING SOLIDIFICATION AND TRANSFORMATION BEHAVIOR RESULTING IN A RANGE OF FERRITE MORPHOLOGIES IN AUSTENITIC STAINLESS STEEL WELDS. SOURCE: REF 43

Information about the solidification mode can be obtained from the chemical composition of the weld metal by referring to the WRC-1992 diagram (Fig. 35). It has been found that this diagram is more accurate than the Schaeffler (for duplex stainless steel welds) and Delong (for 300 series austenitic steel welds) diagrams developed earlier. All of these diagrams are strictly applicable only for the cooling rates obtained in manual metal arc (MMA) welding because the data for establishing the statistical correlations have been taken from MMA welds. The dotted lines in Fig. 35 are the demarcation lines between the different solidification modes shown (that is, A, AF, FA, and F) corresponding to the types in Fig. 34(a), 34(b), 34(c), 34(d), and 34(e), respectively. The AF-FA boundary in Fig. 35 (which, as discussed earlier, corresponds to the onset of cracking) intersects the iso-ferrite number lines at an angle. This is consistent with the findings of several investigators that the minimum ferrite content necessary to avoid hot cracking is different for different weld metal compositions (that is, for weld metals deposited with E 316, E 308L, E 309, and so on).

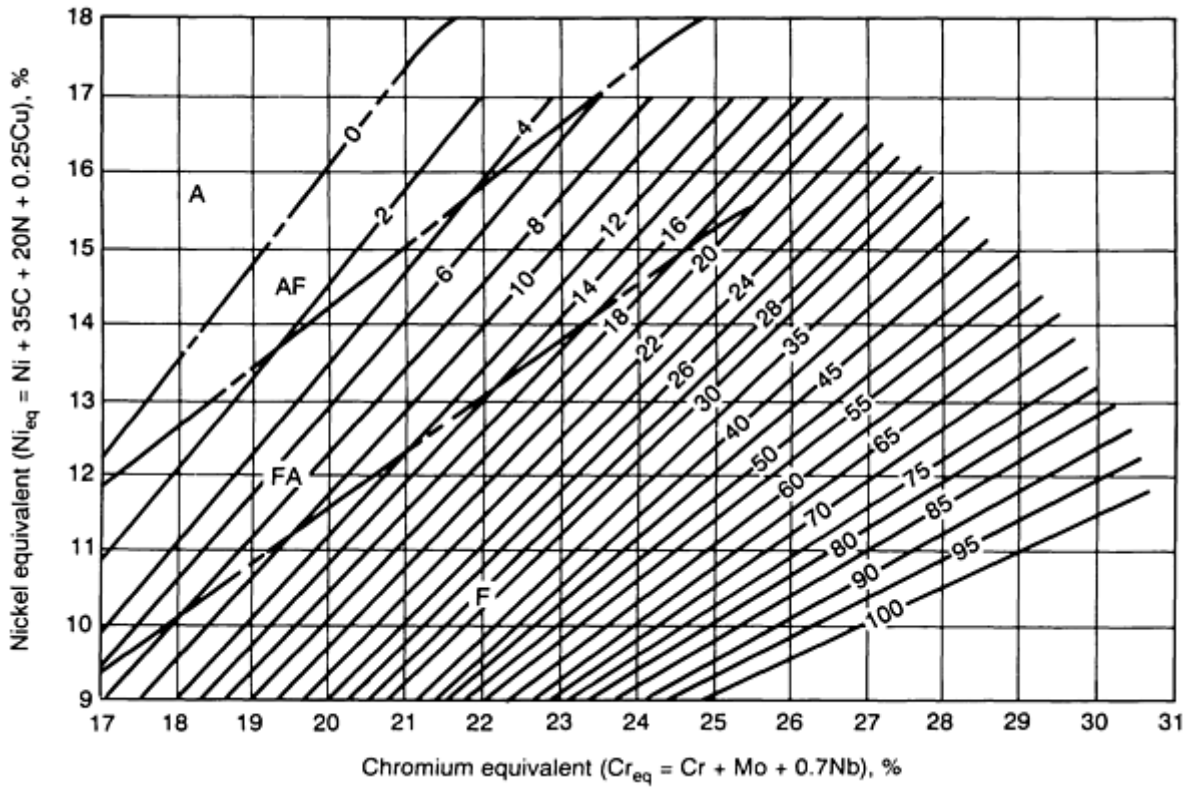

FIG. 35 WRC-1992 DIAGRAM PREDICTING FERRITE CONTENT IN STAINLESS STEELS. FERRITE CONTENT IS GIVEN BY THE FERRITE NUMBER (FN), WHERE 100 FN IS APPROXIMATELY EQUAL TO 65 VOL% FERRITE. BOUNDARIES DENOTING A CHANGE IN SOLIDIFICATION MODE (A, AF, FA AND F PER FIG. 34) ARE ALSO SHOWN (INDICATED BY DOTTED LINES). SOURCE: REF 45

It is a fortunate coincidence that the coefficients in the Cr_{eq} and Ni_{eq} expressions (see Fig. 35), which have been obtained by statistical fitting methods, result in satisfactory correlations with both the solidification mode and the ferrite number (a precisely measurable quantity that is roughly proportional to the actual volume percentage of ferrite at room temperature) (Ref 44). Indeed, it has been found that the same Cr_{eq} and Ni_{eq} expressions (that is, with the same elements and coefficients) are not able to satisfactorily fix the locations of the martensite and martensite-austenite phase fields seen in the lower left region of the Schaeffler diagram. For this reason, such regions of Cr_{eq} and Ni_{eq} are excluded in the WRC-1992 diagram.

A discussion of weld decay due to sensitization and knife line attack in the HAZ of austenitic stainless steels can be found in Ref 14 and 46.

Aluminum Alloys

The main problems in the welding of heat-treatable aluminum alloys are liquation cracking in the partially melted zone (see the section "Unmixed and Partially Melted Zones in a Weldment" in this article) and softening in the HAZ (Ref 14, 47). The latter means that the weld joint strength can be reduced. Reasons for the softening can be understood by referring to Fig. 36. The parent material is assumed to be a 2000- or 6000-series aluminum alloy, artificially aged to contain the metastable phase of θ' (in aluminum-copper alloys), S' (in aluminum-copper-magnesium alloys), or β' (in aluminum-magnesium-silicon alloys). A very fine dispersion of precipitate particles is obtained in the parent material by a solution heat treatment followed by aging, and this is the reason for the high strength in the materials. Figure 36(b) shows that a gradient in hardness is obtained in the HAZ immediately after welding. At location 1, the high peak temperature causes the precipitate particles to go into solution, and the cooling rate is too high for reprecipitation. At locations 2 and 3, the precipitate particles partially dissolve and coarsen. After postweld artificial aging, fine precipitate particles are again formed at location 1, causing the hardness to increase to the parent material level. However, at locations 2 and 3, only a lower hardness can be obtained because of the formation of coarse precipitate particles. For increasing weld heat inputs, the width of the softened zone increases. A good discussion of how the above phenomenon can be modeled is found in Ref 48.

Nickel-Base Superalloys

Nickel-base superalloys have a very high creep resistance, making them attractive for critical high-temperature applications such as gas turbines. Yet it is this very characteristic that gives rise to the problem of strain age cracking in the weld HAZ (Ref 14, 19, 49). The high-temperature creep strength in the parent materials is obtained by forming fine precipitates of γ' (Ni_3(Al, Ti)) or γ" (Ni_3Nb) in them. In the region of the weld HAZ subjected to high peak temperatures, these precipitates dissolve, similar to the case of aluminum alloys. After welding, the weldments are again solution heat-treated and aged (note the difference between aluminum alloys and the nickel-base superalloys in this respect). The purposes of this treatment are to obtain the same uniform and fine precipitation in the weld as in the parent material and to relieve the weld residual stresses.

Normally (for example, in the case of low-alloy or carbon steel welds), PWHT in a furnace relieves the residual stresses because the yield stress at the PWHT temperature is very low. A residual stress greater than the yield stress cannot be supported, and stress relief is brought about by a process of creep and plastic deformation. This process is difficult in nickel-base superalloy weldments, however, because of their high creep strength and low creep ductility. Reprecipitation in the solutionized regions of the HAZ (during the heating-up to the PWHT temperature) strengthens the matrix and does not allow any creep or plastic deformation (necessary for the relief of residual stress) to take place. Cracking can occur in this condition at the grain boundaries in the grain-coarsened region of the HAZ. Cracks initiated here have been known to run far into the base material. This problem is very difficult to solve, and the best solution has been found to be to switch over to materials such as Inconel 718 alloy that are inherently less susceptible to cracking, even though their creep strength is somewhat lower. Inconel 718 alloy contains γ" precipitate, and the slow kinetics of precipitation in this alloy allow substantial stress relief to be achieved before precipitation increases the creep strength in the HAZ.

Solid-State Transformations in Weldments

P. Ravi Vishnu, Luleå University of Technology, Sweden

Titanium Alloys

Titanium alloys find use in aerospace applications, pressure vessels, and so on because of their high strength-to-weight ratio, high corrosion resistance, and high fracture toughness. Pure titanium has two allotropic forms: low-temperature hexagonal close-packed (hcp) α-phase and elevated-temperature body-centered cubic (bcc) β-phase. Various alloying elements tend to preferentially stabilize one or the other of these phases. As a result, titanium alloys are generally classified as α, α+ β, metastable β, and β alloys (Fig. 37).

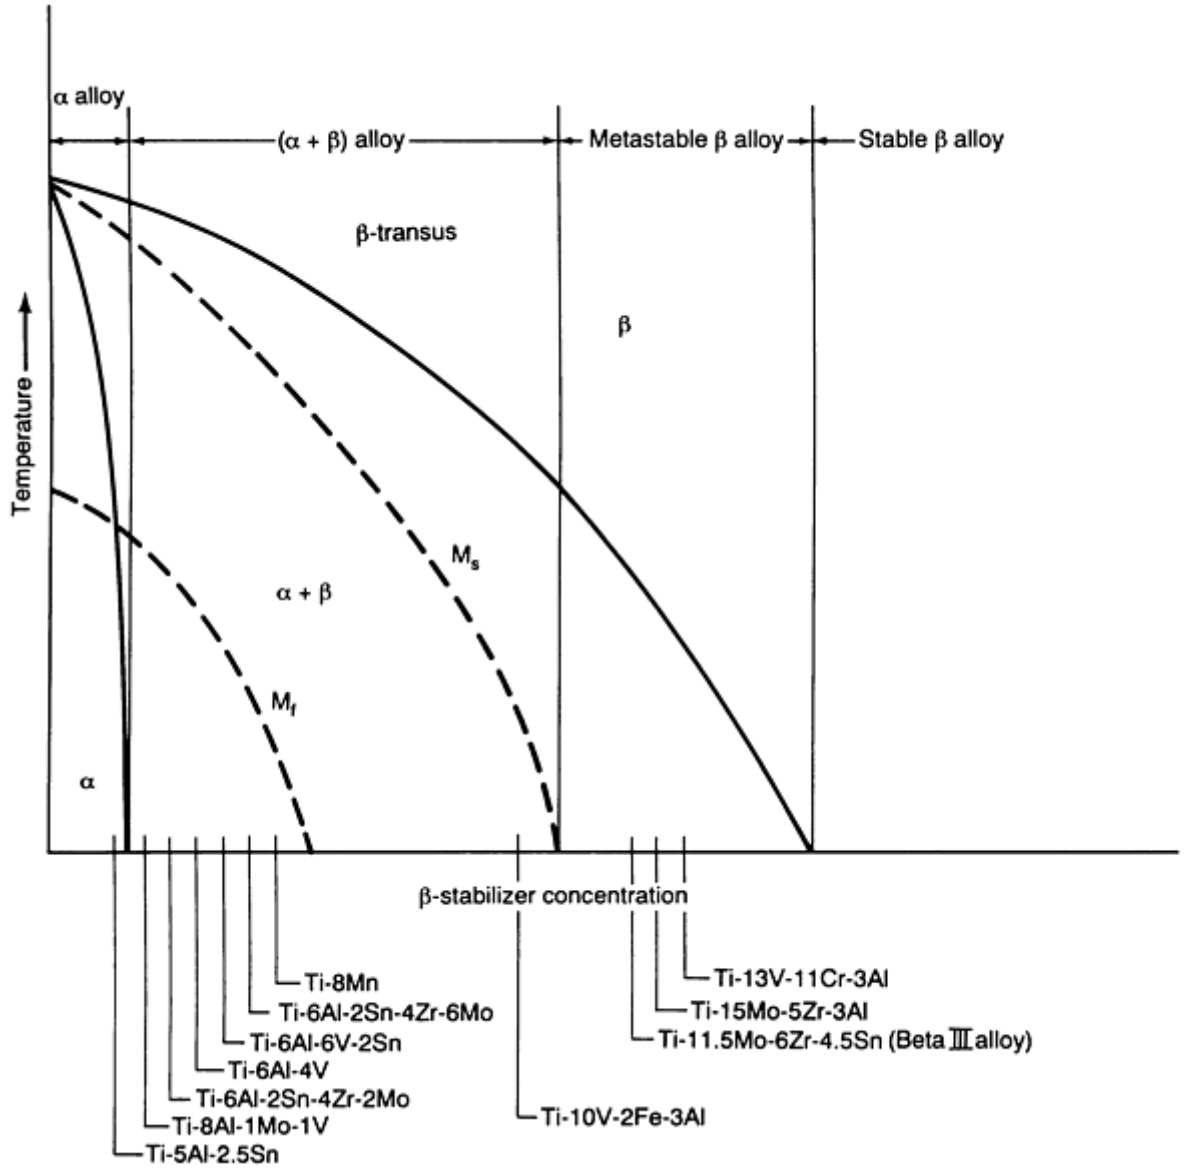

FIG. 37 HYPOTHETICAL β ISOMORPHOUS PHASE DIAGRAM THAT SHOWS RELATION BETWEEN β -STABILIZER SOLUTE CONTENT AND TITANIUM ALLOY FAMILY DESCRIPTION. SELECTED COMMON ALLOYS ARE LISTED ALONG THE *X*-AXIS OF THE DIAGRAM BASED ON THEIR COMPOSITIONS. SOURCE: REF 50

The α-alloys are not heat-treatable (that is, a significant increase in strength and toughness cannot be obtained by heat treatment), and they have the lowest strength of the four titanium alloy families. Interestingly enough, these alloys are thus considered to have excellent weldability. What this means in practice is that there is no significant degradation in the properties of the weld and HAZ with regard to the parent material due to the weld thermal cycles. Also, the β ↔ α transformation in the weld and near HAZ means that the extent of grain coarsening will not be so high as in other single-phase materials in which no phase transformation occurs upon heating or cooling, such as stabilized ferritic stainless steels (Ref 51), pure aluminum, and so on.

In the α+ β alloys, a higher strength is obtained with a higher volume fraction of the β phase, which in turn is obtained with a higher β -stabilizing alloy content (Fig. 37). The effect of cooling rate on the phase transformations in two α+ β alloys is shown schematically in Fig. 38. As in the case of steels, it is seen that the β ↔ αtransformation can occur either by nucleation and growth at slower cooling rates or martensitically at higher cooling rates. The martensitic product in the lean α+ β alloys has an hcp crystal structure (designated as α') or an orthorhombic one (designated as α") in the β-stabilized α+ β alloys. It is seen that the C-curve for the β ↔ intergranular α transformation is shifted to the right for alloys with increasing β-stabilizing alloy content, while that for the allotriomorphic α (more commonly referred to as GB

α) is relatively insensitive to alloy concentration (Ref 52). As a result, alloys that are fairly rich in β-stabilizing additions exhibit a stronger tendency to form a continuous network of GB α than do leaner α + β alloys.

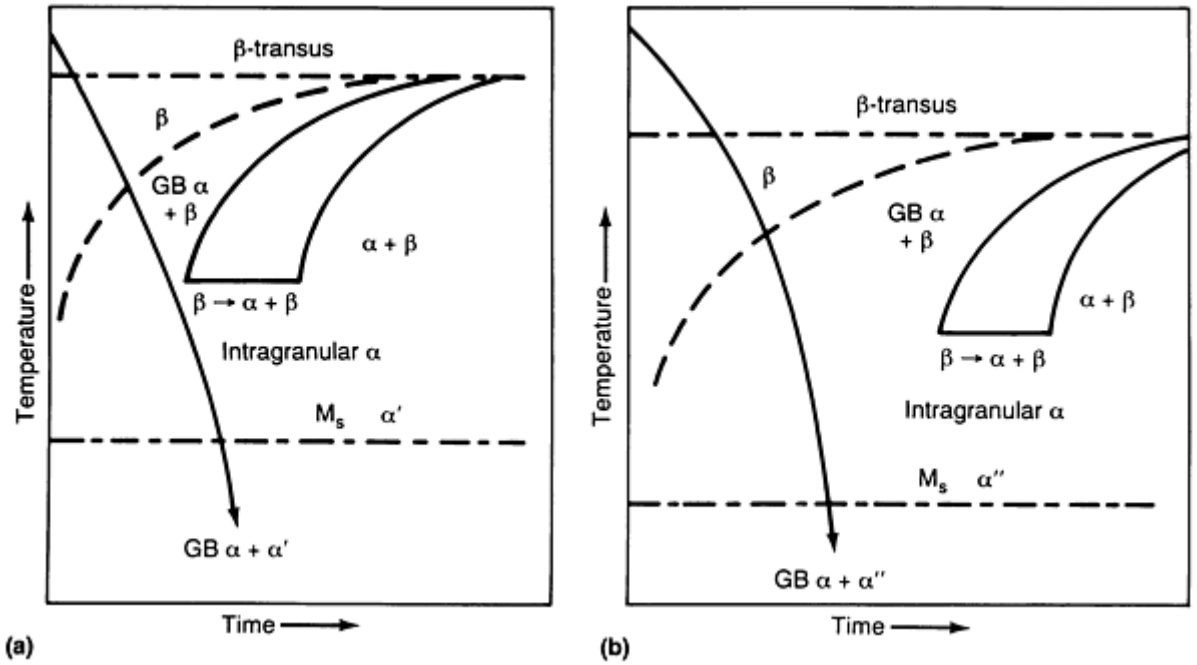

FIG. 38 SCHEMATIC CCT DIAGRAMS FOR TWO α + β TITANIUM ALLOYS WITH DIFFERENT β -STABILIZER SOLUTE CONTENTS. (A) LEAN α + β ALLOY (FOR EXAMPLE, TI-6AL-4V). (B) α + β ALLOY (FOR EXAMPLE, CORONA 5 [TI-4.5AL-5MO-1.5CR]) RICHER IN β -STABILIZING SOLUTE CONTENT

The morphology of the α and β phases in the α + β base materials is strongly dependent on thermomechanical processing (TMP) and heat treatment, which are performed either in the β-phase field or in the two-phase α + β phase field. When TMP is done in the α+ β phase field, the α that forms on cooling is continuously deformed. After recrystallization, a near-equiaxed α structure is obtained after this α + β processing. Very little GB α is formed because deformation introduces sufficient alternate heterogeneous nucleation sites in the form of dislocations. On the other hand, if TMP is done above the β-transus temperature (β-processing) and cooled, α forms at grain boundaries (giving GB α) and in the interior of grains as a Widmanstätten structure (also referred to as an acicular, lenticular, or basketweave structure). The microstructure in the weld and the near HAZ is closer to that obtained after β-processing.

Figure 39 shows the effect of α + β processing and β-processing on the strength and toughness of α + β alloys with increasing β-stabilizing alloy content. At the lower strength levels obtained with a lower β-stabilizing alloy content (because of a lower volume fraction of β-phase present), the finer Widmanstätten structure obtained after β-processing has a higher toughness than the coarser structure obtained by α + β processing. At higher strength levels, the trend reverses with the α + β processed structure having a higher toughness. This result can be understood in terms of the strength differences between GB α and the interior of the prior β grains (Fig. 40). At lower strengths, when the grain interiors are relatively weak, the crack tip plastic zone is distributed between the GB α and the grain interiors. However, as the α-phase precipitates are refined by lower aging temperatures, as in the case of the metastable β alloys, the grain interiors are strengthened considerably. Under such circumstances, the cracks are essentially constrained to follow the GB α layer. This results in a contraction of the plastic zone, a reduction in the crack tip opening displacement for crack extension, and an attendant drop in the toughness.

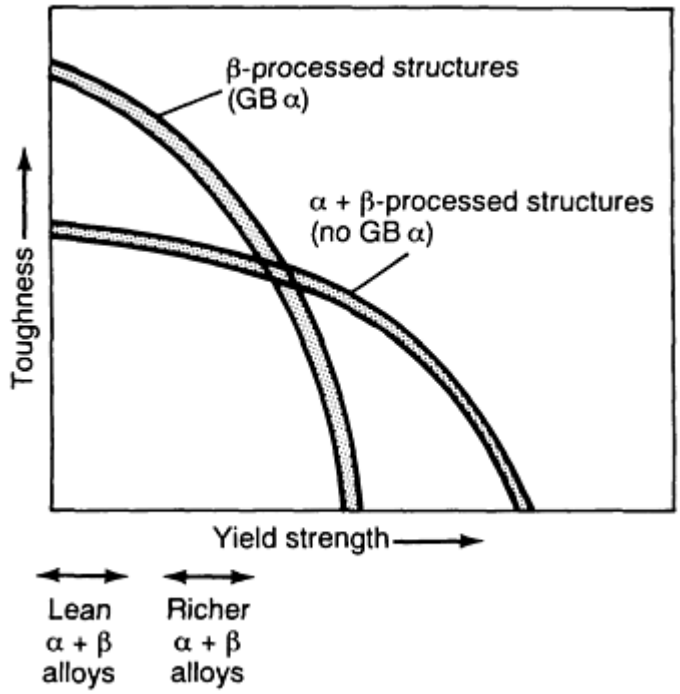

FIG. 39 SCHEMATIC PLOT OF TOUGHNESS VERSUS YIELD STRENGTH FOR α + β AND β-PROCESSED STRUCTURES. APPROXIMATE LOCATIONS OF LEAN (FOR EXAMPLE, TI-6AL-4V) AND RICHER β STABILIZED α + β ALLOYS (FOR EXAMPLE, CORONA 5 [TI-4.5AL-5MO-1.5CR]) ARE SHOWN. SOURCE: REF 52

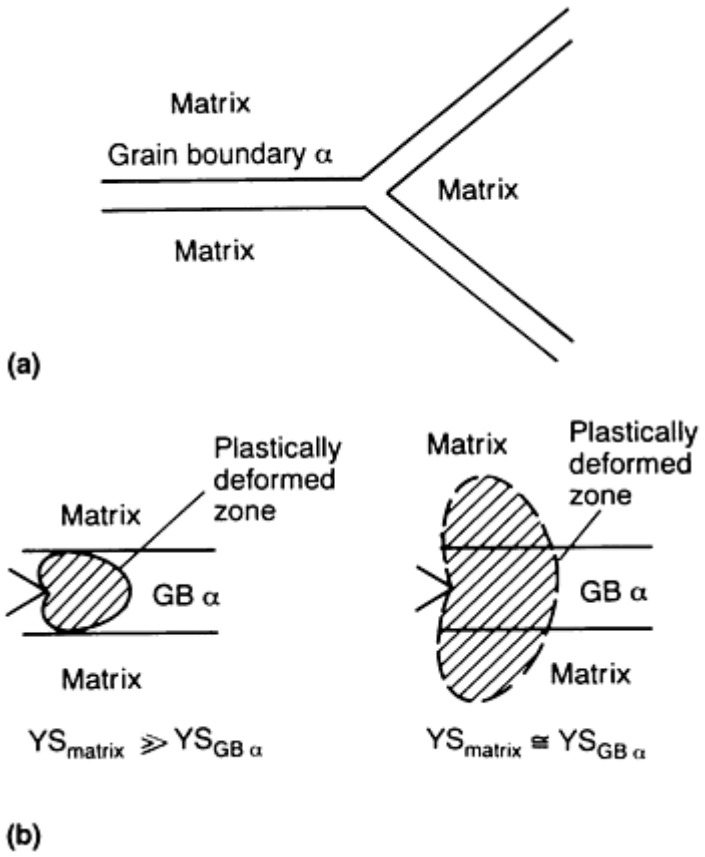

FIG. 40 SCHEMATIC SHOWING THE EFFECT OF THE RELATIVE STRENGTHS OF GB α AND MATRIX ON THE

PLASTIC ZONE SIZE. (A) GB α LOCATION RELATIVE TO MATRIX. (B) EFFECT OF PLASTIC ZONE SIZE ON YIELD STRENGTHS OF MATRIX AND GB α. SOURCE: REF 52

The microstructures in the weld metal and the near HAZ (the region where the peak temperature exceeds the β-transus temperature) resemble those obtained after β-processing. This means that it is easier to get a matching toughness in the weld metal at the lower strength levels referred to in Fig. 39. Even this is made somewhat difficult by the coarser β grain size in the weld and HAZ. Grain coarsening in the HAZ induces coarse β grains to form in the weld also, because solidification in the weld metal occurs by epitaxial growth from the HAZ. The extent of grain coarsening is such that it is not uncommon to find a single columnar β grain traversing the entire thickness in gas-tungsten arc welds on thin sheet (Ref 53). If high energy density welding processes are used (for example, electron-beam welding or laser-beam welding), it is possible to limit the extent of β grain coarsening. However, the high cooling rates in the weld and HAZ will mean that a martensitic structure will be obtained.

To obtain adequate ductility and toughness, PWHT will have to be done at temperatures close to the β-transus temperature. This can be a problem because the low strength at these temperatures can cause sagging in large welded structures, and complex fixturing will be necessary to maintain dimensional tolerances. It can also be expensive, because inert gas shielding is required for almost the entire time of PWHT (it is assumed in the present discussion that adequate care is taken to maintain proper shielding during welding). Moreover, it can be difficult to increase the ductility in the weld metal and HAZ to a level equal to that in an α+ β processed base material (Fig. 41). The trends seen in Fig. 39 and 41 can be understood by noting that crack nucleation is more difficult in an equaixed structure (because the strain concentration effects are less) and that the plastic zone sizes are bigger (Table 1). This results in a higher tensile ductility. However, because crack propagation follows a less tortuous path, the toughness is lower. The reverse is true for a Widmanstätten structure (referred to as a lenticular structure in Table 1). Table 1 explains the apparently strange observation in titanium alloys that a structure having a high strength and toughness is not necessarily the one having a high tensile ductility. The implication of this for weldments is that for many applications it may be more important to optimize the welding and PWHT procedure with respect to the toughness than with respect to the ductility.

TABLE 1 EFFECT OF MORPHOLOGICAL FEATURES OF THE MICROSTRUCTURE ON CRACK NUCLEATION AND PROPAGATION IN α + β TITANIUM ALLOYS

Note: Voids initiated at the α -β interfaces are shown as black regions. Source: Ref 54

Structure	Crack nucleation	Crack growth	Tensile ductility as a function of plastic zone size	Toughness as a function of crack propagation
Lenticular (Widmanstätten)	Easy	Difficult	 Low ductility	 High toughness
Globular (equiaxed)	Difficult	Easy	 High ductility	 Low toughness

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Introduction

THE FORMATION OF DEFECTS in materials that have been fusion welded is a major concern in the design of welded assemblies. Four types of defects in particular have been the focus of much attention because of the magnitude of their impact on product quality. These defects, all of which manifest themselves as cracks, are characteristic of phenomena that occur at certain temperature intervals specific to a given alloy. Colloquially, these four defect types are known as hot cracks, heat-affected zone (HAZ) microfissures, cold cracks, and lamellar tearing.

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Solidification Cracking (Hot Cracking)

Hot cracks are solidification cracks that occur in the fusion zone near the end of solidification. Simplistically, they result from the inability of the semisolid material to accommodate the thermal shrinkage strains associated with weld solidification and cooling. Cracks then form at susceptible sites to relieves the accumulating strain. Susceptible sites are interfaces, such as solidification grain boundaries and interdendritic regions, that are at least partially wetted.

Figure 1 is a photomicrograph of a metallographic section showing the appearance of a typical solidification crack in a fusion weld. Note the intergranular nature of the crack path. Figure 2 shows the surface morphology of a solidification crack, reflecting the nearly solidified nature of the interface at the time of failure. Note the smooth dendritic appearance of this surface.

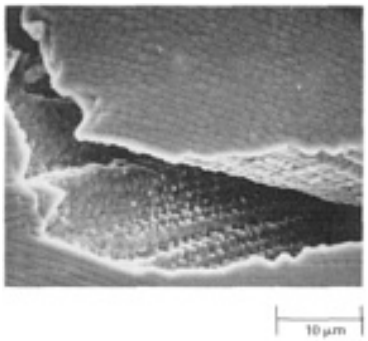

FIG. 1 SOLIDIFICATION CRACK IN A PULSED ND:YAG LASER WELD JOINING HASTELLOY C-276 TO 17-4 PH STAINLESS STEEL. YAG, YTTRIUM-ALUMINUM-GARNET

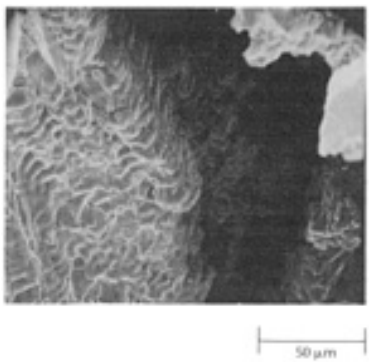

FIG. 2 SURFACE OF A SOLIDIFICATION CRACK IN AN ALLOY 214 VARESTRAINT TEST SPECIMEN

Solidification cracking requires both a sufficient amount of mechanical restraint (strain) and a susceptible microstructure. Knowledge regarding the development of shrinkage strains at the microstructural scale of a solidifying dendrite is still quite limited, making it nearly impossible to quantify *a priori* the amount of local strain required to initiate solidification cracks. Furthermore, the rate at which the strain is applied can influence the ability of an alloy to survive the solidification process without cracking. At temperatures near their melting points, metal alloys can readily dissipate applied loads by time-dependent deformation processes (i.e., creep processes). At high rates of applied stress, both the fusion zone and the HAZ have limited time to accommodate this mechanical imposition. Under conditions of rapid solidification and cooling, the rate of strain accumulation is rapid, leading to an increased cracking susceptibility. Inherently, then, requisite strains for solidification cracking are more likely to be experienced with welding processes that promote rapid solidification and cooling.

Because of the limited quantitative understanding of strain development in a solidifying weld, the practical approach taken to minimize the mechanical factor is to reduce the overall weld restraint through judicious joint design and appropriate choice of welding parameters. A simple way to minimize the restraint on a solidifying weld joint is to keep the joint gap to a minimum by designing hardware with good fit-up. Another approach, particularly attractive for small parts, is to design the weld joint as a standing edge. Welding parameters can have a profound influence on the occurrence of solidification cracking. The natural tendency to use high-speed welding to improve productivity can have detrimental effects. Formation of a teardrop-shaped weld pool, which may occur as the weld travel speed increases, can result in centerline solidification cracks. The solidification pattern associated with this type of weld pool is such that solidifying grains meet at the weld centerline, forming a particularly susceptible site for solidification crack initiation.

The manner in which a fusion weld is terminated can also influence cracking behavior. In a closure weld, simply extinguishing the power can result in the formation of "crater cracks" as the final weld pool rapidly solidifies in on itself. A common method used to minimize this problem is to ramp down the power slowly, either while the workpiece remains stationary or as it continues to travel a short length under the heat source. In some cases, the use of a runoff tab as a site for weld termination may be appropriate.

The extent to which special joint designs or precisely controlled welding parameters can be used to produce welds without solidification cracks is specific for a given alloy. Alloys that are microstructurally susceptible to cracking will necessarily have a more limited set of joint designs and processing parameters around which defect-free welds can be produced.

Alloys with a wide solidification temperature range are more susceptible to solidification cracking than alloys that solidify over a narrow temperature range. Simply described, this is because accumulated thermal strain is proportional to the temperature range over which a material solidifies. This temperature range is determined primarily by chemical composition. For many binary alloy systems and a few ternary alloy systems, the equilibrium solidification (or melting) temperature range has been established in phase diagram studies. For the vast majority of commercial alloys, however, these data are not precisely known.

Borland (Ref 1, 2) attempted to establish a general quantitative method for comparing the effects of various alloying elements on the melting temperature range of a given solvent element. Figure 3 shows a schematic binary alloy phase diagram having linear liquidus and solidus boundaries. For an alloy of composition C_0, T_L is the liquidus composition and T_S is the solidus composition, where the alloy would be completely solidified under conditions of equilibrium cooling. T_M is the invariant melting temperature of the solvent element. The slope of the liquidus is m_L, and the slope of the solidus is m_S. The equilibrium distribution coefficient, k, is defined as the ratio of the composition of the solid, C_S, to the composition of the liquid, C_L, at a given temperature (i.e., $k = C_S/C_L|_T$). For a linear liquidus and solidus, this value is constant and also equal to m_L/m_S.

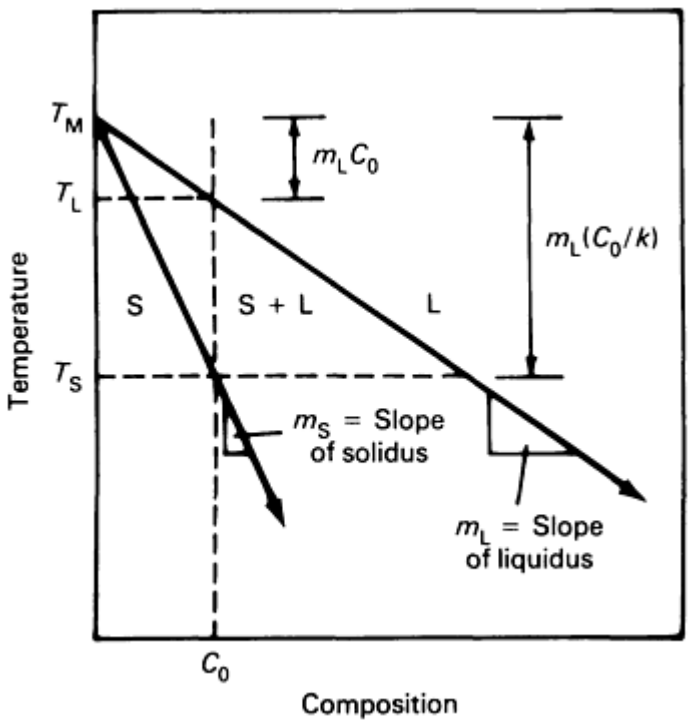

FIG. 3 HYPOTHETICAL BINARY ALLOY PHASE DIAGRAM SHOWING KEY PARAMETERS REQUIRED TO DERIVE THE RELATIVE POTENCY FACTOR (RPF)

With these terms thus defined, a derivation of the relative potency factor (RPF), after Borland (Ref 2), follows:

$$T_L = T_M - M_L C_0 \quad \textbf{(EQ 1)}$$

$$T_S = T_M - M_S C_0 \quad \textbf{(EQ 2)}$$

However, $m_S = m_L/k$:

$$T_s = T_M - \frac{M_L}{K} C_o \quad \textbf{(EQ 3)}$$

Then:

$$T_L - T_S = \frac{m_L C_o (K-1)}{K} \quad \textbf{(EQ 4)}$$

The RPF, always a positive number, is defined as the change in melting temperature ranger per weight percent of solute added, or:

$$RPF = \frac{T1 - Ts}{C_o} = \frac{M_L (k-1)}{K} \quad \textbf{(EQ 5)}$$

where for $k < 1$, $m_L < 0$; and for $k > 1$,$m_L > 0$. The larger the RPF, the wider the melting temperature range and the higher the solidification cracking susceptibility. The final form of Eq 5 indicates that as k becomes very small (indicating a high level of microsegregation), the solidification cracking sensitivity increases. Similarly, as the magnitude of m_L increases (that is, becomes more highly negative), indicating a rapid decrease in liquidus with alloying concentration, the cracking propensity also increases.

Table 1 lists RPF values for various alloying elements in binary iron (Ref 2), nickel-base alloys (Ref 3), and aluminum alloys. It is clear that certain alloying elements, such as sulfur, phosphorus, and boron, are detrimental to the weldability of these alloy systems. This has been borne out by field experience.

TABLE 1 RELATIVE POTENCY FACTORS FOR SELECTED ALLOYING ELEMENTS IN BINARY IRON, NICKEL, AND ALUMINUM SYSTEMS

SYSTEM	RPF FOR:										
	Al	**B**	**C**	**Co**	**Mn**	**Nb**	**Ni**	**P**	**S**	**Si**	**Ti**
BINARY IRON	1.5	. . .	322	0.3	26.2	28.8	2.9	121	925	1.8	13.8
BINARY NICKEL	1.7	22700	330	. . .	0.7	. . .	. . .	556	244000	11	5.4

	Cu	**Li**	**Mg**	**Si**	**Zn**
BINARY ALUMINUM	16.6	9.0	8.0	42.4	2.3

Source: Ref 2, 3

Although the exact derivation of the RPF is specific to a very simple binary system solidifying under equilibrium conditions, the methodology provides general insight that can be applied to commercial alloys. The association of cracking susceptibility with solidification temperature range has implications for alloy design and primary melt processing. An extended melting/solidification temperature range can be the result of either intentional alloying or impurities present after refining.

An example (Ref 4) of the application of Borland's concepts to the solidification cracking propensity of a commercial alloy system involves alloy 625. This alloy is derived from the ternary Ni-Cr-Mo system, a very common base system for alloys designed to survive aggressive corrosive or high-temperature environments. A factorially designed set of alloys was produced to identify the effects of the alloying elements niobium, silicon, and carbon on the temperature range of

two-phase coexistence of liquid and solid (equilibrium melting/solidification temperature range) and on solidification cracking susceptibility.

Solidification cracking susceptibility was measured with the varestraint test, using the maximum crack length (MCL) parameter as the quantitative measurement (Ref 5). The melting temperature ranges of these same alloys were measured using differential thermal analysis (DTA). Table 2 lists the compositions of the alloys examined.

TABLE 2 SELECTED ALLOY 625 COMPOSITIONS USED IN WELDABILITY STUDY

ALLOY NO.	COMPOSITION, %										
	C	Cr	Fe	Mn	Mo	Nb	Ni	P	S	Si	Ti
NIOBIUM-FREE											
1	0.006	22.10	2.56	0.02	9.54	0.01	BAL	0.005	0.002	0.03	0.06
2	0.031	21.95	2.55	0.02	9.61	0.01	BAL	0.005	0.002	0.03	0.06
3	0.006	21.63	2.18	0.02	9.60	0.02	BAL	0.005	0.002	0.35	0.06
4	0.036	21.57	2.59	0.03	9.63	0.02	BAL	0.005	0.003	0.39	0.06
NIOBIUM ALLOYED											
5	0.009	21.81	2.30	0.03	9.81	3.61	BAL	0.006	0.003	0.03	0.06
6	0.038	21.83	2.31	0.03	9.81	3.60	BAL	0.006	0.003	0.03	0.06
7	0.008	21.65	2.26	0.03	9.68	3.57	BAL	0.006	0.004	0.38	0.06
8	0.035	21.68	2.29	0.03	9.67	3.53	BAL	0.006	0.003	0.46	0.06

The results of the varestraint testing are shown in Fig. 4. These data clearly show that the alloys that contain intentionally alloyed niobium (alloys 5 to 8) are more susceptible to solidification cracking (larger MCL) than niobium-free alloys (1 to 4). Furthermore, the alloy with no intentionally alloyed carbon, silicon, or niobium (alloy 1) is the least susceptible to cracking.

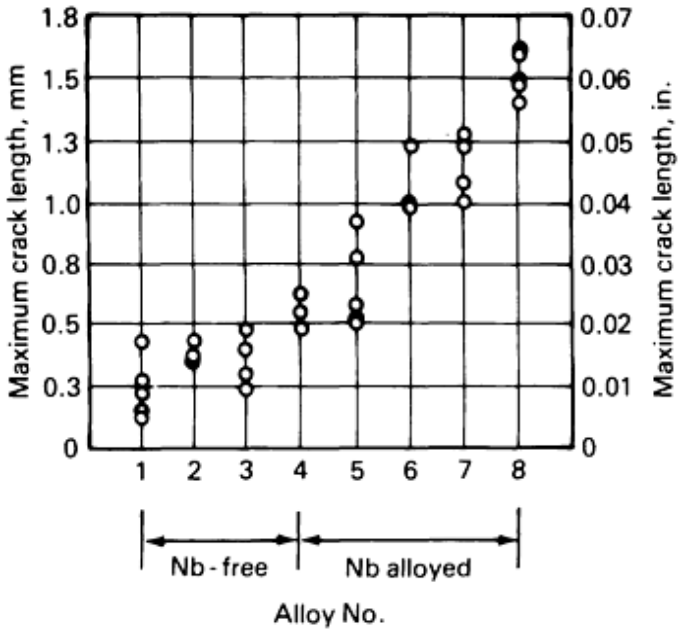

FIG. 4 MAXIMUM CRACK LENGTH DATA OBTAINED FROM VARESTRAINT TEST FOR ALLOY 625 WELDABILITY STUDY

The results of the DTA testing are given in Table 3. Listed are the liquidus (T_L), solidus (T_S), and melting temperature range (ΔT) data obtained from multiple tests. The baseline ΔT of an alloy without intentionally alloyed carbon, silicon,

and niobium (alloy 1) is 26.5 °C (79.7 °F). Increases in ΔT are observed when carbon or silicon is added (alloys 2 and 3) at levels that would be considered high for commercial alloys. When niobium is added (alloy 5) at a level that would be considered nominal for alloy 625 (~3.6 wt%), the melting temperature range effectively doubles to 55.3 °C (131.5 °F). Additions of carbon and silicon to the high-niobium alloys (alloys 6 to 8) further increase this value.

TABLE 3 MELTING TEMPERATURE DATA FOR ALLOY 625 WELDABILITY STUDY

The correlation of cracking susceptibility with melting temperature range is shown in Fig. 5. Linear regression analysis performed on the data set resulted in the following functional relationship:

$$MCL = 0.00087(\Delta T) - 0.015 \qquad \textbf{(EQ 6)}$$

The incomplete statistical correlation ($R^2 = 0.86$) suggests that other factors are necessarily involved.

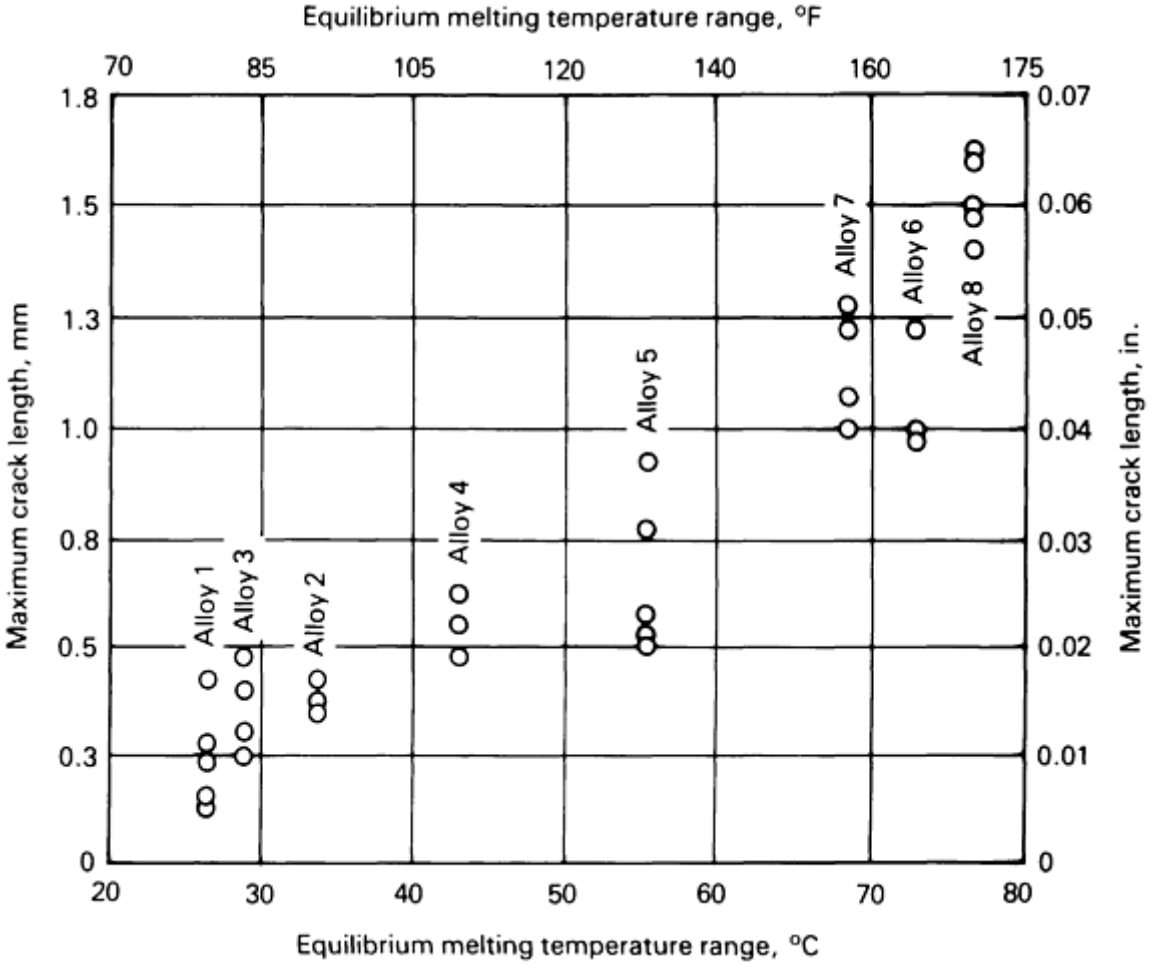

FIG. 5 RELATIONSHIP BETWEEN MAXIMUM CRACK LENGTH AND EQUILIBRIUM MELTING TEMPERATURE RANGE IN ALLOY 625 WELDABILITY STUDY

The solidification behavior of fusion welds is nonequilibrium in nature and may result in an extension of the solidification temperature range significantly beyond that measured under "equilibrium" conditions. Indeed, the niobium-bearing alloys terminate weld solidification below the equilibrium solidus with the formation of nonequilibrium eutecticlike constituents involving niobium carbides and Laves-type phases. Nonetheless, it is clear from an engineering perspective that Borland's concepts are valid enough to allow the establishment of a useful alloy ranking system from a solidification cracking perspective.

In addition to the effect of melting temperature range. Borland realized that the distribution of liquid along solidifying grain boundaries plays an important role in determining the solidification cracking susceptibility on an alloy (Ref 1). If the terminal solidification liquid easily wets the solidifying grain boundary (that is, has a low solid/liquid surface tension), it will tend to be spread out over a wider area, easing separation of the grains under a mechanical imposition. Conversely, if the liquid does not readily wet these boundaries, it will be more localized, creating a smaller area of liquid-solid contact and more solid-solid bridging, resulting in a more robust mechanical structure with increased cracking resistance. Elements such as sulfur and boron have been suggested as providing this surfactant property to terminal solidification liquids in iron and nickel alloys. Manganese may serve to increase the surface tension of terminal solidification fluids.

Figure 6 shows the results (Ref 6) of varestraint testing on two heats of Cabot alloy 214, a Ni-16Cr-4.5Al-2.5Fe alloy designed for use in high-temperature environments. The two alloys differ primarily in their boron content. With no boron intentionally added (0.0002 wt%), the alloy is extremely resistant to solidification cracking. With boron intentionally added at a level of 0.003 wt%, the solidification cracking propensity is much greater. Figures 7 and 8 are surface images of pulsed Nd:YAG laser welds made on the two alloys. Extensive cracking is evident in the high-boron alloy. Figure 7(b) is a good example of the extensive terminal "crater cracking" discussed above.

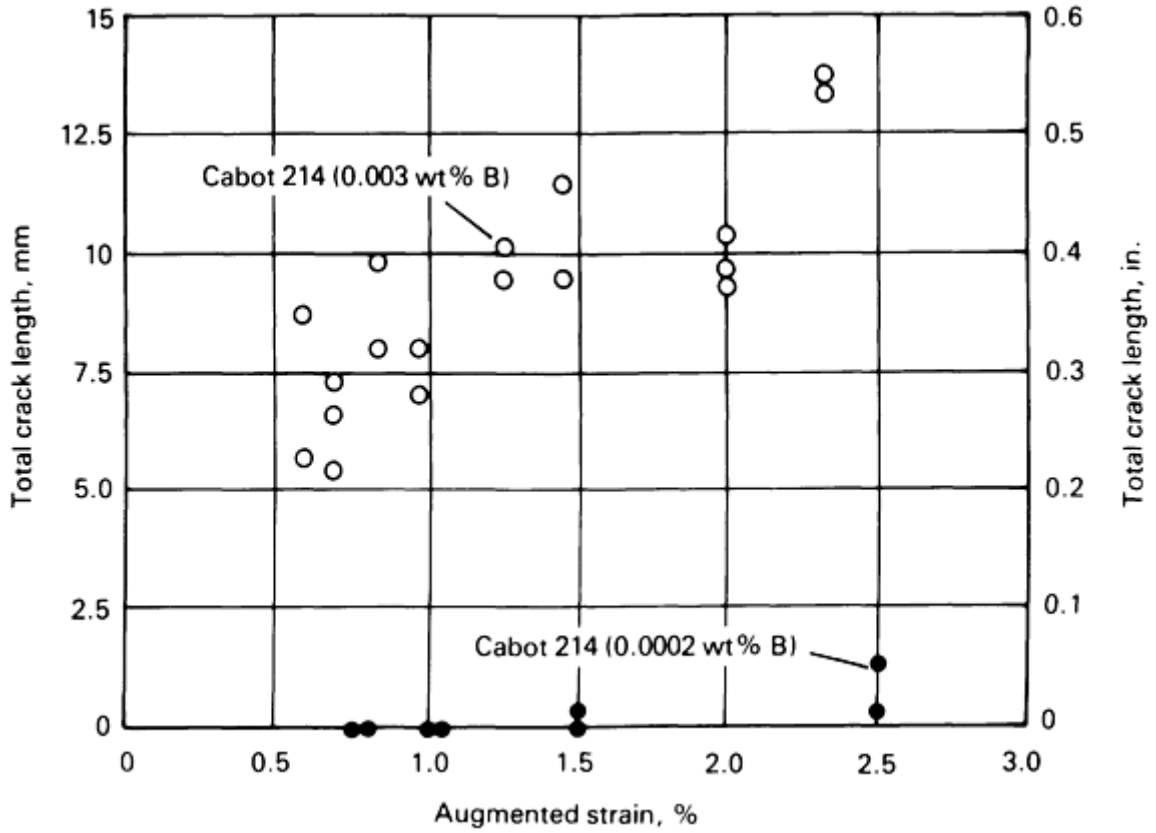

FIG. 6 VARESTRAINT TEST WELDABILITY DATA FOR CABOT ALLOY 214 WITH VARYING BORON CONCENTRATIONS

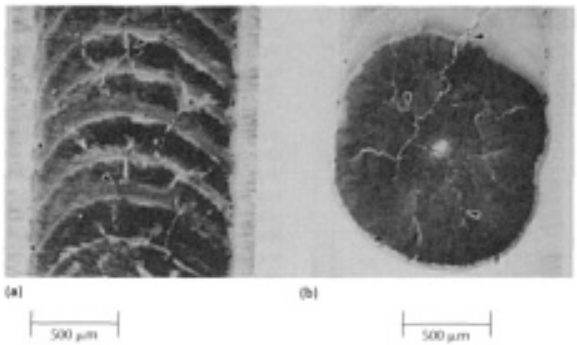

FIG. 7 SEM SURFACE IMAGE OF PULSED ND:YAG LASER WELDS IN HIGH-BORON ALLOY 214. (A) SOLIDIFICATION CRACKING. (B) CRATER CRACKING

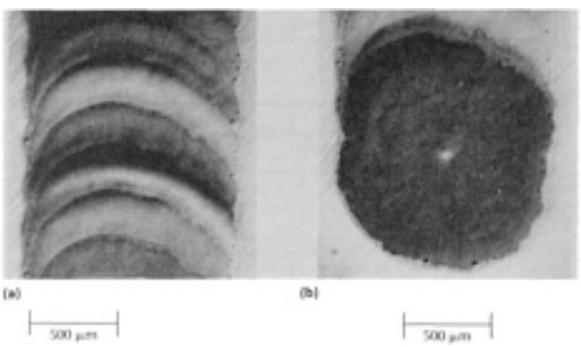

FIG. 8 SEM SURFACE IMAGE OF PULSED ND:YAG LASER WELDS IN LOW-BORON CONTENT ALLOY 214. (A) SOLIDIFICATION CRACKING. (B) CRATER CRACKING

Figures 9 and 10 summarize parameters that affect hot cracking in the weld metal and in the base metal HAZ, respectively. For most alloys that are highly susceptible to solidification cracking, filler metals of different composition have been developed to minimize the cracking that accompanies fusion welding.

Heat-Affected-Zone Cracks

Microfissures are cracks that occur in the area of partial melting and the HAZ adjacent to the fusion line. Because no material can be purified to the state where it solidifies truly as an invariant, all materials have a temperature region of stable two-phase coexistence of solid and liquid. In fusion welding, this manifests itself in the formation of a zone of

partial melting at temperatures below the alloy liquidus. The extent of this zone may be enlarged by the presence of chemical inhomogeneity in a material. Local chemical variations will result in local variations in the melting point. Segregation of specific alloying elements to grain boundaries may cause a reduction in the melting temperatures of these areas.

Many microfissures form in a manner somewhat analogous to the formation of solidification cracks in that susceptible sites, generally grain boundaries that intersect the fusion zone, are wetted with liquid from one of various sources. shrinkage strains accumulating as the weld pool advances past the liquated boundary can develop to a level sufficient to cause boundary separation (i.e., cracking). Figure 11 is a photomicrograph of an HAZ microfissure in a cast austenitic stainless steel (this crack also extends into the fusion zone as a solidification crack). Cast microstructures are highly inhomogeneous, raising the possibility of extensive partial melting. Note the melting associated with interdendritic constituents in Fig. 11.

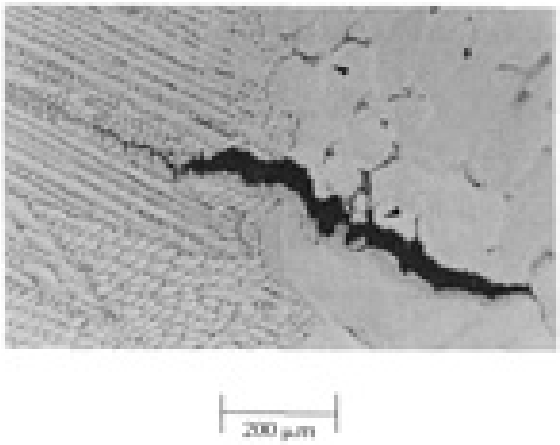

FIG. 11 HAZ MICROFISSURE IN A CAST STAINLESS STEEL. NOTE EXTENSIVE REGION OF PARTIAL MELTING.

Castings represent a special case of inhomogeneity on a continuous scale. Chemical inhomogeneities in wrought products are more discrete, generally involving minor phase particles. In many cases, these minor phases arise from thermomechanical processing of alloys well below the solidus, where the solubility for specific alloying elements can be lower. Because of the potential for extremely rapid rates of heating and cooling (especially heating) in the HAZ of fusion welds, it is entirely possible that minor phases not thermodynamically stable under equilibrium conditions may continue to exist at near-solidus temperatures. Under these conditions, the minor phases may interact with the matrix to form a liquid product. This reaction, often referred to as constitutional liquation (Ref 7), can provide the liquid required to wet grain boundaries producing a microstructure that may be susceptible to cracking.

Hot ductility testing is a common method of assessing the susceptibility of an alloy to this form of cracking. In this test, a laboratory-scale specimen is subjected to a thermal cycle representative of what the material would experience in the HAZ during fusion welding. At various temperatures during both the heating and cooling portions of the cycle, samples are strained to failure. The ductility response (usually expressed in terms of reduction of area) as the alloy progresses through the thermal cycle simulates the response of the alloy to an actual welding situation. In particular, the ability of the material to reestablish ductility after experiencing the peak temperature is a critical measure of sensitivity to this form of cracking.

Figures 12(a) and 12(b) show the hot ductility response of two heats of Cabot alloy 214 containing two different concentrations of boron. The return of ductility in the low-boron alloy after cooling from a peak temperature of 1345 °C (2453 °F) indicates that this alloy should be virtually immune to this form of cracking, as weldability tests confirmed (Ref 6). The high-boron heat showed no appreciable recovery of ductility until a temperature approximately 250 °C (450 °F) below the thermal peak temperature. This alloy should be quite susceptible to this form of cracking, as weldability tests also confirmed (Ref 6). Figure 13 is a fractograph of a hot ductility test specimen from the high-boron alloy taken from the sample strained at 1150 °C (2102 °F) on cooling from the peak temperature. The smooth, intergranular appearance is characteristic of this type of cracking. Although the presence of a liquid phase along this fracture surface could not be

unequivocally established by fractographic techniques, it was noted that the failure occurred at an exceedingly low load (Ref 6), consistent with the presence of a liquid film.

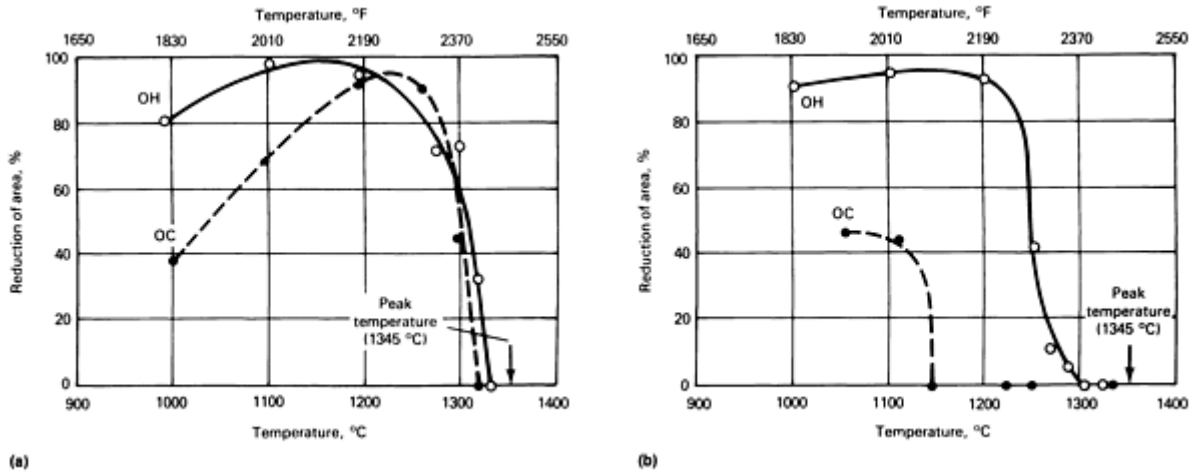

FIG. 12 HOT DUCTILITY RESPONSE OF CABOT ALLOY 214 WITH VARYING BORON CONCENTRATIONS. (A) LOW-BORON CONTENT (0.0002 WT% B). (B) HIGH-BORON CONTENT (0.003 WT% B). (OH, TESTING DONE ON HEATING; OC, TESTING DONE ON COOLING FROM 1345 °C (2455 °F)

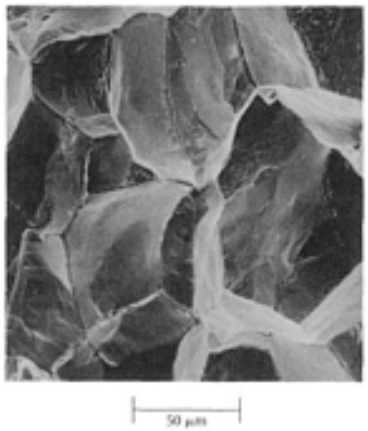

FIG. 13 FRACTURE SURFACE OF A HOT DUCTILITY SAMPLE OF HIGH-BORON ALLOY 214 TESTED AT 1150 °C (2100 °F) ON COOLING FROM 1345 °C (2455 °F)

The presence of a liquid is not essential to the formation of HAZ cracks, as they may occur at temperatures well below the solidus. Poor ductility inherent in certain materials, such as intermetallics, can lead to solid-state failure during welding if the thermal stresses associated with the weld thermal cycle exceed the local tensile strength.

Cracks may also occur in alloys that undergo polymorphic transformations during the weld thermal cycle. The act of fusion welding subjects the fusion zone and the HAZ to temperatures above those normally encountered during prior deformation processing. The resultant HAZ microstructure may be substantially different from that of the base material. In the case of martensitic-type transformations, there is often a relatively large, discontinuous change in the molar volume occurring very rapidly with decreasing temperature below the M_s. If that event causes a local shrinkage, then large, localized tensile stresses can develop. If the newly transformations microstructure has limited ductility (not uncommon in shear transformations or in transformations that result in ordered structures), the likelihood of cracks forming at susceptible sites, such as grain boundaries, matrix/minor phase interfaces, and slip band intersections, is increased.

Reheat cracking, also referred to as stress-relief of strain-age cracking, is another defect type observed in certain alloys that undergo precipitation reactions. Historically observed in several nickel-base superalloys and creep-resistant steels, this type of defect manifests itself during postweld heat treatment, generally as intergranular HAZ cracks.

Postweld heat treatment is often a recommended practice for high-strength thick-section welded steels, where reduction of residual stresses developed as a result of welding is desired. In the case of welded nickel-base superalloys, postweld heat treatment is used both to relieve residual stresses and to achieve optimum mechanical properties through precipitation-hardening reactions.

In alloys that undergo precipitation reactions, the rate at which the alloy strengthens may greatly exceed the rate at which residual stresses are thermally diminished. This can be especially true in the case of heavy-section welds or in alloys with relatively poor thermal conductivity. (That is, before the alloy can reach the temperature at which residual stresses begin to be eliminated, it has aged and lost ductility relative to its as-welded state.) At this new lower level of ductility, the residual stresses present may induce cracks to eliminate the accumulated strain energy.

In principle, the problem of reheat cracking could be largely eliminated if the rate of heating through the precipitation temperature range was rapid enough to prevent precipitate formation. However, extremely rapid rates of heating in welded hardware would likely lead to problems such as excessive distortion; therefore, improved alloys (e.g., alloy 718 among the nickel-base superalloys) have been developed in which the kinetics of precipitate formation have been sufficiently retarded to allow for successful postweld heat treatment.

Dealing with HAZ cracks, however they might form, is generally more difficult than attending to the problem of solidification cracking. Modifying the composition in the HAZ through the addition of consumables is not a viable option. Prior heat treatment may allow the production of a less susceptible starting microstructure, but this option generally is quite limited. Optimization of weld process parameters to minimize the extent of tensile stress and strain development should always be considered, as should optimizing weld joint design as discussed above.

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Hydrogen-Induced Cracking (Cold Cracking)

Cold cracks are defects that form as the result of the contamination of the weld microstructure by hydrogen. Whereas solidification cracking and HAZ cracking occur during or soon after the actual welding process, hydrogen-induced cracking is usually a delayed phenomenon, occurring possibly weeks or even months after the welding operation. The temperature at which these defects tend to form ranges from -50 to 150 °C (-60 to 300 °F) in steels. The fracture is either intergranular or transgranular cleavage.

As with other forms of cracking, hydrogen-induced cracking involves both a requisite microstructure and a threshold level of stress. It also involves a critical level of hydrogen, which is alloy and microstructure dependent.

In the case of ideal weld processing, hydrogen-induced cracking would be at most a minor welding engineering concern. However, excluding hydrogen from structures during welding is exceedingly difficult. Although the primary source of hydrogen in weld metal is considered to be the disassociation of water vapor in the arc and absorption of gaseous or ionized hydrogen into the liquid, other sources are also available. All organic compounds contain hydrogen in their

molecular structure, and all may be broken down in the intense thermal environment of a welding heat source. Organic compounds are ubiquitous in the welding environment, from lubricants in assembly areas to body oils on the hands of welding operators. Plated hardware may also contain high levels of residual hydrogen.

The mechanism of hydrogen-induced crack formation is still being investigated. An early hypothesis, involving the buildup of hydrogen gas pressure in voids, is now generally discredited. Currently, the most widely accepted model involves the presence of preexisting defect sites in the material--small cracks or discontinuities caused by minor phase particles or inclusions. In the presence of existing stress, these sites may develop high local areas of biaxial or triaxial tensile stress. Hydrogen diffuses preferentially to these sites of dilated lattice structure. As the local hydrogen concentration increases, the cohesive energy and stress of the lattice decrease. When the cohesive stress falls below the local intensified stress level, fracture occurs spontaneously. Hydrogen then evolves in the crack volume, and the process is repeated. This model of hydrogen-induced cracking is consistent with the relatively slow and discontinuous nature of the process.

In steels, where the problem of hydrogen-induced cracking is extremely significant, cracking susceptibility has been correlated both with material hardness and strength, and with specific microstructure. Higher-strength steels are more susceptible to hydrogen-induced cracking than low-strength steels. Steels that transform martensitically are particularly susceptible, especially the higher-carbon alloys with twinned martensitic structures. The desire to avoid martensite formation has driven the development of high-strength structural steels for welded applications.

Production of the newer high-strength low-alloy (HSLA) steels uses a variety of precisely controlled alloying additions (for example, aluminum, titanium, vanadium, and niobium) along with meticulous thermomechanical processing to develop a very fine-grained ferrite microstructure possessing substantial strength and fracture toughness with a high degree of resistance to hydrogen-induced cracking. The form of the ferrite produced during transformation on cooling from the austenite phase field is also critical, with acicular ferrite resulting in improved properties compared with grain-boundary, polygonal, or Widmanstätten ferrite. Acicular ferrite is often nucleated on minor phase particles, such as specific oxides or borides. Acknowledgement of the beneficial effect of certain oxides in providing sites for acicular ferrite nucleation in modern steels is in sharp contrast to steel design of earlier decades, when elimination of oxygen to the greatest extent possible was considered essential to the development of optimal fracture behavior.

A useful concept for understanding the susceptibility of carbon and alloy steels to hydrogen-induced cracking is the carbon equivalent (CE), an empirical relationship that attempts to reduce the number of significant compositional variables affecting the weldability of steels into a single quantity. Several carbon equivalent relationships have been developed for different classes of steels. An example is:

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%Cr + \%Mo + \%V}{5} + \frac{\%Si + \%Ni + \%Cu}{15} \qquad \textbf{(EQ 7)}$$

From a metallurgical perspective, the carbon equivalent can be related to the development of hydrogen-sensitive microstructures. That is, as the carbon equivalent increases, microstructures are evolved during cooling through the transformation temperature range that are increasingly more susceptible to hydrogen-induced cracking. At high carbon equivalent values, martensitic structures can be expected.

Carbon equivalent formulas are usually developed from large databases of critical hydrogen concentrations and weld joint restraints that will result in hydrogen-induced cracking in the steels under consideration. At various levels of carbon equivalent, certain weld preheat requirements are often established. In the example of Eq 7, when the carbon equivalent exceeds 0.35%, preheats are recommended to minimize susceptibility to hydrogen cracking. At higher levels of carbon equivalent, both preheats and postheats may be required.

Most structural carbon and low-alloy steels that may be susceptible to hydrogen-induced cracking transform from austenite during cooling through the temperature range of 800 to 500 °C (1470 to 930 °F). The length of time a steel spends in this temperature range during cooling will establish its microstructure and hence its cracking sensitivity. This time segment is generally referred to as $t_{8/5}$ (in seconds). To maximize cracking resistance, a microstructure free of untempered martensite is desired.

Using a specifically developed carbon equivalent, Yurioka (Ref 8) formulated a relationship to establish the critical $t_{8/5}$ for a martensite-free HAZ in low-carbon alloy steels. The carbon equivalent is defined as:

$$CE = \%C^* + \frac{\%Mn}{3.6} + \frac{\%Cu}{20} + \frac{\%Ni}{9} + \frac{\%Cr}{5} + \frac{\%Mo}{4} \qquad \textbf{(EQ 8)}$$

where %C* = %C for C $\leq$ 0.3% and %C* = %C/6 + 0.25 for %C > 0.3%. The critical time length in seconds, $t_{8/5}$, for the avoidance of martensitic transformation is given as:

$$\text{LOG } t_{8/5} = 2.69\ CE^* + 0.321 \qquad \textbf{(EQ 9)}$$

When this quantity is known, welding parameters and preheat temperature for the given thickness of material being welded can be established to produce cooling rates that avoid formation of a martensitic constituent in the HAZ.

The use of preheating and postheating to minimize the susceptibility to hydrogen-induced cracking is an accepted welding procedure for many steels. Preheating controls the cooling rate through the transformation temperature range; a higher base metal temperature in a slower cooling rate through the transformation temperature range and thus a larger $\tau_{8/5}$. Thicker sections often require preheating because of the greater heat-sinking capability of a thick section, for which a given set of welding parameters will produce a faster cooling rate and a smaller $t_{8/5}$. Preheating may also reduce the level of residual stress in the welded assembly.

There are, of course, practical limits to the use of preheating. Excessively high base metal temperatures can make welding difficult, especially manual welding. A high preheat temperature will result in the flattening of temperature gradients, increasing the spatial extent of and the time spent in the austenite phase field. This may result in excessive grain growth in the HAZ, which can lead to a loss of fracture toughness independent of hydrogen content. Preheat temperatures up to 150 °C (300 °F) are not uncommon for low-alloy steels and may increase up to 425 °C (800 °F) for higher-carbon equivalent martensitic steels.

Several benefits can be realized by postheating. At high enough temperatures (550 to 600 °C, or 1020 to 1110 °F), postheating can diminish residual stresses present in the as-welded structure. Microstructural modifications such as tempering can also occur, producing a microstructure less susceptible to hydrogen-induced cracking. Finally, the higher temperature may allow hydrogen to diffuse into the bulk of the structure or even to the surface, where it may recombine and exit as a gas. In either case, the level of hydrogen concentration may be reduced below that required to initiate cracks.

The following guidelines should be followed to minimize the occurrence of hydrogen-induced cracking. For a given level of required strength, the steel with the lowest carbon equivalent should be considered. Low-hydrogen welding practice should be followed. This involves elimination of possible sources of hydrogen by using ultrahigh-purity gases and moisture-free gas lines and by baking coated electrodes following the manufacturer's recommendations to ensure removal of nascent water. Finally, preheating and postheating requirements should be followed assiduously. Figures 14 and 15 summarize the causes and cures of hydrogen-induced cracking in the weld metal and in the base metal, respectively.

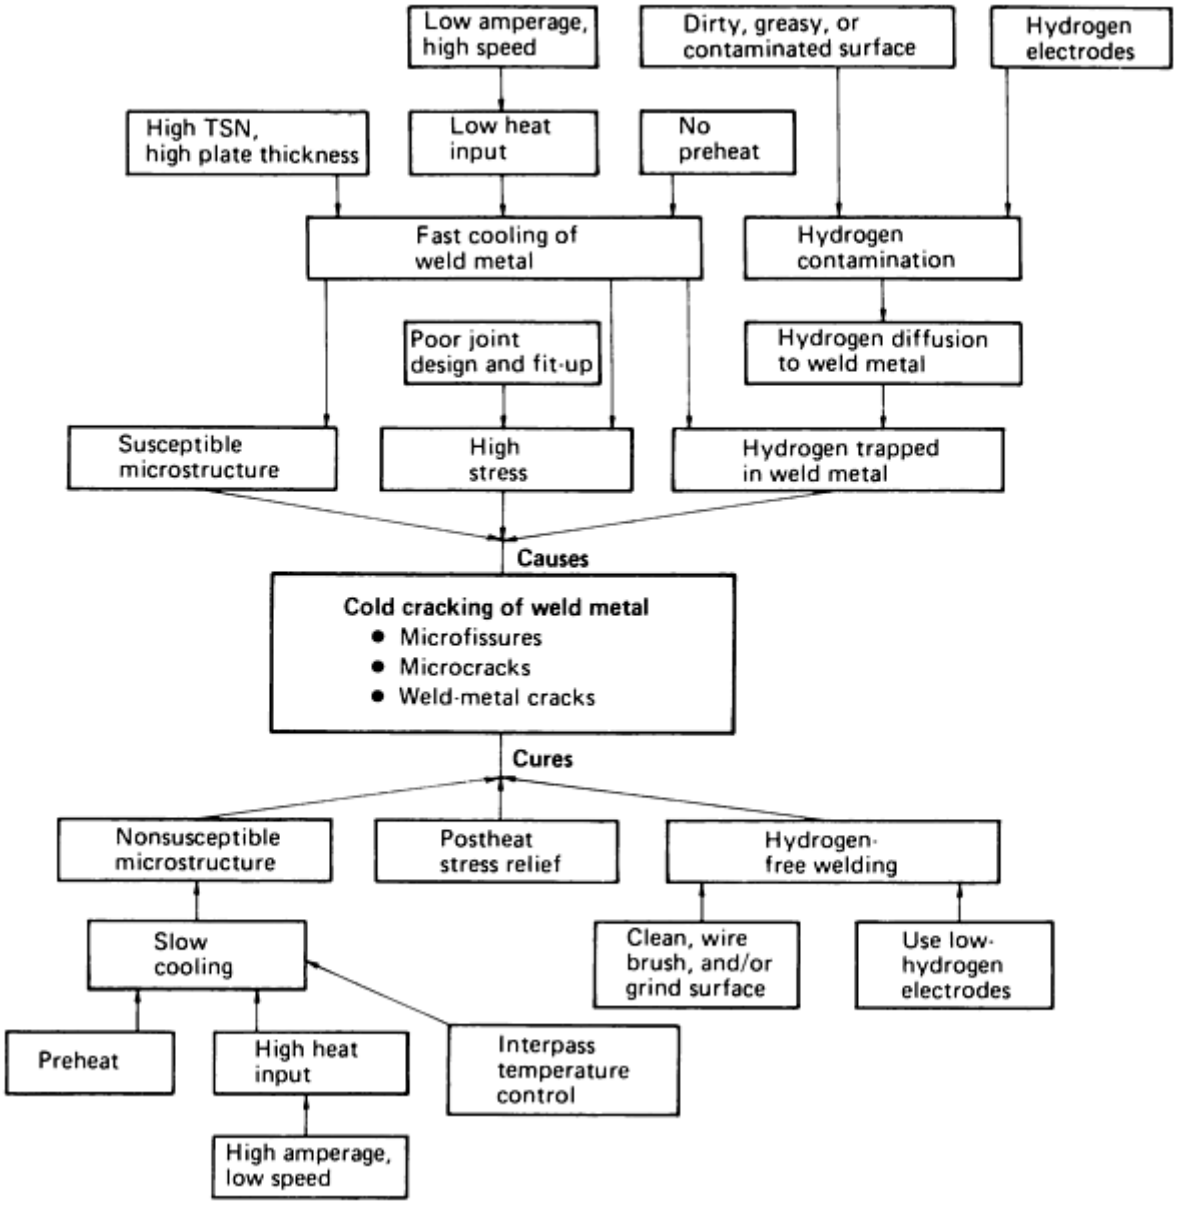

FIG. 14 CAUSES AND CURES OF HYDROGEN-INDUCED CRACKING IN WELD METAL. THERMAL SEVERITY NUMBER (TSN), WHICH IS FOUR TIMES THE TOTAL PLATE THICKNESS CAPABLE OF REMOVING HEAT FROM THE JOINT, IS A MEASURE OF THE ABILITY OF THE MEMBER TO SERVE AS A HEAT SINK.

Cracking Phenomena Associated With Welding

Michael J. Cieslak, Physical and Joining Metallurgy Department, Sandia National Laboratories

Lamellar Tearing (Ref 9)

Lamellar tearing is cracking that occurs beneath welds. It is found in rolled steel plate weldments. The tearing always lies within the base metal, generally outside the HAZ and parallel to the weld fusion boundary. The problem is caused by welds that subject the base metal to tensile loads in the *z*, or through, direction of the rolled steel. Occasionally the tearing comes to the surface of the metal, but more commonly remains under the weld (Fig. 16) and is detectable only by ultrasonic testing. Lamellar tearing occurs when three conditions are simultaneously present:

- STRAINS DEVELOP IN THE THROUGH DIRECTION OF THE PLATE. THEY ARE CAUSED BY WELD METAL SHRINKAGE IN THE JOINT AND CAN BE INCREASED BY RESIDUAL STRESSES AND BY LOADING.
- THE WELD ORIENTATION IS SUCH THAT THE STRESS ACTS THROUGH THE JOINT ACROSS THE PLATE THICKNESS (THE *Z* DIRECTION). THE FUSION LINE BENEATH THE WELD IS ROUGHLY PARALLEL TO THE LAMELLAR SEPARATION.
- THE MATERIAL HAS POOR DUCTILITY IN THE *Z* DIRECTION.

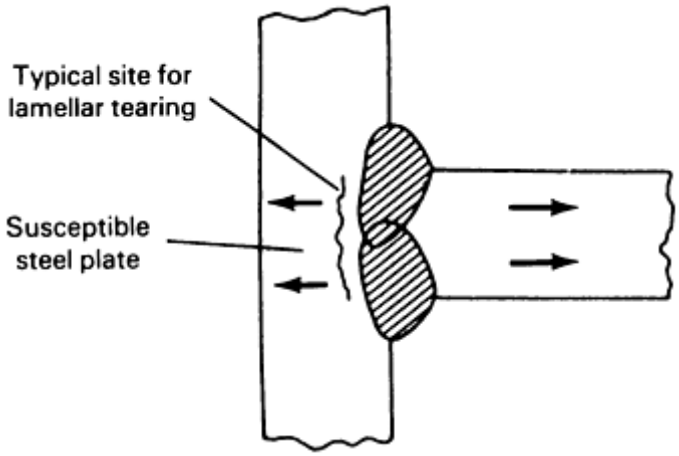

FIG. 16 TYPICAL LOCATION FOR LAMELLAR TEARING IN A T-JOINT

Lamellar tearing can occur during flame cutting and cold shearing operations. Low material strength in the *z* direction is the primary cause, with stress in that direction initiating the tearing. Thermal heating and stresses from weld shrinking create the fracture. Lamellar tearing can take place shortly after welding or occasionally months later. Thicker, higher-strength materials appear to be more susceptible. However, the phenomenon affects only a very small percentage of steel plates, as all three of the above conditions rarely occur in combination.

The problem can be avoided by proper attention to joint details. In T-joints (Fig. 16), double-fillet welds appear to be less susceptible than full-penetration welds. Also, balanced welds on both sides of the joint appear to present less risk than large, single-sided welds. In corner joints, common in box columns, lamellar tearing can be readily detected on the exposed edge of the plate (Fig. 17a). The problem can be overcome by placing the bevel for the joint on the edge of the plate that would exhibit the tearing rather than on the other plate (Fig. 17b). Butt joints rarely exhibit lamellar tearing, because weld shrinkage does not set up a tensile stress in the thickness direction of the plates.

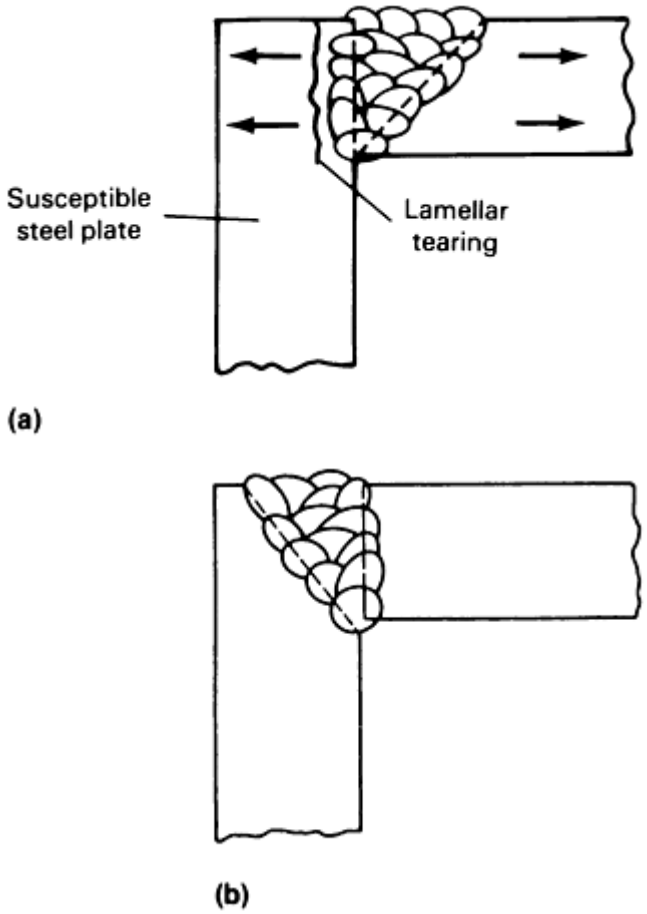

FIG. 17 CORNER JOINT. (A) LAMELLAR TEARING SURFACES AT THE EXPOSED PLATE EDGE. (B) REDESIGNED JOINT

Arc welding processes with high heat input are less likely to create lamellar tearing, perhaps because of the fewer number of applications of heat and the lesser number of shrinkage cycles involved in making a weld. Also, filler metal with lower yield strength and high ductility appears to lessen the possibility of tearing. Preheating does not appear to be particularly advantageous, nor does stress relieving. The "buttering" technique of laying one or more layers of low-strength, high-ductility weld metal deposit on the surface of the plate stressed in the *z* direction will reduce the possibility of lamellar tearing. However, this is an extreme solution and should be used only as a last resort.

Characterization of Welds

Craig B. Dallam, The Lincoln Electric Company; Brian K. Damkroger, Sandia National Laboratories

Introduction

WELDS CAN BE CHARACTERIZED according to a number of criteria, including the welding process used, size, shape, mechanical properties, chemical composition, and a number of others. The appropriate methods of characterization depend on the weld's function and the particular set of properties required for the application. In some instances, the ability of a weld to function successfully can be addressed by characterizing the size or shape of the weld. An example of this is where factors related to the welding procedure, such as inadequate weld size, convexity of the bead, or lack of penetration, may cause a weld to fail. In other cases, it is important to characterize metallurgical factors such as weld metal composition and microstructure. Examples might include welds for which the goal is to avoid failures due to inadequate strength, ductility, toughness, or corrosion resistance. In general, the goals of weld characterization are to assess the ability of a weld to successfully perform its function, to thoroughly document a weld and welding procedure that have been demonstrated to be adequate, or to determine why a weld failed.

In the first part of this article, characterization of welds will be treated as a sequence of procedures, each more involved than the last and concerned with a finer scale of detail. Initially, non-destructive characterization procedures will be the focus. The first level of characterization involves information that may be obtained by direct visual inspection and measurement of the weld. A discussion of nondestructive evaluation follows. This encompasses techniques used to characterize the locations and structure of internal and surface defects, including radiography, ultrasonic testing, and liquid penetrant inspection.

The next group of characterization procedures discussed are destructive, requiring the removal of specimens from the weld. The first of these is macrostructural characterization of a sectioned weld, including features such as number of passes; weld bead size, shape, and homogeneity; and the orientation of beads in a multipass weld. Macroscopic characterization is followed by microstructural analysis, including microsegregation, grain size and structure, the phase makeup of the weld, and compositional analysis.

The third component of weld characterization is the measurement of mechanical and corrosion properties. The goal of any weld is to create a structure that can meet all the demands of its service environment. In many cases, the best way of assessing the performance of a weld is to establish its mechanical properties. In addition to a number of standard material tests, many mechanical tests are directed specifically at determining a weld's capabilities. Examples of mechanical properties typically characterized for welds include yield and tensile strength, ductility, hardness, and impact or fracture toughness. Corrosion testing is often employed in situations where a welding operation is performed on a corrosion-

resistant material, or in a structure exposed to a hostile environment. Although absolute corrosion performance is important, a major concern is to ensure that a weld and its heat-affected zone (HAZ) are cathodic to the surrounding metal.

Following the discussion of the characterization procedures, the second part of this article will give examples of how two particular welds were characterized according to these procedures.

Nondestructive Characterization Techniques

Externally Observed Macroscopic Features. Several factors associated with the production and performance of welds are macroscopic and easily observed. The most obvious of these are the size, shape, and general appearance of the weld. To a large extent, these parameters depend on the geometry of the weld joint and the welding process selected. Figure 1 shows schematic representations of fillet, lap, butt, and groove welds, in which a number of features (defined in Table 1) are labeled.

TABLE 1 NONMENCLATURE FOR FILLET, LAP, BUTT, AND GROOVE WELDS

FEATURE	DEFINITION
FACE	EXPOSED SURFACE OF A WELD ON THE SIDE FROM WHICH THE WELDING WAS PERFORMED
ROOT	POINTS, AS SHOWN IN CROSS SECTION, AT WHICH THE BACK OF THE WELD INTERSECTS THE BASE METAL SURFACE
LEG	SHORTEST DISTANCE FROM ROOT TO TOE IN A FILLET WELD
TOE	JUNCTION BETWEEN THE WELD FACE AND THE BASE METAL
THROAT	SHORTEST DISTANCE FROM ROOT TO FACE IN A FILLET WELD
PENETRATION	DEPTH A GROOVE WELD EXTENDS INTO THE ROOT OF A JOINT, MEASURED ON THE CENTERLINE OF A ROOT CROSS SECTION
REINFORCEMENT	WELD METAL IN EXCESS OF THE SPECIFIED WELD SIZE
FACE REINFORCEMENT	REINFORCEMENT AT THE SIDE OF THE WELD FROM WHICH WELDING WAS PERFORMED
SIZE (GROOVE WELD)	JOINT PENETRATION (DEPTH OF ROOT PREPARATION) PLUS THE ROOT PENETRATION (WHEN SPECIFIED)
SIZE (FILLET WELD)	LEG OF THE LARGEST ISOSCELES RIGHT TRIANGLE THAT CAN BE INSCRIBED WITHIN THE FILLET WELD CROSS SECTION

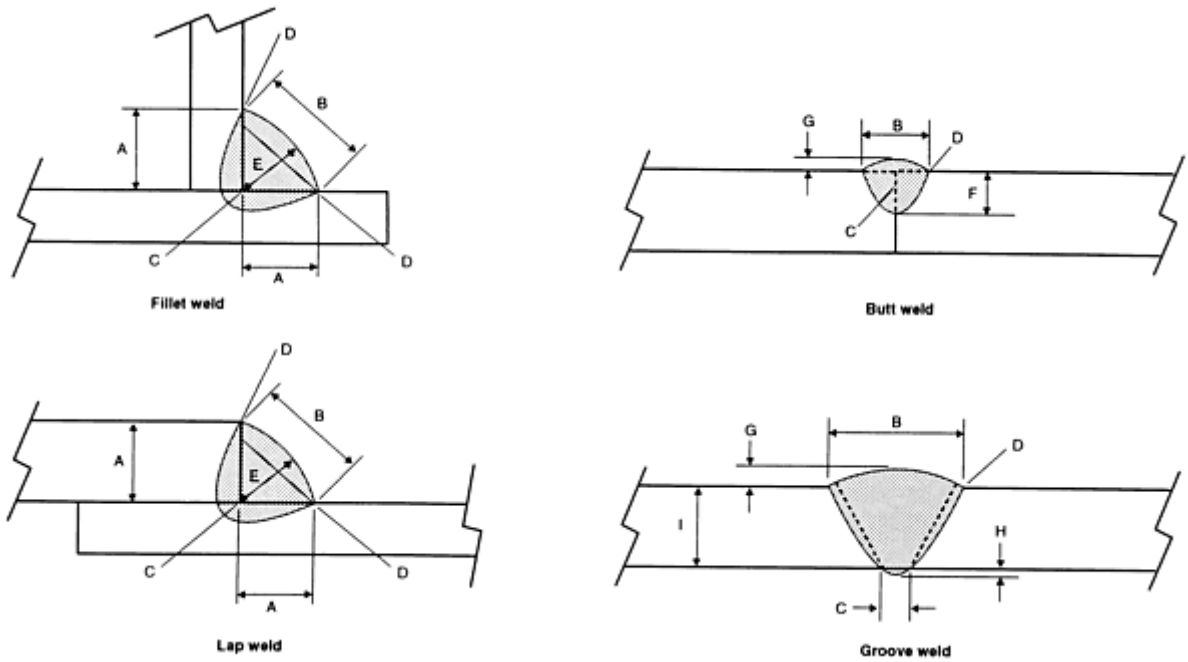

FIG. 1 SCHEMATICS SHOWING PARAMETERS OF COMMONLY USED JOINT GEOMETRIES. A, LEG; A', SMALLER LEG SIZE (EQUAL TO SIZE OF WELD); B, FACE, C, ROOT; D, TOE; E, THROAT; F, PENETRATION (EQUAL TO SIZE OF WELD); G, FACE REINFORCEMENT; H, ROOT REINFORCEMENT; I, SIZE OF WELD

Methods of Characterization. The primary tools used in the external macrocharacterization of a weld are the unaided eye and a hand lens. A number of macrocharacterization parameters (for example, weld location, size, shape, and general uniformity) can be assessed by visual inspection. Figure 2 shows top-view macrographs of two welds that illustrate several of these considerations. In many cases, the presence of gross defects such as hot cracking or porosity may also be detected by visual inspection and a top-view photograph. Additional examples of factors included in overall weld bead appearance include distortion, discoloration due to inadequate shielding or excessive heat, undercut, excessive crater size, and uneven bead width. In fillet welds, a number of performance aspects can be affected by the relative geometry of the joint. Fillet gages can be used to determine the size of a weld, the curvature of the face, and the length of the weld legs.

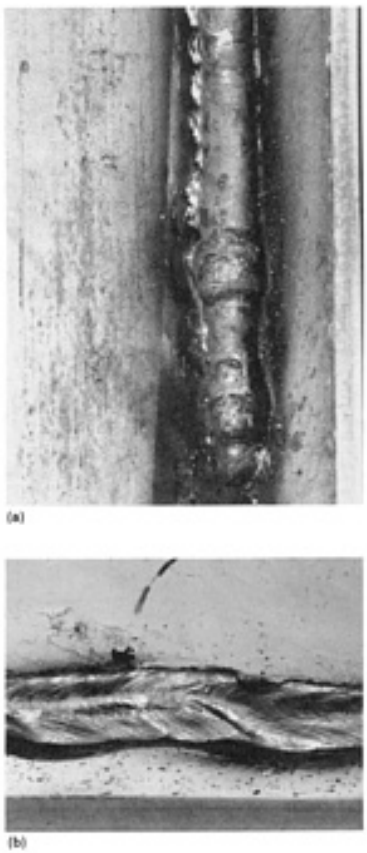

FIG. 2 MACROGRAPHS SHOWING TOP VIEW OF FILLET WELDS. (A) VERTICAL WELD IN TYPE 304L STAINLESS STEEL (NOTE CONVEXITY OF BEAD AND NONUNIFORM REGIONS). (B) HORIZONTAL E 7024 WELD (NOTE WELD PLACEMENT AND LACK OF UNIFORMITY)

General Considerations. Most types of welds will be evaluated with respect to specific macrocharacteristics deemed to be either desirable or undesirable. However, a number of general considerations apply to most types of welds. These include:

- *SIZE:* THE SIZE OF THE WELD SHOULD BE APPROPRIATE FOR THE PART (AS AN EXAMPLE, A GENERAL RULE FOR FILLET WELDS IS THAT THE RATIO OF LEG SIZE/PLATE THICKNESS SHOULD BE BETWEEN 3:4 AND 1:1.
- *LOCATION:* AN INCORRECTLY LOCATED BUTT WELD MAY NOT ALLOW THE PART TO FUNCTION CORRECTLY. A LESS EXTREME EXAMPLE IS A FILLET WELD WITH UNEQUAL LEG LENGTHS, LEADING TO AN UNEVEN STRESS DISTRIBUTION AND PERHAPS LAMELLAR TEARING.
- *UNIFORMITY:* DISTORTION, THE PROBABILITY OF SLAG ENTRAPMENT ON MULTIPASS WELDS, AND UNIFORMITY OF LOAD-CARRYING ABILITY ALL DEPEND ON THE RELATIVE UNIFORMITY OF THE WELD.
- *DEFECTS:* IDEALLY, A WELD SHOULD BE FREE OF MACROSCOPIC DEFECTS. COMMON DEFECTS INCLUDE UNDERCUTTING, LACK OF FUSION, PINHOLE POROSITY, AND SLAG ENTRAPMENT.
- *FACE SHAPE:* A WELD SHOULD HAVE A RELATIVELY FLAT FACE. IF THE WELD IS TOO CONVEX, STRESS WILL BE CONCENTRATED ALONG THE TOE OF THE WELD. CONVERSELY, A HIGHLY CONCAVE WELD FACE WILL RESULT IN LOCALLY HIGH STRESSES IN THE THROAT REGION OF THE WELD.

Defects. The presence of surface or internal defects can degrade the performance of a weld that may appear to be sound in a cursory examination. The causes and means of preventing defects are covered in Ref 2, 3, and 4. Typical defects found in welds include:

- POROSITY
- UNDERCUT
- OVERLAP
- LACK OF PENETRATION
- LACK OF FUSION
- SHRINKAGE VOIDS
- CRATER CRACKING
- MELT-THROUGH OR BURN-THROUGH
- SUBSOLIDUS OR HOT CRACKING
- INCLUSIONS DUE TO ENTRAPPED SLAG, TUNGSTEN ELECTRODE PIECES, OR DEFECTS PRESENT IN THE STARTING MATERIAL

A number of techniques are widely used to assess the presence of surface and subsurface defects in welds. The most common of these are liquid penetrant inspection for surface cracks, magnetic particle inspection, x-ray radiography, and ultrasonic inspection. Penetrant inspection involves the application of an indicator fluid that has a surface tension sufficiently low to be drawn into surface cracks too small to be detected visually. The excess dye or fluorescent material is then removed from the surface, but it remains in and highlights the cracks when a developer is applied. Figure 3 shows cracks in a flux-cored are weld highlighted by dye penetrant inspection. Table 2 lists the characteristics of several types of nondestructive inspection techniques. Additional information is available in the article "Inspection of Welded Joints" in this Volume.

TABLE 2 GUIDELINES FOR SELECTING TECHNIQUES

Technique	Equipment Requirements	Defects Detected	Advantages	Limitations	Comments
liquid-penetrant or fluorescent-penetrant inspection	fluorescent or visible penetration liquids and developers; ultraviolet light for fluorescent dyes	defects open to the surface only; good for leak detection	detects small surface imperfections; easy application; inexpensive; use on magnetic or nonmagnetic material; low cost	time-consuming; not permanent	used on root pass of highly critical pipe welds; indications may be misleading on poorly prepared surfaces
magnetic particle inspection	wet or dry iron particles, or fluorescent; special power source; ultraviolet light for fluorescent dyes	surface and near-surface discontinuities: cracks, porosity, slag	indicates discontinuities not visible to the naked eye; useful for checking edges before welding; no size limitations	for magnetic materials; surface roughness may distort magnetic field; not permanent	test from two perpendicular directions to detect any indications parallel to one set of magnetic lines
radiographic inspection	x-ray or γ ray; film processing and viewing equipment	most internal discontinuities and flaws; limited by direction of discontinuity	provides permanent record of surface and internal flaws; applicable to any alloy	usually not suitable for fillet weld inspection; film exposure and processing	popular technique for sub-surface inspection

				critical; slow and expensive	
ultrasonic inspection	ultrasonic units and probes; reference patterns	can locate all internal flaws located by other methods, as well as small flaws	extremely sensitive; complex weldments restrict usage; can be used on all materials	highly skilled interpretor required; not permanent	required by some specifications and codes

Source: Ref 5

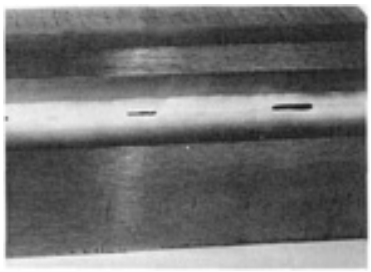

FIG. 3 SURFACE CRACKS IN A FLUX-CORED ARC WELD HIGHLIGHTED BY DYE PENETRANT INSPECTION

X-ray radiography is used to detect internal defects such as porosity or inclusions: these defects show up because of the difference in x-ray absorption between the matrix and defect materials. Although a number of factors affect the resolution level of radiographic techniques (Ref 5, 6), the minimum size of defects considered in AWS specifications is 0.4 mm (0.0156 in.). In practice, this refers to slag entrapment and large inclusions that were present in the starting material. Defect structures are usually quantified by comparison with an existing standard, of which several exist. An example of such a standard is American Petroleum Institute (API) 1104 (Ref 7), a pipeline welding specification. The API 1104 standard includes criteria for acceptance of steel welds based on a number of defects, including inadequate penetration, incomplete fusion, internal concavity, burn-through, slag inclusions, and porosity. For example, one section of API 1104 can be summarized as follows:

> Slag inclusions--50 mm (2 in.) maximum length for elongated slag inclusions, 50 mm (2 in.) limit per 305 mm (12 in.) of weld, 1.6 mm ($\frac{1}{16}$ in.) width limit per elongated slag inclusion. Isolated slag inclusions, 13 mm ($\frac{1}{2}$ in.) per 305 mm (12 in.) of weld, width greater than 3.2 mm ($\frac{1}{8}$ in.), 105 mm ($4\frac{1}{8}$ in.) isolated slag inclusions per 305 mm (12 in.) of weld. Aggregate length of isolated slag inclusion indications may not exceed two times the thinner of the nominal wall thickness and the width may not exceed one-half the thinner of the wall thicknesses joined.

Other examples include ASTM E 390 (Ref 8), which contains reference radiographs for steel welds and the *Structural Welding Code* (Ref 9), which includes a group of radiographic plates showing defect patterns for rounded inclusions corresponding to grade 1 and grade 2 quality levels. Several industries and product categories have applicable specifications and standards. A number of these are given in Ref 5.

Ultrasonic testing can also be used to locate internal defects, including porosity and inclusions. Ultrasonic testing involves transmitting mechanical vibrations through a piece of metal and analyzing both reflected and transmitted vibrations. Vibrations interact with discontinuities in the media through which they are passing, so the operator can detect voids, inclusions, and other internal interfaces. Table 2 includes ultrasonic testing, and Ref 5 lists a number of example specifications and detailed references.

Characterization of Welds

Craig B. Dallam, The Lincoln Electric Company; Brian K. Damkroger, Sandia National Laboratories

Internal Characterization Requiring Destructive Procedures

This section briefly covers macrostructural and microstructural characterization and compositional analysis. These procedures are usually based on a cross section of the weld, referred to as a transverse section. The transverse section may be supplemented by the top-view photograph, the longitudinal section, and the normal section (Fig. 4). In particular, the top-view photograph will depict the general appearance of the weld, illustrating surface irregularities, spatter, or macroscopic defects such as hot cracking or porosity.

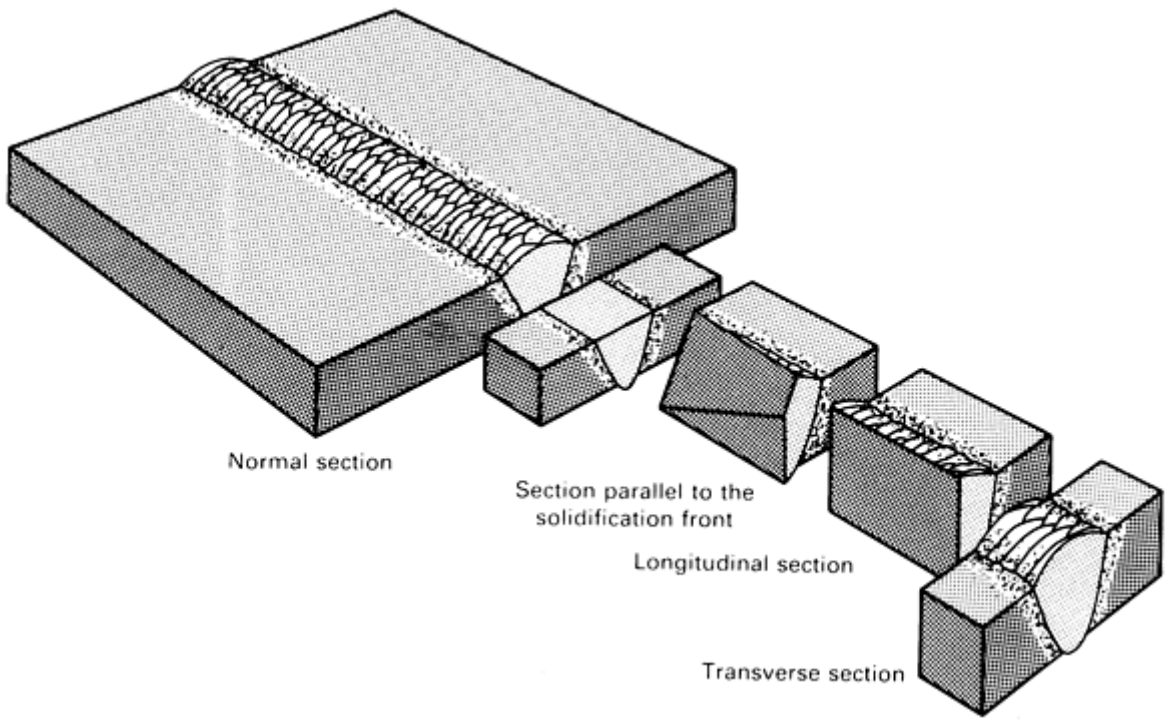

FIG. 4 TYPICAL SECTIONS USED IN THE METALLOGRAPHIC EXAMINATION OF WELDED JOINTS

Weld Macrostructure

Figures 5(a) and 5(b) show transverse sections of two welds, a submerged arc weld made on a 25 mm (1 in.) thick ASTM A 36 steel and a flux-cored weld made on a 50 mm (2 in.) thick ASTM A 537 steel. Readily apparent features include the number of passes and number of layers, fusion zone area, weld aspect ratio, extent of penetration, face width, and the reinforcement and curvature of the top bead. A transverse macrosection will also show any gross porosity or large inclusions present in a weld and the extent of the HAZ. It is important to note that quantitative measurements of weld features made based on a transverse section will be accurate only if the section is properly done. Potential errors, sectioning procedures, and sample preparation techniques are discussed in Ref 10.

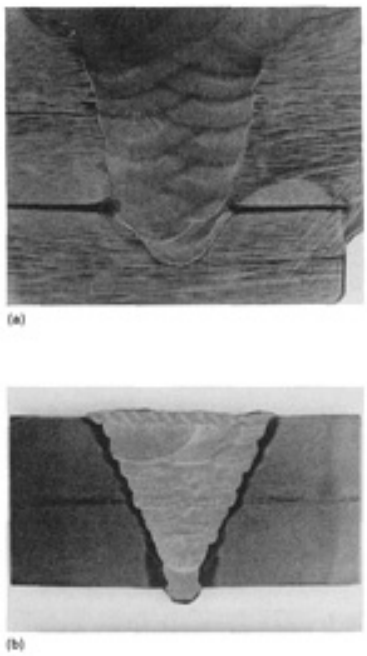

FIG. 5 TYPICAL MULTIPASS ARC WELDS IN STEELS USED IN STRUCTURAL APPLICATIONS. (A) SUBMERGED ARC WELD ON A 25 MM (1 IN.) THICK A 36 STRUCTURAL STEEL; THE MUSHROOM SHAPE OF THE LAST BEAD IS TYPICAL OF WELDS PRODUCED BY THIS PROCESS. (B) FLUX-CORED ARC WELD ON A 50 MM (2 IN.) THICK A 537 STEEL USED IN PRESSURE VESSEL AND STRUCTURE APPLICATIONS (THE LAST LAYER WAS MADE WITH SEVERAL SMALL PASSES TO IMPROVE MECHANICAL PROPERTIES)

Weld Microstructure

In many cases, it is important to examine and characterize the weldment microstructure and to understand its formation and effects on properties. This is the case when the materials and processes involved are not well characterized, so specifications have not been established. Other problems arise where the potential exists for the formation of detrimental microconstituents and/or where the consequences of weld failure are severe. Welding of high-strength or brittle materials are typical examples.

The microstructure of a weld consists of three regions: a fusion zone (material that has been melted); a heat affected zone (material that was not melted, but whose microstructure has been altered); and the base metal. These three regions can be seen in the transverse section shown in Fig. 5(b). Weld microstructures are examined using standard specimen removal and preparation techniques, with some concessions made for their inhomogeneous nature (Ref 10). Similarly, the parameters used to characterize the weld microstructures, such as grain size, grain morphology, and the amount of the various phases or microconstituents present, are those used to characterize monolithic materials. The equipment, procedures, and techniques used are well described in Ref 10.

Special importance may be attached to one or more specific features of a weld microstructure. An example is the classification of ferrite and carbide microconstituents in a low-ally steel weld. The various morphologies included in a characterization of a low-alloy steel weld are listed in Table 3. In these welds, a large amount of acicular ferrite is associated with high toughness levels, whereas martensitic or bainitic microstructures have much lower toughness levels. Bainite and martensite are also associated with higher effective cooling rates, so decreasing the weld metal manganese content, or reducing the cooling rate with increased heat input or preheat, will increase the amount of acicular ferrite and improve weld metal toughness.

TABLE 3 DESCRIPTION OF FERRITE/CARBIDE MICROCONSTITUENTS IN LOW-CARBON STEEL WELDS

Microconstituent	Description
Primary ferrite	
Grain boundry ferrite	Proeutectoid ferrite that grows along the prior austenite grain boundaries. It is equiaxed or polygonal, and it may occur in veins
Intragranular polygonal ferrite	Polygonal ferrite that is not associated with the prior austenite grain boundaries. Much larger than the average width of the surrounding acicular ferrite laths
Ferrite with second phase	
With aligned second phase	Parallel ferrite laths. Further classifications are widmanstätten ferrite and upper/lower bainite
With nonaligned second phase	Ferrite that completely surrounds either equiaxed, randomly distributed microphases, or solitary ferrite laths
Ferrite/carbide aggregate	Fine ferrite/carbide structures, including pearlite
Acicular ferrite	Small nonaligned ferrite grains found within prior austenite grains
Martensite	Martensite colony larger than adjacent ferrite laths

Microstructural characterization of welds has two purposes: to evaluate the microstructure with respect to properties and to relate the microstructure to the process used. The ultimate goal is to optimize the process to produce the most desirable microstructure. In general, the effects of a process and parameters on microstructure are due to the compositional and thermal effects. The compositional effects are largely limited to the fusion zone and will be discussed in the next section. Thermal cycles affect both the fusion zone and HAZ. Microstructural development in the HAZ has been the subject of much study, and a number of computational tools have been developed specifically for the prediction of HAZ microstructures (Ref 11).

Composition of a Weld

The composition of a weld will have a significant effect on its performance, contributing to both the mechanical and corrosion properties of the weld. In some instances, the effects can be drastic, such as sensitization of stainless steel or changing the ductile-to-brittle transition temperature of ferritic steels by an amount sufficient to cause brittle failure under normal use. In a number of cases, particular elements will govern the propensity toward certain defects or behavior. For example, a low-alloy steel weld with a carbon equivalent of over 0.4% is considered to be a high-carbon deposit, and it is treated differently than a low-carbon weld. Similarly, deposit silicon levels in excess of approximately 0.4% are often associated with a defect called "hollow bead," where the root pass in a pipe weld made with a cellulosic electrode has a continuous pore. In general, care must be taken to either minimize the compositional changes associated with welding or to factor the composition and property changes into the design.

Factors Affecting Weld Composition. The composition of a weld is affected by the base metal composition, the composition of any filler metal used (and dilution between the two), reactions with flux or shielding gas, and any material losses associated with the process. These factors are, in turn, largely controlled by the welding setup, process selection, parameters, and stability. The Schaeffler diagram (Ref 12) for stainless steels is an example of composition being controlled by dilution. The weld metal composition and microstructure are predicted based on the "ferrite stabilizer" and the "austenite stabilizer" content of the base metal, the nickel equivalent and chromium equivalent of the filler metal, and the level of dilution. The microstructure will be predicted as martensitic, ferritic, or austenitic, and the level of ferrite in the weldment will be estimated. In these welds, ferrite numbers below 4 indicate microstructures in which low-melting-

point compounds may be formed at the grain boundaries, and the welds can be prone to hot cracking. Conversely, welds with ferrite numbers above 10 have reduced corrosion resistance and can be susceptible to the formation of σ phase at high temperatures (Ref 13). The Schaeffler diagram has been revised many times for adaptation to different alloy modifications. An example is the inclusion of nitrogen in the nickel equivalent. Many stainless steels often contain small amounts of nitrogen, and in fact some stainless steels are deliberately strengthened with nitrogen additions. Other modifications include copper in the nickel equivalent and vanadium and aluminum in the chromium equivalent (Ref 14). Additional information is available in the Section "Selection of Stainless Steels" and in the article "Welding of Stainless Steels" in this Volume.

An example of the effect of flux on weld metal composition is seen when low-carbon steel is welded with E6010 and E7018 electrodes, using identical parameters. Although the core wire composition of the two electrodes is identical, the E6010 electrode will produce a deposit with approximately 0.15 to 0.25% Si, and the E7018 electrode will produce a deposit with 0.5 to 0.6% Si. An example of a procedure-related effect is seen when the arc length is changed for welds made with an E7018 electrode. Arc length changes can alter the silicon content from 0.3 to 0.6%, and they can alter the manganese content from 0.8 to 1.3%.

Measurement Techniques and Procedures. The usual techniques for compositional analysis of metallic samples can be used on welds and are covered in Ref 15. However, some considerations must be made when dealing with welds, because of their inhomogeneity. The most commonly used method for compositional analysis of welds is optical emission spectroscopy, where a spot of material (typically 6 mm, or $\frac{1}{4}$ in., in diameter) is ablated off the surface of the specimen and the light emissions are analyzed. In many welds, a spot this size will encompass several passes in a multipass weld, and it will perhaps encompass weld metal, HAZ, and base metal in a single-pass weld. An average composition over this large an area may not address local effects, for example, sensitization of stainless steel.

Welds are prone to both macrosegregation and microsegregation, and the properties may be governed by the composition in a very local region. A thorough characterization of welds requires techniques with sufficient spatial resolution to characterize their inhomogeneity. Scanning electron microscopy with wavelength or energy dispersive x-ray analysis systems, electron microprobes, and x-ray fluorescence techniques are often employed. Often, a number of closely spaced analyses are made along a line traversing a weld. This data may then be coupled with a similar microhardness traverse and microstructural analyses to characterize the variation across the weld. Thorough treatments of a number of microanalytical techniques are contained in Ref 16.

Mechanical Testing

A number of mechanical properties are used to characterize welds, including strength, ductility, hardness, and toughness. In general, the same samples and procedures are used in other areas of metallurgy (Ref 17). However, a prominent concern regarding the mechanical performance of welds is the direct comparison with base material. The goal is to ensure that the weld is not the weakest component of a structure, or if it is, to compensate for this in the design.

Strength. Yield and tensile strength are measured for all-weld-metal specimens using a standard tensile test (Ref 18), but with specimens removed from test plates welded according to AWS-specified procedures (Ref 19). These tests form the basis for the assignment of yield and ultimate strength values to welds made using a specific electrode and according to a set procedure. Additional tests are sometimes performed to compare the base metal and weld metal strengths. An example of this type of test is the transverse tensile test, in which the specimen is removed from the weld so that the loading axis is perpendicular to the weld bead and the weld reinforcement is left intact. The goal of this test is to verify that overload failure will occur in the base metal rather than in the weld metal or HAZ.

Ductility is another critical weld property. In addition to defects, many welding processes can produce hard, brittle microstructures. The standard measures of ductility--percent reduction in area and percent elongation--are obtained in a uniaxial tensile test. Another test often specified for welds is a bend test (face bends, roof bends, and side bends). In this test, a strip of material containing a weld is deformed around a specified radius and its surface is examined. The criteria for success or failure are the number and size of defects seen on the outer surface of the bend. An example of bend test criteria is the AWS *Structural Welding Code* (Ref 9), which calls for bending around a 19 mm (0.75 in.) radius for materials with yield strengths less than or equal to 345 MPa (50 ksi), a 25 mm (1 in.) radius for 345 to 620 MPa (50 to 90 ksi) materials, and a 32 mm (1.25 in.) radius for materials with yield strengths greater than or equal to 620 MPa (90 ksi).

Hardness. One common use of hardness values in weld specifications is as a check for the formation of microstructures that might have low ductility and toughness and thus are prone to cracking. For example, in pipeline steels, the formation of martensite in the HAZ is a cause for concern because of the potential for cracking. This is addressed by specifying maximum values for microhardness traverses across several sections of the weld. Hardness values are also used as an indicator of susceptibility to some forms of stress-corrosion cracking.

Toughness is the ability of a material to absorb energy during fracture. There are two approaches to toughness testing: impact toughness testing and fracture mechanics testing.

Impact Toughness Testing. To test impact toughness, a sample of specified geometry is subjected to an impact load, and the amount of energy absorbed during fracture is recorded. Usually the specimen is oriented so that the notch and expected plane of fracture run longitudinally through the weld metal. Charpy tests do not measure an inherent material property, but they result in a relative measure of impact toughness between materials. A very common use of the Charpy test is to determine a material's ductile-to-brittle transition temperature by performing tests at several different temperatures. AWS A5.1 (Ref 19) gives minimum Charpy impact values, at several temperatures, for welds made on carbon steel using a number of different electrodes.

Fracture Mechanics Testing. The second type of toughness testing is based on fracture mechanics, and it can use either linear elastic or elastic-plastic methodologies. Although elastic-plastic behavior (J_{Ic}) is becoming of interest in some cases, the bulk of fracture mechanics testing is based on linear elastic considerations. These tests, using specimens and procedures given in ASTM E 399 (Ref 20), are used to measure a material's fracture toughness (K_{Ic}), which is a material property. In the case of welding, fracture toughness is usually expressed using a value for crack tip opening displacement (Ref 21). Fracture toughness testing has only recently begun gaining acceptance as applicable to welds. The major shortcomings of this approach include the complexity and cost of testing and the wide variability in fracture toughness values for weld metal, due largely to the inhomogeneous nature of welds and residual stress effects.

Characterization of Welds

Craig B. Dallam, The Lincoln Electric Company; Brian K. Damkroger, Sandia National Laboratories

Weld Characterization Examples

In this section, two weld will be analyzed to serve as examples of techniques discussed thus far in this article. The first of these welds is a multipass shielded metal arc weld/flux-cored arc weld made on pipe steel for an industrial application. This type of weld would typically be made in great quantity. In practice, it would be characterized largely on the basis of its external appearance, perhaps supplemented by nondestructive testing. The initial characterization of a weld and procedure, however, would be based on chemical composition and mechanical properties. Primary concerns are whether the weld being examined is representative of a normal weld of this type and can thus be reasonably well described based on the materials, process, and specifications involved in its production. The bulk of the actual characterization of such a weld would be done during the development and certification of the initial process to determine its suitability for the intended application.

The second example is a weld used for a very specific application. This weld is a butt weld made on Ti-6Al-4V, with a tantalum shim inserted between the base metal sections. Among the requirements for this weld are that it have microstructural and property homogeneity and stability at elevated temperatures and that it be cathodic to the base metal under unusual and extremely severe environmental conditions. In this case, the concerns center less on the eventual application and more on building a thorough database regarding the metallurgical and microstructural characteristics of the weld.

Example 1: Multipass Weld in a 1.07 m (42 in.) Diameter X-65 Pipe.

This weld is a circumferential weld on a 12.7 mm (0.50 in.) thick, 1.07 m (42 in.) diameter X-65 pipe. The X-65 materials is designated by API as a pipe steel with at least 448 MPa (65 ksi) yield strength and 566 MPa (82 ksi) tensile strength. This type of weld is typical for a large oil or gas pipeline. However, for this example, procedures were deliberately selected to produce a weld with a range of defects. These procedures, given by Table 4, are not representative of standard practice.

TABLE 4 PARAMETERS (NOT STANDARD PROCEDURE) USED TO OBTAIN MULTIPASS WELD IN 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

PROCESS	PASS NO.	ELECTRODE	DIAMETER		WIRE FEED		CURRENT, A	VOLTAGE, V	TRAVEL SPEED	
			mm	in.	mm/s	in./s			mm/s	in./s
SMAW	1	E8010-G	4.0	0.16	. . .	. . .	150	26-28	5.9-7.2	2.3-2.8
	2	E8010-G	4.0	0.16	. . .	. . .	180	26-28	5.9-7.2	2.3-2.8
FCAW	3	E71T8-K6	1.73	0.068	47	1.9	200	19	4.5	1.8
	4	E71T8-K6	1.73	0.068	47	1.9	200	19	4.0	1.6
	5	E71T8-K6	1.73	0.068	47	1.9	200	19	4.0	1.6
	6	E71T8-K6	1.73	0.068	47	1.9	200	19	4.7	1.9
	7	E71T8-K6	1.73	0.068	47	1.9	200	19	5.9	2.3
	8	E71T8-K6	1.73	0.068	42	1.7	180	18	4.2	1.7
	9	E71T8-K6	1.73	0.068	42	1.7	180	18	4.5	1.8

Additional specifications include: 12.7 mm (0.50 in.) wall thickness; 1.59 mm (0.0625 in.) land; 1.59 mm (0.0625 in.) gap; 60° bevel in groove; vertical down position; preheat and interpass temperature of 150 °C (300 °F)

Visual Observation. The weld was initially characterized by visual observation. From the top of the joint, the size and uniformity of the weld and undercut can be observed (Fig. 6a). From the underside, spatter, lack of penetration, and internal undercut can be seen (Fig. 6b).

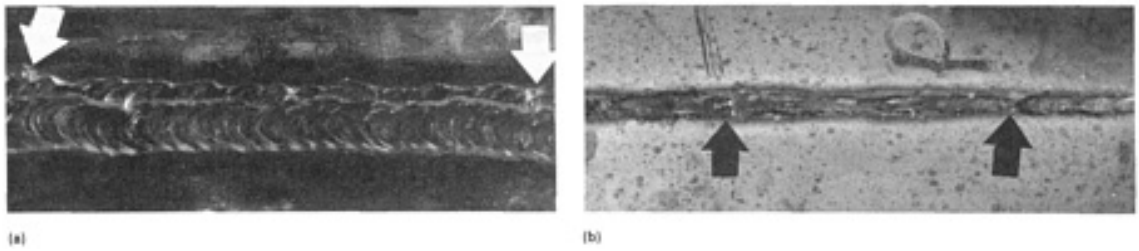

FIG. 6 DEFECTS IN A MULTIPASS WELD MADE ON A 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE. (A) EXTERIOR VIEW SHOWING LACK OF UNIFORMITY (RIGHT ARROW) AND UNDERCUT (LEFT ARROW). (B) INTERIOR VIEW SHOWING LACK OF PENETRATION (RIGHT ARROW) AND BURN-THROUGH (LEFT ARROW)

Nondestructive evaluation was then used to examine the weld for internal and surface defects. Slag entrapment and lack of fusion are typical internal defects for this type of weld, and they can be seen in the radiograph shown in Fig. 7. Figure 7 also shows the external defects noted during visual observation. In addition to nondestructive evaluation, other tests that highlight defects (for example, "nick-break" tests and face or root bend tests) can be run, but these were not used in this case. Similarly, ultrasonic testing, magnetic particle testing, and penetrant testing were not used in this characterization.

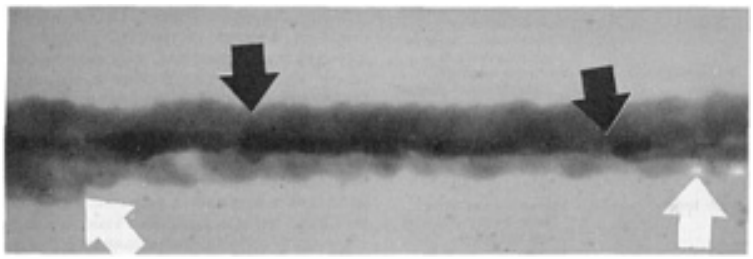

FIG. 7 RADIOGRAPH SHOWING POSITIVE IMAGE OF MACROSCOPICALLY VISIBLE DEFECTS IN THE X-65 PIPE STEEL OF FIG. 6. SEE FIG. 6 FOR DESIGNATION OF SPECIFIC DEFECTS.

Weld Macrostructure. Destructive evaluation begins by removing a transverse section from the weld and preparing it for metallographic examination (Fig. 8). The welding pass sequence (that is, number and size of passes, number of passes per layer, amount of penetration, and extent of HAZ) is apparent. In addition, any gross defects present in the sectioning plane are visible. In this example, nine passes were made, three layers with one pass and three with two passes. Figure 8 also shows four small pores, one each in the third, fourth, sixth, and ninth passes. In this case, the porosity was induced by deliberately varying the electrode stickout.

FIG. 8 TRAVERSE SECTION OF THE X-65 PIPE STEEL SHOWN IN FIG. 6 AND 7. PORES IN PASSES 3, 4, 6, AND

8 WERE CAUSED BY INTENTIONALLY VARYING THE ELECTRODE STICKOUT.

Weld Metal Composition. Compositional analysis of the weld was performed at this point. For this application, the bulk, or average, composition of the weld is of the most interest. The bulk composition of the weld was measured using an emission spectrometer, and the results are given in Table 5. The interstitial content of the weld is also of interest, and the levels of oxygen and nitrogen were measured with dedicated instruments. The oxygen level of the weld was found to be 110 ppm and the nitrogen level, 330 ppm. For some welds, techniques can be used to map compositional variations within the weld. In this case, the bulk composition, measured at the weld center, is considered adequate to characterize the weld.

TABLE 5 BULK COMPOSITION OF WELD IN 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

SAMPLE	COMPOSITION, WT. %									
	C	Mn	Si	Al	Ni	Cr	Mo	Ti	V	Nb
WELD METAL	0.062	0.85	0.22	0.76	0.65	0.02	0.02	0.011	0.008	0.003

Weld Microstructure. The transverse section was also used for examination and characterization of the microstructure of the weld. Figure 9 shows micrographs of different regions of the weld. Figure 9(a) shows weld metal that has not been reheated by successive passes. Figure 9(b) shows weld metal that has been reheated and has a finer structure than the non-reheated weld metal. Figure 9(c) shows a location in the HAZ that closely resembles the structure seen in the reheat zone. The important parameters to characterize for this type of weld are the percentage of reheat zone, the relative amount of various microconstituents, and the average grain size. In the example weld, the weld metal is approximately 80% reheat zone. In the non-reheated zone (Fig. 9a), quantitative microstructural analysis showed that the structure consisted of 20% grain boundary ferrite, 20% intergranular polygonal ferrite, 16% acicular ferrite, 32% ferrite with an aligned second phase, and 12% ferrite with a nonaligned second phase. No martensite or ferrite-carbide aggregate was found.

Mechanical Testing. Following the characterization of the microstructure, specimens were removed and used for mechanical testing. For this application, the pertinent mechanical tests are tension tests (transverse and all-weld-metal), Charpy impact tests, fracture toughness tests, and a microhardness traverse. A transverse tensile test is primarily used to ensure that the welded joint is not the weak link in the final structure. In this case, a 305 × 32 mm (12.0 × 1.25 in.) specimen was removed from the pipe, the long axis perpendicular to the weld bead. The specimen was loaded to 247 kN (27.8 tonf) and failed in the base metal. Based on a weld cross-sectional area of 5.08 cm^2 (0.787 $in.^2$), a minimum weld tensile strength was calculated as 487 MPa (70.6 ksi).

An all-weld-metal tensile test was run using a specimen removed from the bead so that its loading axis was parallel to the weld direction. In this case, the weld was aged prior to testing, with the heat treatment being 48 h at 104 °C (220 °F). The results of the tensile test are shown in Fig. 10. The yield strength was found to be 520 MPa (75.4 ksi), the ultimate strength 594 MPa (86.1 ksi), and the percent elongation 30%. With respect to a typical vendor specification for this type of weld, these values indicate that the weld is adequate.

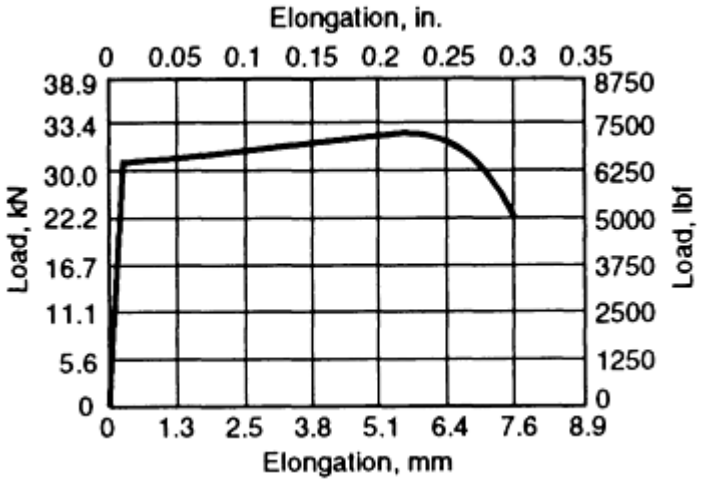

FIG. 10 PLOT OF LOAD VERSUS ELONGATION FOR ALL-WELD-METAL TENSILE TEST OF A 6.4 MM (0.25 IN.) DIAMETER SPECIMEN TAKEN FROM THE 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

Charpy V-notch impact specimens were removed from the weld as shown in Fig. 11. For this type of application, tests are usually run at only one temperature, dictated by a specification and/or past experience. For a full characterization, however, tests will be run over a broad enough range to clearly establish the upper- and lower-shelf energy levels and to identify the ductile-to-brittle transition temperature (DBTT). For this example, tests were run at several temperatures, and the results are shown in Fig. 12. This figure clearly shows that the upper shelf energy is approximately 200 J (150 ft · lbf), the lower shelf 2 J (1.5 ft · lbf), and the DBTT -10 °C (14 °F).

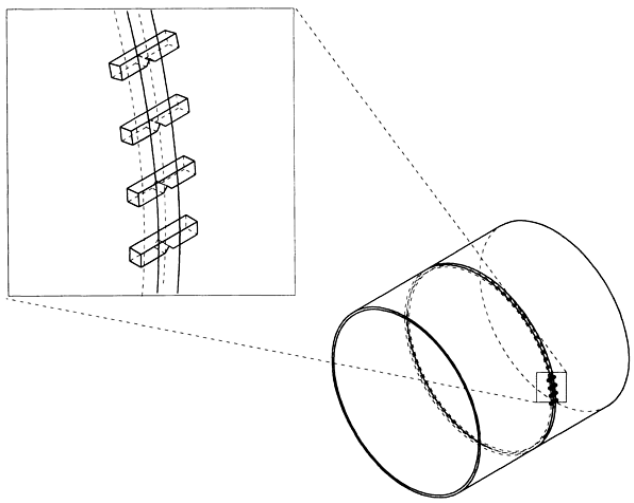

FIG. 11 SCHEMATIC SHOWING LOCATION AND ORIENTATION OF CHARPY V-NOTCH SPECIMENS TAKEN FROM THE 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE. ALTHOUGH INSET SHOWS WIDELY SPACED SAMPLES FOR THE SAKE OF CLARITY, ACTUAL SAMPLES REMOVED ARE TYPICALLY ADJACENT TO ONE ANOTHER.

