The penetration depth obtained in laser welding is less than that observed in electron-beam welding. The maximum thickness of type 304 stainless steel plate that can be welded using a 77 kW (105 hp) CO_2 laser is 50 mm (2 in.) (Ref 3), whereas EBW can produce welds in type 304 stainless steel up to several inches in thickness. However, the penetration depth of EBW extends only a relatively short distance under atmospheric pressure. Welding under a vacuum is required to obtain optimum efficiency in EBW. A laser beam, however, can be transmitted an appreciable distance through the atmosphere without serious attenuation or optical degradation because of its coherent nature. Laser-beam welding thus offers an easily maneuverable, chemically clean, high intensity, atmospheric welding process with narrow HAZ and subsequent low distortion. Peak penetration, p_{max}, for LBW is defined by:

$$P_{MAX} \propto P^{0.7} \qquad \textbf{(EQ 1)}$$

where P is the power (in watts). In terms of weld width (w) and depth (d), both conduction-mode welding (w/d [ges] 1) and deep-penetration welding ($w/d < 1$) can be obtained with lasers.

Laser-Beam Welding

Jyoti Mazumder, University of Illinois at Urbana-Champaign

Process Applications

A large variety of metals and alloys have been welded with pulsed or CW lasers. Until the first reported demonstration of deep-penetration laser-beam welding by Brown and Banas (Ref 4), most laser welds were made with pulsed lasers.

The localized heating obtained with laser sources was soon realized to be an important advantage. Anderson and Jackson (Ref 5) reported an interesting comparison between heating effects produced with a conventional arc source and those occurring with a pulsed laser for an iron substrate. They show that not only is the laser-produced HAZ small, but also that the laser source is more efficient because it requires only 37.8 J/cm^2 (0.229 Btu/in.^{2}) to produce melting to the required depth, while the arc source must deliver 246 J/cm^2 (1.49 Btu/in.^{2}) to the workpiece. Localized heating makes the laser ideal for welding electronic components on a printed circuit board (PCB) where high average temperatures in even small volumes surrounding the weld region cannot be tolerated (Ref 6).

Microwelding with Pulsed Lasers. Microwelding with pulsed ruby lasers and pulsed Nd:YAG lasers is credited with some of the earliest successful applications of laser welding, including laser welding of thermocouple gages in the Apollo lunar probes in the late 1960s (Ref 7). Table 2 shows the various lasers available for welding and the maximum thicknesses that can be welded with these lasers.

(B) DATA PROVIDED BY TRUMPF INDUSTRIAL LASER.

Microwelding with pulsed solid-state lasers is now used to:

- SEAL BATTERIES FOR DIGITAL WATCHES AND PACEMAKERS
- SEAL INK CARTRIDGES FOR FOUNTAIN PENS
- WELD WIRES TO TERMINALS ON SHUNT PLATES
- WELD TELEPHONE SWITCHING DEVICES
- ATTACH BATTERY TERMINALS IN DISK CAMERAS
- JOIN LAMP TERMINAL FEED-THROUGHS
- ASSEMBLE GYROSCOPE BEAMING DEVICES
- CONSTRUCT TANTALUM DIAPHRAGMS
- WELD REPAIR INCONEL 718 CASTINGS

Laser microwelding has found its way into almost all types of manufacturing industries including aerospace, automotive, electronics, and consumer durables (Ref 11). Figure 1 shows the approximate penetration possible for high-quality welds using Nd:YAG lasers. It should be noted that for the same average power, pulsed Nd:YAG lasers provide much higher penetration levels than continuous-wave Nd:YAG lasers.

Penetration Welding. The scope of technically and commercially feasible LBW applications has increased greatly since the demonstration of penetration welding using a multikilowatt CW CO_2 laser by Brown and Banas (Ref 4). Numerous experiments have shown that the laser produces precision weld joints of high quality in ferrous alloys, nickel alloys, and titanium alloys that is rivaled only by those made by EBW. Data describing the plate thickness of different laser-welded materials are given in Table 3.

Aluminum and its alloys have recently generated lots of interest in the laser welding community because of their potential application in the auto industry for their weight reduction properties (Ref 14, 15, 16, 17, 18, 19). During the 1970s and 1980s, aluminum alloys were reported to be rather difficult to weld due to the high initial surface reflections of 10.6 μm (417 μin.) radiation emitted by CO_2 lasers (Ref 20, 21, 22, 23, 24, 25, 26, 27). Surface coating often reduces this problem. Low melting point and relevant fluidity sometimes lead to "drop through" problems, and thus energy input is a critical parameter for laser welding. Another critical factor involving laser welding is the vaporization of alloying elements such as magnesium. Suppression of the plasma with a properly designed shielded gas nozzle can be used to avoid the loss of alloying elements (Ref 25). The other alternative is to use filler metal (Ref 17). Although the welding of aluminum is difficult with LBW, it has already been demonstrated that, with proper precautions, welds having tensile strength equivalent to the parent materials can be obtained.

Steels. A great deal of laser welding research has been conducted on ferrous alloys. Most of the initial parametric studies were carried out on stainless steel (Ref 4, 27, 28). Stainless steel was investigated (Ref 28, 29) because of its importance in the power plant and chemical industries. Laser welding of rimmed steel sheet was evaluated for automotive applications by Baardsen *et al.* (Ref 30). High-speed LBW of tin plate and tin-free steel for container industries was reported by Mazumder and Steen (Ref 31). Results in HY-alloy steels were evaluated and reported by Banas (Ref 32) and by Metzbower and Moon (Ref 21). Laser-beam welding of modified 4340 alloy was reported by Seaman and Hella (Ref 33). Several other ferrous alloys that have been studied for the applicability of laser welding include X-80 Arctic pipeline steel (Ref 34), tanker construction steels (Ref 35), D-6ac low-alloy ultrahigh-strength steel (Ref 36), and high-strength low-alloy grade steels (Ref 36).

One of the earliest applications of LBW was for the welding of planetary gear assemblies for the automotive industry. Welding was carried out at 10 m/min (400 in./min) using a 5 kW (7 hp) laser. Subsequently, LBW was applied to produce automobile powertrain components. A most recent mass production application is in the production of the "body-in-white" tailored blank shown in Fig. 2. An LBW process developed by Fraunhofer Institute at Aachen that uses a polarized beam was applied by Krupps Steel to produce steel pipe (Ref 38).

Titanium and Titanium Alloys. Until recently, the EBW technique has been the most popular method used to weld Ti-6Al-4V, which is the most widely used titanium material in the aerospace industry due to its remarkable strength-to-weight ratio. However, the deep penetration of EBW can be obtained only up to a short distance under nonvacuum conditions. For optimum efficiency, electron beam welding must be carried out in an evacuated chamber (Ref 24). In contrast, CO_2 laser beams can be transmitted for appreciable distances through the atmosphere without serious attenuation or optical degradation.

The application of the laser technique to a metal such as a titanium alloy, which is normally difficult to weld, is not only of direct interest to the aerospace and chemical industries, but also is of interest to those who need to weld chemically sensitive metals with complex temperature-dependent structures. The need for better joining methods for titanium and its alloys resulted in several investigations of LBW techniques over various power ranges (maximum 16 kW, or 21 hp). A detailed review is available in Ref 13. Welding speeds in excess of 15 m/min (49 ft/min) were used to weld 1 mm (0.04 in.) thick Ti-6Al-4V with a 4.7 kW (6.3 hp) CO_2 laser, and materials up to 12.5 mm (0.492 in.) thick were joined using an 11 kW (15 hp) CO_2 laser.

Fundamentals of Laser Welding

Lasers are capable of both conduction-mode welding and deep-penetration welding.

Conduction-Mode Welding. Momentum transfer or convection dominates conduction-mode welding. High-power density (10^5 to 10^7 W/cm^2, or 6×10^5 to 6×10^7 W/in.^{2}) in laser welding produces a temperature gradient of the order of 10^6 K/cm (5×10^6 °F/in.) and this in turn leads to surface-tension-driven thermocapillary flow (Marangoni convection) with surface velocities of the order of 1 m/s (Ref 39). Convection is the single most important factor affecting the geometry of the laser melt pool (that is, pool shape, aspect ratio, and surface ripples) and can result in defects such as variable penetration, porosity, and lack of fusion. Convection is also responsible for mixing and therefore affects the composition of the melt pool during laser welds because pool configuration in conduction-mode laser welding is a function of the Prandtl number (kinematic viscosity/molecular diffusivity), Pr_m, of the materials (Ref 40). In materials with low Prandtl numbers (for example, aluminum, with $Pr_m = 0.02$), the pool shape is more spherical and is dominated by conduction heat transfer when compared to high Prandtl number material (for example, steel, with $Pr_m = 0.1$), where pool shape is shallow and wide because it is dominated by the surface-tension-driven flow (Ref 40). Free surface deformation leading to defects such as undercuts is also influenced by convection. A small amount of surface reactant elements (for example, sulfur) can change the convection direction. For most metals, thermocapillary flow drives the hot metal to the cold side (Fig. 3), but the addition of sulfur changes the sign of the temperature dependence function of the surface tension and drives the liquid metal to the center of the pool.

Deep-Penetration-Mode Welding. The mechanism of deep-penetration welding by a laser beam is very similar to that encountered with an electron beam (that is, energy transfer is via "keyhole" formation) (Ref 41, 42, 43). This keyhole may be produced when a beam of sufficiently high power density causes vaporization of the substrate and the pressure produced by the vapor in the crater causes displacement of the molten metal upward along the walls of the hole. This hole acts as a blackbody, aiding the absorption of the laser beam as well as distributing the heat deep in the material. The energy in most conventional welding processes is deposited at the surface of the workpiece and brought into the interior by conduction.

The conditions of energy and material flow during beam welding were investigated theoretically by Klemens (Ref 44). According to Klemens, the keyhole or cavity is formed only if the beam has sufficient power density. The keyhole is filled with gas or vapor created by continuous vaporization of wall material by the beam. This cavity is surrounded by liquid that, in turn, is surrounded by solid.

The flow of the liquid and the surface tension tends to obliterate the cavity while the vapor, which is continuously generated, tends to maintain the cavity. There is a continuous flow of material out of the cavity at the point where the beam enters. For a moving beam, this "keyhole" achieves a steady state (that is, the cavity and the beam associated with the molten zone move forward at the speed set by the advance of the beam). The material lost by vaporization shows up as a depression in the solidified melt as porosity, as an inward deformation of the workpiece, or possibly as a combination of these effects. The requirement that sufficient vapor be produced to maintain a steady state leads to a minimum advance speed for a steady state. While the cavity moves through the solid and liquid material at a speed determined by the motion of the beam, material must be moved continuously from the region ahead of the cavity to the region behind it. This is confirmed by the experimental work of Sickman and Morijn (Ref 45, 46) and Arata *et al.* (Ref 47).

An interesting experiment on the mechanism of deep-penetration welding with a CW CO_2 laser has been reported by Sickman and Morijn (Ref 45, 46). It was conducted on transparent fused quartz so that the formation of the weld as a function of time could be photographed. The tip of the hole appears to bend toward the direction in which the workpiece is moving. This process is caused by the reflection of laser light from the leading edge of the hole. Material evaporated at this surface is effectively trapped by the cooler trailing edge. Thus, material is transported across the laser beam from the hot leading edge to the cooler trailing edge without significant ejection of material back out toward the beam. For welding speeds in the range of 10 to 45 mm/min (0.4 to 1.8 in./min), the depth of penetration was linearly related to welding speed. As expected, the minimum penetration was obtained at maximum welding speed.

Fluid flow during penetration welding was also studied by Arata *et al.* (Ref 47), using laser beam irradiation of low-viscosity glass at high temperature. High-speed photography of the phenomenon, taken at 8000 frames per second (fps), clearly shows melt flow and the motion of the cavity. Molten fluid, which forms at the front wall of the cavity, accelerates at an angle along the wall as it is driven by the forces of the turbulence generated by laser vaporization. In this process, a large vortex is formed behind the cavity near the weld surface. This vortex is considered to be the cause of the so-called "wine-glass" beads that are produced by the process.

The transport of material is mainly due to flow in the liquid. However, part of the material is transported in the vapor phase, and this vapor transport generates the excess pressure that drives the liquid flow.

Laser Welding Parameters. The major independent process variables for laser welding include:

- INCIDENT LASER BEAM POWER
- INCIDENT LASER BEAM DIAMETER
- ABSORPTIVITY
- TRAVERSE SPEED OF THE LASER BEAM ACROSS THE SUBSTRATE SURFACE

Parameters such as weld design, shielding gas, gap size for butt welds, and depth of focus with respect to the substrate also play important roles. These parameters are discussed in the article "Procedure Development and Practice Considerations for Laser-Beam Welding" in this Volume.

The dependent variables are considered to be:

- DEPTH OF PENETRATION

- MICROSTRUCTURE AND METALLURGICAL PROPERTIES OF THE LASER-WELDED JOINTS

The effects of some of the important variables are briefly discussed below.

Laser-Beam Power. The depth of penetration with laser welding is directly related to the power density of the laser beam and is a function of incident beam power and beam diameter. For a constant beam diameter, penetration typically increases as the beam power is increased. Locke *et al.* (Ref 27) and Baardsen *et al.* (Ref 30) report that penetration increases almost linearly with incident laser power. It is generally observed that for LBW of a particular thickness, a minimum threshold power is required.

Laser-Beam Diameter. This parameter is one of the most important because it determines the power density. However, it is very difficult to measure for high-power laser beams. This difficulty is due partly to the nature of the beam diameter and partly to the definition of what is to be measured. A Gaussian beam diameter, d_G, can be defined as the diameter where the power has dropped to $1/e^2$ or $1/e$ of the central value:

$$\frac{1}{e^2} < P_{dG} < \frac{1}{e} \qquad \textbf{(EQ 2)}$$

The beam diameter defined on the basis of $1/e^2$ of the central value contains more than 80% of the total power, whereas the power contained for $1/e$ beam definition is slightly over 60% (Ref 49). Therefore, the $1/e^2$ beam diameter is recommended.

Many techniques have been used to measure the beam diameter, but most are unsatisfactory in some respect. Single isotherm contouring techniques (for example, charting paper and drilling acrylic or metal plates) suffer because the particular isotherm they plot depends both on power and on exposure time. These techniques are also highly unlikely to coincide with either the $1/e$ or $1/e^2$ diameters. Multiple isotherm contouring techniques overcome these difficulties but are tedious to interpret. However, several commercial systems are now available (see the article "Procedure Development and Practice Considerations for Laser-Beam Welding" in this Volume).

Absorptivity. The efficiency of LBW depends on the absorption of light energy by the workpiece. Any heat transfer calculation for laser processing is based on the energy absorbed by the workpiece.

The infrared absorption of metals largely depends on the conductive absorption by free electrons. Therefore, absorptivity is a function of the electrical resistivity of the substrate material. Arata and Miyamoto (Ref 50) and McCay *et al.* (Ref 51) measured the absorptivity of polished surfaces of various materials and concluded that absorptivity is proportional to the square root of the electrical resistivity. This agrees closely with:

$$A = 112.2\sqrt{r_r} \qquad \textbf{(EQ 3)}$$

where A is the absorptivity and ρ_r is the electrical resistivity. A temperature-dependent relationship between the electrical resistivity and emissivity of the metal was derived by Bramson (Ref 52). Bramson's formula can be used for theoretical calculation of the absorptivity from the electrical resistivity because absorptivity equals emissivity. However, Eq 4 will be valid only for metals without surface oxide layers that are heated in a vacuum. The presence of an oxide layer will increase the absorptivity. The relationship between the emissivity and the electrical resistivity of a substrate for the perpendicular incidence of radiation of long wavelength derived by Bramson is:

$$e_l(T) = 0.365\left[\frac{r_r(T)}{l}\right]^{1/2} - 0.667\left[\frac{r_r(T)}{l}\right] + 0.006\left[\frac{r_r(T)}{l}\right]^{3/2} \qquad \textbf{(EQ 4)}$$

where $\rho_r(T)$ is the electrical resistivity at absolute temperature, T, expressed in Ohm-centimeter ($\Omega \cdot$ cm), and $\varepsilon\lambda(T)$ is the emissivity of the substrate at temperature T (in °C) for radiation having a wavelength, λ.

The estimated absorptivity for Ti-6Al-4V at 300 °C (572 °F) using Bramson's formula is approximately 15%. Experimental data published by Arata and Miyamoto (Ref 50) and Bramson (Ref 52) indicate that the absorptivities of aluminum, silver, and copper are between 2 to 3% and those of stainless steel (type 304), iron, and zirconium are below 15% even in the molten state. Reflection losses of this magnitude are significant. Therefore, when a sheet metal product form is welded, measures must be taken to avoid reflection losses. Applying an absorbent powder to the surface or forming an anodized film on the surface are two techniques that are considered to be very effective (Ref 51).

Absorptivity can also be increased by the use of reactive gases. Jørgensen (Ref 53) reported that the addition of 10% O_2 to an argon shielding gas gives an increase of up to 100% in welding depth. Jørgensen also found that gas flow had no significant effect on weld depth. However, an increase in depth was associated with a decrease in reflectivity, which was obtained by the addition of a small amount of oxygen.

Although metals are poor absorbers of infrared energy at room temperature, above a certain threshold (approximately 10^6 to 10^7 W/cm^2, or 6×10^6 to 6×10^7 W/in.^{2}) energy transfer via the keyhole leads to much higher effective absorptivity. Once a keyhole has formed, absorptivity increases rapidly. Multiple internal reflections inside a keyhole are responsible for the deep-penetration welding by the laser despite the large convergence angles for laser beams relative to electron beams (Ref 51). However, the threshold energy required for keyhole formation in laser welding is higher than that required for an electron beam (1.5×10^5 W/cm^2, or 9.5×10^5 W/in.^{2}) because of the poor absorptivity. Nevertheless, energy transfer by this keyhole mechanism permits the laser to provide efficient welding of even highly reflective materials (for example, aluminum) (Ref 25).

Traverse Speed. The correlation of penetration depth relative to welding speed with both LBW and EBW processes was studied by Duley (Ref 41) and Locke and Hella (Ref 27). The penetration in the laser weld is consistently less than that obtained with an electron beam, but the relative difference between the two penetration depths diminishes as the welding speed is increased. However, Duley (Ref 41) found this somewhat surprising because as pointed out by Baardsen *et al.* (Ref 48), the time to form a void or keyhole depends on the illumination time for a particular area on the surface of the workpiece as the welding speed is increased. When this occurs, the average power dissipated in the sheet is expected to drop because the keyhole is no longer a completely effective trap for the incident laser radiation. For an electron beam, absorptivity of the material is independent of the shape and extent of the keyhole. Hence, the total power dissipated in the workpiece is less dependent on the welding speed. However, Crafer (Ref 54) reports that the keyhole penetration threshold for laser beams or electron beams of radius 0.1 mm (0.004 in.) incident on a steel surface of thermal diffusivity 10 mm^2/s (0.4 ft^2/h) is achieved in 1 ms. This could be regarded as instantaneous. Again, for very low welding speeds, the penetration depth of laser welds becomes significantly less than that attainable with the electron beam. According to Locke *et al.* (Ref 28), this can be attributed to the formation of a plasma cloud, which attenuates the incident beam.

Laser-Beam Welding

Jyoti Mazumder, University of Illinois at Urbana-Champaign

Processing Equipment

Solid-State Optically Pumped Lasers. The majority of pulsed ruby and Nd:YAG solid-state lasers are used for microwelding applications. Continuous wave CO_2 (commercially available up to 25 kW, or 34 hp) and Nd:YAG (commercially available up to 2.4 kW, or 3.2 hp) versions are primarily used for deep-penetration welding. Table 2 gives the capabilities of lasers used for welding. Typical specifications of commercially available Nd:YAG lasers feature:

- UP TO 400 TO 600 W (0.5 TO 0.8 HP) AVERAGE POWER WITH PEAK POWER OF UP TO 8 TO 10 KW (11 TO 13 HP)
- PULSING WIDTH OF 250 MS
- PULSING RATE OF 400 PULSES PER SECOND (PPS)

Nd:YAG rods used as the active medium are pumped by a xenon flash lamp arranged in an elliptical cavity (Fig. 4). Typically, the cavity is coated with gold to maximize reflection of the flash lamp and subsequently to maximize the absorption in the rod. Recently, diode lasers have been explored as the pumping source to replace the flash lamp as the energy source. This improves the pumping efficiency and minimizes the thermal distortion of the medium.

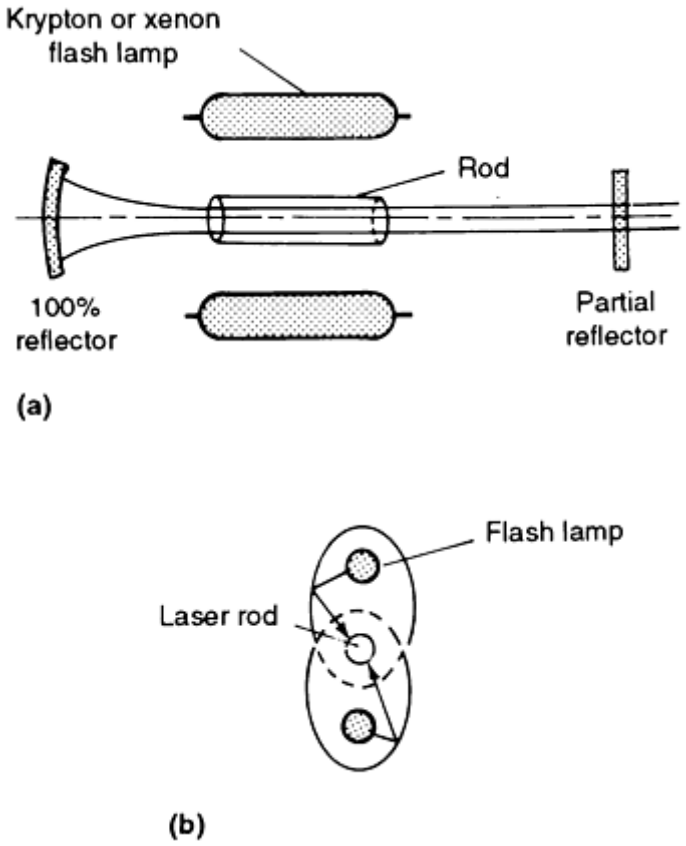

FIG. 4 TYPICAL CONSTRUCTION OF A PULSED OPTICALLY PUMPED ND: YAG SOLID-STATE LASER. (A) TOP VIEW. (B) END VIEW, SHOWING ELLIPTICAL CROSS SECTION OF REFLECTOR CAVITY HAVING THE ROD AT ONE FOCUS OF THE ELLIPSE AND THE FLASH LAMP AT THE OTHER FOCUS

Another new development in the Nd:YAG laser field is the face-pumped Nd:YAG laser (Fig. 5). The crystal slab provides much better beam quality because the temperature fluctuation across the active medium is much less for the slab configuration than the rod configuration. The "rod" geometry is at a disadvantage because only the surface of the rod is used as the active medium to produce a temperature gradient between the center and the surface. In the slab geometry, however, almost the entire crystal serves as the active medium, thus minimizing temperature gradient, which in turn reduces the thermal lensing effect. Although these solidstate optical systems have been used internally by General Electric for a long time, only recently, after the patent expired, did commercial systems become available. Beam generation in most rod systems is pulsed, whereas in most slab systems it is continuous wave.

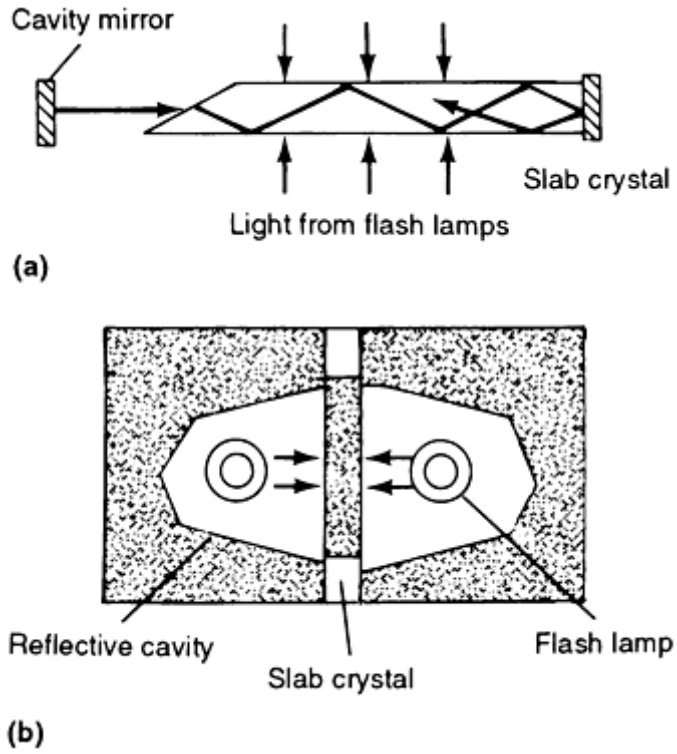

FIG. 5 KEY COMPONENTS OF A FACE-PUMPED ND:YAG SOLID-STATE LASER INCORPORATING A SLAB CRYSTAL. (A) FRONT VIEW. (B) END VIEW (CROSS SECTION)

The emergence of commercial multikilowatt (up to 2.4 kW, or 3.2 hp) CW Nd:YAG lasers is a recent development that has generated considerable interest with the laser industry because the energy can be transmitted through fiber optics. The maneuverability of the beam provided by fiber optics opens many complicated manufacturing operations previously closed to LBW processing.

Gas Lasers. Continuous wave CO_2 lasers are generally chosen for penetration welding applications. Figure 6 shows different types of pumping designs for CO_2 lasers. The primary components of a fast-axial-flow (FAF) CO_2 laser are shown in Fig. 7. Table 4 gives the four major types of CO_2 lasers commercially available.

TABLE 4 TYPICAL OUTPUT POWER OF COMMERCIALLY AVAILABLE CW CO_2 LASERS

DESIGNATION		ELECTRIC EXCITATION DISCHARGE(A)	OUTPUT POWER PER CAVITY LENGTH	
FLOW CONFIGURATION	TYPE		w/m	w/ft
AXIAL	SLOW	DC	60	18
	FAST	DC	600	180
		RF	750	230
TRANSVERSE	. . .	. . .	7000	2100

Robotics. Robotic equipment is now available that can be integrated with lasers to provide beam delivery to the workpiece. In addition, almost any multiaxis or single-axis workstation can be integrated with lasers to steer the beam to the workpiece.

Ergonomics. Proper use of the laser as a machine tool requires a basic knowledge of optics. Knowledge of optical properties such as beam spatial distribution, depth of focus, and wavelength is critical to LBW processing. Textbooks should be consulted to make operators familiar with the fundamentals of laser physics and optics.

Laser-Beam Welding

Jyoti Mazumder, University of Illinois at Urbana-Champaign

Health and Safety

Laser-beam welding hazards differ substantively from hazards encountered in other welding techniques. The hazards are not readily apparent, and inexperienced personnel may suffer permanent injury before the existence of hazardous conditions is recognized. For this reason, the American National Standards Institute specification ANSI Z136.1, "Safe Use of Lasers" (latest edition), requires that each facility using lasers designates an individual as "laser safety officer." This individual should be familiar with laser safety and ANSI Z136.1. The officer should monitor the use of lasers to ensure adherence to safe laser practice and the ANSI requirements. Because of the complexity of laser safety, this approach is strongly endorsed. The following brief review of laser safety by itself is not sufficient to ensure personnel safety.

Electrical Hazards. All lasers used for welding employ high voltages capable of inflicting lethal electric shocks. Therefore, maintenance should be performed by personnel familiar with high-voltage safety procedures.

Power supplies for high-power lasers contain capacitors capable of lethal shock even after initial discharge due to a phenomenon known as charge buildup. To facilitate safe maintenance access, the following provisions should be included:

- AN AUTOMATIC DISCHARGE AND GROUNDING CIRCUIT THAT IS ACTUATED WHEN THE LASER IS TURNED OFF
- DISCHARGE AND GROUNDING INTERLOCKS ON ALL ACCESS PANELS
- GROUNDING RODS FOR MANUAL VERIFICATION OF COMPLETE DISCHARGE. SAFETY GLASSES SHOULD BE USED, BECAUSE EXPLOSION-LIKE DISCHARGES ARE POSSIBLE ON PARTLY CHARGED CAPACITORS
- GROUNDING STRAPS TO SHORT OUT CAPACITORS TO PREVENT CHARGE BUILD-UP

In addition, all capacitors should be discharged and grounded before any work is performed on or near high-voltage components.

Control of laser performance usually requires switching of capacitors. Insulated switches that do not expose personnel to electric conductors are preferred. If switching requires work on bus bars, the procedure listed above should be followed, and the use of insulated tools should be considered. Cooling water leaks are not acceptable, especially when electrical and cooling lines share the same umbilical.

Eye Hazards. Any laser beam capable of welding metals is also capable of causing serious eye damage. Personnel exposure to the beam and any specularly reflected beam must therefore be prevented at all times. Certain lasers, however, are also capable of producing diffuse reflections that can cause permanent eye damage. Hence, viewing of the impact area of the laser beam or reflected beams also must be prevented. The preferred method for this is by complete enclosure.

Enclosures can range from a simple sleeve between the laser optic and the part to be welded to fully automatic operations in enclosed rooms. The following are general guidelines:

- THE ENCLOSURE MUST BE OPAQUE TO THE LASER WAVELENGTH. METAL ENCLOSURES ARE GENERALLY SUITABLE, BUT PLASTICS ALSO ARE A POSSIBLE SELECTION. INFRARED LASERS, FOR EXAMPLE, CAN BE ENCLOSED IN CLEAR POLY METHYLMETHACRYLATE. THE REQUIRED THICKNESS CAN BE CALCULATED USING ANSI Z136.1 AND THE TRANSMITTANCE PROPERTIES OF THE MATERIAL.
- THE ENCLOSURE MUST BE INTERLOCKED TO PREVENT FIRING OF THE LASER BEAM WHEN PERSONNEL COULD BE EXPOSED. WHEN THE PIECE TO BE WELDED IS A PART OF THE ENCLOSURE, THE INTERLOCKS SHOULD ALSO PREVENT FIRING, UNLESS THE PIECE IS IN PLACE. IN THE CASE OF PULSED LASERS, BREAKING OF THE INTERLOCKS SHOULD ALSO DISCHARGE THE STORED ENERGY INTO A DUMMY LOAD.
- SIGNS ARE REQUIRED AT ACCESS POINTS TO THE ENCLOSURES; SEE ANSI Z136.1.
- VIEWING OF THE WELD AREA CAN BE ACCOMPLISHED IN SEVERAL WAYS. MOST COMMON ARE VIEWING PORTS WITH FILTERS AND TELEVISION MONITORS. FOR MICROWELDING, MICROSCOPES SHOULD HAVE FILTERED VIEWING OPTICS OR FLIP MIRRORS THAT PERMIT EITHER WELDING OR VIEWING.
- ALIGNMENT OF LASER WELDING SYSTEMS SHOULD BE ACCOMPLISHED USING LOW-POWER LASERS.

Laser welding can also be performed with personnel in attendance. When done in this manner, the hazard must be evaluated for each welding process using the ANSI standard. General requirements include:

- THE LASER WELDING AREA MUST BE COMPLETELY ENCLOSED AND ACCESS MUST BE

RESTRICTED.

- IN MOST CASES, LASER EYE PROTECTION IS REQUIRED FOR ALL PERSONNEL IN THE AREA. THE OPTICAL DENSITY OF THE EYE PROTECTION MUST BE CALCULATED TO REDUCE THE POTENTIAL EYE EXPOSURE TO LESS THAN THE MAXIMUM PERMISSIBLE EXPOSURE (MPE) LEVEL.
- THE WELDING BEAM MUST BE CAREFULLY CONTROLLED AND SHOULD STILL BE ENCLOSED TO THE GREATEST EXTENT POSSIBLE. EYE PROTECTION IS LIKELY TO FAIL ON EXPOSURE TO THE PRIMARY BEAM.
- COMPLIANCE WITH PERSONNEL TRAINING REQUIREMENTS IS EXCEEDINGLY IMPORTANT.

Skin Exposure. Skin exposure to the primary beam obviously can result in thermal burns and must be prevented by complete enclosure and operator training. Even in attended operations where the operator is permitted to view the welding process, provision of partial enclosures to prevent personnel from placing any part of the body into the beam path is desirable.

The ANSI standard also prescribes MPE values for skin exposure. In the visible and near infrared regions, these are much greater than the MPE values for the eyes; hence, a problem from excessive exposure due to diffuse reflections at these wavelengths rarely occurs. Excessive skin exposures in the ultraviolet and far infrared regions are possible, however. Typically, ultraviolet exposures can be controlled with clothing of tightly woven material and barrier creams applied to exposed skin. Harmful levels of ultraviolet light can also be generated by flash lamps; hence, covers should be kept in place.

Chemical Hazards. Laser welding generates metal fumes similar to other welding processes, and the hazard is largely dependent on the composition of the welded metals. Ventilation is required to meet OSHA standards and American Conference of Governmental and Industrial Hygienists (ACGIH) threshold limit values. In high-power welding applications, fumes can be generated in sufficient quantities to make local exhaust ventilation, in addition to general room ventilation, both necessary and economical.

Harmful fumes or vapors can also be generated when laser energy is deposited in unwanted materials, such as breakdown of plastic enclosure materials due to laser exposure and failure of exotic lens materials due to thermal runaway. These conditions are best controlled by careful material selection and monitoring of welder performance. Finally, laser optics cleaning agents may be toxic and flammable and should be handled accordingly.

Training, Medical Examinations, and Documentation. ANSI Z136.1 requires that training in the potential hazards and control measures be provided to operators, engineers, technicians, and maintenance and service personnel. Special training on subjects such as potential hazards (including biological effects), control measures, and applicable standards is required for the laser safety officer. A model safety and training program is outlined in Appendix D of the standard.

Routine medical surveillance of laser users is no longer mandated by the standard. However, an employer may wish to provide such for medical/legal reasons (that is, to document what eye damage existed prior to commencement of laser work and that no additional damage has occurred).

Good documentation includes:

- LISTING OF LASERS, DURATION OF USE
- RESULTS OF HAZARD SURVEYS AND CALCULATIONS OF ACCESSIBLE LASER RADIATION
- INTERLOCK TESTS
- LASER USE PROCEDURES
- EMPLOYEES WORKING IN LASER AREA
- DATE AND EXTENT OF EMPLOYEE TRAINING
- DATES AND RESULTS OF MEDICAL EXAMINATIONS (IF ANY)
- TRAINING AND QUALIFICATIONS OF LASER SAFETY OFFICER

Electroslag and Electrogas Welding*

S. Liu, Colorado School of Mines; S.D. Brandi, Escola de Politecnica da USP; R.D. Thomas, Jr., R.D. Thomas and Company

Introduction

ELECTROSLAG WELDING AND ELECTROGAS WELDING are two related procedures that are presently used to weld thick-section materials in the vertical or near-vertical position between retaining shoes. Primarily applied for joining steels of thicknesses over 50 mm (2 in.), electroslag welding (ESW) involves high energy input relative to other welding processes, resulting in generally inferior mechanical properties, specifically lower toughness of the heat-affected zone (HAZ). However, the high deposition rate and relatively low cost of the process make it attractive for heavy structural fabrication. The as-welded properties of electrogas welding (EGW), usually applied to steels under 50 mm (2 in.), are generally superior to those of electroslag welds, and the process is commonly applied to the field erection of storage vessels and other less critical structures.

Electroslag welding is a vertical welding process producing coalescence with molten slag which melts the filler metal and the surface of the work to be welded. Confined by cooling shoes, the molten weld pool is shielded by the molten slag, which moves along the full cross section of the joint as welding progresses. The conductive slag is maintained in a molten condition by its resistance to electric current passing between the electrode and the work (Ref 1). ESW can be considered a progressive melting and casting process in which the heat of a bath of molten flux is used to melt the filler metal and the edges of the plates to be welded. Electric arc occurs only at the beginning of the process, and once a molten bath is achieved, the arc is extinguished. During the process, flux is added periodically or continuously to maintain an adequate slag covering over the pool of molten metal. Two or more retaining shoes hold the molten metal in place until it has solidified. In normal operation with a constant potential power source, the electrode melts off while dipping only partly through the flux bath and gathers in the molten metal puddle. In the case of low-carbon steel, the temperature of the bath is reported to be in the vicinity of 1925 °C (3500 °F), while the surface temperature is approximately 1650 °C (3000 °F) (Ref 2). The major process variables are welding current and voltage. Welding current is directly responsible for the electrode melt rate, while voltage influences the base metal penetration and weld bead width. Both variables are sensitive to the physical properties of the welding flux, such as electrical resistivity and fluidity.

Electrogas welding is a method of gas-metal arc welding (if a solid wire is used) or flux-cored arc welding (if a tubular wire is used), wherein an external gas is supplied to shield the arc and molding shoes are used to confine the molten weld metal for vertical position welding (Ref 2). Electrogas welding may or may not use an added flux. In the solid wire process, CO_2 shielding gas is commonly used and no flux is added. With the flux-cored process, the core ingredients provide a small amount of flux to form a thin deposit of slag between the weld and the shoes. Self-shielding electrodes eliminate the need for external shielding gas. A major difference between ESW and EGW is that the former relies on slag conduction to carry the welding current and the latter uses arc conduction. Despite the differences, similarities between ESW and EGW in terms of equipment, joint preparation, and welding procedures are such that they can be grouped into one category and described as allied processes.

Fundamentals of the Electroslag Process

Heat Flow Conditions. Electroslag welding is quite similar to *in situ* casting, with large volumes of molten metal and high heat content. When compared with other arc welding processes, electroslag welds have a long thermal cycle with very slow cooling rate. Electroslag welding generally consumes hundreds of kilo-joules per inch, as compared to 10 to 40 kJ/mm (250 to 1000 kJ/in.) found in most arc welding. Figure 1 shows a typical thermal cycle of an electroslag weld compared with that of an arc welded weld. As a consequence of the thermal experience, weld metal solidification is extremely slow, resulting in a coarse primary solidification structure. The heat absorbed into the base metal also creates an extremely large HAZ (Fig. 2).

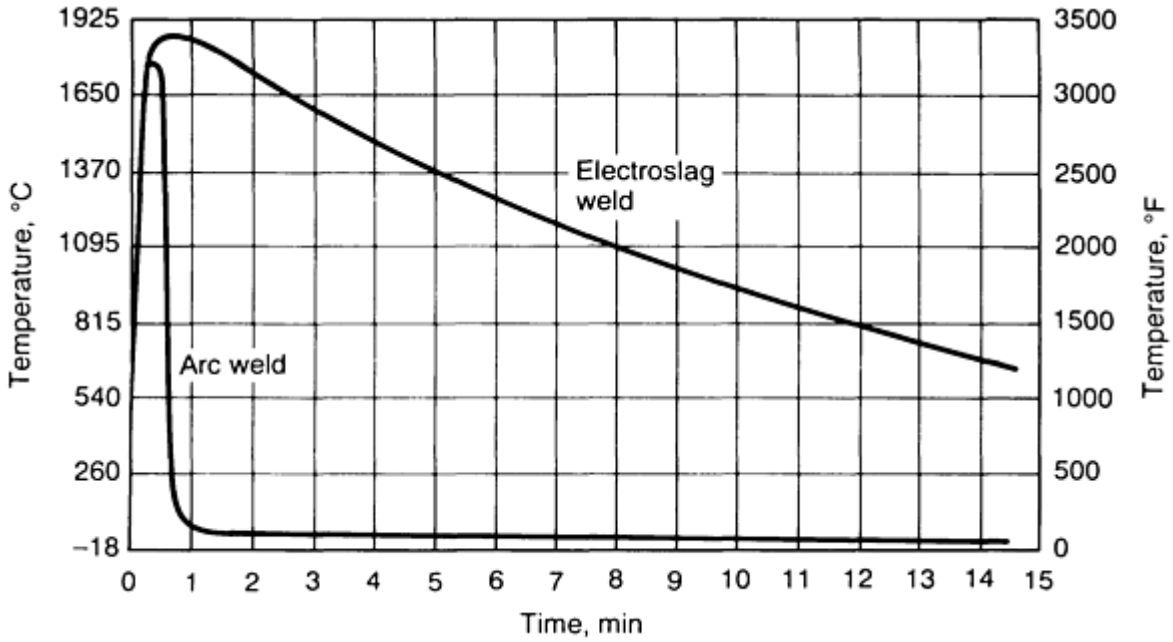

FIG. 1 TYPICAL THERMAL CYCLE OF AN ELECTROSLAG WELD RELATIVE TO THAT OF AN ARC WELDED WELD

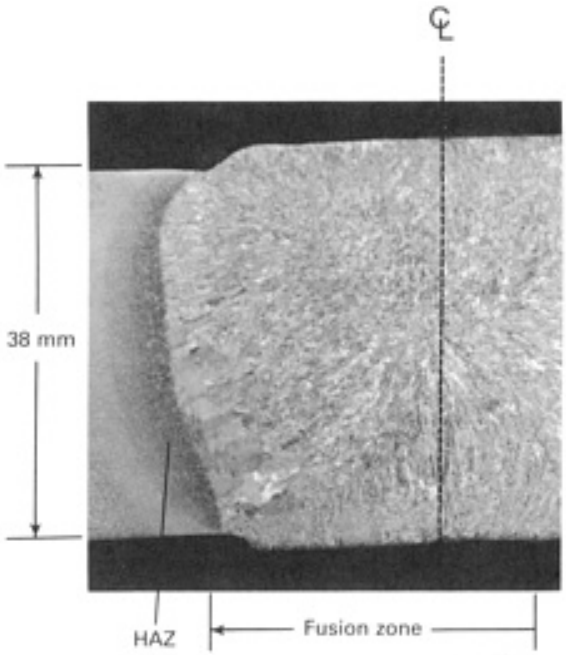

FIG. 2 MACROGRAPH SHOWING FUSION ZONE AND HEAT-AFFECTED ZONE IN AN ELECTROSLAG WELDMENT

A heat balance diagram of a typical electroslag weld (Fig. 3) illustrates that approximately 60% of the heat is absorbed by the workpart, close to 25% of the total heat is expended in the melting of the electrode, and around 10% of the heat is used to superheat the molten metal (Ref 3). The amount of heat extracted by the cooling shoes varies, depending on the thickness of the plate and on the welding conditions. In the welding of steel plates 90 mm (3 $\frac{1}{2}$ in.) thick, less than 10% of the heat of the molten slag and metal pool is transferred to the cooling shoes. In thinner plates, however, the cooling shoes play a more significant role in the heat balance.

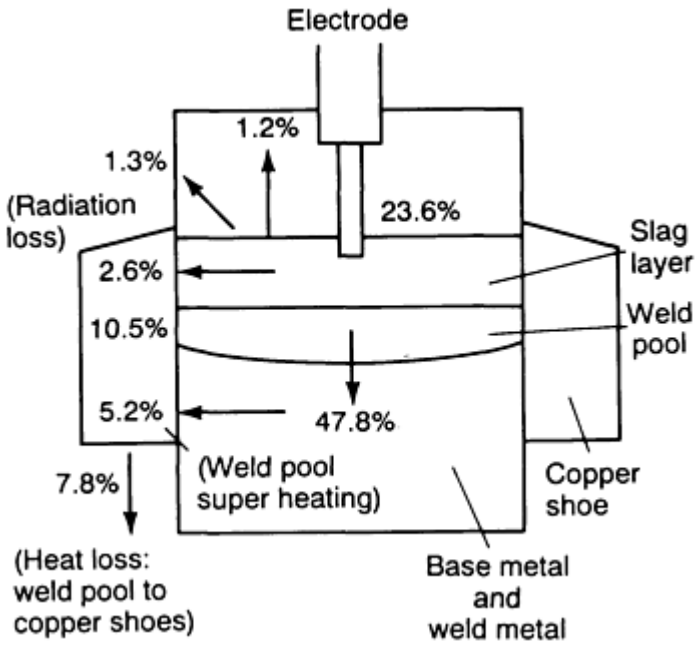

FIG. 3 HEAT BALANCE DIAGRAM OF A TYPICAL ELECTROSLAG WELDMENT. SOURCE: REF 3

Mathematical models are used to estimate the three-dimensional temperature field in the slag, metal pool, and base metal regions in an electroslag weldment, and to predict HAZ size and grain growth in the HAZ. Figure 4 shows an example of the calculated temperature distribution for a base plate 25.4 mm (1 in.) thick, 470 mm (18.5 in.) long, and 610 mm (24 in.) wide, at the time that corresponds to half the total time required for completion of the weld (Ref 4). The maximum temperatures reached in the slag and weld pool were 2230 K (3555 °F) and 1900 K (2960 °F), respectively. The temperature distribution in a weldment along planes parallel and normal to the parent plate surface can also be represented in the form of isometric temperature plots (Fig. 5).

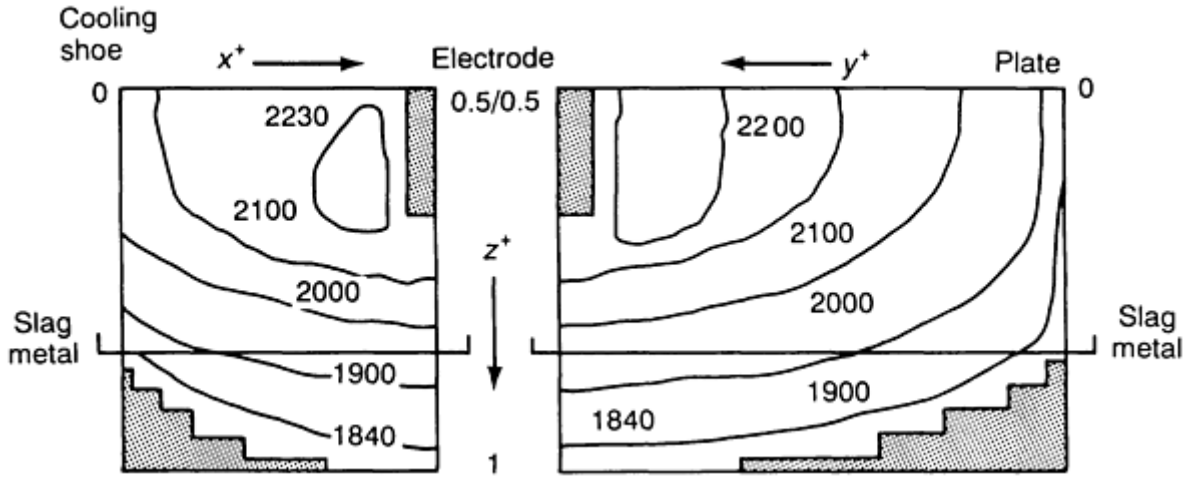

FIG. 4 CALCULATED TEMPERATURE DISTRIBUTION OF AN ELECTROSLAG WELDMENT SHOWING THREE-DIMENSIONAL TEMPERATURE FIELD IN THE SLAG, METAL POOL, AND BASE METAL. ALL TEMPERATURES SHOWN ARE IN KELVIN. SOURCE: REF 4

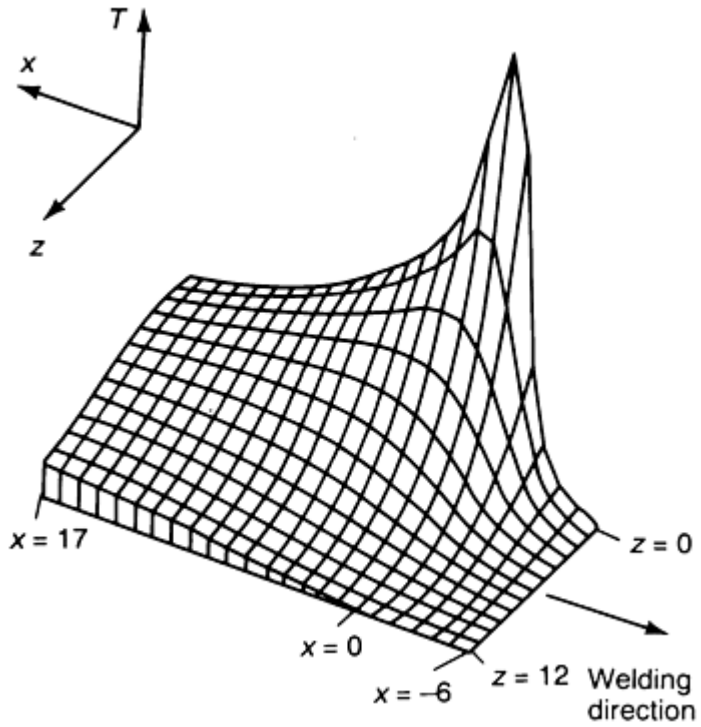

FIG. 5 ISOMETRIC THREE-DIMENSIONAL TEMPERATURE DISTRIBUTION IN AN ELECTROSLAG WELDMENT ALLOWING IMPROVED VISUALIZATION OF THE TEMPERATURE PROFILE. SOURCE: REF 5

The energy balance in the slag phase is summarized in Table 1. A major portion of the heat generated in the slag layer was transferred to the cooling shoes (36.1%). Approximately 22 and 15% of the heat was used in base metal heating and electrode melting, respectively. The heat-generating patterns are highly sensitive to the geometric location of the electrode in the slag. With careful control of the process variables (such as gap distance and convective flow suppression) by external application of electromagnetic field, reductions of two or three times the usual heat input could be practical.

TABLE 1 ENERGY BALANCE IN THE SLAG PHASE OF ELECTROSLAG WELDING

PARAMETER[(A)]	ENERGY DISSIPATED, %
HEAT TRANSFER FROM SLAG:	
TO COPPER SHOE	36.10
TO BASE PLATES	20.22
TO LIQUID METAL	8.71
HEAT USED TO HEAT THE ELECTRODE TO ITS MELTING POINT	15.26
HEAT REQUIRED:	
TO MELT THE ELECTRODE	4.07
TO HEAT FLUX COOLING ON THE CONSUMABLE GUIDE	1.84
HEAT CARRIED BY LIQUID METAL DROPS	2.04
RADIATION LOSS FROM THE SLAG SURFACE	1.75
ELECTROCHEMICAL LOSS	10.00

(A) ACTUAL WIDTH OF THE SLAG POOL 0.044 MM (0.0017 IN.); CURRENT 534 A; OTHER CONDITIONS ARE THE SAME AS THOSE PRESENTED IN TABLE 2.

To distribute the energy uniformly across the thickness of the weldment, empirical rules have been developed (Table 2) to determine the preferred number of electrodes, the wire spacing, and the traverse (oscillation) distance (Fig. 6). Oscillation speeds depend on the plate thickness, usually allowing a traverse time of 3 to 5 s; a dwell time at the end of each traverse ensures adequate penetration at the plate edges.

TABLE 2 EFFECT OF JOINT GEOMETRY ON MULTIPLE-WIRE BUTT ELECTROSLAG WELDING

STEEL PLATE THICKNESS		NUMBER OF WIRES	OSCILLATION	SQUARE BUTT GAP OPENING	
mm	in.			mm	in.

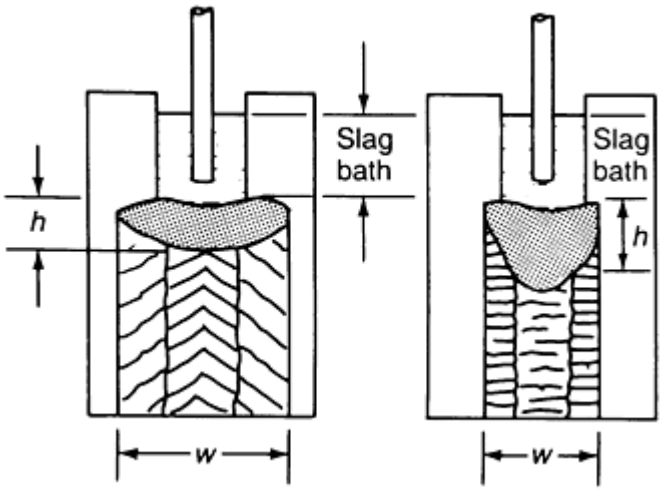
Metal Transfer and Weld Pool Morphology. The droplet transfer rate and the length of time each droplet is in contact with the slag layer profoundly affect the chemical composition and the metallurgical properties of the weld pool.

Droplet Formation. In steady-state operation, the molten filler metal transfers into the weld pool in a globular mode. Current and voltage oscillograms indicate that despite the droplet size decrease observed with increasing voltage, welding current has no significant effect on the size of the droplets. Rather, the length of time that a droplet is in contact with the slag layer decreases considerably with increasing current. On the other hand, the length of time a droplet is in contact with the layer of slag increases with voltage, because the electrode tip is further away from the molten metal pool. The extent of interaction between a metal droplet and the slag layer determines the chemical composition of the weld pool.

Weld Pool Morphology. In an electroslag weldment, solidification begins at the fusion line, surfaces adjacent to the retaining shoes, and progresses toward the center of the weld. Because the process is continuous in a vertical or near vertical-up position, solidification also progresses from the bottom toward the top part of the joint. The angles at which the columnar grains meet at the center of the weld depend on the shape of the weld pool, which can be described by the weld pool form factor. Form factor is defined as the ratio between the width, *W*, and the maximum depth, *h*, of the pool (Fig. 7). Welds having a high form factor (>2.0) will have grains meeting at an acute angle at the center line, while welds with a low form factor (<1.0) will solidify with grains meeting at an obtuse angle. Low form factor is highly undesirable

because of the potential accumulation of residual elements at the center of the weld joint. High welding current usually results in a low form factor, while low welding current usually results in a high form factor and shallow metal pool. High voltage promotes shallow pools and low voltage. Figure 7 shows two examples of different pool morphologies and form factors as a function of the welding current and voltage.



EFFECT OF WELDING PARAMETERS ON WELD METAL POOL SHAPE

PARAMETER	EFFECT OF PARAMETER INCREASE ON WELD-METAL POOL DIMENSION[A]		
	POOL WIDTH (*W*)	POOL DEPTH (*H*)	FORM FACTOR (*F* = *W*/*H*)
CURRENT OR WIRE-FEED SPEED:			
LOW VALUES	A	A	B
HIGH VALUES	D	A	D
VOLTAGE	A	B	A
SLAG POOL DEPTH	D	B	D
ROOT OPENING	A	C	A

FIG. 7 EFFECT OF INCREASE IN WELDING PARAMETERS ON WELD POOL FORM FACTOR. (A) OPTIMUM WELD POOL DIMENSIONS (SHALLOW WELD POOL, HIGH FORM FACTOR, ACUTE ANGLE BETWEEN GRAINS). (B) UNDESIRABLE WELD POOL DIMENSIONS (DEEP WELD POOL, LOW FORM FACTOR, OBTUSE ANGLE BETWEEN GRAINS). SOURCE: REF 6

An additional factor controlling the weld puddle morphology is the welding flux conductivity. Actually, the bulk of the electrical energy is converted into thermal energy in a thin layer of the slag contiguous to the electrode tip, which acts as the heat source in ESW (Ref 3). High conductivity fluxes generate less heat and result in less base metal penetration and shallower weld pools.