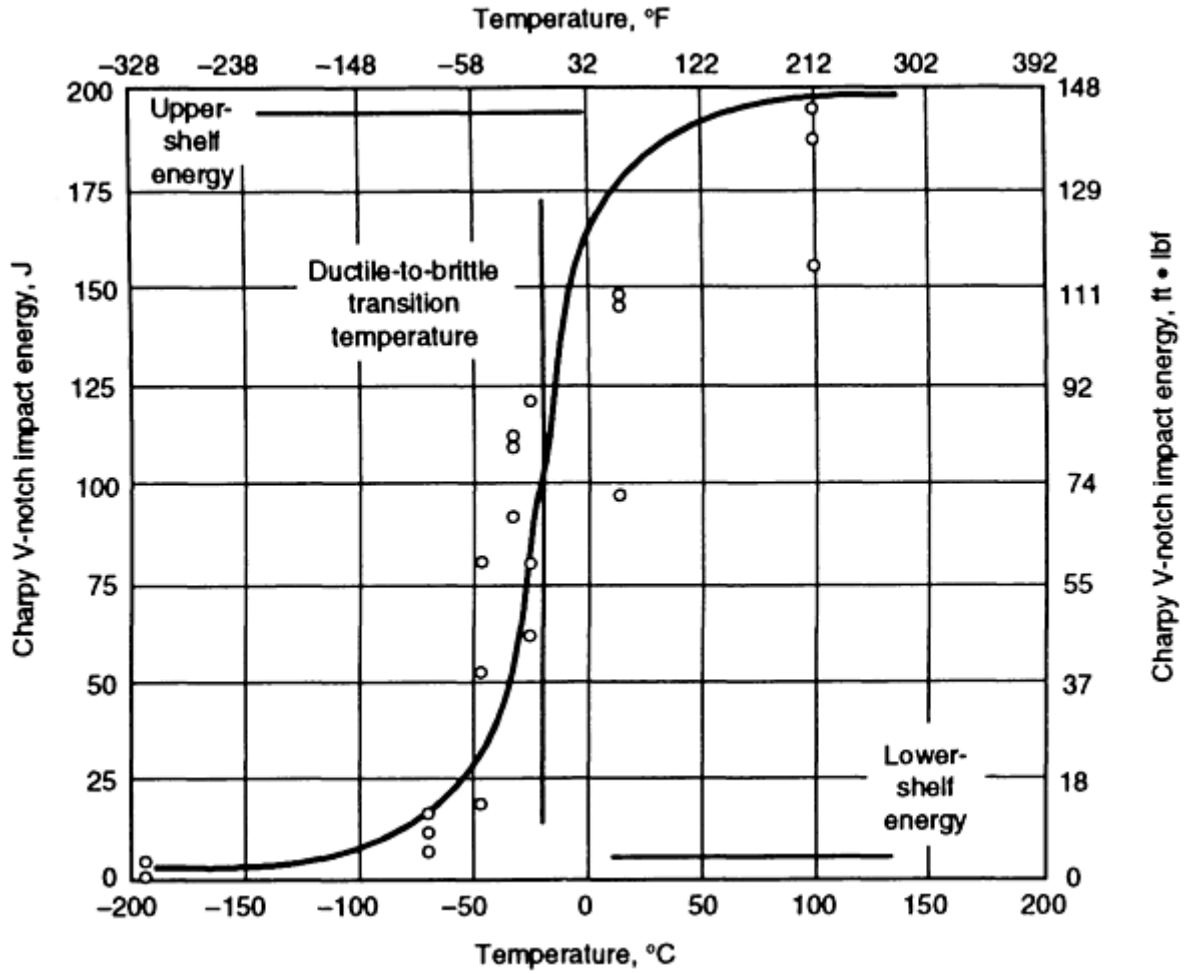

FIG. 12 CHARPY V-NOTCH IMPACT ENERGY TEST RESULTS USED TO OBTAIN DUCTILE-TO-BRITTLE TRANSITION TEMPERATURE (-10 °C, OR 14 °F) FOR THE 1.07 M (42 IN.) DIAMETER X-65 STEEL PIPE

Fracture toughness specimens were removed from the weld in an orientation similar to that of the Charpy specimens. As with Charpy tests, fracture toughness specifications usually require a certain value at a given temperature, usually the minimum service temperature. Crack tip opening displacement tests were conducted at -45 °C (-50 °F) on three specimens removed from the example weld. The results were found to vary from 0.137 to 0.322 mm (0.005 to 0.013 in.), with the average being 0.229 mm (0.009 in.). Figure 13 shows the fracture surface of one of the test specimens, on which the ductile fracture mode and overload zone can be clearly seen.

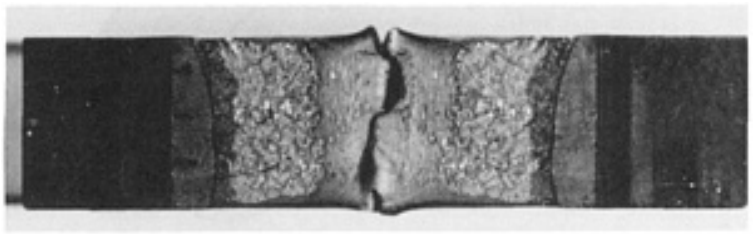

FIG. 13 MACROGRAPH OF THE FRACTURE SURFACE OF A CRACK TIP OPENING DISPLACEMENT TEST SPECIMEN REMOVED FROM THE 1.07 M (42 IN.) X-65 STEEL PIPE. THE REGIONS OF THE SURFACE SHOWN CORRESPOND WITH THE NOTCH, PRECRACK, STABLE CRACK GROWTH, FAST FRACTURE, AND OVERLOAD ZONES.

In addition to the previous mechanical tests, microhardness testing is often used for this type of weld. The primary purpose of microhardness testing is to check for the presence of martensite in the HAZ. Figure 14 shows a schematic of the example weld and the location and values of several microhardness tests. In this case, none of the values exceeded 240 HV, the level associated with the presence of martensite.

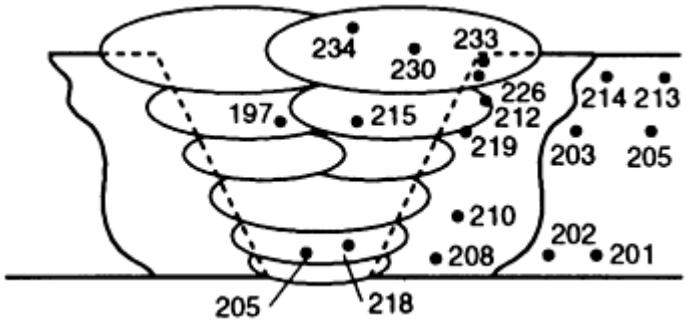

FIG. 14 MICROHARDNESS READINGS (LOCATION IN MULTI-PASS WELD INDICATED BY DOTS) BELOW 240 HV INDICATING THAT NO MARTENSITE STRUCTURE IS PRESENT IN THE 1.07 M (42 IN.) X-65 STEEL PIPE

Typically, this type of pipe weld is characterized with respect to stress-corrosion cracking resistance. In addition, testing is often performed to characterize the HAZ toughness.

Example 2: Welding of 2.5 mm (0.100 in.) Thick Ti-6Al-4V Sheet using a 0.127 mm (0.005 in.) Thick Tantalum Shim.

Figure 15 shows a transverse section of a butt weld, where the base metal is 2.5 mm (0.100 in.) thick Ti-6Al-4V and a 0.127 mm (0.005 in.) thick tantalum shim has been placed in the joint. This weld geometry was used in a study of the effect of dilution on the microstructures and properties of dissimilar metal welds of titanium to refractory metals. The questions to be answered in the characterization of this weld were:

- HOW UNIFORMLY WOULD THE TANTALUM BE DISTRIBUTED IN THE WELD POOL?
- HOW ACCURATELY COULD THE COMPOSITION OF THE WELD POOL BE PREDICTED BASED ON DILUTION CALCULATIONS?
- WHAT PHASES AND MICROCONSTITUENTS ARE PRESENT IN THE WELD METAL?
- WHAT ARE THE MECHANICAL PROPERTIES OF THE WELD METAL?

In addition, a number of very application-specific corrosion and elevated-temperature tests were performed on the dissimilar metal welds. In contrast with the pipe weld of the first example, the primary tools used in this characterization were macrostructural examination, compositional mapping, x-ray diffraction, tension testing of all weld metal specimens, and microhardness traverses.

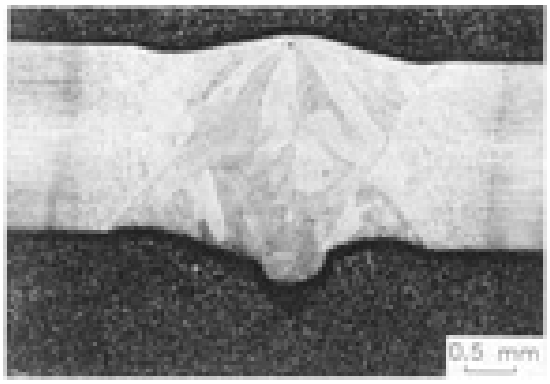

FIG. 15 MICROGRAPH OF TRANSVERSE SECTION OF AN ELECTRON-BEAM WELDED BUTT WELD JOINING 2.5 MM (0.100 IN.) THICK TI-6AL-4V SHEET USING A 0.127 MM (0.005 IN.) THICK TANTALUM SHIM PLACED IN THE JOINT. KROLL'S REAGENT WAS USED AS ETCHANT.

Weld Macrostructure. The weld shown in Fig. 15 was made with the electron-beam welding process, using sharp focus, 100 kV power, 16 to 25 mA current, and a travel speed of 12.7 mm/s (30 in./min). As can be seen in the transverse section, a full penetration weld was achieved using one pass from each side of the weld. The transverse section also shows that no obvious discontinuities exist in the weld pool and that the weld metal microstructure is fairly uniform. Figure 15 also suggests that the tantalum shim was completely melted.

Weld Metal Composition. An initial examination of the weld metal composition was performed to help assess the uniformity of the weld macrostructure. Figure 16 shows tantalum, titanium, vanadium, and aluminum elemental scan lines traversing the weld. These data were generated using a scanning electron microscope with energy-dispersive spectroscopy capability, and they confirm that the elements in question are uniformly distributed throughout the weld pool. Based on these analyses and the macrostructural characterization, it was determined that this combination of welding processes and parameters was successful in producing a full-penetration weld and a macroscopically homogeneous and defect-free weld pool.

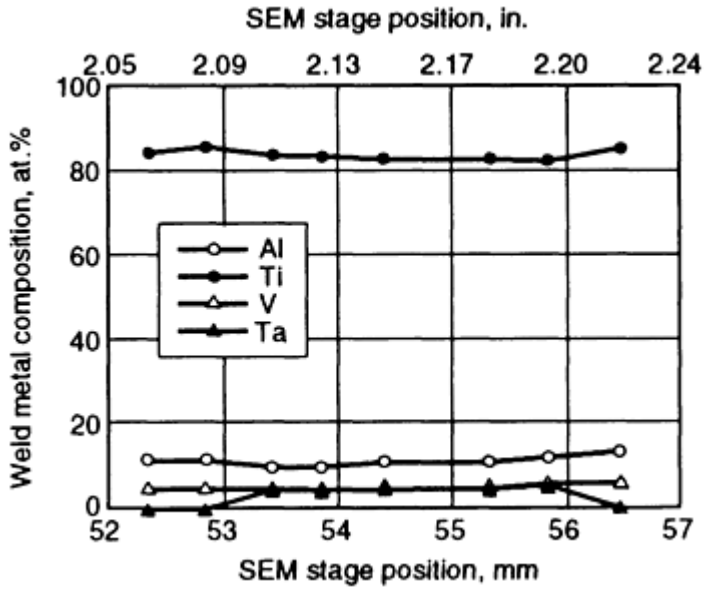

FIG. 16 ELEMENTAL LINE SCANS OF TITANIUM, ALUMINUM, VANADIUM, AND TANTALUM SPANNING THE HAZ AND FUSION ZONE OF THE 2.5 MM (0.100 IN.) THICK TI-6AL-4V SHEET WELDED USING A 0.127 MM (0.005 IN.) THICK TANTALUM SHIM.

The properties of titanium alloys can be strongly affected by the phases present in the microstructure, which are largely controlled by the weld metal composition. In this example, aluminum stabilizes the hexagonal close-packed (hcp) α and/or α' phases, and vanadium and tantalum, the body-centered cubic (bcc) β phase. In titanium alloys, the composition can be expressed as an electron/atom (*e*/*a*) ratio, which allows the phase stabilization effects of different elements to be combined. Table 6 lists the calculated (based on dilution) and measured compositions of the weld. This table shows that the measured and calculated compositions agree reasonably well. The measured aluminum values are somewhat lower than the calculations predict, perhaps due to some loss of aluminum during the welding process. Of most interest is that the measured and calculated *e*/*a* ratios are 3.96 to 3.98. This compositional range indicates that the weld metal microstructure should be α', a hexagonal martensite structure associated with good mechanical properties (Ref 20).

TABLE 6 COMPOSITION OF TI-6AL-4V RELATIVE TO THAT OF TI-6AL-4V PLUS TANTALUM WELD METAL

SAMPLE	COMPOSITION, AT.%				
	Ti	V	Al	Ta	*E/A* RATIO
TI-6AL-4V	86.2	3.6	10.2	. . .	3.93
TI-6AL-4V WELDED TO TA SHIM:					
CALCULATED	83.9	3.5	9.9	2.7	3.96
MEASURED	83.0	3.9	9.5	3.6	3.98

Weld Microstructure. The microstructure of the weld was analyzed using optical microscopy, transmission electron microscopy, and x-ray diffraction. Of particular interest were the structure of any martensitic phase present and the possible existence of ω, an ordered phase that can severely embrittle the material. The composition of the weld metal suggests that the structure will be α' hexagonal martensite. Figure 17 shows an optical micrograph of the fusion zone. Examination of Fig. 17 and comparison with Ti-6Al-4V (no tantalum shim) welds further suggest that the weld metal microstructure is α'. This was further supported by x-ray diffraction and TEM data. Figure 18 shows an x-ray diffraction trace for the weld metal. Aside from peaks from the specimen-mounting material, only peaks associated with a hexagonal structure were detected.

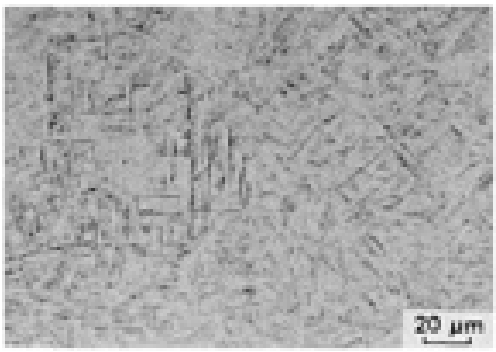

FIG. 17 OPTICAL MICROGRAPH OF FUSION ZONE OBTAINED WITH THE TI-6AL-4V SHEET WELDED USING A TANTALUM SHIM. KROLL'S REAGENT WAS USED AS THE ETCHANT. MICROSTRUCTURE CONSISTS OF WIDMANSTÄTTEN α+ β AND α' MARTENSITE.

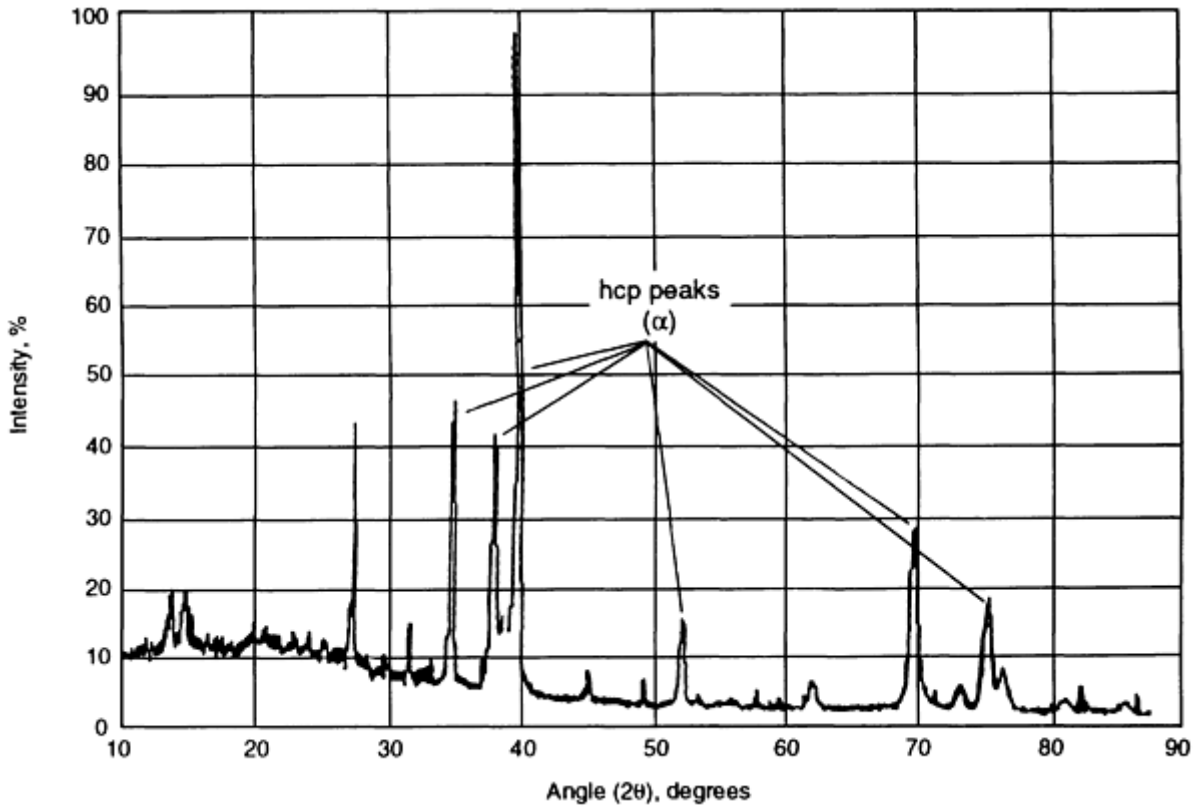

FIG. 18 X-RAY DIFFRACTION TRACE OF FUSION ZONE IN TI-6AL-4V SHEET WELDED USING A TANTALUM SHIM, SHOWING PEAKS THAT IDENTIFY HEXAGONAL STRUCTURES

Based on the compositional analysis, diffraction results, and microstructural analysis, the weld metal can be characterized as α' hexagonal martensite. By comparison with Ti-6Al-4V base metal and (no shim) weld metal, it was determined that the weld metal could be treated as a slightly more heavily stabilized variant of Ti-6Al-4V. This analysis allowed its properties and performance to be reasonably predicted.

Mechanical Testing. Microhardness traverses and all-weld-metal tension tests were performed on this weld. Figure 19 shows the results of two microhardness traverses, one across the second pass only, and one across the middle of the weld where the two passes overlap. Both traces are very similar, and the hardness is fairly constant across the fusion zone. These data confirm that the weld metal is relatively homogeneous. The hardness of the fusion zone is slightly higher than that of the base metal, as would be expected because of the martensitic structure and slightly higher β-stabilizer content.

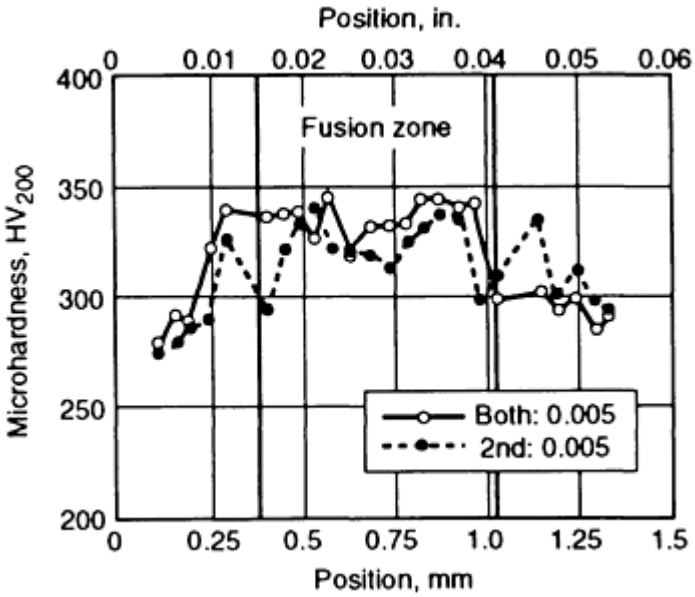

FIG. 19 MICROHARDNESS TRAVERSE DATA IN TWO LOCATIONS FOR THE TI-6AL-4V SHEET WELDED USING A TANTALUM SHIM. DATA LABELED "2ND" REFER TO TRAVERSE OVER SECOND PASS OF WELD ONLY. DATA LABELED "BOTH" INDICATE TRAVERSE ACROSS CENTER OF WELD WHERE TWO PASSES OVERLAP (SEE FIG. 15).

The tensile testing further confirmed that the weld metal could be considered to be a more heavily stabilized variant of Ti-6Al-4V. Table 7 compares the results of tensile tests performed on a baseline Ti-6Al-4V (no shim) weld with those of tests performed on the example weld. As the data show, the tantalum-containing weld had slightly higher strength and lower ductility than the baseline weld. Again these data are consistent with a slightly higher β-stabilizer content. However, the differences were not as great as in the microhardness testing, because in the case of the tensile tests, both structures were α' martensite.

TABLE 7 TENSILE PROPERTIES OF BASELINE TI-6AL-4V WELD COMPARED TO TI-6AL-4V WELDED USING TANTALUM SHIM

SAMPLE	YIELD STRENGTH		ULTIMATE TENSILE STRENGTH		YOUNG'S MODULUS		MAXIMUM STRAIN, %
	MPA	KSI	MPA	KSI	GPA	10^6 PSI

(A) REPLICANTS OF TI-6AL-4V WELDED TO TANTALUM SHIM

Test Results. The goal of the Ti-6Al-4V/tantalum dissimilar metal weld study was to thoroughly characterize the homogeneity, structure, and properties of the weld, relative to a baseline Ti-6Al-4V weld, and to determine the effect of the tantalum additions. The study showed that the tantalum shim could be completely melted using the chosen welding procedure and that a uniform weld bead could be produced. The compositional and microstructural analyses showed that the weld was very similar to the baseline weld. The tantalum-alloyed weld metal appeared to be consistent with standard principles regarding titanium alloy compositions and structure, and it was what would be expected in a weld made on slightly more heavily alloyed material. The mechanical test results confirmed this interpretation as well. In total, the

characterization showed that this weld could be made and that its properties could be predicted and/or interpreted accurately as an extrapolation of the baseline weld.

Characterization Objectives. A number of characterization techniques have been briefly discussed with respect to their application to welds. Examples 1 and 2 show that the choice and emphasis of the characterization procedure are largely determined by the intended application of the weld and the goals to be accomplished by the characterization. Each of the procedures in Examples 1 and 2 are discussed in great detail in the cited references. Additional information is available in the Section "Joint Evaluation and Quality Control" in this Volume and in Ref 16, 17, and 22

Introduction to Brazing and Soldering

Melvin M. Schwartz, Sikorsky Aircraft

Introduction

BRAZING AND SOLDERING require the application of a number of scientific and engineering skills to produce joints of satisfactory quality and reliability. Brazing employs higher temperatures than soldering, but the fundamental concepts are similar, particularly with respect to metallurgy and surface chemistry (Table 1). However, joint design, materials to be joined, filler metal and flux selection, heating methods, and joint preparation can vary widely between the two processes. Economic considerations involving filler metal and process technology are also varied, particularly in relation to automated techniques and inspection and testing. Brazing and soldering are performed in many industries, from exotic applications in the electronics and aerospace field to everyday plumbing applications.

TABLE 1 COMPARISON OF SOLDERING, BRAZING, AND WELDING

Parameter	**Process**		
	Soldering	**Brazing**	**Welding**
Joint formed	Mechanical	Metallurgical	Metallurgical
Filler metal melt temperature, °c (°f)	<450 (<840)	>450 (>840)[(a)]	>450 (>840)[(b)]
Base metal	Does not melt	Does not melt	. . .
Fluxes used to protect and to assist in wetting of base-metal surfaces	Required	Optional	Optional
Typical heat sources	Soldering iron; ultrasonics; resistance; oven	Furnace; chemical reaction; induction; torch; infared	Plasma; electron beam; tungsten and submerged arc; resistance; laser
Tendency to warp or burn	Atypical	Atypical	Potential distortion and warpage of base-metal likely
Residual stresses	. . .	. . .	Likely around weld area

(A) LESS THAN MELTING POINT OF BASE METAL.

Introduction to Brazing and Soldering

Melvin M. Schwartz, Sikorsky Aircraft

Brazing

Many products are assembled from two or more individual components that are often permanently joined to produce structurally sound assemblies. Joining methods include various fasteners, interference-type joints, adhesives, and, for the highest-integrity joints, the many techniques classified under welding. Brazing, although fundamentally indifferent from welding, is one such technique.

Early metalworkers, stimulated by a desire to produce structures that were difficult or impossible to build using methods then in existence, realized that it was possible to fill the joint between two metal pieces with molten metal and allow it to solidify. These artisans soon learned by experience that, in order to achieve adherence, the metals to be joined and the brazing filler metal had to be kept free of oxides and the filler metal had to have a lower melting point, and, furthermore, that a given filler metal would not necessarily adhere to all metals. From these basic requirements, brazing grew into a craft whose practitioners were well versed in what to do and what not to do in order to produce sound joints.

Just as the technique of brazing developed empirically, so did the lower-melting point filler metals. Workers first used lead and tin solders as well as silver and copper-arsenic ores, which were readily available and had low melting points. Later, the alloy brass was developed and found to be more desirable for joining copper, silver, and steel structures, because it provided higher-strength joints and could withstand higher temperatures.

Early silversmiths, probably wanting to produce white solder joints for aesthetic reasons, melted brass and silver together and found it to have an even lower melting point than brass, good adherence, and better corrosion resistance. Although innumerable combinations of silver, copper, and zinc subsequently evolved, primarily to meet melting-point requirements, these silver-brass, brass, and lead-tin alloys were essentially the only brazing and soldering filler materials available for generations.

Advantages of Brazing. Brazing has many distinct advantages, including the following:

- ECONOMICAL FABRICATION OF COMPLEX AND MULTI-COMPONENT ASSEMBLIES
- SIMPLE METHOD TO OBTAIN EXTENSIVE JOINT AREA OR JOINT LENGTH
- JOINT TEMPERATURE CAPABILITY APPROACHING THAT OF BASE METAL
- EXCELLENT STRESS DISTRIBUTION AND HEAT-TRANSFER PROPERTIES
- ABILITY TO PRESERVE PROTECTIVE METAL COATING OR CLADDING
- ABILITY TO JOIN CAST MATERIALS TO WROUGHT METALS
- ABILITY TO JOIN NONMETALS TO METALS
- ABILITY TO JOIN METAL THICKNESSES THAT VARY WIDELY IN SIZE
- ABILITY TO JOIN DISSIMILAR METALS
- ABILITY TO JOIN POROUS METAL COMPONENTS
- ABILITY TO FABRICATE LARGE ASSEMBLIES IN A STRESS-FREE CONDITION
- ABILITY TO PRESERVE SPECIAL METALLURGICAL CHARACTERISTICS OF METALS
- ABILITY TO JOIN FIBER- AND DISPERSION-STRENGTHENED COMPOSITES
- CAPABILITY FOR PRECISION PRODUCTION TOLERANCE
- REPRODUCIBLE AND RELIABLE QUALITY CONTROL TECHNIQUES

Strong, uniform, leakproof joints can be made rapidly, inexpensively, and even simultaneously. Joints that are inaccessible and parts that may not be joinable at all by other methods often can be joined by brazing. Complicated assemblies comprising thick and thin sections, odd shapes, and differing wrought and cast alloys can be turned into

integral components by a single trip through a brazing furnace or a dip pot. Metal as thin as 0.01 mm (0.0004 in.) and as thick as 150 mm (6 in.) can be brazed.

Brazed joint strength is high. The nature of the interatomic (metallic) bond is such that even a simple joint, when properly designed and made, will have strength equal to or greater than that of the as-brazed parent metal. The natural shapes of brazing fillets are excellent. The meniscus surface formed by the fillet metal as it curves across corners and adjoining sections is ideally shaped to resist fatigue. (It should be noted that in brazed joints using eutectic-type filler metal, fillets often contain an excessive amount of brittle intermetallic compounds. In fact, fillets are 5 to 10 times thicker than the joint and thus have a much higher volume of the liquid phase from which these brittle phases crystallize. Therefore, crack nucleation often originates in fillets.)

Complex shapes with greatly varied sections can be brazed with little distortion, and precise joining is comparatively simple. Unlike welding, in which the application of intense heat to small areas acts to move the parts out of alignment and introduces residual stresses, brazing involves fairly even heating and thus part alignment is easier.

Limitations of Brazing. A brazed joint is not a homologous body but rather is heterogeneous, composed of different phases with differing physical and chemical properties. In the simplest case, it consists of the base metal parts to be joined and the added filler metal. However, partial dissolution of the base metal, combined with diffusion processes, can change the composition and therefore the chemical and physical properties of the boundary zone formed at the interface between base metal and filler metal and often of the entire joint. Thus, in addition to the two different materials present in the simplest example given above, a complicated transitional or even completely different zone must be considered.

In determining the strength of such heterogeneous joints, the simplified concepts of elasticity and plasticity theory--valid for a homogeneous metallic body where imposed stresses are uniformly transmitted from one surface or space element to the adjacent ones--no longer apply. In a brazed joint formed of several materials with different characteristics of deformation resistance and deformation speed, the stresses caused by externally applied loads are nonuniformly distributed.

Mechanics of Brazing. Brazing involves a limited dissolution or plastic deformation of the base metal (Ref 1). Brazing comprises a group of joining processes in which coalescence is produced by heating to a suitable temperature above 450 °C (840 °F) and by using a ferrous or nonferrous filler metal that must have a liquidus temperature above 450 °C (840 °F) and below the solidus temperature(s) of the base metal(s). The filler metal is distributed between the closely fitted surfaces of the joint. Brazing is distinguished from soldering in that soldering employs a filler metal having a liquidus below 450 °C (840 °F) (Table 1).

Brazing proceeds through four distinct steps:

- THE ASSEMBLY OR THE REGION OF THE PARTS TO BE JOINED IS HEATED TO A TEMPERATURE OF AT LEAST 450 °C (840 °F).
- THE ASSEMBLED PARTS AND BRAZING FILLER METAL REACH A TEMPERATURE HIGH ENOUGH TO MELT THE FILLER METAL (FOIL, WIRE, PASTE, PLATINGS, ETC.) BUT NOT THE PARTS.
- THE MOLTEN FILLER METAL, HELD IN THE JOINT BY SURFACE TENSION, SPREADS INTO THE JOINT AND WETS THE BASE METAL SURFACES.
- THE PARTS ARE COOLED TO SOLIDITY, OR "FREEZE," THE FILLER METAL, WHICH IS HELD IN THE JOINT BY CAPILLARY ATTRACTION AND ANCHORS THE PARTS TOGETHER BY METALLURGICAL REACTION AND ATOMIC BONDING.

Brazing Versus Other Welding Processes. The mere fact that brazing does not involve any substantial melting of the base metals offers several advantages over other welding processes. It is generally possible to maintain closer assembly tolerances and to produce a cosmetically neater joint without costly secondary operations. Even more important, however, is that brazing makes it possible to join dissimilar metals (or metals to ceramics) that, because of metallurgical incompatibilities, cannot be joined by traditional fusion welding processes. If the base metals do not have to be melted to be joined, it does not matter that they have widely different melting points. Therefore, steel can be brazed to copper as easily as to another steel.

Brazing also generally produces less thermally induced distortion, or warping, than fusion welding. An entire part can be brought up to the same brazing temperature, thereby preventing the kind of localized heating that causes distortion in welding.

Finally, and perhaps most important to the manufacturing engineer, brazing readily lends itself to mass production techniques. It is relatively easy to automate, because the application of heat does not have to be localized, as in fusion welding, and the application of filler metal is less critical. In fact, given the proper clearance conditions and heat, a brazed joint tends to "make itself" and is not dependent on operator skill, as are most fusion welding processes.

Automation is also simplified by the fact that there are many means of applying heat to the joint, including torches, furnaces, induction coils, electrical resistance, and dipping. Several joints in one assembly often can be produced in one multiple-braze operation during one heating cycle, further enhancing production automation.

As noted in Table 1, essentially no melting of the base metal occurs in brazing; however, the temperatures involved can affect the properties of the metals being joined. For example, base metals whose mechanical properties were obtained by cold working may soften or undergo grain growth if the brazing temperature is above their recrystallization temperatures. Mechanical properties obtained by heat treatment may be altered by the heat of brazing. On the other hand, materials in the annealed condition are usually not altered by brazing.

As with other welding processes, brazing produces a heat-affected zone (HAZ) with a strongly altered microstructure due to intensive mutual mass transfer between base metal and filler metal. The width of this zone varies with the heating process used. In torch and induction brazing, for example, only a localized zone is heated; in france and dip brazing, the entire part is subjected to the brazing temperature. As a rule, the HAZ produced during brazing is wider and less sharply defined than those resulting from other fusion-related processes.

Several elements of the brazing process must be understood in order to produce satisfactory brazed joints:

- FILLER METAL FLOW
- BASE METAL CHARACTERISTICS
- FILLER METAL CHARACTERISTICS
- SURFACE PREPARATION
- JOINT DESIGN AND CLEARANCE
- TEMPERATURE AND TIME
- RATE AND SOURCE OF HEATING

Each of these topics is discussed in detail in the article "Fundamentals of Brazing" in this Volume.

Introduction to Brazing and Soldering

Melvin M. Schwartz, Sikorsky Aircraft

Soldering

Like brazing and other joining processes, soldering involves several fields of science, including mechanics, chemistry, and metallurgy. Soldering is a simple operation (Ref 2), consisting of the relative placement of the parts to be joined, wetting the surfaces with molten solder, and allowing the solder to cool until it has solidified.

Soldering in the field of electronics is in many respects different from soldering in other branches of industry. Although the physical principles of all soldering (and brazing) processes are the same, the features specific to their use in electronics are so numerous that it is possible to speak of soldering in electronics as a separate subject.

Soldering Versus Other Joining Technologies. Soldering has several clear advantages over competitive joining techniques, such as welding or bonding with conductive adhesives:

- THE SOLDER JOINT FORMS ITSELF BY THE NATURE OF THE FLOW, WETTING, AND SUBSEQUENT CRYSTALLIZATION PROCESS, EVEN WHEN THE HEAT AND THE SOLDER ARE NOT DIRECTED PRECISELY TO THE PLACES TO BE SOLDERED. BECAUSE SOLDER DOES NOT ADHERE TO INSULATING MATERIALS, IT OFTEN CAN BE APPLIED IN EXCESS QUANTITIES, IN CONTRAST TO CONDUCTIVE ADHESIVES. THE SOLDERING TEMPERATURE IS RELATIVELY LOW, SO THERE IS NO NEED FOR THE HEAT TO BE APPLIED LOCALLY AS IN WELDING.
- SOLDERING ALLOWS CONSIDERABLE FREEDOM IN THE DIMENSIONING OF JOINTS, SO THAT IT IS POSSIBLE TO OBTAIN GOOD RESULTS EVEN IF A VARIETY OF COMPONENTS ARE USED ON THE SAME PRODUCT.
- THE SOLDERED CONNECTIONS CAN BE DISCONNECTED IF NECESSARY, THUS FACILITATING REPAIR.
- THE EQUIPMENT FOR BOTH MANUAL SOLDERING AND MACHINE SOLDERING IS RELATIVELY SIMPLE.
- THE SOLDERING PROCESS CAN BE EASILY AUTOMATED, OFFERING THE POSSIBILITY OF IN-LINE ARRANGEMENTS OF SOLDERING MACHINES WITH OTHER EQUIPMENT.

Mass soldering by wave, drag, or dip machines has been the preferred method for making high-quality, reliable connections for many decades. Despite the appearance of new connecting systems, it still retains this position. Correctly controlled, soldering is one of the least expensive methods for fabricating electrical connections. Incorrectly controlled, it can be one of the most costly processes--not because of the initial cost, but because of the many far-reaching effects of poor workmanship.

Chronology of Soldering. Soldering is not a new process (Ref 2). It probably dates to the Bronze Age, when some metalworker discovered the affinity of a tin-lead mixture for a clean copper surface. As recorded in the writings of Pliny, the Romans used 60Sn-40Pb mixture to solder their lead water pipes.

During the late 19th and early 20th centuries, a great deal of work was devoted to the development and improvement of the soldering process and to the determination of the fundamental principles involved. Examination of the books, papers, and especially the patents of the era shows that soldering as a science was clearly understood long before the start of the electronics industry. There has certainly been a great improvement in the materials and machines used in the process, but the basics have changed little since the early part of this century.

Soldering in the electronics field has undergone many dramatic changes since the first radios were built. Between the 1920s and the 1940s, all interconnections were made using the point-to-point wiring method, and the solder joints were made using soldering irons. After World War II (Ref 3, 4), the demand for consumer electronics began to increase, and by the 1950s a mass market had developed. To meet this demand, the first mass soldering technique, dip soldering, was used with boards that were the precursors of printed wiring boards (PWBs). By the late 1950s, wave soldering had been developed in England and soon thereafter reached the United States. This development was necessitated by the introduction of PWBs. Wave soldering continued to be the method of choice through the 1980s and is still widely used.

The development and maturation of the multi-layer PWB and the first major effort toward miniaturization occurred in the 1970s. The dual inline integrated circuit package replaced many discrete components. By the early 1980s, the pressure to increase component densities had grown to such a degree that a new technique for attachment was needed, and surface mounting was developed. Surface mount technology in turn required new ways to make solder joints, prompting the development of vapor phase, infrared, hot gas, and other reflow soldering techniques.

Soldering remains the attachment method of choice in the evolving electronics industry. It is the only metallurgical joining technique suitable for the mass manufacture of electronic and electrical interconnections within the temperature restrictions of electronic components and substrates.

Solder Metals. The solder metal business has changed dramatically, having moved from merely producing wire to producing bulk, preform, and paste in order to meet the needs of soldering techniques. Solder can be applied in several ways (Ref 2, 3):

- A MIXTURE OF SOLDER POWDER AND FLUX, KNOWN AS SOLDER PASTE (REF 5), CAN BE APPLIED TO THE JOINTS BY SCREENING, STENCILING, OR USING ONE OF THE MACHINES THAT APPLIES DOTS OF THE PASTE BY A SIMPLE PNEUMATIC SYSTEM. THIS METHOD IS ESPECIALLY USEFUL WHERE SURFACE-MOUNTED COMPONENTS ARE TO BE SOLDERED AND CANNOT BE PASSED THROUGH THE SOLDER WAVE.
- PARTS CAN BE PRETINNED, THAT IS, COATED WITH A LAYER OF SOLDER BY FLUXING AND DIPPING INTO A BATH OF THE MOLTEN METAL.
- SOLDER CAN BE OBTAINED IN THE SHAPE OF RINGS, WASHERS, OR TUBES, WHICH ARE PLACED ON OR ADJACENT TO THE PARTS TO BE JOINED. THESE SOLDER PREFORMS CAN BE OBTAINED WITH OR WITHOUT A FLUX COATING.

The two latter methods of providing solder for the joint are used in many areas of the electronics industry where machine soldering is not possible. Tiny solder rings are placed over long wire wrap pins on a mother board, where the gold plating of the pins in the wrapping area must not be coated with solder. Solder washers are fitted under bolts that must be soldered to a ground plane. Wires and tinned before soldering into a pretinned wiring lug. The possibilities are seemingly limitless (Ref 6).

Solder filler metals have also changed. The first electronic soldering was done with the 50Sn-50Pb solder material used by plumbers. By the 1950s, the choice of materials had switched to eutectic tin-lead solders to counter the problems created by a vibrating wave solder machine conveyor. Today a wide range of filler materials is used in the electronics industry. With the spread of electronics technology into every facet of life, the environmental and materials demands have grown substantially, requiring the use of such specialized materials as indium and gold-tin fillers.

Flux technology has also evolved (Ref 3, 5). As a result of the restraints of military and government specifications, the emphasis has been on the addition of new flux types rather than on the replacement of old ones. Extensive work has been done with organic acids, which enlarge the processing windows. Other categories include synthetic activated materials, which are non-rosin fluorocarbon solvent-removable types, and low solids fluxes for surface mounting that can be used instead of the classic fully activated rosin formulations.

Other materials, such as adhesives for the surface mounting of components intended for wave soldering, are new to soldering technology. These materials must be specially designed to avoid interference with the soldering process, yet must remain intact through the solvent action of fluxes and, often, flux removal.

Mass Soldering. With the introduction of mass soldering techniques (Ref 1, 6), the issue of solderability has become one of the major interest. Mass production processes are not as tolerant as the hand soldering process. In addition, modern components cannot withstand as much heat, as for example, a tube socket. Lower soldering temperatures and less mechanical working have made it necessary to attain the highest solderability to ensure a metallurgically sound and reliably solder joint.

Machine or mass soldering (Ref 2, 4, 6) can make thousands of joints in a few seconds, providing the electrical connections and simultaneously mechanically fastening the components. No other process has yet been developed that can so economically interconnect electronic circuitry.

Wave Soldering. From the original concept of hand dipping boards came the idea of pumping solder through a slot or nozzle to form a wave, or mound, of constantly moving, dross-free metal through which the board could be passed. This offered several advantages: the surface of the solder was always clean and did not require skimming, the pumping action maintained an even temperature, and the raised wave provided an easy form for adding a conveyor system for automatic movement of the board over the solder.

Once the idea of the solder wave had been born, it was logical to use a similar method to apply the flux, and the basic soldering machine appeared. These original machines were quite crude, consisting of individual modules with a freestanding conveyor (often added by the user) placed over them. There was little attempt to integrate the parts into one system, and the smoke and fumes were left to escape into the factory exhaust, aided by a makeshift canopy hung over the machine.

Much work was done on the development of the actual wave in an attempt to improve the speed of soldering and to reduce the incidence of shorts and icicles. The solder weir, the double wave, and the cascade all experienced brief popularity. The cascade wave, which consists of several waves in series, was one of the more interesting of these developments. It was used with an inclined conveyor and was the basis of machines built for in-house use by several manufacturers. However, it never achieved great popularity.

Another development was the use of ultrasonics to form a wave, with the intention of causing cavitation at the joint of avoiding the use of flux, or at least reducing the activity required. Some experimental machines were built, but the cost was excessive, the soldering results were no better than those produced with the conventional pumped wave, and the power of the ultrasonic energy had to be so high that the matching horns used to energize the pot were quickly eroded away. With the advent of the semiconductor, ulrasonics were found to cause occasional damage to the devices. Today the main use for ultrasonics in the soldering industry is to be found in the pots used for tinning components prior to assembly. This era also saw the introduction of oil into the solder wave. This idea worked extremely well and has been a feature of some soldering machines for many years (Fig. 1) (Ref 2, 3, 4, 5, 6, 7).

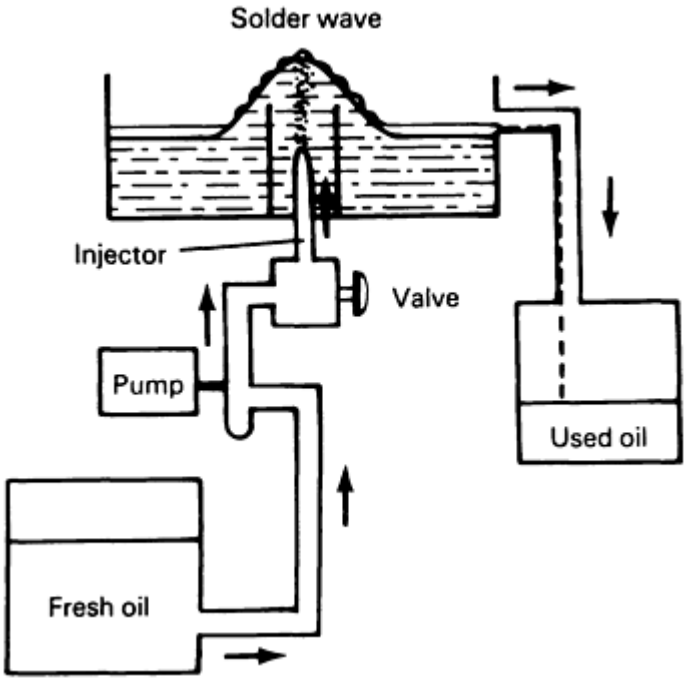

FIG. 1 SCHEMATIC SHOWING SIMPLE OIL INJECTION OF A SOLDER WAVE

Drag Soldering. In a totally different direction, the static solder bath soldering process, or drag soldering, was developed, and machines were designed using this principle (Fig. 2). These machines have been developed to a high level of sophistication, initially in Europe and Japan and later in the United States. As has often been the case in the growth of the soldering machine industry, initial developments were prompted because of patent restrictions that at the time prevented the free use of the more conventional solder wave. These restrictions have often proved beneficial to the industry by forcing creative thinking that has eventually resulted in improved products (Ref 2, 3, 4, 5, 6).

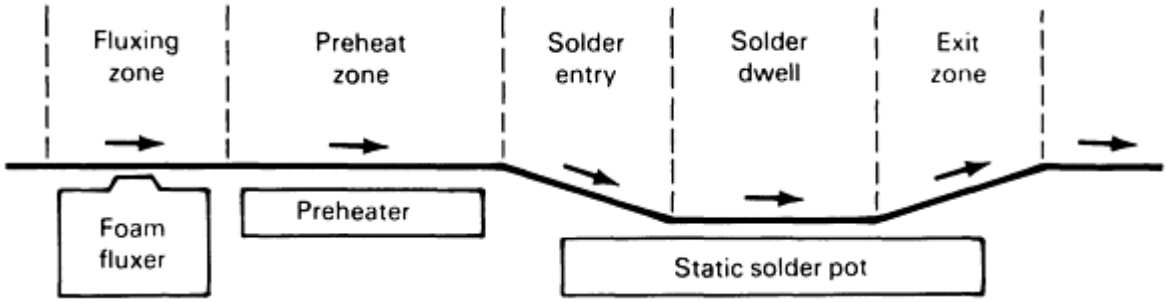

FIG. 2 SCHEMATIC SHOWING SEQUENCE OF OPERATIONS FOR A DRAG SOLDERING MACHINE

Current Technology. Today machines are available from many different manufacturers, each with its own particular features. These machines have various levels of sophistication and capability, ranging from small laboratory units to high-production systems, often complete with in-line cleaning and assembly and return conveyors. Machines in use today are generally self-contained, with a high degree of control, optional auxiliary systems, and exhaust venting. Coming onto the market are systems with computer-controlled operation and setup, which practically eliminate human error from the machine soldering process.

Soldering processes have evolved dramatically since the introduction of mass soldering techniques. Wave machines have become highly specialized, especially since the introduction of surface-mount technology. Reflow techniques (Ref 8), which were once limited to hybrid technology and leaded flatpacks, have grown remarkably. Vapor phase, infrared, and hot gas soldering equipment have initiated a new process of evolution.

The performance of a solder joint in its service environment is a strong consideration in modern electronics. Many applications, such as jet engines, dishwashers, and automobiles, impose a repeated cyclic thermal cycle on the equipment. This produces thermomechanical strains, which result in fatigue or creep failure if the joint design is poor or if life predictions have been incorrectly calculated. Each situation must be carefully analyzed and the correct design employed for the equipment to fulfill its intended service life.

Thermally induced fatigue and creep failures, virtually unknown in the 1950s but common today, are illustrative of the added stresses and strains placed on joints. It should be emphasized that miniaturization of electronic parts, particularly current paths, results in a dramatic increase in current density, which generates strong thermal and mechanical shocks upon switching. Proper design can minimize these strains and make the joints more highly producible. Design has become even more critical with the introduction of surface-mount technology.

Quality Control. Once a joint is made, its quality must be assessed through inspection. Advanced technology has produced some electronic assembly designs that are impossible to inspect visually, and an entire group of automated inspection tools has thus evolved. These tools include radiography, infrared signature, and two- or three-dimensional vision systems. Most of these are aided with very sophisticated computer software. The role of inspection, which historically was to locate those joints that needed rework, is changing along with the technology. Inspection is now used as a process-control audit to locate those portions of the process that need improvement or should returned to a position within the control limits. Therefore, the emphasis has shifted from merely shipping an acceptable product to manufacturing it correctly the first time.

Future Trends. Several other technologies and materials for soldering are being developed and tested (Ref 2, 3, 4, 5). One process that is becoming widely used is condensation, or vapor phase, soldering. In this process, the vapor from a liquid with a high-temperature boiling point is allowed to condense on the items to be soldered and, in giving up the latent heat of vaporization, quickly and evenly raises their temperature and produces a sound soldered joint. The method is simple, clean, and extremely well controlled. It requires-special equipment, and, of course, the parts are all exposed to the same temperature.

In another method, the parts are dipped into an oil heated above the melting point of the solder. Peanut oil can be used, although several excellent synthetic products are available. Here again, the component parts are subjected to the same temperature as the joint. This is a messy process, and the parts must be cleaned after soldering to remove the oil.

Infrared heating is a useful method for producing the temperature necessary for soldering. The shorter wavelengths can be focused onto very small areas, allowing selective heating of the joints to be soldered, without subjecting nearby components to the soldering temperature. Equipment and tooling are expensive if complex assemblies have to be soldered, and the relative emissivity of the joint metals and the adjacent materials can cause processing problems. For example, the base laminate of a PWB can be burned before the joint to be soldered has even reached the soldering temperature. This process thus requires very careful control.

Resistance heating can be used for soldering in two ways. The first method passes a current through the parts of the joint, causing their temperature to rise by virtue of the resistance existing in the joint structure. This is not a very controllable process and is primarily used for less critical applications on large connections. The second method passes a current through a wire that is shaped to touch the parts to be heated. Despite the lack of precise control, the process is often used to solder the leads on surface-mounted components.

Lasers have been used to provide the heat for soldering, although this is not yet a common method. A laser can provide a very high-energy, small-area beam, and heating is therefore extremely fast, localized, and limited only by the ability of the joint materials to absorb this energy. However, the shiny metal surfaces in the joint reflect most of the energy of the commonly used lasers, and coupling the laser and the joint is a major problem. The soldering flux is often used as a coupling medium. When correctly set up, laser soldering offers a fast, clean method of making joints. The cost of the equipment is quite high.

Since 1980, significant improvements and innovations in the soldering arena with respect to materials, equipment, and processes have occurred. However, two main tasks remain: developing environmentally friendly solder materials and establishing failure-free solder joint technology (Ref 2, 3, 4, 6, 7, 8).

For solders and soldering, two issues that are directly related to environmental concerns are the replacement of chlorofluorocarbon (CFCs) as the primary cleaning agent for electronic assemblies and the feasibility of using alternatives to lead-containing solders. For electronic assembly solders (Ref 4), in addition to using CFC substitutes and other solvents (e.g., hydrocarbon-based systems), aqueous cleaning and "no-clean" setups are two viable solutions.

The other task to be accomplished is the development of failure-free solder joint technology. Strengthened solder materials are expected to possess the properties that impede the occurrence of undesirable metallurgical phenomena during their service life under various in-circuit and external conditions, particularly temperature and induced stresses. Three approaches are being examined: macroscopic blends of selected fillers in a tin-rich matrix (composite solder), microscopic incorporation of doping additives to tin-rich base material, and atomic-level interaction. Preliminary experiments have been carried out to accomplish the first approach. Figure 3 demonstrates the increased yield strength of the 63Sn-37Pb composite solder with various amounts of filler (Ref 9).

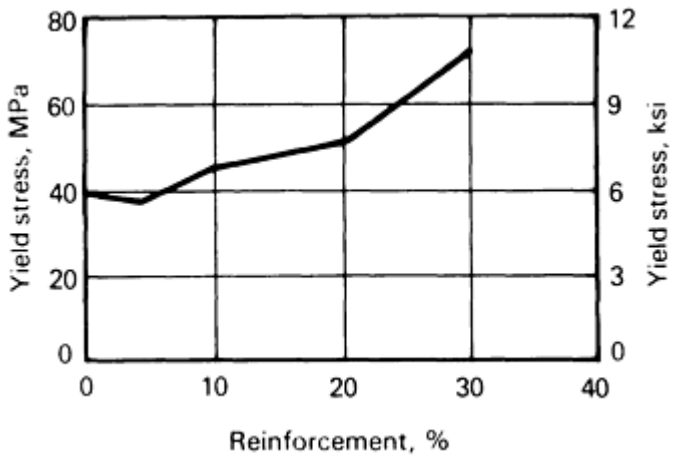

FIG. 3 EFFECT OF FILLER REINFORCEMENT ON THE YIELD STRENGTH OF 63SN-37PB COMPOSITE SOLDER. SOURCE: REF 9

The intrinsic properties of the new materials are expected to possess the following characteristics, while maintaining thermal and electrical conductivities:

- STABLE MICROSTRUCTURE
- INCREASED THERMAL AND MECHANICAL FATIGUE RESISTANCE
- HIGH CREEP RESISTANCE
- DECREASED THERMAL EXPANSION COEFFICIENT

These aggregate characteristics constitute the "strengthened" solder materials that are able to withstand harsher application conditions. The reduced thermal expansion coefficient of these new solders is expected to be more compatible with that of state-of-the-art electronic components and with ceramic substrates.

With respect to quality, solder joints have historically been judged by visual criteria. However, due to the nature of solder materials and the effect of the solder joint-forming process on appearance, many serviceable solder joints are often rejected, while other potentially questionable joints are accepted to carry out critical missions. This not only adds to manufacturing costs, but can also jeopardize service performance. Strengthened solder joints are expected to relieve the necessity of on-line inspection and rework while also reducing manufacturing costs and enhancing life span and tolerance of harsh service conditions in many military applications.

Fundamentals of Brazing

Mel M. Schwartz, Sikorsky Aircraft

Introduction

BRAZING is a process for joining solid metals in close proximity by introducing a liquid metal that melts above 450 °C (840 °F). A sound brazed joint generally results when an appropriate filler alloy is selected, the parent metal surfaces are clean and remain clean during heating to the flow temperature of the brazing alloy, and a suitable joint design is used. Like the other joining processes, brazing encompasses a variety of scientific disciplines (for example, mechanics, physics, and chemistry).

Recently, the demands of more-sophisticated structures have forced technicians and engineers to encourage metal producers to apply their metallurgical knowledge to produce brazing filler metals that meet more-specific needs. To ensure the production of good brazed joints, the technicians and engineers also had to appeal to mechanical engineers for improved joint design, to chemical engineers for solutions to corrosion problems, and to metallurgists and ceramists for proper material selection.

Brazing has been embraced by the engineering community and has now reached a very successful plateau within the joining field. This has come about because of the:

- DEVELOPMENT OF NEW TYPES OF BRAZING FILLER METALS (RAPID SOLIDIFICATION AMORPHOUS FOILS AND TITANIUM-ADDED FILLER METALS FOR CERAMIC JOINING
- AVAILABILITY OF NEW FORMS AND SHAPES OF FILLER METALS
- INTRODUCTION OF AUTOMATION THAT HAS BROUGHT BRAZING PROCESSES TO THE FOREFRONT IN HIGH-PRODUCTION SITUATIONS
- INCREASED USE OF FURNACE BRAZING IN A VACUUM, AS WELL AS ACTIVE AND INERT-GAS ATMOSPHERES

Since the early 1980s, other developments, such as aluminum-clad foils for fluxless aluminum brazing, copper-nickel-titanium filler metals for brazing titanium and some of its alloys, cadmium-free silver filler metals, and vacuum-grade metal brazing foils, have evolved to be used in production applications.

Fundamentals of Brazing

Mel M. Schwartz, Sikorsky Aircraft

Physical Principles

Capillary flow is the dominant physical phenomenon that ensures good brazements when both faying surfaces to be joined are wet by the molten filter metal. The joint must be properly spaced to permit efficient capillary action and coalescence. More specifically, capillarity is a result of the relative attraction of the molecules of the liquid to each other and to those of the solid. In actual practice, brazing filler metal flow characteristics are also influenced by dynamic considerations involving fluidity, viscosity, vapor pressure, gravity, and, especially, by the effects of any metallurgical reasons between the filler metal and the base metal.

Capillary attraction makes the brazing of leak-tight joints a simple proposition. In a properly designed joint, the molten brazing filler metal is normally drawn completely through the joint area without any voids gaps when processed in a protective atmosphere. Solidified joints will remain intact and gas will remain tight under heavy pressures, even when the joint is subjected to shock or vibrational type of loading. Capillary attraction is also the physical force that governs the action of a liquid against solid surfaces in small, confined areas.

The phenomena of wetting and spreading are very important to the formation of brazed joints. Other significant factors that also must be considered include the condition of the solid surface in terms of the presence of oxide films and their effects on wetting and spreading, surface roughness, alloying with between the brazing filler metal and base metal, and the extent to which alloying is affected by the thermodynamic properties of the brazing atmosphere. A number of studies (Ref 1, 2) have been conducted on surface activation, contact angle, equilibrium, and surface energies. Some of these alloy systems have a finite contact angle that is thermodynamically unstable, because the solid-vapor surface energy exceeds the sum of the liquid-solid surface energies, that is, an alloy system in which thermodynamics would predict complete spreading. In actual fact, spreading may or may not occur in this type of alloy system, and the rate of spreading can be markedly dependent on surface chemistry.

Wetting is, perhaps, best explained by the following example. If a solid is immersed in a liquid bath and wetting occurs, then a thin continuous layer of liquid adheres to the solid when it is removed from the liquid (Fig. 1). Technically, the force of adhesion between the solid and liquid (during the wetting process) is greater than the cohesive force of the liquid. In practical terms, with respect to brazing, wetting implies that the liquid brazing filler metal spreads on the solid base metal, instead of balling up on its surface. It has been demonstrated that wetting actually depends on a slight surface alloying of the base metal with the brazing filler metal. Lead, for example, does not alloy with iron and will not wet it. Tin, on the other hand, does form an alloy with iron, and, therefore, a tin-lead solder will wet steel.

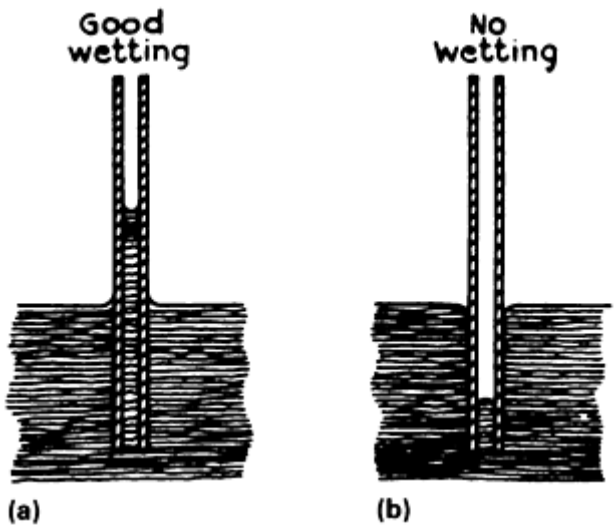

FIG. 1 SCHEMATIC SHOWING PRINCIPLE OF CAPILLARY ATTRACTION FOR SELECTED LIQUIDS WHEN THE LIQUID IS SANDWICHED BETWEEN TWO CLEAN GLASS PLATES. (A) WHEN IMMERSED IN WATER OR INK, A COLUMN WILL RISE BETWEEN THE PLATES BECAUSE OF WETTING. (B) WHEN THE PLATES ARE IMMERSED IN MERCURY, NO WETTING OCCURS AND THE COLUMN IS DEPRESSED. IF PARAFFIN PLATES ARE USED IN PLACE OF THE GLASS PLATES, IMMERSION OF THE PLATES IN MERCURY WILL PRODUCE WETTING.

A comprehensive theory of the wetting or spreading of liquids on solid surfaces and a complete and detailed derivation of the quantitative relationships are presented by Harkins (Ref 3) and Schwartz (Ref 4).

Experimentally, it has been observed that liquids placed on solid surfaces usually do not completely wet, but, rather, remain as a drop that has a definite contact angle between the liquid and solid phases (Ref 5). This condition is illustrated in Fig. 2. The Young and Dupré equation (Eq 1) permits the determination of change in surface free energy, ΔF, accompanying a small change in solid surface covered, ΔA (Ref 5). Thus,

$$\frac{\partial F}{\partial A}_{p,T} = g_{LV} + g_{SL} - g_{SV} \qquad \textbf{(EQ 1)}$$

where γ_{LV} is the liquid-vapor surface energy, γ_{SL} is the solid-liquid surface energy, and γ_{SV} is the solid-vapor surface energy.

$$\Delta F = \Delta A\,(\gamma_{SL} - \gamma_{SV}) + \Delta A \gamma_{LV}\,\mathrm{COS}\,(\theta - \Delta\theta) \qquad \textbf{(EQ 2)}$$

At equilibrium,

$$\lim_{\Delta A \to \Delta 0} \frac{\Delta F}{\Delta A} = 0 \qquad \textbf{(EQ 3)}$$

and

$$\gamma_{SL} - \gamma_{SV} + \gamma_{LV}\,\mathrm{COS}\,\theta = 0 \qquad \textbf{(EQ 4)}$$

or

$$\gamma_{SL} = \gamma_{SV} - \gamma_{LV}\,\mathrm{COS}\,\theta \qquad \textbf{(EQ 5)}$$

In Eq 4 and 5, it can be seen that θ is greater than 90° (1.6 rad) when γ_{SL} is larger than γ_{SV}, as shown in Fig. 3, and the liquid drop tends to spheroidize.

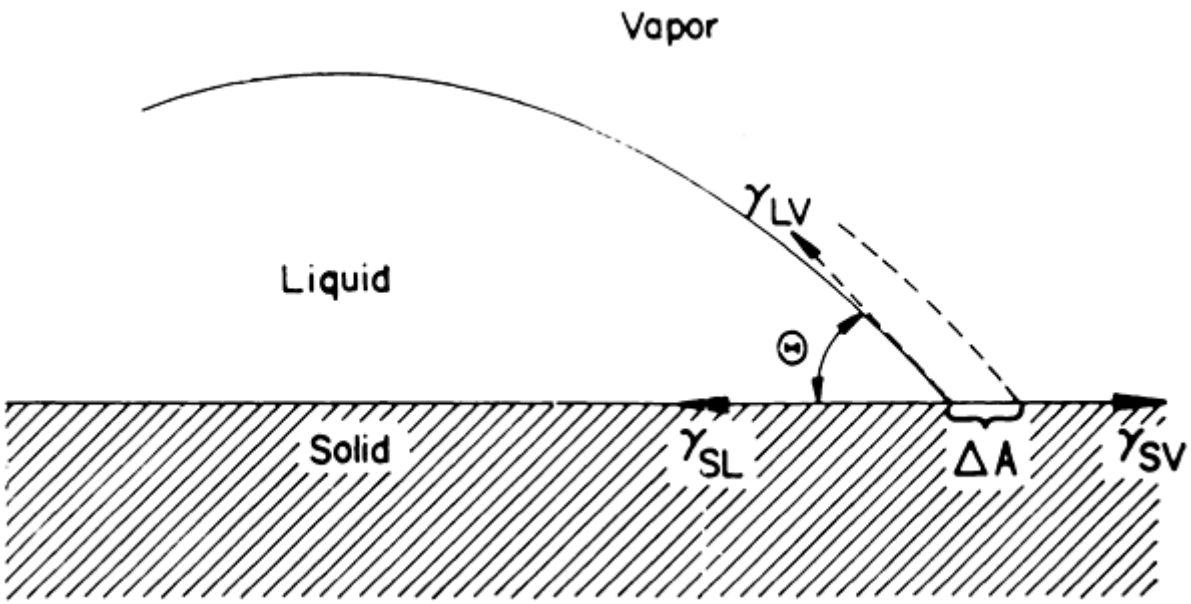

FIG. 2 SESSILE DROP LOCATED ON A SURFACE AND DIRECTIONS OF VECTORS OF THE SURFACE ENERGIES FOR THE SYSTEM

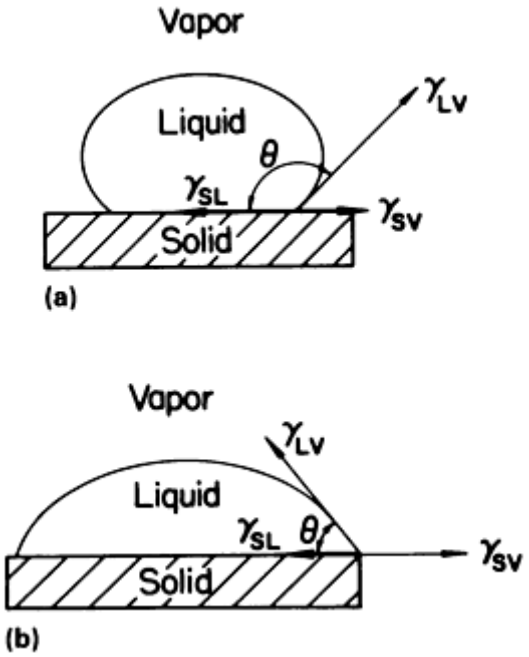

FIG. 3 EFFECT OF INTERFACIAL ENERGIES ON SESSILE DROPS. (A) NO WETTING TAKES PLACE WHEN CONTACT ANGLE IS > 90°. (B) WETTING OCCURS WHEN CONTACT ANGLE IS < 90°.

The contact angle, θ, is less than 90° (1.6 rad) when the reverse is true, as shown at right in Fig. 3, and the liquid drop flattens out and wets the solid. If the balance in such that θ is zero (0 rad) and greater wetting is desired, θ should be as small as possible so that cos θ approaches unity and the liquid spreads over the solid surface.

These considerations show the importance of surface energies in brazing. If brazing filler metal is to successfully form a joint, it must wet the solid material. The surface-energy balance must be such that the contact angle is less than 90° (1.6 rad). The energy equation shows that if θ is to be less than 90° (1.6 rad) (cos θ > 0), then γ_{SV} must be greater than γ_{SL}. This is demonstrated in Table 1, which gives contact-angle measurements of several liquid metals on beryllium at various test temperatures in argon and vacuum.

Although during the testing period minor fluctuations in angle were noted, the overall tendency was for the contact angles to decrease with increasing time at test temperature. This behavior is reflected in the data presented in Table 2. The fluctuations can be attributed to alloying effects, because as alloying progresses, composition and temperature variations change the interfacial energies.

(A) AVERAGE OF TWO TESTS.

(B) ONE TEST ONLY

These data provide a means of comparing the wettability of beryllium by various liquids. If one assumes wettability for contact angles less than 90° and nonwetting for angles greater than 90°, then these data permit qualitative separation of the systems into two classes: those with contact angles less than 90°, and those with contact angles greater than 90°. Gold, Pd-2.1Be, and Ti-6Be were found to wet beryllium at both temperatures. The latter two brazing filler metals, as well as silver and gold, did not wet when tested in argon atmospheres at the lower temperature. However, it was found that an increase of 50 °C (90 °F) resulted in wetting. Aluminum exhibited a nonwetting behavior at both temperatures and in both atmospheres. Copper was nonwetting at both temperatures in vacuum, but underwent extensive alloying with the solid

beryllium at these temperatures in argon. From these data it appears that the binary alloys have the greatest tendency to wet beryllium (Ref 6).

Surface-energy calculations have been performed on beryllium-base metals brazed with Al, Zr-5Be, and Ti-6Be filler metals. The calculated spreading coefficient were negative for all system test conditions, except with Ti-6Be. Negative spreading coefficients indicated a very definite trend. The greater the system wettability, as indicated by lower contact angles and liquid-vapor surface tensions, the greater the numerical magnitude of the spreading coefficient.

Of the three systems used, Ti-6Be was observed to provide the best wetting of beryllium, followed by Zr-5Be. Although no basic significance can be given to the absolute values of the calculated surface-tension properties, they are useful in indicating the relative tendencies for these liquids to wet beryllium.

The above observations indicate that some liquid-metal systems will wet beryllium, whereas some system that should wet it do not, in actual practice. The problem is more complex than it seems at first.

Recent work in Japan (Ref 7) and the United States (Ref 8) has shown that the effects of the base-metal/filler-metal reaction on the wetting of silicon nitride (Si_3N_4) and titanium-added active filler metals vary with reaction-layer thickness and morphology, as well as with the composition of the reaction layer. Several results of thermodynamic studies on the formation of the compound by the interfacial reaction are reported (Ref 7, 9). Moreover, kinetic studies (Ref 7) were also performed to achieve a quantitative understanding of the formation of the reaction layer.

It can be concluded that wetting is the ability of the molten brazing filler metal to adhere to the surface of a metal in the solid state and, when cooled below its solidus temperature, to make a strong bond with that metal. Wetting is a function not only of the nature of the brazing filler metal (Table 3), but of the degree of interaction between materials (ceramics, and so on) to be joined. There is considerable evidence that in order to wet well, a molten metal must be capable of dissolving, or alloying with, some of the metal on which it flows.

Wetting is only one facet of the brazing process. Another factor that affects wetting is the cleanliness of the surface to be wetted. Oxide layers inhibit wetting and spreading, as do grease, dirt, and other contaminants that prevent good contact between the brazing filler metal and the base metal. One of the functions of a flux the oxide layer on the joint area and thereby expose clean base metal.

Good wetting and spreading of the liquid filler metal on the base metal are necessary in brazing because the mechanics of the process demand that the filler metal be brought smoothly, rapidly, and continuously to the joint opening. If the conditions within the capillary space of the joint do not promote good wetting, then the filler metal will not be drawn into the space by capillary attraction.

Kim *et al.* (Ref 10) investigated the wettability and reactivity of pressureless sintered Si_3N_4 with powdered copper-titanium filler metal using sessile drop tests conducted in a vacuum where Si_3N_4 was bonded to itself and joint strength was evaluated by shear testing. The wettability of Si_3N_4 on copper-titanium base filler metals was improved greatly by adding up to 50 wt% titanium. However, the reaction-layer thickness was increased up to 10% and, thereafter, decreased up to 50 wt%.

Wettability improved with the increment of titanium concentration, and no linear proportionality was found between the reaction and the wettability. As titanium concentration increased, a continuous thin layer tended to form at the interface and markedly improved wettability.

The thickness of the reaction layer was not in proportion to the titanium concentration. For a copper-titanium filler metal with a low titanium concentration (less than 5 wt%), the initial reaction layer tended to form discontinuously, whereas the reaction layer thickness increased with titanium concentration. On the contrary, in the filler metal with a high titanium concentration (15 wt%) the reaction-layer thickness decreased as titanium concentration increased because a continuous thin reaction layer tended to form (Ref 10).

The shear strength of the Si_3N_4-Si_3N_4 joint using copper-titanium filler metal is influenced by reaction-layer thickness and morphology. Strength increased with the increment of titanium concentration, and was accompanied by improved wettability, because the tendency of the continuous thin reaction layer to form increased.

With the development of new steels, Keller *et al.* (Ref 11) undertook an extensive study of the wettability of commercial braze filler metals on type 304 stainless steel, the most common of the austenitic stainless steels; type 316 stainless steel, which is often substituted for type 304 when increased corrosion resistance is desired; and 21-6-9, a new high-manganese stainless steel that is an attractive alternative to types 304 or 316 for certain applications. Because the 21-6-9 steel has a very stable austenitic structure, it is attractive for cryogenic applications (Ref 12).

Because high wettability means that the thermocapillary attraction that fills the braze joint is strong, wettability is an important component of braze performance. The wettability index (WI) developed by Feduska (Ref 13) is used as the measure of wettability. The WI is defined as the area covered by the braze metal filler times the cosine of the contact angle between the braze and the base metal. Therefore, the higher the WI, the better the braze filler metal wets the base metal. It should be emphasized that the WI, as defined, is a relative measure, and depends on the volume of filler metal used (Table 4).

The WIs for each braze filler metal at each temperature on type 316 stainless steel, type 304L stainless steel, and 21-6-9 stainless steel are provided in Table 4. Wetting indices greater than 0.05 are indicative of good performance during brazing, whereas WI values greater than 0.10 are indicative of excellent performance during brazing (Ref 13).

A comparison of the WI of the braze filler metals on the three stainless steels revealed these trends:

- FILLER METALS GENERALLY WET TYPE 316 STAINLESS STEEL BETTER THAN TYPE 304 STAINLESS STEEL AND GENERALLY WET TYPE 316 STAINLESS BETTER THAN 21-6-9 STAINLESS.
- THE DEGREE OF WETTING OF MOST BRAZE FILLER METALS ON 21-6-9 STAINLESS WAS EQUAL TO OR BETTER THAN IT WAS ON TYPE 304 STAINLESS (REF 12).
- THE IMPROVED WETTABILITY OF BRAZE FILLER METALS ON TYPE 316 STAINLESS IS BELIEVED TO BE DUE TO THE PRESENCE OF MOLYBDENUM IN THE SURFACE OXIDE, WHEREAS THE ENHANCED WETTING ON 21-6-9 STAINLESS VERSUS TYPE 304 STAINLESS IS BELIEVED TO BE DUE TO THE HIGHER MANGANESE CONTENT OF THE SURFACE OXIDE.

Essentially, the successful joining of components by the brazing process depends on the selected brazing filler metal having a melting point above 450 °C (840 °F) and wetting the base metal without melting it. Furthermore, the joint must be designed to ensure that the mating surfaces of the components are parallel and close enough together to cause capillary attraction.

Mel M. Schwartz, Sikorsky Aircraft

Elements of the Brazing Process

An engineer must consider reliability and cost when designing the braze joint. Joint strength, fatigue resistance, corrosion susceptibility, and high-temperature stability are additional concerns that determine the selection of joint design, braze filler materials, and processing parameters.

A careful and intelligent appraisal of the following elements is required in order to produce satisfactory brazed joints:

- FILLER-METAL FLOW
- BASE-METAL CHARACTERISTICS
- FILLER-METAL CHARACTERISTICS
- SURFACE PREPARATION
- JOINT DESIGN AND CLEARANCE
- TEMPERATURE AND TIME
- RATE AND SOURCE OF HEATING
- PROTECTION BY AN ATMOSPHERE OR FLUX

Filler-Metal Flow. As mentioned previously, wetting is only one important facet of the brazing process. A low contact angle, which implies wetting, is also necessary, but is not a sufficient condition itself for flow. Viscosity is also important. Brazing filler metals with narrow melting ranges that are close to the eutectic composition generally have lower viscosities than those with wide melting ranges. Thus, a high surface tension of liquid filler metal, a low contact angle, and low viscosity are all desirable.

Flowability is the property of a brazing filler metal that determines the distance it will travel away from its original position, because of the action of capillary forces. To flow well, a filler metal must not gain an appreciable increase in its liquidus temperature even though its composition is altered by the addition of the metal it has dissolved. This is important because the brazing operation is carried out at temperatures just above the liquidus of the filler metal.

The composition and surface energy of liquids and solids are assumed to remain constant. In real systems, however, these interactions occur (Ref 14):

- ALLOY FORMATION BETWEEN LIQUID AND BASE METAL
- DIFFUSION OF BASE METAL INTO BRAZING FILLER METAL
- DIFFUSION OF FILLER METAL INTO GRAINS OF BASE METAL
- PENETRATION OF FILLER METAL ALONG GRAIN BOUNDARIES
- FORMATION OF INTERMETALLIC COMPOUNDS

In practice, interactions are usually minimized by selecting the proper brazing filler metal; keeping the brazing temperature as low as possible, but high enough to produce flow; and keeping the time of brazing temperature short and cooling the brazed joint as quickly as possible without causing cracking or distortion. When diffusion brazing is desired, higher brazing temperatures and longer times at brazing temperatures are employed.

Base-Metal Characteristics. The base metal has a prime effect on joint strength. A high-strength base metal produces joints of greater strength than those made with softer base metals (other factors being equal). When hardenable metals are brazed, joint strength becomes less predictable. This is because more-complex metallurgical reactions between hardenable base metals and the brazing filler metals are involved. These reactions can cause changes in the base-metal hardenability and can create residual stresses (Ref 15).

In cases where different materials make up the assembly and gaps may open or close as heating proceeds to the joining temperature, the coefficient of thermal expansion becomes vitally important.

Several metallurgical phenomena influence the behavior of brazed joints and, in some instances, necessitate special procedures. These base-metal effects include alloying by brazing filler; carbide precipitation; stress cracking; hydrogen, sulfur, and phosphorus embrittlement; and oxidation stability.

The extent of interaction varies greatly, depending on compositions (base metal and brazing filler metal) and thermal cycles. There is always some interaction, except in cases of mutual insolubility.

The strength of the base metal has a profound effect on the strength of the brazed joint. Therefore, this property must be carefully considered when designing the joint to have specific properties. Some base metals also are easier to braze than others, particularly by specific brazing processes.

Filler-Metal Characteristics. The second material involved in joint structures is the brazing filler metal. Unfortunately, it cannot be chosen to provide a specific joint strength. Actually, strong joints can be brazed with almost any good commercial brazing filler metal if correct brazing methods and joint design are implemented.

Necessary characteristics of brazing filler metals are:

- PROPER FLUIDITY AT BRAZING TEMPERATURES TO ENSURE FLOW BY CAPILLARY ACTION AND TO PROVIDE FULL ALLOY DISTRIBUTION
- STABILITY TO AVOID PREMATURE RELEASE OF LOW-MELTING-POINT ELEMENTS IN THE BRAZING FILLER METAL
- ABILITY TO WET THE BASE-METAL JOINT SURFACE
- LOW VOLATILIZATION OF ALLOYING ELEMENTS OF THE BRAZING FILLER METAL AT BRAZING TEMPERATURES
- ABILITY TO ALLOY OR COMBINE WITH THE BASE METAL TO FORM AN ALLOY WITH A HIGHER MELTING TEMPERATURE
- CONTROL OF WASHING OR CONTROL OF EROSION BETWEEN THE BRAZING FILLER METAL AND THE BASE METAL WITHIN THE LIMITS REQUIRED FOR THE BRAZING OPERATION

It should be noted that the strength of the brazed joint is not directly related to the method of filler-metal melting. For example, if constructional metals are produced by vacuum melting, then there is a definite relationship between the vacuum-melting practice and the final strength of the ingot, bar, or rolled sheet. With a brazing filler metal, however, joint strength is dependent on joint design, brazing temperature, amount of brazing filler metal applied, location and method of application, heating rate, and many other factors that constitute the brazing technique.

The degree to which brazing filler metal interacts with and penetrates the base metal during brazing depends on the intensity of mutual diffusion processes that occur between both those materials. In applications that require strong joints for high-temperature, high-stress service conditions (such as turbine rotor assemblies and jet-engine components), it is generally wise to specify a brazing filler metal that has high diffusion and solution properties with the base metal. When the assembly is constructed of extremely thin base metals (as in honeycomb structures and some heat exchangers), good practice entails specifying a brazing filler metal that contains elements with a low-diffusion characteristic relative to the base metal being used. Diffusion, a normal part of the metallurgical process, can contribute to good brazed joints when brazing, for example, high-temperature metals with nickel-base brazing filler metals.

Brazing Temperature. When choosing a brazing filler metal, the first selection criterion is the brazing temperature. Some brazing-temperature ranges are given in Table 5. Very few brazing filler metals possess narrow melting ranges. Brazing filler metals in which the solidus and liquidus temperatures are close together do not usually exhibit a strong tendency to coexist as a mixture of liquid and solid phases or to liquate. They flow readily and should be used with small joint clearances. As the solidus and liquidus temperatures diverge, the tendency to liquate increases, requiring greater precautions in brazing filler metal application. The mixture of solid and liquid metal can aid gap filling.

MG-AL-ZN	585-615	1085-1139

The necessity for the brazing filler metal to melt below the solidus of the base metal is just one of several factors that affect its selection. It may be necessary for the brazing filler metal to melt below the temperature at which parts to be brazed lose strength or above the temperature at which oxides are reduced or dissociated. Joining may have to be carried out above the solution-treatment temperature of the base metal, or at a structure refining temperature, or below the remelt temperature of a brazing filler metal used previously in the production of a brazed subassembly.

Liquidation. During melting, the composition of the liquid and solid filler metal phases changes as the temperature increases from the solidus to the liquidus point. If the portion that melts first is allowed to flow out, then the remaining solid phases have higher melting points than the original composition and may never melt, remaining behind as a residue, or "skull." Filler metals with narrow melting ranges do not tend to separate, but flow quite freely in joints of extremely narrow clearance as long as the solution and diffusion rates of the filler metal with the base metal are low (as in aluminum brazing, the use of silver filler metal on copper, and so on). The rapid heating of filler metals with wide melting ranges or their application to the joint after the base metal reaches brazing temperature will minimize the separation, or liquation. However, liquation cannot be entirely eliminated and wide-melting-range filler metals, which tend to have more sluggish flow, will require wider joint clearances and will form larger fillets at the joint extremities. A few brazing filler metals become sufficiently fluid below the actual liquidus temperature, and satisfactory joints are achieved, even though the liquidus temperature has not been reached.

When sluggish behavior is needed, such as in filling large gaps, brazing can be accomplished within the melting range of the filler metal. However, the brazing temperature is usually 10 to 93 °C (20 to 170 °F) above the liquidus of the filler metal. The actual temperature required to produce a good joint filling is influenced by factors such as heating rate, brazing environment (atmosphere or flux), thickness of parts, thermal conductivity of the metals being joined, and type of joint to be made.

Large-scale mechanical properties of brazing filler metals can be a guideline for their suitability (in terms of strength, oxidation resistance, and so on) for use in different capillary joining applications. However, designers cannot use the mechanical properties of brazed assemblies that are related to different joint configurations brazed at given cycles of time and temperatures.

The placement of the brazing filler metal is an important design consideration, not only because the joint must be accessible to the method chosen, but because, in automatic heating setups, the filler metal must be retained in its location until molten. Brazing filler metals are available in different forms (Table 6) and filler-metal selection may depend on which form is suitable for a particular joint design.

Several general rules apply in the filler-metal placement. Wherever possible, the filler metal should be placed on the most slowly heated part of the assembly in order to ensure complete melting. Although brazing is independent of gravity, gravity can be used to assist filler-metal flow, particularly for those filler metals having wide ranges between their solidus and liquidus temperatures. Brazing filler metals can be chosen to fill wide gaps or to flow through joint configurations where the gap may vary, for example, around a corner. Unless movement between the components being joined is unimportant or can be corrected manually (through self-jigging or by using fixtures after the filler metal is molten), the filler metal should be placed outside the joint and allowed to flow into it. It should not be placed between the joint members. If erosion of thin members is possible, then the brazing filler metal should be placed on the heavier sections, which heat up more slowly, so that flow proceeds toward the thin sections. Apart from suiting the placement method selected for the joint, the form chosen for the brazing filler metal may be needed to accurately gage the amount applied, not just for economy and reproducibility, but to regulate and maintain joint properties and configuration.

Surface Preparation. A clean, oxide-free surface is imperative to ensure uniform quality and sound brazed joints. All grease, oil, dirt, and oxides must be carefully removed from the base and filler metals before brazing, because only then can uniform capillary attraction be obtained. Brazing should be done as soon as possible after the material has been cleaned. The length of time that the cleaning remains effective depends on the metals involved, atmospheric conditions, storage and handling practices, and other factors. Cleaning operations are commonly categorized as being either chemical or mechanical. Chemical cleaning is the most effective means of removing all traces of oil or grease. Trichloroethylene and trisodium phosphate are the usual cleaning agents employed. Oxides and scale that cannot be eliminated by these cleaners should be removed by other chemical means.

The selection of the chemical cleaning agent depends on the nature of the contaminant, the base metal, the surface condition, and the joint design. Regardless of the nature of the cleaning agent or the cleaning method used, it is important that all residue or surface film be adequately rinsed from the cleaned parts to prevent the formation of other equally undesirable films on the faying surfaces.

Objectionable surface conditions can be removed by mechanical means, such as grinding, filing, wire brushing, or any form of machining, provided that joint clearances are not disturbed. When grinding the surfaces of the parts to be brazed, care should be exercised to ensure that the coolant is clean and free from impurities to avoid grinding these impurities into the finished surfaces.

When faying surfaces of parts to be brazed are prepared by blasting techniques, several factors should be considered. There are two purposes behind the blasting of parts to be brazed. One is to remove any oxide film and the other is to roughen the mating surfaces in order to increase capillary attraction of the brazing filler metal. The blasting material must be clean and must not leave any deposit on the surfaces to be joined that restricts filler-metal flow or impairs brazing. The particles of the blasting material should be angular rather than spherical, so that the blasted parts are lightly roughened, rather than peened, after the scale is removed. The operation should not distort or otherwise harm delicate parts. Vapor blasting and similar wet blasting methods require care, because of the possibility of surface contamination.

Mechanical cleaning may be adequate, in which case it should be permitted (by the design) during manufacture. In those cases that require chemical cleaning, the cleaning operation may be followed by protective electroplating, which necessitates access to the faying surface by the liquids involved.

Another surface protection technique is the use of solid and liquid brazing fluxes. At temperatures up to about 1000 °C (1830 °F), fluxes often provide the easiest method of maintaining or producing surface cleanliness. In such cases, the design must not only permit easy ingress of the flux, but should allow the filler metal to wash it through the joint. Above 1000 °C (1830 °F), the flux residues can be difficult to remove, and surface cleaning can be accompanied by brazing in furnaces with protective atmospheres. However, the design must permit the gas to penetrate the joint.

In addition to cleanliness and freedom from oxides, another important factor in determining the ease and evenness of brazing filler metal flow is surface roughness. Generally, a liquid that wets a smooth surface will wet a rough one even more. A rough surface will modify filler-metal flow from laminar to turbulent, prolonging flow time and increasing the possibility of alloying and other interactions. Surfaces often are not truly planar, and, in some instances, surface roughening will improve the uniformity of the joint clearance. A rough surface features a series of crests and troughs that produce turbulent flow. These irregularities on the surface simulate grips to prevent the flow of the filler metal.

Conversely, there may be a requirement that brazing filler metal not flow onto some surfaces. Stop-off materials will often avoid flow, but the design must permit easy application of the stop-off material without contaminating the surfaces to be joined.

Self-fluxing filler metals, in a suitably protective environment such as vacuum, may provide the essential surface wetting.

Joint Design and Clearance. A brazed joint is not a homogeneous body. Rather, it is a heterogeneous area that is composed of different phases with different physical and chemical properties. In the simplest case, it consists of the base-metal parts to be joined and the added brazing filler metal. However, dissimilar materials must also be considered.

Small clearances are used because the smaller the clearance, the easier it is for capillarity to distribute the brazing filler metal throughout the joint area and the less likely it is that voids or shrinkage cavities will form as the brazing filler metal solidifies. The optimum joints are those in which the entire joint area is wetted and filled by the brazing filler metal. Typically, brazing clearances that range from 0.03 to 0.08 mm (0.001 to 0.003 in.) are designed for the best capillary action and greatest joint strength.

Because brazing relies on capillary attraction, the design of a point must provide an unobstructed and unbroken capillary path to enable the escape of flux, if used, as well as allow the brazing filler metal into the joint. In cases where filler metal is added to a joint by hand, such as by feeding in a rod or wire, the joint entry must be visible and accessible.

Some of the more-important factors influencing joint design are the required strength and corrosion resistance, the necessary electrical and thermal conductivity, the materials to be joined, the mode of application of the brazing filler metal, and the postjoining inspection needs.

Consideration also should be given to the ductility of the base metal, the stress distribution in the joint, and the relative movements of the two surfaces during joining, which may introduce distortion in dimensions of the work to be brazed.

Viscosity, surface tension, and specific gravity of the brazing filler metal are not the only factors that determine the gap-filling capability of a given filler metal. Joint strength increases as joint gap decreases, down to a minimum. Table 7 gives the allowable joint clearances for various filler-metal systems. Other factors that influence optimum joint gap with a specific brazing filler metal are joint length, brazing temperature, and base-metal/filler-metal metallurgical reactions.

TABLE 7 RECOMMENDED GAP FOR SELECTED BRAZE FILLER METALS

BRAZING FILLER-METAL SYSTEM	JOINT CLEARANCE	
	mm	in.
AL-SI ALLOYS[(A)]	0.15-0.61	0.006-0.024
MG ALLOYS	0.10-0.25	0.004-0.010
CU	0.00-0.05	0.000-0.002
CU-P	0.03-0.13	0.001-0.005
CU-ZN	0.05-0.13	0.002-0.005
AG ALLOYS	0.05-0.13	0.002-0.005

AU ALLOYS	0.03-0.13	0.001-0.005

NI-CR ALLOYS(B)	0.03-0.61	0.001-0.024
PD ALLOYS	0.03-0.10	0.001-0.004

(A) IF JOINT LENGTH IS LESS THAN 6 MM (0.240 IN.), GAP IS 0.12 TO 0.75 MM (0.005 TO 0.030 IN.). IF JOINT LENGTH EXCEEDS 6 MM (0.240 IN.), GAP IS 0.25 TO 0.60 MM (0.010 TO 0.24 IN.).

(B) MANY DIFFERENT NICKEL BRAZING FILLER METALS ARE AVAILABLE, AND JOINT GAP REQUIREMENTS MAY VARY GREATLY FROM ONE FILLER METAL TO ANOTHER

It is important to remember that an assembly expands during heating and that the joint gap can either widen or close by the time the brazing filler metal starts to melt and move. It is desirable to design the joint to expose the solidifying filler metal to compressive, rather than tensile, stress. This is much more important in brazing than in soldering, because brazing temperatures are higher, increasing the total thermal expansion. With cylindrical joints, the components with the larger coefficient of expansion should be on the outside, whenever possible.

Joint clearance is probably one of the most significant factors in vacuum brazing operations. Naturally, it receives special consideration when joint are designed at room temperature. Actually, joint clearance is not the same at all phases of brazing. It will have one value before brazing, another value at the brazing temperature, and still another value after brazing, especially if there has been a substantial interaction between the brazing filler metal and the base metal. To avoid confusion, it has become general practice to specify joint clearance as the value at room temperature before brazing.

The recommended joint clearances given in Table 7 are based on joints that have members of similar metals and equal mass. When dissimilar metals and/or metals of widely differing masses are joined by brazing, special problems arise. These problems necessitate specialized selection of brazing filler metals. Furthermore, the most suitable joint clearance for the specific job must be carefully determined. Thus, clearances given in Table 7 are the clearances that must be attained at the brazing temperature.

Although there are many kinds of brazed joints, the selection of joint type is not as complicated as it may seem, because butt and lap joints are the two fundamental types used. All other types, such as the scarf joint, are modifications of these two. The scarf joint of the scarf angle. It approaches the lap joint at the other extreme of the scarf angle.

Selection of joint type is influenced by the configuration of the parts, as well as by joint strength and other service requirements, such as electrical conductivity, pressure tightness, and appearance. Also influential in the selection of joint type are fabrication techniques, production quantities, and methods of feeding brazing filler metal. Lap joints are generally preferred for brazing operations, particularly when it is important that the joints be at least as strong as the weaker member. For maximum strength, lap-joint length should equal three to four times the thickness of the thinner member.

Temperature and Time. The temperature of the brazing filler metal has an important effect on the wetting and alloying action, which increases with increasing temperature. The temperature must be above the melting point of the brazing filler metal and below the melting point of the parent metal. Within this range, a brazing temperature that is most satisfactory overall is generally selected.

Usually, low brazing temperatures are preferred in order to economize on the heat energy required, minimize the heat effect on the base metal (annealing, grain growth, or warpage, for example), minimize base-metal/filler-metal interactions, and increase the life of fixtures, jigs, or other tools.

Higher brazing temperatures may be desirable so as to:

- ENABLE THE USE OF A HIGHER-MELTING, BUT MORE ECONOMICAL, BRAZING FILLER METAL
- COMBINE ANNEALING, STRESS RELIEF, OR HEAT TREATMENT OF THE BASE METAL WITH BRAZING
- PERMIT SUBSEQUENT PROCESSING AT ELEVATED TEMPERATURES
- PROMOTE BASE-METAL/FILLER-METAL INTERACTIONS IN ORDER TO CHANGE THE

COMPOSITION OF THE BRAZING FILLER METAL (THIS TECHNIQUE IS USUALLY USED TO INCREASE THE REMELT TEMPERATURE AND DUCTILITY OF THE JOINT)

- EFFECTIVELY REMOVE SURFACE CONTAMINANTS AND OXIDES WITHIN PROTECTIVE ATMOSPHERES BRAZING (ALSO APPLIES TO PURE DRY HYDROGEN, TO ARGON, AND TO VACUUM)
- AVOID STRESS CRACKING

The time at brazing temperature also affects the wetting action. If the brazing filler metal has a tendency to creep, the distance generally increases with time. The alloying action between filler metal and parent metal is, of course, a function of temperature, time, and quantity of filler metal. For production work, temperature, time, and quantity of filler metal are generally kept at a minimum, consistent with good quality, where diffusion is not required.

Heating Methods

The numerous heating methods available for brazing often represent constraints on the designer or engineer when selecting the best type of capillary joint (Table 8). However, because effective capillary joining requires the efficient transfer of heat from the heat source into the joint, one cannot braze a 0.025 mm (0.001 in.) diam wire to a 2.3 kg (5.1 lb) lump of copper with a small torch.

TABLE 8 RELATIVE RATING OF SELECTED BRAZING PROCESS HEATING METHODS

(A) H, HIGH; M, MEDIUM; L, LOW

The size and value of individual assemblies, the numbers required, and the required rate of production will influence the selection of heating method. Other factors that also must be considered include the rate of heating, differential thermal gradients, and both external and internal cooling rates. These factors vary tremendously with different methods of heating, and their effects on dimensional stability, distortion, and joint structure must be considered.

Manual torch brazing is the method most frequently used for repairs, one-of-a-kind brazing jobs, and short production runs, as an alternative to fusion welding. Any joint that can be accessed by a torch and brought to brazing temperature (by the torch alone or in conjunction with auxiliary heating) can be readily brazed by this technique.

Although any flame-producing device can be used for torch brazing, commercial applications are accomplished with the same type of torch, controls, and gases used for torch fusion welding. Conversion to brazing merely requires changes in torch nozzles and goggle lenses.

The torch brazing technique is relatively simple and can be mastered by the mechanically adept in a short time. Those already experienced in torch welding and the brazing of other metals generally encounter little difficulty learning torch brazing.

Depending on the temperature and heat required, all commercial gas mixtures can be used to fuel the torch: oxyacetylene, oxyhydrogen, oxy-natural gas, acetylene and air, hydrogen and air, propane, methane, and natural gas and air. Oxyacetylene and oxy-natural gas are the mixtures most often used commercially and are preferred in that order. Flame adjustment is very important. Generally, a slightly reducing flame is desirable in order to preserve part surfaces from oxidation.

The oxyacetylene combination produces the highest temperature. The other gases are cooler and their flames have relatively lower intensity. Thus, they are easier to use and are applied advantageously to light-gage material.

Manual torch brazing is particularly useful on assemblies with sections of unequal mass. As warranted by the rate of production, machine operations can be set up using one or more torches equipped with single or multiple flame tips. The machine can be designed to move either the work or the torches.

Torch brazing can be rather easily automated with appropriate gas supplies, indexing fixtures, and cycle controls. Usually, such systems involve multiple-station rotary indexing tables. The part is fed into a holding fixture at the first station and is then indexed to one or more preheating stations, depending on the heating time required. A brazing station is next, followed by a cooling station and an ejection station (see Fig. 4).

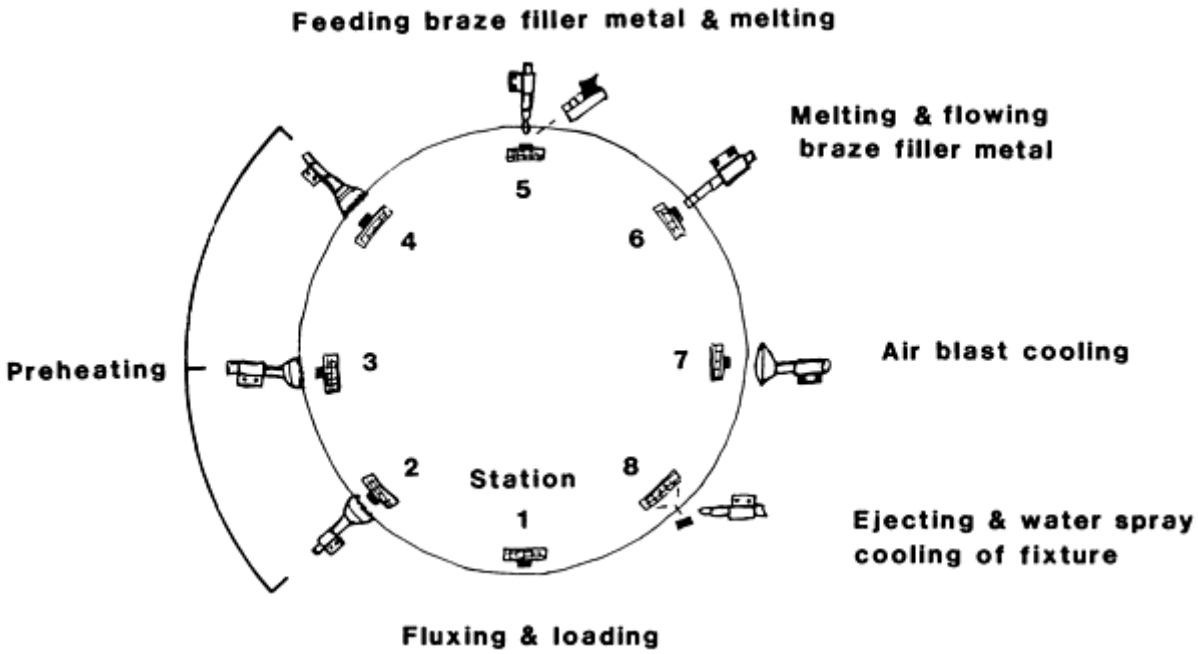

FIG. 4 SCHEMATIC OF AN EIGHT-STATION AUTOMATIC TORCH BRAZING OPERATION THAT PRODUCES MAGNET ARMATURE ASSEMBLIES (230 PIECES/H) USED AS STRIKING MEMBERS OF A PRINTING MACHINE

Additional information is available in the article "Torch Brazing" in this Volume.

Furnace brazing is popular because of its comparatively low equipment cost, furnace adaptability, and minimal required jigging. Furnace brazing is a low-cost process relative to other processes such as torch brazing, induction brazing, or salt-bath brazing when high-volume production output is a primary factor. Secondary factors include tooling requirements, fluxing, and cleaning requirements. With many brazing assemblies, the weight of the parts alone is sufficient to hold them together. Other configurations require only one or two rectangular fixturing blocks of metal.

Four basic types of furnaces are used:

- BATCH, WITH EITHER AIR OR CONTROLLED ATMOSPHERE (FIG. 5)
- CONTINUOUS, WITH EITHER AIR OR CONTROLLED ATMOSPHERE (FIG. 6)
- RETORT, WITH CONTROLLED ATMOSPHERE
- VACUUM

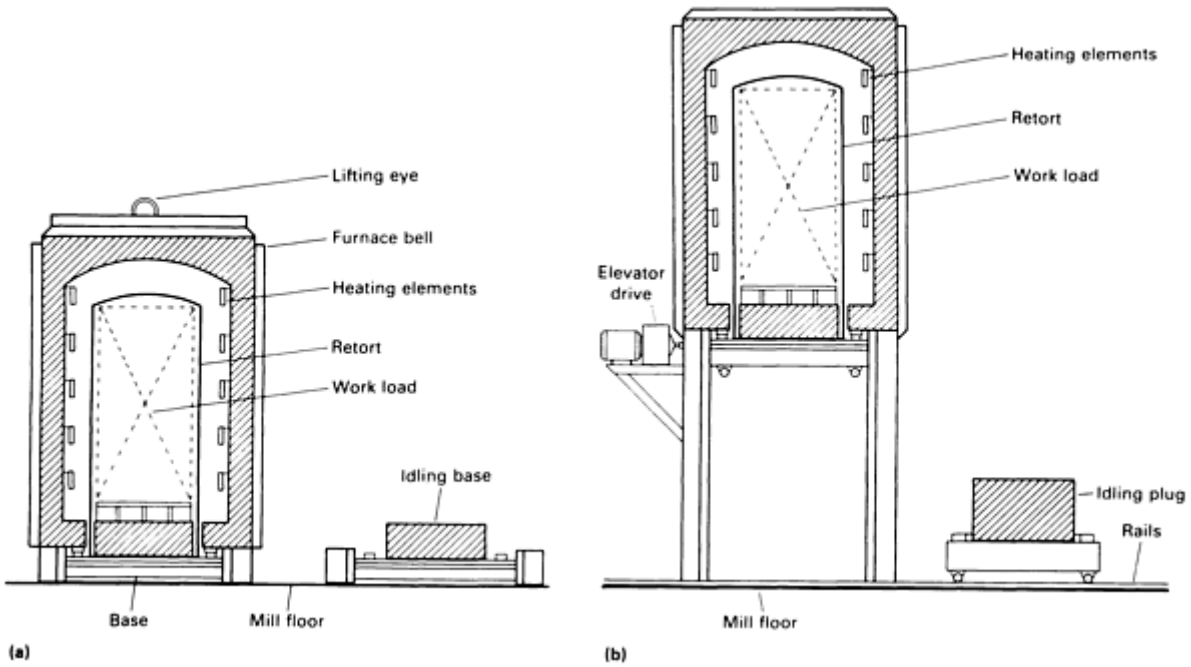

FIG. 5 BATCH-TYPE BRAZING FURNACES. (A) BELL FURNACE. (B) ELEVATOR FURNACE

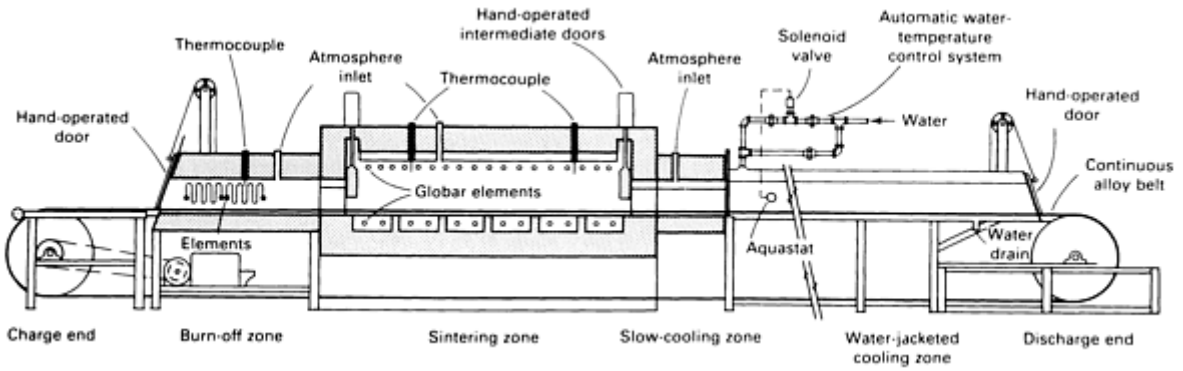

FIG. 6 CONTINUOUS-TYPE BRAZING FURNACE WITH WATER-JACKETED COOLING CHAMBER FOR USE IN AIR OR CONTROLLED ATMOSPHERES

Furnace brazing is used extensively where the parts to be brazed can be assembled with the brazing filler metal preplaced near or in the joint. Furnace brazing is particularly applicable for high-production applications in which continuous

conveyor-type furnaces are used. For medium-production work, batch-type furnaces are best. Regardless of furnace type, heating is usually produced by electrical resistance, although other types of fuel can be used in muffle-type furnaces.

The parts should be self jigged or fixtured and assembled, with brazing filler metal preplaced near or in the joint. Fluxing is used, except in cases where a reducing atmosphere, such as hydrogen, and either exothermic or endothermic combusted gas can be introduced into the furnace. Sometimes, both flux and a reducing atmosphere are necessary. Pure and dry inert gases, such as argon and helium, are used to obtain special atmosphere properties. Fluxes should never be used when furnace brazing with a vacuum atmosphere.

When continuous-type furnaces are used (Ref 16, 17), several different temperature zones can be set up to provide the proper preheating, brazing, and cooling temperatures. The speed through a conveyor-type furnace must be controlled to provide the appropriate time at the brazing temperature. It is also necessary to properly support the assembly so that it does not move while traveling on the belt (Ref 18).

A large volume of furnace brazing is performed in a vacuum atmosphere, which prevents oxidation during the heating cycle and eliminates the need for flux (Ref 19) (Fig. 7). Vacuum brazing has found wide application in the aerospace and nuclear fields, where reactive metals are joined or where entrapped fluxes would not be tolerable. Vacuum brazing does not allow as wide a choice of brazing filler metals as does atmosphere brazing (Ref 20, 21).

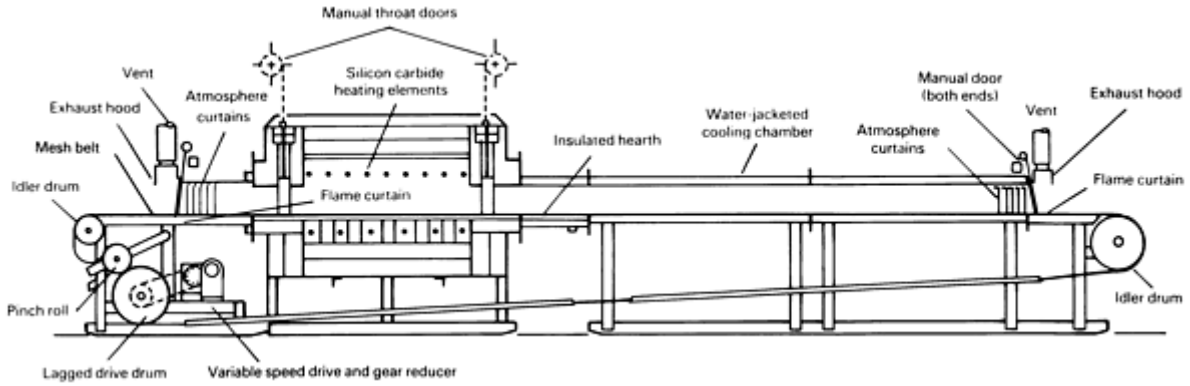

FIG. 7 HIGH-VACUUM BOTTOM-LOADING VACUUM FURNACE FOR MEDIUM-PRODUCTION APPLICATIONS

In most cases, vacuum furnaces are heated by electrical resistance heaters in a numbers of different forms. The overall time of a vacuum brazing operation is usually much longer than that of other batch brazing techniques and involves typing up expensive equipment for long periods to process comparatively small workloads. However, most of the metals on which vacuum brazing excels are also costly, the use of a process that permits material economics through fabrication while ensuring the necessary joint properties often can be justified (Ref 22, 23, 24).

Detailed information is available in the article "Furnace Brazing" in this Volume.

Induction Brazing. The high-frequency induction heating method for brazing is clean and rapid, lends itself to close control of temperature and location, and requires little operator skill.

The workpiece is placed in or near a coil carrying alternating current (ac), which induces the heating current in the desired area (Fig. 8). The coils, which are water cooled, are designed specifically for each part. Therefore, heating efficiency relies on establishing the best coil design and power frequency for each application. In most cases, the coils provide heat only to the joint area.

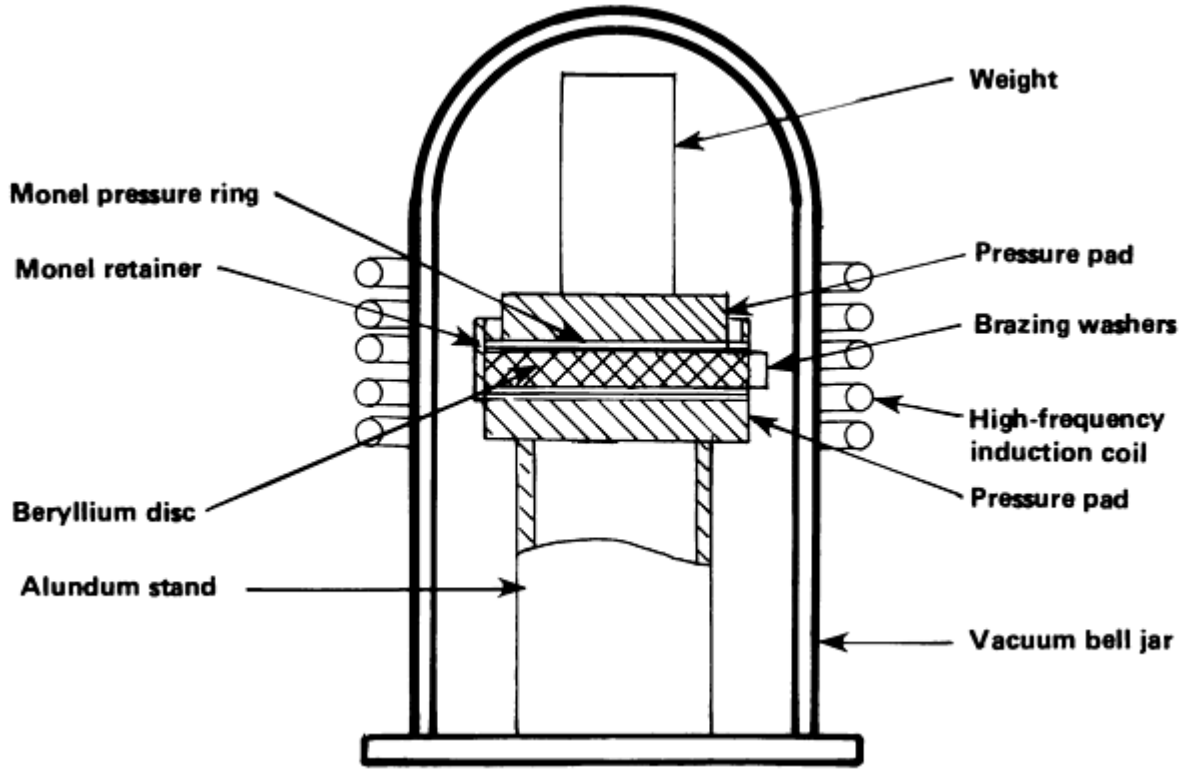

FIG. 8 INDUCTION HEATING APPARATUS USED TO VACUUM BRAZE BERYLLIUM AND MONEL COMPONENTS

The capability to heat selectively enables the induction method to be used when the nature of the brazement demands localized brazing.

There are several types of high-frequency sources to supply power to induction coils, each with a different range of frequencies:

- MOTOR GENERATORS (5 TO 10 KHZ)
- SPARK-GAP OSCILLATORS (20 TO 30 KHZ)
- VACUUM-TUBE OSCILLATORS (20 TO 5000 KHZ)
- SOLID-STATE POWER SUPPLIES (VARIABLE HZ)

The frequency of the power source determines the type of heat that will be induced in the part: high-frequency sources produce "skin" heating, whereas lower-frequency sources provide heating in thicker areas. The brazing heat usually develops within 10 to 60 s.

Induction brazing is well suited for mass production. Mechanized brazing lines for moving assemblies to and from the coils are very common. Brazing filler metals is normally preplaced in the joint, and the brazing can be done in air with the use of a flux, in an inert atmosphere, or in a vacuum atmosphere. The rapid heating rates available with induction heating are a major advantage when using brazing filler metals that tend to vaporize or segregate. The heating cycle for induction brazing is invariably automated, even when manual loading of assemblies is used.

Additional information is available in the article "Induction Brazing" in this Volume.

Dip brazing involves immersion of assembled parts into a suitable molten bath to effect brazing. The bath can be molten brazing filler metal, molten chemical flux, or molten chemical salts. The molten material is contained in a "pot" furnace heated by oil, gas, or electricity. In some instances, electrical-resistance heaters are used in the bath (Fig. 9). In the first type of bath, the parts being joined are held together and immersed in flux-covered molten filler metal, which flows into

the joints when the parts reach the bath temperature. The flux cleans the workpiece as it is introduced and protects the brazing filler metal by preventing oxidation and the loss of volatile elements from the bath.

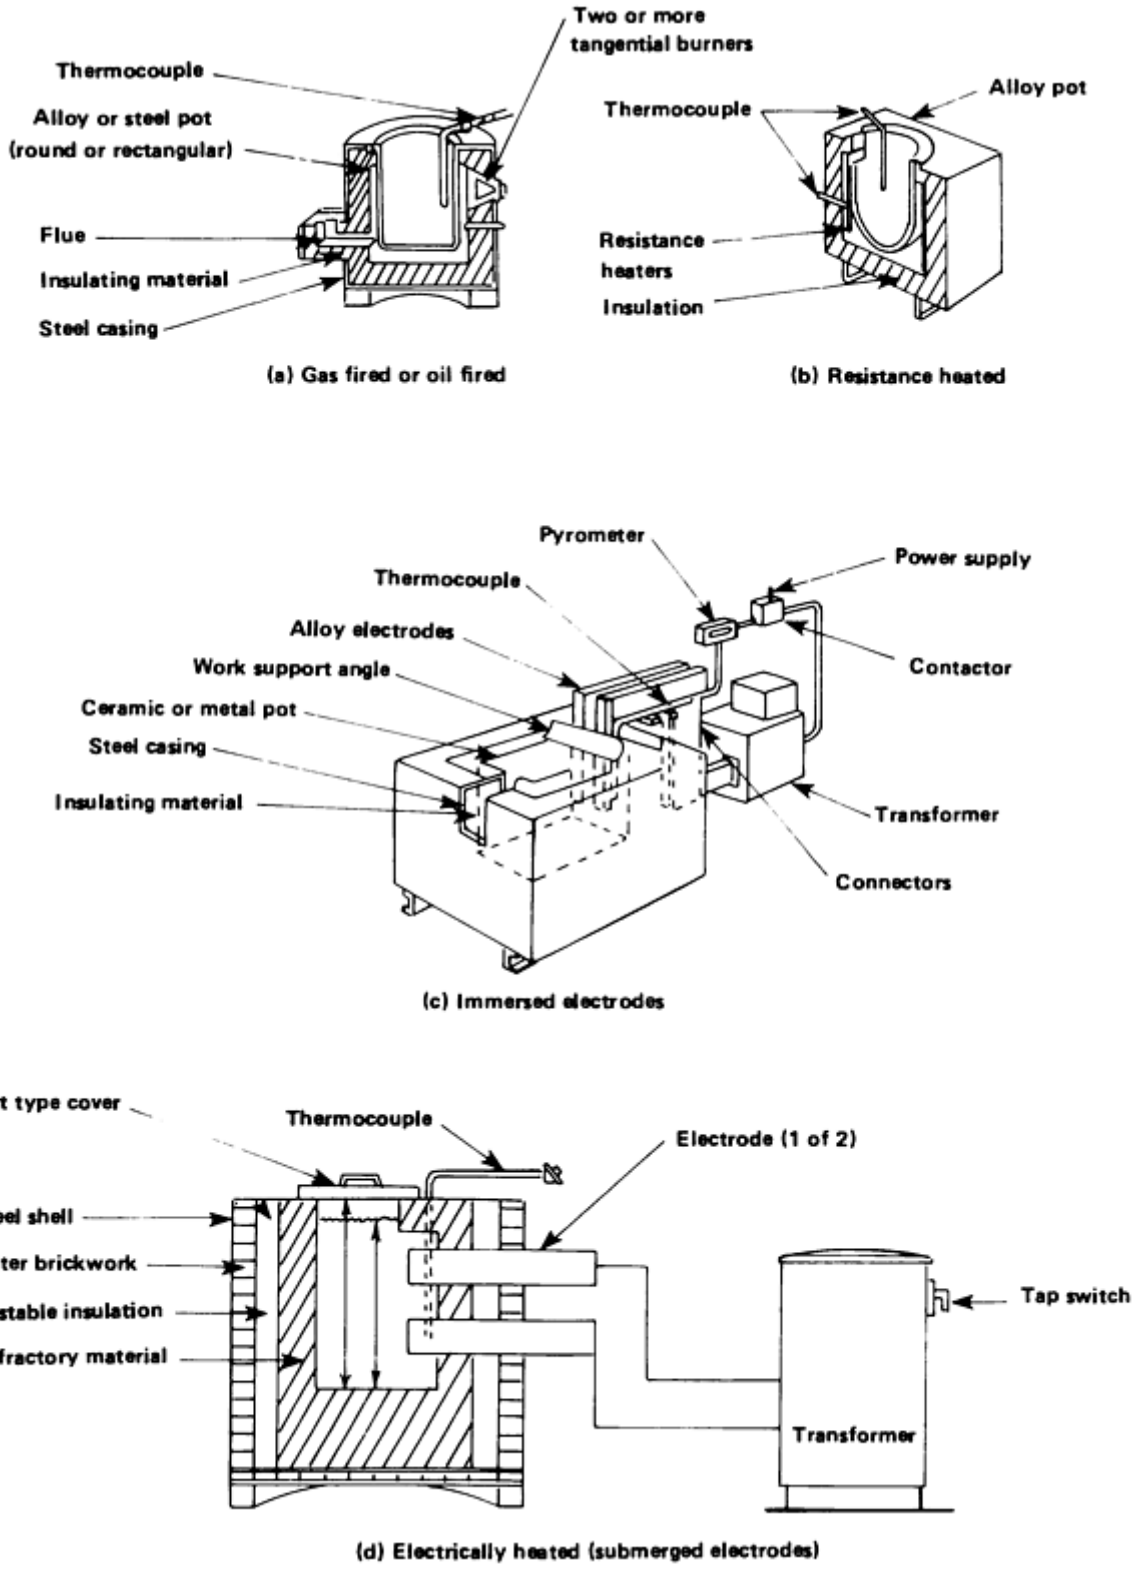

FIG. 9 EXTERNALLY AND INTERNALLY HEATED FURNACES USED FOR DIP BRAZING APPLICATIONS

The pot, or crucible, used in the molten-metal method is usually made of graphite. Jigging to maintain alignment is generally necessary. Because of the difficulties of heating and containing metals at high temperatures, filler metals that

require a brazing temperature above 1000 °C (1830 °F) are rarely used. Therefore, the choice of brazing filler metal is restricted to straight brasses and silver-base filler metals.

In the molten-flux method, the brazing filler metal is located in or near the joints and is heated to the required temperature by immersion in a bath of molten flux. Molten salt bath brazing has a greater scope than any other single brazing process. It can be used on as wide a range of parent metals as torch brazing, but is not subject to the same maximum temperature limitations. Unfortunately, it is an inflexible process. The type of salt used for a particular application depends on the ease with which the parent-metal surface oxides can be removed and on the temperature required for brazing.

The molten-flux method is used extensively for brazing aluminum and its alloys. The flux bath provides excellent protection against metal reoxidation, which can occur quite easily with aluminum.

The dip brazing method generally causes less distortion than torch brazing, because of its uniform heating. However, it may require relatively complex tooling and is therefore best used in medium- to high-production runs. This process is particularly well suited for small- to medium-sized parts with multiple hidden joints.

Detailed information is available in the article "Dip Brazing" in this Volume.

Resistance brazing is most applicable to relatively simple joints in metals that have high electrical conductivity. In this process, the workpieces are heated locally. Brazing filler metal that is preplaced between the workpieces is melted by the heat obtained from its resistance to the flow of electric current through the electrodes and the work. Usually, the heating current, which is normally ac, is passed through the joint itself. The joint becomes part of an electrical circuit, and the brazing heat is generated by the resistance at the joint.

Equipment is the same as that used for resistance welding, and the pressure needed for establishing electrical contact across the joint is ordinarily applied through the electrodes. The electrode pressure also in the usual means for providing the tight fit needed for capillary behavior in the joint. The component parts are generally held between copper or carbon-graphite electrodes.

The flux that is used must be conductive. Normally, fluxes are insulators when cool and dry, but are conductive when wet. The process is generally used for low-volume production in joining electrical contacts, related electrical elements, copper commutator segments, stainless steel tube to fittings, and so on.

Additional information is available in the article "Resistance Brazing" in this Volume.

Infrared (Quartz) Brazing. The development of high-intensity quartz lamps and the availability of suitable reflectors have made the infrared heat technique commercially important for brazing. Infrared heat is radiant heat that is obtained with the sources having energy frequency below the red rays in the light spectrum. Although there is some visible light with every "black" source, heating is principally done by the invisible radiation. Heat sources (lamps) capable of delivering up to 5000 W of radiant energy are commercially available. The lamps do not need to follow the contour of the part in order to hear the joint area, even though the heat input varies inversely as the square of the distance from the source, unless reflectors are used to concentrate the heat.

Lamps are often arranged in a toaster-like configuration, with parts traveling between two banks of lamps (Fig. 10). Infrared brazing can concentrate large amounts of heat in small areas, which can be advantageous in certain applications. Infrared brazing setups are generally not as fast as induction brazing, but the equipment is less expensive.

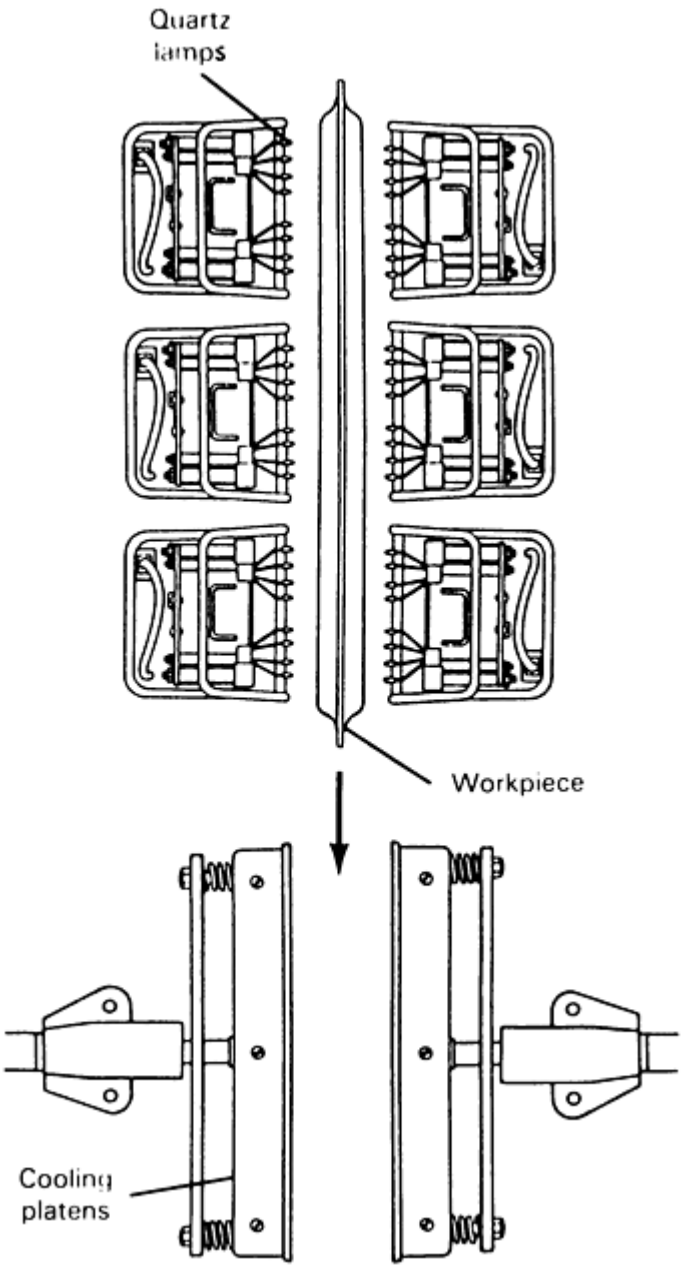

FIG. 10 WORKPIECE SUBJECTED TO INFRARED BRAZING PROCESS PRIOR TO BEING MOVED TO COOLING PLATENS

Exothermic brazing is a special process, but is rarely used because there are more-economical production methods. In this process, the heat required to melt and flow the brazing filler metal is produced by a solid-state exothermic chemical reaction, which is defined as any reaction between two or more reactants that involves the free energy of the system. Although nature provides countless numbers of these reactions, only the solid-state or nearly solid-state metal/metal-oxide reactions are suitable for use in exothermic brazing units.

Additional information is available in the article "Exothermic Brazing" in this Volume.

Electron-beam and laser brazing have been used in a limited number of applications. A laser can be used when a very small localized area of heat is required, such as for brazing small carbide tips on printer heads for electronic printers. The electron beam can be used for brazing by defocusing the beam to provide a wider area of heating. Because this is done in a vacuum, fluxes cannot be used and the brazing filler metal must be selected so that there is little or no vaporization during brazing.

Microwave Brazing. One of the newest heating methods to be developed is the use of microwaves. This technique is being used to join ceramics in high-temperature, corrosion-resistant, and high-performance applications. These applications require complex ceramics parts with strong, durable joints (Ref 25, 26).

The technique uses a single-mode microwave cavity. An iris controls the percent of microwaves reflected in the cavity, and a plunger adjusts the frequency. Together, they focus microwaves on the joint. The major advantage of this technique in terms of ceramic parts is that the entire part does not have to be heated in order to make a joint. Reheating finished ceramic parts can subject them to thermal stresses and cause cracking, which weakens the part. With microwave joining, only the interface between the pieces is heated. The technique is faster than conventional joining, which requires long times to heat ceramics uniformly. Large pieces, can, in principle, be joined at a lower cost.

One disadvantage of microwave joining is that commercial equipment is only produced by a few companies, mostly for research and development purposes.

Some microwave units feature 2.45 GHz single-mode or controlled multimode operation. Their cavity is designed to provide controlled-mode patterns that can focus high-energy microwave fields to heat a part only where it is needed, such as at a joint. The joint or part can be heated up to 2200 °C (3990 °F). Researchers have joined 92% Al_2O_3 ceramic parts in a 6 GHz single-mode microwave cavity at various temperatures and times. The bending strength of this joint gradually increased from the solidus temperature of 1400 °C (2550 °F) and reached a peak of 420 MPa (60 ksi) at about 1750 °C (3180 °F).

Braze welding is a joining process in which a filler metal is melted and deposited in a specific joint configuration, and a metallurgical bond is obtained by a wetting action that is often accompanied by some degree of diffusion with the base metals. Braze welding requires heating and melting of the filler metal that has a melting (liquidus) temperature above 450 °C (840 °F).

Stringent fit-up is not critical, because the filler metal is deposited in grooves and spaces and flows into gaps wider than those used for brazing. Fabricators use braze welding as a low-temperature substitute for oxyfuel welding or as a low-cost substitute for brazing. Joint designs for braze welding are the same as for oxyfuel welding (OFW). Braze welding has been used to join cast iron, steels, copper, nickel, and nickel alloys.

Compared to conventional fusion-welding processes, braze welding requires less heat input, permits higher travel speeds, and causes less distortion. Deposited filler metal is soft and ductile, providing good machinability, and residual stresses are low. The process joins brittle cast irons without extensive preheating.

Although most braze welding initially used an OFW torch, copper filler metal brazing rod, and a suitable flux, present applications use carbon arc welding (CAW), gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), or plasma arc welding (PAW) without flux in the manual, semiautomatic, or automatic modes to economically bond and deposit the filler metal in the braze weld joints. OFW is, however, still widely used in machinery repair applications. Filler metal selection, proper wetting and compatibility with the base metals, and shielding from air are important to the effective use of the process with any suitable heating method.

A wide variety of parts can be braze welded using typical weld joint designs. Groove, fillet, and edge welds can be used to join simple and complex assemblies made from sheet, plate, pipe, tubing, rods, bars, castings, and forgings. Sharp corners that are easily overheated and may become points of stress concentrations should be avoided. To obtain good strength, an adequate bond area is required between filler metal and the base metal. Weld groove geometry should provide an adequate groove face area, so that the joint will not fail along the interfaces. Proper joint design selection will produce deposited filler-metal strengths that may meet or exceed the minimum base-metal tensile strengths. Because of the inert shielding gas, electrical arc methods have fewer included flux compounds and oxides at the faying surfaces. The result is higher joint strength and improved corrosion resistance. Original surfaces are restored by overlayments and subsequent machining.

Introduction

SOLDERING is an ancient joining method. It is mentioned in the Bible (Isaiah, 41:7), and there is evidence of its use in Mesopotamia 5000 years ago, well before the time of Cleopatra, as well as later, in Egypt, Greece, and Rome (Ref 1). Pliny the Elder, in his *Historia Naturalis,* written 2000 years ago, mentions (in Chapter XLVIII of Book XXXIV) that the soldered connections of the pipes of the Roman aqueducts were made with a so-called "tertiarium" mixture, an alloy of two parts lead and one part tin. The earliest solders were alloys found in nature, which meant that only a few solders, with a severely limited range of properties, were available. Because these early solders were generally used to join jewelry parts or to attach handles to decorative vessels, the primary concerns were appearance, melting point, and, to a lesser degree, strength. The materials were rare and costly, and the work was done by highly skilled artisans. Therefore, only the wealthy could hope to own such articles.

It has only been in the last two centuries that some metals have become cheap and that strictly utilitarian parts are soldered. In the 1800s, low-cost steels made household tinware practical for most families, and the "tinner" became the common solder practitioner. The emergence of electrical technology required the attachment of electrical leads, which became a most common use of solders. This meant that the electrical properties of solders became a consideration, and the electrical continuity of the joint was of paramount importance, rather than strength or appearance, as had been the case with jewelry or utensils. The use of solders for electrical attachments also involved simple mechanical joints and repetitive operations. The cost of the materials was generally much less, because lead-tin solders were usually used. Even today, it is customary to give the tin content first when designating a solder (for example, 40/60 solder refers to a solder that is 40% Sn and 60% Pb). These new criteria promoted a new type of artisan whose skills were more oriented to engineering and production than to aesthetics, although most of the work was still done manually.