Out-of-Position (Nonvertical) ESW. Electroslag welding has been successfully done in joints that are inclined from the vertical position. The stability of the process and the quality of the weld joint are both functions of the angle of inclination. Weld morphology, including penetration, HAZ, and weld metal microstructure, is sensitive to the welding parameters. Preferential radiative heating of the upper weld surface is considered the cause of asymmetric penetration and HAZ geometry (Ref 7).

Weld Pool Penetration and Magnetic Field Coupling. Magnetic field is not generally applied in ESW. For electroslag overlays, however, some use of magnetic field to promote fluid flow and to drive the molten slag layer from the hotter region to the colder region to eliminate undercutting has been reported (Ref 8). However, the effect of magnetic stirring, which induced convective fluid motion in the weld pool and disrupted the solidification and growth of the columnar dendrites, can be seen in Fig. 8 (Ref 9, 10). Mechanical vibration on electroslag weld pools generally does not cause significant microstructural modification. However, some refinement of the as-deposited grains can result when the slag-molten metal interface is disturbed. The use of a quartz-shielded electrode guide tube as an extended stirrer has been reported to form a deeper weld pool, with the form factor decreasing from 3 to 1.5 (Ref 11, 12). Other techniques for refining weld metal microstructures include ultrasonic cavitation and the use of chemical inoculators.

Constitutive Equations for Welding Current, Voltage, and Travel Rate

The power input per unit length of a weld is the primary variable that influences the degree of base metal melting, the amount of filler metal deposition, and the thermal history of the weldment. In ESW, current and travel speed are not independent variables, as in the other arc welding processes. For a constant voltage power supply, the current and power are both functions of the resistance of the slag pool. Hence, they are functions of the electrode feed rate, the mechanics of electrode melting, and the nature of the electrical and thermal transport at the electrodeslag interface. To control the welding process, a constitutive equation has been proposed (Ref 13):

$$I = B\,W^{1/2}V^{1/3} \qquad \textbf{(EQ 1)}$$

where I is the welding current, W is the electrode feed rate, V is the welding voltage, and B is a proportionality constant. Equation 1 expresses the functional relationship between the various process variables and has the primary objective of selecting a voltage and current range that provides sufficient energy input for base plate penetration without excessive overheating of the HAZ. The relation can be empirically determined from Fig. 9. The total energy input per unit area of weld surface, E, can also be determined:

$$E = B\frac{L_g}{2p\,r^2(L+g)}\cdot\frac{V^{5/3}}{I} \qquad \textbf{(EQ 2)}$$

where L is the width of the base plate, g is the root gap opening, and r is the radius of the welding electrode. Note also that this equation takes into consideration the electrode-to-joint geometry, which is related to the electrical and thermal transport in the process.

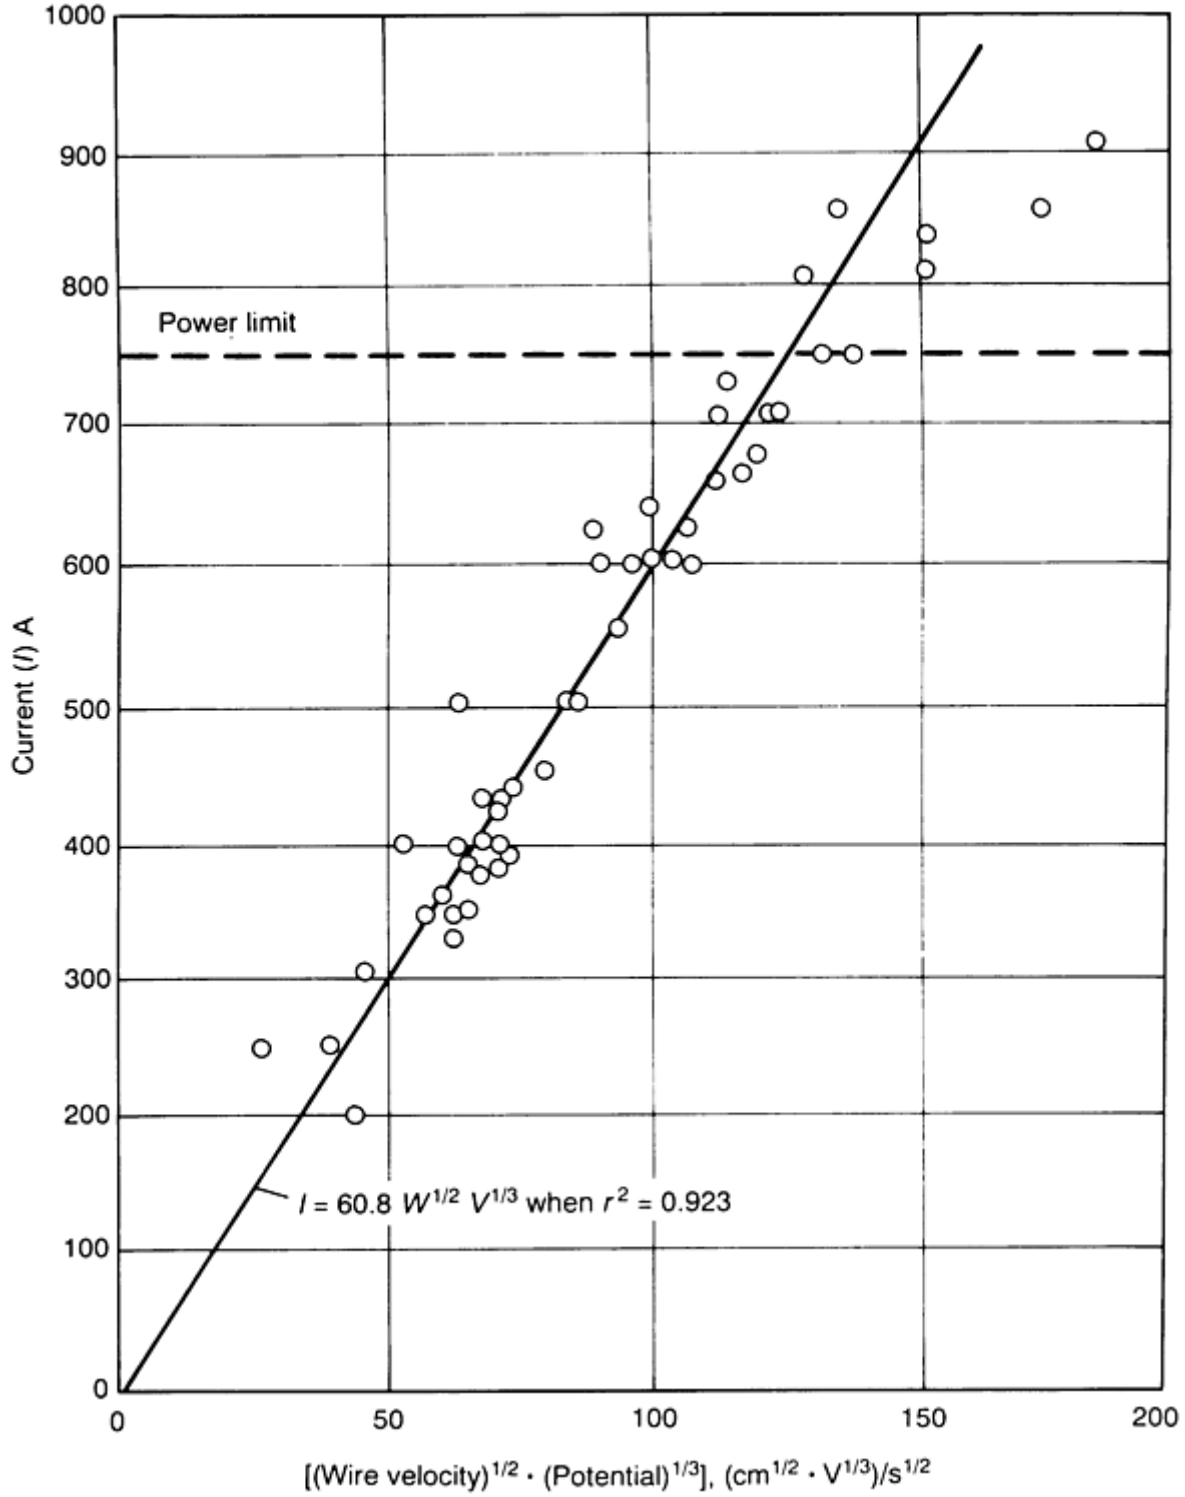

FIG. 9 FUNCTIONAL RELATION AMONG WELDING CURRENT (*I*), POTENTIAL (*V*), AND WIRE-FEED RATE (*W*) FOR ELECTROSLAG WELDING OF 2 $\frac{1}{4}$ CR-1MO STEEL. LINE INDICATES VALUE OF $I = BW^{1/2}V^{1/3}$ FOR $B = 60.8$ AND $R = 0.923$. SOURCE: REF 14

Unlike arc welding processes, in which an increase in current results in greater energy input and deeper penetration, the reverse occurs in ESW. An increase in current requires an increase in electrode burn-off rate, which increases the welding speed and decreases the energy input per unit area of weld. An excessive increase in the current at constant voltage, however, can shift the process from penetration to nonpenetration of the base plate. The process control boundaries for ESW can be easily developed (Fig. 10). Boundaries A through D enclose an operating space that exhibits good process

stability and base metal melting. Outside the indicated boundary, the process often appears to operate well but with inadequate base metal penetration (Ref 13).

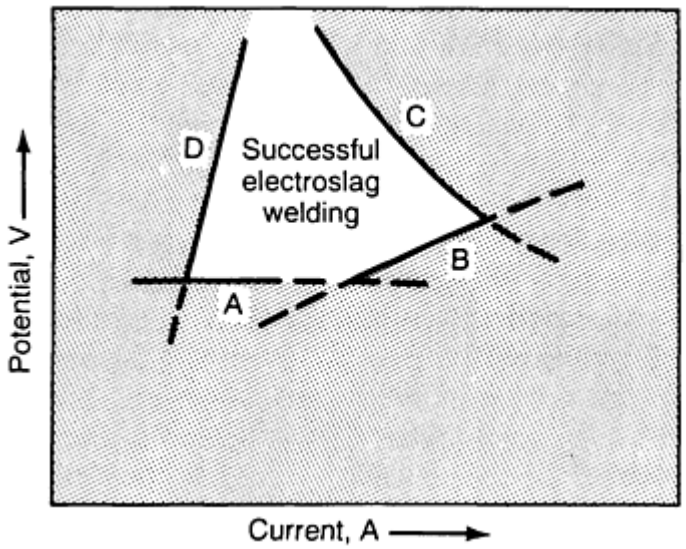

FIG. 10 OPERATING PARAMETER WINDOW FOR ELECTROSLAG WELDING. BOUNDARY A REPRESENTS THE VOLTAGE THRESHOLD FOR PARENT PLATE FUSION AT LOW-POWER INPUTS. BOUNDARY B REPRESENTS THE CONSTITUTIVE EQUATION FOR ADEQUATE PENETRATION AT HIGH POWER LEVELS. BOUNDARY C REPRESENTS THE MAXIMUM POWER OUTPUT OF THE WELDING POWER SUPPLY. BOUNDARY D REPRESENTS THE LIMIT OF ELECTRODE FEED RATE AT WHICH THE WIRE ELECTRODE MELTS BY OHMIC HEATING. SOURCE: REF 14

A change in electrode geometry and nature (cored) may result in a different constitutive equation (Ref 9, 15):

$$I = B' W^{0.35} V^{1.63} \qquad \textbf{(EQ 3)}$$

where B' is the proportionality constant. The total energy input, E, is:

$$E = B' \frac{L_g - 2w_g t_g}{[L + (g + 2t_g)][w_c t_c d_c]} \cdot \frac{V^4}{I^2} \qquad \textbf{(EQ 4)}$$

where w_g is width of the consumable plate guide; t_g is the thickness of the consumable plate guide; w_e is the width of the consumable electrode; and t_e is the thickness of the consumable electrode.

ESW Consumables

ESW Fluxes. Similar to the fluxes used in other welding processes, ESW fluxes are formulated to refine the weld metal, to coat the surface of the retaining shoes and the completed weld metal, and to protect the molten metal from oxidation. However, several physical and chemical properties distinguish ESW fluxes from the others used in arc welding. Electroslag welding fluxes are invariably fused, rather than agglomerated. Compared with the arc welding fluxes, fluxes for ESW are higher in resistivity, because the arc is extinguished soon after the process becomes stable. Sometimes, an agglomerated starting flux with high conductivity is used to initiate the process and form the weld pool. After that, a running flux of high resistivity is added to generate heat for melting the filler metal and to maintain steady welding operation. In fact, for high-current welding the use of starting flux is often omitted.

A typical running flux for low-carbon steels has the following composition (Ref 11):

CONSTITUENT	CONTENT, WT%
SIO_2	25
MNO	10
CAF_2	15
AL_2O_3	25
CAO	15
MGO	10

Electrical Resistivity. A flux of high resistance (or low conductivity) will draw less current, resulting in a colder weld pool and lower base metal penetration. It will also allow the wire to drive deeper into the pool. On the other hand, a flux of low resistance may draw excessive current, raising the temperature of the bath until the process stabilizes with a shorter electrode extension. However, if resistance is too low, then arcing may occur between the electrode and the slag bath surface, especially at higher voltages. This condition is aggravated in fluxes that show steeply increasing conductivity with rising temperature. In terms of process conditions, lower slag resistivity may result in operation at lower voltage.

Fluidity. In addition to its heat-generating ability, the molten slag must also have sufficient fluidity to cause rapid convection and good circulation, needed to distribute heat throughout the weld joint. Fluidity of a slag depends mainly on its chemical composition and operating temperature. The melting point of a flux must be below that of the base metal for weld pool refining, and its boiling temperature must be higher than the operating temperature to avoid loss by vaporization. Any preferential loss (of one or more ingredients) will alter the bath composition, which may greatly change the slag fluidity and electrical conductivity, resulting in improper shielding. If the composition of the fluxes is altered during operation, the change in energy imparted to the slag may cause an increase in temperature and in conductivity during welding of long seams, which may give rise to arcing on the top surface of the slag bath.

Low fluidity will tend to trap slag inclusions in the weld metal; excessive fluidity will cause leakage through the small space between the work and the retaining shoes. For joining thin plates, higher fluidity fluxes are desirable to obtain good circulation in the relatively small bath.

Metallurgical Compatibility. Finally, the slag should be metallurgically compatible with the alloy being welded. For steel welding, the fluxes are generally mixed oxides of silicon, manganese, titanium, calcium, magnesium, and aluminum (Ref 1). These oxide components play an important role in the shielding and refining of the weld pool. Calcium fluoride (CaF_2) is added to basic oxides or silicate systems to achieve the proper resistivity and fluidity. Increasing CaF_2 decreases viscosity, melting point, and resistivity. Additions of TiO_2 also decrease resistivity, while Al_2O_3 increases it. However, TiO_2 also increases slag viscosity (Ref 2, 3). Special applications, such as inclusion control or sulfur removal, may require the addition of rare-earth compounds (Ref 16).

Slag detachability after weld metal solidification is not a major problem in ESW. The addition of large quantities of TiO_2, however, will often result in difficult slag removal. Fluoride additions generally improve slag detachability.

ESW Electrodes. Various ESW techniques are available, depending on the type of electrodes and the feeding mechanism. The electrodes can be solid wires, tubular flux-cored wires, large-section solid electrodes, and large-section cored electrodes. The guides or nozzles can be consumable or nonconsumable. The conventional method uses nonconsumable guides (also known as snorkels), which are maintained approximately 50 to 75 mm (2.0 to 3.0 in.) above the molten flux. In this case, a mobile feeding head is used and is raised vertically to match the weld pool travel speed. If the electrode feeding mechanism is stationary, then the nozzle will be "consumed," becoming part of the weld metal when it is reached by the slag pool. Accordingly, the materials used in consumable guides generally match the chemical composition of the electrode or base metal. A consumable guide can either be a thin-wall tube or an assembly of plates or rods with conduits to feed the electrode wire. Fin-shape guide tubes are prepared by welding webs to circular-section guide tubes to obtain more uniform weld pool heating (Ref 1, 3, 6). Among the different types of electrodes, only the wire type and the large-section cored electrodes require the use of nozzles for delivering the electrode into the root gap. Bare guides sometimes need insulation along their lateral surfaces if they cannot be precisely aligned within the weld joint. One solution is to insert insulating plugs at critical locations in the assembly. Flux-coated consumable nozzles are available to minimize the problem of insulating the electrode assembly. Figure 11 shows several shapes of electrodes and guides used in ESW.

Metallurgical and Chemical Reactions

Fusion Zone Compositional Effects. In ESW of carbon and low-alloy steels, the major reactions involve manganese, silicon, carbon, and impurities such as oxygen, sulfur, and phosphorus. In the welding of high-alloy steels, reactions involving chromium, titanium, aluminum, and other elements are important. The extent and control of reactions are determined mainly by the concentrations of the elements in the liquid metal and by the concentrations of their oxides in the slag. The temperature in the reaction zone, the metal droplet-slag surface area, and the duration of contact between the molten metal and slag are other factors that affect the final weld metal composition. The concentration of elements in the metal and slag is determined by the electrode wire and flux compositions and by the renewal of the slag pool (that is, the frequency with which the make-up flux is added to the pool).

Thermochemistry. In the case of slags containing high MnO and SiO_2, the reactions between the metal and slag can be described:

$$[FE] + (MNO) \rightarrow [MN] + (FEO) \quad \textbf{(EQ 5)}$$

$$2[FE] + (SIO_2) \rightarrow [SI] + 2(FEO) \quad \textbf{(EQ 6)}$$

In Eq 5 and 6, [*M*] and (*N*O) represent the activities of the metal *M* in the weld pool and of the oxide of element *N* in the slag layer. However, for all practical purposes, concentrations of the metallic element and oxide can be used instead of their activities in thermodynamic calculations. When electrodes containing high silicon are used, the reduction of manganese oxide by silicon must also be taken into account:

$$[SI] + 2(MNO) \rightarrow 2[MN] + (SIO_2) \quad \textbf{(EQ 7)}$$

The lower the temperature, the more intense will be the reaction between manganese oxide and silicon. Changes in welding conditions, such as power input and temperature distribution, will have a definite effect on the recovery of alloying elements.

Like silicon, aluminum is often employed as a deoxidizer for steels and, to a lesser degree, as a microalloying element. The deoxidation reaction is:

$$2[AL] + 3(FEO) \rightarrow 3[FE] + (AL_2O_3) \qquad \textbf{(EQ 8)}$$

The reaction of aluminum with nitrogen is also important because it has a strong affinity for dissolved nitrogen in the weld pool and because aluminum nitride is responsible for the pinning of grain boundaries and grain growth control.

Titanium is widely used to alloy and modify steels. In welding, it is oxidized by the slag:

$$[TI] + 2(FEO) \rightarrow 2[FE] + (TIO_2) \qquad \textbf{(EQ 9)}$$

Similar to aluminum, titanium also reacts with carbon, nitrogen, and oxygen to form TiN, TiC, Ti(C,N), TiO, and TiO_2 particles that may remain trapped in the weld metal, moderating excessive grain growth.

The oxidation of carbon may take place as a result of carbon reacting with dissolved oxygen and metal oxides in the liquid metal:

$$[C] + [O] \rightarrow CO \qquad \textbf{(EQ 10)}$$

$$[C] + (MnO) \rightarrow CO + [Mn] \qquad \textbf{(EQ 11)}$$

$$2[C] + (SiO_2) \rightarrow 2CO + [Si] \qquad \textbf{(EQ 12)}$$

$$[C] + (FeO) \rightarrow CO + [Fe] \qquad \textbf{(EQ 13)}$$

Other minor constituents, such as vanadium and niobium, are oxidized by the slag at the expense of FeO to form a series of oxides, such as VO, V_2O_5, NbO, and Nb_2O_5.

When ESW is used to surface machine parts, metal-cored tubular wire electrodes are often used to provide high contents of alloy elements, such as chromium, molybdenum, vanadium, or titanium, in the deposited metal. When silicate fluxes are used, the oxidation of chromium takes place according to the following main reactions:

$$[Cr] + (MnO) = (CrO) + [Mn] \qquad \textbf{(EQ 14)}$$

$$[CR] + (FeO) \rightarrow (CrO) + [Fe] \qquad \textbf{(EQ 15)}$$

The welding consumables (fluxes and welding electrodes) and base metal are the major contributors of tramp elements, such as sulfur and phosphorus, to the weld pool. In addition, the temperature and welding conditions in ESW are not optimal for dephosphorization. As a result, increased migration of phosphorus from the slag to the weld pool occurs not only at the initiation of the weld but also at points where the electroslag process is resumed after an interruption. Sulfur in carbon steel welds is considerably more dangerous than phosphorus because it is the main cause of hot cracking. More recently, desulfurization slags with approximately 60 to 85 wt% CaF_2, and 15 to 40 wt% CaO have been adopted in ESW. Substantial desulfurization can also be achieved when carbon is added to a lime-fluorspar system.

There is also indication that in ESW the slag bath receives oxygen continuously from the surrounding atmosphere. With higher oxygen potential, the slag will also tend to oxidize the weld metal. Therefore, some modified electroslag processes include an inert gas cover on top of the slag layer to ensure a more deoxidized weld pool.

Electrochemistry. In addition to the thermochemistry of the process, electrochemistry plays an important role in ESW (Ref 17, 18). Because the anode and cathode reactions all occur in one pool, the weight of electrode melted is

approximately equal to the weight recovered in the weld pool. Current efficiency can then be expressed as a function of electrode melted and element concentration change. Anodic current efficiency data show that the bulk of the current at the anode is carried by the oxidation reactions of iron, chromium, manganese, and silicon (Ref 19), which also indicates that electrochemical reactions account for a large fraction of the charges transferred. The major charge-carrying reactions at the cathode are the reductions of iron, aluminum, chromium, manganese, and silicon cations from the flux. Furthermore, the current efficiencies for electrochemical reactions involving chromium, manganese, silicon, molybdenum, oxygen, and aluminum increase with increasing current density. The concentration changes are directly proportional to the welding current and to the current efficiency for the reactions, and they are inversely proportional to the electrode melt rate.

Weld Metal Inclusions. Due to the almost "equilibrium" operating conditions of ESW as compared with other arc welding processes, inclusion separation is expected to be more complete. The larger volume of molten metal, less turbulent weld pool, slower cooling, and slower solidification rate in ESW contribute to a cleaner weld metal with relatively few submicron-size inclusions.

Solidification Structure. The morphology of steel electroslag weld deposits was first characterized and summarized by Paton (Fig. 12). Yu, Ann, Devletian, and Wood (Ref 20) further characterized the solidification substructure of low-carbon structural steel electroslag weldments and related them to the weld pool form factor:

- *GROUP 1:* TRANSITION FROM CELLULAR TO COLUMNAR DENDRITES OCCURS AT A SHORT DISTANCE FROM THE FUSION LINE. WELDS FROM THIS GROUP SHOW SHALLOW MOLTEN METAL POOLS WITH HIGH FORM FACTOR.
- *GROUP 2:* CELLULAR TO COLUMNAR DENDRITE TRANSITION OCCURS FURTHER AWAY FROM THE FUSION LINE, WITH A FINE COLUMNAR GRAIN ZONE AT THE CENTER OF THE WELD.
- *GROUP 3:* CHARACTERIZED BY A SHALLOW ANGLE OF INCLINATION (APPROXIMATELY 10°) BETWEEN THE COLUMNAR GRAINS AND THE FUSION LINE. THE TRANSITION FROM DENDRITIC TO COLUMNAR DENDRITES OCCURS CLOSE TO THE CENTER LINE OF THE WELD. THE GRAINS MEET AT THE CENTER AT AN OBTUSE ANGLE.
- *GROUP 4:* DENDRITIC TO COLUMNAR DENDRITE TRANSITION OCCURS CLOSE TO THE CENTER LINE, WITH EQUIAXED GRAINS AT THE CENTER OF THE WELD.

The deep pools and low form factor generally found in group 3 and group 4 welds are also responsible for the high sensitivity to centerline cracking and radial hot cracking of these welds.

Solid-State Transformations. The cooling rate of an electroslag weld metal is so much slower than those of other welding processes that reasonably coarse microstructures are found. During the austenite-to-ferrite transformation, primary ferrite and grain boundary ferrite are the principal constituents, along with carbides, mostly in the form of pearlite. In low-alloy steels, acicular ferrite, martensite, bainite, and retained austenite can be found only in those welds that have considerable amounts of alloying ingredients.

Electroslag Process Development

High-Productivity Electroslag Processes. Responding to the technological challenge of the need for a large volume of deposited metal and low heat input, many high-speed ESW techniques have been developed (Ref 9, 10, 11, 12, 15, 21, 23, 24, 25, 26). There have been essentially two approaches:

- NARROWING THE GAP TO DECREASE THE VOLUME OF METAL DEPOSIT (THEREBY SHORTENING THE TIME NEEDED TO FORM THE WELD JOINT)
- INCREASING THE WELDING SPEED

With either approach, the productivity is increased and the heat can be distributed throughout a longer section of the weld.

With respect to the narrow-gap approach, the extent of gap cross-sectional area reductions is limited by the stability of the process and the size of the electrode and guide tube. Too narrow a gap may cause arcing between the electrode and the base metal. Solid flux blocks may be inserted at regular intervals to avoid arcing between a solid strip electrode in a thin-channel consumable guide and the base metal. Gaps as small as 12 mm ($\frac{1}{2}$ in.) have been reported (Ref 22). Narrow-gap welding, however, can result in higher base metal dilution.

The use of powdered filler metal has been reported to increase the deposition rate in ESW (to over 24 kg/h, or 53 lb/h) with reduction in the specific heat input and to refine the weld metal and HAZ microstructure. The supply of metal powder (ferrous, mainly) to the weld metal can be obtained by a flow of argon gas (Fig. 13). Welding speed as high as 230 mm (9 in.) per minute has been reported. Notch impact testing results measured with samples taken 1 to 2 mm (0.04 to 0.08 in.) from the fusion line showed good Charpy impact toughness.

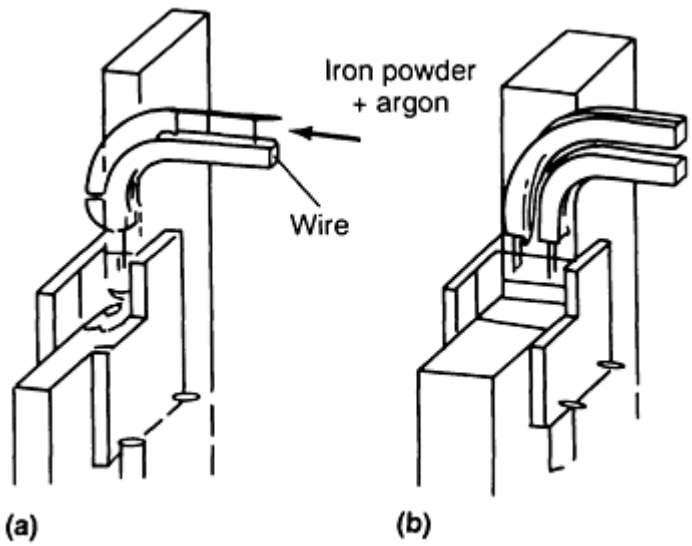

FIG. 13 EQUIPMENT SETUP FOR SQUARE-GROOVED HIGH-SPEED WELDING WITH METAL POWDER ADDITION. (A) PLATE THICKNESS OF 10 TO 40 MM ($\frac{3}{8}$ TO 1 $\frac{9}{16}$ IN.). (B) PLATE THICKNESS OF 40 TO 100 MM (1 $\frac{9}{16}$ TO 4 IN.). SOURCE: REF 25

Metal powder cored strip electrode for consumable guide ESW has also been used (Ref 9, 17). The average weld deposition rate is approximately two to three times higher than the solid wire process, over 38 kg/h (85 lb/h). The specific

heat input of these welds was lower, at 0.8 kJ/mm^2 (520 kJ/in.^{2}). Rather than add metal powder to increase the deposition rate and absorb the excess thermal energy in the molten metal bath, a separate filler wire can be used (Ref 27). This is shown in Fig. 14. This setup resembles the feeding of a cold wire into plasma arc welding or gas-tungsten arc welding processes. Not only is the productivity of the process increased, but the HAZ width is also reduced.

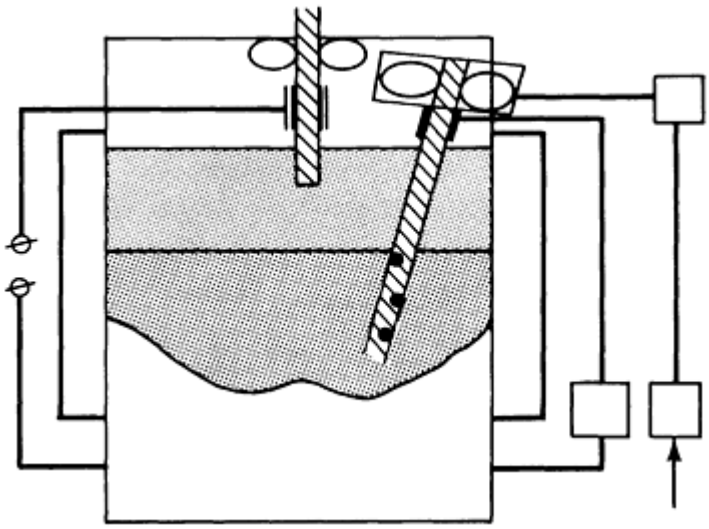

FIG. 14 SCHEMATIC OF ELECTROSLAG WELDING PROCESS USING SEPARATE FILLER WIRE TO INCREASE DEPOSITION RATE AND ABSORB EXCESS THERMAL ENERGY IN MOLTEN METAL BATH. SOURCE: REF 28

Electroslag Surfacing. Surfacing by means of weld overlays has a long history. Electroslag surfacing can be done in either the vertical or flat position. Where the area to be surfaced is small relative to the base metal, vertical electroslag surfacing is usually used. Adapting the vertical orientation of ESW to produce composite metallic structures involves replacing one of the parent metal plates with a water-cooled mold. An interesting application is tool steel ingots that are given a soft steel electroslag welded deposit on each end to facilitate the rolling operation.

For large areas, such as plates for tube sheets or cylindrical pressure vessels, electroslag surfacing is conducted in the flat position. Excellent process stability is one of the characteristics of the process. Even with electrodes as wide as 150 mm (6 in.), the quality of the surface weld is still comparable to that of welds produced by other processes. To minimize the undercutting problem and improve bead smoothness, Kawasaki Steel (Ref 6) developed the Maglay process, which utilizes an external magnetic field to control the flow of molten slag and metal. Dilution can also be controlled, to less than 10%. Forsberg (Ref 28) reports the development of a similar process, which uses strips of 60 to 90 mm (2.4 to 3.5 in.) width and emphasizes the higher deposition rate and lower dilution ratio.

Electroslag and Electrogas Welding*

S. Liu, Colorado School of Mines; S.D. Brandi, Escola de Politecnica da USP; R.D. Thomas, Jr., R.D. Thomas and Company

Electrogas Welding

Electrogas welding (EGW) can be classified as a gas-metal arc welding process. It was introduced in the early 1960s to perform single-pass welding of relatively thin plates in the vertical position. As shown in Fig. 15, the process is very similar to ESW, with the exception of the presence of an arc and the weld pool shielding mechanism (Ref 6). In most cases, shielding gas is used together with a bare or flux-cored wire to provide a shielding gas on top of the molten pool of slag and weld metal. Self-shielded flux-cored wires are often used without a separate gas shield. The production rate can be as high as 34 kg/h (75 lb/h), depending on the joint configuration and plate size. Special flux-cored wires that contain fewer slagging ingredients must be formulated for EGW, because slag buildup on the molten weld metal surface can affect arc stability and cause slag entrapment. The thicker the plate being welded, the less flux needed. When bare wire is used, small amounts of granular flux are usually added at the start. The slag needed for protection is produced from the deoxidizers in the electrode wire. For steel welding, the most common shielding gas is carbon dioxide. Additions of argon (75 to 80 vol%) to carbon dioxide seem to improve the arc stability and weld metal properties. Flow rates are usually of the order of 14 to 19 L/min (30 to 40 ft^3/h).

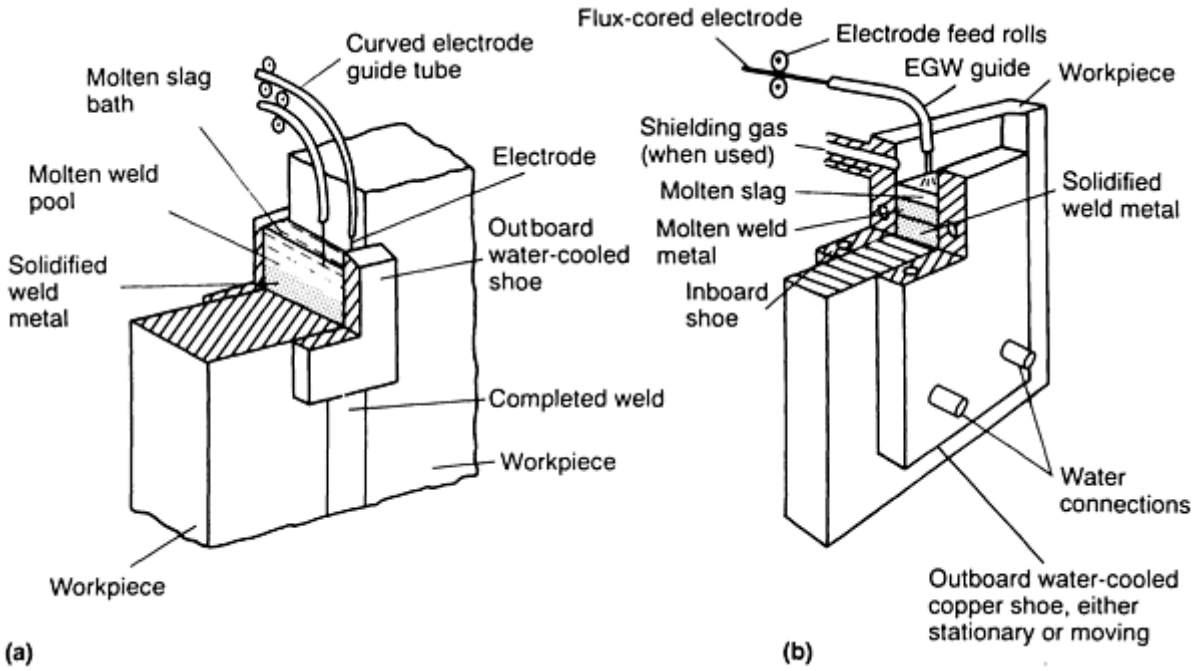

FIG. 15 SCHEMATICS COMPARING PRIMARY COMPONENTS OF TWO VERTICAL WELDING PROCESSES IN WHICH MOLTEN WELD POOLS ARE CONFINED BY COOLING SHOES. (A) ELECTROSLAG WELDING. (B) ELECTROGAS WELDING

Heavy aluminum weldments are produced by EGW using argon-helium gas shielding with flow rates of 28 to 38 L/min (60 to 80 ft^3/h).

In addition to its higher deposition rate, EGW presents the advantages of lower heat input, more refined microstructure, and improved HAZ properties. Consequently, postweld heat treatment is not mandatory in many EGW applications. The process also offers easy restarting if the weld is interrupted (complicated in ESW). However, as the thickness of a plate increases, the shielding gas often fails to cover the entire joint area, leading to unacceptable porosity. Thick plates favor the choice of ESW because electroslag welds exhibit fewer inclusions and defects.

Multipass ESW and EGW. The metallurgical problems encountered in single-pass electroslag and electrogas processes can be largely overcome by multipass welding. An example is a thick steel square-butt electroslag weld joint with a fixed copper chill bar or water-cooled copper tube inserted at midwall, and a weld being produced with a moving shoe on one side. The copper chill is then removed, and the opposite side is welded. In practice, however, several problems may appear. One is related to the removal of the copper chill, gripped by the shrinkage that occurs during the first weld pass. Another is the problem of ensuring penetration by the second pass into the first pass. Unless the plate edges are machined and carefully fitted up, slag leakage may also occur.

Reference 29 reports the use of a copper chill bar that penetrated to the root of one side of a double V-joint preparation while EGW proceeded from the opposite side. An alternative method is to manually deposit the root pass, to avoid the problem of close fit-up tolerances needed for complete penetration. Where welding can only be approached from one side, conventional backing bars are used, and the copper shoe protrudes into the joint to mold the initial pass, followed by the surface pass deposited in the conventional manner. This technique is satisfactory for EGW, but slag retention in the cavity formed by the protruding shoe and the base plates is a challenge in the electroslag process.

The consumable nozzle electroslag process can be used to make a multipass electroslag weld with a pass from each side. A tightly fitted spacer bar is placed at midwall. The electroslag weld pass from the first side partially penetrates the spacer bar, and the second pass from the opposite side consumes the remaining spacer and penetrates the first pass.

These process modifications do not solve the problem of the wide HAZ on the surface of the plates being welded, because toughness and fatigue properties at or near the outer surface of a weld are essential for the integrity and performance of the structure.

Electroslag and Electrogas Welding*

S. Liu, Colorado School of Mines; S.D. Brandi, Escola de Politecnica da USP; R.D. Thomas, Jr., R.D. Thomas and Company

Electroslag and Electrogas Process Applications

Carbon and Low-Alloy Steels. The joining of heavy-section steels is the most common application of both ESW and EGW. As previously stated, ESW is commonly done on plates of thickness 50 mm (2 in.) and greater. In fact, economy is greatly increased if the section thickness is greater than 100 mm (4 in.). The range of application of EGW is between 9.5 mm ($\frac{3}{8}$ in.) and 75 mm (3 in.). When compared with arc welding processes, minimum distortion, vertical position, and minimum joint penetration are the major advantages. Typical applications include fabrication of pressure vessels, nuclear components, power generation equipment, rolling mills, heavy presses, bridges, ships, and oil drilling rigs (Ref 30). Other structural applications reported are blast furnace shells (carbon steel) and a wind tunnel structure (HY-100 steel) (Ref 31, 32).

Structural Steels. A considerable number of highway bridges were fabricated using ESW prior to its ban in bridge construction. Some failures have been attributed to defects such as hydrogen cracking, lack of fusion, low HAZ fatigue properties, and so on. However, properly made welds were found to meet the radiographic standards required for impact and fatigue loading of structural members (Ref 33). In the case of low-alloy steels for structural applications, austenitizing postweld heat treatments have been considered necessary for electroslag welds. However, when proper attention is given to consumable (flux and electrode) selection, a stress-relieving heat treatment is generally sufficient to obtain good impact properties (Ref 34).

Shipbuilding. Electroslag and electrogas welding can be used for the welding of components and for on-ship welding. One application is the propeller shaft bracket assembly for natural gas and oil tankers. Stem frame parts, heavy rudderstock plates, longitudinal and vertical hull stiffeners, and shaft struts are often electroslag welded (Ref 35).

Pressure Vessels. Thick-wall pressure vessels used in the chemical, power generating, petroleum, and marine industries are manufactured using ESW. Plates are rolled to form the shell of the pressure vessel, and the longitudinal seam created is then welded. Lifting lugs on the vessels, nozzles, and branch pipes are also electroslag welded to thick-walled vessels. Due to the high heat input, the welding practice must be critically controlled. Where code requirements are specified, a normalizing heat treatment is also performed.

Penetrating members, such as nozzles and pipe fittings, are often costly to weld into thick-wall pressure vessels by conventional processes. A unique method employing both welding and casting techniques has been proposed by Norcross (Ref 36). A cylindrical water-cooled mold is tightly affixed to the outside surface of the vessel, and weld metal is cast in place. The hole of the nozzle is then machined to provide an opening into the vessel, at the end of which pipes or other attachments can be easily welded (Fig. 16). Even large-diameter penetrating members can be made by this method, by casting hollow cylinders after first tapering the vessel wall to allow the starting zone of the electroslag weld to be machined away (Ref 38, 39).

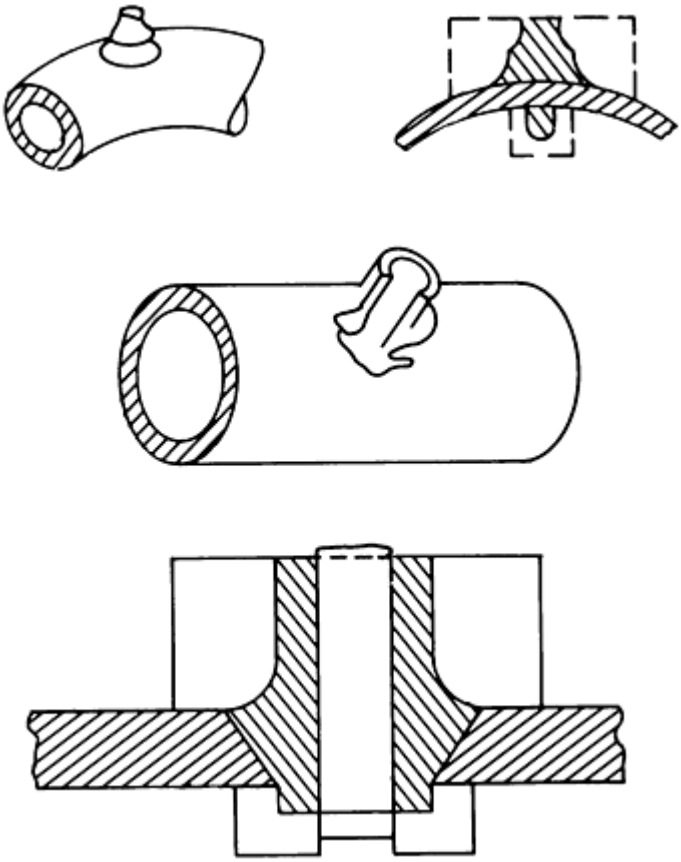

FIG. 16 APPLICATION OF ELECTROSLAG WELDING TO INCORPORATE PENETRATING MEMBERS SUCH AS NOZZLES ONTO THICK-WALL PRESSURE VESSELS. SOURCE: REF 39

Heavy Machinery. Large presses and machine tools are often manufactured from plates that are larger than the mills can produce, so ESW is used to join large plates together. Motor frames, press frames, gear blanks, turbine rings, crane rails, and crusher bodies are some of the common applications. In the transmission pipeline industries, ball valves and stop-gate valves are often electroslag welded.

Dissimilar Metal Joining. Electroslag remelting has been used to develop transition pieces for heavy-wall steam piping where low-alloy chromium-molybdenum steel pipe is to be joined to austenitic stainless steel pipe. Two round ingots, one of the ferritic alloy and one of the austenitic stainless steel, are welded together to form the electrode for electroslag remelting. As the electrode is melted in the molten slag bath, the composition gradually changes from one to the other, depositing a graded alloy billet which is later pierced and formed into a transition piece (Ref 37, 39, 40).

Joining and Repairing of Castings. Electroslag welding is also used to weld cast components. Instead of producing a large casting, many small castings of lower cost and simpler fabrication are produced and welded together. One such application is described by Brosholen, Skaug, and Vesser (Ref 41) to construct a cast steel propeller shaft bracket. Cast iron has been electroslag welded using a cored wire containing either white or gray cast iron powders and a graphite nozzle (Ref 42). Defective thick sections of cast steels can be repaired by ESW, by drilling a series of connecting holes into the defect zone. A close-fitting water-cooled copper mold is inserted in one of the drilled holes while welding proceeds in the adjacent hole. On completion of that weld, the mold is moved to the next hole before the molten slag has cooled, which allows ESW to start in the vacated hole (Ref 43, 44).

Tool and Die Surfacing and Welding. The slow thermal cycles involved in ESW are favorable for depositing hardenable alloys. For large forging hammers and forming dies, hard wear-resisting alloys can be spilled to the surface of a carbon steel backing using multiple electrodes and current pulsing techniques (Ref 45, 46, 47).

Stainless Steel and Nickel-Base Alloys. Two halves of large 38 tonne (42 ton) cast stainless steel pumps for nuclear electric power facilities have been successfully joined by circumferential welding of their equatorial surfaces and have

been qualified to rigid nuclear code requirements. As-welded electroslag welds in austenitic stainless steels were found to be insensitive to knife-line attack after sensitization for 1 to 5000 h at temperatures ranging from 450 to 750 °C (842 to 1382 °F) in tests (Ref 48). It has also been demonstrated that ESW is suitable for welding 25 mm (1 in.) thick alloy 600 plates and 25 mm (1 in.) and 114 mm ($4\frac{1}{2}$ in.) thick plates of alloy 800. Matching filler metals and Inconel filler-metal 82 produced sound welds with excellent elevated-temperature strength and stress-rupture results. Because stainless steels and nickel-base alloys do not undergo allotropic transformations, electroslag welds do not require a high-temperature postweld heat treatment.

Aluminum. Both ESW and EGW have been used to join thick sections of aluminum. One such application is to join 240 mm (9.5 in.) thick electrical conductors (busbars). Instead of the typical copper shoes, graphite shoes are used to obtain satisfactory weld surfaces and edge penetration (Ref 49). Gagan *et al.* (Ref 50) reported erratic penetration encountered in ESW of thick-section aluminum due to the magnetic fields generated by the welding process, which required special shielding screens around the weld zone. The high conductivity of aluminum and the prompt formation of a refractive oxide are also of concern. High-fluoride-content fluxes and an inert gas shield in EGW typically produce good results in welding thick-section aluminum. For ESW of aluminum containing 4.5 wt% Mg, the following flux has been suggested (Ref 51):

CONSTITUENT	CONTENT, WT%
MGF_2	1-30
$MGCL_2$	5-60
LIF	5-60
KCL	5-6

As welding progresses, additions are made to the flux containing 30 wt% each of KCl, LiF, and $MgCl_2$, and 10 wt% MgF_2. This flux is reported to work well for ESW of aluminum with copper shoes (Ref 51).

Titanium. The reactivity of titanium requires that residual elements such as hydrogen, oxygen, and nitrogen be minimized in ESW. A slag bath high in halides and containing virtually no oxides, and an inert gas (argon) shield over the bath, are required. Plate electrodes seem to produce better results (Ref 3, 52). Commonly, fluxes are halide compounds based on CaF_2 with ram-earth additions to produce welds low in oxygen, nitrogen, and hydrogen. Devletian (Ref 53) reported that because the high resistivity of titanium promotes rapid ohmic heating of the titanium consumables, stable welding operation generally requires large-diameter electrodes for nonconsumable guide welding, and nozzles or guide plates for consumable guide welding.

Problems and Quality Control

Fusion Zone. As discussed earlier in the section "Solidification Structure" of this article, both cellular and columnar dendrites are observed in the solidification structure of an electroslag weldment. Particularly in the cases of welds with low form factor, in which the transition from cellular to columnar dendrites occurs close to the centerline of the weld and

the grains meet at an obtuse angle, centerline cracking and radial hot cracking are more frequently observed. These defects can be attributed to the combined effects of temperature gradient, solidification rate, degree of restraint in fit-up of the weld, high welding speed, and low form factor. In general, a long, straight-sided columnar grain structure (the result of high welding speed) tends to be weaker under load than the more equiaxed and finer grain structure of a slow-speed weld. At the same time, the cellular structure may be coarser and higher in segregation for the case of low welding speed. Figure 17 shows a proposed mechanism of solidification cracking.

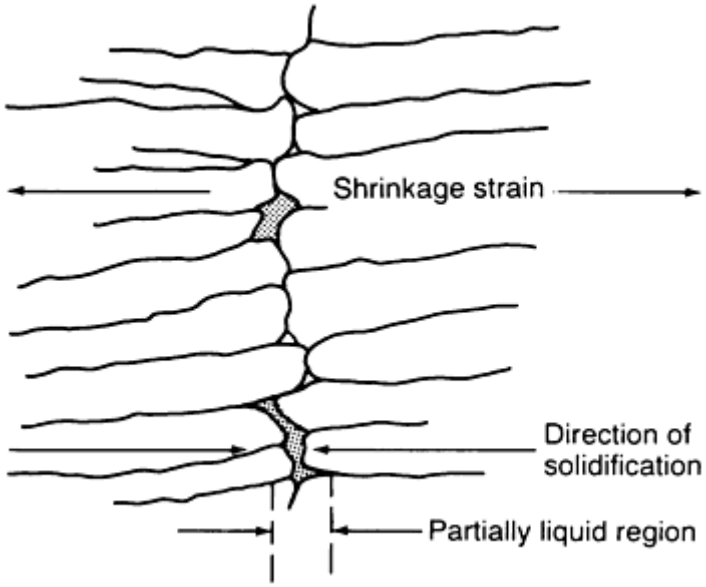

FIG. 17 SCHEMATIC INDICATING PROJECTED MECHANISM OF SOLIDIFICATION CRACKING IN AN ELECTROSLAG WELDMENT. SOURCE: REF 54, 55

Partially Melted Zone. Liquation cracking is associated with the melting of heavily segregated grain boundaries near the fusion line region. Carbon and manganese are the most common alloying elements involved in the formation of compounds such as (Mn,Fe)S that lower the melting temperature of the grain boundaries. Phosphorus, nitrogen, and boron are some of the other embrittling agents found in ferrous alloys. During cooling, residual stresses may build up and rupture these weakened boundaries. Under the slow heating and cooling conditions experienced by an electroslag weld, the susceptibility of a ferrous alloy to liquation cracking is increased. It has been reported that liquation cracks can be eliminated in heavy electroslag welds by microalloying the steels with cerium, titanium, and other elements to combine with sulfur and form small high-melting-point inclusions (Ref 56).

Temper Embrittlement. Thick-section $2\frac{1}{4}$ Cr-1Mo steel plates used in pressure vessels for petroleum and chemical service at elevated temperatures are susceptible to temper embrittlement in service. The problem has been attributed to the presence of residual elements such as phosphorus and antimony. Bruscato (Ref 55) established an *X* factor to describe the effect of the residual elements:

$$X = \frac{10P + Sb + 4Sn + As}{100} \qquad \textbf{(EQ 16)}$$

where *X* is in parts per million. Acceptable weld metal ductility can be obtained if the manganese and silicon contents and the *X* factor are low. Reduction of these elements can be achieved using basic fluxes. Another indicator, the Watanabe number, *J*, shows that welds and base metal are not susceptible to temper embrittlement if *J* is less than 200 (Ref 57):

$$J = (\mathrm{SI} + \mathrm{MN})\,(\mathrm{P} + \mathrm{SN}) \times 10^4 \qquad \textbf{(EQ 17)}$$

Hydrogen Cracking. Generally speaking, ESW is performed under perfect slag shielding conditions, and the rate of cooling of the weld metal is low. Therefore, the occurrence of hydrogen-induced cracking is minimal. However, under circumstances that require the use of a moist argillaceous material to prevent the slag from leaking out of the joint region, an atmosphere high in water vapor is present. Microcracks, and sometimes blowholes, may result in the weld metal. Grain boundary separation, observed in some electroslag welds, can be completely eliminated by postweld heat treating at 300 °C (570 °F) immediately after welding, which indicates that by allowing hydrogen to diffuse out of the specimen, the integrity of the welds can be maintained. This effect is further evidenced by the higher cracking incidence at the bottom part of an electroslag weld. In addition, diffusible hydrogen content is high at a region close to the weld start, decreasing to a relatively constant value at short distances from the starting point. By increasing the depth of the pool, the cooling rate is reduced, and hydrogen escapes by diffusion before it causes damage (Ref 58).

Weld Distortion. When compared with welds produced using other processes, electroslag slag welds do not present significant distortion problems. Measurements show that both transverse and angular distortion are present and that the gap distance changes as welding progresses. However, the distortion is only of the order of 1 to 2%. Angular distortion occurs because of the rapid cooling of the welded portion of the joint, which tends to draw the parts together, reducing the gap distance. Material ahead of the weld is separated by a gap, so heating has no effect. Material in the weld is either liquid or so hot that it is soft. Neither can support much of a load. As the weld progresses, the very bottom of the weld (coldest metal) resists motion. A contraction of 3 mm ($\frac{1}{8}$ in.) at the top of a weld 1.3 m (4.3 ft) long is normal. This separation must be allowed during joint setup to avoid jamming the guides and disrupting the normal progress of welding. Parts to be joined must be fitted up so that the gap is wider at the top of the joint. For improved dimensional accuracy, welding must be done at the maximum travel speed attainable.

Postweld Heat Treatment. As discussed in the previous section "Solidification Structure" of this article, most of the as-welded electroslag weldments have very coarse as-cast structure in the weld metal and coarse grains in the HAZ. As a result, such electroslag weldments may not qualify for many critical applications. For example, in the case of ferritic steels, normalizing is generally required to refine the weld metal and HAZ structure. In the case of electroslag welded nuclear transport flasks, normalizing is frequently followed by tempering (Ref 59). In some low-alloy steels, subcritical postweld heat treatments (for example, stress relief) may not be useful because they can be either detrimental or harmful to mechanical properties, particularly notch toughness. As an example, stress relief 2 $\frac{1}{4}$ Cr-1Mo steel weldments at 760 °C (1400 °F) significantly increased the fusion zone and HAZ toughness, but they coarsened the carbides in the base metal, reducing its toughness (Ref 60). Quenched and tempered material, when joined by ESW, must be heat-treated after welding to obtain adequate mechanical strength in the weld and HAZ. Kapadia (Ref 61) examined the need for stress-relieving components that will be exposed to fatigue loading and determined that in butt welds in the as-welded condition the outside surfaces cool and contract before the center, and thus compressive residual stresses are present, which improves fatigue life. Stress-relief heat treatments actually reduce this beneficial effect.

Introduction

OXYFUEL GAS WELDING (OFW) is a manual process in which the metal surfaces to be joined are melted progressively by heat from a gas flame, with or without filler metal, and are caused to flow together and solidify without the application of pressure to the parts being joined. The most important source of heat for OFW is the oxyacetylene welding (OAW) torch.

The simplest and most frequently used OFW system consists of compressed gas cylinders, gas pressure regulators, hoses, and a welding torch. Oxygen and fuel are stored in separate cylinders. The gas regulator attached to each cylinder, whether fuel gas or oxygen, controls the pressure at which the gas flows to the welding torch. At the torch, the gas passes through an inlet control valve and into the torch body, through a tube or tubes within the handle, through the torch head, and into the mixing chamber of the welding nozzle or other device attached to the welding torch. The mixed gases then pass through the welding tip and produce the flame at the exit end of the tip. This equipment can be mounted on and operated from a cylinder cart, or it can be a stationary installation. Filler metal, when needed, is provided by a welding rod that is melted progressively along with the surfaces to be joined.