By the 20th century, metallurgical science had developed to the point that new solders could be tailored specifically for electrical, plumbing, or structural applications. The emerging electronics industry required solders having the following properties:

- COMPATIBILITY WITH COPPER (ESPECIALLY WITH RESPECT TO ALLOYING BEHAVIOR AND MELTING TEMPERATURES)
- GOOD ELECTRICAL CONDUCTIVITY
- WORKABILITY TO ENABLE FACTORY WORKERS TO RAPIDLY FORM LOW-COST, RELIABLE SOLDER JOINTS

Engineers now had formal rules to govern the design of joints used in various applications to ensure the required levels of strength. The materials and processes involved in soldering were now becoming established in engineering practice (Ref 2, 3, 4, 5).

Process Overview

Soldering is defined as a joining process by which two substrates are bonded together using a filler metal (solder) with a liquidus temperature that does not exceed 450 °C (840 °F). The substrate materials remain solid during the bonding process. The solder is usually distributed between the properly fitted surfaces of the joint by capillary attraction.

The bond between solder and base metal is more than adhesion or mechanical attachment, although these do contribute to bond strength. Rather, the essential feature of the soldered joint is that a metallurgical bond is produced at the filler-metal/base-metal interface. The solder reacts with a small amount of the base metal and wets the metal by intermetallic compound formation. Upon solidification, the joint is held together by the same attraction, between adjacent atoms, that holds a piece of solid metal together. The ease of wetting is related to the ease with which this solvent action occurs. The presence of the base-metal/filler-metal reaction is one factor in the wetting action of the solder. Other factors include surface cleanliness and solder surface tension (that is, capillary flow).

Fundamentals of Soldering

Mel M. Schwartz, Sikorsky Aircraft

Fundamentals of Soldering

Pure metals have a crystalline state and a well-defined melting temperature. They also possess reasonable ductility and strength. Metals are excellent electrical conductors, when compared with ceramics or plastic polymer materials. Thermal conductivity generally follows electrical conductivity (that is, a good electrical conductor also is a good thermal conductor).

Melting and Solidification of Pure Metals. The melting behavior of pure lead is plotted in Fig. 1. From point A, which is room temperature, heat is applied to raise the temperature to 327 °C (621 °F), the melting point of lead, represented as point B, whereupon the heat of fusion is absorbed and the temperature remains constant until all the lead becomes liquid. At point C, when all of the solid is molten, the temperature of the liquid will again rise (to point D) upon the application of heat.

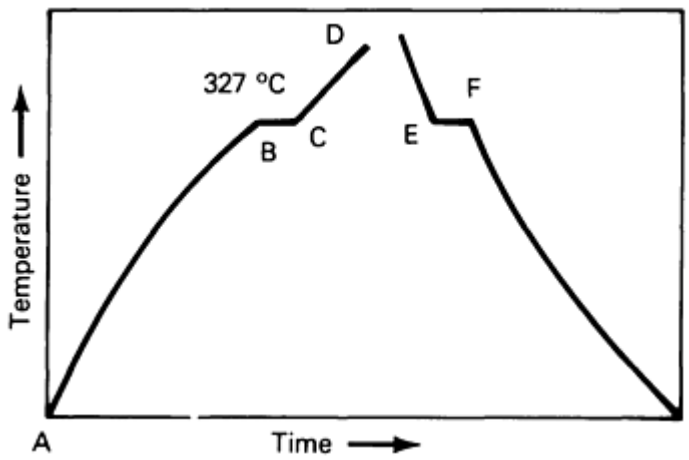

FIG. 1 PLOT OF THE HEATING AND COOLING CURVES OF PURE LEAD. SEE TEXT FOR DETAILS.

If the process is reversed and the heat source is turned off, then the temperature will fall from point D to E, where the liquid will begin to give off its heat of fusion, as atoms assume a solid crystalline form. A nucleus is formed and gradually grows as the atoms attach themselves in a regular crystalline pattern, forming dendritic crystals, which have a main trunk

and branches. As the solid forms, the release of the heat of fusion causes the temperature to remain constant (point E to F) at 327 °C (621 °F), until all the lead has solidified. Then, the solid cools back to room temperature. Under equilibrium conditions, lead will always be in the liquid phase at temperatures above 327 °C (621 °F), and will always be in the solid phase below that temperature. This behavior is observed for all pure metals, although each has a specific melting temperature. The solidification and cooling curve for pure tin is shown in Fig. 2. The cooling arrest at the solidification temperature is typical of all pure metals (Ref 3).

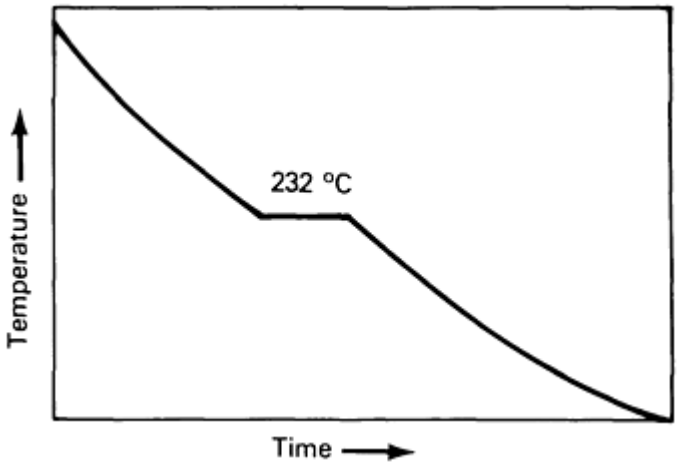

FIG. 2 COOLING CURVE FOR PURE TIN

Alloy Formation and Phase Diagrams. The best vehicle for portraying the behavior of alloys is the equilibrium phase diagram (also called equilibrium or constitution diagram), which represents the phases present under equilibrium conditions in a given alloy system. Phase diagrams are plots of alloy equilibrium composition versus temperature. The diagrams are generally worked out by measuring the melting and solidification behaviors of alloys of different compositions and then observing the resultant microstuctures. Understanding phase diagrams is essential to working effectively with solders, because they are used to predict solder microstructure and behavior.

When two or more metals are melted together, they form an alloy that behaves as a unique material with specific properties that can significantly differ from the properties of the individual pure metals. Alloy properties depend on the atomic structure and thermal-physical properties of its constituent elements. For example, the addition of tin to lead will result in an alloy that has a lower melting point than either tin or lead. Perhaps more surprising is that the addition of lead to tin will also result in an alloy with a lower melting point. The physical and mechanical properties of the alloys will also differ from the properties of the pure metals.

In Fig. 3, 327 °C (621 °F) is the melting point of pure lead (point A) and 232 °C (450 °F) is the melting point of pure tin (point B). The line AEB, which separates the liquid field from the rest of the diagram, represents the "liquidus." For any given composition in this system, the alloy is completely molten at any temperature above that line. The line below which any lead-tin alloy will be solid is called the "solidus" (represented by ACEDB).

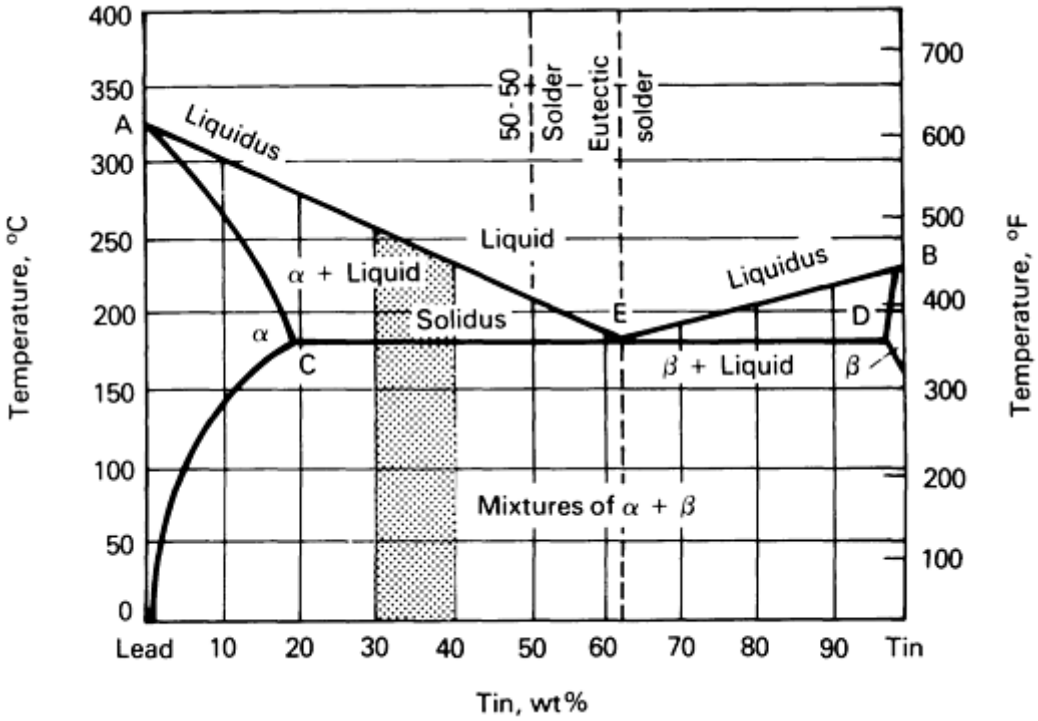

FIG. 3 CONSTITUTIONAL DIAGRAM FOR THE TIN-LEAD ALLOY SYSTEM

The CEB segment of this line is a special case known as the "eutectic" temperature. It should be noted that the fields on the phase diagram are labeled to indicate the phases existing in those regions, which enables the quick determination of the state of an alloy or the phases present at a temperature in that region.

Some metals, such as gold and silver, form alloys simply because of their mutual solubility. Such alloy formation is called a solid solution.

Two metals that have somewhat greater differences in their basic properties may not dissolve completely, that is, they have limited solubility in one another. The combination of silver and copper, however, causes a large drop in the melting temperatures, forming a eutectic (low melting) alloy system. In addition, the eutectic alloy composition itself exhibits a unique type of melting and solidification behavior, melting and solidifying at a single, specific temperature just as a pure metal does. The solid eutectic alloy is a mixture comprising two phases, rather than a solid solution. Eutectic alloy structures and behavior are of critical importance in soldering.

Wettability of Metals by Solder. Solder wetting necessarily involves the metallurgical reactions between the filler metal and the base metal. This interaction at the solder/base-metal interface can result in a covalently bonded layer of material, referred to as an intermetallic compound. Examples include tin and gold ($AuSn_4$), copper and tin (Cu_6Sn_5 and Cu_3Sn), or nickel and tin (Ni_3Sn_4). As opposed to the metallic bond of metals and alloys, the covalently bonded structure causes the intermetallic to be hard and brittle, to have a high melting point, and to be resistant to chemical attack. Excessively hard intermetallic layers can jeopardize the physical and mechanical integrity of solder joints.

All electrical/electronic applications require soldering to a base metal. This base metal can be the metal that makes up the physical structure of the electrical/electronic lead or it can constitute an underplate or a barrier metallization. In all cases, the metal must be metallurgically wettable by the solder.

Intermetallic compounds are more similar to chemical compounds than they are to metallic alloys. In soldering, intermetallic compounds in thin and uniform layers represent the "glue" that forms the structural bond between the solder and the metal being soldered. Therefore, the base metal must be metallurgically compatible with at least one of the metallic components in the solder.

This intermetallic compound formation can occur by a solid/liquid reaction (molten solder against a solid base metal) or a solid-state diffusion reaction (solder plate against a solid base metal). In either case, the solder and base metal react to form a film of intermetallic compound between the two metals, which holds them together. When tin-lead solders are used with copper, a widely used base metal, the tin reacts with the copper.

Two intermetallics discussed previously in this article can form in this metallurgical system. The compound Cu_6Sn_5 will primarily form during liquid/solid reactions. In addition, Cu_6Sn_5 continues to grow in the solid state at elevated temperatures. The compound Cu_3Sn will be present during any solid-state reactions. All base-metal solder systems form one or more such compounds. For example, soldering to nickel instead of copper will result in tin-nickel intermetallics (Ni_3Sn_4) at the interface. The Ni_3Sn_4 layer grows very slowly in the solid state and is typically difficult to observe.

The ability of base metal to form a stable intermetallic compound layer with a solder limits the number of base-metal/solder combinations that are suitable for the majority of applications. The formation kinetics of intermetallic layers must permit the thorough wetting of the solder for efficient processing. Therefore, some metals are more readily soldered than others.

Another factor is the passivation characteristic of the base metal. Passivation layers form a physical barrier to metallurgical wetting. Before the base metal can be metallurgically wet by the solder, the solder must make intimate contact, on an atomic scale, with clean base metal. Passivation layers are normally oxide films that may be only a few atomic layers thick. Even so, they affect the ability of the solder to contact the base metals underneath them. Many metals will passivate extremely rapidly. Stainless steel becomes unwettable, even with the use of very active fluxes after a short exposure in the atmosphere at room temperature.

Another issue that relates to passivation layers is their chemical and mechanical stability. Because the passivation layer that forms on solder is chemically weak, it can be reduced by weak fluxes. Nickel, on the other hand, forms a passivation film that is strong both chemically and mechanically. It is adherent to the base metal and requires much stronger fluxes to remove chemically.

Figure 4 shows the phase diagram for lead-tin. The solid solution of tin in lead is designated by α, whereas the solution of lead in tin at the other extreme of the diagram is designated by β. The line ADF, which separates the α from the rest of the diagram, is the solvus, as is the similar line (CEG) isolating the β phase.

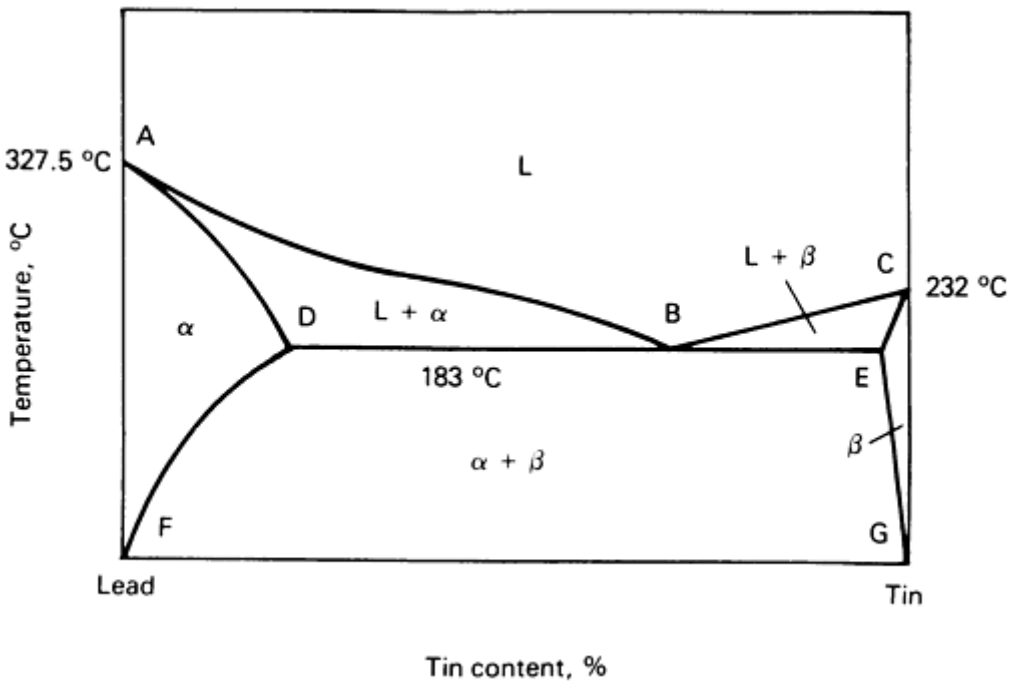

FIG. 4 LEAD-TIN PHASE DIAGRAM SHOWING EUTECTIC TEMPERATURE AT POINT B WITH 63SN-37PB

The segments D-F and E-G denote the limits of solid solubility of tin or lead in the α or the β solid solution, respectively. If the amount of tin in an alloy exceeds the solid solubility as shown by D-F, then a second phase, β, will precipitate. The amount of precipitation depends on the amount by which the Sn exceeds the solubility limit at that temperature.

Effect of Wetting Phenomena on Solderability. Solderability is a property of electronic and other components that is crucial both to the efficiency of manufacture and the reliability of the product (Ref 6). Good component solderability is important for three basic reasons:

- IT ALLOWS THE USE OF LESS-ACTIVE FLUXES, THEREBY REDUCING THE REQUIREMENT FOR CLEANING FLUX RESIDUES. (THIS IS AN ENVIRONMENTAL BENEFIT. IN ADDITION, THE REMOVAL OF FLUX RESIDUE ELIMINATES POTENTIAL CORROSION PROBLEMS THAT ARE DUE TO THAT RESIDUE.)
- IT PRODUCES GREATER "FIRST-PASS" SOLDERING YIELDS AND, CONSEQUENTLY, LESS HAND WORKING OF THE SOLDER JOINTS (IMPORTANT BECAUSE REWORKING CAN REDUCE THE FATIGUE PERFORMANCE OF A JOINT, COMPARED WITH A SUCCESSFUL FIRST-PASS JOINT).
- IT RESULTS IN A GREATER UNIFORMITY OF SOLDER FILLET, WITH A GEOMETRY THAT IS CLOSE TO THE IDEAL FOR MAXIMUM FATIGUE PERFORMANCE.

Solderability depends on the wettability of the two surfaces being joined. Poor component solderability can, to some extent, be overcome by using more-active fluxes, but the trend toward denser component packing makes it difficult to remove flux residue after assembly. Therefore, less-active fluxes are preferred. Environmental concerns (such as those about the use of chlorofluorinated carbon solvents) are also becoming important. The cost of inspection, testing, and component replacement or solder fillet rework increases the desirability of defect-free soldering. Therefore, solderability is an increasingly important manufacturing issue.

The solderability of a component, defined as its suitability to be soldered by a given method, is a complex processing parameter. The relationship between wettability and solderability represents a major unresolved gap in the understanding of the soldering process. As described in the section "Physics of Wetting," wettability can be measured directly. Solderability, however, cannot be directly measured in a quantifiable way, and its relationship to wettability has not yet been explicitly defined.

There are three important aspects to solderability:

- THERMAL DEMAND
- WETTABILITY
- RESISTANCE TO SOLDERING HEAT

The thermal characteristics of the component must allow the joint to be heated to the soldering temperature within the specified time. The solderable surfaces must allow the molten solder to wet and spread during the available time without subsequent dewetting. The soldering heat and the induced thermal stresses associated with it must not affect the functioning of the components. Each of these solderability aspects can be engineered to fit a particular application by the suitable choice of solder alloys and process control parameters. The most restraining of the solderability aspects, in regard to design for performance, is component wettability.

Wettability. When discussing the wetting characteristics of a surface by molten solder, there are two important factors to consider: the extent of wetting and the rate of wetting (Ref 6). The extent of wetting (as indicated by the contact angle) is an equilibrium governed by the laws of thermodynamics and depends on the surface and interfacial energies involved at the liquid/solid interface (Fig. 5). The rate of wetting (that is, how rapidly the solder wets and spreads) is governed by the thermal demand of the system, the ability of the heat source to supply heat, the efficacy of the flux, the viscosity of the solder, and the chemical reactions that occur at the interfaces.

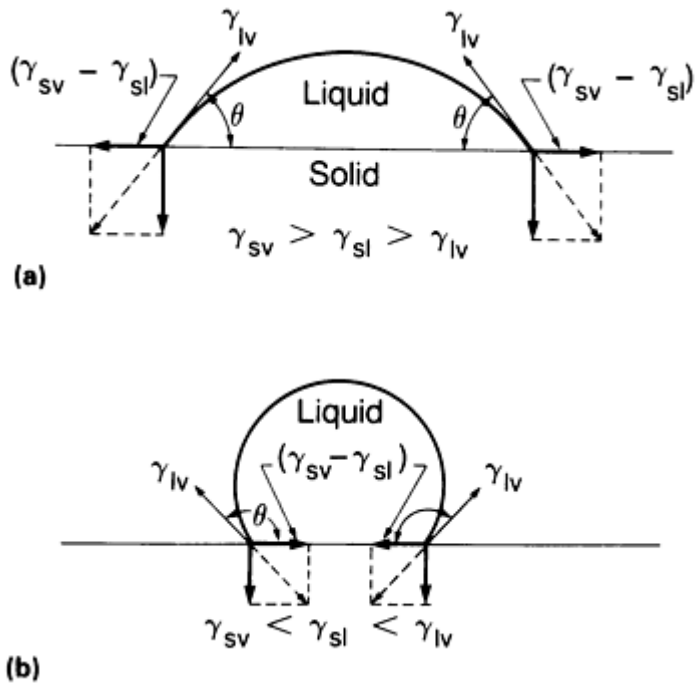

FIG. 5 LIQUID SOLDER DROPLETS ON A SOLID SURFACE UNDER TWO CONDITIONS. (A) WETTING. (B) NONWETTING. ARROWS INDICATE SURFACE TENSION.

The physics of wetting is the governed by Young's equation (also known as Young-Depre equation because Young described the problem quantitatively in 1805 and Depre put it in mathematical terms in 1869):

$$\gamma_{SV} = \gamma_{SL} - \gamma_{LV} \cos \theta \qquad \textbf{(EQ 1)}$$

where γ_{sv}, γ_{sl}, and γ_{lv} refer to the solid-vapor, solid-liquid, and liquid-vapor surface tensions, respectively. Relative to each other, these parameters can be defined by:

$$\gamma_{SV} > \gamma_{SL} > \gamma_{LV} \qquad \textbf{(EQ 2)}$$

For soldering, the vapor phase will be replaced in nearly all processes by flux (that is, γ_{sv} is replaced by γ_{sf} and γ_{lv} is replaced by γ_{lf}).

For optimum wetting, the contact angle, θ, must be minimized and, therefore, γ_{sv} must be maximized. Oxides and contamination lower the value of γ_{sv} (or γ_{sf}). A function of the flux is to remove or disperse oxides and contaminants, thereby increasingly γ_{sv}. An important function of flux is to lower the value of γ_{lf} (or γ_{lv}). The flux also maintains a local environment around the surfaces being joined, protecting them from reoxidation during soldering, as well as enhancing heat transfer from the heating source to the substrate and the solder.

Equation 1 shows that wetting is also enhanced by minimizing γ_{lv}, a value commonly referred to as the surface tension of the solder. Although γ_{lv} is a function of the solder composition, the flux covering the liquid solder, and the temperature, it is normally close to 0.4 J/m^2 (4×10^{-5} Btu/ft^2).

A typical example of nonwetting occurs when a liquid metal droplet is placed on a nonmetallic surface, such as copper oxide. Because there are no metallic bonds at the oxide surface, the liquid metal will have little tendency to interact with that surface. The metal droplet will behave as though it is repelled, and will try to ball up to minimize the area of contact with the nonmetallic surface. One method for quantifying wettability is to observe the behavior of solder droplets on the metal surface. The contact angle formed between the surface of the liquid solder and the surface of the solid can be

measured (Fig. 5). If the solder droplet forms an angle, θ, of less than 90°, then the solder is said to wet the metal. If the angle is greater than 90°, the solder is nonwetting. This is one method used to qualitatively assess solderability.

The formation of intermetallic compounds can affect Young's equation because it alters the value of γ_{sl}. The influence of this term has been recognized (Ref 6), but the magnitude has not yet been calculated quantitatively.

Surfaces of a metal crystal have a higher free energy than the bulk of the crystal because of the existence of unsatisfied metallic bonds. When a liquid metal or alloy is brought into contact with this solid surface, the liquid will proceed to interact with the solid to satisfy those dangling surface bonds and thus reduce the surface free energy of the system. To the extent that a liquid solder can satisfy these surface bonds, it will wet the solid metal and spread across its surface. If no exchange of bonding energy takes place, then wetting will not occur and the solder will tend to ball up on the surface of the solid, minimizing the area of contact between liquid and solid.

Information about selecting solders for specific applications is provided in the article "General Soldering" in this Volume.

Guidelines for Flux Selection

A flux promotes solder wetting of the base materials by:

- REMOVING TARNISH FILMS FROM PRECLEANED SURFACES
- PREVENTING OXIDATION DURING THE SOLDERING OPERATION
- LOWERING THE SURFACE TENSION OF THE SOLDER

Successful establishment of a solder joint requires that the liquid solder make contact with the metal to which it is to be joined, so that wetting can be initiated. Unfortunately, almost all of the metals involved in soldering are oxidized during exposure to elevated temperatures in air. This prevents metal-to-metal contact, as well as the wetting and formation of a metallurgical bond, unless the oxides are removed. Fluxes are used in soldering to remove such films and to protect the surfaces against reoxidation during soldering.

In addition to cleaning metal surfaces, a flux also:

- AIDS IN THE WETTING PROCESS
- IMPROVES HEAT TRANSFER (ESPECIALLY IN SOLDER PASTES)
- CARRIES OXIDES AND SOLID DEBRIS AWAY FROM THE JOINT

Fluxes are chemical (liquid, solid, or gaseous materials) that remove oxide layers from the base metal and solder. When heated, fluxes either promote or accelerate the wetting of metals by solder. Flux selection usually depends on the ease with which a material can be soldered. Rosin fluxes are used with solderable base metals or with metals that are precoated

with a solderable base metal or with metals that are precoated with a solderable finish. Inorganic fluxes are often used on metals such as stainless steel. Table 1 indicates the relative ease with which a number of alloys and metals can be soldered, based on flux requirements.

Types of Fluxes

Fluxes can be categorized by their chemical makeup (Ref 2, 3, 9, 10, 11):

- ROSIN-BASE FLUXES
- ORGANIC FLUXES
- INORGANIC FLUXES
- SYNTHETICALLY ACTIVATED FLUXES (RESINS)

These materials vary in their activity (that is, aggressiveness). Rosin-base fluxes are very mild, whereas inorganic fluxes can be extremely active and corrosive. Because of the potential for corrosion by inorganic fluxes in electronic assemblies, the rosin-base fluxes (with their low flux activity) are favored by the electronics industry.

Rosin Fluxes. Water-white rosin dissolved in a suitable organic solvent is the closest model of a flux with noncorrosive residue. Rosin fluxes possess important physical and chemical properties that make them particularly suitable for use in the electrical industry. They are solid and inactive chemically at room temperature, but at soldering temperatures they gain sufficient activity to remove weakly adherent oxides from the noble metals gold and silver, as well as copper.

Nonactivated Rosin Flux. Although its noncorrosive nature has led to its widespread use in microelectronics, rosin-base flux is lacking in chemical activity, which essentially limits its use to precleaned parts and to only a few metals that do not have adherent oxides. The active constituent, abietic acid ($C_{20}H_{30}O_2$), with a melting point of 173 °C (343 °F), becomes mildly active at soldering temperatures ranging from 177 to 316 °C (350 to 601 °F). The residue is hard, nonhygroscopic, electrically nonconductive, and noncorrosive.

Mildly Activated Rosin Flux. The very low chemical activity of rosin-base flux can be countered by the addition of activators, usually organic acids or amines. The end product, rosin mildly activated (RMA) flux, is still essentially noncorrosive, but is sufficiently active to remove oxides more reliably than the rosin-base flux. In addition, the residues are noncorrosive. However, care must be exercised in cases of high-reliability applications. It is advisable to specify that these fluxes be halide-free, in order to ensure that specific safety requirements are met in critical components. Even so, cleaning is now required to remove the flux residue. Both polar and nonpolar solvents have been used. These RMA fluxes are preferred for military, telephone, and other high-reliability electronic products.

Activated rosin fluxes were developed to provide more chemically active fluxes for mass-produced electronics, such as packaged components. Most mass-produced electronics are manufactured using RMA fluxes. The use of chlorides in these fluxes requires effective cleaning after soldering to prevent corrosion and electrical leakage, because the presence of chloride ions in flux residue makes it conductive. Because of the chemistry of the activators, a double solvent cleaning is normally required. Activated rosin fluxes are widely used in commercial electronics and in high-reliability applications where the residue can be completely removed after soldering.

Inorganic Fluxes. Inorganic acids and salts that are highly corrosive and extremely active compose this class of fluxes. In many instances, they are not acceptable for use on electronics, but are suitable for plumbing and industrial applications. Inorganic fluxes do enable the soldering of ferrous alloys and high-nickel alloys used in electronic packages and hermetic enclosures. The difficulty of chloride ion removal has led to the gradual abandonment of inorganic fluxes, even for tinning purposes.

Inorganic fluxes are used to optimum advantage where conditions require rapid and highly active fluxing action. They can be applied as solutions, pastes, or dry salts in many general soldering applications. They function equally well with torch, oven, resistance, or induction soldering methods, because they neither char nor burn. These fluxes can be formulated to provide stability over the entire soldering temperature range.

One distinct disadvantage of inorganic fluxes is that their residue remains chemically active after soldering. If this residue is not removed, then severe corrosion can occur at the joint. Adjoining areas can also be attacked by residues from the spray of flux and from flux vapors. Fluxes that contain ammonium salts can cause stress-corrosion cracking (SCC) when soldering brass, as well as most iron-nickel alloys.

Organic acid fluxes, although less active than inorganic fluxes, are effective at soldering temperatures ranging from 90 to 320 °C (195 to 610 °F). They consist of organic acids and bases and, often, hydrohalides. They are active at soldering temperatures, but the period of activity is short because of their susceptibility to thermal decomposition. Their tendency to volatilize, char, or burn when heated limits their use with torch or flame heating. When these fluxes are properly used, their residues are relatively inert and can be removed with water.

Organic acid fluxes are particularly useful in applications where controlled quantities of flux can be applied and where sufficient heat can be used to fully decompose or volatilize the corrosive constituents. Caution is necessary to prevent undecomposed flux from spreading to insulating sleeving. Care must also be taken when soldering in closed systems where corrosive fumes can condense on critical parts of the assembly.

Flux Evaluation

Several tests are used to evaluate the relative activity of fluxes. The most common are the copper mirror test, the halide test, a surface conductivity test, and a test based on the resistivity of a water extract present in the flux. In all cases, a measure of the chemical activity of the flux is obtained.

Because the fluxes all depend on other properties (for example, viscosity, ease of removal, and thermal behavior), chemical activity is only one factor in flux selection for a given application. Information about selecting fluxes for specific applications is provided in the article "General Soldering" in this Volume.

Fundamentals of Soldering

Mel M. Schwartz, Sikorsky Aircraft

Joint Design

Joints should be designed to fulfill the requirements of the finished assembly, as well as to permit the application of the flux and solder. Joint design should maintain proper clearance during heating and upon solidification of the filler metal. Special fixtures may be necessary or the units can be crimped, clinched, wrapped, or otherwise held together.

The selection of a joint design for a specific application will primarily depend on the service requirements of the assembly. It may also depend on such factors as the heating method to be used, the fabrication techniques utilized prior to soldering, the number of items to be soldered, and the method used to apply the solder. In general, solders have low

strength when compared with the metals for which they are used to join. Therefore, the soldered joint should be designed to avoid dependence on solder strength. The necessary strength can be provided by shaping the parts to be joined so that they engage or interlock, requiring the solder only to bond, seal, and stiffen the assembly.

Figure 6 shows joint designs commonly used for soldering applications. The lap joint and the lock seam joint are used when soldering sheets. Lap joints are also applied to join pipes. Actually, the lap type of joint should be used whenever possible because it offers the best chance to obtain joints with maximum strength. It should also be used whenever a seal is required. Butt joints should be avoided whenever possible.

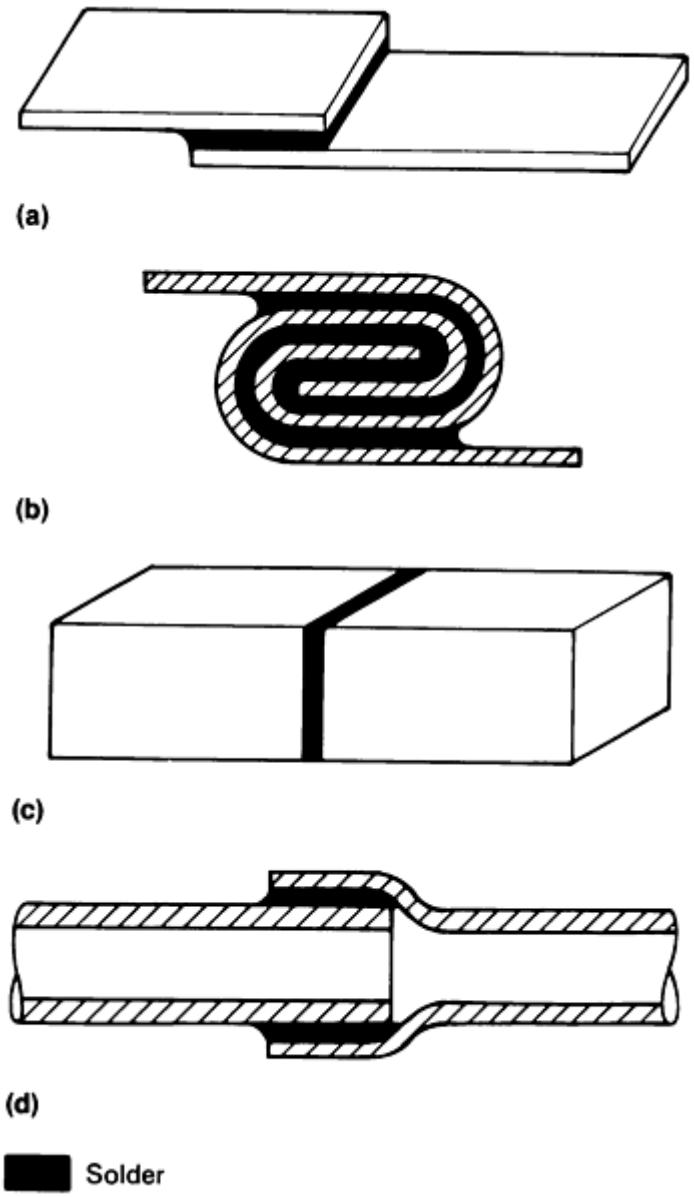

FIG. 6 BASIC JOINT CONFIGURATIONS USED FOR SOLDERING APPLICATIONS. (A) LAP JOINT. (B) LOCK SEAM JOINT. (C) BUTT JOINT. (D) PIPE JOINT

An important factor in joint design is the manner in which the solder will be applied to the joint. The designer must consider the number of joints per assembly and the number of assemblies to be manufactured. For limited production using a manual soldering process, the solder can be face-fed into the joint with few problems. However, for a large production lot of assemblies containing multiple joints, an automated process such as condensation/vapor-phase reflow soldering can be advantageous (Ref 12, 13, 14). In this case, the design must provide for accessible joints that are suitable for automated fluxing, soldering, and cleaning.

There should be enough clearance between the parts being joined to allow the solder to be drawn into the space by capillary action, but not so much that the solder is unable to fill the gap. Joint clearances ranging from 0.075 to 0.150 mm (0.0030 to 0.059 in.) are preferred for optimum strength, but variations are allowed in specific cases. It is often necessary to fabricate sample parts and to test the joints to ensure their producibility and capability regarding strength properties (Ref 2, 3, 10, 15, 16, 17).

Other commonly used soldered joints are shown in Fig. 7; self-jigging joints are shown in Fig. 8. The most definitive work available on the loading of soldered joints is that used for the load-carrying capabilities of copper tube with sleeve-type joints or fittings. Conservative joint design requires that only 50% of the joint be considered filled. Under normal conditions, it would be considered good soldering practice if 70% or more of the joint consists of sound joint material (Ref 2, 3, 4, 5, 6, 11, 15, 18). Additional information about joint configurations is provided in the article "General Soldering" in this Volume.

Fundamentals of Soldering

Mel M. Schwartz, Sikorsky Aircraft

Precleaning and Surface Preparation

An unclean surface will not permit the solder to flow, which makes soldering either difficult or impossible and contributes to the formation of a poor joint. Materials such as oil, grease, paint, pencil markings, drawing, and cutting lubricants, general atmospheric dirt, oxide, and rust films must be removed before soldering. The importance of cleanliness cannot be overemphasized in ensuring sound soldered joints. Fluxing alone cannot substitute for adequate precleaning (Ref 19). Because cleaning methods are often designed for a specific soldering operation, their suitability for a particular application should be investigated thoroughly.

Degreasing. Either solvent or alkaline degreasing is recommended for the cleaning of oily or greasy surfaces. Of the solvent degreasing methods, the vapor condensation of the trichloroethylene-type solvents probably minimizes residual film on the surface. In the absence of vapor degreasing apparatus, immersion in liquid solvents or in detergent solutions is a suitable procedure. Hot alkali detergents are widely used for degreasing. All cleaning solutions must be thoroughly removed before soldering. Residues from hard-water rinses can interfere with soldering. Material compatibility is a prime consideration.

Pickling. The purpose of pickling, or acid cleaning, is to remove rust, scale and oxides, or sulfides from the metal in order to provide a clean surface for soldering. All of the inorganic acids (that is, hydrochloric, sulfuric, phosphoric, nitric, and hydrofluoric acids), singly or mixed, will fulfill this function, although hydrochloric and sulfuric acids are the most widely used. The pieces should be washed thoroughly in hot water after pickling and then dried as quickly as possible.

Mechanical cleaning includes the following methods:

- GRIT AND SHOTBLASTING
- MECHANICAL SANDING AND GRINDING
- FILING AND HAND SANDING
- CLEANING WITH STEEL WOOL
- WIRE BRUSHING AND SCRAPING

For best results, cleaning should extend beyond the joint area. Shot or steel gritblasting is often effective and is preferable to sandblasting because it avoids the embedding of silica particles on the surface, which interferes with the flow of solder. Mechanical cleaning is not recommended for softer metals, such as copper.

Precoating. The coating of the base metal surfaces with a more-solderable metal or alloy prior to the soldering operation can facilitate soldering. Coatings of tin, copper, silver, cadmium, iron, nickel, and the alloys of tin-lead, tin-zinc, tin-copper, and tin-nickel are used for this purpose. The advantages of precoating include the following:

- SOLDERING IS MORE RAPID AND UNIFORM.
- STRONG ACIDIC FLUXES CAN BE AVOIDED DURING SOLDERING.

The precoating of metals that have tenacious oxide films (for example, aluminum, aluminum bronzes, highly alloyed steels, and cast iron) is almost mandatory. The precoating of steel, brass, and copper, although not entirely essential, is of great value in some applications.

A number of different methods are used to precoat the metal surfaces. Solder or tin can be applied using a soldering iron or an abrasive wheel, ultrasonic soldering, immersion in molten metal, electrodeposition, or chemical displacement.

Hot dipping can be accomplished by fluxing and dipping the parts in molten tin or solder. Often, small parts are initially placed in wire baskets and then cleaned, fluxed, and dipped in the molten metal. Finally, they are centrifuged to remove the excess metal. Coating by hot dipping is applicable to carbon steel, alloy steel, cast iron, copper, and certain copper alloys. Prolonged immersion in molten tin or solder should be avoided to prevent the excessive formation of intermetallic compounds at the coating/base-metal interface.

Electrodeposition. Precoating by electrodeposition can be accomplished in stationary tanks, in conveyorized plating units, or in barrels. This method is applicable to all steels, copper alloys, and nickel alloys. The coating metals are not limited to tin and solder. Copper, cadmium, silver, precious metals, nickel, iron, and alloy platings such as tin-copper, tin-zinc, and tin-nickel are also commonly used.

Certain combinations of electrodeposited metals (that is, duplex coatings), where one metal is plated over another, are becoming more popular as an aid to soldering. A coating of 0.005 mm (0.0002 in.) of copper plus 0.0075 mm (0.0003 in.) of tin is particularly useful for brass. The solderability of aluminum is enhanced by a coating of 0.013 mm (0.0005 in.) of nickel, followed by 0.008 mm (0.0003 in.) of tin or by a combination of zincate (zinc), 0.005 mm (0.0002 in.) copper, and tin. An iron plating followed by tin plating is extremely useful over a cast iron surface.

Immersion coatings (that is, chemical displacement coatings) of tin, silver, or nickel can be applied to some of the common base metals. These coatings are usually very thin and generally have a poor shelf life.

The shelf life of a coating is defined as its ability to withstand storage conditions without impairing solderability. Hot tinned and brightened electrotin coatings have an excellent shelf life. Inadequate thicknesses of electrotinned or immersion-tinned coatings have a limited shelf life. Tin or solder coating thicknesses ranging from 0.003 to 0.008 (0.0001 to 0.0003 in.) are recommended to ensure maximum solderability after prolonged storage.

Soldering in Electronic Applications

This section addresses some general considerations in the soldering of electronic devices. More detailed information is provided in the article "Soldering in Electronic Applications," in this Volume.

Substrates for Electronic Component Applications

A substrate is the platform on which the electrical/electronic circuitry is built. Many different types of substrates are used in the electronics field. Early substrates were sheets of material to which insulated, stand-off terminals were attached by bolting or riveting. The circuitry was then obtained by point-to-point wiring between these terminals. Although this approach is still used, the most common substrate in use today has circuitry that is laid on it in planar form, with the components already attached. Attachment is normally accomplished through the soldering process. The most common form of this substrate is the printed wiring board (PWB).

A substrate can actually have numerous forms:

- CIRCUITRY CAN BE LAID ON ONE SIDE OF THE SUBSTRATE OR ON BOTH SIDES.
- CIRCUITRY CAN BE NOT ONLY ON THE OUTER SURFACES OF THE SUBSTRATE, BUT IN LAYERS WITHIN THE SUBSTRATE MATERIAL (MULTILAYERING).
- THE SUBSTRATE CAN BE RIGID OR FLEXIBLE.

There are many methods of applying the conductive patterns that make up the circuitry and each has its own specific soldering solutions.

Many different materials are used for substrates. Substrates used for electrical/electronic applications must be insulators to allow the conductive circuitry to function in the manner of a network made from separate insulated wires. Common substrate materials for this application include ceramics and organic laminates. Metals can also be used as substrates if they are coated with a substantial insulating material that can withstand the rigors of assembly.

Ceramic Substrates. Many types of ceramics can be used as substrates, but the most common is a high-fired alumina that is either 96 or 99% Al_2O_3. The 96% Al_2O_3 material is usually employed when thick-film materials are placed on the surface to form the circuitry. The 99% Al_2O_3 material is most often used for the evaporation or sputtering of thin materials. The materials that are laid down for terminal and component bonding pads are usually gold (or alloys high in gold), silver, and copper. Because these metals are laid down in thin layers, a soldering problem called leaching occurs. Leaching is the migration of the components of a substrate into a working solution. The process must be controlled because soldering results in bonding between the solder and the metals being attached. If the soldering process is not controlled, it can literally dissolve the metallization from the surface of the substrate. A gold-platinum alloy is more resistant to leaching than pure gold.

Thin-film (10 to 500 nm, or 100 to 5000 Å) deposits are more susceptible to leaching than are thick-film (10 to 25 μm, or 400 to 1000 μin.) deposits, because the thin layer is more susceptible to being consumed by the leaching. Therefore, the time at temperature and the maximum temperature become very important. In leaching, temperature is more important than time. Significantly, more leaching will be generated by a small increase in temperature than would be produced with even a moderate increase in time.

Composite Laminates. The most popular composites are the copper-clad laminates used for PWB substrates. The metal cladding is usually copper, but could be nickel or some other metal. Copper cladding can be either a plated material or wrought rolled foil. From a soldering standpoint, the rolled material is preferable, but it is more costly and more difficult to bond to the laminate material. Many PWBs are passed through numerous heat cycles during the manufacturing process. In addition, the use of multilayer designs is increasing dramatically. Plated foil, contaminated with codeposited organics,

can become brittle at elevated temperatures. Hence, foil coppers are available in several classes, depending on their application.

Printed Wiring Laminate Materials. The laminate upon which the metal cladding is applied is available in many composite forms. Originally, layers of paper or cloth impregnated with a phenolic resin and designated XP, XXP, or XXXP were used. The latter became the standard in the mid-1950s.

The selection of organic-based laminate materials as electronic substrates has certain limitations, the most common of which is temperature. In addition, soldering must not degrade the material by burning or charring. Laminate selection should depend on the application of the electronic hardware. A glass-epoxy laminate material known as FR-4 is commonly used in consumer and industrial electronics. The "FR" designation indicates that the material is fire resistant.

Metal Substrates. There are some applications in which metals can be used as base substrates. Because the presence of an insulating material is required, the metal must be coated with a suitable material (for example, porcelain enamel).

Solder Application

Because of the small distances between components, when soldering electronics, it is often necessary to measure carefully the amount of solder that must be applied to form a satisfactory joint. It is not only a matter of providing a sufficient amount of solder for a good fillet, but it is also important to not have excess solder in the joint. This can sometimes be accomplished by plating the area to be soldered to a predetermined solder thickness, so that the solder forms a good fillet when it is reflowed. This is often the method used to accomplish "flip-chip" bonding to produce tape automated bonding (TAB) assemblies (Ref 20).

Solder can also be apportioned in proper amounts to individual joints by using preforms. In the case of surface-mount technology (SMT), the solder is often screened onto the substrate in the form of solder paste or it is dispersed in small quantities in precise locations by using tiny nozzles or tubes.

Preforms. When a square or round lid is attached to a device, but solder is not desired in the enclosed area, the solder application is often accomplished by using squares or annular rings that are punched from solder sheet. The solder quantity is usually sufficient to fill the asperities in the surfaces. The thickness and the lateral dimensions are determined by the location and the amount of solder needed to make a satisfactory joint. The solder preform is placed in the space between the parts to be joined, and then this assembly is subjected to sufficient heat to fuse the solder and hermetically seal the assembly. The entire body is then cooled. If the parts were clean and the proper amount of solder was supplied, a good solder joint results.

Heat for soldering can be applied in a number of different ways. In automated processing, the parts to be soldered are often passed through the hot zone of a furnace on a belt. This makes it possible to provide adequate preheating of the parts, the proper maximum temperature, and a gentle cooling cycle to minimize stresses. This method is fast and allows easy control of the measured amounts of solder to precise locations in a variety of geometric shapes. However, the cost of the preforms is a drawback.

Solder Pastes. The rapid development of SMT processing, which can involve very dense populations of devices and leads, necessitated a method to precisely place controlled amounts of solder on a substrate, either for lead attachment or for bonding of the device to attain more-effective heat transfer. Solder pastes that are applied by screening or printing through a mask or by application through a fine tube can fulfill these needs.

The screening method, although ancient, has been modernized by the development of new high-precision screens, solder pastes, and equipment for screening and curing the screened materials.

Solder paste also can be applied through a metal mask, or stencil. Although the location of the solder is not as precise as that obtained with screening, the metal masks are more durable and provide better control of solder thickness as it is applied.

Another paste placement method is to use fine tubes or nozzles to deliver the paste to precise locations. This method is ideal for placing discrete dots of paste, rather than covering large areas.

Paste Composition. A solder paste must contain solder particles of the desired composition to yield the melting and joining requirements of the application. The metal particles must be sized to provide good screenability and to avoid excessive oxide content. The shape of the particles is important. Spherical particles are lower in oxide content because there is less surface area and they are able to flow more freely in screening applications.

A paste must also contain a vehicle to control its rheological, or flow, properties; its drying behavior; its surface activity (wetting behavior); and the solubility of the residues left after reflow. The vehicle usually consists of a rosin (pine derivative) or a synthetic resin, solvents to adjust drying time and temperature, modifiers to control rheological behavior, and an activator, or flux, to remove oxides from the solder and to protect the liquefied solder from oxidation.

Paste Properties. The paste must set and hold its shape and location after screening so that subsequent processing maintains the solder in the desired locations and amounts. The assembly is then subjected to heat and the solder is melted and joined to the part being soldered. This reflow can be conducted either as the final step in soldering or as a separate step. The parts must generally be cleaned after soldering.

Solder resists enable control over the PWB areas that will be wet by the solder. The resist, or mask, is an organic coating placed selectively on the board. Only the uncoated areas are exposed to and are wettable by the solder. The higher interconnect densities now being attained by SMT processing make solder resists a valuable method.

Solder resists can be either permanent or temporary, depending on the application. The permanent resists must resist not only the solder, but any fluxes or solvents applied later in the manufacturing sequence. Compatibility with the process and the circuit materials is a consideration, as is the ability to withstand soldering temperatures. In addition, the solder resist offers the circuits some protection against dirt and contamination. Commonly used resist materials are polystyrene, epoxides, and acrylics, although more-costly materials, such as polyimides, are sometimes used because of their greater thermal resistance.

Screened Materials. Solder masks are commonly applied by screening. The films are subsequently dried and cured thermally. The elevated temperatures involved in the curing cycle can cause oxidation of the conductors on the PWB, resulting in a loss of solderability. Lower curing temperatures are desirable. Some of the resists are cured by exposure to ultraviolet light, rather than by heating. This approach is very fast, involves less emission of volatile pollutants, and does not cause oxidation of the metal surfaces.

Photographic Films. A second method of applying solder resists is to use sheets of photosensitive material laminated to the surface of the circuit. Although these are more expensive than screened materials, the photographic films enable much higher pattern resolution. Dry film resists are much stronger and more resistant to damage during soldering and cleaning operations. The use of these photosensitive materials increases the complexity of the process.

Temporary solder masks are often used as production aids, offering local protection from solder at locations such as:

- CONTACT PADS THAT HAVE BEEN GOLD PLATED
- PLATED-THROUGH HOLES THAT MUST BE SOLDERED IN A LATER OPERATION
- PADS THAT MUST BE KEPT FREE OF SOLDER

Adhesive solder-mask tapes that specifically protect edge connectors on PWBs are also available, and numerous mechanical approaches to limiting solder contact exists (Ref 18).

Soldering Process Parameters

The parameters that affect wetting and spreading phenomena include:

- TEMPERATURE
- TIME
- VAPOR PRESSURE
- METALLURGICAL AND CHEMICAL NATURE OF THE SURFACES
- GEOMETRY OF THE SOLID

The manipulation of each parameter can result in some control of the wetting and soldering processes.

Temperature is important to wetting and spreading for several reasons. Higher temperatures result in greater atomic activity and provide some of the energy needed to overcome surface barriers. Higher temperatures also increase reaction rates exponentially. Temperature determines phase relationships for a given alloy composition, whether for the formation of a solid solution or for that of an intermetallic compound. The fluidity of the liquid solder is also increased with increasing temperature. In addition, higher temperatures promote the formation of oxides, which can be troublesome when soldering.

Time. Wetting is time dependent because of the rate of kinetics of the solder-substrate interaction, the flux action, and the heat conduction of the substrate. The soldering process is time sensitive, because time is needed to provide sufficient opportunity for the solder to wet, penetrate, or "wick up" into the various areas of the substrate that must be incorporated into the solder joint. It is clear that measures of the time to initiate wetting and of the time it takes for spreading to occur are needed.

Vapor pressure is considered to be negligible for lead-tin solders, but it can be a significant factor when working with certain solders. Caution must be exercised when selecting and working with alloys that have appreciable vapor pressures.

The chemical and metallurgical nature of a surface affects wetting and spreading in several ways. Alloy content, as well as the fluidity of the liquid, both affect wetting and, thus, the rate of spreading. Grain boundaries are wet differently than the bulk of the metal. The formation of solid solutions or intermetallic compounds also can have a considerable effect on wetting and spreading.

The presence of oxide skins will prevent wetting and spreading, because the solder generally will not wet oxides. Likewise, films or particles of organic matter will interfere with wetting. Oils and silicones are frequent offenders and usually require different types of cleaning materials for their removal than the types used for oxides.

Surface Geometry. Because contact angle is a critical measure of wetting and spreading behavior, surface geometry is an important factor in the control of spreading. Soldering artisans have long used a wire brush not only to clean the surface to be soldered, but also to aid the spreading of the solder by providing sharp grooves that act as small capillaries to assist wetting. Isotropic spreading is actually what is needed.

Another condition of surface interaction that is sometimes encountered in soldering is dewetting, where a metal surface is initially wet by solder, but as the solder cools, its cohesive forces exceed the forces involved in wetting, and the solder balls up on the metal surface. This usually results from surface contamination of the metal or from the entrapment of foreign particles in the metal surface, leading to weak wetting or, possibly, only local wetting.

Base-Metal Selection. A sound soldered joint is achieved by selecting and using the proper materials and processes. Base metals are usually selected to achieve the specific property requirements of a component. These properties can include strength, ductility, electrical conductivity, weight, corrosion resistance, and others. When soldering is required, the solderability of the base materials should also be a selection factor. Both flux selection and surface preparation will be affected by the solderability of the base materials to be joined.

The solderability of metals and alloys is not simply a matter of chemical nobility, as might be supposed when regarding the good solderability of the noble metals, which do not readily form oxide or tarnish films. Although cadmium and tin both form oxides readily, they are considered easy to solder. On the other hand, chromium, nickel, and aluminum also form oxide films readily, but are difficult to solder. The difference is in the extremely adherent, protective nature of the oxides formed on chromium, nickel, and aluminum, compared with the oxides that form on tin and cadmium (Table 2).

TABLE 2 RELATIVE SOLDERABILITY OF SELECTED METALS AND ALLOYS

EASY TO SOLDER • PLATINUM • GOLD • COPPER • SILVER • CADMIUM PLATE • TIN • SOLDER PLATE
LESS EASY TO SOLDER • LEAD • NICKEL PLATE • BRASS • BRONZE • RHODIUM • BERYLLIUM COPPER
DIFFICULT TO SOLDER • GLAVANIZED IRON • TIN-NICKEL • NICKEL-IRON • MILD STEEL
VERY DIFFICULT TO SOLDER • CHROMIUM • NICKEL-CHROMIUM • NICKEL-COPPER • STAINLESS STEEL
MOST DIFFICULT TO SOLDER • ALUMINUM • ALUMINUM BRONZE
NOT SOLDERABLE • BERYLLIUM • TITANIUM

It should be noted that chromium, nickel, and aluminum are all soldered regularly with good results, but that special attention must be given to the selection of fluxes, which must be very active. In many cases, the use of active fluxes is either restricted or not allowed. Therefore, these hard-to-solder metals and alloys always require special consideration in order to provide reproducible soldering.

Numerous tests and methods to measure solderability are available. The tendencies of solder to either wet or spread on a given material are critical when evaluating candidate soldering systems. When hand soldering on single, large-dimension bodies prevailed, the skilled artisan could adjust parameters while watching the results develop. In most cases, visual determinations of wetting and spreading characteristics provided a sufficient basis for process control.

Today, operating parameters must be controlled very carefully, because the soldering of components and/or electronic assemblies can involve many joints that are soldered at one time, or joints that are often hidden, or dimensions that are extremely small, or situations where joint-to-joint accommodations cannot be made. This necessitates the use of automatic soldering systems. Moreover, conditions must be uniform over the whole structure being soldered. In this environment, it is essential that the processes be based on measurements of wetting and spreading behavior, so that the controlling parameters can be accurately set.

Fundamentals of Soldering

Mel M. Schwartz, Sikorsky Aircraft

Soldering Equipment

The proper application of heat is of paramount importance in any soldering operation. The solder should melt while the surface is heated to permit the molten solder to wet and flow over the surface. The best heating method is therefore another important consideration.

Soldering Irons. The traditional soldering tool is the soldering iron, or bit, with a copper tip than can be heated electrically, by direct flame, or in an oven. Because soldering is a heat-transfer process, the maximum surface area of the heated tip should contact the base metal. The solder itself should not be melted upon the tip of the iron when a joint is being made. To lengthen the usable life of a copper tip, a coating of solder-wettable metal, such as iron with or without additional coatings, is applied to the surface of the copper. The rate of dissolution of the iron coating in molten solder is substantially less than the rate for copper. The iron coating also shows less wear, oxidation, and pitting than uncoated copper.

Soldering irons are available in a large variety of sizes and designs, ranging from a small pencil to special irons or bits that weigh 2 kg (5 lb) or more. The selection of the iron depends on the application and the quantity of heat needed at the joint. The heat recovery time of the iron should be fast enough to keep up with the job.

Regardless of the heating method, the tip performs the following functions:

- STORING AND CONDUCTING HEAT FROM THE HEAT SOURCE TO THE PARTS BEING SOLDERED
- STORING MOLTEN SOLDER
- CONVEYING MOLTEN SOLDER
- WITHDRAWING SURPLUS MOLTEN SOLDER
- BRINGING THE WORKPIECE JOINT AREA TO THE SOLDERING TEMPERATURE

The angle at which the copper tip is applied to the work is important in terms of delivering maximum heat. The flat side of the tip should be applied to the work to obtain the maximum area of contact. Flux-cored solders should not be melted on the soldering tip, because this destroys the effectiveness of the flux. The cored solder should be touched to the

soldering tip to initiate good heat transfer, and then the solder should be melted on the work parts to complete the solder joint (Ref 11).

Additional information is available in the article "Iron Soldering" in this Volume.

Torch Soldering (TS). The selection of a gas torch is controlled by the size, mass, and configuration of the assembly to be soldered. When fast soldering is necessary, a flame is frequently used. The flame temperature is controlled by the fuel mixture used. Fuel gas burned with oxygen gives the highest flame temperature possible with that gas. The highest flame temperatures are attained with acetylene. Lower temperatures are obtained with propane, butane, natural gas, and manufactured gas.

Multiple flame tips, or burners, often have shapes that are suitable to the work. They can be designed to operate on oxygen and fuel gas, compressed air and fuel gas, or Bunsen-type torches.

When adjusting tips or torches, care should be taken to avoid adjustments that result in a "sooty" flame, because the carbon deposited on the work will prevent the flow of solder (Ref 11, 15).

Detailed information is available in the article "Torch Soldering" in this Volume.

Dip soldering (DS) utilizes a molten bath of solder to supply both the heat and solder required to produce the joints (Fig. 9a). This method is useful and economical, because an entire unit comprising any number of joints can be soldered in one operation after proper cleaning and fluxing. Fixtures are required to contain the unit and maintain proper joint clearances during solder solidification. The soldering pot should be large enough so that, at a given rate of production, the units being dipped will not appreciably lower the temperature of the solder bath.

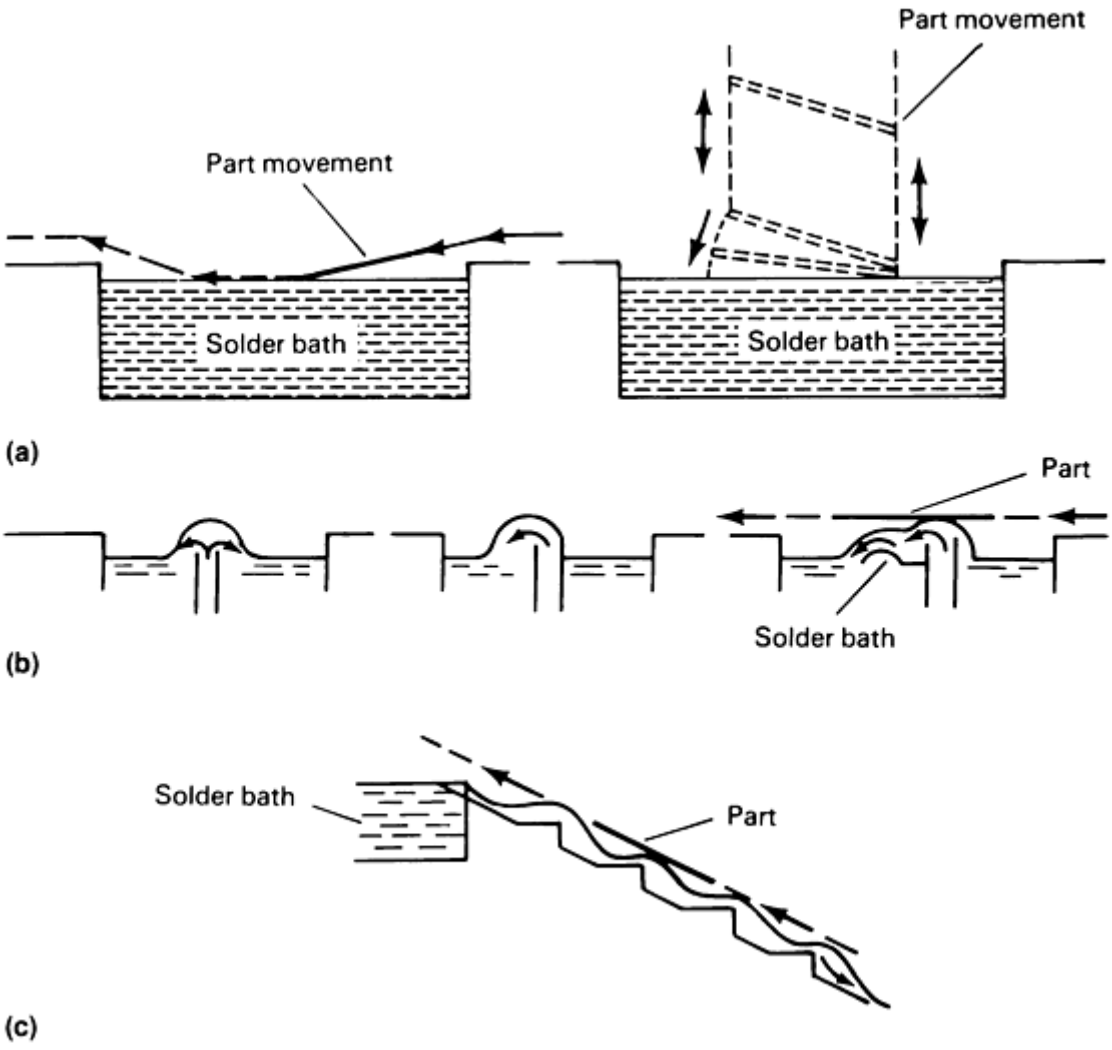

FIG. 9 SELECTED SOLDERING TECHNIQUES USED FOR HIGH-VOLUME PRODUCTION APPLICATIONS. (A) DIPPING ON A STATIC BATH. (B) WAVE SOLDERING SYSTEM. (C) CASCADE SOLDERING SYSTEM

Additional information is available in the article "Dip Soldering" in this Volume.

Wave Soldering (WS). Electronic components are commonly soldered to PWBs by wave soldering (Fig. 9b). The solder is pumped out of a narrow slot to produce a wave or series of waves. This approach, which lends itself to automatic soldering, involves a continuously pumped crest of solder that peaks at the PWB. Another method is "drag," or planar, soldering. This method uses a bath, into which the board is automatically dipped with controlled conveyorization (Ref 21, 22).

In cascade soldering (Fig. 9c), the solder flows down a trough because of gravity and is returned by pump to the upper reservoir. Both of these wave solder systems are excellent in that a virtually oxide-free solder surface is presented to the part, and the flux and vapors are dislodged by the flow of the solder.

Integrated wave soldering systems for printed wiring assemblies provide units that can apply the flux, dry and preheat the board, solder components, and clean the completed assembly. Some systems have special features that apply the flux by passing the assemblies through a wave, by spraying, by rolling, or by dipping. Several systems use oil mixed with the solder to aid in eliminating icicles and bridging between conductor paths. Another system features dual waves that flow in the opposite direction to the travel of the board.

Additional information is available in the article "Wave Soldering" in this Volume.

Induction Soldering (IS). The only requirement for a material that is to be induction soldered is that it be an electrical conductor. The rate of heating depends on the induced current flow. The distribution of heat obtained with induction heating is a function of the induced current frequency. The higher frequencies concentrate the heat at the surface of the workpiece.

Several types of equipment are available for induction heating: the vacuum tube oscillator, the resonant spark gap, the motor-generator unit, and solid-state units.

Induction heating is generally applicable for soldering operations, with the following requirements and attributes:

- LARGE-SCALE PRODUCTION
- APPLICATION OF HEAT TO A LOCALIZED AREA
- MINIMUM OXIDATION OF SURFACE ADJACENT TO THE JOINT
- GOOD APPEARANCE AND CONSISTENTLY HIGH JOINT QUALITY
- SIMPLE JOINT DESIGN THAT LENDS ITSELF TO MECHANIZATION

The induction technique requires that the parts being joined have clean surfaces and that joint clearances be maintained accurately. High-grade solders are generally required to obtain rapid spreading and good capillary flow. Preforms often afford the best means of supplying the correct amount of solder and flux to the joint.

When induction soldering dissimilar metals (particularly joints composed of both magnetic and nonmagnetic components), attention must be given to the design of the induction coil in order to bring both parts to approximately the same temperature.

Additional information is available in the article "Induction Soldering" in this Volume.

Furnace Soldering. There are many applications, especially in high-production soldering, where a furnace will produce consistent and satisfactory soldering. Although this method is not widely used, furnace heating should be considered under the following circumstances:

- WHEN ENTIRE ASSEMBLIES CAN BE BROUGHT TO THE SOLDERING TEMPERATURE WITHOUT DAMAGE TO ANY OF THE COMPONENTS
- WHEN PRODUCTION IS SUFFICIENTLY LARGE TO ALLOW EXPENDITURES FOR JIGS AND FIXTURES TO HOLD THE PARTS DURING THE SOLDERING PROCESS
- WHEN THE ASSEMBLY IS COMPLICATED IN NATURE, MAKING OTHER HEATING METHODS IMPRACTICAL

The proper clamping fixtures are very important during furnace soldering. Movement of the joint during solder solidification can result in a poor joint.

Another important consideration in furnace soldering is flux selection. Rosin and organic fluxes are subject to decomposition when maintained at elevated temperatures for an extended period of time. When either rosin or organic flux is used, the part must be brought rapidly to the liquidus temperature of the solder. It is sometimes beneficial to dip the parts in a hot flux solution before placing them in the oven. When using rosin-base flux, it is generally necessary to use a solder with a tin content of 50% or more.

The reducing atmosphere used in the furnace does not allow joints to be made without flux, because the temperatures at which these atmospheres become reducing are far above the liquidus temperature of the solders. The use of inert atmospheres will prevent further oxidation of the parts, but flux must be used to remove the oxide that is already present.

The furnaces should be equipped with adequate temperature controls because solder flow begins at approximately 45 to 50 °C (80 to 90 °F) above the solder liquidus temperature. The optimum condition exists when the heating capacity of the furnace is sufficient to heat the parts rapidly to the liquidus temperature of the solder.

Detailed information is available in the article "Furnace and Infrared Soldering" in this Volume.

Resistance soldering (RS) involves placing the workpiece either between a ground and a movable electrode or between two movable electrodes as part of an electrical circuit. Heat is applied to the joint both by the electrical resistance of the metal being soldered and by conduction from the electrode, which is usually carbon. Production assemblies can utilize multiple electrodes, rolling electrodes, or special electrodes, depending on which setup offers the most advantageous soldering speed, localized heating, and power consumption. Resistance soldering electrode bits generally cannot be tinned, and the solder must be fed directly into the joint.

Additional information is available in the article "Resistance Soldering" in this Volume.

Infrared Soldering (IRS). Optical soldering systems that focus infrared light (radiant energy) on the joint by means of a lens are available. Lamps with power ratings that range from 45 to 1500 W (140 to 4700 Btu/h) can be used for different application requirements. The devices can be programmed through a silicon-controlled rectifier (SCR) power supply with an internal timer.

The most common sources of infrared heating for soldering applications are heated filaments. The quartz-iodine tungsten-filament lamp is widely used because it is very stable and reliable over a wide range of temperatures.

In general, infrared soldering systems are simple and inexpensive to operate. One of the most critical operating parameters is surface condition. Variations in the condition of the solder surface can be compensated for, to some extent, by adjusting the heating power. Advantages are process repeatability, ability to concentrate or focus the energy with reflectors and lenses, economy of operation, and absence of contact with the workpiece.

Detailed information is available in the article "Furnace and Infrared Soldering" in this Volume.

Ultrasonic Soldering. This process uses a transducer as the source of ultrasonic energy. The transducer is energized in a bath of molten solder, and sound waves are coupled between the transducer and the workpiece, allowing the oxides in the base metal to be disrupted so that the solder melts the base metal. Sound waves are transmitted throughout the base metal, permitting wetting to occur on surfaces that are "blind" to the source. Ultrasonic soldering is also used to apply solderable coatings on difficult-to-solder metals.

Additional Soldering Processes. In addition to the above-mentioned processes, hot-gas soldering, spray-gun soldering, and condensation soldering are also used.

Hot gas soldering utilizes a fine jet of inert gas, heated to above the liquidus of the solder. The gas acts as a heat-transfer medium and as a blanket to reduce access of air at the joint.

Additional information is available in the article "Hot Gas Soldering" in this Volume.

Spray gun soldering is a heating method used when the contour of the part to be soldered is difficult to follow with either a wiping or drop method or when the part is placed in the assembly in such a way that the solder cannot be applied after the parts are assembled.

Gas-fired or electrically heated guns are available. Each type is designed to spray molten or semimolten solder on the work from a continuously fed solid solder wire. Soldering guns use either propane mixed with oxygen or natural gas mixed with air to heat and to spray a continuously fed solid solder wire of approximately 3.2 mm (0.12 in.) diameter. About 90% of the solder wire is melted by the flame of the gun. The solder contacts the workpiece in a semiliquid form. The workpiece then supplies the balance of the heat required to melt and flow the solder. Adjustments can be made within the spray gun to control the solder spray.

Vapor-phase soldering (also known as condensation soldering) utilizes the latent heat of vaporization of a condensing saturated liquid to provide the heat required for soldering. A reservoir of saturated vapor over a boiling liquid provides a constant controlled temperature with rapid heat transfer. This method is useful for large assemblies, as well as for temperature-sensitive parts.

Detailed information is available in the article "Vapor-Phase Soldering" in this Volume.

MENISCUS RISE	NO STANDARDS TO DATE
TIMED SOLDER RISE	ANSI/IPC-S-804 (BOARDS)

Dip Test. The most useful test for assessing solderability is the dip test, because of its accuracy and simplicity. It is conducted with the additions of cams and timers so that standardized conditions are established. The dip test is a reasonable simulation of practical soldering conditions and starts with a test specimen that has been dipped in a mild flux, as is usually the case with soldering tests. The dip test involves immersing the test specimen into a clean solder bath, waiting an appropriate length of time, and then withdrawing the specimen from the bath. In most cases, the test is automated to ensure reproducibility. The results are evaluated by means of visual inspection and comparison with a set of standards. Thus, the dip test is operator sensitive, somewhat subjective, and of limited value, because it is not quantitative.

Rotary Dip Test. This test was devised to provide a better simulation of the dynamic conditions that exist in machine soldering operations. It is used to evaluate the solderability of PWBs, and involves bringing the specimen into moving contact with the molten solder for a specified period of time. This is a "go/no-go" test that requires complete wetting of the specimen surface within a set time, and is thus dependent on visual inspection of the test specimen.

Wetting Balance (Meniscograph). Another common test employs the wetting balance, which gives a numerical result. The equipment consists of a balance that records the forces exerted on a fluxed test specimen during a controlled dipping cycle in a clean solder bath. From the values obtained, it is possible to compare the rate of wetting, as well as the forces involved for various flux formulations.

The speed of wetting is an especially important factor in the wave soldering process, where automation requires a time-based response of flux and solder as the work moves through the process machine at a constant speed.

The wetting balance test cannot be used on finished, etched printed circuits or on single-sided circuits. It is often used on specimens cut from double-sided clad materials prior to etching.

Although this test gives numerical results, they are not strictly quantitative. However, the results do provide the basis for a meaningful comparison among fluxes.

Additional Tests. There are several other tests that provide practical information for special purposes, such as the spreading test and the globule test. These tests are sometimes used to evaluate incoming materials or to aid in the selection of materials. They are not universally employed.

The spreading test is used to provide a numerical rating for both fluxes and solders. It is described in detail in MIL-F-14256, "Flux, Soldering, Liquid (Rosin Base)," and in QQ-S-571, "Solder, Electronic," which are national-level specifications.

The globule test was once widely applied, but is now limited to being used to determine the wetting of component leads and wires (Ref 24).

Additional information is available in the article "Evaluation and Quality Control of Soldered Joints" in this Volume.

Future Outlook

The quality soldered joints obtained by automation have resulted in the widespread use of automated equipment throughout the electronics industry, as well as throughout the world (Ref 25).

When compared to processes such as adhesive bonding, welding, brazing, or mechanical joining, soldering offers many advantages. Automated soldering equipment for wave or planar soldering can be easily and economically installed. The high reliability that can be achieved with soldering results in a quality end product. Soldering offers the additional benefit of providing sequential assembly, a common practice in the electronics industry.

Introduction to Solid-State Welding

Ray Dixon, Los Alamos National Laboratory

Solid-State Welding

(SSW) processes are those that produce coalescence of the faying surfaces at temperatures below the melting point of the base metal being joined without the addition of brazing or solder filler metal. Pressure may or may not be applied. These processes involve either the use of deformation or of diffusion and limited deformation in order to produce high-quality joints between both similar and dissimilar materials.

Dissimilar metal joints are necessary in applications that require a variety of material properties within the same component. For example, heat exchangers often require different types of stainless steels at each end, because of temperature-induced corrosion. Under laboratory conditions, dissimilar materials can be chosen based on physical or material properties that influence the phenomenon being studied. For whatever reason, and appropriate method of producing dissimilar metal joints can usually be determined (assuming it is even possible) by examining the phase diagram. If the diagram indicates difficulty in joining the materials (intermetallics, and so on), then a solid-state (nonmelting) process may be applicable. When a nonmelting process is chosen, it is only successful if a relatively strong joint is produced.

There is considerable interest is quantifying joint strength, and extensive literature (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14) exists to help design and evaluate various specimen geometries. This experience includes not only techniques for conducting the tests, but analysis and interpretation of the data with respect to the physical properties of individual materials.

The study of dissimilar welds necessarily leads to studies of the interfacial region, because it is the most likely site of part failures. In a two-component system (materials A and B), interfacial failure can be a result of the individual properties of either A and B, but they are by necessity synergistic. These synergisms and the resulting complex interactions that they produce are what is significant. From an engineering and processing standpoint, an interfacial "cookbook" that provides

all the answers would be ideal. However, this capability is not yet available, and, as explained in this Section, researchers are still far from reaching that goal. This is the case even for simple systems, such as metal pair that form solid solutions.

The opportunities for understanding interfacial behavior come from studies conducted at the atomic level (for example, using scanning tunneling microscopy, transmission electron microscopy, first principles energy band calculations, and embedded atom potential calculations) with appropriate correlations to both micromechanics and a macroscopic level, and vice versa. The computational and experimental tools that begin to provide insight at these levels have only recently been developed.

Because the interest in interfaces is so diverse (all combinations of metals, ceramics, semiconductors, glasses, and conducting polymers), the advances in interfacial science encompass the creative efforts of a large number of people and organizations. Thus, the quantity of available literature seems overwhelming, and perhaps, disjointed. It will become apparent that there is no preferred approach to the treatment of dissimilar welds or welding. It really depends on the interests and objectives of each engineer.

For example, if you know that what you are doing actually works (that is, produces a joint) and are searching for understanding, then this Section of the Handbook will guide you to the appropriate technical literature. If you have an idea and need guidance for bonding, testing, processing, or interpreting the data, then this Section should also provide that direction. Lastly, if the reader wants state-of-the-art research and development topics, then those can be found in this Section, as well. This should provide the reader with a comprehensive overview of the welding of dissimilar metals.

Therefore, this Section is concerned with the fundamentals of welding and joining materials via the application of a nonmelting process. The specific processes usually associated with this technology are also discussed. Before considering nonmelting processes in detail, however, a brief discussion of adhesion is presented. This is followed by articles that discuss the fundamentals of the major solid-state welding techniques.

Introduction

IN ANY SOLID-STATE (NONMELTING) WELDING PROCESS, there are two primary areas of concern: Will the material bond and how strong is the bond? Literature that deals with the science and technology of material compatibility and bond strength is readily available. This article will review recent work in quantifying adhesion, bonding, and interfacial characterization and strength. Subsequent articles in this Section of the Handbook focus on the engineering principles associated with the formation of welds using these techniques. This discussion concentrates on metal-metal configurations, with only passing comments on metal-ceramic and metal/ceramic-semiconductor interfaces. This restriction is necessary to limit the length of this article. Wherever appropriate, applications of thin films on substrates will also be used.

Fundamentals of Metal and Metal-to-Ceramic Adhesion

Ray Dixon and S.P. Chen, Los Alamos National Laboratory

Adhesion Energy

Surface energy, Γ_{surf}, is defined as the increase in energy, ΔE, of a system divided by the area, A, caused by the creation of the surface:

$$\Gamma_{SURF} = \Sigma \Delta E_I / A \qquad \textbf{(EQ 1)}$$

The atoms that contribute to the extra energy, ΔE_i, are usually within 10 lattice parameters or less of the surface (or interface) (Ref 1, 2, 3). A freshly created surface has a high surface energy, whereas a relaxed or reconstructed one is lower, by about 3 to 5%. At 0 K (-459 °F), surface energies vary about 15 to 25% for planes of various indices. The variation is less at higher temperatures, because of entropy. For example, the (111) surface of a face-centered cubic (fcc) structure has the lowest energy, whereas the (210) surface is about 15% higher (Ref 1, 2, 3). The ideal fracture energy, Γ_{coh}, which is used in estimating the Griffith criterion, is twice the surface energy:

$$\Gamma_{COH}\,(HKL) = 2 \cdot \Gamma_{SURF}\,(HKL) \qquad \textbf{(EQ 2)}$$

where (hkl) are the indices of the plane. The actual energy consumed in fracture or crack propagation is composed of two terms: one is the Γ_{coh} and the other is the plastic work consumed per unit area $\Gamma_{plastic}$ (Ref 4, 5, 6, 7, 8). For ionic crystals, $\Gamma_{plastic}$ is usually a few times Γ_{coh}; for metals, Γ_{coh} is about 1 to 4 J/m^2 (2×10^{-5} to 1×10^{-4} cal/cm^2); and $\Gamma_{plastic}$ is about 1000 J/m^2 (2×10^{-2} cal/cm^2). For ceramic systems, Γ_{coh} is about the same, but $\Gamma_{plastic}$ is about 10 to 100 J/m^2 (2×10^{-4} to 2×10^{-3} cal/cm^2) (Ref 7). $\Gamma_{plastic}$ and Γ_{coh} are related, because when Γ_{coh} is zero, no plastic work ($\Gamma_{plastic}$) will be consumed. The exact form of this dependence is not known, although some attempts have been made (Ref 4, 5, 6) to correlate the two terms.

Grain Boundary Energy

The grain boundary energy, Γ_{gb}, is defined the same way as surface energy is, but it depends on the relative orientation of the adjacent grains (Ref 1):

$$\Gamma_{GB} = \Sigma \Delta E_I / A_I \text{ (GB)} \qquad \textbf{(EQ 3)}$$

At misorientation angles of greater than 25°, Γ_{gb} usually reaches a plateau that characterizes random grain boundaries. Special grain boundaries, like Σ5 (210) or (310), tend to have slightly lower energies (Ref 1, 2, 3, 9). Twin boundary energies are even lower than special grain boundaries. For metals, Γ_{gb} usually ranges from 40 to 60% of the surface energy (Ref 10), whereas the twin energy is only about 5 to 15%. Grain boundary cohesive energy is defined as (Ref 1):

$$\Gamma_{COH} \text{ (GB)} = \Gamma_{SURF} \text{ (GRAIN A)} + \Gamma_{SURF} \text{ (GRAIN B)} - \Gamma_{GB} \qquad \textbf{(EQ 4)}$$

For general and random grain boundaries, grain boundary cohesive energy is smaller. General grain boundaries tend to be weaker than the small angle boundaries.

Interfacial Energy

By definition, the interfacial energy (Ref 2, 3) between two bulk materials (A and B) is the same as the grain boundary energy, except that there are two reference states:

$$\Gamma_{INTERFACE} = [\Sigma\Delta E_I\,(A) + \Sigma\Delta E_J(B)]/A \qquad \textbf{(EQ 5)}$$

where $\Delta E_i(A) \cdot [(\Delta E_j(B)]$ is the extra energy of atom *i* of A (B) type, compared to its bulk state of A (B) materials. The interfacial energy between similar metals tends to be small. For dissimilar materials, however, interfacial energies tend toward large positive values if they do not form compounds and large negative values if they do form compounds. The ideal adhesion energy is similar to grain boundary cohesion and is the difference between the two surfaces and the interfacial energies:

$$\Gamma_{ADHESION} = \Gamma_{SURFACE}\,(A) + \Gamma_{SURFACE}\,(B) - \Gamma_{INTERFACE}\,(A/B) \qquad \textbf{(EQ 6)}$$

Ray Dixon and S.P. Chen, Los Alamos National Laboratory

Theory of Adhesion

Rose *et al.* (Ref 11) have calculated the bimaterial interfacial cohesion for many combinations of elements using band structure methods. They found a universal scaling relationship for the adhesion of different materials that extends beyond metal-metal interfaces to nonmetal systems. A few calculations are necessary to identify the adhesion behavior of the system and set the appropriate energy, length, and elastic constant scales. Plastic contributions are not treated in this formalism. The plastic work is more likely to be solved by incorporating the atomistic simulation and continuum analysis of Jokl *et al.* (Ref 4, 5) and Hack *et al.* (Ref 6).

The tight binding method give qualitative trends as the energy band is filled for calculations using the elements in the periodic table (Ref 12, 13, 14). The correct trend seems to be captured by the band-filling argument pioneered in the original work of Friedel (Ref 15). For noble metals, a rigid band picture is preferred (Ref 14). Another useful tool is the Pettifor structure map. By using the Mendelev number for each of the 103 elements (Ref 13, 16), Pettifor found that alloying tendencies can be grouped into separate regions. If the interfacial chemistry and average Mendelev number are known, then the interfacial structure can be found from the Pettifor map.

Extensive atomistic simulation work, using effective medium theory (Ref 17, 18), embedded atom potentials (Ref 19), or local volume potentials (Ref 1, 2, 3, 8, 9, 20, 21, 22, 23) had been very useful in describing the properties of many metals and compounds and their interactions with impurities such as boron and sulfur in Ni_3Al and NiAl (Ref 20, 21). These atomic interaction descriptions include pair potential and many body interactions and have been obtained for systems that include Ni_3Al, Cu_3Au, NiAl, nickel, aluminum, iridium, gold, platinum, silver, copper, molybdenum, tantalum, iron, tungsten, niobium, beryllium, titanium, hafnium, zirconium, and rhenium (Ref 1, 2, 3, 9, 20, 21, 22, 23, 24, 25, 26, 27). These studies indicate that stoichiometry (Ref 1, 20, 21) and impurities (Ref 20, 21) can be crucial in determining ideal and realistic adhesion, including effects induced by boron and sulfur. They represent the fundamentals for future work,

which is expected to have significant impact on the theory using atomistic simulation under well-controlled situations for all conditions of stress, temperature, and chemical environments. These calculations should enable direct linking of theoretical studies and materials by design concepts, as applied in NiAl microalloyed with boron or iron (Ref 24, 25, 26, 27).

DeBoer *et al.* (Ref 28) have developed excellent tools for screening bonding materials, based on two properties of the elements: electronegativity and electron density. One can use the Miedema formula for the adhesion of a bimetallic interface, based on the work function (closely related to the Pauling electronegativity), Φ, and the electron density, *n*, at the Wigner-Seitz radius, as described in Ref 28.

Properties Affecting Adhesion

Large impurities, such as bismuth, sulfur, phosphorus, and so on, tend to lower grain boundary adhesion, whereas small interstitial atoms, such as boron, carbon, and beryllium tend to increase cohesion in nickel, Ni_3Al, and Ni_3Si (Ref 1, 20, 21). Deviations from stoichiometry can either increase or decrease cohesion, depending on whether amounts of strong bonding elements, like nickel in Ni_3Al, are increased or decreased. Although stoichiometry may slightly affect the ideal cohesion energy, its effect on the consumption of plastic work is potentially higher, as demonstrated in Co_3Ti. Researchers (Ref 29) found that excess cobalt suppressed intergranular brittleness and rendered the material ductile, without adding strengtheners such as boron or beryllium. Sometimes impurity effects only work in off-stoichiometric compounds, such as boron in Ni_3Al. Quantitative analysis of these kinds of effects have been attempted for impurity-controlled fracture properties in iron, which has been studied extensively by Hondros and Seah (Ref 30). A simple linear formula linking cohesion and level of impurities has been extracted from many experiments (Ref 30).

Adhesion Measurement

Sikorski (Ref 31) describes two modifications of the twist-compression bonding method for adhesion testing and concludes that the measured coefficient of friction supports the adhesion theory of friction. This correlation implies that a large coefficient of adhesion (ratio of the force necessary to break a bond to the normal loading force used to produce the bond) corresponds to a large coefficient of friction.

Experimentally, he showed that the coefficient of adhesion was inversely proportional to the melting point, which meant that higher melting point materials had lower adhesion. This agress with the observation that higher melting point materials have higher hardness, which also corresponds to lower adhesion coefficients. Gerkema and Miedema (Ref 32) considered lubrication of iron substrates by thin films of lead and silver with copper, platinum, or molybdenum additions by calculating surface adhesion using heats of solution and surface energies. Their predictions agree well with sliding wear experiments.

Pashley and Tabor (Ref 33) measured adhesion between tungsten and nickel using techniques similar to those used in atomic force microscopy (AFM). They were able to verify surface cleanliness and ensure that the adhesion measured was between clean tungsten and nickel by using Auger spectroscopy (AES). In a subsequent publication, Pashley and Pethia again measured the surface energy of adhesion between tungsten and nickel (Ref 34). This work was done between a tungsten tip and a nickel flat in high vacuum and showed that surface forces alone could cause plastic flow. The loading/unloading curves provide information on the elastic/plastic response of the material. This in turn determines the interpretation of the adhesion.

Johnson and Keller (Ref 35) used a torsion balance with a 3 mm (0.12 in.) diameter ball against a flat plate to measure the force of adhesion between silver-silver, copper-nickel, and silver-nickel couples. They concluded that mutual solubility did not affect the tendency for adhesion. However, surface contaminants did have a significant effect on the adhesion (joint strength) between silver-silver couples when the vacuum varied. The difference in joint strength for a clean surface at 130 μPa (5×10^{-10} torr) and for the same surface after a few microns of argon was 50 GPa (5×10^{8} dynes/cm^2).

Conrad and Rice (Ref 36) studied the cohesion of fcc metals (silver, aluminum, copper, and nickel) by fracturing the metals in high vacuum, rewelding the metals by compressing the fractured surfaces, and retesting the metals by fracturing. They found that the cohesive strength of the weld increased with compressive load when both were normalized to the initial fracture strength. Results for all materials fell on a single curve. They proposed that the essentially constant cohesion coefficient was due to the fact that the contact area produced by a given compressive load was inversely proportional to the fracture stress of the metal, whereas the cohesive strength was directly proportional to the fracture stress.

Acoustic emission was used to measure and monitor cohesion. In one case, this technique was used to signal the onset of fiber debonding and to determine crack initiation locations in fiber-reinforced ceramic-matrix composites (Ref 37). This approach is a valuable and viable technique for monitoring debonding, but cannot be used to provide quantitative information on either bond strength or fundamental material parameters. It can be used to locate the origin of the debonding, but the error is on the order of the dimensions used for continuum calculations, which are much larger than the atomic dimensions.

In another study (Ref 38), acoustic measurements were used to monitor fatigue cracks and interfaces by defining a spring stiffness (for continuous and discontinuous spring models) that represented the degree of contact across an interface. A measured acoustic reflection coefficient was found to be in good agreement with one predicted for the same geometry. In addition, a single stress-intensity factor was found to determine bond strength.

In a similar vein, Neid (Ref 39) developed a technique for measuring bond integrity by propagating a planar shock were through the bond region. Depending on the shock energy, defects developed in the bond. The change in density was used to detect defects created at the interface, because other nondestructive test (NDT) methods were not sensitive enough to detect the small defects created. The defects were subsequently verified using optical microscopy.

Itou (Ref 40) used electrical resistance to monitor crack tip contact in order to verify crack tip shielding in aluminum, steel, and cork. The results were inconclusive, although he found that there was no oscillating stress singularity around the crack tip. From this discussion, one can see that no generally quick, accurate, and easy-to-use technique has been developed to measure adhesion.

Fundamentals of Metal and Metal-to-Ceramic Adhesion

Ray Dixon and S.P. Chen, Los Alamos National Laboratory

Interfacial Analysis

Electron spectroscopies are extremely valuable for the quantitative and qualitative analysis of surfaces. Fundamental information about the atomic forces and energies of the regions being probed, as well as their geometry, can be obtained. The shortcoming of these techniques in analyzing interfaces is that the interfacial volume is a small fraction of the probed volume and the effects of the interface cannot be separated from the signal. This condition can be overcome by using scanning tunneling microscopy (STM) or AFM. However, preparation of the surface is extremely difficult, the equipment requires a skilled and trained operator, the data are fundamental, and engineering information is not obtained. The crux of the problem is that there is no simple connection between condensed matter theory, micromechanics, and continuum

mechanics. The following discussion briefly reviews some of the available technical literature that describes the use of these spectroscopies and their application to bimaterial systems.

Photoelectron spectroscopy has been used to study electron core-level shifts for ytterbium, aluminum, and silicon grown on molybdenum (110) (Ref 41, 42). The core-level shifts between the film and the substrate are expressed in terms of adhesion energy. In this case, the adhesion energy is the difference between the energy of the neutral and excited atoms per atom, which is readily found from the spectra. The measured adhesion energy is in good agreement with the adhesion energy determined using the Miedema technique (Ref 28). High-resolution electron microscopy (HREM), electron energy loss spectroscopy (EELS), microspectroscopy, and microdiffraction have been used to analyzed the chemical distributions on or near interface planes (Ref 43). This information can be used to support models requiring detailed stoichiometry, but does not yield adhesion values.

Gerberich *et al.* (Ref 44) used selected-area-electron channeling patterns (SACP) and stereoimaging to quantify the strain in grains. The work was carried out under plane strain and plane stress conditions. The researchers determined strain distributions within 1 μm (40 μin.) of a stationary or growing crack in Fe-3Si single crystals with a {100}<010> crack. Although this arrangement is not a bimaterial interface, the results reflect the effort needed to obtain fundamental materials information.

Optical techniques, such as reflection (Ref 45), have also been used to probe interfaces and to aid in determining interfacial electronic structure. The data, in turn, are related to adhesion and segregation. For example, Lanning *et al.* (Ref 46) recently correlated reflectance spectra with surface free energy. This was then used as a measure of surface energy and the work of decohesion was calculated.

The most promising technology for understanding interfaces is probably STM and associated techniques. Advances in the science and technology of scanning tunneling microscopy/spectroscopy (STM/S), AFM, photon scanning tunneling microscopy (PSTM), scanning chemical potential microscopy (SCPM), and related spectroscopies/microscopies offer new insight into interfaces (Ref 47). Low-energy electron diffraction (LEED), LEED-spot profile analysis (SPA-LEED), scanning low-energy electron microscopy (SLEEM), and photoemission electron microscopy (PEEM) are also being applied to surface analysis and adhesion. These technologies, although currently applied to the vacuum-surface interface, are appropriate tools for the study of grain boundaries and dissimilar metal surfaces. They provide excellent methods for measuring the electronic behavior at interfaces and, thus, the fundamental interactions that occur at these interfaces. This information must then be correlated to engineering properties predicted by micromechanical and continuum mechanics methods, as well as experiments.

Fundamentals of Metal and Metal-to-Ceramic Adhesion

Ray Dixon and S.P. Chen, Los Alamos National Laboratory

Welding (Bonding)

An extensive review of diffusion bonding is given by Gerken and Owczarski (Ref 48). This treatise reviewed the status of theory at that time (1965) and cited numerous examples. Eleven years later, Williams and Crossland (Ref 49, 50) highlighted cold and diffusion welding. They pointed out that the major technical concerns for these processes had not significantly changed in the interim. As recently as 1986, there was concern over the knowledge base of bonding and adhesion at interfaces (Ref 51). This group felt that detailed mechanisms of adhesion were largely missing, but that first-principle theories were beginning to appear. A strong need for collaboration between theorists and experimentalists was indicated. Furthermore, much information was still unknown about interfaces, and the field was ripe for expansion. This situation still applies. Described below are examples of some of the proposed models for bonding.

Several mechanisms have been proposed to explain the formation of solid-state welds (Ref 52, 53). Mohamed and Washburn (Ref 52) proposed a two-stage mechanism that depends on breaking the surface oxide. Their work is supported by the work of Bay. (Ref 54), who developed a theoretical model for oxide breakage and bond formation on aluminum. Kawakatsu and Kitayama (Ref 53) describe bonding as being controlled by three metallurgical factors, which have been identified as bonds between solid-solution, two-phase, or intermetallic materials. Their studies involved bond-strength measurements and microstructural examination as a function of bonding conditions for copper-nickel, copper-silver, and iron-aluminum couples. They concluded that a minimum bonding temperature occurs at about the softening temperature of one of the materials. They also found that bond strength depends on recrystallization temperature. In the case of solid-solution materials, the interfaces tend to disappear after sufficient time above the recrystallization temperature, whereas this does not occur in two-phase and intermetallic materials.

Excellent treatises on surface and interfacial segregation are provided by Dowben and Miller (Ref 55) and Hondros and Seah (Ref 30). The concept of migration or segregation of one component of a system to a surface or interface is considered in detail. This work provides insight into the behavior that must be considered when determining the possibility of adhesion between two dissimilar materials.

Garmong *et al.* (Ref 56) describe the rate-limiting step in bonding as the complete elimination of porosity from the bond line and have developed a time-prediction model to support it. The model proceeds in two stages. First, long-wavelength asperities (roughness) are eliminated by plastic flow. Second, voids are eliminated by plastic flow and vacancy diffusion. This model is similar to that proposed by Hill and Wallach (Ref 57), who consider void elimination at the bond line. In this case, voids are created by surface asperities on the mating surfaces and pressure sintering is invoked for its elimination. The effect of grain size is also considered.

Cahn (Ref 58) derived interfacial energy from thermodynamic considerations. He considered how the order parameter changes surface tension, elastic energy, and excess free energy when it affects the lattice parameter of an ordered material at an antiphase boundary. The work is not only appropriate for grain boundary interfaces in ordered materials, but is also relevant for dissimilar materials.

Cline (Ref 59) reviews the difference between deformation and diffusion bonding. He defines diffusion bonding as not requiring significant deformation for bond formation. With respect to deformation bonding, Cline discusses the "film" and "energy barrier" theories and reviews the factors affecting the resultant bond. With respect to diffusion bonding, he defines two stages for bonding: microscopic deformation and diffusion. He then reviews the results for bonding aluminum and titanium and shows that both can be readily deformation bonded. The diffusion bonding of aluminum was simplified

by using a silver interlayer, whereas titanium required smooth, clean surfaces and protection from atmospheric contaminants.

Derby and Wallach (Ref 60, 61) developed a thorough model for diffusion welding which accounts for:

- SURFACE DIFFUSION FROM SURFACE SOURCES TO A NECK
- VOLUME DIFFUSION FROM SURFACE SOURCES TO A NECK
- DIFFUSION ALONG THE BOND INTERFACE FROM INTERFACIAL SOURCES TO A NECK
- VOLUME DIFFUSION FROM INTERFACIAL SOURCES TO A NECK
- POWER-LAW CREEP DEFORMING THE RIDGE (SURFACE ROUGHNESS)
- PLASTIC YIELDING DEFORMING THE RIDGE
- VAPOR PHASE MASS TRANSPORT

Mass transport rate equations were developed in terms of the process variables (time, temperature, pressure, and material properties). The model is in reasonable agreement with experiment (Ref 62, 63).

Guo and Ridley (Ref 64) consider the rate-limiting step in bonding to be the removal of interfacial voids that are due to the surface roughness and have developed a model to support this position. The main difference between their model and that of Derby and Wallach (Ref 60) is the void geometry used. Guo and Ridley use a lenticular-shaped cavity and have developed a model that agrees reasonably with the experimental data.

Fundamentals of Metal and Metal-to-Ceramic Adhesion

Ray Dixon and S.P. Chen, Los Alamos National Laboratory

Interface Formation

When considering the compression needed to bond dissimilar materials, the deformation-mechanism map work of Frost and Ashby (Ref 65) is helpful. The maps are in a stress/temperature space in which a single deformation mechanism is dominant. The stress used is a normalized tensile stress (tensile stress/shear modulus), and the temperature is the homologous temperature T/T_m, where T is the test temperature and T_m is the melting point of the material being tested, where both temperatures are expressed in degrees K. From these maps and the corresponding constitutive equations, contour plots of constant strain rate can be plotted. At this point, knowing any two values of strain rate, stress, or temperature, a point on the map will give the third variable and thee dominant deformation mechanism. This information can be a guide to determining the bonding mechanism when considering one of the previously discussed mechanisms that requires elimination of defects at the interface.

Dammer *et al.* (Ref 66) describe a study where type 347 stainless steel was bonded to itself with several different interlayers. The interlayers were electrolytic-grade copper foil, electrolytic tough pitch (ETP) copper sheet, 80Au-20Cu foil, 72Ag-28Cu foil, and several combinations of silver, copper, and gold electroplates. They successfully bonded the specimens at temperatures below 540 °C (1005 °F), but found that the intermediate materials were essential to forming the weld.

Bachin (Ref 67) discusses the interactions of metals and oxides when diffusion welding metals to metals and to ceramics. He discusses the reactions and exchanges at the interface by considering the formation of spinels and oxides. This leads to the conditions under which each is known to be operative and to the possibility of diffusion across the resulting interface. For example, Al + SiO_2 proceeds by exchange:

$$4AL + 3SIO_2 \rightarrow 2AL_2O_3 + 3SI \qquad \textbf{(EQ 7)}$$

When thin silicon dioxide is joined through a thin intermediate interlayer of aluminum, new phases precipitate at the dividing boundaries and the solid solution is decomposed when the limit of solubility is reached for the reaction products. This behavior results in high internal stresses and resultant microcracks. Caution is therefore required when welding these systems. A thorough review of the thermodynamics involved for the systems being considered is essential.

Munir (Ref 68) developed equations that predict the amount of time required to dissolve oxides into their host metals for systems that have unstable oxides with respect to dissolution. He considered niobium, zirconium, titanium, copper, tantalum, cobalt, nickel, and iron and found reasonable agreement with the theory.

Wang and Vehoff (Ref 69) discuss the segregation of atoms to interfaces. Their work deals with grain boundaries as interfaces, and they conclude that the cohesive energy of the interface at a fixed chemical potential is always less than the cohesive energy at a fixed concentration. The concept of segregation to the interface is probably important for bimaterial interfaces because of the different chemical potentials, diffusion rates, and, thus, concentrations that can exist. Because

these parameters are all temperature dependent, the bonding process and the service temperature will affect the interface segregation and, thus, its performance. This work provides a way to consider these effects.

Fundamentals of Metal and Metal-to-Ceramic Adhesion

Ray Dixon and S.P. Chen, Los Alamos National Laboratory

Strength of Interfaces

One of the most important and probably the most frequent questions: What is the strength of the interfacial bond? This question has often been answered by tensile testing. The difficulty is that the failure is often not at the interface and that it must be forced there. Additionally, there is concern that the strain is not one-dimensional across the bond and that the bond experiences triaxial strain in service. For these reasons, there has been considerable interests in determining fracture toughness and in detecting the failure of interfaces.

Several reviews on the importance and extent of interfacial science were recently presented in one technical journal (Ref 70). Three reviews are noteworthy because they discuss the mechanical properties of interfaces (Ref 71, 72, 73). The efforts of Hutchinson and Suo (Ref 71) bring together much of the recent work on elastic fracture phenomena for bimetallic systems and builds on it to support work being done to understand mixed-mode failure in systems with interfaces. Shih (Ref 72) summarizes progress on interfacial mechanics and points out that fracture toughness, at various mode mixities, is needed to characterize fracture resistance of a weak plane in a composite. An application of this analysis has been demonstrated on the alumina/niobium metal-ceramic system by Stout *et al.* (Ref 74). Comninou (Ref 73) reviews the interface crack problem from the standpoint of open and closed crack tips and describes preliminary experimental results on fatigue and fracture of interface cracks in aluminum bonded by epoxy.

Interface Strength Models. There has been considerable progress in analyzing the fracture behavior of interfaces with various configurations. This work has led to the development of specimen geometries for systems with differing physical and mechanical properties. The analysis work is reviewed in this section and the experimental work is described in the section "Interface Strength Measurements" of this article.

Suo and Hutchinson (Ref 75) have provided a complete solution to the semi-infinite crack lying along the interface of two infinite elastic layers under edge loads. This solution allows the determination of material properties for complex geometries, as well as the effect of welding two dissimilar materials. Jensen (Ref 76) demonstrates that shielding the full effect of mode II and III loading is important for interface cracks in brittle materials and that a proper interface fracture criteria needs to be modeled. He discusses a method for comparing different phenomenological fracture criteria and sets up micromechanical models describing shielding for interface geometries with kinks.

The models of He and Hutchinson (Ref 77) explain conditions for interfacial crack propagation (kinking) into material on either side of the interface. Their models suggest that a crack propagates along an interface as long as the compliant material is tough and that the stiff material is at least as tough as the interface. They also show that the energy release rate is increased if the crack kinks into the more-compliant material and is diminished if it kinks into the stiff material.

Qu and Li (Ref 78) also analyzed cracks and dislocations at the interface between two anisotropic elastic half spaces. They obtained an explicit and real solution to the dislocation problem in the Stroh (Ref 79) formalism and showed that a planar interface between dissimilar anisotropic solids is completely characterized by no more than nine independent parameters. The work by Li and Ting (Ref 80, 81) is also relevant.

Evans *et al.* (Ref 82, 83) concluded that fracture energy is not unique and is usually greater than the thermodynamic work of adhesion. The nonuniqueness is related to the mixity experienced by interface cracks. As a result, the fracture energy is influenced by the choice of test specimen. This result implies that when considering fracture energy for specific material combinations, the test geometry must be known, reported, and maintained. This also means that it is now possible to systematically study interfacial mechanical behavior and produce meaningful data on interface fracture toughness.

Fischmeister *et al.* (Ref 84) modeled simple crack propagation, dislocation emission from crack tips, and twinning using atomistic calculations (molecular dynamics) embedded in a finite-element continuum. They also studied the behavior of cracks propagating in tungsten and iron on different planes and in different directions within these planes. Their results confirm that {100} should be the easiest cleavage plane in these body-centered cubic (bcc) tungsten and iron crystals. They further studied the propagation direction restrictions for cracks on particular planes. The modeling work was supported by experiments to verify the crack propagation behavior in WC-Co alloy, high-speed steel consolidated with nickel particles, and nickel coated on high-speed steel.

Chen *et al.* (Ref 1, 9, 20, 21) studied crack growth in nickel, Ni_3Al, Ni_3Al plus boron, Ni_3Al plus sulfur, and iridium grain boundaries using local volume potentials. They found that cohesive strength is important in determining grain boundary fracture and can be strongly affected by impurities and stoichiometry.

Another approach to modeling fracture is given by Needleman (Ref 85), who used a cohesive zone-type interface model. His model takes full account of finite geometry changes and is used to study decohesion of a viscoplastic block from a rigid substrate. He found that the normal traction versus separation relation had an exponential form consistent with the universal binding energy relationship of Rose *et al.* (Ref 86) and of Ferrante and Smith (Ref 87).

Ting (Ref 88) showed that oscillatory displacement at the interfacial crack surface in a bimaterial under a two-dimensional deformation depends only on the material properties and is independent of specimen orientation. The exception is that bimaterials always produce oscillation and that there is an exception for one choice of relative orientation in one material combination. He also shows that for two different orthotropic materials, the oscillation depends on whether or not the Voigt elastic constants combinations, $\sqrt{C_{11}+C_{22}+C_{12}}$, for the two materials are different.

Cook (Ref 89) explains crack propagation threshold in brittle materials through the work done by the applied loading and that which is needed to create new surfaces during crack propagation. He showed that the mechanical energy release rate was a measure of the equilibrium surface energy of the material and the chemical environment. The latter affects the surface tension of both the fresh and aged crack.

Reynolds *et al.* (Ref 90) investigated the difference between the concepts of cracks with zero normal and shear traction over the entire face of the crack and cracks with normal and shear traction specified at zero on the crack surface, except near the tip, where zero shear fraction and continuity of displacements normal to the crack were required. Of these two approaches, the first leads to oscillatory stress singularities and interpenetration of the material near the crack tip, whereas the second shows that a small region of contact exists at the tip, regardless, of the loading. The two methods require different treatments in terms of stress intensity, but predict the same strain-energy release rate. The work was done using the finite-element method (FEM) and, thus, also served to verify the formulation of each problem by FEM analysis. The results showed that the two formulations could be modeled by the absence or presence of interface elements that prevent interpenetration of the crack surfaces. Additionally, fracture parameters were calculated and compared well with previous analytic solutions.

Interface Strength Measurements. Based on the theoretical analysis described above, as well as their own models, the authors identified below have carried out excellent experimental work in measuring the mechanical properties of interfaces.

Charalambides *et al.* (Ref 91) developed a test procedure to measure interface fracture resistance under mixed-mode conditions. Strain-energy release rates and stress-intensity factors can be obtained using this test. O'Dowd *et al.* (Ref 92) developed FEM model solutions and tested several geometries to determine interfacial fracture toughness as a function of mixity. They were able to explain near-tip contact and variation of mixity with distance. They also developed a procedure

for determining the effect of residual stress on the stress-intensity factor. Brady *et al.* (Ref 93) developed a buckled plate test to determine the transverse fracture toughness of unidirectional continuous-fiber composites. Their test was found to be independent of sample geometry and testing conditions. Mecholsky and Baker (Ref 94) developed a double cantilever beam specimen with a chevron notch to measure fracture toughness of ceramic-metal interfaces. The specimen is easy to make and introduces its own crack, and the test is easy to perform. Zhu and Byrne (Ref 95) looked at the effect of interfacial defects by bonding and subsequent tensile, fatigue, and photomicroscopy tests. They measured void ratios at the bond line and found the defects smaller than those detectable by current nondestructive test methods (~0.2 to 0.5 mm^2 by 1 to 3 μm, or 3×10^{-4} to 8×10^{-4} $in.^2$, or 40 to 120 μin., thick) could still significantly affect bond strength. They concluded that fatigue testing is a better test method than tensile testing because it is sensitive to a void ratio of approximately 27%, whereas tensile tests were not.

Thouless (Ref 96) used epoxy-bonded glass slides to investigate interfacial failure under mixed-mode loading. He found that when the scale is sufficiently large, the sample could be considered homogeneous with a weak planar interface. This result produced a correlation between apparent fracture resistance and the degree of mixity. At a very detailed scale, the lack of homogeneity required that the crack-tip stress be determined by the position of the crack within the interface (epoxy). This condition leads to a change in failure mechanisms, whereby under pure mode-I conditions, the crack propagates entirely within the interfacial layer, whereas mode-II effects drive the crack toward the glass-epoxy interface.

Nickel specimens with known surface roughnesses were diffusion welded under controlled conditions of temperature and pressure (Ref 97). The welds were interrupted at several different time intervals and the resulting interface was examined. The defect sizes were successfully related to surface tension and diffusion. It was also found that temperature increases produced a greater effect on reducing interfacial defects than did pressure. Meriin and Sliozberg (Ref 98) make the point that sound welds (bonds) cannot be obtained unless the voids are eliminated at the interface, which requires high temperatures and pressures. It further requires that mechanical tests be used as the principal detection method.

This article has shown that there has been and continues to be active interest in interfacial behavior. The science is sufficiently complex that numerous approaches are useful to evaluate interfacial behavior, depending on the specific goal. However, it is obvious that the seemingly unrelated approaches all seek to understand the interface. It is therefore incumbent upon scientists in this field to be familiar with all developments concerning adhesion so that they can contribute to its understanding and future advancement.

Fundamentals of Friction Welding

J.W. Elmer and D.D. Kautz, Lawrence Livermore National Laboratory

Introduction

FRICTION WELDING (FRW) is a solid-state welding process in which the heat for welding is produced by the relative motion of the two interfaces being joined. This method relies on the direct conversion of mechanical energy to thermal energy to form the weld, without the application of heat from any other source. Under normal conditions no melting

occurs at the interface. Figure 1 shows a typical friction weld, in which a nonrotating workpiece is held in contract with a rotating workpiece under constant or gradually increasing pressure until the interface reaches the welding temperature. The rotational speed, the axial pressure, and the welding time are the principal variables that are controlled in order to provide the necessary combination of heat and pressure to form the weld. These parameters are adjusted so that the interface is heated into the plastic temperature range where welding can take place. Once the interface is heated, axial pressure is used to bring the weld interfaces into intimate contact. During this last stage of the welding process, atomic diffusion occurs while the interfaces are in contact, allowing a metallurgical bond to form between the two materials.

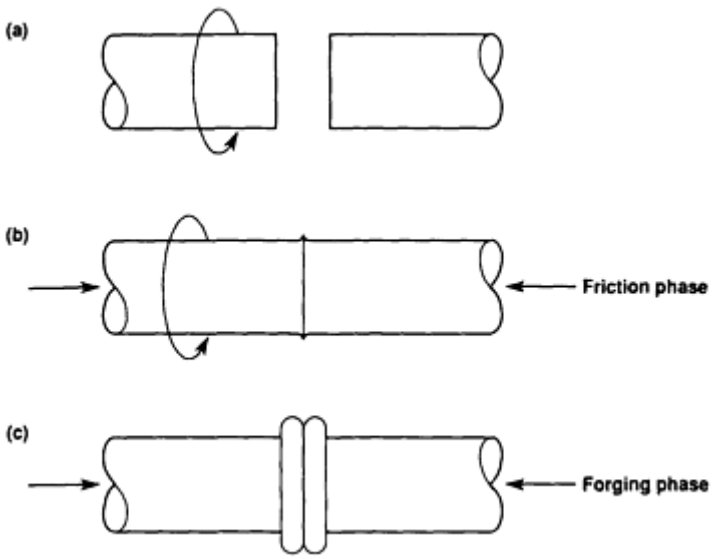

FIG. 1 SCHEMATIC SHOWING FUNDAMENTAL STEPS IN THE FRICTION WELDING PROCESS. (A) ONE WORKPIECE IS ROTATED, AND THE OTHER WORKPIECE IS HELD STATIONARY. (B) BOTH WORKPIECES ARE BROUGHT TOGETHER, AND AXIAL FORCE IS APPLIED TO BEGIN THE UPSETTING PROCESS. (C) WORKPIECE ROTATION IS STOPPED, AND THE UPSETTING PROCESS IS COMPLETED

Friction welding involves heat generation through friction abrasion (Ref 1, 2, 3), heat dissipation, plastic deformation, and chemical interdiffusion. The interrelation among these factors during FRW to complications when trying to develop predictive models of the friction welding process. However, from a qualitative standpoint the process is well understood through empirical FRW studies that have been performed on a wide variety of materials. Five qualitative factors influence the quality of a friction weld (Ref 4):

- RELATIVE VELOCITY OF THE SURFACES
- APPLIED PRESSURE
- SURFACE TEMPERATURE
- BULK MATERIAL PROPERTIES
- SURFACE CONDITION AND PRESENCE OF SURFACE FILMS

The first three factors are related to FRW, while the last two are related to the properties of the materials being joined.

During FRW, the relative velocity, the applied pressure, and the duration of the force are the three variables that are controlled. The effect of these variables on weld quality will be discussed for the two basic friction welding processes: direct-drive welding and inertia-drive welding. The surface temperature is the critical parameter for ensuring good welds and is dependent on the processing conditions and the materials being joined. Although the surface temperature is not measured or directly controlled the effects of insufficient or excessive temperature are generally apparent through visual examination of the finished weld. The bulk material properties and the condition of the surfaces being joined affect both the frictional forces and the forging characteristics of the materials being joined. These factors will be discussed for the friction welding of both similar-material and dissimilar-material combinations.

Commercial FRW applications employ a number of variations on the basic FRW concepts. These variations were developed to accommodate different part geometries and to produce different metallurgical effects (Ref 5) and will not be discussed in this article.

Fundamentals of Friction Welding

J.W. Elmer and D.D. Kautz, Lawrence Livermore National Laboratory

Friction Welding Technology

There are two principal FRW methods: direct-drive welding and inertia-drive welding. Direct-drive FRW, sometimes called conventional friction welding, uses a motor running at constant speed to input energy to the weld. Inertia-drive friction welding, sometimes called flywheel friction welding, uses the energy stored in a flywheel to input energy to the weld. These two FRW technologies produce inherently different metallurgical effects at the joint interface.

Both FRW technologies can be applied through different types of relative motion in order to generate the friction necessary to form the weld. The most common FRW geometry is that shown in Fig. 1, in which one cylindrical component is held stationary and the other is rotated. However, in other methods, both components are rotated in opposite directions, or two-stationary components are pushed against a rotating piece positioned between them. Additional forms of FRW, such as radial, orbital, and linear reciprocating motions, have been developed for special part geometries. These alternate methods are discussed elsewhere (Ref 5, 6).

Direct Drive Welding

In direct-drive FRW, a machine resembling a lathe is equipped with a brake and clutch, a means of applying and controlling axial pressure, and a weld-cycle timer and displacement controller. The operation of a direct-drive machine consists of a friction phase where heat is generated, a stopping phase where the rotation is terminated, and a forging phase where the pressure is applied to join the pieces. The relationships among the process variables are shown in Fig. 2, which plots the rotational speed and the axial pressure as a function of time for typical weld. The time required to stop the spindle is also an important variable because it affects the weld temperature and the timing of the forging force.

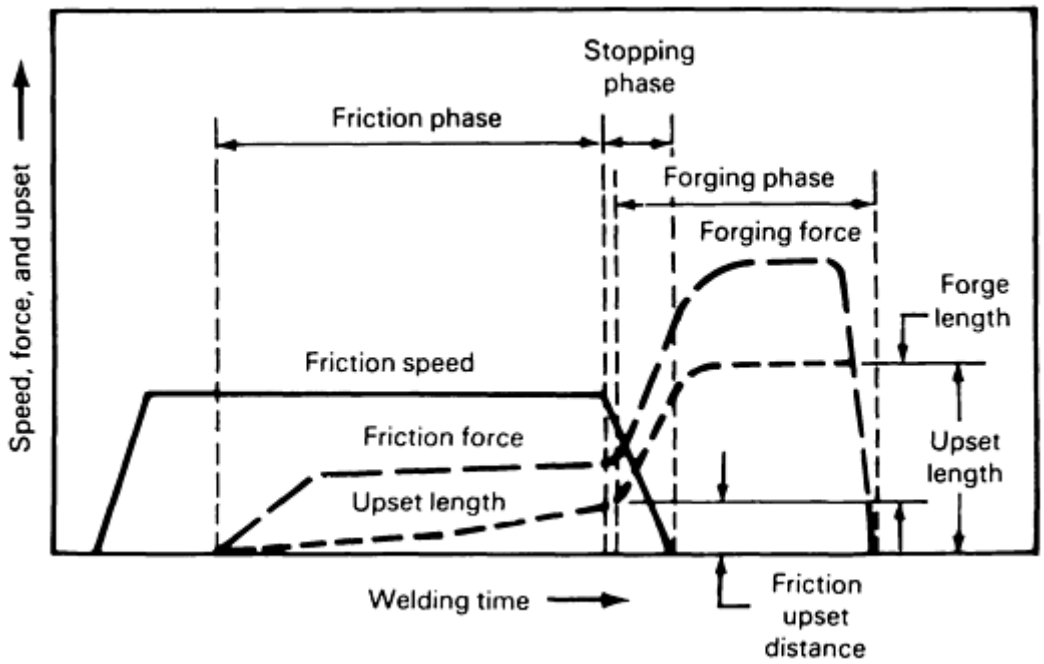

FIG. 2 PLOT OF SELECTED PARAMETERS VERSUS TIME RELATIVE TO THE THREE PHASES OF THE DIRECT-DRIVE FRW PROCESS

The forging phase starts at the instant when higher pressure (that is, a larger forging force) is applied in the weld cycle. Thus, the forging phase actually starts somewhere in the stopping phase. In general, the larger forging force can be applied (case 1) while the spindle is decelerating in the stopping phase (Fig. 2) or (case 2) after the spindle has stopped rotating at the end of the stopping phase. The difference in the two applications of the larger forging force is the presence of a second friction peak. In case 1, the torque will rise again to reach a second peak before dropping. This produces a torsional force. In case 2, especially when the stopping phase is very short due to rapid braking, frictional torque does not rise but actually starts to decrease at the onset of the forging phase. In this case, there is no torsional force, and forging is affected only by the upsetting force.

The speed of rotation is the least sensitive process variable in that it can be varied over a wide range if heating time and pressure are properly controlled. For steels, the recommended peripheral velocity varies from 75 to 215 m/min (250 to 700 ft/min) (Ref 7). In general, higher speeds correspond to low weld heat inputs and are used to weld heat-sensitive materials such as hardenable steels.

The friction force is generally applied gradually to the weld to help overcome the initial contact-torque peak. For carbon steels, a friction pressure of about 70 MPa (10 ksi) at the interface area is required to form a good joint. After the drive motor is disengaged from the workpiece, the forging force is applied to complete the weld. Typical forging forces for carbon steel are of 140 MPa (20 ksi) at the weld interface.

Inertia-Drive Welding

The inertia-drive FRW method uses a similar type of machine except that the spindle holding the rotating piece is attached to a flywheel. The flywheel controls the energy input to the weld. The moment of inertia of the flywheel is an important variable that is adjusted by adding or removing flywheels. The amount of energy stored in the flywheel is controlled by its speed. Once the spindle is at the correct speed, the drive system is disengaged, leaving a rotating flywheel mass. Axial pressure is then applied and held constant throughout the welding process. The applied pressure results in a decrease in the rotational speed, typically referred to as deceleration. In some cases, when the spindle has either nearly stopped or come to a complete stop, a higher forging force may be used.

Figure 3 illustrates the inertia-drive FRW process, which is similar to the direct-drive method in that the weld typically takes place in two stages: friction and forging. However, some weld schedules do not require a forging stage.

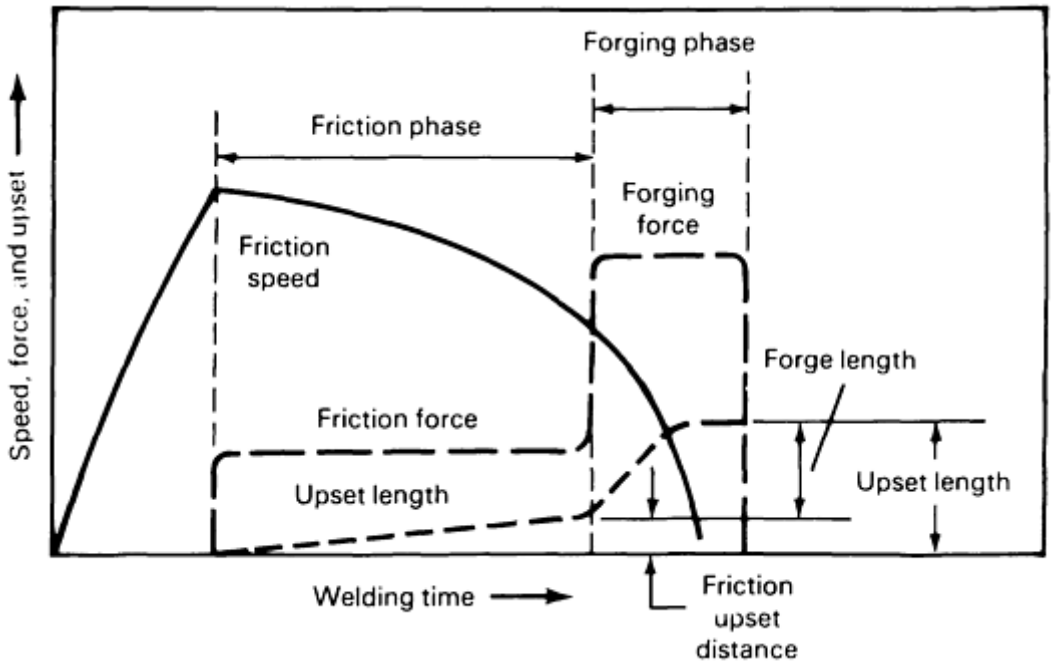

FIG. 3 PLOT OF SELECTED PARAMETERS VERSUS TIME RELATIVE TO THE TWO PHASES OF THE INERTIA-DRIVE FRW PROCESS

The major difference between the direct-drive and inertia-drive methods is the friction speed. In inertia welding, the friction speed continuously decreases during the friction stage, while in direct welding the friction speed stays constant.

The heat generated by the plastic deformation of materials at the faying surfaces, not the heat generated by friction in the friction phase, is the primary source in the forging phase of preventing rapid decrease of the temperature at the interface.

The process variables that control the characteristics of an inertia weld are the flywheel size (moment of inertia), the flywheel speed, and the axial pressure. The weld energy is related to the first two variables and is a fixed quantity once they have been determined. The kinetic energy in the flywheel at any time during the weld is given by:

$$E = \frac{S^2.1}{C}$$

where E is the energy (ft · lbf, or J), I is the moment of inertia (lb/ft^2, or kg/m^2), S is the flywheel speed (rev/min), and C is a conversion constant that is equal to 5873 for English units or 182.4 for metric units.

The constant C is derived from:

$$E = \frac{1}{2}mv^2$$

where $v = \omega r$. Because $\omega = 2\pi s$, $v = 2\pi sr$:

$$E = \frac{1}{2}m(2p)^2s^2r^2$$

$$E = \frac{1}{2}mr^2(2p)^2s^2$$

Making $mr^2 = I$, the previous equation becomes:

$$E = \frac{1}{2} I (2p)^2 s^2$$

In SI units, the previous equation becomes:

$$E = \left[\frac{m^2.Kg}{s^2}\right] = \frac{1}{2}(2p)^2 s^2 \left[\frac{1}{\min^2}\right] I \left[m^2.Kg\right] \left[\frac{\min}{60s}\right]^2$$

$$E = \frac{1}{2}\frac{(2p)^2}{60^2} s^2 I$$

$$E = \frac{Is^2}{C}$$

Solving for C in the previous equation:

$$C = \frac{2*60^2}{(2p)^2} = \frac{60^2}{2p^2} = 182.378$$

The energy stored in the flywheel is proportional to its speed of rotation squared, S^2. Therefore, a wide range of energy levels can be obtained without changing the flywheel to accommodate changes in part geometries. For large changes in the parts being joined, the capacity of an inertia welding machine can be modified by changing the flywheel moment of inertia if necessary.

Flywheel Energy. The moment of inertia of the flywheel is selected to produce both the desired amount of kinetic energy and the desired amount of forging. Forging results from the characteristic increase in torque that occurs at the weld interface as the flywheel slows and comes to rest. This increased torque, in combination with the axial pressure, produces forging. Because forging begins at some critical velocity, the amount of forging depends on the amount of energy remaining in the flywheel, which is a linear function of the flywheel moment of inertia. Large, low-speed flywheels produce greater forging force than small, high-speed flywheels even though they contain the same amount of kinetic energy. Although small, medium, and large amounts of flywheel energy produce similar heating patterns, the amount of energy greatly affects the size and shape of the weld upset, as shown in Fig. 4(a) for similar-metal joints.

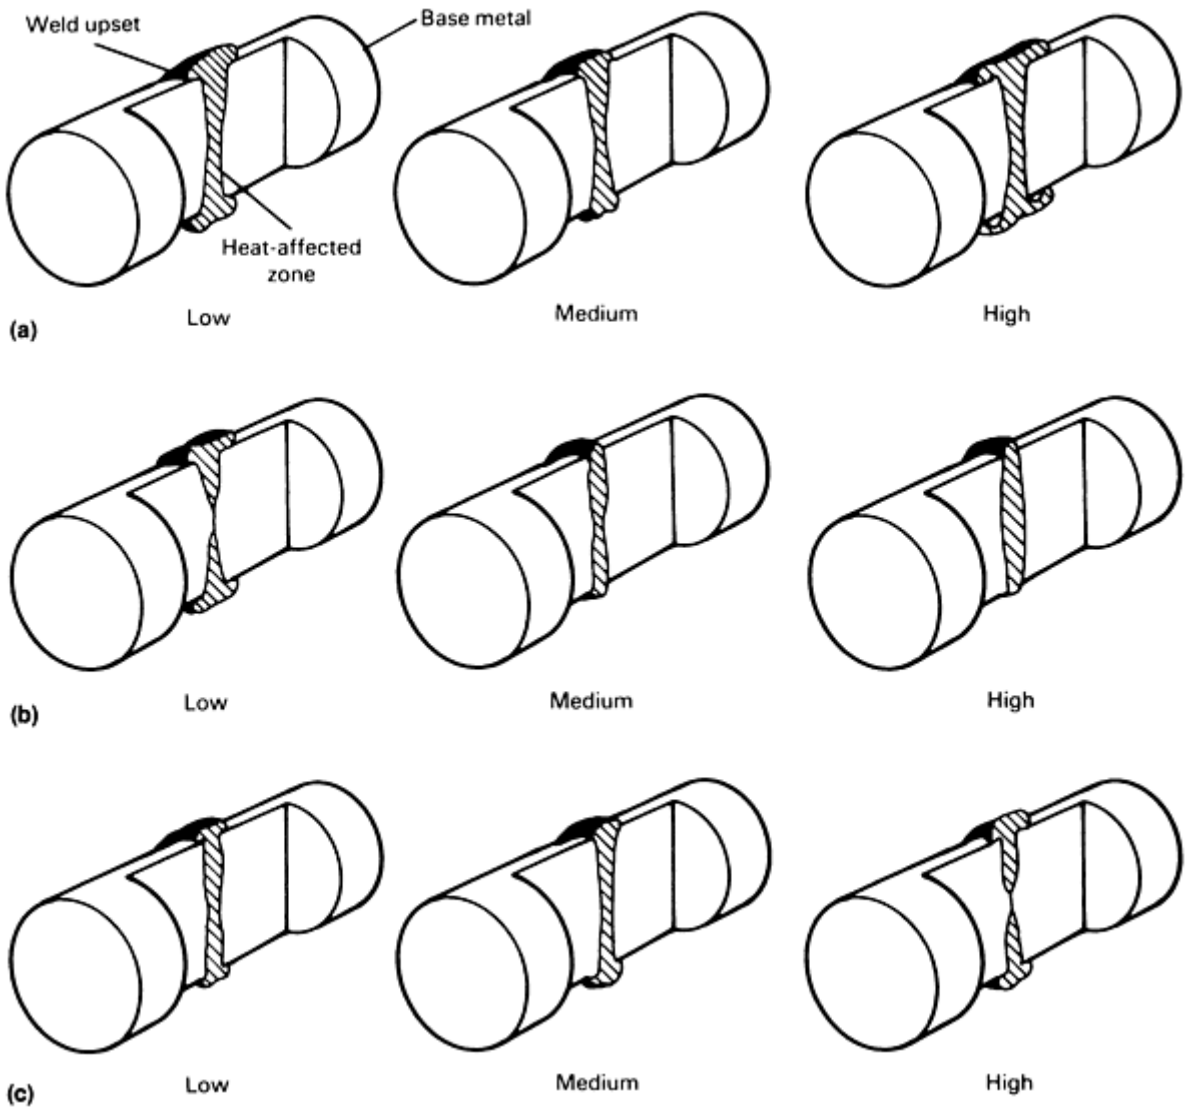

FIG. 4 SCHEMATIC SHOWING EFFECT OF WELDING PARAMETERS ON THE FINISHED WELD NUGGET OBTAINED WHEN SIMILAR METALS ARE WELDED USING INERTIA-DRIVE FRW EQUIPMENT. (A) FLYWHEEL ENERGY. (B) INITIAL PERIPHERAL VELOCITY OF WORKPIECE. (C) AXIAL PRESSURE. SOURCE: REF 7

Peripheral Velocities. There is an optimum range of peripheral or linear surface velocities for each combination of metals being joined. For welding steel to steel, the recommended initial peripheral velocity ranges from 90 to 460 m/min (300 to 1500 ft/min). However, welds can be made at velocities as low as 85 m/min (275 ft/min). Figure 4(b) shows the effect of initial peripheral velocity on weld shape for similar-metal welds.

Axial Pressure Versus Peripheral Velocities. The effect of varying the axial pressure is opposite to the effect of varying the velocity. Welds made at low axial pressure resemble welds made at medium velocity relative to the formation of weld upset and heat-affected zones (HAZ), as shown in Fig. 4(c). Excessive pressure produces a weld that has poor quality at the center and has a large amount of weld upset, similar to a weld made at a low velocity.

Fundamentals of Friction Welding

J.W. Elmer and D.D. Kautz, Lawrence Livermore National Laboratory

Metallurgical Parameters

Friction welding can be used to join a wide range of similar and dissimilar materials. Metals, ceramics, metal-matrix composites (MMC), and polymers have all been joined by FRW, and many of the dissimilar-metal combinations that cannot be joined by conventional fusion welding techniques are readily joined by FRW methods. This section summarizes some of the metals that have been joined by FRW and discusses the metallurgical considerations that govern the properties of the resulting weld.