Acknowledgements

This article was revised from "Oxyfuel Gas Welding Processes and Their Application to Steel" in Volume 6 of the 9th Edition of *Metals Handbook.* Special thanks are due to the authors of that article: Gene Meyer, Victor Equipment; Joseph E. McQuillen, Air Products and Chemicals, Inc.; and Clarence E. Vaughn, Chicago Bridge & Iron Company.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Capabilities, Advantages, and Limitations

In OFW, the welder has considerable control over the temperature of the metal in the weld zone. When the rate of heat input from the flame is properly coordinated with the speed of welding, the size, viscosity, and surface tension of the welding pool can be controlled, permitting the pressure of the flame to be used to aid in positioning and shaping the weld. The welder has control over filler-metal deposition rates because the sources of heat and filler metal are separate. Heat can be applied preferentially to the base metal or the filler metal without removing either from the flame envelope. With these capabilities, OFW can be used for joining thin sheet metal, thin-walled tube, small pipe, and assemblies with poor fit-up, as well as for smoothing or repairing rough arc welds.

The equipment is versatile, low-cost, self-sufficient, and usually portable. It can be used for preheating, postheating, welding, braze welding, and torch brazing, and it is readily converted into oxygen cutting. The process can be adapted to short production runs, field work, repairs, and alterations.

Metals That Can Be Oxyfuel Gas Welded. Most ferrous and nonferrous metals can be oxyfuel gas welded. Oxyacetylene supplies the heat intensity and flame atmosphere necessary for welding carbon steel, cast iron, and other ferrous, copper, and nickel alloys (Table 1). Aluminum and zinc alloys can also be welded by the oxyacetylene process. Oxyfuel gas welding of steel is done almost exclusively with an oxyacetylene flame. Hydrogen, natural gas, propane, and several proprietary gases are used as fuel gases in welding metals with lower melting temperatures, such as aluminum, magnesium, zinc, lead, and some precious metals. Metals unsuited to OFW are the refractory metals, such as niobium, tantalum, molybdenum, and tungsten, as well as the reactive metals, such as titanium and zirconium.

TABLE 1 FERROUS AND NONFERROUS METALS THAT CAN BE WELDED BY OXYACETYLENE WELDING

Base metal	Filler-metal type	Flame type	Flux type
Aluminums	(a)	Slightly reducing	Aluminum
Brasses	Navy brass	Slightly oxidizing	Borax
Bronzes	Copper tin	Slightly oxidizing	Borax
Copper	Copper	Neutral	(b)
Copper nickel	Copper nickel	Reducing	(b)

(A) MATCH BASE METAL.

(B) NO FLUX REQUIRED.

Fluxes. Except for lead, zinc, and some precious metals, OFW of nonferrous metals, cast irons, and stainless steels generally requires a flux. In welding carbon steel, the gas flame shields the weld adequately, and no flux is required. Adjustment for correct flame atmosphere is important, but the absence of flux results in one less variable to control.

Major Applications. Oxyfuel gas welding can be used to join thin carbon steel sheet and carbon steel tube and pipe. The advantages of OFW include the ability to control heat input, bridge large gaps, avoid melt-through, and clearly view the weld pool. Carbon steel sheet, formed in a variety of shapes, can often be welded more economically by OFW than by other processes. Oxyfuel gas welding is capable of joining small-diameter carbon steel pipe (up to about 75 mm, or 3 in., in diameter) with resulting weld quality equal to competitive processes and often with greater economy. Pipe with wall thickness up to 4.8 mm ($\frac{3}{16}$ in.) can be welded in a single pass.

Welder Skill. Oxyfuel gas welding requires skill in manipulating the welding rod and the torch flame. In depositing a weld, the welder uses both hands to melt base metal and filler metal, control the weld pool, and obtain progressive solidification of weld metal in the correct bead shape.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Gases

Oxygen and acetylene are the principal gases used in OFW. Oxygen supports combustion of the fuel gases. Acetylene supplies both the heat intensity and the atmosphere needed to weld steel. Hydrogen, natural gas, propane, and proprietary gases are used only to a limited extent in oxyfuel gas welding or brazing of metals with a low melting temperature.

Oxygen. Only by burning selected fuel gases with high-purity oxygen in a high-velocity flame can the high heat transfer intensity required in OFW be obtained. Oxygen is supplied for oxyfuel gas welding and cutting at a purity of 99.5% and higher, because small percentages of contaminants have a noticeable effect on combustion efficiency.

When the consumption requirement is relatively small, the oxygen is supplied and stored as a compressed gas in a standard steel cylinder under an initial pressure of up to 180 MPa (26 ksi). The most frequently used cylinder (Fig. 1) has a capacity of 6.91 m^3 (244 scf).* The gas is distributed for use under reduced pressure. When consumption of oxygen is somewhat greater, banks of cylinders are joined through a manifold to permanent pipeline systems that terminate at various stations of use.

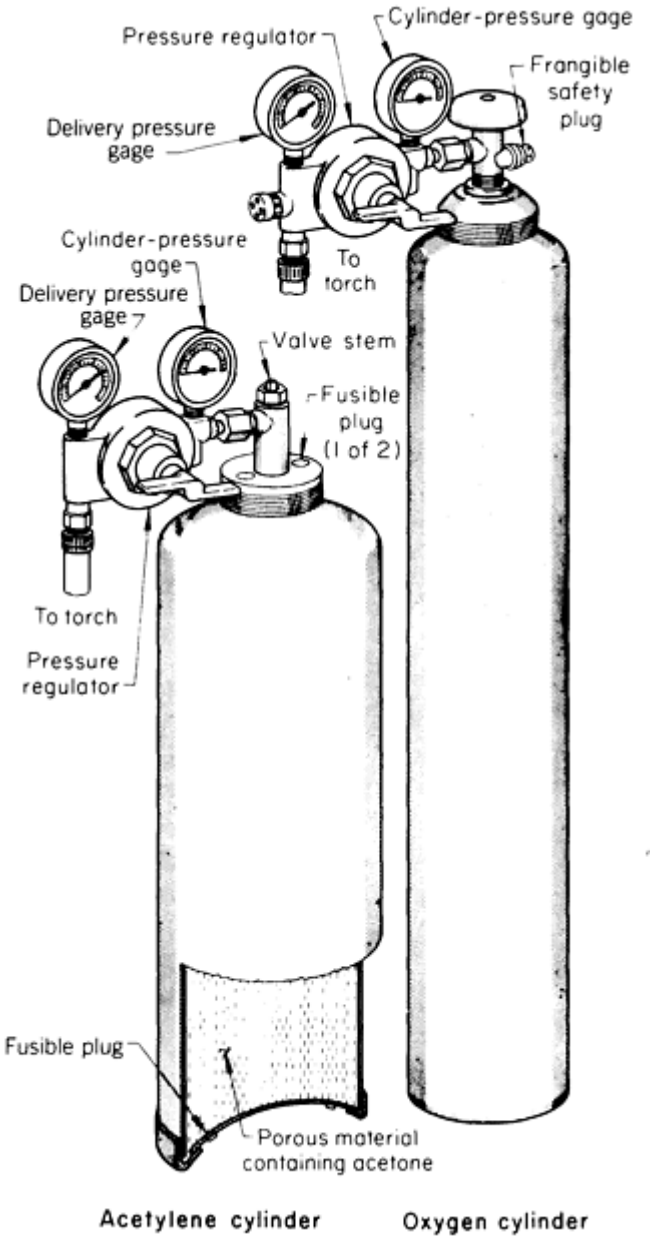

FIG. 1 GAS CYLINDERS AND REGULATORS USED IN OXYFUEL GAS WELDING. THE ACETYLENE CYLINDER SHOWN IS 1029 MM (40.5 IN.) HIGH, 314 MM (12.35 IN.) IN DIAMETER, AND HAS A WALL THICKNESS OF 4.4 MM (0.175 IN.). THE OXYGEN CYLINDER IS 1295 MM (51 IN.) HIGH, 229 MM (9 IN.) IN DIAMETER, AND HAS A WALL THICKNESS OF 6.3 MM (0.25 IN.).

When oxygen consumption exceeds approximately 6.91 m^3 (244 scf) cylinders per week, it may be more economical to obtain and store oxygen in liquid form. Liquid oxygen can be supplied in portable cryogenic cylinders of 130 m^3 (4500 scf) capacity, or it can be delivered in bulk to an on-site cryogenic storage tank. The gas is then piped to points of use. The distribution and use of oxygen are covered by laws and safety regulations designed to help prevent injury to persons and damage to property.

Acetylene is a hydrocarbon gas with the chemical formula C_2H_2. When under pressure of 203 kPa (29.4 psi) and above, acetylene is unstable, and a slight shock can cause it to explode, even in the absence of oxygen or air. Safety rules for the use of acetylene and the handling of acetylene equipment are extremely important.

Acetylene should not be used at pressure greater than 105 kPa (15 psi). Acetylene generators for on-site gas production are constructed so that the gas is not given off at pressures much greater than 105 kPa (15 psi). Commercially supplied portable cylinders are specially constructed (Fig. 1) to store acetylene under high pressure. By dissolving acetylene in

liquid acetone, a cylinder such as that shown in Fig. 1 can be used to store about 7.79 m^3 (275 scf) of acetylene under a pressure of 1.7 MPa (250 psi). This pressure must be reduced to 105 kPa (15 psi) or less by the regulator (Fig. 1) before the gas enters the hose or distribution line.

Acetylene cylinders must not be subjected to sudden shock and should be stored well away from any source of heat or sparks. The cylinders must be stored in an upright position to keep the acetone from escaping during use. Under normal sustained use, withdrawal rate from an acetylene cylinder should not exceed one-seventh of the cylinder capacity per hour.

Hydrogen is used chiefly for welding lower-melting-temperature metals, such as aluminum, magnesium, and lead. It cannot be used to weld common thicknesses of steel sheet, because it results in a flame temperature that is too low to produce good fusion. Hydrogen has, however, been used in welding thin sheet, where its lower combustion intensity (about 60% of that of acetylene) can be an advantage. It is used for brazing and, to some extent, for braze welding. Hydrogen is available in compressed-gas cylinders of various sizes.

Natural gas, propane, and proprietary gases can be used with oxygen to weld some lower-melting-temperature metals. Special welding rods may be required depending on the gas, base metal, and quality of metal desired. These gas mixtures cannot usually be applied to the welding of steel because when they are burned at temperatures high enough for welding, their flame atmospheres are excessively oxidizing. When ratios of oxygen to fuel gas are reduced to a carburizing condition, flame temperatures are too low. Therefore, these gases are usually limited to brazing, braze welding, heating, and related processes.

Note cited in this section

* * A STANDARD CUBIC FOOT (SCF) OF GAS IS DEFINED AS EQUIVALENT TO 0.028 M^3 (1 FT^3) OF GAS AT 20 °C (70 °F) AND 100 KPA (1 ATM, OR 14.7 PSI) PRESSURE. THIS DEFINITION, WHICH IS USED IN THE GAS INDUSTRY AND SOME ENGINEERING PRACTICE, DIFFERS FROM THE STANDARD TEMPERATURE AND PRESSURE OF 0 °C (32 °F) AND 100 KPA (1 ATM) USED IN SCIENTIFIC WORK.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Equipment

The principal function of OFW equipment is to supply the oxyfuel gas mixture to the welding tip at the correct rate of flow, exit velocity, and mixture ratio. The rate of gas flow affects the quantity of metal melted; the pressure and velocity affect the manipulation of the weld pool and the rate of heating; and the ratio of oxygen to fuel gas determines the flame temperature and the atmosphere, which must be chemically suited to the metal being welded. Important elements in an OFW system include gas storage facilities, pressure regulators, hoses, torches, related safety devices, and accessories.

Gas Storage Equipment. Compressed-gas cylinders and storage tanks are used as on-site supply sources for gases. They are constructed under regulations of the Department of Transportation and are regulated to some extent by federal, state, and local laws. Cylinders are designed for specific gases and are not generally interchangeable. Sizes and threading of cylinder connections for oxygen, for example, differ from those for acetylene, hydrogen, and other gases. Only the appropriate fittings can be used for delivery of compressed gas. Users should not tamper with valves or safety devices on cylinders.

When portable equipment is not required and gas consumption is large enough, permanent installations are constructed. Gases can be supplied from a variety of bulk-storage vessels, manifolded gas cylinders, or gas generators. The gases are then separately piped, at suitable pressure, to terminal stations, where they are drawn off through station regulators and used as in a portable setup (Ref 2).

Pressure regulators reduce the supply gas pressure to a desired delivery pressure. They are designed for specific gases and are not generally interchangeable. In Fig. 1, oxygen and acetylene pressure regulators used in OFW are shown attached to their respective cylinders and hoses. In operation, gas enters the inlet side of the regulator at cylinder pressure and emerges from the outlet side at the desired delivery pressure.

Regulators are made for various ranges of inlet and outlet pressure. They can be adjusted within their delivery pressure range by turning an adjusting screw. Although some regulators do not have gages and are preset to deliver at a specific and constant pressure, most are equipped with two pressure gages. The one on the outlet side permits the operator to read the adjusted delivery pressure; the one on the inlet side indicates the pressure in the cylinder.

Two basic types of regulators are used in OFW: single-stage and two-stage. Both are available with either direct or inverse actuation of the valve mechanism. Regulators with direct actuation are known also as positive or nozzle regulators; those with inverse actuation, as negative or stem regulators. All single-stage regulators reduce cylinder pressure in one step. Pipeline regulators, made for lower pressures, must not be used on cylinders (the higher cylinder pressure can blow apart a pipeline regulator).

When adjusted for a desired delivery pressure, regulators continue to deliver gas at the pressure shown on the outlet gage within a fairly narrow range of deviation, as the cylinder pressure drops. The amount and direction of the deviations depend on the design of the regulator. The variation in delivery pressure as cylinder pressure decreases is shown in Fig. 2 for three types of regulators. Both types of single-stage regulators may require occasional adjustment as cylinder pressure drops. The more costly two-stage regulator supplies a more constant working pressure until cylinder pressure nearly equals delivery pressure. On full oxygen cylinders exposed to low outdoor temperatures in winter, two-stage regulators are more reliable than single-stage regulators. The temperature drop of expanding gas is less severe because pressure is reduced in two steps. Less chance exists for ice to form and clog regulator passages if water vapor is present.

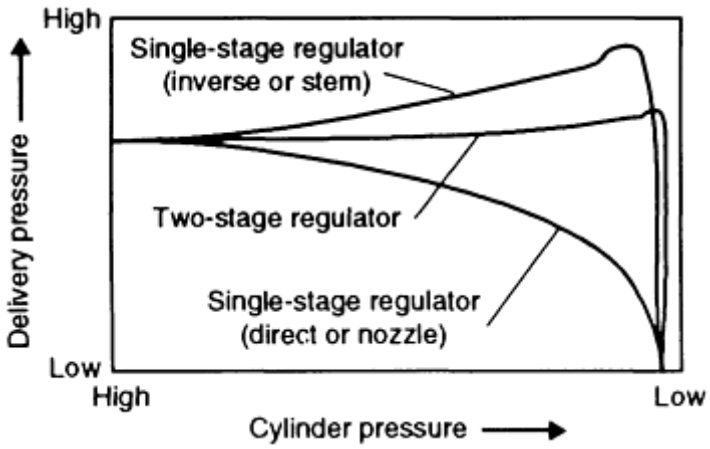

FIG. 2 DELIVERY PRESSURE FOR SELECTED TYPES OF PRESSURE REGULATORS

Hoses. Flexible hoses permit gas cylinders and regulators to be kept at a safe distance from the working area and also allow the welder freedom of movement. Hoses usually range from 3.2 to 13 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) in inside diameter, with larger sizes available for special applications, and are usually available in 7.6 m (25 ft) lengths. If hoses are longer than 7.6 m (25 ft), either the next larger size hose or a length of larger diameter hose with a short length of the usual size hose should be used to connect to the welding torch. This facilitates ease of movement. To ensure that oxygen and fuel gas hoses are used with the proper gas and correct fittings, oxygen hoses are generally green, with right-hand threaded fittings; acetylene and other fuel gas hoses are generally red, with left-hand threaded fittings. Left-hand threaded fittings are grooved on the outside so they can be readily identified.

Welding torches control the operating characteristics of the welding flame and enable the flame to be manipulated during welding. The choice of torch size and style depends on the work to be performed. Aircraft welding torches, for example, are small and light to permit ease of handling. Most torch styles permit one of several sizes of welding tips or a cutting attachment to be added.

The general construction of an OFW torch is shown schematically in Fig. 3. The principal operating parts are inlet valves, rear body, handle, and head. A mixing chamber with a welding tip, heating nozzle, or cutting attachment is added to the head. By unscrewing the sleeve nut (Fig. 3), the welding tip and mixing-chamber assembly can be removed and replaced by units with different capacity.

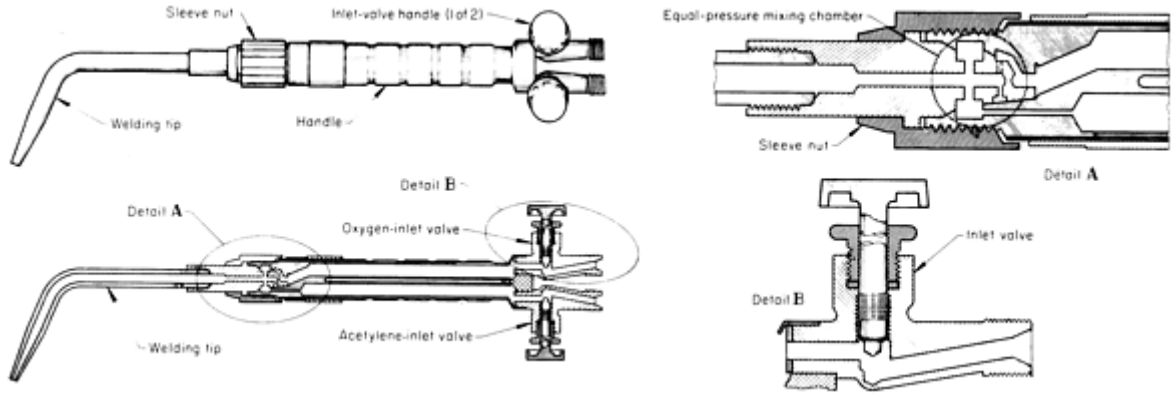

FIG. 3 SCHEMATIC SHOWING CROSS-SECTIONAL VIEWS OF GAS PASSAGES IN A TYPICAL OXYFUEL GAS WELDING TORCH

Torch inlet valves provide the welder with two important controls. First, the gas pressure, velocity, and flow rate can be adjusted within the limits set by the pressure regulators and the practical requirements of the welding flame. Second, the ratio of oxygen to fuel gas can be varied. The ability of the oxyfuel flame to produce the combustion intensity needed for welding, while providing a suitable protective atmosphere for the weld metal, is largely a property of the fuel gas, but correct torch settings must be used.

Mixing Chambers. In Fig. 3, the mixing chamber is shown as part of an assembly with the welding tip. Two general mixing chambers are available: equal-pressure (also called positive-pressure and medium-pressure) and injector. In an equal-pressure mixing chamber, gases are at approximately the same pressure and are mixed by directing the fuel gas into the oxygen stream. Detail A in Fig. 3 shows an equal-pressure mixing chamber assembled in position. Figure 4 is a spiral equal-pressure mixer.

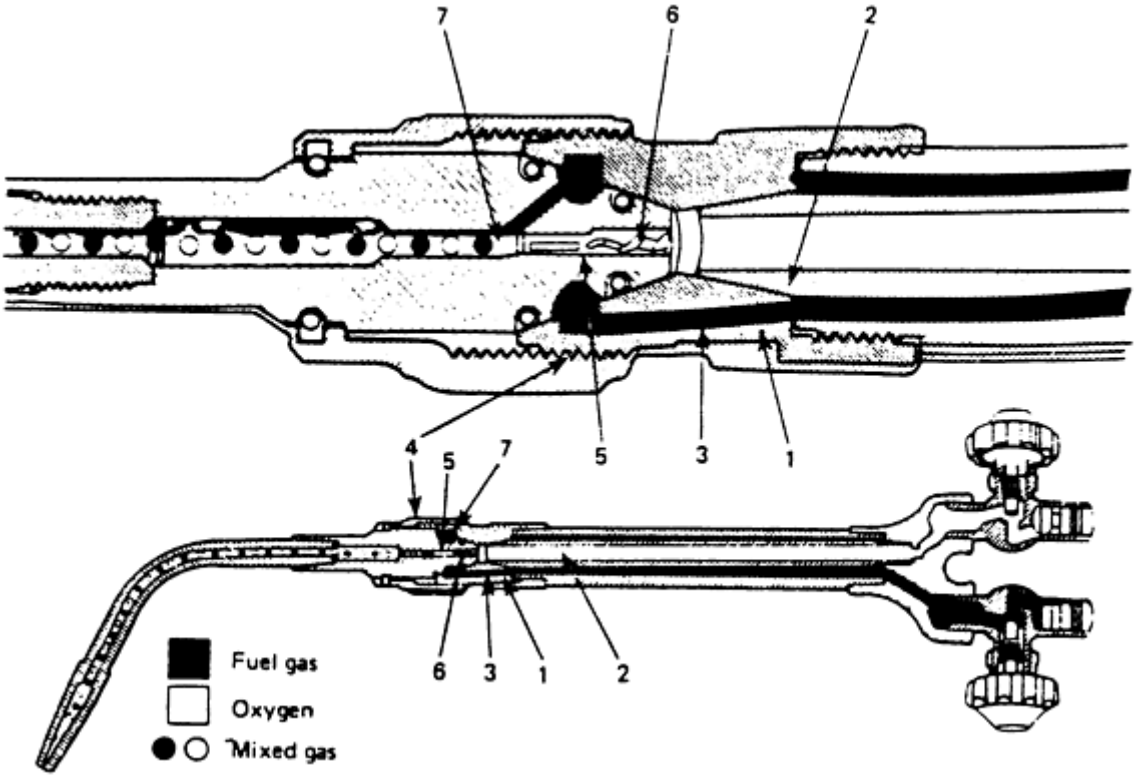

FIG. 4 SCHEMATIC SHOWING CROSS-SECTIONAL VIEW OF A SPIRAL EQUAL-PRESSURE MIXER. (1) WELDING TORCH HEAD. (2) OXYGEN TUBE FROM TORCH HEAD. (3) ACETYLENE (FUEL GAS) PASSAGES FROM TORCH HEAD. (4) NOZZLE NUT. (5) WELDING NOZZLE CONE END. (6) SPIRAL IN WELDING NOZZLE. (7) MIXER ORIFICE AND MIXING CHAMBER

In the injector mixing chamber, low-pressure fuel gas is aspirated by directing it into a high-velocity stream of oxygen. A nozzle system based on the flow principles of the venturi tube is used. Injector torches are useful when fuel gases are supplied at pressures too low to produce a flame of adequate combustion intensity. Supplying oxygen at desired pressure is not usually difficult. By varying the design of the injector nozzle, different degrees of aspiration can be obtained, and designs for injector mixing chambers differ considerably in detail.

Welding tips are replaceable nozzles that control gas flow through the diameter of the exit orifice. Tips of various orifice diameter are usually available for any welding torch. Orifice diameters are identified by drill-size number, decimal size in inches, or manufacturer's code number. Because code numbers of different manufacturers do not necessarily correspond, drill sizes or decimals are needed to compare the orifice size of different makes of tips. The performance of tips of equal size at equal pressure-regulator settings may differ, however, because of differences in torch and mixing-chamber designs.

Small-diameter tips produce small flames for welding thin sections; large-diameter tips are required for heavier work. Welding tips are made with a smooth bore at the exit end to ensure laminar flow and a uniform flame. The influence of bore shape on the shape of the flame is shown in Fig. 5. When foreign matter, such as carbon, dirt, or weld spatter, enters the welding-tip orifice, it must be carefully removed. Specially designed dressing tools (known as tip cleaners) are available for this purpose.

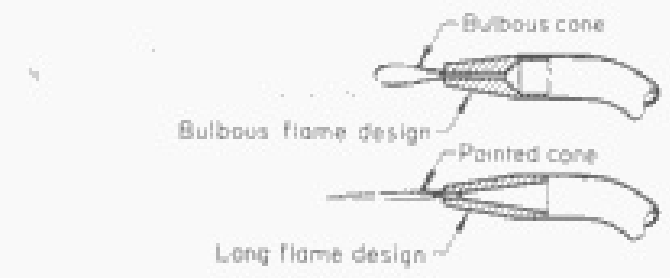

FIG. 5 VARIATION IN THE SHAPE OF THE INNER CONE OF AN OXYACETYLENE WELDING FLAME PRODUCED BY WELDING TIPS WITH TWO DIFFERENT BORE SHAPES. VARYING THE TRANSITION TAPER PRODUCES CONE SHAPES INTERMEDIATE BETWEEN THOSE SHOWN.

Accessories essential to OFW include a friction lighter for igniting the torch; welder's goggles, gloves, and protective clothing; and related safety devices.

Welder's goggles are covered by ANSI standard Z49.1 (Ref 3), which suggests the following lens shade numbers for use in OFW of steel:

STEEL THICKNESS		SHADE NUMBER
MM	IN.	
≤ 3.2	≤ $\frac{1}{8}$	4 OR 5
3.2-13	$\frac{1}{8}$ - $\frac{1}{2}$	5 OR 6
>13	> $\frac{1}{2}$	6 TO 8

For general OFW, goggles must have side shields.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Selection of Tip-Orifice Size and Gas Pressure

Torch manufacturers provide charts that give tip-orifice sizes to be used for welding different thicknesses of metal. Table 2 presents the data from a chart showing these relationships. Tip size number and drill size are not precise means of comparing tips because significant differences exist between tips of the same dimensions when operated under positive pressure and when operated under injector pressure. The only valid basis of comparison is the volume of fuel passing

through the tip in a unit of time. Most tips operate within a range, usually recorded as cubic feet of fuel per hour. The manufacturer's recommendations should always be followed for optimum performance and safety.

TABLE 2 TYPICAL TIP-ORIFICE SIZES AND ACETYLENE CONSUMPTION FOR OXYFUEL GAS WELDING OF 0.25 TO 6.4 MM (0.010 TO $\frac{1}{4}$ IN.) THICK STEEL

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Flame Adjustment

Different welding atmospheres and flame temperatures can be produced by varying the relative amounts of oxygen and fuel gas in the gas flowing to the tip of the torch. Usually, a welder makes the appropriate adjustments in gas flow based on the appearance of the flame. This is not true for oxyhydrogen welding, however. The sequence for setting up a positive-pressure welding outfit is:

- CHECK ALL PARTS OF THE APPARATUS, MAKING SURE THEY ARE FREE OF DIRT, OIL, OR GREASE AND IN PROPER WORKING CONDITION.
- CRACK EACH CYLINDER VALVE INDIVIDUALLY TO BLOW OUT FOREIGN MATTER. MAKE SURE VENTED GASES ARE SAFELY DISPERSED. WIPE OUT THE CYLINDER-VALVE OUTLET WITH A CLEAN, LINT-FREE CLOTH.
- ATTACH THE OXYGEN REGULATOR TO THE OXYGEN CYLINDER OR MANIFOLD.
- ATTACH THE ACETYLENE (OR FUEL GAS) REGULATOR TO THE FUEL CYLINDER OR SOURCE.
- CONNECT THE WELDING HOSE TO THE REGULATORS AND THE WELDING TORCH.
- OPEN THE CYLINDER VALVE SLOWLY AND CAREFULLY. THE OPERATOR SHOULD NEVER STAND IN FRONT OF THE REGULATOR WHEN OPENING THE CYLINDER VALVE.
- PURGE THE OXYGEN LINE WHILE THE ACETYLENE LINE IS CLOSED AND THE ACETYLENE LINE WHILE THE OXYGEN LINE IS CLOSED. VENT GASES SAFELY.
- SET THE OXYGEN AND FUEL GAS REGULATORS TO THE RECOMMENDED WORKING

PRESSURE WITH APPROPRIATE TORCH VALVE OPEN.

- OPEN THE ACETYLENE (OR FUEL GAS) INLET VALVE AND LIGHT THE WELDING TORCH, USING A SPARK LIGHTER.
- OPEN THE OXYGEN INLET VALVE AND ADJUST THE FLAME, USING BOTH INLET VALVES.

For injector equipment, the sequence and method of setting up differ because high-pressure oxygen aspirates low-pressure acetylene into the torch. The differences among brands make it essential to always follow the manufacturer's directions for setting up.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Oxyacetylene Combustion

As the acetylene/oxygen mixture burns from the tip of the welding torch, it displays several clearly recognizable zones of combustion. The overall chemical equation for the complete combustion of acetylene is:

$$2C_2H_2 + 5O_2 \rightarrow 4CO_2 + 2H_2O \qquad \textbf{(EQ 1)}$$

Combustion takes place in two stages. The first stage:

$$2C_2H_2 + 2O_2 \rightarrow 4CO + 2\,H_2 \qquad \textbf{(EQ 2)}$$

uses the oxygen supplied from the cylinder and available in the oxyacetylene mixture. The reaction can be seen as the small inner cone of the flame. The highest temperature is at the point of this cone. The second stage:

$$4CO + 2H_2 + 3O_2 \rightarrow 4CO_2 + 2H_2O \qquad \textbf{(EQ 3)}$$

uses the oxygen supplied from the air surrounding the flame. This combustion zone constitutes the outer envelope of the flame.

About two-fifths of the oxygen necessary for the complete combustion of acetylene comes from the oxygen cylinder; the remainder comes from the air. Because of the need for supplemental oxygen from the atmosphere, the acetylene/oxygen flame cannot be used inside tubes of structures subject to oxygen depletion from OFW. By varying the relative amounts of acetylene and oxygen in the gas mixture in the torch, a welder can produce different flame atmospheres and temperatures.

The second equation shows that in the first stage, when equal amounts of oxygen and acetylene are burning, neither excess acetylene nor excess oxygen is present at the high-temperature tip of the inner cone. For this reason, the flame is called neutral, and the gas mixture is often described as an acetylene-to-oxygen ratio of 1 to 1, or an equal ratio. The condition of the flame is important because the inner cone is held close to, but not touching, the work metal. If excess oxygen is present, the molten metal foams and sparks, and brittle oxides may form in the weld metal. If acetylene is present in sufficient excess, indicated by an acetylene feather greater than about one-half the length of the inner cone, carbon can enter the metal. Some of the carbon forms carbides and some burns, causing gas and porosity in the solidified weld metal. In austenitic stainless steels, carbides formed in this manner aggravate susceptibility to intergranular corrosion. In welding steel, the flame should be as nearly neutral as possible, but a perfectly neutral flame is difficult to recognize, and a flame containing a slight excess of acetylene is often used.

A neutral flame is obtained by observing the size and color of the combustion zones in the flame as the oxygen-to-acetylene ratio is changed by adjusting the torch inlet valves. Figure 6 shows five typical flame conditions that appear as

oxygen flow is increased from zero to excess oxygen, as well as a separated flame condition that results from excessive gas pressure.

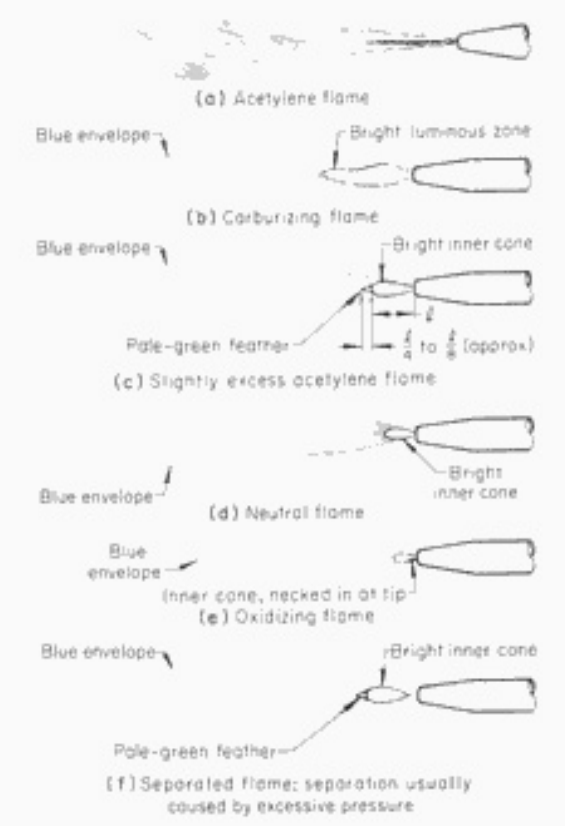

FIG. 6 FLAME CONDITIONS OBTAINED AS OXYGEN FLOW RATE INCREASES FROM ZERO TO AN EXCESS OF OXYGEN IN AN OXYACETYLENE WELDING TORCH

Acetylene Flame. When acetylene alone is burned in air, it produces a flame that varies in color from yellow near the torch tip to orange-red at the outer extremity. If soot particles are present at the end of the flame, the volume of gas should be increased until the flame burns clear (Fig. 6a).

Carburizing Flame. As the oxygen valve in the torch is progressively opened and the ratio of oxygen to acetylene increases, the flame becomes generally luminous. Then, the luminous portion contracts toward the welding tip, forming a distinct bright zone within a blue outer envelope (Fig. 6b). This is a carburizing flame because it has a large excess of acetylene; it is sometimes described as a soft flame because it has very little force. It has a relatively low temperature and is used in silver brazing and soldering, as well as in the welding of lead.

Reducing Flame. As more oxygen is introduced, the bright zone of the flame contracts farther and is seen to consist of two parts: a bright inner cone and a pale-green streamer, or feather, trailing off its end into the blue envelope. The streamer or feather is caused by a slight excess of acetylene. It disappears as the oxygen-to-acetylene ratio approaches 1 to 1. In Fig. 6(c), the feather is shown adjusted to about one-quarter the length of the inner cone. For welding steel, the length of the feather should be about one-eighth to one-quarter, but never more than one-half, the length of the inner cone. The flame is properly described as a slightly excess acetylene or reducing flame. It should not be called a carburizing flame because it does not carburize the metal, but it does ensure the absence of the oxidizing condition. It is frequently used for welding with low-alloy steel rods. The flame temperature at the tip of the inner cone is about 2930 to 3040 °C (5300 to 5500 °F).

Neutral Flame. In the neutral flame shown in Fig. 6(d), the oxygen-to-acetylene ratio is 1 to 1 (more accurately, 1.1 to 1), and the temperature at the tip of the inner cone is probably above 3040 °C (5500 °F) (Fig. 7). As pointed out earlier, making the precise adjustment of the inlet valves that results in a neutral flame is difficult, particularly in sunlight, because the oxidizing flame is of similar appearance. The neutral flame is ideal for the welding of steel, and it is also

needed when the presence of carbon must be strictly avoided. When the oxidizing condition is unacceptable, as in welding stainless steel, the use of a neutral flame is essential for good results.

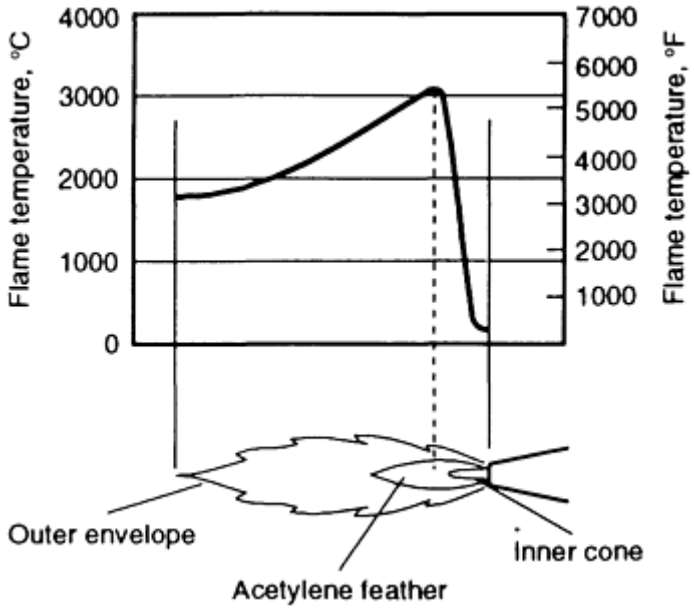

FIG. 7 FLAME TEMPERATURE AS A FUNCTION OF RELATIVE DISTANCE FROM THE TORCH TIP FOR A NEUTRAL (1:1 RATIO OF ACETYLENE TO OXYGEN) OXYACETYLENE FLAME. SOURCE: REF 4

Oxidizing Flame. An oxidizing flame is shown in Fig. 6(e). The adjustment of the inlet valves for this flame is difficult because it cannot be made on the basis of luminosity. When the flame tends to neck in at the juncture of the inner cone and the tip of the torch, this best indicates an oxidizing condition. When the flame is adjusted to be extremely oxidizing, it may also produce a hissing sound. An oxidizing flame should never be used in welding steel. It is used only in welding copper and certain copper-base alloys, and the flame should be sufficiently rich in oxygen to ensure that a film of oxide slag forms over the weld to provide shielding for the weld pool. With oxygen-to-acetylene ratios of about $1\frac{3}{4}$ to 1, flame temperature can approach 3315 °C (6000 °F).

Separated Flame. When gas pressure is too high for the size of the tip used, the flame can separate from the tip (Fig. 6f) and may even blow out. This is an unusable flame condition and must be avoided. Another cause of this condition is a clogged tip orifice.

Shape of Flame Cone. The design of the welding tip largely determines the shape of the inner cone of the oxyacetylene flame (Fig. 5); however, as the amount of oxygen used in the gas mixture is increased, the shape of the cone becomes more pointed. Both bulbous and pointed cones produce sound welds. The flame with the bulbous inner cone is preferred for welding in deep grooves in heavy sections. The flame with the long, pointed inner cone is softer and is generally preferred for welding thin sheet and aircraft assemblies.

Revised by William Ballis, Columbia Gas of Ohio

Oxyhydrogen Combustion

Complete combustion of hydrogen requires an oxygen-to-hydrogen ratio of 1 to 2, as can be seen from the following equation:

$$2H_2 + O_2 \rightarrow 2H_2O \qquad \textbf{(EQ 4)}$$

This gas mixture produces a strongly oxidizing flame having a temperature of about 2760 °C (5000 °F).

It is impossible to obtain a neutral oxyhydrogen flame by the visual methods of flame adjustment described for the oxyacetylene flame. The oxyhydrogen flame itself is scarcely visible, and no combustion zones, typical of the hydrocarbon gases, can be determined. To avoid an oxidizing flame, the pressure regulators must be set to ensure an excess of hydrogen. The flame is then reducing, but not carburizing. It has no carbon, and the temperature is several hundred degrees lower than that of the neutral flame. Metering flow regulators permit establishing the desired ratio of hydrogen to oxygen, usually 4 to 1. The oxyhydrogen flame is useful for welding and brazing aluminum alloys and lead.

Combustion of Natural Gas and Propane

Complete combustion of natural gas (methane) and propane is shown, respectively, by the following equations:

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \qquad \textbf{(EQ 5)}$$

$$C_3H_8 + 5O_2 \rightarrow 3CO_2 + 4H_2O \qquad \textbf{(EQ 6)}$$

When the flame temperature is high enough to weld steel, the flame atmosphere is excessively oxidizing, but when the ratio of oxygen to fuel gas is decreased to produce a carburizing condition, flame temperature is too low for welding steel.

Welding Rods

Filler metal for OFW of low-carbon steel is available in the form of cold-drawn steel rods 915 mm (36 in.) long and 1.6 to 4.0 mm ($\frac{1}{16}$ to $\frac{5}{32}$ in.) in diameter. Welding rods for OFW of other metals are supplied in various lengths, depending on whether they are wrought or cast.

Specifications. Steel welding rods have been standardized in the American Welding Society (AWS) specification A5.2, "Iron and Steel Gas Welding Rods." This specification shows three classifications of welding rods based on the minimum tensile strength of all-weld-metal and transverse weld test specimens:

AWS	**MINIMUM TENSILE**	MINIMUM

CLASSIFICATION	STRENGTH[A]		ELONGATION IN $4D$[B], %
	MPA	KSI	
RG65	460	67	**16**
RG60	415	60	**20**
RG45	**310**	**45**	**. . .**

(A) ALL-WELD-METAL TEST SPECIMENS, 6.40 ± 0.13 MM (0.252 ± 0.005 IN.) IN DIAMETER.
(B) ELONGATION IN APPROXIMATELY 25 MM (1 IN.)

The mechanical properties specified for the RG65, RG60, and RG45 rods are obtained by welding in a neutral to slightly excess acetylene atmosphere.

The specification covers the chemical composition of the welding rods only to the extent of limiting sulfur and phosphorus to 0.040% maximum, and aluminum, if present, to 0.02% maximum. Therefore, welding rods of different manufacturers may vary appreciably in chemical composition.

Rods for OFW of steel have no flux covering. In the absence of flux coverings, weld-metal properties depend on chemical composition of the welding rod, control of the welding atmosphere, and techniques used to provide for mixing of base metal and filler metal.

Weld-Metal Strengthening. The ability to control the properties of the weld by mixing base metal and filler metal in the weld pool means that the choice of welding rod can influence weld strength to a considerable extent. Fully reinforced welds in thin-walled tubes of 4130 welded with RG45 rod consistently showed tensile strengths of 620 to 690 MPa (90 to 100 ksi). When the welds were made with RG60 rods, the strengths increased to 690 to 860 MPa (100 to 125 ksi), and with RG65 rods, strengths as high as 1000 MPa (145 ksi) were attained when the joint was heat treated after welding.

Class RG65 welding rods have a low-alloy steel composition and are used for OFW of carbon and low-alloy steels that have strengths of 450 to 515 MPa (65 to 75 ksi). They are used on sheet, plate, tube, and pipe. These rods give the highest strengths in welding 4130, 4340, and 8630 alloy steels when base metal and filler metal are mixed properly. The end use has a marked effect on selection of filler metal. If the base metal was selected to meet a specific corrosion- or heat-resistant application, the filler metal should be of similar composition. However, if a room-temperature mechanical property is the primary requirement, the strength and ductility of the filler metal should be the basis of selection.

Class RG60 welding rods are probably used most widely. They are generally made of low-alloy steel and are preferred for OFW of carbon and low-alloy steels in the tensile-strength range of 345 to 450 MPa (50 to 65 ksi). Class RG60 rods are most commonly used for welding carbon steel pipes for power plants.

Class RG45 welding rods have a simple low-carbon steel composition. These rods can be used for OFW of carbon and low-alloy steels.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Welding Techniques

Most OFW is done with the one-pass forehand technique, particularly on thinner materials. A two-pass weld, using the backhand technique for the first pass and the forehand technique for the second pass, is preferred for thicker material (maximum thickness of 4.8 mm, or $\frac{3}{16}$ in.).

Forehand Welding. In forehand welding (Fig. 8), the flame is pointed away from the completed weld in the direction of welding. The torch is held at about 90° to the workpiece. The welding rod is held at an angle of about 30° to the workpiece, and the flame is between the tip of the rod and the weld. The inner cone of the flame is held close to the work

without actually touching it. The torch is moved from side to side or oscillated so that the flame heats the welding rod, the edges to be welded, and the weld metal ahead of the flame. The rod may be oscillated in a direction counter to the side-to-side movement of the torch. Both the welding rod-tip and the weld pool should be kept under the shielding influence of the flame. The forehand technique utilizes a zero work angle for both the torch and the welding rod.

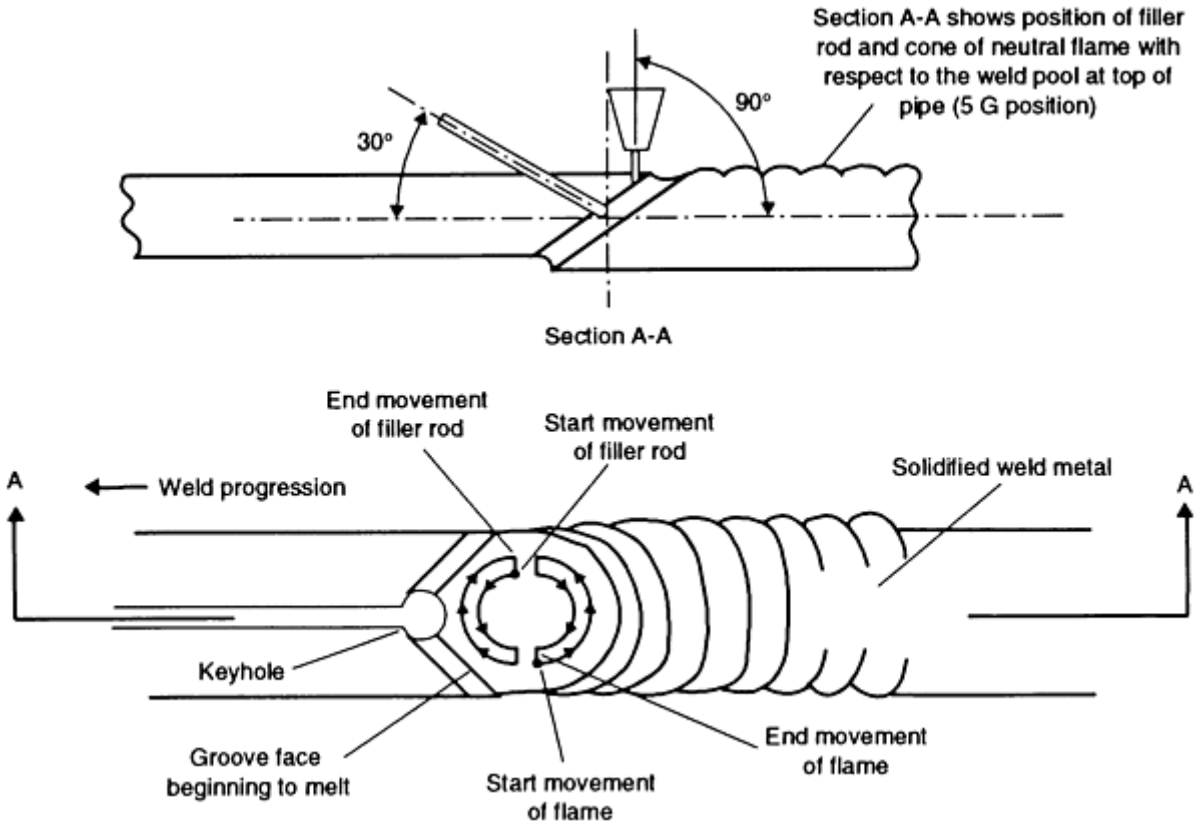

FIG. 8 ORIENTATION AND MOTION OF TORCH RELATIVE TO WORKPIECE IN ONE-PASS FOREHAND OXYACETYLENE WELDING. THE CONE OF FLAME SHOULD BE KEPT CLOSE TO, BUT SHOULD NEVER TOUCH, THE WELD POOL OR PIPE GROOVE FACE. SOURCE: REF 5

Backhand Welding. In backhand welding (Fig. 9), the flame is pointed toward the completed weld. The tip of the welding rod is held between the flame and the weld at an angle of about 30° to the workpiece, and the torch is held at an angle of about 30° to the workpiece. Rod and torch are usually oscillated as shown in Fig. 9. Because of less side-to-side movement of the flame and less melting of the joint edges, a backhand weld is more likely to retain the properties of filler metal unaltered by the base metal. The weld pool receives less agitation, and the weld metal is better protected by the flame.

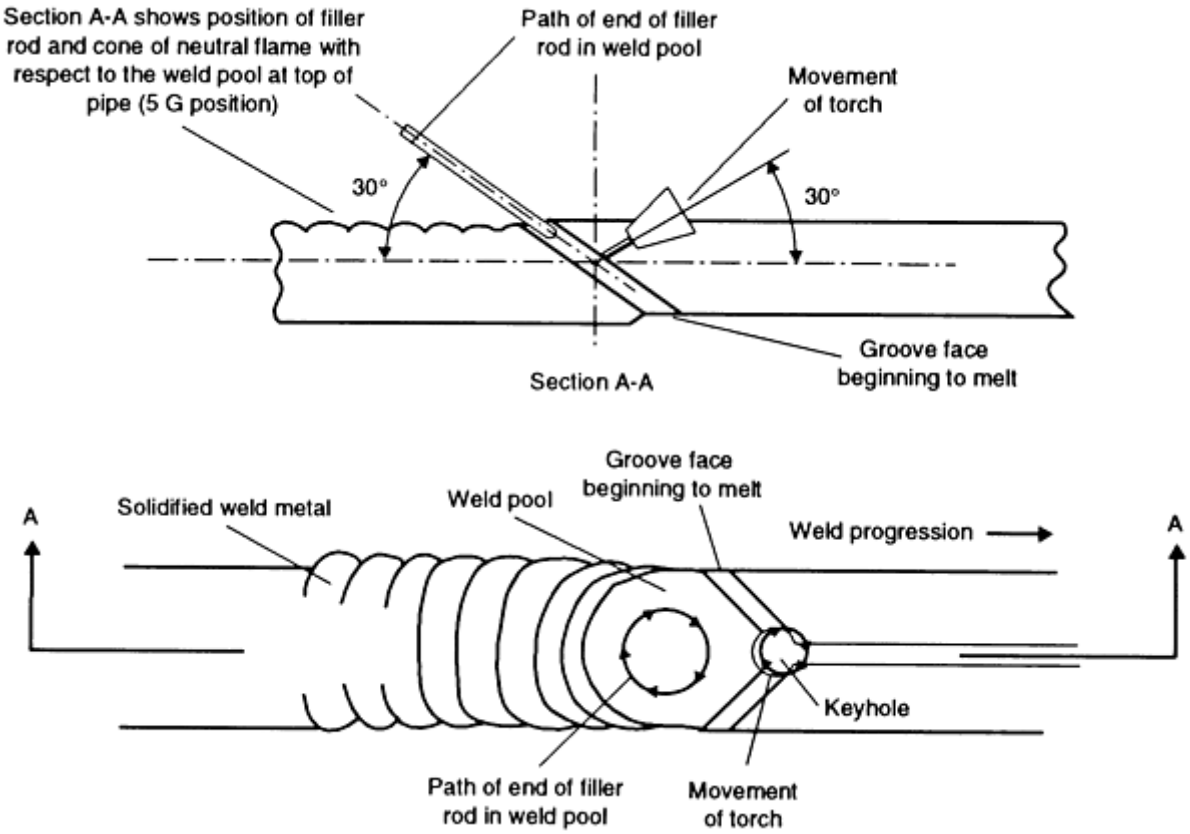

FIG. 9 ORIENTATION AND MOTION OF TORCH RELATIVE TO WORKPIECE IN ONE-PASS BACKHAND OXYACETYLENE WELDING. THE CONE OF FLAME SHOULD BE KEPT CLOSE TO, BUT SHOULD NEVER TOUCH, THE WELD POOL OR PIPE GROOVE FACE. SOURCE: REF 5

Backhand welding is often preferred for joints in the 2G fixed position. Smaller grooves can be used with this method because the flame does not need to be moved around the rod to melt the edges of the groove. Proponents of this technique believe that it saves time, filler metal, and gas. When working with a weld fillet, the flame should be directed primarily at the heavier and continuous section of base metal.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Joint Design and Edge Preparation

Joints used in OFW are butt, lap, edge, T-, and comer joints. Either fillet or groove welds are used, depending on workpiece and strength requirements.

Sheet. Five joints used for single-pass OFW of low-carbon steel sheet are shown in Fig. 10. For OFW, beveling of joint edges is not needed in sheet up to 3.2 mm ($\frac{1}{8}$ in.) thick, and if proper shearing practice has been followed in trimming sheets to size, no special edge preparation is required. However, edges must be free of rust, dirt, oil, and grease.

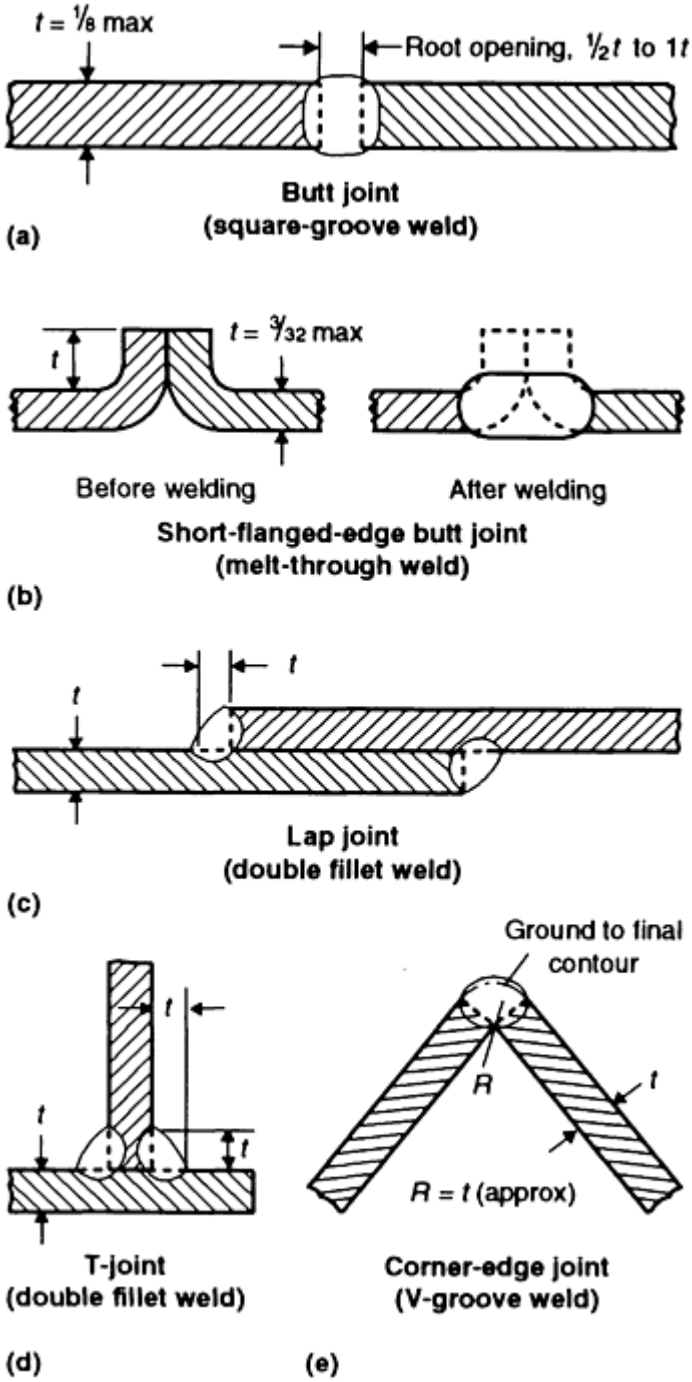

FIG. 10 TYPES OF JOINTS AND RESULTING SINGLE-PASS WELDS OBTAINED WITH OXYFUEL GAS WELDING OF THIN SHEET MATERIAL. MEASUREMENTS IN INCHES

Square-groove butt joints (Fig. 10a) can be single-pass welded from one side in sheet up to approximately 3.2 mm ($\frac{1}{8}$ in.) thick. Complete-penetration welds, properly made, develop the same or greater strength in low-carbon steel as the members joined.

Short-Flanged-Edge Butt Joints. For making butt joints in sheet up to about 2.4 mm ($\frac{3}{32}$ in.) thick, a short flanged edge (Fig. 10b) is beneficial. The weld is called a melt-through weld, because the flanges are melted down to form the butt joint. Filler metal is not required. The oscillating technique for melting down the flanges is shown in Fig. 11. The flanges keep the sheet in flat alignment.

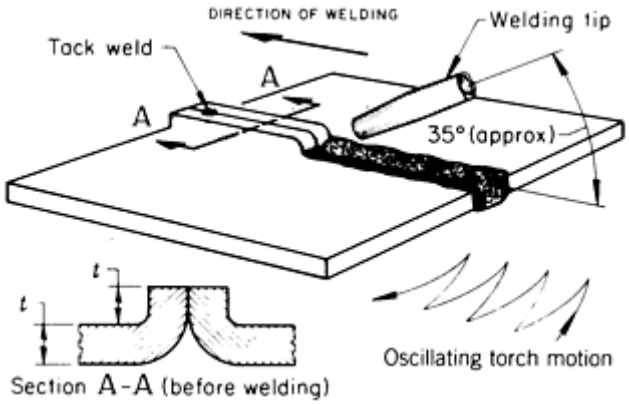

FIG. 11 OXYFUEL GAS WELDING PRACTICE USED TO PRODUCE A SHORT-FLANGED-EDGE BUTT JOINT IN THIN SHEET MATERIAL ($\leq$ 2.4 MM, OR $\frac{3}{32}$ IN., THICK)

Although the sheet has to undergo a special flanging operation, this joint is practical for long production runs when filler-metal deposition and melt-through are difficult to control. High welding speeds can be attained. Sheet thicknesses are limited to approximately 0.8 mm ($\frac{1}{32}$ in.) because short flanges are difficult to bend in heavier material. In other flanged-edge joints, the weld is deposited on the edges, and the flanges retain their structural identity.

Without support from adjacent sheet, long sections of thin material cannot be welded without buckling and distortion. The amount of distortion resulting from expansion during welding and contraction during cooling of the welded sheet-metal section or structure is proportional to the amount of heat applied to the metal as well as to its inherent stiffness and rigidity. Jigs and fixtures are essential to counteract the adverse effects of welding heat. Figure 12(a) shows the elements of a jig used for making butt or flange welds in thin sheet.

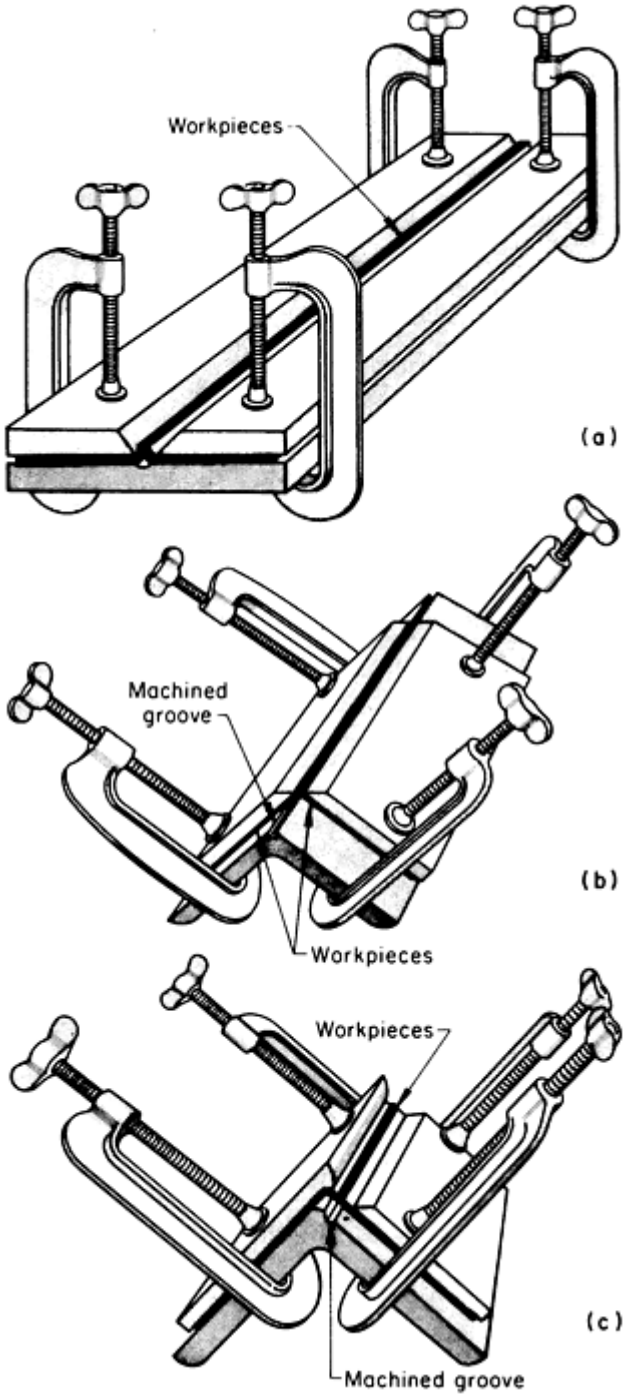

FIG. 12 APPLICATION OF JIGS TO MAINTAIN FLATNESS AND TO MINIMIZE DISTORTION WHEN WELDING THIN SHEET MATERIAL

Lap and T-joints, shown in Fig. 10(c) and 10(d), are single or double fillet welded, depending on strength requirements. A single fillet weld should not be used if the joint is likely to open under service loads. The amount of overlap in lap joints varies with design requirements and sheet thickness. For double-welded lap joints, a minimum overlap of approximately 25 mm (1 in.) is usually adequate for sheet.

The size of fillet weld, with size defined as the length of the shortest side of the fillet, is generally equal to the thickness of the sheet, because this size weld is easily produced in a single pass and has a good appearance.

Both lap and T-joints are somewhat more difficult to weld in thin sections than in thick sections. Danger of melt-through exists when a welder attempts to penetrate to the root of the joint.

Corner-edge joints (Fig. 10e) are used in thin material, mainly because of their simplicity and low cost. In addition, skillful OFW can produce a weld of good external appearance in a single pass.

To improve internal appearance and to provide added strength, an internal pass or removable ceramic backing is needed. Square comer joints in thin material can be made with good appearance and strength and with little or no distortion by using a jig as shown in Fig. 12(b). A recess is machined or ground in the corner of the backing plate to provide for root reinforcement of the V-groove weld.

When parts with rounded corner joints are designed in thin sheet, corners should be bent rather than joined. Joints next to corners can be made by butt welding in a jig constructed as shown in Fig. 12(c). Note the use of a recess in the backing member to provide for root reinforcement of the weld.

Plate. Butt, lap, T-, and corner joints are oxyfuel gas welded in steel plate up to 4.8 mm ($\frac{3}{16}$ in.) thick.

Butt joints welded from one side only require beveled edges in thicknesses 3.2 mm ($\frac{1}{8}$ in.) and over.

Fillet Welds. When compared to groove welds, fillet welds have advantages and limitations. No edge preparation such as chamfering or beveling of joint edges is required. If the weld serves mainly to hold structural members together, or if forces transmitted by the weld are low, fillet welds can be relatively small and economical.

Groove welds are used in butt joints and can be used in lap, T-, and corner joints as an alternative to fillet welds. In low-carbon steel, properly made complete-penetration groove welds develop strength equal to the strength of the members joined.

Typical grooves used for OFW of butt, T-, and corner joints in steel plate with thicknesses of 4.8 mm ($\frac{3}{16}$ in.) or less are shown in Fig. 13. Grooves for OFW are the same as those for arc welding, except that the root opening is larger.

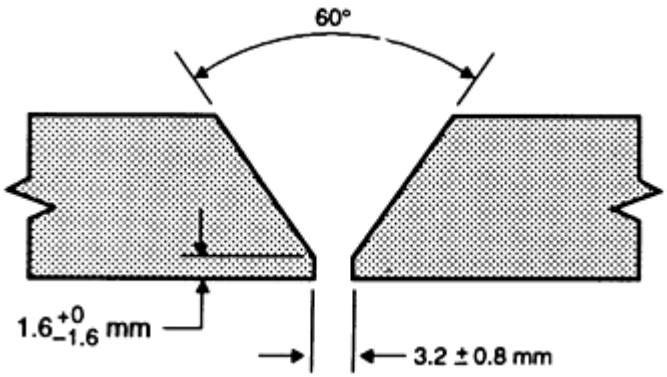

FIG. 13 USE OF GROOVES TO FACILITATE OXYFUEL GAS WELDING OF ≤ 4.8 MM (≤ $\frac{3}{16}$ IN.) THICK PLATES

Pipe. All OFW of low-carbon steel pipe is done with the oxyacetylene process. The techniques used are the one-pass forehand technique, the one-pass backhand technique, or the two-pass technique using a backhand first pass with a forehand second pass. Most production oxyacetylene welding (OAW) in the horizontal fixed (5G) or rolled position (1G) is done using the two-pass technique. When the pipe is fixed in the vertical position (2G), most welders use the one-pass

backhand technique. Oxyacetylene welding is cost effective for pipe with diameters of 150 mm (6 in.) and less and with wall thicknesses of 4.8 mm ($\frac{3}{16}$ in.) or less.

Most OAW of low-carbon steel pipe is done using a neutral flame and a work angle of 0°. The travel angles for the torch and welding rod vary with position (Ref 3).

Full-Penetration Welds. If a full penetration weld is desired, a keyhole must be maintained at all times. The torch and rod movements are shown in Fig. 8 for the one-pass forehand method and in Fig. 9 for the one-pass backhand method.

Tack welds should be small and have the general appearance shown in Fig. 14. Both ends of the tack should have a keyhole. The start end of the tack is reheated to form the start keyhole in order to obtain completed fusion when the first pass is connected with the tack weld.

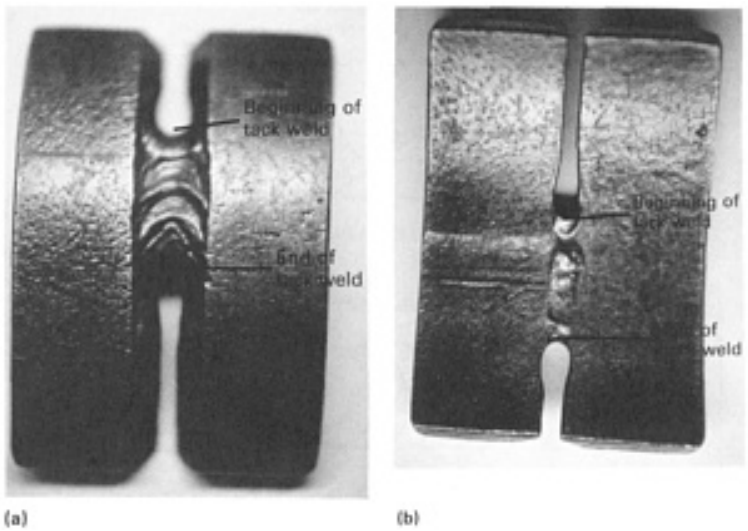

FIG. 14 TACK WELD IN API 5L STEEL PIPE. PIPE DIAMETER, 150 MM (6 IN.) WALL THICKNESS, 7 MM (0.28 IN.). (A) OUTSIDE DIAMETER VIEW. (B) INSIDE DIAMETER VIEW

The 1G, 2G, and 5G positions for welding pipe are shown in Fig. 15.

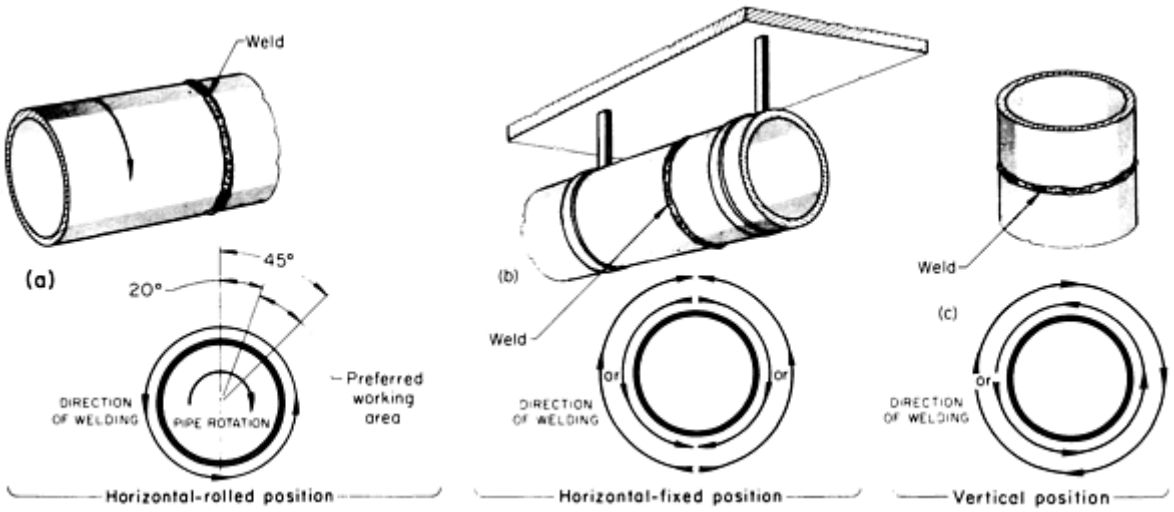

FIG. 15 TYPICAL WELDING POSITIONS FOR OXYFUEL GAS WELDING OF PIPE

Applications. The oxyacetylene process can be used to join low-carbon steel pipe having a maximum diameter of 150 mm (6 in.) and a maximum wall thickness of 4.8 mm ($\frac{3}{16}$ in.). Because of the slow travel speed and close adjustment of welding heat that characterize OAW, small-diameter steel pipe can be oxyacetylene welded faster and with better quality than can be obtained by using most other welding processes.

One of the reasons that the oxyacetylene process is seldom used today is that it is becoming a lost art. There are very few welders that are knowledgeable in the techniques used to oxyacetylene weld steel pipe. Good sources of information on oxyacetylene welding practices are manufacturers of oxyacetylene torch equipment, the American Welding Society, and welding textbooks.

Thin Sheet. Techniques used in OFW of thin sheet depend on joint design and welding position, as well as on the style used by the welder. Although forehand and backhand techniques can be used for OFW of thin sheet, forehand welding is often preferred because the flame points away from the completed weld. This results in less heat buildup and less risk of distortion and melt-through. Proponents of the forehand technique also believe that thin sections can be forehand welded faster using flat or horizontal positions because the flame forces the weld metal to flow in the direction of welding. Figure 11 shows forehand welding of a short-flanged-edge butt joint.

Assemblies of steel sheet less than 3.2 mm ($\frac{1}{8}$ in.) thick are often made by OFW. Because of the relatively long welding time involved, OFW does not permit critical control over total heat input, and distortion can occur when long, continuous welds are made in large, flat thin sheets. For this reason, OFW of thin sections should be done on small parts, where welds can be short, or on sections that have been strengthened by forming. Welding fixtures are often used to prevent distortion and to maintain alignment of joint edges.

The problems arising from difficulties in heat control in joining thin sections by OFW are sometimes solved by using other metal-joining processes:

- SHORT CIRCUITING GAS METAL ARC WELDING
- PULSED ARC WELDING
- GAS TUNGSTEN ARC WELDING
- PLASMA ARC WELDING
- ELECTRON-BEAM WELDING
- ULTRASONIC WELDING
- RESISTANCE WELDING
- BRAZING
- BRAZE WELDING

Products made by OFW of thin sheet use materials ranging in thickness from 0.607 mm (0.0239 in., or 24 gage) to 3.038 mm (0.1196 in., or 11 gage). Typical items include truck bodies, furniture, office equipment, utensils, enclosures, and refrigeration equipment.

Revised by William Ballis, Columbia Gas of Ohio

Repairs and Alterations

Oxyfuel gas welding is frequently used for repairs and alterations because the equipment is portable, welding can be done in all positions, and acetylene and oxygen are readily available. Also, gas cutting, braze welding, brazing, or flame heating is often needed, and the same personnel, equipment, and gases required for these operations can be used for OFW.

Repair Welding. Edge preparation for repair welding generally involves cutting a V-groove to expose clean metal down to the root of the joint. The groove must be large enough to allow room for manipulation of the torch and welding rod.

On many repair welding jobs, sections that must be rebuilt to specific contours or dimensions require backing to support the weld metal. Carbon paste, which can be molded, or carbon plate, which can be easily machined, can be used for backing (Fig. 16). To avoid carbon pickup, copper or a thick steel plate can be used. Welding of the backing to the part should be prevented.

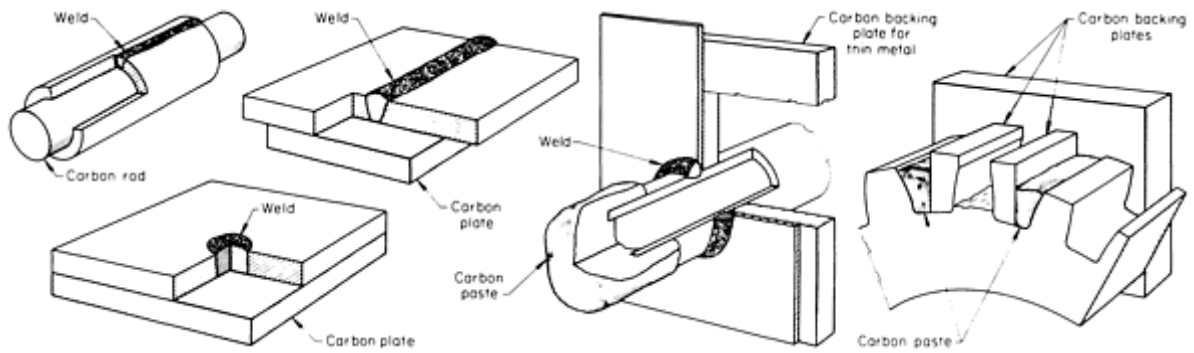

FIG. 16 USE OF CARBON BACKING TO PROVIDE SUPPORT WHEN REPAIR WELDING SURFACES AND CONTOURS

In weld repairing of parts that have cracked, the crack should be fully dressed out. Metal can be removed by chipping, grinding, machining, arc air gouging, or oxyfuel gouging. For OFW, oxyfuel gouging is convenient, because a cutting torch is generally available and only a special gouging tip is needed.

When using oxyfuel gouging for dressing cracks, the crack remains visible until it is completely removed. Grinding may result in a fine crack being smeared over, and chipping is also likely to cover the crack. The disadvantage in using oxyfuel gouging is that the heat input may cause the crack to propagate through differential expansion in the workpiece. The risk is especially great if some of the stresses that caused the crack are still present. Drilling a 6.4 to 13 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) hole at the end of the crack may prevent the crack from propagating. Cleanliness of the joint is also a prerequisite for OFW. Rust, scale, dirt, grease, oil, paint, and slag must be removed from the joint areas. The soundness of the weld metal depends in large part on the care used in cleaning. To ensure complete crack removal, liquid-penetrant or magnetic-particle testing can be used.

Workpiece Alterations. When OFW is used to correct production parts that would be rejected because of a small error or defect in manufacture, it must be determined if the salvaged part, after welding, is as good as a new part for the required service. Some fabricating codes identify the defects that may be rectified by welding and define the standards for repair. Rectification may include correction of defects, building up of undersize parts, and filling in of drilled holes.

Preheating and Postheating

Preweld and postweld heat treatments are not usually required to reduce the hardness of low-carbon steel, but either or both treatments are beneficial and can be effective in avoiding or reducing distortion. Most steels that are oxyacetylene gas welded fall within the low-carbon range.

Oxyacetylene gas welding distributes a large amount of heat over a wide area. This results in relatively slow cooling rates and relatively low stress gradients, which, in turn, reduce the degree of hardening and the magnitude of residual stresses that are usually associated with welding heat cycles.

Example 1. Use of Oxyacetylene Welding to Eliminate Postweld Tempering. Aircraft landing gear side stay assemblies made of 1330 steel (Fig. 17) were joined in the form of a trapezoid. The assembly was originally welded by the shielded metal arc welding process; E7016 electrodes were used. Several assemblies cracked in a tube adjacent to a weld after a short time in service. Examination revealed high hardness (50 HRC) in the heat-affected zone (HAZ) was caused by the chilling effect of the large mass of metal in the end fittings. A postweld tempering treatment at 650 °C (1200 °F) to reduce the high hardness could not be used because the tubes became distorted.

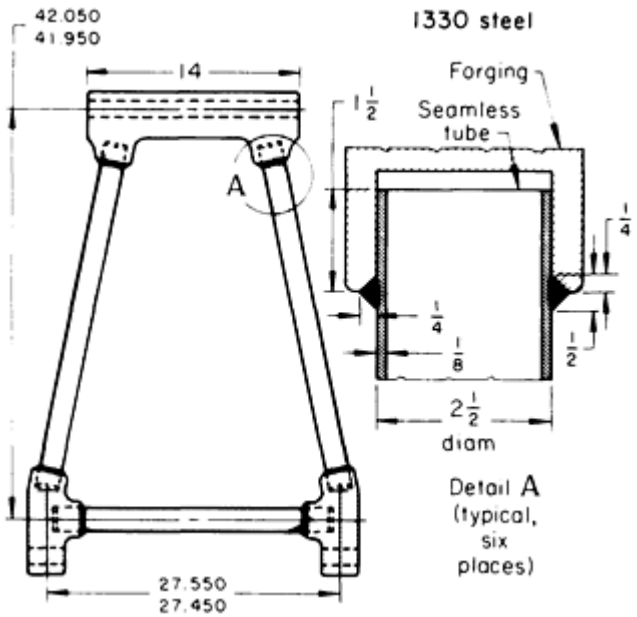

FIG. 17 OXYACETYLENE WELDING OF AIRCRAFT LANDING GEAR SUPPORT. USE OF OAW REDUCED HAZ HARDNESS AND ELIMINATED NEED FOR POSTWELD TEMPERING. MEASUREMENTS SHOWN IN SCHEMATIC ARE IN INCHES.

Local stress relief of the welded joint with a gas torch was successful but laborious, and it was finally decided to oxyacetylene gas weld the assembly. Hardness tests in the area of the welded joint showed that the maximum hardness in the HAZ was 285 HB (29 HRC). This was only moderately higher than the hardness of the end fittings and tubes, which had a hardness of 223 HB (98 HRB). The improvement was believed to result from the wider area heated during OAW, which produced a lower temperature gradient.

Bridging Gaps in Poor Fit-Ups

The ability to control the flow of molten weld metal in OFW provides a high degree of versatility in bridging large gaps caused by a poor fitup. By manipulating the gas torch, weld-metal temperature can be held to the minimum, and the pressure of the gas flame can be used to help support the weld pool in any position, including overhead.

Oxyfuel Gas Welding

Revised by William Ballis, Columbia Gas of Ohio

Safety

The gases used in OFW can form explosive mixtures if improperly handled, and burning of these gases must be controlled within recommended limits for the safety of the welder and surrounding property. Workers must be familiar with safe welding practices and should be aware that any deviation from recognized safety standards can result in damage to apparatus or in personal injury. Workers in charge of welding operations should be instructed and judged competent by their employers.

Rules and instructions covering safety, operation, and maintenance procedures are readily available. Federal, state, and local governments, in addition to equipment manufacturers, gas suppliers, and regulatory agencies, have cooperated in publishing documents on safe welding practices.

Additional safety guidelines and reference sources for further information are provided in the article "Safe Practices" in this Volume.

Thermite Welding

Bernard Schwartz, Norfolk Southern Railway Company

Introduction

THERMITE WELDING (TW) is a fusion welding process in which two metals become bonded after being heated by superheated metal that has experienced an aluminothermic reaction. The liquid metal that results from the reaction between a metal oxide and aluminum acts as the filler metal. This exothermic process was discovered in 1898, in Germany, by Dr. Hans Goldschmidt of Goldschmidt AG.

In the United States, this process was used in the early 1920s to join trolley car track. In 1933, thermite welding was used on the Delaware and Hudson Railroad at Albany, NY to produce long rail sections. In 1938, a researcher at the Electric Railway Improvement Company invented a copper-base aluminothermic process for welding copper conductors to steel rails. Currently, thermite welding is widely used in the field welding of track, where its portability and versatility are strong assets.

It should be noted that the standard term for this process is often listed as "thermit" welding. However, Thermit is a registered trademark of Th. Goldschmidt AG of Essen, Germany. Therefore, this Volume uses the generic term, "thermite."

Thermite Welding

Bernard Schwartz, Norfolk Southern Railway Company

Thermite Welding Principles

The aluminothermic reaction that occurs in thermite welding follows the general formula:

$$\textit{metal}\ \text{oxide} + \underset{\text{(reducing agent)}}{\text{Aluminum}} \rightarrow \underset{\text{oxide+metal+heat}}{\text{Aluminum}}$$

whereas the typical reaction that occurs in the thermite welding of rails is:

$$FE_2O_3 + 2AL \rightarrow 2FE + AL_2O_3\ (HEAT \rightarrow 850\ KJ)$$

and the typical reaction that occurs in the welding of copper conductors to steel rails is:

$$3CU_2O + 2AL \rightarrow 6CU + AL_2O_3\ (HEAT \rightarrow 1060\ KJ)$$

This exothermic reaction is extremely violent if only the metal oxide and aluminum reducing agent are used. Pellets of ferroalloy are added to cool this reaction from a typical temperature of 3090 °C (5600 °F) to 2480 °C (4500 °F). These additions also are used to produce the desired chemistry. The amount of added alloy is very critical, because larger

amounts will cool the reaction to temperatures below 2040 °C (3700 °F), at which point the slag/metal separation could be incomplete.

Thermite Welding Metallurgy

Metallurgical structures that are present in thermite welds depend on the chemical composition of the weld metal and on the cooling rate of the joint after pouring is completed.

Figure 1 shows a typical macrostructure of a carbon steel rail thermite weld and the microstructure of the fusion zone, the fusion line, the end of the heat-affected zone (HAZ), and the unaffected rail. Typically, the weld is 100% pearlite with varying degrees of coarseness. This is due to the slow cooling rate that completes transformation before reaching the martensite start temperature and the formation of untempered martensite.

Thermite Welding

Bernard Schwartz, Norfolk Southern Railway Company

Applications for Thermite Welding

Rail welding is the most widely used application of the thermite welding process. The use of that process, as well as the electric flash butt welding process, has eliminated joint bars (mechanical fasteners) and greatly lessened track maintenance. Long sections of continuous welded rail (CWR) (typically, 440 m, or 1440 ft) that are welded by the flash butt welding process are transported to the track site and set into place. Then, the CWR sections are joined by thermite welding. A short preheating process is typically used in the thermite welding of rail.

The thermite process is also utilized to replace rail defects, to weld insulated joint assemblies into track, and to make electrical bonding connections using copper conductors between rails that will not be welded together.

Process Description. The thermite welding of rails, including a short preheat, involves the following basic operations:

- CUT OR SPACE THE RAILS TO BE WELDED SO THAT THE GAP SPECIFIED BY THE MANUFACTURER IS ACHIEVED
- REMOVE SLAG, MOISTURE, FOREIGN MATTER, AND SUCH FROM THE AREA TO BE WELDED
- ALIGN THE RAIL ENDS, BOTH VERTICALLY AND HORIZONTALLY
- CENTER THE THERMITE MOLDS OVER THE RAIL GAP AND SEAL THE GAPS WITH LUTING MATERIAL
- SITUATE THE PREHEATING EQUIPMENT, MOLD CLAMPS, AND THERMITE CRUCIBLE IN POSITION ABOVE THE JOINT GAP AND THE MOLD OPENING (FIG. 2)
- ADJUST THE PREHEATING EQUIPMENT TO ACHIEVE THE MOST UNIFORM HEATING OF THE RAIL ENDS FROM ONE SIDE TO THE OTHER AND FROM TOP TO BOTTOM
- IGNITE THE THERMITE CHARGE AND ALLOW IT TO TAP INTO THE MOLD, THE TIMING OF WHICH IS USUALLY CONTROLLED BY A SELF-TAPPING THIMBLE. THE LIQUID METAL FLOWS ONTO A DIVERTER PLUG TO REDIRECT THE FLOW OF LIQUID METAL INTO THE SIDE SPRUES SO THAT THE CASTING IS PRODUCED FROM THE BOTTOM UPWARD
- ALLOW THE PROPER SOLIDIFICATION TIME, AS RECOMMENDED BY THE MANUFACTURER
- REMOVE THE MOLD MATERIAL AND FINISH-GRIND THE WELD TO RAILROAD SPECIFICATIONS
- CONDUCT A FINAL INSPECTION OF THE WELD, BOTH VISUALLY AND WITH THE AID OF ULTRASONIC EQUIPMENT

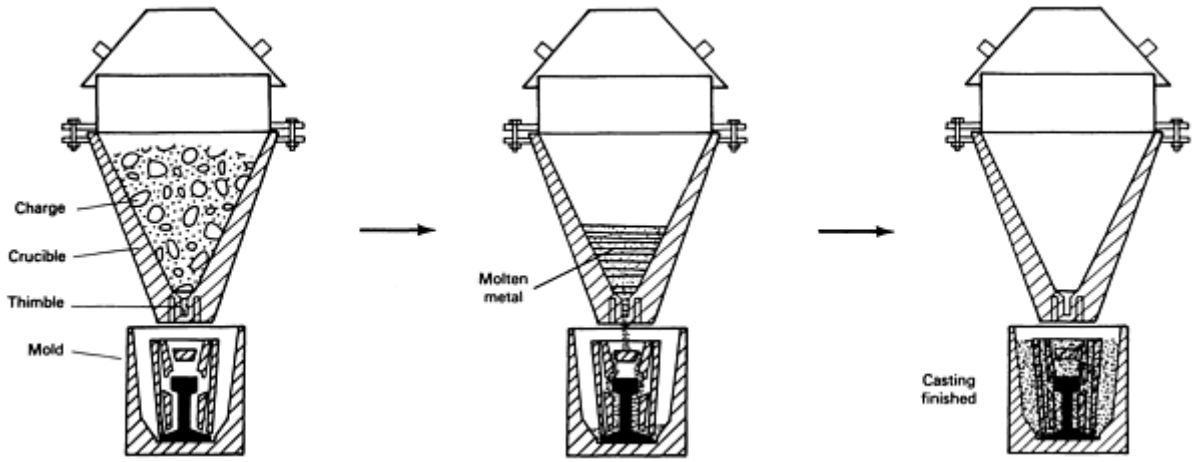

FIG. 2 TYPICAL CRUCIBLE-MOLD SETUP FOR RAIL THERMITE WELDING

Electrical Connections. The thermite welding process also is used to weld electrical conducting joints, particularly to provide electrical continuity for railroad signal systems. A copper oxide powder is reduced by aluminum to form a

metallurgical bond between the steel rail and the copper conductor. The resulting joint has an excellent current-carrying capacity and the ability to withstand corrosion, when compared with a mechanical bond.

Repair Welding. Large-diameter rolls, shafts, ingot molds, and heavy mill housings can be successfully repaired by using the thermite welding process. The metallurgical aspects of the process, when used to make repair welds, are similar to those of rail welding, except for the large volume of the weld. The primary difference is that a customized mold, which is usually manufactured on-site, is used. A wax pattern is built around the weld cavity, and a collar is shaped in wax to overlap the base metal. Sand is hand rammed around the pattern within a mold box. Then, sufficient gates and risers are incorporated into the system.

New Railroad Applications. Recent developments include:

- HIGHER-STRENGTH THERMITE MIXTURES THAT MORE CLOSELY MATCH THE HARDNESS OF CURRENT HIGH-STRENGTH RAILS (RAIL HARDNESS HAS STEADILY INCREASED TO 300 HB, MINIMUM, FOR STANDARD CARBON RAILS AND TO 360 HB, MINIMUM, FOR PREMIUM RAILS)
- ONE-USE CRUCIBLES THAT REDUCE OR ELIMINATE WELD-METAL CONTAMINATION BY THE RESIDUAL ELEMENTS AND IMPURITIES THAT REMAIN IN CONVENTIONAL REUSABLE CRUCIBLES
- POSTWELD HEAT TREATMENT THAT REFINES THE GRAINS IN OLDER WELDS AND IMPROVES THE STRUCTURAL PROPERTIES OF THE THERMITE WELD TO THE LEVEL OF THOSE OF ELECTRIC FLASH BUTT WELDS
- A HEAD WASH REPAIR WELD THAT CAN REPAIR DISCONTINUITIES ON THE RUNNING SURFACE OF THE RAIL HEAD. (IN THE HEAD WASH REPAIR, RAIL SURFACE DEFECTS OR DISCONTINUITIES ARE TORCH WASHED AWAY DOWN TO THE SOUND METAL. THIS OCCURS OVER A VERY SHORT TIME SPAN. THE TORCH WASH AREA IS CLEARED, A THERMITE MOLD IS APPLIED, AND THE AREA IS PREHEATED AND THEN THERMITE WELDED TO PRODUCE A COMPLETE RAIL HEAD OF SOUND METAL.)
- WIDE-GAP REPAIR WELDS (50 AND 75 MM, OR 2 AND 3 IN.) THAT CAN BE UTILIZED TO WELD WIDER GAPS AND TO ELIMINATE SPECIFIC RAIL DEFECTS, WITHOUT REQUIRING THE INSTALLATION OF A PLUG RAIL
- NEW MOLD CONFIGURATIONS (REPOSITIONED RISERS, METAL GUSSETS, AND SO ON) THAT MAY INCREASE THE MECHANICAL PROPERTIES OF RAIL THERMITE WELDS
- A ZIRCON-BASE MOLD WASH COATING FOR THERMITE WELD MOLDS THAT IMPROVES THE SURFACE CONDITION OF RAIL THERMITE WELDS, THEREBY IMPROVING FATIGUE LIFE

Thermite Welding

Bernard Schwartz, Norfolk Southern Railway Company

Thermite Welding Safety

As already noted, the thermite welding process produces a violent reaction and a large release of heat. The presence of moisture in the charge, crucible, molds, or tooling should be avoided in order to prevent the rapid release of steam and the resulting ejection of molten metal from the crucible. The thermite charge and molds must be stored in a dry location. Tooling should be preheated prior to use, and the surrounding work area should be dry and free of combustible materials.

Appropriate protective clothing, safety boots, gloves, safety glasses, or a full face shield with filter lenses should be worn by all personnel in the immediate vicinity.

High-Temperature Solid-State Welding

W. Lehrheuer, Forschungszentrum Jülich GmbH

Introduction

HIGH-TEMPERATURE SOLID-STATE WELDING is used to join members of similar or dissimilar materials by compressing and heating the surfaces to be joined in a suitable atmosphere and by maintaining pressure and temperature until the parts are joined.

The processes that occur on the surfaces to be joined can be categorized by three stages.

Primary Bonding. In this first stage, the surface layers of the pieces being welded are prepared to accept the initial bond. The deformation of rough points will crack brittle surface layers and, thus, will achieve limited local bonding of metallic surfaces, leading to reactions between the atoms of the pieces being welded.

Bond-Surface Extension. In this second stage, the bond surface is enlarged by virtue of plastic flow processes, which are determined by surface loading, and the mechanical properties of the pieces being welded. An expansion of the weld surface area occurs because of diffusion along the surfaces being bonded. The metallic bond becomes improved as a result of the removal of surface films and impurities by dissolution and diffusion into the base material. The diffusion process actually reorients surface atoms, thereby providing a configuration that is more suitable for bonding. Finally, the reaction processes that occur between the atoms (and their electrons) of the enlarged bond surfaces of the pieces being welded result in good adhesion between the components.

Elimination of the Original Joining Surface. In this third stage, the joined zone experiences recrystallization, grain growth, and diffusion that are beyond the characteristics of the original weld interface. The formation of a largely homogeneous weld with normal metallic cohesion is achieved by reactions that occur between the materials being joined.

Because diffusion processes have a significant role in this type of welding, the operation is frequently called "diffusion welding" or "diffusion bonding."

High-Temperature Solid-State Welding

W. Lehrheuer, Forschungszentrum Jülich GmbH

Process Advantages and Disadvantages

The major advantages of the process are that:

- IT ALLOWS THE PREPARATION OF STRESS-RELIEVED AND, IN MANY CASES, PRIMARILY HOMOGENEOUS 0JOINTS ON VERY DIFFERENT MATERIALS.
- IT ALLOWS THE WELDING OF MATERIAL COMBINATIONS THAT CANNOT BE JOINED BY FUSION WELDING. THIS APPLIES TO MATERIALS THAT FORM BRITTLE INTERMETALLIC PHASES AND TO METALS THAT ARE JOINED TO NONMETALS.
- IT ENABLES THE JOINING OF COMPONENTS WITH VERY DIFFERENT JOINING SURFACE GEOMETRIES THAT ARE NOT SUBJECT TO ANY PARTICULAR REQUIREMENTS. HOWEVER, THE PRESSURE APPLICATION METHOD CAN BE A LIMITING FACTOR. MATERIALS ARE JOINED IN THE SOLID STATE. METALLURGICAL CONDITIONS ARE GENERALLY FAVORABLE AND EASY TO INFLUENCE, BECAUSE THERE IS LESS SHRINKAGE AND FEWER STRESSES.
- COMPONENT DEFORMATION IS KEPT WITHIN RELATIVELY CLOSE LIMITS, THEREBY OMITTING THE NEED FOR REWORKING, IN MANY CASES.
- THE PROCESS MAY BE ALMOST FULLY AUTOMATED. THEREFORE, HIGHLY QUALIFIED TECHNICIANS ARE NOT REQUIRED FOR PRODUCTION TASKS.

The disadvantages of the process are:

- HIGH EQUIPMENT COST
- HIGH DEMANDS IN TERMS OF SURFACE CLEANLINESS AND PRECISION, AS WELL AS WELDING ATMOSPHERE
- CONSIDERABLE TIME REQUIREMENTS FOR EXECUTING THE JOINT, EXCEEDING BY FAR THE REQUIREMENTS OF MOST OTHER PROCESSES
- INCREASED CAPITAL COSTS WITH INCREASING COMPONENT SIZE, BECAUSE A WELDING CHAMBER BECOMES NECESSARY
- VERIFICATION OF PROPER JOINT EXECUTION BY NON-DESTRUCTIVE TESTING IS SIGNIFICANTLY IMPAIRED, IN MANY CASES

Although these disadvantages and process features prevent large-scale technical applications that replace welding, the possibilities for using this process to solve special problems are impressive.

High-Temperature Solid-State Welding

W. Lehrheuer, Forschungszentrum Jülich GmbH

Equipment

Mass production is not possible when this process is used. The type of equipment, process temperatures, atmospheres, materials, component sizes, and numbers of workpieces can differ in each application and can result in entirely different systems and devices. The process is frequently conducted in facilities designed for other purposes, such as hot presses, hot isostatic pressing facilities, and vacuum or inert-atmosphere furnaces (with dead-weight loading). The configuration shown in Fig. 1 represents a typical equipment design.

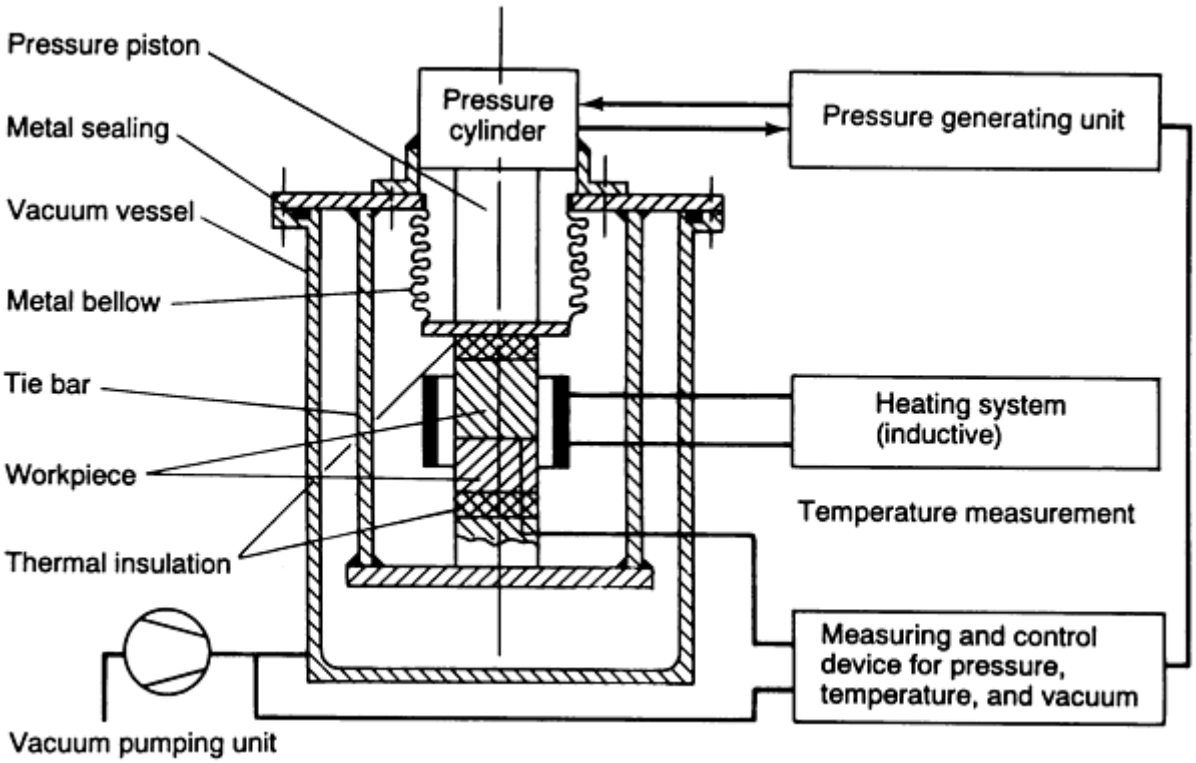

FIG. 1 PRINCIPLE OF OPERATION OF TYPICAL HIGH-TEMPERATURE SOLID-STATE WELDING EQUIPMENT

High-Temperature Solid-State Welding

Procedures for High-Temperature Solid-State Welding

The procedures used to make this type of weld can be described in simple terms. Clean surfaces are pressed together in an atmosphere that is suited for the materials being joined and then heated to welding temperatures. The temperature is maintained until welding is completed. The component is then cooled.

The most important process parameters are temperature, pressure, welding time, and welding atmosphere. Figure 2 shows the dependence of the strength of a diffusion weld on temperature, pressure, and time. It should be noted that these three parameters are not independent of one another. Within certain limits, higher temperature can shorten the time required for welding and reduce the pressure, and vice versa.

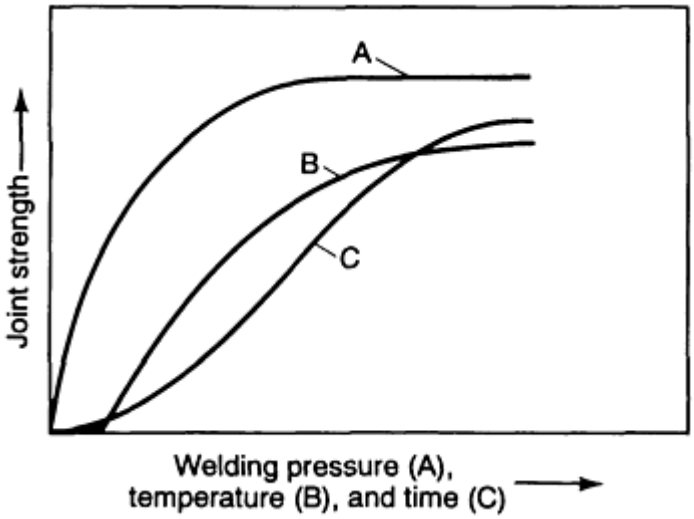

FIG. 2 INFLUENCE OF WELDING PRESSURE, TEMPERATURE, AND TIME ON JOINT STRENGTH

Temperature is the most important welding parameter. The requisite temperature depends on the material or the combination of materials. It must be sufficiently high to ensure plastic flow and intimate contact of the surfaces at the selected surface pressure, as well as adequate diffusion within a reasonable time. As a general rule, a welding temperature ranging from 0.5 to 0.7 T_s is advisable, where T_s is the melting temperature, in K, of the lower-melting-point material or component.

Pressure is required in order to achieve a large contact area at the welding temperature. The pressure level depends on the mechanical properties of the materials being joined. Its upper limit is determined by the admissible degree of deformation. A pressure increase beyond a certain level does not improve strength any further. As a general rule, a surface pressure that ranges from 1 to 20 MPa (0.15 to 2.9 ksi) can be considered adequate for the execution of high-temperature solid-state welds. The deformation at the joint interface, as a result of surface pressure, also has a positive influence on the joint. Surface impurity layers, such as oxides, are cracked, surface roughness is removed, and the atoms in the joint surfaces are brought close together. Plastic deformation facilitates the approach of the metallic atoms by fragmentation and dispersion of surface oxide and impurity barriers. Therefore, it is often better to match a surface of elevated roughness by deformation in the surface region than it is to bond, for example, highly polished surfaces with minor deformation. A precondition, however, is good surface cleaning and the removal of impurity surface layers prior to welding.

The welding time required for the preparation of a proper joint can range from a few minutes to several hours, depending on the material or material combination, as well as on the selected welding temperature.

The welding atmosphere used in most welding systems is a vacuum. In most cases, a vacuum of 0.01 Pa (1.4×10^{-6} psi) is sufficient. The use of high-purity shielding gases, such as argon or helium, is possible for many materials, but generally does not present any technical or economic advantages. Materials that are relatively insensitive to oxygen, such as structural steels, have been successfully welded in air. Welding has also been performed in liquids, such as molten salt.

Prior to welding, it is important to clean the surfaces to be joined and to remove any surface layers, especially oxide films. Although it is not possible to prevent the formation of new layers in air, these newly formed layers are very thin and hardly impair the welding process. Higher welding temperatures and greater deformation on the surfaces reduce the influence of such layers. Surface cleaning can be accomplished by chemical or mechanical methods. Proven techniques are degreasing with a suitable agent or removing the layers with wire brushes immediately prior to welding.

The most metallurgically simple type of weld results when similar materials are joined without using an interlayer material. In this case, the properties of only one material determine the process parameters. Two materials are involved in the rarely practiced joining of similar materials using an interlayer of softer material, which may facilitate surface matching or improve diffusion. An interlayer is more frequently used in the joining of dissimilar materials. When interlayers are used, the welding process involves a metallurgically complicated multicomponent system, even in the case

of pure metals. The interlayers primarily serve to bridge different melting points and different coefficients of thermal expansion, improve the diffusion properties, and form favorable structures in the joining zones. Practically any metal combination can he joined using suitable interlayers. Even extreme combinations, such as molybdenum and lead or tungsten and lead, can be processed by selecting several suitable interlayers, although several welding operations at different temperatures would be required.

In addition to welding metals to each other, diffusion welding permits the joining of metals to nonmetals. However, the problems encountered in this case are even more complex, because the chemical and physical properties of the components being welded differ significantly from each other. Nevertheless, welds between metals and glasses, as well as between metals and ceramics, have been successfully produced. The main problems arise from differences in the coefficients of thermal expansion and in the brittleness of the nonmetallic members.

High-Temperature Solid-State Welding

W. Lehrheuer, Forschungszentrum Jülich GmbH

Practical Applications

The high-temperature solid-state welding process has been primarily used on an industrial scale in the fields of aerospace and nuclear engineering. A typical application is the fabrication of complicated hollow structures. Figure 3 shows a cross section of a rotating-anode x-ray tube. The body consists of austenitic stainless steel, whereas the outer welded ring is made of aluminum. Both parts form several cooling channels.

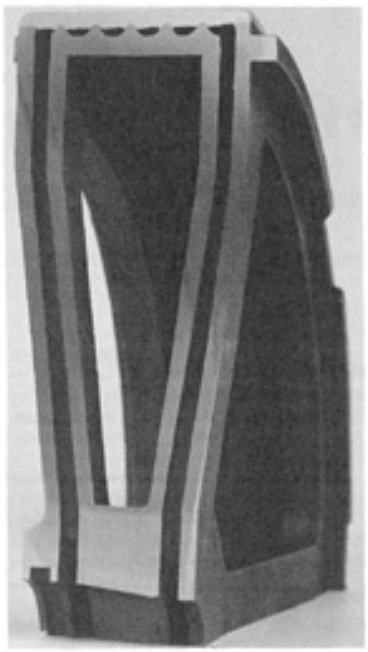

FIG. 3 ROTATING X-RAY ANODE WITH OUTER ALUMINUM RING DIFFUSION WELDED TO STAINLESS STEEL BODY

Another important application is the joining of dissimilar materials. Of particular significance to nuclear engineering applications are joints made of aluminum and stainless steel. Figure 4 shows welds of these materials in different joint geometries. An economical use of this process for mass production frequently is not possible, because of the long welding times and expensive equipment involved. Therefore, applications will probably continue to be limited to special complicated geometries, expensive materials and dissimilar material combinations. In recent years, the combined use of this process with a heat-treatment step has been increasing. Economic efficiency is much easier to achieve with such a process combination. The process is undoubtedly of great significance for joining very dissimilar materials, including

metals and ceramics, and the newly developed high-temperature materials, anisotropic materials, and fiber-reinforced materials.

Low-Temperature Solid-State Welding

R.S. Rosen, Lawrence Livermore National Laboratory

Introduction

SOLID-STATE WELDING is the joining of base metals (metals, alloys, ceramics, etc.) by chemical bond formation without heating the base metals above their respective melting points. The advantages of solid-state welding processes include the ability to join parts to a finished size or shape without additional machining, and the ability to join multiple interfaces during a single welding cycle. The disadvantages of solid-state welding processes compared with conventional fusion welding or brazing include generally longer welding cycles, and more restrictive size limitations for the parts to be joined. In this article, low-temperature solid-state welding processes are described in relation to the interlayer fabrication method, welding method, and welding parameters. These findings are discussed relative to the mechanical properties of the joints.

Low-Temperature Solid-State Welding

R.S. Rosen, Lawrence Livermore National Laboratory

Applications

The utilization of soft-metal interlayers for solid-state welding may be an appropriate joining method when brittle intermetallic formation, differential thermal contraction during cooling, or oxide dissociation and dissolution temperatures preclude conventional methods such as fusion welding, brazing, and direct solid-state welding of the base metals. An interlayer can be in the form of a foil, or it can be applied to one or both of the base-metal surfaces by various coating methods (e.g., electrodeposition, plasma spraying, or vapor-deposition methods). Methods utilizing coated interlayers require a two-step joining procedure (coating and welding) as opposed to joints fabricated with foil interlayers, which may only require a single solid-state welding step. However, methods utilizing coated interlayers have the advantage over foil interlayers in not requiring solid-state welding at the interlayer/base-metal interface. Solid-state welding of some interlayer/base-metal combinations may require high temperatures and/or pressures, due to the high dissociation temperatures of the surface oxides, which may preclude or restrict the use of foil interlayers.

Interlayer Materials. Silver is the predominant material utilized as a low-temperature interlayer because high-strength joints can be fabricated at relatively low temperatures (473 to 673 K, or 392 to 752 °F) and pressures (100 to 200 MPa, or 15 to 30 ksi) due to the low dissociation temperature (<460 K, or 370 °F) of silver oxide. Other interlayer materials utilized--such as copper (Ref 1), aluminum (Ref 2), and aluminum-silicon alloys (Ref 3)--require higher welding temperatures (873 to 1273 K, or 1110 to 1832 °F) to achieve joint strengths comparable to those of silver. Gold, thought to be a promising interlayer material for low-temperature applications due to the absence of a surface oxide layer at room temperature, has not been utilized as much. This may be due to its propensity to form brittle intermetallics at relatively low temperatures with a number of base metals (Ref 4). Low-temperature (616 K, or 525 °F) solid-state welding of dissimilar (electroplated) interlayer materials, such as gold-to-silver and gold-to-copper, has been achieved at a pressure of 50 MPa (7 ksi) for 3 h using various base metals (Ref 5).

Joint Geometry. Soft interlayer welds between stronger base materials may have ultimate tensile strengths much higher than those of the bulk interlayer materials. For example, the tensile strength of silver interlayer solid-state welds between maraging steel base metals has been reported to be nearly 800 MPa (115 ksi) (Ref 6), while the ultimate tensile strength of the bulk silver is only about 250 MPa (35 ksi) (Ref 7). The high tensile strength of the joint is due to the mechanical constraint provided by the stronger base metal, which restricts transverse contraction of the interlayer. The constraint establishes radial (triaxial) stresses that inhibit the development of shear stresses within the joint, thereby decreasing the effective stress in the interlayer. This reduction in stress inhibits the plastic flow that leads to the ductile fracture. The base metals provide relatively little mechanical constraint of the interlayer during shear loading because the shear stress is parallel to the plane of the interlayer. Therefore, soft interlayer welds between stronger base metals are capable of higher loads in tension (loading perpendicular to the plane of the interlayer, such as in a butt joint) than in shear (loading parallel to the plane of the interlayer, such as in a lap joint).

In general, joint strengths of soft interlayer solid-state welds increase with decreasing interlayer thickness and increasing welding temperature and pressure. However, increasing welding times do not necessarily result in increased joint strength. For example, resultant joint strengths of silver solid-state welds have been reported to be independent of welding times from 1 to 240 min (Ref 4). In addition, decreasing interlayer thickness-to-diameter ratios to less than 0.025 does not result in higher joint strengths and may actually result in a lowering of tensile strength (Ref 8, 9).

Surface Preparation

Surface Cleaning. Prior to coating and/or welding, machined base-metal surfaces are usually degreased by a multiple-step procedure. The following method (Ref 8) has been used to clean a variety of base metals (for example, type 304 stainless steel, maraging steel, uranium, beryllium, and aluminum) before they undergo subsequent ion-sputter etching and silver interlayer deposition in vacuum:

1. WASH WITH ABRASIVE DETERGENT FOLLOWED BY A HOT-WATER RINSE
2. RINSE IN DEIONIZED WATER
3. ULTRASONICALLY CLEAN IN ETHYL ALCOHOL
4. BLOW DRY USING INERT GAS

For other fabrication methods, such as electrodeposited interlayers or foils, the base metal surfaces are degreased prior to plating or joining to remove organic surface films that would otherwise degrade the metallic bonding at the interlayer/base-metal interfaces.

Surface Finish. Joint strength generally increases with decreasing base-metal surface roughness and flatness. This is true for foil interlayers and for coated interlayers, where the surface roughness of the coating generally replicates that of the underlying base-metal surface. Table 1 shows the increases in tensile strengths of silver interlayer welds utilizing lapped base-metal surfaces (0.15 μm, or 6 μin., flatness, 0.03 μm, or 1.2 μin., arithmetic average surface roughness, R_a) over those of machined surfaces (2 μm, or 80 μin., flatness, 0.1 μm, or 4 μin., R_a) (Ref 8, 10). The increase in strength achieved

through use of smoother base-metal surfaces is generally attributed to more complete welding from the increased contact area of the laying surfaces.