Joining of Similar Metals

The two general requirements for forming good friction welds are, first, that the materials to be joined can be forged and, second, that the materials can generate friction at the weld interface. The first requirement eliminates similar-metal welds in brittle materials such as ceramics, cast irons, and cemented carbides. However, ductile materials can sometimes be joined to these materials. The second requirements eliminates materials that contain alloying that provide dry lubrication. Free-machining additives to steel, graphite-containing alloys such as cast iron, and lead alloys may suffer from this requirement.

Almost all other metal alloys can be welded to themselves by FRW techniques. Table 1 summarizes a number of common similar-metal weld joints that have been made using inertia-drive FRW. Metallic alloys known to form high-quality FRW joints include alloys based on aluminum, copper (copper-nickel, brass, bronze), iron (low-alloy steel, tool steel, stainless steel, maraging steel), nickel, titanium, tantalum, and many others (Ref 5, 6). Near full-strength metallurgical bonds can be produced for a very wide range of similar-metal alloy friction welds. The microstructure and mechanical properties of inertia-welded similar-metal joints for the following alloys can be found in the sources listed:

(B) TOTAL SHORTENING OF THE WORKPIECES DURING WELDING.

(C) SUM OF HEATING TIME PLUS WELDING TIME.

The relative ease of friction welding metals to themselves is related to the matching properties at the weld interface. Because the materials properties are matched, heat is distributed uniformly on both sides of the joint, and the deformation characteristics are identical on both sides of the joint. This results in symmetric welds with good properties. In general, the process variables do not vary significantly for different alloys within a given class of materials. However, there can be a significant variation in processing variables between different classes of materials (Table 1).

Because FRW generates localized heating at the interface, the HAZ is subject to rapid cooling due to heat transfer to the cold base metal. This rapid quenching may sufficiently alter the mechanical properties of the base metal in the HAZ region to require postweld heat treatment. For example, in order to restore ductility, stress relieving or tempering may be required to friction weld steels with hardenability greater than that of AISI 1035 (Ref 5, 6). In addition, age-hardenable alloys will lose strength in the HAZ during welding and may require postweld solution heat treating and/or postweld aging to restore their strength. Other alloys, such as those that obtain their strength from cold working, will lose strength in the HAZ of the weld, and their properties cannot be restored with postweld treatments.

Joining of Dissimilar Metals

While many similar-metal FRW joints are produced because of economic considerations, many dissimilar-metal FRW joints are produced because there are no alternative welding methods that can be used. Examples of these types of joints include dissimilar-metal combinations with widely different melting points and dissimilar-metal combinations that form incompatible phases when fusion welded. Table 2 gives parameters used for inertia welding several common dissimilar-material combinations.

TABLE 2 PARAMETERS FOR INERTIA-DRIVE FRICTION WELDING OF TWO 25-MM (1-IN.) DIAM BARS MADE OF DISSIMILAR METALS

Low-Carbon Steels to Medium-Carbon Steels. In general, low- and medium-carbon steels are joined to each other under a wide range of conditions, and high-carbon steels are readily joined to alloy steels (Ref 7) using friction welding. High-speed tool steels are welded to alloy steel shanks for numerous machine-tool applications. Steel with carbon contents as high as 1.0%, such as 52100 steel, can be joined to lower-carbon alloys. Preweld heat treating may be required in some cases to better match the properties at the interface, and postweld heat treatment may be required in some cases to temper the interface region of the high-carbon steel grades.

Stainless Steels to Other Selected Metals. Stainless steel alloys are comparatively easy to friction weld to other metals. For example, austenitic stainless steel to low-alloy steel (Ref 15), titanium and copper to stainless steel (Ref 16), and 1100 aluminum to stainless steel (Ref 17) are examples of transition joints that are made by FRW.

Titanium can be welded to stainless steel with extreme care (Ref 18), and other incompatible dissimilar combinations may be successfully welded using interlayer techniques (Ref 19). Figure 5 shows a micrograph of the interfacial region of an inertia weld between Monel 400 and 21-6-9 stainless steel. The joint properties are excellent, with plastic flow occurring in Monel 400 before joint failure during bend testing.

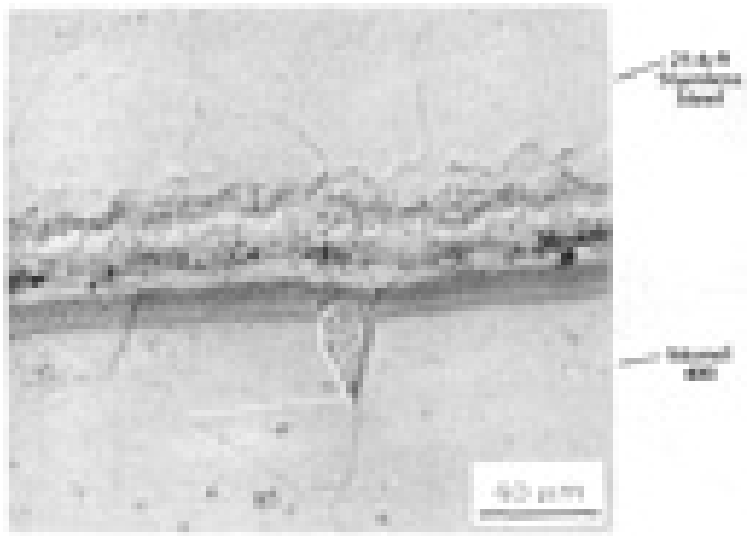

FIG. 5 METALLOGRAPHIC CROSS SECTION OF THE INTERFACE OF A MONEL 400 TO 21-6-9 STAINLESS STEEL WELD PRODUCED BY INERTIA-DRIVE FRW. NOTE THE FINE GRAIN SIZE PRESENT AT THE INTERFACE.

Such transition joints can often be used as interlayers for the friction welding of incompatible materials. For example, it is difficult to weld 5083 aluminum directly to stainless steel. However, by first friction welding aluminum alloy 1100 to the stainless steel, and machining the 1100 aluminum alloy back to an interlayer thickness of about 1 mm (0.04 in.), the 5083 aluminum alloy can be joined to the stainless steel via this 1100 interlayer with high joint efficiencies (Ref 20).

Figure 6(a) shows an example of an aluminum-base MMC that was friction welded to 1100 aluminum. The MMC is a 2024 aluminum alloy with 15 vol% Al_2O_3 particles. The interface region between these materials is shown at higher magnification in Fig. 6(b), where intermixing of both the materials is shown to occur.

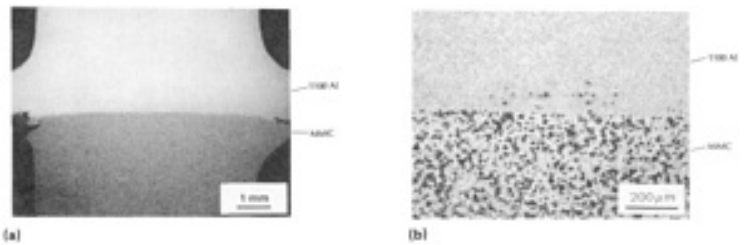

FIG. 6 CROSS SECTION OF THE INTERFACE OF A DIRECT-DRIVE FRICTION WELD JOINING 1100 ALUMINUM TO A 2024 ALUMINUM ALLOY WITH 15 VOL% AL_2O_3 PARTICLES. (B) HIGHER MAGNIFICATION OF THE SAME WELD SHOWING THE EXCELLENT WELD FORMED AT THE INTERFACE

Problems Common to Welding of Dissimilar Materials. In general, the same problems encountered when welding similar materials must be addressed when welding dissimilar materials. However, some problems are associated only with the welding of dissimilar materials or are greatly magnified during the welding of dissimilar materials. These factors include joint interfaces, low-melting phases, brittle phases, and different thermal expansions.

Joint Interfaces. While most similar-material welds are made with little concern for surface preparation, highly dissimilar-metal combinations are more sensitive. This happens for various reasons. In stainless steel to aluminum alloy welds, the oxide surface that forms on the aluminum picks up contaminants such as water and hydrocarbons, forming extremely tenacious surface layers (Ref 21). If this layer is not removed prior to welding, poor structural welds may occur. In stainless steel to refractory metal alloy welds, the oxide on the faying surfaces again contain contaminants such as water and hydrocarbons. The contaminants in this case are likely to alloy into the finished weldment. This alloying causes a reduction of structural integrity through the formation of low-melting or brittle phases at the weld interface.

Surface-treated interfaces frequently cause problems during FRW. Steels that have been carburized or nitrided, titanium alloys that have been nitrided, and other hardfaced alloys are difficult to friction weld due to the inherently low friction coefficient and low forgeability. The repeatability of welds made on materials with hard surface layers is difficult to characterize due to several factors, including coating thickness, coating quality, and physical properties of the coating. In most instances, weldability is improved if the surface-treated area is removed from the faying surface before welding.

Low-Melting Phase Formation. Some material combinations have very low melting point phases associated with mixing of constituents at the weld interface. The formation of these phases during the welding cycle is deleterious to the finished weld properties. Examples of combinations that fall into this category include iron-base alloys to titanium alloys and aluminum alloys to magnesium alloys. Low melting point eutectics are found in both of these metallurgical systems, and great care must be exercised during parameter development to prevent the formation of liquid phases during the completion of successful welds.

Other weld combinations may be affected by contaminants at the weld interface. Examples include sulfur and phosphorus in iron-base alloys and bismuth in copper alloys. These contaminants may cause problems with hot shortness in very low concentrations. It is imperative that good cleaning practices be implemented when materials may have been contaminated with these elements or with material containing these elements.

Brittle Phase Formation. Many materials, when combined, are susceptible to the formation of brittle phases. In some combinations, this occurs during the welding cycle; in others, service conditions after welding cause the problem. Two main reasons exist for brittle phase formation in friction welds:

- SURFACE CONTAMINANTS THAT EMBRITTLE THE WELD INTERFACE (SEE THE SECTION "JOINT INTERFACES" IN THIS ARTICLE)
- FORMATION OF INTERMETALLIC PHASES BETWEEN NORMAL CONSTITUENTS OF THE ALLOYS BEING WELDED

Intermetallic phase formation is common when welding refractory metal alloys to stainless steel alloys and in several other systems. In the case of stainless steels to refractory metals, σ phase or similar phases may occur upon welding at the interface. Proper weld procedure development reduces the amount of brittle phases that are formed, but typically does not eliminate their formation completely. Properly developed welds have satisfactory structural properties, because only small, noncontinuous areas of the brittle phase are present at the weld interface. Figure 7(a) shows an inertia-drive welded joint between vanadium and 21-6-9 stainless steel. The interface is smooth and shows no areas of brittle phases. Electron microscopy techniques are needed to find the small areas of σ phase present at the weld interfaces.

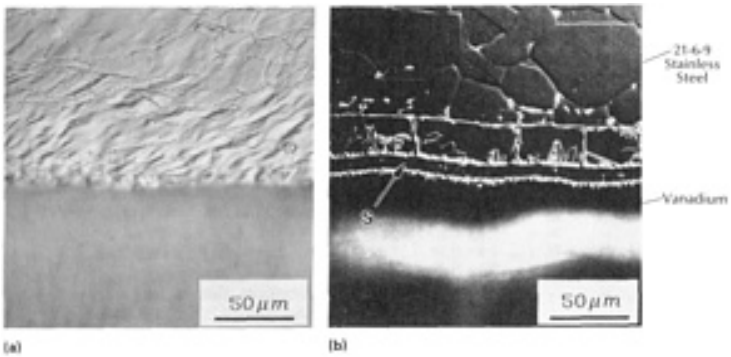

FIG. 7 METALLOGRAPHIC CROSS SECTION OF AN INERTIA-DRIVE FRW JOINT BETWEEN VANADIUM AND A 21-6-9 STAINLESS STEEL. NOTE THE EXCELLENT WELD QUALITY AT THE INTERFACE. (A) WELD INTERFACE WITH NO σ-PHASE GROWTH. (B) WELD INTERFACE WITH σ-PHASE GROWTH (INDICATED BY S) AND A SOLID-SOLUTION MIXING CAUSED BY CHEMICAL DIFFUSION AFTER EXPOSURE TO A 1000 °C (1830 °F) THERMAL CYCLE

Caution must be used when designing components for use at elevated-temperature extremes. In many instances, material combinations in which no brittle phases form during welding are susceptible to brittle phase formation at the interface during high-temperature use. This is not a design issue when the welds are used for near-room-temperature applications. Figure 7(b) shows the vanadium to 21-6-9 stainless steel inertia-drive weld after a severe thermal cycle of 1000 °C (1830 °F) for 2 h with σ-phase and solid-solution growth at the weld interface. The thick layer next to the stainless steel is a solid solution of iron and vanadium. The thin layer next to the vanadium is σphase and forms a continuous brittle fracture path across the weld interface.

Differential Thermal Expansion. Some material combinations are difficult to weld because of the large differences in thermal expansion. Low-expansion materials such as refractory metals, ceramics, and low-expansion iron-nickel and iron-nickel-cobalt alloys may fail or be highly stressed during cooling when welded to high-expansion material such as austenitic stainless steels and nickel-base and cobalt-base superalloys. Use of these combinations requires the designer to consider the large stresses developed within the fabricated structure if the welds are restrained when exposed to large temperature changes. Intermediate expansion materials and multiple friction welds may be required to allow for the transition from high to low thermal expansion materials.

Fundamentals of Diffusion Bonding

Murray W. Mahoney and Cliff C. Bampton, Rockwell International Science Center

Introduction

DIFFUSION BONDING is only one of many solid-state joining processes wherein joining is accomplished without the need for a liquid interface (brazing) or the creation of a cast product via melting and resolidification (welding). In its most narrow definition, which is used to differentiate it from other joining processes such as deformation bonding or transient liquid phase joining, diffusion bonding (DB) is a process that produces solid-state coalescence between two materials under the following conditions:

- JOINING OCCURS AT A TEMPERATURE BELOW THE MELTING POINT, T_M, OF THE MATERIALS TO BE JOINED (USUALLY $>1/2T_M$).
- COALESCENCE OF CONTACTING SURFACES IS PRODUCED WITH LOADS BELOW THOSE THAT WOULD CAUSE MACROSCOPIC DEFORMATION TO THE PART.
- A BONDING AID CAN BE USED, SUCH AS AN INTERFACE FOIL OR COATING, TO EITHER FACILITATE BONDING OR PREVENT THE CREATION OF BRITTLE PHASES BETWEEN DISSIMILAR MATERIALS, BUT THE MATERIAL SHOULD NOT PRODUCE A LOW-TEMPERATURE LIQUID EUTECTIC UPON REACTION WITH THE MATERIALS TO BE JOINED.

Thus, diffusion bonding facilitates the joining of materials to produce components with no abrupt discontinuity in the microstructure and with a minimum of deformation.

Within the confines of this definition, the DB process, in practice, is limited to either press or gas pressure or bonding approaches. Illustrations and discussions of equipment and systems are presented elsewhere within this Handbook (see the Section "Solid-State Welding, Brazing, and Soldering Processes"). This article offers a qualitative summary of the theory of diffusion bonding. For those who require a more quantitative assessment, refer to the Selected References at the end of the article.

It should be noted that the preferred term for this process, according to the American Welding Society, is diffusion *welding.* However, because diffusion *bonding* is used more commonly in industry, it is the term that will be used in this article.

Fundamentals of Diffusion Bonding

Murray W. Mahoney and Cliff C. Bampton, Rockwell International Science Center

Diffusion Bonding Process

The DB process, that is, the application of pressure and temperature to an interface for a prescribed period of time, is generally considered complete when cavities fully close at the faying surfaces. Relative agreement is found for the mechanisms and sequence of events that lead to the collapse of interface voids, and the discussion below describes these metallurgical processes. Although this theoretical understanding of the DB process is universally applicable, it should be understood that parent metal strength is only approached for materials with surface conditions that do not have barriers to impede atomic bonding such as the absence of surface oxides or absorbed gases at the bonding interface.

In practice, oxide-free conditions exist only for a limited number of materials. Accordingly, the properties of real surfaces limit and impede the extent of diffusion bonding. The most notable exception is titanium alloys, which, at DB temperatures greater than 850 °C (1560 °F), can readily dissolve minor amounts of adsorbed gases and thin surface oxide films and diffuse them away from the bonding surfaces, so that they will not impede the formation of the required metallic bonds across the bond interface, as shown in Fig. 1(a). An example of a successful diffusion bond in a titanium alloy is illustrated in Fig. 1(b), where the integrity of the bonded interfaces was demonstrated with subsequent superplastic expansion without interface failure.

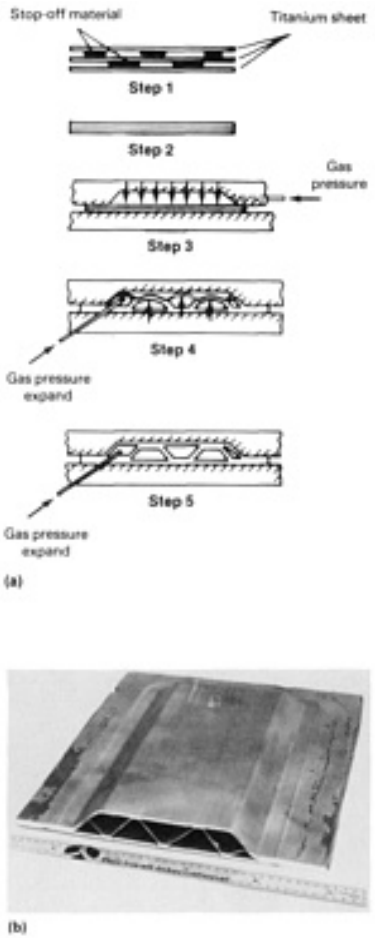

FIG. 1 SUPERPLASTIC FORMING/DIFFUSION BONDING (SPF/DB) OF TITANIUM SHEET. (A) SEQUENCE OF OPERATIONS REQUIRED TO JOIN THREE SHEETS OF SUPERPLASTIC TITANIUM ALLOY USING SPF/DB PROCESS. (B) TYPICAL THREE-SHEET TITANIUM ALLOY COMPONENT SUPERPLASTICALLY FORMED FOLLOWING DIFFUSION BONDING.

Similarly, the joining of silver at 200 °C (390 °F) requires no deformation to break up and disperse oxides, because silver oxide dissociates completely at 190 °C (375 °F). Above this temperature, silver dissolves its oxide and also scavenges many surface contaminants. Other examples of metals that have a high solubility for interstitial contaminants include tantalum, tungsten, copper, iron, zirconium, and niobium. Accordingly, this class of alloy is easiest to diffusion bond.

A second class of material, that is, metals and alloys that exhibit very low solubility for interstitials (such as aluminum-, iron-, nickel-, and cobalt-base alloys) are not readily diffusion bondable. Special consideration must be given to remove surface barriers to atomic diffusion prior to joining and subsequently prevent their reformation during the joining process. This is not an easy processing matter. Accordingly, the potential for high-strength bond interfaces for alloys with low interstitial solubility should be considered on an individual alloy basis.

Fundamentals of Diffusion Bonding

Bonding Surfaces Containing Oxides

Diffusion bonding can be achieved for materials with adherent surface oxides, but the resultant interface strengths of these materials are considerably less than that measured for the parent material. Aluminum alloys are prime examples of this class of material. Research since 1960 has demonstrated only limited diffusion bond properties. Although interface

strength can be increased for oxide-bearing materials, it requires considerable surface extension of the faying interfaces to create localized plastic flow of the metal and concurrent oxide breakage. This introduces an increased number of locations for metal-to-metal contact via plastic flow around or microextrusion through the broken oxide. In general, the oxide is not removed, but is simply dispersed over a greater surface area in an enclosed environment, in which oxidation cannot recur. Thus, even with significant surface deformation, only a fraction of the interface area contributes to the strength of the bond. The proportion of oxide-free metallic area revealed is dependent on the relative hardness of the metal and its oxide film, as well as on the mechanical properties of the oxide. This type of bonding, although often considered as diffusion bonding, is better described as deformation bonding and does not fit within the strict definition of the low deformation associated with diffusion bonding.

Factors that affect the relative difficulty of diffusion bonding oxide-bearing surfaces include:

- *SURFACE ROUGHNESS PRIOR TO WELDING.* A ROUGHER SURFACE WILL RESULT IN GREATER SHEAR DEFORMATION.
- *MECHANICAL PROPERTIES OF THE OXIDE.* THE MORE BRITTLE THE OXIDE, THE GREATER THE DISPERSION FOR A GIVEN LEVEL OF DEFORMATION.
- *RELATIVE HARDNESS OF THE METAL AND ITS OXIDE FILM.* BECAUSE PLASTIC FLOW CONTROLS THE AMOUNT OF BONDING AREA, LARGE DIFFERENCES IN THEIR HARDNESS SHOULD FACILITATE BONDING.
- *PRESTRAINING OR WORK HARDENING OF THE MATERIAL.* INITIATION OF BONDING WILL OCCUR AT LOWER DEFORMATIONS FOR PRESTRAINED OR WORK-HARDENED MATERIALS, AND THE DEGREE OF SURFACE EXTENSION IN THE CENTRAL REGION OF THE INTERFACE IS CONSIDERABLY GREATER FOR COLD-WORKED MATERIAL. THUS, ANNEALED MATERIAL REQUIRES A LARGER TOTAL DEFORMATION BEFORE BONDING WILL INITIATE.

It is clear that with the appropriate information, sufficient experiments can be performed to determine the diffusion bondability of most materials. Parent metal strength will not always be attained using the DB approach, particularly for materials with adherent oxides, but interface strength can be maximized if the fundamentals of the process are understood.

Fundamentals of Diffusion Bonding

---

Mechanism of Diffusion Bonding

In diffusion bonding, the nature of the joining process is essentially the coalescence of two atomically clean solid surfaces. Complete coalescence comes about through a three-stage metallurgical sequence of events. Each stage, as shown in Fig. 2, is associated with a particular metallurgical mechanism that makes the dominant contribution to the bonding process. Consequently, the stages are not discretely defined, but begin and end gradually, because the metallurgical mechanisms overlap in time. During the first stage, the contact area grows to a large fraction of the joint area by localized deformation of the contacting surface asperities. Factors such as surface roughness, yield strength, work hardening, temperature, and pressure are of primary importance during this stage of bonding. At the completion of this stage, the interface boundary is no longer a planar interface, but consists of voids separated by areas of intimate contact. In these areas of contact, the joint becomes equivalent to a grain boundary between the grains on each surface. The first stage is usually of short duration for the common case of relatively high-pressure diffusion bonding.

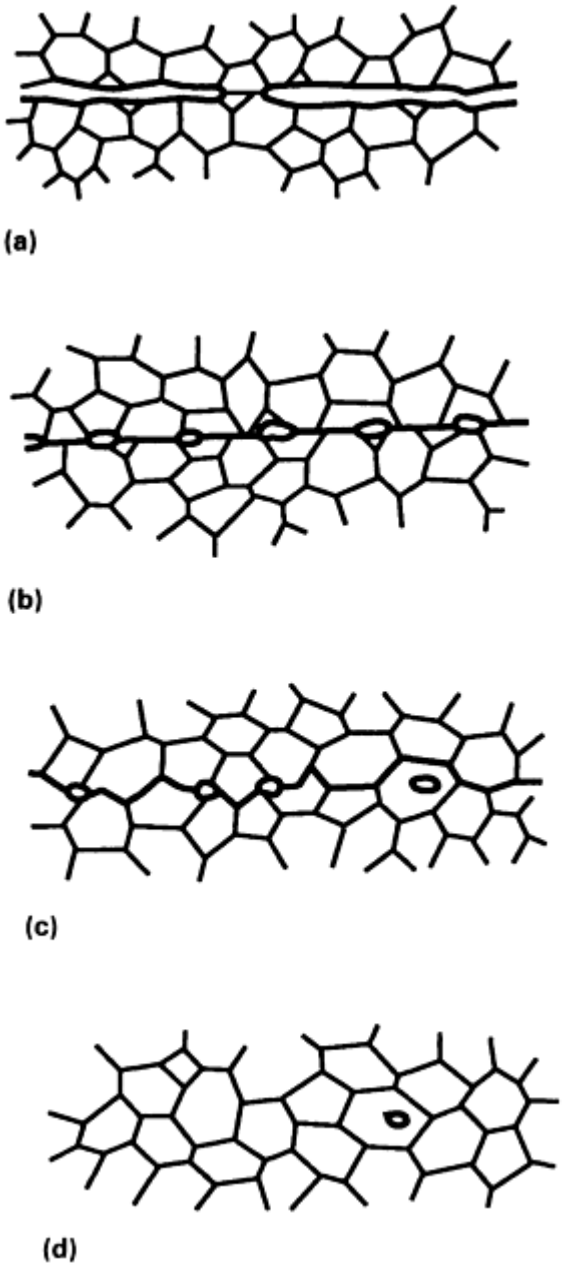

FIG. 2 SEQUENCE OF METALLURGICAL STAGES IN DIFFUSION BONDING PROCESS. (A) INITIAL CONTACT: LIMITED TO A FEW ASPERITIES (ROOM TEMPERATURE). (B) FIRST STAGE: DEFORMATION OF SURFACE ASPERITIES BY PLASTIC FLOW AND CREEP. (C) SECOND STAGE: GRAIN BOUNDARY DIFFUSION OF ATOMS TO THE VOIDS AND GRAIN BOUNDARY MIGRATION. (D) THIRD STAGE: VOLUME DIFFUSION OF ATOMS TO THE VOIDS

During the second stage of joint formation, two changes occur simultaneously. All of the voids in the joints shrink, and most are eliminated. In addition, the interfacial grain boundary migrates out of the plane of the joint to a lower-energy equilibrium. Creep and diffusion mechanisms are important during the second stage of bonding and for most, if not all, practical applications, bonding would be considered essentially complete following this stage. As the boundary moves, any remaining voids are engulfed within grains where they are no longer in contact with a grain boundary. During this third stage of bonding, the voids are very small and very likely have no impact on interface strength. Again, diffusional processes cause the shrinkage and elimination of voids, but the only possible diffusion path is now through the volume of the grains themselves.

Stage I: Microasperity Deformation

The nature of the starting surface is of considerable importance, because of the small macroscopic deformation allowed during diffusion bonding. A real surface is never perfectly clean or perfectly smooth, and the area of metal-to-metal contact between faying surfaces is a very small fraction of the area of joint contact. Contact is limited to a relatively few microasperities. At room temperature and under load, these asperities deform as long as the surface area of contact is such that the yield strength of the material is exceeded. The extent of this deformation is limited at room temperature, and is even more limited for work-hardenable materials. As temperature increases to the diffusion bonding temperature, the flow stress of the material decreases and additional asperity deformation occurs through plastic flow. Again, flow occurs until the area of contact increases to an extent that the yield strength of the material is exceeded. If the temperature is above the recrystalization temperature of the material, then work hardening is no longer a consideration. With time at temperature, creep mechanisms now control the rate of asperity deformation, and the area of contact or bond continues to grow. As the area of contract grows, the stress acting on the surface asperities decreases. Consequently, creep deformation progressively slows and diminishes in significance.

The contributions of temperature and pressure to both plastic and creep deformation during this initial stage of diffusion bonding are synergistic, that is, at higher temperatures, less pressure is required and vice versa. However, for any combination of temperature and pressure, bulk deformation to the part is limited to a small percentage (<2 to 3%). Ideally, at the completion of the first stage, the extent of asperity collapse should result in a planar area of contacting surfaces with individually dispersed voids. It is necessary to achieve this extend of contact in order to complete the final stages of diffusion bonding in a reasonable period of time.

For example, Fig. 3 illustrates the influence of pressure on the bond line morphology for a titanium alloy. At lower pressures, where surface asperity deformation is less during the first stage of bonding, large voids remain at the interface, even after a reasonable time at temperature. Conversely with a higher applied pressure and a correspondingly greater initial interface deformation, the bond interface becomes indistinguishable from the matrix alloy. It should be remembered that, by definition, very little bulk deformation is allowed and that only interface microdeformation contributes to the growth in contact area of the faying surfaces.

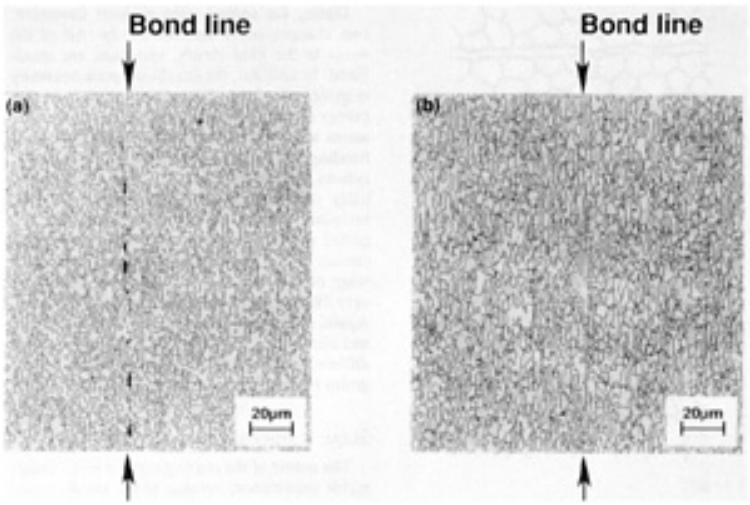

FIG. 3 EFFECT OF PRESSURE ON PRESENCE OF VOIDS AT BAND INTERFACE OF TITANIUM ALLOY DIFFUSION BONDED AT TEMPERATURES OF 980 °C (1795 °F) FOR 2 H. (A) INCOMPLETE BOND AT 7.0 MPA (1.0 KSI). (B) COMPLETE BOND AT 10.0 MPA (1.5 KSI)

Surface Roughness. When considering the sequences in the stages of diffusion bonding, it is clear that the original surface finish plays a significant role in the time dependency for the completion of the different stages. The surfaces that are mated at the bond line are usually rather irregular, as a result of the machining or other surface preparation steps. As shown in Fig. 4, the surface roughness can be viewed as a bimodal distribution of asperities, that is, small, short-wavelength asperities (surface roughness) arrange on larger, long-wavelength asperities (surfaces waviness).

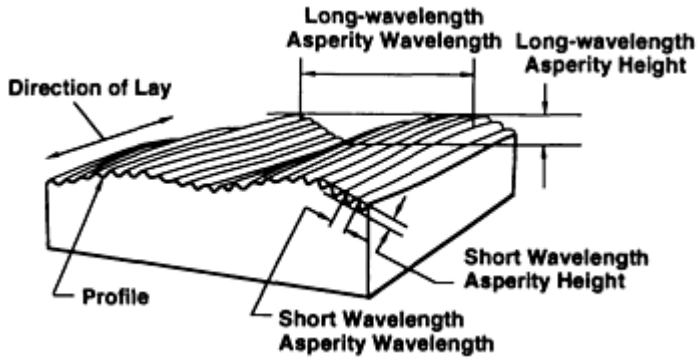

FIG. 4 BIMODAL TOPOGRAPHY OF MECHANICAL SURFACES

It is expected that during the first bonding stage, a more uneven initial surface that is due to either roughness or waviness would produce more large voids than would a smooth initial surface. For example, as load is applied, asperities on rough surfaces will experience higher stresses on the points of contact. Plastic flow will occur at a lower load, and greater interface shear will occur. Although first-stage plastic flow and creep will create more localized interface deformation for a rough surface, fewer but larger voids will remain at the interface (the contact area should approach an equilibrium value independent of the initial surface roughness). In addition to size, the shape and curvature of the voids would be considerably different, with higher aspect ratio voids for the rougher starting surfaces. For the subsequent diffusion-controlled collapse of interface voids during second-stage bonding, an initially rough surface will require a longer time or higher temperatures for the mass-transport processes to shrink and eliminate the voids.

Conversely, because real surfaces are not perfectly clean, some limited degree of interface deformation is necessary for the diffusion bonding of even oxide-free materials. Experimental evidence has demonstrated that even gold is not joined unless some shear displacement occurs as the two faying surfaces come into contact. It seems that the importance of the shear displacement, besides increasing the contact area, is that it destroys the continuity of any adsorbed oxygen layer that can contaminate the oxide-free area because of trapped air at the interface. Procedures as simple as wire brushing have been shown to be a particularly effective surface preparation. This can be partly attributed to the creation of rough layers on the surface.

Stage II: Diffusion-Controlled Mass Transport

The densification or collapse of interface cavities during the second stage of diffusion bonding is attributable to the lowering of the surface free energy by the decrease in surface area. This takes place with the formation of new, but lower-energy, solid-solid interfaces. Because the driving force is the same (reduction of surface energy) for all systems, the considerable differences in behavior in various types of systems are related to the different mechanisms of material transfer.

In diffusion bonding, a number of mass-transport processes are operative simultaneously, including time-dependent plastic flow, diffusion from the interface to the cavity via the lattice and the interface and grain boundaries, and diffusive flow around the surface of the void via the lattice and vapor phase. These different paths of mass transfer are illustrated in Fig. 5 and include:

- PLASTIC YIELDING THAT DEFORMS AN ORIGINAL CONTACTING ASPERITY
- SURFACE DIFFUSION FROM A SURFACE SOURCE TO A NECK
- VOLUME DIFFUSION FROM A SURFACE SOURCE TO A NECK
- EVAPORATION FROM A SURFACE SOURCE TO CONDENSATION AT A NECK
- GRAIN BOUNDARY DIFFUSION FROM AN INTERFACIAL SOURCE TO A NECK
- VOLUME DIFFUSION FROM AN INTERFACIAL SOURCE TO A NECK
- POWER-LAW CREEP

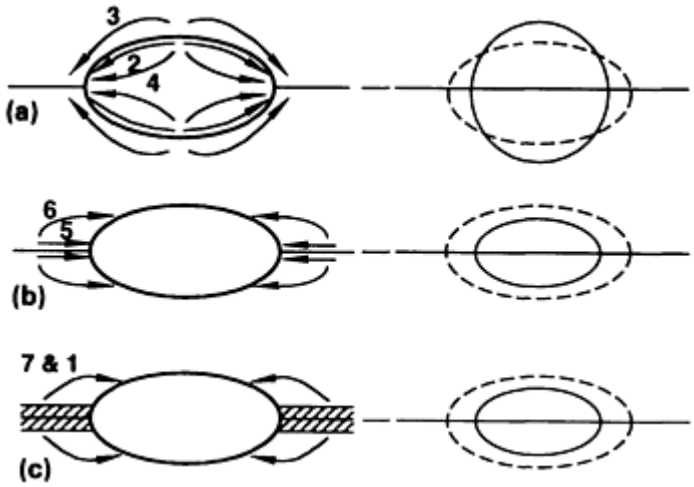

FIG. 5 SCHEMATIC OF NUMEROUS PATHS OF MATERIAL TRANSFER GENERATED DURING DIFFUSION BONDING PROCESS. (A) SURFACE SOURCE MECHANISMS. (B) INTERFACE SOURCE MECHANISMS. (C) BULK DEFORMATION MECHANISMS. SEE TEXT FOR SPECIFIC MECHANISMS INDICATED BY NUMBERS SHOWN IN SCHEMATIC.

Although vapor transport and surface transport of matter change the shape of the void, they do not directly alter the volume. Thus, these transport paths have only a secondary influence on the rate of void collapse indirectly, through a change in void curvature. Only the transfer of matter from the matrix volume or from grain boundaries causes shrinkage and pore elimination. Thus, only the first two mechanisms, plastic flow and interface diffusion, actually reduce the volume of the interfacial voids. The dominance of either of these two processes is dependent on many inseparable factors, including material system, void geometry, microstructure, and bonding parameters.

When considering diffusion, evidence seems to suggest that the most efficient path for atom flow and counterdiffusing vacancies is along the interfacial grain boundary and along grain boundaries that intersect the void when the grain size is less than the pore size. Although the area of a grain boundary is small in comparison to the void surface, this high-diffusivity path has been shown to dominate. For example, bonding has been shown to be enhanced by first blasting the faying surfaces with chilled iron grit. This treatment promoted recrystallization and, thus a finer grain size across the interface, creating additional high-diffusivity paths. In a related process (the sintering of Al_2O_3), porosity was shown to be eliminated next to grain boundaries, with residual porosity remaining at grain centers. Similarly, fine grain size, as exists in superplastic alloys, should create higher rates of void coalescence via grain boundary diffusion. However, because the chemical potential driving force for grain boundary diffusion mechanisms is partly dependent on the angle between the applied pressure and a particular grain boundary, its actual contribution will be dependent on its precise orientation with respect to the applied pressure. The driving force will be maximal when the two are perpendicular and minimal when they are parallel.

Although there is insufficient evidence for generalization, evidence also exists to illustrate that diffusion is, at times, the rate-controlling factor for void coalescence. For example, maintaining temperature while removing pressure following the first bonding stage was shown to not significantly impede the joining process. The rate of void elimination was only slightly slower without the applied pressure. However, this change in rate could be due to either the lost contribution that deformation makes to void coalescence or a reduction in efficiency of the stress-enhanced grain boundary contribution.

Stage III: Interface Migration

During the second stage of diffusion bonding, voids become much smaller and many are eliminated. Their grain boundary pinning influence decreases, so that interfacial grain boundary migrates toward an equilibrium configuration, which is indistinguishable from the other grain boundaries in the microstructure. The driving force for the boundary migration is the reduction in grain boundary area. The initially straight interfacial bond line becomes distorted with local penetrations of a few microns of one material into the other at triple points. As the boundary moves, any remaining voids become enclosed within grains where they are no longer in contact with a grain boundary. Diffusional processes continue to shrink and eliminate these cavities, but the diffusion path is now restricted to volume diffusion through the matrix lattice.

Accordingly, the elimination of this final small volume of porosity would be likely to contribute an inordinate time to the bonding process for any interface strength benefits that might be achieved.

Diffusion Bonding with Interface Aids

Additional layers of material in the form of coatings or foils are often used as bonding aids for a variety of reasons. For example, an intermediate material can be used when joining dissimilar materials where a brittle intermetallic would otherwise form. In this case, the interfacial material would be selected for its compatibility with each of the materials to be joined and for its ability to prevent the creation of a brittle reaction layer. To promote diffusion in materials that contain elements with low diffusivities, the interfacial material should contain an element with a higher mobility than elements found in the joined materials. A common material for such applications is electroless nickel, which contains phosphorus (phosphorus has been shown to have a high diffusivity in other metallic systems). However, caution should be exercised when considering the addition of high-diffusivity elements, because of their potential for accumulation at grain boundaries and their resultant influence on mechanical properties.

Another approach is to add an interfacial material that will scavenge impurity elements at the interface and thus produce clean surfaces *in situ.* Materials with high solubilities for interstitial elements, such as titanium alloys, can be appropriate for this purpose. Because of the importance of localized plastic flow at the interface, a soft material addition can also be of benefit to maximize interfacial contact during the first bonding stage, where deformation mechanisms dominate.

With the addition of interfacial materials, geometric as well as metallurgical considerations become important. The mechanical strength of solid-state metallic bonds achieved with a thin interfacial layer of bonding material goes through a maximum, with decreasing joint thickness. For thick joints, tensile strength is directly related to the bulk properties of the interfacial layer material. As joint thickness decreases, the tensile strength of these joints increases, because of the matrix material restraint on the plastic flow of the interfacial layer. However, for very thin joints, the problems of surface roughness and cleanliness start to diminish the contact area and, thus, effectively reduce the joint tensile strength. experimental studies should be performed for individual materials. In general, thicknesses of approximately 0.025 mm (0.00098 in.) yield maximum interface strengths.

Fundamentals of Explosion Welding

R. Alan Patterson, Los Alamos National Laboratory

Introduction

EXPLOSION WELDING (EXW), also known as explosive bonding, is accomplished by a high-velocity oblique impact between two metals. The impact must have sufficient energy to cause the colliding metal surfaces to flow hydrodynamically when they intimately contact one another in order to promote solid-state bonding. Oblique impact is important because conservation of momentum allows for a reentrant jetting action that is due to hydrodynamic flow of the faying metal surfaces. The jet is ejected outward from the collision apex between the metals and produces a cleaning action by scarfing or effacing the metal surfaces. The resulting virgin metal surfaces are then compressed together under high pressure from the explosion, which promotes atomistic bonding.

This phenomenon was first observed during World War I, when fragments from bombs or shells were often found to be welded to surrounding metal structures (Ref 1). The first publication to recognize the potential for generating metallic welding by using explosively driven plates appeared in 1944 (Ref 2). The first explosive bonding patent associated with the commercial application of the technique was issued in 1962 (Ref 3).

The most beneficial attribute of the technique is that dissimilar metal systems can be bonded even when conventional fusion welding techniques are metallurgically inappropriate, because of the formation of intermetallic compounds. Applications of explosive bonding are diverse and include the production of sandwiched metal for coinage (1965 to 1971), the more-sophisticated use of titanium-to-stainless steel transition joints in the Apollo spacecraft (Ref 4), and the use of aluminum-to-steel transition joints in ships. The most common utilization of explosive bonding is the production of clad metals for the purpose of corrosion resistance and for transition joints that are used to aid dissimilar metal welding. Practical applications of explosive bonding are addressed in greater detail in the article "Explosion Welding" and the Section "Procedure Development and Practice Considerations for Solid-State Welding" in this Volume.

It should be noted that the discussion in this article is restricted to the "parallel gap" explosive bonding technique. Several other bonding geometries that are fundamentally similar to the geometry of the parallel gap technique are utilized in a variety of other techniques. For example, the "preset angle" bonding technique is used to produce flat-plate clads.

Circumferential techniques are used to produce tube-to-tube welds or tubular clads. Spot welding and seam welding techniques, as well as others, are also used in certain situations. All of these techniques require the jet to travel in a straight line between the two metal surfaces (see the section "Flyer Plate Acceleration" in this article).

Several very good reviews of the explosive bonding process have been published (Ref 4, 5, 6, 7, 8). These articles should be used to augment the information presented here. This article attempts to describe the practice of producing an explosive bond/weld and draws on many previous research results in order to explain the mechanisms involved.

Fundamentals of Explosion Welding

R. Alan Patterson, Los Alamos National Laboratory

Bonding Practice

Figure 1 shows the arrangement used in the parallel gap explosive bonding process. The explosive charge is placed in contact with the top plate, hereafter called the flyer plate. The explosive detonation is initiated from one end to generate a linear detonation front, which runs along the flyer plate length. Pressure generated by the expansion of the explosive products accelerates the flyer plate downward at the point where the explosive is reacting and results in the desired impact on the stationary base plate. The principal parameters that affect bond success with this arrangement are:

- DETONATION VELOCITY AND ENERGY, WHICH ARE CHARACTERISTICS OF THE EXPLOSIVE USED AND RESULT IN FLYER PLATE ACCELERATION
- IMPACT ENERGY, WHICH IS A FUNCTION OF THE FLYER PLATE STANDOFF DISTANCE, THE DETONATION ENERGY, AND THE ENERGY TRANSFER CHARACTERISTICS
- DYNAMIC BEND ANGLE AND THE PHYSICAL AND MECHANICAL PROPERTIES OF THE METAL CONSTITUENTS

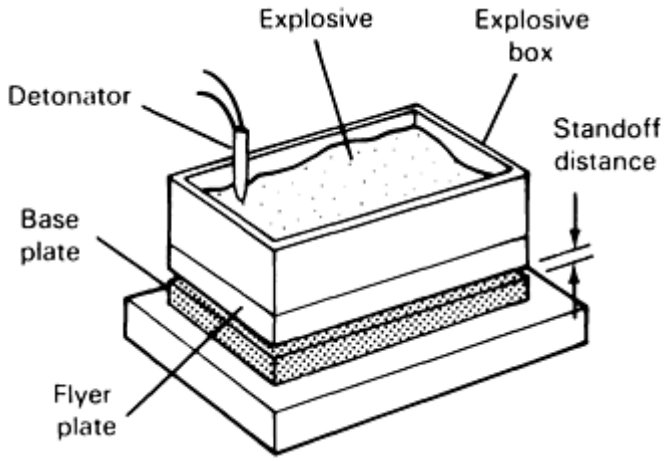

FIG. 1 SCHEMATIC SHOWING KEY COMPONENTS USED IN THE PARALLEL GAP EXPLOSIVE WELDING PROCESS

Flyer Plate Acceleration

Figure 2, an intermediate view of the explosive bonding process, shows an idealization of the metal deformation that results after explosive detonation. Flash radiography performed during the bonding process has been used to develop this pictorial representation (Ref 6, 7). The energy produced by detonating the explosive results from a very rapid expansion of detonation products, which impacts an acceleration to the flyer plate and maintains a high-pressure region in the atmosphere behind the detonation front (Ref 1). Rapid flyer plate acceleration results in a dynamic bending action (Fig. 2). The dynamic bend angle, β, results in an oblique impact between the flyer and base plates, which promotes the hydrodynamic flow of the metal surfaces and a resulting jetting actions.

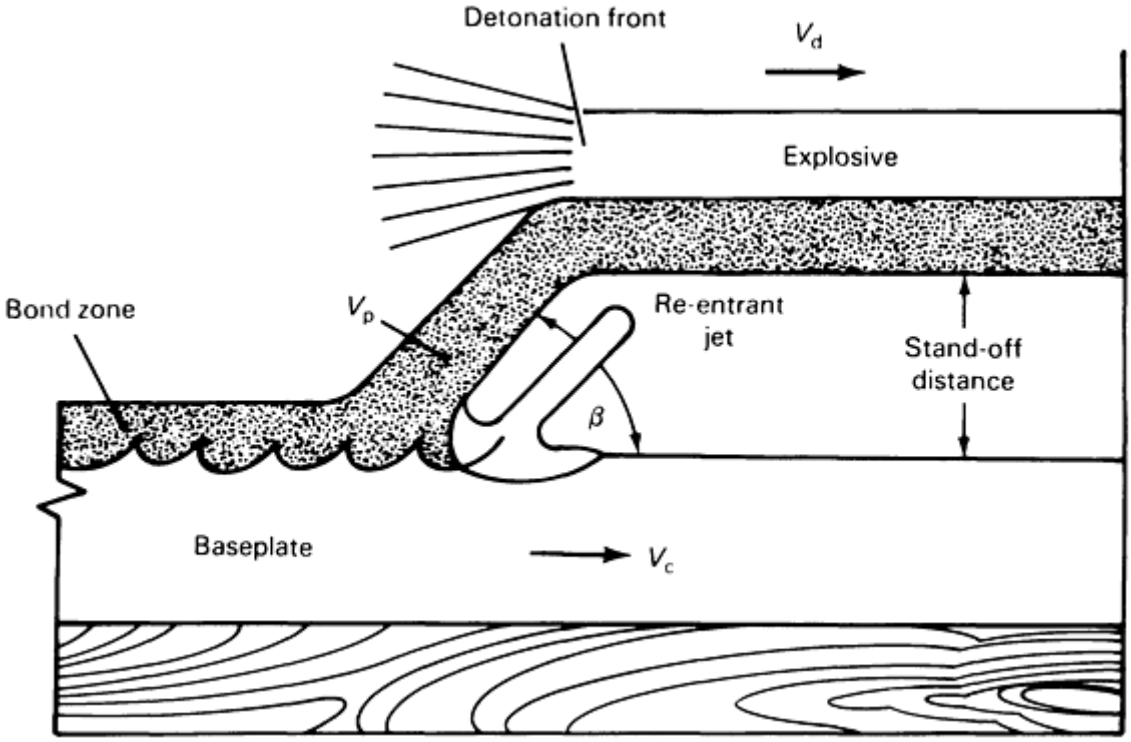

FIG. 2 SCHEMATIC SHOWING AN IDEALIZED VIEW OF THE FLYER PLATE DEFORMATION AND IMPACT RESULTING FROM A MOVING EXPLOSIVE DETONATION FRONT

Conservation of momentum is used to describe the bonding mechanism in which three velocity vectors are of primary importance. The detonation velocity, V_d, is a characteristic of the explosive and is generally directly proportional to the explosive density. From the geometry of the system, it is obvious that the collision point between the impacting metals propagates at the same speed as the explosive detonation front. The collision-point velocity is represented by V_c in Fig. 2. The flyer plate velocity, V_p, can be calculated based on an energy balance and conservation of momentum (Ref 9).

Impact Energy

Impact energy is generally assumed to equal the maximum kinetic energy that is due to the acceleration of the flyer plate. In simpler terms, it is assumed that the flyer plate has been accelerated to the terminal velocity as calculated from models like that proposed by Gurney (Ref 9), and that no deceleration occurs because of atmospheric interference. Furthermore, energy loss that is due to the bending strain energy in the flyer plate has been ignored in much of the earlier literature, because of its complexity. Recent estimates of energy partitioning suggest that only 15 to 20% of the flyer plate energy is used for cladding, whereas 66% is absorbed in flyer plate forming and 15% is dissipated as excess energy in the base plate (Ref 10, 11). The flyer plate standoff distance is therefore a very important factor, because it physically limits the flyer plate acceleration and dynamic bend angle.

Simple determinations of flyer plate standoff distance resulting from empirical testing are often used. Carpenter *et al.* (Ref 10) state that the standoff distance should be small enough to allow continuous acceleration of the flyer plate. Standoff distances that are twice the flyer plate thickness for thin components (up to 6.5 mm, or 0.26 in.) and are equal to the flyer plate thickness for thicker components (up to 13 mm, or 0.5 in.) are generally used (Ref 12). Other studies have indicated that a uniform flyer plate velocity is obtained with a separation distance equal to only a few multiples of the flyer plate thickness (Ref 13, 14, 15). Wolf *et al.* (Ref 16) performed a systematic evaluation of standoff distance and dynamic bend angle, which indicated that:

- A LAMINAR BOND WAS ACHIEVED AT DISTANCES EQUAL TO APPROXIMATELY HALF THE FLYER PLATE THICKNESS
- A STABLE WAVY BOND ZONE WAS PRODUCED AT INTERMEDIATE STANDOFF DISTANCES EQUAL TO 1.0 TO 1.5 TIMES THE FLYER PLATE THICKNESS
- DELAMINATION OCCURRED AT DISTANCES ABOVE TWO TIMES THE FLYER PLATE THICKNESS

Dynamic Bend Angle and Material Properties

Attempts to correlate bonding success to starting material properties have been extremely difficult, because most material property compilations are determined at ambient conditions and do not account for the high strain rates associated with explosive conditions. Rules of thumb often dominate. Carpenter *et al.* (Ref 10) indicated that materials exhibiting tensile ductilities greater than 5% will survive the bending associated with the flyer plate acceleration. It is also generally recognized that the material with the lowest density and tensile yield strength should be used as the flyer plate material. However, brittle materials (for example, refractory metals such as molybdenum and tungsten) have been explosively bonded by elevating the metal temperature above the ductile-to-brittle transition temperature (DBTT) (Ref 17).

Some correlations between initial material properties and the minimum dynamic bend angle, β_{min}, that is required to achieve the desired shear deformation to promote jetting and bonding success have been reported (Ref 18, 19). The suggested relationship between flyer plate hardness, H_v; density, ρ; and the collision-point velocity, V_c, is given by:

$$b_{\min} = k\left(\frac{H_v}{rV^2_c}\right) \qquad \textbf{(EQ 1)}$$

Fundamentals of Explosion Welding

R. Alan Patterson, Los Alamos National Laboratory

Fundamentals of Bonding

Several important concepts pertaining to the explosive parameters, hydrodynamic flow, jetting, and metal properties were discussed above. The following discussion summarizes the criteria used to model the explosive bonding process.

Explosive Parameters and Shock Effects

Although many different types of explosives have been used for explosive bonding, those that have a broad range of low-detonation velocities are the most appropriate, because fo the deleterious effects of shock rarefaction. Shock fronts are described by a sharp discontinuity in pressure on one side of the transmitting medium where the violent motion that is due to high pressure is separated from a near-quiescent state in the unaffected material (Ref 1). This condition can produce tensile stresses of sufficient magnitude to fracture the explosive bond. Shock waves are not pronounced unless the velocity of the shock front exceeds the sonic velocity of the transmitting medium. Sonic velocity is defined as:

$$U_s = \sqrt{\frac{E'}{r}} \qquad \textbf{(EQ 2)}$$

where U_s is the sonic velocity, E is the appropriate elastic modulus, and ρ is the material density. If the shock wave propagation does not exceed the sonic velocity, then a broadening of the shock front occurs and the magnitude of resultant stress and stress gradients is greatly reduced. Because most metals have a sonic velocity that ranges from 2000 to 6000 m/s (6600 to 20,000 ft/s), it is desirable to use explosives with detonation velocities within this range. Carpenter *et al.* (Ref 10) indicate that explosives with detonation velocities greater than 120% of the sonic velocity of the metal should not be used.

Detonation velocity is a characteristic of the type of explosive and has been shown to be directly proportional to the explosive density. This proportionally is shown in Eq 3, as derived empirically for nitroguanidine explosive (Ref 13):

$$V_D = 1440 + 4020\rho_E \qquad \textbf{(EQ 3)}$$

where V_d equals the detonation velocity and ρ_e is the explosive density. The typical operating range for nitroguanidine is from 2000 to 5000 m/s (6600 to 16,000 ft/s), which corresponds to explosive densities that range from 0.14 to 0.9 g/cm^3 (0.0051 to 0.033 lb/in.^{3}).

The explosive pressure, P, is also proportional to the explosive density, ρ_e, as shown by the Bernoulli equation:

$$P \propto V_d^2 \rho_E \qquad \textbf{(EQ 4)}$$

Flyer plate velocities can be calculated from models like that presented by Gurney (Ref 9), who assumed that the driven metal was accelerated perpendicular to the direction of the detonation propagation and used a specific energy with a characteristic value for each explosive (the Gurney energy). Kennedy (Ref 20) gave a very good explanation of the Gurney model, along with several reconstructions of the Gurney equation, to account for changes in geometry. The equation that is applicable to the parallel gap explosive bonding technique is:

$$V_p^2 = 2E' \frac{3}{\left[1+5+\left(\frac{m}{c}\right)+4\left(\frac{m^2}{c^2}\right)\right]} \qquad \textbf{(EQ 5)}$$

where V_p is the flyer plate velocity, E' is the Gurney energy, m is the flyer plate mass, c is the explosive mass, and m/c is the explosive load factor.

Once the flyer plate and detonation velocities are known, it is a simple matter to define the dynamic nature of the flyer plate bend angle through geometry. The following equation holds for the parallel gap geometry illustrated in Fig. 1 and 2:

$$V_p = 2V_d \sin\left(\frac{b}{2}\right) \qquad \textbf{(EQ 6)}$$

where V_p and V_d are the velocities defined in Eq 5 and 6, respectively, and β is the flyer plate dynamic bend angle.

Equations 1, 2, 3, 4, 5, and 6, as well as an understanding of the metal physical-mechanical properties, are the basis for most models developed for explosive bonding. These models are discussed below in general terms, beginning with a description of jetting phenomena, followed by a description of bonding and the methods used to define explosive parameter boundaries that will produce acceptable bonds.

Jet Formation

During World War II, it was discovered that a hollowed explosive charge lined with metal could be used to produce a high-energy jet to perforate armor plate. Several investigators (Ref 21, 22, 23) have described the limiting conditions for the formation of jets in high-velocity collisions. Walsh *et al.* (Ref 22) indicated that a critical impact angle must be exceeded before jetting will occur. On the other hand, Cowan and Holtzman (Ref 23) indicated that for subsonic collisions, the elastic strength of the metal must be exceeded before jetting will occur. In both cases, jetting is described

by a hydrodynamic flow of the metal surfaces. Walsh *et al.* (Ref 22) presented equations based on this principle and the "equations of state," which enable a calculation of the critical angle for jetting.

Kowalick and Hay (Ref 24) reported an experimental technique to evaluate both the critical angle for jetting and the morphological changes in explosion bonds resulting from changes in collision angle. The experimental setup consisted of the normal flyer plate arrangement used in the parallel gap technique, but with the base plate replaced by a half cylinder. Each bonding trial produced continuously changing flayer plate collision angles that resulted in surface deformation and bond morphology variations. This analysis expands upon the work of previous researchers by evaluating the geometry of fluid flow, jetting, and their effects on bond morphology.

Laminar fluid flow (low collision-point velocity and low Reynolds numbers) was correlated with direct bonding and a very flat bond interface. Turbulent fluid flow was separated into two regimes:

- AT INTERMEDIATE COLLISION-POINT VELOCITIES, THE FLOW WAS DESCRIBED BY VORTICE FORMATION INTO A VON KARMAN VORTEX STREET AND THE PRODUCTION OF A WAVY BOND INTERFACE
- AT HIGH COLLISION-POINT VELOCITIES, THE FLOW WAS DISTURBED BY A DISORDERING OF THE JET WAKE, WHICH LED TO A MOLTEN LAYER BOND INTERFACE.

Selection of Bonding Parameters

The preceding discussion introduced the primary variables used to predict explosive bonding parameters. The following four conditions are used to define a window of acceptable bonding parameters:

- CRITICAL ANGLE FOR JETTING (REF 25)
- CRITICAL FLOW TRANSITION VELOCITY (REF 23, 24)
- MINIMUM FLYER PLATE IMPACT FOR JETTING, BASED ON ANALYSIS OF THE STRESS REQUIRED TO CAUSE FLOW
- MAXIMUM FLYER PLATE IMPACT FOR THE LIMITATION OF WELD DEFECTS, BASED ON JET ENTRAPMENT (REF 23)

The critical angle for jetting is used to define the upper boundary for collision-point velocities. The lower limit in collision velocity is determined by the transition from laminar to turbulent flow, where turbulent flow is preferred (Ref 23). The other two limiting conditions are specified by using the physical and mechanical properties of the material to determine the maximum amount of energy required to either produce hydrodynamic flow (that is, overcome a critical shear stress) or avoid extensive melting. Once the correct set of explosive parameters has been determined by utilizing either predictive models or an empirical approach, the production of explosively welded metal is a relatively simple task.

Bond Morphology and Properties

In the discussion of the Kowalick and Hay (Ref 24) experiment, reference was made to three types of bond morphologies:

- LAMINAR INTERFACE, OR FLAT BOND
- WAVY INTERFACE
- MOLTEN LAYER INTERFACE

A typical clad trilayer that contains a mixture of wavy interface morphology (with melt pockets decorating each wave crest) and laminar interface (with fairly uniform melt entrapment) is shown in Fig. 3.

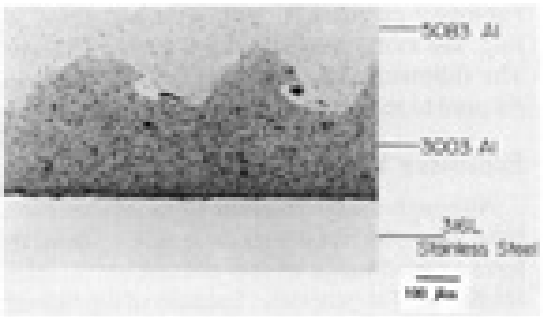

FIG. 3 CROSS-SECTIONAL PHOTOMICROGRAPH OF A 5083 AL-3003 AL-TYPE 316L STAINLESS STEEL CLAD TRI-LAYER TAKEN PARALLEL TO THE BONDING DIRECTION. NOTICE THE WELL-DEVELOPED WAVE MORPHOLOGY AND DARK ETCHING MELT POCKETS IN THE ALUMINUM-TO-ALUMINUM BOND. IN ADDITION, THE LAMINAR ALUMINUM-TO-STAINLESS STEEL BOND INTERFACE INDICATES INTERMITTENT SECOND-PHASE ENTRAPMENT.

Wave Formation. Abrahamson (Ref 26) examined the formation of surface deformations that were caused by a traveling jet using projectiles shot at thin metal targets, resulting in oblique impact. Two primary conclusions drawn from this work were that the target metal deformation was a horizontal shear in the direction of impact and that the resultant wave peaks were deformed in such a pattern that they turned back in the direction opposite to impact. When the angle of impact was varied, two important responses occurred. First, below an impact angle of 5°, no wave formation was observed. Second, as the angle of impact was increased above 5°, the amplitude and wavelength increased.

The proposed mechanism for wave formation in high-velocity oblique impacts was based on subsonic or supersonic metal flow. Good bonding was achieved with low-impact angles, because of a need to prevent jet instabilities.

Baharani *et al.* (Ref 27) and Hunt (Ref 28) drew upon this hypothesis and proposed a physical description of wave formation in explosive bonding, which included the following sequence of events:

- *STEP 1:* IMPACT PRODUCES SHEAR DEFORMATION IN THE STATIONARY BASE PLATE, WHICH RESULTS IN A DEPRESSION
- *STEP 2:* CONSERVATION OF VOLUME CRITERIA PRODUCES AN UPHEAVAL OF METAL (A HUMP) AHEAD OF THE IMPACT APEX
- *STEP 3:* HUMP INTERFERES WITH THE JET FLOW AND PRODUCES AN EDDY IN THE JET, WHICH TRAPS MOLTEN MATERIAL IN THE REAR VORTEX
- *STEP 4:* ALLOWING FOR COLLISION-POINT VELOCITY CAUSES A FORWARD DEFORMATION OF THE HUMP AND FURTHER JET TURBULENCE, WHICH AGAIN CAUSES JET ENTRAPMENT IN THE FRONT VORTEX
- *STEP 5:* PROCESS IS THEN REPEATED, STARTING WITH STEP 1

Lucas *et al.* (Ref 29) reported that when the flyer and base plates of a copper-to-copper explosive bond were electroplated with 1 μm (40 μin.) of nickel, the wave vortices were found to contain free nickel, which was assumed to result from jet entrapment caused by turbulence. Trueb (Ref 30, 31) indicated a similar phenomenon when bonding titanium to steel. The vortices appeared to contain a mix of both metals arranged in an eddy pattern that was "frozen in" by rapid solidification.

Bond Microstructure. Microstructural analysis of explosive bond zones has revealed several interesting results. Numerous metallurgical reactions have been reported:

- EXTENSIVE GRAIN ELONGATION IN THE DIRECTION OF BONDING, WITHIN SEVERAL HUNDREDS OF MICRONS OF THE BOND INTERFACE, AND MEASURED ELONGATIONS OF SEVERAL THOUSAND PERCENT (REF 31)
- RESIDUAL DISLOCATION DENSITIES ON THE ORDER OF $10^{11}/CM^2$ NEAR THE BOND INTERFACE (REF 31)
- MICROTWINNING HAS BEEN OBSERVED (REF 31, 32) IN LOW STACKING FAULT ENERGY METALS (FOR EXAMPLE, COPPER)
- RECRYSTALLIZATION AND RECOVERY HAVE BEEN OBSERVED IN BANDS ON BOTH SIDES OF HIGH-DISLOCATION-DENSITY REGIONS (REF 29)
- VERY LITTLE DIFFUSION OCCURS ACROSS THE BOND INTERFACE (REF 29)

These observations support the hypothesis that says that wave formation is a result of extreme metal deformation and that bonding is a result of solid-state processes with very little diffusion.

However, Hammerschmidt and Kreye (Ref 33) have presented an alternative mechanism for bonding based on the formation of a submicroscopic layer of molten metal, rather than solid-state bonding. Their investigation revealed that in bonds between copper and aluminum, a layer up to 5 μm (200 μin.) wide was obviously molten and resolidified as a fine-grained equiaxed structure. This conclusion raises several questions as to the appropriateness of dissimilar metal systems for explosive bonding, especially when brittle intermetallic compounds can result. Similarly, jet entrapment must be considered deleterious with respect to intermetallic compound formation. Therefore, close attention must be given to the metallurgy of the dissimilar metal couple and bonding parameters when high-strength explosive bonds are required.

The preceding discussion indicates that a very complex combination of metallurgical reactions occur during explosive bonding. These effects have been researched to a limited degree and the general results appear to be understood, but controversy over actual bonding mechanisms still remains.

Oberg *et al.* (Ref 34) used the Miedema model for alloy formation to explain the metallurgical details of explosion bonds. In their analysis, they suggest strong correlations between interfacial bond strength and the formation energies between binary alloy constituents. If the theoretical formation energy, γ_{AB}, is high, then a low bonding success would be predicted, indicating that low formation energies are preferred. Also, if the chemical portion of the interfacial free energy, g_{AB}^{chem},

deviates from theoretical mixing in a negative fashion, then the formation of intermetallic compounds would be favored. Positive deviations indicate the tendency for solid-solution formation and strong bonding.

Explosive bond strength is often negatively affected by the formation of intermetallics and defects that result from rapid quenching of melt regions. Counteracting these effects is the localized hardening and high dislocation densities that occur in a heavily worked structure adjacent to the bond interface. In fact, bonds produced by extreme metal deformations that result in a wavy interface have been reported to be optimum, with respect to strength (Ref 35).

Bond Strength Determination. Bond strength can be measured by a variety of mechanical testing techniques, including the simple bend and shear test identified in the ANSI/ASTM standard specifications A 263, A 264, A 265, and B 432. A special "top hat" tensile test has also been utilized (Fig. 4).

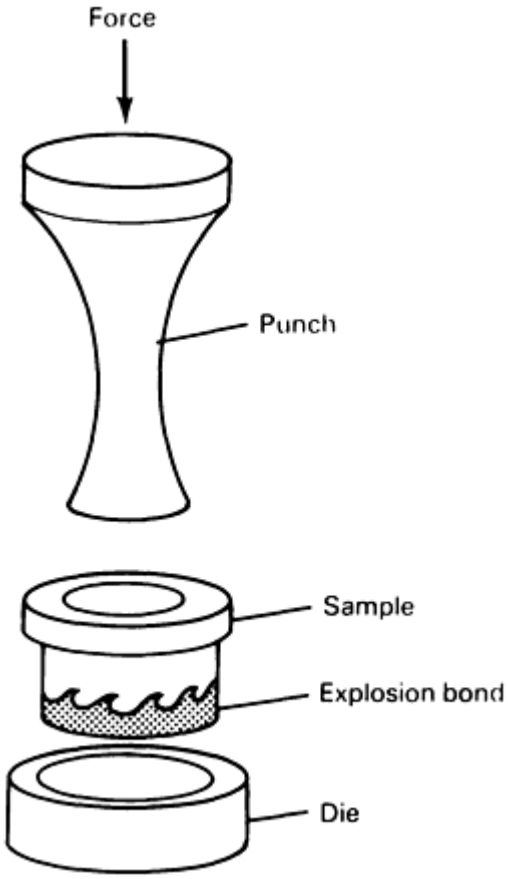

FIG. 4 SCHEMATIC SHOWING TOP-HAT TENSILE TEST APPARATUS AND RELATION OF SAMPLE TO PUNCH-DIE TOOLING COMPONENTS

Figure 5 is a cross-sectional view of a copper-to-stainless steel clad tensile specimen, where failure occurred in the copper base metal (Ref 13). Note the wavy bond interface to the right of the necked fracture zone (Fig. 5a) and the normal dimpled appearance of the copper fracture surface as revealed by the scanning electron microscope (Fig. 5b). This particular sample agrees with accepted bond strength trends, because the well-developed wavy bond performs better than the weaker of the two parent materials.

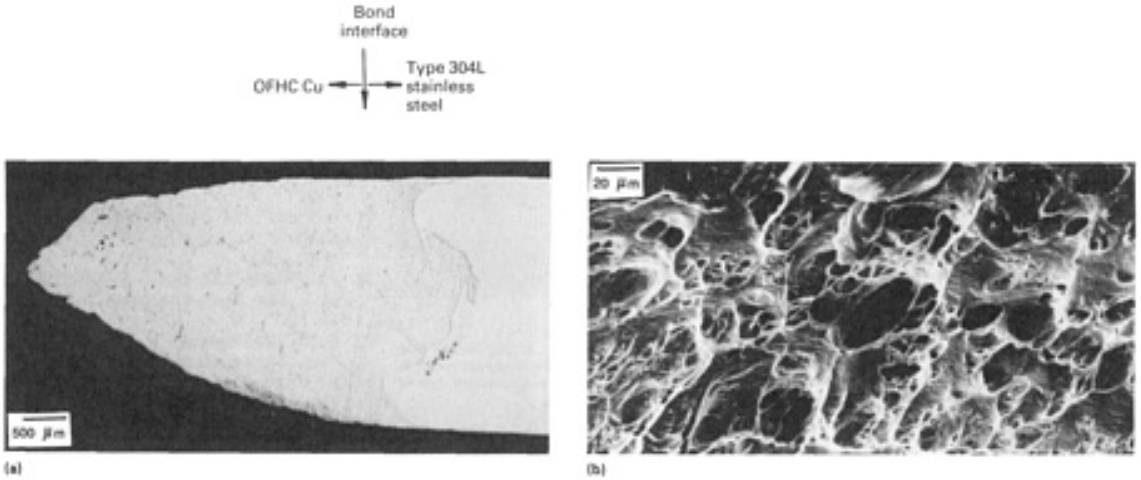

FIG. 5 FAILURE IN COPPER-TO-STAINLESS STEEL TENSILE SPECIMEN THAT WAS EXPLOSION WELDED. (A) PHOTOMICROGRAPH OF FAILED SPECIMEN SHOWING WAVY BOND LINE AND DUCTILE FRACTURE IN PARENT COPPER METAL. 16×. (B) SCANNING ELECTRON FRACTOGRAPH OF COPPER FRACTURE SHOWING DIMPLED APPEARANCE OF TYPICAL DUCTILE TENSILE OVERLOAD FAILURE. 395×

Figure 6, on the other hand, shows scanning electron fractographs of a tensile specimen that failed in the explosive bond interface. This tri-layer specimen (a bond between 5083 A 1-5052 Al-type 304L stainless steel) illustrates one important fact: wavy interface morphologies are not always the strongest (Ref 13). The principal fracture occurred in the wavy interface between the 5083 Al and the 5052 Al layers, whereas the laminar interface between the 5052 Al and the type 304L stainless steel exhibited an incipient fracture appearance with unconnected cracking along the interface. This is a direct contradiction to the previous statements that a wavy bond increases strength and further illustrates the need to evaluate each clad specimen using destructive test methods.

Future Outlook

In this discussion, brief descriptions of bonding techniques and bonding parameters have been correlated with current experimental results. As shown, attempts to gain a fundamental understanding of explosive bonding involve a large number of highly interactive variables (for example, explosive detonation dynamics, dynamic materials deformation, and solid-state bonding). May of these interactive variables have been defined in this discussion, and the references cited offer additional detail and explanation. However, much of the available knowledge relating to explosive bonding is still based on experimental observation. Models and predictive algorithms have been published, but to a large extent bonding is still considered an art practiced by a rather select group of experienced technologists. Insight into the practice of producing explosive bonds and an introduction to the specific applications is available in the articles "Explosion Welding" and "Procedure Development and Practice Considerations for Explosion Welding," in this Volume.

Mechanical Properties of Soft-Interlayer Solid-State Welds

R.S. Rosen, Lawrence Livermore National Laboratory; M.E. Kassner, Oregon State University

Introduction

THE UTILIZATION OF METAL INTERLAYERS for solid-state welding can be an appropriate joining method when brittle intermetallic compound formation, differential thermal contraction during cooling, or oxide dissociation and dissolution temperature preclude the use of conventional methods, such as fusion welding, brazing, and direct solid-state welding of the base metals. An interlayer can have the form of a foil (Ref 1, 2, 3, 4, 5, 6, 7, 8), or it can be applied to one or both of the base-metal surfaces by various coating methods, such as electrodeposition (Ref 1, 2, 4, 9), plasma spraying (Ref 2), or vapor-deposition methods.

Methods that utilize coated interlayers require a two-step joining procedure (coating and welding), as opposed to joints fabricated with foil interlayers, which may only require a single solid-state welding step. However, methods that utilize coated interlayers have the advantage of not requiring solid-state welding at the interface of the interlayer and base metal, as necessitated by the use of foil interlayers. The solid-state welding of some foil interlayer and base-metal combinations may require high temperatures and/or pressures, because of the high dissociation temperatures of the surface oxides, which may preclude or restrict their use (Ref 10, 11, 12).

Various base-metal combinations have been solid-state welded using coated silver as the interlayer metal. The principal advantage of silver as an interlayer for solid-state welding is that high-strength joints can be fabricated at relatively low temperature (473 to 673 K) and pressures (100 to 200 MPa, or 15 to 30 ksi), because of the low dissociation temperature (<460 K) for silver oxide. Depending on the strength of the base metals and the method (hydrostatic or uniaxial stress) by which pressure is applied to the silver/silver interface, the joining process may result in variable deformation in the base metals. Because some plasticity in the base metal may be important to assist with intimate atomic contact across the interface, "soft" interlayers are often preferred.

Silver interlayers for solid-state welding are usually applied to one or both of the base metals by deposition using either electrodeposition (Ref 1, 13, 14, 15, 16, 17) or vacuum-coating methods. The vacuum-coating methods have included electron-beam evaporation (Ref 18), hot-hollow cathode (HHC) evaporation (Ref 15, 19, 20, 21, 22, 23, 24, 25, 26), ion-plating using sputtering (Ref 27, 28, 29), and planar-magnetron (PM) sputtering (Ref 30, 31, 32, 33).

Prior to deposition, the surface oxide layer may require removal from the base metal in order to achieve adequate adhesion of the silver. The surface oxide layer is usually removed by chemical- or sputter-etching methods. One

advantage of vacuum coating over electrodeposition is the ability to sputter-etch the base metal *in situ.* This permits silver deposition with minimal recontamination of the oxygen on the base-metal surface (Ref 34).

Soft-interlayer solid-state welds that join stronger base metals have unique mechanical properties that are of fundamental interest and may be of critical importance to designers. These assemblies can be subjected to various applied stress states, such as tensile, where the load is applied perpendicular to the interlayer/base-metal interfaces, or shear, where the applied shear stress lies within the plane of the interlayer. Of course, in application, the interlayer may be subjected to a combination of applied tensile and shear loads. This is important because these types of welds are, mechanically, quite anisotropic. This includes the case where interlayers may be subjected to residual stresses from fabrication. The loading may be continually increasing, as with a conventional tensile test, or static, as with creep tests. Again, these behaviors are quite different.

Additionally, some interlayer/base-metal interfaces have been shown to be susceptible to stress-corrosion cracking when exposed to critical environments (Ref 35). The mechanical properties of soft-interlayer solid-state welds and the implications of these behaviors to service stress states and environments are discussed in this article. It should be noted that although silver interlayers are emphasized, primarily because of their selection by previous researchers and industrial fabricators, the described trends appear to be completely consistent with joints that use other soft-interlayer metals.

Mechanical Properties of Soft-Interlayer Solid-State Welds

R.S. Rosen, Lawrence Livermore National Laboratory; M.E. Kassner, Oregon State University

Microstructure of Interlayer Welds

As-Deposited Coatings. A fine-grained (typically <1 μm, or 40 μin., in diameter) columnar structure commonly forms in coatings that are vacuum deposited onto low-temperature substrates (~0.3 T_m) using a low working-gas pressure (~1 Pa, or 1.5×10^{-4} psi). This type of structure has been reported previously in silver coatings fabricated for interlayer welding by HHC evaporation (Ref 20) and PM sputter deposition (Ref 30). The columns are perpendicular to the base-metal surface, and the axes of the columns are oriented perpendicular to a close-packed crystallographic direction. The columnar grains resulting from the PM sputter-deposition of silver often contain a high density of growth twins that are approximately 15 nm (0.6 μin.) thick (Ref 30).

Solid-State-Welded Interlayers. Figure 1 shows a solid-state-welded silver interlayers that is 150 μm (6 mils) thick between steel base metals after solid-state welding at 673 K (Ref 17). The silver interlayer typically consists of two types of structures: nonrecrystallized silver that has retained the columnar grains and fine microtwins of the as-deposited coating and silver that has recrystallized into large grains (>1 mm, or 0.04 in., in diameter) containing a high density of annealing twins. The solid-state-welded interfaces are generally free of any large voids, or nonbonded regions. In the case of rough base-metal surfaces, large voids can remain along the silver/silver interface.

Tensile Loading of Soft-Interlayer Welds

Despite the relatively low strength of the interlayer material, it has long been known that thin (1 μm to 1 mm, or 40 μin. to 0.04 in.) interlayer welds or brazes between stronger base material can have ultimate tensile strengths (UTS) that are much higher than that of the bulk interlayer material (Ref 36, 37). For example, the UTS of silver-interlayer solid-state welds between maraging steel base metals has been reported to be nearly 800 MPa (120 ksi) (Ref 32, 3), whereas the UTS of the bulk silver is only about 250 MPa (35 ksi) (Ref 38). The high tensile strength of the joint is due to the mechanical constraint provided by the stronger base metal, which restricts transverse contraction of the interlayer (Ref 36, 37, 39, 40, 41, 42, 43, 44, 45). The constraint establishes radial (triaxial) stresses that inhibit the development of shear stresses within the joint, thereby decreasing the effective, or von Mises, stress in the interlayer. This inhibits the plastic flow that leads to ductile fracture.

Effect of Interlayer Thickness on Stress. The degree of mechanical constraint in the soft interlayer and the joint strength tend to increase with a decreasing thickness-to-diameter ratio, *t*/*d*, of the interlayer (Ref 36, 37, 39 , 40, 41, 42, 44, 46, 47, 48, 49, 50, 51, 52, 53). Figure 2 summarizes the effect of *t*/*d* on the UTS of solid-state-welded silver interlayers fabricated using PM sputter deposition (Ref 30) and electrodeposition (Ref 15), compared with Ag-4Pd brazed interlayers (no hardening, because of the addition of palladium) (Ref 41). The UTS is shown to increase with a decreasing *t*/*d* ratio to about 0.002, below which only small strength increases can be expected. The higher UTS of sputter-deposited silver interlayer, compared with those utilizing electrodeposition or brazed-silver alloy, are discussed in the section "Effect of Interlayer Fabrication Method" in this article.

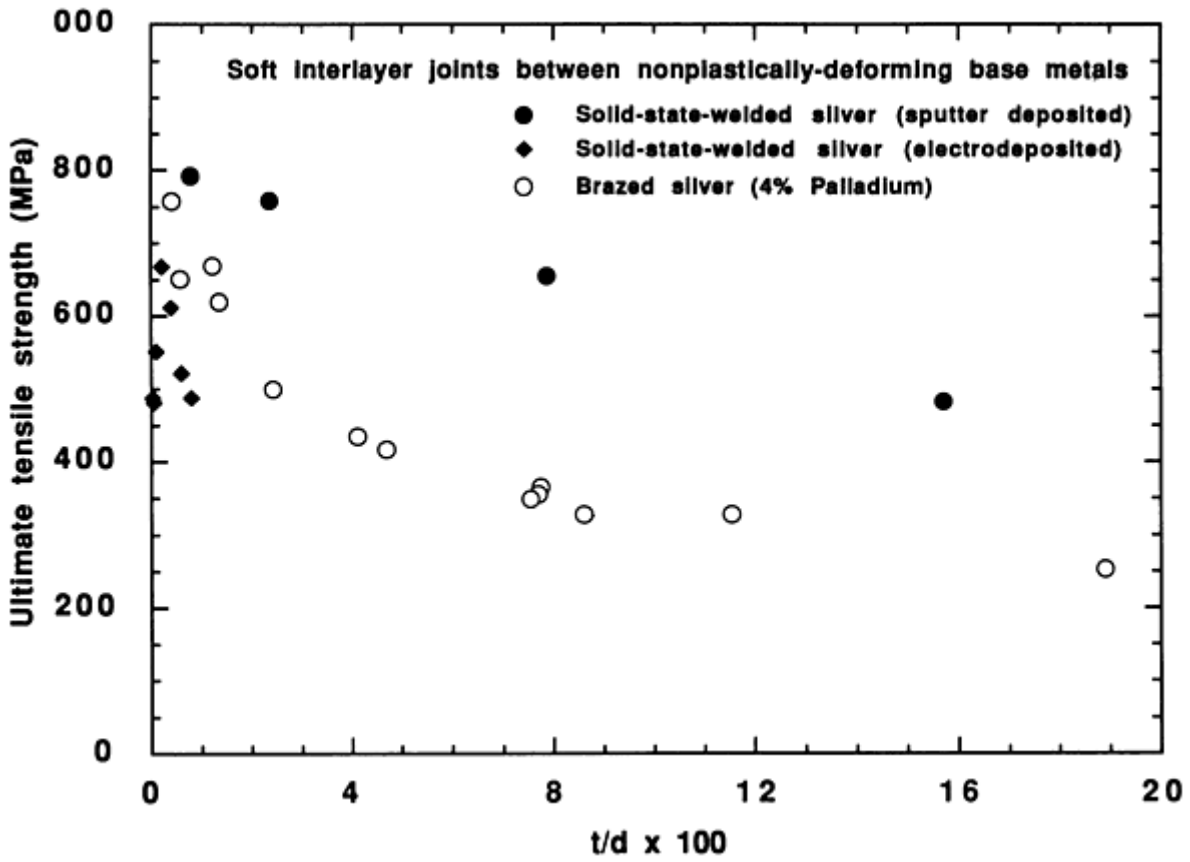

FIG. 2 EFFECT OF INTERLAYER THICKNESS TENSILE STRENGTH OF SOLID-STATE-WELDED SILVER INTERLAYERS FABRICATED USING PM SPUTTER DEPOSITION AND ELECTRODEPOSITION, COMPARED WITH

Although the tensile behavior of interlayer joints has been reasonably well understood qualitatively, particularly for thick interlayers, quantitative prediction has only recently been accomplished with finite-element method (FEM) codes. Orowan (Ref 36, 37) was perhaps the first to derive an analytical expression for the radial (constraining) stress within the interlayer. It was proposed that

$$s_r = \frac{s_y}{t}\left(\frac{d}{2} - r\right) \qquad \textbf{(EQ 1)}$$

where σ_r is the radial stress, t is the thickness, d is the diameter, r is the radius, and σ_y is the yield stress of the interlayer. This equation was originally derived by assuming ideal plastic behavior (that is, no strain hardening) of the interlayer and uniform plastic in the interlayer. Analytical attempts to account for strain hardening within the interlayer have led to modifications of Eq 1 that have, experimentally at least, provided reasonable correlation with upper bounds for UTS of soft-interlayer joints (Ref 41, 43, 48, 49).

More recently, FEM analyses (REf 53, 54) reveal significant deviation from q 1. Figure 3(a) illustrates the effect of *t*/*d* on th radial stress distribution at the center plane for silver interlayer welds between nonplastically deformation base metals at a fixed applied tensile stress. These were determined from a FEM analysis that included the observed strain hardening of the interlayer metal and are plotted along with results predicted by Eq 1. This comparison shows that for large *t*/*d* ratios ("thick" interlayers), Eq 1 predicts qualitatively correct behavior for the radial stress distribution. However, for small *t*/*d* ratios ("thin" interlayers), the FEM results indicate a relatively uniform and substantially lower stress distribution over most of the central portion of the interlayer than predicted by Eq 1. This is partly due to the simplifying assumptions in Eq 1, particularly that of a radially uniform strain state.

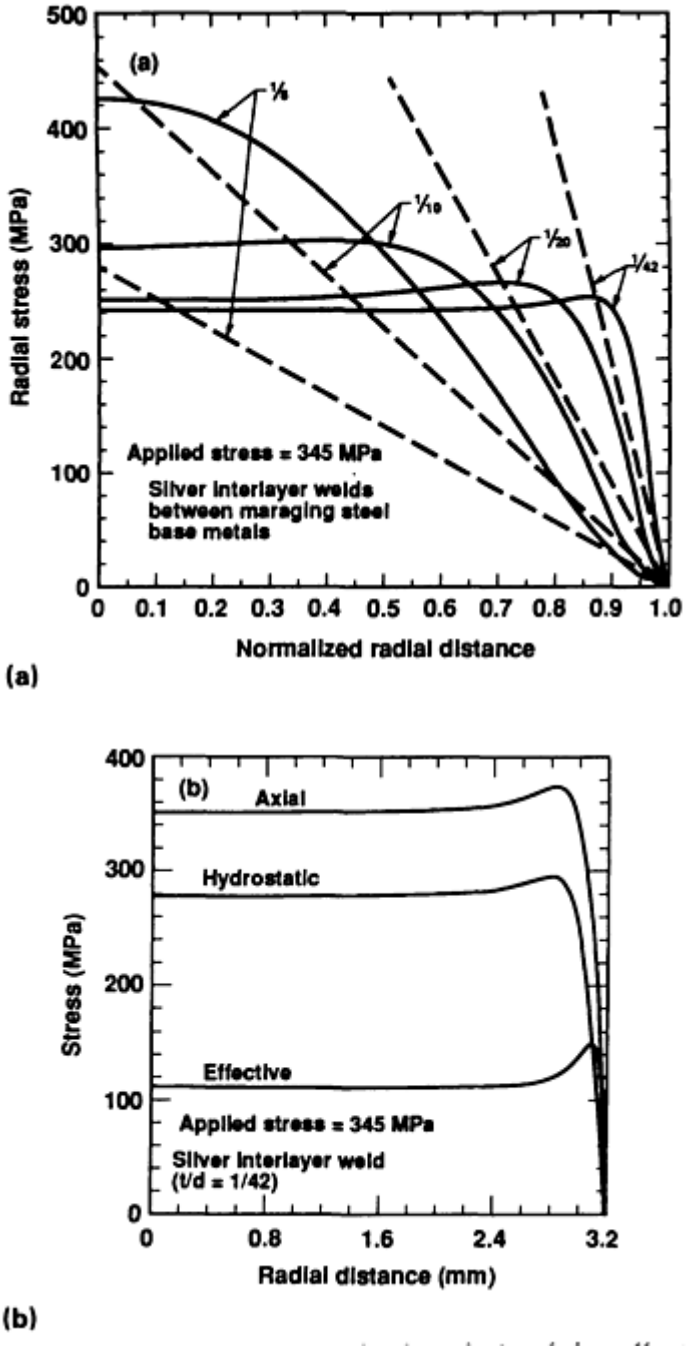

FIG. 3 FINITE-ELEMENT METHOD ANALYSIS OF THE EFFECT OF *T*/*D* ON THE RADIAL STRESS DISTRIBUTION AT THE CENTER PLANE FOR SILVER INTERLAYER WELDS BETWEEN NONPLASTICALLY DEFORMING BASE METALS AT A FIXED APPLIED TENSILE STRESS. (A) PREDICTIONS OF EQ 1 ARE GIVEN BY DASHED LINES. (B) THE STRESS STATE IN A STRAIN-HARDENING SILVER INTERLAYER AT A SMALL FIXED *T*/*D* RATIO

This effect is further illustrated in Fig. 3(b), which shows the stress state in a strain-hardening silver interlayer at a small fixed *t*/*d* ratio. Although it is not shown, the effective (von Mises) stress, which measures the tendency to plastically deform, decreases with decreasing *t*/*d*, down to approximately 0.025. Hence, a decreasing *t*/*d* ratio increases the mechanical constraint in the interlayer such that a larger applied stress is needed to produce a given amount of plastic strain in the interlayer. Interestingly, and in contrast with Eq 1, the effective stress does not appear to substantially changes with decreases in *t*/*d* that are less than approximately 0.025 (Ref 54). This is qualitatively consistent with the extrapolations of the solid-state-welded silver data in Fig. 2 (but not the braze data).

Early investigators (Ref 15, 40, 44, 45, 55) believed that this phenomenon was due only to discontinuities (solidification shrinkage cavities, surface flatness, and such) in very thin brazes and solid-state welds. Recent results (Ref 17, 30) of

solid-state-welded interlayers fabricated using sputter-deposited silver onto lapped base metals (surface roughness of 0.03 μm, or 1.2 μin.) indicate that the modest increase (or plateau) in strength occurs even in the absence of preexisting voids that are common in thin brazes.

Interlayer Strain. Associated with the increased UTS of the constrained interlayers, compared to the UTS of the bulk or unconstrained interlayer metal, is a decreased plastic strain-to-failure, ε_f, of the interlayer. Early results (Ref 42) found that for brazed-silver interlayers joining elastically deforming base metals with a t/d ratio of 0.016, the ε_f is about 0.01. The results from specimens fabricated using solid-state welding of PM sputter-deposited silver interlayers, in which the base metals did not plastically deform, indicated plastic strains of only abut 0.001 for a comparable t/d ratio of 0.024 (Ref 17, 33). The reason for the disparity is not clear. Perhaps the relatively large number of interfaces in the PM sputter-deposited interlayers in the PM sputter-deposited interlayers (Ref 30, 33) led to higher cavity-nucleation rates. Other works do not appear to have made reliable attempts at determining the plastic strain-to-failure value. It should be emphasized that despite the relatively low plastic strain-to-failure, the fracture surface is that of a classic, ductile, microvoid-coalescence type of failure (Ref 33).

Time-Dependent Failure. It has been observed that at stresses substantially less than the UTS, delayed or time-dependent ductile fracture may occur. For at least the case of silver interlayers, decreases in the applied stress are associated with increased times-to-rupture,f as indicated in Fig. 4. This figure shows that decreasing the t/d ratio (to about 0.02) and/or improving the base-metal surface finish (lapping) results in longer tensile creep-rupture times. Time-dependent failure is believed to be a consequence of cavity nucleation and/or growth (Ref 33), as is observed in short-term tensile tests that determine the UTS. For solid-state welds in which two coatings are joined, nucleation occurs principally at the silver/silver welded interface or the base-metal/silver coated interface. The cavities appear to nucleate as a consequence of time-dependent plasticity within the interlayer. The cavities expand in diameter and final interlinkage and failure appears to occur at relatively low "macroscopic" strains within the interlayer (for example, $\varepsilon_f < 10^{-3}$).

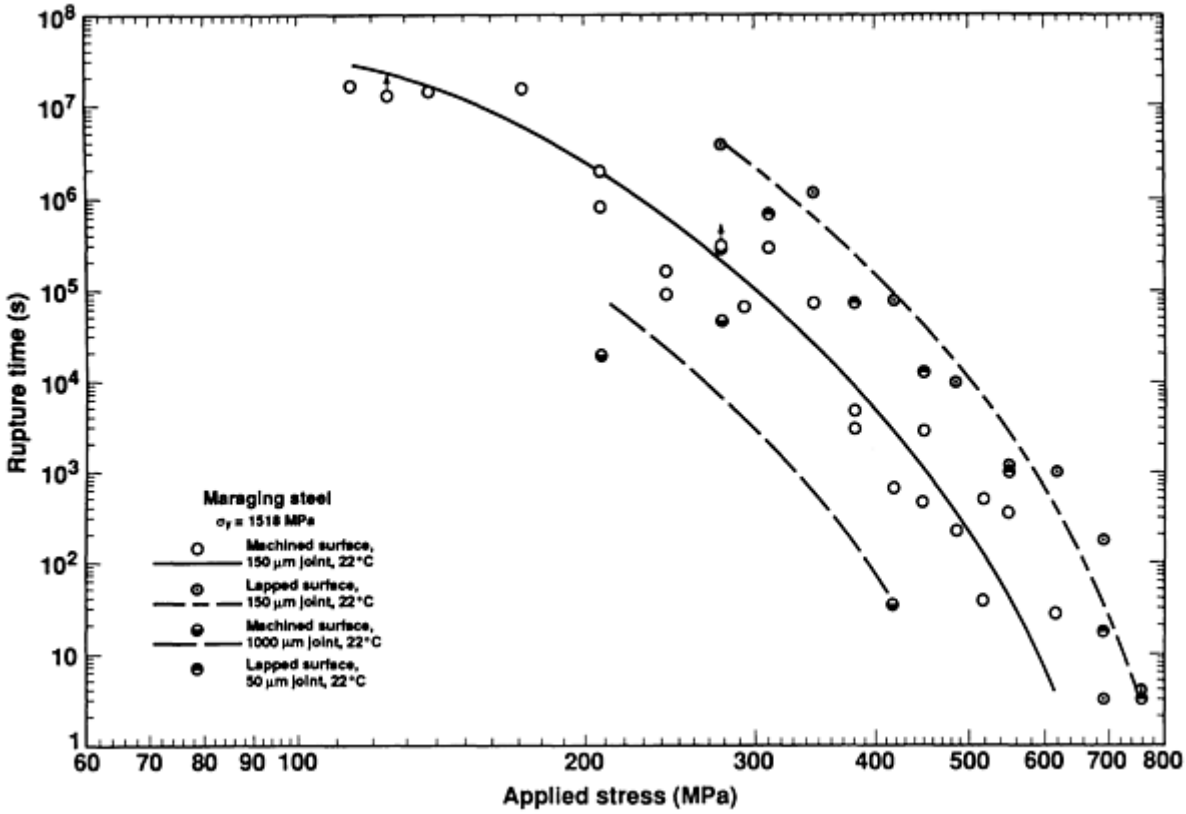

FIG. 4 EFFECT OF INTERLAYER THICKNESS AND BASE-METAL SURFACE FINISH ON CREEP RUPTURE OF SOLID-STATE-WELDED SILVER JOINTS BETWEEN NONPLASTICALLY DEFORMING BASE METALS

Figure 5 shows scanning electron micrographs of a solid-state-welded silver interlayer joining steel base metals, loaded at the relatively low stress level of 207 MPa (30 ksi) (albeit, for a substantial fraction of the expected creep-rupture time).

Some of the larger cavities consist of clusters of smaller (<0.5 μm, or 200 μin., in diameter) microvoids. A typical fracture surface of a creep-rupture specimen is illustrated in Fig. 6. Naturally, the fracture surfaces appear identical to those of the short-term tests in which UTS values were measured. It should be emphasized that, consistent with Fig. 2, as the interlayer metal strength increases, the strength of the weld joint increases. Similarly, as the interlayer metal creep resistance increases, the rupture times of the weld joint should increase. Hence, as reported for gold-nickel high-strength/creep-resistant interlayer brazes (Ref 56), time-dependent failure has not been observed over periods of about 1 y. Also, it appears that for silver brazes (Ref 33), time-dependent failure is observed, but at increasingly longer times at decreasing stresses, perhaps because of differences in substructures, compared with solid-state-welded silver interlayers.

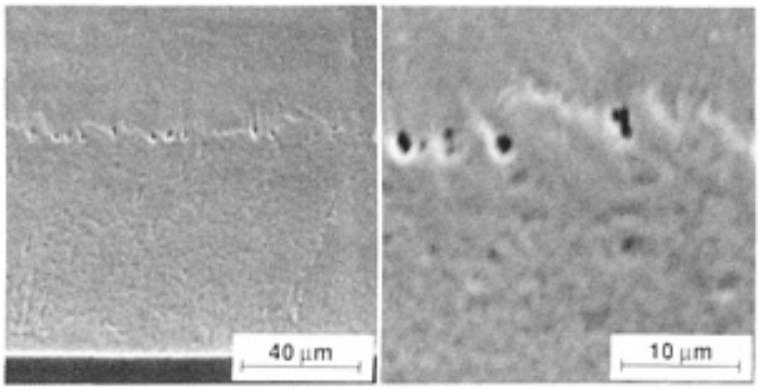

FIG. 5 SCANNING ELECTRON MICROGRAPHS SHOWING SOLID-STATE-WELDED SILVER INTERLAYER JOINING NONPLASTICALLY DEFORMING BASE METALS, LOADED AT 207 MPA (30 KSI) (~$\frac{1}{3}$ ULTIMATE TENSILE STRENGTH) FOR A SUBSTANTIAL FRACTION OF THE EXPECTED CREEP-RUPTURE TIME

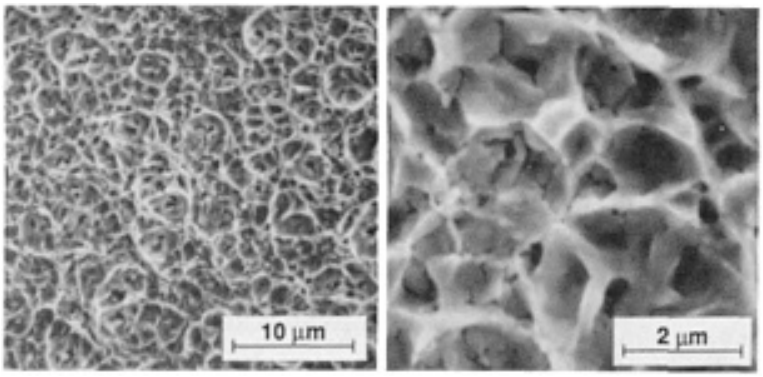

FIG. 6 SOLID-STATE-WELDED SILVER INTERLAYER FRACTURE SURFACE BETWEEN LAPPED MARAGING STEEL BASE METALS

A nucleation-based theory has been proposed to explain the low plastic strain, time-dependent failures of soft-interlayer solid-state welds in which preexisting voids do not exist, and the base metal does not plastically deform (Ref 17, 33, 57). Plastic deformation of the interlayer, acting under the effective stress, causes cavity nucleation by dislocation pile-ups at interfaces. Nucleation continues with further creep of the interlayer, until the concentration of nuclei is sufficiently high to lead to instability in the material between the cavities. Coalescence by interlinkage or by uniform wall expansion ("growth") then occurs. The point of instability between two small nanometer-sized cavities or nuclei separated by a few diameters or so may lead to subsequent rapid nucleation between the cavities, resulting in the formation of a single, larger cavity (as shown in Fig. 5). This process is repeated and eventually leads to the onset of final rupture, and gives the appearance of a classic, ductile, microvoid-coalescence type of fracture.

In contrast with this nucleation-based theory, other investigators (Ref 42) suggest that the macroscopic strain-to-failure is determined by the details of the uniform cavity expansion (growth). Here, once the cavities expand and come in proximity

to other cavities, coalescence and ductile fracture occurs. In a creep experiment, according to the usual cavity-growth models, the rupture time is determined by the cavity growth rate or the speed of the expanding cavity wall. In the absence of vacancy-controlled growth, this speed is controlled by the macroscopic plastic strain rate. Therefore, the static (or creep) and dynamic (or quasi-static) failures of the thin interlayer welds should be, according to cavity-growth-based theories, related to the macroscopic strain in the interlayer. If steady-state plasticity is achieved throughout the silver interlayer material surrounding the cavities, then unstable cavity wall expansion may occur. However, since the macroscopic strains-to-failure are small ($\varepsilon_f < 10^{-3}$, the time or strain up to the onset of final catastrophic failure (where a large ductile-dimple fracture surface begins to form) is not easily explained by a cavity-growth model in a strain-hardening material.

The silver-plasticity concept for rationalizing creep rupture is consistent with the temperature dependence of the time-to-rupture. The activation energy for the creep of silver at ambient and near-ambient temperatures for various substructures falls within the range of 50 to 71 kJ/mole (Ref 38, 58). The activation energy for the creep rupture of the solid-state-welded silver joints of Fig. 2, equal to 65 kJ/mole (Ref 33), falls within the range of activation energies for silver plasticity.

Effect of Base-Metal Properties. Time-dependent tensile fracture can be dramatically accelerated if there is creep, or time-dependent plasticity, of the base materials. Figure 7 shows the creep-rupture behavior of solid-state-welded silver interlayers (t/d = 0.024) joining one of two different strengths of type 304 stainless steel base metals: annealed or cold-worked (Ref 17, 33). Interestingly, these base metals undergo time-dependent plasticity, or creep, at ambient temperatures at stresses that are less than the conventionally yield stress of the metal. Although the accumulated plastic strain in the creeping stainless steel is only about 0.001 to 0.01 at low stress levels, this nonetheless induces concomitant plastic strain within the interlayer that exceeds that which would occur within the interlayer in the absence of base-metal plasticity, resulting in shorter creep-rupture times. This behavior is consistent with previous reported data for creep ruptures of interlayers that join plastically deforming base metals (Ref 25, 26, 59, 60).

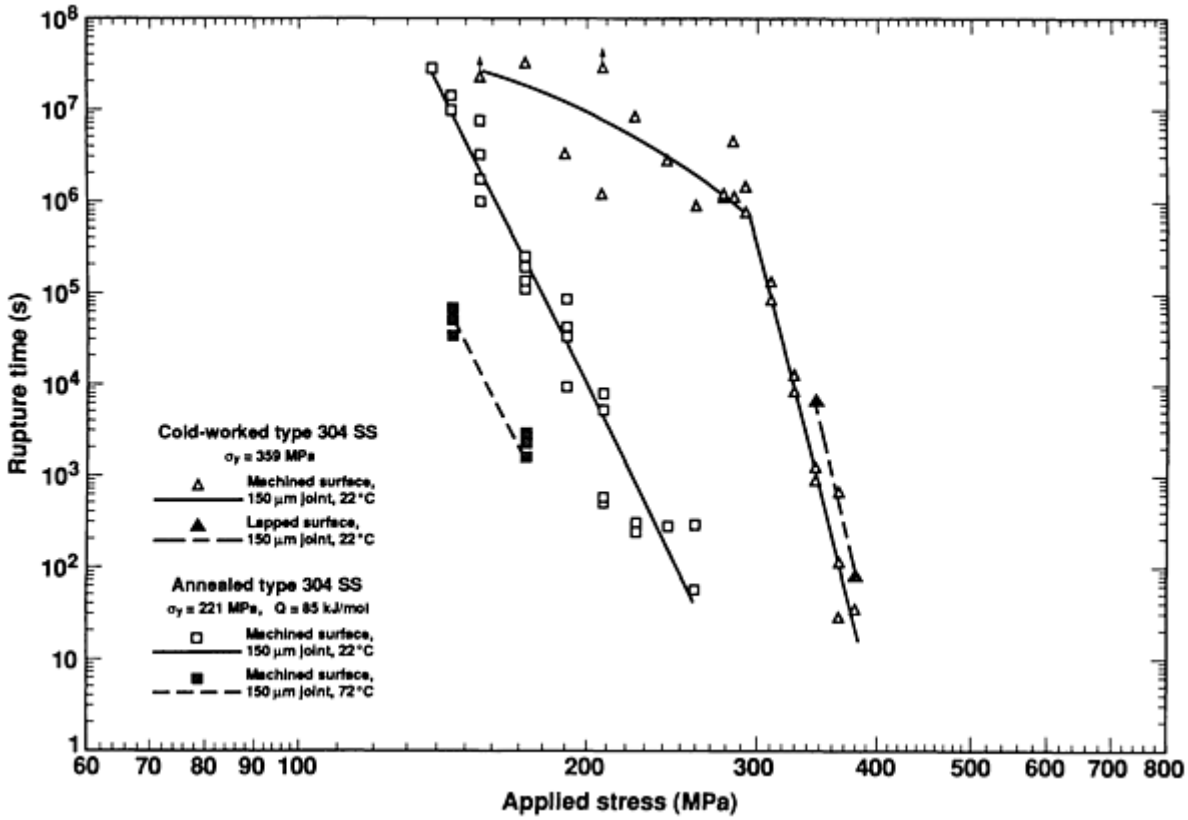

FIG. 7 CREEP-RUPTURE BEHAVIOR OF SOLID-STATE-WELDED SILVER INTERLAYERS (*T/D* = 0.024) JOINING ONE OF TWO DIFFERENT STRENGTHS OF TYPE 304 STAINLESS STEEL BASE METALS (ANNEALED OR COLD-WORKED), BOTH OF WHICH UNDERGO TIME-DEPENDENT PLASTICITY OR CREEP AT AMBIENT TEMPERATURES AT STRESSES LESS THAN THE CONVENTIONAL YIELD STRESS OF THE METAL

Finite-element analyses have confirmed that plasticity in the base metal allows the interlayer to plastically deform to a much greater extent than if the base metal deforms only elastically (Ref 54). This observation is important, because these small levels of time-dependent plasticity (0.001 to 0.01) are often observed, over time, in other structural metals and alloys at ambient temperature at stresses significantly below the conventionally define yield stress. With an increase in test temperature, the stainless steel base-metal creep rate significantly increases and rupture times decrease. The activation energies for the creep rupture of silver interlayers between stainless steel base metals and for plastic flow in stainless steel are comparable, further suggesting that the temperature dependence of creep rupture is determined by creep plasticity in the stainless steel base metal. The transition from base-metal to interlayer-controlled creep rupture occurs at the "knee" of the cold-worked stainless steel data plot, at stress levels below which base-metal creep is negligible.

Figure 7 also shows the effect of base-metal surface finish, which is eventually coated, on the creep-rupture behavior of joints utilizing cold-worked type 304 stainless steel. Lapped cold-worked stainless steel base-metal specimens have longer rupture times than those of machined cold-worked stainless steel, as was the case with the maraging steel specimens. However, the increase in creep-rupture times of specimens utilizing lapped versus machined plastic base metals is only a factor of 5, which is considerably less than the increase of approximately 50 for specimens utilizing lapped versus machined elastic base metals. The difference between the increases in creep-rupture times for lapped plastic versus lapped elastic base-metal specimens may be due to the difference in failure processes. For the case of a plastic base metal, the strain in the silver is externally and uniformly imposed by the deformation of the base metal. For elastic base metals, plasticity is caused by the effective stress within the interlayer. It is believed that the heterogeneities along the solid-state-welded silver interface caused during the joining of the comparatively rough machined surfaces could result in regions that may be more resistant to plasticity than other regions. The heterogeneities at the solid-state-welded silver interface may be less significant in increasing the nucleation and coalescence rate of cavities in specimens utilizing plastic base metals than those utilizing elastic base metals, where the strain is indigenous to the interlayer, rather than being imposed by base-metal deformation.

Effect of Interlayer Fabrication Method. In general, the tensile strengths of PM sputter-deposited silver joints between various base metals have been reported to be equal to or greater than those utilizing other silver-coating methods and similar solid-state-welding parameters. For elastic base metals with lapped surfaces, PM sputter-deposited silver joint tensile strengths (Ref 30) of 758 and 793 MPa (110 and 115 ksi) using interlayers that are 150 and 50 μm (6 and 2 units thick, respectively, are comparable with HHC-deposited silver joints (758 MPa, or 110 ksi, using 10 μm, or 0.4 mil, thick interlayers) and greater than those of electrodeposited silver joints (669 MPa, or 97 ksi, using 25 μm, or 1 mil, thick interlayers) (Ref 15). However, the tensile strength values for silver-interlayer welds fabricated using these other two coating methods are achieved with considerably thinner interlayers, which have the advantage of greater plastic constraint produced by the base metals. For type 304 stainless steel (plastically deforming) base metals with machined surfaces and 150 μm (6 mil) thick joints, PM sputter-deposited silver joint tensile strengths (Ref 30) of 304 MPa (44 ksi) ($\sigma_{y,SS}$ = 221 MPa, or 32 ksi) and 400 MPa (60 ksi) ($\sigma_{y,SS}$ = 359 MPa, or 52 ksi) are comparable with electrodeposited silver joint strengths of 321 to 367 MPa (47 to 53 ksi) ($\sigma_{y,SS}$ = 296 MPa, or 43 ksi) (Ref 16). For uranium (plastic) base metals with machined surface, the PM sputter-deposited silver joint tensile strength of 442 MPa (64 ksi) $\sigma_{y,U}$ =242 MPa, or 35 ksi) (Ref 30) exceed electrodeposited silver joint strengths of approximately 255 MPa (37 ksi) (despite the higher base-metal yield stress; $\sigma_{y,U}$ = 345 MPa, or 50 ksi) and HHC-deposited silver joint strengths of 345 to 373 MPa (50 to 54 ksi) (Ref 16, 61). However, the lower joint strength using HHC-deposited silver (Ref 61) may have resulted from a lower solid-state welding pressure (138 MPa, or 20 ksi) and temperature (589 K) than those using PM sputter-deposited silver. The tensile strength of solid-state-welded silver joints between dissimilar metals, such as uranium (σ_y = 345 MPa, or 50 ksi) and type 304 stainless steel (σ_y = 296 MPa, or 45 ksi) fabricated using HHC deposition has been reported to average 442 MPa (64 ksi) (Ref 25). The tensile strength of electrodeposited silver joints between the same uranium and stainless steel base metals that were solid-state welded at the same pressure (207 MPa, or 30 ksi), temperature (873 K), and time (2 h) averaged only 345 MPa (50 ksi) (Ref 17, 30). Therefore, solid-state-welded silver joints fabricated using electrodeposition appear to be weaker than those fabricated using HHC deposition or PM sputter deposition.

Although there is only a limited amount of published test results of interlayer joint strengths fabricated by low-temperature solid-state welding of foils, it appears that interlayer/base-metal adhesion is difficult to achieve at temperatures below approximately 0.7 T_m of the interlayer. Tensile strengths of silver joints between alumina and type 321 stainless steel were reported to be only 40 MPa (5.8 ksi) when solid-state-welding parameters were 1073 K and 50 MPa (7.3 ksi) for 0.5 h (Ref 11). The investigators reported threshold solid-state-welding temperatures below which no measurable bonding was produced for each of the foils utilized (silver, aluminum, copper, and nickel). The threshold temperature to achieve solid-state welding of silver foils to alumina and type 321 stainless steel was reported to be 873 K (0.7 T_m of the silver), considerably higher than the temperature required to achieve solid-state welding of silver to itself (0.35 T_m) (Ref 18). Joint strengths of the previous interlayer fabrication processes were reported to be comparable (40) to 50 MPa, or 5.8 to 7.3 ksi) to those of silver foils (Ref 11). Tensile tests reported for silver-foil interlayers between type

304L stainless steel and Ti-6Al-4V alloy suggest that higher strengths may be achieved with coated interlayers than with foil interlayers (Ref 62). These joints were fabricated by solid-state welding a 125 μm (5 mil) thick silver foil between the base metals at 1153 K (0.94 T_m). The investigators (Ref 62) reported average joint strengths of 280 MPa (40 ksi). For annealed type 304 stainless steel and 150 μm (6 mil) thick joints fabricated using PM sputter deposition, the reported (Ref 30) tensile strength of 304 MPa (44 ksi) is higher, despite the higher base-metal yield stress of Ti-6Al-4V alloy used in the silver-foil study.

Shear Loading

Effect of Microstructure. The base metals provide relatively little mechanical constraint of the interlayer during shear loading (shear stress is parallel to the plane of the interlayer) and, therefore, reveals the mechanical behavior of the interlayer material itself. The behavior of the interlayer to shear can be converted to equivalent uniaxial tensile behavior using the von Mises stress and strain criteria, $\bar{s} = t\sqrt{3}$, and $\bar{e} = \gamma\sqrt{3}$, where t and γ are shear stress and strain, respectively. Effective (von Mises) stress-strain ($\bar{s}$ -ε) behavior for a 150 μm (6 mil) thick (t/d = 0.024) silver joint, fabricated using PM sputter-deposition (between maraging steel) and tested in torsion is shown in Fig. 8 (Ref 33), along with the reported results for bulk polycrystalline (annealed) silver (Ref 38). The yield stress ($\bar{e}_p$ = 0.2%) of the solid-state-welded joint is six times greater than the bulk-silver value, presumably because of the much more refined, twinned substructure. The strain-hardening rate, $d\sigma_{eff}/d\varepsilon_{eff}$, at an effective stress of 100 MPa (15 ksi) is over nine times greater than bulk polycrystalline silver (Ref 38). The maximum interlayer stress is attained after a strain of only 0.3 (99% of the maximum value is attained after a strain of only 0.1). Therefore, although the interlayer silver has a higher yield stress and strain hardens at a higher rate, it reaches essentially the same maximum stress as bulk silver at a substantially lower strain.

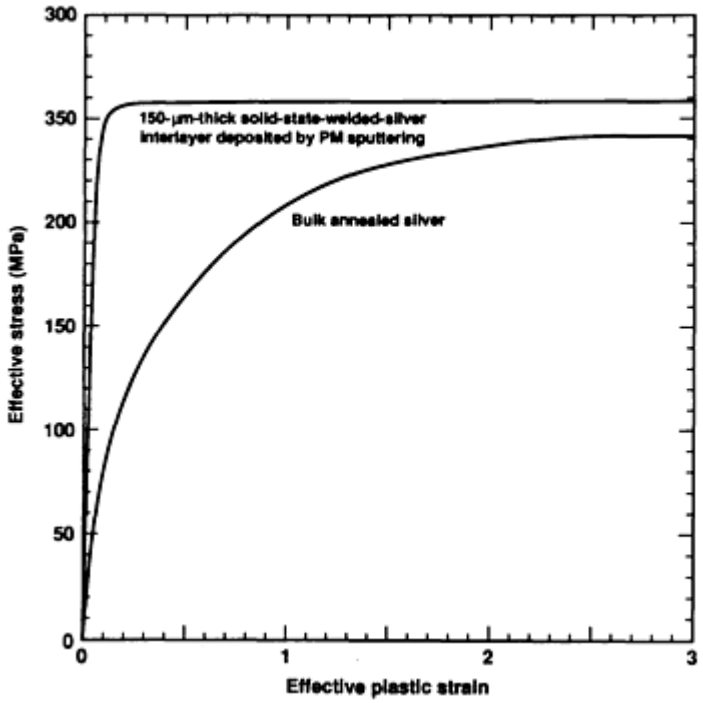

FIG. 8 EFFECTIVE (VON MISES) STRESS-STRAIN BEHAVIOR FOR A 150 μM (6 MIL) THICK SILVER INTERLAYER (*T/D* = 0.024), FABRICATED USING PM SPUTTER DEPOSITION, TESTED IN TORSION, ALONG WITH RESULTS REPORTED FOR BULK POLYCRYSTALLINE (ANNEALED) SILVER

Differences in the maximum (steady-state) stress may result from two factors. First, the interlayer microstructure may not be identical to that of the bulk material. The second explanation is that slip (plasticity) is not isotropic. The plasticity is not isotropic. The plasticity is the result of dislocation activity on limited slip planes with specific Burgers vectors. The shear displacements of individual grains in the interlayer must generally by accommodated by neighboring grains. However, near the base metal, the accommodation is not possible, and additional slip systems may operate in the interlayer grains near the base metal, leading to greater local hardening and higher flow stresses, Torsion tests of solid-state-welded silver interlayers coated by HHC evaporation, using uranium-to-stainless steel base metals (Ref 26), showed similar increases in the yield stress and strain-hardening rates, compared with those of bulk-silver values. However, the steady-state stress of silver joints was approximately 25% higher than that of bulk silver, compared with 105 higher

values for interlayers using PM sputter-deposited silver. One explanation for this difference may be the presence of HHC posits, which may further raise the maximum, or steady-state, stress.

Time-Dependent Failure. Although not shown in Fig. 8, the plastic strain-to-failure in pure shear is very high ($\bar{e}_f$ = 5 to 10) for thin, silver-interlayer specimens, just as for macroscopic, or bulk, silver specimens (Ref 33). This is nearly four orders of magnitude higher than for the case of tension. As previously discussed, cavity nucleation is promoted by the triaxial stress state established with simple uniaxial loading of constrained interlayers. The fact that torque saturates is consistent with the observation that some face-centered cubic (fcc) metals, such as aluminum, copper, and silver (Ref 38), show a saturation in the flow stress. This fact is important because such saturations imply constant torque, or time-dependent, shear-stress failures. Figure 9 shows a comparison between the rupture time versus effective (von Mises) stress behavior in shear (Ref 26) (at torsional stresses less than the maximum of HHC-deposited-silver interlayers), compared with that of tension (Ref 17) (calculated using FEM analyses of PM sputter-deposited silver interlayers). The shear rupture times are longer than tensile rupture times at equivalent uniaxial stresses (calculated using the von Mises relation), consistent with the higher plastic strains-to-failure that are much higher for the torsion specimens ($\bar{e}_f > 5$) than for the tensile specimens ($\varepsilon_f \sim 0.001$). The shorter rupture times for tensile joints are a direct result of the hydrostatic tensile stresses superimposed on the effective stresses caused by the mechanical constraint imposed by the base metal.

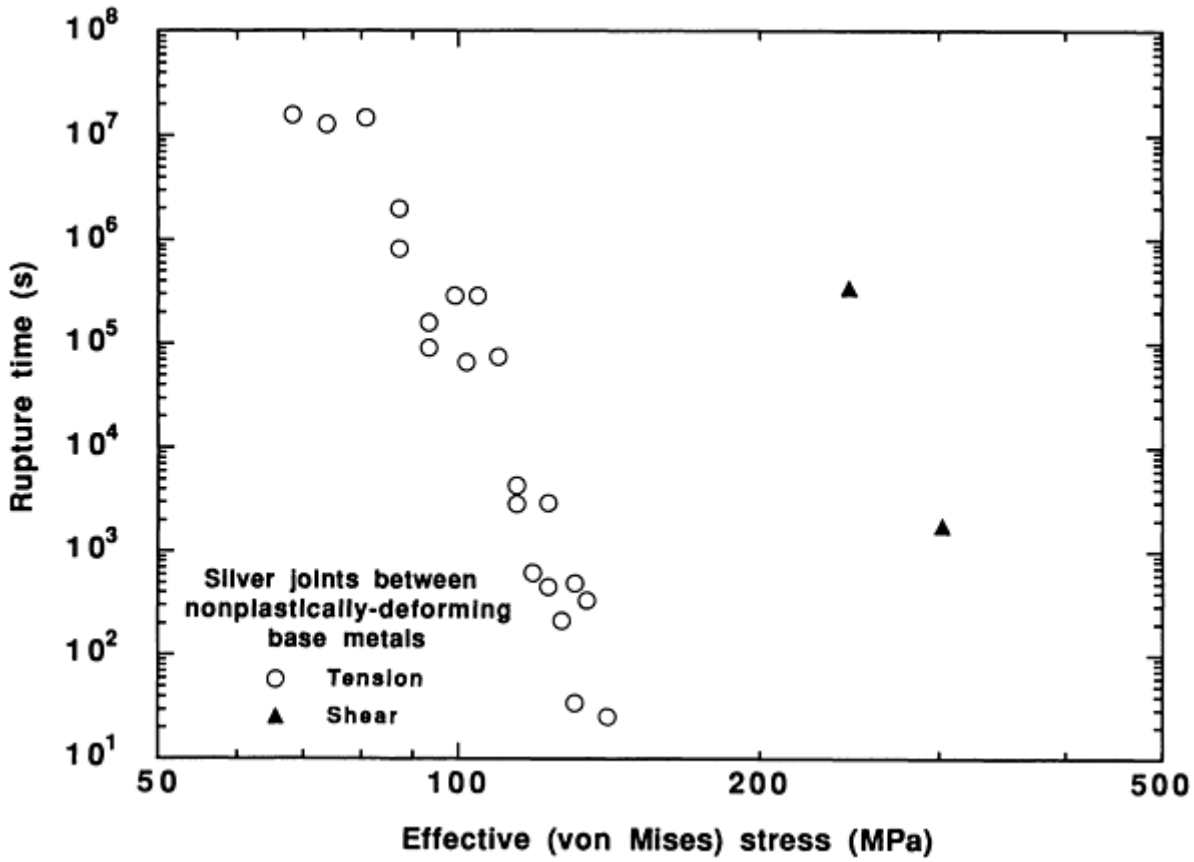

FIG. 9 COMPARISON BETWEEN THE RUPTURE TIME VERSUS EFFECTIVE (VON MISES) STRESS BEHAVIOR IN SHEAR, AT TORSIONAL STRESSES LESS THAN THE MAXIMUM OF HHC-DEPOSITED SILVER INTERLAYERS, COMPARED WITH THAT OF TENSION, CALCULATED USING FEM ANALYSES OF PM SPUTTER-DEPOSITED SILVER INTERLAYERS

The change in steady-state strain-rate (or time-to-rupture, according to the Monkman-Grant relationship) with applied stress is predictable according to the steady-state stress exponent, *n*,

$$n = \left(\frac{\partial \ln e}{\partial \ln s} \right) \qquad \textbf{(EQ 2)}$$

where *n* is about 30 for silver at ambient temperature (Ref 38). Naturally, the steady-state strain rate of the torsional specimens shown in Fig. 9 is less than the constant applied strain rate of the torsional specimens shown in Fig. 8. If the steady-state rate if not achievable in the interlayer metal, then time-dependent failure in shear is not expected to occur.

It is important to realize the consequence of the difference in plastic strains-to-failure between the constant shear-stress case and the constant tensile-stress case. For example, residual shear or tensile stresses may develop during fabrication of interlayer brazes or solid-state welds. This is particularly true in cases where dissimilar base materials are joined, but have substantially different coefficients of thermal expansion. For thin interlayers subjected to residual shear stresses, the dimensions of the base metal and interlayer may be such that the stress is relaxed at strains less than the shear strain-to-failure. However, because the observed tensile strains-to-failure are small, creep rupture by residual tensile stresses is possible, provided a significant stress level exists. If the interlayer metal is resistant to tim-dependent failure, then only the indirect implications of residual stress are important (for example, environmentally induced failure).

Multiaxial Loading

As discussed earlier, in tension there is significant mechanical constraint by the base material, which tends to reduce the effective stress. In torsion, where the shear stress is parallel to the plane of the interlayer, there is not constraint, other than, perhaps, the relatively minor constraint associated with plastic strain incompatibilities between the interlayer and the base metal. It was also mentioned earlier that the equivalent uniaxial strain-to-failure for torsional deformation of soft-interlayer joints is roughly four orders of magnitude higher than the values for uniaxial tension, and the (effective) shear stress-to-failure is only about one-half the UTS. This suggests that the interlayers will behave anisotropically to imposed stresses. The mechanical properties of the intermediate cases of biaxial deformation are not readily interpolated between these limits. The authors have preliminary experimental evidence, for example, that low-strain ductile failures in thin interlayers may occur at particularly low stress levels and strains for cases where tensile loads are accompanied by in-plane shear stresses (Ref 63). This implies that some multiaxial residual stress states may render solid-state-welded interlayer joints substantially more vulnerable to failure than simple tensile-stress states, even though the "macroscopic" effective stress may be comparable, when calculated on the basis of the applied stress state in the base material away from the interlayer.

Environmentally Induced Failure of Interlayers

The interlayer/base-metal interfaces of some soft-interlayer welds appear particularly vulnerable to failure when exposed to external (corrosive) environments. For example, it is known that brazed silver interlayers between stainless steel are subject to galvanic corrosion in aqueous NaCl media (Ref 64, 65). When dissimilar base materials are joined, the potential for stress-corrosion cracking (SCC) exists if the joints are exposed simultaneously to some external (corrosive) environments and either shear or tensile stresses. If an interlayer is subjected to stress, then a determination of the vulnerability to SCC is appropriate. It was mentioned earlier that elevated-temperature joining using either solid-state or brazing processes may leave the joint under substantial residual stress, particularly in the case of dissimilar metals for which the coefficients of thermal expansion are significantly different. The authors have reported (Ref 35) that the uranium to type 304 stainless steel solid-state welds, fabricated using HHC-deposited silver interlayers (Ref 25, 26), are very susceptible to SCC. These silver solid-state welds were joined at 873 K, and the difference in thermal expansion coefficients leaves the joints of cylindrical specimens under significant residual shear stresses after cooling to ambient temperature. It was found that these residual stresses led to SCC at the uranium/silver interface in air saturated with water vapor (100% relative humidity) (Ref 35). This cracking resulted in reduced tensile strengths and rupture times, when compared with those specimens tested in laboratory air (~40% relative humidity). Specimens subjected to the same 100% relative humidity in air in an unstressed state exhibited no loss in strength, even after lengthy exposure. This, or course, emphasizes the importance of considering the residual stresses as not only rendering the interlayer joints vulnerable to "pure mechanical" rupture, but also to environmentally induced failures such as SCC, hydrogen embrittlement, and metal-induced embrittlement, if exposed to critical environments.

Shielded Metal Arc Welding

Raymond H. Juers, Naval Surface Warfare Center

Introduction

SHIELDED METAL ARC WELDING (SMAW), commonly called stick, or covered electrode, welding, is a manual welding process whereby an arc is generated between a flux-covered consumable electrode and the workpiece. The process uses the decomposition of the flux covering to generate a shielding gas and to provide fluxing elements to protect the molten weld-metal droplets and the weld pool.

Shielded Metal Arc Welding

Raymond H. Juers, Naval Surface Warfare Center

The SMAW Process

The important features of the SMAW process are shown in Fig. 1. The arc is initiated by momentarily touching or "scratching" the electrode on the base metal. The resulting arc melts both the base metal and the tip of the welding electrode. The molten electrode metal/flux is transferred across the arc (by arc forces) to the base-metal pool, where it becomes the weld deposit covered by the protective, less-dense slag from the electrode covering.

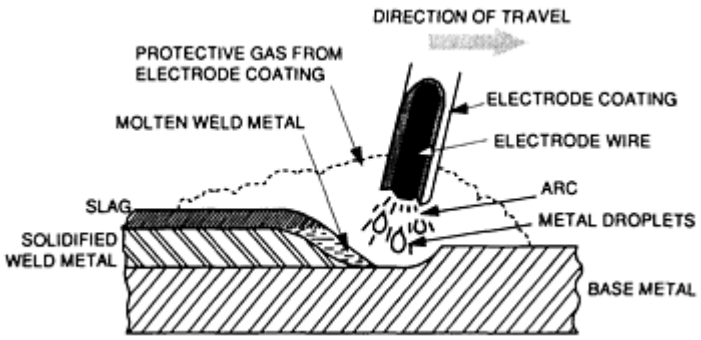

FIG. 1 SMAW PROCESS

Advantages and Limitations. The SMAW process is the most widely used welding process. It is the simplest, in terms of equipment requirements, but it is, perhaps, the most difficult in terms of welder training and skill-level requirements. Although welder skill level is a concern, most welders entering the field start as "stick welders" and develop the necessary skills through training and experience. The equipment investment is relatively small, and welding electrodes (except the very reactive metals, such as titanium, magnesium, and others) are available for virtually all manufacturing, construction, or maintenance applications. Shielded metal arc welding has the greatest flexibility of all the welding processes, because it can be used in all positions (flat, vertical, horizontal, and overhead), with virtually all base-metal thicknesses (1.6 mm, or $\frac{1}{16}$ in., and greater), and in areas of limited accessibility, which is a very important capability.

Because the SMAW process is basically a manual process, the skill level of the welder is of paramount importance in obtaining an acceptable weld. The welder duty cycle is generally low, because of the built-in work break, which occurs after each electrode is consumed and requires replacement. In addition to replacing the electrode when the arc is stopped (broken), the welder may "chip" or remove slag and clean it away from the starting and welding area with a wire brush to allow the proper deposition of the subsequent weld. This electrode replacement and cleaning operation occurs many times during the work day (about every two minutes, or the time it generally takes to consume an electrode). This stopping,

chipping, wire brushing, and electrode replacement prevents the welder from attaining an operator factor, or duty cycle, that is much greater than 25%.

Weld Quality. The quality of the weld depends on the design and accessibility of the joint, as well as on the electrode, the technique, and the skill of the welder. If joint details vary greatly from established design details, then a lower-quality weld can result. Other factors that also reduce quality are improper interbead cleaning, poor location of individual weld beads within the joint, and various problems with individual electrodes, including partially missing flux and core wires that are not centered within the flux covering. Overall, welds of excellent quality can be obtained with the SMAW process, as demonstrated by its use in joining submarine pressure hull sections and high-pressure oil/gas pipe lines.

The base-metal thicknesses. that can be welded using the SMAW process generally range from 1.6 mm ($\frac{1}{16}$ in.) to an unlimited thickness. The thinner materials require a skilled welder, tight fitup, and the proper small-diameter welding electrode. Welding position also is important when determining the minimum plate thicknesses that can be welded. Flat-position butt welds and horizontal fillet welds are generally considered the easiest to weld. Out-of-position welding (vertical, overhead) requires greater skill.

Welding Circuit. The circuit diagram for the SMAW process is shown in Fig. 2. The equipment consists of a power source, electrode holder, and welding cables that connect the power source to the electrode holder and the workpiece. Alternating current (ac), or direct current, electrode negative (DCEN), or direct current, electrode positive (DCEP) can be used, depending on the electrode coating characteristics. The DCEN source is also called dc straight polarity, whereas the DCEP source is also called dc reverse polarity.

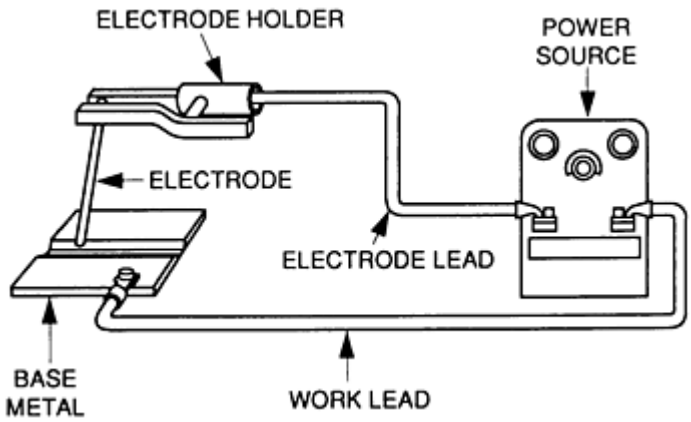

FIG. 2 SHIELDED METAL ARC CIRCUIT DIAGRAM

Equipment. The welding machine, or power source, is the crux of the SMAW process. Its primary purpose is to provide electrical power of the proper current and voltage to maintain a controllable and stable welding arc. Its output characteristics must be of the constant current (CC) type. SMAW electrodes operate within the range from 25 to 500 A. The electrode producer should suggest a narrow optimum range for each size and type of electrode. Operating arc voltage varies between 15 and 35 V.

The electrode holder, which is held by the welder, firmly grips the electrode and transmits the welding current to it. Electrode holders are available in several designs, such as the pincher type and the collet, or twist, type, shown in Fig. 3. Each style has its proponents and the selection is usually a personal preference. Electrode holders are designated by their current capacity. Selection factors, such as the current rating, duty cycle, maximum electrode size, and cable size, are shown in Table 1. The most lightweight holder that will accommodate the required electrode size is usually desired.

TABLE 1 SIZE AND CAPACITY OF ELECTRODE HOLDERS

ELECTRODE HOLDER	RATING	MAXIMUM	MAXIMUM

			ELECTRODE SIZE		CABLE SIZE
	MAXIMUM CURRENT, A	DUTY CYCLE, %	mm	in.	
SMALL	100	50	3.2	$\frac{1}{8}$	1
	200	50	4.0	$\frac{5}{32}$	1/0
MEDIUM	300	60	5.5	$\frac{7}{32}$	2/0
LARGE	400	60	6.4	$\frac{1}{4}$	3/0
EXTRA LARGE	500	75	7.9	$\frac{5}{16}$	4/0
	600	75	9.5	$\frac{3}{8}$	4/0

FIG. 3 SMAW ELECTRODE HOLDERS

All electrode holders should be fully insulated. Because they are used in proximity to the arc and are exposed to high heat, they will deteriorate rapidly. It is extremely important to maintain electrode holders to ensure that they retain their current-carrying efficiency, their insulating qualities, and their electrode gripping action. Manufacturers supply spare parts so that the holders can be rebuilt and maintained for safe and efficient operation.

Certain pieces of auxiliary equipment can be used with the SMAW process, such as low-voltage control circuits, which enable the relatively high open-circuit voltage to be cut off until the electrode touches the workpiece. Other items include remote-control switches for the contactors, remote-control current adjusting devices, and engine idling controllers for engine-driven power sources.

Shielded Metal Arc Welding

Raymond H. Juers, Naval Surface Warfare Center

Applications

Most manufacturing operations that require welding will strive to utilize the mechanized processes that offer greater productivity, higher quality, and, therefore, more cost-effective production. For these reasons, the SMAW process has been replaced where possible. However, the simplicity and ability of the SMAW process to achieve welds in areas of restricted accessibility means that it still finds considerable use in certain situations and applications. Heavy construction, such as shipbuilding, and welding "in the field," away from many support services that would provide shielding gas, cooling water, and other necessities, rely on the SMAW process to a great extent.

Although the SMAW process finds wide application for welding virtually all steels and many of the nonferrous alloys, it is primarily used to join steels. This family of materials includes low-carbon or mild steels, low-alloy steels, high-strength steels, quenched and tempered steels, high-alloy steels, stainless steels, and many of the cast irons. The SMAW process is also used to join nickel and its alloys and, to a lesser degree, copper and its alloys. It can be, but rarely is, used for welding aluminum.

In addition to joining metals, the SMAW process is frequently used for the protective surfacing of base metals. The surfacing deposit can be applied for the purpose of corrosion control or wear resistance (hard surfacing).

Shielded Metal Arc Welding

Raymond H. Juers, Naval Surface Warfare Center

Electrodes

The electrodes used in the SMAW process have many different compositions of core wire and a wide variety of flux-covering types and weights. Standard electrode diameters of the core wire range from 1.6 to 8 mm ($\frac{1}{16}$ to $\frac{5}{16}$ in.). Electrode length usually ranges from 230 to 455 mm (9 to 18 in.); the shorter lengths are associated with the smaller-diameter electrodes. A bare, uncoated end of the electrode (the grip end) is provided for making electrical contact in the electrode holder.

The coating on the electrode has numerous functions. It provides:

- GAS (NORMALLY, CARBON DIOXIDE), FROM THE DECOMPOSITION OF CERTAIN COATING INGREDIENTS TO SHIELD THE ARC AND WELD ZONE FROM THE ATMOSPHERE
- DEOXIDIZERS, FOR SCAVENGING AND PURIFYING THE DEPOSITED WELD METAL
- SLAG FORMERS, TO PROTECT THE DEPOSITED WELD METAL FROM ATMOSPHERIC OXIDATION AND TO HELP SHAPE THE WELD BEAD
- IONIZING ELEMENTS, TO MAKE THE ARC MORE STABLE AND TO OPERATE WITH ALTERNATING CURRENT
- ALLOYING ELEMENTS, TO PROVIDE SPECIAL CHARACTERISTICS TO THE WELD DEPOSIT
- IRON POWDER, IN CERTAIN ELECTRODES, TO INCREASE PRODUCTIVITY FOR WELDING FERROUS METALS

The American Welding Society (AWS) has established a system for identifying and classifying the different types of welding electrodes. All SMAW electrodes have the prefix letter E to indicate welding electrode. The symbols that follow the prefix are based on criteria that best describe the welding capabilities of the electrode metal. These criteria include chemical composition of the deposited weld metal, weld-metal mechanical properties, certain process parameters, or combinations of all factors.

Mild and Low-Alloy Steel-Covered Electrodes. The prefix used to identify these electrodes is followed by a number series that indicates minimum strength level, position capability, and type of covering and welding current. Table 2 explains how the number series is used in AWS A5.1, the specification for carbon steel electrodes for shielded metal arc welding and AWS A5.5, the specification for low-alloy steel electrodes. The first two digits after the E in the E6010 electrode designate a tensile strength of at least 430 MPa (62 ksi) for the deposited metal in the as-welded condition. The third digit indicates the position in which satisfactory welds can be made with the electrode. Thus, the 1 in E6010, for example, means that the electrode is satisfactory for use in all positions (flat, vertical, horizontal, and overhead). The 2 in E6020 indicates that the electrode is suitable for the flat position and horizontal fillets. The last digit or last two digits, taken together, indicate the applicable current type to be used and the type of covering on the electrode.

TABLE 2 CARBON AND LOW-ALLOY STEEL COVERED ELECTRODE IDENTIFICATION SYSTEM

AWS CLASSIFICATION[A]	MINIMUM TENSILE STRENGTH		MINIMUM YIELD STRENGTH		MINIMUM ELONGATION, %
	MPA	KSI	MPA	KSI	

E70XX	480-500	70-72	390-420	57-60	17-25

(A) FIRST TWO OR THREE DIGITS INDICATE TENSILE STRENGTH IN UNITS OF KSI AND OTHER MECHANICAL PROPERTIES (MECHANICAL PROPERTY REQUIREMENTS VARY WITHIN EACH CLASSIFICATION).

(B) THIRD (OR) FOURTH (SECOND TO LAST) DIGIT INDICATES THE WELDING POSITION THAT CAN BE USED.

(C) LAST DIGIT INDICATES USABILITY OF THE ELECTRODE.

(D) IRON POWDER PERCENTAGE BASED ON WEIGHT OF THE COVERING

Stainless Steel Covered Electrodes. The three-digit number that follows the prefix E indicates the chemical composition. In addition, letters or numbers can be used to indicate composition modifications or position usability. The specification AWS A5.4 identifies and classifies covered corrosion-resisting chromium and chromium-nickel steel welding electrodes.

Nickel and Copper Alloys. The designations for nonferrous product classifications, such as nickel and nickel alloys in AWS A5.11 and copper and copper alloys in AWS A5.6, follow the prefix with a list of chemical element abbreviations that are significant in identifying product composition, such as ENiCu, ENiCrFe, ECuSi, and ECuNi.

Surfacing Welding Electrodes. The designations for these products are contained in specifications AWS A5.13 and A5.21. They are very similar to the system used to identify nonferrous electrodes.

Aluminum and Aluminum Alloys. The specification for aluminum and aluminum alloy arc welding electrodes, AWS A5.3, uses the E prefix to indicate a covered electrode, followed by a series of numbers that identify the chemical composition that is equivalent to Aluminum Association alloy designations (for example, E1100, E3003, and E4043).

Suffix symbols are used in various classifications. The AWS A5.5 specification for low-alloy filler metals uses suffixes such as -A1, -B2, -B2L, and -C1 to indicate chemical compositions. Table 3 identifies the weld deposit chemical composition associated with a number of suffixes found on low-alloy electrodes. The classifications for nonferrous products in the AWS A5.6 specification for copper alloys and in the AWS A5.11 specification for nickel alloys list a letter or number suffix that indicates position in a series of similar alloy groupings. A similar suffix pattern is also used in the AWS A5.13 and AWS A5.21 specifications for surfacing welding electrodes. Covered stainless steel electrodes employ a number, -15 or -16, as a suffix to identify usability. The -15 suffix indicates that the electrode is designed for all-position operation using DCEP electrical current. The -16 suffix indicates all-position operation with either ac or DCEP.

TABLE 3 SUFFIX SYMBOLS AND CORRESPONDING COMPOSITIONS FOR LOW-ALLOY STEEL COVERED ELECTRODES

SUFFIX(A)	COMPOSITION, %

(A) THE SUFFIX INDICATES THE CHEMICAL COMPOSITION OF THE WELD-METAL DEPOSIT.

(B) AMOUNT DEPENDS ON ELECTRODE CLASSIFICATION. SINGLE VALUES INDICATE MAXIMUM, CHECK AWS A5.5 FOR THE DIFFERENT ELECTRODE CLASSES.

(C) THERE ARE SEVERAL DIFFERENT M CLASSES; M CLASSIFICATIONS ARE INTENDED TO CONFORM TO MILITARY SPECIFICATIONS.

Deposition Rates. The melting rate of the electrode is directly related to the welding current. The current density in the electrode increases with higher current, which increases the melting rate, which, in turn, increases the deposition rate.

The electrode coating also affects deposition rate. The iron powder types are designed to have higher deposition rates and, therefore, greater productivity. Figure 4 shows the expected deposition rate versus amperage for various electrodes at a 100% duty cycle. (The actual deposition rate will be considerably less. Deposition rate is a function of the duty cycle, which is affected by the time spent changing the electrodes, cleaning slag off of the weld, etc.) Electrode size and, therefore, usable current range are determined by the base-metal thickness, welding position, welder skill level, and joint details.

Weld Schedules and Procedures

Welding schedules are tables of operating parameters that will provide high-quality welds under normal conditions. Strict welding schedules are not as important for the manual SMAW process as they are for semiautomatic and automatic welding for several reasons. First, in a manual welding process, the welder controls conditions by arc manipulation, which achieves better control than any of the other arc welding processes. The welder also directly controls the arc voltage and travel speed and, indirectly, the welding current.

Second, meter readings are rarely used in the SMAW process for the duplication of jobs. It is generally considered that the recommended welding current ranges given in Table 4 for the different types of electrodes are sufficient for most operations. The settings provide a good starting point when first welding on a new application, although they are not necessarily the only welding settings that can be used under every condition. For example, for high-production work, the current settings could be increased considerably over those shown. Factors such as weld appearance, welding position, and welder skill also allow variations from the settings.

(A) THESE DIAMETERS ARE NOT MANUFACTURED IN THE E7028 CLASSIFICATION.

Welder Training. The SMAW process generally requires a high degree of welder skill to consistently produce quality welds. As a result, many training programs emphasize the SMAW process because of the arc manipulation skills developed by the welder. This acquired skill level makes the training on other processes much easier.

The exact content of a training program will vary, depending on the specific application of the process. The complexity of the parts to be welded and the governing codes or specifications involved also dictate the length of the training program. For example, because a pipe welder would need more skill than a tack welder, the length of his training program would be greater.

The job title of arc welder (DOT 810.384-014) describes a person whose responsibility is to weld together many components. This job includes setting up the machine and part to be welded, striking the arc and guiding it along the joint, and performing such duties as chipping, grinding, and slag removal. The welder should be able to:

- WELD IN ALL POSITIONS
- PASS EMPLOYER PERFORMANCE TESTS
- MEET CERTIFICATION STANDARDS OF GOVERNMENTAL AGENCIES OR PROFESSIONAL AND TECHNICAL ASSOCIATIONS

A tack welder (DOT 810.684-010) makes short beads at specific points to hold the parts in place for final welding. The tack welder also performs the duties of fitter helper.

A combination welder (DOT 819-384-010) welds metal parts together to either fabricate or repair assemblies. The combination welder is able to create gas welds and electric arc welds, and to perform flame-cutting operations.

The welder portion of the pipefitter description (DOT 862.381-018) must weld the pipe joint after it has been assembled and tacked in place.

Procedures. There is a definite relationship between the welding current, the size of the welding electrodes, and the welding position. These parameters must be selected to ensure that the welder has the molten weld-metal pool under complete control at all times. If the pool becomes too large, then it becomes unmanageable, perhaps allowing molten metal to run out, particularly during out-of-position welding. The welder should maintain the steady frying and crackling sound that comes with the use of correct procedures. The shape of the molten pool and the movement of the metal at the rear of the pool both serve as guides in checking weld quality. The ripples produced on the bead should be uniform and have good side tie-in with no undercut or excessive reinforcement. The factors described below are essential for maintaining high-quality welding.

Correct Electrode Type. It is important to select the proper electrode for each job. The selection should be based on the type of base metal, expected service, and mechanical properties required.

Correct Electrode Size. The choice of electrode size should depend on the type of electrode, welding position, joint preparation, base-metal thickness, and welder skill.

Correct Current. If the current is too high, then the electrode melts too fast and the molten pool becomes large, irregular, and difficult to control. Current that is too low will not provide enough heat to melt the base metal, causing the molten pool to be sluggish, with a high, irregular, ropey weld bead. It should also be noted that the electrode has inherent

current limits. If the current is too high, then the core wire overheats and the coating cracks. If the current is too low, then there is insufficient heat to maintain the arc and form the protective gas shield.

Correct Arc Length. If an arc is too long, then the metal melts off the electrode in large globules that wobble from side to side, resulting in a wide and irregular weld bead with considerable spatter, and, possibly, porosity and mechanical property degradation. If the arc is too short, then it has insufficient heat to melt the base metal and electrode, which often results in the electrode sticking to the work.

Correct Travel Speed. A speed that is too fast allows the weld pool to freeze before impurities and gases can escape, and the bead will be narrow and inadequate in size. When the speed is too slow, the metal piles up and the bead is larger than required.

Correct Electrode Angle. In fillet welding and deep groove welding, the electrode angle is particularly important. When making a fillet weld, the electrode should be held so that it bisects the angle between the plates and is perpendicular to the line of the weld. When undercut occurs in the vertical member, the angle should be lowered and the arc directed toward the vertical member.

Correct Arc Manipulation. When weaving is used, the width of the weave and the pause at the ends of the weave become important. The welder must pause at each end of the weave to allow adequate fill buildup and fusion to occur. The welder should also quickly move across the center of the weld, because heating is more concentrated in the center than at the edges.

Breaking the Arc. Before an arc is broken, it is important to know whether it will be reestablished with the next electrode and the weld continued or whether it is the end of a weld pass. If welding is to continue, then the crater should remain and the arc quickly broken. If it is the end of a weld pass, then the arc should not be broken until the crater has filled.

Correct Interbead Cleaning. Proper interbead cleaning to remove slag and any spatter is essential to the production of high-quality welds. Proper cleaning prevents slag inclusions, "lack of fusion" defects, and porosity.

Shielded Metal Arc Welding

Raymond H. Juers, Naval Surface Warfare Center

Variations of the SMAW Process

Gravity Welding. Gravity feed is considered to be an automatic method of applying the SMAW process. It utilizes a relatively low-cost mechanism that includes an electrode holder attached to a bracket, which slides down an inclined bar arranged along the line of weld. Special electrodes with a heavy coating are maintained in contact with the workpiece by the weight of the electrode holder and electrode. Once the process is started, it continues automatically until the electrode has burned to a short stub, whereupon the bracket and electrode holder are automatically kicked up to break the arc. One welder can operate several gravity feeders at the same time (Fig. 5). This increases productivity, reduces welder fatigue, and requires less-skilled welders, all of which result in substantial savings in welder labor costs. Table 5 compares the deposition rate, based on pounds per hour, when using one electrode manually versus two, three, four, or five gravity feeders.

TABLE 5 COMPARISON OF DEPOSITION RATES FOR CONVENTIONAL SMAW AND MULTI-ARC GRAVITY-FED WELDING

Data are for making 7.9 mm ($\frac{5}{16}$ in.) fillet welds using E6027 electrodes.

METHOD	DEPOSITION RATE, LB/H
MANUAL, ONE ARC	9
GRAVITY, TWO ARCS	17
GRAVITY, THREE ARCS	26

GRAVITY, FOUR ARCS	34
GRAVITY, FIVE ARCS	43

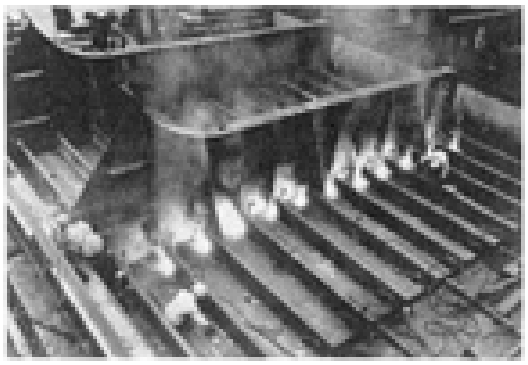

FIG. 5 GRAVITY FEEDERS BEING USED ON SHIP SUBASSEMBLIES

Although gravity-fed SMAW was investigated in the United States, England, and the Scandinavian countries in the late 1940s and early 1950s, credit must be given to the Japanese shipbuilders for perfecting and utilizing the process on a large scale in the early 1960s. The gravity welding process is being used in shipyards, railroad car shops, and barge yards throughout the world. It has reasonable acceptance in applications where large amounts of horizontal fillet welds must be made in a relatively small area.

Firecracker welding is an automatic method by which shielded metal arc welds are made using a long electrode with an electrically nonconductive coating. Human involvement is not required after the arc is initiated. A firecracker weld is generally positioned in the flat position. The welding electrode is placed in the joint and a retaining bar is placed over it. The arc is started by shorting the end of the electrode to the workpiece. The arc length is controlled by the coating thickness. As the arc travels along the stationary electrode, the electrode melts and makes a deposit on the metal immediately underneath. Once the arc is started, the process proceeds to completion automatically. Electrodes that are up to 1 m (39 in.) long and have a core diameter of 5, 6, or 8 mm (0.20, 0.24, or 0.32 in.) have been used. Both alternating and direct current have been applied, and the former may be preferred, because of arc blow problems associated with direct current.

Raymond H. Juers, Naval Surface Warfare Center

Special Applications of the SMAW Process

Underwater welding began during World War I when the British naval force used it to make temporary repairs of leaking rivets on ship hulls. The introduction of covered electrodes enabled succesful underwater welding and the production of welds having approximately 80% of the strength and 40% of the ductility of similar welds made in air. Because of the somewhat diminished weld properties, this SMAW application is generally restricted to salvage operations or underwater repair work.

Underwater welding can be subdivided into two major categories: welding in a wet environment and welding in a dry environment.

Wet Welding. The relatively poor quality of welds made in a wet environment is due primarily to the problem of heat transfer, welder visibility, and the presence of hydrogen in the arc atmosphere during the welding operation. When the base metal and the arc area are surrounded entirely by water, there is no temperature or heat buildup of the base metal at the weld, nor is preheating possible. This creates a weld-metal quench effect, which traps damaging amounts of hydrogen and also produces a weld solidification structure with reduced toughness and ductility. Both conditions contribute to the weld-metal cracking problems experienced when welding steels underwater. Another disadvantage is the restricted visibility, which is due to the equipment and the existing local contaminants in the water, as well as those generated by the welding arc. Under the most ideal conditions, welds produced in wet environments using covered electrodes are

marginal, at best. They can be placed in service for short periods of time under reduced operating conditions, but should be replaced with quality welds as quickly as possible.

The covered electrodes used for wet welding must be waterproofed prior to underwater use. This can be done by wrapping them with waterproof tape or by dipping them in special sodium silicate mixes and allowing them to dry.

Dry Welding. The dry environment enables the production of high-quality welds that meet all code quality requirements. The SMAW process is not very popular for welding in the dry environment, because large amounts of smoke and fumes are produced. An extensive air moving, filtering, and refrigeration system must be employed when the SMAW process is used, because a dry-environment area will quickly fill with the welding fumes, making it impossible for the welder to see that weld area and to function. For this reason, the gas-tungsten arc welding and gas-metal arc welding processes have broader use in dry welding applications.

The article "Underwater Welding" in this Volume explores the topic in greater detail.

Shielded Metal Arc Welding

Raymond H. Juers, Naval Surface Warfare Center

Safety Considerations

The SMAW process, like all open arc welding processes, has a number of potential hazards. To alert welders about these safety concerns, all SMAW electrode containers carry a warning label that identifies the three most common safety hazards in these terms:

- ELECTRIC SHOCK CAN KILLDO NOT PERMIT ELECTRICALLY LIVE PARTS OR ELECTRODES TO CONTACT SKIN . . . OR YOUR CLOTHING OR GLOVES IF THEY ARE WETINSULATE YOURSELF FROM WORK AND GROUND
- FUMES AND GASES CAN BE DANGEROUS TO YOUR HEALTHKEEP FUMES AND GASES FROM YOUR BREATHING ZONE AND GENERAL AREAKEEP YOUR HEAD OUT OF FUMESUSE ENOUGH VENTILATION OR EXHAUST AT THE ARC, OR BOTH
- ARC RAYS CAN INJURE EYES AND BURN SKINWEAR CORRECT EYE, EAR, AND BODY PROTECTION

In addition to the general warnings on the container, further detailed information relating to safety is contained in ANSI/AWS Z49.1, "Safety in Welding and Cutting." The information described below is intended to expand on the general warnings, and should be particularly useful for SMAW welders.

First, the filter plates installed within welding shields must be capable of stopping the harmful levels of infrared, ultraviolet, and visible light rays originating in the arc. Filter plates are now able to absorb 99% or more of the infrared and ultraviolet rays from the arc. The shade of the filter plate suggested for use with SMAW electrodes is given in Table 6.

TABLE 6 RECOMMENDED FILTER LENS SHADES USED IN SHIELDED METAL ARC WELDING

ELECTRODE DIAMETER		LENS SHADE NO.
mm	in.	
1.6	$\frac{1}{16}$	10
2.4	$\frac{3}{32}$	
3.2	$\frac{1}{8}$	

4.0	$\frac{5}{32}$	
4.8	$\frac{3}{16}$	12
5.6	$\frac{7}{32}$	
6.4	$\frac{1}{4}$	
7.9	$\frac{5}{16}$	14
9.5	$\frac{3}{8}$	

Source: ANSI/AWS Z49.1

Second, in addition to protecting himself, the welder must also be aware of others in the area who need protection, which can usually be provided by portable screens. The failure of those working around the arc to use adequate protection can result in eye burn, which is similar to sunburn and is extremely painful for a period of up to 48 h. Usually, eye burn does not permanently injure the eyes, but it can cause intense pain. A physician should be consulted in the case of severe arc burn, regardless of whether it involves the skin or the eyes.

Third, the welding area must be adequately ventilated because of the heavy concentrations of smoke and fumes generated in the SMAW process. If welding is being performed in confined spaces with poor ventilation, such as in a tank, an external air supply in the form of a mask or special helmet may be required. In addition, a second person should be stationed at the tank manhole to provide any necessary assistance. Special ventilation is required when welding stainless steels or metals coated with copper, zinc, lead, or cadmium, because of the toxic nature of these fumes.

Fourth, cables with frayed or cracked insulation and faulty or badly worn connections can cause electrical short circuits and electrical shocks to personnel. When it is necessary to weld in a damp or wet area, the welder should wear rubber boots and stand on a dry, insulated platform.

Gas-Metal Arc Welding

D.B. Holliday, Westinghouse Electric Corporation

Introduction

GAS-METAL ARC WELDING (GMAW) is an arc welding process that joins metals together by heating them with an electric arc that is established between a consumable electrode (wire) and the workpiece. An externally supplied gas or gas mixture acts to shield the arc and molten weld pool.

Although the basic GMAW concept was introduced in the 1920s, it was not commercially available until 1948. At first, it was considered to be fundamentally a high-current-density, small-diameter, bare-metal electrode process using an inert

gas for arc shielding. Its primary application was aluminum welding. As a result, it became known as metal-inert gas (MIG) welding, which is still common nomenclature.

Subsequent process developments included operation at low current densities and pulsed direct current, application to a broader range of materials, and the use of reactive gases (particularly carbon dioxide) and gas mixtures. The latter development, in which both inert and reactive gases are used, led to the formal acceptance of the term gas-metal arc welding.

The GMAW process can be operated in semi-automatic and automatic modes. All commercially important metals, such as carbon steel, high-strength low-alloy steel, stainless steel, aluminum, copper, and nickel alloys can be welded in all positions by this process if appropriate shielding gases, electrodes, and welding parameters are chosen.

Advantages. The applications of the process are dictated by its advantages, the most important of which are:

- ELECTRODE LENGTH DOES NOT FACE THE RESTRICTIONS ENCOUNTERED WITH SHIELDED-METAL ARC WELDING (SMAW).
- WELDING CAN BE ACCOMPLISHED IN ALL POSITIONS, WHEN THE PROPER PARAMETERS ARE USED, A FEATURE NOT FOUND IN SUBMERGED ARC WELDING.
- WELDING SPEEDS ARE HIGHER THAN THOSE OF THE SMAW PROCESS.
- DEPOSITION RATES ARE SIGNIFICANTLY HIGHER THAN THOSE OBTAINED BY THE SMAW PROCESS.
- CONTINUOUS WIRE FEED ENABLES LONG WELDS TO BE DEPOSITED WITHOUT STOPS AND STARTS.
- PENETRATION THAT IS DEEPER THAN THAT OF THE SMAW PROCESS IS POSSIBLE, WHICH MAY PERMIT THE USE OF SMALLER-SIZED FILLET WELDS FOR EQUIVALENT STRENGTHS.
- LESS OPERATOR SKILL IS REQUIRED THAN FOR OTHER CONVENTIONAL PROCESSES, BECAUSE THE ARC LENGTH IS MAINTAINED CONSTANT WITH REASONABLE VARIATIONS IN THE DISTANCE BETWEEN THE CONTACT TIP AND THE WORKPIECE.
- MINIMAL POSTWELD CLEANING IS REQUIRED BECAUSE OF THE ABSENCE OF A HEAVY SLAG.

These advantages make the process particularly well suited to high-production and automated welding applications. With the advent of robotics, gas-metal arc welding has become the predominant process choice.

Limitations. The GMAW process, like any welding process, has certain limitations that restrict its use:

- THE WELDING EQUIPMENT IS MORE COMPLEX, USUALLY MORE COSTLY, AND LESS PORTABLE THAN SMAW EQUIPMENT.
- THE PROCESS IS MORE DIFFICULT TO APPLY IN HARD-TO-REACH PLACES BECAUSE THE WELDING GUN IS LARGER THAN A SMAW HOLDER AND MUST BE HELD CLOSE TO THE JOINT (WITHIN 10 TO 19 MM, OR $\frac{3}{8}$ TO $\frac{3}{4}$ IN.) TO ENSURE THAT THE WELD METAL IS PROPERLY SHIELDED.
- THE WELDING ARC MUST BE PROTECTED AGAINST AIR DRAFTS THAT CAN DISPERSE THE SHIELDING GAS, WHICH LIMITS OUTDOOR APPLICATIONS UNLESS PROTECTIVE SHIELDS ARE PLACED AROUND THE WELDING AREA.
- RELATIVELY HIGH LEVELS OF RADIATED HEAT AND ARC INTENSITY CAN HINDER OPERATOR ACCEPTANCE OF THE PROCESS.

Process Fundamentals

Principles of Operation. In the GMAW process (Fig. 1), an arc is established between a continuously fed electrode of filler metal and the workpiece. After proper settings are made by the operator, the arc length is maintained at the set value, despite the reasonable changes that would be expected in the gun-to-work distance during normal operation. This automatic arc regulation is achieved in one of two ways. The most common method is to utilize a constant-speed (but adjustable) electrode feed unit with a variable-current (constant-voltage) power source. As the gun-to-work relationship changes, which instantaneously alters the arc length, the power source delivers either more current (if the arc length is decreased) or less current (if the arc length is increased). This change in current will cause a corresponding change in the electrode melt-off rate, thus maintaining the desired arc length.

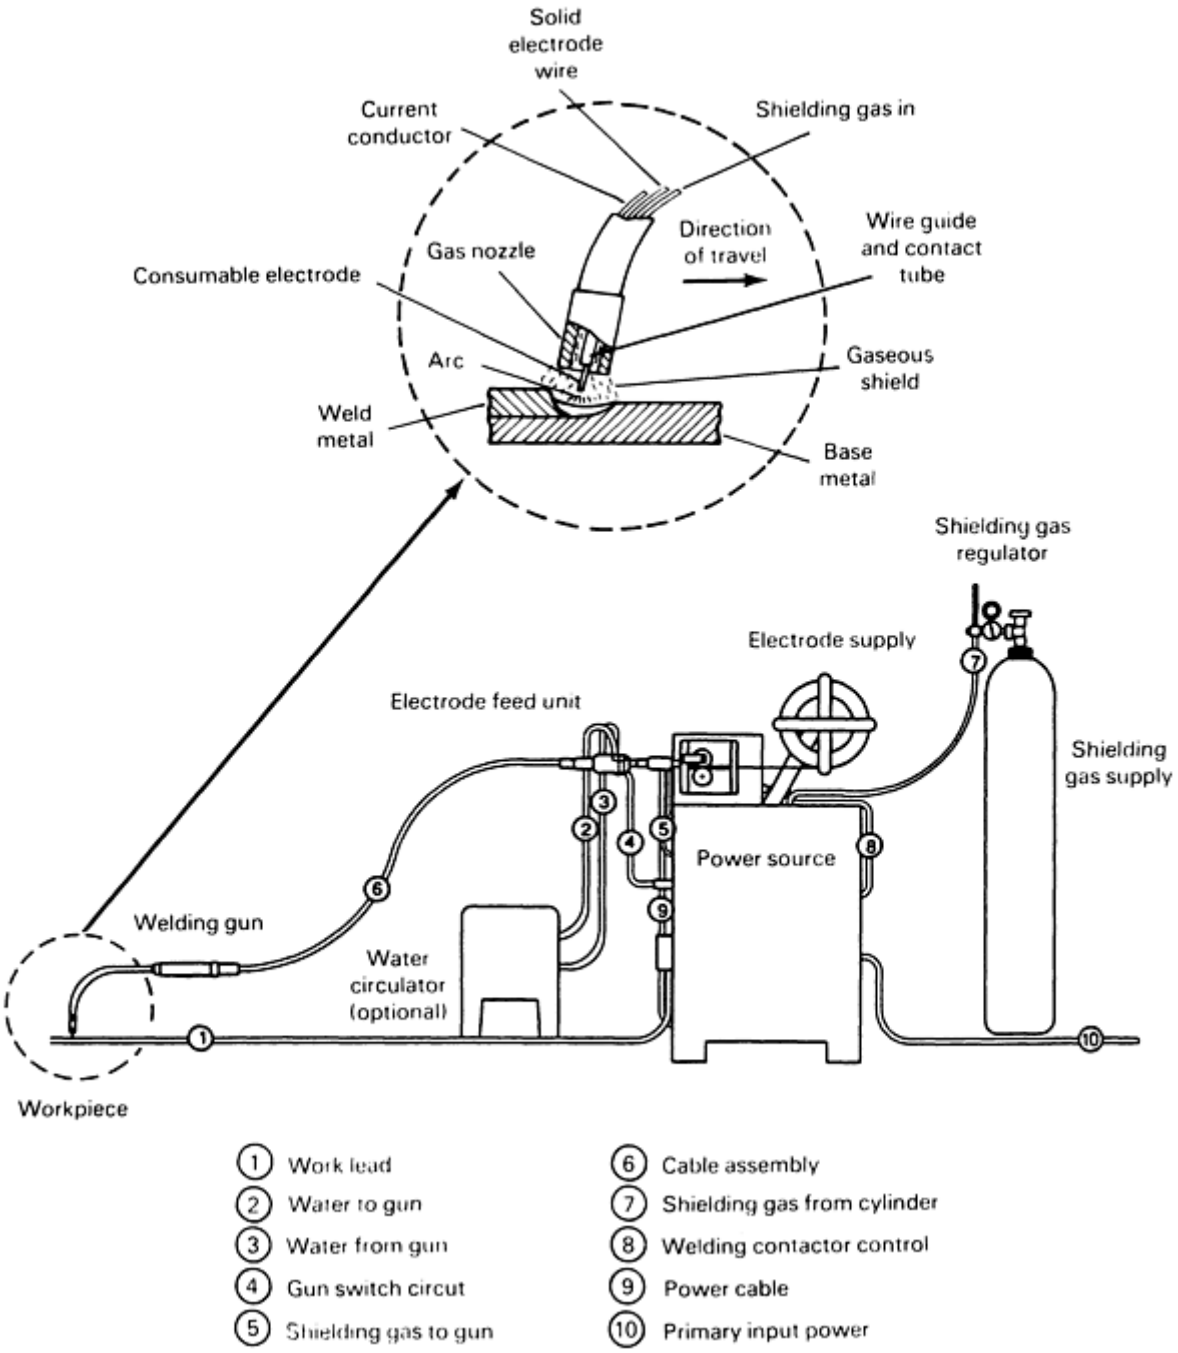

FIG. 1 SCHEMATIC OF GMAW PROCESS

The second method of arc regulation utilizes a constant-current power source and a variable-speed, voltage-sensing electrode feeder. In this case, as the arc length changes, there is a corresponding change in the voltage across the arc. As this voltage change is detected, the speed of the electrode feed unit will change to provide either more or less electrode per unit of time. This method of regulation is usually limited to larger electrodes with lower feed speeds.

Metal Transfer Mechanisms. The characteristics of the GMAW process are best described by reviewing the three basic means by which metal is transferred from the electrode to the work: short-circuiting transfer, globular transfer, or spray transfer. The type of transfer is determined by a number of factors, the most influential of which are:

- MAGNITUDE AND TYPE OF WELDING CURRENT
- ELECTRODE DIAMETER
- ELECTRODE COMPOSITION
- ELECTRODE EXTENSION BEYOND THE CONTACT TIP OR TUBE
- SHIELDING GAS
- POWER SUPPLY OUTPUT

Short-circuiting transfer encompasses the lowest range of welding currents and electrode diameters associated with the GMAW process. This type of transfer produces a small, fast-freezing weld pool that is generally suited for joining thin sections, for out-of-position welding, and for bridging of large root openings. Metal is transferred from the electrode to the workpiece only during a period when the electrode is in contact with the weld pool, and there is no metal transfer across the arc gap (Fig. 2).

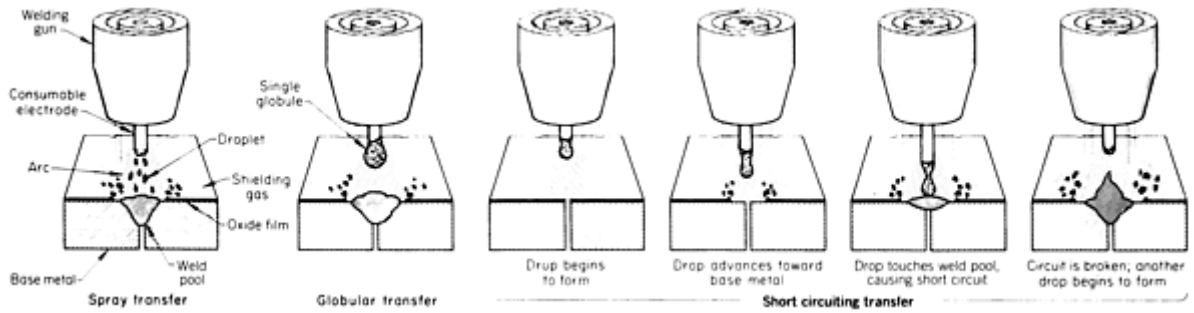

FIG. 2 TRANSFER MODES IN GMAW PROCESS

The electrode contacts the molten weld pool at a steady rate that can range from 20 to over 200 times per second. As the wire touches the weld metal, the current increases and the liquid metal at the wire tip is pinched off, initiating an arc. The rate of current increase must be high enough to heat the electrode and promote metal transfer, yet low enough to minimize spatter caused by violent separation of the molten drop. The rate of current increase is controlled by adjusting the power source inductance. The optimum setting depends on the electrical resistance of the welding circuit and the melting temperature of the electrode. When the arc is initiated, the wire melts at the tip as it is fed forward toward the next short circuit. The open-circuit voltage of the power source must be low enough so that the drop of molten metal cannot transfer until it contacts the weld metal.

Because metal transfer only occurs during short circuiting, the shielding gas has very little effect on the transfer itself. However, the gas does influence the operating characteristics of the arc and the base-metal penetration. The use of carbon dioxide generally produces high spatter levels, when compared with inert gases, but it allows deeper penetration when welding steels. To achieve a good compromise between spatter and penetration, mixtures of carbon dioxide and argon are often used. With nonferrous metals, argon-helium mixtures are used to achieve this compromise.

Globular Transfer. With a positive electrode, globular transfer takes place when the current density is relatively low, regardless of the type of shielding gas. However, the use of carbon dioxide or helium results in this type of transfer at all usable welding currents. Globular transfer is characterized by a drop size with a diameter that is greater than that of the electrode. This large drop is easily acted upon by gravity, which limits successful transfer to the flat position.

At average currents that are slightly higher than those used in short-circuiting transfer, axially directed globular transfer can be achieved in a substantially inert gas shield. However, if the arc length is too short, then the enlarging drop can short to the workpiece, become superheated, and disintegrate, producing considerable spatter. Therefore, the arc length must be long enough to ensure that the drop detaches before it contacts the weld pool. However, when higher voltage values are used, the weld is likely to be unacceptable, because of a lack of fusion, insufficient penetration, and excessive reinforcement. This limits the use of this transfer mode to very few production applications.

Carbon dioxide shielding produces a randomly directed globular transfer when the welding current and voltage values are significantly higher than the range used for short-circuiting transfer. Although severe spatter conditions result when conventional techniques are used, carbon dioxide is still the most commonly used shielding gas for welding mild steel when the quality requirements are not too rigorous. The spatter problem is controlled by "burying" the arc below the weld/base-metal surface. The resulting arc forces are adequate enough to produce a depression that contains the spatter. This technique requires relatively high currents and results in very deep penetration. Good operator setup skills are required. However, poor wetting action can result in an excessive weld reinforcement.

Spray Transfer. A very stable, spatter-free "spray" transfer mode can be produced when argon-rich shielding is used. This type of transfer requires the use of direct current with the electrode positive and a current level that is above a critical value called the "transition current." Below this current level, transfer occurs in the globular mode at the rate of a few drops per second. At values above the transition current, transfer occurs in the form of very small drops that are formed and detached at the rate of hundreds per second and are accelerated axially across the arc gap.

The transition current is proportional to the electrode diameter, and, to a lesser extent, to the electrode extension. It also has a direct relationship to the filler metal melting temperature. Transition currents for various materials and electrode diameters are shown in Table 1.

The spray transfer mode results in a highly directed stream of discrete drops that are accelerated by arc forces to velocities that overcome the effects of gravity. This enables the process to be used in any position, under certain conditions. Because the drops are separated, short circuits do not occur, and the spatter level is negligible, if not totally eliminated.

Another characteristic of spray transfer is the "finger" penetration pattern that it produces directly below the electrode tip. Although the penetration can be deep, it can be affected by magnetic fields that must be controlled to ensure that it is always located at the center of the weld penetration profile. Otherwise, a lack of fusion and an irregular bead surface profile can result.

The spray transfer mode can be used to weld almost any metal or alloy, because of the inert characteristics of the argon shield. Sometimes, thickness can be a factor, because of the relatively high current levels required. The resultant arc forces can cut through, rather than weld, thin sheets. In addition, high deposition rates can result in a weld pool size that cannot be supported by surface tension in the vertical and overhead positions. However, the thickness and position limitations of spray transfer have been largely overcome by specially designed power supplies. These machines produce carefully controlled current outputs that "pulse" the welding current from levels below the transition current to levels above it.

Figure 3 shows the two levels of current provided by these machines. One is a constant, low-background current that sustains the arc without providing enough energy to cause the formation of drops on the wire tip. The other is a superimposed pulsing current with an amplitude that is greater than the transition current necessary for spray transfer. During this pulse, one or more drops are formed and transferred. The frequency and amplitude of the pulses control the energy level of the arc and, therefore, the rate at which the wire melts. By reducing the arc energy and the wire melting rate, it is possible to retain many of the desirable features of spray transfer while joining sheet metals and welding thick metals in all positions.

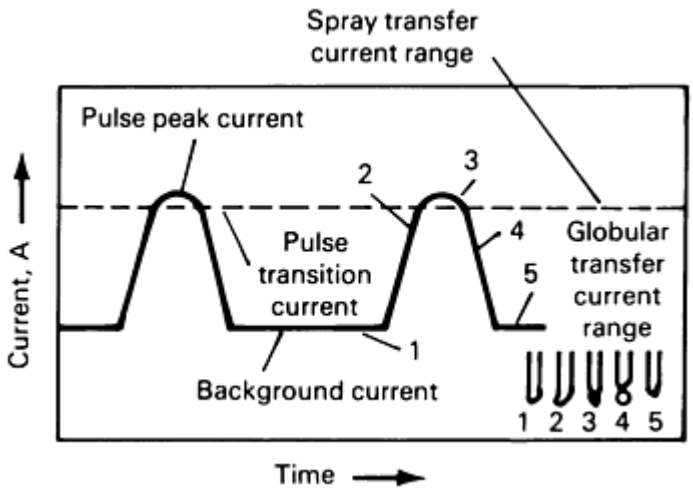

FIG. 3 CHARACTERISTIC CURRENT WAVEFORM FOR A "PULSING" POWER SUPPLY

Many variations of such machines are available. The simplest provide a single frequency of pulsing (60 or 120 pulses/s) and independent control of the background and pulsing current levels. Synergic machines, which are sophisticated, automatically provide the optimum combination of background and pulsing current levels for any given setting of wire feed speed. Normally, these settings are specific to an electrode/shielding gas combination and must be changed or reprogrammed when the combination is changed.

Process Variables. The important variables of the GMAW process that affect weld penetration, bead geometry, and overall weld quality are:

- WELDING CURRENT (ELECTRODE FEED SPEED)
- POLARITY
- ARC VOLTAGE (ARC LENGTH)
- TRAVEL SPEED
- ELECTRODE EXTENSION
- ELECTRODE ORIENTATION (GUN ANGLE)
- ELECTRODE DIAMETER

Knowledge and control of these variables are essential to consistently produce welds of satisfactory quality. Because they are not completely independent of one another, changing one variable generally requires changing one or more of the others to produce the desired results. The effects of these variables on deposit attributes are shown in Table 2.

TABLE 2 EFFECT OF CHANGES IN PROCESS VARIABLES ON WELD ATTRIBUTES

WELDING VARIABLES TO CHANGE	DESIRED CHANGES

GUN ANGLE	DRAG	PUSH	LITTLE EFFECT	LITTLE EFFECT	LITTLE EFFECT	LITTLE EFFECT	PUSH	DRAG

(A) WILL RESULT IN DESIRED CHANGE IF CURRENT LEVELS ARE MAINTAINED BY ADJUSTMENT OF WIRE FEED SPEED

Considerable skill and experience are necessary to select the optimal combination for each application. This selection is further complicated by the fact that the optimal settings for the variables are also affected by the type of base metal, the electrode composition, the welding position, quality requirements, and the number of completed weldments required. Thus, no single set of parameters provides optimal results in every case.

Welding Current. As the electrode feed speed is varied, the welding current varies in a like manner when a constant-voltage power source is used. This occurs because the current output of the power source varies dramatically with the slight changes in the arc voltage (arc length) that result when changes are made in the electrode feed speed. When all

other variables are held constant, an increase in welding current results in an increase in the depth and width of penetration, deposition rate, and weld bead size.

Polarity is the term used to described the electrical connection of the welding gun in relation to the terminals of a direct-current (dc) power source. When the gun power lead is connected to the positive terminal, the polarity is designated as direct current, electrode positive (DCEP). Alternatively, a connection to the negative terminal is designated as direct current, electrode negative (DCEN). The vast majority of GMAW applications utilize DCEP, because it provides for a stable arc, low spatter, a good weld bead profile, and the greatest depth of penetration.

Arc voltage and arc length are related terms that are often used interchangeably. However, they are different. Arc voltage is an approximate means of stating the physical arc length in electrical terms. The same physical arc length, however, could yield different arc voltage readings, depending on factors such as shielding gas, current, and electrode extension. When all variables are held constant, a reliable relationship exists between the two: an increase in voltage setting will result in longer arc length. Although the arc length is the variable of interest and the one that should be controlled, arc voltage is more easily monitored. Because of this fact, and because the arc voltage is normally required to be specified in welding procedures, it is the term that is more commonly used. From any specific value of arc voltage, an increase tends to flatten the weld bead and increase the width of the fusion zone. Excessively high voltage can cause porosity, spatter, and undercut. A reduction in voltage results in a narrower weld bead with a higher crown.

Travel speed is the linear rate at which the arc is moved along the weld joint. When all other conditions are held constant, weld penetration is a maximum at an intermediate travel speed. When travel speed is decreased, the filler metal deposition per unit length increases. At very slow speeds, the welding arc impinges on the molten weld pool, rather than the base metal, thereby reducing the effective penetration.

As the travel speed is increased, the thermal energy transmitted to the base metal from the arc increases, because the arc acts more directly on the base metal. However, further increases in travel speed impart less thermal energy to the base metal. Thus, melting of the base metal first increases and then decreases with increasing travel speed. As travel speed is increased further, there is a tendency toward undercutting along the edges of the weld bead, because there is insufficient deposition of filler metal to fill the path melted by the arc.

Electrode orientation is described in two ways: by the relationship of the electrode axis with respect to the direction of travel (the travel angle) and by the angle between the electrode axis and the adjacent work surface (work angle). When the electrode points in a direction opposite to the travel direction, it results in a trail angle and is known as the backhand welding technique. When the electrode points in the direction of travel, it results in a lead angle and is called the forehand welding technique.

For all positions, a trailing travel angle that ranges from 5 to 15° (from perpendicular) provides a weld with maximum penetration and a narrow, convex surface configuration. It also provides for maximum shielding of the molten weld pool. However, the common technique utilizes a leading travel angle, which provides better visibility for the operator and a weld with a flatter surface profile. For some materials, such as aluminum, a leading angle is preferred, because it provides a "cleaning action" ahead of the molten weld metal, which promotes wetting and reduces base-material oxidation.

When producing fillet welds in the horizontal position, the work angle should be about 45° to the vertical member.

The electrode extension is the distance between the last point of electrical contact (usually the gun contact tip or tube) and the end of the electrode. An increase in the amount of this extension causes an increase in electrical resistance. This, in turn, generates additional heat in the electrode, which contributes to greater electrode melting rates. Without an increase in arc voltage, the additional metal will be deposited as a narrow, high-crowned weld bead. The optimum electrode extension generally ranges from 6.4 to 13 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) for short-circuiting transfer and from 13 to 25 mm ($\frac{1}{2}$ to 1 in.) for spray and globular transfers.

The electrode diameter influences the weld bead configuration. A larger electrode requires a higher minimum current than a smaller electrode does to achieve the same metal transfer characteristics.

Higher currents, in turn, produce additional electrode melting and larger, more-fluid weld deposits. Higher currents also result in higher deposition rates and greater penetration, but may prevent the use of some electrodes in the vertical and overhead positions.

Gas-Metal Arc Welding

D.B. Holliday, Westinghouse Electric Corporation

Equipment

The basic equipment for a typical GMAW installation is shown in Fig. 1. The major components are discussed below.

A welding gun provides electrical current to the electrode, directs it to the workpiece, and provides a vehicle for directing shielding gas to the weld area. Different types of guns have been designed for many varied applications, ranging from heavy-duty guns for high-current, high-volume production to lightweight guns for low-current or out-of-position welding. The most commonly used guns are designed to be cooled by the surrounding air (Fig. 4). However, as amperage requirements increase, a water-cooled gun may be required. Guns are rated based on their current-carrying capacity, generally with a CO_2 shielding gas. If inert gases are used, these gun ratings must be reduced significantly. Guns can also be equipped with their own integral electrode feed units.

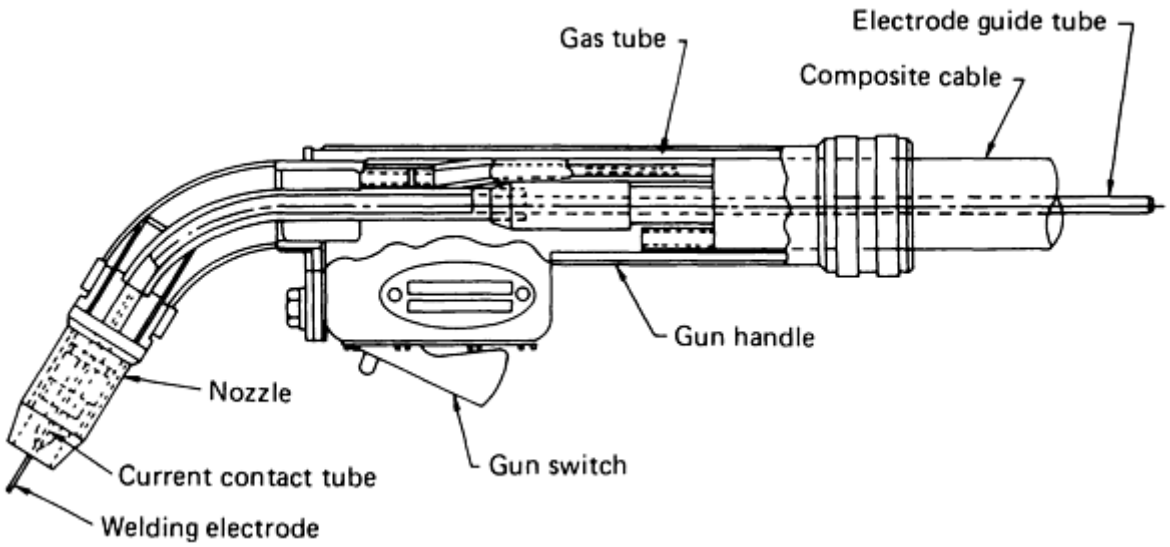

FIG. 4 CROSS SECTION OF AN AIR-COOLED GMAW GUN

The contact tube, usually made of copper or a copper alloy, is used to transmit welding current to the electrode, as well as to direct the electrode toward the work. The contact tube is connected electrically to the welding power supply by the power cable. The inner surface of the contact tube is very important, because the electrode must feed easily through this tube while making a good electrical contact. Generally, the hole in the contact tube would be from 0.13 to 0.25 mm (0.005 to 0.010 in.) larger than the wire being used, although larger sizes may be required for materials such as aluminum. The hole should be checked periodically and replaced if it has become elongated because of excessive wear. If a tip in this condition is used, it can result in poor electrical contact and erratic arc characteristics.

The nozzle directs an even-flowing column of shielding gas into the welding zone. It is extremely important to maintain an even flow in order to adequately protect the molten weld metal from atmospheric contamination. Different-sized nozzles are available and should be chosen according to the application, that is, larger nozzles for high-current work where the puddle is large and smaller nozzles for low-current and short-circuiting welding.

The electrode conduit and liner are connected to a bracket adjacent to the feed rolls on the electrode feed motor. The conduit and liner support both protect and direct the electrode from the feed rolls to the gun and contact tube. Uninterrupted electrode feeding is necessary to ensure good arc stability. A steel liner is recommended when using hard

electrode materials, such as steel and copper, whereas nylon liners should be used for soft electrode materials, such as aluminum and magnesium.

The electrode feed unit, or wire feeder, consists of an electric motor, output shaft, drive rolls, and accessories for maintaining electrode alignment and pressure (Fig. 5). These units can be separate or integrated with the speed control or located remotely from it. The electrode feed motor is usually a direct-current type and provides the mechanical energy for pushing the electrode through the gun and to the work. It has a control circuit that varies the motor speed over a broad range. The feed unit can be an integral component of the gun (Fig. 6) or dual-feed units, one in the gun and one in a separate feeder, can be electrically coupled together to provide a "push-pull" system. The spool-gun and push-pull systems are often used on aluminum, where difficulty can be encountered in trying to push the wire through a conduit to the gun.

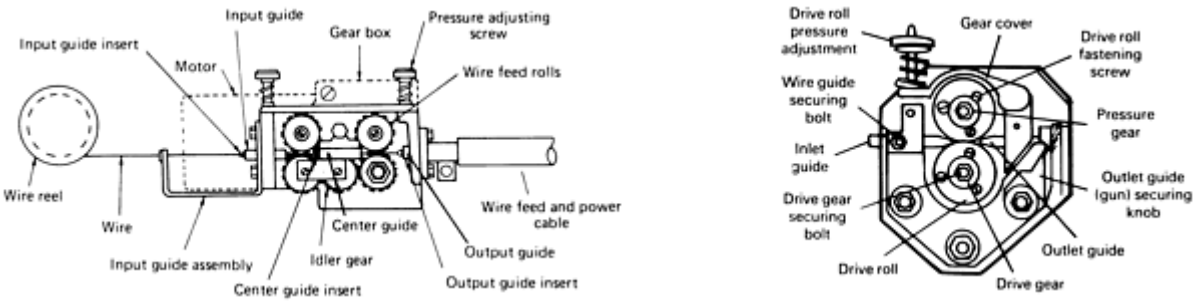

FIG. 5 TYPICAL REMOTE-WIRE FEED UNITS. (A) SCHEMATIC OF A TYPICAL FOUR-ROLL SYSTEM MECHANISM. (B) CLOSE-UP VIEW OF A TYPICAL TWO-ROLL SYSTEM GEARBOX

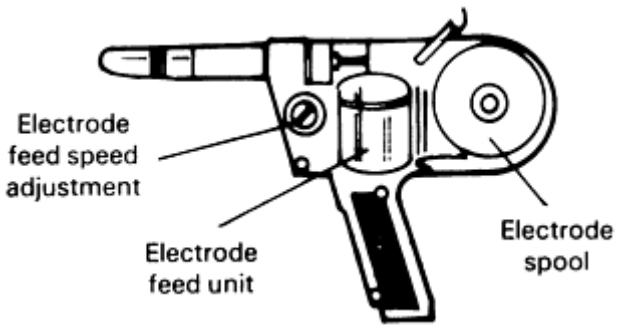

FIG. 6 SPOOL-ON-GUN TYPE TORCH WITH COVER REMOVED TO SHOW SELF-CONTAINED PULL-TYPE FEED-UNIT SYSTEM

The feed motor is connected through a gear reducer to a set of wire feed rolls that transmit mechanical energy to the electrode, pulling it from the source and pushing it through the welding gun. Various types of rolls are available, including knurled, "U" groove, "V" groove, and flat. The knurled design is used for harder wires, such as steel, and allows maximum frictional force to be transmitted to the wire with a minimum of drive roll pressure. These types of rolls are not recommended for soft wires, such as aluminum, because they tend to cause the wire to flake, which can eventually clog the gun or liner. For these softer wires, the "U" groove or "V" groove type will allow the application of uniform pressure around the wire without deforming it. The flat rolls can be used with the smaller-diameter wires and in combination with a "U" or "V" groove.

The welding control mechanism and the electrode feed motor for semiautomatic operation are usually provided in one integrated package. The main function of the welding control mechanism is to regulate the speed of the electrode feed motor, usually through an electronic governor. The control also regulates the starting and stopping of the electrode feed through a signal received from the gun switch.

Normally, shielding gas, water (when used), and welding power are also delivered to the gun through the control mechanism, which requires direct connection to these facilities and the power supply. Gas and water flow are regulated to coincide with the weld start and stop by using solenoid valves. The control mechanism can also sequence gas flow starts and stops and energize the power source contractor. The control mechanism may allow some gas to flow before welding starts (preflow) and after welding stops (postflow) to protect the molten weld puddle. The control mechanism is usually independently powered by 115 V ac.

The welding power source provides suitable electrical power (generally 20 to 80 V) that is delivered to the electrode and workpiece to produce the arc. Because the vast majority of GMAW applications utilize DCEP, the positive lead is connected to the gun and the negative lead, to the workpiece. The power source can be the "static" type in which incoming utility power (120 to 480 V) is reduced to welding voltage by a transformer or solid-state inverter. It could also be the "rotating" type in which the welding power is provided by a rotating generator driven by a motor or internal combustion engine. The static type is normally used in shops where there is an available source of power. It has advantages over the rotating type in that it can respond more rapidly to varying arc conditions. The rotating type is generally used at field sites where external power in unavailable. Both types of power sources can be designed and built to provide either a constant current or constant potential (cp) output, the latter of which is the most common by far. On newer power sources, this cp output can be pulsed at either a constant or variable frequency. With the advent of solid-state electronic power sources, such as inverters, even further control over the pulsing variables (for example, frequency, pulse width, and so on) can be obtained.

When used in conjunction with a constant-speed wire feeder, the constant-voltage power source compensates for the variations in the contact-tip-work-distance that can occur during normal welding operations. It does this by instantaneously increasing or decreasing welding current to increase or decrease the electrode burnoff rate. The initial arc length is established by adjusting the voltage at the power source. Once this is set, no other changes are required during welding. The wire feed speed, which is also the current control, is then set by the operator and adjusted as necessary. In addition to this self-regulating feature of the CP power source, control over slope and inductance is included on those machines intended for short-circuiting transfer. Additional controls are also provided when using power sources that have pulsing capabilities.

Additional information is available in the article "Power Sources" in this Volume.

Electrode Source. The GMAW process uses a continuously fed electrode that is consumed at relatively high speeds. Therefore, the electrode source must provide a large volume of material that can readily be fed to the gun to ensure maximum process efficiency. This source is usually in the form of a spool or coil that can hold from 7 to 27 kg (15 to 60 lb) of wire that has been wound to allow free feeding without kinks or tangles. Larger spools of up to 115 kg (250 lb) are also available, and material can be provided in drums of 340 to 455 kg (750 to 1000 lb). Small spools of 0.45 to 0.9 kg (1 to 2 lb) are used for spool-on-gun equipment.

Regulated Shielding Gas Supply. A system is required to provide constant shielding gas pressure and flow rate during welding. This system consists of a regulator connected to a supply of "welding grade" shielding gas, as well as the necessary hoses or piping. The regulator is a device that reduces the source gas pressure to a constant working pressure, regardless of variations at the source. It can be a single-stage or dual-stage type and may have a built-in flowmeter. The shielding gas source can be a high-pressure cylinder, a liquid-filled cylinder, or a bulk-liquid tank. Gas mixtures are available in a single cylinder. Mixing devices can also be used to obtain the correct proportions when two or more gases or liquids are used. The type and size of the gas storage source depend on economic considerations that are based on the volume of shielding gas consumed per unit of time.

D.B. Holliday, Westinghouse Electric Corporation

Consumables

The two consumable, but essential, elements of the GMAW process are the electrode and the shielding gas, each of which is described below.

The chemical composition of the electrode must be selected to achieve the desired properties in the weld metal. The composition is designed with extra deoxidizers or other scavenging agents to compensate for reactions with the

atmosphere and the base metal. The deoxidizers most commonly used in steel electrodes are silicon and manganese. Silicon can also be added in all transfer modes to increase weld metal fluidity or it can be added when a 300 series stainless steel electrode is used.

The physical characteristics (finish, straightness, and others) of electrodes used in the GMAW process are important to successful welding. The material specifications for these electrodes establish manufacturing requirements to ensure that users receive a uniform product that feeds smoothly through the equipment and has these characteristics, as well:

- UNIFORM WINDING ON THE SPOOL OR COIL WITH NO KINKS OR BENDS
- SMOOTH SURFACE FINISH FREE OF SLIVERS, SCRATCHES, OR SCALE
- PRESCRIBED CAST AND HELIX
- UNIFORM DIAMETER

Cast and helix refer to dimensions of a single coil of wire removed from a spool or coil and layed (that is, cast) on a flat surface. If this coil is too small in diameter (cast) or shows an excessive lift from the flat surface (helix) wire, feeding problems during welding can be anticipated.

Shielding Gas

The primary function of the shielding gas in most of the welding processes is to protect the surrounding atmosphere from contact with molten metal. In the GMAW process, this gas plays an additional role in that it has a pronounced effect on arc characteristics, mode of metal transfer, depth of fusion, weld bead profile, welding speed, and cleaning action.

Inert gases, such as argon and helium, are commonly used, as is the active gas, CO_2. It is also common to use mixtures of these gases and to employ small additions of oxygen.

Information about shielding gas compositions and about which gases to use for specific joining applications is provided in the article "Shielding Gases" in this Volume.

Gas-Metal Arc Welding

D.B. Holliday, Westinghouse Electric Corporation

Safety

The major hazards of concern during GMAW are: the fumes and gases, which can harm health; the high-voltage electricity, which can injure and kill; the arc rays, which can injure eyes and burn skin; and the noise which may be present that can damage hearing.

The type and amount of fumes and gas present during welding depend on the electrode being used, the alloy being welded, and the presence of any coatings on the base metal. To guard against potential hazards, a welder should keep his head out of the fume plume and avoid breathing the fumes and gases caused by the arc. Ventilation is always required.

Electrode shock can result from exposure to the high open-circuit voltages associated with welding power supplies. All electrical equipment and the workpiece must be connected to an approved electrical ground. Cables should be of sufficient size to carry the maximum current required. Insulation should be protected from cuts and abrasion, and the cable should not come into contact with oils, paints, or other fluids which may cause deterioration. Work areas, equipment, and clothing must be kept dry at all times. The welder should be well insulated, wearing dry gloves, rubber-soled shoes, and standing on a dry board or platform while welding.

Radiant energy, especially in the ultraviolet range, is intense during GMAW. To protect the eyes from injury, the proper filter shade for the welding-current level selected should be used. These greater intensities of ultraviolet radiation can cause rapid disintegration of cotton clothing. Leather, wool, and aluminum-coated cloth will better withstand exposure to arc radiation and better protect exposed skin surfaces.

When noise has been determined to be excessive in the work area, ear protection should be used. This can also be used to prevent spatter from entering the ear.

Conventional fire prevention requirements, such as removal of combustibles from the work area, should be followed. Sparks, slag, and spatter can travel long distances, so care must be taken to minimize the start of a fire at locations removed from the welding operation. For further information, see the guidelines set forth in the National Fire Protection Association Standard NFPA No. 51B, "Fire Protection in Use of Cutting and Welding Processes."

Care should be exercised in the handling, storage, and use of cylinders containing high-pressure and liquefied gases. Cylinders should be secured by chains or straps during handling or use. Approved pressure-reducing regulators should be used to provide a constant, controllable working pressure for the equipment in use. Lubricants or pipe fitting compounds should not be used for making any connections, as they can interfere with the regulating equipment, and in the case of oxygen service, they can contribute to a catastrophic fire.

For further safety information, see ANSI/AWS Z49.1, "Safety in Welding and Cutting."

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Introduction

IN THE FLUX-CORED ARC WELDING (FCAW) process, the heat for welding is produced by an electric arc between a continuous filler metal electrode and the workpiece. A tubular, flux-cored electrode makes this welding process unique. The flux contained within the electrode can make the electrode self-shielding. Alternatively, an external shielding gas may be required.

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Process Features

Flux-cored arc welding has two major variations. The gas-shielded FCAW process (Fig. 1) uses an externally supplied gas to assist in shielding the arc from nitrogen and oxygen in the atmosphere. Generally, the core ingredients in gas-shielded electrodes are slag formers, deoxidizers, arc stabilizers, and alloying elements.

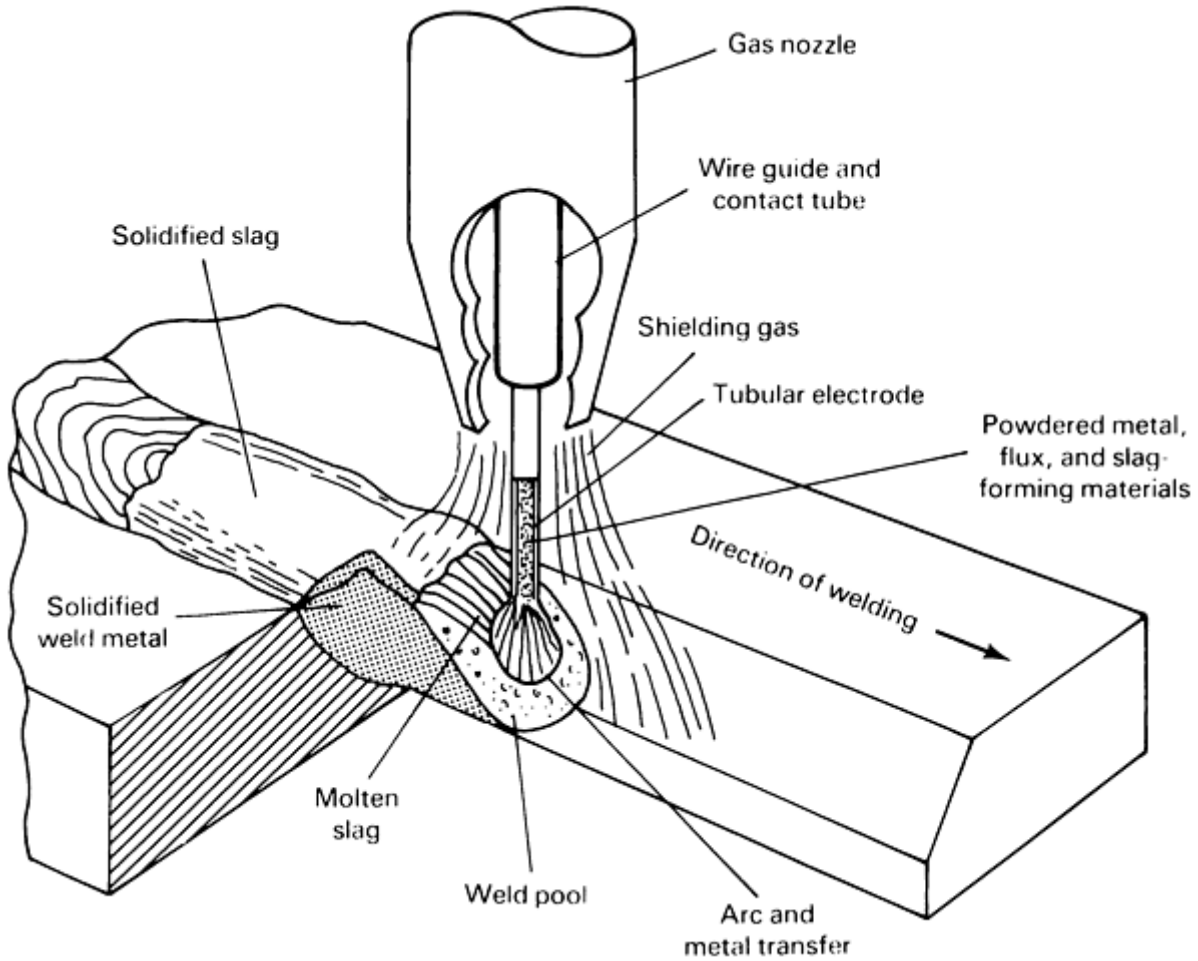

FIG. 1 GAS-SHIELDED FLUX-CORED ARC WELDING. SOURCE: REF 1

In the self-shielded FCAW process, the core ingredients protect the weld metal from the atmosphere without external shielding. Some self-shielded electrodes provide their own shielding gas through the decomposition of core ingredients. Others rely on slag shielding, where the metal drops being transferred across the arc and the molten weld pool are protected from the atmosphere by a slag covering. Many self-shielded electrodes also contain substantial amounts of deoxidizing and denitrifying ingredients to help achieve sound weld metal. Self-shielded electrodes can also contain arc stabilizers and alloying elements.

Advantages. Because it combines the productivity of continuous welding with the benefits of having a flux present, the FCAW process has several advantages relative to other welding processes. These advantages include:

- HIGH DEPOSITION RATES, ESPECIALLY FOR OUT-OF-POSITION WELDING
- LESS OPERATOR SKILL REQUIRED THAN FOR GAS-METAL ARC WELDING (GMAW)
- SIMPLER AND MORE ADAPTABLE THAN SUBMERGED ARC WELDING (SAW)
- DEEPER PENETRATION THAN SHIELDED METAL ARC WELDING (SMAW)
- MORE TOLERANT OF RUST AND MILL SCALE THAN GMAW

Disadvantages of the FCAW process include:

- SLAG MUST BE REMOVED FROM THE WELD AND DISPOSED OF
- MORE SMOKE AND FUME ARE PRODUCED IN FCAW THAN IN THE GMAW AND SAW PROCESSES

- FUME EXTRACTION IS GENERALLY REQUIRED
- EQUIPMENT IS MORE COMPLEX AND MUCH LESS PORTABLE THAN SMAW EQUIPMENT

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Applications

Flux-cored arc welding enjoys widespread use in many industries. Both the gas-shielded and self-shielded FCAW processes are used to fabricate structures from carbon and low-alloy steels. Both process variants are used for shop fabrication, but the self-shielded FCAW process is preferred for field use. The acceptability of the FCAW process for structural use is illustrated by the fact that prequalified joints are included in the structural welding code of the American Welding Society (AWS).

Gas-shielded flux-cored electrodes are commonly used to weld carbon, low-alloy steel, and stainless steels in the construction of pressure vessels and piping for the chemical processing, petroleum refining, and power-generation industries. In addition, flux-cored electrodes are used to weld some nickel-base alloys.

Flux-cored electrodes are also used in the automotive and heavy-equipment industries in the fabrication of frame members, axle housings, wheel rims, suspension components, and other parts. Small-diameter flux-cored electrodes are used for automotive body repair.

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Equipment

The FCAW process utilizes semiautomatic, mechanized, and fully automatic welding systems. The basic equipment includes a power supply, wire feed system, and welding gun. The required auxiliary equipment, such as shielding gas, depends on the process variant used and the degree of automation. Fume removal equipment must also be considered in most applications of the FCAW process.

Typical semiautomatic equipment is shown in Fig. 2. The equipment used in the gas-shielded FCAW process is typically identical to GMAW equipment.

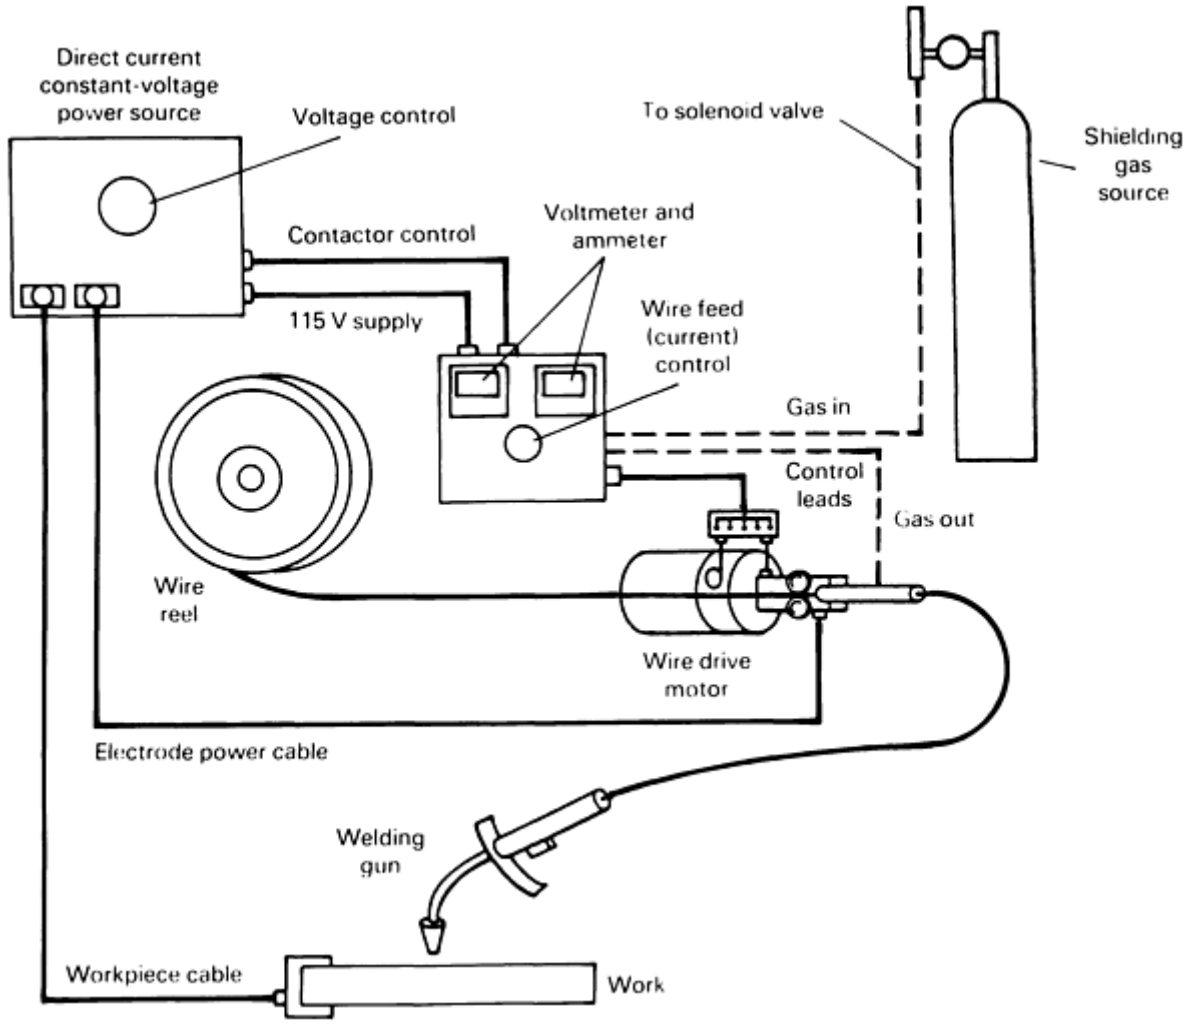

FIG. 2 SEMIAUTOMATIC FCAW EQUIPMENT. SOURCE: REF 1

The recommended power supply for the semi-automatic FCAW process is a constant-voltage direct current (dc) machine. Most power supplies used for semiautomatic FCAW have output ratings of 600 A or less. A power supply rated at 60% or more duty cycle is the best choice for most industrial applications, whereas a duty-cycle rating as low as 20% may be sufficient for maintenance and repair applications.

Constant-current power supplies are used in certain situations, such as field welding applications, where portable constant-current SMAW power supplies are readily available. The addition of a contactor and a voltage-sensing wire feeder makes this an adequate welding system. However, such a system is only recommended when the use of a constant-voltage system is not feasible, because constant-current systems produce an inherently less-stable welding arc than constant-voltage systems.

Wire feeders for constant-voltage FCAW systems are generally simple devices that provide a constant wire feed speed. The power supply provides sufficient current to maintain an arc at the voltage that is preset at the power supply. A change in wire feed speed results in a change in the welding current.

In a constant-current system, the wire feeder is somewhat more complex. The welding current is preset at the power supply. The wire feeder has a voltage-sensing feedback loop that allows it to adjust the wire feed speed to maintain the desired welding voltage. The wire feeder generally contains systems to close the contactor and open the shielding gas solenoid valve (gas-shielded FCAW process only) when welding is started.

Because flux-cored wires are easily deformed by excessive feed roll pressure, knurled feed rolls are generally used in the FCAW process. Some wire feeders use a single drive roll paired with an undriven pressure roll. Others have one or two

pairs of drive rolls. It is generally believed that systems having two pairs of drive rolls require the least drive roll pressure to provide dependable feeding.

Both air-cooled and water-cooled welding guns are used in the semiautomatic FCAW process. Air-cooled guns are generally preferred, because they are simpler to maintain, lighter in weight, and less bulky. Water-cooled guns may be required when welding currents over 500 A are used, especially when the shielding gas is rich in argon.

Air-cooled guns designed for gas-shielded welding should not be used for self-shielded welding, because the gun depends on the flow of shielding gas for proper cooling. Although curved-neck guns are the most common, straight guns are used to a limited extent.

A trigger switch on the welding gun is closed to initiate wire feeding, welding current flow, and shielding gas flow. The electrode is delivered from the wire feeder to the gun through a flexible conduit. Standard conduit lengths are 3, 3.7, 4.6, and 6 m (10, 12, 15, and 20 ft). Other lengths may also be available.

Mechanized and automatic FCAW equipment is not substantially different from that used in the semiautomatic FCAW process. The power supply should be rated for 100% duty cycle. Power supplies capable of outputs up to 1000 A may be required for some applications. Constant-current systems are very seldom used for mechanized and automatic welding.

The wire feed system is separated into a drive motor assembly and a welding control device, the latter of which often has a system to automatically start the travel mechanism when wire feed, current flow, and shielding gas flow are initiated. The welding control device is often equipped with a voltmeter and ammeter, as well.

The welding gun in mechanized and automatic systems is often mounted directly to the drive motor assembly, eliminating the need for a conduit. The gun is usually straight, but curved-neck guns are also used. Both water- and air-cooled guns are used, depending on the welding current level and shielding gas.

Most of the commonly available air-cooled guns can be used at levels up to 500 A with CO_2 shielding gas. When argon-rich shielding gas is used, the same gun may only be suitable for use at levels up to 300 A. Water-cooled guns are generally used at higher current levels.

Various travel mechanisms are used, depending on the applications. These mechanisms include side-beam carriages, tractor-type carriages, and robots.

Fume-Removal Equipment. In many cases, the amount of fumes generated by the FCAW process is sufficient to require fume-removal equipment. Although such equipment can be as simple as exhaust fans in the shop roof, local fume collection is often necessary. These systems can be either collection hoods (located above the welding gun) or fume-extractor guns. These guns are more efficient at collecting fumes, but are heavier and more bulky than standard welding guns. Fume collection hoods must be repositioned each time the welding location is moved in order to be effective.

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Base Metals

Most weldable carbon and low-alloy steels can be welded by the FCAW process if suitable electrodes are available. Steels for which electrodes are available include:

- MILD STEELS, SUCH AS AISI 1010 TO 1030, ASTM A 36, A 285, A 515, AND A 516

- WEATHERING STRUCTURAL STEELS, SUCH AS ASTM A 588
- HIGH-STRENGTH, LOW-ALLOY STEELS, SUCH AS ASTM A 710
- HIGH-TEMPERATURE CHROMIUM-MOLYBDENUM STEELS, SUCH AS ASTM A 387 GRADES 12 (1CR-0.5MO) AND 22 (2.25CR-1MO)
- NICKEL-BASE STEELS, SUCH AS ASTM A 203
- HIGH-STRENGTH QUENCHED AND TEMPERED STEELS, SUCH AS HY-80 AND ASTM A 514 AND A 517
- MEDIUM-CARBON, HEAT-TREATABLE, LOW-ALLOY STEELS, SUCH AS AISI 4130

Several grades of stainless steel are welded with both gas-shielded and self-shielded flux-cored electrodes. Electrodes designed for welding AISI types 304, 316, 347, and others are available. Also available are electrodes suitable for joining stainless steels to carbon and low-alloy steels.

Electrodes that can be used to weld some nickel-base alloys have also been introduced. Among the nickel-base alloys that have been joined using the FCAW process are alloy 600 (UNS N06600) and alloy 625 (UNS N06625). Some cast irons are also welded using nickel-base flux-cored electrodes designed specifically for this purpose.

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Electrode Manufacture

Flux-cored electrodes are generally manufactured using the process shown in Fig. 3. A flat sheath material is first formed into a "U" shape. The core ingredients are poured into this "U" at the desired rate. The sheath is then closed around the core materials to form a round tube. The diameter of this tube is then reduced, generally by drawing or rolling operations, to compress the core materials and bring the electrodes to a size that is usable for welding. The finished wire is than wound on spools, coils, or other packages. Other manufacturing methods, which are generally considered proprietary, are also used.

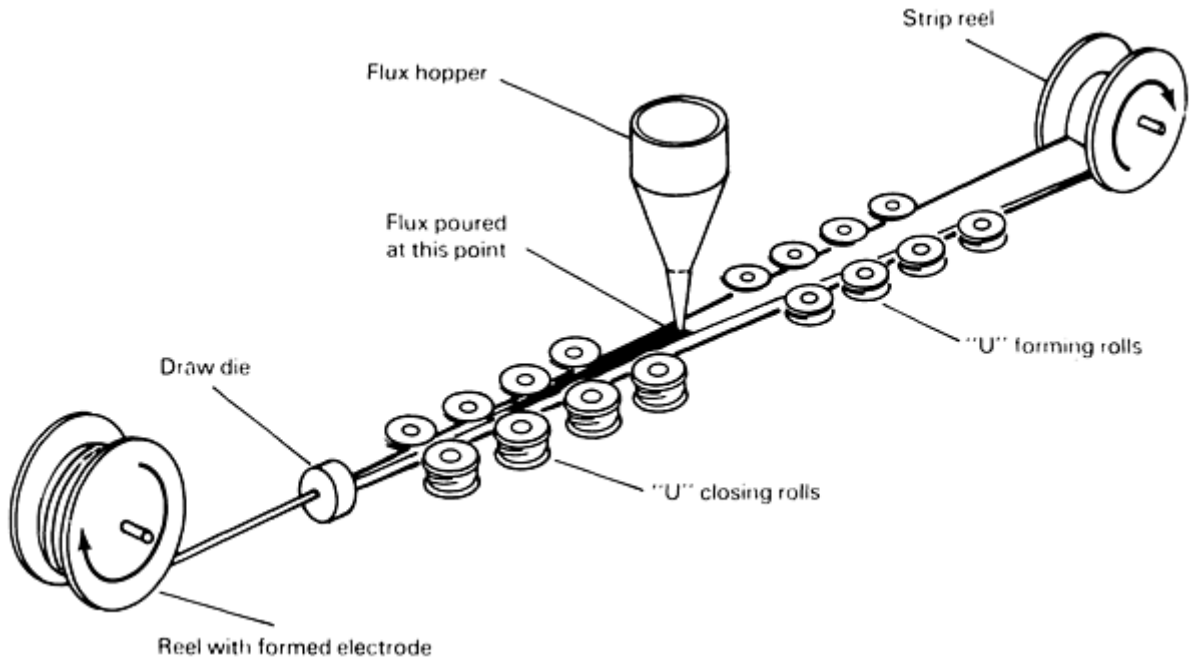

FIG. 3 FLUX-CORED ELECTRODE MANUFACTURING PROCESS. SOURCE: REF 2

The usability of a flux-cored electrode, as well as the properties and chemistry of the weld it deposits, primarily depends on the ingredients in the electrode core. Common core ingredients and their functions are listed in Table 1.

TABLE 1 FUNCTIONS OF COMMON CORE INGREDIENTS IN FCAW ELECTRODES

CORE INGREDIENT	GAS FORMER	DEOXIDIZER	DENITRIFIER	SLAG FORMER	VISCOSITY CONTROL	ARC STABILIZER	ALLOY

Flux-Cored Arc Welding

David W. Meyer, The Esab Group, Inc.

Electrode Diameters

Flux-cored electrodes are produced in diameters ranging from 0.8 to 3.2 mm (0.030 to $\frac{1}{8}$ in.). Electrodes for all-position welding may be available in 0.8 mm (0.030 in.), 0.9 mm (0.035 in.), 1.2 mm (0.045 in.), 1.4 mm (0.052 in.), and 1.6 mm ($\frac{1}{16}$ in.) diameters. Electrodes for flat- and horizontal-position welding may be available in 1.6 mm ($\frac{1}{16}$ in.), 2.0 mm ($\frac{5}{64}$ in.), 2.4 mm ($\frac{3}{32}$ in.), 2.8 mm ($\frac{7}{64}$ in.), and 3.2 mm ($\frac{1}{8}$ in.) diameters. Other diameters may be made available by agreement between the manufacturer and the purchaser.

Electrode Classification

Carbon and Low-Alloy Steel Electrodes. Carbon steel flux-cored electrodes are classified by AWS A5.20, "Specification for Carbon Steel Electrodes for Flux Cored Arc Welding." The layout of this classification system is defined in Fig. 4; an "X" indicates a position where a designator would be. For example, the designator indicating minimum tensile strength can be a 6, to denote 62 ksi (430 MPa), or a 7, to denote 72 ksi (495 MPa). The assignment of the final designator depends on the shielding requirements and features of the electrode, as well as the recommended welding polarity. These are described in Table 2. The designations EXXT-G and EXXT-GS are designed to allow the classification of electrodes that are not covered by any of the other classifications.

TABLE 2 USABILITY TYPE DESIGNATORS FOR FLUX-CORED ELECTRODES

TYPE	SHIELDING[A]	SINGLE OR MULTIPASS[B]	TRANSFER	IMPACT TOUGHNESS REQUIREMENT	POLARITY[C]	SPECIAL CHARACTERISTICS
T-1	GAS	MULTIPASS	SPRAY-LIKE	27 J AT -18 °C (20 FT · LBF AT 0 °F)	DCEP	LOW SPATTER, FULL SLAG COVERAGE
T-2	GAS	SINGLE	SPRAY-LIKE	NO REQUIREMENT	DCEP	LOW SPATTER, FULL SLAG COVERAGE, HIGH DEOXIDIZERS
T-3	SELF	SINGLE	SPRAY-LIKE	NO REQUIREMENT	DCEP	HIGH SPEED
T-4	SELF	MULTIPASS	GLOBULAR	NO REQUIREMENT	DCEP	HIGH DEPOSITION, LOW PENETRATION, CRACK RESISTANT
T-5	GAS	MULTIPASS	GLOBULAR	27 J AT -30 °C (20 FT · LBF AT -20 °F)	DCEP[D]	IMPROVED TOUGHNESS, CRACK RESISTANT, THIN SLAG
T-6	SELF	MULTIPASS	SPRAY-LIKE	27 J AT -30 °C (20 FT · LBF AT -20 °F)	DCEP	IMPROVED TOUGHNESS, DEEP PENETRATION
T-7	SELF	MULTIPASS	GLOBULAR	NO REQUIREMENT	DCEN	CRACK RESISTANT, GOOD SLAG REMOVAL
T-8	SELF	MULTIPASS	GLOBULAR	27 J AT -30 °C (20 FT · LBF AT -20 °F)	DCEN	IMPROVED TOUGHNESS, CRACK RESISTANT
T-10	SELF	SINGLE	GLOBULAR	NO REQUIREMENT	DCEN	HIGH SPEED
T-11	SELF	MULTIPASS	SPRAY-LIKE	NO REQUIREMENT	DCEN	GENERAL PURPOSE
T-G	NOT SPECIFIED	MULTIPASS	NOT SPECIFIED	NO REQUIREMENT	NOT SPECIFIED	NOT SPECIFIED
T-GS	NOT SPECIFIED	SINGLE	NOT SPECIFIED	NO REQUIREMENT	NOT SPECIFIED	NOT SPECIFIED

Source: AWS A5.20

(A) GAS-SHIELDED ELECTRODES ARE CLASSIFIED USING CO_2 SHIELDING; HOWEVER, AR-CO_2 MIXTURES ARE COMMONLY USED IN PRACTICE.

(B) MULTIPASS ELECTRODES ARE SUITABLE FOR SINGLE-PASS OR MULTIPASS WELDING; SINGLE-PASS ELECTRODES ARE SUITABLE FOR SINGLE-PASS WELDING ONLY.

(C) DCEP, DIRECT-CURRENT ELECTRODE POSITIVE; DCEN, DIRECT-CURRENT ELECTRODE NEGATIVE.

(D) T-5 ELECTRODES ARE CLASSIFIED USING DCEP; HOWEVER, THEY ARE SOMETIMES USED WITH DCEN IN PRACTICE.

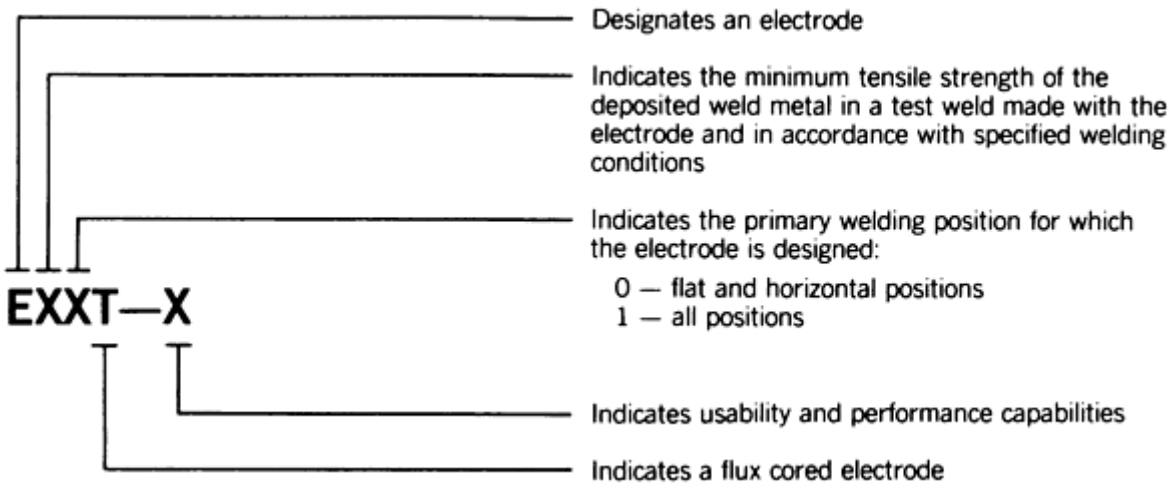

FIG. 4 CLASSIFICATION SYSTEM FOR CARBON STEEL FLUX-CORED ELECTRODES. THE LETTER "X" AS USED IN THIS FIGURE AND IN ELECTRODE CLASSIFICATION DESIGNATIONS IN AWS SPECIFICATION A5.20-79 SUBSTITUTES FOR SPECIFIC DESIGNATIONS INDICATED BY THIS FIGURE. SOURCE: REF 3

It should be noted that the Canadian Standards Association specification W48.5-M1990, "Carbon Steel Electrodes for Flux- and Metal-Cored Arc Welding," includes two additional electrode types that are planned for inclusion in the next revision of the AWS A5.20 specification. These classifications are EXXT-9 and EXXT-12. T-9 electrodes are generally similar to T-1 electrodes, but with improved toughness. T-12 electrodes are generally similar to T-9 electrodes, but with a maximum tensile strength also specified.

Low-alloy steel electrodes are classified under AWS A5.29, "Specification for Low Alloy Steel Electrodes for Flux Cored Arc Welding." This specification uses a classification system very similar to that used in specification AWS A5.20, except that a chemical composition designator is added to the designation. An electrode classified according to this specification will have the form EXXTX-X. All of the positions before the dash have the same meaning as those in specification AWS A5.20. The position behind the dash is the chemical composition designator, which consists of a letter and a number. The letter denotes the alloy type of the electrode as follows:

DESIGNATOR	ALLOY TYPE
A	CARBON-MOLYBDENUM STEEL
B	CHROMIUM-MOLYBDENUM STEEL
NI	NICKEL STEEL
D	MANGANESE-MOLYBDENUM STEEL
W	WEATHERING STEEL
K	OTHER LOW-ALLOY STEELS
G	NOT SPECIFIED

Specification AWS A5.29 classifies only the EXXT1-X, EXXT4-X, EXXT5-X, and EXXT8-X electrode types, and the usability designator has the name meaning as that in specification A5.20. Minimum tensile strengths of up to 830 MPa (120 ksi) are included in specification AWS A5.29. Impact toughness requirements are based on the strength, usability, and chemical composition requirements of the electrode.

Stainless steel electrodes are classified under AWS A5.22, "Specification for Flux Cored Corrosion Resisting Chromium and Chromium-Nickel Steel Electrodes." Classifications to this specification have the form EXXXT-X. The first three positions are the chemical composition designator, which corresponds to the American Iron and Steel Institute (AISI) designations (such as 308, 316, and 410) of steels having a similar composition. The final position is the shielding-type designator. T-1 types are designed for use with CO_2 or Ar-CO_2 shielding gases (classification requires the use of CO_2). T-2 types are designed for use with Ar-$2O_2$ shielding gas. T-3 types are self-shielded. A T-G type is included for electrodes that are not covered by the other shielding-type designators.

Nickel-Base Electrodes. A specification for nickel-base flux-cored electrodes has not yet been published. The manufacturers of these electrodes should be consulted for information on their usability, composition, and properties.

Gas-Tungsten Arc Welding

Grant Ken-Hicken, Sandia National Laboratory

Introduction

GAS-TUNGSTEN ARC WELDING (GTAW), also known as HeliArc, tungsten inert gas (TIG), and tungsten arc welding, was developed in the late 1930s when a need to weld magnesium became apparent. Russell Meredith (Ref 1) developed a welding process using the inert gas helium and a tungsten electrode to fuse magnesium. This joining method replaced riveting as a method of building aircraft with aluminum and magnesium components. The HeliArc welding has continued to this day with many refinements and name changes, but with no change in the fundamentals demonstrated by Meredith (Ref 1).

The melting temperature necessary to weld materials in the GTAW process is obtained by maintaining an arc between a tungsten alloy electrode and the workpiece (Fig. 1). Weld pool temperatures can approach 2500 °C (4530 °F). An inert gas sustains the arc and protects the molten metal from atmospheric contamination. The inert gas is normally argon, helium, or a mixture of helium and argon.

Gas-Tungsten Arc Welding

Grant Ken-Hicken, Sandia National Laboratory

Applications

Gas-tungsten arc welding is used extensively for welding stainless steel, aluminum, magnesium, copper, and reactive materials (for example, titanium and tantalum). The process can also be used to join carbon and alloy steels. In carbon steels, it is primarily used for root-pass welding with the application of consumable inserts or open-root techniques on pipe. The materials welded range from a few thousandths of an inch to several inches in thickness.

Advantages and Limitations

Advantages of GTAW include (Ref 3):

- PRODUCES HIGH-QUALITY, LOW-DISTORTION WELDS
- FREE OF THE SPATTER ASSOCIATED WITH OTHER METHODS
- CAN BE USED WITH OR WITHOUT FILLER WIRE
- CAN BE USED WITH A RANGE OF POWER SUPPLIES
- WELDS ALMOST ALL METALS, INCLUDING DISSIMILAR ONES
- GIVES PRECISE CONTROL OF WELDING HEAT

The GTAW process is applicable when the highest weld quality is required. It can be used to weld almost all types of metals. The operator has excellent control of heat input, and vision is not limited by fumes or smoke from the process.

Limitations of GTAW include (Ref 4):

- PRODUCES LOWER DEPOSITION RATES THAN CONSUMABLE ELECTRODE ARC WELDING PROCESSES
- REQUIRES SLIGHTLY MORE DEXTERITY AND WELDER COORDINATION THAN GAS METAL ARC WELDING (GMAW) OR SHIELDED METAL ARC WELDING (SMAW) FOR MANUAL WELDING
- LESS ECONOMICAL THAN CONSUMABLE ELECTRODE ARC WELDING FOR THICK SECTIONS GREATER THAN 9.5 MM ($\frac{3}{8}$ IN.)
- PROBLEMATIC IN DRAFTY ENVIRONMENTS BECAUSE OF DIFFICULTY IN SHIELDING THE WELD ZONE PROPERLY

Additional problems with the process may include:

- TUNGSTEN INCLUSIONS IF THE ELECTRODE IS ALLOWED TO CONTACT THE WELD POOL
- CONTAMINATION OF THE WELD METAL, IF PROPER SHIELDING OF THE FILLER METAL BY THE GAS STREAM IS NOT MAINTAINED
- LOW TOLERANCE FOR CONTAMINANTS ON FILLER OR BASE METALS
- CONTAMINATION OR POROSITY, CAUSED BY COOLANT LEAKAGE FROM WATER-COOLED TORCHES
- ARC BLOW OR ARC DEFLECTION, AS WITH OTHER PROCESSES

Power supplies for GTAW are usually the constant-current type with a drooping (negative) volt-ampere (V-A) curve. Saturable reactors and thyristor-controlled units are the most common. Advances in the electronics industry have readily been accepted in the welding community, resulting in sophisticated, lightweight power supplies. Transistorized direct current (dc) power supplies are becoming common, and the newer rectifier-inverter supplies are very compact and versatile. The inverter power supply consists of three converters:

- 60 HZ PRIMARY ALTERNATING CURRENT (AC) IS RECTIFIED TO DC
- DIRECT CURRENT IS INVERTED TO HIGH-FREQUENCY AC
- ALTERNATING CURRENT IS RECTIFIED TO DC (REF 5)

The inverter supplies can be switched from constant current to constant voltage for GMAW, resulting in a very versatile piece of equipment. The inverter-controlled power supplies are more stable and have faster response times than conventional silicon-controlled rectifier (SCR) power supplies. Figure 2 compares the response of an inverter-controlled arc welding machine and a thyristor-controlled welding machine.

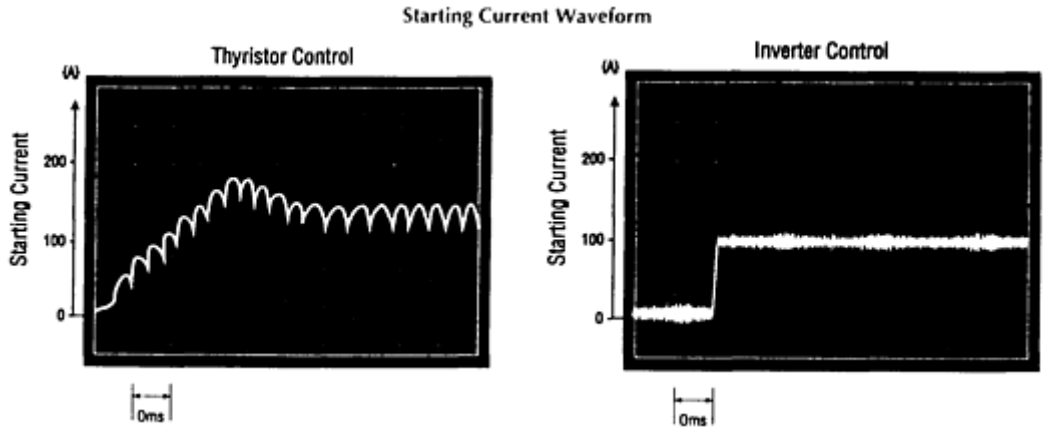

FIG. 2 STARTING CURRENT WAVEFORMS OF TWO POWER SOURCES TO SHOW RELATIVE RESPONSE TIMES OF EACH SOURCE. (A) THYRISTOR-CONTROLLED SOURCE. (B) INVERTER-CONTROLLED SOURCE. FASTER RESPONSE OF INVERTER-CONTROLLED ARC WELDING MACHINE (2 MS TO GO FROM 0 TO 100 A) INDICATES A MORE STABLE ARC.

Torch Construction. The welding torch holds the tungsten electrode that conducts the current to the arc, and it provides a means of shielding the arc and molten metal. The major components of a typical welding torch are shown in Fig. 3.

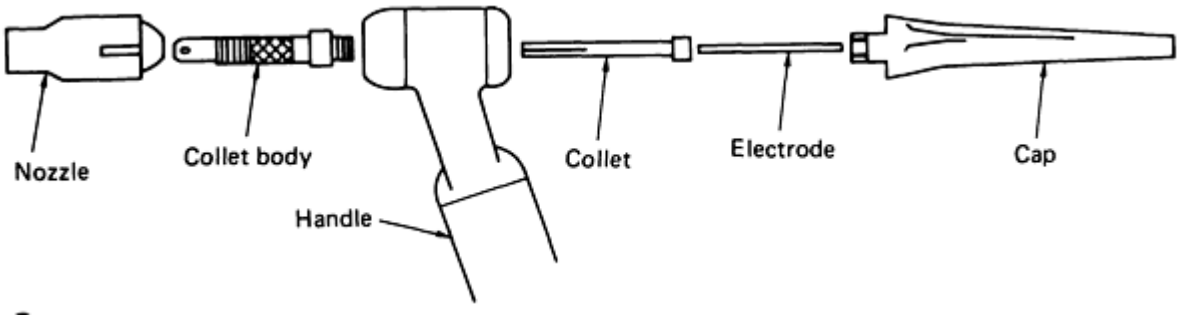

FIG. 3 SCHEMATIC SHOWING EXPLODED VIEW OF KEY COMPONENTS COMPRISING A GTAW MANUAL TORCH

Welding torches rated at less than 200 A are normally gas-cooled (that is, the shielding gas flows around the conductor cable, providing the necessary cooling). Water-cooled torches are used for continuous operation or at higher welding currents and are common for mechanized or automatic welding (see the section "GTAW Process Variations" in this article). The cooling water may be supplied to the torch from a recirculating tank that uses a radiator or chiller to cool the water.

Electrodes. The nonconsumable electrodes used in GTAW are composed of tungsten or alloys of tungsten. The most common electrode is a 2% ThO_2-W alloy (EWTh-2). This material has excellent operating characteristics and good stability. Thoria is radioactive, so care must be taken when sharpening electrodes not to inhale metal dust. The grindings are considered hazardous waste in some states, and disposal may be subject to environmental regulations. Lanthaniated (EWLa-1) and yttriated tungsten electrodes have the best starting characteristics in that an arc can be started and maintained at a lower voltage. Ceriated tungsten (EWCe-2) is only slightly better than the thoriated tungsten with respect to arc starting and melt-off rate. Any of the aforementioned electrodes produce acceptable welds. The easy starting of the lanthaniated electrode is a result of the lower work function (Ref 6) which allows it to emit electrodes readily at a lower voltage.

Pure tungsten is used primarily in ac welding and has the highest consumption rate. Alloys of zirconium are also used. Tungsten electrodes are classified on the basis of their chemical composition (Table 1). Requirements for tungsten

electrodes are given in the latest edition of ANSI/AWS A5.12 ("Specification for Tungsten and Tungsten Alloy Electrodes for Arc Welding and Cutting"). The shape of the electrode tip can affect the resulting weld shape. Electrodes with included angles from 60 to 120° are stable and give good weld penetration depth-to-width ratios (Ref 7). Electrodes with smaller included angles (5 to 30°) are used for grooved weld joints to eliminate arcing to the part side walls.

TABLE 1 CLASSIFICATION OF ALLOYING ELEMENTS IN SELECTED TUNGSTEN ALLOY ELECTRODES FOR GTAW APPLICATIONS

AWS CLASSIFICATION	COLOR[A]	ALLOYING ELEMENT	ALLOYING OXIDE	ALLOYING OXIDE, WT%
EWP	GREEN	. . .	. . .	
EWCE-2	ORANGE	CERIUM	CEO_2	2

EWG	GRAY	NOT SPECIFIED[B]	. . .	. . .

Source: Ref 4

(A) COLOR MAY BE APPLIED IN THE FORM OF BANDS, DOTS, AND SO ON, AT ANY POINT ON THE SURFACE OF THE ELECTRODE.

(B) MANUFACTURER MUST IDENTIFY THE TYPE AND NOMINAL CONTENT OF THE RARE-EARTH OXIDE ADDITION.

Wire feed systems are made from a number of components and vary from simple to complex. The basic system consists of a means of gripping the wire sufficiently to pull it from the spool and push it through the guide tube to the point of welding. Electronic switches and controls are necessary for the electric drive motor. The wire will be fed into the leading edge for cold wire feeds and into the trailing edge for hot wire feeds.

Cables, hoses, and gas regulators are necessary to deliver the process consumable of electricity, water, and inert gas to the welding torch.

Arc oscillation is used in both manual and mechanized welding (see the section "GTAW Process Variations" in this article). The benefits in manual welding are basic to the control of the weld when adapting to changes in the weld joint and gap. In mechanized welding, the oscillation is typically produced by moving the entire welding torch mechanically or by moving the arc plasma with the aid of an externally applied magnetic field. Oscillation allows the welding heat to be placed at precise locations. This is advantageous when welding irregularly shaped parts. The number of welding passes and total heat input can be decreased when arc oscillation is used, because it reduces the cost as well as the weld shrinkage and upsetting.

Figure 4 shows the effect of magnetic oscillation on distortion. Some alloys need the tempering produced by multipass stringer bead welding techniques, and arc oscillation should not be used. Externally applied magnetic fields can be used to stabilize the arc, minimize arc blow, and displace the arc plasma forward of the welding torch. This results in improved weld appearances and increased welding speeds in tube mills and other high-speed applications (Ref 9).

Process Parameters

Welding Current. Current is one of the most important operating conditions to control in any welding operation, because it is related to the depth of penetration, welding speed, deposition rate, and quality of the weld.

Fundamentally, there are but three choices of welding current:

- DIRECT CURRENT ELECTRODE NEGATIVE (DCEN)
- DIRECT CURRENT ELECTRODE POSITIVE (DCEP)
- ALTERNATING CURRENT

Figures 5 and 6 show the effect of dc and ac on weld shape. Table 2 gives the recommended current relative to workpiece material.

TABLE 2 SUITABILITY OF TYPES OF CURRENT FOR GTAW OF SELECTED METALS

METAL WELDED	ALTERNATING CURRENT[A]	DCEN	DCEP
LOW CARBON STEEL:			
0.38-0.76 MM (0.015-0.030 IN.)[A]	G[B]	E	NR
0.76-3.18 MM (0.030-0.125 IN.)	NR	E	NR
HIGH-CARBON STEEL	G[B]	E	NR
CAST IRON	G[B]	E	NR

Note: E, excellent; G, good; NR, not recommended.

(A) STABILIZED. DO NOT USE ALTERNATING CURRENT ON TIGHTLY JIGGED ASSEMBLIES.

(B) AMPERAGE SHOULD BE ABOUT 25% HIGHER THAN WHEN DCEN IS USED.

(C) UNLESS WORK IS MECHANICALLY OR CHEMICALLY CLEANED IN THE AREAS TO BE WELDED

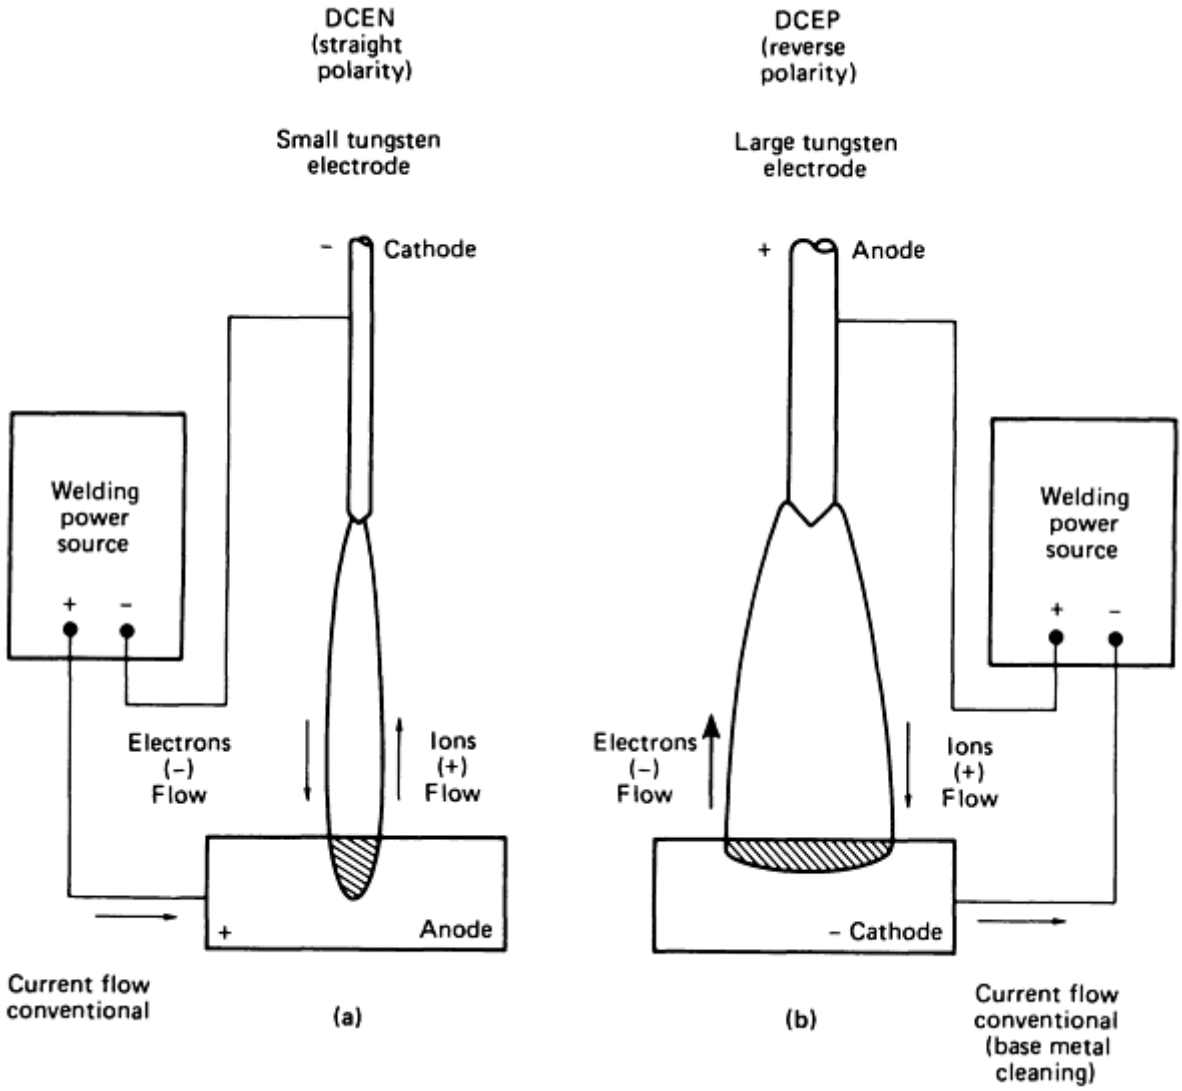

FIG. 5 EFFECT OF POLARITY ON GTAW WELD CONFIGURATION WHEN USING DIRECT CURRENT. (A) DCEN. DEEP PENETRATION, NARROW MELTED AREA, APPROXIMATE 30% HEAT IN ELECTRODE AND 70% HEAT IN BASE METAL. (B) DCEP. SHALLOW PENETRATION, WIDE MELTED AREA, APPROXIMATE 70% HEAT IN ELECTRODE AND 30% HEAT IN BASE METAL

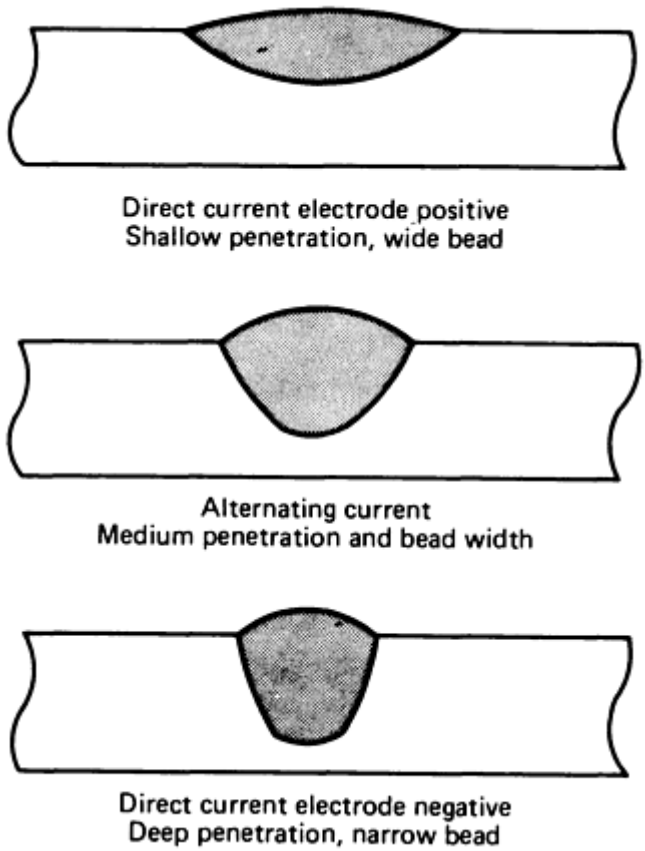

FIG. 6 WELD CONFIGURATION AS A FUNCTION OF TYPE OF CURRENT (AC OR DC) USED

Alternating current is characterized as reversing the polarity of the work and electrode at 60 Hz. The rapidly changing polarity gives a cathodic cleaning action that is beneficial for oxide removal when welding aluminum and magnesium. The alternating currents result in electrode heating during the DCEP portion of each cycle. This necessitates the use of larger-diameter electrodes, normally made of pure tungsten. Variable polarity welding allows the frequency of polarity switching to be preset. This can produce the cleaning effects to ac welding and the high efficiency of dc welding. Direct current electrode negative is most often used in the GTAW process. This results in maximum application of heat to the work and maximum melting of the workpiece.

Pulsed versus Nonpulsed Current. Nonpulsed or continuous current is the standard for GTAW. However, there are several advantages to using pulsed current. Pulsing produces the maximum amount of penetration while minimizing the total heat applied to the part. Pulsing also aids in timing the motion necessary in manual welding and allows the weld pool to cool between pulses.

Microwelding refers to a class of weldments that are made at welding currents from 1 to 20 A. In most cases, the welding is used for electronic applications, bellows, wires, and other components where heat input must be precisely controlled.

Shielding Gases. The original GTAW process used helium as the shielding gas for welding magnesium and aluminum. Today, argon is the predominant shielding gas.

Argon is the least expensive of the inert gases used for shielding gas-tungsten arc welds, which is only partially responsible for its widespread use. Argon has a low ionization potential (2.52×10^{-18} J, or 15.7 eV), making it easier to form an arc plasma than with other shielding gases. Argon is approximately 1.4 times heavier than air, so it displaces air, resulting in excellent shielding of the molten weld pool.

Helium has an ionization potential of 3.92×10^{-18} J (24.5 eV), which results in more difficult arc initiation and operation at a higher arc voltage. The higher arc voltage, *V,* results in a higher heat input, *Q,* for a given arc length and current, *I:*

$$Q = IVT \qquad \textbf{(EQ 1)}$$

where Q is in Joules, I is in amperes; and t is in seconds. This high heat input can be very beneficial when welding copper, aluminum, and other high-conductivity materials. Helium shielding used with DCEN is very effective for welding thick aluminum.

Gas Purity. Most materials can be welded using a welding grade torch gas with a purity of 99.995% or 50 ppm impurities. However, some reactive materials (for example, titanium, molybdenum, and tantalum) require that the contaminant level be less than 50 ppm, which may require certified purity or the use of gas filters and purifiers (Ref 10).

Gas Flow Rates. Helium, because of its low density, must be used at higher flow rates than argon. Typical flow rates for argon are 7 L/min (15 ft^3/h) and 14 L/min (30 ft^3/h) for helium.

Backup Purge. Protecting the molten weld pool from the atmosphere is very important in GTAW. Atmospheric contamination can result in weld cracks, porosity, scaling, and an unacceptable granular appearance. The gas cup on the welding torch is the primary outlet of shielding gas for most GTAW applications. Back side shielding is important because the presence of oxygen can reduce weld metal penetration and result in the effects mentioned above (Ref 11). Balloon and water-soluble paper dams are sometimes used to minimize the volume to be purged. Copper backing bars and ceramics are sometimes used to hold shielding gas against the back surface of the molten weld and support the molten underbead. Reactive materials and special applications may require more elaborate shielding. This can be in the form of a simple trailing device providing the inert shielding gas or may be as elaborate as a special welding chamber equipped with gas purifiers and analyzers. Specially constructed plastic bags have been used successfully to weld large, irregularly shaped components (Fig. 7).

FIG. 7 PLASTIC BAG ENCLOSURE THAT SIMULATES A GLOVE BOX, USED TO PURGE IRREGULARLY SHAPED COMPONENTS IN GTAW OPERATIONS

Filler Metals. The thickness of the part to be welded will determine the need for filler metal additions. Material thinner than 3.2 mm (0.125 in.) can be successfully welded without filler metal additions. Filler metal, when needed, can be added manually in straight length or automatically from a roll or coil. The filler metal is normally added cold; hot wire can be used for automatic applications (Fig. 8). A welding insert is preplaced filler material of several possible configurations to aid in root-pass welding.

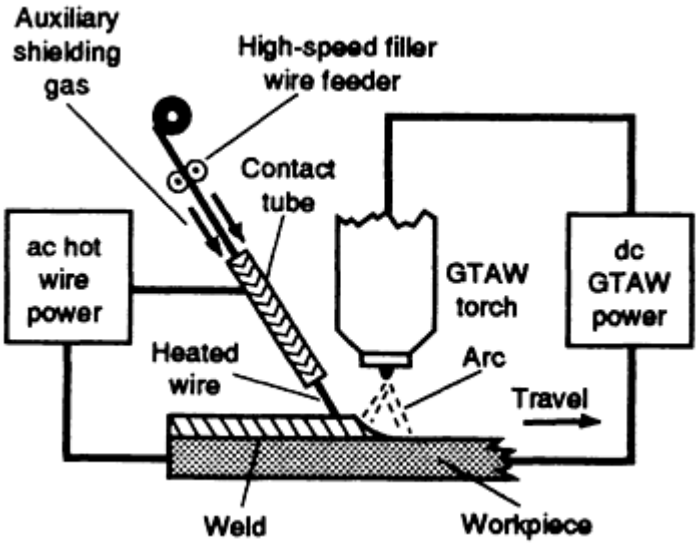

FIG. 8 SCHEMATIC SHOWING KEY COMPONENTS AND PARAMETERS OF A GTAW HOT WIRE SYSTEM. SOURCE: REF 4

Rods. Straight lengths of filler wire, typically 915 mm (36 in.) in length, are used for manual welding. Most straight lengths are round in cross section, but some aluminum fillers are somewhat rectangular.

Cold Wire. Coiled wire may be acquired in small 100 mm (4 in.) spools. Larger 305 mm (12 in.) spools or large coils can weigh over 225 kg (500 lb). The larger coils are normally used with GMAW because it requires larger quantities of filler metal. The filler wire is fed into the leading edge of the weld pool during cold-wire welding.

Hot wire GTAW utilizes a heated filler metal to increase the deposition rate of the process (Fig. 9). The wire is resistance heated to near the melting temperature and fed into the trailing edge of the weld pool. Deposition rates to 29 kg/h (65 lb/h) are achievable. The higher deposition rates obtained with hot wire make the process competitive for welds and overlays and improve productivity. Table 3 lists typical hot wire parameters.

TABLE 3 TYPICAL PARAMETERS FOR AUTOMATIC HOT WIRE GTAW

ARC CURRENT, A	ARC VOLTAGE, V	TORCH TRAVEL SPEED		WIRE FEED RATE[A]		DEPOSITION RATE

Welding inserts are used to produce a smooth uniform underbead. The insert is normally a separate piece of material, although integral inserts are sometimes used. Smooth underbead can be produced in a mechanized system or in manual systems when highly skilled welders are available. The insert can be obtained in several different configurations (Fig. 10). The purpose of the insert is to preplace the filler metal at the joint root. Inserts with compositions that differ from that of the base metal can be used to improve the weldability of some materials.

GTAW Process Variations

Manual welding refers to the GTAW process in which the welder manipulates the welding torch by hand. If a motorized wire feeder is attached to the torch, the process is classified as semiautomatic welding.

Products generated by skilled manual welders account for a large proportion of GTAW applications. The equipment can be quite inexpensive, and properly trained welders can join a wide variety of materials. Manual welding is used extensively in stainless steel piping as well as for the root pass in carbon steel pipe welds.

Mechanized welding may require adjustment to welding parameters in response to visual observation of the weld. Machine or mechanized welding requires some specialized accessories. The basic system contains a means for holding and moving the welding torch as well as the workpiece. Because arc voltage is an essential variable in GTAW and is proportional to arc length, voltage feedback devices are often used with motorized torch holders to control the arc length.

Narrow groove welding makes use of the GTAW cold wire welding process with a narrowed weld joint. Figure 11 shows a typical weld. Narrow groove welding is limited to mechanized welding applications where precise torch location can be maintained.

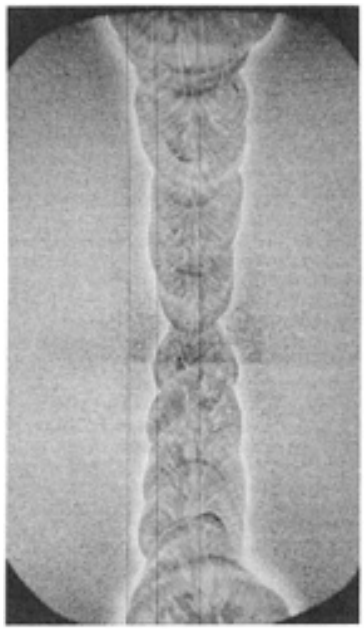

FIG. 11 TYPICAL NARROW GROOVE WELD PRODUCED IN MECHANIZED WELDING APPLICATIONS

Automatic welding does not require manual 0parameter adjustment or observation of the weld during the welding process. The most common application of automatic welding is associated with orbiting weld heads used to weld pipe and tubing. These devices attach to the workpieces and move around the circumference, fusing the metal. Most systems perform an autogenous weld; others have wire feed and oscillation capabilities. These systems are often used in conjunction with a computer to control the welding variables. Automatic controls utilizing microprocessors and computer numerical control servodrives make it possible to use one welding system to weld a variety of materials and shapes. Figure 12 shows 14 different parts welded with an automatic GTAW system.

Plasma Arc Welding

Ian D. Harris, Edison Welding Institute

Introduction

PLASMA ARC WELDING (PAW) can be defined as a gas-shielded arc welding process where the coalescence of metals is achieved via the heat transferred by an arc that is created between a tungsten electrode and a workpiece. The arc is constricted by a copper alloy nozzle orifice to form a highly collimated arc column (Fig. 1). The plasma is formed through the ionization of a portion of the plasma (orifice) gas. The process can be operated with or without a filler wire addition.

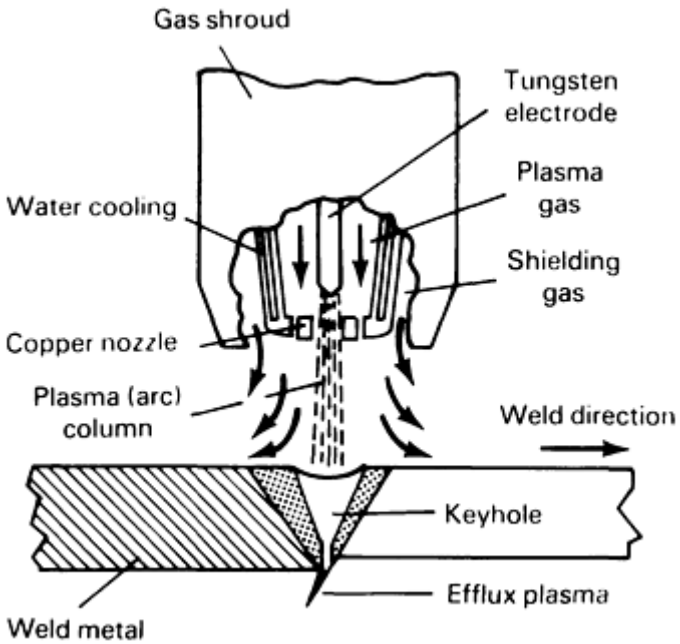

FIG. 1 PLASMA ARC WELDING PROCESS, SHOWING CONSTRICTION OF THE ARC BY A COPPER NOZZLE AND A KEYHOLE THROUGH THE PLATE

Principles of Operation. Once the equipment is set up and the welding sequence is initiated, the plasma and shielding gases are switched on. A pilot arc is then struck between a tungsten alloy electrode and the copper alloy nozzle within the torch (nontransferred arc mode), usually by applying a high-frequency open-circuit voltage. When the torch is brought in close proximity to the workpiece or when the selected welding current is initiated, the arc is transferred from the electrode to the workpiece through the orifice in the copper alloy nozzle (transferred arc mode), at which point a weld pool is formed (Fig. 1).

The PAW process can be used in two distinct operating modes, often described as the melt-in mode and the keyhole mode.

The melt-in-mode refers to a weld pool similar to that which typically forms in the gas-tungsten arc welding (GTAW) process, where a bowl-shaped portion of the workpiece material that is under the arc is melted.

In the keyhole mode, the arc fully penetrates the workpiece material, forming a nominally concentric hole, or keyhole, through the thickness. The molten weld metal flows around the arc and resolidifies behind the keyhole as the torch traverses the workpiece.

Current and Operating Modes. The PAW process uses three current modes: microplasma (melt-in mode), medium-current plasma (melt-in mode), and keyhole plasma (keyhole mode). This categorization is primarily based on the level of welding current. The microplasma mode is usually defined in the current range from 0.1 to 15 A. The medium-current plasma mode ranges from 15 to 100 A. The keyhole plasma mode is above 100 A. There is a certain degree of overlap between these current ranges. For example, keyholing can be achieved at 70 A on a 2 mm (0.08 in.) sheet. Equipment is available for welding currents up to 500 A, although a 300 A maximum is typical. Microplasma and medium-current melt-in modes are used for material up to 3 mm (0.12, or $\frac{1}{8}$, in.) thick, whereas the keyhole plasma mode is used for greater thicknesses and higher travel speeds.

In addition to operating in a continuous and steady direct current electrode negative (DCEN) mode, the PAW process can be carried out using DCEN pulsed current, as well as in the variable polarity mode, which uses both direct current electrode positive (DCEP) and electrode negative polarity switching. The pulsed current mode (both DCEN and DCEN/DCEP) is most often used when current levels (typically, above 100 A) are employed for keyhole plasma welding. Pulsing the current widens the tolerance region of acceptance welding parameters, primarily by further stabilizing the formation of the keyhole itself (Fig. 2).

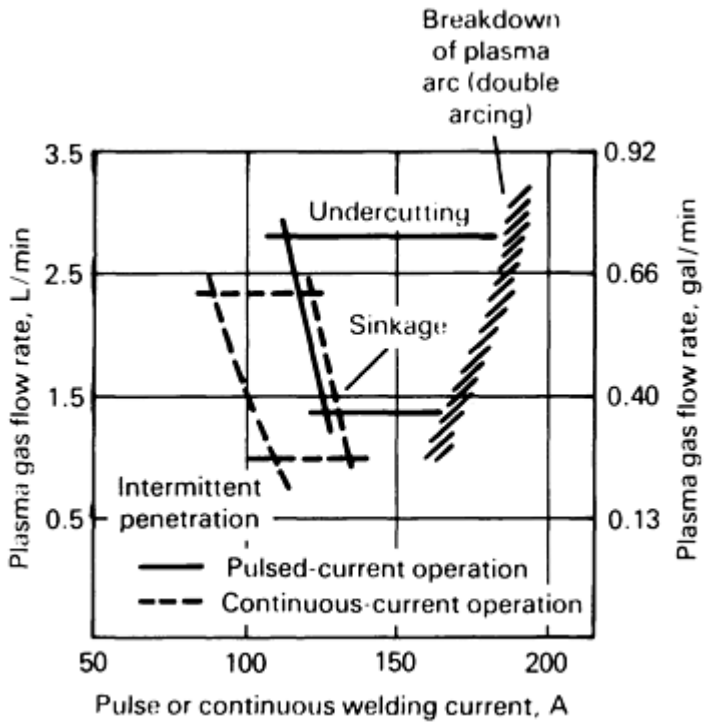

FIG. 2 TOLERANCE TO VARIATION IN WELDING CURRENT AND PLASMA GAS FLOW RATE IN PULSED AND CONTINUOUS CURRENT KEYHOLE WELDING; BOUNDARIES SHOW THE WELDING PARAMETER COMBINATIONS AT WHICH SPECIFIC DEFECTS ARE LIKELY TO OCCUR. WELDING PARAMETERS; NOZZLE BORE, 2.36 MM (0.0929 IN.); ELECTRODE DIAMETER, 4.8 MM (0.19 IN.)

The electrode positive component of the variable polarity plasma arc (VPPA) welding process promotes cathode etching of the tenacious surface oxide film when welding aluminum alloys, allowing good flow characteristics and consistent bead shape. Pulsing times are typically 20 ms for the electrode negative component and 3 ms for the electrode positive polarity. The VPPA welding process is used very effectively in specialized aerospace applications.