Low-Temperature Solid-State Welding

R.S. Rosen, Lawrence Livermore National Laboratory

Interlayer Fabrication Method

Vacuum Coated Interlayers. Specimens to be coated are usually mounted in a fixture (which may be water-cooled) inside the vacuum chamber, with the base-metal surfaces facing the evaporation or sputtering source. The chamber is evacuated using a roughing pump is conjunction with an ultrahigh vacuum turbomolecular or cryogenic pump. After achieving the desired chamber base pressure (typically 10 μPa, or 0.075 μtorr), argon gas is then introduced into the vacuum chamber and maintained at a pressure of about 5 Pa (38 mtorr) for sputtering. A glow-discharge power supply is then used to initiate a plasma at 1 to 2 kV with reference to the base-metal specimens. Depending on the base metals utilized, specimens are usually sputter-etched for 5 to 45 min, resulting in 0.1 to 1 μm (4 to 40 μin.) etched from the surfaces. Figure 1 shows a schematic of a typical vacuum chamber and the two-stage etching and sputter-coated procedure. The shutter is shown placed between the target surface during the etching phase. The coating phase is accomplished (after evacuating the argon gas from the chamber) by evaporation of the interlayer material, or by using a high-rate sputter-target source such as a planar magnetron. Deposition of interlayer metal onto the specimens is usually started after reducing the chamber pressure to 1 t 2 Pa (8 to 15 mtorr). Typical deposition rates at the specimen surfaces are 5 to 20 nm/s (50 to 200 Å/s). Some interlayer/base-metal combinations are capable of achieving high interfacial

strengths without having to sputter-etch the native oxide layer prior to deposition. Adhesion of the deposited material is enhanced by preheating the base metals prior to deposition. For the case of beryllium base metal, high-strength joints result when silver is vacuum coated onto the beryllium surfaces at base-metal temperatures exceeding 773 K (932 °F).

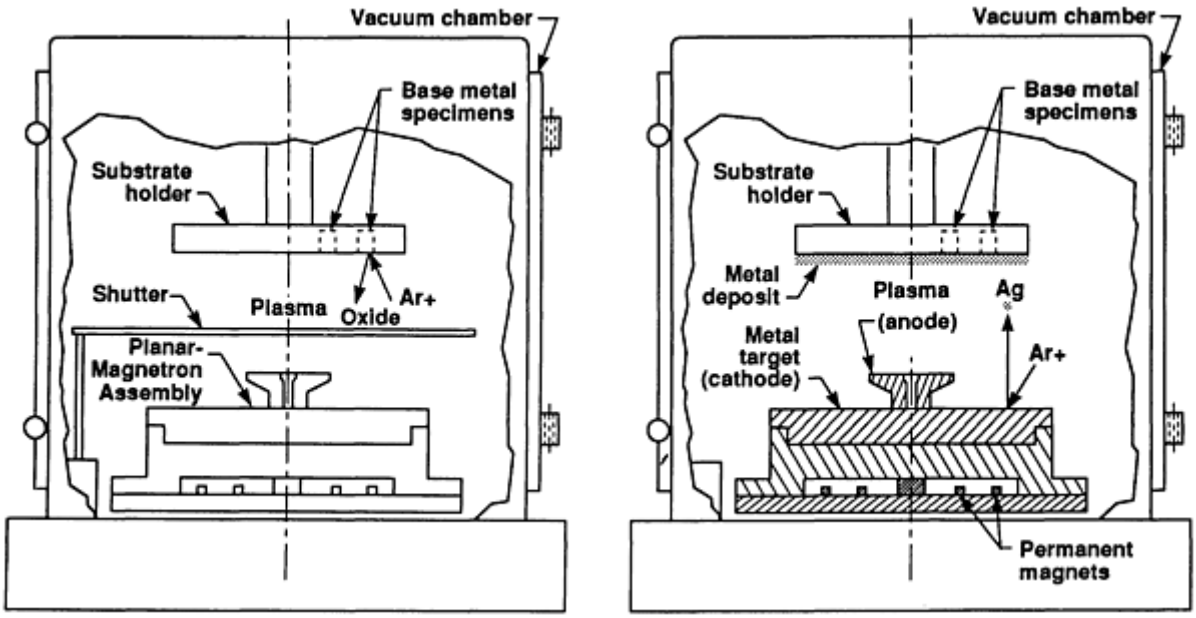

FIG. 1 SCHEMATIC OF VACUUM COATING CHAMBER AND ASSOCIATED HARDWARE SHOWING (A) ION-ETCHING AND (B) INTERLAYER METAL DEPOSITION PHASES. AN EVAPORATION SOURCE MAY BE USED INSTEAD OF THE SPUTTERING SOURCE TO DEPOSIT THE INTERLAYER MATERIAL.

Electrodeposited Interlayers. Prior to plating of the interlayer metal onto the base-metal surfaces, the specimens are generally masked to restrict the deposition to the surfaces to be joined. The specimens are usually degreased and then chemically or electrochemically etched in an appropriate solution to remove surface oxide layers. The initial plated layer (~1 to 5 μm, or 40 to 200 μin.) may be deposited at higher current densities (>200 A/m^2, or 20 A/ft^2) to improve the adhesive strength, followed by plating of the remaining interlayer thickness (~10 to 100 μm, or 400 to 4000 μin.) at lower current densities (~40 A/m^2, or 4 A/ft^2). It should be noted that electrodeposited interlayer metals are usually not as pure as vapor-deposited metals due to the presence of impurities in the plating solutions.

Foil Interlayers. Use of foils requires the same cleaning considerations for surface oxides and contaminants as that of deposited interlayers. The base metal as well as the foil material may be etched to remove the oxide layer prior to welding. Foils are usually cut to the desired shape prior to placing between the base metal surfaces to be joined.

Low-Temperature Solid-State Welding

R.S. Rosen, Lawrence Livermore National Laboratory

Welding Methods

The mechanism of solid-state welding is believed to consist of:

- PLASTIC DEFORMATION OF THE CONTACTING SURFACE ASPERITIES DURING INITIAL APPLICATION OF THE LOAD
- OXIDE DISSOLUTION AND DIFFUSION AWAY FROM THE FORMING INTERFACE
- TIME-DEPENDENT PLASTICITY (CREEP) AND/OR DIFFUSION OF METALS TO THE

In addition to these processes, recrystallization and grain growth of the (formed) interface may occur.

Uniaxial Compression. Solid-state welding by uniaxial compression is usually accomplished in a vacuum furnace; for the case of silver at temperatures above about 473 K (392 °F), welding may be accomplished directly in air. Pairs of specimens to be joined are usually loaded with a hydraulic ram. If a vacuum furnace is used, the chamber is evacuated to a gas pressure below about 100 μPa (0.75 μtorr) prior to applying the peak welding pressure (~70 to 210 MPa, or 10 to 30 ksi) to the coated surfaces in contact. The specimen temperature is then elevated to peak temperature (~473 to 873 K, or 392 to 1110 °F) and maintained for 10 to 240 min. The furnace is usually cooled to below 323 K (122 °F) before the pressure is relieved.

Figure 2 shows a schematic of a typical vacuum furnace used for brazing. The constraining fixture shown surrounding the specimen is used to prevent excessive deformation from base-metal yielding during applied loading. This is often the case when dissimilar metals such as aluminum and stainless steels are joined at temperatures and pressures exceeding 473 K (392 °F) and 100 MPa (15 ksi), respectively, using silver as the interlayer material.

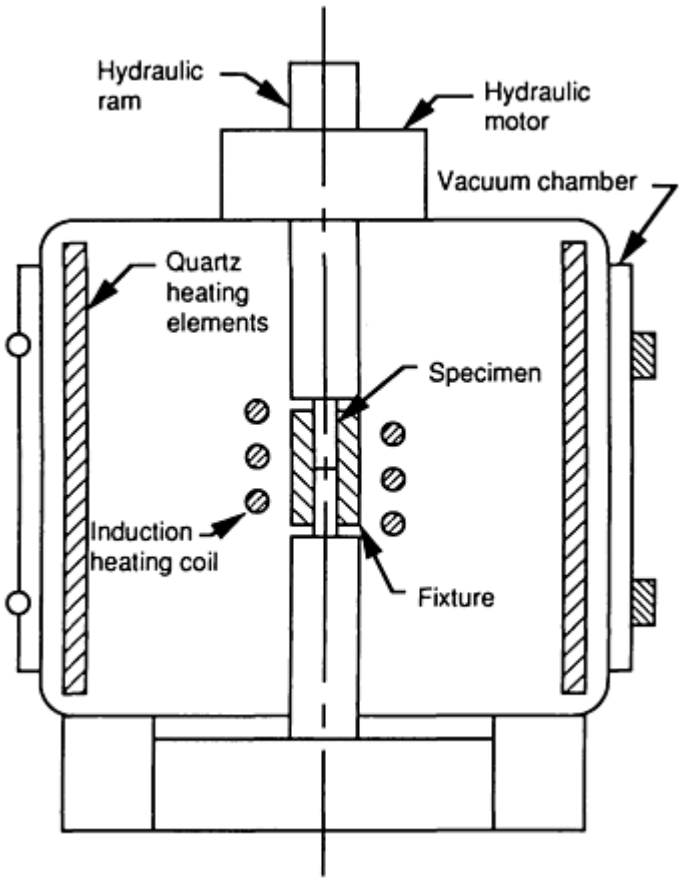

FIG. 2 SCHEMATIC OF A TYPICAL VACUUM FURNACE USED FOR SOLID-STATE WELDING BY UNIAXIAL COMPRESSION. HEATING WOULD BE BY EITHER AN INDUCTION COIL OR RADIANT ELEMENTS AS SHOWN. THE CONSTRAINING FIXTURE SURROUNDING THE SPECIMEN IS USED TO PREVENT EXCESSIVE DEFORMATION FROM BASE-METAL YIELDING DURING APPLIED LOADING.

Isostatic Pressure. Solid-state welding by hot isostatic pressing is accomplished in an autoclave. Parts to be joined are placed with the coated surfaces in contact and then encapsulated with a thin (0.25 to 1 mm, or 0.01 to 0.04 in.) stainless steel membrane, or "can." The cans are sealed using a suitable fusion welding method such as electron-beam or gas-tungsten arc welding. The sealed assemblies are usually evacuated through a small tube welded on one end of the can using a vacuum pump. The evacuated assemblies are placed in an autoclave and isostatically compressed with gas or

liquid to a pressure of about 100 MPa (15 ksi). The temperature is then raised to the peak value of 473 to 873 K (392 to 1110 °F) while the gas pressure is increased to the desired peak value (~70 to 350 MPa, or 10 to 50 ksi). Peak temperature and pressure are maintained for 1 to 2 h. The autoclave is usually cooled to below 373 K (212 °F) before the gas is vented.

Final Machining of Welded Parts

After welding, the parts may be finish machined if desired. For the case of dissimilar base metals where one material is considerably stiffer than the other, some allowances may have to be made for single-point cutting-type operations where the tool passes over the joint. For example, machining by lathe turning has resulted in a step remaining at the joint between the base metals due to the differences in elasticity of the base metals. Additionally, lathe cutting with a single-point tool may result in a smearing of the harder base metals across surfaces of the softer interlayer material. These problems can be avoided by utilizing surface grinding as the final machining operation.

Explosion Welding

John G. Banker and Edward G. Reineke, Explosive Fabricators, Inc.

Introduction

EXPLOSION WELDING (EXW) is a solid-state metal-joining process that uses explosive force to create an electron-sharing metallurgical bond between two metal components. Although the explosive detonation generates considerable heat, there is not time for heat transfer to the component metals; therefore, there is no appreciable temperature increase in the metals. The physics of the process are discussed in the article "Fundamentals of Explosion Welding" in this Volume.

Explosion Welding

John G. Banker and Edward G. Reineke, Explosive Fabricators, Inc.

EXW Process Attributes

Metallurgical Attributes. Because of the absence of heating, EXW products do not exhibit many of the metallurgical characteristics of fusion-welded, brazed, or hot-rolled/forged products. Unlike those processes, in EXW (Ref 1, 2, 3, 4):

- THE COMPONENT METALS REMAIN IN THEIR WROUGHT STATES; CONTINUOUS CASE STRUCTURES ARE NOT CREATED.
- THE MICROSTRUCTURES, MECHANICAL PROPERTIES, AND CORROSION PROPERTIES OF THE WROUGHT PARENT COMPONENTS ARE NOT ALTERED FROM APPLICABLE PREBONDING SPECIFICATION REQUIREMENTS.
- THERE ARE NO HEAT-AFFECTED ZONES.
- THERE ARE NO CONTINUOUS-MELT BANDS EXHIBITING MIXED CHEMISTRY.
- THERE IS ALMOST NO DIFFUSION OF ALLOYING ELEMENTS BETWEEN COMPONENTS.

Metals Combinations. Explosion welding is an effective joining method for virtually any combination of metals. The only metallurgical limitation is sufficient ductility and fracture toughness to undergo the rapid deformation of the process without fracture. Generally accepted limits are 10% and 30 J (22 ft · lbf) minimum, respectively.

Explosion welding is suitable for joining metals of the same type--for example, steel to steel--as well as metals with substantially different densities, melting points, and/or yield strengths--for example, tantalum to alloy titanium. The process is commonly used to join corrosion-resistant alloys to carbon or alloy steels.

Size Limitations. Explosion welding is appropriate for use over a broad range of sizes. It has been used for joining electronic components of widths less than 0.5 mm (0.020 in.) and for cladding plates up to 5 × 13 m (16 × 40 ft). Cladding metal thicknesses can range from 0.025 to 100 mm (0.001 to 4 in.), and base metal thickness can range from 0.025 mm (0.001 in.) to over 1 m (40 in.). The size limits are generally mandated by component metal manufacturability and transport requirements.

Configuration Limitations. Explosion welding is limited to the bonding of flat surfaces or coaxial cylindrical surfaces. It is ideally suited for bonding large, flat areas, as in clad plate manufacture.

Bond Zone Morphology. Explosion welding is traditionally known for its wavy bond zone morphology. The physics of the wave formation process and its relation to process variables are discussed in the article "Fundamentals of Explosion Welding" in this Volume. The EXW bond zone morphology is flat at the low end of the bonding velocity range and transitions to wavy as the velocity is increased. Through proper selection of EXW parameters, the bond zone morphology

can be tailored to satisfy product performance requirements. Although a low-velocity wavy bond zone is preferred for most needs (Fig. 1), certain applications are better served by flat or turbulent-wavy interfaces (Ref 5).

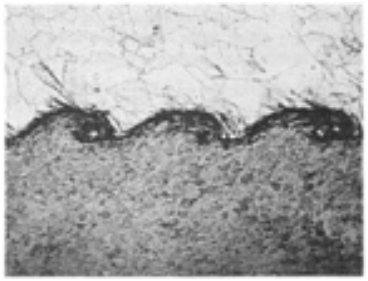

FIG. 1 BOND ZONE PATTERN TYPICAL OF EXPLOSION CLAD METALS. MATERIALS ARE TYPE 304L STAINLESS STEEL AND MEDIUM-CARBON STEEL. 20×

Interlayers. The physical and mechanical performance requirements of the EXW bond zone are determined by the product application. With some combinations of metals, the required bond zone performance characteristics are best achieved with an interlayer between the two primary metals. For example, a titanium interlayer can be used to increase the performance temperature of an aluminum/copper weld, and a silver interlayer can be used to improve the leak tightness of an aluminum/stainless steel weld.

EXW Products and Applications

Common Industrial Applications. Because of the unique safety and noise-vibration considerations, EXW is generally performed in relatively isolated facilities by companies specializing in explosives operations. The major products are large clad plates, which are used in pressure vessel, heat exchanger, and electrochemical process applications (Fig. 2). The dissimilar-metal welding features of EXW are made available to a broader industrial base through the concept of welding transition joints (Fig. 3).

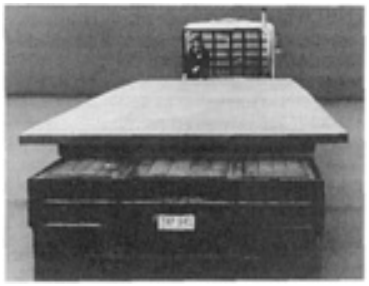

FIG. 2 TITANIUM/STEEL EXPLOSION-BONDED CLAD PLATE

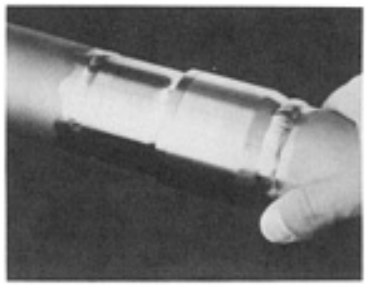

FIG. 3 ALUMINUM-TO-STAINLESS WELD ACCOMPLISHED WITH AN EXPLOSION-BONDED TUBULAR TRANSITION JOINT. ALUMINUM AND STAINLESS STEEL ARE WELDED TO THE RESPECTIVE ENDS USING CONVENTIONAL FUSION-WELDING PROCESSES.

Transition joint components are produced by explosion welders at their production facilities and then provided in the form of blocks, strips, or tubular couplings to equipment fabricators for use in the conventional welding of dissimilar metals. Common applications are aluminum/steel (Ref 6, 7), aluminum/titanium, and aluminum/copper-nickel for shipboard construction (Fig. 4); aluminum/copper and aluminum/steel for electrical contacts and buss systems; aluminum/stainless steel for cryogenic pipe couplings; titanium/stainless steel for aerospace and aircraft applications (Fig. 5); and Kovar/copper and Kovar/aluminum for electronic packaging (Ref 8).

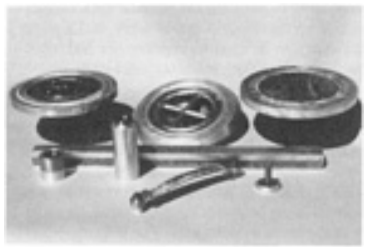

FIG. 4 TRANSITION JOINT MATERIALS FOR JOINING DISSIMILAR METALS IN SHIPBOARD AND MARINE EQUIPMENT CONSTRUCTION

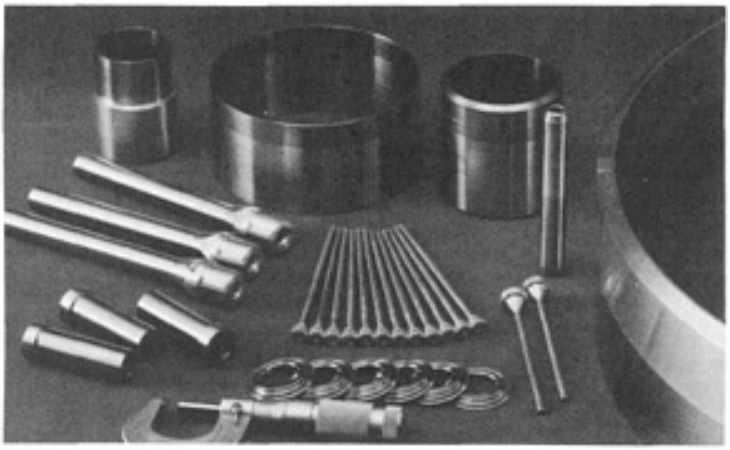

FIG. 5 TUBULAR WELDING TRANSITION JOINTS FOR HERMETIC WELDS BETWEEN TITANIUM, ALUMINUM, AND ZIRCONIUM AND STAINLESS STEEL

Shop Welding Applications. Small, specialty EXW devices have been developed for a few unique shop applications. Explosion welding is used in heat exchanger shops for joining tubes to tubesheets and tube plugging. Explosion spot welding devices have also been used in limited commercial applications (Ref 9).

EXW Manufacturing Process and Practice

Safety and Regulations. Safety is of critical importance in the practice of EXW. Guidelines and regulations for the safe handling and transport of explosives are provided by the U.S. Bureau of Alcohol, Tobacco, and Fire Arms (Ref 10), the U.S. Department of Transportation in its Federal Motor Carrier Safety Regulations (Ref 11), and the Institute of Makers of Explosives Safety Library Publications (Ref 12). Licensing and regulations for the purchase, transport, manufacture, and use of explosives may vary significantly among states and municipalities. Depending on the types of explosives used, the detonation by-products may be subject to environmental regulation. Potential practitioners of explosion-bonding operations should understand the safety standards and regulations before proceeding (Ref 13).

Noise and Vibration Abatement. The sound and ground vibration generated during EXW can be considerable. Common methods for noise abatement include performing the operation in a highly remote geographic location, in a mine

or bunker, or in a specially designed blast chamber or vacuum chamber. Safety considerations vary among these options. Precautions must be taken to ensure that personnel are protected from shrapnel and facility deterioration.

Process Geometry. Two basic geometric configurations of the EXW process are commonly used: angle bonding and parallel-plate bonding. Angle bonding is normally used for bonding sheet components and tubes, where the required bond width does not exceed 20 times the flyer plate thickness. The more commonly used parallel-plate geometry (Fig. 6) is applicable for welding larger flat areas and concentric cylinders (Ref 14).

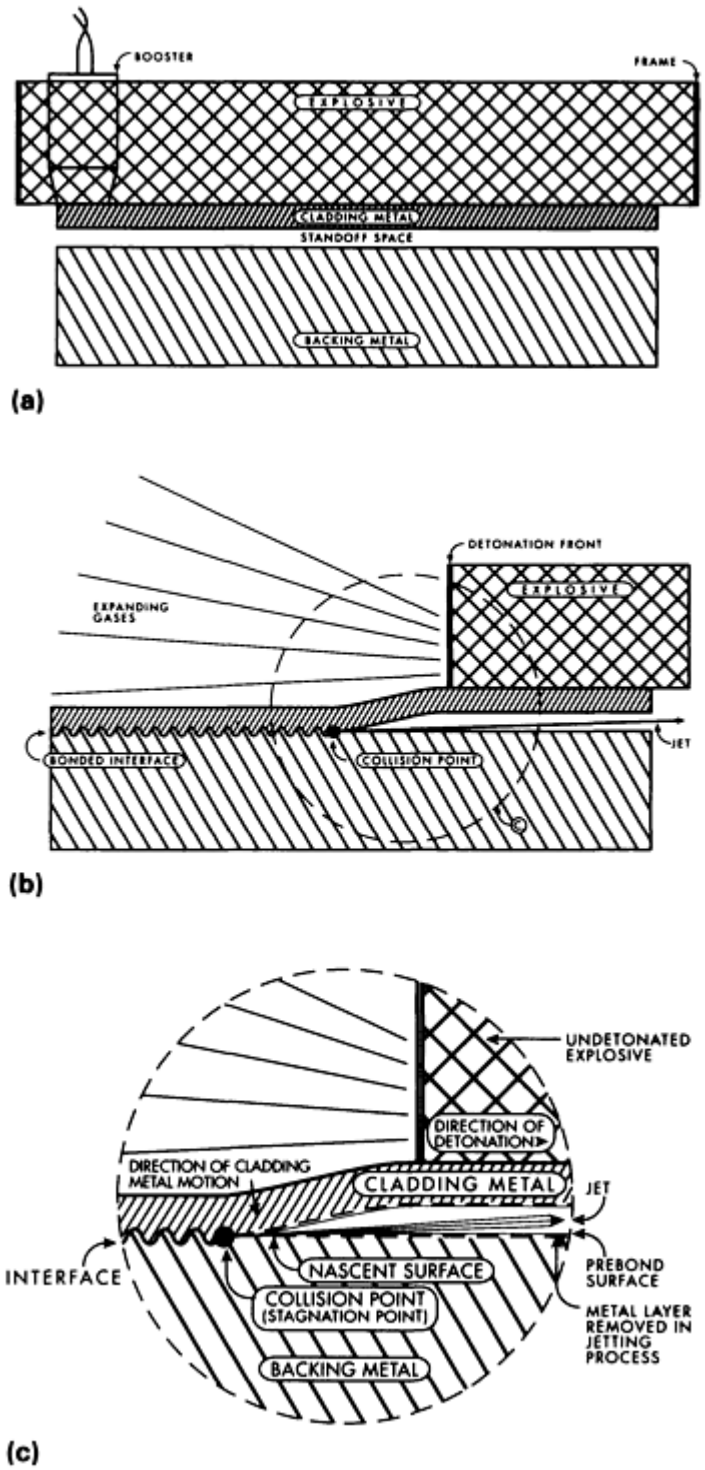

FIG. 6 PARALLEL-PLATE EXPLOSION WELDING PROCESS. (A) EXPLOSION-CLADDING ASSEMBLY BEFORE DETONATION. (B) EXPLOSION-CLADDING ASSEMBLY DURING DETONATION. (C) CLOSE-UP OF (B) SHOWING MECHANISM FOR JETTING AWAY THE SURFACE LAYER FROM THE PARENT LAYER

Basic parameters of EXW are flyer plate velocity, collision point velocity, and collision angle. The process variables that affect these parameters are explosive detonation rate, explosive mass, flyer plate mass, standoff distance, and/or preset angle. These process variables are normally controlled to provide:

- A FLYER PLATE VELOCITY OF 250 TO 500 M/S (820 TO 1600 FT/S)
- A COLLISION POINT VELOCITY OF 1500 TO 3500 M/S (4900 TO 11,000 FT/S) BUT LESS THAN 120% OF THE SONIC VELOCITY OF THE COMPONENT METALS
- A COLLISION ANGLE OF 5 TO 20°

Selecting the specific parameters is discussed in the Section "Procedure Development and Practice Considerations for Solid-State Welding" in this Volume.

Sizing Considerations. It is common practice to provision materials that are wider, longer, and thicker than required in the finished product to compensate for thinning and edge effects. In most situations, metals cannot be reliably bonded fully to the edges. Typically, edge nonbond allowances are four to eight times flyer plate thickness, depending on the combination of metals. Additionally, an area of nonbond is typical near the explosive initiator.

The thickness of the component metals is reduced during surface preparation and bonding. Surface conditioning removes up to 0.75 mm (0.030 in.) from the thickness. During the bonding operation, the force vector parallel to the detonation causes a 1 to 2% increase in plate lateral dimensions; this is accomplished by a corresponding reduction in thickness. The jetting of the metal surfaces during the bonding process causes only a thin layer to be removed, usually less than 0.05 mm (0.002 in.).

Explosion Welding

John G. Banker and Edward G. Reineke, Explosive Fabricators, Inc.

Typical EXW Process Sequence (Parallel-Plate Bonding)

Surface Preparation. The faying surfaces of the components are ground to achieve a smooth, pitfree finish of 1 to 3 μm (50 to 100 μin.).

Assembly. The plates are fixtured parallel while separated by a standoff gap. Methods for determining the standoff gap are presented in the article "Introduction to Solid-State Welding" and the Section "Procedure Development and Practice Considerations for Solid-State Welding" in this Volume. Small standoff devices are required to bear the weight of the flyer plate and the explosive. Edge standoff devices are easily ejected from the system during bonding; therefore, material of construction is rarely critical. Internal standoff devices must be of sufficiently low mass to be removed by the jet, or must be located in trim regions. Commonly used internal standoff materials are thin metal ribbons and foam blocks.

Explosive Loading. The explosive is placed on top of the flyers metal surface. The most commonly used explosives are granular or liquid and are typically contained within a simple box structure fabricated around the perimeter of the flyer plate. Initiating explosives are positioned in a suitable location on the plate surface.

The required detonation range of EXW is below that of most commercially manufactured explosives. Consequently, most practitioners of EXW use proprietary explosive blends. Appropriate detonation characteristics can be achieved by specialized blending of commercial explosives such as Amatol, Dynamite, or NCN.

Bonding. The primer is electrically initiated, causing a progressive detonation of the explosive, which creates the actions shown in Fig. 6 and welds the plates together.

Flattening. The energy of bonding typically creates sufficient deformation that flattening or straightening is required prior to further processing. Flattening is performed with equipment of the same design used in plate and sheet manufacture.

Testing and inspection are performed as mandated by the product specifications. Ultrasonic inspection, using standard procedures such as ASTM A 578, is the most commonly accepted method for inspecting the bond continuity. Bond shear strength is normally measured using the test defined in ASTM A 265. The tensile strength of the bond is normally measured using a Ram Tensile Procedure; the standard design is presented in MIL-J-24445.

Preparation of the Required Product. Because of the process edge effects, it is common practice to cut the product from a larger plate after bonding. The process options vary with the metal combinations and include oxyfuel gas cutting, plasma cutting, waterjet cutting, sawing, and machining.

Heat Treatment. Most metal systems do not require postbond heat treatment; however, some combinations provide superior properties if they are given a stress relief after bonding. For example, titanium/steel and zirconium/steel exhibit improved bond toughness after stress relief, and ferritic stainless steels exhibit an improvement in ductile-to-brittle transition temperature after stress relief.

Specifications

There are no universal ASTM, ASME, or military standard specifications for EXW products. Specific combinations of metals are covered in ASTM A 263, A 264, A 265, and B 432 (and their ASME equivalents) and in MIL-J-24445. The International Explosion Metalworking Association (IEMA) has established IEMA Guide Note 100, which provides recommended specification content.

Explosion Welding

John G. Banker and Edward G. Reineke, Explosive Fabricators, Inc.

Process Variations

The preceding discussion describes the process for welding a two-component flat plate product. Essentially the same approach can be used for producing multilayer products or cylindrical shapes:

- MULTIPLE LAYERS CAN BE BONDED SEQUENTIALLY IN A SINGLE BONDING OPERATION; AS MANY AS 50 INDIVIDUAL THIN LAYERS HAVE BEEN IN A SINGLE ASSEMBLY.
- TWO-SIDED CLAD PLATES, WITH A HEAVY CORE METAL, CAN BE PRODUCED BY

SIMULTANEOUSLY BONDING BOTH SIDES USING A VERTICAL ASSEMBLY.

- TWO OR MORE CYLINDERS CAN BE BONDED CONCENTRICALLY. THE EXPLOSIVE IS PLACED EITHER INSIDE OF THE CYLINDER OR OUTSIDE OF THE OUTER CYLINDER, DEPENDING ON DIAMETER AND WALL THICKNESS.

Forge Welding

FORGE WELDING (FOW) is a solid-state process in which the workpieces are heated to the welding temperature and then applied with blows sufficient to cause permanent deformation at the faying surfaces. It is most commonly applied to the butt welding of steels. As contrasted with hot pressure (thermocompression) welding of ductile face-centered cubic (fcc) metals, which is normally performed at temperatures of less than one-half the melting temperature (T_m), forge welding is typically conducted at temperatures in the 0.8 to 0.9 T_m range. The forge welding temperature is generally selected to be as high as possible with due consideration to avoiding such metallurgical problems as hot shortness, embrittlement, sensitization, and excessive grain coarsening. This implies an understanding of the unique metallurgical problems of the alloy to be welded.

Forge welding requires the application of pressure by means of either a hammer (hammer welding), rolls (roll welding), or dies (die welding). Joint configurations differ depending on whether the joints are to be produced manually or using automatic equipment. Typical joint designs used in manual forge welding operations are shown in Fig. 1. The joint surfaces in Fig. 1 are slightly rounded or crowned to ensure that the centerline region of the components joined will be welded first to force any contaminants (for example, slag, dirt, or oxide) present on the surfaces out of the joint. Typical joint configurations used for automatic forge welding operations are shown in Fig. 2 (Ref 1).

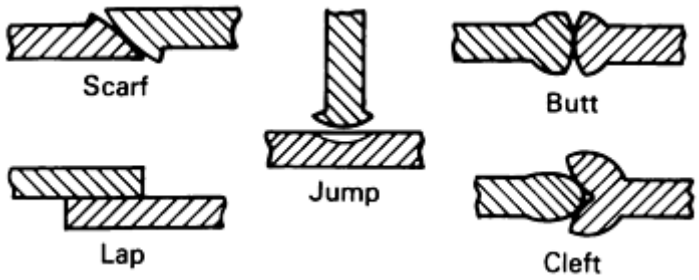

FIG. 1 TYPICAL JOINT CONFIGURATIONS USED FOR MANUAL FORGE WELDING APPLICATIONS. SOURCE: REF 1

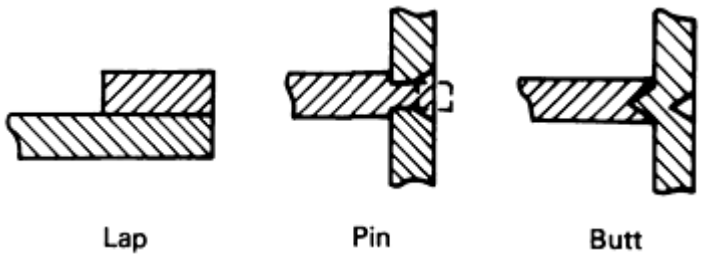

FIG. 2 RECOMMENDED JOINT CONFIGURATIONS USED IN AUTOMATIC FORGE WELDING APPLICATIONS. SOURCE: REF 1

Hydraulic presses are typically employed to apply pressure. Presses are often highly automated, featuring microprocessor control of pressure and temperature cycles. Heat is applied locally to the joint area by multiple-tip oxyacetylene torches, resistance heating, or induction heating. Often the oxyacetylene torches are oscillated to ensure uniformity of heating. In a closely related process, magnetically induced arc butt welding, the surfaces to be welded are heated by a rapidly rotating arc plasma. Generally, the process is conducted in the open air, with oxygen partially occluded from the joint area by the initial contact of the faying surfaces. When employing oxyacetylene torches, a slightly reducing flame affords some atmospheric protection. Vacuum, inert, and reducing atmospheres have been used.

The normal welding sequence is to (1) apply sufficient pressure to firmly seat the faying surfaces against one another, (2) heat the joint to welding temperature, and (3) rapidly apply additional pressure to upset the weld zone. Typical weld durations are 1 to 2 min. A less common procedure is to initially apply high pressure and permit deformation to occur during the heating cycle. Most forge welding employs sufficient pressure to upset the surface until the increase in the

surface area is 125% or more. However, such high deformation tend to cause flow lines to bend toward the surface during upsetting. Consequently, alloys that contain significant stringers and inclusions may exhibit poor impact or fatigue properties when welded with high amounts of upset. This effect may be minimized by reducing the upset, which normally requires increasing welding temperature and/or time to ensure complete elimination of voids and surface oxide.

Forge welding is most commonly applied to carbon and low-alloy steels, with typical welding temperatures of about 1125 °C (2060 °F). Low-carbon steels can be used in the as-welded condition, but medium-carbon steels and low-alloy steels normally are given full heat treatments following welding. In those cases where full heat treatment is impractical, but hardening due to rapid cooling has occurred, induction heating may be used to temper the weld zone. Other metals welded by forge welding include high-alloy steels, nickel-base alloys, cobalt-base alloys, aluminum alloys, titanium alloys, and tungsten. Applications of this process include welding rods, bars, tubes, rails, aircraft landing gear, chains, and cans. The forge welding process is competitive with flash welding (see the article "Flash Welding" in this Volume) and friction welding (see the article "Friction Welding" in this Volume).

Flux must be added when forge welding certain meals to prevent the formation of oxide scale. The flux and the oxides present combine to form a protective coating on the heated surfaces of the metal that prevents the formation of additional oxide and lowers the melting point of the existing oxide.

Silica sand and borax are two fluxes commonly used on steels. Silica sand can be used as a flux in the forge welding of low-carbon steel. The oxides of very low-carbon steels (ingot irons) and wrought irons do not require fluxes because their oxides have low melting points. Borax, sprinkled on the workpiece while it is in the process of being heated, is commonly used in the forge welding of high-carbon steels because of its low fusion point (Ref 1).

Weld durations for resistance welding are very short (seconds) compared to those for forge welding where gas torches are employed. This is because heat is generated internally in resistance welding, but externally with gas torches. Terms that are sometimes used synonymously with forge welding include pressure welding, upset welding, and solid-state resistance welding.

Cold Welding

Karl Thomas, Technische Universität Braunschweig; Manfred Petri, Gerhard Petri GmbH + Co. KG

Introduction

COLD WELDING (also known as cold pressure welding) in normal ambient conditions involves the destruction of the surface (that is, oxide) layers of the metallic materials in the weld area. This exposes areas of clean metal surface on the two components to be welded, which must be brought into contact with each other to generate the interatomic forces needed to form a weld. Examinations of butt-welded joints of aluminum using transmission electron microscopy (TEM) have shown that the common deformation of the material in the weld zone leads to the destruction of the surface (that is, oxide and contaminant). TEM showed these surface layers in the form of numerous minute particles in the joint. The largest of these particles had a diameter of 12 nm (120 Å).

The actual interface between two dissimilar materials is a phase boundary, the same as a grain boundary between similar materials. Thermally induced processes such as recrystallization or diffusion are not required for welding to take place (Ref 1, 2). This makes cold-formable materials with a brittle cover layer especially suitable for cold pressure welding. The technique is frequently used with nonferrous metals (primarily copper and aluminum) (Fig. 1).

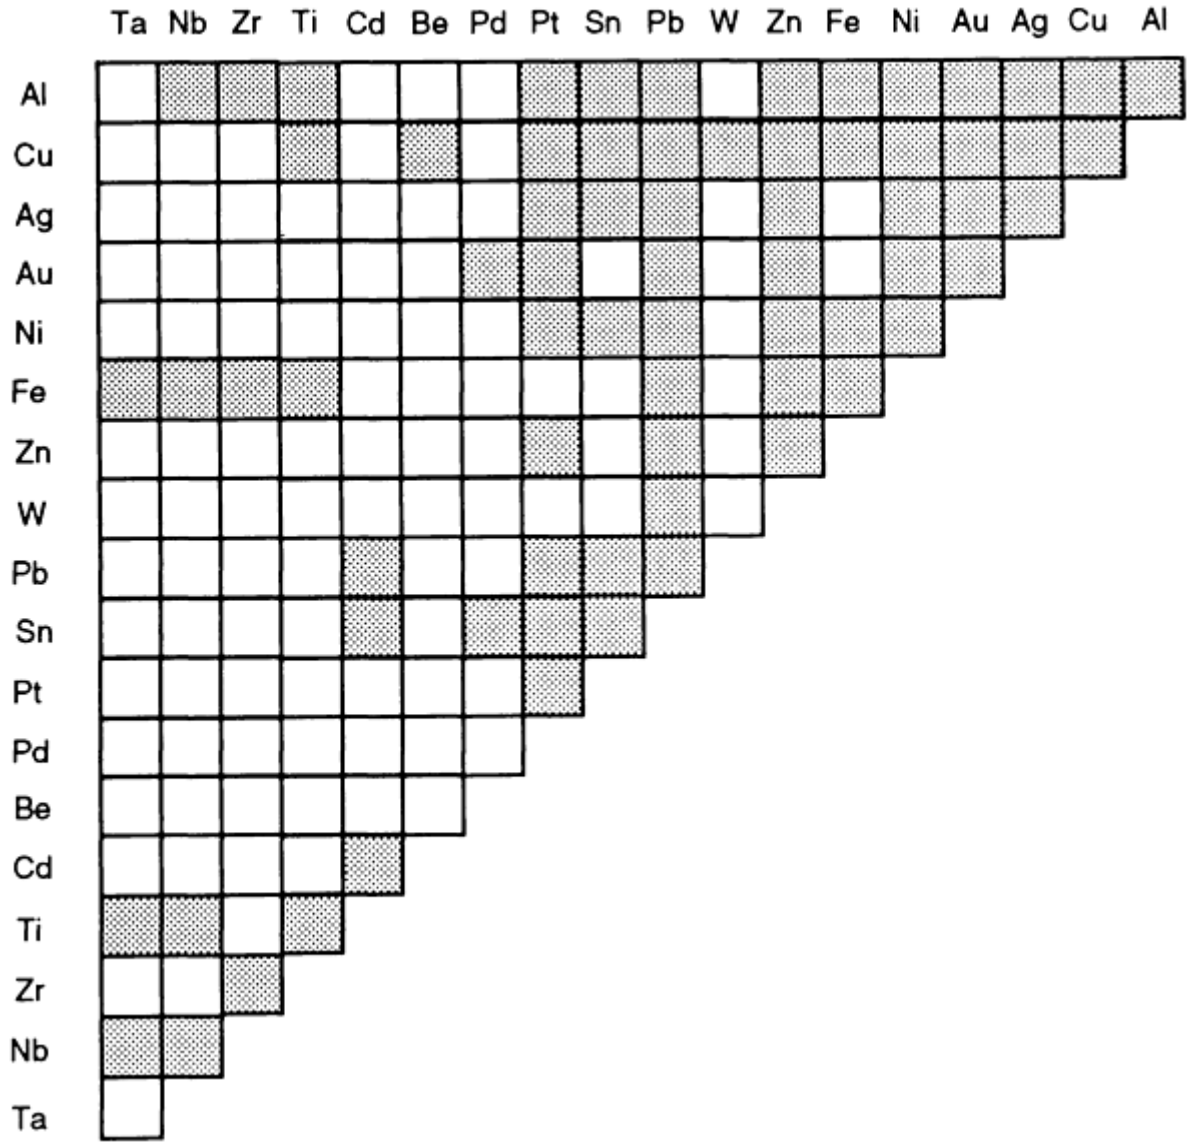

FIG. 1 CHART SHOWING COMBINATIONS OF METALS THAT CAN BE SUCCESSFULLY COLD WELDED (INDICATED BY SHADED BOX). SOURCE: ADAPTED FROM REF 3

In general, welds are examined by destructive techniques. As with other pressure welded joints, nondestructive testing methods fail to generate reliable results. It is expedient, therefore, to prepare the parts to be joined with great care and to control the parameters of the welding process as closely as the equipment tolerance specifications allow.

Cold Welding

Karl Thomas, Technische Universität Braunschweig; Manfred Petri, Gerhard Petri GmbH + Co. KG

Variations of Cold Pressure Welding

Because welding lends itself to numerous techniques of forming, there are many variants of the cold pressure welding process. Cold pressure welding can be accomplished by deforming in a lap or butt configuration, drawing, extrusion, and rolling. The following discussion deals with only the first three variants.

Cold Pressure Lap Welding. The geometry of the cold pressure lap welding method (Fig. 2) is similar to the geometry of resistance spot welding. Two sheets of metal are joined in such a way that the direction of material flow is perpendicular to the direction of pressure. After a material-dependent reduction of the sheet thickness, the joint is formed. A high-quality joint will not be formed unless all superfluous oil has been removed and the contact surfaces have been mechanically cleaned (for example, by scratch-brushing with a rotating steel brush). Cleaning should be performed immediately before welding. Depending on the material, sheet thicknesses between 0.1 to 15 mm (0.004 to $\frac{19}{32}$ in.) can be welded.

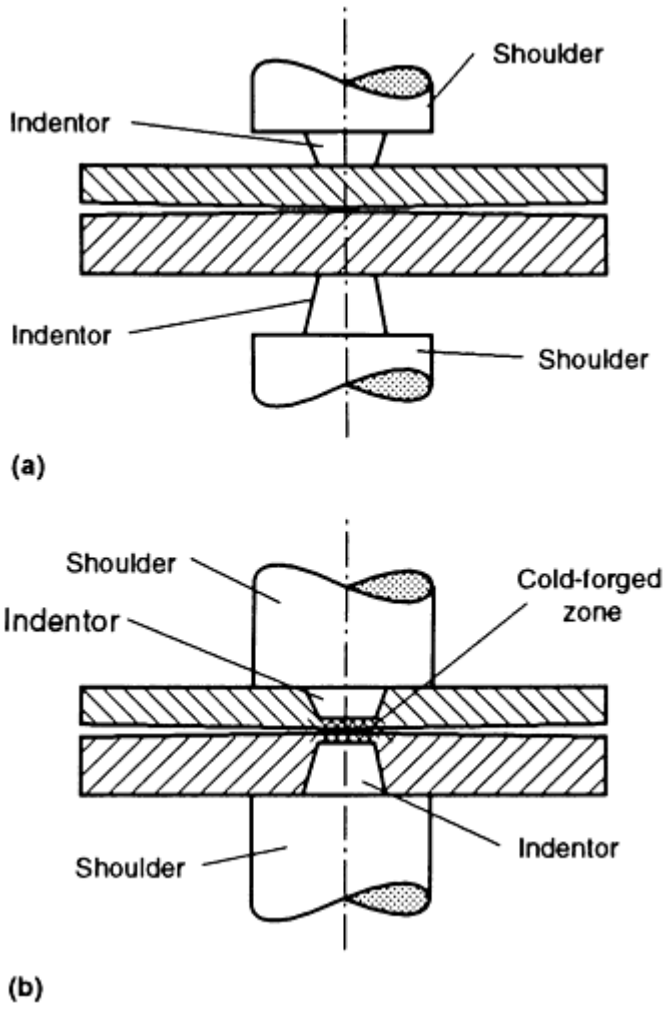

FIG. 2 SCHEMATIC SHOWING TWO DIES BEING USED FOR COLD PRESSURE LAP WELDING OF TWO METALLIC SHEETS. (A) DIE POSITION BEFORE WELDING. (B) DIE POSITION AFTER WELDING

The welds are produced by annular, point, or line-shaped pressure dies in mechanical or hydraulic presses or pneumatic clamps. The reduction in thickness produced by the dies must be limited by a solid stop or deformation measurement method. The bending distortion of the sheets is small when several spots or adjacent narrow areas are welded at the same time. Dies that generate a ring-shaped area of pressure produce welds superior to dies that generate a circular area of pressure. For line welds, dies with relatively long and narrow pressure areas should be used. The width of the pressure area and its distance to an adjacent pressure area will be greater with increasing thickness of the plate. For example, coils of aluminum and copper for electric machines were welded to each other and to connecting pieces. The joints consisted of two aluminum parts having cross-sections measuring 7 by 1.6 mm (0.3 by 0.063 in.) and welds between aluminum measuring 7 by 1.6 mm (0.3 by 0.063 in.) and copper measuring 7 by 1 mm (0.3 by 0.039 in.) cross section (Ref 4). It is possible to produce cold pressure lap welds with very large cross sections if the proper tooling and required pressure forces are available.

Cold pressure butt welding implies that the ends of two bars of similar or dissimilar metals are jointly upset. The two bars are placed in a device or machine having suitable clamping shoes (Fig. 3). The compressive force applied along the axis of the bars causes an expansion of the contact surfaces and forms a bulb. Both bar ends will weld together when the contact surfaces have reached a certain size, which depends on both the material and the condition of the contact surface. The strength of the joint increases as the contact surface expands until it reaches the strength of the softer of the two materials used. The strength of the softer material is thus enhanced by cold work hardening.

FIG. 3 COLD PRESSURE BUTT WELDING OF TWO BARS USING MULTIPLE-STEP UPSETTING METHOD

Cold pressure butt welding may require one or more steps of upsetting. The parameter characterizing the weld is the surface extension parameter, V_o:

$$Vo = \left(\frac{A_s}{A_o} \right) - 1 \qquad \textbf{(EQ 1)}$$

where A_s is the size of the contact surface after welding and A_o is the original surface area. The extension of the surface area can be particularly large when several steps of upsetting are used on materials that are easily cold-formed. When single-step upsetting and a rather simple upsetting device are used, the material ends that project from the clamping shoes may buckle. This limits the surface expansion that can be obtained.

When single-step upsetting is applied on machines made for this purpose and in multiple-step upsetting, buckling is not a consideration, because only very short rod ends will project from the clamping shoes. Because the clamping shoes with an initial loading are transposed in multiple-step upsetting, no cracks can form in the weld during transposition (Fig. 3). No gases from the ambient atmosphere can contact the exposed surface and, hence, no new oxides form.

Many devices have been developed for cold pressure butt welding. There are hand-held tongs for wires in diameters up to 1 mm (0.04 in.) and even an oil-hydraulically powered welding machine with a programmable device to interface with a multiple-step upsetting system. The largest known system applies upsetting forces as high as 1.2 MN (135 tonf), which permits the joining of aluminum up to 1500 mm^2 (2.3 $in.^2$) in cross-sectional area and of copper up to 1000 mm^2 (1.55 $in.^2$) in cross-sectional area (Ref 4). A system capable of butt welding of plastic-coated aluminum ribbons of 0.1 to 0.2 mm (0.004 to 0.008 in.) thickness and up to 50 mm (2 in.) wide has been constructed. This system can complete as many as 99 upsetting steps to produce a weld (Ref 5).

Figure 4 is a schematic of the mechanical part of a servohydraulic, computer-aided cold pressure welding machine. The base, which consists of a base plate and two vertical side plates, houses two horizontally arranged structural members. These structural members support two traverses, one of which can be moved by two hydraulic actuators that operate in unison. The second traverse is held by several binder plugs that have to be loosened only for changeover to a new welding job. Bolted to the traverse are two dies that support the blanks to be welded. The dies, in turn, are attached to two fixtures to which the piston rods of the hydraulic actuators are bolted. Each hydraulic actuator has a sensor to monitor the inductive force acting on the piston rod and to record the inductive displacement. Software is available to produce butt-welded joints by two methods. In cold pressure butt welding with continuous thrust, the piston rods of the 630 kN cylinders are displaced by the same amount. The 250 kN cylinders maintain their positions as set by the computer program. They determine the thickness of the upset. Three bladelike cutters are arranged on the spot faces on the dies. They produce notches in the forming flash that cause the flash to rupture under circumferential tension. While weld material is flowing, the flash is automatically sheared off. The surface extensions obtained are very large. Because of the high tool load, this method should be used only with materials of low tensile strength and moderate work-hardening properties.

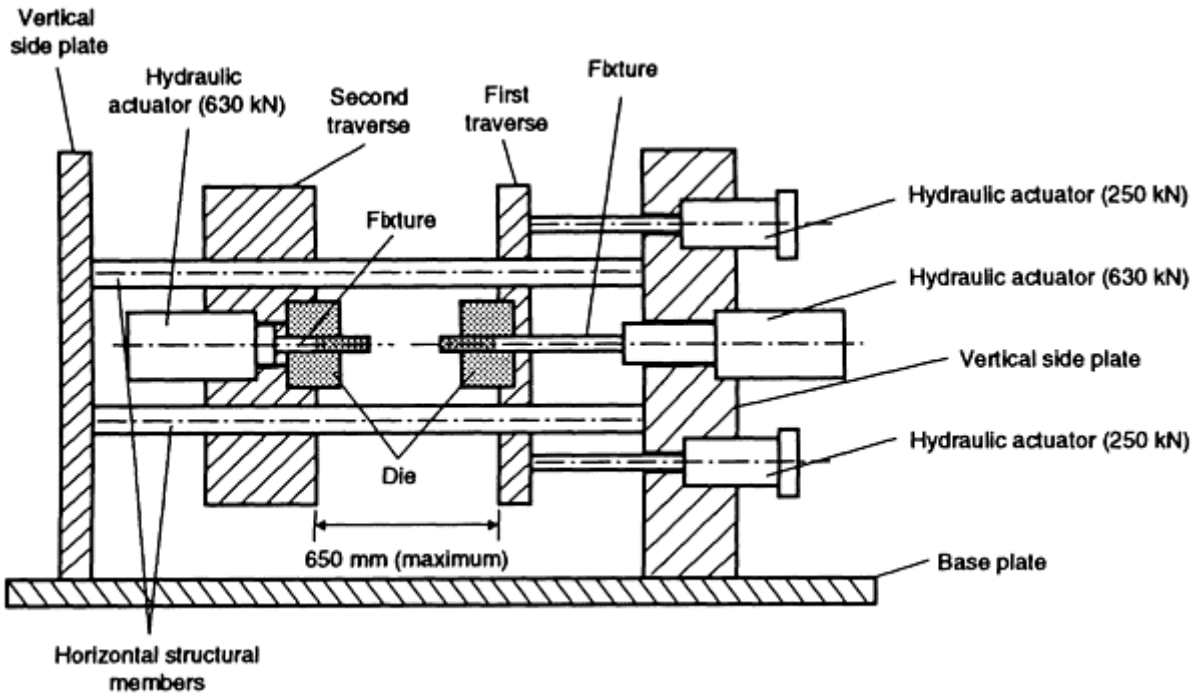

FIG. 4 SCHEMATIC SHOWING SERVOHYDRAULIC, COMPUTER-AIDED COLD PRESSURE WELDING MACHINE CONSISTING OF TWO 250 KN (28 TONF) ACTUATORS AND TWO 630 KN (71 TONF) ACTUATORS

In the second method, multiple-step upsetting, the computer controls a sequence of operations that corresponds to the schematic in Fig. 3. Large surface extensions are obtained with this method, but the tool load is lower than in the continuous thrust method. Figure 5 illustrates two copper-aluminum joints produced by the two methods in which the upset metal was not removed automatically (Ref 6).

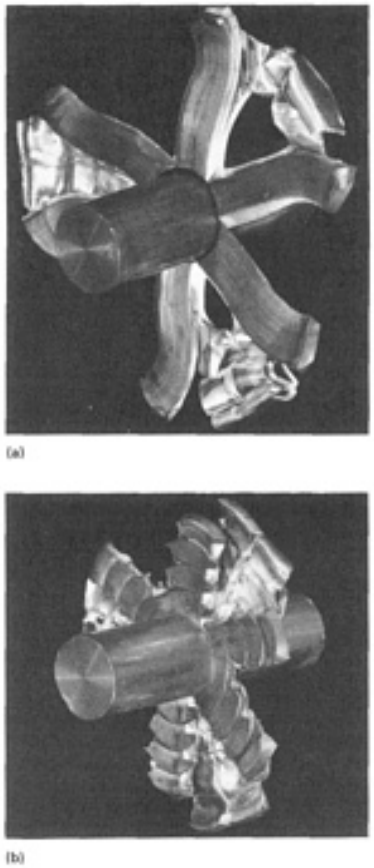

FIG. 5 COPPER-ALUMINUM JOINT OBTAINED BY BUTT WELDING OF TWO 20 MM ($\frac{25}{32}$ IN.) COMPONENTS USING TWO DIFFERENT TECHNIQUES. (A) CONTINUOUS THRUST METHOD. (B) MULTIPLE-STEP UPSETTING METHOD

An example of multiple-step upsetting is the production of interlocking connections of copper and aluminum components for installation in national power grids. The connecting pieces are welded by the single-step upsetting method from 12 to 45 mm ($\frac{15}{32}$ to $1\frac{3}{4}$ in.) diameter blanks. Before welding, the contact surfaces on the blanks are machined with a dry milling tool. The milling tool is periodically cleaned with a solvent. In a manual operation, the blanks are inserted in the upsetting die of a power press without touching the contact surfaces. They are welded together and ejected, and the flash is immediately removed by subsequent machining. Before the mechanical operation is finished, a connecting plate is attached to the copper side of the component by deformation and a hole with a cross-section formed by backward extrusion is made in the aluminum. By deforming the copper closely adjacent to the seam, the quality of the joint can be safely assessed because welds of insufficient strength would rupture along the seam (Ref 7).

Cold Pressure Welding in Drawing Processes. By common deformation in the drawing tool of a drawing bench, multilayer tubes or solid multilayer (clad) bars can be made that have numerous inside and outside layers that consist of different materials (Fig. 6). In this variant also, the contact surfaces must be thoroughly cleaned before welding. This need for cleanliness limits the initial tube length to 800 mm (32 in.). High-intensity compressive stresses exist between the commonly deformed contact surfaces during the drawing operation. The extension of the contact surfaces along the longitudinal axis of the bar is the essential characteristic of the weld. Shear strength values of about 50 MPa (7 ksi) have been reported for copper-aluminum joints after a surface extension of 300% (Ref 8).

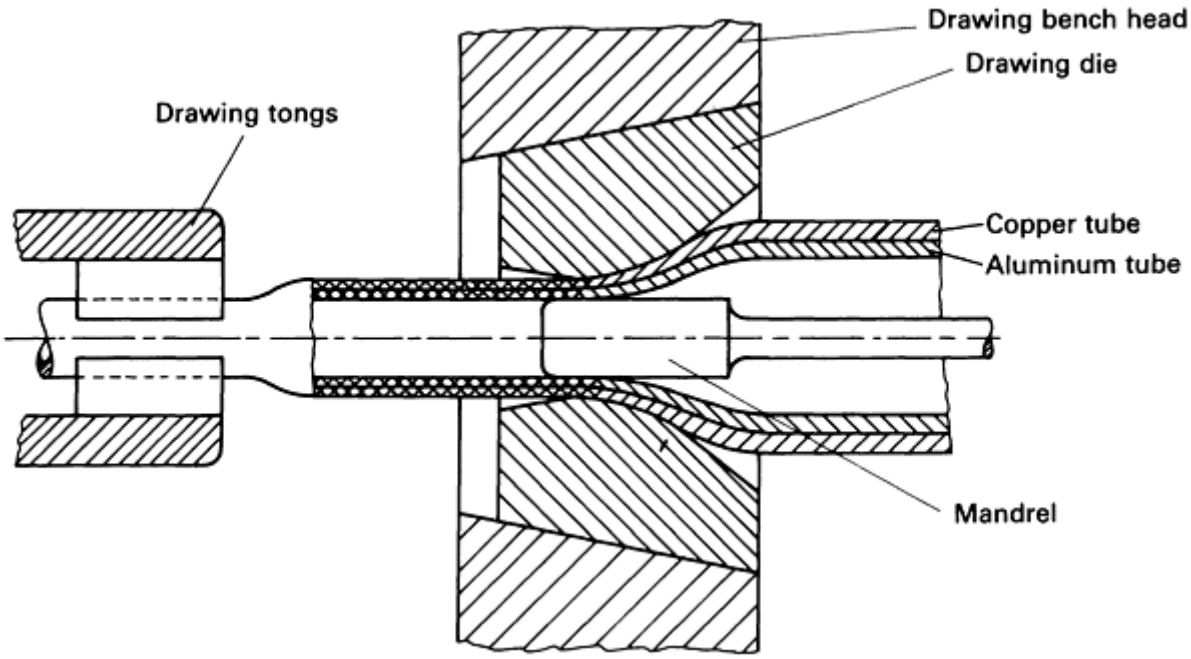

FIG. 6 APPLICATION OF DRAWING TO COLD PRESSURE WELD MULTILAYER TUBES INCORPORATING COPPER ON THE OUTSIDE DIAMETER AND ALUMINUM ON THE INSIDE DIAMETER

Coextrusion Welding

Introduction

COEXTRUSION WELDING (CEW) is a solid-state process that produces a weld by heating two or more workpieces to the welding temperature and forcing them through an extrusion die. The process typically is conducted at elevated temperatures not only to improve welding but also to lower extrusion pressures. Some cold coextrusion welding of aluminum and copper has been performed. For hot coextrusion, the parts to be welded are often assembled in a can or retort that is designed with the appropriate leading taper and wall thickness to promote initiation of extrusion. For reactive metals, such as zirconium, titanium, and tantalum, the retort may be evacuated and sealed. Both forward and back coextrusion have been employed, but forward coextrusion is the usual mode. A principal advantage of coextrusion welding is that the high isostatic pressures associated with the process are favorable to the deformation welding of low-ductility alloys.

In a similar process, extrusion welding has been used to butt weld tubes. The ends of the tubes are prepared for extrusion by beveling at a 45 to 60° angle to produce an overlapping joint (Fig. 1). The leading tube contains the female portion of the beveled joint and is the stronger of the two metals in dissimilar metal joints. Extrusion press die angles of 30 to 35° are common. An advantage of extrusion welding over other methods of deformation butt welding of tubes is that there is no flash or upset to remove following extrusion.

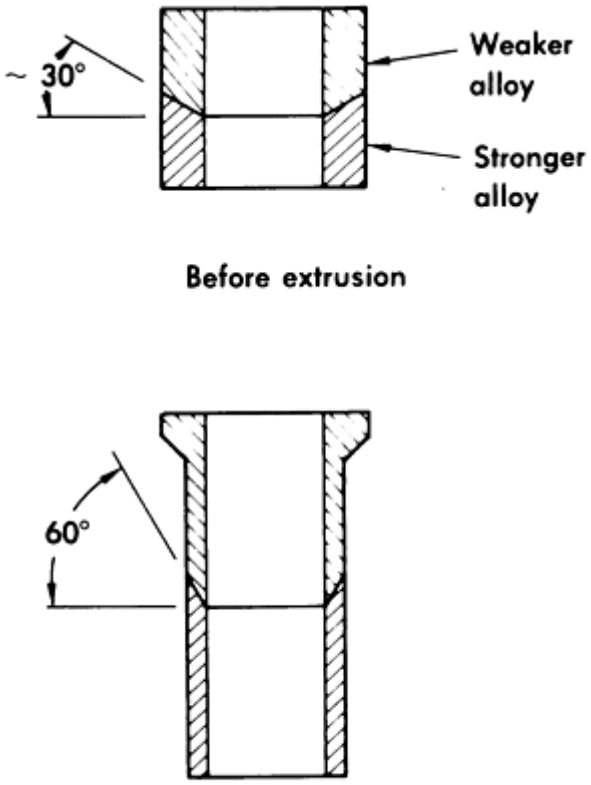

FIG. 1 DESIGN FOR BUTT WELDING OF TUBES BY EXTRUSION

Coextrusion Welding

Common Metals Welded

The most common metals welded by the coextrusion process include low-carbon steel, aluminum, aluminum alloys, copper, and copper alloys. Additional applicable materials include nickel, nickel-base alloys, zirconium, titanium, tantalum, and niobium.

Roll Welding

Introduction

ROLL WELDING (ROW) is a process in which two or more sheets or plates are stacked together and then passed through rolls until sufficient deformation has occurred to produce solid-state welds.

Roll Welding

Process Description

Two modes of roll welding are common. In the first, the parts to be welded are merely stacked and passed through the rolls. The second method, usually termed pack rolling, involves sealing the parts to be rolled in a pack or sheath and then roll welding the pack assembly.

The first method is more generally employed in the cold welding of ductile metals and alloys. Sometimes the stack to be welded is first tack welded at several locations to ensure alignment during rolling. Also, when using this method, the

deformation during the first rolling pass must exceed the threshold for welding (typically greater than 60% for cold rolling) to keep the parts together. The required first pass reduction can be reduced by hot rolling, if the metals to be rolled can tolerate preheating without excessive oxidation. Once the first pass has been accomplished, the reduction per pass can be decreased, as is often desirable because roll-separating forces increase as the parts to be rolled become thinner. However, the nonuniform stress distribution that builds up during a sequence of very light passes can cause the weld to open up or "alligator." Therefore, the reduction for subsequent passes is generally a compromise between applying excessive separating forces and "alligatoring."

In pack roll welding, the parts to be welded are completely enclosed in a pack that is sealed (typically by fusion welding) and often evacuated to provide a vacuum atmosphere. This may be accomplished by a frame that surrounds the parts to be welded, which is sandwiched by two lids, or may simply consist of two covers formed to encapsulate the parts to be welded (Fig. 1). Semikilled or killed low-carbon steel is a common material for the pack, but is not suitable for all alloy and temperature combinations. Although the preparation costs of pack roll welding are significant, the process has the advantages of (1) providing atmospheric protection, which may be particularly important for reactive alloys such as those of titanium, zirconium, niobium, and tantalum; and (2) permitting welding of complex assemblies involving several layers of parts. A significant limitation of the process is that packs become difficult to process when their length exceeds several feet.

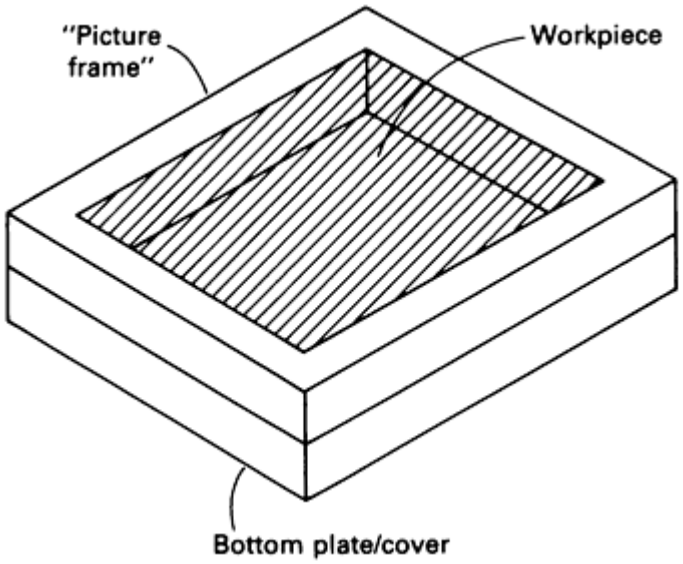

FIG. 1 PACK USED FOR ROLL WELDING. THE TOP COVER, WHICH WOULD BE WELDED IN PLACE BEFORE ROLLING, IS NOT SHOWN.

Titanium and titanium alloys are considerably more difficult to pack roll than are either steels or copper and aluminum alloys because most titanium alloys have very narrow working temperature ranges. To overcome this problem, titanium alloys that are pack rolled are sometimes encased in a steel envelope, or can. The can is evacuated to minimize oxidation of the work metal, and also serves to minimize heat loss to the relatively cold rolls upon deformation. The narrow working temperature range of titanium alloys makes the rolling of these materials labor intensive. Rolling passes are done by hand on relatively small pieces, and many intermediate reheating steps are required. Some β titanium alloys, however, are being continuously rolled on hot and cold strip mills.

Nonpack rolling, of course, can employ continuous strip rolling. A seldom used hybrid version of roll welding is to seal the edges of the parts to be welded by fusion welding prior to rolling. This method does not provide atmospheric protection to the outer surfaces, as in pack roll welding, but does occlude air from the more critical inner surfaces.

In roll welding, successful welding depends not only on the total amount of deformation but also on the pressure during rolling. A high isostatic pressure component during rolling is promoted by large reductions per pass, large roll diameters, and rough roll surfaces. A nonuniform distribution of normal stresses, referred to as pressure hill effects, is caused by frictional and mechanical restraint and results in lower pressure near the outer edges of the parts being rolled. Therefore, rolling conditions must be such to ensure sufficient pressure near the edges to avoid weak welds in these regions.

Copper, aluminum, and their alloys are often cold roll welded. Hot rolling is applicable to a wide spectrum of alloys. Typically, hot rolling is performed above recrystallization temperatures. In practice, weldability is often improved by raising the temperature to the region where oxygen mobility becomes significant to promote oxide assimilation by diffusion. Also, welded assemblies are often postheat treated to cause recrystallization (in cold rolling), oxygen diffusion, and/or sintering. In welding dissimilar metals, selection of temperatures for rolling and postheating must take into consideration the possibility of intermetallic compound formation, eutectic melting, and/or porosity due to Kirkendall diffusion. The most common metals that are roll welded are low-carbon steels, aluminum and aluminum alloys, copper and copper alloys, and nickel. Low-alloy steels, high-alloy steels, nickel-base alloys, and titanium and titanium alloys have also been roll welded.

Applications

One of the more important applications of roll welding is the fabrication of heat exchangers. A patented roll welding process is described in the section "Roll Welding Heat Exchangers" in this article. This process is used to fabricate flat solar collectors. In another method of heat-exchanger fabrication, three plates are stacked, with the middle plate containing the flow channels. The stacked plates are initially held together by tack fusion welds or resistance spot welds. This approach has been employed for both aluminum and steel heat exchangers. A second important application of this process is in the cladding of sheet metal products.

Roll Welded Heat Exchangers. A principal application of roll welding is the production of heat-exchanger panels with flow tubes as an integral part of the composite. Millions of refrigerator evaporator plates have been formed by this process. A cross section of a similar application, solar collector panels, is illustrated in Fig. 2. Roll welded heat-exchanger panels are most often made of aluminum, although copper and stainless steel panels have also been produced commercially.

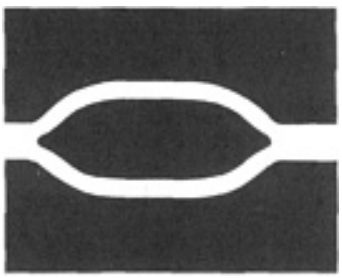

FIG. 2 CROSS SECTION OF AN ALUMINUM SOLAR COLLECTOR PANEL PRODUCED BY THE ROLL WELDING PROCESS

The first major step in the production of roll welded heat exchangers is to thoroughly clean the surfaces of the sheets to be joined by combinations of solvent cleaning, chemical cleaning, and wire brushing. Next, a stop-weld pattern is reproduced on one of the sheets that will later form the passageways in the heat exchanger. This is accomplished by transferring ink onto the surface by silkscreen processing. These stop-off inks contain materials such as graphite or titanium oxide.

The prepared plates are placed together and temporarily joined by spot welding to form a sandwich that is then roll welded, with at least partial welding occurring during the first rolling pass. The sandwich sometimes is heated prior to this first rolling pass. Whether hot rolling or cold rolling is employed, the major reduction takes place in this first pass (50 to 80%). Subsequently, cold rolling may be employed to reduce the panel to final gage. Also, panels are generally given a postweld heat treatment. This heat treatment results in an annealed part and, particularly in the case of cold rolled panels, may improve the weld quality through recrystallization and diffusion. Finally, the passageways are formed by inflating them with air pressure while the sandwich is held between platens. The panel is then ready for trimming, additional forming, and painting, as required for the application.

The process has been used to produce heat exchangers for refrigerators, solar panels, poultry incubators, electronic equipment temperature controllers, industrial heat exchangers, and special applications such as thermal control of spacecraft. Modifications of the process permit as many as six sheets to be welded at one time and inclusion of passageways oriented along different principal directions at the different layers. Also, it is possible to produce panels where the passageways are expanded on one side only.

Cladding of Metals by Strip Roll Welding. The common early application of strip roll welding was the fabrication of bimetallic strips for thermostats. This remains an important application, with thermostats taking many complex forms and finding use in furnaces, color televisions, cars, and numerous industrial controls.

A key cladding application is the production of coins by the U.S. Mint. Silver shortages in the 1960s and 1970s resulted in the introduction of coins made from new materials. These coins required a unique set of properties for acceptance by the general public and use in automatic vending machines. Copper clad with cupro-nickel was found to meet these requirements (Fig. 3). The cladding process is relatively simple, although stringent in its requirement for surface preparation. Cladded strips are produced by continuous rolling with the surfaces prepared just prior to rolling by processes such as wire brushing. Welding typically is accomplished in a single rolling pass. Subsequent heat treatments may be employed to improve the weld quality by processes such as sintering, diffusion, and recrystallization.

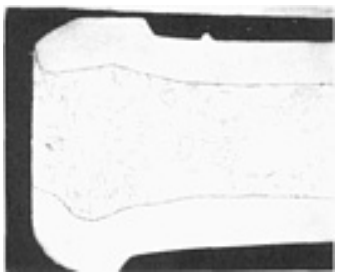

FIG. 3 METALLOGRAPHIC CROSS SECTION OF THE EDGE OF A CUPRONICKEL-CLAD COPPER COIN

The starting material for the U.S. quarter is two outer layers of 75Cu-25Ni, each 1.2 mm (0.048 in.) thick, with an inner layer of pure copper that is 5.1 mm (0.20 in.) thick. To obtain good bond strength, the surfaces are chemically cleaned and wire brushed. The strips are then roll welded to a combined thickness of 2.29 mm (0.090 in.) (Fig. 4). A second rolling operation reduces the final thickness 1.36 mm (0.0535 in.). The strips thus undergo a total reduction of 82% (Ref 1).

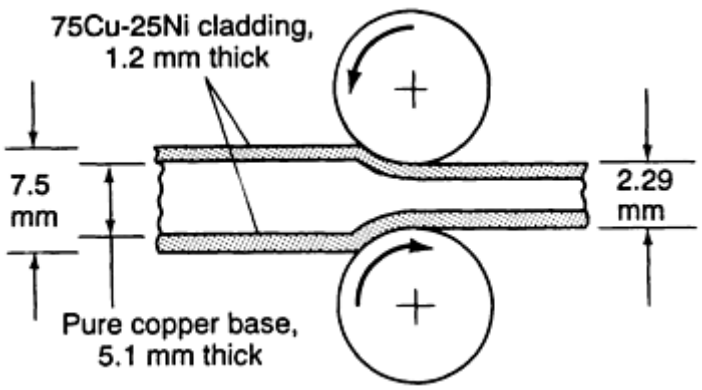

FIG. 4 SCHEMATIC SHOWING 70% REDUCTION IN CROSS SECTION OF A U.S. MINT QUARTER COIN (COMPOSED OF AN INSIDE LAYER OF PURE COPPER SANDWICHED BETWEEN TWO THIN LAYERS OF CUPRONICKEL MATERIAL) AS IT UNDERGOES AN INITIAL ROLL WELDING OPERATION. A SECOND ROLLING OPERATION FURTHER REDUCES THE MATERIAL TO A FINAL THICKNESS OF 1.36 MM (0.0535 IN.) FOR A TOTAL REDUCTION OF 82%. SOURCE: REF 1

Similar processing is applied to many new products, including electrical contacts, conductive springs, automotive windshield wiper sockets, automotive trim, clad cookware, wrap for underground cable, and electromagnetic shielding (Table 1).

Essentially all combinations of ductile metals and alloys can be clad by roll welding, although the oxides of some metals may make welding difficult and other combinations may suffer from intermetallic compound formation on heating. Most engineering metals and alloys can be processed into clad-laminate form, but some cannot (Table 2). One characteristic that makes some metals difficult or impossible to combine by deformation is low ductility. Such metals cannot be co-reduced to the extent necessary to achieve a metallurgical bond. Another characteristic that can cause problems is the tendency of some metals to form a tenacious oxide film that inhibits weld formation. Finally, some metals are thermally unstable; they form brittle intermetallic compounds when heated above a certain temperature. Those metals that are readily processed into clad laminates have opposite characteristics. They are ductile and easily cleaned of oxides, and they form no intermetallic compounds. In most cases, when a metal is named, alloys of that metal also apply.

Friction Welding

Schillings Tsang, EG&G Rocky Flats

Introduction

FRICTION WELDING (FRW), in its simplest form, involves two axially aligned parts. While one part is rotated, the other stationary part is advanced to make pressure contact. Axial force then increases to generate the frictional heat necessary for welding at the abutting surfaces in order to form a solid-state joint. Friction welding can be divided into two major process variations, depending on the manner by which rotational energy is converted into frictional heat. The first process, direct-drive, or continuous-drive, FRW, has been used commercially since the 1940s. It requires constant energy from a source for any desired duration. The second process, inertia-drive FRW, which was developed in the early 1960s, uses the kinetic energy stored in a rotating flywheel.

Friction Welding

Schillings Tsang, EG&G Rocky Flats

Direct-Drive Friction Welding

Figure 1 shows the layout of a direct-drive FRW system. The spindle is first driven to a predetermined constant speed, and the two parts are brought together under a preset axial force. Both rotation and force are maintained for a specific period determined either by a time or a distance, so that the frictional heat will raise temperatures at the abutting surfaces enough to render the material plastic and suitable for welding. (However, direct-drive friction welds are almost never made using a single level of axial load. The vast majority of welds are made using a minimum of two axial force levels. The second axial load is basically added to the beginning of the weld cycle to yield a preheating phase. In fact, direct-drive friction welds using three axial loads are more commonly applied than those using a single load.) The spindle is then disengaged from the driving unit, and a brake is applied to bring the spindle to rest. At the same time, axial force either remains unchanged or is raised to complete the weld.

Schillings Tsang, EG&G Rocky Flats

Inertia-Drive Friction Welding

In inertia-drive FRW (Fig. 2), a flywheel and the rotating part are mounted in a spindle, which is driven to the desired speed. The drive source is then disengaged, and the two parts make contact under a preset axial force. The free-rotating flywheel decelerates under either the same applied force or later under a larger force. Meanwhile, kinetic energy stored in the flywheel and spindle is converted to frictional heat at the abutting surfaces. The weld is complete when the flywheel comes to a stop. A subsequent higher forging force may be used after the flywheel has stopped.

Welding Parameters

Direct-Drive FRW Variables. Three parameters control the character of a weld in direct-drive FRW: rotational speed, duration of rotation, and axial force. During welding, there is not only an axial shortening of the part length, often called axial displacement or upset, but also a resisting torque of friction to rotation, which also undergoes change. Figure 3 shows the change in various events occurring throughout the whole process. Based on the shape of the friction torque curve, it is convenient to divide direct-drive FRW into three phases:

- *PHASE 1:* INITIAL FRICTION (THAT IS, BREAK-IN OR FIRST FRICTION) PHASE
- *PHASE 2:* HEATING (THAT IS, FRICTION) PHASE
- *PHASE 3:* FORGING (THAT IS, UPSETTING) PHASE

In phase 1, the torque rises rapidly after the start of the process. It then peaks and drops before leveling off when phase 1 ends. The rapid rise and gradual fall of torque is associated with the interlocking and breaking of asperities and subsequent softening of the material at the faying surfaces by frictional heating.

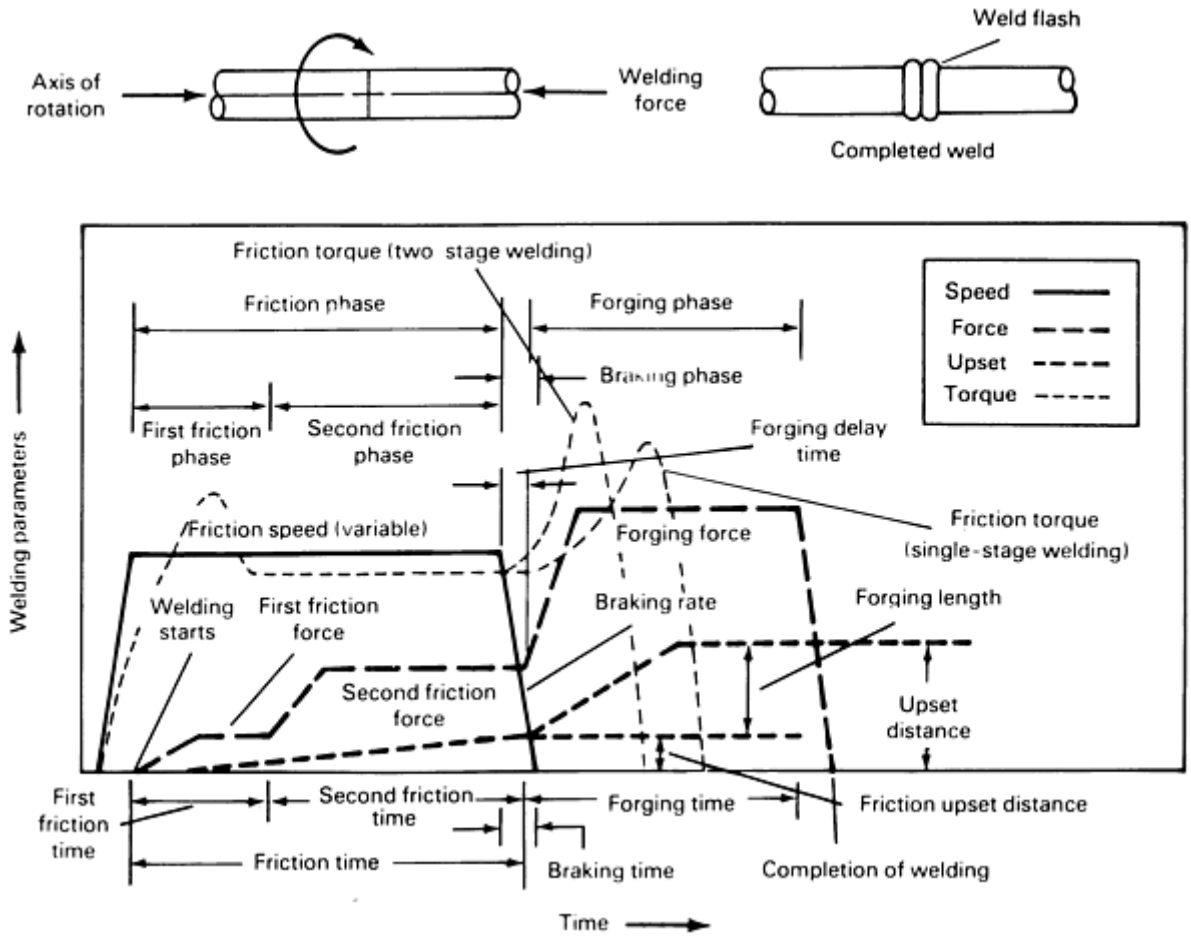

FIG. 3 PLOT OF WELDING PARAMETERS VERSUS TIME FOR A DIRECT-DRIVE FRW SYSTEM. COURTESY OF D.L.

Friction torque remains somewhat constant in phase 2, indicating that the process reaches a balance of effects between strain hardening and thermal softening. Both the faying surfaces and material immediately behind are by then sufficiently heated to permit the two parts to be forged together.

Forging takes place in phase 3, which starts at the time of declutching and braking. Spindle rotation is immediately retarded, and the deceleration depends on braking time. Because the brake force itself can be set, braking time can also be a variable. Deceleration varies in the welding of different materials. However, the torque may not rise at all but drops abruptly at the onset of phase 3 if braking is sudden. This brings the rotating spindle to rest almost instantly, and the larger force is applied after spindle rotation stops. In this case, there is no torsional forge, and forging is brought about by upsetting.

Axial force in phase 3 is usually increased to effect forging. The friction torque again rises after the onset of this phase, reaching another peak before sharply falling off to zero. This peak varies with deceleration and applied axial force. Under some circumstances, this final peak can be omitted by delaying the onset of the forging force.

This is done only at or after the stoppage of spindle rotation by braking. In this case, forging is carried out by upsetting without torsional forging. Although two-stage welding is applied more frequently in direct-drive friction welding, one-stage welding is sometimes used, especially in research work (Ref 2).

When the axial force remains unchanged, slower deceleration (longer braking time by reduced braking) leads to higher peak. If the axial force is increased in phase 3, braking time is shortened, but the peak still rises because of the larger applied force. Rising friction torque in phase 3, characteristic of FRW, contributes to torsional forge, which is more effective than conventional forge by upsetting. Phase 3 ends shortly after spindle rotation stops. This period of forging or upsetting time can also be considered a fourth welding parameter.

Inertia-Drive FRW Variables. There are three welding parameters in inertia-drive FRW: flywheel mass (expressed by moment of inertia), rotational speed, and axial force. The events described for direct-drive FRW also occur in inertia-drive FRW. Except for rotational speed, the curves shown in Fig. 4 are similar to those shown in Fig. 3. The process can also be divided into three phases based on the shape of the friction-torque curve. Unlike direct-drive FRW, duration of rotation and forging time in phase 3 are not predetermined but controlled by the three welding parameters.

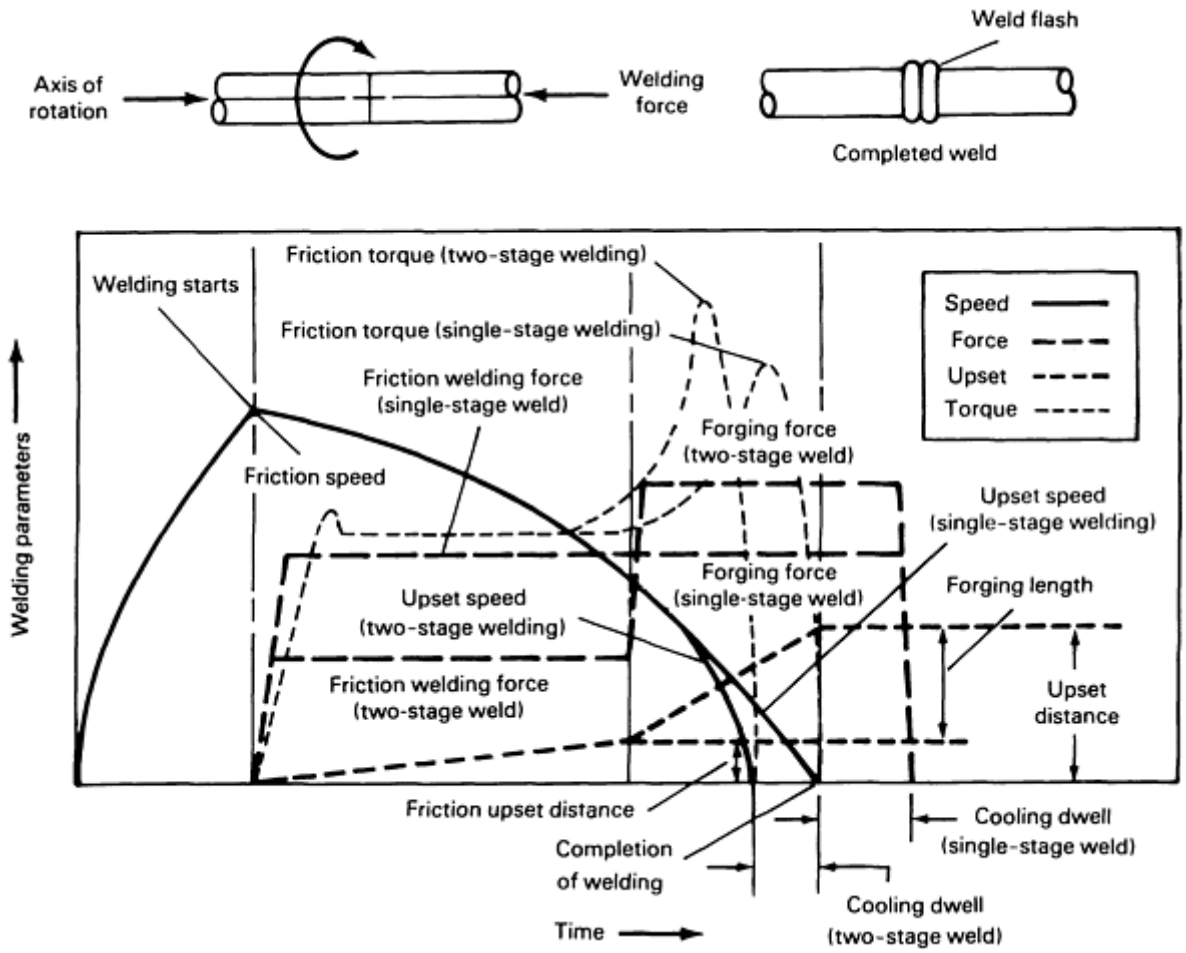

FIG. 4 PLOT OF WELDING PARAMETERS VERSUS TIME FOR AN INERTIA-DRIVE FRW SYSTEM. COURTESY OF D.L. KURUZAR, MANUFACTURING TECHNOLOGY, INC.

If axial force differs in phases 2 and 3, the process is called two-stage welding, and the forces, called heating force and forging force, respectively, are both included as a welding parameter of axial force. On the other hand, when the force remains constant throughout the process, it is called one-stage welding. The second friction-torque peak in two-stage welding is generally higher than that in one-stage welding because of the larger axial force applied in phase 3. As stated in the section "Direct-Drive FRW Variables" in this article, the peak in one-stage welding depends on braking time: It rises with longer braking time.

In two-stage welding, the larger axial forging force is applied when the flywheel rotational speed decreases to a fraction of the initial value--for example, 0.1 to 0.5. Friction torque again rises to a second peak, which as in direct-drive FRW, is higher than in one-stage welding. This phase is prolonged beyond cessation of the flywheel rotation. This extra time, called dwell time, is used for cooling of the joint to avoid debonding by the release of stored strain energy. Although dwell times can range from 0 to 30 s, 1 to 2 s is typical.

The kinetic energy used for inertia-drive FRW depends on the product of the flywheel moment of inertia and the square of rotational speed. The frictional heat generated at the faying surfaces, however, is determined by the rate of change of this energy (or the energy delivery rate), which is influenced by the moment of inertia of the flywheel and the axial force. For a given kinetic energy input and a given axial force, a smaller flywheel (with smaller moment of inertia) delivers the energy at the faying surfaces faster than a larger flywheel (with larger moment of inertia). For a given energy input using the same flywheel, a larger axial force increases flywheel deceleration rates, intensifies heat generation, and raises temperatures at the faying surfaces. A rapid energy input and a high rate of heat generation, typical of inertia-drive FRW, result in very short weld cycles. There is little time for heat to dissipate in the axial direction, so the heat-affected zone (HAZ) remains narrow.

Direct-Drive Versus Inertia-Drive FRW. Lower rotational speed and smaller axial force are generally used in direct-drive FRW. Direct-drive FRW also offers greater latitude in process variables, because heating time in phases 1 and 2 is preset as duration of rotation or upset distance, which is a welding parameter, and because forging phase can be controlled by braking time, axial force, and forging time. Nevertheless, both processes do produce welds of equal quality when proper welding parameters are implemented. Torsional forging is required when forging by upsetting with inertia-drive friction welding; it is not required when forging by upsetting with direct-drive friction welding. A comparison of the two processes is presented in Table 1.

TABLE 1 PROCESS PARAMETERS OF DIRECT-DRIVE FRW SYSTEMS RELATIVE TO INERTIA-DRIVE FRW SYSTEMS

It is assumed that similar or dissimilar metals of the same size are being joined.

PROCESS PARAMETER	**DIRECT-DRIVE FRW**	INERTIA-DRIVE FRW
WELDING PARAMETERS	ROTATIONAL SPEED	**FLYWHEEL MOMENT OF INERTIA**
	DURATION OF ROTATION OR FRICTION BURNOFF DISTANCE	**ROTATIONAL SPEED**
	AXIAL FORCE	**AXIAL FORCE**
CONVERSION OF ENERGY TO FRICTIONAL HEAT	CONSTANT ENERGY IN A PRESET DURATION OF ROTATION	**FIXED ENERGY IN FLYWHEEL; DURATION OF ROTATION DETERMINED BY WELDING PARAMETERS**
ENERGY INPUT	LOW	**HIGH**
HEAT GENERATION RATE	LOW	**HIGH**
CYCLE TIME	SIMILAR	**SIMILAR**
HAZ WIDTH	WIDE	**NARROW**
MACHINE SYSTEM SPINDLE RIGIDITY	**LESS RIGIDITY**	**GREATER RIGIDITY AND MORE POWERFUL CLAMPING FORCES REQUIRED**

Weld Quality and Product Evaluation

At present, there is no satisfactory nondestructive method for detecting a friction weld of poor strength. (X-rays are used to identify defects that can cause welds of poor quality.) Weld quality control and product evaluation must rely on the control of the process and the machine that is used to produce the welds.

In direct-drive FRW, both rotational speed and axial force affect axial shortening or upset in addition to the mechanical properties of the weld produced. There can be a correlation between the upset and the quality of the weld. Further, upset in phase 2 increases almost linearly with time. The upset of this phase, often called friction burn off, and its rate, the friction burn off rate, have been believed to control weld quality. Indeed, some researchers use burn off instead of duration of rotation as a welding parameter. In inertia-drive FRW, because duration of rotation is not preset but controlled by the three welding parameters, the total upset, instead of friction burn off, is supposed to indicate weld quality. This presumes that the same amount of kineticenergy and axial force will produce the same amount of upset at the end of the process (given the same materials and cross sections).

The welding parameters of either direct-drive or inertia-drive FRW are set using a particular machine. So once this machine is properly calibrated, the process becomes almost entirely machine-dependent. Regardless of the process used to evaluate the product of friction welding under a given set of parameters, once variations in machine components and

dimensional tolerances for a particular weld are determined, an acceptable tolerance band of the total upset can be established as a standard. A monitor will compare the upset of each weld relative to this reference. The machine will automatically stop to indicate a defective weld when its upset falls outside the proven band of the standard.

Advantages and Limitations

Advantages of FRW. Friction welding has a number of advantages over other joining processes (such as fusion welding, brazing, and diffusion bonding):

- SPECIAL ATTENTION TO SURFACE CLEANLINESS IS NOT NECESSARY, BECAUSE FRW TENDS TO DISRUPT, DISPLACE, AND FINALLY REMOVE SURFACE FILMS IN WELD FLASH (THIS DOES NOT APPLY TO HEAVY MILL OR HEAT-TREAT SCALES, WHICH CAN INTERFERE WITH FRICTIONAL HEATING).
- FILLER METAL, FLUX, AND SHIELDING GAS ARE NOT REQUIRED. UNLIKE FUSION WELDING, FRICTION WELDING IS NOT HAZARDOUS TO OPERATOR HEALTH AND IS SAFER, BECAUSE THERE IS NO METAL SPATTER, RADIATION, FUME, OR ELECTRIC HAZARD INVOLVING HIGH VOLTAGE, ARCS, AND SPARKS.
- DEFECTS ASSOCIATED WITH MELTING-SOLIDIFICATION PHENOMENA ARE NOT PRESENT IN FRW, BECAUSE IT IS A SOLID-STATE PROCESS.
- IT IS POSSIBLE TO MAKE TRANSITION JOINTS OF DISSIMILAR METALS THAT ARE DIFFICULT OR EVEN IMPOSSIBLE TO WELD BY OTHER PROCESSES (FOR EXAMPLE, REFRACTORY AND EXOTIC METALS).
- LOWER LABOR COSTS, SIMPLE PART DESIGN, SIMPLER WELD FIXTURES, LOWER ENERGY REQUIREMENTS, AND A SHORT WELD CYCLE (A MATTER OF SECONDS) MAKE THE PROCESS COST EFFECTIVE FOR PRODUCING COMPONENTS NORMALLY MADE BY OTHER PROCESSES.

Limitations of FRW include the following:

- THE WELDING AREA OF AT LEAST ONE PART MUST BE ROTATIONALLY SYMMETRICAL, SO THAT THE PART CAN ROTATE ABOUT THE AXIS OF THE WELDING PLANE. TYPICAL PART GEOMETRIES THAT CAN BE FRICTION WELDED ARE: BAR TO BAR, BAR TO TUBE, BAR TO PLATE, TUBE TO TUBE, AND TUBE TO PLATE.
- THIS PROCESS IS NORMALLY LIMITED TO MAKING FLAT AND ANGULAR (OR CONICAL) BUTT JOINTS.
- THE MATERIAL OF AT LEAST ONE COMPONENT MUST BE PLASTICALLY DEFORMABLE UNDER THE GIVEN WELDING CONDITIONS. FOR EXAMPLE, ALUMINA CAN BE JOINED TO ALUMINUM, BUT ALUMINA CANNOT BE JOINED TO ALUMINA. ANOTHER EXAMPLE IS THE JOINING OF POLYMERS (THAT IS, PLASTICS). THERMOPLASTICS, UNLIKE THERMOSETTING PLASTICS, CAN BE FRICTION WELDED BECAUSE THERMOPLASTICS ARE SOFTENED BY FRICTIONAL HEAT BUT THERMOSETTING PLASTICS DECOMPOSE.

Process Applications

The applications of FRW fall into two categories:

- *BATCH AND JOBBING WORK:* USED WHEN A RELATIVELY LOW VOLUME OF PARTS IS REQUIRED, ESPECIALLY WHEN EXPENSIVE DIES MUST BE USED BUT CANNOT BE JUSTIFIED
- *MASS PRODUCTION:* APPLICATIONS THAT SPAN A WIDE RANGE OF INDUSTRIES (AGRICULTURAL, AIRCRAFT ENGINE, AUTOMOTIVE, EARTHMOVING, ELECTRICAL, PETROLEUM, AND SO ON) PRODUCING COMPONENTS RANGING FROM SIMPLE BUTT JOINTS OF DRIVE SHAFTS AND OIL DRILLING PIPES TO COMPLICATED OR CRITICAL AIRCRAFT ENGINE COMPONENTS

Radial Friction Welding

E.D. Nicholas, The Welding Institute

Introduction

THE CONVENTIONAL FRICTION-WELDING PROCEDURE of rotating one component against another while an axial thrust is being applied is well known. Autogenous welds in the solid state are made in one operation. The procedure is an accepted production joining method because it provides excellent weld quality and good productivity, it allows the use of unskilled labor, and it enables a wide range of similar and dissimilar metal combinations to be joined. However, continuous-drive and stored-energy (inertia) friction-welding systems have not been as successfully exploited for the joining of long, hollow sections, where restrictions in the bore cannot be tolerated.

The difficulties involved in rotating an intermediate length of hollow section, and in applying uniform and consistent welding forces to both weld interfaces, represent some of the problems that face the machine designer. Furthermore, because two internal upset metal collars are formed, additional machining of the bore is necessary in order to avoid restriction. In 1975, a new approach, called radial friction welding (Ref 1), attempted to provide a means for overcoming these limitations.

Method. The radial friction-welding process adopts the principle of rotating and compressing a solid ring around two stationary pipe ends (Fig. 1a). The pipes to be welded are bevelled to provide a "V" groove when they are butted together. They are then securely clamped to prevent axial and rotational movement. A solid, internally bevelled ring of compatible material with a bevelled angle that is less than that of the pipes is positioned around the pipe ends.

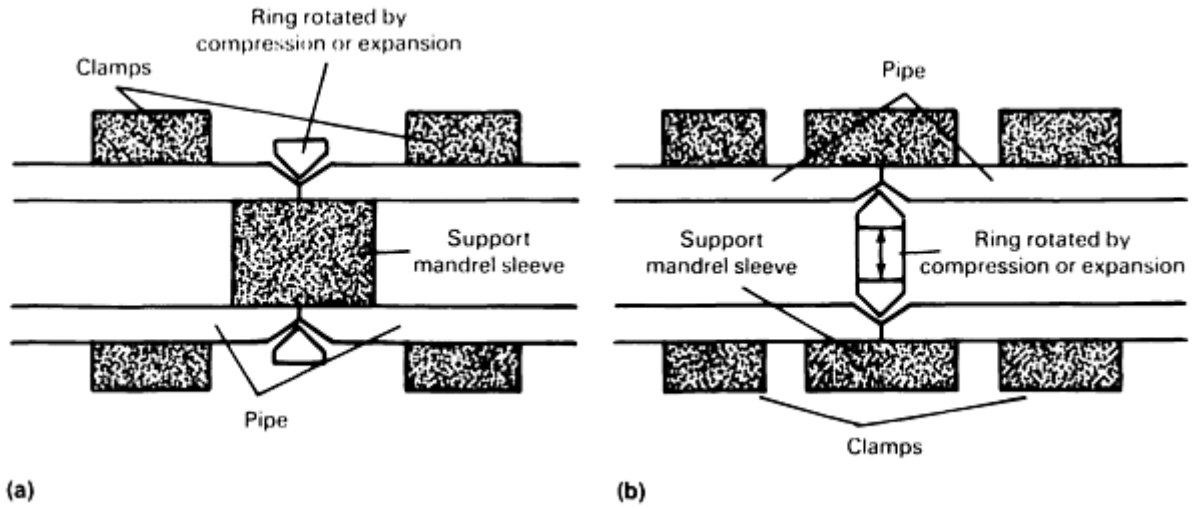

FIG. 1 RADIAL FRICTION WELDING. (A) USING COMPRESSION. (B) USING EXPANSION

The "V" groove for the 108 mm ($4\frac{1}{4}$ in.) outside diameter by 9.5 mm ($\frac{3}{8}$ in.) wall thickness pipe is typically 100°, while the internal bevel of the ring is 80°. It is important for the latter angle to be less than that of the groove in order to limit the initial peak torque and also to promote metal flow from the bottom of the groove in an outward direction toward the outside diameter. Optimum angles for selected sizes of tubes and pipes are determined experimentally.

A support mandrel is located in the bore at the weld position, in order to prevent both the flow of metal into the bore and the collapse of the pipe ends. The ring is then rotated and subjected to radial compressive loading in order to obtain the frictional interaction between the rubbing surfaces, which, in turn, will generate the thermomechanical conditions necessary for weld formation. After a predetermined heating duration, the ring rotation is terminated. The level of compressive load is then either maintained or increased to consolidate the bond. Alternatively, it is also feasible to change the direction of deformation (Fig. 1b). Thus, by providing an expansion load to the ring, the ring can be deformed radially outwards to make the weld.

The included, or bevelled, angle of the solid-compression ring (Fig. 1a) or the expansion ring (Fig. 1b) can have a pronounced effect on weld integrity. The joining of the abutted area is effected and promoted by metal flow from the bore to the outer surface of the pipe. There can be little or no penetration at the pipe root. If the included angle is too narrow, the result will be a weak bond area at the weld root, leading to poor weld strength and a short fatigue life.

Process Development. It was first necessary to prove that the concept of both rotating and compressing/expanding solid rings was feasible. Consequently, conventional friction-welding machines that could provide both rotary motion and axial force were used in the initial development trials. Various bolt-on units were designed, built, and then fitted to these machines.

The results of these initial experiments are summarized in Fig. 2. Although the units were relatively simple, the concept was able to produce sound, solid-state welds with a variety of material combinations. One important outcome of this development effort was that nickel-base alloys were identified as being necessary for the internal mandrel, because they provided good resistance to radial compression loads and wear at the elevated temperatures that were attained during welding. Additional information is available in the section "Prototype/Production Machine" in this article.

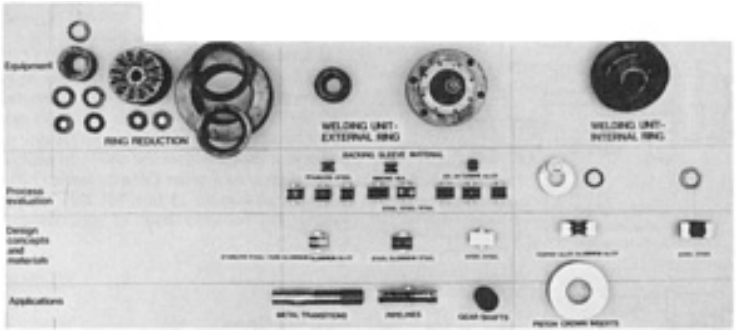

FIG. 2 PROCESS EVOLUTION OF RADIAL FRICTION WELDING

Radial Friction Welding

E.D. Nicholas, The Welding Institute

Equipment

When a prototype radial friction welder was built in the mid-1970s, the primary emphasis was directed toward the application of pipe joining. From the early experimental trials, it was recognized that the shortcomings of using this process in production would be:

- THE NEED FOR AXIAL MOVEMENT OF THE RING THROUGH A TAPER HOUSING
- THE ADDITIONAL MACHINING OF DRIVE GROOVES IN THE RING
- THE RELATIVELY COMPLEX RING GEOMETRY, WHICH WOULD INCLUDE A TAPER SURFACE ON ITS PERIPHERY

Consequently, the idea of using circumferentially located individual jaws (similar to multijaw collet chucks) to provide radial compression and rotation of simple rings was considered. An evaluation program using the arrangement (Ref 2) proved to be successful and, thus, provided the impetus to design and construct a prototype machine based on the multijaw rotation/compression arrangement.

Research Machine. A unique friction-welding facility was developed in order to join pipe of maximum dimensions, that is, 51 mm (2 in.) in outside diameter (OD), by 6 mm (0.24 in.) in wall thickness. The resulting machine is shown in Fig. 3 and its major features are described below.

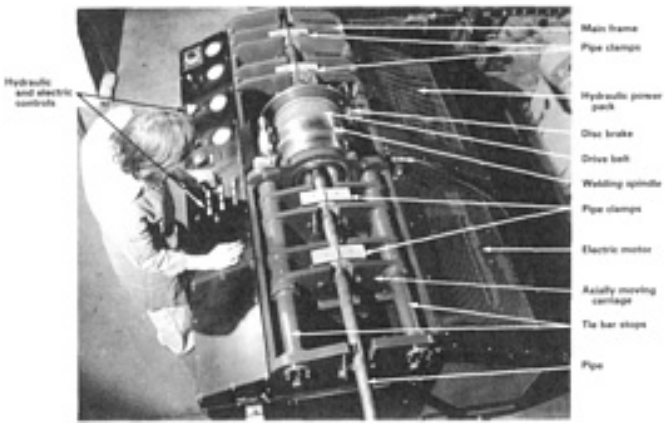

FIG. 3 RADIAL FRICTION-WELDING MACHINE WITH A 51 MM (2 IN.) DIAMETER

Welding Spindle. It was imperative that the ring rotation/compression unit, or welding spindle, be capable of exerting a grip on the ring that was adequate for the transmission of welding power during rotation and of delivering a radial compressive force to reduce the ring into the weld groove. The welding spindle was supposed to incorporate a multijaw arrangement. The heavy steel body of the welding spindle, which needed to contain the radial compressive forces, was supported at each end by simple bearings, and was rotated through a "V"-drive pulley on its outside surface. The spindle was fixed in the machine frame using two simple yoke clamps. A hydraulic caliper disk brake unit was incorporated, when necessary, to assist ring deceleration.

An electric motor rated at 56 kW (75 hp) provided rotation to the welding spindle via a clutch and transmission. The latter enables the setting of rotation speeds ranging from 700 to 2000 rev/min, after a suitable selection of pulley ratios. The clutch and final belt drive were located in line with the welding spindle. The inside of the welding spindle housed an annular piston, which moved in an axial direction, when actuated by hydraulic means, to operate the 12 ring compression jaws via wedges. A maximum axial load of 350 kN (7.8×10^4 lbf) could be generated when oil was supplied to the piston through a rotary oil distributor, at a pressure of 3.4 MPa (0.5 ksi).

The welding spindle had a 340 mm (13.4 in.) OD and was 595 mm (23.4 in.) in length. Consequently, the pipe that passed through it had to be supported close to the weld area by a manually operated collet assembly at the center of the welding spindle.

Pipe Clamping. In order to react to both the axial and torsional forces generated on the pipes, four clamps (two for each pipe) were housed in the top bed of the machine (Fig. 3). The clamps opened and closed by the vertical movement of hydraulic rams that forced wedges between the pivoted jaws. These rams are capable of exerting a maximum thrust of 200 kN (4.5×10^4 lbf).

The machine framework was manufactured as two main assemblies. The machine bed was a heavy-section box-type fabrication that housed the welding spindle and pipe clamps. In contrast, the support framework was of a lighter construction in order to accommodate the motor drive, transmission, and other auxiliary equipment.

Hydraulic Services. The hydraulic circuit had a conventional layout, in that all services were supplied from a dual pump. A gear pump that operated at a pressure of 13.8 MPa (2 ksi) supplied the clutch, bore support mandrel, and moving carriage, whereas a high-volume vane pump that was set to provide a maximum pressure of 3.4 MPa (0.5 ksi) fed only the welding head through a flow-control valve, in order to operate the axially moving annular piston. The latter pump was used to developed the radial compressive forces on the ring. The flow-control valve could be set to provide different rates of piston movement and, thus, varying radial displacement rates to the ring.

Electrical Services. The electrical circuit utilized standard machine controls with relays and timers to sequence the operation of the initial ring preload pressure, the weld heating cycle, the disk brake, the application of forge force, the compression jaws, the mandrel, and the retraction of the moving carriage.

Internal Support Mandrel. The ideal arrangement for a support mandrel should include materials that possess good wear resistance at elevated temperatures and the capability to expand and contract from the pipe bore. The ability of the mandrel to expand proved to be useful to both round and size the pipe ends prior to welding. However, problems were anticipated during the development effort because of the limited working area available for the 50 mm (2 in.) OD pipe (that is, the 38 mm, or 1.5 in., bore), and because of the requirement to eliminate longitudinal gaps in the mandrel.

An expanding mandrel that closed 1 mm (0.039 in.) below the minimum bore diameter was devised. It was operated by a hydraulic cylinder through a draw bar. The mandrel consisted of six segments machined from a nickel-base superalloy (Nimocast PK24). Earlier trials had proved the suitability of this material. Three of the segments were used as wedges, and all segments were operated by the tapered cone on the draw bar, with the wedge segments being removed by the extraction cone first, upon release of the mandrel.

The operating sequence to produce a weld was determined to consist of the steps described below. First, both pipes and ring were machined to provide the necessary weld groove and bevel, respectively. Then, the 16 mm (0.630 in.) wide ring was located in the reduction jaws and held under a light preload pressure.

Next, one pipe was positioned in the welding spindle and clamped, while the collet-steadying device was locked. (The collet-steadying device is of tubular construction and located around that portion of the pipe positioned inside the radial compression. When activated, it provides additional support to the pipe.) Then, the second pipe was fitted with the bore support mandrel, loaded into the machine, and clamped so that it butted against the other pipe.

After setting the rotation speed, as well as the friction welding force timing device that controlled heating duration and the flow-control valve that provided a fixed rate of piston movement (compression rate), the weld sequence was initiated. Upon completion of the weld cycle, the reduction jaws were retracted and the mandrel was sequenced to be extracted after 5 s. To remove the welded pipe, the collet-steadying device was released, along with both pairs of clamps.

Subsequent trials with this research machine demonstrated that the radial friction-welding process could produce welds of acceptable mechanical and metallurgical properties (Ref 3), and that the process could operate in the field, either on land or offshore.

Prototype/Production Machine. During the 1980s, a Norwegian company continued with the development of the process. Its efforts culminated in the design, manufacture, and subsequent commissioning of a prototype/production machine that could weld pipes ranging in size from 89 to 170 mm (3.5 to 6.625 in.) (Ref 4). This machine, which was constructed by another firm based in Oslo Norway, was designed on a twin tie-bar arrangement, upon which the welding head and pipe clamps were mounted (Fig. 4). The welding head, which consists of the drive spindle for rotating the ring, is driven by a 370 kW (500 hp) direct-current motor. The pipe clamps operate hydraulically, as does the ring compression. Additional pipe support and alignment are provided by collets located near and inside the welding head. Although it is not yet fitted as such, the machine has space for a machining station to allow the removal of excess ring/flash metal soon after welding.