The PAW process is generally applied when the high penetration of the keyhole welding mode can be exploited to minimize the number of welding passes and, hence, welding time. The time saved can reduce the direct labor element of the welding operation. At the other end of the scale, the microplasma operating mode is used to weld small, thin-section components (as low as 0.025 mm, or 1 mil, thick), where the high arc constriction and low welding current can be beneficial in controlling heat input and distortion.

Advantages and Disadvantages. The advantages of the PAW process are primarily intrinsic to the keyhole mode of operation, because greater thicknesses of metal can be penetrated in a single pass, compared with other processes, such as GTAW. This greater amount of penetration allows a reduced amount of joint preparation. In some materials, for example, a square-grooved butt joint preparation can be used for thicknesses up to 12 mm (0.5 in.). The process can produce high weld integrity (similar to GTAW) while minimizing weld passes and, hence, welding times and labor costs. The columnar shape of the arc results in a greater tolerance to variations in torch standoff distance, when compared with the conical arc shape of a GTAW arc. The tungsten electrode used in the PAW process is protected from contamination by the constricting nozzle (Fig. 1). The longer arc length allows better viewing of the weld pool, which is important in manual welding.

Disadvantages include the greater capital equipment cost, when compared with its main rival, the GTAW process. Although high arc constriction achieves higher penetration, it also reduces the tolerance of the process to joint gaps and misalignment, when compared with the broader, conical arc of the GTAW process. The greater complexity of the PAW torch design and the greater number of parts requires more scheduled maintenance. The accurate set-back of the electrode tip, with respect to the nozzle orifice, is required to maintain consistent results. However, this task is facilitated by a general-purpose tool designed for nozzle removal and replacement and for electrode set-back adjustment.

Plasma Arc Welding

Ian D. Harris, Edison Welding Institute

Equipment

A basic PAW system consists of a power source, a plasma control console, a water cooler, a welding torch, and a gas supply system for the plasma and shielding gases (Fig. 3).

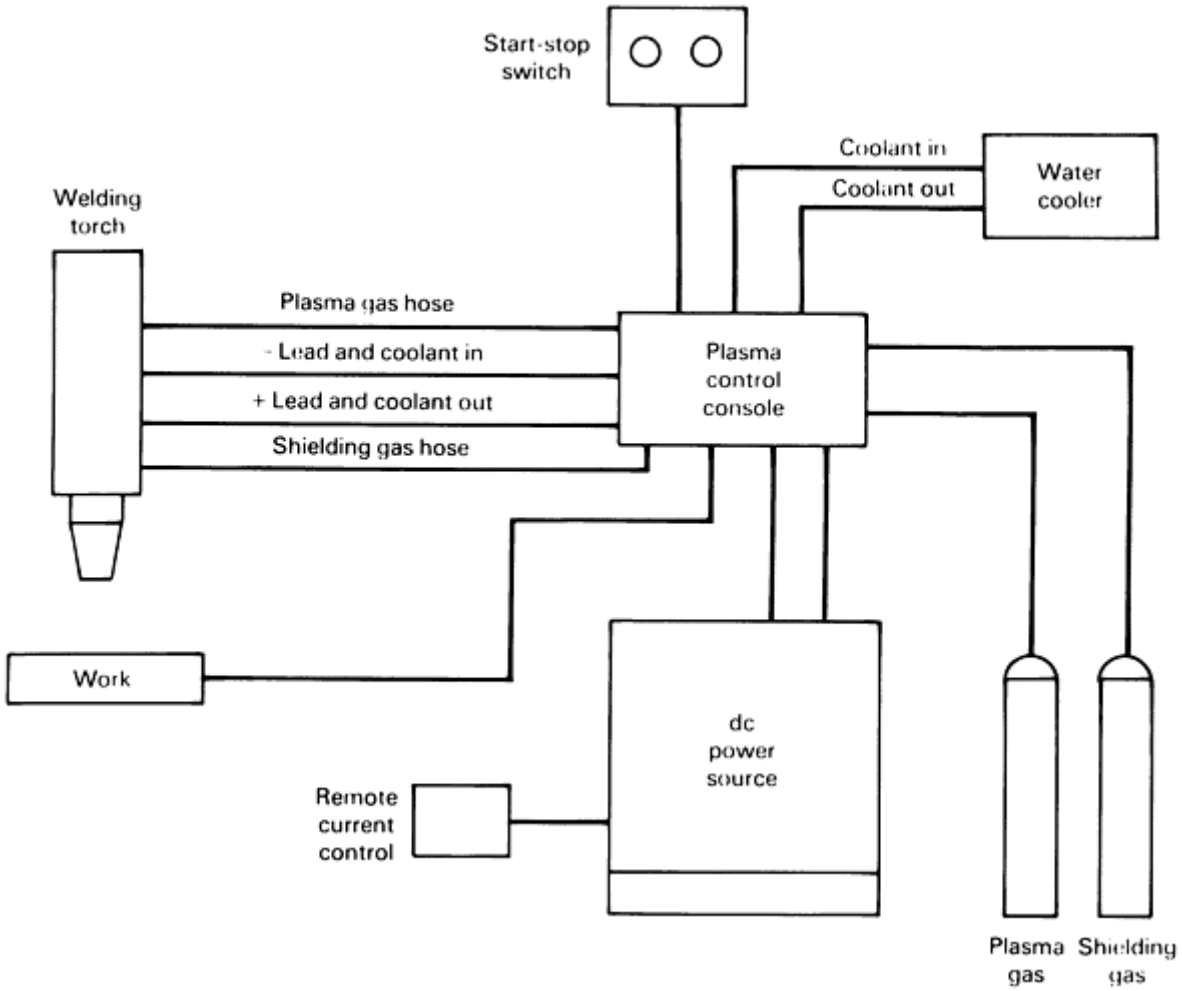

FIG. 3 TYPICAL EQUIPMENT FOR PLASMA ARC WELDING

The power source, which supplies the main power for the welding system, is usually supplemented with a sequence controller and control console. The sequence controller sequences the timing of gas flow, arc initiation, main welding current control, and any up-slope and downslope parameters. In its simplest form, the plasma control console controls the gas flow for plasma and shielding gases from separate flow-meters and incorporates the high-frequency pilot arc initiation circuit. The welding torch can be manual or mechanized and is water cooled to avoid torch overheating and to maximize component life.

In most PAW installations, plasma and shielding gases are supplied from separate gas cylinders, although bulk gas can readily be used. The gas supply is usually routed through the plasma control console, where the individual flow rates are set by the operator.

The power source should be of a constant-current design. Transistorized power sources are most common, although inverter power supplies are also available. It should have a minimum open-circuit voltage of 80 V to ensure the reliable initiation and transfer of the main arc current. The power source can be adjusted for welding current and it should have the capability to adjust the up slope and down slope of the current. It may be equipped with thumbwheels or potentiometers to select the parameters for pulse current operation, that is, peak and background current levels, as well as peak and background times.

Welding Torches. Like those of the other arc welding processes, PAW torches are available in a range of sizes for different power ratings and in manual and mechanized versions. The design principles are the same in each case. A tungsten alloy electrode is held in a collet within the torch body. To avoid one of the most common defects in plasma torches, it is critical to hold concentricity between the tungsten electrode and the orifice in the design and manufacture of the torch. The electrode assembly is set inside a plenum chamber and the plasma gas is supplied to this chamber. A

threaded copper alloy nozzle forms the front of this chamber and contains the nozzle orifice that is used to constrict the plasma arc. A shielding gas nozzle, usually of an insulating ceramic material, is threaded onto the front end of the torch and surrounds the constricting nozzle, creating an annulus through which the shielding gas is supplied. The torch is connected electrically to the power source and the electrode forms the negative pole of the circuit for dc welding. The gas hoses that supply the plasma and shielding gases and the water hoses that supply and remove water from the torch are all connected to the torch body or handle. These hoses are enclosed in a flexible sheath that extends from the torch to the components of the welding system.

Most constricting nozzles have a single orifice in the center. However, multiple-nozzle orifices can be used with higher-power torches to achieve further arc constriction. The most common version of this type of nozzle has a central orifice flanked by a smaller orifice on each side. The common centerline of the three orifices is arranged at 90° to the weld line during operation.

Electrodes. The nonconsummable electrode employed is usually a 2% thoriated tungsten electrode, that is, tungsten with 2% thorium oxide. The electrode specification is covered in AWS A5.12-92. The electrode size is selected according to the welding current level that will be used. The electrode is ground with a tapered point on the end, the angle of which depends on the selected welding current level. Electrode sizes and tip angles for a range of welding current levels are shown in Table 1.

(D) MULTIPORT NOZZLE

The new types of tungsten electrodes, which contain oxides of rare-earth elements in place of the thorium oxide, can also be used. These electrodes have been shown to have greater tip life. However, they are more expensive and their usefulness in plasma arc welding may be limited because of the high level of protection provided by the nozzle. In low-current microplasma welding applications, their better emissivity provides easier arc transfer and better overall performance.

If a finer wire is required, to fit the joint or to avoid undercut at the weld toes, then wires suitable for gas-shielded arc welding (for example, those used for GTAW) should be employed. The appropriate AWS specification series is AWS A5.XX.

Plasma (Orifice) and Shielding Gases. The plasma gas is used to generate the arc, whereas the shielding gas is used to provide the weld pool with supplementary shielding from atmospheric contamination while it solidifies and cools. The plasma gas is almost always argon. Gas properties affect both weld shape and quality. Flow rates, particularly of the plasma gas, are also important, because they control the extent of plasma constriction. The flow rate can vary from 0.1 L/min (0.026 gal/min) for microplasma welding up to 10 L/min (2.6 gal/min) for keyhole plasma welding. Considerable care is needed to regulate the gas flow rate if keyhole closure is required, because the flow rate must be sloped out to 1 to 2 L/min (0.26 to 0.52 gal/min) within about 1 s. Gas flow control is best achieved by electronic means.

The design and current rating of welding torches are based on argon plasma gas. Argon provides effective shielding, being heavier than air, and is cheaper than helium. Shielding gas selection is based on the type of base metal (Table 2).

TABLE 2 PLASMA AND SHIELDING GAS COMPOSITIONS

MATERIAL	PLASMA GAS	SHIELDING GAS

COPPER AND COPPER ALLOYS	ARGON	ARGON 75HE-25AR[A]

(A) ALSO USED

Helium and argon-helium mixtures can be used as shielding gases to increase the thermal conductivity of the gas and, hence, the heating effect on the weld pool. Helium results in wider weld pools than argon, because it produces a higher arc voltage. Hydrogen additions to argon shielding gas tends to promote slightly narrower weld pools through arc constriction and achieves a very clean weld pool appearance, because it is a reducing gas. Although helium and hydrogen can be added to argon in the shielding gas to give higher heat input, the use of gases with higher heat contents in the plasma gas can result in torch overheating and potential damage.

Ian D. Harris, Edison Welding Institute

Applications

Material Types. The PAW process is commonly used to weld stainless steels in a wide range of thicknesses. The process can also be used with carbon and alloy steels, aluminum alloys, titanium alloys, copper and nickel alloys, and more specialized materials, such as zirconium and tantalum. The thicknesses that can be welded in a single pass range from 0.025 mm (1 mil) for microplasma applications to 12.5 mm (0.5 in.) for the VPPA welding of aluminum. Direct-current pulsing can be used on most materials.

The PAW process is often carried out in an autogenous mode, that is, without filler wire. When edge beveling is used, a filler wire is required to complete the joint. A filler wire can also be used with the keyhole mode of operation to avoid undercut at high welding speeds. Wire composition depends on that of the parent materials in the joint. The same continuous-wound wire that is used in GTAW operations is suitable.

The industries that use the PAW process can be categorized as those that weld thin-section sheet using microplasma or medium-current plasma welding and those that weld plate using keyhole plasma welding.

A wide range of small devices and assemblies made from thin stainless steel sheet, including bellows assemblies and associated fittings, are welded using the microplasma operating mode. The narrow weld bead that can be produced provides sheet-metal fabrications with a good cosmetic appearance. Furthermore, the high welding speed that can be achieved, coupled with the good tolerance to stand-off variations resulting from the columnar nature of the arc, makes the process attractive for high-volume production work.

Microplasma, as well as medium-current plasma modes, can be used to spot weld guide wires and lamp filaments, as well as in other applications that require highly repetitive autogenous welds. This type of application allows a user to limit the number of high-frequency arc starts that would be required with tungsten-inert gas welding.

Keyhole plasma welding is extensively used to weld stainless steel pipe and tankage. The process is applied to individual strakes from plate to make stainless steel vessels in the food and chemical processing industries. Circumferential welding of strakes also can be used to create these products. Longitudinal seam welds in stainless steel pipe with wall thickness of [ges]3 mm ([ges]0.12 in.) are ideally suited to keyhole plasma welding, because joint preparation is minimized and single-pass welding can be consistently achieved without the use of weld-backing devices. Pipes with wall thickness above 5 to 6 mm (0.20 to 0.24 in.) employ the keyhole mode of operation for the root pass. Depending on the material type and wall thickness, melt-mode PAW, GTAW, gas-metal arc welding (GMAW), or submerged arc welding (SAW) are used to complete the joint. High-alloy composition piping is similarly manufactured.

The manufacturing of stainless steel tube from strip was one of the first applications of the PAW process. Because the process can reliably produce full-penetration welds without the use of backing, it is extensively used on tube mills, because a lack of access precludes welding from the inside.

The VPPA welding process has been very effective for welding large space shuttle orbiter sections of aluminum alloys, particularly the external fuel tank. The cathodic cleaning action of the electrode positive portion of the current cycle breaks up tenacious surface oxide film on the aluminum. The process can be used on thicknesses up to 12.5 mm (0.5 in.) with square-grooved butt joints, and it can be used for the root pass on thicker sections with edge beveling. It is anticipated that this technique will be extensively employed in building aluminum alloys structures in a modular space station.

Ian D. Harris, Edison Welding Institute

Typical Components and Joints

The most common joint configuration used with the PAW process is a butt joint. The microplasma mode is used with overlapped butt (micro-lap) joints and with joints that have integral weld metal as a result of flanged, butted edges on very thin metals (Table 3). Corner joints with edge welds are also commonly welded using the microplasma and medium-current modes.

TABLE 3 JOINT CONFIGURATIONS FOR PLASMA WELDING SHEET AND TUBULAR COMPONENTS

Thickness range						
mm	in.	Joint type	Joint configuration	Process variant	No. of runs	Comments
0.5–1.0	0.02–0.04	Micro-lap		Microplasma	1	Edges fully fused to produce additional weld metal; good clamping essential
0.5–1.5	0.02–0.06	Flanged edge	0.5-1.0 mm 	Microplasma	1	Edges fully fused to produce additional weld metal
3.0–6.0	0.12–0.24	Square butt		Keyhole plasma	1	Grooved backing bar required to prevent disturbance of the efflux plasma. Additional (cosmetic) run using melt mode may be employed
6.0–15	0.24–0.60	Single-V butt		Keyhole plasma	2 or more	Keyhole technique used for root run only. Joint completed with the melt mode plus filler wire

Because the keyhole operating mode fully penetrates the workpiece, it is used exclusively on square-grooved butt joints and single-V joints with a root face (Table 3). For square-grooved butt joint preparation, the thickness that can be welded in a single pass depends on the fluid flow characteristics of the workpiece material for a given heat input from the plasma torch. Thus, alloys of titanium and zirconium can be butt welded with square-grooved preparation at greater thicknesses than steels and stainless steels. Generally, it is an industry-accepted practice to use square-grooved preparation without edge beveling for stainless steels up to 6 mm (0.24 in.) in thickness.

A 4 or 5 mm (0.16 or 0.20 in.) root face and a single-V preparation, usually with a 60° included angle, are used on steels thicker than 6 mm (0.24 in.) (Table 4). The root is welded in the keyhole mode and the rest of the joint is completed with a filler wire addition by melt-mode PAW, GTAW, GMAW, or SAW, depending on the material type, joint volume to be filled, and the mechanical property requirements of the joint.

(a) Welded thickness, 5 mm (0.20 in.). (b) Welded thickness, 6 mm (0.24 in.)

(a) Welded thickness, 5 mm (0.20 in.). (b) Welded thickness, 6 mm (0.24 in.)

In the PAW process, fixturing for part fit-up is more critical than it is for the GTAW process, primarily because of the narrower, more-constricted arc in PAW. The backing bar design and shielding gas techniques employed for GTAW are appropriate for microplasma and medium-current modes. During keyhole welding, however, the arc passes right through the workpiece, forming an efflux plasma (Fig. 1) that normally extends 10 mm (0.4 in.) below the back face of the joint. This characteristic must be accommodated when designing backing systems. Failure to allow sufficient gap can result in turbulence in the efflux plasma, causing weld pool disturbance and porosity.

When welding longitudinal seams in tube or pipe, the weld can be started and stopped on run-on and run-off tabs, precluding the need for keyhole closure. However, when using the keyhole mode on circumferential seams of vessels or on butt joints in tubes or pipes, the keyhole will overlap the start of the weld to produce a complete joint. Keyhole closure without porosity has been an area of difficulty, particularly when butt welding tubes, and it represented an important concern for more-widespread use of the process. Modern electronic controls for simultaneous reduction in gas flow and current slope-out provide a more reliable method for keyhole closure.

Plasma Arc Welding

Ian D. Harris, Edison Welding Institute

Procedures

Process Operating Procedure. Welding parameters, such as welding current, arc voltage, travel speed (for mechanized/automatic operation), and plasma and shielding gas flow rates, are set by the procedure and implemented by the welder. Torch parameters include the correct electrode vertex angle and set-back distance, as well as the correct orifice diameter for the welding current level.

The operating sequence for the PAW process was described in the section "Principles of Operation" at the beginning of this article. After the weld pool or keyhole is formed, the torch is traversed across the workpiece at the preset welding speed. Welding is terminated by the down slope of the welding current, with simultaneous sloping of the plasma gas flow rate if keyhole welding and keyhole closure are desired. Slope control for the keyhole mode is shown in Fig. 4.

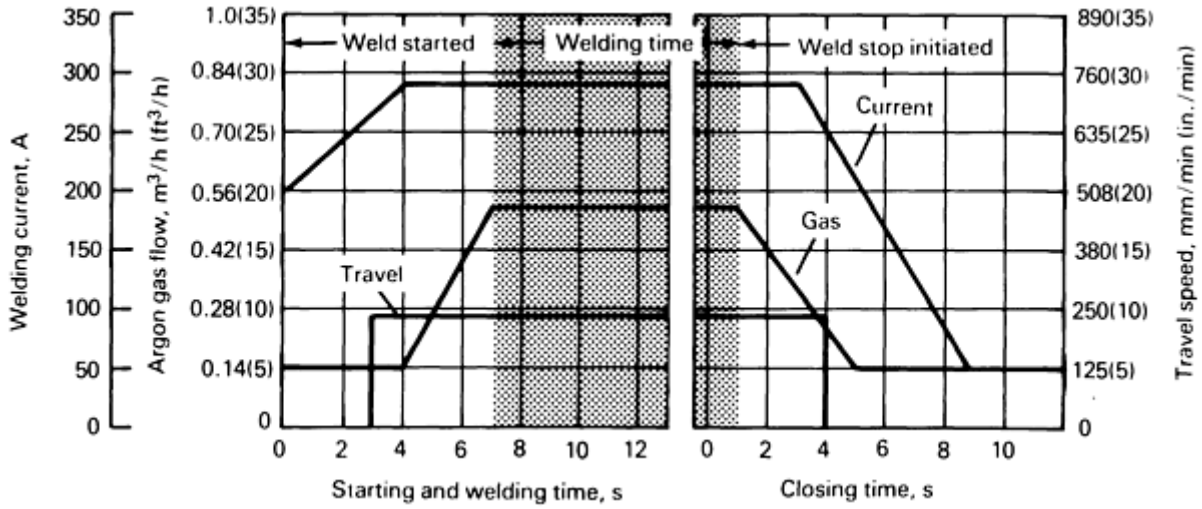

FIG. 4 TYPICAL SLOPE CONTROL PATTERN FOR WELDING CURRENT AND PLASMA GAS FLOW WHEN STARTING AND CLOSING A KEYHOLE; EXAMPLE IS FOR 9.5 MM ($\frac{3}{8}$ IN.) THICK STEEL

Most plasma arc welding is done in a mechanized or automated operation that does not require much operator intervention, except initially to set the parameters and to position the workpiece and torch. When current pulsing and keyhole closure operations are involved, numerous parameters must be set, which requires strict attention to detail, accurate part fit-up, and careful alignment of the torch relative to the joint.

Inspection and Weld Quality Control. All of the common nondestructive evaluation (NDE) techniques are applicable to plasma arc welds. Radiography and ultrasonic inspection are the most common techniques used. The fact that most plasma arc welding is carried out in the keyhole mode means that there is a penetration bead on the root side of the joint. Visual inspection for full penetration, as well as for correct width and profile of both the penetration bead and the weld surface profile, can readily be accomplished. Smooth, even underbeads can be achieved through good procedure development with tolerances improved through current pulsing.

Troubleshooting. When troubleshooting a PAW operation, all of the previously defined basic parameters of the welding schedule should be checked. Welding discontinuities can result from incorrect electrode set-back or from a worn or damaged nozzle orifice. The concentricity of the diameter of the nozzle orifice and the alignment of the electrode and nozzle orifice are very important. Worn nozzles should be replaced. The condition of the tungsten electrode tip should also be checked.

An undercut is one of the most common defects in the PAW process. Depending on material type, thickness, and preset welding parameters, a two-sided undercut can occur above certain threshold welding speeds. This can only be eliminated by increasing welding current. A one-sided undercut can result from misalignment of the torch, the electrode/orifice and multiport nozzles, or from the mismatched fit-up of the workpieces. Correct alignment is essential.

Plasma Arc Welding

Ian D. Harris, Edison Welding Institute

Personnel Requirements

The skill level and training requirements for the PAW process are generally similar to those for the GTAW process. When manual welding, the columnar nature of the plasma arc allows greater variation of the torch-to-workpiece distance without altering the size and shape of the weld pool. The fact that the electrode is protected from contamination by the nozzle means that tungsten contamination and tungsten inclusions in the weld metal are more readily avoided than they are in the GTAW process. From the viewpoint of an operator, disadvantages include the greater complexity of the torch,

in terms of nozzle orifice and electrode set-back considerations, and the correct setting of two gases (plasma and shielding gas).

When mechanized welding is carried out, which is usually the case for the keyhole mode, the operator is required to set a greater number of parameters (compared to GTAW), particularly if current pulsing and keyhole closure operations are required. Specific operator training is required for pulsed keyhole operation, and particularly for VPPA operations, which are usually carried out in the vertical position, welding upward, and thus require a high level of operator competence. Computerization of welding parameter selection is the trend for VPPA welding and other mechanized or automated PAW operations.

The health and safety issues related to the PAW process are very similar to those of other gas-shielded arc welding processes, especially GTAW. These include electrical shock; electromagnetic radiation hazards, particularly ultraviolet radiation; burns from hot metal parts; and welding fumes and gases, including ozone. The volume of welding fumes produced is low and is similar to that produced by the GTAW process. Hexavalent chromium and ozone are concerns when welding stainless steels and aluminum alloys, respectively. Like the GTAW process, the low level of general welding fumes associated with PAW results in a comparatively higher level of ozone. However, the rapid decay of ozone within a short distance of the arc, coupled with the high degree of mechanization and automation typical of the keyhole plasma welding operation, means that operator exposure is generally very low. The microplasma mode, which is more commonly used manually, employs such low current levels that fume and ozone levels are very low.

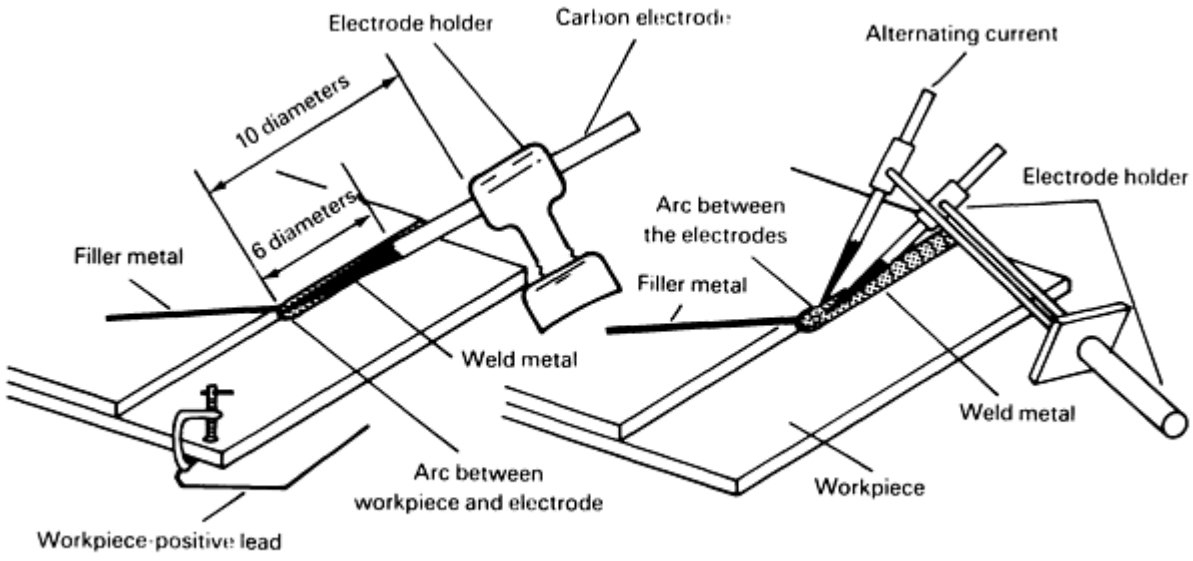
Carbon Arc Welding

Lance Soisson, Welding Consultants, Inc.

Introduction

CARBON ARC WELDING (CAW) utilizes what is considered to be a nonconsumable electrode, made of carbon or graphite, to establish an arc between itself and either the workpiece or another carbon electrode. However, this electrode erodes fairly quickly and generates carbon monoxide (CO) gas that partially replaces the air around the arc, thereby providing the molten weld with some protection.

The CAW process, which uses either single or twin electrodes, most closely resembles gas-tungsten arc welding (GTAW), where the arc is used only as a source of heat. The single-electrode arrangement usually operates with direct current (dc), electrode negative (straight polarity), using most dc power supplies. The twin-electrode arrangement usually operates with alternating current (ac), generally with small ac power supplies. Figure 1 shows typical configurations for both procedures.



Single-electrode CAW **Twin-electrode CAW**

FIG. 1 TYPICAL ARRANGEMENTS FOR SINGLE-ELECTRODE AND TWIN-ELECTRODE CARBON ARC WELDING

Although the CAW process has been almost completely replaced by the newer processes used in the welding industry, it is still used in certain applications. The process does produce adequate welds in thin-sheet steel, but should be used with caution in any critical application because it provides only limited shielding from the atmosphere.

Carbon Arc Welding

Lance Soisson, Welding Consultants, Inc.

Operation

CAW electrodes can be either carbon or graphite, although baked carbon electrodes are most commonly used because they last longer and are more readily available. Electrode sizes range from 3.2 to 22 mm ($\frac{1}{8}$ to $\frac{7}{8}$ in.). The typical torch is air cooled for the smaller electrodes, but water cooled for the larger ones. The recommended current ranges for both electrode types are given in Table 1.

TABLE 1 RECOMMENDED CURRENT RANGES FOR CARBON AND GRAPHITE ELECTRODES

ELECTRODE DIAMETER		CURRENT, A	
mm	in.	CARBON	GRAPHITE
SINGLE ELECTRODE			
3.2	$\frac{1}{8}$	15-30	15-35
4.8	$\frac{3}{16}$	25-55	25-60
6.4	$\frac{1}{4}$	50-85	50-90
7.9	$\frac{5}{16}$	75-115	80-125
9.5	$\frac{3}{8}$	100-150	110-165
11.1	$\frac{7}{16}$	125-185	140-210
12.7	$\frac{1}{2}$	150-225	170-260
15.9	$\frac{5}{8}$	200-310	230-370
19	$\frac{3}{4}$	250-400	290-490
22.2	$\frac{7}{8}$	300-500	400-750
TWIN ELECTRODES			
6.4	$\frac{1}{4}$	55	. . .
7.9	$\frac{5}{16}$	75	. . .
9.5	$\frac{3}{8}$	95-120	. . .

In the single-electrode operation, the carbon electrode is prepared to a long tapered point that is one half the electrode diameter (see Fig. 1). The arc is established by "scratch starting," that is, by bringing the electrode into contact with the workpiece and immediately withdrawing it to the correct length for welding. The generally accepted arc length is maintained between 6.4 and 9.5 mm ($\frac{1}{4}$ and $\frac{3}{8}$ in.). Holding the length too short can result in carburization of the base metal, creating potentially brittle welds. This is particularly true when welding without filler metal.

When the joint requires filler metal, the same technique that is used in GTAW or oxyfuel gas welding (OFW) should be employed. The welding rod should be fed into the weld pool with one hand while manipulating the arc with the other.

If the arc is broken for any reason, then restart should not occur directly at the hot metal where welding stopped, because a hard spot could result. Rather, a restart should occur in front or to one side of the weld, followed by a quick return to the point where welding stopped. Care should be taken to either incorporate the restart area into the weld or to grind the arc strike after welding is completed. The arc strike areas can be very hard and can cause cracking if they are not fused into the weld or ground out.

In the twin-electrode operation, the workpiece is not part of the electrical circuit. The heat for welding is produced by creating an arc between the two electrodes. The electrode holder has two adjustable arms that grip the carbon electrodes at the proper length to maintain the arc. The operator maintains a constant distance between the carbon electrodes by adjusting them as they are consumed. An experienced welder can make these adjustments while still welding or brazing.

Small ac machines are normally used in the twin-electrode process because the electrodes will wear at an equal rate. Direct current can be used as long as the positive-side electrode is one size larger than the negative electrode. The larger electrode compensates for the faster consumption rate on the positive side of the direct current.

Electrodes range in size from 6.4 to 9.5 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.) and are copper coated for better current flow. The heat must be maintained so that the copper does not melt more than 13 mm ($\frac{1}{2}$ in.) back from the electrode tip. Only enough heat to cause the filler metal to flow easily should be used (Table 1). High heat causes excessive electrode consumption and could cause carburization of the weld metal.

Carbon Arc Welding

Lance Soisson, Welding Consultants, Inc.

Applications

The single-electrode carbon arc process is primarily used on steel, cast iron, and copper, although it can be used on most ferrous and nonferrous materials. With steels, it is principally applied to make outside corner welds on thinner-gage materials, where no filler metal is used. A good fit-up is required, and a fluxing agent is often used to promote better welds. The resulting welds arc smoother and, frequently, more economical than similar welds created by the shielded metal arc welding (SMAW) process.

Another application is the welding of galvanized steel using a silicon bronze filler metal. In this instance, it is important to maintain a short arc and to direct the heat to the filler metal to minimize damage to the galvanic coating.

Cast iron can be welded using the carbon arc process, but it is more often used in brazing. The casting must be preheated to approximately 650 °C (1200 °F) and then slowly cooled to reduce the possibility of cracking and to produce machinable welds.

The process is also used on copper, because of the high heat capabilities of the larger electrodes. Direct current, electrode negative, should always be used when welding or brazing copper. The workpiece should be preheated to a temperature between 150 and 650 °C (300 and 1200 °F), or at least locally preheated in the weld area. Holding a long arc will allow the carbon to combine with oxygen to form the CO that somewhat shields the weld.

Twin carbon arc welding is used primarily as a maintenance tool in small shops, farms, or homes. It is most commonly applied in brazing or soldering operations, although it can be used to weld, preheat, or postheat smaller parts.

Submerged Arc Welding

Jonathan S. Ogborn, The Lincoln Electric Company

Introduction

SUBMERGED ARC WELDING (SAW) is an arc welding process in which the arc is concealed by a blanket of granular and fusible flux (Ref 1, 2, 3). Heat for SAW is generated by an arc between a bare, solid-metal (or cored) consumable-wire or strip electrode and the workpiece. The arc is maintained in a cavity of molten flux or slag, which refines the weld metal and protects it from atmospheric contamination. Alloy ingredients in the flux may be present to enhance the mechanical properties and crack resistance of the weld deposit.

Submerged Arc Welding

Jonathan S. Ogborn, The Lincoln Electric Company

Principles of Operation

Figure 1 shows a typical setup for automatic SAW. A continuous electrode is being fed into the joint by mechanically powered drive rolls. A layer of granular flux, just deep enough to prevent flash through, is being deposited in front of the arc. Electrical current, which produces the arc, is supplied to the electrode through the contact tube. The current can be direct current (dc) with electrode positive (reverse polarity), with electrode negative (straight polarity), or alternating current (ac). Figure 2 shows the melting and solidification sequence of SAW. After welding is completed and the weld metal has solidified, the unfused flux and slag are removed. The unfused flux may be screened and reused. The solidified slag may be collected, crushed, resized, and blended back into new flux. Recrushed slag and blends of recrushed slag with unused (virgin) flux are chemically different from new flux. Blends of recrushed slag may be classified as a welding flux, but cannot be considered the same as the original virgin flux (Ref 4).

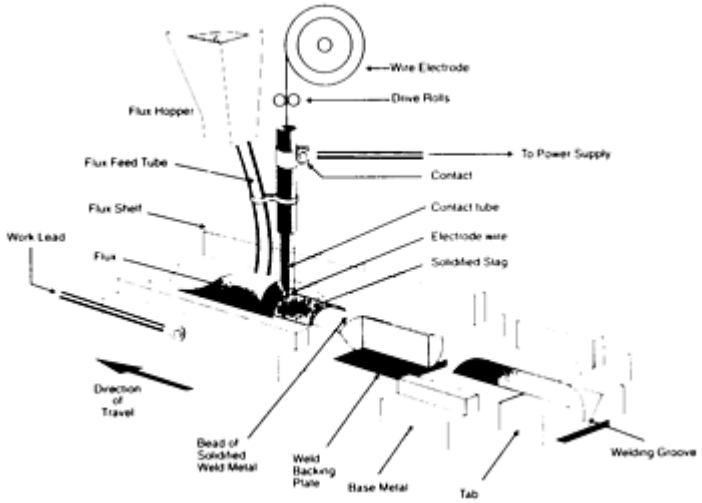

FIG. 1 SCHEMATIC SHOWING KEY COMPONENTS OF AUTOMATIC SUBMERGED ARC WELDING SETUP

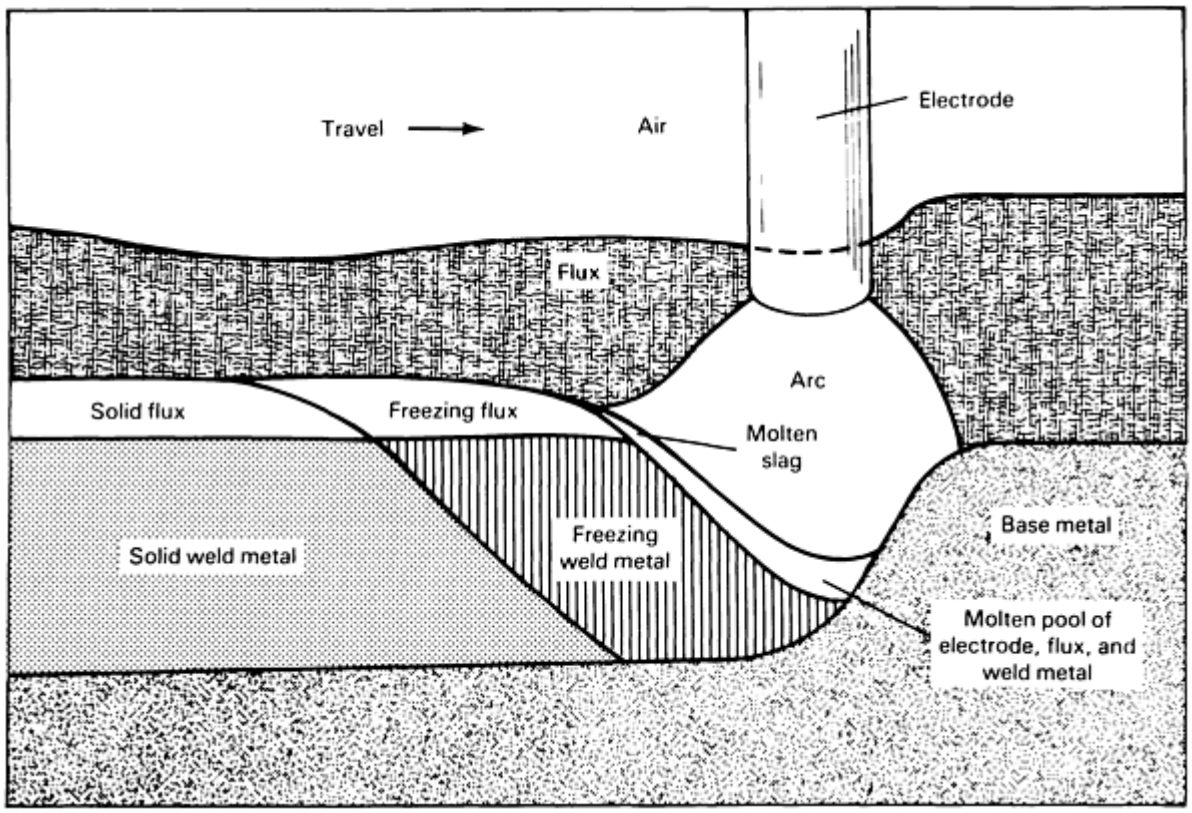

FIG. 2 SCHEMATIC SHOWING TYPICAL WELD POOL DYNAMICS OF A SUBMERGED ARC WELD

Submerged arc welding is adaptable to both semiautomatic and fully automatic operation, although the latter, because of its inherent advantages, is more popular (see the section "Advantages of Submerged Arc Welding" in this article). In semiautomatic welding, the welder controls the travel speed, direction, and placement of the weld. A semiautomatic welding gun is designed to transport the flux and wire to the operator, who welds by dragging the gun along the weld joint. Semiautomatic electrode diameters are usually less than 2.4 mm ($\frac{3}{32}$ in.) to provide sufficient flexibility and feedability in the gun assembly. Manually guiding the gun over the joint requires skill because the joint is obscured from view by the flux layer. In automatic SAW, travel speed and direction are controlled mechanically. Flux may be

automatically deposited in front of the arc, while the unfused flux may be picked by a vacuum recovery system behind the arc.

To increase deposition rate or welding speed, more than one wire can be fed simultaneously into the same weld pool. For example, in the twin arc process, two electrodes are fed into the same weld pool while sharing a common power source and contact tip. In tandem arc SAW, multiple electrodes are arranged with one in front of the other. Each electrode has an independent power supply and contact tip. The spacing, configuration, and electrical nature of the electrodes may be arranged to optimize welding speed and bead shape (Ref 5).

Advantages of submerged arc welding include the following:

- THE ARC IS UNDER A BLANKET OF FLUX, WHICH VIRTUALLY ELIMINATES ARC FLASH, SPATTER, AND FUME (THUS MAKING THE PROCESS ATTRACTIVE FROM AN ENVIRONMENTAL STANDPOINT).
- HIGH CURRENT DENSITIES INCREASE PENETRATION AND DECREASE THE NEED FOR EDGE PREPARATION.
- HIGH DEPOSITION RATES AND WELDING SPEEDS ARE POSSIBLE.
- COST PER UNIT LENGTH OF JOINT IS RELATIVELY LOW.
- THE FLUX ACTS AS A SCAVENGER AND DEOXIDIZER TO REMOVE CONTAMINANTS SUCH AS OXYGEN, NITROGEN, AND SULFUR FROM THE MOLTEN WELD POOL. THIS HELPS TO PRODUCE SOUND WELDS WITH EXCELLENT MECHANICAL PROPERTIES.
- LOW-HYDROGEN WELD DEPOSITS CAN BE PRODUCED.
- THE SHIELDING PROVIDED BY THE FLUX IS SUBSTANTIAL AND IS NOT SENSITIVE TO WIND AS IN SHIELDED METAL ARC WELDING AND GAS METAL ARC WELDING.
- MINIMAL WELDER TRAINING IS REQUIRED (THUS, RELATIVELY UNSKILLED WELDERS CAN BE EMPLOYED).
- THE SLAG CAN BE COLLECTED, REGROUND, AND SIZED FOR MIXING BACK INTO NEW FLUX AS PRESCRIBED BY MANUFACTURERS AND QUALIFIED PROCEDURES.

Limitations of submerged arc welding include the following:

- THE INITIAL COST OF WIRE FEEDER, POWER SUPPLY, CONTROLS, AND FLUX-HANDLING EQUIPMENT IS HIGH.
- THE WELD JOINT NEEDS TO BE PLACED IN THE FLAT OR HORIZONTAL POSITION TO KEEP THE FLUX POSITIONED IN THE JOINT.
- THE SLAG MUST BE REMOVED BEFORE SUBSEQUENT PASSES CAN BE DEPOSITED.
- BECAUSE OF THE HIGH HEAT INPUT, SAW IS MOST COMMONLY USED TO JOIN STEELS MORE THAN 6.4 MM ($\frac{1}{4}$ IN.) THICK.

Submerged Arc Welding

Jonathan S. Ogborn, The Lincoln Electric Company

Process Applications

If a steel is suitable for welding with gas-metal arc welding, flux-cored arc welding, shielded metal arc welding, or gas-tungsten arc welding, procedures can be developed to weld the steel with SAW (Ref 6). The main limitations of SAW are plate thickness and position. Because SAW is a high heat input and high deposition rate process, it is generally used to weld thicker-section steels. Although the welding of 1.6 mm ($\frac{1}{16}$ in.) thick steel is possible, most SAW is done on plate over 6.4 mm ($\frac{1}{4}$ in.) in thickness.

Types of Metals. Submerged arc welding is most commonly used to join plain carbon steels. Alloy steels can be readily welded with SAW if care is taken to limit the heat input as required to prevent damage to the heat-affected zone (HAZ). Low-heat-input procedures are available for welding alloy steels and heat-treated steels to prevent grain coarsening and cracking in the HAZ. Maintaining proper preheat and interpass temperature is also important when welding alloy steels to prevent weld metal and HAZ cracking and to develop the required mechanical properties in the weld deposit. Submerged arc welding can be used to join stainless steels and nonferrous alloys. It is also commonly used to produce a stainless or nonferrous overlay on top of a base metal.

Joint Configurations. The most common weld deposits made with SAW are groove, fillet, and plug welds, and surfacing deposits. For groove welds, the characteristic deep penetration of SAW plays a role in joint selection. Plate up to 15.9 mm ($\frac{5}{8}$ in.) thick can be completely welded from one side using a square butt joint with a 0.8 mm ($\frac{1}{32}$ in.) root opening. Beveled joints should be used for multiple-pass welds on plate thicknesses greater than 15.9 mm ($\frac{5}{8}$ in.). Backing bars should be used to prevent loss of flux, to prevent melt through, and to ensure full-penetration weldments on one-sided joints. Although groove welds are generally made in the flat position, it is possible to develop special procedures to weld horizontally.

Single-pass fillet welds with throat sizes up to 7.9 mm ($\frac{5}{16}$ in.) thick and multiple-pass fillet welds are usually made in the horizontal position. Single-pass fillet welds over 7.9 mm (5/16 in.) thick are usually made in the flat position. Submerged arc plug welds are made in the flat position by puddling the electrode into the center of the hole until the weld is complete. Surfacing welds are made with both wire and strip electrode. Surfacing is done to rebuild worn parts with a wear-resistant material or to overlay a plain steel part with stainless steel or other alloys (Ref 7, 8, 9).

To prevent porosity, the surface to be welded should be clean and free of grease, oil, paints, moisture, and oxides. All slag from tack welds or previous layers should be removed. Tack welds should be positioned so that the submerged arc weld completely melts out the tack. The workpiece should be firmly clamped to minimize distortion and the need for tack welds.

Industrial Uses for SAW. Because SAW is used to join thick steel sections, it is primarily used for shipbuilding, pipe fabrication, pressure vessels, and structural components for bridges and buildings. Other than joining, SAW is used to build up parts and overlay with stainless or wear-resistant steel (for example, rolls for continuous casting steel, pressure vessels, rail car wheels, and equipment for mining, mineral processing, construction, and agriculture).

Equipment and Supplies

The power supplied to the contact tip may be direct current or alternating current. In the United States, dc power is most common for welding applications that require less than 1000 A. In Europe and the Far East, however, ac is used extensively, even in applications requiring less than 1000 A. Currents over 1000 A dc tend to create arc blow problems. Alternating current is most commonly used for high-current applications, for applications where arc blow may be a problem, and in multiwire applications. Direct-current power supplies may be either transformer-rectifiers or motor/engine generators that produce either constant voltage or constant-current power. Alternating-current power sources are most commonly transformers.

To produce a submerged arc weld, both flux and electrode are consumed. Each flux and electrode combination, along with the variation of base material and process parameters, will produce a unique weld deposit. Because the integrity of the weld deposit depends on these parameters, specific fluxes and electrodes must be used in combination to optimize the weld metal properties.

Power Sources

A constant-voltage power supply is self-regulating, so it can be used with a constant-speed wire feeder. No voltage or current sensing is required. The current is controlled by the wire diameter, the electrical stickout, and the wire-feed speed, while the voltage is controlled by the power supply. Constant-voltage dc power is the best choice for the high-speed welding of thin steel.

Unlike constant voltage, constant-current power supplies are not self-regulating, so they must be used with voltage-sensing variable-wire-feed speed controls. A constant-current wire feeder monitors arc voltage and adjusts the wire-feed speed in response to changes in the arc voltage. The wire-feed speed control attempts to maintain a constant arc length, while the power supply controls the arc current.

The constant-current output of a conventional ac machine varies with time like a sine wave dropping through zero with each polarity reversal. The voltage associated with the current is approximately a square wave. Because the power output is zero with each polarity change, an open-circuit voltage greater than 80 V may be required to ensure arc initiation. The constant-current ac machine requires voltage-sensing variable-wire-feed speed controls. On newer, solid-state power supplies, the current and voltage output both approximate square waves, with the instantaneous polarity reversal reducing arc initiation problems. The solid-state power supplies have constant-voltage characteristics that may be used with constant-speed wire-feed controls.

Flux Classification

Fluxes can be categorized depending on the method of manufacture, the extent to which they can affect the alloy content of the weld deposit, and the effect on weld deposit properties.

Classification Relative to Production Method. Based on the manufacturing process, there are two different types of fluxes: fused and bonded.

Fused Fluxes. The raw materials for a fused flux are dry mixed and melted in a furnace. The molten mixture is then rapidly solidified, crushed, screened, and packaged. Because of their method of manufacture, fused fluxes typically do not contain ferroalloys and deoxidizers.

Bonded Fluxes. The powdered ingredients of a bonded flux are dry blended, and then mixed with a binder, usually potassium or sodium silicate. After pelletizing, the wet flux is dried in an oven or kiln, sized appropriately, and then packaged. The relatively low baking temperatures allow bonded fluxes to contain deoxidizers and ferroalloys.

Classification Relative to Effect on Alloy Content of Weld Deposit. Independent of manufacturing method, a given flux may be described as an active, neutral, or alloy flux, depending on its ability to change the alloy content of the weld deposit. With all submerged arc fluxes, variations in arc voltage and other welding variables will change the ratio of flux

consumed to electrode or weld metal deposited. This ratio is often referred to as the flux-to-wire ratio. Normal flux-to-wire ratios for SAW are 0.7 to 0.9. An increase in the flux-to-wire ratio may be caused by either an increase in arc voltage or a decrease in the welding current. Likewise, a decrease in the flux-to-wire ratio may be caused by a decrease in arc voltage or an increase in the welding current. How the weld deposit composition changes with voltage (flux-to-wire ratio) provides an additional means of describing a flux.

Active fluxes contain controlled amounts of manganese and/or silicon. These alloys are added as ingredients in the flux to provide improved resistance to porosity and weld cracking caused by contaminants such as oxygen, nitrogen, and sulfur on the plate or in the plate composition itself. Active fluxes are primarily used to make single-pass welds. Because active fluxes contain deoxidizers such as manganese and silicon, the alloy in the weld metal will change with the flux-to-wire ratio. Changes in manganese and silicon content in the weld deposit will affect the strength and impact properties of the weld metal; therefore, the arc voltage must be more tightly controlled when welding with active fluxes than with neutral fluxes.

Neutral fluxes contain little or no deoxidizers, and by definition, will not produce any significant change in the weld metal composition as a result of a large change in arc voltage. Because neutral fluxes contain little or no alloy, they must rely on alloy in the electrode to provide deoxidation. Single-pass welds on oxidized plate may be prone to cracking or porosity due to insufficient alloy content and are usually best welded with active fluxes. Neutral fluxes are primarily used for welding multiple passes on plate exceeding 25 mm (1 in.) in thickness.

To quantify the active/neutral behavior of a flux, the Wall neutrality number (*N*) was developed (Ref 10) and is defined as:

$$N = 100\ [|\Delta\%SI| + |\Delta\%MN|] \qquad \textbf{(EQ 1)}$$

where Δ%Si is the change in the weight percent of silicon, and Δ%Mn is the change in the weight percent of manganese. To determine the Wall neutrality number, two different weld deposit pads must be made. One weld pad is welded with the same parameters as those specified for the weld test plate for the flux and electrode being used. The other weld pad is welded with the same parameters except that the voltage is increased by 8 V. The Δ%Si and Δ%Mn quantities in Eq 1 are then determined by the difference in the amount of silicon and manganese in the two deposits. A flux electrode combination that produces a Wall neutrality number of 40 or less is considered neutral, while a number of 40 indicates an active flux.

Alloy fluxes contain enough alloy as a flux ingredient to produce an alloy weld metal with a carbon steel electrode. They are also used with alloy and stainless steel wire and strip electrodes. Alloy fluxes find application primarily in welding alloy steels and hardfacing. Because the alloy in the weld deposit is a function of arc voltage (flux-to-wire ratio), it is important to follow the manufacturer's recommended procedure for obtaining proper weld deposit composition.

Classification Relative to Basicity Index. Aside from the manufacturing method and the active, neutral, or alloy behavior of flux types, another common method used to describe submerged arc fluxes is the basicity index, *BI*. The basicity index is the ratio of strongly bound metallic oxides to weakly bound metallic oxides (Ref 11). The Boniszewski basicity index is defined by:

$$BI = \frac{\begin{array}{c}CaO + CaF_2 + MgO \\ + K_2O + Na_2O + Li_2O + \\ BaO + SrO + \frac{1}{2}(MnO + FeO)\end{array}}{SiO_2 + \frac{1}{2}(Al_2O_3 + TiO_2 + ZrO_2)} \qquad \textbf{(EQ 2)}$$

The basicity index is an estimate of the oxygen content in the weld metal and is therefore used to predict weld metal properties. Basic fluxes tend to have lower weld metal oxygen content with good weld metal toughness, while acidic fluxes tend to produce higher weld metal oxygen content and coarser microstructure with a lower resistance to cleavage. Fluxes with a basicity index greater than 1.5 are considered basic; fluxes below 1.0 are considered acidic.

Acid fluxes are typically preferred for single-pass welding because of their superior operating and bead-wetting characteristics. In addition, acid fluxes usually have more resistance than basic fluxes to porosity caused by plate contamination by oil, rust, and mill scale.

Basic fluxes tend to have better impact properties than acid fluxes. This advantage is particularly evident on large multiple-pass welds. Highly basic fluxes generally produce weld metal with very good impact properties in large multiple-pass weldments. Basic fluxes tend to exhibit poorer welding characteristics than acid fluxes on single-pass welds. Their use should be limited to large multipass weldments where good weld metal notch toughness is required.

Selection of Electrodes Relative to Steel and Alloy Type

There are three different types of consumable electrodes: solid wire, cored wire, and strip. Electrodes for SAW are available for welding carbon steel, low-alloy steel, stainless steel, and nickel-base alloys. Wire diameters vary from 1.6 to 6.4 mm ($\frac{1}{16}$ to $\frac{1}{4}$ in.). Carbon steel wire usually has a light copper coating, which protects the wire from corrosion and provides good electrical contact in the welding tip.

Cored electrodes were developed to provide a low-cost method of increasing the number of alloys that can be welded with SAW. Cored electrodes typically consist of a mild steel tube with alloying elements in the center. Compositions of cored electrodes vary from mild and low-alloy steels through tool steels to stainless steels and high-alloy austenitic steels.

Strip electrodes are generally used for welding overlays and for hardfacing applications. The advantages of strip are wide weld beads, low penetration, low dilution, and high deposition rates. The equipment is very similar to SAW with wire except that special drive rolls are needed to feed the strip, and sometimes auxiliary magnetic fields are set up to improve bead shape and tie-in. Strip thicknesses vary from 0.5 to 1.0 mm (0.02 to 0.04 in.), and widths vary from about 25 to 100 mm (1 to 4 in.).

Plain Carbon Steels. The requirements for the classification of electrodes and fluxes for welding carbon steels are detailed in Ref 12. Compositional requirements for solid electrodes are given in Table 1. Requirements for composite electrodes are defined in Table 2. Classification of solid electrodes is based on the chemical composition of the electrode. Classification of composite electrodes is based on weld deposit composition. Flux classification is based on the soundness and mechanical properties of the weld metal produced with a particular flux and electrode combination. The classification system used to describe flux-electrode combinations for mild steel welding is defined in Fig. 3. Interpretation of the classification system code is illustrated in the flux-electrode combination examples that follow.

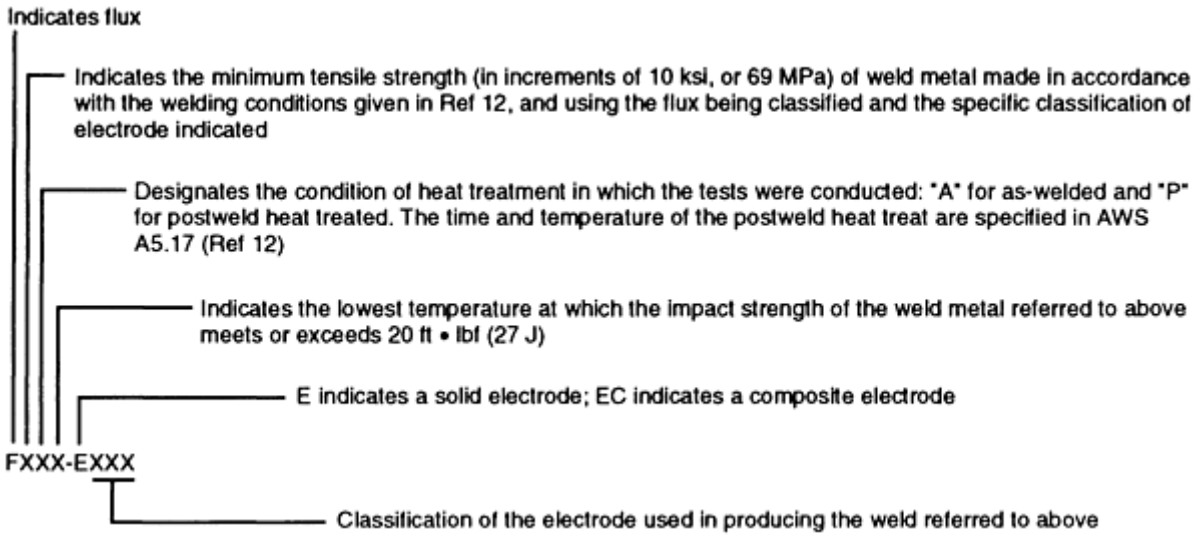

FIG. 3 CLASSIFICATION SYSTEM FOR CARBON STEEL ELECTRODES AND FLUXES USED IN SAW APPLICATIONS. SOURCE: REF 12

F7A6-EM12K is a complete designation. It refers to a flux that will produce weld metal that, in the as-welded condition, will have a tensile strength no lower than 485 MPa (70 ksi) and Charpy V-notch impact strength of at least 27 J (20 ft · lbf) at -51 °C (-60 °F) when produced with an EM12K electrode under the conditions called for in this specification.

F7A4-EC1 is a complete designation for a flux when the trade name of the electrode used in classification is indicated as well. It refers to a flux that will produce weld metal with that electrode, which in the as-welded condition, will have a tensile strength no lower than 485 MPa (70 ksi) and Charpy V-notch energy of at least 27 J (20 ft · lbf) at -40 °C (-40 °F) under the conditions called for in this specification.

Low-Alloy Steels. The requirements for low-alloy steel welding electrodes are detailed in Ref 13. The classification system for flux-electrode combinations of low-alloy steel is shown in Fig. 4. Table 3 shows the AWS electrode classification as determined by the composition of the solid electrode composition, while Table 4 is the flux-electrode classification requirement for the weld deposit composition of both solid and composite flux-electrode combinations. Interpretation of the classification system code is illustrated in the flux-electrode combination examples that follow.

Source: Ref 13

(A) THE FILLER METAL SHALL BE ANALYZED FOR THE SPECIFIC ELEMENTS FOR WHICH VALUES ARE SHOWN IN THIS TABLE. IF THE PRESENCE OF OTHER ELEMENTS IS INDICATED, IN THE COURSE OF THIS WORK, THE AMOUNT OF THOSE ELEMENTS SHALL BE DETERMINED TO ENSURE THAT THEIR TOTAL (EXCLUDING IRON) DOES NOT EXCEED 0.50 WT%.

(B) SINGLE VALUES ARE MAXIMUM.

(C) THE LETTER "N" AS A SUFFIX TO A CLASSIFICATION INDICATES THAT THE ELECTRODE IS INTENDED FOR WELDS IN THE CORE BELT REGION OF NUCLEAR REACTOR VESSELS. THIS SUFFIX CHANGES THE LIMITS ON THE PHOSPHORUS, VANADIUM, AND COPPER AS FOLLOWS: P = 0.012% MAXIMUM: V = 0.05% MAXIMUM; CU = 0.08% MAXIMUM. "N" ELECTRODES SHALL NOT BE COATED WITH COPPER OR ANY MATERIAL CONTAINING COPPER. THE "EF5" AND "EW" ELECTRODES SHALL NOT BE DESIGNATED AS "N" ELECTRODES.

(D) THE COPPER LIMIT INCLUDES ANY COPPER COATING THAT MAY BE APPLIED TO THE ELECTRODE.

(E) THE EL12 AND EM12K CLASSIFICATIONS ARE IDENTICAL TO THOSE SAME CLASSIFICATIONS IN ANSI/AWS A5.17-89 (REF. 10). THEY ARE INCLUDED IN THIS SPECIFICATION BECAUSE THEY ARE SOMETIMES USED WITH AN ALLOY FLUX TO DEPOSIT SOME OF THE WELD METALS CLASSIFIED IN TABLE 4.

(F) THE EB6 AND EB8 CLASSIFICATIONS ARE SIMILAR, BUT NOT IDENTICAL, TO THE ER502 AND ER505 CLASSIFICATIONS, RESPECTIVELY, IN ANSI/AWS A5.9-80, "SPECIFICATION FOR CORROSION-RESISTING CHROMIUM AND CHROMIUM-NICKEL STEEL BARE AND COMPOSITE METAL CORED AND STRANDED ARC WELDING ELECTRODES AND WELDING RODS." THESE CLASSIFICATIONS WILL BE DROPPED FROM THE NEXT REVISION OF A5.9 (SEE REF 14).

(G) THE COMPOSITION RANGES OF CLASSIFICATIONS WITH THE "EM" PREFIX ARE INTENDED TO CONFORM TO THE RANGES FOR SIMILAR ELECTRODES IN THE MILITARY SPECIFICATIONS.

TABLE 4 COMPOSITION OF LOW-ALLOY STEEL WELD METAL (BOTH SOLID FLUX-ELECTRODE AND COMPOSITE FLUX-ELECTRODE COMBINATIONS)

AWS WELD METAL CLASSIFICATION[E]	UNS NO.		COMPOSITION, WT%[A][B][C][D]

(A) THE WELD METAL SHALL BE ANALYZED FOR THE SPECIFIC ELEMENTS FOR WHICH VALUES ARE SHOWN IN THIS TABLE. IF THE PRESENCE OF OTHER ELEMENTS IS INDICATED, IN THE COURSE OF THIS WORK, THE AMOUNT OF THOSE ELEMENTS SHALL BE DETERMINED TO ENSURE THAT THEIR TOTAL (EXCLUDING IRON) DOES NOT EXCEED 0.50%.

(B) SINGLE VALUES ARE MAXIMUM.

(C) THE LETTER "N" AS A SUFFIX TO CLASSIFICATION INDICATES THAT THE WELD METAL IS INTENDED FOR WELDS IN THE CORE BELT REGION OF NUCLEAR REACTOR VESSELS. THIS SUFFIX CHANGES THE LIMITS ON PHOSPHORUS, VANADIUM, AND COPPER AS FOLLOWS: P = 0.012% MAXIMUM; V = 0.05% MAXIMUM; CU = 0.08% MAXIMUM. "N" ELECRODES SHALL NOT BE COATED WITH COPPER OR ANY MATERIAL CONTAINING COPPER. THE F5 AND W CLASSIFICATIONS SHALL NOT BE DESIGNATED AS "N" WELD METALS.

(D) A LOW-DILUTION AREA OF THE GROOVE WELD OR THE REDUCED SECTION OF THE FRACTURED TENSION TEST SPECIMEN MAY BE SUBSTITUTED FOR THE WELD PAD, AND SHALL MEET THE ABOVE REQUIREMENTS. IN CASE OF DISPUTE, THE WELD PAD SHALL BE THE REFEREE METHOD.

(E) THE ELECRODE DESIGNATION FOR COMPOSITE ELECTRODES IS OBTAINED BY PLACING AN "EC" BEFORE THE APPROPRIATE WELD METAL CLASSIFICATION.

(F) MANGANESE IN NI1 AND NI2 CLASSIFICATIONS MAY BE 1.80% MAXIMUM WHEN CARBON IS RESTRICTED TO 0.10% MAXIMUM.

(G) A SINGLE VALUE SPANNING THE COLUMNS FOR VANADIUM, TITANIUM, AND ZIRCONIUM IS THE TOTAL OF THESE ELEMENTS.

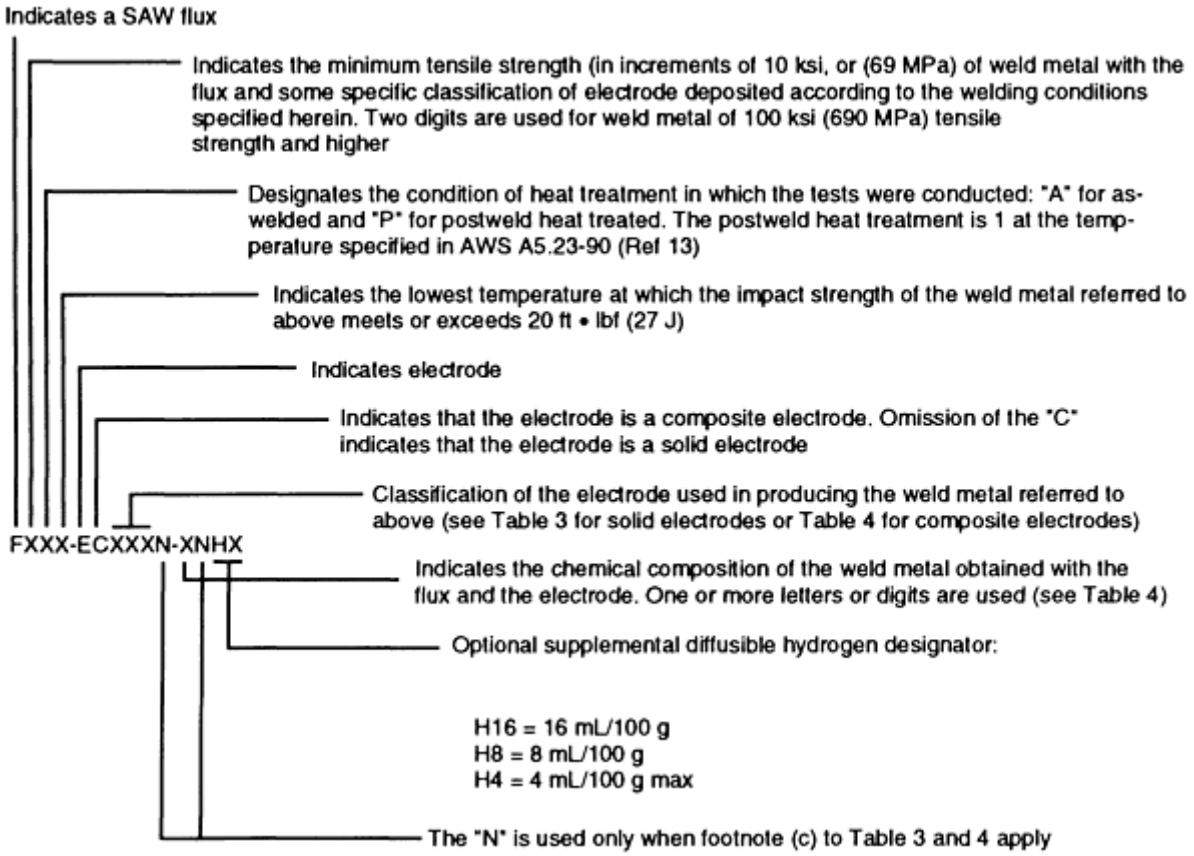

FIG. 4 CLASSIFICATION SYSTEM FOR LOW-ALLOY STEEL ELECTRODES AND FLUXES USED IN SAW APPLICATIONS

F9PO-EB3-B3 is a complete designation for a flux-electrode combination. It refers to a flux that will produce weld metal that, in the postweld heat-treated condition, will have a tensile strength of 620 to 760 MPa (90 to 110 ksi) and Charpy V-notch impact strength of at least 27 J (20 ft · lbf) at - 18 °C (0 °F) when made with an EB3 electrode under the conditions called for in this specification. The composition of the weld metal will be B3 (Table 4).

F9A2-ECM1-M1 is a complete designation for a flux when the trade name of the composite electrode used in the classification tests is indicated as well. The designation refers to a flux that will produce weld metal that, with the M1

electrode, in the as-welded condition, will have a tensile strength of 620 to 760 MPa (90 to 110 ksi) and Charpy V-notch impact strength of at least 27 J (20 ft · lbf) at -29 °C (-20 °F) under the conditions called for in this specification. The composition of the weld metal will be M1 (Table 4).

Stainless and Nickel-Base Alloys. For welding with corrosion-resistant chromium and chromium-nickel bare and composite metal cored and stranded electrodes, the composition of the filler metal is classified according to AWS A5.9 (Table 5). There is no AWS classification of fluxes or of flux-electrode combinations for stainless steel SAW.

(A) ANALYSIS SHALL BE MADE FOR THE ELEMENTS FOR WHICH SPECIFIC VALUES ARE SHOWN IN THIS TABLE. IF, HOWEVER, THE PRESENCE OF OTHER ELEMENTS IS INDICATED IN THE COURSE OF ROUTINE ANALYSIS, FURTHER ANALYSIS SHALL BE MADE TO DETERMINE THAT THE TOTAL OF THESE OTHER ELEMENTS, EXCEPT IRON, IS NOT PRESENT IN EXCESS OF 0.50 %.

(B) SINGLE VALUES SHOWN ARE MAXIMUM PERCENTAGES EXCEPT WHERE OTHERWISE SPECIFIED.

(C) THESE GRADES ARE AVAILABLE IN HIGH-SILICON CLASSIFICATIONS THAT SHALL HAVE THE SAME CHEMICAL COMPOSITION REQUIREMENTS AS GIVEN BELOW WITH THE EXCEPTION THAT THE SILICON CONTENT SHALL BE 0.65 TO 1.00%. THESE HIGH-SILICON CLASSIFICATIONS SHALL BE DESIGNATED BY THE ADDITION `SI' TO THE STANDARD

CLASSIFICATION DESIGNATIONS INDICATED BELOW. THE FABRICATOR SHOULD CONSIDER CAREFULLY THE USE OF HIGH-SILICON FILLER METALS IN HIGHLY RESTRAINED FULLY AUSTENITIC WELDS. A DISCUSSION OF THE PROBLEM IS PRESENTED IN REF 14.

(D) CARBON SHALL BE REPORTED TO THE NEAREST 0.01% EXCEPT FOR THE CLASSIFICATION E320LR, FOR WHICH CARBON SHALL BE REPORTED TO THE NEAREST 0.005%.

(E) TITANIUM: 9 × C MIN TO 1.0 MAX.

(F) TITANIUM: 0.10 TO 0.30. TUNGSTEN IS 1.25 TO 1.75%.

(G) NICKEL, MAX: 0.5 MINUS THE COPPER CONTENT.

Like stainless steels, nickel and nickel alloys are classified according to the composition of the filler metal only (Ref 15). Classifications of filler metal are shown in Table 6. There is no AWS classification of fluxes or of flux-electrode combinations for nickel alloy SAW.

TABLE 6 COMPOSITION OF NICKEL AND NICKEL-ALLOY BARE ELECTRODES AND RODS

(A) THE FILLER METAL SHALL BE ANALYZED FOR THE SPECIFIC ELEMENTS FOR WHICH VALUES AVE SHOWN IN THIS TABLE. IN THE COURSE OF THIS WORK, IF THE PRESENCE OF OTHER ELEMENTS IS INDICATED, THE AMOUNT OF THOSE ELEMENTS SHALL HE DETERMINED TO ENSURE THAT THEIR TOTAL DOES NOT EXCEED THE LIMIT SPECIFIED FOR "OTHER ELEMENTS, TOTAL" IN

THE LAST COLUMN OF THE TABLE.

(B) SINGLE VALUES ARE MAXIMUM, EXCEPT WHERE OTHERWISE SPECIFIED.

(C) INCLUDES INCIDENTAL COBALT.

(D) COBALT: 0.12 MAXIMUM, WHEN SPECIFIED.

(E) TANTALUM: 0.30 MAXIMUM, WHEN SPECIFIED.

(F) BORON IS 0.006% MAXIMUM.

Personnel Considerations

Employee Training. Submerged arc welding is an automatic or semiautomatic process carried out primarily in the flat or horizontal position with the arc obscured from view and does not require a high level of skill. The primary expenditures both in cost and time are consumed in designing jigs and fixtures to hold and position the workpiece so that SAW can be performed. While the actual welding process does not require a high degree of skill, the setup procedure requires skilled personnel with an aptitude for fabricating the fixtures and clamps necessary to position the workpiece in an acceptable position (usually flat).

Health and Safety in the Workplace. The main safety concerns in welding are electric shock, fume inhalation, and burns from both the arc ultraviolet source and the hot-metal infrared source (Ref 16). To reduce the risk of electrical shock, all equipment must be properly grounded and welding cables must be in good condition. The fume is nearly eliminated in SAW. However, certain vaporized elements (for example, chromium, cobalt, manganese, nickel, and vanadium) can be potentially dangerous. To prevent exposure to these elements, the welding area should have adequate ventilation. In SAW, the arcflash and its accompanying spatter are nearly eliminated because of the slag and the depth of the flux pile. However, eye protection should always be worn.

Additional information is available in the article "Safe Practices" in this Volume.

Submerged Arc Welding

Jonathan S. Ogborn, The Lincoln Electric Company

SAW Parameters

While SAW is the most inexpensive and efficient process for making large, long, and repetitive welds, much time and energy are required to prepare the joint. Care must be taken to line up all joints to have a consistent gap in groove welds and to provide backing plates and flux dams to prevent spillage of flux and molten metal. Once all the pieces are clamped or tacked in place, welding procedures and specifications should be consulted before welding begins.

Procedural Variations and Effect on Weld Bead Characteristics

Procedural variations in SAW include current, voltage, electrical stickout (distance from last electrical contact to plate), travel speed, and flux depth. Variation in any of these parameters will affect the shape and penetration of the weld, as well as the integrity of the weld deposit.

Weld Current. Because the welding current controls such parameters as deposition rate, penetration, and dilution, it is the most important welding variable. An increase in welding current at a constant voltage will decrease the flux-to-wire ratio, while a decrease in current will increase the flux-to-wire ratio. The effect of current variation on weld bead profile is shown in Fig. 5. Welds made at excessively low current will tend to have little penetration and higher width-to-depth ratios. Welds made at an excessively high current will have deep penetration, high dilution, more shrinkage, and excess buildup. Low current will also produce a less stable arc than higher currents.

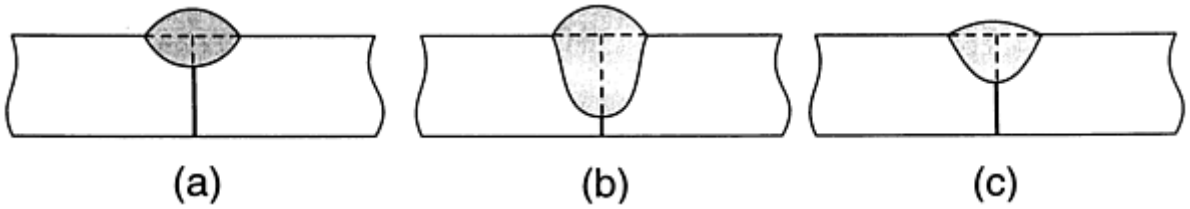

FIG. 5 EFFECT OF VARIATION IN WELDING CURRENT ON WELD BEAD PROFILE. (A) EXCESSIVELY LOW CURRENT. (B) EXCESSIVELY HIGH CURRENT. (C) RECOMMENDED CURRENT

The direction of current flow will also affect the weld bead profile. The current may be direct with the electrode positive (reverse polarity), electrode negative (straight polarity), or alternating. Reverse polarity is most commonly used. For a given set of welding conditions, reverse polarity will produce wider beads with more penetration at a lower deposition rate than straight polarity. Straight-polarity welding will contribute to narrower beads with less penetration and more buildup. Because straight polarity reduces base plate dilution, it is frequently used in surfacing applications. For the same welding current, the deposition rate with straight polarity is higher than with reverse polarity. Straight polarity is preferred for poor fitup. The bead shape, penetration, and deposition rate for alternating current fall between those of straight and reverse polarity. Alternating Current is used when welding current exceeds 1000 A and on multiple-wire applications to reduce arc blow and arc interaction.

In SAW, the current density in the electrode also plays a role in bead shape and penetration. Smaller-diameter electrodes with a high current density will produce narrower beads with deeper penetration than larger-diameter electrodes. Larger-diameter electrodes are able to bridge larger root openings. In cases where a given current can be achieved with two different electrode diameters, the smaller electrode will produce the higher deposition rate.

Weld Voltage. Like current, welding voltage will affect the bead shape and the weld deposit composition. Increasing the arc voltage at a constant current will increase the flux-to-wire electrode ratio, while decreasing the voltage will reduce the flux-to-electrode ratio. The effect of the magnitude of arc voltage on bead shape is shown in Fig. 6. Increasing the arc voltage will produce a longer arc length and a correspondingly wider, flatter bead with less penetration. Higher voltage will increase flux consumption, which could then change deposit composition and properties. Slightly increasing the arc voltage will help the weld to bridge gaps when welding in grooves. Excessively high voltage will produce a hat-shaped concave weld, which has low resistance to cracking and a tendency to undercut. Lower voltages will shorten the arc length and increase penetration. Excessively low voltage will produce an unstable arc and a crowned bead, which has an uneven contour where it meets the plate.

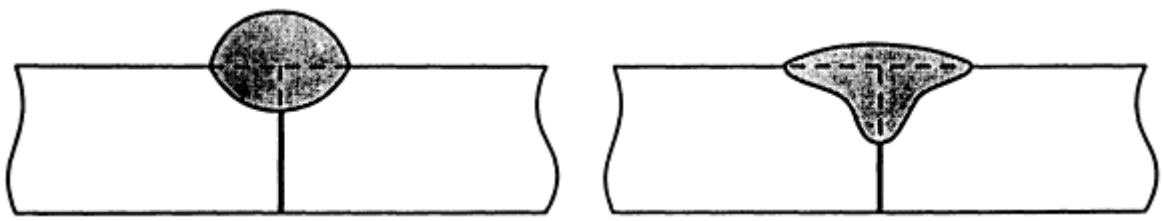

FIG. 6 EFFECT OF VARIATION IN WELDING VOLTAGE AT CONSTANT CURRENT ON WELD BEAD PROFILE. (A) EXCESSIVELY LOW VOLTAGE. (B) EXCESSIVELY HIGH VOLTAGE

Electrical Stickout. In SAW, the current flowing in the electrode between the contact tube and the arc (electrode extension) will cause some I^2R heating, resulting in a voltage drop across that length of electrode. This resistance heating and subsequent voltage drop can be used to obtain higher deposition rates. Normal electrode extension for solid SAW wire is approximately 8 to 12 times the electrode diameter. As this length increases at a constant current, so does the resistance heating and the melt-off rate. To compensate for the voltage drop and the increase in wire-feed speed, the voltage must be increased to obtain a properly shaped bead. Extending the electrode 20 to 40 times the diameter can

increase deposition rates by more than 50% (Ref 17). Although higher deposition rates can be achieved by extending the electrode, keeping the electrode aligned with the joint becomes increasingly difficult as the extension increases.

Travel Speed. Variations in travel speed at a set current and voltage also affect bead shape. As welding speed is decreased, heat input per length of joint increases, and the penetration and bead width increase. The penetration will increase until molten metal begins to flow under the arc and interfere with heat flow at excessively slow speeds. Excessively high travel speeds will promote a crowned bead as well as the tendency for undercut and porosity.

Flux layer depth is another variable that will alter the appearance, penetration, and quality of a submerged arc weld. If the flux layer is too deep, a greater-than-normal amount of flux will be melted, resulting in weld beads that are narrower than normal. Some surface imperfections may also appear because gases may be trapped by the deep flux layer. If the flux layer is too shallow, the arc will flash through, and the bead will have a rough appearance or porosity due to lack of shielding from the atmosphere. The correct depth of flux is just enough to prevent flash through. This will allow welding gases to escape while providing adequate protection.

Sources of Defects in SAW

The fact that SAW is a high heat input process under a protective blanket of flux greatly decreases the chance of weld defects. However, defects such as lack of fusion, slag entrapment, solidification cracking, hydrogen cracking, or porosity occasionally occur.

Insufficient Fusion and Slag Entrapment. Lack-of-fusion defects and slag entrapment are most commonly caused by improper bead placement or procedure. Improper placement can cause the weld metal to roll over and trap slag underneath, or if the weld bead is placed away from the edge to be joined, the liquid metal may not fuse to the base material. A crown-shaped bead caused by low welding voltage may also contribute to slag entrapment and lack of fusion by not allowing the liquid metal to spread out evenly.

Solidification cracking of SAW along the center of the bead is usually due to bead shape, joint design, or incorrect choice of welding consumables. A convex bead shape with a bead width-to-depth ratio greater than one will decrease solidification cracking tendencies. If weld penetration is too deep, the shrinkage stresses may cause centerline cracking. Joint design may also contribute to excessive shrinkage stresses, again increasing the risk of solidification cracking. Because cracking is related to stresses in the weld, high-strength materials will have a greater tendency to crack. Therefore, special care must be taken to generate proper bead shape, preheat temperatures, and interpass temperatures, in addition to correct electrode and flux combinations, when welding these materials.

Hydrogen Cracking. Unlike solidification cracking, which appears immediately after welding, hydrogen cracking is a delayed process and may occur from several hours to several days after welding has been completed. To minimize hydrogen cracking, all possible sources of hydrogen (for example, water, oil, grease, and dirt) present in the flux, electrode, or joint should be eliminated. The flux, electrode, and plate should be clean and dry.

To prevent moisture pickup, fluxes and electrodes should be stored in moisture-resistant containers in dry areas. If a flux or electrode becomes contaminated with moisture, it should be dried according to manufacturer recommendations.

Selection of the consumable, especially when welding high-strength steels that are more susceptible to hydrogen cracking, can also play a role in hydrogen cracking. Special consumables have recently been developed that produce weld deposits that are very low in diffusible hydrogen.

To further reduce hydrogen-related cracking, the joint to be welded should be preheated. Because hydrogen is fairly mobile in steel at temperatures above 95 °C (200 °F), the recommended preheat temperatures should be followed to allow most of the hydrogen to escape and to reduce the risk of hydrogen damage (Ref 18). In thick weldments, maintaining preheat for several hours after welding is completed will also reduce the risk of hydrogen cracking.

Porosity caused by trapped gas is uncommon in SAW because of the protection provided by the flux. When porosity does occur, it may be in the form of internal porosity or as depressions on the weld bead surface. The gas bubbles that cause porosity originate either from a lack of protection from the atmosphere or from contaminants such as water, oil, grease, and dirt. To reduce porosity in SAW, the weld should have sufficient flux coverage, and all water, grease, and dirt should be removed from the plate, electrode, and flux. Another cause of porosity in SAW is excessive travel speed. Travel

at excessively high speeds will not allow the gas bubbles to escape from the weld, and the bubbles may become trapped in the weld metal at the slag-to-metal interface.

Stud Arc Welding

Harry A. Chambers, TRW Nelson Stud Welding Division

Introduction

STUD ARC WELDING (SW), also known as arc stud welding, is a commonly used method for joining a metal stud, or fastener, to a metal workpiece. The process has been used as an alternative metal-fastening method since the 1940s. Millions of specially designed and manufactured metal studs are welded by this process every week in such diverse industries as construction, shipbuilding, automotive, and hard goods, as well as in miscellaneous industrial applications.

This article will serve as a basic information source for those interested in accomplishing one-sided, no-hole attachment of metal fasteners. The SW process represents an alternative to other welding processes, and is also a substitute for other fastening procedures, such as drilling and tapping, bolting, and self-tapping screws.

Stud Arc Welding

Harry A. Chambers, TRW Nelson Stud Welding Division

Process Overview

Stud arc welding is similar to many other welding processes, including arc and percussion welding, in that the base (weld end) of a specifically designed stud is joined to a base material by heating both parts with an arc that is drawn between the two. Equipment that is unique to this process regulates the arc length and arc dwell time. After an arc is struck, the stud weld end and the workpiece surface are brought to the proper temperature for joining and, after a controlled period of time, the two heated surfaces are brought together under pressure, creating a metallurgical bond capable of developing the full strength of the stud.

There are two basic types of stud arc welding, which are differentiated by the source of welding power. One type uses direct current (dc) power provided by a transformer/rectifier or a motor generator similar to that used in the shielded metal arc welding (SMAW) process. The second type uses power discharged from a capacitor storage bank. The process based on a dc power source is known as stud arc welding, whereas the process that utilizes capacitors is known as capacitor discharge stud welding (CDSW).

Both the SW and CDSW processes overlap in some areas of application. Generally, the SW process is used in applications that require similar stud and workpiece metals, the workpiece thickness is greater in relation to the stud diameter, and an accommodation must be made for the stud flash (fillet). The term "flash" is preferred to the term "fillet," because the metal that forms the flash during the stud arc welding process is expelled, rather than added, as occurs with other welding processes.

In contrast, the CDSW process is used extensively when welding to thin sheet metal, and is used frequently with dissimilar workpiece and stud alloys. It is also used in cases where marks on the opposite side of the workpiece must be avoided or minimized. With this process, the stud diameter is limited to smaller sizes. The CDSW process is more fully described in the article "Capacitor Discharge Stud Welding" in this Volume. The factors on which process selection should be based are fastener size, base-metal thickness, base-metal composition, and reverse-side marking requirements (Table 1).

Equipment. As shown in Fig. 1, the basic equipment used for stud arc welding consists of a control system, which regulates the arc time and controls gun movement; a fixed or portable stud-welding gun, which holds the stud in position during the welding process to create the proper arc length and joining pressure; and connecting cables, which must be connected to a separate source of dc power. The other items that are needed to weld the workpiece are the studs themselves and ceramic arc shields, or ferrules. The equipment used for stud welding is comparable, in terms of size, portability, and ease of operation, to the equipment used in the SMAW process. Although the initial cost of stud-welding systems varies with the method selected, stud size, and productivity requirements, it is generally competitive with other fastening methods on an in-place or finished part cost basis.

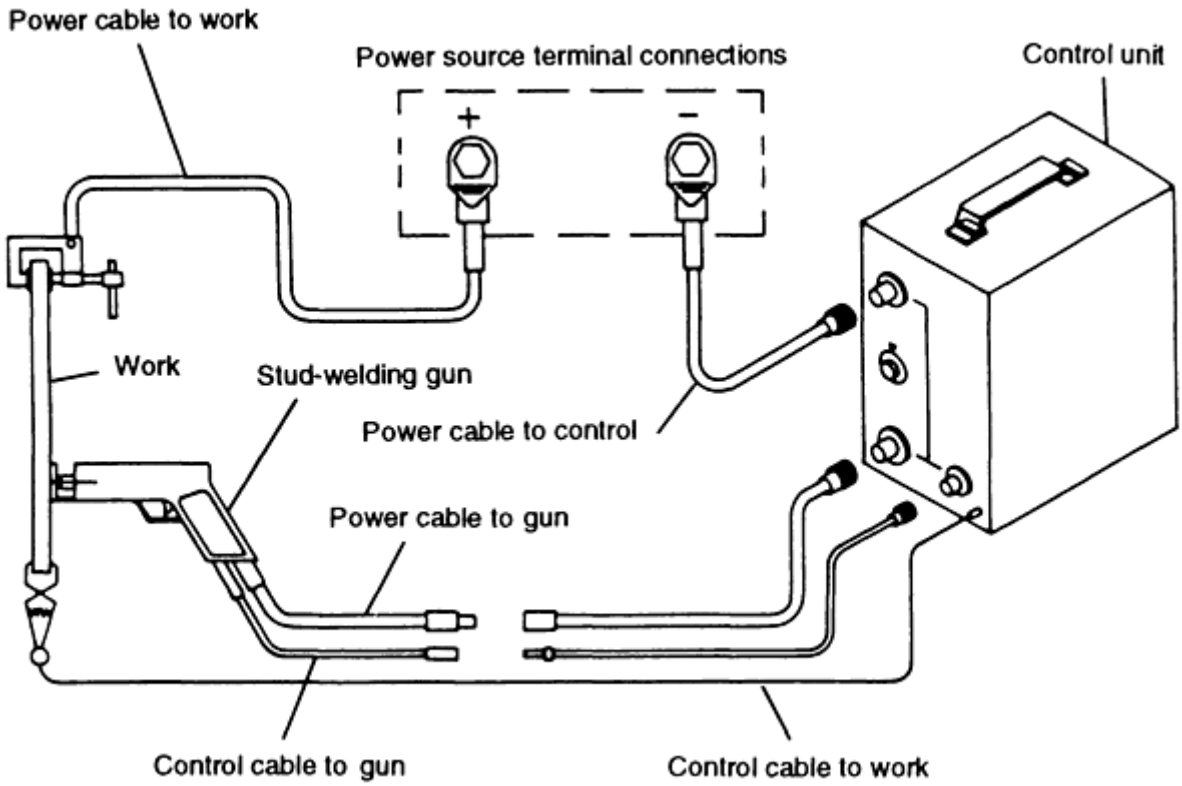

FIG. 1 STUD ARC WELDING CONTROL SYSTEM. THE CONTROL SYSTEM MUST BE CONNECTED TO A DC POWER SOURCE FOR WELDING. IN MOST APPLICATIONS, THE STUD (ELECTRODE) SHOULD BE NEGATIVE.

A stud-welding control system that has been integrated in a transformer/rectifier power source is shown in Fig. 2. This type of equipment, which is the most widely used, is called a power/control system. It can weld studs with diameters up to 28.5 mm ($1\frac{1}{8}$ in.). Either a single gun or dual guns can be used. Although a light-duty control system can weigh 11.3 kg (25 lb), the system shown in Fig. 2 weighs approximately 450 kg (1000 lb) and can be put on a wheeled cart for mobility.

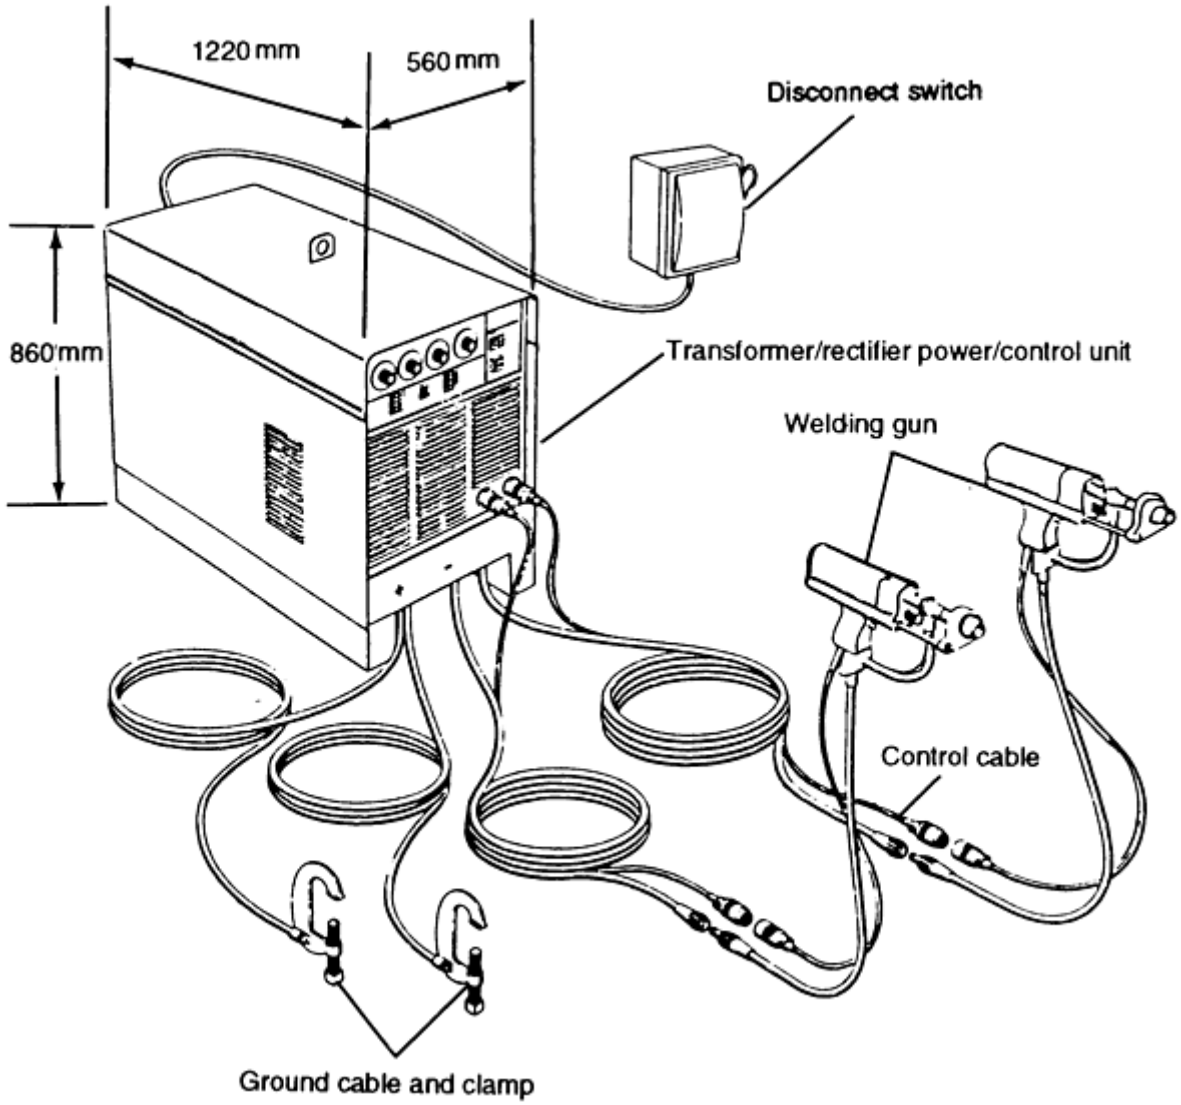

FIG. 2 TYPICAL INTEGRATED POWER/CONTROL SYSTEM FOR STUD ARC WELDING

A typical stud-welding gun (Fig. 3) is usually available in at least two sizes: standard duty, for use with studs up to 16 mm ($\frac{5}{8}$ in.) in diameter, and heavy duty, for use on larger-diameter studs. The weight of the gun can vary from approximately 1.8 kg (4 lb), for a standard-duty gun, to 6.8 kg (15 lb), for heavy-duty models.

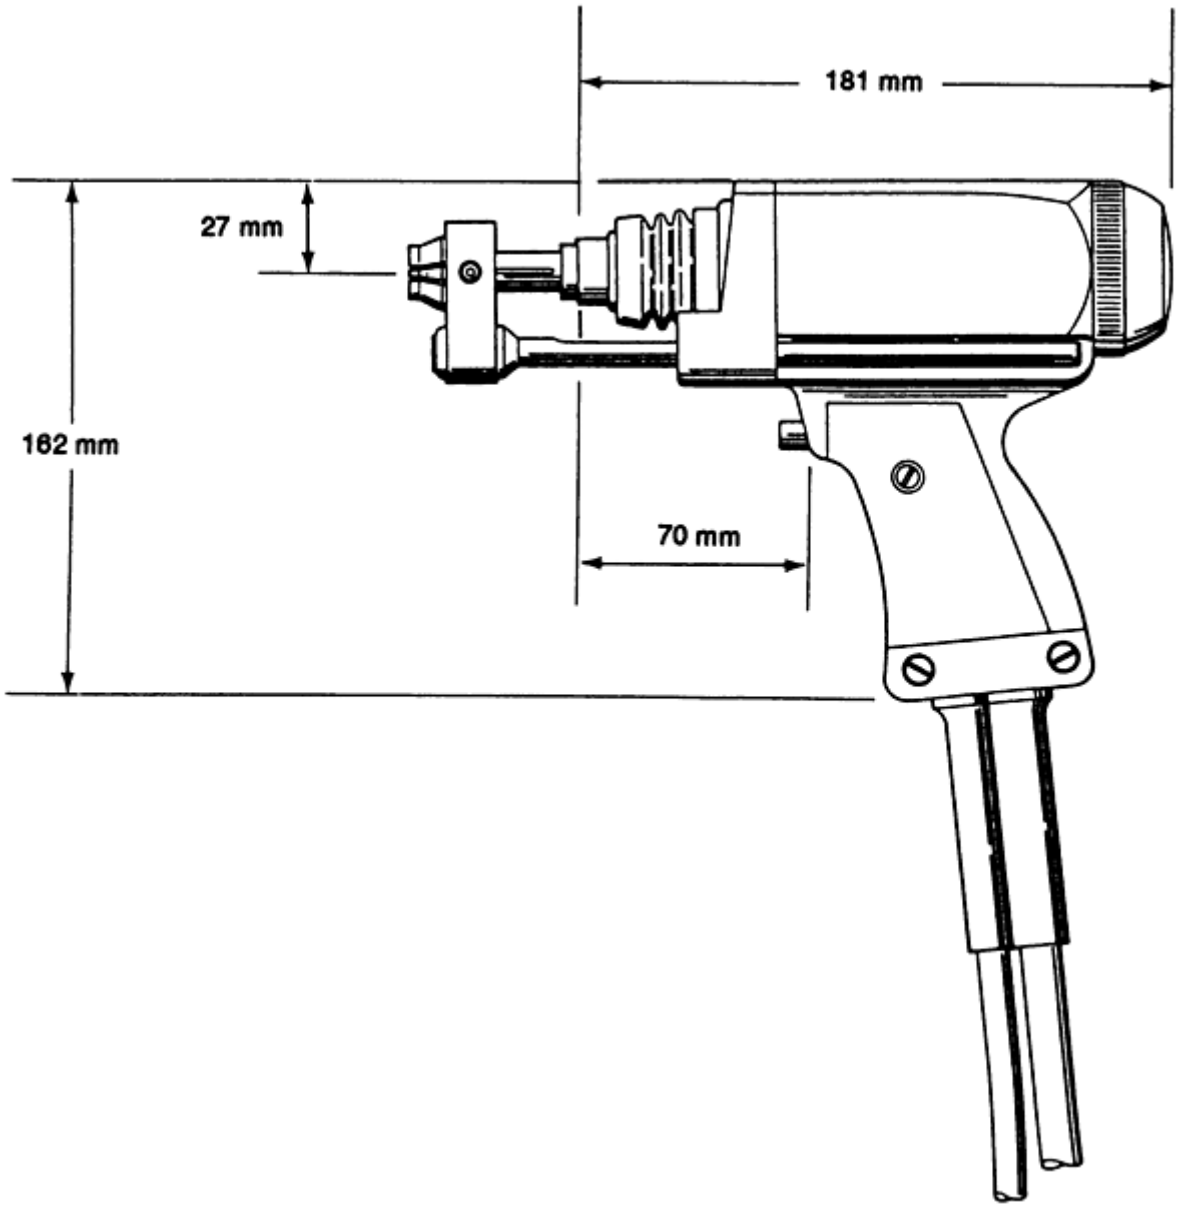

FIG. 3 TYPICAL STANDARD-DUTY GUN FOR STUD ARC WELDING

Operation. The stud arc welding process utilizes the same principles as any other arc welding procedure. First, the stud, which acts as an electrode, is inserted into a chuck on the end of the gun, surrounded by a ceramic ferrule, and positioned against the workpiece (Fig. 4a). Next, the gun trigger is depressed, which starts the automatic weld cycle by energizing a solenoid coil within the gun body that lifts the stud off the work and draws an arc. The arc melts the end of the stud and a portion of the workpiece (Fig. 4b). After a preset arc time (set on the control unit), the welding current is shut off and the solenoid is de-energized (Fig. 4c). A mainspring in the gun forces the stud into the molten pool of metal, producing a full-strength weld, which is shown in Fig. 4(d) after the gun has been lifted off the stud and the ceramic ferrule removed. The result is a full-penetration, full-strength stud-to-workpiece weld, as shown in Fig. 5. This weld is similar to that obtained with other types of arc-welding processes.

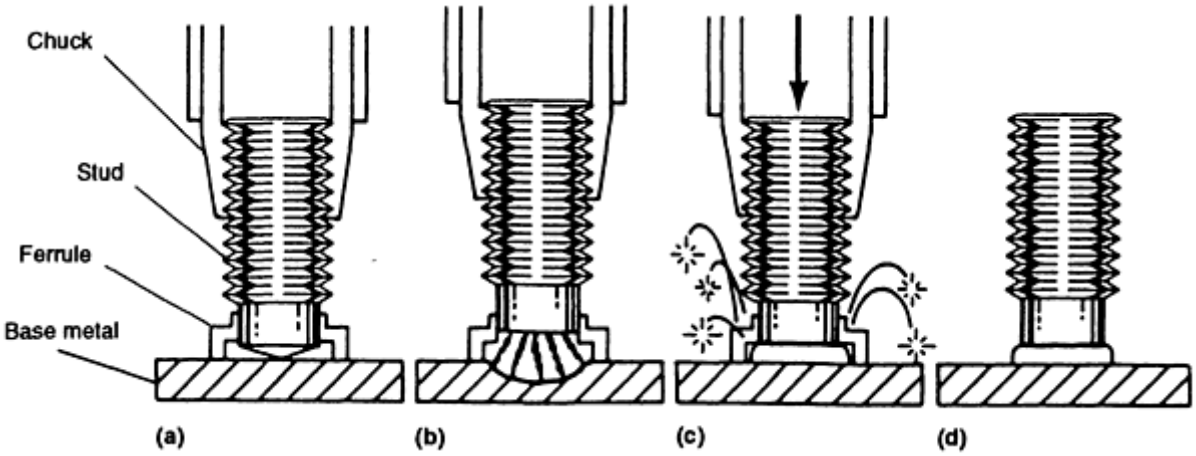

FIG. 4 STUD ARC WELDING PROCESS. (A) GUN IS PROPERLY POSITIONED. (B) TRIGGER IS DEPRESSED AND STUD IS LIFTED, CREATING AN ARC. (C) ARCING PERIOD IS COMPLETED AND STUD IS PLUNGED INTO MOLTEN POOL OF METAL ON BASE MATERIAL. (D) GUN IS WITHDRAWN FROM WELDED STUD AND FERRULE IS REMOVED.

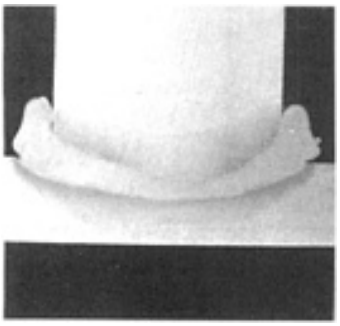

FIG. 5 MACROSECTION OF LOW-CARBON STEEL STUD WELD

Studs and Ferrules. With the exception of special processes, the stud arc welding of steel, stainless steel, and aluminum studs requires the use of a specifically designed weld stud and ceramic ferrule.

Studs. A wide range of studs are made by stud-welding manufacturers for the SW process. They vary in size and weld-base configuration, depending on the application requirements. The typical stud styles that are available include threaded, unthreaded, headed, and rectangular studs (Fig. 6). The steel stud diameters that are commonly welded using the SW process range from 2.7 to 25.4 mm (0.105 to 1.00 in.).

FIG. 6 COMMON STUD CONFIGURATIONS FOR STUD ARC WELDING

Full-strength welds result when using studs made from low-carbon steel that conforms to ASTM A-108 grades C-1010 through C-1020, although other steel grades can be used on a special-application qualified basis (Ref 2). Stainless steel studs are typically made from the austenitic series, including AISI 302, 302 HQ, 304, 305, 308, 309, 310, 316, 321, and 347, in both normal-carbon and low-carbon varieties. Stainless steel 303 is not an acceptable stud alloy. Aluminum studs are usually made from aluminum-magnesium alloys, including 5183, 5356, 5556, 5086, and 5456 (Ref 3).

Steel and stainless steel arc welded studs that are larger than 6.4 mm (0.250 in.) in diameter use a welding flux to stabilize the welding arc and to deoxidize the weld area. The most commonly used flux is commercially pure aluminum, which is installed onto the weld end of the stud by thermal spraying, staking, or pressing a slug into a drilled hole in the end of the stud (Fig. 7). Studs that are 6.4 mm (0.250 in.) and under usually do not require fluxing.

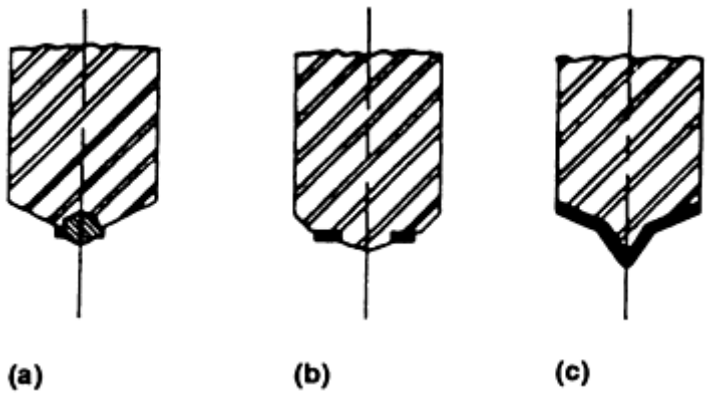

FIG. 7 METHODS OF FLUX LOADING STUDS. (A) PRESSED IN SLUG. (B) STAKED ON WASHER. (C) COATING

Aluminum studs do not have to be flux loaded. Instead, the weld end of the stud has a conical or cylindrical tip that is shaped into the parent metal to help initiate the arc and control the arc length. To prevent the oxidation and embrittlement of the stud/plate weld zone during aluminum stud arc welding, the weld area is purged with an inert gas during the weld cycle. Argon gas is commonly used for this purpose, although helium also can be used. The typical gas flow rates for aluminum studs of various diameters are shown in Table 2.

TABLE 2 GAS FLOW RATES FOR ALUMINUM STUD ARC WELDING

STUD WELD BASE DIAMETER		SHIELDING GAS FLOW[(A)]	
mm	**in.**	**l/min**	**ft^3/h**
6.4	$\frac{1}{4}$	7.1	15
7.9	$\frac{5}{16}$	7.1	15
9.5	$\frac{3}{8}$	9.4	20
11.1	$\frac{7}{16}$	9.4	20
12.7	$\frac{1}{2}$	9.4	20

(A) SHIELDING GAS, 99.95% PURE ARGON

When stud arc welding low-carbon and stainless steel studs, the stud (electrode) should be negative. Aluminum stud arc welding should be set up so that the stud is positive.

Obtaining a full-quality stud arc weld requires a sufficient amount of total energy input to the weld joint in order to produce melting and complete metallurgical bonding of the stud and workpiece. The energy input or weld current that is necessary depends on the stud diameter. Other parameters in the stud arc welding process are: arc voltage, arc time, and plunge. Arc voltage is a function of the arc length, which is set as "lift," or the length the stud is drawn away from the workpiece during weld-cycle initiation. Plunge is the length of stud that extends past the end of the ceramic ferrule and is available for melt off during the weld cycle.

Studs are reduced in length during the weld cycle. Table 3 shows the typical reductions for steel and aluminum studs as a result of welding.

(A) STUD ARC WELDED ALUMINUM STUDS REQUIRE INERT GAS SHIELDING: SEE TABLE 2.

There is a range of setting combinations for all stud diameters. The same total energy input can be obtained by varying current input and arc time. For example, a low current input can be compensated for, to some extent, by increasing weld time. Table 3 also shows typical weld settings for various SW stud diameters. The ideal settings in each weld position for a particular stud and workpiece should be established by beginning with typical settings and then varying them within the allowable range to meet the required conditions.

Typical settings are based on good weld conditions, such as a clean workpiece, good ground, and others. Also necessary is a proper dc power source, which should have the following characteristics:

- HIGH OPEN-CIRCUIT VOLTAGE (70 TO 100 V)
- RAPID OUTPUT CURRENT RISE
- DROOPING OUTPUT VOLT-AMPERE CURVE
- HIGH CURRENT OUTPUT OVER A SHORT TIME

Stud arc welding requires a very short weld time (Table 3), but a very high current input, when compared with other types of arc welding. Usually, the duty cycle for this process is much lower than that of other welding processes. Constant-voltage types of dc power sources are not suitable for stud welding. Many of the available dc power sources are acceptable for stud welding, including those supplied as integrated power/control systems by the stud-welding manufacturer. These integrated systems use both three-phase and single-phase incoming alternating current (ac) power. Both standard and special voltage units are available. Single-phase units are relatively low cost, portable systems that are usually suitable for smaller-diameter (≤ 12.7 mm, or $\frac{1}{2}$ in.) stud arc welding. Three-phase units are preferred for larger-diameter studs, because they provide a balanced load on incoming power lines and have smoother arc characteristics. A transformer/rectifier power source, combined with an integral stud-welding control system, is shown in Fig. 2.

Weld cable length and cable size also can affect the total output of a power source. Basically, a larger welding cable size minimizes current loss that is due to cable length, resistance, and heating. Thus, when the distance from the power source to the gun increases significantly, or when the number and size of studs applied per minute are large, larger welding cables should be used. Smaller dc power sources suitable for stud arc welding can be wired in parallel to produce the necessary current range.

Ferrules, or ceramic arc shields, are used in most stud arc weld applications. They are available in a wide variety of sizes and shapes to fit specific stud base designs and applications. For example, there are specific designs for welding studs through metal deck, to the fillet or heel of an angle, to round pipes or bars, or in a vertical position. A ferrule is placed over every stud at the weld end, where it is held in place by a grip on the stud-welding gun. The ferrule is used only once and must be removed from the stud after welding is completed to allow the inspection of the completed weld. Typical ferrule configurations are shown in Fig. 8.

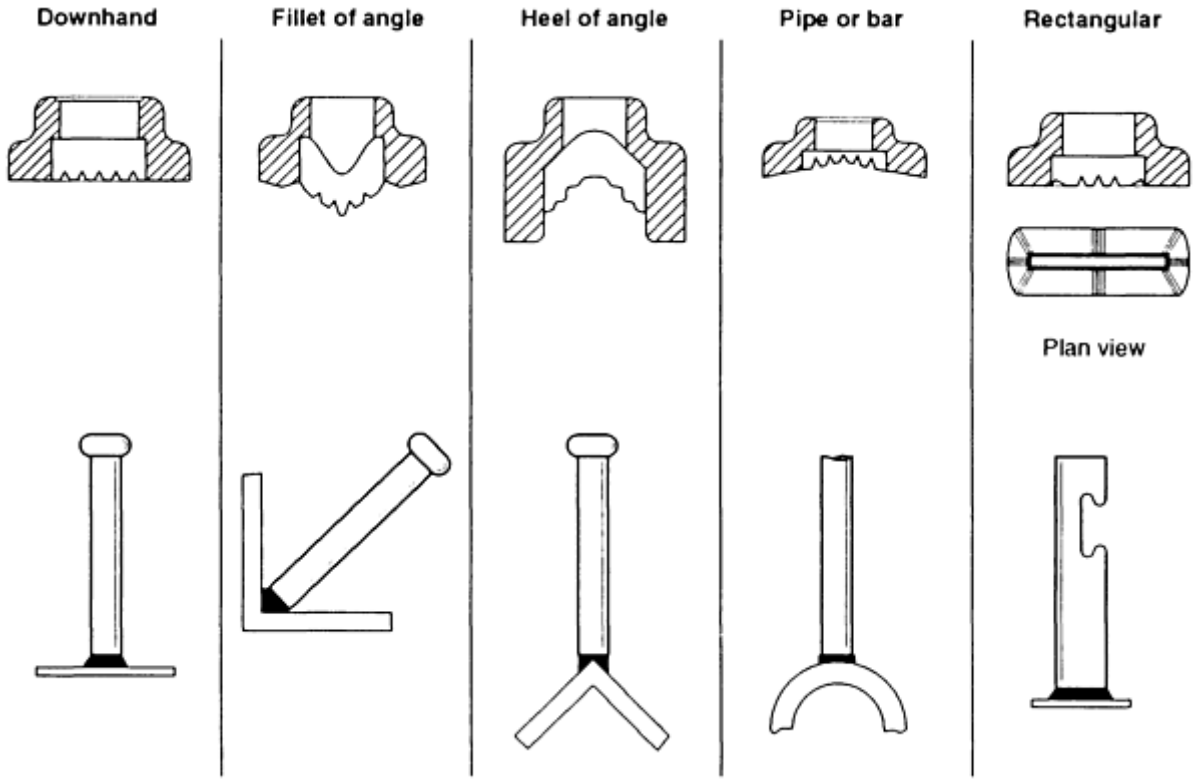

FIG. 8 CROSS SECTIONS OF FERRULES SHOWING SOME OF THE MANY VARIETIES AVAILABLE FOR DIFFERENT STUD BASE GEOMETRIES, WELD POSITIONS, AND APPLICATIONS

Ferrule design is important, because it controls certain functions during welding. For example:

- VENTS ON THE BOTTOM OF THE FERRULE ALLOW WELD GASES TO ESCAPE FROM THE WELD AREA AND RESTRICT THE INFLOW OF AIR TO MINIMIZE WELD POROSITY AND OXIDATION.
- THE INTERNAL CAVITY OF THE FERRULE CONFINES AND SHAPES THE MOLTEN METAL INTO A FLASH (FILLET) AROUND THE STUD PERIPHERY.
- HEAT IN THE WELD AREA IS CONCENTRATED AND CONTAINED.
- FLASH AND WELD SPATTER ARE MINIMIZED.

Although the dimensions of the flash are controlled by the ferrule configuration, the flash diameter and height must be taken into consideration when designing mating parts. Manufacturer specifications on finished stud flash dimensions should be followed, and test welds should be made to establish part fit. Flash dimensions can be accommodated by any of the five methods shown in Fig. 9.

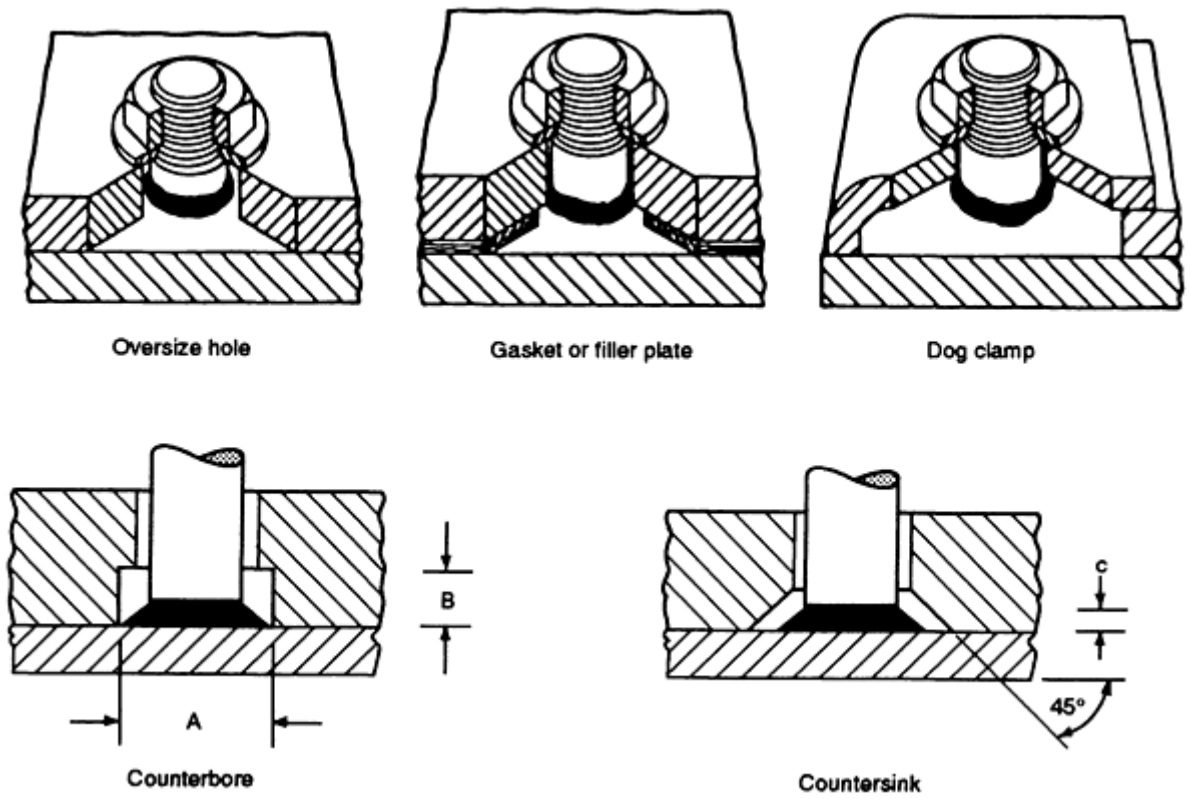

FIG. 9 COMMON METHODS FOR ACCOMMODATING WELD FLASH (FILLET) WITH STUD ARC WELDS. TYPICAL DIMENSIONS FOR A, B, AND C ARE GIVEN IN TABLE 4.

The typical dimensions for flash clearance are shown in Table 4. It should be noted that the flash (fillet) of a stud weld is not the same as the fillet that is produced by conventional welding techniques. It may have areas of nonfusion on its vertical leg or shrink fissures, which have no adverse affect on weld strength or ductility (Ref 4). Consequently, it is not subject to the profile and inspection criteria used for a conventional weld fillet.

TABLE 4 DIMENSIONS FOR COUNTERBORE AND COUNTERSINK WELD FLASH CLEARANCE

A, B, and C are shown in Fig. 9.

STUD BASE DIAMETER		COUNTERBORE				90° COUNTERSINK

19.1	3/4	28.6	1.125	7.9	0.312	4.7	0.187

Note: Dimensions can vary, depending on stud style and ceramic arc shield selected. Consult manufacturer for details.

Base Plate Material and Thickness. To obtain full strength, the stud arc welding of low-carbon steel, stainless steel, or aluminum studs should be made to a base material of sufficient thickness so that the stud fails in tension or torque, rather than by pulling a hole in the base-metal workpiece. In the case of stainless or low-carbon steel studs, the base-metal thickness should be at least one-third that of the stud diameter. For aluminum studs, the aluminum base plate material should be at least half that of the stud diameter. Thinner base plates can be used if strength is not the primary design characteristic that is required. On thinner materials, the studs will pull a hole in the plate at strength levels below their maximum. If the plate is too thin, then the stud will bum a hole through it. The recommended base plate thickness for full-strength development and the minimum thicknesses required to prevent burning through the base plate are given in Table 5.

(A) NEAREST COMMONLY AVAILABLE BASE METAL THICKNESS.

(B) STEEL WITHOUT BACKUP--WILL NOT DEVELOP FULL STUD STRENGTH.

(C) METAL BACKUP REQUIRED TO PREVENT MELT-THROUGH OF BASE METAL

The most widely used combinations of base plate and stud materials are shown in Table 6. With low-carbon steel studs, no preheat or postheat treatments are needed when welding to low-carbon steel or austenitic stainless steel base plate materials. As carbon content in the base plate increases into the medium range, heat treatment for stud welding may be required. Welding to high-carbon base plate is not suggested. When base plate/stud combinations are questionable, an application qualification test is suggested (Ref 5). Details on this procedure are provided in the section "Stud-Welding Quality Control, Qualification, and Inspection" in this article. For best results when welding stainless steel studs to low-carbon steel plate (especially when working stress levels are very high or there are repetitive loading cycles), the studs should either be manufactured from annealed-in-process materials or postmanufacture annealed before use.

Good welding practice requires that the base plate material at the weld spot be cleaned. Common contaminants that can result in unsatisfactory welds if not removed include paint, heavy mill scale, heavy rust, oxidation, oil or grease, and plating, such as galvanizing and anodizing on aluminum. Removal methods vary according to the contaminant, the base material, and the end use. Wire brushing and grinding may be satisfactory on heavy structural steel but can be destructive to thin-gage metals or anodized aluminum, because they may reduce the thickness to a point where bum through or less-than-full-strength welds result.

Suggested cleaning methods include grinding, wire brushing, or needle scaling on heavy materials; using solvents to clean grease and oil; and using a noncontaminating stainless wire brush or a nonmetallic foam disk to clean aluminum and milling. Because anodizing is difficult to remove from aluminum without reducing the metal thickness, consideration should be given to anodizing the base plate and stud after the welding operation.

Similarly, the weld end of the stud should be free from materials that would contaminate the weld, including paint, rust, galvanizing, and others. Studs cannot be coated with any nonconductive material that would interfere with the flow of welding current. Light copper flashing and nickel or chrome plating usually do not cause welding problems.

Because a high-amperage, short-time current is typical in the stud arc welding process, it is also important that the grounding spot(s) on the base material be clean, that the ground be tight, and that all cables be in good condition and have tight connections.

The position of the ground(s) also can influence stud-welding quality. This depends on the geometry of the base-metal shape and is the result of electromagnetic arc deflection, or arc blow (Ref 6). Occurrences are more common when studs are very near a free edge or are on long and narrow base plates, hollow pipe sections, or irregular peripheries, and can be corrected by moving the ground to a central position or using multiple grounds. Because current flow is usually away from the ground toward the heavier or larger area of the base plate, arc blow is characterized by a lack of flash or fillet on the side of the stud nearer the edge, end, or smaller area.

Stud Strength. Fasteners will develop full material strength when they have been stud arc welded to compatible base plate alloys. Tables 7, 8, and 9 show the tension and torque loads for various threaded stud diameters, based on minimum specified stud strengths (Ref 2, 3, and 6). For unthreaded stud fasteners, the yield strength and tensile or ultimate strength is calculated by:

$$\text{YIELD STRENGTH} = A_S F_Y$$
$$\text{TENSILE STRENGTH} = A_S F_U$$

where A_s is the area of the stud shank (in.^{2}), F_y is the specified stud material yield strength (minimum psi) and F_u is the specified stud material ultimate strength (minimum psi).

TABLE 7 MECHANICAL PROPERTIES OF LOW-CARBON STEEL STUD ARC WELDED FASTENERS

Fasteners have 380 MPa (55 ksi) minimum ultimate strength and 345 MPa (50 ksi) minimum yield strength.

(F) VALUE GIVEN IN IN. · LBF.

For threaded studs, the area is based on the mean effective thread area, which is calculated by:

$$A_S = 0.7854\ [D - (0.9743/N)]^2$$

where *D* is the nominal diameter of the stud and *N* is the number of threads per inch.

Process Variations and Special Equipment. There are several specific applications that lend themselves to special variations of the stud arc welding technique. One application is the welding of studs to thin base materials that are less than the minimum thicknesses listed in Table 5. Although full weld base strength is usually not achieved, the resulting strength level is suitable for the application loadings involved. This process variation, which is called short-cycle stud arc welding, does not use a ceramic ferrule. Instead, higher weld current is used with very short times, which minimizes penetration of the stud into the base plate. Normally, this variation is used with stud diameters ≤ 9.5 mm (≤ 0.375 in.) in situations where backside marking is not considered detrimental.

The second special process is gas-shielded arc welding, which also does not use a ceramic ferrule. Instead, the stud-welding area is shielded by an inert gas, usually argon. This process can be used with both steel and aluminum, but is more widely used with the latter material. The welding variables fall into a very narrow range, and conditions for application usually include tight tolerances and a tightly controlled setup. Consequently, the stud arc welding equipment most often consists of a fixed-gun production unit. A typical application is the welding of aluminum studs with special end configurations to aluminum kitchen utensils.

Special equipment is frequently used with the short-cycle and/or gas-shielded arc welding processes, because the application parameters must be tightly controlled and involve large quantities of studs applied in a production environment. Equipment manufacturers assemble many types of special equipment for production-line use. The equipment can be used with automatic stud feed, automatic stud and ferrule feed, computer-programmed indexing, robotic stud-welding guns, and other mechanisms. A typical automated stud arc welding production unit is shown in Fig. 10. A unit can involve simple, column-mounted, single-gun systems or sophisticated, multigun, multiple feed units that cost thousands of dollars.

Stud Arc Welding

Harry A. Chambers, TRW Nelson Stud Welding Division

Fixturing and Tooling for Stud Arc Welding

Regardless of the stud-welding method employed, certain "expendable" accessories are required. These include such items as a chuck or collet to hold the particular stud being welded, a ferrule grip for the fastener, a foot that holds the ferrule grip, legs that attach to the gun and adjust to accommodate various stud lengths, and other minor items. The operating life of these items is variable, depending on the care and maintenance they receive. For example, a chuck may last for 5000 to 25,000 welds. Legs last indefinitely, whereas ferrule grips and feet usually have a shorter usage life. Accessories are relatively inexpensive items that should be planned for when preparing budgetary estimates on any given project.

The extent and sophistication of tooling for stud welding reflects the required production rate and the total number of studs to be welded. Locating the stud arc welding centers can be as simple as laying out the workpiece and center punching the locations either directly or through a template, as shown in Fig. 11. The studs are then placed in the punch marks, the stud-welding gun is held vertically, and the weld is initiated. Although operator skill is a factor, careful welders can achieve a perpendicularity of ±5° and a location tolerance of approximately 1.2 mm (0.046 in.). Often, the cover plate in a base plate/cover plate assembly can be used as the template for marking.

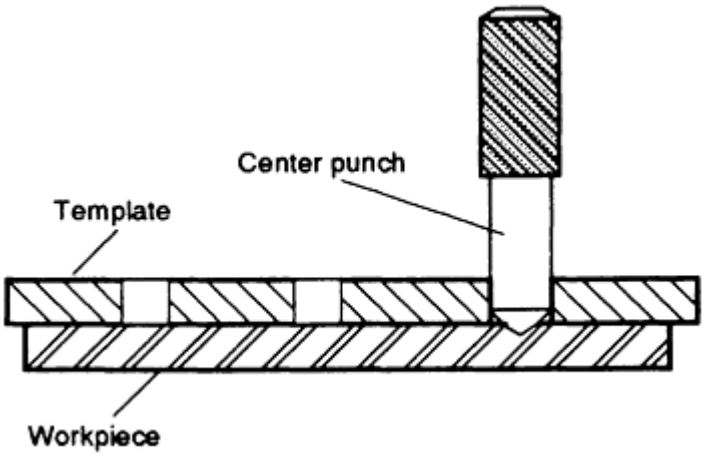

FIG. 11 CENTER PUNCHING BASE MATERIAL THROUGH A TEMPLATE

A permanent template becomes more practical when an increasing number of studs are to be welded on repetitive locations. Stud arc welded fasteners can be welded directly through temperature-resistant material which should be spaced off the work by 1.65 to 6.35 mm (0.065 to 0.250 in.) to allow expelled weld gases and weld spatter to escape without restriction, which could adversely affect weld quality. This type of template arrangement is shown in Fig. 12. Note that the template holes are drilled slightly larger than the outside dimension of the ceramic ferrule. Before the

template is prepared, it is good practice to consult the manufacturer specifications for the ceramic ferrule dimensions to be used with the stud being welded. Location accuracy, in this case, can be as tight as ±0.78 mm (±0.031 in.).

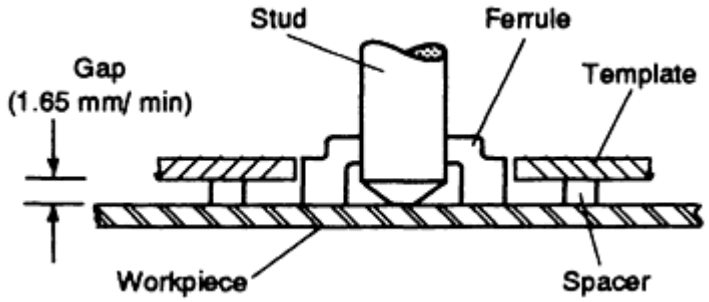

FIG. 12 WELDING THROUGH A TEMPLATE USING A FERRULE WITH STUD ARC WELDING FASTENERS

Even greater accuracy can be obtained, both in the vertical and horizontal directions, by adapting the template hole to fit a drill jig bushing tightly and by inserting the template adapter (or a ferrule tube adapter) through the bushing to the workpiece. The ferrule tube adapter also can be used for welding down into deeply drilled holes or into tight-fit areas (Fig. 13).

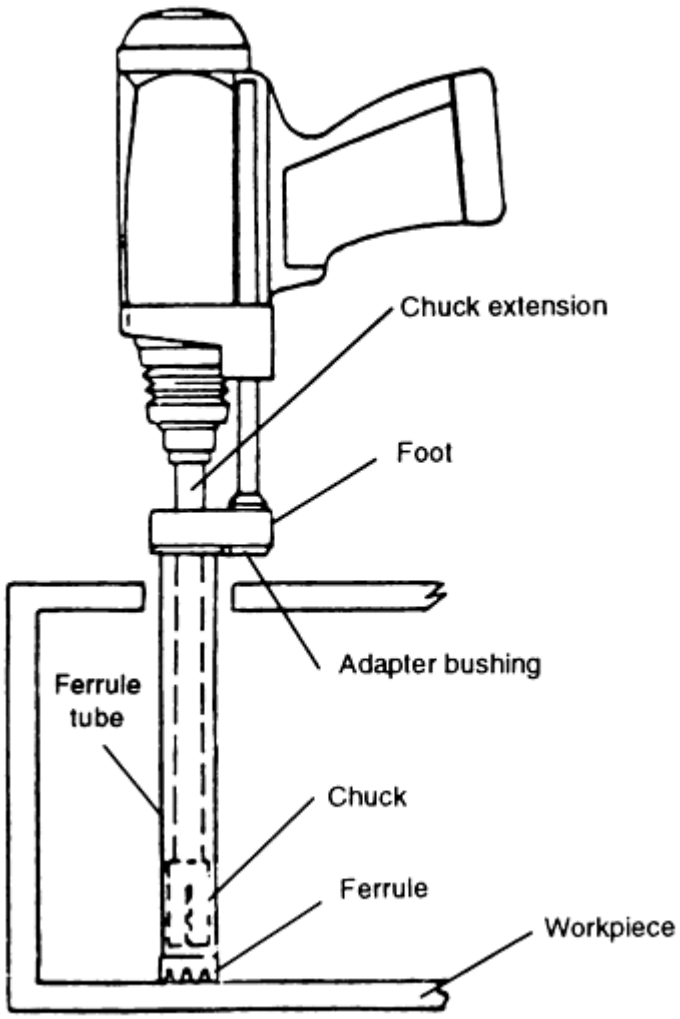

FIG. 13 PORTABLE STUD ARC WELDING GUN EQUIPPED WITH ACCESSORIES FOR WELDING STUDS THROUGH

OR INTO A DRILLED OR FORMED HOLE

With closely spaced studs, the foot grip is sometimes modified so that after welding the initial stud at a center-punched location, the foot can be held against the reference stud to weld the next or adjacent stud on the required spacing.