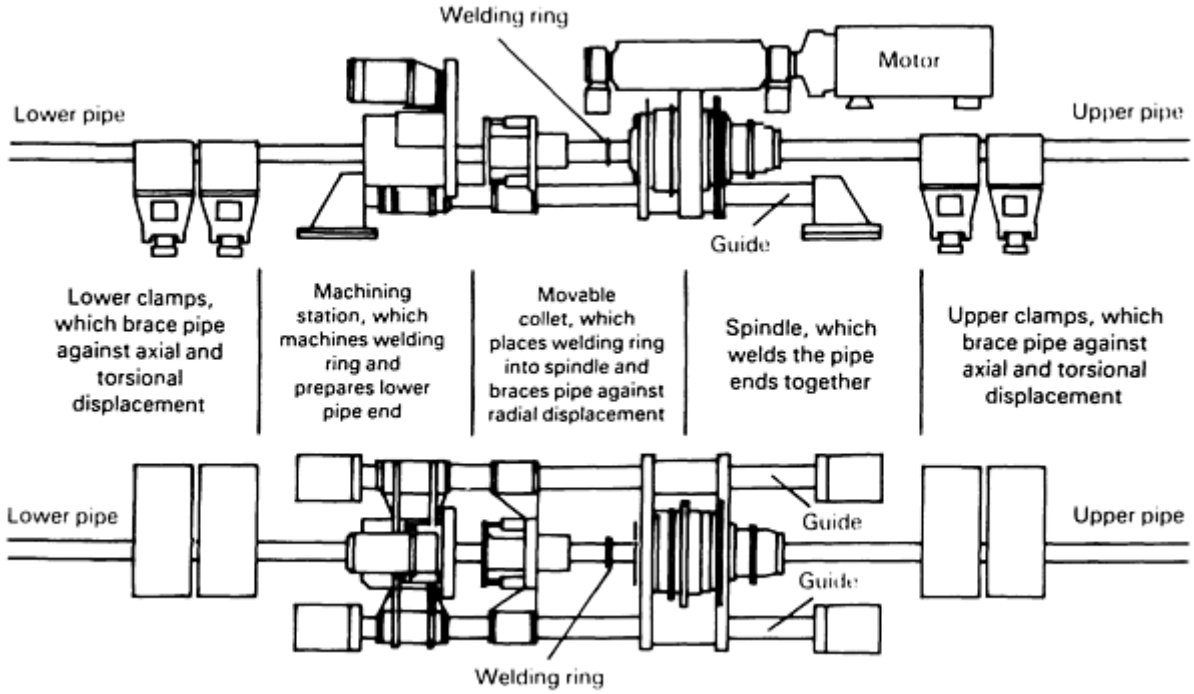

FIG. 4 SCHEMATIC OF THE PROTOTYPE RADIAL FRICTION-WELDING MACHINE

In a parallel effort to the development of this machine, special compression rigs for radial friction welding were manufactured to interface with 1000 to 1800 kN (110 to 200 tonf) axial thrust friction welders. These units provide experimental facilities with the ability to evaluate the process over a wider OD size range (100 to 273 mm, or 4 to 10.75 in.), not only for pipe joining, but for other areas of application, as well.

Radial Friction Welding

E.D. Nicholas, The Welding Institute

Applications

The applications that would be suitable for radial friction welding are:

- ATTACHMENT OF COLLARS TO SHAFTS
- WELDING OF ROTATING DRIVING BANDS TO ARTILLERY SHELLS
- ATTACHMENT OF WEAR/SUPPORT RINGS ONTO CYLINDRICAL BODIES
- PIPE JOINING AT BOTH LAND AND OFFSHORE SITES
- FABRICATION OF SHAFTS OR PIPEWORK SYSTEMS WITH CORRECT ALIGNMENT OF

PARTS

- REPAIR OF PIPELINES, BOTH ABOVE WATER AND UNDERWATER
- MANUFACTURE OF BIMETAL TRANSITIONS USING A COMPATIBLE INTERMEDIATE MATERIAL
- INSERTION OF NONMAGNETIC CENTER PIECES
- INSERTION OF BETTER HEAT- OR WEAR-RESISTANT MATERIALS INTO DIESEL PISTON COMBUSTION BOWLS

Friction Surfacing

E.D. Nicholas, The Welding Institute

Introduction

FRICTION WELDING, a solid-state (non-melting) joining process, relies on the presence of relative motion between the parts while they are being pressed together under an applied axial force to generate the thermomechanical conditions for welding. The process, in its simplest form, makes use of rotary motion. A modification of conventional friction welding makes it possible to deposit layers of metal onto a substrate, a metal-transfer method that is called "friction surfacing."

Although surfacing by friction can be regarded as novel, the original concept was reported, and a patent application filed, in 1941 (Ref 1). The technology was dormant until the late 1950s, when the process was rediscovered by Russian workers (Ref 2). A review of the literature has identified a wide variety of applications that utilized the process at that time:

- SHAFT RECLAMATION (REF 3)
- HARDFACING OF AGRICULTURAL PARTS (REF 4)
- RECONDITIONING BUSHINGS OF SLIDING FRICTION BEARINGS AND ROLL TRUNNIONS (REF 5, 6, 7, 8, 9)
- HARDFACING (REF 10) AND IMPROVING WEAR RESISTANCE IN GAS AND OIL EQUIPMENT (REF 11)

Friction Surfacing

E.D. Nicholas, The Welding Institute

Process

In the friction-surfacing process, a rotating consumable is brought into contact with a moving substrate, which results in a deposited layer on the substrate (Fig. 1). First, the consumable rod is rotated to the desired speed. Next, it is brought into contact, under an axial force, with the stationary substrate. An initial rubbing period is required to allow the generation of a plasticized layer in the consumable. Several seconds are required before this condition is achieved. Then, the substrate is traversed across the consumable, leaving a layer of deposited material. The deposit is characterized by a fine hot-worked microstructure, zero dilution, and a very strong bond with the substrate.

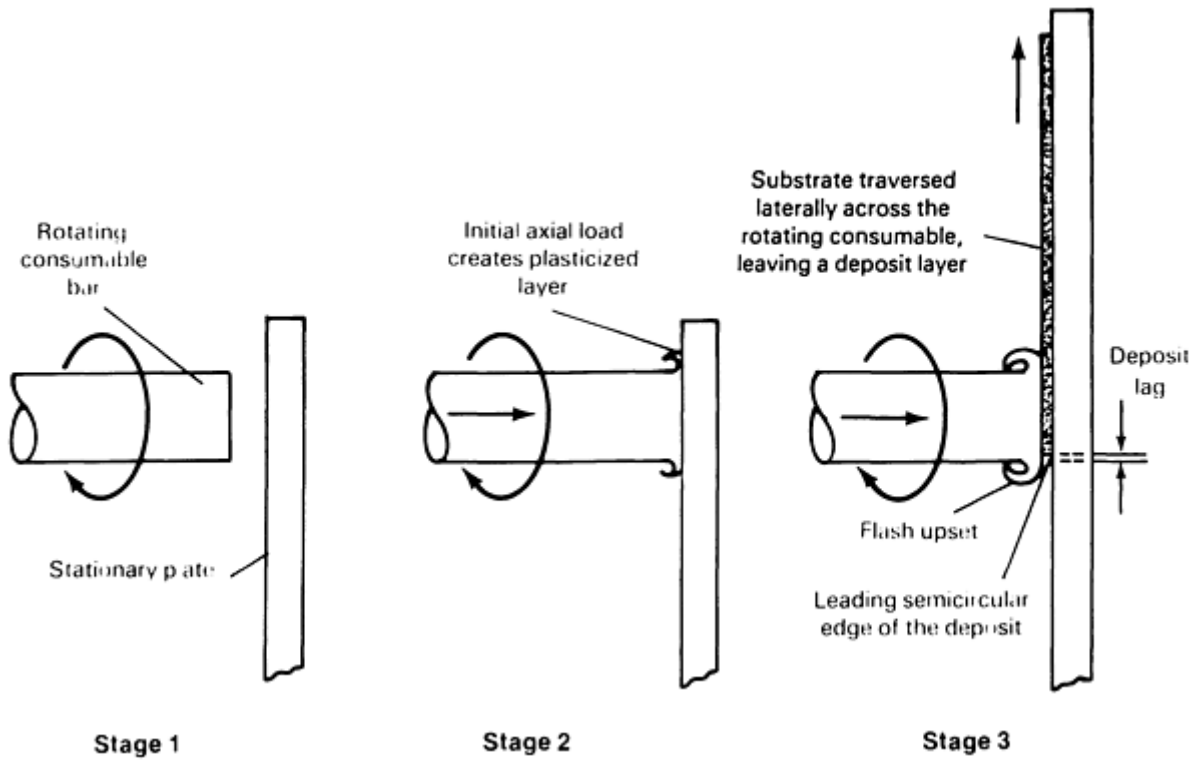

FIG. 1 BASIC TECHNIQUE FOR FRICTION SURFACING

The process utilizes equipment that is similar to a machine tool, for which the surfacing conditions are preset. Therefore, the process can provide good reproducibility, and is not dependent on operator skill.

The width and thickness of the deposited layer is influenced by the primary surfacing variables of rotational speed, axial force, substrate traverse rate, consumable diameter, and type of material. Generally, the fully bonded width of the deposit is approximately 1 to 3 mm (0.04 to 0.12 in.) less than the diameter of the consumable, with the extreme angles of the deposit being characterized by lack of bond. It is thought that this lack of bond is associated with nonuniform pressure distribution across the consumable; lack of restraint to the highly plasticized flowing material; and the reduced time in action seen at the outer edges as compared to the center of the consumable.

The deposit thickness in a single pass is considerably influenced by the type of consumable material. Materials that have good resistance to plastic deformation at elevated temperatures, such as the nickel-base alloys and the Stellite alloys, will only yield thicknesses of the order of 0.5 to 1 mm (0.02 to 0.04 in.). When austenitic stainless steel and carbon steels are used, the thickness increases to approximately 3 mm (0.12 in.). For materials with low strength at elevated temperature, such as aluminum and its alloys, thicknesses can approach 5 to 6 mm (0.20 to 0.24 in.).

Representative variables associated with friction surfacing conditions are shown in Table 1. A typical deposit of austenitic stainless steel from a 25 mm (1 in.) diameter rod that has been laid down on mild steel by the friction surfacing process is shown in Fig. 2(a). The layer is characterized by a uniformly rippled surface of consistent width and thickness. A transverse section reveals lack of bond at the edges and sound bond formation between the deposit and substrate, above the narrow, crescent-shaped, heat-affected zone (HAZ) in the latter (Fig. 2b). Figure 2(c) shows the microstructural features at the bond interface. It is important to remember that a uniform and smooth mushroom-shaped upset is continuously formed on the consumable rod during the surfacing operation.

TABLE 1 FRICTION-SURFACING PARAMETERS FOR SELECTED MATERIAL COMBINATIONS

COMBINATION	CONSUMABLE DIAMETER		ROTATION SPEED, REV/MIN	APPLIED FORCE		TRAVERSE RATE	
	mm	in.		kn	10^3 lbf	mm/s	in./s
AUSTENITIC STAINLESS STEEL TO MILD STEEL	25	1.0	550	50	11.3	5	0.20
STELLITE 6 TO AUSTENITIC STAINLESS STEEL	20	0.8	330	50	11.3	2.5	0.10
AL-4CU TO AL-4CU	25	1.0	780	17	3.8	4	0.16

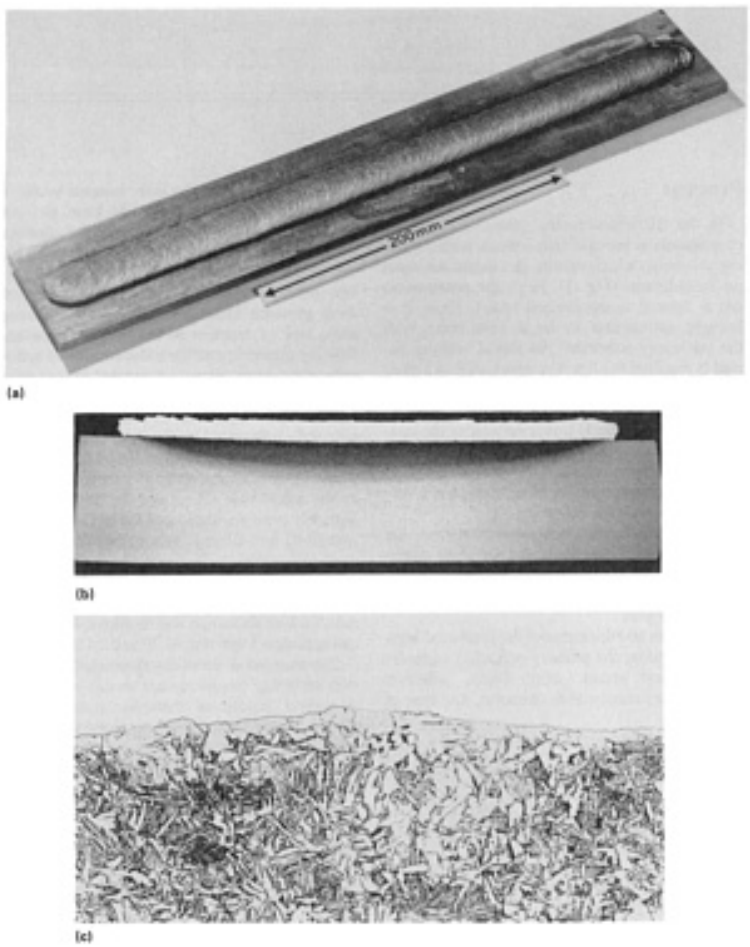

FIG. 2 THREE VIEWS OF 500 MM (20 IN.) FRICTION-SURFACED DEPOSIT OF AUSTENITIC STAINLESS STEEL ON MILD STEEL. (A) VIEW SHOWING ENTIRE SECTION. (B) TRANSVERSE SECTION OF DEPOSIT. (C) MICROSTRUCTURE AT THE DEPOSIT SUBSTRATE WELD INTERFACE. 550×

If it is necessary to clad larger surface areas, then multiple side-by-side layers can be laid down. If thicker deposits are needed, then layers one on top of another can be used. If both approaches are called for, then interpass machining may be required to ensure sound adhesion properties.

Friction Surfacing

E.D. Nicholas, The Welding Institute

Equipment

The earliest feasibility studies were conducted on a modified, continuous-drive, friction-welding machine (Ref 12). However, further practical investigations necessitated an increased surfacing capacity. Therefore, a milling machine (Ref 13) designed for the heaviest class of milling was used for longer deposition runs and larger-diameter components.

Ample power for the steady rotation of 64 spindle speeds between 12 and 540 rev/min is provided by the two-speed reversing motor, which develops 22 kW at 1430 rev/min and 15 kW at 960 rev/min. The robust machine frame minimizes deflection during friction surfacing, and the table, which moves longitudinally and transversely, also is designed to withstand large loads. The table is driven by a 2.2 kW variable-speed motor for 1575 mm (65 in.) of longitudinal travel and 724 mm (30 in.) of transverse travel at a lateral rate between 0.5 and 17 mm/s (0.02 and 0.68 in./s).

A rotary manipulator is used for circumferential deposition onto curved surfaces that are up to 480 mm (20 in.) in diameter. This manipulator is designed to handle the desired radial compressive loads while providing the required peripheral velocity. Similarly, by using a 610 mm (24 in.) diameter rotary table, annular deposits can be applied to the contact face of disks and flanges. Modifications have included fitting a direct-current variable-speed 2.2 kW motor to allow the feed rate of the consumable bar to be varied independently of the table traverse. Changes include a control system that allows consumable feed rates to be changed during the process, in these ways:

- TOUCH DOWN (SLOW FEED RATE, WITH NO LATERAL MOVEMENT)
- RAMP-UP (GRADUAL INCREASE IN THE FEED RATE TO THE SET VALUE)
- CONSTANT FEED RATE DURING LATERAL MOVEMENT
- PAUSE (IN LATERAL MOVEMENT) AT END OF RUN
- WITHDRAWAL OF THE CONSUMABLE (WHILE STILL ROTATING)
- STOP

The ability to use converted machine tools offers a low-cost option in the technology of friction surfacing. A certain manufacturer has recently designed and built a machine dedicated to this surfacing method (Fig. 3). The machine, which is particularly suited for longitudinal deposition, can:

- PUT DOWN RUNS OF 3 M (10 FT)
- USE CONSUMABLES UP TO 70 MM (3 IN.) IN DIAMETER
- PROVIDE A RANGE OF ROTATION SPEEDS FROM 250 TO 1800 REV/MIN
- DEVELOP AXIAL FORCES UP TO A MAXIMUM OF 180 KN (40.5×10^3 LBF)

Friction Surfacing

E.D. Nicholas, The Welding Institute

Applications

The available methods, in terms of surfacing and surface-treatment technology, are far from complete. The development of friction surfacing provides an alternative (in some cases, complementary) technique. The process may increasingly accompany other solid-state, large-overlay techniques, especially with respect to localized repair and the reclamation of explosively clad and roll-bonded composite materials.

Hardfacing applications on cutting edges and agricultural tools have been reported to be successful (Ref 11). Other workers (Ref 14, 15) suggest that thin-clad sheet can be produced from heavily cold-rolled friction-surfaced deposits. They believe that another promising application is the hermetic sealing of containers with heat-sensitive contents. Friction surfacing also will undoubtedly be applied to the reclamation of worn parts. The reconditioning of worn shafts, in which good-quality deposits were achieved, has been described (Ref 13).

Initially, potential applications for this solidstate technique are in the cladding of localized areas. Typical examples include the anticorrosion surfacing of slide valve plates, the surfacing of the annular contact face of composite pipe flanges, the inlay cladding by suitable strategic materials in positions that suit bearings and seal-contact areas on shafts, and the cladding of the exposed regions of shafts that are used in pernicious environments.

Various substrate geometries that have interesting potential for friction cladding are shown in Fig. 4. Shell banding may be another application, where suitably soft material is friction surfaced to the bodies of artillery shells (Ref 16). Other possibilities include the manufacture of specialized wear tiles (for sinter plant and quarrying equipment) and the in-situ reclamation of worn railway points. Turbine blades, guillotine and shear blades, disk brakes, machine-tipped tools, and press tool dies are also considered to be potential friction-surfacing applications.

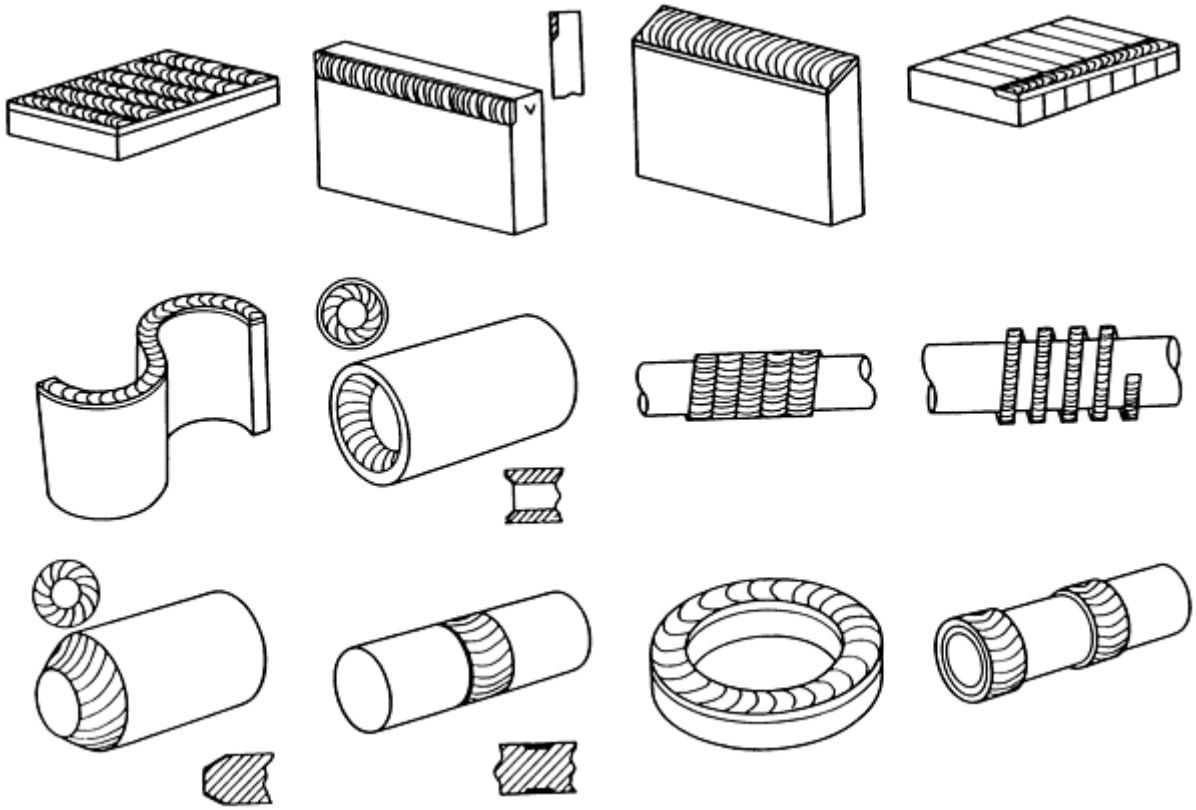

FIG. 4 GEOMETRIC ARRANGEMENTS FOR FRICTION SURFACING

Monolithic Structures. Friction surfacing has now been applied to a wide range of monolithic deposit/substrate combinations. There has been considerable success in producing high-strength bonding, fine-grained forged microstructures, and full homogeneity. A lack of porosity has also been attained, as have desirable surface properties, such as corrosion and wear characteristics that either equal or surpass the bar stock from which the deposit originated. Combinations include:

- INCO 625 TO AUSTENITIC STAINLESS STEEL
- AUSTENITIC STAINLESS STEEL TO CARBON STEEL
- STELLITE 6 AND 12 TO AUSTENITIC STAINLESS STEEL
- HASTELLOY TO AUSTENITIC STAINLESS STEEL
- TI-6AL-4V ALLOY TO TI-6AL-4V ALLOY
- AL-4CU ALLOY TO AL-4CU ALLOY
- HARDFACING STEELS, SUCH AS D2 AND H13, TO MEDIUM-CARBON STEELS

These and other applications are evidence that the process is coming of age and should be given serious consideration in the high-technology industries.

Metal-matrix composites. (MMC) offer considerable potential in high-temperature and wear-resistant applications. During 1988, friction surfacing with a MMC was accomplished using a consumable rod (matrix) that had a predrilled hole filled with alumina powder. Success was achieved, particularly when the matrix metal was 6063 aluminum alloy. It was equally possible to deposit a ferrous-based MMC (5 to 7 vol% of alumina in 4130 steel) from a proprietary MMC consumable rod produced by the Osprey process. The MMC deposited most easily onto a carbon steel, providing a hard, fine-grained martensitic matrix with uniformly distributed particulates of alumina. Further work was done to increase the volume fraction and distribution of the particulate in the matrix for the inclusion of zirconia and alumina by introducing changes in hole geometry and position in the consumable rod (Ref 17). An encouraging volume fraction of approximately 14% was obtained, although the particulate distribution needed to be improved.

Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics

Introduction

ULTRASONIC WELDING (USW) is a quasi-solid-state process that produces a weld by introducing high-frequency vibration to the weldment as it is held under moderately high clamping forces. The weld is produced without significant melting of the base materials.

In some respects, ultrasonic welding is an infant process that still awaits thorough exploration. A greater understanding is needed of the processes that occur at the bond interface. Specifically, the interaction of the process parameters, as well as their role in bond development, needs to be better understood.

The advantages of ultrasonic welding are that it:

- PERMITS JOINING OF THIN MATERIALS TO THICK MATERIALS
- PERMITS DISSIMILAR METAL JOINTS
- PROVIDES JOINTS WITH GOOD THERMAL AND ELECTRICAL CONDUCTIVITY
- JOINS METALS WITHOUT THE HEAT OF FUSION
- PROVIDES EFFICIENT ENERGY USE
- TYPICALLY REQUIRES NO FILLER MATERIAL, FLUX, OR SPECIAL ATMOSPHERE
- TYPICALLY REQUIRES NO SPECIAL CLEANING PROCESSES
- WELDS THROUGH MOST OXIDES

Applications. Commercially successful applications generally have certain characteristics. First, joints must be lap joints, not butt joints. Second, thin sections are required adjacent to the welding tip. Third, better results are obtained with nonferrous alloys.

Production applications include electrical wire harnesses for the appliance and automotive industry; buss bars; fuses; circuit breakers; contacts; ignition modules; starter motors; aluminum and copper foil; battery foils; capacitors; encapsulation of explosives; microelectronic wires; heating, ventilation, and air conditioning (HVAC) tubing; and many others. Military applications in the aircraft industry are described in MIL-STD 1947, issued May 15, 1985.

Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics

Equipment and Process Parameters

An ultrasonic welding system requires a power supply that converts line power to the high frequency and high voltage needed by the transducer. The transducer transforms high-frequency electrical energy to vibratory energy and is incorporated into the welding head, which also provides the means (that is, either pneumatic, hydraulic, or mechanical) to clamp the workpieces. The transducer assembly also incorporates components or waveguides to transmit the energy to the desired weld area.

Process Mechanism. Ultrasonic welding products a weld by oscillating shear forces at the interface between the two metals being joined while they are held together under moderate static clamping force. The resulting internal stresses result in elastoplastic deformation at the interface.

Highly localized interfacial slip at the interface tends to break up oxides and surface films, permitting metal-to-metal contact at many points. As continued oscillation breaks down the points and the contact area grows, diffusion occurs across the interface to produce a structure similar to that of a diffusion weld.

Ultrasonic welding produces a localized temperature rise from the combined effects of elastic hysteresis, interfacial slip, and plastic deformation. The welding process is completed without having fully melted metal at the interface when the correct combination of force, power, and time parameters are used.

Interface temperature rise is greater for metals with low thermal conductivity (for example, steel) than it is for metals of high conductivity (for example, aluminum or copper). Ultrasonic welding of such high-conductivity materials consumes substantially less energy than does resistance welding.

In the case of alloys that have a broad melting temperature range, it is likely that as the low end of the range is reached, a slushing condition that facilitates plasticity in the weld interface is produced.

Process Variations and Limitations. Variations of the USW process produce different weld geometries. There are spot, line, continuous seam, and ring welding machines. Two other versions of spot welding machines are used to join microelectronic components.

Spot welds can be circular, elliptical, or rectangular, and solid or ringlike in geometry. They are formed when the material is clamped between a shaped tip (sometimes called a sonotrode) and an anvil (Fig. 1). The tip vibrates as ultrasonic energy is momentarily introduced in a plane parallel to the interface and perpendicular to the clamping force. Although weld time varies according to the thickness and composition of the material to be joined and the power of the welding machine, most spot welds can be produced in less than 1.5 s (Fig. 2).

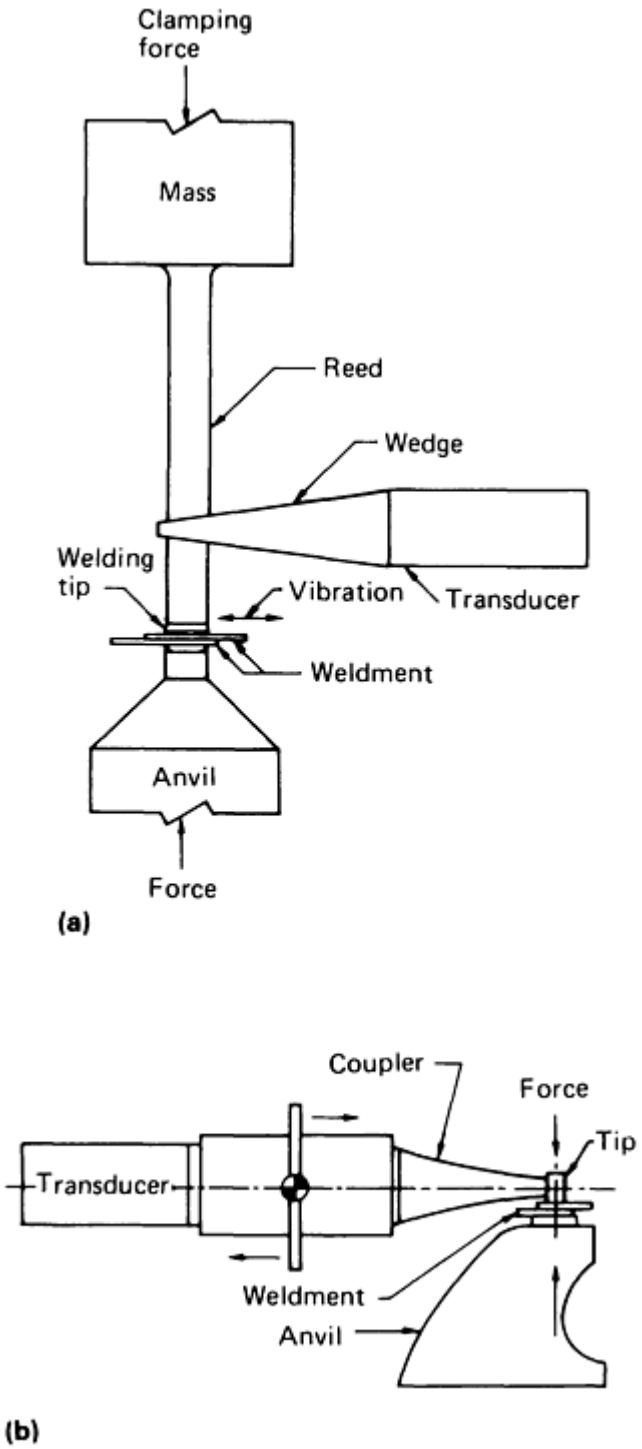

FIG. 1 TWO VERSIONS OF AN ULTRASONIC WELDING SYSTEM USED FOR SPOT WELDING APPLICATIONS. (A) WEDGE-REED SYSTEM. (B) LATERAL DRIVE SYSTEM

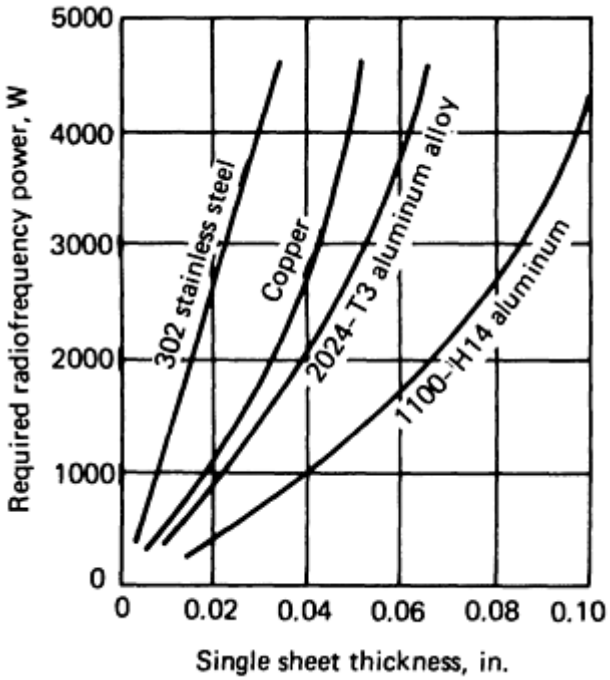

FIG. 2 PLOT OF WELDING MACHINE POWER CONSUMPTION VERSUS MATERIAL THICKNESS FOR SELECTED METALS JOINED BY ULTRASONIC WELDING

Welds can be made adjacent to or overlapping previous welds to form a continuous welded joint. A product clamp may be necessary to prevent the dispersion of ultrasonic energy into adjacent areas of the workpiece. The product clamp is usually concentric with the welding tip and has a slightly larger diameter than the tip.

Line welds are produced by a variation of spot welding in which the weld geometry is elongated by using a linear sonotrode tip and anvil. Custom multiple transducer heads have been used to produce line welds that are several inches long, but most commercially available equipment is limited to lines of 38 mm (1.5 in.) or less in length. Adjacent welds can produce a longer line. Typically, the longer welds are attainable only in thin materials (that is, less than 0.25 mm, or 0.010 in., thick). Single line welds up to 50 mm (2 in.) long have been made to join expanded nickel foil to solid foil for a lithium battery application.

Line welding is also used to seal copper tubes in HVAC applications (Fig. 3). This technique can replace seals normally produced by crimping and brazing.

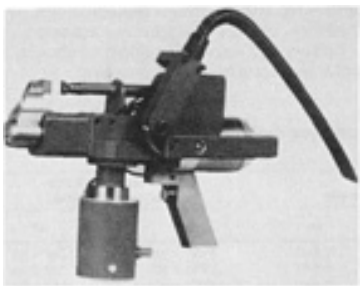

FIG. 3 TYPICAL ULTRASONIC LINE WELDER USED FOR METAL TUBE CLOSURE APPLICATIONS

Continuous seam welds are produced when a disk-shaped ultrasonically vibrating roller is rotated and traversed over a workpiece that is supported on a fixed anvil. Typical uses include joining foil ends in aluminum and copper foil mills. Commercial equipment is available to weld sheet thicknesses up to about 0.15 mm (0.006 in.). High-frequency systems

(typically, 50 kHz) permit excellent welds in even the thinnest of foils, such as 0.0043 mm (0.00017 in.), without tearing or puckering. This technique is also used to join 0.038 mm (0.0015 in.) aluminum interconnects to foil in photovoltaic panels.

Ring Welds. A circular tip used on a spot welder can be used to form a ring weld. Systems designed especially for ring welding often use the torsional or circular motion of an annular-shaped tip instead of a forward and backward motion. Such a system utilizes two transducers, one of each side of a hollow reed. Each transducer produces motion 180° out of phase with the other, thus causing a torsional motion at the interface of the weldment.

Ring welds with diameters up to about 50 mm (2 in.) and an annular weld track of about 1.25 mm (0.050 in.) have been produced in thin aluminum or copper foils. Typical applications include the encapsulation of liquid and powder propellant or explosive materials by welding a thin foil cover on a container. Foils are usually 0.2 mm (0.008 in.) or less. The weld process does not produce much heat, which makes it suitable for use with heat-sensitive materials. Many small, high-frequency (28 kHz) systems are in operation to hermetically seal small explosive initiators or fuses for armaments.

Microelectronic Welds. fine wire bonding represents the earliest widely used USW application and still accounts for a large volume of industrial activity. Millions of wire bonds are performed daily. Figure 4 shows an ultrasonic wire welding apparatus.

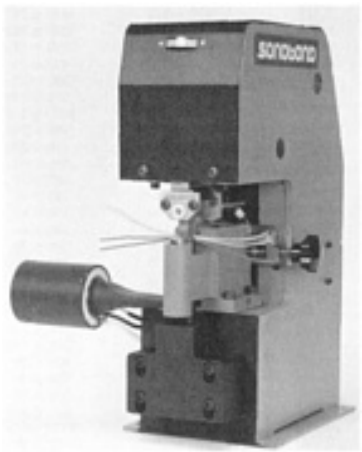

FIG. 4 ULTRASONIC WIRE WELDER USED TO BOND WIRES FOR MICROELECTRONIC APPLICATIONS

Wire diameters range from less than 0.025 to 0.5 mm (0.001 to 0.020 in.), and the highest volume occurs in the 0.025 to 0.050 mm (0.001 to 0.002 in.) diameter range. Vibratory action at high frequency (typically, 60 kHz) removes surface contaminants, induces material flow, and permits a solid-state weld between the wire and either the metallized bond pad or the leads on the semiconductor package.

A combination of ultrasonic and thermocompression bonding techniques, known as thermosonic bonding, is now a popular wire bonding method. The technique involves ultrasonic welding with heated substrates, typically with interface temperatures that range from 100 to 200 °C (210 to 390 °F).

Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics

Personnel

Operators of the USW process do not need elaborate or extensive training. Once the process parameters have been determined by a process engineer, the operator is required only to load the parts into a nest of supporting/locating anvil

assembly, to press the palm buttons or other starting device, and then to unload the finished part. In-process monitoring can be performed either electronically, using a microprocessor, or visually by the operator, which usually requires the operator to look at a power indication gage. The process engineer needs to work closely with the equipment manufacturer for guidance regarding tooling design and the selection of process parameters.

No arc, spark, or molten filler material is associated with ultrasonic welding, and no electrical current passes through the weldment. Because the welder is usually configured in a press form with moderately high forces, the normal precautions need to be observed to ensure operator safety, that is, the use of anti-tie-down palm buttons or a similar provision to protect the hands of the operator. Another common consideration involves the high-frequency noise level produced by the ultrasonic vibration. In some instances, especially with the higher power level equipment, the noise exceeds the Occupational Safety and Health Administration (OSHA) approved levels and sound-deadening barriers or enclosures must be provided. Even where the noise level meets the approved requirements, the operator may find it necessary to wear ear protection.

Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics

USW Procedures

The USW process requires the overlapping of the materials to be welded. Generally, the materials need only be presented to the welder in proper orientation. Correct orientation is usually achieved by using a nest or anvil fixture, which supports the parts while they are being welded. When joining stranded wires to other solid or stranded wires or to a terminal, a "gathering" fixture must be used to pull the wires together and to exert a slight pressure while welding to prevent the wires from escaping from the intended weld area. This type of fixture is usually supplied by the manufacturer with machines intended for use with wires and can be adjusted to accommodate a wide range of sizes and combinations.

Special considerations described below include the condition of the surface, the use of an interlayer, and the control of resonance.

Surface Condition. Most of the readily weldable materials, such as aluminum, copper, or brass, can be welded as received from the mill or must be degreased with a common solvent or detergent to remove surface lubricants. Oxide coatings will disperse during the process, unless they are very thick. Heavy surface scale should be removed by mechanical abrading or chemical etching before welding. The time lapse between cleaning and welding is generally not critical, unless the atmosphere is corrosive. Some types of coatings and insulations (for example, low-temperature magnet-wire coating) may be penetrated during the welding process, whereas other types must be mechanically removed. Fairly consistent surface cleanliness and quality must be maintained to ensure uniform weld quality.

Use of an Interlayer. A useful technique for improving the weld quality of some weldments involves placing a thin foil, usually aluminum or copper, between the metals to be bonded. This is particularly useful when materials of varying hardness are to be bonded. This interlayer is sometime more convenient and cost effective than plating the materials with a more weldable material (for example, copper or gold).

In a technique known as weld bonding, a layer of adhesive is placed between the panels to be ultrasonically welded. This technique not only provides a watertight seal, but also increases the weld strength beyond that obtained by either adhesive bonding or ultrasonic welding alone. Either a paste adhesive or a fabric-supported adhesive can be used in the ultrasonic bonding process.

Control of Resonance. Complex workpieces, especially those with multiple parts or thin wall sections, may be induced to vibrate by the ultrasonic welding system, which can produce fractures in the workpiece itself and in previously made welds or can cause inconsistent weld quality. This resonance can be either eliminated or minimized by applying pressure to the vibrating section. For example, in the ultrasonic welding of aluminum foil layers to the studs of capacitor caps, the stud must be clamped tightly or else the vibration will not only prevent the formation of a good joint, but can even melt the plastic cap that surrounds the stud.

Another option is to clamp the vibrating part to a comparatively large fixture or anvil. Significant pressure is required, and some machines come equipped with a product clamp for this purpose. Because resonance in the tooling can also occur, fixtures should be rugged and should not contain multiple small devices, such as springs or pins. It is best to avoid using light materials (for example, aluminum) for part fixtures, anvils, or supports. Steel is the preferred material for these components.

Tooling, Tips, and Anvils. The welding tip (or sonotrode) that contacts the weldment is usually made of the high-quality heat-treated tool steel. A precision fit between the tip and the waveguides is necessary to ensure efficient transmission of the vibratory energy. A locking (Morse) taper is frequently used, and the fit should cover 75% of the contacting surface area between the tip and its matching receptacle. In lower-power systems, the tip and the waveguide (horn) can be integral and can sometimes have several surfaces for welding. Rotation of the horn provides a new welding surface. A welding tip with a taper lock fit is less expensive to replace and easier to resurface, when necessary, than an integral horn-tip combination.

Certain alloys, especially the very soft aluminum alloys, may stick to the tip when welded. A mechanical stripper may be needed to pull the part free. Sometimes, a low-power, ultrasonic pulse may be sufficient to remove the stuck part from the tip. If a nugget remains on the tip, a weld pulse, with the tip clamped against a thick piece of brass, can remove the sticking nugget easier than mechanical abrasion methods.

Tips composed of exotic alloys have been used to prevent particularly tenacious sticking conditions, but with limited success. A steel shim with an oxidized surface was found to be particularly effective in preventing both sticking and deformation when bonding high-strength aluminum and titanium alloys, which are extensively used by the aircraft industry.

The anvil tip is subject to the same problems of wear and tip sticking that plague the sonotrode tip. The same high-strength heat-treated tool steel (typically, M2 heat treated to 58 to 60 HRC hardness) is recommended.

Welding tip and anvil tip surfaces with serrated or crosshatched patterns are useful in preventing slip between the tip and the weldment. Slip can result in a weld location between the metal and the tools, instead of at the required interface. A typical crosshatched pattern would be 0.5 mm (0.02 in.) peak-to-peak and about 0.2 mm (0.008 in.) deep.

Special Atmospheres. Although ultrasonic welding does not require a special atmosphere, it may be applicable under certain conditions. For example, use of an inert gas can reduce or prevent oxidation when bonding a metal such as lithium. Ultrasonic welding is not adversely affected by the presence of an inert atmosphere.

Weld quality is described below in terms of influencing factors, surface appearance and deformation, and metallographic examination.

Influencing Factors. The quality of ultrasonic welds is affected by these parameters:

- COMPOSITION AND GEOMETRY OF THE WELDMENT
- HARDNESS OF THE WORKPIECE
- CLEANLINESS OF THE WELDMENT
- SELECTION OF WELDING CONDITIONS, SUCH AS POWER, CLAMPING FORCE, AND WELD TIME
- CAPACITY OF THE TOOLING TO PROPERLY SUPPORT AND CLAMP THE PARTS TO PREVENT UNWANTED VIBRATION

Surfaces to be welded should be reasonably flat the parallel. This is especially critical for ring welding where a high degree of hermeticity is required. Some materials may be weldable in the as-received condition. However, a change in lubricants or other surface condition can require an adjustment in machine settings to maintain quality. Therefore, it is sometimes advisable to degrease or to abrade surfaces before welding to maintain a certain level of consistency.

Surface Appearance and Deformation. Depending on the material and the tip geometry, the surface of an ultrasonic weld can leave a slight scuff mark or a significant depression. This thickness deformation is more visible in soft, ductile

materials, such as soft aluminum. The actual weld interface is usually smaller than the surface impression. Harder materials generally have a shallower and smaller surface depression than soft, ductile materials.

A tip surface that has serrations or a cross-hatched pattern will replicate this pattern in the surface of the weldment. A spherical radius on the tip will generally produce a deeper, bowl-shaped depression than a flat tip of the same diameter.

Stranded or braided wires can be welded to form a solid cross section, if required. Slightly lower power, time, or force can give a compressed, but not solid, cross section.

Judicious radiusing and angling of tools is recommended to avoid sharp transitions in areas that can lead to early failure of an assembly.

The metallographic examination of ultrasonic welds in a wide variety of metals reveals phenomena that occur in the microstructure, such as surface film and oxide disruption, plastic flow and extrusion, recrystallization, phase transformation, and diffusion. Photomicrographs of selected ultrasonically welded materials are shown in the Section "Procedure Development and Practice Considerations for Solid-State Welding" in this Volume.

A heat-affected zone is significant in certain alloys, such as aluminum and nickel. Phase transformation, recrystallization, and precipitation may occur.

Diffusion across the interface is usually shallow, because of the relatively short weld times required, although significant penetration across the interface can take place. Alloying may occur then welding certain dissimilar metals, and the possibility of galvanic corrosion should be considered.

Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics

Mechanical Properties

Tensile shear tests conducted on single-weld lap joints indicated that failure was caused by a fracture in the base metal itself or by a tear out of the weld button, rather than shear in the actual weld. Typical spot weld strengths in a variety of metals are summarized in Tables 1 and 2. These data were published as the result of a government-sponsored research program undertaken in the 1970s. With more modern equipment and practices, improved results can be obtained.

TABLE 1 TYPICAL SHEAR STRENGTHS OF ULTRASONIC SPOT-TYPE WELDS IN SELECTED PURE METALS AND ALLOYS

Consistency is generally good, with one standard deviation, σ, typically less than 5% of the average strength value. Consistency of results in the manufacturing environment will follow from control of vital parameters (for example, part temperature, tooling temperature, machine and tooling stability, and surface condition of the parts).

Welds tested after thermal cycling, exposure to salt baths, and other corrosive environments maintain a relatively high tensile strength level.

Fatigue strength of ultrasonically welded metals often exceeds that of fusion-welded metals, because the ultrasonic bonding does not leave the cast button structure that is typical of melted and resolidified metal.

For relatively thin foils, the ductility of the ultrasonic bond permits the reforming of parts after welding without cracking the welded joint.

Introduction

TORCH BRAZING (TB) utilizes a fuel gas flame as the heat source for the brazing process. The fuel gas is mixed with either air or oxygen to produce a flame, which is applied to the workpiece until the assembly reaches the proper brazing temperature. Then, preplaced filler metal will be melted or hand-fed wire can be introduced.

Torch Brazing

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Advantages and Limitations

Torch brazing is used with various base metals and on many different sizes of assemblies. The process offers many advantages, including:

- FLEXIBILITY, IN THAT ONE TORCH WITH MULTIPLE TIPS CAN BE USED TO BRAZE A VARIETY OF ASSEMBLIES
- LOW CAPITAL EQUIPMENT COST (MANUAL TORCH BRAZING)
- ENTIRE ASSEMBLY DOES NOT HAVE TO BE HEATED; SMALL JOINTS ON LARGE ASSEMBLIES CAN BE HEATED LOCALLY
- AUTOMATION IS POSSIBLE IN MANY CASES
- MOST BASE METALS AND COMBINATIONS OF BASE METALS CAN BE TORCH BRAZED IF A SUITABLE FLUX IS AVAILABLE

Although the process provides versatile, low-cost heating for brazing, its limitations include:

- OXIDATION/DISCOLORATION CAN OCCUR ON SURFACES OF THE ASSEMBLY NOT COVERED WITH FLUX, BECAUSE PROCESS IS CONDUCTED IN AIR
- FLUX RESIDUES NEED TO BE REMOVED AFTER BRAZING
- HIGHLY REACTIVE MATERIALS, SUCH AS TITANIUM AND ZIRCONIUM, CANNOT BE TORCH BRAZED, BECAUSE NO FLUX IS AVAILABLE
- LARGE ASSEMBLIES CAN BE DIFFICULT TO HEAT, BECAUSE OF THE LOCALIZED NATURE OF FLAME HEATING

Applications

Torch brazing is commonly used on copper, brass, and other copper alloys, as well as steel, stainless steel, aluminum, carbides, and various heat-resistant materials. Most combinations of these materials can also be torch brazed. It is necessary to use flux with these materials, except when a phosphorus brazing alloy is used to braze pure copper parts. In this case, the phosphorus acts as the flux. The low-temperature silver-base and silver/copper/phosphorus filler metals are commonly used with torch brazing. Various other copper-base and gold-base filler metals can also be used with this process.

Torch brazing is often used to join copper and Bundy steel tube assemblies for the heating, air conditioning, and refrigeration industries. The process is also commonly used when brazing heat exchangers, bicycles, furniture, carbide tools, plumbing components, automotive subassemblies, medical instruments, and many other workpiece types. A wide range of components can be torch brazed, including small joints for jewelry parts, large-diameter (75 mm, or 5 in.) tubes, and fitting joints. The process provides strong, leak-tight joints on a wide variety of base materials.

Torch Brazing

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Equipment

The equipment for torch brazing has several components. Single torches are typically used for hand brazing, whereas multiple torches can be used in an automated system. The gas-oxygen is mixed in the torch body and is adjusted using the needle valves on the torch. Gas-air combinations can be mixed at the torch or, alternatively, a central mixing system can be used to supply many torches, particularly in automated applications.

The typical fuel gases used in torch brazing are acetylene, propane, and methane (natural gas). Various flame temperatures and heat contents are given in Table 1.

TABLE 1 COMMON FUEL GASES USED IN TORCH BRAZING

FUEL GAS	FORMULA	OXYGEN-TO-FUEL GAS RATIO(A)	FLAME TEMPERATURE FOR OXYGEN		HEAT CONTENT	
			°c	°f	mj/m^3	btu/ft^3
ACETYLENE	C_2H_2	2.5	3087	5589	55	1470
PROPANE	C_3H_8	5.0	2526	4579	104	2498
METHANE	CH_4	2.0	2538	4600	37	1000

(A) THE VOLUME UNITS OF OXYGEN REQUIRED TO COMPLETELY BURN A UNIT VOLUME OF FUEL GAS; A PORTION OF THE OXYGEN IS OBTAINED FROM THE ATMOSPHERE.

An automated brazing system that can braze up to 40,000 heat-exchanger return bend joints per hour is shown in Fig. 1. Multiple torches are used to provide the necessary heat.

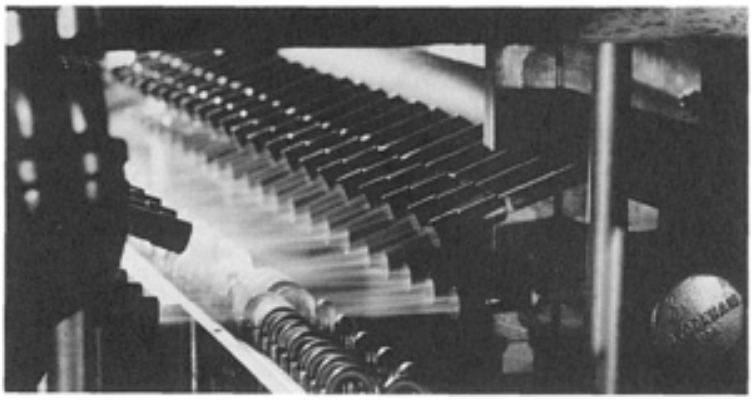

FIG. 1 AUTOMATED TORCH BRAZING SYSTEM

Torch brazing gases are normally supplied from bulk sources. An individual gas cylinder may supply one torch, whereas large bulk tanks are used to supply many torches or an automated system utilizing many burners. In all torch brazing systems, regulators are used to safely control the gas distribution. Individual regulators are used on the gas and oxygen lines. Standard safety precautions should be utilized when handling the equipment, and operators should be thoroughly trained in safety practices related to the use of compressed and combustible gases.

Torch Brazing

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Techniques

The key to torch brazing, as in all methods of heating, is to heat evenly the components to be brazed. This may require directing the torch primarily on a large, rather than small, component. Because the filler metal will flow to the hottest portion of an assembly, the flame should be applied in such a way as to flow the filler metal in the required direction.

When preplaced (preform or paste) filler metal is used in torch brazing, the operator need only know where and how much heat to apply. When the operator is also responsible for the filler metal, he must not apply it until the assembly has reached brazing temperatures. This may require practice and experience. Torch brazing is a skill that can be attained relatively quickly with the proper training.

Torch Brazing

Furnace Brazing

Toshi Oyama and Howard Mizuhara, WESGO, Inc.

Introduction

FURNACE BRAZING is a mass production process for joining the components of small assemblies with a metallurgical bond, using a nonferrous filler metal as the bonding material and a furnace as the heat source (Fig. 1). Furnace brazing technology was initiated in the 1920s and was first used commercially circa 1930, primarily to provide a brazing process that did not require a chemical flux, thereby eliminating the flux entrapment problem. Currently, furnace brazing is widely applied in a variety of industries. The essentially automatic nature of the process and its use of unskilled labor account for its popularity.

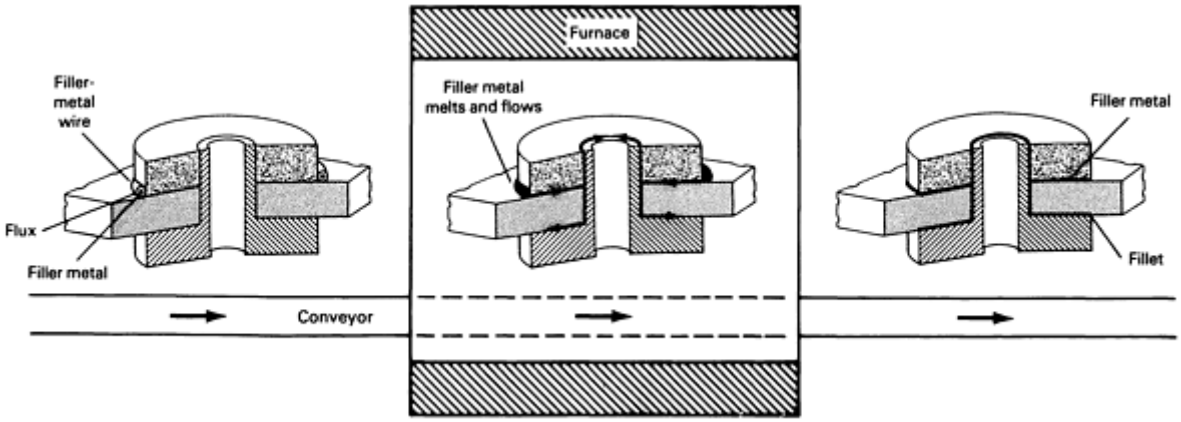

FIG. 1 CROSS-SECTIONAL VIEW OF THREE-PART ASSEMBLY AS IT PROCEEDS THROUGH FURNACE BRAZING OPERATION. FILLER-METAL WIRE (FILLER METAL ENCIRCLED BY FLUX) GRADUALLY MELTS AND FLOWS INTO VOIDS BETWEEN THE THREE SECTIONS AND THEN COOLS TO FORM A SINGLE-UNIT WORKPIECE AS IT IS CONVEYED THROUGH THE FURNACE.

In the furnace brazing process, cleaned parts and brazing filler metal are assembled, placed in a furnace, and heated to the brazing temperature. Furnace brazing is only practical if the filler metal can be placed on the joint before brazing and retained in position during brazing. Heating rate, brazing temperature and time, and cooling rate are controlled. Furthermore, in most cases, the brazing is carried out in a controlled atmosphere, which may be either reducing, inert, or vacuum. The advantages and limitations of furnace brazing are identified below.

Process Advantages. There are at least five advantages to using the furnace brazing process:

- IT IS A METHOD IN WHICH MANY VARIABLES CAN BE EASILY CONTROLLED TO ENSURE REPEATABILITY OF THE PROCESS AND GUARANTEE A HIGH-QUALITY JOINT. BRAZING TEMPERATURE AND PROCESS DURATION, AS WELL AS HEATING AND COOLING RATES, CAN BE CONTROLLED AND MONITORED. IN ADDITION, THE BRAZING ATMOSPHERE CAN BE EASILY REGULATED.
- WHEN ALL THE BRAZING PROCEDURES ARE WELL ESTABLISHED, RELATIVELY UNSKILLED OPERATORS CAN CARRY OUT EVERYDAY MANUFACTURING OPERATIONS.
- THE ABSENCE OF FLUX ENTRAPMENT ALLOWS MORE FLEXIBILITY IN JOINT DESIGN. THE POSTBRAZE CLEANING OF THE BRAZED PART AND THE FURNACE ARE UNNECESSARY.
- BECAUSE A WHOLE ASSEMBLY IS HEATED, DISTORTION OF THE PARTS CAN BE MINIMIZED OR ELIMINATED. IN SOME CASES, HEAT TREATMENT OF THE PART CAN BE INCORPORATED INTO THE BRAZING CYCLE.
- MORE THAN ONE JOINT PER WORKPIECE CAN BE BRAZED IN A BRAZING CYCLE. SEVERAL DIFFERENT ASSEMBLIES REQUIRING THE SAME BRAZING CONDITIONS CAN ALSO BE BRAZED SIMULTANEOUSLY.