The verticality of the weld stud can be ensured by several methods. The most accurate is obviously a fixed gun on a slide mechanism of the type used for automatic-feed, high-production work. This type is also the most expensive. A portable gun can be mounted on a machine slide or drill press by fabricating a bracket (Fig. 14) in cases where production quantities do not justify the expense of automatic equipment.

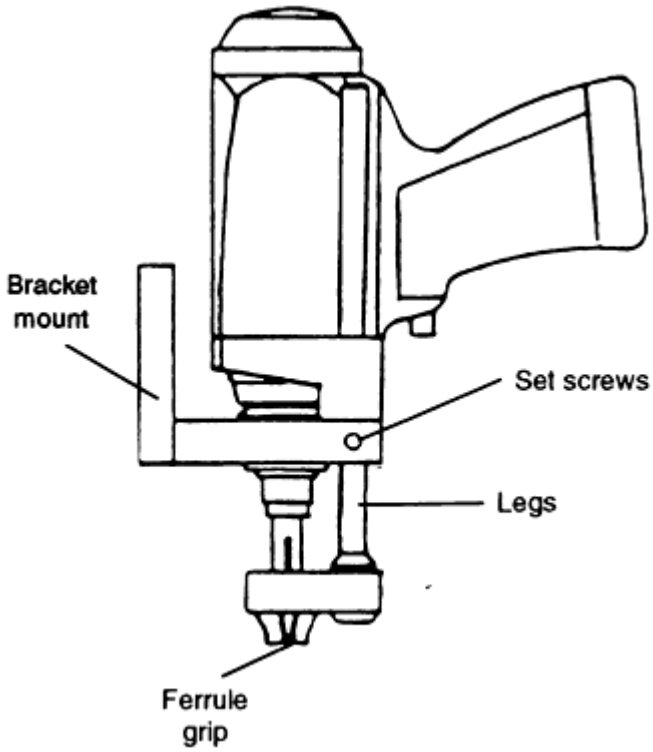

FIG. 14 INEXPENSIVE METHOD OF MOUNTING PORTABLE HAND GUN TO MACHINE SLIDE OR DRILL PRESS TO OBTAIN FIXED-POSITION ACCURACY

Other methods of ensuring verticality are to use a bushing-type template, a bubble level mounted on the rear of the gun, or a bipod foot arrangement, as shown in Fig. 15. With the stud and ferrule acting as one fixed point, the two bipod screws are adjusted to obtain perpendicularity. Vertical variations that are less than ±1° can be achieved with proper accessories and adjustments.

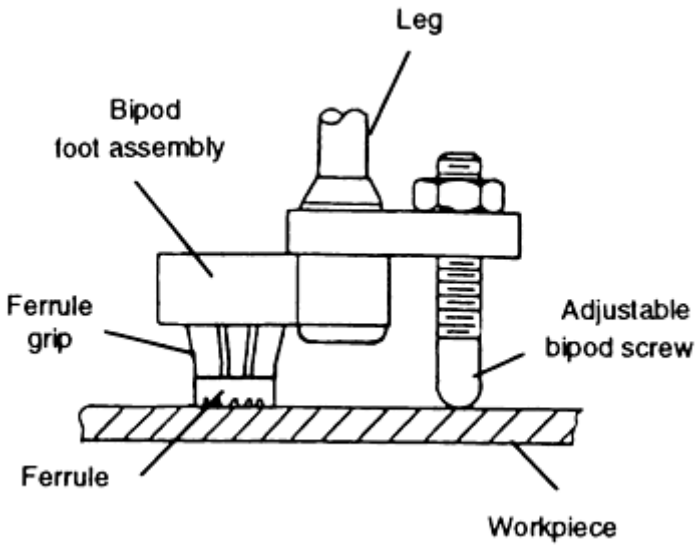

FIG. 15 USE OF AN ADJUSTABLE BIPOD FOOT ASSEMBLY TO PROVIDE THREE-POINT CONTACT, ENSURING PERPENDICULARITY OF STUD TO WORKPIECE

A wide range of accessories is available for welding studs of different lengths or for welding studs into areas with limited access. Two widely used special accessories are shown in Fig. 16 and 17. For unusual situations, the manufacturer should be consulted to suggest or, possibly, design stud-welding accessories.

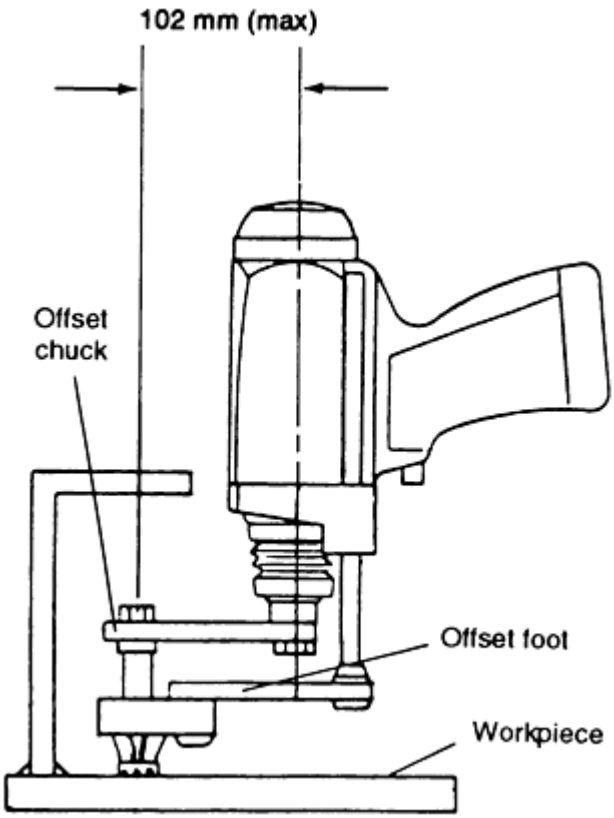

FIG. 16 TYPICAL OFFSET ASSEMBLY USED WHEN STUD ARC WELDED FASTENERS MUST BE WELDED BELOW AN OBSTRUCTION

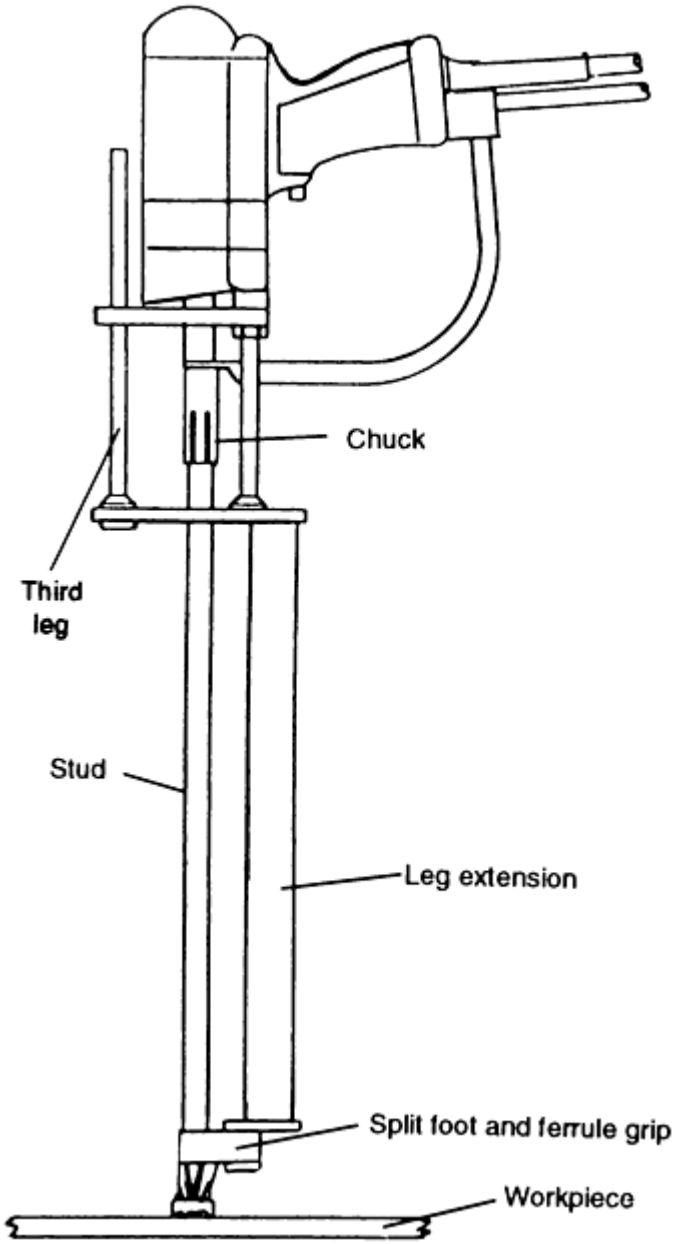

FIG. 17 TYPICAL LEG-EXTENSION ACCESSORY FOR WELDING LONG STUDS (UP TO 1.83 M, OR 6 FT). NOTE THE USE OF A SPLIT FOOT AND FERRULE GRIP; THE GUN DOES NOT HAVE TO BE STRIPPED THE FULL LENGTH OF THE STUD WHEN THE STUD IS WELDED.

Harry A. Chambers, TRW Nelson Stud Welding Division

Stud-Welding Quality Control, Qualification, and Inspection

Because of its broad use for many years and the relative simplicity of its applications, stud welding in the downhand position is considered to be a prequalified procedure, that is, it is only necessary to weld two studs satisfactorily in the downhand position to qualify both the process and the operator. The two qualification studs can be bend tested, torque tested, or tension tested. The physical test is satisfactory if no failure occurs in the weld or the heat-affected zone.

Stud-welding code requirements (for example, Ref 2 and 7) define the necessary tests for prequalified stud welding to the flat or down-hand position, as well as other positions. The limit on the flat position is defined as 0 to 15° slope on the

surface to which the stud is applied. Beyond 15°, a ten-stud test is required. Again, each of the ten studs in the nonflat position must be bend, tensile, or torque tested. Bend testing is 90° from the original axis, whereas torque and tension testing are conducted until failure. Failure must occur in the stud shank or in the workpiece material, not in the weld or the heat-affected zone. All failures require retesting. Satisfactory testing qualifies the welder and the process.

Typical bend, torque, and tensile testing setups are shown in Fig. 18, 19, and 20. Qualification records, including stud drawings, ceramic arc shield drawings (if used), weld settings, and position should be kept.

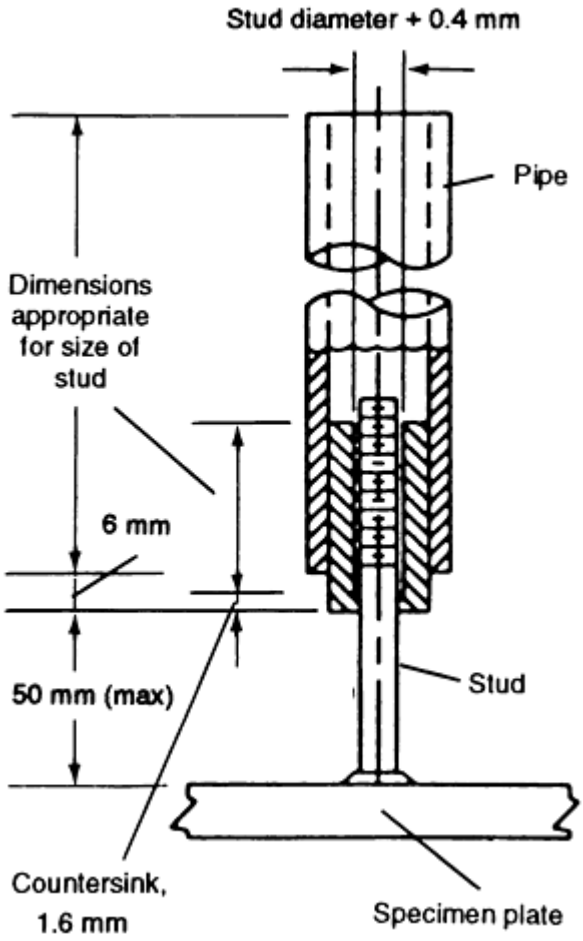

FIG. 18 TYPICAL BEND TESTING SETUP. STUDS THAT MUST UNDERGO APPLICATION QUALIFICATION SHOULD BE BENT 90° WITHOUT WELD FAILURE (15° FOR ALUMINUM STUDS). TESTING FOR PREPRODUCTION OR TESTING DURING PRODUCTION FOR INSPECTION PURPOSES REQUIRES BEND TESTING TO 30° FROM ORIGINAL POSITION (15° FOR ALUMINUM STUDS). FOR THREADED STUDS, TORQUE TESTING PER FIG. 19 SHOULD BE USED. SOURCE: REF 2

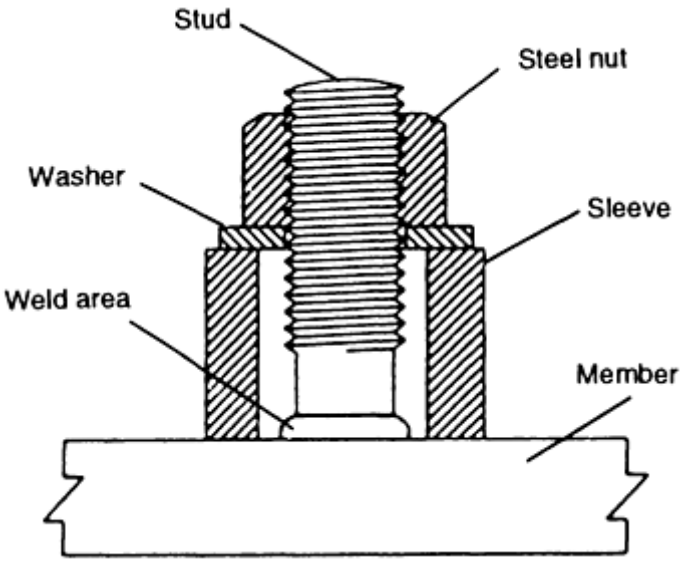

FIG. 19 TYPICAL TORQUE TESTING ARRANGEMENT. STUDS THAT MUST UNDERGO APPLICATION QUALIFICATION OR PREPRODUCTION TESTING SHOULD BE TORQUED TO DESTRUCTION WITHOUT FAILURE IN THE WELD. PROOF TORQUE TESTING DURING INSPECTION OF THREADED STUDS SHOULD BE APPLIED AT 60 TO 66% OF THE YIELD TORQUE LOAD FOR THE STUD SIZE TESTING. REFER TO TABLES 7, 8, AND 9. SOURCE: REF 2

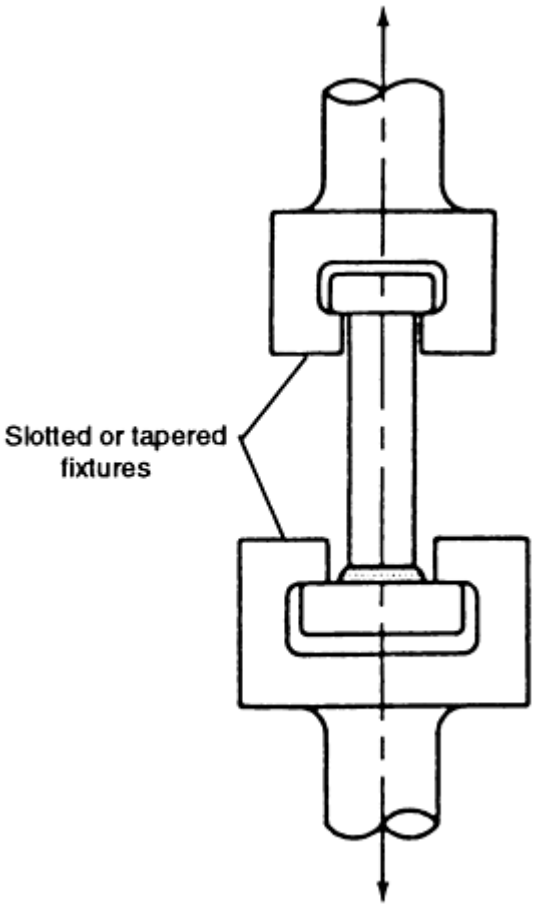

FIG. 20 TYPICAL TENSION TEST FIXTURE. FOR QUALIFICATION OF APPLICATION OR PREPRODUCTION TESTING, EITHER BEND OR TORQUE TESTING CAN BE SUBSTITUTED FOR TENSION TESTING.

Either two-stud or ten-stud testing should be conducted on a production piece or on a separate piece of the same type and thickness (±25%) of material that will be used in the application, in the same position in which the studs will actually be applied.

In addition to physical testing, the studs that are welded for qualification also must be visually inspected, whether there are two or ten. Visual inspection consists of verifying that a full 360 ° weld flash (fillet) is formed around the stud base. There should be no gaps or undercuts in the flash or in the wetted area. As mentioned previously, flash can be irregular in both height and evenness and it can contain shrinkage fissures or cracks. Because flash is expelled, not deposited, metal, it should not be subject to the usual inspection criteria for a weld fillet.

The final visual inspection should be a measurement of the after-weld length. With stud arc welding, the after-weld length of the stud will be shorter by the lengths shown in Table 3. A consistent after-weld length, combined with acceptable visual inspection and physical testing, are assurances of satisfactory welds. Figure 21 shows typical stud arc weld appearances for both acceptable and problematic welds.

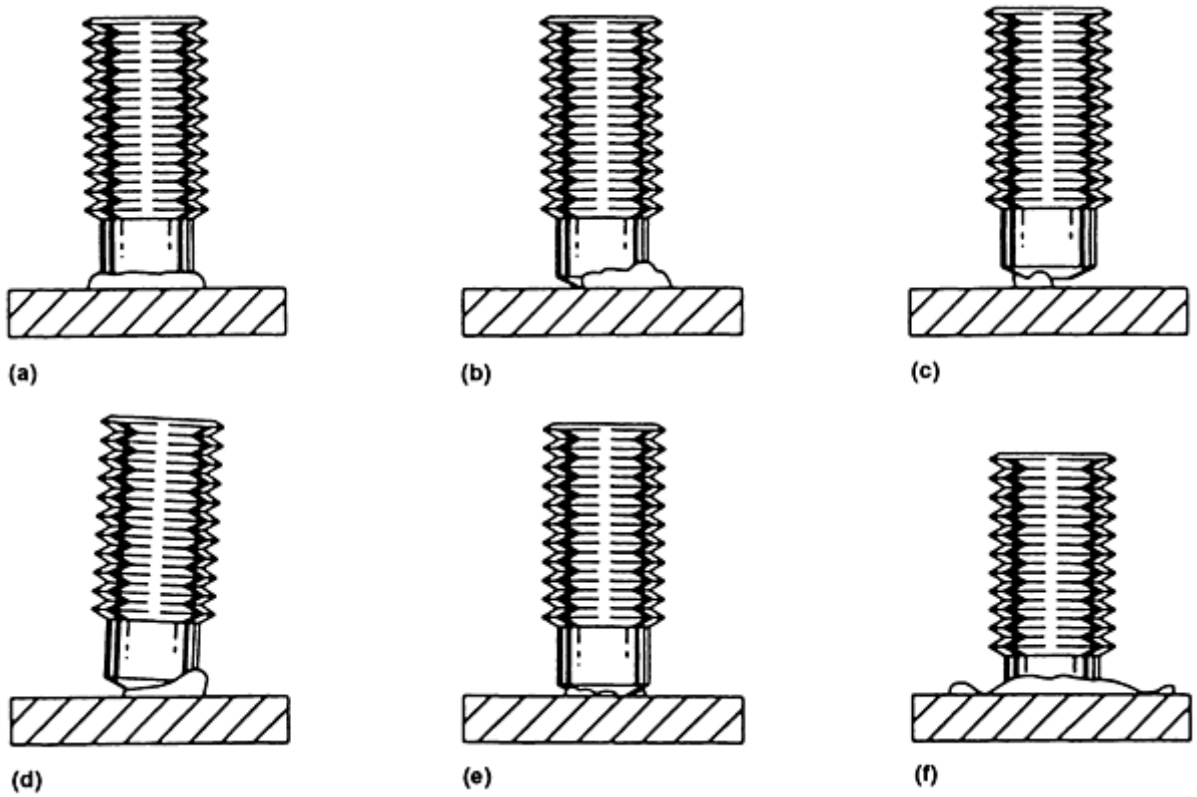

FIG. 21 STUD ARC WELD CHARACTERISTICS FOR SATISFACTORY AND UNSATISFACTORY WELDS. (A) SATISFACTORY; GOOD FLASH FORMATION, WETTING ENTIRE PERIPHERY OF STUD BASE. (B) UNSATISFACTORY; PLUNGE TOO SHORT, NOT ENOUGH MATERIAL ALLOWED FOR BURN-OFF. STUD MUST PROJECT AN ADEQUATE LENGTH BEYOND THE FERRULE. THIS CONDITION CAN ALSO BE CAUSED BY BAD GROUNDING PRACTICE. (C) UNSATISFACTORY; HANG UP CAUSED BY INADEQUATE ARC LENGTH LIFT OR BY MISALIGNMENT OF STUD, RESTRICTING FREE MOVEMENT. (D) UNSATISFACTORY; MISALIGNMENT OF STUD BY POOR GUN POSITION. (E) UNSATISFACTORY; COLD WELD, RESULTING IN NONUNIFORM OR INCOMPLETE FLASH AROUND STUD PERIPHERY. (F) UNSATISFACTORY; HOT WELD, WHERE MOLTEN MATERIAL IS EXPELLED VIOLENTLY FROM WELD, RESULTING IN POOR FLASH FORMATION.

Passing the two-stud preproduction or the ten-stud application qualification test approves the procedure and operator. Production stud welding is then allowed to proceed. However, at the start of each new production period, a two-stud test is again required before production can begin. Similarly, a change in stud diameter, equipment, settings, or operator requires requalification.

During production, welding inspection and testing should be used on a continuous basis to confirm acceptable quality. This can be done on a reasonable number of studs, depending on the welding conditions and stud appearance. After the visual inspection of all stud welds, physical testing of at least one weld per hundred is usually suggested. Any weld that does not show a full 360° flash or wetness should be tested. Welds without a full flash can be repair welded, but repaired welds are also required to be physically tested.

In the case of unthreaded studs, the quality inspection test can be to bend 15°. The studs can be straightened after testing, if required. Threaded studs can be subjected to a torque test to approximately 80% of the yield torque load, rather than a bend test. Failure in the weld or heat-affected zone is cause to reject the weld being tested. Failure also requires that the quantity of studs welded from the previous test to the present test be carefully inspected for weld deficiencies. Additional tests may be necessary to confirm weld quality.

If the quality inspection test studs must be straightened for end use, then they should be returned to the vertical position by using a bending tool. Continuous slow pressure should be applied during the straightening process.

Temperature at the time of stud welding and during stud testing is an influential parameter. Stud welding should not be conducted at temperatures below -18 °C (0 °F). When the temperature is below 0 °C (32 °F), one additional stud per hundred welded should be tested to verify weld quality. Below 10 °C (50 °F), welded studs should be tested using the bending tool, rather than by hammer testing. In colder welding temperature conditions, threaded studs should always be tested by torque, rather than by bending. Impact testing at low temperatures produces brittle failures. This is not a function of weld quality, but of the ambient temperature at the time of welding and testing. Data resulting from extensive tests conducted on studs welded and tested at various temperatures have shown that it is the temperature and manner of testing that influences the failure mode, rather than the temperature at the time of welding (Ref 8).

Another factor, besides temperature, that can affect weld quality is cleanliness of the weld area. Although stud arc welding does provide some cleaning action during welding, it is not sufficient to remove heavy contaminants. Coatings or rust on studs also can cause poor welds. Plating, except for a copper flash, nickel plating, or chromium plating, should be removed from the stud end prior to welding. This includes such materials as paint, zinc, and cadmium. Stud arc welded fasteners are usually capped during plating so that the weld end is left clean.

The plating or contaminant removal methods should be compatible with the base-material thickness and composition. For example, a heavy paint or rust cover on thick structural steel can be removed by grinding, needle scaling, sand blasting, or chipping, and the weld surface will still be acceptable for stud welding. Stainless steel, brass, aluminum, or other polished surfaces should be cleaned with appropriate solvents or other cleaning methods that will not destroy the material finish or contaminate the weld area. For example, a carbon-steel wire wheel or brush should not be used to clean stainless steel or aluminum base material.

Studs and ferrules should be kept clean and dry prior to welding. Although cold conditions will not adversely affect either, they should be protected from exposure to adverse weather conditions, high humidity, marine atmospheres, and other extremes. When ferrules absorb water, the steam generated during the welding process can cause very poor welds and excessive weld spatter. Ferrules exposed to moisture should be oven dried at a temperature between 101 and 120 °C (215 and 250 °F) for 2 h before use.

The condition of weld cables, connections, and ground clamps can affect weld quality. These items should be checked frequently and either repaired or replaced, so that the cables are not frayed, connections are tight and clean, and ground clamps are properly functioning. Ground clamps should be tightly connected to the workpiece or work platen and attached to areas that have been cleaned of all deleterious materials that would prevent good current flow.

Stud-Welding Safety Precautions

Any welding process can be dangerous if proper safety precautions are not followed. Equipment should be properly installed according to the directions of the manufacturer and maintained in good condition. Operators should be thoroughly trained in the use of the stud-welding process. They also should be familiar with the installation, operation, and maintenance procedures for the equipment being used.

Electrical shock is a potential cause of injury or death. Stud-welding systems should be properly installed and grounded using electrical connections made according to national (Ref 9) and local code guidelines.

Neither operators nor anyone else in the welding area should ever touch live electrical parts, or weld in wet areas, or wear wet gloves or clothing. In addition, all workers should ensure that they are insulated from shock.

All electric cables and connections should be kept in good condition. They should be inspected on a regular basis and frayed sections, broken insulation, or broken connectors should be repaired or replaced at once. Stud welding frequently uses long cable lengths, particularly on construction sites, where the cables are subject to abuse by towmotors, trucks, material storage, or foot traffic. It should be ensured that these conditions do not result in cable damage.

Although weld spatter and arc flash are minimal with the stud-welding process, they do occur and precautions should be taken. All combustible or volatile materials should be removed from the weld area so that sparks or spatter cannot reach them. Gas cylinders should be stored and secured properly and checked to ensure that they do not contact any electrical cables in the welding circuit. Proper protective clothing should be worn, including boots, aprons, and gloves, as necessary. Eye protection is always necessary. Eye glasses with spectacle frames, side shields, and lenses with shade number three absorption filters should be worn by the operator at all times (Ref 10). Helpers or workers within 1.5 m (5 ft) of the weld area also should wear clear safety glasses with side shields. Fire-suppression equipment should be available in or adjacent to the weld area for immediate use in emergencies.

Ventilation of the welding area is necessary. Fumes from welding and cleaning materials, such as solvents, as well as paints, epoxies, and galvanizing or other coatings, can be harmful. Ventilation can be either forced or natural, depending on the job conditions. Material suppliers should provide material safety data sheets on any items being used in the welding area, and proper precautions for potentially dangerous contents should be followed.

Pinch points where fingers or hands can be caught should be avoided during material handling or where moving parts are involved in the welding process.

The instructions of the manufacturer should be followed when maintaining and servicing the stud-welding equipment. If possible, all electric supplies should be disconnected and locked out during maintenance or troubleshooting work.

Finally, certain welding operations produce elevated noise levels during the weld cycle. Operators and other workers near the equipment should use hearing protection that can adequately protect them, in accordance with Ref 11.

Capacitor Discharge Stud Welding

Richard L. Alley, American Welding Society

Introduction

CAPACITOR DISCHARGE STUD WELDING is a stud arc welding process in which the tip of the stud melts almost instantly when energy stored in capacitors is discharged through it. The three basic modes of capacitor discharge (CD) stud welding are initial-gap welding, initial-contact welding, and drawn-arc welding. Figure 1 shows current-versus-time curves for the three process variations.

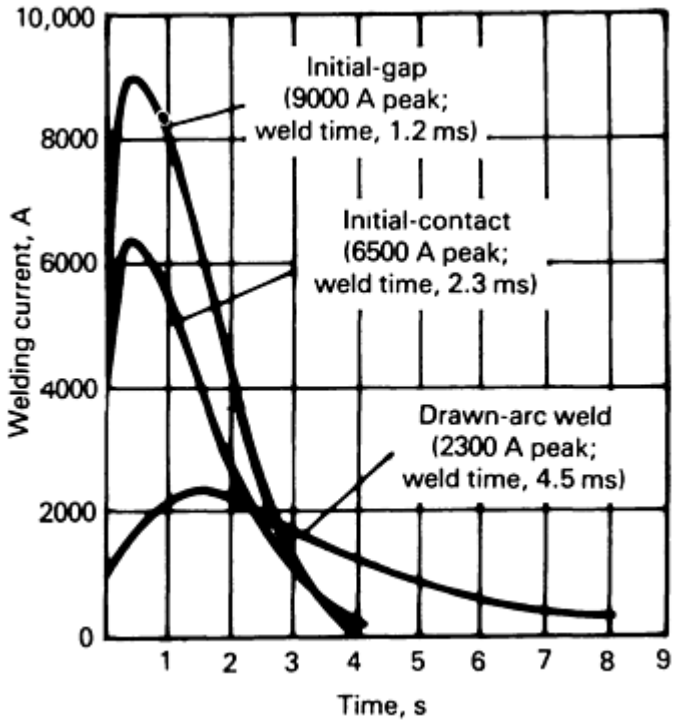

FIG. 1 TYPICAL CURRENT-VERSUS-TIME CURVES FOR THE THREE CD STUD WELDING METHODS. SOURCE: REF 1

The initial-gap mode (Fig. 2) is begun with the stud held away from the work surface by the welding head. At the beginning of the weld cycle, the stud is forced against the work surface, melting the tip, the face of the stud, and the adjoining work surface upon contact with the work surface. The weld is completed using the gun forces (i.e., spring pressure or air pressure) to plunge the stud into the molten materials, forming a strong welded bond between the stud and the work surface. The weld cycle time (Fig. 1) for this process is from 4 to 6 ms, and the penetration of the weld zone into the work surface is normally from 0.10 to 0.15 mm (0.004 to 0.006 in.).

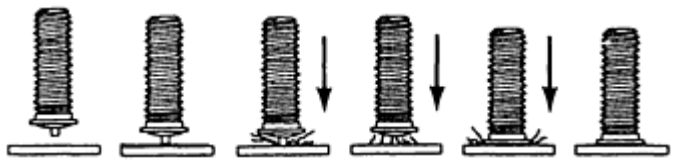

FIG. 2 INITIAL-GAP CD STUD WELDING. SEE TEXT FOR EXPLANATION. SOURCE: REF 1

The initial-contact mode (Fig. 3) begins with the weld stud in contact with the work surface. The weld cycle is initiated with a surge of current that disintegrates the weld tip, thus melting the stud face area and the work surface that it immediately contacts. The stud is forced into the molten material, forming a strong homogeneous weld. This process has a weld cycle time of approximately 6 ms, much like the gap process.

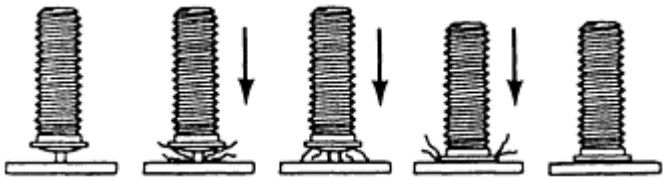

FIG. 3 INITIAL-CONTACT CD STUD WELDING. SEE TEXT FOR EXPLANATION. SOURCE: REF 1

The drawn-arc mode (Fig. 4) begins with the stud in contact with the work surface. When the weld cycle is initiated, a current surge is applied to the weld tip and the stud is retracted from the work surface, drawing an arc that melts the face of the stud and the work surface directly beneath it. The stud is then plunged into the molten pool of material, forming a welded connection. The weld cycle time for this process is longer than for the other two processes, and the heat-affected zone (HAZ) is thicker than it is in the preceding two processes.

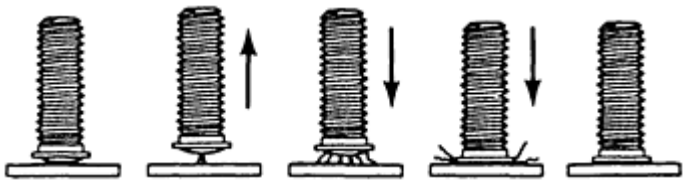

FIG. 4 DRAWN-ARC CD STUD WELDING. SEE TEXT FOR EXPLANATION. SOURCE: REF 1

Advantages and Disadvantages. A major reason for using the CD stud welding process is that it provides a strong welded fastener with either a minimum or no reverse side marking of the work material. Another reason is that it is cost effective, especially for small-diameter fasteners. This process also allows fasteners to be welded to very thin sections of work material, as well as to thick sections (as thick as necessary), with reliable results. Furthermore, the process allows the welding of many dissimilar material combinations, such as aluminum studs to zinc die castings. The disadvantages of using the CD process are the limited stud diameters available and the fact that the work surface must be clean of mill scale, dirt, oxidation products, and oil.

Richard L. Alley, American Welding Society

Applications

The CD process is normally used for fastener sizes of 4-40 through $\frac{1}{4}$-20, with lengths from 6.4 to 38.1 mm ($\frac{1}{4}$ to 1.5 in.). Although there are limited uses of $\frac{5}{16}$-18 and $\frac{3}{8}$-16 diameter studs in special applications, only the more-common

stud diameters will be considered in this article. The work material thickness can typically range from 0.25 mm (0.010 in.) to as thick as the application requires. The determining factors for making successful welds are the stud diameter, the materials being used, the strength required, and the amount of allowable reverse side marking. See Table 1 for guidance on the expected strength parameters.

(B) OTHER MATERIALS, SUCH AS 7000 SERIES ALUMINUM, TITANIUM ALLOYS, INCONEL, AND SO ON, CAN BE WELDED UNDER SPECIFIED CONDITIONS.

CD stud welding is used in many industries in a large variety of applications because it is one of the most versatile and reliable processes available. The food processing industry utilizes this process on stainless steel utensils and machinery, aluminum cookware, and appliances. The aerospace industry applies the process to aircraft engines, aircraft parts and instrument areas, and components for outer space vehicles. The appliance industry uses CD welding for its cabinets, trims, and other components. The building industry uses it for doors, facia, subassemblies, and other exposed finished areas. The insulation industry uses it in securing insulation to heating and air conditioning duct work, as well as on apparatus at power plants, schools, and other major buildings. The automotive industry uses the process to secure trim and various components to cars and trucks. The ship-building industry uses it in fabricating components in ship kitchens, in insulation applications aboard ship and in other areas where components and instruments must be secured. The electrical industry uses this process when securing components inside various controllers and equipment, as well as in trim parts for cabinets. The sign industry uses it on both structural and component members of large and small signs.

Capacitor Discharge Stud Welding

Richard L. Alley, American Welding Society

Equipment

The equipment used for CD stud welding can be either portable or stationary production-type units. The portable units consist of the basic controller that utilizes standard 110 V alternating current (ac) power input to charge the capacitors and a lightweight gun-shaped tool used for placing and welding the fasteners. The production-type units typically require

240/480 V ac three-phase incoming power and a compressed air supply. The production units are normally used for higher rates of productivity, close-tolerance work (down to ±0.13 mm, or 0.005 in.), critical reverse side marking requirements, automatic stud feeding, automatic feeding of the part to be welded, automatic location of the stud on the part, and exotic materials.

The production rate of portable equipment normally ranges from 4 to 6 studs/min, depending on the application. Material handling and other factors could cause this rate to be either slower or faster. The production rates for the permanent production equipment can range from 3 to 20 studs/min, depending on the application, special requirements, and tooling.

When the initial-gap or initial-contact modes of stud welding are used, welds are made on all materials without the use of shielding gases or ceramic arc shields. When using the drawn-arc mode while working with aluminum, a shielding gas would be necessary. This mode is also less flexible when working with exotic materials.

Personnel Responsibilities

The CD stud welding process is easy to operate and maintain. The operator must first ensure that his unit is connected to the proper incoming voltage. The operator then determines whether the weld gun is connected to the negative and the ground is connected to the positive. Straight polarity is used for welding in nearly all applications. The operator places a given diameter of fastener into the stud gun. The gun is then placed on the work surface. The operator closes the trigger of the gun and the welding process begins. After the welding process is completed, the operator lifts the gun off the welded stud.

The operator needs to inspect the welds to ensure that the settings were correct. The controller voltage, which is set according to the recommendations of the equipment manufacturer, depends on the material and diameter of the fastener to be welded, as well as on the thickness and type of base material being used.

There are also other parameters that should be considered. If it is desirable to reduce spatter and smoky conditions in the weld area, then wetting the weld area with a wetting agent just prior to making the weld is recommended. If a wetting agent is used, then it is best to add a few drops of liquid hand soap to a pint of plain water and to spray or brush the solution into the weld area. This will produce a clean weld with reduced, if not eliminated, spatter in the weld area. However, the noise of welding increases when a wet weld is made.

Weld inspection is normally done by bending the fastener by applying either a torque or tensile force to it. If a tensile force is applied, then care should be given to the diameter of the hole used to secure the plate material. A hole that is as small as possible should be used to accommodate the flange of the stud. If a large hole is used, the tensile factors may be reduced, because the plate material could yield prematurely. Prior to production welding, it is recommended that sample welds be made on similar materials and tested to destruction. During production, operators should visually inspect the welds periodically. If weld inconsistency occurs, the process should cease, and the cause should be determined and eliminated.

A common occurrence that contributes to inconsistency is movement of the plate material during the short weld cycle. This can occur when working with materials that are less than 3.2 mm (0.125 in.) thick. There should not be a gap between the workpiece and the backup material of the fixture or table being used. Proper fixtures and attention to their clamping system can alleviate this problem.

Plasma-MIG Welding

Ian D. Harris, Edison Welding Institute

Introduction

PLASMA-MIG WELDING can be defined as a combination of plasma arc welding (PAW) and gas-metal arc welding (GMAW) within a single torch, where a filler wire is fed through the plasma nozzle orifice. The process can be used for both welding and surfacing. The plasma-metal inert gas (MIG) welding process was invented at the Philips Research Laboratories in Eindhoven, Netherlands, around 1969 (Ref 1).

For descriptions of the PAW and GMAW processes, see the articles "Plasma Arc Welding," and "Gas-Metal Arc Welding" in this Section of the Handbook.

The principles of operation, in terms of equipment, are illustrated in Fig. 1. Separate power supplies are used for the PAW and the GMAW elements of the equipment. An arc is struck between the tungsten electrode and the workpiece in a similar fashion to that of a PAW system. The filler wire can be fed to the plasma arc, either with or without the GMAW arc established. Without power supplied to the filler wire, the system can be operated as a PAW system with concentric feed of filler wire. Later versions of the system incorporated an annular electrode to replace the offset tungsten electrode in the welding torch.

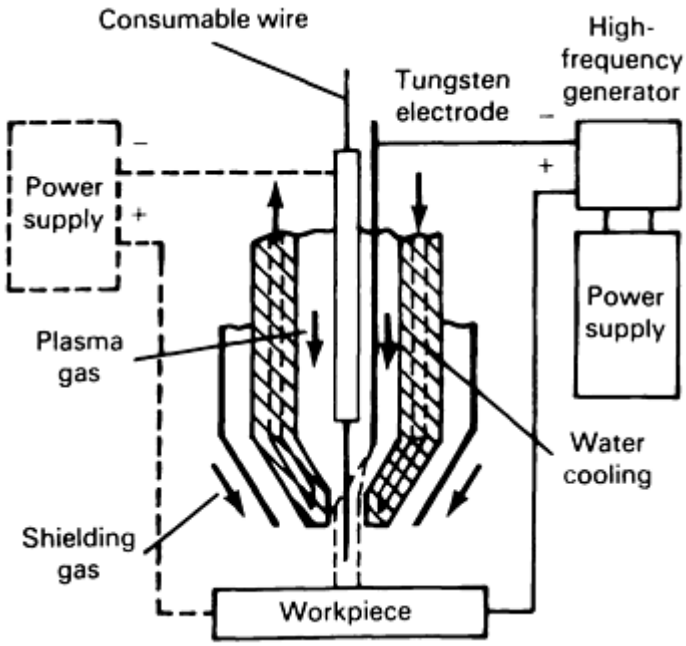

FIG. 1 SCHEMATIC OF PLASMA-MIG WELDING EQUIPMENT. SOURCE: REF 1

Current and Operating Modes. The equipment can be operated either with a single power source, effectively as a PAW system with concentric filler wire feed, or with two power sources, for the plasma-MIG operation.

The polarity of the tungsten electrode is direct current, electrode negative (DCEN), as is that of the GMAW part of the system. The heat of the plasma arc is sufficient to achieve good metal transfer stability for the GMAW element, despite the fact that when this process is used separately, it is almost always used in a direct-current, electrode positive (DCEP) mode. The filler wire is heated by the constricted plasma arc, as well as by the cathode heating of its own arc, and by resistance heating along the wire extension. Therefore, the melting and deposition rates of the wire are higher than the rates achieved by heating with either arc alone.

Metal transfer is governed not only by plasma streaming, but also by arc forces between the wire tip and the workpiece. Because the metal droplets are totally enclosed by the plasma stream, spray transfer takes place even though the GMAW element operates on negative polarity.

Advantages and Disadvantages. The advantages of the plasma-MIG process include deposition rates and joint completion rates that are higher than those of the conventional GMAW process. The independent control of the plasma arc and current to the filler wire leads to more control of metal deposition. This capability can yield improved productivity and good flexibility for controlling heat input and arc characteristics in both welding and surfacing operations. Good control of dilution is achieved by running the system without any power applied to the filler wire. Metal transfer stability is increased, compared to that of the conventional GMAW process, and results in lower spatter levels. The cleaning action of the plasma arc results in lower porosity in aluminum alloys, compared to that of the conventional GMAW process.

Disadvantages include the capital cost of two power sources (although there are systems that are designed to operate with one), the greater complexity of the torch, and the increased maintenance time and cost associated with this complexity. With two power sources, more welding parameters need to be set up, compared to the conventional GMAW process.

Equipment

As noted earlier, the basic equipment includes a power source for the plasma arc and a power source for the GMAW part of the system. A special torch incorporating both a contact tip for the GMAW element and a cathode for the PAW element is required. The initial design incorporated an offset tungsten electrode, as well as a concentric conduit and

contact tip for the delivery of the consumable wire (Fig. 1). A later design incorporated a concentric cathode for the plasma arc (Fig. 2).

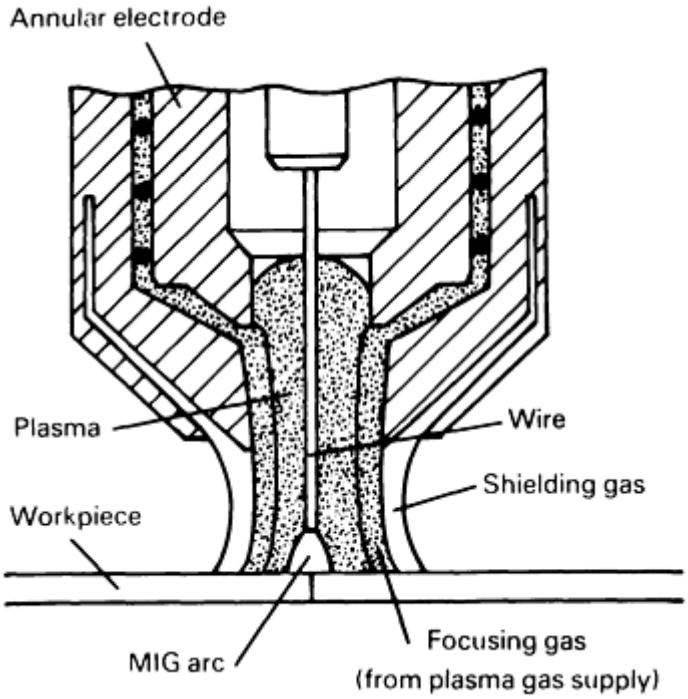

FIG. 2 SCHEMATIC OF MODERN PLASMA-MIG TORCH WITH ANNULAR PAW ELECTRODE AND ADDITIONAL (FOCUSING) GAS STREAM. SOURCE: REF 2

The plasma-MIG torch can be readily fitted to existing welding equipmentsuch as side beams and welding carriages, to replace the GMAW process in mechanized welding operations.

Power Sources. A constant-current power source with a high-frequency circuit to initiate the pilot arc is used for the plasma arc component of the system. The power source for the GMAW component can be used as a constant-voltage or a constant-current rectifier. Power sources have welding currents that typically range from 40 to 200 A for the plasma arc and from 60 to 300 A for the GMAW element at 100% duty cycle. However, equipment with welding currents up to 800 A is available and can be used for surfacing applications.

Welding Torches. A special torch with a concentric cathode for the plasma arc and a concentric conduit and contact tip for the delivery of the consumable wire is required (Fig. 2). A water-cooled copper alloy nozzle is used to constrict the arc and to form a collimated plasma jet that exits the nozzle orifice. A plasma orifice gas and a focusing gas from the same supply are used; the latter is delivered via channels between the plasma welding electrode and the constricting nozzle. The focusing gas results in greater arc constriction and arc stability and prolongs the life of the constricting nozzle by creating a boundary gas layer between the nozzle orifice and the plasma arc. The contact tip, plasma cathode, and the constricting nozzle are all directly water cooled to provide 100% duty cycle at the typical welding currents identified in the preceding section, "Power Sources."

Shielding Gases. Three shielding gases are utilized: one for the plasma (orifice) gas, one to provide additional arc constriction and arc stability, and one for supplementary shielding. The plasma gas and the focusing gas are usually argon, because an inert gas is required to prevent oxidation of the PAW electrode. The supplementary shielding gas can be argon, argon-oxygen, argon-carbon dioxide, or argon-hydrogen, depending on the nature of the workpiece being welded or, in the case of a surfacing operation, on the material being deposited. Argon is used when welding aluminum alloys, whereas argon-oxygen and argon-carbon dioxide are used when welding steels. Argon-hydrogen is used when welding stainless steels or when surfacing with them.

Plasma-MIG Welding

Ian D. Harris, Edison Welding Institute

Procedure

Process Operating Procedure. The plasma arc is ignited using a pilot arc in a fashion similar to that of a PAW system. The main arc is transferred from the electrode to the workpiece and the plasma jet passes through the nozzle orifice. The system can be operated in this way, with the concentric cold wire being fed through the axis of the torch. A higher melting rate is achieved when power is applied to the wire through the contact tip and when both arcs are run simultaneously. The higher energy imparted to the wire by the plasma arc results in an increased wire deposition rate (Table 1). In this operating mode, deposition rates higher than those typical of the GMAW process can be achieved.

Source: Ref 1

Inspection and Weld Quality Control. Inspection requirements are similar to those of other arc welding or surfacing operations. Visual, ultrasonic, and radiographic inspection techniques are most appropriate. The dual action of the GMAW and plasma arcs results in weld quality that is sometimes higher than that achieved by the GMAW process alone. This is particularly true for aluminum alloys, because the cleaning action of the plasma arc often results in reduced porosity.

Quality control requires monitoring the welding parameters for both power sources, as well as monitoring the wire feed. In addition, the condition of the nozzle orifice (that is, the wear and concentricity of the orifice) should be monitored.

Troubleshooting. The relatively complex nature of the welding torch involves increased maintenance time. Erosion of the copper alloy nozzle orifice will cause a change in the arc shape and will affect the weld profile. Therefore, the nozzle should be checked periodically.

Plasma-MIG Welding

Ian D. Harris, Edison Welding Institute

Applications

Material Types. The plasma-MIG process is suitable for welding a wide variety of materials. The high heat energy supplied by the plasma and gas-metal arcs makes the process suitable for high-melting-point materials, such as tungsten and molybdenum. The most common application is welding aluminum sheet and plate. Wear-resistant steels are used with the process in hardfacing applications. Austenitic stainless steels, such as types 308, 309, and 347, as well as nickel alloys, such as alloy 625, are used in cladding applications. Both solid and flux-cored wires (Ref 3) can be employed for welding and surfacing, although most applications involve solid wires.

Industries. The plasma-MIG welding process has been used for the deposition of corrosion-resisting stainless steel and nickel-base alloys in the offshore industry, for the general fabrication of silos and tank trailers made from aluminum alloys (Ref 2), and for hardfacing applications in the excavation equipment industry, as well as the dredging and offshore industries.

Typical Components and Joints. The plasma-MIG process is suitable for welding of joints and for surfacing operations. The wide range of heat inputs available by choosing how to apply current to the consumable electrode provides additional flexibility for surfacing operations, compared to the range of heat inputs available with an external wire feed using the GTAW/PAW or the conventional GMAW process.

Single-V butt joints are commonly used for the plasma-MIG welding of plate. A full-penetration weld can be made in a single pass on a 9.5 mm ($\frac{3}{8}$ in.) thick mild steel plate when operating the plasma and gas-metal arcs simultaneously. This compares to three passes when just the PAW process is used. One would expect the same joint to require two or three passes for the conventional GMAW process.

When butt welding aluminum alloy sheet and plate in thicknesses ranging from 4.6 to 6.1 mm (0.18 to 0.24 in.), single-pass welds can be made at travel speeds that are more than twice as fast as when the GMAW process is used alone (Table 2). Lower porosity levels are achieved with the plasma-MIG process because of the cleaning action of the plasma arc. When using mild steel and stainless steel, the plasma-MIG process can make butt welds comparable to those made with the GMAW process alone at almost twice the travel speed (Table 2).

The hardfacing of dredging equipment with martensitic steel was made more productive by using the plasma-MIG process, rather than the conventional GMAW process. Higher deposition rates were achieved, resulting in reduced labor costs for the semiautomatic welding operation. Deposition rates of up to 20 kg/h (44 lb/h) can be achieved by plasma-MIG surfacing of mild steel with stainless steel flux-cored wires (Table 3).

TABLE 3 WELD SURFACING PARAMETERS FOR STAINLESS STEEL DEPOSITS ON MILD STEEL USING PLASMA-MIG WITH FLUX-CORED WIRES

Personnel

Skill Level and Training. The plasma-MIG process can be used for semiautomatic, mechanized, or automated operation. It requires a skill level comparable to that of the conventional GMAW process, although additional parameters

need to be set for the plasma arc. Most welding and surfacing activities are carried out with mechanized equipment. When welding parameters are set, operation is similar to that of the GMAW process.

Health and safety issues are similar to those of other arc welding processes. Electric shock, eye protection, burns, ultraviolet radiation, and fume exposure are typical concerns. The plasma-MIG process generates more radiant heat than the conventional GMAW process.

Resistance Spot Welding

Neville T. Williams, British Steel

Introduction

RESISTANCE SPOT WELDING (RSW) is a process in which faying surfaces are joined in one or more spots by the heat generated by resistance to the flow of electric current through workpieces that are held together under force by electrodes. The contacting surfaces in the region of current concentration are heated by a short-time pulse of low-voltage, high-amperage current to form a fused nugget of weld metal. When the flow of current ceases, the electrode force is maintained while the weld metal rapidly cools and solidifies. The electrodes are retracted after each weld, which usually is completed in a fraction of a second.

Spot welding is the most widely used joining technique for the assembly of sheet metal products such as automotive body-in-white assemblies, domestic appliances, furniture, building products, enclosures and, to a limited extent, aircraft components.

Many assemblies of two or more sheet metal stampings that do not require gas-tight or liquid-tight joints can be more economically joined by high-speed RSW than by mechanical methods. Containers frequently are spot welded. The attachment of braces, brackets, pads, or clips to formed sheet-metal parts such as cases, covers, bases, or trays is another common application of RSW.

Major advantages of spot welding include high operating speeds and suitability for automation or robotization and inclusion in high-production assembly lines together with other fabricating operations. With automatic control of current, timing, and electrode force, sound spot welds can be produced consistently at high production rates and low unit labor costs using semiskilled operators.

Most metals can be resistance spot welded if the appropriate equipment is used coupled with suitable welding conditions. This is particularly true for thin sheet or strip steel products, whether uncoated or coated.

Neville T. Williams, British Steel

Equipment

The equipment needed for RSW can be simple and inexpensive or complex and costly, depending on the degree of automation. Spot welding machines are composed of three principal elements:

- *ELECTRICAL CIRCUIT*, WHICH CONSISTS OF A WELDING TRANSFORMER, TAP SWITCH, AND A SECONDARY CIRCUIT
- *CONTROL CIRCUIT*, WHICH INITIATES AND TIMES THE DURATION OF CURRENT FLOW AND REGULATES THE WELDING CURRENT
- *MECHANICAL SYSTEM*, WHICH CONSISTS OF THE FRAME, FIXTURES, AND OTHER DEVICES THAT HOLD AND CLAMP THE WORKPIECE AND APPLY THE WELDING FORCE

Specifications for resistance welding equipment have been standardized by the Resistance Welder Manufacturers Association (RWMA), and specifications for controls are issued by the National Electrical Manufacturers Association (NEMA).

Resistance Spot Welding

Neville T. Williams, British Steel

Electrical Circuit

The transformer used in a direct energy resistance delivers the power to the workpiece by changing the input high-voltage, low-amperage, alternating current (ac) in the primary winding to a low-voltage, high-amperage current in the secondary winding. This system forms the basis of pedestal, or gun-type, welding machines where the output of the secondary transformer is applied directly to the welding electrodes. More complex secondary circuits are used in multiwelders.

To minimize the size and cost of multiwelders, transformers can be designed with two or more secondary circuits supplied from the same primary circuit. This design is achieved by using transformers in which the primary current is supplied to two or more separate secondary windings. Split or multiple secondary transformers are generally used to produce four or more welds at the same time. One controller is used for control of the timing and current supplied to the electrode, which means that it is not possible, under these circumstances, to achieve individual control or setting of the welding conditions for each pair of welding electrodes. Difficulties can arise in optimizing the necessary welding conditions to maximize the electrode life for each welding station under these conditions. In addition, the possibility exists for developing shunt currents, or an out-of-balance welding current, between each secondary circuit. Multiwelders make large use of single-welding and multiple-welding configurations based on direct, indirect, series, and push-pull secondary circuits (see Fig. 7 of the article "Procedure Development and Practice Considerations for Resistance Welding" in this Volume).

Single-Weld Configurations. Most pedestal and portable gun-welding machines employ direct welding, where the current flows directly through the welding electrodes and the workpiece to produce a single weld. In areas of difficult access, indirect welding may be necessary. Indirect welding is generally used when welding is carried out using either stationary or indexing welding guns and when access to the sheets being welded is limited to one side. In this case, the backing electrode generally consists of a large bar or platen, and the welding current flows from one side of the transformer secondary to the active electrode, through the welded area, and then along the platen/bar electrode or connecting jumper cable to the dummy electrode, which is connected to the other leg of the transformer secondary. Higher welding currents are generally necessary when using dummy welding guns, which can lead to a shorter electrode life. The extent to which larger currents are required depends largely on the distance between the welding electrode and the dummy return electrode. In a multiwelder, this distance can be either fixed or variable, depending on whether a

stationary or indexing head is used. Both types of welding heads can lead to losses due to stray current paths and extensive shunting of the current through jigs and fixtures. These factors need to be considered in any design concept for a multiwelder station.

Two-Weld Configurations. Because of the need to minimize the number of transformers and the overall size and cost of a multiwelder, it is necessary to utilize configurations whereby two welds are made in one stroke of an electrode. Parallel, series, or push-pull welding configurations are used for this purpose.

In parallel welding, two or more direct welds, usually closely spaced, are made simultaneously with all upper electrodes connected to one side of the transformer, and all bottom electrodes connected to the other side of the transformer. Parallel welding has the advantage of lower shunt currents, thereby allowing shorter interweld spacings to be used. However, if two or more circuits are fed from a common transformer secondary winding, the current in each circuit will not be equal unless the impedances of each circuit are identical. This is often difficult to achieve in practice, and the electrode life obtained can, therefore, be different for each of the electrode pairs connected to the same transformer.

Series and Push-Pull Welding. Two simultaneous welds can also be produced by means of series welding in which the secondary circuit is connected to two contoured electrodes that contact the workpiece from the same side, and a current backup bar/platen is used on the reverse side. Push-pull welding is also employed whereby either one or two welds are made, depending on the electrode configuration. In push-pull RSW, two transformers are used to form the circuit between the welding electrodes; such a configuration has advantages, particularly where a deep-throated machine is required. Such machines ordinarily require a large secondary loop because of the need for conducting the welding current around the large working area. Using a push-pull configuration, where the upper set of transformers matches the lower set, eliminates the need for long cable loops to the electrodes, resulting in a lower secondary impedance. A longer electrode life can be obtained in push-pull welding compared to series welding.

It should also be noted that current shunting between the electrodes occurs in both series and push-pull welding configurations, but to a lower extent in the latter. The magnitude of the shunt currents depends on interelectrode distance and the type of material being welded. In all cases, current shunting will lead to a lower electrode life when welding zinc-coated steels due to the need to use higher welding currents to compensate for the shunt currents (this can also lead to additional electrode sticking problems) and to the rapid falloff in weld size that occurs under conditions where current compensation is insufficient or nonexistent. To some extent, the effects of both high secondary circuit impedance and current shunting can be overcome by using a constant-current facility fitted into the welding machine control circuit, but there is a limit to the effectiveness of these controls in a production situation. In addition, direct current (dc) welding systems can be used in which secondary inductance/reactance effects are minimized. However, the effectiveness of using dc depends on the method used to develop the dc waveform and on the extent of the superimposed ac ripple on the dc waveform.

Secondary Impedance. The electrical characteristics of a spot welding machine are best defined in terms of their effect on the impedance of the secondary circuit. The latter is composed of two components:

- *REACTANCE*, WHICH IS DETERMINED PRIMARILY BY THE DEPTH AND HEIGHT OF THE THROAT OF THE MACHINE AND THE AMOUNT OF STEEL IN THE THROAT. ANOTHER CRITICAL FACTOR IS THE FREQUENCY OF THE APPLIED CURRENT.
- *RESISTANCE*, WHICH DEPENDS ON THE LENGTH AND CROSS SECTION OF THE CONDUCTORS. CONDUCTOR MATERIAL AND OPERATING TEMPERATURE NEED ALSO TO BE CONSIDERED.

Cables can be classified into three types: air-cooled jumper cables, water-cooled jumper cables, and kickless cables. In any application, it is necessary to ensure that the type and dimensions of cables are chosen to achieve the best balance between the total circuit resistance and the electrode life to be obtained with a multiple spot welder.

Machine Construction

Welding operations in highly automated production lines are based primarily on multiple spot welders and robotic cells. In addition, manual welding operations can be used to manufacture either subassemblies, which are fed into the main production/assembly lines, or, in many instances, finished products. These differing end uses require welding machines of varying designs and characteristics. RSW machines can be divided into three basic types:

- PEDESTAL-TYPE WELDING MACHINES
- PORTABLE WELDING GUNS
- MULTIPLE SPOT WELDING MACHINES INCORPORATING LIGHTWEIGHT GUN WELDING UNITS

Pedestal-type welding machines form the basis of most resistance spot or projection welding operations. Standard machines are either of the rocker arm type, as determined by the rocker action of the moving upper electrode arm, or stationary, direct-acting machines. The latter outnumber the former because rocker arm machines are difficult to align due to the movement of the electrode in an arc motion. As the electrode wears, various skidding actions can be created between the upper and lower welding electrodes, depending on the extent of the electrode wear. This can change the point at which the electrodes meet relative to the fulcrum point of the moving arm. If the electrodes meet at a point above the fulcrum point, they have a tendency to slide outward from the machine. On the other hand, if the electrodes meet on a line below the fulcrum of the moving arm, the electrodes show a tendency to slide inward toward the machine. These relative movements can be different between the top and bottom electrodes, a consequence of which is a reduction in electrode life, particularly if welding coated steels. Other advantages of direct-acting machines include a lower electrode assembly mass, faster "follow up" during welding, and a degree of rigidity that is impossible to obtain with an ordinary rocker arm machine. Press-type direct-acting machines have an upper electrode and welding head that move vertically in a straight line. The welding head is guided in bearings or guideways of sufficient proportion to withstand the offset loads imposed upon them. All of these factors tend to increase the electrode life obtained in a particular welding cell.

Portable welding guns are used in RSW when it is impractical or inconvenient to transport the work to the machine. The portable welding gun consists of water-cooled electrode holders, an air or hydraulic actuating cylinder, hand grips, and an initiating switch. The gun usually is suspended from an adjustable balancing unit, and the welding force is supplied by an air cylinder. Because of the high secondary losses of portable machines, transformers used in these machines have a secondary voltage two to four times as great as the voltage of transformers used in stationary machines of equal rating.

Welding current is transmitted between the transformer terminals and gun terminals through a secondary cable, usually of the low-impedance or kickless type. The reactance of this type of cable is near zero, which results in a high power factor and reduced kilovolt-ampere (kVA) demand. For safety reasons, the current initiating switch is usually operated at low voltage. Recent developments in encapsulated transformers and high-speed fail-safe devices enable the transformer to be integral with the welding gun. This results in lower secondary losses and is particularly preferred in robotic applications.

Gun welders typical of portable manually operated and robotic welding cells can be classified into two basic types:

- S-TYPE (SCISSORS)
- J-TYPE (DIRECT ACTION OR C/J TYPE)

Two important features that influence the performance of these types of welding guns are the rate of force buildup and the extent to which the arms of the gun deflect under load. These features characterize the welding gun in terms of rigidity and the mechanics involved in their operation. An S-type gun utilizes a lever action to transmit the force applied by the cylinder head to the welding electrodes. However, due to an unbalanced pivot point, the force measured at the electrodes is less than that applied at the cylinder. With J-type welding guns, the force applied by the pneumatic cylinder is transmitted directly to the welding electrode. The rigidity of the framework of the welding gun is characterized by the extent to which the electrode arms deflect on application of the electrode force. This is an important factor in determining weld quality and the amount of skidding that can occur between the two welding electrodes. It should be noted that extensive skidding can lead to elliptical welds and/or decreased electrode life.

Neville T. Williams, British Steel

Welding Electrodes

Materials for RSW electrodes should have sufficiently high thermal and electrical conductivities and sufficiently low contact resistance to prevent burning of the workpiece surface or alloying at the electrode face. In addition, the electrode should have adequate strength to resist deformation at operating pressures and temperatures. Because the part of the electrode that contacts the workpiece becomes heated to high temperatures during welding, hardness and annealing temperatures must also be considered. Electrode materials for RSW have been classified by RWMA and in International Standards Organization (ISO) standard ISO 5182.

When welding two sheets of thickness up to 3 mm ($\frac{1}{8}$ in.) using truncated cone-type electrodes, the electrode tip diameter should be determined from:

$$D_2 = \sqrt{t} \qquad \textbf{(EQ 1)}$$

where d_2 is the initial tip diameter (in mm) and t is the thickness (in mm) of the sheet in contact with the electrode. When using truncated cone electrodes, the initial or set-up weld diameter should be equal to the diameter of the electrode tip:

$$D = D_2 = 5\sqrt{t} \qquad \textbf{(EQ 2)}$$

where d is the weld diameter (in mm). Whenever welding two sheets of dissimilar thicknesses, the electrode dimensions and the required weld size should be specified appropriate to the thinner sheet thickness. In the case of three thicknesses, the second thinnest sheet should be used.

When using domed or pointed electrodes, Eq 1 may not apply and the electrode dimensions will depend on accessibility and flange width. In this case, the electrode tip dimensions and welding conditions should be chosen to give an initial weld diameter as specified in Eq 2. Where a pad or mandrel is used as the second electrode, its surface must be maintained to match the profile of the work.

During normal production, electrodes tend to mushroom leading to an increase in electrode tip size. According to trends in automotive practice and international standards, the diameter of at least one of the electrode tips should not normally be allowed to increase above a value that results in a reduction greater than 30% from the starting weld diameter during a production run. This is equivalent to an increase in the electrode diameter to 1.3*d*. When this diameter has been reached, the electrode should be replaced or redressed to its original size and contour.

Electrode shapes have been standardized by RWMA. Figure 1 shows the six standard face or nose shapes, identified by letters A through F. Electrodes with type A (pointed) tips are used in applications for which full diameter tips are too wide. Type D (eccentric, formerly called offset) faces are used in comers or close to upturned flanges. Special tools are available for dressing the electrode faces, either in or out of the welding machine.

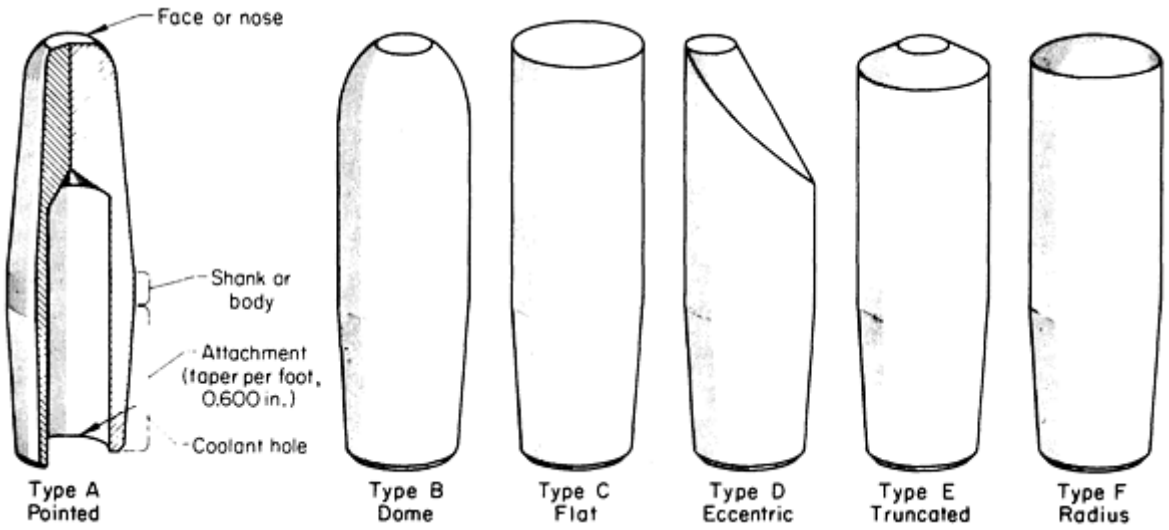

FIG. 1 STANDARD-RESISTANCE SPOT WELDING ELECTRODE FACE AND NOSE CONFIGURATIONS

Electrode Coolant Parameters. Generally, it is recommended that the water flow to the electrodes should be a minimum of 4 L/min (1.1 gal/min) for welding two uncoated steel sheets of thickness up to and including 3.0 mm ($\frac{1}{8}$ in.). Higher flow rates are recommended when welding coated steels. The internal water cooling feed tube should be arranged to ensure that the water impinges onto the back working face of the electrode. The distance between the back and the working face of the electrode should not exceed the values given in the appropriate ISO or RWMA standard. The inlet water temperature should not exceed 20 °C (70 °F), and the outlet temperature should not exceed 30 °C (85 °F). To maintain these temperature levels, the electrode cooling water supply should be independent of transformer and thyristor water cooling circuits. Separate water circuits should be used for both top and bottom electrodes.

Resistance Spot Welding

Neville T. Williams, British Steel

Weldability of Steel

Uncoated Steels. Low-carbon steel can be satisfactorily resistance spot welded using a wide range of time, current, and electrode force parameters. Practices recommended for spot welding SAW 1010 steel have been issued by the RWMA (Ref 1) and the American Welding Society (Ref 2). These data can serve as starting points for the establishment of optimum settings but may require modification, depending on the type of welding machine, the dynamic properties of the welding machine, the pneumatic characteristics, the characteristics of the secondary circuit, the electrode shape, and the material. Sufficient squeeze time should be chosen to enable the electrode force to build up to its preset value. For lightweight gun welders with limited force capability, the electrode force values are reduced up to 30% for sheet thicknesses greater than 1.6 mm ($\frac{1}{16}$ in.). The welding current needs to be adjusted accordingly. When welding sheets of dissimilar thickness, welding conditions may be based on the thinner sheet, or on the second thinnest sheet when welding three thicknesses.

In the case of high-strength low-alloy (HSLA) steels, up to 20% higher electrode force may be necessary. Welding currents may be reduced up to 20%, depending on the type of high-strength steel being welded. Pulse welding schedules may be necessary at the higher carbon equivalent levels and at sheet thicknesses greater than 2.0 mm ($\frac{5}{64}$ in.). The welding conditions required may depend greatly on the analysis of the steel because of differences in the resistivity of the various types of high-strength steel. For example, carbon content has the greatest effect on weldability of steels; weld

hardness increases rapidly with small increases in carbon content. This high hardness causes nugget interfacial tears and nugget deterioration. To obtain acceptable weld performance, carbon content should be kept below 0.10% + 0.3*t*, where *t* is the sheet thickness in inches. For materials above this range, postweld tempering may be necessary.

Low-carbon steels are generally considered to be spot weldable. These steels can be obtained from a number of suppliers with reasonable certainty of only minor variations in weldability. On the other hand, HSLA steels are sold on the basis of strength, with each steelmaker producing its own composition. Therefore, this variation in composition may cause variations in weldability, which the steel user must consider.

Specific alloying elements or combinations of elements can impart desired nugget properties in low-carbon or HSLA steels. The effects of particular elements are discussed below.

Phosphorus and Sulfur. Phosphorus and, to some extent, sulfur, are generally considered to promote nugget interface tearing. When the total content of phosphorus, sulfur, and carbon exceeds a critical value, spot weld interfacial failure is observed. This interfacial tearing during peel testing results in reduced current ranges and minimal lobe curve areas.

Titanium. Data on the effect of titanium on both hot-rolled and cold-rolled steel indicate that the spot weldability of these steels is not as good as that of the HSLA steels containing niobium and/or vanadium. Increasing titanium content generally reduces maximum button diameter, shear and cross-weld tensile strength, and welding current range. Titanium content should not exceed 0.18%, and the use of oversized electrodes and higher force may be required when welding titanium-bearing steels.

Nitrogen. In HSLA steels, nitrogen promotes interfacial nugget failure. Nitrogen appears to be more critical in unkilled cold-rolled steel. However, the sensitivity can be reduced by decreasing the nitrogen content or by combining the nitrogen with aluminum as in aluminum-killed steels.

Zinc-Coated Steels. The present trend in the automotive industry toward the use of larger amounts of zinc-coated steels in automotive assemblies demands that certain strict guidelines regarding the selection of equipment, choice of welding schedules, and maintenance procedures are rigidly followed.

Two basic types of alloy coating are available:

- ZINC-IRON (BOTH HOT-DIP AND ELECTRODEPOSITED)
- ELECTRODEPOSITED ZINC-NICKEL (SUPPLIED WITH OR WITHOUT AN ORGANIC PRIMER TOP COAT)

The available welding ranges for zinc-iron and zinc-nickel coated steels are similar to those for uncoated mild steel although displaced toward slightly higher currents (Fig. 2). When these steels are coated, it is essential that the film thickness not exceed 1 to 1.5 μm (40 to 60 μin.) in order to facilitate breakthrough of the film to enable current flow between the welding electrodes at the low secondary voltages typical of RSW machines.

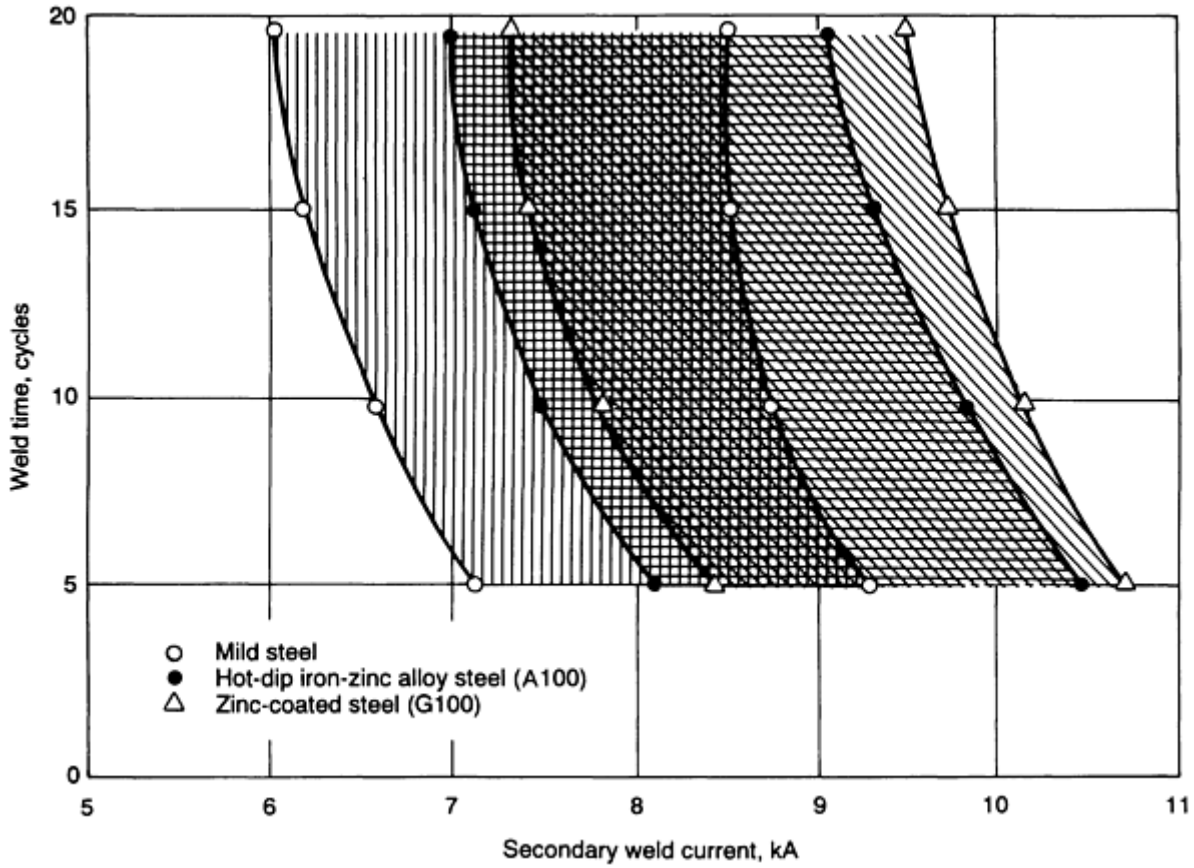

FIG. 2 PLOT OF WELD TIME VERSUS SECONDARY WELD CURRENT TO OBTAIN WELDABILITY LOBES FOR SELECTED 0.8 MM (0.03 IN.) THICK STEELS. ELECTRODE PARAMETERS: FORCE, 1.8 KN (0.20 TONF); TIP DIAMETER, 5.0 MM (0.20 IN.)

Welding conditions can be optimized easily when using pedestal-type welding machines; however, this may not be the case in body-in-white assembly where a combination of multiple spot welders and robotic cells are more commonly used. Such operations are susceptible to poor fit-up of parts, access problems, and electrode configurations that give rise to electrode skidding. Consequently, the welding parameters may need to be adjusted to compensate for such situations. In many instances, one welding gun is called on to weld a range of sheet thickness combinations or even a variety of material combinations in a particular part. Although a multi-program welding control can be used to adjust for the different welding currents necessary for the various combinations, the actual current values may not be optimum because, more often than not, a single compromise electrode force value has to be used.

In these circumstances, the electrode life obtained may be lower than that derived using optimized welding conditions. For example, the electrode life obtained can depend greatly on the type of welding gun used (Fig. 3) or the angle of approach of the electrode. For multiple spot welders, it is essential that all welding stations are balanced electrically and that the same air pressure is supplied to each station. Electrode shape and configuration, water cooling arrangements, and electrode dressing schedules need to be optimized. The last item is most important because satisfactory weld quality can only be provided when the necessary electrode condition and shape are maintained over a production run.

Resistance Spot Welding

Neville T. Williams, British Steel

Weldability of Aluminum Alloys

Most of the commercial aluminum alloys produced in sheet form can be spot welded provided that suitable welding equipment is used. Because of the low electrical resistance of aluminum alloys, considerably higher welding currents are required relative to welding mild steel. In addition, the narrow plastic range between softening and melting means that welding forces, time, and current need to be closely controlled. For consistent weld quality, it is essential that the tenacious surface oxide films are removed by mechanical or chemical techniques prior to welding.

To minimize the likelihood of cracking or porosity in the weld, careful control of the electrode force is necessary. If the force is applied too soon, the welding current may be insufficient due to a premature loss of contact resistance. Thus, correct initiation of the force relative to the current is essential. Dual force schedules are frequently used; therefore, a low-inertia welding head can be beneficial because it allows a more effective buildup of force to its final level.

Because of the higher secondary currents required when welding aluminum alloys, direct current secondary rectified or frequency converter welding machines are favored, particularly if high-quality welds are required (such as in aircraft applications).

Projection Welding

Jerry E. Gould, Edison Welding Institute

Introduction

PROJECTION WELDING (PW) is a variation of resistance welding in which current flow is concentrated at the point of contact with a local geometric extension of one (or both) of the parts being welded. These extensions, or projections, are used to concentrate heat generation at the point of contact. The process typically uses lower currents, lower forces, and shorter welding times than does a similar application without the projections. Projection welding is often used in the most difficult resistance-welding applications because a number of welds can be made at one time, which speeds up the manufacturing process.

PW applications are generally categorized as being either embossed-projection welding or solid-projection welding. These variations are shown in Fig. 1 and 2. Embossed-projection welding is generally a sheet-to-sheet joining process, in which a projection is stamped onto one of the sheets to be joined. Then, resistance welding is conducted on a stack of sheets. Heat initially concentrates at the contact point and in the walls of the projection during resistance welding. Early in the process, the projection itself collapses back into the original sheet. However, the initial heating raises the local resistivity of the joint area, allowing continued resistance heating at this location. Weld development then proceeds in the conventional manner, by forming a fused weld nugget.

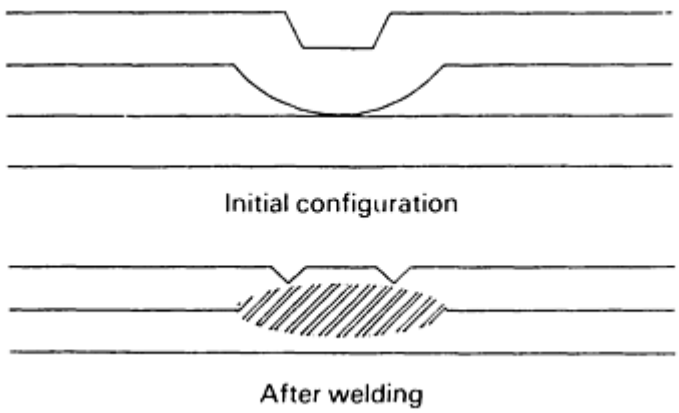

FIG. 1 TYPICAL STACKED CONFIGURATION FOR EMBOSSED-PROJECTION WELDING OF SHEET

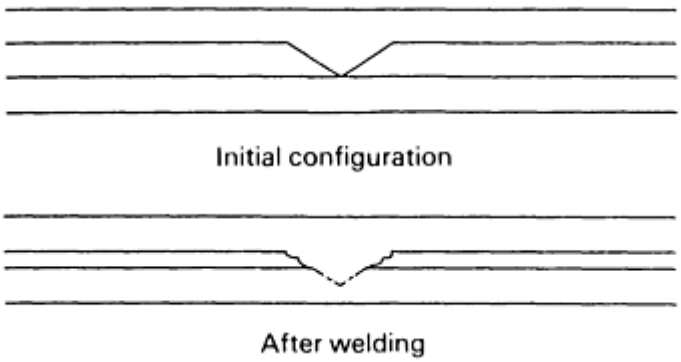

FIG. 2 TYPICAL CONFIGURATION FOR SOLID-PROJECTION WELDING

Solid-projection welding requires that the projection be forged onto one of the two components. Then, during resistance welding, the contact point and the projection itself experience preferential heating. In this case, the projection cannot simply collapse, as it does in embossed-projection welding. Rather, the projection collapses by penetrating the opposing material and by extrusion to the periphery. When compared with embossed-projection welding, the resulting joints are solid-state, rather than fusion, welds. The actual joints are caused by a combination of material forging and diffusion bonding, much like they are in resistance butt and flash butt welding.

Jerry E. Gould, Edison Welding Institute

Applications

Examples of projection welding are shown in Fig. 3. These applications, which range from sheet-to-sheet joints, to cross-wire welds, to annular attachments, to nut welds, to weld screws, include both embossed- and solid-projection types of welding. Specific welding examples, as well as material effects, are described below.

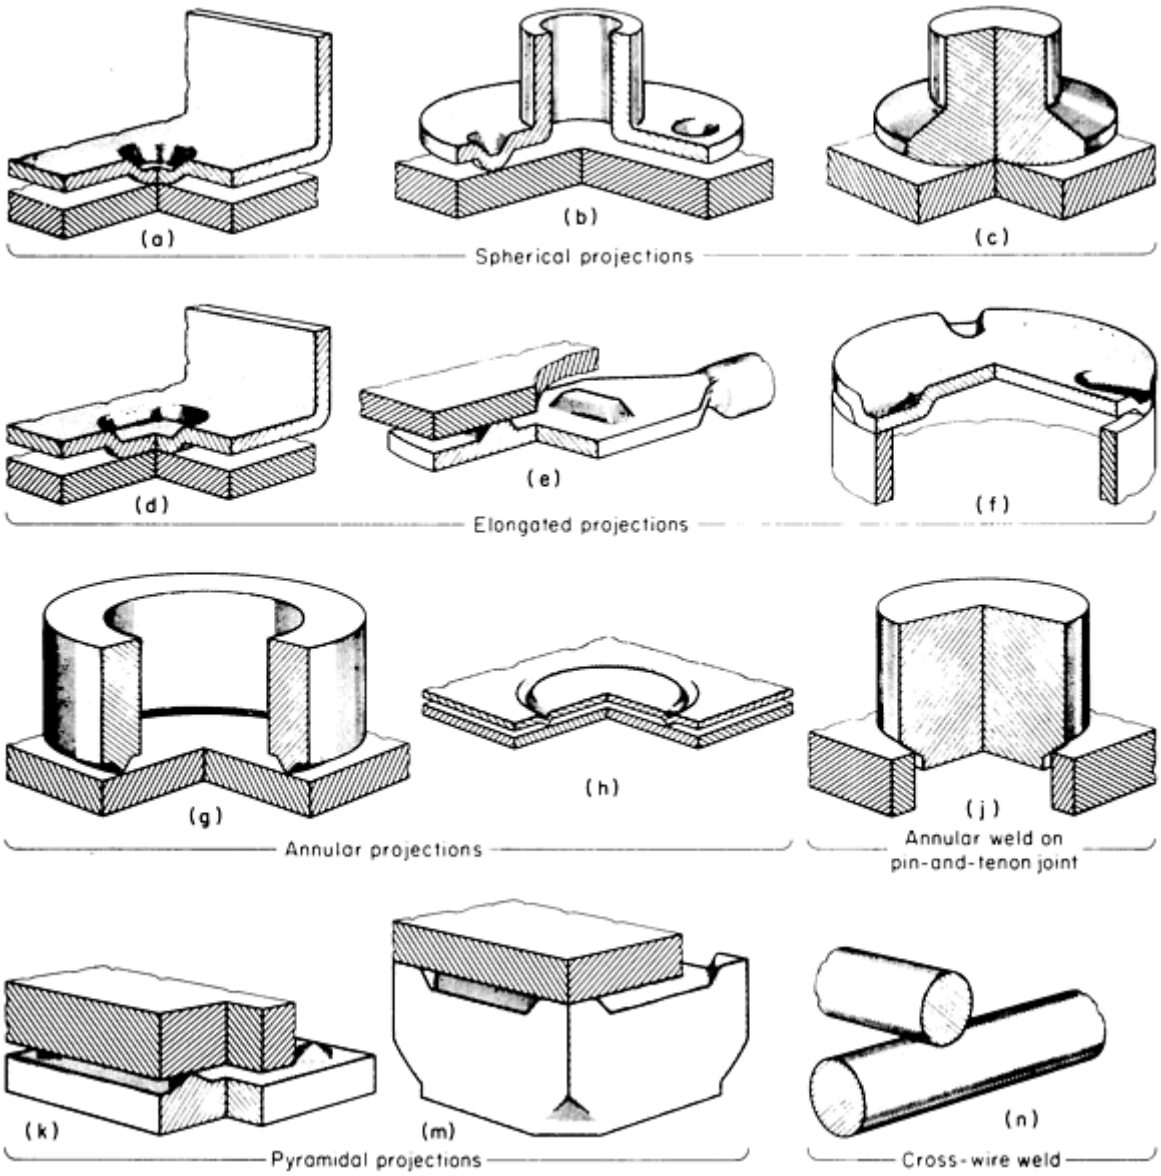

FIG. 3 DIFFERENT PROJECTION-WELDING CONFIGURATIONS

Embossed Projections

Typical embossed-projection weld configurations are shown in Fig. 3(a), (b), (d), and (h). The embossed-projection technique is primarily used for sheet-to-sheet applications. It does involve the additional expense of stamping the projections and ensuring that the electrodes are properly located over the projections. However, the ability of the projection to create highly localized joints allows this technique to extend the applications of resistance welding. Most notably, projection welding widely increases the allowable thickness mismatch associated with resistance welding.

Generally, resistance welding is considered adaptable to thickness variations of less than 3:1. However, with the addition of the projection, there is no limit to the difference in joinable thicknesses. Similarly, embossed-projection welding is highly adaptable to the joining of multiple-sheet stacks. The approach is similar in that the projections are used to localize heat at critical interfaces in the overall joint.

Another more recent use of embossed-projection welding is in applications where external marking must be minimized. This is a concern when a primer has been applied to one side of one of the sheets being joined. Because it is very effective at localizing heat at the interface, and because it uses shorter welding times, the PW process is more adiabatic and there is less residual heat that can damage outside surfaces. However, surface marking still does occur.

Solid Projections

A considerably wider range of solid-projection welding processes is commonly used in production applications. Annular projection welding, like embossed-projection welding, is commonly used to provide a highly localized joint and to minimize thermal damage to other parts of the structure. Common variations of solid-projection welding are described below.

Annular Projection Welds. One of the most common applications of solid-projection welding is to attach either tubular components or members with circular bases to flat or curved substrates. This is commonly accomplished by annular projection welding, in which the projection is machined onto the circular base or tubular section. Then, resistance welding is conducted to set the projection into the substrate. A typical weld geometry is shown in Fig. 3(g). Annular projection welding generally provides high-integrity joints and can be used for leak-tight applications.

Cross-wire welding is a variation of solid-projection welding in which the projection is formed by the contact point of two crossing wires. The geometry for cross-wire welding is shown in Fig. 3(n). Upon resistance welding, heat is maximized at the location of the wire-wire contact, and the parts are subsequently forged together. Depending on the application, either highly localized joints (minimal forging) or heavily forged joints can be made. In some applications, cross-wire welding is conducted at rates up to 30 welds/s.

Weld nuts represent an application of solid-projection welding in which the projections themselves occur as actual extensions of material from the nut. Typically, weld nuts contain 3, 4, or 6 of these projections, or feet, spaced around the nut periphery. During welding, all projections are attached simultaneously. Examples of weld nut geometries are shown in Fig. 3(k) and 3(m).

Edge-to-sheet welds are typically a cross between embossed- and solid-projection welding. They are used to attach the end of a sheet to the flat face of an opposing sheet (Fig. 3f). The projections for welding are generally stamped into the face of the attaching sheet. During welding, the projection does collapse locally back into the base sheet. However, bonding is strictly solid state, similar to that of other solid-projection welding processes.

Material Effects

Solid-projection welds are essentially strain-assisted diffusion bonds. Because the projections typically collapse at very high temperatures (generally, within several hundred °C of the melting point), diffusion bonding can occur within the very limited available time (usually, less than 1 s).

Not surprisingly, some of the material-related factors that affect diffusion bonding also affect solid-projection welding. The most notable of these is the ability of the metal to dissolve its own oxide. As a result, materials that do not energetically favor the solid solubility of oxygen, rather than the formation of the oxide at aluminum forging temperatures, will be relatively difficult to projection weld.

The strength-temperature relationship also affects projection weldability. Materials that maintain their strengths at relatively high temperatures permit substantial heating to occur before projection collapse. This heat then becomes available to promote diffusion after projection collapse. Premature collapse results in lower temperatures in which diffusion can occur and in reduced current density, which prohibits further resistance heating.

Bulk resistivity also plays a role in projection welding, but to a lesser degree. Increased bulk resistivity can reduce the effectiveness of the projection as a current concentrator. With increasing bulk resistivity, the tendency is for delocalized heating and general, rather than local, collapse of the projection. As a result, high-resistivity materials are more difficult to projection weld.

Mild steels and low-alloy, nickel-base alloys are ideal materials for projection welding, because they readily dissolve their own oxides and have adequate strength-temperature and resistivity properties. Stainless steels and higher-alloy nickel-base materials become slightly more difficult to weld, because of the formation of more-stable chromium and aluminum oxides, increased high-temperature properties, and higher resistivities.

Projection welding is commonly applied to copper and copper-base alloys. In many applications, projections are virtually required for resistance welding, because of the high conductivity of these materials.

On the other hand, aluminum and aluminum-base alloys are very difficult to projection weld. The aluminum oxide is so tenacious that solid-projection welding, in particular, is nearly impossible. In addition, it is very difficult to localize heat, because aluminum alloys soften at such low temperatures.

Conventional titanium alloys are also relatively difficult to projection weld. Although titanium readily dissolves its own oxide, its high resistivity and low forging temperature generally cause premature collapse of the projection.

Jerry E. Gould, Edison Welding Institute

Equipment

Resistance projection welding generally utilizes slightly modified resistance-welding equipment. Because the nature of projection welding is to direct current flow to the desired weld locations, there is considerably more flexibility in tooling. A specific example is spot welding that requires electrodes of specific sizes and shapes in order to localize current for welding.

Projection welding is typically done with large, flat electrodes. In most applications, tooling is simply shaped to match the contour of the part in the contacting location. Given the current-locating characteristic of projections, multiple projection welds can be made simultaneously.

Projection welding does require high compliance or the rapid response of the loading system. This is necessary because projection welding requires the collapse of a projection, which, in turn, requires some motion of the welding head. If the follow-up of the welding head is insufficient, then a local loss of force will occur, potentially causing catastrophic overheating of the contacting surfaces. Therefore, PW systems typically utilize "fast follow-up" heads (Fig. 4), which consist of relatively low inertia (mass) head components and mechanisms to maintain a nominally constant force. The head shown in Fig. 4 uses a relatively low volume diaphragm assembly and a spring to maintain this force on the components. Most systems, however, use either these low-volume diaphragm assemblies or springs to accomplish fast follow-up.

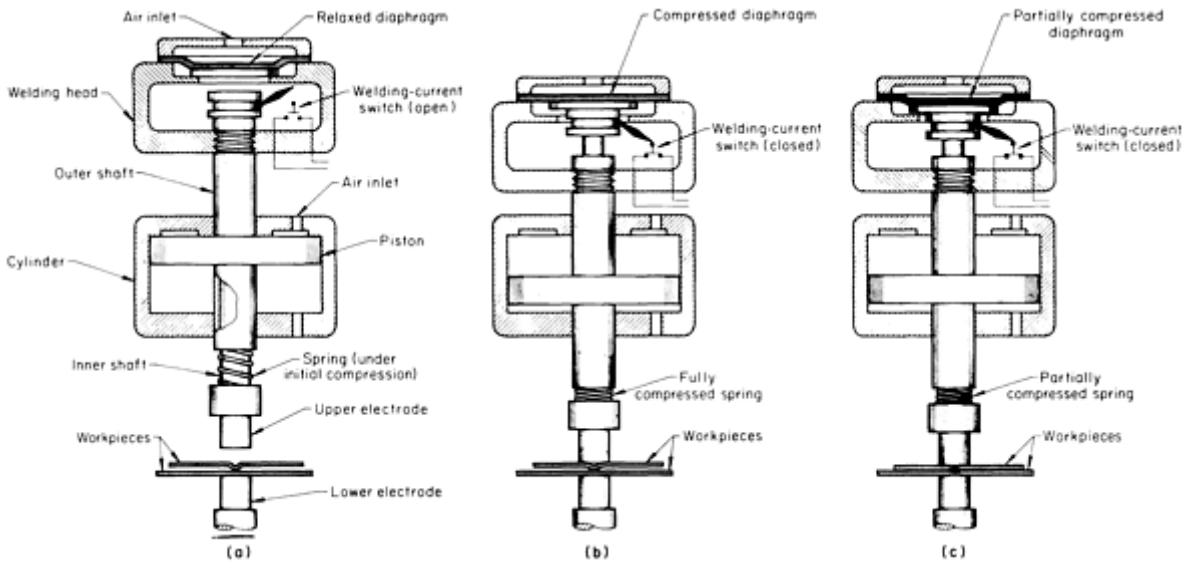

FIG. 4 TYPICAL FAST FOLLOW-UP (LOW INERTIA) HEAD FOR PROJECTION WELDING. (A) IN OPEN POSITION. (B) IN POSITION FOR SQUEEZING AND HEATING THE PROJECTION. (C) AT INSTANT OF PROJECTION COLLAPSE AND START OF NUGGET FORMATION

Personnel

Like all resistance welding processes, PW processes utilize basically automated equipment, which means that the expertise level to operate the equipment is relatively low. Generally, the skill levels and the health and safety issues are identical to those of conventional resistance spot welding. An area in which expertise is beneficial to hardware function and on-stream weld quality is operator attention to detail. Resistance welding is subject to variations in setup conditions, and projection welding may be extraordinarily sensitive to setup variations in situations where the placement of projections is critical.

With limited expertise, operators or supervisory staff can visually inspect the characteristics of the process and the welds themselves to identify improper setups, as well as maintenance needs. These quality assurance efforts, which fall under the auspices of total quality management or total quality joining, can be established with a minimum of on-line training and experience.

Projection Welding

Jerry E. Gould, Edison Welding Institute

Process Requirements

The types of hardware required for projection welding are analogous to those required for other resistance-welding processes.

The embossed-projection welding of heavy-gage, intermediate-gage, and thin-gage sheet, as well as joints of dissimilar thicknesses, is described below.

Heavy-Gage Sheet Steels. The projection welding of heavy-gage steels, which involves an embossed-projection welding process, has many of the characteristics of solid-projection welding particularly in its early stages, because of the thickness of the sheet.

In addition to defining the geometry of the projection, projection designs should provide an annular relief for projection material that is forged to the side during welding. Projection and die geometries for steels that range from 3.12 to 6.22 mm (0.123 to 0.245 in.) are shown in Table 1. The process requirements for forming these welds are given in Table 2. All welding schedules described in this article are single-pulse welding schedules.

(A) LOW-CARBON STEEL, SAE 1005-1010, 290-380 MPA (42-55 KSI) ULTIMATE TENSILE STRENGTH.

(B) SURFACE OF STEEL MAY BE OILED LIGHTLY BUT FREE FROM GREASE, SCALE, AND DIRT.

(C) ON SINGLE FORCE WELDS USE ONLY WELD FORCE AS ELECTRODE FORCE. ELECTRODE FORCE CONTAINS NO FACTOR TO FURTHER FORM POORLY MADE PARTS.

(D) BASED ON 60 HZ.

(E) STARTING VALUES SHOWN ARE BASED ON EXPERIENCE OF RWMA MEMBER COMPANIES.

(F) TENSILE-SHEAR STRENGTH PER PROTECTION DEPENDS ON THE JOINT DESIGN.

Slope control is recommended to prevent preflashing of the projection upon initiation of the welding current. Forge forces are also recommended, because weld porosity is often a concern with heavy-gage steel. Electrode or die wear may also be a concern, as it is in the spot welding of heavy-section steels. In such applications, pulsation welding schedules might be recommended.

Intermediate-Gage Sheet Steels. The projection welding of steels ranging in gage from 0.56 to 3.43 mm (0.022 to 0.135 in.), using single-point projections with single-impulse welding schedules, is well established. Projection-stamping die designs are given in Table 3, whereas process requirements are given in Table 4. Lower forces and shorter welding times are required, when compared with the conventional spot welding of these gages.

(A) CONFIGURATION DESIGNATIONS ARE FOR THE PURPOSES OF THIS TABLE ONLY.

(B) BASED ON 60 HZ.

(C) ELECTRODE FORCE CONTAINS NO FACTOR TO FURTHER FORM POORLY MADE PARTS.

(D) STARTING VALUES SHOWN ARE BASED ON EXPERIENCE OF RWMA MEMBER COMPANIES.

(E) TENSILE-SHEAR STRENGTH PER PROJECTION DEPENDS ON THE JOINT DESIGN.

(F) SCHEDULE A IS USABLE FOR WELDING MORE THAN ONE PROJECTION IF CURRENT IS DECREASED, BUT EXCESSIVE WELD EXPULSION MAY RESULT AND POWER DEMAND WILL BE GREATER THAN THAT FOR SCHEDULE B OR C.

(G) SCHEDULE B IS USABLE FOR WELDING MORE THAN THREE PROJECTIONS, BUT SOME WELD EXPULSION MAY RESULT, AND POWER DEMAND WILL BE GREATER THAN THAT FOR SCHEDULE C.

(H) SCHEDULE C IS USABLE FOR WELDING LESS THAN THREE PROJECTIONS WITH WELD CURRENT INCREASED APPROXIMATELY 15% AND POSSIBLE OBJECTIONABLE FINAL SHEET SEPARATION.

Thin-Gage Sheet. The projection welding of thin-gage steel sheet (<0.50 mm, or 0.020 in.) differs significantly from the projection welding of intermediate-gage sheet in that single-point projections become mechanically unstable. It also becomes increasingly difficult to use single-point projections to make adequate-sized welds. Therefore, annular projections are typically recommended for thin-gage steel. Table 5 provides the annular projection weld geometry, as well as the required process conditions.

TABLE 5 PROJECTION DESIGNS AND PROCESS REQUIREMENTS FOR ANNULAR PROJECTION WELDING OF THIN-GAGE LOW-CARBON STEEL

(A) SAE 1010, LOW-CARBON STEEL, 290-380 MPA (42-55 KSI) ULTIMATE TENSILE STRENGTH.

(B) SURFACE OF STEEL MAY BE OILED LIGHTLY, BUT MUST BE FREE FROM GREASE, SCALE, AND DIRT.

(C) ELECTRODE FORCE CONTAINS NO FACTOR TO FURTHER FORM POORLY MADE PARTS.

(D) BASED ON 60 HZ.

(E) STARTING VALUES SHOWN ARE BASED ON EXPERIENCE OF RWMA MEMBER COMPANIES.

(F) APPROXIMATE STRENGTH PER PROJECTION DEPENDS ON JOINT DESIGN.

Dissimilar Thickness Joints. As previously noted, the PW process is ideally suited for the joining of sheets of widely disparate thickness. When fabricating such joints, the best practice is to place the projection on the thicker sheet, where possible, using the projection design that is appropriate for the thinner sheet. This is done because the projection has the effect of concentrating the heat at the contact surface, regardless of the thicknesses of the sheets being joined. As a result, selecting conditions based on the thinner sheet has the effect of sizing the weld for that (attached) material.

The solid projections that are described below include nut, cross-wire, and annular projection configurations.

Nut Welding. Specific criteria for the design of weld nut projections, as well as appropriate processing conditions, are not well established. However, there is a general consensus that the ideal number of projections on a weld nut is three, because it is assumed that all three will contact the opposing surface when the electrode force is applied, if the projections are of the same height and if the electrodes are aligned properly.

The actual design of the welding projections is not well established, although 90° included angle square pyramidal and hemispherical projections are common. Such projections are nominally scaled according to the opposing sheet. Designs for embossed projections of the appropriate sheet size can be used as a guideline.

Cross-Wire Welding. The process conditions for the cross-wire welding of a range of wire thicknesses are given in Table 6. The conditions are usually specified in terms of requirements to achieve a certain level of compression set-down for the wires. Set-down is defined in Fig. 5. In general, joint strength increases as the degree of set-down increases. The defined process conditions are for mild steels. Higher-strength materials, such as stainless steels or nickel-base alloys, will require higher forces and longer welding times to promote wire collapse and diffusion across the bond line.

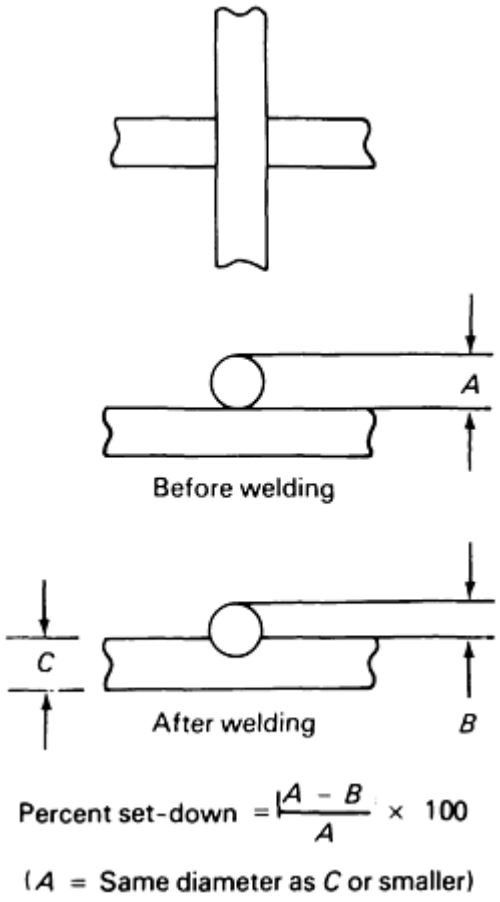

FIG. 5 DEFINITION OF HOW SET-DOWN IS ESTIMATED ON CROSS-WIRE WELDS. SOURCE: REF 1

Annular Projection Welding. Neither specific projection designs nor process conditions for annular projection welding are well established. There is a general consensus on the use of 90 ° included angle triangular cross section projections in sizes that are scaled to the thickness of the opposing sheet. Typical practice includes approximately 4.5 to 8.9 kN (1000 to 2000 lbf) of force per linear inch (or 25 mm) of projection. Weld times for annular projections for diameters ranging from 6.4 to 25 mm (0.25 to 1.0 in.) usually range from a single cycle to about 10 cycles. Typically, longer welding times result in more-robust processing conditions. However, maximum welding times are often limited by concerns over peripheral thermal damage.

The best annular projection design will recess the base diameter of the projection from the outside diameter of the part. Reasons for this are shown in Fig. 6. Projection designs that extend to the outside diameter of the part have the potential for unstable projection collapse, which can result in the formation of an incipient notch at the outside diameter of the part and an increase in the incidence of weld-related failures.

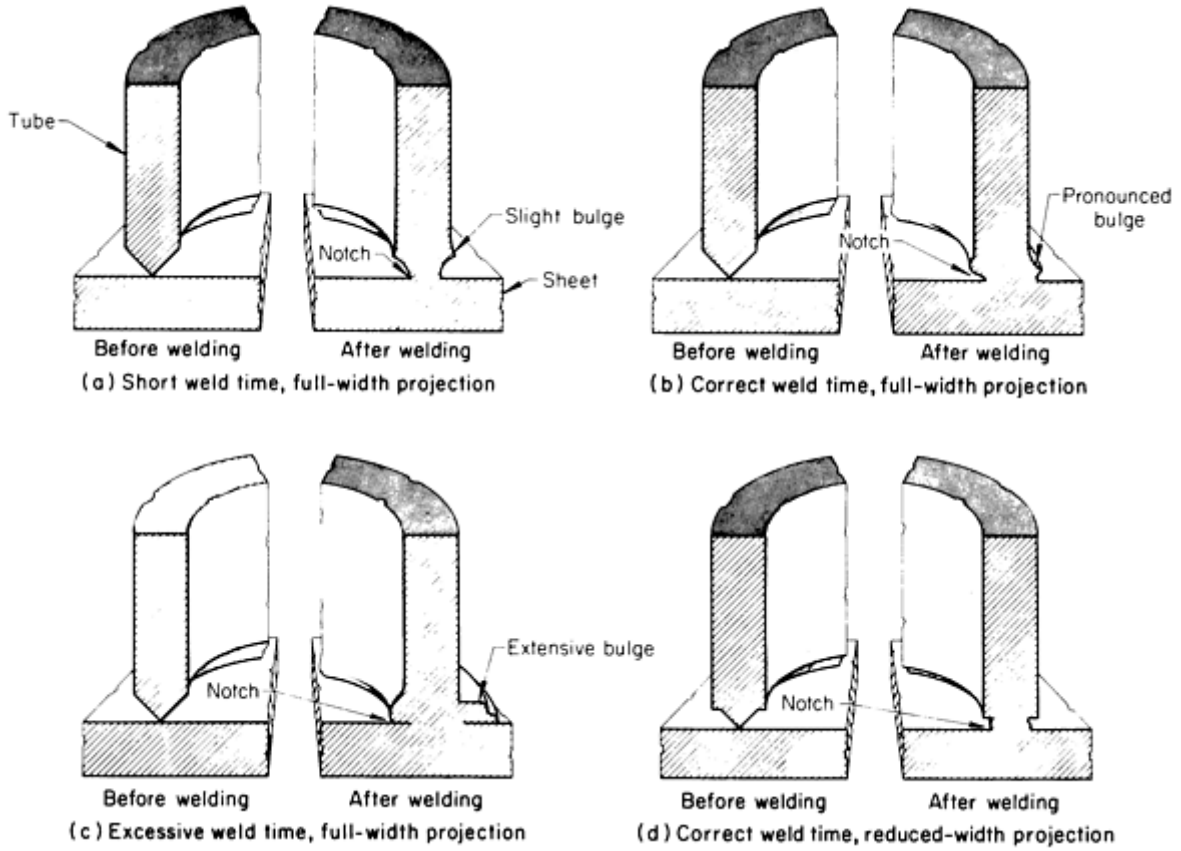

FIG. 6 CHARACTERISTICS OF PROJECTION COLLAPSE DURING ANNULAR PROJECTION WELDING WITH DIFFERENT BASE PROJECTION WIDTHS. (A) SHORT WELD TIME, FULL-WIDTH PROJECTION. (B) CORRECT WELD TIME, FULL-WIDTH PROJECTION. (C) EXCESSIVE WELD TIME, FULL-WIDTH PROJECTION. (D) CORRECT WELD TIME, REDUCED-WIDTH PROJECTION

Larger-diameter annular projection welds do cause a problem in attaining the proper heat balance around the periphery of the projection. Typically, the side of the projection that is toward the throat of the machine will heat preferentially for two reasons. First, the shortest conductive (and highest current flow) path is along the inside of the throat, including the inboard side of the projection. Second, there is an inductive "skin" effect associated with alternating-current machines, which tends to concentrate current along the inside of the welder throat. Intermediate-diameter projections have been successfully welded using direct current, because it minimizes the skin effect and appears to allow better heat balance.

Larger-diameter projections may require dual-throat machines, which have dual transformers located on opposite sides of the workpiece. Each has its own "throat." The effect is to balance the resistive/inductive effects, allowing the welding of very large diameter projections.

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

Introduction

RESISTANCE SEAM WELDING (RSEW) is a process in which heat generated by resistance to the flow of electric current in the work metal is combined with pressure to produce a welded seam. The resulting seam consists of a series of spot welds. The specific seam weld process can be classified as:

- *ROLL SPOT WELDING* (RELATIVELY LARGE UNWELDED GAPS BETWEEN NUGGETS)
- *REINFORCED ROLL SPOT WELDING* (SMALL GAPS BETWEEN NUGGETS)
- *LEAK-TIGHT SEAM WELDING* (NUGGET OVERLAP)

Two rotating circular electrode wheels are often used to apply current, force, and cooling to the work metal. A variety of workpiece/wheel configurations are possible (Fig. 1). When two electrode wheels are used, one or both wheels are driven, either by a direct drive of the wheel axles or by a knurl drive that contacts the peripheral surface of the electrode wheel (Fig. 2). For some applications, the electrode wheels idle while the workpiece is driven.

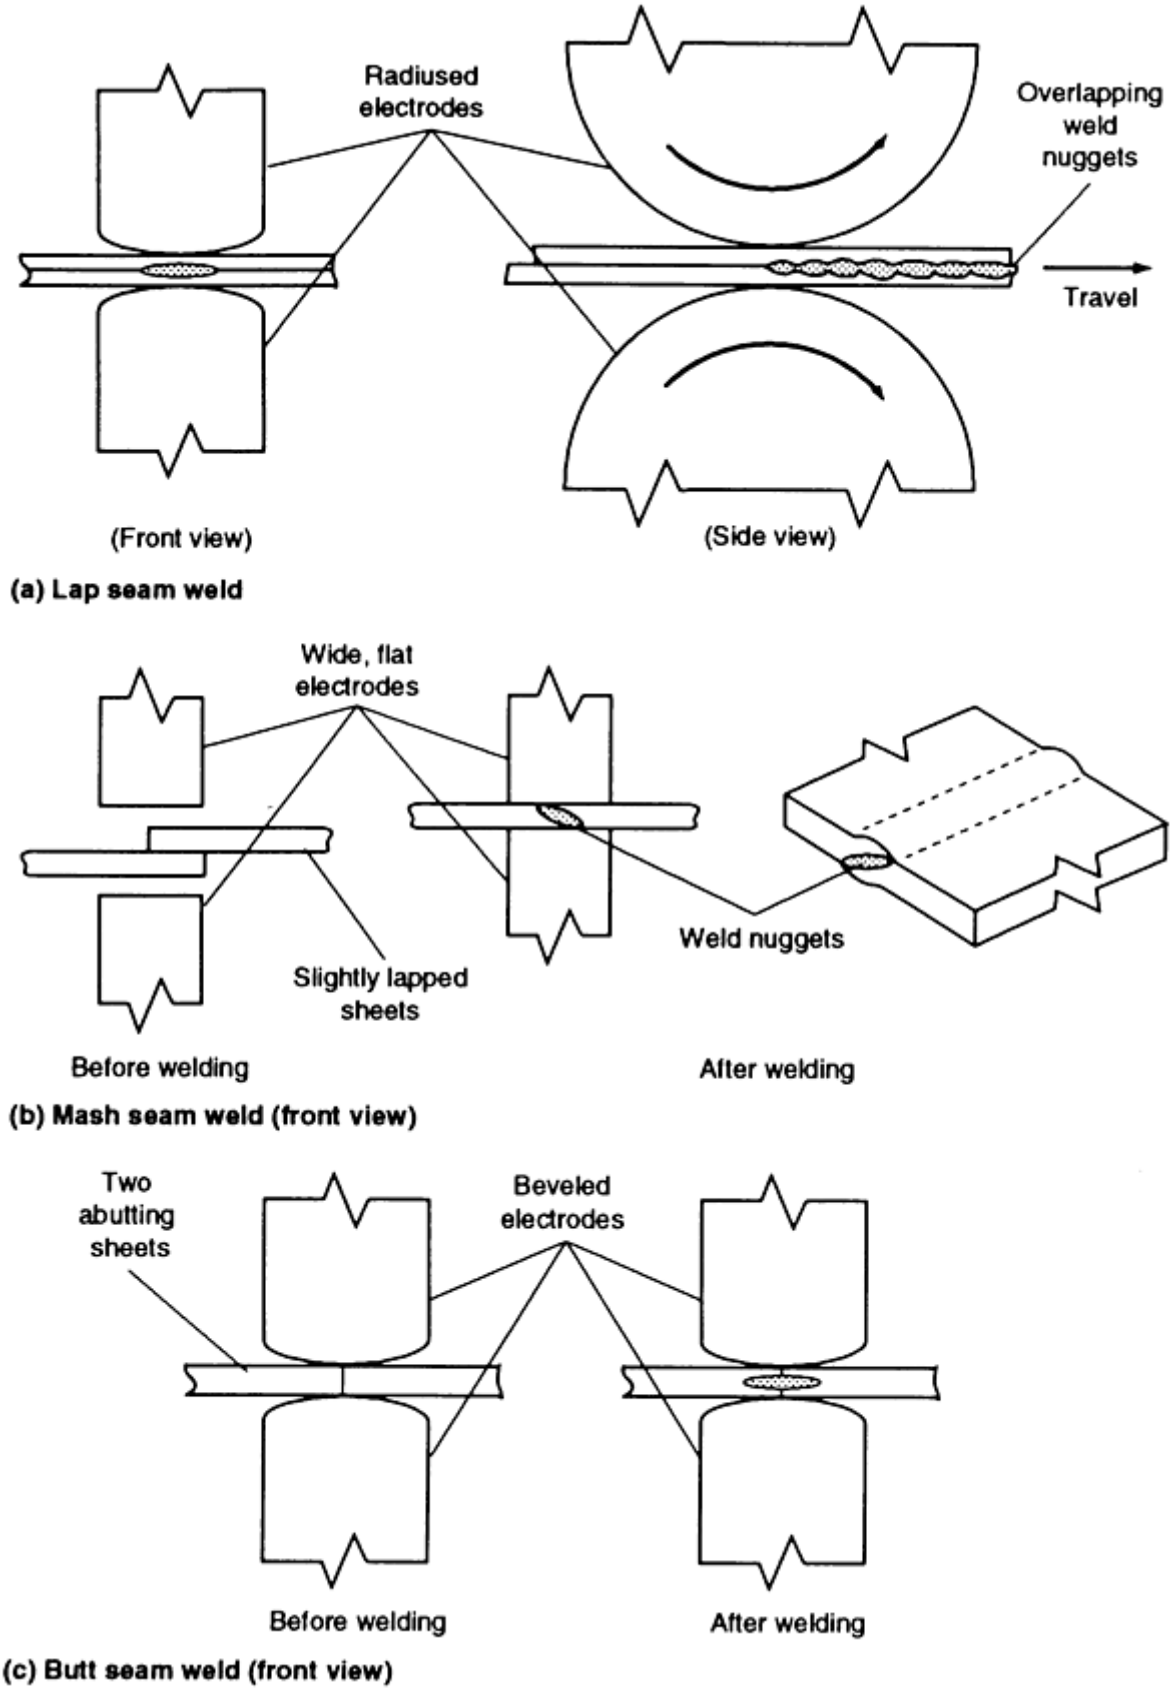

FIG. 1 BASIC CONFIGURATION OF JOINTS AND RESULTANT WELDS FORMED IN RESISTANCE SEAM WELDING. ADAPTED FROM *WELDING HANDBOOK*, 8TH ED., VOL 2, AMERICAN WELDING SOCIETY, 1991, P 554

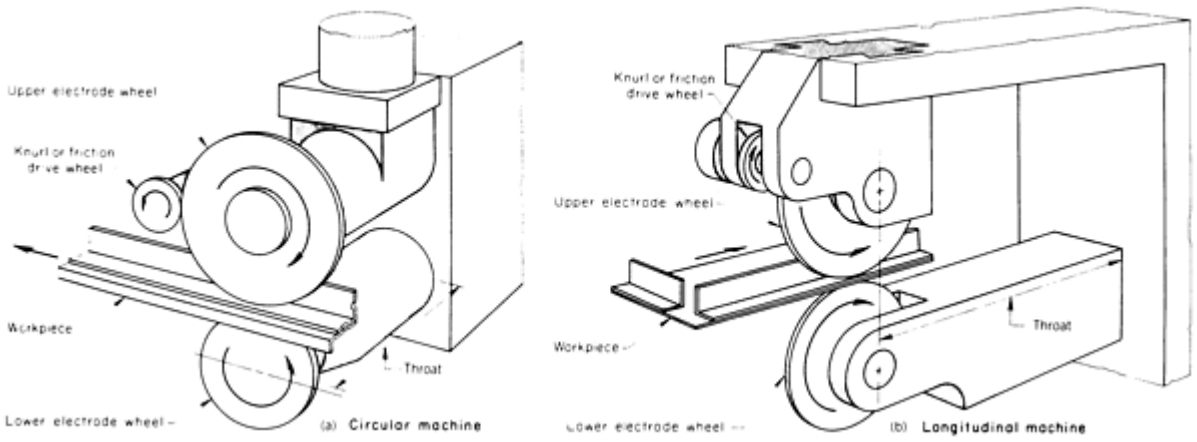

FIG. 2 POSITION OF ELECTRODE WHEELS RELATIVE TO THROAT ON RESISTANCE SEAM WELDING MACHINES

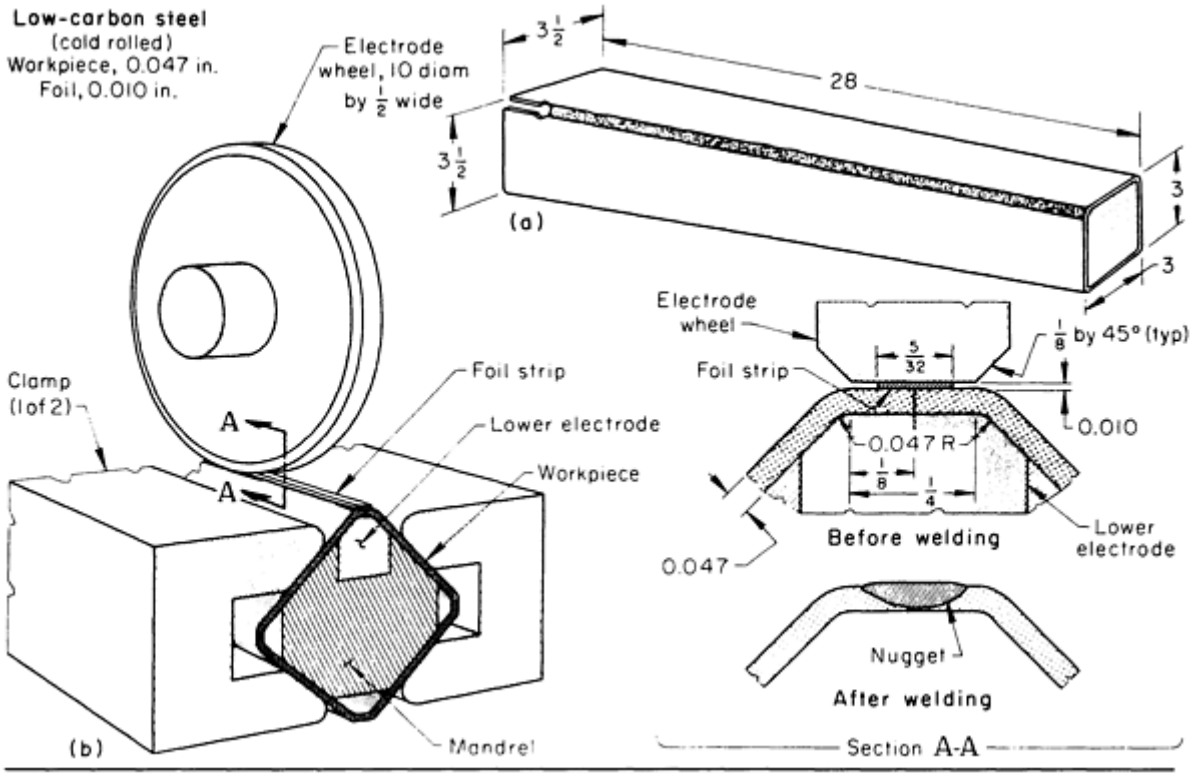
Other electrode systems for seam welding may use one wheel and one flat bar-type electrode (Fig. 3), or a wire-feed system in which a copper wire is fed into a groove on the wheel. This wire-feed process continuously provides a new copper surface for contact with the work metal (Fig. 4).



EQUIPMENT SPECIFICATIONS AND WELDING PARAMETERS	
POWER SUPPLY	440 V, SINGLE PHASE
WELDING MACHINE	AUTOMATIC, LONGITUDINAL, WITH MOVABLE CARRIAGE FOR UPPER ELECTRODE

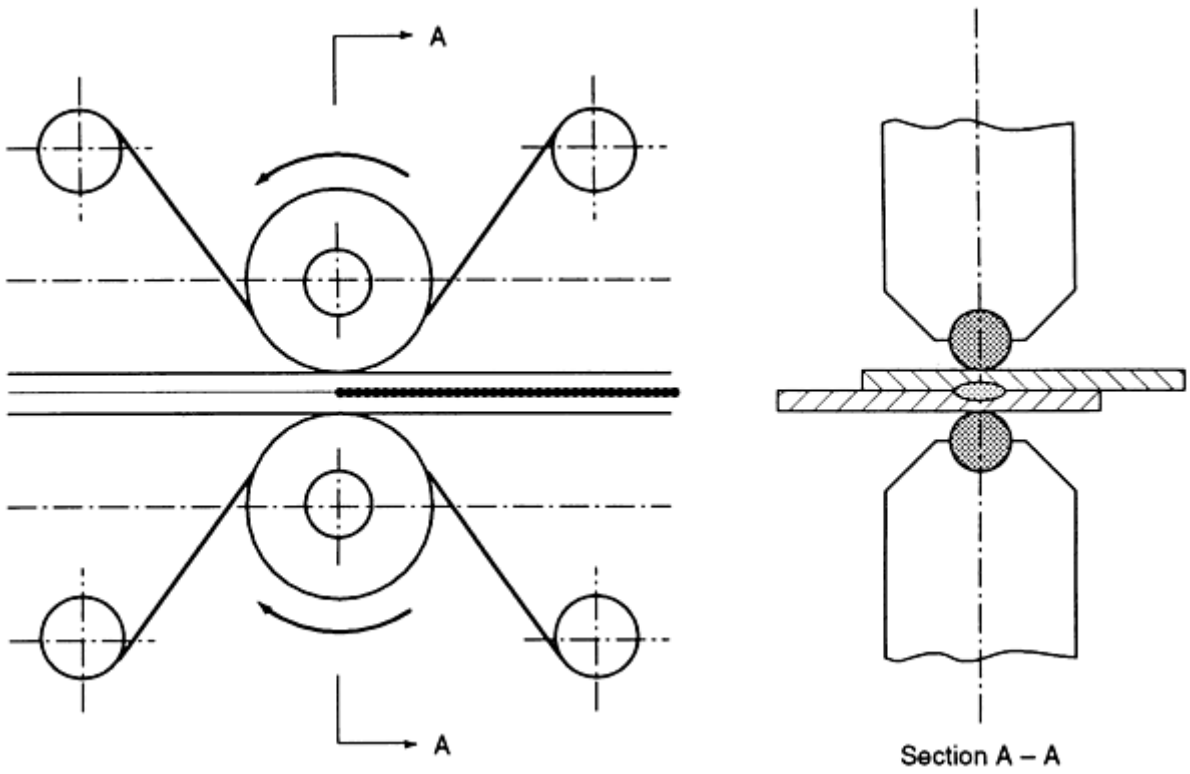

FIG. 4 TYPICAL SETUP FOR AN ELECTRODE WIRE SEAM WELDING PROCESS SHOWING POSITIONS OF WIRE RELATIVE TO GROOVED WHEEL

In seam welding, a series of spot welds is made without retracting the electrode wheels or releasing the electrode force between spots. The electrode wheels may rotate either continuously or intermittently. Weld speed, current magnitude, current waveform, cooling system, and the electrode parameters of force, shape, and diameter are all related and must be carefully selected to optimize the process and produce the highest quality weld.

The principles described in the article "Resistance Spot Welding" in this Volume are also generally applicable to seam welding.

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

RSEW Applications

Lap Seam Weld. A joint in which the workpieces are overlapped sufficiently to prevent the sheet edges from becoming part of the weld is classified as a lap seam weld (Fig. 1a). Lap seams are popular in automotive applications, such as automotive fuel tanks, catalytic converters, mufflers, and roof joints, as well as in nonautomotive applications, such as furnace heat exchangers, water tanks, and certain types of can making (Fig. 5). Lap seam welding of multiple stackups and dissimilar thicknesses is also possible.

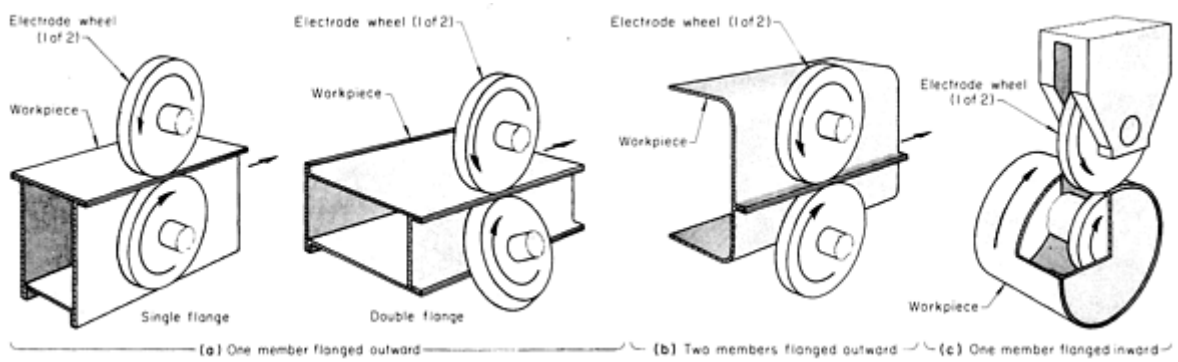

FIG. 5 ARRANGEMENT OF ELECTRODE WHEELS RELATIVE TO WORKPIECE FOR SELECTED FLANGE-JOINT LAP SEAM WELDS

Mash Seam Weld. A joint in which two sheets are overlapped by only one to two times the sheet thickness is classified as a mash seam weld (Fig. 1b). The weld area is forged or mashed down during welding to an overthickness 5 to 25% greater than a single sheet thickness. It is necessary to have some amount of overthickness so the current path can be controlled, because the electrode wheels in mash seam welding are wide and flat-edged. Surface appearance and thickness can be improved through the use of hard steel planishing wheels to cold work the joint before or after welding. Because of the excessive hardening induced by cold work, postweld heat treatment may be necessary (Ref 1).

Typical applications include drums, buckets, vacuum-jacketed bottles, aerosol cans, water tanks, and steel mill coil joining. Sheets of dissimilar thicknesses and/or coatings have been successfully mash seam welded. This development has created a whole new set of applications in tailored blank manufacturing, primarily for automotive use (Ref 2).

Butt Seam Weld. A joint in which two abutting edges are welded is classified as a butt seam joint (Fig. 1c and 3). The thickness of the weld should be approximately the same, or slightly less than, the sheet thickness. Butt seam welding is typically reserved for applications in which other butt welding processes cannot be used (for example, for tube welding and for sheet metal in railroad cars).

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

Advantages and Limitations

Advantages of seam welding, compared to resistance spot welding, projection welding, and laser welding, are:

- GAS-TIGHT OR LIQUID-TIGHT JOINTS CAN BE PRODUCED (NOT POSSIBLE WITH SPOT WELDING OR PROJECTION WELDING).
- SEAM WIDTH MAY BE LESS THAN THE DIAMETER OF SPOT WELDS, BECAUSE THE ELECTRODE CONTOUR CAN BE CONTINUOUSLY DRESSED AND IS THEREFORE OF A STABLE SHAPE.
- HIGH-SPEED WELDING (ESPECIALLY ON THIN STOCK) IS POSSIBLE.
- TOOLING COST IS GENERALLY FAVORABLE PER INCH OF FLANGE WELDED.
- COATED STEELS ARE GENERALLY MORE WELDABLE USING SEAM WELDING THAN SPOT WELDING, BECAUSE COATING RESIDUE CAN BE CONTINUOUSLY REMOVED FROM THE ELECTRODE WHEELS IF SPECIAL PROVISIONS ARE MADE.
- COATED STEELS ARE GENERALLY MORE WELDABLE USING SEAM WELDING THAN LASER WELDING, BECAUSE COATING VOLATILITY IS MINIMIZED BY THE INTENSE PRESSURE FIELD IN THE WELD ZONE.
- RESISTANCE SEAM WELDING IS NOT PARTICULARLY FITUP-SENSITIVE COMPARED TO LASER WELDING.
- THE HARDNESS OF RESISTANCE SEAM WELDS MADE WITH AIR COOLING IS LESS THAN THAT OF LASER WELDS (120 HV VERSUS 250 HV, RESPECTIVELY, FOR DRAWING-QUALITY BARE STEEL, AND 170 HV VERSUS 300 HV, RESPECTIVELY, FOR ORGANIC COATED DRAWING-QUALITY STEEL) (REF 3).

Limitations of seam welding, apart from those it shares with spot welding and projection welding, are:

- WELDS MUST ORDINARILY PROCEED IN A SINGLE PLANE OR ON A UNIFORMLY CURVED SURFACE. FOR SPECIAL CASES, MULTIPLANE WELDING HAS BEEN ACHIEVED USING A TILTING WELDING HEAD. THE RADIUS OF CURVATURE CONNECTING THE PLANES MUST BE SUFFICIENTLY LARGE.
- OBSTRUCTIONS ALONG THE PATH OF THE ELECTRODE WHEEL MUST BE AVOIDED OR COMPENSATED FOR IN THE DESIGN OF THE WHEEL.
- MATERIAL HANDLING MUST NOT INDUCE EXTRANEOUS FORCES INTO THE FRAGILE, MOLTEN WELD ZONE DURING WELDING.
- THE LENGTH OF SEAMS MADE IN A LONGITUDINAL SEAM WELDING MACHINE IS LIMITED BY THE THROAT DEPTH OF THE MACHINE (FIG. 2B). CURRENT SHUNTING THROUGH THE WELD, OR A CHANGE IN ELECTRICAL IMPEDANCE CAUSED BY THE MOVEMENT OF THE PRODUCT INSIDE THE THROAT OF THE MACHINE, CAN REQUIRE CURRENT COMPENSATION AS WELDING PROCEEDS.
- COMPONENTS USING MULTIPLE CROSSING SEAM WELDS CAN BE QUALITY-SENSITIVE AT THE WELD INTERSECTIONS.
- EXTERNAL WATER COOLING OF THE ELECTRODES AND THE WELD ZONE MAY BE REQUIRED FOR HIGH-SPEED WELDING. (UNDER HIGH-SPEED CONDITIONS THE WELD

NUGGETS ARE STILL MOLTEN AS THEY LEAVE THE PRESSURE FIELD OF THE WHEELS). EXTERNAL COOLING MAY ADD TOOLING COST FOR WATER CONTAINMENT AND WATER REMOVAL FROM THE PARTS AFTER WELDING.

- MATERIALS REQUIRING POSTHEAT AND TEMPER SHOULD NOT BE SEAM WELDED WITHOUT SPECIAL CONSIDERATIONS.
- CHROMATES AND INSULATING LACQUER COATINGS ARE NOT RESISTANCE SEAM WELDABLE.

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

Fundamentals of Lap Seam Welding

Empirical seam welding parameters have been developed over the years and have proven useful under many conditions (Ref 4, 5). However, this discussion is devoted to an alternative approach to process optimization, based on principles of heat transfer in the weld. Hopefully, this approach will shed some light on difficult applications in which traditional methods may fall short of what is necessary to make quality welds.

Weld Time, Speed, and Current Pulsation

Certain concepts from resistance spot welding begin to explain resistance seam welding, because seam welding generally consists of a series of overlapping spot welds.

Spot Weld Analogy. Empirically, the optimum time for the spot welding of low-carbon steel sheet is approximately (Ref 6):

$$T = 0.0292\ S^2 \qquad \textbf{(EQ 1)}$$

where S is the thickness of the total stackup of sheets (in millimeters) and t is the optimum weld time (in seconds).

Applying current for this length of time maximizes the current range from minimum weld diameter through the onset of either cracking, overindentation, or electrode sticking. If weld time is less than this, there will be insufficient time for proper heat flow to occur inside the weld. As such, the weld will begin to exhibit adiabatic character ("thermal runaway"), nugget size instability, and surface expulsion. By the same measure, if weld time is too long, the extra cycles simply heat up the electrodes. Hot electrodes are less capable of keeping the surface of the weld cool to avoid electrode sticking and metallurgical discontinuities on the weld surface. In addition, excessive weld time will also compromise electrode life, waste energy, and could even slow down the production rate of an entire manufacturing line. Thus in any case, for spot welding there seems to be a proper rate of welding, based on material thickness and thermal diffusivity (in the thickness direction).

Application to Seam Welding. For seam welding, the same principle of optimum weld time applies, but weld time refers to how long a given point on the weld will be in contact with the wheel as it passes through the welder. In practice, travel speed and electrode footprint length, L, should be controlled so that the resulting weld time is matched with the $0.0292\ S^2$ rule (see Eq 1, Eq 5, and Fig. 6). The following equations may be used (forward or backward) to fix some variables and calculate the others that result from these assumptions.

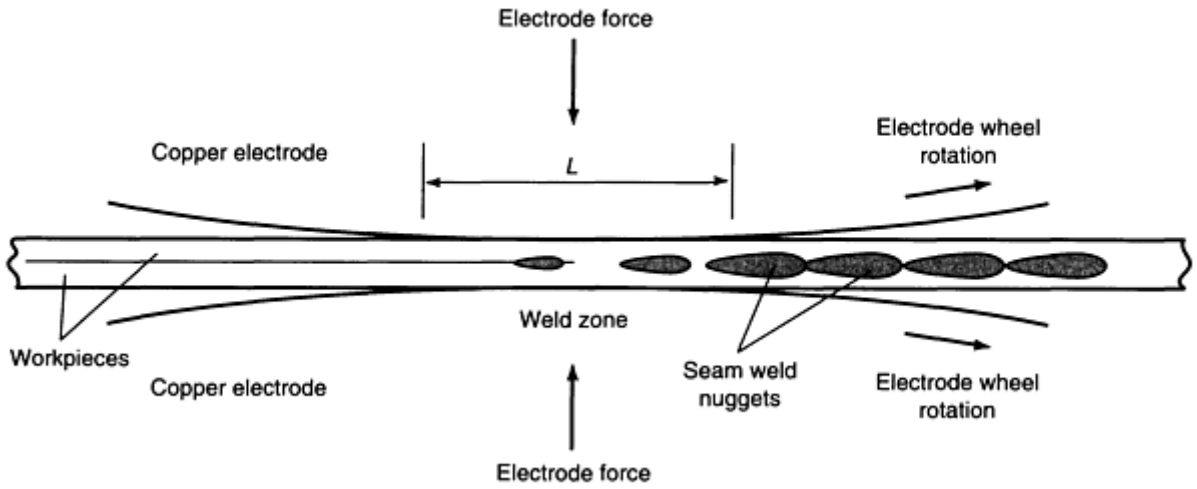

FIG. 6 SCHEMATIC SHOWING LENGTHWISE SECTIONAL VIEW OF PROPER NUGGET DEVELOPMENT IN THE WELD ZONE OF A PULSED LAP SEAM WELD. THE LENGTH OF THE CONTACT FOOTPRINT, *L*, IS SUFFICIENT TO CONTAIN THREE NUGGETS UNDER THE WHEEL (THAT IS, *N* = 3).

For lap seams of low-carbon sheets, Eq 1 becomes:

$$T = N/F = 0.0292\ S^2 \qquad \textbf{(EQ 2)}$$

where *n* is the number of nuggets under development inside the weld zone footprint at any one time (Fig. 6) and *f* is the impulse frequency of the applied current (on-time and off-time).

For process control and leak-tight welds, a good rule for the nugget spacing is:

$$1.7\ S \leq D \leq 2.5\ S \qquad \textbf{(EQ 3)}$$

where *d* is the nugget spacing (in mm).

Welding speed, *v* (in mm/s), is therefore:

$$V = D \cdot F \qquad \textbf{(EQ 4)}$$

However, to predict the optimum welding speed, one must first know *L*, the length of the contact footprint (in mm):

$$L = D \cdot N \qquad \textbf{(EQ 5)}$$

One can calculate the required *L* from *d* and *n*, and then determine the wheel diameter, force, and current needed to achieve *L*.

Substituting Eq 5 and Eq 3 into Eq 4:

$$V = L \cdot F/N \qquad \textbf{(EQ 6)}$$

and

$$L_{MAX} = 2.5\ N \cdot S \qquad \textbf{(EQ 7)}$$

Rearranging Eq 2:

$$N = 0.0292\ F \cdot S^2 \qquad \textbf{(EQ 8)}$$

and:

$$V_{MAX} = L_{MAX} \cdot F/N \qquad \textbf{(EQ 9)}$$

to obtain:

$$V_{MAX} = 85.6\ N/S \qquad \textbf{(EQ 10)}$$

It is important to note that the current range of seam welding is widened by the judicious use of impulsed current to form distinct nuggets. Impulse profiles of 25 to 33% off-times are commonly used. Impulses contain off-time for the electrodes to draw heat away from the weld surface. Therefore, the occurrence of surface discontinuities is lessened. In addition, off-time allows heat to redistribute itself within the weld, away from local hot spots. Hot spots are places within the weld where thermal spikes may be occurring due to either a relatively high local resistance, a nonuniform current density, a multiple stackup, or a stackup of unequal sheets. Hot spots are especially common along the weld interface when welding either thick plates or prepainted sheets. Hot spots on the outside surface of a weld occur naturally with unequal sheet thicknesses (on the thin side), or when welding is faster than permitted by Eq 2. On the other hand, hot spots can also occur within the sheet bulk, if due to erratic time distribution of current during on-time. Bulk hot spots begin to occur when welding near the maximum speed for a material, because current is actually not applied uniformly throughout the on-time, and time is required for the resulting nonuniform heat pattern to redistribute itself (Fig. 7). The ideal impulse shape under high-speed conditions would seem to be a square wave (Fig. 8a). Because typical industrial power sources can only approximate this shape (Fig. 8b), it is worthwhile to accurately record the waveform of the actual secondary current in order to monitor its shape and stability during welding.

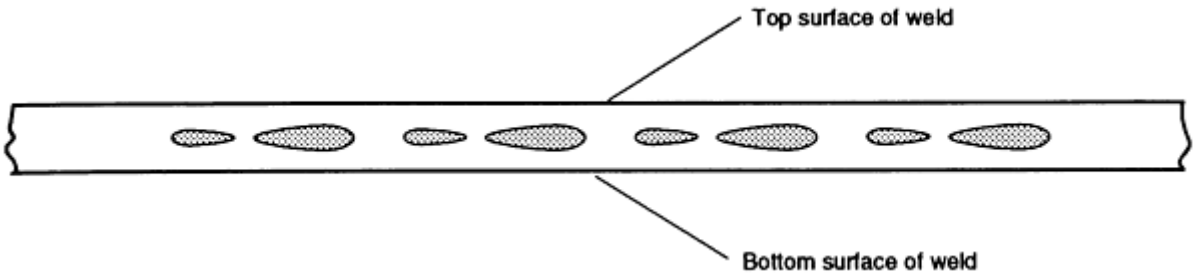

FIG. 7 SCHEMATIC SHOWING LENGTHWISE SECTIONAL VIEW OF THE WELD CENTERLINE OF A LAP SEAM JOINT WITH IRREGULAR NUGGET SHAPES. THE LACK OF UNIFORMITY IN THE SHAPE OF THE NUGGETS IS ATTRIBUTABLE TO AN IRREGULAR PULSE SHAPE THAT DOES NOT PROVIDE SUFFICIENT TIME FOR HEAT FLOW TO BLEND TOGETHER THE DOUBLETS.

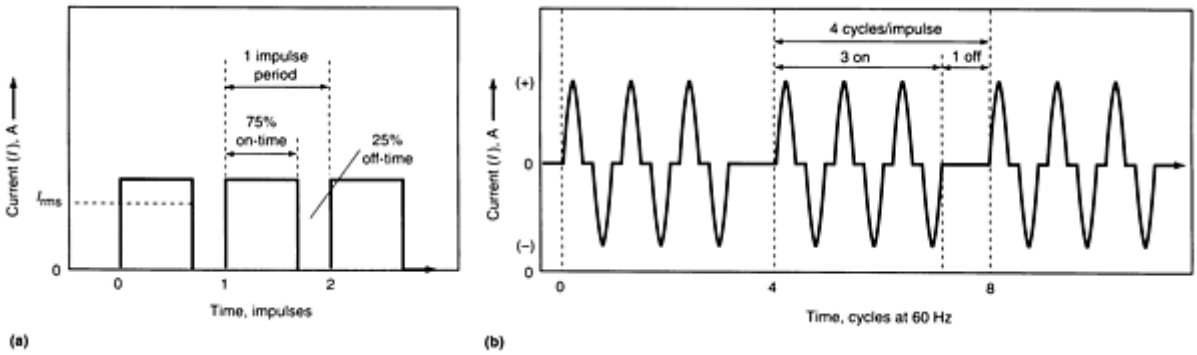

FIG. 8 WELD CURRENT PROFILES FOR SEAM WELDING. (A) IDEAL IMPULSE SHAPE. ON-TIME IS 75% OF IMPULSE PERIOD WHILE OFF-TIME IS 25% OF IMPULSE PERIOD. (B) ACTUAL IMPULSE SHAPE IS TYPICALLY COMPLEX AND NON-IDEAL. IN THIS SPECIFIC CASE, IMPULSES ARE FROM AN AC SINGLE-PHASE (3 ON/1 OFF) CURRENT SOURCE.

Current range is greater in impulse mode than in nonimpulse (continuous current) mode. The extra range seems to provide more robust penetration under difficult welding conditions, such as when intersecting other welds or turning corners with the seam.

One of the disadvantages of seam welding relative to spot welding is that solidification of the weld nugget occurs after the weld metal leaves the pressure field of the electrode wheels. Thus, if there is a large separating force on the weld before it freezes, it can come apart as it leaves the wheels. This postweld separation has been called "unzipping" or "alligatoring." Impulses effectively cure this problem because the off-times create a modulating penetration profile (Fig. 6), providing cool tack joints between the molten spots.

It is desirable from a process control standpoint to select an impulse schedule that will produce nuggets of nearly equal length and width, in conjunction with the other parameters used (speed, wheel diameter, wheel width, and power source).

In Table 1, theoretical parameters from Eq 2, 3, 4, 5, 6, 7, 8, 9, and 10 have been calculated for several commonly available impulse frequencies. The results can be used to predict optimum welding parameters from these basic principles.

TABLE 1 THEORETICAL PARAMETERS FOR LAP SEAM WELDING OF TWO EQUAL SHEETS OF MILD STEEL (PER EQ 2, 3, 4, 5, 6, 7, 8, 9, 10)

(A) *N*, NUMBER OF NUGGET SPOTS UNDER THE ELECTRODE WHEEL; *S*, STACKUP, SUM OF BOTH SHEET THICKNESSES; *L*, CONTACT LENGTH OF ELECTRODE ON WORKPIECE.

(B) 60 HZ CONTINUOUS

The optimum weld speed may be identified experimentally as the speed with the widest current range for making good welds. Good welds are nominally free of typical metallurgical discontinuities (for example, surface cracks, gross lack of fusion at the weld interface, or surface melting eruptions).

When welding dissimilar thicknesses, on-time must not be greater than the optimum weld time for the thinnest outer sheet (*TOS*). Mathematically:

$$T = 4(0.0292)\,(TOS)^2 \qquad \textbf{(EQ 11)}$$

where *TOS* is in millimeters.

One way to satisfy the weld time needs of both total stackup, *S* (Eq 1) and *TOS* for thick-thin welding is to raise *n*, the number of nuggets in the weld zone, to 2 or 3. The goal here is to weld for the proper total time dictated by Eq 1, but to do it with pulses of on-time no greater than dictated by Eq 11. To increase *n*, one must carefully consider the electrode wheels as well as the impulse schedule. Even when taking advantage of pulsation, it may become impossible to seam weld extremely dissimilar thicknesses without damaging the thinnest outer sheet. This difficulty should become pronounced for thickness ratios above about 3 to 1.

Wheel Geometry, Weld Force, and Wheel Maintenance

The primary role of wheel geometry and force in seam welding is to control the dimensions of the weld zone or the size of the footprint that the wheel makes on the workpiece while welding.

The length of the footprint, *L*, is an important factor in the weld time equation (see the section "Weld Time, Speed, and Current Pulsation" in this article). The variable *L* is primarily controlled by wheel diameter, force, and current. (As either force or current is increased, the wheel will sink deeper into the work and *L* will increase.) It is worthwhile to measure or estimate *L*. This has been done experimentally using special voltage probes on the electrodes and by an optical silhouette method (Ref 7). A less accurate (but simpler) method is to read the heat pattern at the beginning and end of the weld, in order to estimate *n*, the number of nuggets under the wheel at any one time. For bare steel, *n* can be as low as 1. However, the weldability of coated materials and dissimilar thicknesses improves when *n* is as high as 2 or 3 (see Fig. 6). Keep in mind that the contact length will decrease somewhat as the wheel wears to a smaller diameter. (Normally this change should not be of concern, except possibly when welding beyond the theoretical top speed for a material combination.)

Footprint width is best matched with impulse length, *d*, to produce nearly round nuggets. Width, however, is of secondary importance to impulse length.

A transverse radius on the wheel generally improves the welding range, because under high current conditions it automatically reduces current density by sinking further into the work.

Under given electrode conditions, increasing weld force improves the welding range for speed and helps control cracking.

It is generally true that the current range improves with higher wheel pressure, until longitudinal splits begin to occur at seam starts or stops. On the other hand, at low force, transverse surface cracks may result at the upper end of the current range, especially on coated steels. A good role of thumb is to weld at 80% of the seam-splitting force, or less. In addition, it may be helpful to de-energize the weld force except while welding, so as not to cause undue wheel wear.

For the highest quality joints it may be necessary to lightly machine the wheels as they are used, in order to maintain a constant edge profile. The types of wheel dressing tools are:

- *SCRAPERS* TO REMOVE CONTAMINATION WHEN WELDING COATED MATERIALS
- *WIDTH CUTTERS* TO REMOVE MUSHROOMED COPPER AND CONTROL WHEEL WIDTH
- *KNURLERS* (FIG. 2), TO MAINTAIN THE TRANSVERSE PROFILE ON THE WHEEL AND DRIVE THE WHEELS AS NEEDED

If wheel maintenance on the machine is not feasible, the wheels can be removed and redressed off-line. Alternatively, the wire-electrode seam welding process provides a constant wheel condition and thus eliminates the need for continuous wheel dressing (Fig. 4).

Cooling the Weld

The weld cooling system is very important for process control of seam welding. Its primary role is to minimize thermal damage to the outer surfaces of the weld while the weld interface is being heated above the melting point. The key elements in the success of the weld cooling system are:

- *ELECTRODE MATERIAL* (THERMAL OR ELECTRICAL CONDUCTIVITY)
- *ELECTRODE TRANSVERSE SHAPE* (RADIUS PROFILE IS BEST)
- *ELECTRODE CLEANLINESS* (SHOULD BE DRESSED FREE FROM PICKUP OF NONCONDUCTING COATINGS)
- *ELECTRODE COOLING SYSTEM*
- *COOLING WATER* APPLIED DIRECTLY TO THE WELD (IF APPLICABLE)

Cooling water for seam welding wheels can be either internal or external. Internal cooling systems cool the wheel but not the weld. The key advantage of internal cooling is that the process is dry; the workpiece, the machine, and the operator stay dry. The cost of installing floor drains and water containment facilities is avoided. Neither is it necessary to remove water from inside the workpiece (as in the case of automotive fuel tanks). However, internally cooled wheels may cost more due to additional machining costs. Thus, operating costs for internal cooling may be higher than for external cooling. Some internal systems do not directly cool the wheel, but only the wheel shaft.

On the other hand, with external cooling, spray nozzles are aimed with some precision at the workpiece-wheel separation point. The benefits of external cooling include:

- THERMAL DAMAGE TO THE WELD SURFACE AND ANY COATINGS IS REDUCED, SO THAT WELDABILITY IS IMPROVED.
- WELD DISTORTION IS REDUCED.
- FUME EMISSION IS REDUCED.
- WHEEL CLEANLINESS IMPROVES, BECAUSE WATER IS DIRECTLY APPLIED TO THE HOTTEST POINT ON THE WHEEL, PRODUCING A QUENCH/CLEANING ACTION ON THE WHEEL SURFACE.
- WELD HARDNESS WILL INCREASE, ADDING STRENGTH TO THE WELD UNDER CERTAIN LOADING CONDITIONS SUCH AS CRUSH LOADING. (*CAUTION: SOME QUENCH-SENSITIVE MATERIALS MAY NOT ALLOW EXTERNAL COOLING.*)

In welding bare steel, rust-preventive water solutions are sometimes used, such as 5% borax ($Na_2B_4O_7 \cdot 10H_2O$).

Metals Welded

Most low-carbon, high-carbon, low-alloy, and stainless steels, and many coated steels above approximately 0.15% tend to form areas of hard martensite upon cooling. In critical applications, the welds may require postweld tempering to reduce the hardness and brittleness. In some cases, this can be done in the welding machine. Tempering can also be done in a furnace or by induction heating.

Aluminum and aluminum alloys can be lap seam welded but not mash seam welded, due to their narrow plastic range. Nickel and nickel alloys can also be seam welded, but seam welding is not recommended for copper and high-copper alloys. Compatible combinations of dissimilar metals and alloys also can be seam welded. For additional information on the seam welding of stainless steel, aluminum alloys, and copper alloys, see the article "Procedure Development and Practice Considerations for Resistance Welding" in this Volume.

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

Types of Seam Welds

Several types of resistance seam welds can be made:

- *LAP SEAM WELDS* JOINING OVERLAPPING FLAT SHEETS (FIG. 1A)
- *FLANGE-JOINT LAP SEAM WELDS* WITH AT LEAST ONE FLANGE OVERLAPPING THE MATING PIECE (FIG. 5A)
- *FOIL LAP SEAM WELDS,* IN WHICH AN ALLOY METAL FOIL IS PLACED AT THE WELD INTERFACE
- *MASH SEAM WELDS* WITH WORK METAL COMPRESSED AT THE JOINT TO REDUCE JOINT THICKNESS (FIG. 1B)
- *BUTT SEAM WELDS* (FIG. 1C AND 3)

In addition, both low-frequency and high-frequency induction and resistance welding are used for butt welding strip stock into tubes and other shapes.

Lap Seam Welds

The most common type of seam weld is a simple lap seam in which the pieces to be welded are lapped sufficiently to prevent the sheet edges from becoming part of the weld (Fig. 1a). Applications include sealing of cans and tanks in which liquid-tight or gas-tight joints are needed.

Flange-joint lap seam welds are used in joining assemblies having one straight member and one outward-flanged member at the joint to be welded (for example, the duct in Fig. 5a) or assemblies with two outward-ranged members (for example, the automotive gasoline tanks in Fig. 5b). Common applications include containers with out-turned bottoms or tops, and ducts or structural parts with out-turned sides. Unless the workpiece length is less than the usable throat depth of a longitudinal machine, seam welds of this type are made on a circular machine.

Often, container ends are dished for added strength, and one or both electrode wheels must be mounted at an angle to clear the workpiece. Wheel diameter limitations may also necessitate setting a wheel at an angle (Fig. 5a, right view).

Flange-joint seam welds can also be used for welding assemblies in which the flanges face inward at the joint (Fig. 5c). However, to reduce overhang of the arm supporting the lower electrode or to reduce the required throat depth of the

machine, the length of the workpiece should be kept to a minimum. If the lower electrode support is small, too much overhang can result in excessive deflection of the support and thus cause inconsistent weld quality because of force variation.

Mash Seam Welds

Mash seam welds are produced by overlapping two sheets by an amount ranging from one to two times the sheet thickness and applying electrode force and current. The resulting over-thickness is 5 to 25%.

Usually wide, flat edges are used on the electrode wheels. The joint itself acts as a current localizer, as in projection welding, because the overlap is thicker than either sheet by itself. Because the wheels are wide and flat-edged, the transverse position of the joint on the wheels can be oscillated as needed to prevent a groove from forming on the wheels and to increase the period between wheel dressings.

Careful selection of an impulse weld schedule will result in higher penetration and greater joint strength, although the "bumpy" appearance of a weld made with pulsating current may not meet product requirements. Cosmetic mash seam welds can be made with nonpulsed (continuous) current, or by pulsing according to the minimum nugget spacing afforded by Eq 3 (for mash seams use S = thickness after welding).

Because sheet overlap is a critical parameter, workpieces must be rigidly and accurately clamped or tack welded to prevent lateral motion during welding. Clamp distance is highly important and is related to stock thickness. On continuously fed, moving-part setups and thin metal processes (where clamp distance would be too small), clamps may not be feasible. In these cases, a Z-bar and nosepiece tooling arrangement is used to help position the edges to be welded.

In applications in which the mashed surface must be as flat and burr-free as possible after welding to facilitate porcelain enameling and to present a good appearance, a bar-type electrode is used against the surface to be enameled, and an electrode wheel is used against the other surface. The bar-type electrode may require periodic dressing to avoid excessive grooving and subsequent loss of current density. When a premium finish appearance is required, the weld can be ground or roll planished to remove surface imperfections.

In steel coil joining, it is sometimes desirable for the final thickness of the mash seam weld to be similar to the single sheet thickness. To minimize the thickness gain from welding, pre- and/or postweld planishing rolls are used. These rolls are hard steel wheels, typically 100 mm (4 in.) in diameter and 20 mm (0.75 in.) in width. Planishing rolls are typically loaded to 22 kN (5000 lbf) to cold work the weld. In this way the overthickness may be held to as little as 5%. Also, the overlap may be retracted slightly after the preweld planish in order to further limit over-thickness.

The highest quality mash seam welds are made in low-carbon steels and stainless steels. The process is widely used in the manufacture of refrigerators, stoves, laundry equipment, and other products that receive porcelain enamel coatings. Mash seams are gaining popularity in automotive applications for creating tailored blanks that reduce weight and material loss in certain large stampings (for example, body sides and doors), reduce manufacturing complexity, and reduce the number of components and welds required to make finished automotive subassemblies.

Because of their narrow plastic range, nonferrous metals generally cannot be mash seam welded.

Butt Seam Welds

Butt seam welds can be classified as either autogenous or exogenous.

Autogenous (nonfilled) butt seam welds are made by a special seam welding technique in which the two abutting edges are heated and lightly forged together. There is a slight depression where the electrode wheels compress the plastic metal. This type of weld usually has low strength and a reduced cross-sectional area. Resistance tube welding may be a better alternative to this process.

Exogenous (Filled) Butt Seam Welds. The strength of a butt seam weld can be increased by adding filler metal to the outer surface of the weld, against the electrode. Filler metal, in the form of a foil or a shaped wire, is introduced on one or both surfaces adjacent to the joint as the workpiece is passed between conventional seam welding electrodes (Fig. 3). This technique produces a smooth, nonoverlapping seam that is high in strength with good appearance. Highest quality exogenous butt seam welds show nugget penetration to the filler-workpiece interface, complete filler bonding, and

smooth, regular surface contours. The only edge preparation required is to ensure that the sheared edges are clean and straight without excessive burr or gap when they are butted together. The filler acts as a bridge to:

- DISTRIBUTE THE WELDING CURRENT MORE EVENLY TO BOTH SHEETS
- CONCENTRATE THE CURRENT IN THE JOINT
- HELP CONTAIN THE MOLTEN NUGGET AS IT GROWS AND THEN COOLS
- PROVIDE METAL FOR A SLIGHTLY RAISED BEAD, WHICH WILL ADD STRENGTH

The variables having the greatest effect on the tensile strength of filled butt seam welds are current, speed, size of the gap between the edges of the butted workpieces, and work metal thickness. Surface grinding will improve cosmetic appearance but also may reduce weld strength.

For the commonly used thicknesses of low-carbon steel, welding speeds similar to those used in lap seam welding are permissible, providing that the gap is no wider than 0.38 mm (0.015 in.). Either pulsed or continuous current can be used.

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

Processing Equipment

A seam welding machine is similar in construction to a spot welding machine, except that one or two electrode wheels are substituted for the spot welding electrodes.

Seam Welding Machines

In general, seam welding is done in a press-type resistance welding machine. Most seam welding machines are powered by alternating current (ac), either three-phase or single phase; some are designed for use with direct current (dc). Others superimpose a high frequency (16.5 kHz) on the basic power line. Stored-energy seam welding machines have been built, but this type finds little use. Direct current frequency converter power supplies are used to tailor custom pulsation schedules.

Equipment for seam welding must be capable of:

- DELIVERING LOW-VOLTAGE, HIGH-AMPERAGE CURRENT
- SUPPORTING THE ELECTRODES AND WORKPIECE AND APPLYING THE ELECTRODE FORCE
- MOVING THE WORKPIECE AND/OR DRIVING THE ELECTRODES
- REGULATING, TIMING, AND SEQUENCING THE APPLICATION OF THE WELDING CURRENT, FORCE, AND COOLING WATER (IF APPLIED)
- CAREFUL PART HANDLING, SUCH THAT EXTRANEOUS FORCES ARE NOT IMPOSED DURING WELDING

Electrode Force and Support. The upper electrode wheel is mounted to, and insulated from, the operating head. The head, which is actuated by a direct-acting air or hydraulic cylinder, applies the electrode force. The lower electrode is either a wheel, a platen, or a mandrel and is mounted on a supporting arm, table, or knee. This lower support can be made adjustable for applications in which the work metals must be maintained at a constant level above the floor.

Electrode or Workpiece Drives. Workpieces are moved by rotating the electrodes with knurl or friction drive, by direct drive of the wheel shaft, by a driven workpiece and idling wheels, or by clamping the workpieces to a bar electrode and moving the bar electrode (Fig. 3).

Weld travel tends to be continuous on thin steel sheets (less than 1.7 mm, or 0.067 in.), whereas it is intermittent on thick sheets (greater than 3.0 mm, or 0.118 in.). The need for intermittent weld travel arises from the longer weld time requirements of thick steel (Eq 1).

Knurl Drive versus Friction Drive. In a knurl drive or friction drive, one or both of the electrodes are rotated by a knurl or friction wheel on the peripheral surface of the electrode wheel, to provide nearly constant linear speed regardless of the diameter of the electrode wheel. The knurl drive, in which ridges or beads on the drive wheel aid in turning the electrode, minimizes slippage and is more positive than the friction drive, in which the turning surface of the drive wheel is smooth. The knurled wheel also removes some of the pickup from the electrode wheels. A knurl drive is used when welding coated metals, such as galvanized steel and terneplate, in any application in which the electrodes are likely to pick up material from the work metal, and for scaled stock that cannot be precleaned. A knurl drive usually is not employed if good cosmetic appearance of the weld is important. Knurl or friction drives can be used only with electrode wheels large enough in diameter to allow clearance.

Gear drive is used if small-diameter electrode wheels cannot be driven by the use of knurled or friction wheels because of interference, or if the application cannot tolerate an electrode wheel that has been roughened by a knurled drive roll. With gear drive, in which the mounting shaft of the electrode wheel is driven, the speed of welding decreases as the wheel wears down.

In a standard seam welding machine, interference may exist at some minimum distance between electrode wheel centers. If one wheel must be small to clear the workpiece, the other must be correspondingly large. If the ratio of the electrode wheel diameters is greater than 2 to 1, the smaller wheel should be driven, to minimize slippage. Welding speed can be kept constant in spite of wheel wear by a variable-speed gear-driven mechanism.

Movable Carriages. When a mandrel or a platen is used as the lower electrode (Fig. 3), the operating head carrying the upper electrode may be mounted in a carriage. The carriage is moved by an air or hydraulic cylinder, or by a motor-driven screw, and thus the upper electrode is passed over both the workpiece and the lower electrode. The upper electrode is free-wheeling, but it may be equipped with an idling knurl for dressing. Sometimes it is necessary to use a high-slip drive to assist on thin materials, to prevent wrinkling. In some machines, the workpiece is clamped to a bar-type lower electrode and moved under an idling fixed-position upper electrode wheel.

Types of Machines. There are four basic types of resistance seam weld machines: circular, longitudinal, universal, and portable.

Circular. The axis of rotation of the electrode wheels is at right angles to the front of the machine (Fig. 2a). This type of machine is used for circular work, such as for welding the heads on containers and for flat work requiring long seams. Head pivot capability for welding on an inclined plane is optional.

Longitudinal. The axis of rotation of the electrode wheels is parallel to the front of the machine (Fig. 2b), and throat depth is typically 305 to 915 mm (12 to 36 in.). This type of machine is used for welding short longitudinal seams in containers, for attaching pieces to containers, for coil joining, and for similar work. Machines with traveling heads or traveling electrodes, in which a mandrel or a platen is used for the lower electrode, are normally of the longitudinal type.

Universal. A swivel-type head and interchangeable lower arms allow the axis of rotation of the electrode wheels to be set either at right angles or parallel to the front of the machine.

Portable. The workpiece is clamped in a fixture, and a portable welding head is moved over the seam, either manually or by using a robot. This type of machine is used when the workpiece is too bulky to be handled by a regular machine or when it is more efficient to move the welding head rather than the workpiece. This type of machine is sometimes used for joining the roof and body sides on automobiles. The portable welding head is moved by motor-driven wheels, and an air cylinder mechanism provides the electrode force.

Common power sources used for seam welding are similar to those used for spot welding. They usually consist of a welding transformer, with a tap switch in the primary circuit, driven by a silicon-controlled rectifier switching system and a secondary circuit with electrodes for transferring the welding current to the work metal.

Controls for seam welding are generally similar to those for spot welding, except for differences related to the relative motion of the work and the electrodes. Most modern weld timers are capable of generating impulse weld schedules for

seam welding. (Higher impulse frequencies for welding thin stock can be obtained using special high-frequency systems, although complete machine redesign may be necessary due to transformer and throat area limitations that are directed by the frequency.) Tap switches and a phase-shift heat control are used as in spot welding for changing the transformer output current. In theory, direct feedback current regulation would be a desirable feature in seam welding, and some work has been done to develop and improve this. Alternating current is inherently more stable in secondary root-mean-square (rms) current than dc, because in ac there is essentially no current memory from one half-cycle to the next, or from one impulse to the next.

Selection of Electrodes

Alloy type and wheel configuration are the primary factors that determine electrode selection.

Class 1 Copper. Electrode wheels made of Resistance Welder Manufacturers Association (RWMA) class 1 copper (RWMA No. 1.16200) have been used for seam welding of aluminum and magnesium alloys, galvanized steel, and tin-plated steel. The minimum electrical conductivity of class 1 copper is 80% International Annealed Copper Standard (IACS). Recently, this material has been replaced by hot-forged and heat-treated RWMA class 2 copper in the overaged condition (RWMA No. 1.18200). With adequate cooling and proper parameters, the high electrical and thermal conductivities of this material keep the electrode-workpiece interface at a temperature below the point where metallurgical discontinuities are formed near the weld surface.

Class 2 Copper. Seam welding of low-carbon and low-alloy steel is usually done with electrodes made of hot-forged and heat-treated RWMA class 2 copper (RWMA No. 2.18200). Minimum conductivity is 75% IACS. Minimum hardness is typically 65 HRB. Class 2 also works well with all types of coated steel, but the metallurgical optimization of weld parameters and provisions for wheel maintenance are critical to the success of welding coated steels. For longer electrode life, premium class 2 wheels are available in the 20% coldworked form, where a minimum hardness of 75 HRB may be specified. Coldworked wheels show no appreciable loss of conductivity over the forged class 2 material.

Class 20 copper (RWMA No. 20.15760) is also used for electrode wheels, with properties similar to those of class 2 premium wheels. Class 20 wheels are made using a powder metallurgy process that produces a pure copper product, dispersion-strengthened with alumina. The alumina adds hot strength and tends to reduce pickup during welding of coated steels.

Class 3 copper (RWMA No. 3.17510) is sometimes used for seam welding materials with lower electrical conductivities, such as stainless steel, Nichrome, and Monel alloys. However, class 3 is used with special ventilation only because of the health hazard of atmospheric beryllium when welding or machining with class 3 material. (Beryllium-free class 3 alloy RWMA 3.18000 is also available.) Class 3 wheels have lower electrical conductivity (45% IACS), so they tend to run hot.

Sizes and Shapes. Electrode wheels range in diameter from 50 to 610 mm (2 to 24 in.). Popular sizes range from 100 to 305 mm (4 to 12 in.), with widths from 6 to 19 mm ($\frac{1}{4}$ to $\frac{3}{4}$ in.). Edge contours may be flat, radiused, beveled flat, or angled. In lap seam welding, weld quality seems to be easiest to control with a radius edge, as discussed above. The need for nonradius contours is usually a matter of cosmetic appearance, or due to a tool access limitation. Mash seam welders very often use a flat-edge wheel, as in Fig. 1(b).

Resistance Seam Welding

Michael J. Karagoulis, General Motors Corporation

Weld Quality and Process Control

Welding Parameters. It is best to design the entire process around proven weld parameters that have been metallurgically validated on workpieces very similar to actual production parts. Sensitive parts of the weld typically are starts, stops, corners, adjacent shunt paths, intersecting seams, and areas of poor metal fit. On coated metal, parameters should be flexible enough to handle normal coating variations.

To select starting weld parameters, use the guidelines presented in the section "Fundamentals of Lap Seam Welding" in this article and Table 1. For process design, the givens are usually material thickness, available pulsation capability, and wheel diameter. From these three independent variables will spring all of the dependent variables (for example, speed, force, current, and so on) from Eq 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11. At this point, estimates of *S* and *L* would be helpful in order to begin the calculations. Use working values that are not too near the extreme limits of either the material, the weld tool, or the plant facilities. To make leak-tight seams, weld spots should have approximately equal length and width. Ideally, the same welding parameters should be used for the entire length of the weld.

Verify the quality of resulting welds using chisel tests, metallographic sections, pressure tests, or fatigue tests, depending on product requirements. Record target values for speed, force, pulsation, and water cooling (if applicable). Record tap setting and lower and upper rms secondary current limits for acceptable weld quality. Record the actual secondary current waveform to see that it is acceptable (as in Fig. 8) and consistent throughout the weld. Process changes should be made only on the basis of data.

Establish production procedures for maintenance of electrode wheels and cooling sprays (if applicable). Check process parameters against required values frequently, and make adjustments and repairs as needed.

Nondestructive testing (for example, resistivity, ultrasonic testing, dye penetrant, magnetic particle, or eddy current) may be useful in some low-volume testing applications. However, such techniques should come into use only after the optimum parameters are verified metallographically and the process is well understood. In many instances, much can be observed from the external appearance of a lap seam weld, provided the weld surface is not planished or scarfed after welding.

Coated Steels. For a process that has been properly set up and optimized as described in the section "Welding Parameters" in this article, the difference in parameters between coated and uncoated steel lies mainly in weld current. Steels with low-melting metallic coatings require more current than uncoated steels. Organic coated steels require about the same current as uncoated steels (although the current range for making good welds will be smaller for the organic coated steels). Some coatings (for example, zinc and aluminum) are particularly active at the electrode-workpiece interface. For these surface-active coatings, speed, force, and pulsation are selected to keep the surface temperature of the weld below the point where metallurgical discontinuities are developed. Diligent maintenance of the wheel condition and the cooling system cannot be overstated for sensitive applications.

Flash Welding

H.J. Latimer and R.B. Matteson, Taylor-Winfield Corporation

Introduction

FLASH WELDING (FW) is a resistance welding process in which a butt joint weld is produced by a flashing action and by the application of pressure. In basic terms, it is a melting and a forging process. The process is capable of producing welded joints with strengths equal to those of the parent materials. Figure 1 is a schematic representation of a typical flash welding operation.

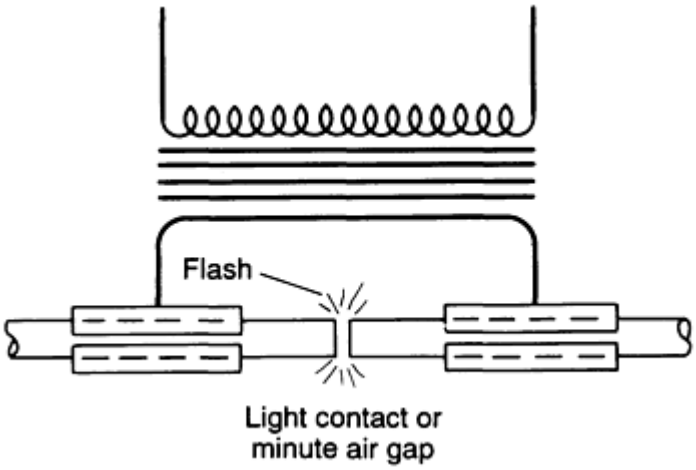

FIG. 1 TYPICAL FLASH-WELDING SETUP SHOWING AIR GAP PRESENT BETWEEN ENDS OF TWO BARS

Flash welding is used to join metallic parts that have similar cross sections, in terms of size and shape. The process lends itself to joining nearly all grades of steel, aluminum, brass, and copper parts, in addition to selected dissimilar materials.

Flash Welding

H.J. Latimer and R.B. Matteson, Taylor-Winfield Corporation

Process Applications

Materials with cross sections ranging from 65 to 13,000 mm^2 (0.1 to 20 $in.^2$) are commonly flash welded. The process is also used to manufacture components of solid and tubular shape, in addition to strips and complex configurations. Flash welding is commonly used to weld rings that range in diameter from a few inches (Fig. 2) to as much as 4.6 m (15 ft) (Fig. 3). The aircraft engine industry uses flash welded rings made from heat-resistant materials in accordance with military specifications for jet aircraft.

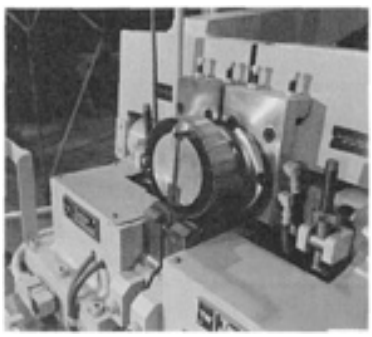

FIG. 2 FLASH-WELDING MACHINE USED TO FABRICATE A COILED STEEL STRIP INTO A SMALL-DIAMETER RING WITH A FLANGE

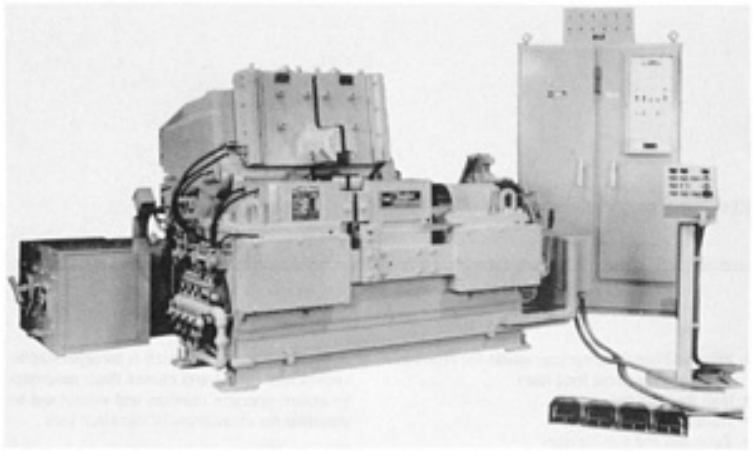

FIG. 3 FLASH-WELDING MACHINE WITH CAPACITY TO WELD RINGS UP TO 4.6 M (15 FT) IN DIAMETER

Other flash-welding applications include:

- CHAIN LINKS
- TRANSMISSION BANDS
- AUTOMOTIVE FLYWHEEL RING GEARS
- STRIPS THAT ARE JOINED FOR CONTINUOUS PROCESSING LINES
- WIRE AND BAR DRAWING OPERATIONS FOR CONTINUOUS STAMPING PRESS FEED LINES
- ROLL FORM LINES
- AIRCRAFT LANDING GEAR
- TUBE AND ROD EYE CLEVISES
- BAND-SAW BLADES (FIG. 4)
- DRILL EXTENSIONS USING TWO DIFFERENT MATERIALS
- MITER JOINTS FOR AUTOMOTIVE AND HOME WINDOW FRAMES
- CRANKSHAFT COUNTER WEIGHTS
- ALUMINUM-TO-COPPER ELECTRICAL TRANSITION FOR POWER TRANSMISSION
- ANODES USED IN ALUMINUM SMELTERS

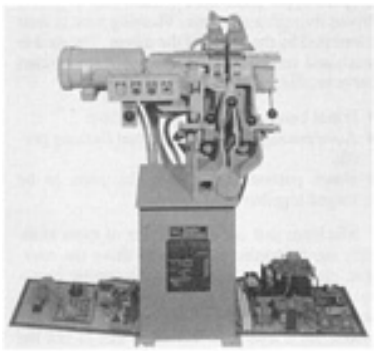

FIG. 4 FLASH-WELDING MACHINE INSTALLATION EQUIPPED TO WELD BAND-SAW BLADES

H.J. Latimer and R.B. Matteson, Taylor-Winfield Corporation

Processing Equipment

A typical flash-welding machine consists of seven major components:

- A MACHINE BED THAT HAS A FIXED PLATEN ATTACHED TO IT, AS WELL AS A SET OF ELECTRICALLY INSULATED WAYS THAT SUPPORT A MOVABLE PLATEN
- A MOVABLE PLATEN, WHICH IS GENERALLY MOUNTED ON THE ELECTRICALLY INSULATED WAYS THAT ARE ATTACHED TO THE MACHINE BED
- TWO CLAMPING ASSEMBLIES, ONE OF WHICH IS RIGIDLY ATTACHED TO EACH PLATEN TO BOTH ALIGN AND HOLD THE PARTS TO BE WELDED IN PLACE
- EQUIPMENT FOR CONTROLLING THE MOTION OF THE MOVABLE PLATEN
- A WELDING TRANSFORMER WITH ADJUSTABLE TAPS
- CONTROLS AND MONITORS FOR MACHINE FUNCTIONS
- A VENT/FLASH CATCHER, WHICH IS INCORPORATED TO COLLECT ANY FUMES AND EXCESS FLASH MATERIALS TO ENSURE OPERATOR COMFORT AND SAFETY AND TO MAINTAIN THE CLEANLINESS OF THE WORK AREA

The movable platen of a flash welder can be driven by a number of different methods. The simplest type often uses a cam that is motor driven through a gear box. Flashing time is then controlled by the speed of the motor. The cam is machined to produce the desired flashing cam curve profile, including the:

- INITIAL BURN-OFF REGION OF LINEAR FLASH
- ACCELERATING CURVE FOR THE ACTUAL FLASHING PROFILE
- UPSET PORTION THAT CAUSES THE PARTS TO BE FORGED TOGETHER AFTER FLASHING

Machines that are either larger or more complex use hydraulic cylinders to drive the movable platen and to incorporate hydraulic servo-systems. Although it is possible to use a servovalve to directly control the position of the platen via a hydraulic cylinder, this is not the preferred method, because contamination by the oil is extremely difficult to prevent. The better approach is to use a hydraulic servoactuator, in which the servovalve operates on its own refined oil system and the oil that circulates through the platen cylinder is derived from another hydraulic source. This approach has been shown to be more reliable and more accurate, and to vastly improve servovalve life.

Controls and Auxiliary Equipment. Electrical controls on flash-welding equipment are designed to sequence the machine, control the weld current, and precisely control the platen position during flashing and upsetting. These controls often comprise programmable controllers, welding current controllers, and either motor or servovalve controllers. Silicon-controlled rectifier (SCR) contactors (solid-state switches) are used as the devices to control the flow of welding current from the power lines to the welding transformer. Older machines used ignitrons for this purpose, but SCRs have fully replaced them in recent years. Preheat and postheat cycles are often required procedures in flash welding operations; timers with phase-shift heat control are used to accomplish these important functions.

Power Sources. The most common source of power for flash welders is single-phase alternating current (ac) power. Flash welding transformers are KVA rated at 50% duty cycle.

Conversions From ac to dc Power. If an extremely large demand current is required and an adequate single-phase ac source is not available, then ac to dc conversion is employed using a three-phase transformer/rectifier. The most frequently used rectifier systems are the three-phase half-wave and three-phase full-wave types. In actual practice, no discernible differences in the weld produced by these two rectifier systems can be detected.

State-of-the Art Welding Unit Components. Devices that monitor and control selected process parameters are commonly incorporated into the latest flash welding units.

A linear ramp preflashing approach rate is usually built into the flashing cam and minimizes any tendency of the weld to freeze at the beginning of flashing. The term "flashing cam" is used regardless of whether the cam is a motor-driven machined cam or if the position curve is generated electronically.

Natural Log Flashing Curves. Numerous technical articles have been published on what constitutes the best flashing curve. Although engineers are divided on this issue, it has been shown that the use of natural log curves results in significantly better welds than are produced using any other curve. The natural log system conforms to the natural heat-transfer characteristics of the metal being welded, thereby creating a flashing progression that parallels the development of heat at the interface with a natural log gradient toward the clamp.

Ramp Turn-On of SCRs. Not to be confused with the linear approach ramp, this control device slowly and progressively turns on the SCRs at the beginning of the flashing cycle. Because the magnetic condition of a weld transformer may be unknown at the end of a previous weld, the ramp turn-on device is used to restore the transformer to a known condition. This greatly extends the life of the transformer itself, in addition to the SCR contactor, because it avoids the high inrush of current that would have occurred when the next weld was initiated.

No Phase Shift During Flashing. This control feature ensures that full voltage will be applied to the dies whenever flashing conditions are present, except during the ramp turn-on interval. A phase shift can reduce the average voltage, but does not reduce the peak voltage. During the phase-delay period of the voltage waveform, the platen continues to travel forward until a peak voltage is suddenly applied, causing violent flashing and deep cratering. Although the pyrotechnics of a phase-shift flashing action can be quite impressive, the resulting weld will be a disaster. The best flashing action is relatively subdued and produces flash particles of significantly lower intensity and size.

The oxygen depletion system used in this process is a patented method of combusting the oxygen that would otherwise exist in the weld interface region. In actual use, the oxygen depletion system does more than remove oxygen. By heating the gases in the interface region, the ionization voltage is reduced and higher flashing currents can be sustained at relatively low flashing voltages.

Upset Welding

W.R. Kanne, Jr., Westinghouse Savannah River Company

Introduction

UPSET WELDING (UW) is a resistance welding process utilizing both heat and deformation to form a weld. The heat is produced by resistance to the flow of electrical current at the interface of the abutting surfaces to be joined. The deformation results from force on the joint in combination with softening from the electrical resistance heat. Upset welding typically results in solid-state welds (no melting at the joint). The deformation at the weld joint provides intimate contact between clean adjoining surfaces, allowing formation of strong metallurgical bonds. If any melting does occur during upset welding, the molten metal is typically extruded out of the weld joint area.

A wide variety of shapes and materials can be joined using upset welding in either a single-pulse or continuous mode. Wire, bar, strip, and tubing can be joined end to end with a single pulse of welding current. Seams on pipe or tubing can be joined using continuous upset welding by feeding a coiled strip into a set of forming rolls, resistance heating the edges with wheel electrodes, and applying a force to upset the edges together.

Equipment for single-pulse upset welding is relatively simple. It consists of a pneumatic or hydraulic system for force application, transformers or a bank of diodes as a source of electrical current, and a standard resistance-welding controller. A data acquisition system usually is employed to record the force, current, voltage, and motion of the weld head during welding. Equivalent welds have been made using both alternating and direct current.

Upset welds have similar characteristics to inertia friction welds, which are also solid-state welds. The amount of deformation is usually less for upset welds, and the deformation can be more precisely controlled using upset welding. For example, a pipe butt weld made using inertia friction welding will have a large upset on both the inside and outside, whereas an upset weld can be controlled, through joint design and welding parameters, to have essentially no internal upset (Fig. 1).

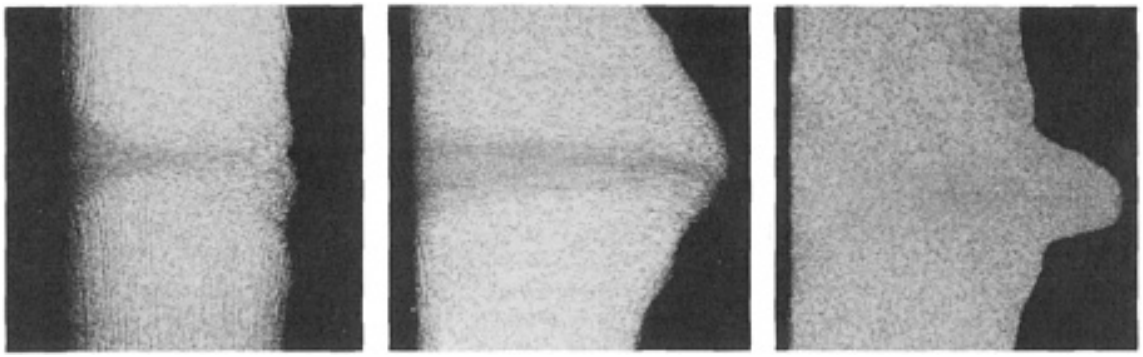

FIG. 1 UPSET WELD CONFIGURATIONS IN BUTT WELDS OF PIPE WITH AN OUTSIDE DIAMETER OF 25 MM (1 IN.) AND A WALL OF 3 MM (0.1 IN.). UPSET HAS BEEN MACHINED FROM THE OUTSIDE SURFACE (ON LEFT). Upset Welding

W.R. Kanne, Jr., Westinghouse Savannah River Company

Advantages

Solid-state upset welding has advantages compared to typical fusion welding processes. These advantages are due to the simplicity of the welding process and the resulting solid-state weld microstructure. These advantages include:

- *SPEED:* THE UPSET WELDING PROCESS IS FAST (USUALLY LESS THAN 1 S).
- *EASE OF CONTROL:* THE PROCESS HAS ONLY THREE PRIMARY VARIABLES (CURRENT, FORCE, AND TIME).
- *FEWER DEFECTS:* TYPICAL FUSION WELDING DEFECTS SUCH AS POROSITY, MISSED JOINTS, INCOMPLETE FUSION, SPATTER, AND SOLIDIFICATION CRACKING DO NOT OCCUR IN UPSET WELDS.
- *ENHANCED WELD PROPERTIES:* THE METALLURGICAL PROPERTIES OF THE WELD METAL AND HEAT-AFFECTED ZONE IN UPSET WELDS ARE THOSE OF HOT-WORKED MATERIAL. IN OTHER WORDS, THE STRENGTH OF THE WELD ZONE IS NOT REDUCED TO THAT OF AN ANNEALED STRUCTURE, AS IN FUSION WELDS.
- *SIMPLICITY OF EQUIPMENT:* UPSET WELDING EQUIPMENT IS NOT COMPLEX, INVOLVES NO ROTATING PARTS, AND REQUIRES MINIMAL MAINTENANCE.
- *LESS-STRICT COMPOSITION REQUIREMENTS:* MINOR ALLOYING ELEMENTS DO NOT AFFECT UPSET WELD QUALITY, AND THUS ATTENTION TO ALLOY COMPOSITION FOR WELDABILITY CAN BE ELIMINATED.
- *ABILITY TO JOIN DIFFICULT-TO-WELD MATERIALS:* ALLOYS NORMALLY CONSIDERED UNWELDABLE CAN BE JOINED BY UPSET WELDING. FOR EXAMPLE, A VARIETY OF STAINLESS STEELS (INCLUDING A-286), SUPERALLOYS (INCLUDING TD NICKEL), REFRACTORY METALS (INCLUDING TUNGSTEN), GRADE 2 TITANIUM, AND ALUMINUM ALLOYS (INCLUDING 2024) HAVE BEEN SUCCESSFULLY UPSET WELDED.

The effect of welding conditions, other than the basic parameters of force, current, and time, is generally minimal. Surface roughness usually has little effect, because it is overshadowed by the deformation that takes place during welding. Surface

cleanliness and welding atmosphere may or may not be important depending on the amount of deformation that occurs to break up any oxide present before, or formed during, welding.

Limitations

A perceived limitation of the UW process is the lack of a good nondestructive testing technique for determining the quality of solid-state bonds. Normally, control of process variables is sufficient to ensure quality. Nondestructive methods, such as ultrasonics, are being applied to solid-state welds for determination of bond quality. For upset welding of large parts, the peak power drawn from the electrical supply may be a disadvantage.

Upset Welding

W.R. Kanne, Jr., Westinghouse Savannah River Company

Types of Upset Welds

Fixturing of the parts to be joined is usually necessary to achieve alignment of the parts, carry the electrical current to the joint area, and confine deformation to the joint area. In some cases the increased heat at the joint--which is caused by the higher electrical resistivity at the joint--is sufficient to limit deformation to the weld joint area. Electrodes are made from class 2 copper, which may be faced with a harder material such as copper-infiltrated tungsten carbide. Fixturing used to join two cylindrical parts consists of a pair of electrodes confined in an alignment sleeve (Fig. 2). The metallurgical structure of the weld area is that of a hot-worked material with a good diffusion bond across the weld interface, as can be seen in Fig. 1. This microstructure results in higher strength in the weld area than can be achieved for fusion welds (Fig. 3).

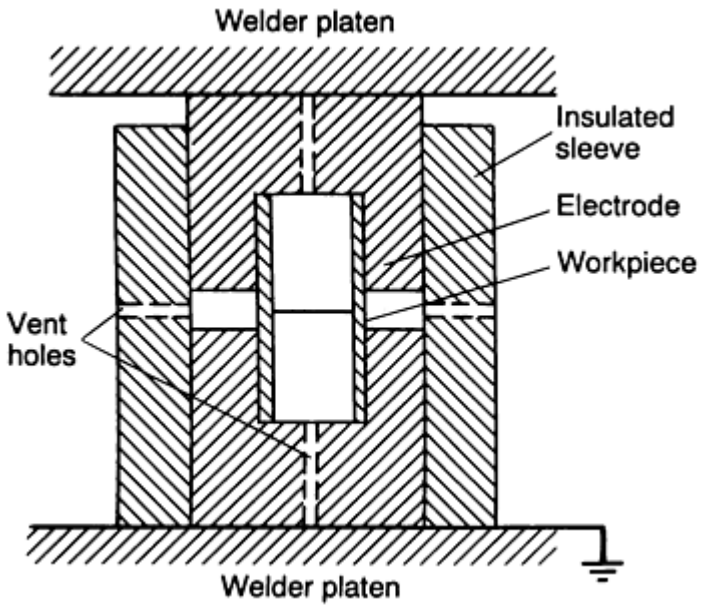

FIG. 2 FIXTURING ARRANGEMENT FOR UPSET WELDING OF CYLINDRICAL PARTS

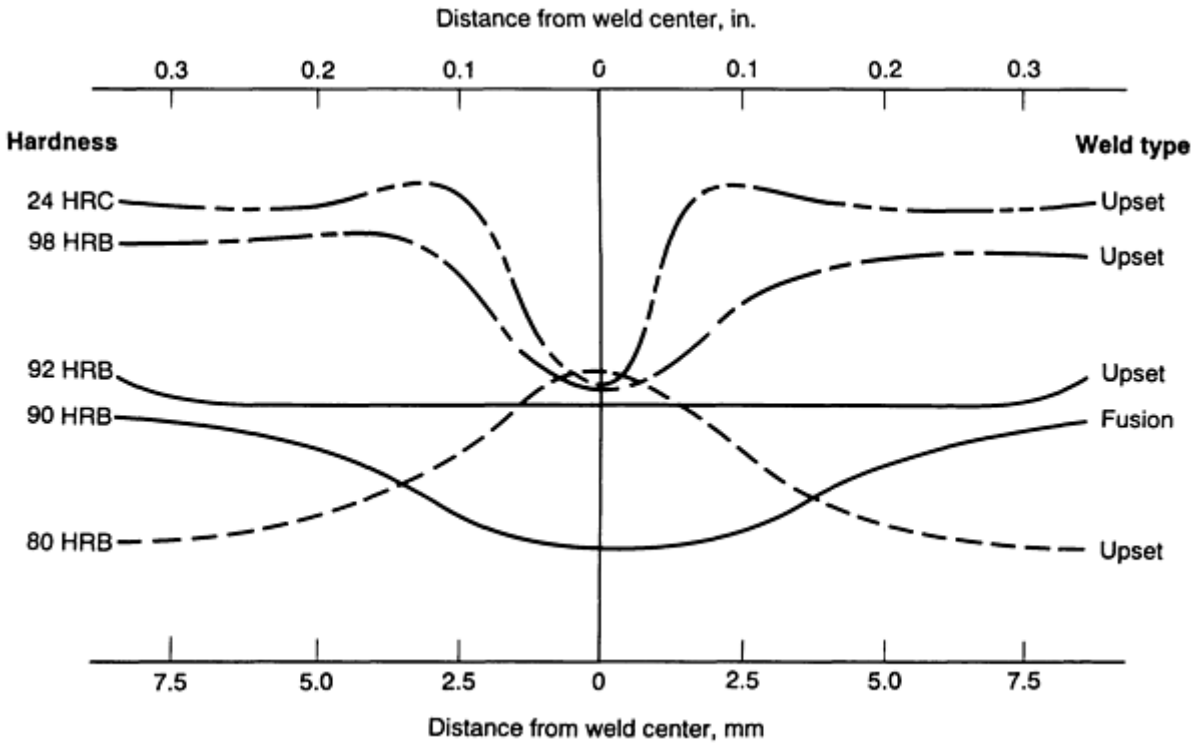

FIG. 3 HARDNESS ACROSS UPSET WELDS AND IN MATERIALS OF VARIOUS STRENGTHS COMPARED TO FUSION WELD HARDNESS. NOTE THAT THE WELD AREA HARDNESS (AND THEREFORE STRENGTH) IS GREATER FOR THE UPSET WELDS THAN FOR THE FUSION WELD.

Plug welds are a type of upset weld that requires little fixturing. Plug welds up to 125 mm (5 in.) in diameter are used to seal the fill holes of canisters employed in the long-term disposal of high-activity nuclear waste. The canisters, which are made from 304L stainless steel, are 610 mm (24 in.) in diameter and 3 m (118 in.) in height. The plug configuration is shown in Fig. 4(a). The considerable upsetting that occurs during the welding process results in a solid-state weld (Fig. 4b). Typically, these welds are made using pressure of 300 kN (75,000 lbf) with 230,000 A current applied for 1.5 s. The resulting welds have the high reliability required for long-term containment of radioactive material.

Alternative Energy Supply

A homopolar generator is an alternative method for supplying the electrical current for upset welding. Homopolar generators store energy in a large flywheel and then quickly convert the stored energy to electrical energy. The demand on utility power lines is thus spread over a considerable time period, yet the high peak power required for upset welding large parts can be met over a period of about 1 s. This low demand on the electrical grid is the principal advantage of the homopolar generator, whereas lack of good control of the current waveform and the complexity of the equipment are drawbacks. The application of homopolar generators to resistance upset welding was developed in the late 1970s and has since been applied to welding of pipes up to 168 mm (6.6 in.) in diameter.

High-Frequency Welding

Warren Smith and Julian Roberts, Thermatool Corporation

Introduction

HIGH-FREQUENCY WELDING is a welding process in which the heat source used to melt the joining surfaces is obtained from high-frequency (HF) alternating current (ac) resistance heating. High-frequency current has certain characteristics that make it useful for welding. Unlike direct current (dc) or low-frequency alternating current, HF current tends to flow at high densities along surfaces (skin effect) and seeks adjacent parallel surfaces for its return path (proximity effect). This means that the heating and subsequent melting can be efficiently concentrated and focused to the surfaces where it is needed.

In nearly all HF welding processes, the joining surfaces are mechanically squeezed together (upset) after they are melted. This procedure helps produce a high-quality weld by squeezing out residual oxides and molten metal, which are detrimental to weld integrity. The removal of molten metal from the weld zone is beneficial because it eliminates the potentially harmful effects associated with cast structures, such as lower fracture toughness and poorer corrosion resistance. The upset also hot-works the bond plane and subsurface material, which can result in enhanced properties.

The tubemaking incorporates the simplest method of controlling HF currents, that is, the generation of an edge "V." High-frequency currents can be supplied to the welding process or workpiece by using either an induction coil (known as high-frequency induction welding, HFIW) or electrical contacts (known as high-frequency resistance welding, HFRW). The

edge "V" is a series component of the circuit (Fig. 1). Because of proximity and skin effects, current flow is concentrated across the full face width of the strip edges, resulting in controlled surface melting and subsequent welding.

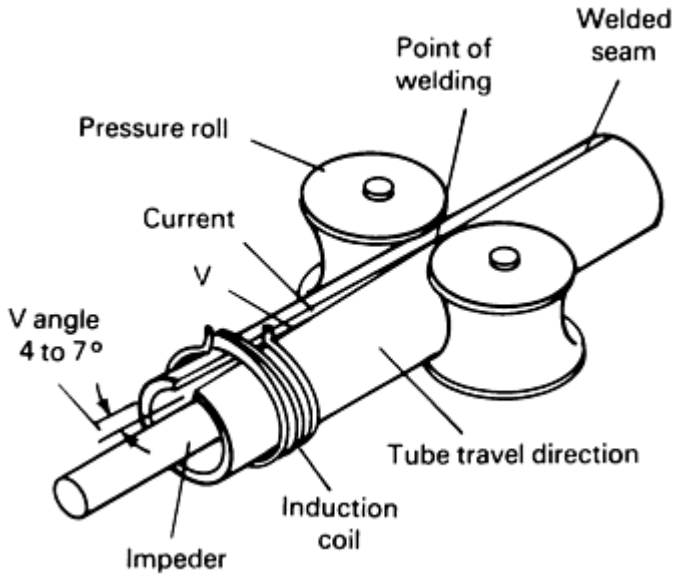

FIG. 1 JOINING A TUBE SEAM BY HIGH-FREQUENCY INDUCTION WELDING

In this process, a coil of strip material is first formed into a longitudinal hollow on a forming mill. The two edges of the strip are then HF welded and squeezed together to form a continuous welded seam.

Materials that can be successfully HF welded into tube and pipe include carbon steels, stainless steels, aluminum, copper, brass, and titanium. Exceptions are materials that are unstable at welding temperatures, have a negligible hot-work capability, or experience property deterioration that cannot be subsequently recovered. Where necessary, a gas shield can be provided for reactive metals. Tube or pipe sizes fabricated by HF welding range in size from 13 to 1220 mm ($\frac{1}{2}$ to 48 in.) in diameter.

The advantages of HF welding are that it is well suited for high-speed welding and can weld a large range of product sizes and materials. Weld quality is not particularly sensitive to the presence of air, and special atmospheres are usually not needed. Weld quality is relatively (but not completely) tolerant of surface oxides and contamination.

The disadvantages of HF welding are that it is not well suited for low welding speeds and small-scale operations where welding is done by hand. HF welding must be done continuously; continuous welds cannot be made in stop/start operations because a discontinuity in the weld will usually occur.

High-Frequency Welding

Warren Smith and Julian Roberts, Thermatool Corporation

Applications

High-frequency welding is most suitable in applications that involve the continuous edge, or butt, joining of metals. The largest single use of HF welding is in the manufacture of tube and pipe. High-frequency welding is useful in the manufacture of certain types of heat-exchanger tube, where the edge of a rectangular strip is continuously welded onto the outside diameter of a tube to form a cooling fin. The fin can be welded around the tube in a spiral configuration (Fig. 2) or it can be straight and parallel to the pipe axis. The greatest volume of heat exchanger tube is made with low-carbon steel for both the tube and fins. However, other alloy combinations are growing in use, such as low-carbon steel fins on both

stainless steel and chromium/molybdenum alloy steel tubes, stainless steel fins on low-carbon steel and stainless steel tubes, and aluminum fins on cupronickel tube.

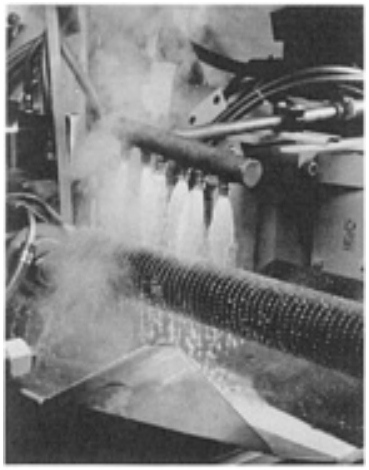

FIG. 2 MANUFACTURING A SPIRAL FIN TUBE USING HIGH-FREQUENCY WELDING

High-frequency welding can also be used for the production of structural shapes, such as T-sections and I- and H-beams. The specific shape is constructed by welding rectangular strips together to produce the desired configuration. A heating "V" is established as the strip materials are brought together.

The end, or butt, welding of metal strip is another application in which HF welding can be used. Single lengths of strip are welded to form a hoop that is subsequently formed into products such as wheel rims. High-frequency butt welding is also used to make long continuous lengths of strip by butt welding together a series of shorter lengths. This is done for certain manufacturing processes that require strip material longer than that which is commercially available.

High-Frequency Welding

Warren Smith and Julian Roberts, Thermatool Corporation

Equipment

Units for producing power for HF welding include vacuum tube oscillators and solid-state inverters. Depending on the application, frequency requirements can vary from 100 to 700 kHz, whereas power requirements vary from 30 to 1000 kW. Solid-state inverters produce frequencies ranging from 100 to 400 kHz. Vacuum-tube oscillators are available in frequencies up to 700 kHz. Because of their improved efficiency, solid-state units are replacing vacuum-tube units when frequency requirements permit.

Water-cooled copper conductors are used to carry the power to the coil or contacts. These conductors must be of minimum length and closely spaced to minimize impedance losses. The use of induction coils or electrical contacts to deliver HF power to the workpiece has specific advantages and disadvantages.

Induction coils are the least-efficient vehicle. They can only be used in applications where the geometry of the workpiece can act as a closed circuit to pick up the induced power (for example, the welding of tube). The advantages of an induction coil are that it is generally more convenient to use and requires less maintenance than contacts. Because the coils do not contact the workpiece, they leave no marks or scratches. Induction coils are usually made from a water-cooled copper conductor that has 1 to 3 turns.

The delivery of HF power through electrical contacts is more efficient than that through the use of coils because the power can be more directly and efficiently distributed to the weld area. The disadvantages of contacts are that they wear

out, require periodic replacement, and can scratch, mar, or leave deposits on the surface of a workpiece, which can be objectionable in some cases.

In the production of tube and pipe, induction coils are usually used to make the smaller diameters (<305 mm, or 12 in.) because their advantages outweigh the loss of efficiency. Contacts are generally used for larger diameters because of their greater efficiency. Contacts are also used in structural shapes and fin heat-exchanger tubes, as well as for end welding, because induction coils cannot induce the current densities necessary for welding.

Impeders are used to improve welding efficiency in tube and pipe production. Impeders that consist of one or more water-cooled cores of ferrite material are placed inside the tube parallel to and under the weld area. The reason for this is the existence of a power-dissipating circuit loop consisting of the inside surface of the tube being welded. The impeder increases the inductive impedance of this path, which bypasses the weld zone.

Inert gases are not needed for HF welding unless certain reactive metals are used. Argon is sometimes employed for the welding of stainless steel, and it is usually necessary for the welding of titanium. Although cleanliness of weld surfaces is not particularly necessary for easily welded materials, a lack of cleanliness is often the cause of problems in more-sensitive metals.

Personnel

A considerable amount of on-the-job training is required for new operators of HF welding equipment, as would be the case in any other mill process. High-frequency welding is a high-speed and, usually, high-volume process that often operates in conjunction with precision forming and handling equipment. The operating speed of tube mills ranges from 30 to 240 m/min (100 to 800 ft/min). A tube must be precisely formed prior to welding. An operator, therefore, must be familiar with both the operation of the welding equipment and the associated mechanical equipment for the forming or handling of the metal. Troubleshooting and repair of the welding equipment generally require specially trained personnel and are often conducted by the manufacturer. Improved and simplified systems for speed and/or power and weld temperature control are reducing the operator dependence of the process.

High-Frequency Welding

Warren Smith and Julian Roberts, Thermatool Corporation

Safety

Serious consideration must be given to the health and safety of welding operators, maintenance personnel, and other workers in the area of the welding operations. Good engineering practice must be followed in the design, construction, installation, operation, and maintenance of equipment, controls, power supplies, and tooling in order to conform to federal, state, and local safety regulations, as well as those of the company using the equipment.

Because HF welding power sources are electrical devices, they require all the usual precautions in handling and repairing such equipment. Voltages, which range from 400 to 25,000 V, can be either low or high frequency and may be lethal. To prevent injury, proper care and safety precautions should be taken while working on high-frequency systems and generators. Modern units are equipped with safety interlocks on access doors, as well as automatic safety grounding devices that prevent unsafe operation of the equipment. The equipment should not be operated when panels or high-voltage covers have been removed or when interlocks and grounding devices have been blocked.

High-frequency, high-voltage leads must be encased in grounded metal ductwork to ensure safety and to minimize electromagnetic radiation. Induction coils and contact systems should always be properly grounded for operator protection. Grounding lines should be kept short to minimize inductive reactance. Injuries from high-frequency power,

especially at the upper range of welding frequencies, tend to produce severe, local, surface tissue damage. Care should be taken that the magnetic field from the output system, particularly the output transformer, does not heat adjacent metallic sections by induction.

Metal or flux fumes should always be vented and the correct safety glasses should be worn in the presence of liquid metal or high-intensity visible radiation.

High-Frequency Welding

Warren Smith and Julian Roberts, Thermatool Corporation

Inspection and Quality Control

Numerous nondestructive and destructive tests can be used to determine weld quality. For example, weld quality can be determined nondestructively by eddy current testing (ASTM E 309 and ASTM A 426), ultrasonic testing (ASTM E 213 and ASTM A 273), flux leakage examination (ASTM E 570), and hydrostatic pressure testing (ASTM 450).

A number of destructive tests that utilize small samples of the product are identified in ASTM A 450. These tests include the flattening test (crush test), reverse flattening test, and the flare test.

Metallographic examination and microhardness testing can also be used to determine weld quality and the character of the adjacent heat-affected zone.

Electron-Beam Welding

Introduction

ELECTRON-BEAM WELDING (EBW) is a high-energy density fusion process that is accomplished by bombarding the joint to be welded with an intense (strongly focused) beam of electrons that have been accelerated up to velocities 0.3 to 0.7 times the speed of light at 25 to 200 kV, respectively. The instantaneous conversion of the kinetic energy of these electrons into thermal energy as they impact and penetrate into the workpiece on which they are impinging causes the weld-seam interface surfaces to melt and produces the weld-joint coalescence desired. Electron-beam welding is used to weld any metal that can be arc welded: weld quality in most metals is equal to or superior to that produced by gas-tungsten arc welding (GTAW).

Because the total kinetic energy of the electrons can be concentrated onto a small area on the workpiece, power densities as high as 10^8 W/cm^2 (10^7 W/in.^{2}) can be obtained (Ref 1). That is higher than is possible with any other known continuous beam, including laser beams. The high-power density plus the extremely small intrinsic penetration of electrons in a solid workpiece results in almost instantaneous local melting and vaporization of the workpiece material. That characteristic distinguishes EBW from other welding methods in which the rate of melting is limited by thermal conduction.

Principles of Operation

Figure 1 shows an electron-beam weld being performed at a weld chamber pressure of approximately 3 Pa (2×10^{-2} torr). The "beam" shown in Fig. 1 is the visible glow that results from the residual (ambient) gas molecules that are excited by the electrons in the actual electron beam.

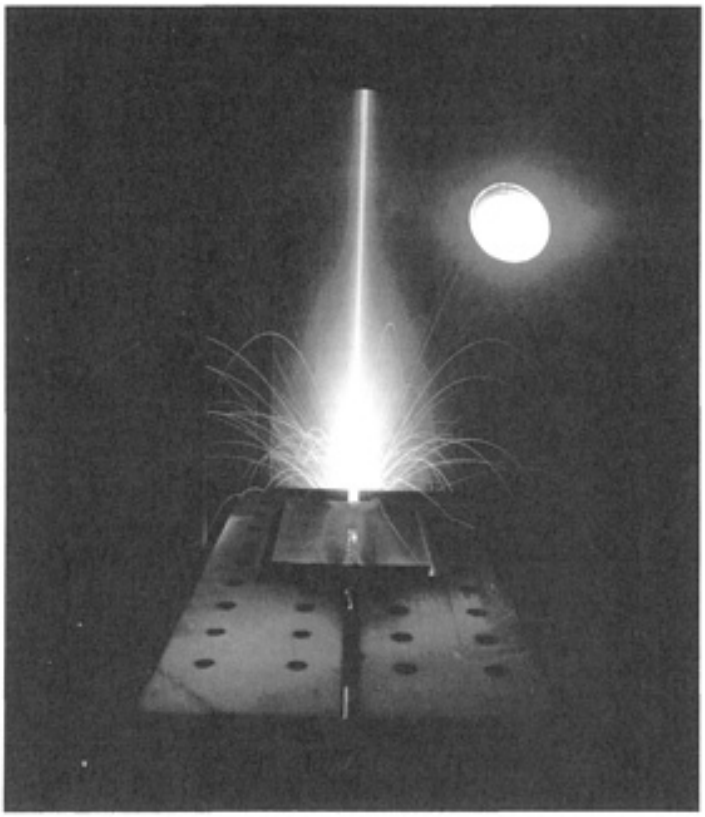

FIG. 1 WELD GENERATED BY AN ELECTRON BEAM OPERATING IN AN ENCLOSED CHAMBER MAINTAINED AT A PRESSURE OF APPROXIMATELY 3 PA (2×10^{-2} TORR)

Basically, the electron beam is formed (under high-vacuum conditions) by employing a triodestyle electron gun consisting of a cathode, a heated source (emitter) of electrons that is maintained at some high negative potential; a grid cup, a specially shaped electrode that can be negatively biased with respect to the hot cathode emitter (filament); and an anode, a ground potential electrode through which the electron flow passes in the form of a collimated beam. The hot cathode emitter (filament) is made from a high-emission material, such as tungsten or tantalum. This emitter material, usually available in wire, ribbon, or sheet form, is fabricated into the desired shape for being either directly or indirectly heated to the required emitting temperature of about 2500 °C (4500 °F).

Electrons emitted from the surface of the filament are accelerated to a high velocity and shaped into a collimated beam by the electrostatic field geometry generated from the cathode/grid/anode configuration employed, thus producing a steady stream of electrons that flows through an aperture in the ground plane anode. By varying the negative potential difference between the grid and cathode, this flow of electrons can be altered easily (i.e., gated "on/off" or ramped up/down to different levels) in a precisely controlled manner.

Diode-style electron guns are also employed, but not to the extent that triode-style electron guns are. In a diode gun, the specially shaped electrode (grid cup) is maintained at the same voltage as the emitter, thus making the diode gun a two-element (cathode and anode) device. With this design, the flow of electrons from a diode gun cannot be adjusted by simply varying a grid voltage, as is done with triode guns, and beam current adjustments are usually accomplished by varying the operating temperature of the cathode emitter instead.

Once the electrons exit the anode, they receive the maximum energy input allowable from the operating voltage being applied to the gun. Electrons then pass down through the electron beam column assembly and into the field of an electromagnetic focusing coil (a magnetic lens). This focusing lens reduces the diameter of the electron beam, as it continues in its passage, and focuses the stream of electrons down to a much smaller beam cross section in the plane of the workpiece. This reduction in beam diameter increases the energy density, producing a very small, high-intensity beam spot at the workpiece. In addition, an electromagnetic deflection coil (positioned below the magnetic lens) can be employed to "bend" the beam, thus providing the flexibility to move the focused beam spot. Figure 2 illustrates the main elements of the electron beam welding head. As described above and shown in Fig. 2, electrons are emitted from the cathode and are accelerated to high speed by the voltage between cathode and anode.

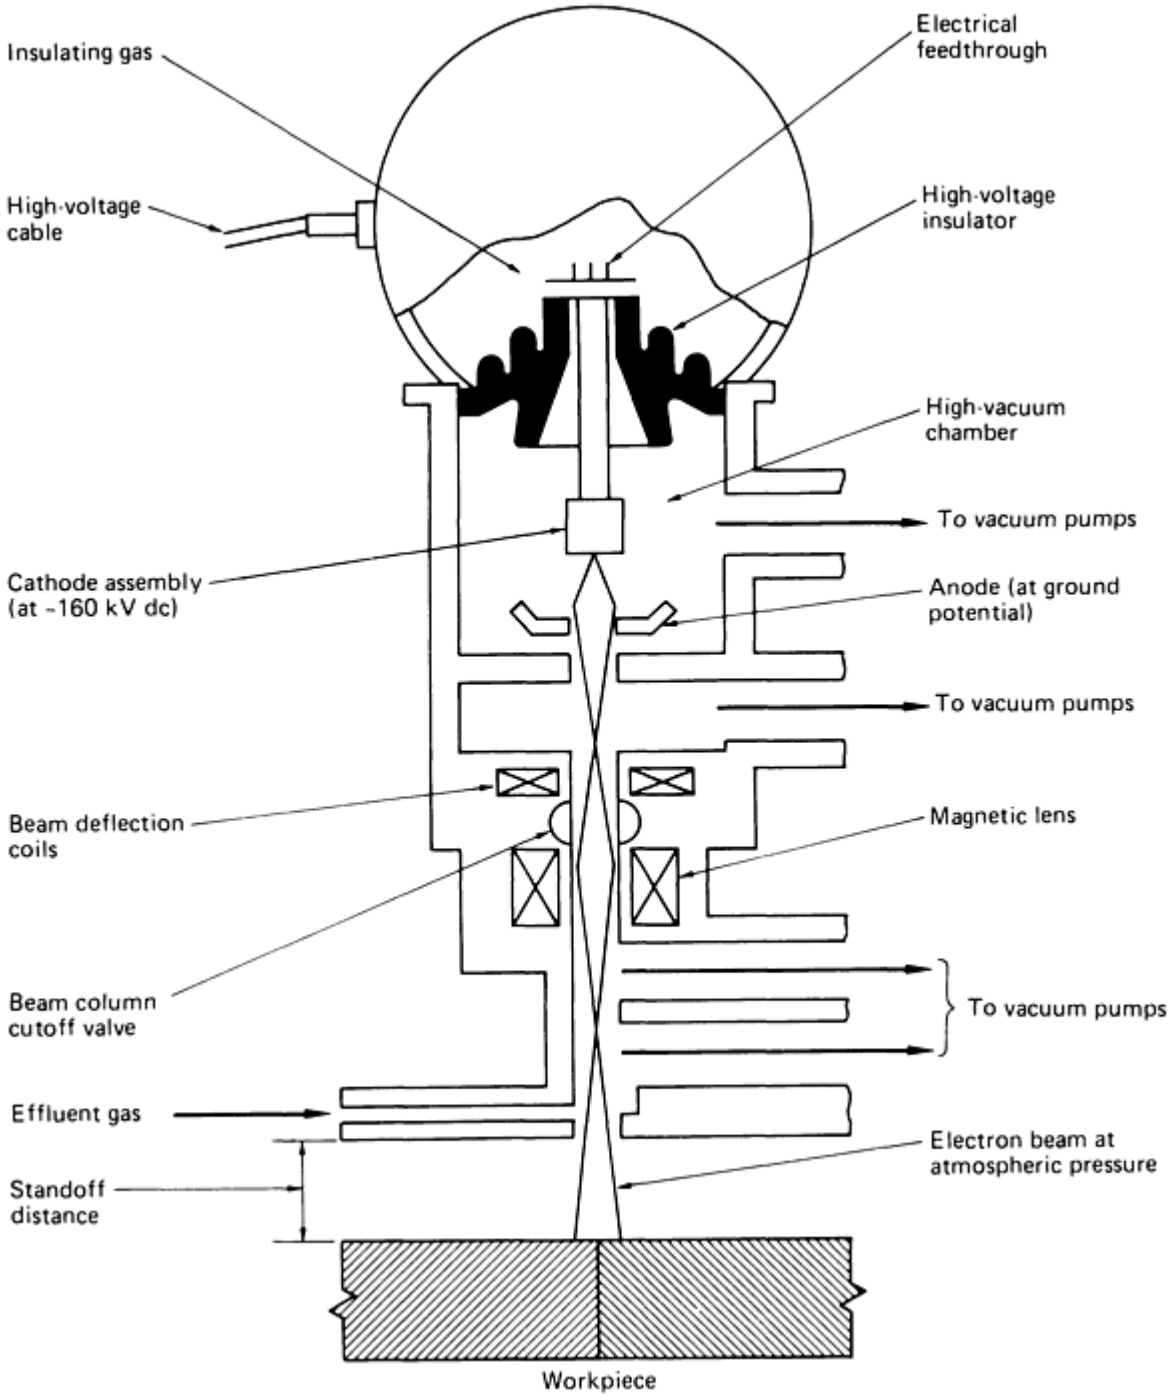

FIG. 2 SCHEMATIC SHOWING PRIMARY COMPONENTS OF AN ELECTRON-BEAM WELDING HEAD

The "gun" portion of an electron gun/column assembly generally is isolated from the welding chamber through the use of valves when desired. The gun may be maintained in a vacuum on the order of 13 mPa (1×10^{-4} torr) when the welding chamber is vented to atmosphere (for access reasons). This level of vacuum in the gun region is needed to maintain gun component cleanliness, prevent filament oxidation, and impede gun arcing (high-pressure short circuiting between electrodes at different voltages). During welding, this same degree of vacuum is required in both the gun column and welding chamber areas to minimize scattering of beam electrons by excitation collisions with residual air molecules as they traverse the distance from the gun to the workpiece. This type of interaction tends to produce a broader beam spot and a resulting decrease in energy density. Generally, electron guns are operated with applied voltages that vary from 30 to 200 kV, and they employ beam currents that range from 0.5 to 1500 mA. Electron-beam welding equipment with power levels up to 30 kW is common, and several units with power levels of up to 200 kW are commercially available.

Typically, high-vacuum EBW beams can be focused down to spot sizes in the range of 0.25 to 1.3 mm (0.010 to 0.050 in.) in diameter, with a power density of about 10^7 W/cm^2 (10^6 W/in.^{2}). This high level of beam spot intensity generates temperatures of approximately 14,000 °C (25,000 °F) and is sufficient to vaporize almost any material, forming a vapor hole that penetrates deep into the workpiece. When this vapor hole is advanced along a weld joint, the weld is produced by three effects that occur simultaneously: (1) the material at the leading edge of the vapor hole melts; (2) this molten material flows around the sides of the vapor hole to the trailing edge; and (3) this continuous flow of molten material fills in the trailing edge of the advancing vapor hole and solidifies as the vapor hole moves forward to produce a continuous weld.

Originally, EBW generally was performed only under high-vacuum ($\leq$13 mPa, or 1×10^{-4} torr) conditions; because an ambient vacuum environment was required to generate the beam, welding the part within the same clean atmosphere was considered beneficial. However, as the demand for greater part production increased, it was found that the weld chamber vacuum level need not be as high as that needed for the gun region; ultimately, the need for any type of vacuum surrounding the workpiece was totally eliminated for some applications. Currently, three distinct modes of EBW are employed:

- HIGH-VACUUM (EBW-HV), WHERE THE WORKPIECE IS IN AN AMBIENT PRESSURE RANGING FROM 0.13 TO 0.30 MPA (10^{-6} TO 10^{-3} TORR)
- MEDIUM-VACUUM (EBW-MV), WHERE THE WORKPIECE MAY BE IN A "SOFT" OR "PARTIAL" VACUUM RANGING FROM 0.13 TO 3300 PA (10^{-3} TO 25 TORR)
- NONVACUUM (EBW-NV), WHICH IS ALSO REFERRED TO AS ATMOSPHERIC EBW, WHERE THE WORKPIECE IS AT ATMOSPHERIC PRESSURE IN AIR OR PROTECTIVE GAS

In all EBW applications, the electron-beam gun region is maintained at a pressure of 13 mPa (10^{-4} torr) or lower.

Advantages

One of the prime advantages of EBW is the ability to make welds that are deeper and narrower than arc welds, with a total heat input that is much lower than that required in arc welding. This ability to achieve a high weld depth-to-width ratio eliminates the need for multiple-pass welds, as is required in arc welding. The lower heat input results in a narrow workpiece heat-affected zone (HAZ) and noticeably fewer thermal effects on the workpiece.

In EBW, a high-purity vacuum environment can be used for welding, which results in freedom from impurities such as oxides and nitrides. The ability to employ higher weld speeds, due to the high melting rates associated with the concentrated heat source, reduces the time required to accomplish welding, thereby resulting in an increased productivity and higher energy efficiency for the process. Total energy conversion efficiency of EBW is approximately 65%, which is slightly higher than so-called conventional welding processes and much higher than other types of high-energy-density welding processes, such as laser-beam welding (EBW). Additional information is available in the article "Laser-Beam Welding" in this Section.

These characteristics (1) minimize distortion and shrinkage during welding; (2) facilitate welding of most hardened or work-strengthened metals, frequently without significant deterioration of mechanical properties in the weld joint; (3) facilitate welding in close proximity to heat-sensitive components or attachments; (4) allow hermetic seal welding of

evacuated enclosures, while retaining a vacuum inside the component; and (5) permit welding of refractory metals, reactive metals, and combinations of many dissimilar metals that are not joinable by arc welding processes. The ability to project the electron beam a distance of over 510 mm (20 in.) under high-vacuum conditions, as well as the low end of medium-vacuum conditions, allows otherwise inaccessible welds to be completed.

Limitations

Equipment costs for EBW generally are higher than those for conventional welding processes. However, when compared to other types of high-energy density welding (such as LBW), production costs are not as high. The cost of joint preparation and tooling is more than that encountered in arc welding processes, because the relatively small electron beam spot size that is used requires precise joint gap and position.

The available vacuum chamber capacities are limited; workpiece size is limited, to some degree, by the size of the vacuum chamber employed. Consequently, the production rate (as well as unit cost) is affected by the need to pump down the chamber for each production load. Because the electron beam is deflected by magnetic fields, nonmagnetic or degaussed metals must be used for tooling and fixturing that are near the beam path.

Although most of the above advantages and disadvantages generally are applicable to all modes of EBW, several do not specifically apply to EBW-NV. Nonvacuum EBW does not offer the advantage of a high-purity environment (unless some form of inert-gas shielding is provided), and it is not subject to vacuum chamber limitations. Because welding is not done within the confines of a vacuum environment, the maximum practical "standoff," the working distance between the bottom of the electron beam column and the top of the workpiece, currently used on EBW-NV systems is limited to approximately 35 mm ($1\frac{3}{8}$ in.). The maximum attainable penetration is currently limited to about 25 to 32 mm (1 to 1.25 in.) for 60-kW, 165 kV machines. These limitations, however, are offset by higher production rates and a lower rate of vacuum-related equipment problems that are typical of EBW-NV systems.

Process Control

Basic variables employed for controlling the results of an electron-beam weld include accelerating (applied gun) voltage, beam current, welding (beam spot travel) speed, focusing current, and standoff (gun column assembly to workpiece) distance. The final beam spot size that is produced in the plane of the workpiece is determined by:

- CHARACTERISTICS OF THE ELECTRON BEAM GUN/COLUMN ASSEMBLY (GUN AND ELECTRON OPTICS)
- FOCUSING CURRENT, WHICH CONTROLS THE FOCAL LENGTH OF THE LENS AND RESULTING BEAM FOCUS LOCATION
- GUN COLUMN ASSEMBLY-TO-WORKPIECE DISTANCE
- ACCELERATING VOLTAGE
- BEAM CURRENT

Each of these variables, separately and jointly, affects final beam spot size.

Increasing the accelerating voltage or beam current increases the depth of penetration; the product of these two variables--the beam power--determines the amount of metal melted for a given exposure time. Increasing welding speed--relative travel motion between beam spot and workpiece--without changing any other process variable, reduces depth of penetration and correspondingly reduces weld width. Changing any of the other basic control variables to increase beam spot size, thereby lowering the beam spot intensity (e.g., reducing the power density), reduces depth of penetration and increases weld width, if welding speed is left unchanged. Beam deflection can be used to change the impact angle of the beam (slightly) or to produce controlled patterns of beam oscillation to create greater beam spot size or other special effects. The beam can also be pulsed to vary the average amount of power inputted per unit of time.

With EBW-NV, the accelerating voltage and focus current are normally preset and held at a fixed value. Beam current may be preset for any application and then turned "on/off" (or programmed to vary in predetermined fashion) with workpiece travel. Workpiece speed and, in certain instances, standoff distance may also be preset to a desired value or varied with workpiece travel. On many of the latest computerized numerical control (CNC) types of EBW-NV systems, beam current, standoff distance, and welding speed are varied simultaneously, as required, throughout the length of the weld. Because of the limited standoff distance involved with EBW-NV, beam deflection normally is not feasible, and beam oscillatory motion generally is not employed.

Operation Sequence and Preparation

Tooling and welding procedures for each EBW application are developed first on experimental workpieces. Details of the welding sequence vary somewhat, depending on equipment differences and application requirements. A typical sequence of operation for welding in vacuum is to:

- ASSEMBLE AND PREPARE WORK AND FIXTURES FOR WELDING. THIS INCLUDES CLEANING AND MAY INCLUDE DEMAGNETIZING, PREHEATING, AND TACK WELDING.
- LOAD FIXTURED WORK ONTO WORKTABLE OR WORK-HOLDING MECHANISM IN WELDING CHAMBER.
- START CHAMBER PUMPDOWN.
- AFTER CHAMBER PRESSURE HAS BEEN REDUCED TO 0.013 TO 13 PA (10^{-4} TO 10^{-1} TORR), FOCUS ON A TARGET BLOCK AND SET BEAM PARAMETERS.
- ALIGN JOINT TO THE BEAM POSITION, USING VERY LOW POWER BEAM SPOT.
- BEGIN WELDING; THIS USUALLY IS PERFORMED AUTOMATICALLY, BUT CAN BE PERFORMED MANUALLY.
- TERMINATE THE WELDING CYCLE.
- ALLOW WORK TO COOL SUFFICIENTLY IF MADE OF REACTIVE MATERIAL, THEN ADMIT AIR TO THE CHAMBER AND REMOVE FIXTURED WORK.

For nonvacuum welding, the electron gun/column assembly is maintained at established pressure levels; work-handling and welding operations for EBW-NV usually are mechanized for high-speed production, and work and fixturing are prepared before a production run is begun, or they are completed as part of the production line operation. Beam parameters, alignment of joint with beam position, and transfer and movement of work for welding are established before a production run. Alignment of the joint with beam position is slightly less critical than for vacuum electron-beam welding, because beam spot size and weld width are slightly larger in nonvacuum welding.

Joint Preparation. A joint for EBW ordinarily has close fitted, abutting, square-groove faces, and filler metal usually is not used. Filler metal can be used if desired, as in EBW of dissimilar metals and alloys. Generally, the faces of the joint are machined to a surface roughness of 3.20 μm (125 μin.) or less.

Surface finish on the weld groove faces may not be critical, depending on part and joint design and the requirements for weld properties. In studies on butt welding of 50 mm (2 in.) thick aluminum alloy 2219 and Ti-6A1-4V specimens that had groove faces with surface roughness values of 1.60, 3.20, 6.3, 12.5, and 25.0 μm (63, 125, 250, 500, and 1000 μin.), respectively, surface finish had no effect on weld quality, as determined by visual examination and x-ray radiography; all welds were sound. Edge surface finish is much less critical on broad welds than on narrow welds. Edge roughness is not critical on lap joints in thin metal, as long as burrs do not separate the surfaces.

Joint Fit-Up. A butt joint is not open, as in arc welding, but has closely fitted, nearly parallel surfaces to enable the narrow electron beam to fuse base metal on both sides of the joint. The members of a joint to be melt-through welded also are closely fitted. Fit-up tolerance depends on work-metal thickness and joint design, but is usually 0.13 mm (0.005 in.) or less. Joint gap is usually smaller for thin work metal and unbacked joints and may be only 0.05 mm (0.002 in.) maximum. Interference fits may be used where shrinkage can cause cracking, as in circular joints on hardenable metals.

Joint gaps of about 0.08 mm (0.003 in.) maximum commonly are used for making narrow vacuum welds, whereas joint gaps of up to 0.8 mm (0.030 in.) are not uncommon in EBW-NV. In making deep welds, poor fit-up or too large a joint

gap can cause excessive shrinkage, underfill, undercut, voids, cold shuts, and missed joints. In most metals, joint gap should not exceed 0.25 mm (0.010 in.) for narrow welds deeper than about 50 mm ($\frac{1}{2}$ in.), although sound welds have been obtained using joint gaps of 0.5 mm (0.020 in.) by increasing the weld width to about 6.4 mm (0.25 in.).

Cleaning. Workpiece surfaces must be properly cleaned for in-vacuum EBW. Inadequate surface cleaning of the weld metal can cause weld flaws and a deterioration of mechanical properties. Inadequate cleaning of weld surfaces also adversely affects pumpdown time and gun operational stability, as well as contributing to the rapid degradation of the oil used in the vacuum pumps.

In EBW-NV, cleanliness of workpiece surfaces is important, but not as critical as with vacuum EBW. Although the effect of workpiece cleanliness on pumpdown time and gun stability is reduced in nonvacuum welding, it still affects final weld quality.

Wire brushing generally is not recommended, because contaminants may become embedded in the metal surface. Acetone is preferred for cleaning electron gun components and workpiece parts. If workpieces are cleaned in chlorine or other halogen-containing compounds, residue from these compounds must be removed by another cleaning method (usually thorough washing in acetone) before welding.

Fixturing Methods. Methods used for fixturing workpieces in EBW are similar to those used for GTAW of precision parts without the use of filler metal, except that clamping force is usually lower and all fixturing and tooling materials should be made of nonmagnetic materials.

Because total heat input to the weld is much less in EBW than for arc welding, and because the heat is highly localized, heavy fixturing, massive heat sinks, or water cooling is not needed. C-clamps are sufficient for many parts. In some applications, clamping may be supplemented or replaced by small tack welds or by a shallow weld pass (sealing pass) over the joint; the penetration weld is completed later at full power.

For EBW-NV, general-purpose welding positioners are satisfactory. Locating and aligning mechanisms are of simpler design than for welding in a vacuum; accessibility and beam widths for nonvacuum welding do not require as much accuracy in tracking of the joint. Maintenance of work-handling equipment for EBW-NV is simplified because of its out-of-chamber location.

Demagnetization. Workpieces and fixtures made of magnetic materials should be demagnetized before welding. Residual magnetism may result from magnetic-particle testing, magnetic chucks, or electrochemical machining. Even a small amount of residual magnetism can cause beam deflection. Workpieces are usually demagnetized by placing them in a 60 cycle inductive field and then slowly removing them. Equipment used for magnetic-particle testing may be used. Before welding, workpieces should be checked with a gauss meter. Acceptable gauss-meter readings vary from 5×10^{-5} T ($\frac{1}{2}$ G) for very narrow (highly critical) welds up to as much as 2×10^{-4} to 4×10^{-4} T (2 to 4 G) for relatively wide welds.

Pumpdown. The time required to pump the work chamber of an in-vacuum EBW unit down to the desired ambient pressure depends on the chamber size used, type of pump employed, and level of vacuum required. Electron-beam welding equipment currently employs either computer or program logic controls, normally providing automatic vacuum sequencing.

For EBW-HV, a pressure of 13 mPa (10^{-4} torr) or less is produced by a mechanical pump (either a simple piston, a rotary vane type, or a combination pump-and-blower package), operating in conjunction with an oil-diffusion pump. The size of these pumps depends mainly on the size of the weld chamber used, as well as on the final operating vacuum level and total pump-down time needed.

Generally, a 1.1 m^3 (40 ft^3) chamber employing a 250 mm (10 in.), 250 m^3/min (8820 ft^3/min) diffusion pump and a 17 m^3/min (600 ft^3/min) mechanical pump package can be expected to reach a welding pressure of less than 40 mPa (3×10^{-4} torr) in approximately 4 min, while an 11 m^3 (400 ft^3) chamber employing a 510 mm (20 in.), 1070 m^3/min (37,800 ft^3/min) diffusion pump and a 37 m^3/min (1300 ft^3/min) mechanical pump package can be expected to pump down to the same pressure in approximately 12 min.

If desired, the pumpdown time of the 11 m^3 (400 ft^3) chamber could be reduced to under 6 min by increasing the size of the pumping system to an 815 mm (32 in.) 3090 m^3/min (109,200 ft^3/min) diffusion pump and a 77.9 m^3/min (2750 ft^3/min) mechanical pump package; however, the higher cost associated with this increased pumping capability would have to be evaluated against the financial benefit of the saving in pumpdown time to determine whether it would be economically feasible. In the examples above, weld chambers are assumed to be clean, dry, and empty. The cleanliness of the work chamber, the amount of water vapor (humidity) in the ambient air, and the workpiece assembly (material and shape of both weldment and fixturing) thus affect the actual pumpdown time obtained in any production application.

For partial-vacuum EBW, where the pressure level required in the weld chamber is approximately 13 Pa (10^{-1} torr) and a pressure level of 13 mPa (10^{-4} torr) is provided only in the electron-beam gun/column regions, diffusion pumps are not needed for the weld chamber, and weld chamber pumping is accomplished strictly by mechanical pumping. For high-production EBW of small parts in a partial vacuum, pumpdown lime ranges from about 20 s for relatively large-volume (general-purpose) partial-vacuum weld chambers of about 0.14 m^3 (5 ft^3) down to less than 5 s for fairly small-volume chambers of 0.014 m^3 (0.5 ft^3), with the use of a mechanical pump rated at 37 m^3/min (1300 ft^3/min).

Preheat and Postheat. Most commonly welded metals can be processed with EBW methods, even in thick sections without preheating, because of the extremely narrow width of the HAZ. Hardenable and difficult-to-weld metals may need to be preheated, especially for thick sections and in applications when the weld is restrained.

High-strength alloy steels and tool steels thicker than about 9.5 mm ($\frac{3}{8}$ in.) ordinarily must be preheated before EBW to prevent cracking. Deep circular welds, especially partial-penetration welds, in thick sections of carbon steel containing more than about 0.35% C usually require preheating. However, welds subject to less restraint, such as circumferential welds on cylindrical shapes, can be made on 13 mm ($\frac{1}{2}$ in.) thick 0.50% C steel without preheating.

Preheating, when required, is usually done before the work is placed in the work chamber. Selection of heating method depends on the size and shape of the work and the preheat temperature; a combination of methods can be used. Torch and furnace heating are widely used; induction and infrared-radiation heating are also used. On small parts or where distortion from localized heating is not a problem and where increased cycle time can be tolerated, heating is sometimes done with a defocused electron beam; this method can also be used to supplement other methods of heating.

When postheating is used on EBW parts, it is accomplished by conventional means (i.e., stress relieving or tempering) after removing the work from the welding chamber.

Operating Conditions. Starting and stopping the weld usually require special consideration to avoid uniformity of the weld at these points and possible melt-through and loss of metal.

One technique that is used to avoid these difficulties is to start the weld at full beam power on a starting tab of the work metal that is tightly fitted against one end of the joint and to conclude the weld on a runoff tab at the other end of the joint. The use of starting and runoff tabs prevents underfill at the ends of the joint, which is caused by the introduction or exit of the beam. Workpieces can also be made oversize to provide extra material for starting and stopping. The tabs or the extra material can be machined off after welding. Starting and runoff tabs are used mainly in low-production operations.

Another technique is to start and stop the weld on the work, raising the current gradually (upslope) at the beginning of the weld and reducing it gradually (downslope) at the end of the weld. Upslope and downslope power may be used at controlled rates and time intervals, as established for a specific application, and can be programmed into the welding procedure. The use of upslope and downslope is of special value where the weld is a closed path, as in welding circular and circumferential joints.

In many applications of closed-path welds, the weld can be started at full power, with downslope at the end providing a sufficiently gradual termination and a suitable distance of overlap. Downslope of current after overlapping the beginning of the weld on circular welds in thick sections of high-hardenability steels is critical to avoid porosity and cracking. Other parameters may also be adjusted to avoid these defects. Upslope is usually rapid; downslope is from a few degrees to a major portion of a revolution.

A "cosmetic pass" is made when needed to smooth or flatten the crown of a weld that is irregular or too high. Such a pass is used to correct undercut or underfill. The beam is usually defocused or reduced in power, or both, in making a cosmetic pass. Filler metal may also be added in making a cosmetic pass intended to correct undercut or underfill.

Weld Geometry

The shape of the parts to be welded and the corresponding joint designs are critical to the successful application of EBW in vacuum or at atmospheric pressures (nonvacuum). While minimum heat input and low thermal distortions are important advantages of EBW, the molten metal still shrinks as it solidifies. Shrinkage stresses may lead to microcracks if parts, due to design restrictions, are unable to shrink at corresponding rates and the joint volume is completely constrained. Additional information is available in the article "Procedure Development and Practice Considerations for Electron-Beam Welding" in this Volume.

Joint Design

Butt, corner, T-, lap, and edge joints can be made by the EBW process using square-groove or seam welds. Fillet welds, which are difficult to make with vacuum EBW, are readily made using EBW-NV. Square-groove welds require fixturing to maintain fit-up and alignment of the joint. They can, however, be self-aligning if a rabbeted joint design is used. Self-alignment is particularly important in batch loading the vacuum chamber for efficient work manipulation. The weld-metal area can be increased using a scarf joint, but fit-up and alignment of the joint are more difficult than with a square-groove weld. Most joints are designed to be welded in a single pass with full penetration or penetration to a specified depth.

Electron-Beam Welding Machines

This brief review is aimed at introducing the potential user to some of the EBW equipment currently available. Further advances in the control and programming of these systems can be expected because of the likelihood of uninterrupted progress in the electronics and computer industries.

As discussed earlier in this article, the EBW process is accomplished at three pressure-dependent lines, referred to as the three modes of EBW. The original mode is the high or "hard" vacuum mode in which welding is carried out in the pressure range of 0.13 to 130 mPa (10^{-6} to 10^{-3} torr). In the second mode, medium vacuum, the pressure ranges from 0.13 to 3300 Pa (10^{-3} to 25 torr). The term "medium vacuum" includes the range of pressure (0.13 to 130 Pa, or 10^{-3} to 1 torr) referred to as the "soft" or partial vacuum. The third mode is called non-vacuum or atmospheric, with welding carried out at atmospheric pressure.

All three modes employ an electron-beam gun/column, a power supply with controls, one or more vacuum pumping systems, and work-handling equipment. Although in nonvacuum welding the workpiece is not placed in an evacuated work chamber, the electron beam gun/column must be in a vacuum environment. The electron gun in all three modes is held at a pressure of 13 mPa (10^{-4} torr) or less; otherwise, the high voltage required for the acceleration of the electrons could not be sustained.

Electron-beam welding equipment comes in two basic designs: (1) the low-voltage system, which uses accelerating voltages in the 15 to 60 kV range; and (2) the high-voltage system, with accelerating voltages in the 100 to 200 kV range. Beam powers up to 100 kW are available with both high-voltage and low-voltage equipment.

The lower-voltage machines operate at a higher current. Typically, 30 to 60 kV machines operate at a 500 mA beam current. The high-voltage machines of 150 kV operate at 40 mA. The higher-voltage machines produce a greater depth-to-width ratio of the weld nugget. This could be the difference between a 12:1 depth-to-width ratio versus a 25:1 depth-to-width ratio. The higher-voltage machines can utilize a longer standoff distance than can low-voltage machines; however, low-voltage machines are simpler in construction and less maintenance is required (Ref 1).

Low-voltage equipment is more suitable for high- and medium-vacuum operations, while nonvacuum welding is carried out at higher voltages (130 to 175 kV minimum). All three modes, however, are operational with high-voltage equipment. The nonvacuum, high-voltage systems generally are used for welding materials less than 25 mm (1 in.) thick. With low-voltage systems, the gun may be fixed in position on the chamber or may be mobile inside the chamber. With high-voltage equipment, the gun is generally fixed in position on the chamber. Figure 3 shows a typical floor plan of a high-voltage, high-vacuum welding facility with a welding chamber size of 1725 by 1725 by 1980 mm (68 by 68 by 78 in.).

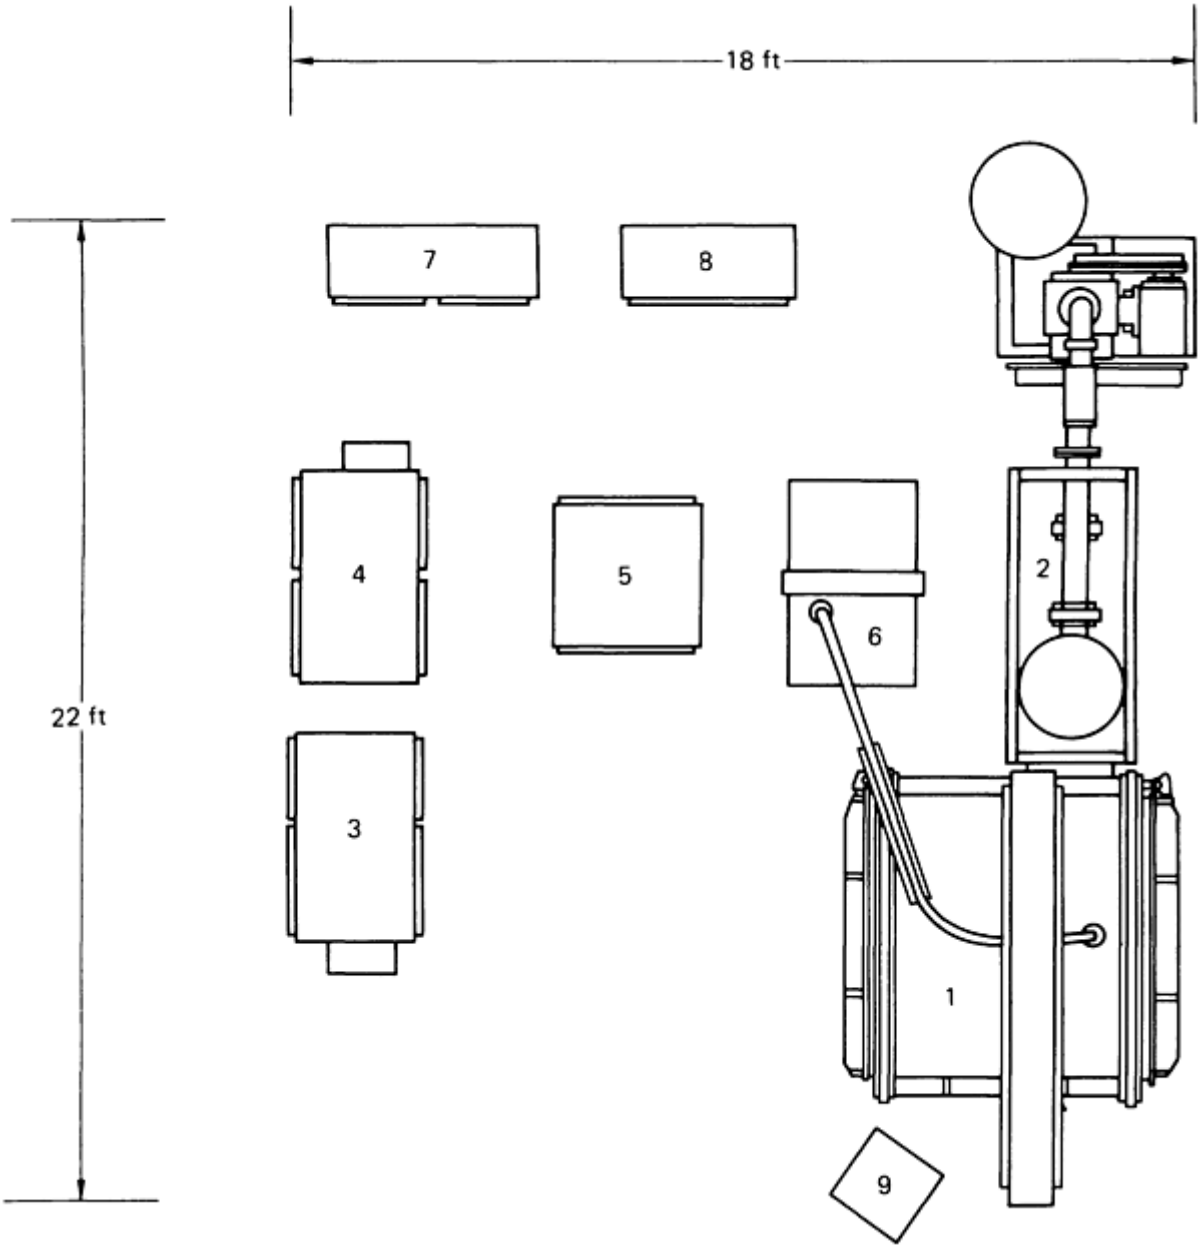

FIG. 3 OVERHEAD VIEW SHOWING TYPICAL FLOOR LAYOUT OF HIGH-VOLTAGE, HIGH-VACUUM EBW SYSTEM. (1) VACUUM CHAMBER AND MANIPULATING MECHANISMS. (2) VACUUM PUMPING SYSTEM. (3) COMPUTER CONTROL CABINET. Figure 4 shows a standard high-vacuum machine with a chamber size of 2845 by 1525 by 1830 mm (112 by 60 by 72 in.). This type of unit is available with power ratings of 7.5 kW (150 kV, 50 mA) and 25 kW (150 kV, 267 mA). The gun/column in this unit is fixed, and the work travels under the gun. Work-handling equipment makes processing of workloads of up to 1400 kg (3000 lb) at welding speeds of 3300 mm/min (130 in./min) possible. This system can be obtained with various degrees of automation; most utilize CNC operations. Figure 5 shows a high-vacuum unit with a chamber size of 3505 by 2845 by 2690 mm (138 by 112 by 106 in.). This installation comes with a movable gun. Low-

voltage, high-vacuum systems with movable guns are available with power ratings of 7.5 kW (60 kV, 125 mA) 15 kW (60 kV, 250 mA), 30 kW (60 kV, 125 mA), and 42 kW (60 kV, 700 mA).

Medium-vacuum machines are frequently special-purpose units tooled for particular assemblies. Figure 6 shows a dual-system partial-vacuum welding installation for joining ring gear and counterweight onto flywheels. Dual medium-vacuum systems of this type, which are used for high-production applications, can be readily modified to produce alternate parts by simple changes in the work-handling components and weld programming. As with the system shown in Fig. 4, a wide range of automation and computer control is available.

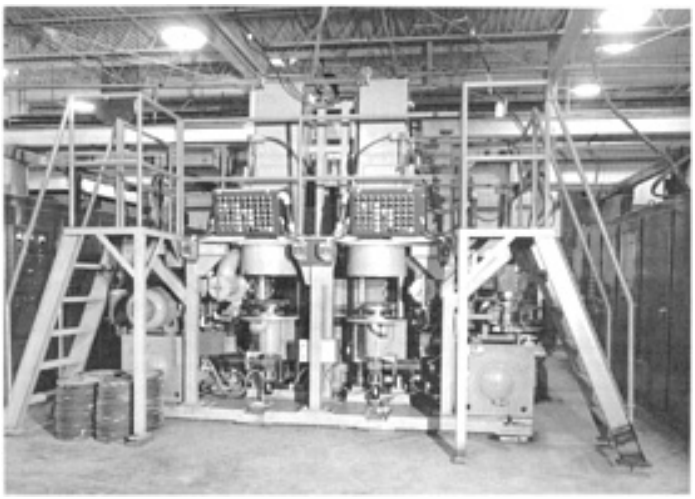

FIG. 6 TWIN EBW-MV INSTALLATION DESIGNED TO WELD A RING GEAR ONTO A FLYWHEEL. COURTESY OF LEYBOLD-HERAEUS VACUUM SYSTEMS INC.

The medium-vacuum mode of EBW was initially employed to increase the production capacity of the process. This mode of application typically involves the use of a chamber custom designed to provide a minimum of weld-zone volume that has to be evacuated during each part cycle (that is, a chamber envelope that is not much bigger in size than the particular workpiece to be welded plus any fixturing it may require). Because only a small volume needs to be evacuated, coupled with the fact that medium-vacuum EBW is normally performed in an ambient vacuum level of nominally 6.5 Pa (5×10^{-2} torr)--which is several orders of magnitude higher in pressure than high-vacuum EBW--the pumpdown times necessary are much less than those required on a high-vacuum EBW system (that is, times of <10 s compared to >3 min). Thus, in order to take advantage of this significant reduction in the time required for evacuating the weld zone, various methods were developed to rapidly transport parts into or out of the weld area on EBW-MV systems. Figure 7 shows one of the conventional methods used for this purpose, employing a dial table arrangement for repeatedly indexing a set of work stations through the weld area. Each individual work station contains whatever fixturing might be required to hold the part. The parts can usually be loaded/unloaded into and out of these work stations either manually or automatically. This particular method for achieving rapid part transfer is capable of being employed both with the drop-bottom (discretely pumped) EBW-MV unit and the sliding-seal (continuously pumped) EBW-MV unit.

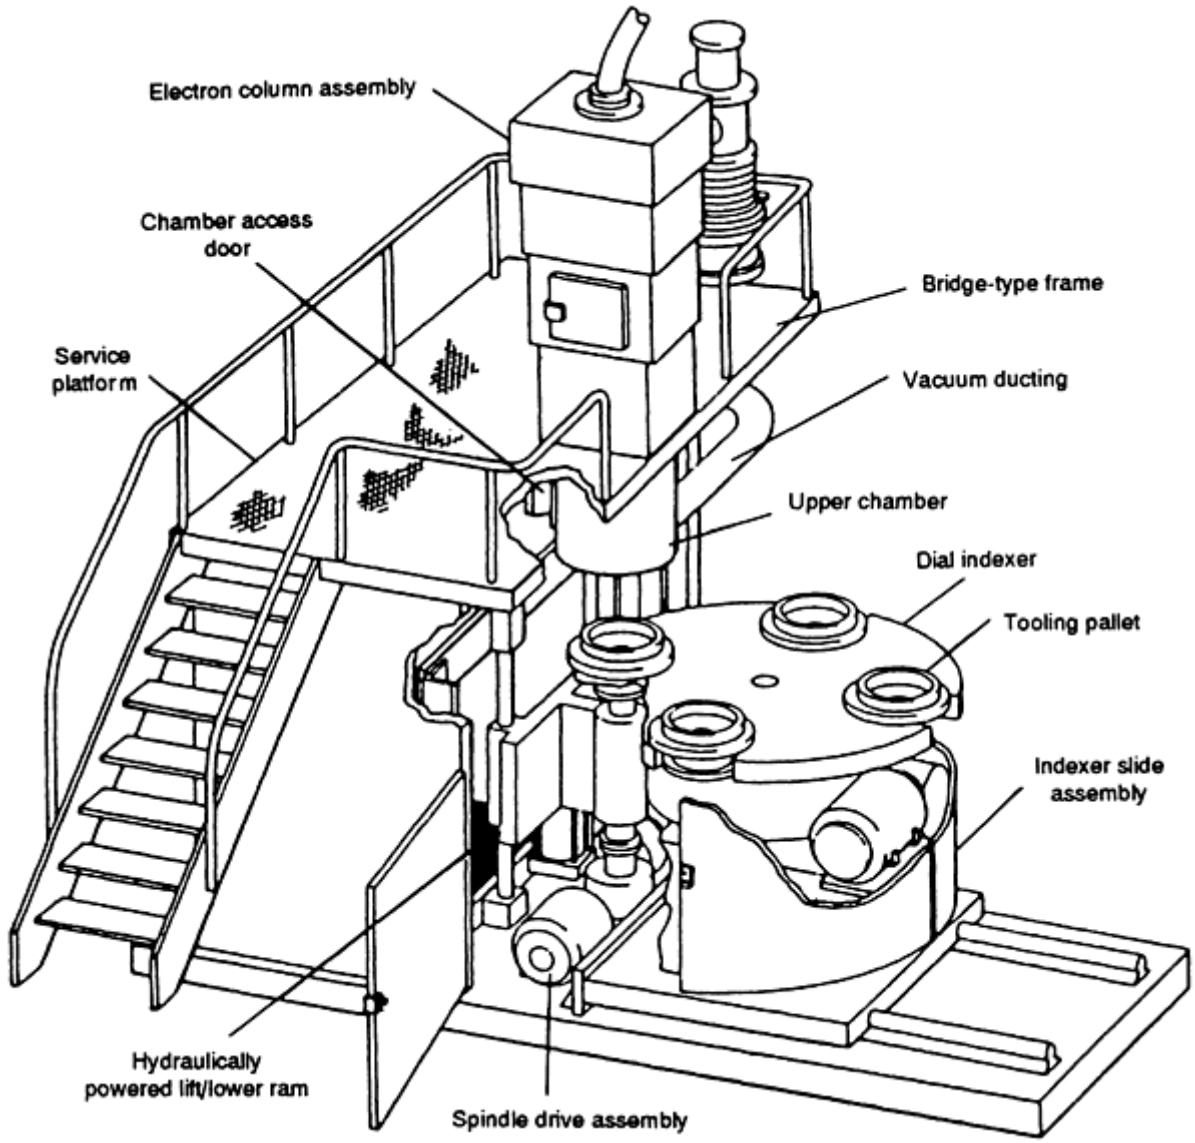

FIG. 7 SCHEMATIC SHOWING A CUTAWAY VIEW OF A DIAL TABLE DEVICE INCORPORATED INTO AN EBW-(MV/PV) SYSTEM TO PROVIDE INDEXING OF WORK STATION INTO WELDING AREA

Figure 8 shows a custom partial-vacuum system, typical of the variety used for high-production automotive parts manufacture. Installations of this type currently are available with power ratings of 100 kW (100 kV, 1 A) for welding heavy cross sections from 50 to 205 mm (2 to 8 in.) thick.

Some smaller units are also available that feature dual-mode operation; they operate in either the high- or medium-vacuum mode, depending on the application. Figure 9 shows a dual-mode portable machine rated at 6 kW (60 kV, 100 mA) with fully automatic and preset pumping and welding cycles. The small weld chamber can be pumped down to 65 mPa (5×10^{-4} torr) in 10 s.

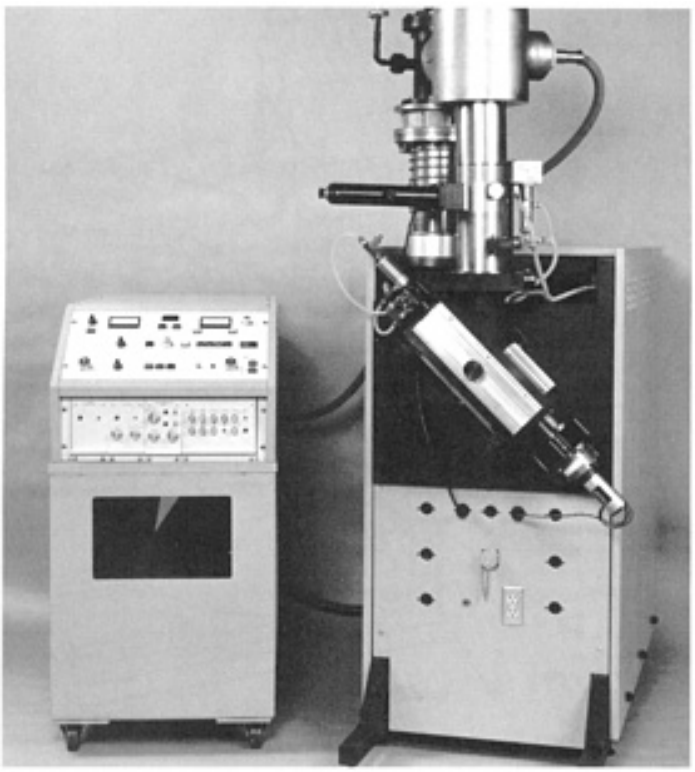

FIG. 9 STANDARD DUAL-MODE PORTABLE EBW SYSTEM. COURTESY OF EBTEC CORP.

The system shown in Fig. 10 is an example of a nonvacuum unit featuring a standard dial index table. Parts are loaded into a fixture nest in the table and are indexed through a small, radiation-tight enclosure in which parts are welded at 100 kPa (1 atm). This nonvacuum unit has power ratings of 17.5 kW (174 kV, 100 mA) or 35 kW (175 kV, 200 mA) and can be used either as a standard system or as a custom-designed special task system.

Computer control systems available in many EBW units. Control of welding operations can be expanded to include joint locators, five-axis programmable contouring, and several digitizing provisions that can be actuated on the basis of information generated by the seam locator. Many EBW systems can also be adapted for electron-beam heat-treating applications.

Safety

Protection must be provided by equipment design and arrangement, and by safety precautions in EBW and related operations, against the usual hazards of welding and the special hazards of exposure to (1) the high voltages involved in generating the electron beam, (2) the beam itself (direct viewing of intense radiation emitted by molten weld metal can be harmful to eyesight and thus the beam operation should be viewed only through a filter lens commonly used for arc welding), and (3) radiation of x-rays produced by impingement of the beam on the work or other materials. From a safety standpoint, an accelerating voltage of less than 20 kV produces soft x-rays, while an accelerating voltage of over 20 kV produces hard x-rays (Ref 1). Shielding is more demanding against radiation as the acceleration voltage increases. Suitable precautionary measures are described in AWS F2.1-78, "Recommended Safe Practices for Electron Beam Welding and Cutting," and in AWS/ANSI Z49.1, "Safety in Welding and Cutting."

Introduction

LASER-BEAM WELDING (LBW) uses a moving high-density (10^5 to 10^7 W/cm^2, or 6×10^5 to 6×10^7 W/in.^{2}) coherent optical energy source called a laser as the source of heat. "Laser" is an acronym for "light amplification by stimulated emission of radiation." The coherent nature of the laser beam allows it to be focused to a small spot, leading to high energy densities.

Lasers have been promoted as potentially useful welding tools for a variety of applications. Until the 1970s, however, laser welding had been restricted to relatively thin materials and low speeds because of the limited continuous power available. By 1965, a variety of laser systems had been developed for making microwelds in electronic circuit boards, inside vacuum tubes, and in other specialized applications where conventional technology was unable to provide reliable joining. The availability of high-power continuous-wave (CW) carbon dioxide (CO_2) and neodymium-doped yttrium aluminum garnet (Nd:YAG) lasers and the limitations of current welding technology have promoted interest in deep-penetration welding in the past 20 years using these devices.

The ability of the laser to generate a power density greater than 10^6 W/cm^2 (6×10^6 W/in.^{2}) is a primary factor in establishing its potential for welding (Table 1). Numerous experiments have shown that the laser permits precision (that is, high quality) weld joints rivaled only by those made with an electron beam.

TABLE 1 ENERGY CONSUMPTION AND EFFICIENCY OF LBW RELATIVE TO OTHER SELECTED WELDING PROCESSES

WELDING PROCESS	INTENSITY OF ENERGY SOURCE		JOINING EFFICIENCY, MM^2/KJ	FUSION ZONE PROFILE
	w/cm^2	w/in.^{3}		
OXYACETYLENE (OAW)	10^2-10^3	6×10^2-6×10^3	0.2-0.5	SHALLOW FOR SINGLE PASS
ARC WELDING	5×10^2-10^4	3×10^3-6×10^4	0.8-2$^{(A)}$ 2-3$^{(B)}$ 4-10$^{(C)}$	SHALLOW FOR SINGLE PASS
PLASMA ARC (PAW)	10^3-10^6	6×10^3-6×10^6	5-10	SHALLOW AT LOW-ENERGY END DEEP PENETRATION AT HIGH-ENERGY END
LASER BEAM	10^5-10^7	6×10^5-6×10^7	15-25	SHALLOW AT LOW-ENERGY DENSITY RANGE DEEP PENETRATION AT HIGH-ENERGY DENSITY RANGE
ELECTRON BEAM	10^5-10^8	6×10^5-6	20-30	DEEP PENETRATION

		$\times 10^8$

Advantages and Limitations of LBW

Laser welding offers the following advantages (Ref 1, 2):

- LIGHT IS INERTIALESS (HENCE, HIGH PROCESSING SPEEDS WITH VERY RAPID STOPPING AND STARTING BECOME POSSIBLE).
- FOCUSED LASER LIGHT PROVIDES HIGH ENERGY DENSITY.
- LASER WELDING CAN BE USED AT ROOM ATMOSPHERE.
- DIFFICULT-TO-WELD MATERIALS (FOR EXAMPLE, TITANIUM, QUARTZ, ETC.) CAN BE JOINED.
- WORKPIECES DO NOT NEED TO BE RIGIDLY HELD.
- NO ELECTRODE OR FILLER MATERIALS ARE REQUIRED.
- NARROW WELDS CAN BE MADE.
- PRECISE WELDS (RELATIVE TO POSITION, DIAMETER, AND PENETRATION) CAN BE OBTAINED.
- WELDS WITH LITTLE OR NO CONTAMINATION CAN BE PRODUCED.
- THE HEAT-AFFECTED ZONE (HAZ) ADJACENT TO THE WELD IS VERY NARROW.
- INTRICATE SHAPES CAN BE CUT OR WELDED AT HIGH SPEED USING AUTOMATICALLY CONTROLLED LIGHT DEFLECTION TECHNIQUES.
- THE LASER BEAM CAN ALSO BE TIME SHARED.

Precise part fit-up and alignment are much more critical in laser welding than in ordinary arc welding. The typical focal spot diameter for a laser beam ranges from 100 to 1000 μm (0.004 to 0.040 in.). In addition, capital cost for laser welding devices is almost 10 times more expensive than comparable power arc welding systems. On the other hand, laser welding can provide much higher throughput relative to conventional arc welding. When the capital cost of laser-beam welding is compared to electron-beam welding (EBW), laser-beam welding becomes the more cost-effective of the two processes because no vacuum enclosure is necessary for laser-beam welding.