Process limitations include:

- THE INITIAL INVESTMENT IN FURNACE BRAZING EQUIPMENT IS RELATIVELY HIGH. FURTHERMORE, THE MAINTENANCE OF THE EQUIPMENT IS CRITICAL AND CAN BE MORE EXPENSIVE THAN OTHER BRAZING TECHNIQUES. THE COST OF A SPECIAL ATMOSPHERE MUST ALSO BE CONSIDERED.
- BECAUSE THE WHOLE ASSEMBLY IS HEATED, THE COST OF HEATING EXCEEDS THAT OF OTHER BRAZING OPERATIONS. IN ADDITION, MICROSTRUCTURAL CHANGES IN THE BASE MATERIAL CAN OCCUR, DEPENDING ON THE MATERIAL BEING BRAZED AND THE BRAZING TEMPERATURE.
- BECAUSE BRAZING IS PERFORMED INSIDE THE FURNACE, JOINT DESIGN IS IMPORTANT. THE FIXTURES FOR HOLDING A BRAZED ASSEMBLY REQUIRE EXTRA HEAT MASS, WHICH INCREASES THE MANUFACTURING COST. PROPER JOINT DESIGN CAN MINIMIZE OR EVEN ELIMINATE FIXTURE COMPLEXITY.

Furnace Brazing

Toshi Oyama and Howard Mizuhara, WESGO, Inc.

Furnaces and Control Instrumentation

Brazing furnaces can be either oxyfuel fire or electrically heated. Whether they furnish heat directly or indirectly, all furnaces must provide a uniform work-load temperature. For example, the brazing of high-temperature nickel-base alloys at 1095 °C (2000 °F) and higher generally requires a hot-zone uniformity of ±8 °C (±15 °F). When brazing aluminum alloys, the temperature uniformity must be ±3 °C (±5 °F). Thus it is vital that each work load be closely monitored with a minimum of two thermocouples attached to or embedded in the parts to be brazed.

There are basically three types of furnaces: continuous, semicontinuous, and batch. Proper furnace selection primarily depends on the application. An example of the continuous-type furnace is a belt-conveyor furnace (Fig. 2). The brazing conditions are controlled by the speed of the conveyor and the set temperature. Because initial start-up involves several days to heat and to prepare the furnace for operation, these parameters are constantly maintained. The furnaces are seldom shut down and, when idling, are usually run at a temperature that is approximately several hundred degrees below the operating temperature. Therefore, the cost of furnace operation is very high if the equipment is not fully utilized. The furnace is used for mass production applications (that is, production rates of a few thousand parts per hour). Typically, a reducing gas is introduced into the brazing chamber. When the furnace is fully utilized, the cost per unit part becomes cost effective.

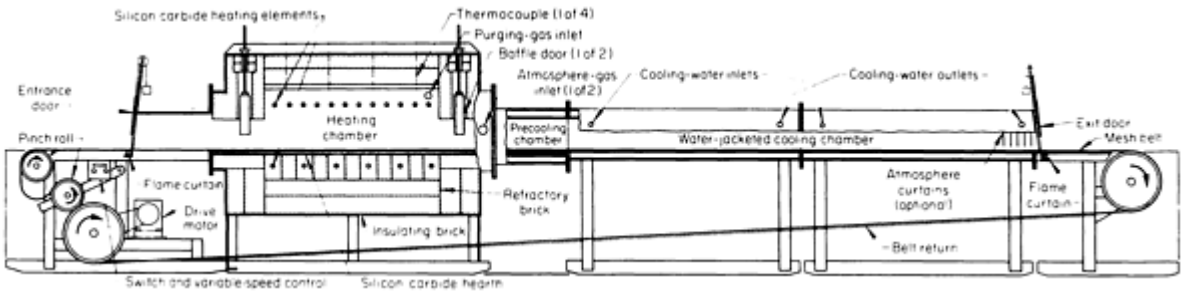

FIG. 2 MESH-BELT CONVEYOR BRAZING FURNACE THAT UTILIZES A WATER-JACKETED COOLING CHAMBER

Retort (or bell-type) furnaces are often used as semicontinuous furnaces (Fig. 3). In this type of furnace, brazing assemblies are encapsulated in the retort and a special gas is introduced. Then, the retort is placed in a furnace for brazing.

In the semicontinuous operation, two or more retorts are used in the production process. While one retort is in a brazing cycle, another retort is cooled, unloaded, and reloaded. Such furnace systems are typically equipped with microprocessors to control the furnace cycle.

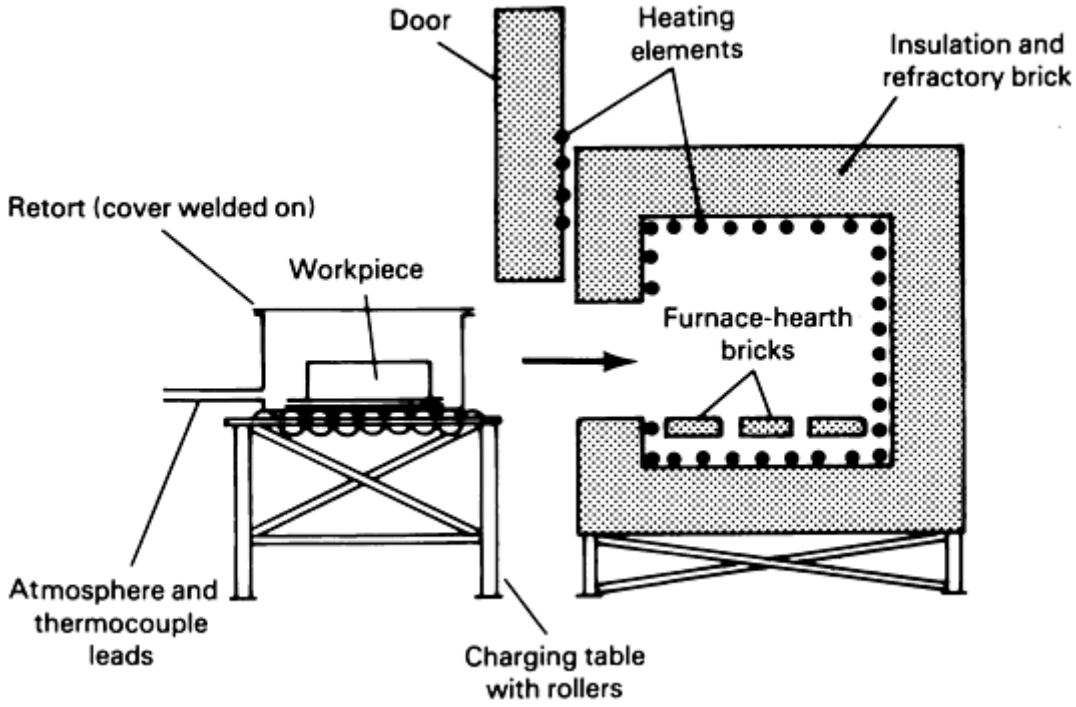

FIG. 3 SEALED RETORT ABOUT TO BE LOADED INTO ELECTRIC-FIRED BOX FURNACE IN ORDER TO BRAZE A WORKPIECE IN A CONTROLLED ATMOSPHERE

The vacuum furnace is typically used for batch processing (Fig. 4), although a semicontinuous vacuum furnace version is also available. The vacuum brazing furnace is typically interfaced with a microprocessor (Fig. 5). The programmable microprocessor controls all of the brazing parameters: heating rate, brazing temperature and time, cooling rate, and back-filled gas. Because several different brazing cycles can be stored in the microprocessor memory, the vacuum furnaces are quite versatile. Furthermore, an alarm system can be installed in the microprocessor to detect any operational abnormality that has the potential to terminate the brazing operation.

FIG. 5 BRAZING FURNACE INSTALLATION SHOWING RELATIVE SIZE OF BRAZING CHAMBER OF THE UNIT TO THE MICROPROCESSOR-BASED CONTROL MODULE. COURTESY OF CENTORR/VACUUM INDUSTRIES

Furnace Brazing

Toshi Oyama and Howard Mizuhara, WESGO, Inc.

Industrial Applications

The furnace brazing process is employed in many industries because of its high quality and reproducibility. The vacuum device, jet engine, and automotive industries represent three examples. In the vacuum device industry, a vacuum tube with an envelope of alumina ceramic is used, the nature of which requires that the whole assembly be heated. The control of heating and cooling rates is very important to the prevention of alumina ceramic cracking.

Other applications of furnace brazing can be found in the jet engine industry, where the quality of the brazed joint and the dimensional control of the brazed assembly are critical. Vacuum furnace brazing is the most common system used in the production of jet engine components.

The automotive industry makes extensive use of the continuous belt furnace because it is easily automated and is a cost-effective, high-production joining process for components made of carbon steel, stainless steel, and aluminum.

Furnace Brazing

Toshi Oyama and Howard Mizuhara, WESGO, Inc.

Health and Safety Guidelines

Although everyday production is relatively simple and trouble-free, the furnace operator should be instructed on the proper use of the equipment, the hazards of the gases and atmospheres used, and the importance of proper operating procedures. An alarm system should be installed to monitor furnace parameters and to alert operators of any potential equipment breakdowns or hazardous working conditions. Routine maintenance of the furnace and auxiliary equipment is vital if accidents are to be prevented.

Induction Brazing

J.F. Libsch, Lepel Corporation

Introduction

INDUCTION BRAZING (IB) is a process that joins metal components to form an assembly by selectively heating the joint area to the brazing temperature with electrical energy transmitted from an inductor that has been energized by a heating generator. It is classified as a brazing process because joints are made at elevated temperatures (540 °C, or 1000 °F, or above), using copper alloys that often contain silver (Ref 1).

Heating results from resistance to the flow of induced current (I^2R losses) in the assembly components. It occurs when the electrically conductive components are placed in the electromagnetic field created by rapidly alternating current flow in the inductor (Fig. 1). With proper coil design, heating occurs rapidly at the joint area, providing localized brazing temperatures. Response to the electromagnetic field depends on the frequency of the alternating current and the nature of the materials being heated, as well as on the shape of the component parts and coil design. Nonmagnetic materials with low electrical resistance such as copper and brass take longer to heat than magnetic, higher resistivity, ferrous materials such as steel.

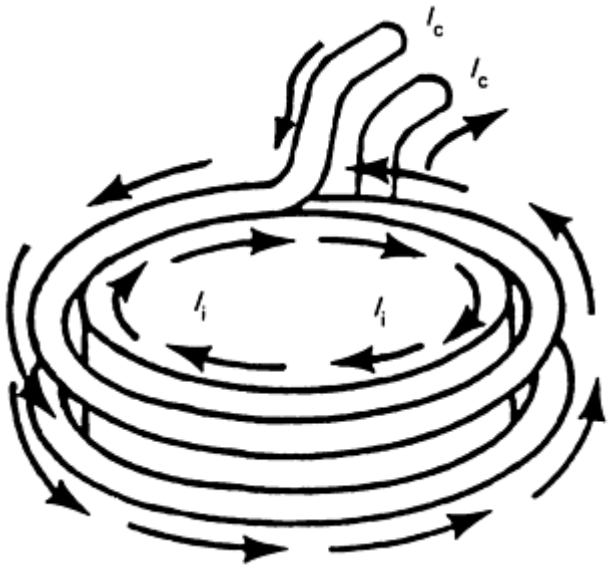

FIG. 1 RELATION OF COIL CURRENT, I_C, TO INDUCED CURRENT IN THE WORKPIECE, I_I, GENERATED BY ELECTROMAGNETIC FIELD IN THE INDUCTION COIL

While a strong electromagnetic field and high power density (2×10^{-3} kW/mm^2, or 1 kW/in.^{2}) can create highly localized temperatures, most brazing applications use relatively low power densities of 1×10^{-3} kW/mm^2 (0.5 kW/in.^{2}) to ensure that the joint area comes to brazing temperature uniformly. Heat conduction plays an important role.

Because a multitude of joint configurations are encountered, proper inductor or coil design is essential to ensure uniform joint temperature and to permit handling of components onto the coil for processing. Some typical coils that are fabricated from copper tubing and that use water cooling are shown in Fig. 2. Inductors made from solid copper bar for single- or multiple-joint heating and that employ both internal and external water cooling are used for some applications.

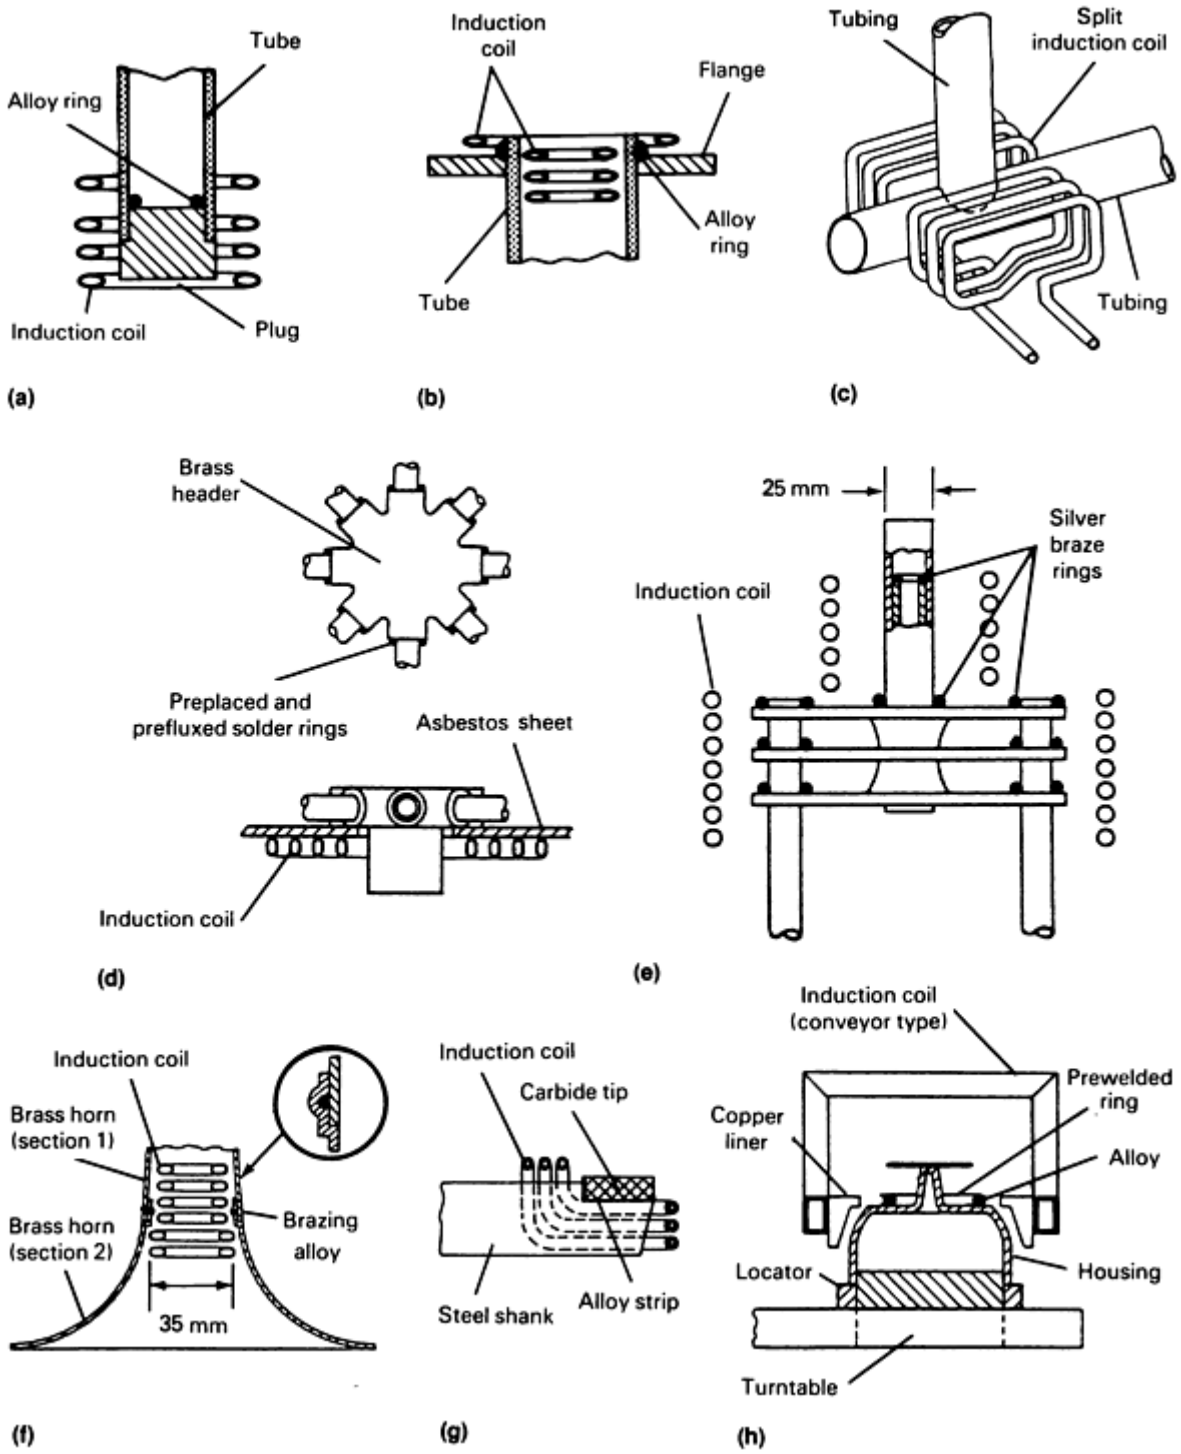

FIG. 2 TYPICAL COIL AND JOINT CONFIGURATIONS USED IN INDUCTION BRAZING. (A) SOLENOID COIL FOR PLUG-TO-TUBE JOINT (NOTE LOCATION OF BRAZING ALLOY RING). Induction Brazing

J.F. Libsch, Lepel Corporation

Process Applications

Induction brazing is used where relatively high-strength heat-resistant joints are required between components parts. The strength of the joint depends on the joint design, the brazing alloy, the strength of the components being joined, and the clearance between the components. A clearance of 0.038 to 0.050 mm (0.0015 to 0.002 in.) is recommended. Induction brazing has been used extensively in the production of consumer and industrial products, structural assemblies, electric and electronic products, mining equipment, machine and hand tools, military and ordnance equipment, and aerospace components.

Advantages. Induction brazing features rapid heating that produces joints in seconds because each joint area is exposed to the electromagnetic field of the specific coil involved. Uniform and reliable joints can be produced piece after piece with smooth joint fillets, eliminating the need for finishing operations. Because a suitable induction coil can provide heat simultaneously at several locations in an assembly, a number of joints can be made in a single heating operation. Induction brazing provides control of the heat pattern and rapid heating, which serve to localize the heated zone, thereby preventing or minimizing deterioration of properties in previously heat-treated or cold-worked materials, and, if desired, permitting sequential brazing of nearby joints using alloys with decreasing melting temperatures.

Induction brazing uses predetermined amounts of brazing alloys in the form of rings, strip, or powder; thus, the possibility of excessive material use is avoided, lowering joining alloy costs. Rapid heating minimizes oxidation and discoloration in most instances, even without the use of a controlled atmosphere.

Limitations of induction brazing include:

- DIFFICULTY IN HEATING OF COMPLEX ASSEMBLIES
- NEED FOR RELATIVELY UNIFORM CLEARANCE BETWEEN COMPONENTS
- INITIAL COST OF EQUIPMENT
- NEED FOR SPECIALIZED KNOWLEDGE FOR SYSTEM DESIGN

For complex assemblies involving several brazed joints and special geometry, induction brazing fixturing may be difficult, and furnace brazing may be a more practical process choice.

Induction Brazing

J.F. Libsch, Lepel Corporation

Brazing Equipment and Fixturing

Major changes have been made in the design of generators and temperature control equipment in recent years. Most significant perhaps has been the development of solid-state generators to complement or replace motor generators and vacuum tube generators. Solid-state generators of intermediate power levels that operate at frequencies of 50 to 200 kHz or 50 to 350 kHz have become available, providing an alternate to tube generators that operate at nominal frequencies of 450 kHz. Improvements have been made in generator control design, permitting precise and instantaneous response to changes transmitted by a suitable sensor element.

The proper size generator required for a given operation is best determined by an actual trial in the laboratory. However, a preliminary estimate can be made by considering the power absorbed by the pieces to be joined, the amount of radiation lost from the heated piece, and the required production rate. (The accuracy of this estimate depends on good coil design and electrical matching between the generator and the work load.) The curves in Fig. 3 represent the approximate heat content or heat energy required to heat 1 kg (2.2 lb) of material to the temperatures indicated from 20 °C (68 °F); these curves reflect the variation in specific heat with temperature for each metal.

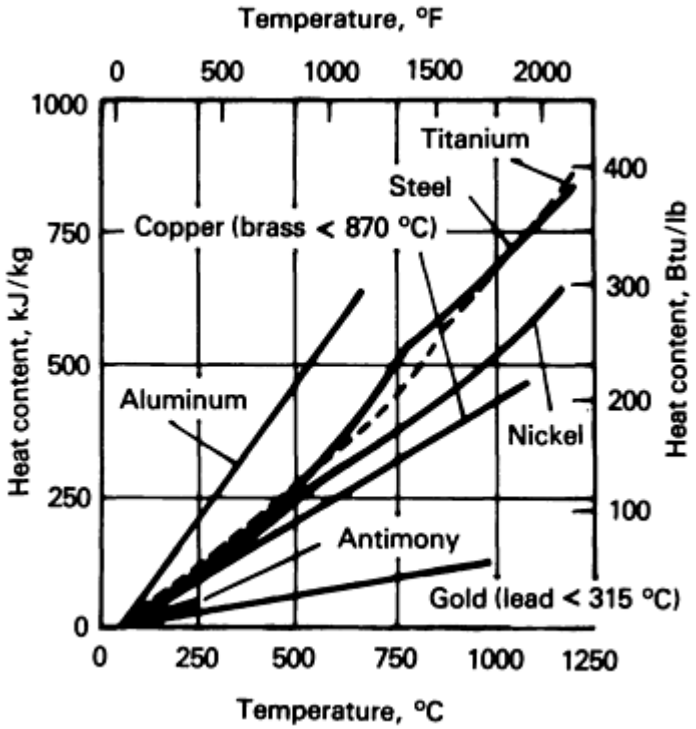

FIG. 3 PLOT OF HEAT CONTENT (MASS BASIS) VERSUS TEMPERATURE FOR SELECTED METALS AND ALLOYS. SOURCE: REF 3

Precise determination of the weight being heated in most brazing applications is difficult because heat is conducted away from the joint area, thus creating a temperature gradient for some distance beyond the induction-heated joint and adding to the amount of energy required. Furthermore, Fig. 3 does not account for the energy required to compensate for radiation losses. Fortunately, the temperatures most often used in induction brazing are relatively low (620 to 815 °C, or 1150 to 1500 °F); thus, radiation losses are small and can generally be neglected in the preliminary estimate. While rapid heating rates using high power may increase production, they are a frequent source of difficulty in induction brazing; very rapid heating exaggerates the effects of electrical resistivity and thermal conduction. Slower heating rates minimize the effects of thermal conduction when dissimilar metal joints, such as steel to copper, are involved. In some situations, slower heating rates can help compensate for considerable differences in the mass of the components being brazed.

The most common frequencies currently used for brazing applications are 10 kHz, 25 to 50 kHz, 50 to 200 kHz, and 50 to 350 kHz with solid-state generators, and 250 to 450 kHz with tube equipment. The lower frequencies heat more deeply and may provide more uniform heating of the matching surfaces if one of the components to be brazed has a large mass. Higher operating frequencies, such as 450 kHz, may be suitable for brazing of nonferrous metals, or for brazing of steel to a nonferrous metal or to a nonmagnetic (austenitic) steel. High frequency may also provide more efficient heating of parts; in fact, tube equipment operating at 2.5 to 8 MHz may be necessary for very thin components. As a general. rule, cost in dollars per kilowatt is lower with lower frequency generators.

Figure 4 shows a system for induction brazing components for refrigeration and air conditioning using a 7.5 kW solid-state unit operating at a frequency of 100 kHz.

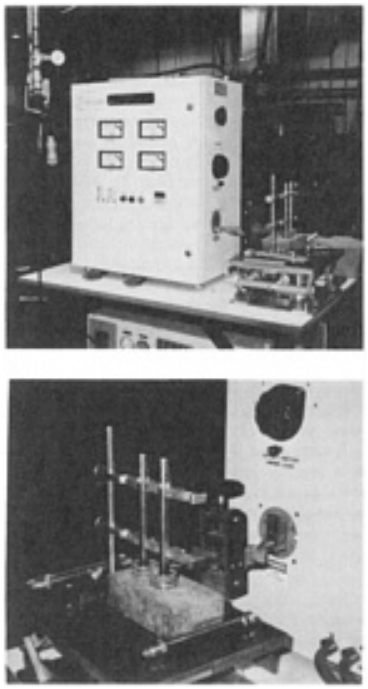

FIG. 4 INDUCTION BRAZING INSTALLATION THAT USES A 7.5 KW SOLID-STATE INDUCTION GENERATOR OPERATING AT 100 KHZ TO JOIN BRASS AND STAINLESS STEEL COMPONENTS FOR HEAVY-DUTY VEHICLE REFRIGERATION AND AIR CONDITIONING SYSTEMS. COURTESY OF RED DOT CORPORATION AND LEPEL CORPORATION

An inert or reducing atmosphere surrounding the brazed joint area is desirable in some applications. Appropriate fixturing and/or bell-jar arrangements (Ref 4) are used in such applications.

Joint Design

Figure 2 illustrates several basic joint designs for induction brazing as well as typical coils and some frequent applications (Ref 5). The schematics show the placement of brazing alloy preforms and coil-part arrangements.

Joint Parameters (Ref 2). The following joint parameters for parts to be brazed by induction heating require special attention:

- HEATING PATTERN
- METHOD OF PREPLACING THE JOINING ALLOY
- CLEARANCES BETWEEN MATING PARTS

- THERMAL CONDUCTIVITY AND EXPANSION CHARACTERISTICS OF THE MATERIALS TO BE JOINED

Effect of Thermal Expansion on Stress (Ref 2). Stress concentration and high residual stresses in the joint become critical factors when the joint members are stronger than the brazing filler metal, or when differential contraction takes place with dissimilar materials. The marked difference in the thermal expansion between tungsten carbide (5.9×10^{-6}/K, or 3.3×10^{-6}/°F) and carbon steel (12.1×10^{-6}/K, or 6.7×10^{-6}/°F) may be particularly troublesome when the carbide is placed in tension. This frequently results in cracked carbide. A "sandwich" braze utilizing a clad brazing strip (that is, copper clad with silver brazing filler metal on both sides) can overcome this problem. In a sandwich braze, stresses are minimized as a result of plastic deformation in the low-yield-strength copper layer.

Induction Brazing

J.F. Libsch, Lepel Corporation

Human Factors Engineering Ergonomics

In induction brazing, the heating function is essentially independent of the operator once the generator, coil, and heating program have been set up. The amount of handling of the component parts, the brazing alloy preforms, and flux depend upon the degree to which the application is automated. In fully automated systems, the operator oversees the operations and ensures the supply of the various joint elements from feed mechanisms, including mechanisms that provide automatic placement of brazing alloy preforms and fluxing. In semiautomatic systems, the operator loads the component parts on a fixture, preplaces the preform, and fluxes the joint region at a workstation on a continuously moving conveyor, rotary, or indexing device. In these systems, the operator serves primarily as an unskilled machine operator. Specialized complex assemblies (for example, electron tubes) that are brazed in controlled atmospheres may require skilled personnel with specialized training in induction heating processing.

Good joint design provides for simple inspection of the assembly, which involves simply noting alloy flow from the joint area to the edges of the joint. The presence of smooth continuous fillets also indicates a successful joint. Complex inspection methods such as radiography or ultrasonic inspection may be specified in critical applications.

Dip Brazing

Daryl D. Peter, Daryl D. Peter and Associates

Introduction

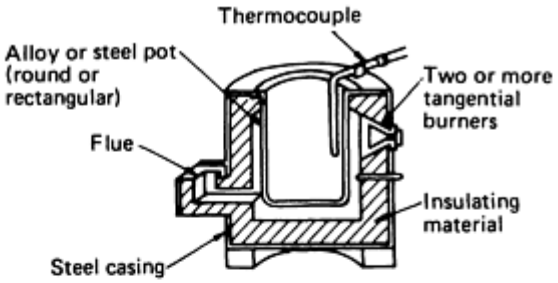
DIP BRAZING (DB) is one of the oldest brazing processes. The materials to be joined are immersed in a hot liquid, which is either a molten flux or a molten filler metal that usually contains a layer of flux to prevent oxidation. Dip brazing is primarily used because of its ability to uniformly heat parts that have a wide range of thicknesses. The process is simple when compared with modem, complex brazing equipment and processes. The drawback of the process is that it coats everything with flux or braze alloy; flux can be corrosive to fixtures and surrounding metal structures and equipment. Even when compared with more modern heating methods, the speed of immersion heating is hard to match and dip brazing, therefore, continues to be a common process.

Dip Brazing

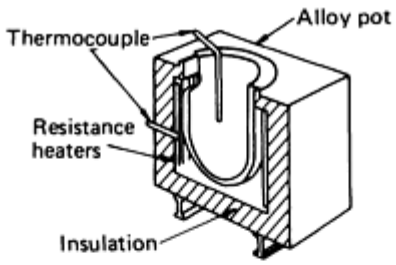
Daryl D. Peter, Daryl D. Peter and Associates

Furnace Construction

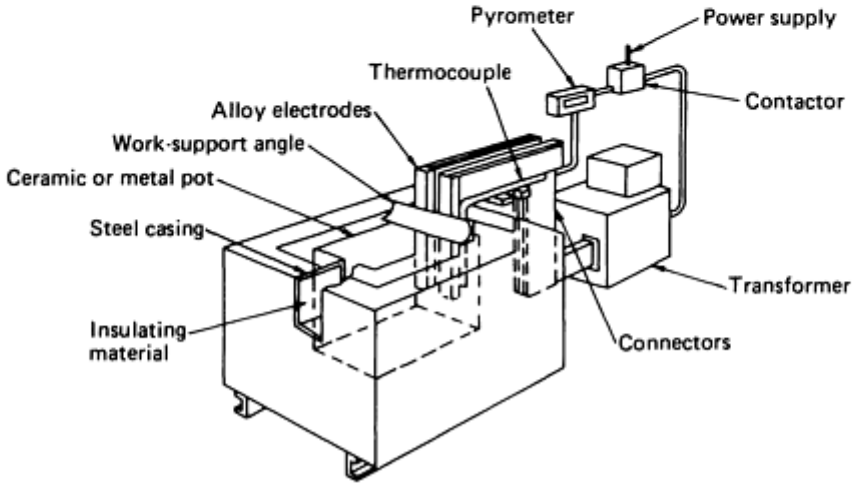
Dip brazing systems can be described by the type of pot vessel, heating method, and heating media that is used. Vessel construction can be ceramic, fired brick, or, possibly, cast (Fig. 1). A metal tank of a suitable alloy can also be used. Heating is facilitated by either gas or electric current. Flux baths favor electric heating, because of their higher resistivity when molten.



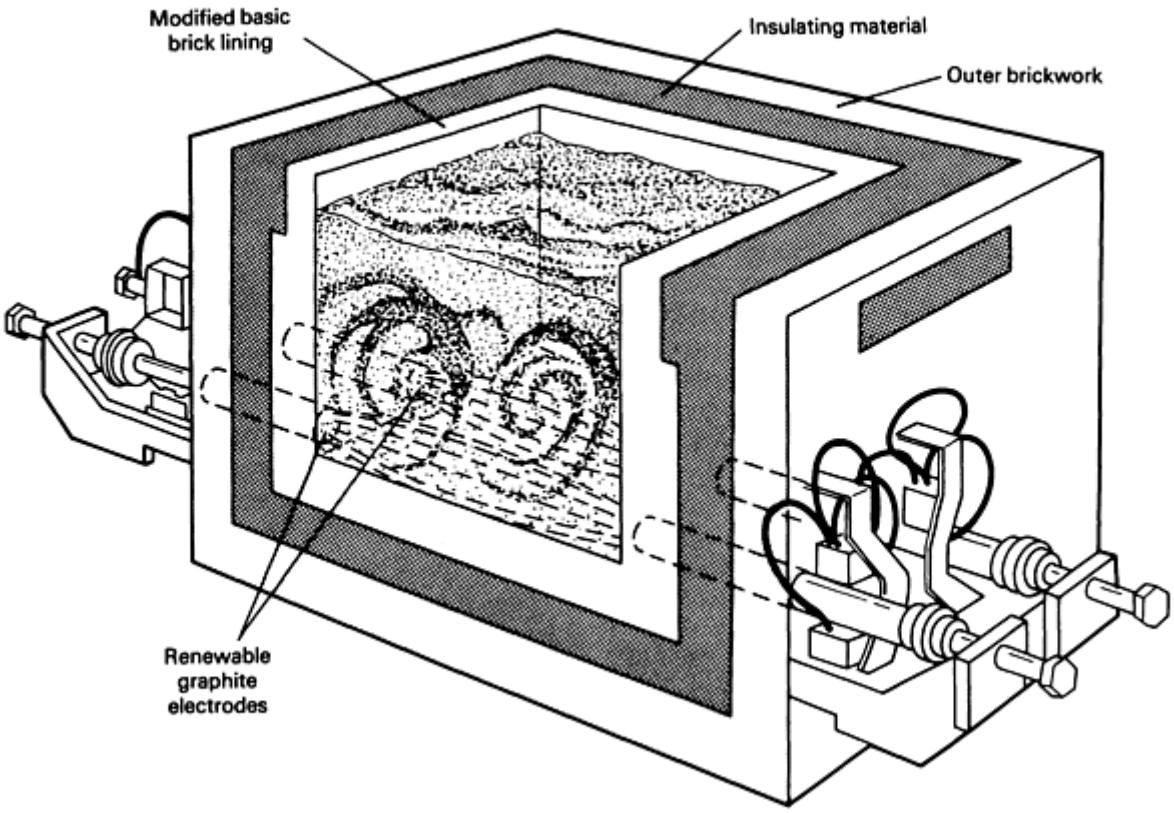
(a) Gas fired or oil fired



(b) Resistance heated



(c) Immersed electrodes



(d) Electrically heated (submerged electrodes)

FIG. 1 PRINCIPAL TYPES OF FURNACES USED FOR MOLTEN-SALT-BATH DIP-BRAZING APPLICATIONS. (A) AND (B) EXTERNALLY HEATED; (C) AND (D) INTERNALLY HEATED

Figure 2 shows a typical furnace used for flux brazing applications. Electricity is conducted into the bath by either carbon or nickel electrodes that penetrate the furnace wall. Ultrasonic generators can also be incorporated into the molten metal processes to provide a scrubbing action.

Process Details

The process for brazing in molten flux is straightforward. To prepare for brazing, the operator must perform the following steps:

- CLEAN THE WORKPIECE
- MAINTAIN FLUX ACTIVITY
- ASSEMBLE THE PARTS AND POSITION THE FILLER METAL
- FIXTURE TO MAINTAIN CONTACT WITH PARTS
- HEAT UNIFORMLY TO MINIMIZE DISTORTION

The fixtured parts are then placed into a preheated furnace and heated to a temperature that is both above the liquidus of the flux in the immersion bath and below any temperature detrimental to the fixtured parts. Next, the parts are transferred to the bath and immersed for a period of time that is sufficient to reach brazing temperatures. They are then removed and allowed to drain and cool enough to set the brazing alloy, before being transferred to a cooling area. When the parts have cooled to a temperature at which distortion is no longer a factor, they are then quenched in hot water. The flux is then removed and the brazements are cleaned.

The process technician must work closely with the designer to ensure that the part design will not trap flux or air during brazing. In addition, the process technician is typically responsible for the choice of materials used in fixturing (ensuring that they are compatible with the material in the bath, immersion angles to prevent trapped air, and speed through the liquid to control erosion). Fluxes can be very damaging to most metals. Stainless steel that is satisfactory for torch or induction brazing applications may not be suitable for dip brazing. High-nickel content alloys are therefore more commonly used, because of their superior corrosion-resistant properties.

Equipment Maintenance

Preventive maintenance is critical to the process and can be divided into three categories:

- TEMPERATURE CONTROL
- CONTROL OF THE LIQUID
- MAINTENANCE OF THE VESSEL

A daily satisfactory braze sample tends to verify that all is well. Once every 30 days, an inspection of the operating electronics for accuracy and a survey of the bath temperature are recommended. The composition of the bath tends to change slowly. However, the time interval between tests will be determined by how the bath is used and by the nature of the bath. This test frequency interval can range from one week to one month in duration.

Care of the vessel is usually the most neglected part of the preventive maintenance system. Besides looking unkempt, it is totally inhospitable, because of the heated liquid. As the repository of the molten material, the vessel also holds some form of solid residues (for example, oxides, salts, and organics) from all items that have been dipped since its last thorough cleaning. It is also likely to contain parts of fixtures, parts that fell off the rack, dripped braze alloy, and other substances.

For the most efficient performance, it is necessary to clean the pot daily. The material (that is, sludge) that collects on the vessel bottom stays soft for a short time and should be removed on a regular basis. Chipping and hammering to remove hardened sludge material on cemented fire brick can shorten the life of the pot. Common techniques for removing sludge before hardening include scraping and scooping. Scooping tools should be ventilated to allow the liquid to drain back into the pot. Disposal of the sludge should conform to environmental regulations. Sludge buildup causes problems with both bath chemistry and heating. If allowed to remain, the buildup will eventually either produce poor-quality brazements or cause damage to the pot.

Dip Brazing

Daryl D. Peter, Daryl D. Peter and Associates

Applications

The use of dip brazing in a molten filler metal bath is limited to the brazing of wire, small components, and aluminum return bends, whereas dip brazing in a molten-salt (flux) bath is used extensively for the brazing of aluminum, copper, and ferrous alloys (Table 1).

TABLE 1 PARAMETERS FOR MOLTEN-SALT DIP BRAZING OF SELECTED ALLOY ASSEMBLIES

WORKPIECE ALLOY(S)	TEMPERATURE		FILTER METAL	SALT
	°C	°F		
ALUMINUM	540-615	1000-1140	[A]	FLUORIDE-CHLORIDE-BASE
COPPER	815-870	1500-1600	BCUP[B]	CHLORIDE-BASE
FERROUS	915-955	1675-	RBCUZN	CHLORIDE-BASE +

		1750		BORAX[C]
	980-1205	1800-2200	BNI	CYANIDE-BASE
	1120	2050	BCU	CHLORIDE-BASE
FERROUS AND NONFERROUS	675-1010	1250-1850	BAG[D]	CHLORIDE-BASE

(A) SALT ACTS AS BOTH FILLER METAL AND HEATING MEDIUM.

(B) SELF-FLUXING.

(C) NO DEZINCIFICATION TAKES PLACE.

(D) SEPARATE FLUX REQUIRED.

Dip-brazed parts are ideally suited for limited as well as high-production runs. The method of applying the process can be either manual or automatic. The process is used to braze small to very large assemblies with multiple or hidden joints. It is appropriate for all metals that can be brazed and is particularly suited for aluminum and other alloys that have melting points very close to the brazing temperature. The brazing operation can also simultaneously serve as a source for heat treating, carburizing, or cyaniding.

Carbon and Low-Alloy Steels

The types of salts used in the dip brazing of carbon and low-alloy steels are neutral chloride salts, neutral chloride salts plus a fluxing agent such as borax or cryolite, and carburizing and cyaniding salts, which are also fluxing types of salts. Specific types and compositions of brazing salts and temperatures used for brazing of carbon and low-alloy steels with various filler metals are given in Table 2.

TABLE 2 TYPICAL SALTS USED FOR MOLTEN-SALT DIP BRAZING OF CARBON AND LOW-ALLOY STEELS WITH SELECTED FILLER METALS

FILLER METAL	TYPE OF SALT	NOMINAL COMPOSITION, %	BRAZING TEMPERATURE RANGE[A]	
			°C	°F
BAG-1 THROUGH BAG-8, AND BAG-18	NEUTRAL	55 $BACL_2$, 25 NACL, 20 KCL	620-870	1150-1600
	CYANIDING-FLUXING	20-30 NA_2CO_3, 20-30 KCL, 30-40 NACN	650-870	1200-1600
	NEUTRAL	50 NACL, 50 KCL	730-870	1350-1600
RBCUZN-A	NEUTRAL	80 $BACL_2$, 20 NACL	915-940	1675-1725

	FLUXING	79 $BACL_2$, 20 NACL, 1 BORAX	915-940	1675-1725
	CARBURIZING-FLUXING (WATER SOLUBLE)	30 NACL, 30 KCL, 20 CARBONATE, 15-20 NACN, ACTIVATOR (PROPRIETARY)	915-940	1675-1725
	CARBURIZING AND SELF-FLUXING	50 CARBONATE, 50 CHLORIDE WITH GRAPHITE ADDITION(B)	815-925	1500-1700
RBCUZN-D	NEUTRAL	90 $BACL_2$, 10 NACL	1040-1050	1900-1925
BCU-1 AND 1A	NEUTRAL	95 $BACL_2$, 5 NACL	1095-1150	2000-2100
	NEUTRAL	100 $BACL_2$	1095-1150	2000-2100

(A) TEMPERATURES SHOWN ARE THOSE OF THE SALT BATH.

(B) USED WITH MECHANICAL AGITATION

Neutral salts, so called because normally they do not add or subtract anything from the surface of the steel being treated, protect the surface from attack by oxygen in the air. Oxide on the workpiece, however, cannot be reduced by the salt, and a flux must generally be provided.

The neutral salts are mildly oxidizing to steel when they are used at recommended austenitizing temperatures. The oxides produced by heating steel in molten salt are largely soluble; hence, the steel is scale-free after heating. The accumulation of oxide in the molten salt, however, progressively makes the salt more decarburizing, and for this reason baths may require periodic rectification.

Flux that is applied to the surface of the assembly and dried before the assembly is immersed in the neutral salt will be quickly dissipated by dissolving in the salt or escaping from the surface of the bath as a volatilized salt or gas. For this reason, there is generally no difficulty in removing flux from an assembly that has been brazed in a salt bath.

Fluxing agents, such as borax and cryolite, are added to neutral chloride salts to produce a fluxing environment in the bath. When these fluxing agents are used with silver alloy or copper-zinc filler metals, periodic flux additions are required to maintain the fluxing potential of the bath. Above 650 °C (1200 °F), the fluxing potential can decrease rapidly because of oxidation from contact with air or the parts being brazed; therefore, the fluxing agent must be replenished more frequently.

Carburizing and cyaniding salts provide their own fluxing action. In addition, they supply carbon or carbon and nitrogen to the surface of the steel assembly as it is being brazed. Although silver brazing alloys have been used successfully, RBCuZn-A filler metal is generally preferred. A case depth of up to 0.30 mm (0.012 in.) can be obtained without adversely affecting the quality of a joint brazed with this copper-zinc filler metal.

Fluxes. An adequate fluxing environment is needed to ensure good flow and penetration of the brazing alloy in molten-salt-bath dip brazing. When brazing is done in a neutral flux chloride salt bath, an active flux is usually applied to the assemblies before brazing. Generally, the application of additional flux to the assembly isnot necessary when using a cyanide bath or another active fluxing bath.

Flux can be applied by brushing, dipping, or spraying the parts to be brazed before, during, or after assembly. After flux application, if any moisture is present, the assemblies must be preheated to dry them before immersion in the salt bath. Typical fluxes employed for prefluxing carbon steels and low-alloy steels that are to be brazed in a salt bath are American Welding Society (AWS) types 3A and 3B.

A temporary insulating cocoon of frozen salt forms instantly around a piece of cold metal when it is immersed in a molten-salt bath, and externally located filler metal can reach the melting temperature range before the workpiece has reached a temperature high enough for proper wetting to take place. When this occurs, the molten filler metal flows away from the joint with no brazing. This can be avoided either by preheating the assembly to a temperature above the melting range of the flux or by relocating the filler metal inside the joint in grooves, recesses, or drilled holes.

Filler Metals. The brazing filler metals shown in Table are the most widely used for molten-salt-bath dip brazing of carbon and low-alloy steels. Although silver alloys BAg-13 and 13A (not shown in Table 2) can be used for brazing in a molten-salt bath, they have been supplanted in most applications by copper-zinc alloys, which are less costly and have similar brazing temperature ranges. The rapid heating rate and nonoxidizing environment in a salt bath minimize dezincification of copper-zinc alloys, thereby facilitating the use of these alloys.

The brazing filler metal must be in contact with the joint. Filler metals in the form of wire, strip, powder, paste, and cladding are available. Special preform rings or other shapes can be obtained for specific joint requirements.

For additional information, see the article "Brazing of Carbon Steel and Cast Iron" in this Volume.

Stainless Steels

The brazing of stainless steel by immersing all or a portion of the assembly in molten salt offers essentially the same advantages that would apply to brazing similar assemblies made of carbon steel. The same limitations are also applicable. See the article "Brazing of Stainless Steels" in this Volume for more information.

Cast Irons

One of the more-common applications for the dip brazing of cast iron is the joining of steel tubing to headers, special fittings, and stanchions. Various mechanical assemblies are brazed to cast iron because different metal properties are needed in different parts of the assembly or, more often, because the fitting portion of such an assembly can be made most economically from cast iron.

Assemblies containing malleable iron castings are water quenched to remove the brazing salt--a practice that is common with steel assemblies. To avoid warpage and cracking, however, brazed assemblies containing gray and ductile iron castings should never be water quenched from the brazing temperature. Instead, the assemblies should be cooled slowly to about 150 °C (300 °F) and then immersed in water to remove the salt.

For additional information, see the article "Brazing of Carbon Steel and Cast Iron" in this Volume.

Aluminum Alloys

The best method of heating and fluxing aluminum joints simultaneously is to immerse the entire assembly in a bath of molten flux. Because of the low specific heat of flux, assemblies usually are heated to about 540 °C (1000 °F) prior to flux immersion. Dip brazing has been used successfully in the manufacture of complex, multiple-joint heat exchangers.

Immersing the entire assembly into molten flux has many advantages. Heat is applied to all parts simultaneously and uniformly, and air is replaced by a buoyant and surface-active environment, promoting brazing filler metal flow. In addition, the uniform temperature permits production assembly of parts with dimensional tolerances as low as ±0.05 mm (±0.002 in.) or even less.

Heat-transfer units assembled from alternate corrugated and flat aluminum brazing sheets or from various crimped and formed pieces are examples of the type of work that dip brazing can handle advantageously. Units weighing up to 9 Mg (20,000 lb) have been joined by dip brazing. Certain designs have to withstand a service pressure of 8 MPa (1150 psi). Brazing sheet is essential to this type of work, reducing assembly and brazing costs. The rapid and even heating and flux buoyancy minimize distortion.

For assemblies designed with components in close proximity, flux removal can be tedious and expensive. For instance, when components such as those of a heat-exchanger matrix are spaced closer than 3.2 mm ($\frac{1}{8}$ in.), the flux holds to the surfaces by surface tension and capillary action; it will not drain from the components freely. This is not as great a problem with spacings greater than 3.2 mm ($\frac{1}{8}$ in.) between components of normal length; wider spacing of long components is desirable.

For additional information, see the article "Brazing of Aluminum Alloys" in this Volume.

Dip Brazing

Daryl D. Peter, Daryl D. Peter and Associates

Safety Precautions

When dip-brazing furnaces contain flux, corrosion of the surroundings is a problem. Ventilation is critical, and protection of all metal exposed to the fumes is mandatory. Scrubbers are often required for the air removed from above the liquid.

Safety equipment, such as full-face protection, heat suits, heat shields, and gloves, should be required when working around molten flux or metal. Clothing of synthetic fibers should be prohibited. In addition, nothing wet or even damp should be immersed, because the resulting burst of steam may blow the molten material over anyone standing near the flux furnace installation.

Resistance Brazing

Allen Cedilote, Industrial Testing Laboratory Services

Introduction

RESISTANCE BRAZING (RB) is a resistance joining process. The workpieces are heated locally, and the filler metal that is preplaced between the workpieces is melted by the heat generated from resistance to the flow of electric current through the electrodes and the work. In the usual application of RB, the heating current is passed through the joint itself. Equipment is the same as that used for resistance welding, and the pressure needed for establishing electrical contact across the joint is ordinarily applied through the electrodes (Fig. 1). The electrode pressure is also the usual means for providing the tight fit needed for capillary behavior in the joint. The heat for resistance brazing can be generated mainly in the workpieces themselves, in the electrodes, or in both, depending on the electrical resistivity and dimensions.

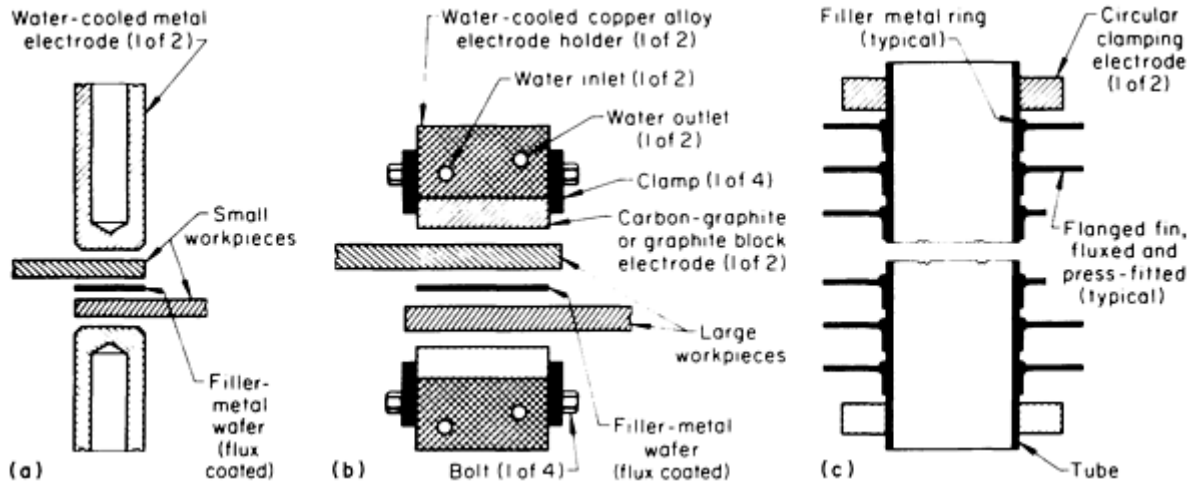

FIG. 1 TYPICAL SETUPS FOR RESISTANCE BRAZING. (A) FOR SMALL PARTS OR SMALL FLAT PORTIONS OF LARGER COMPONENTS, USING OPPOSED WATER-COOLED METAL ELECTRODES OF THE CONVENTIONAL RESISTANCE WELDING TYPE. (B) FOR LARGE FLAT PARTS, TYPICALLY OF A HIGHLY CONDUCTIVE METAL (FOR EXAMPLE, COPPER), USING OPPOSED CARBON BLOCK ELECTRODES ATTACHED TO WATER-COOLED COPPER ALLOY ELECTRODE HOLDERS. (C) FOR JOINING FLANGED FINS TO A TUBE, USING CIRCULAR CLAMPING ELECTRODES

Resistance brazing is used for many applications involving small workpieces, for small joints that are part of very large equipment, or for low-volume production runs because it provides:

- VERY RAPID AND HIGHLY LOCALIZED HEATING
- FLAMELESS, CLEAN OPERATION
- PRECISE BRAZING THAT IS EASY TO CONTROL
- HIGH-QUALITY JOINTS WITHOUT EXTENSIVE OPERATOR TRAINING
- EQUIPMENT COST SAVINGS (ONE TRANSFORMER AND A PAIR OF ELECTRODES CAN BE USED FOR A WIDE VARIETY OF JOINT DESIGNS)
- EASY PORTABILITY IN SOME OF ITS EQUIPMENT (FIG. 2)

However, RB is impractical for:

- JOINT AREAS THAT EXCEED APPROXIMATELY 1300 MM^2 (2 $IN.^2$)
- WORKPIECES THAT ARE LARGE OR HEAVY
- WORKPIECES THAT HAVE VARIABLE THICKNESS OR COMPLEX CONTOURS

Resistance Brazing

Allen Cedilote, Industrial Testing Laboratory Services

Process Parameters

Workpiece material, workpiece size and shape, and joint design are the major factors that must be considered in developing a detailed RB procedure. The workpiece material is of primary importance because it has the greatest influence on the choice of electrode material and on the type of filler metal selected (see the Sections "Brazeability and Solderability of Engineering Materials" and "Procedure Development and Practical Considerations for Brazing and Soldering" in this Volume).

High-resistance workpieces should be brazed with low-resistance electrodes; conversely, high-conductivity (that is, low-resistance) workpieces must be brazed with low-conductivity electrodes. If at least one workpiece is made of a high-resistance material and if that workpiece is of sufficient mass, then the electrodes can be a high-conductivity material, such as a chromium-copper alloy (UNS C18200). When such an RB electrical circuit (which includes not only the transformer and electrodes but also at least one workpiece) is energized, heat will be generated within the high resistance circuit component of the circuit (that is, the workpiece). Conversely, if all workpieces have low electrical resistance, then the brazing current flowing through them will not generate enough heat to melt the filler metal. In this case, the electrodes must supply the necessary heat by virtue of their electrical resistance. Consequently, in resistance brazing high-conductivity workpieces, graphite (and in some cases, tungsten or molybdenum) electrodes are used. The heat generated in the electrodes flows into the workpieces by conduction or convection through the electrode-to-workpiece contact areas.

Assuming that the brazing procedure is fundamentally correct and capable of yielding properly bonded workpieces, there are a number of factors that strongly affect the quality of an RB joint. In descending order of priority, the factors that contribute to high quality in an RB joint are:

- CLEANLINESS OF THE WORKPIECES AND FILLER METAL SURFACES
- PROPER FIT BETWEEN THE WORKPIECES
- UNIFORMITY OF HEATING TO BRAZING TEMPERATURE
- MAINTAINING UNIFORM TEMPERATURE DURING BRAZING
- AVOIDING OVERHEATING
- MAINTAINING THE BRAZING TEMPERATURE FOR NO LONGER THAN SPECIFIED
- KEEPING THE PROPER LEVEL OF PRESSURE ON THE WORKPIECES DURING BRAZING

Each of these vital factors is influenced by the joint/workpiece design and the brazer's skill, experience, and ability to focus on the dynamic details of the process.

Workpiece and braze filler metal cleanliness is an absolute requirement for all types of brazing. In particular, cleanliness is of utmost importance in RB because in torch, furnace, and induction brazing the gaseous atmosphere around the workpieces can be controlled relatively easily to decompose surface oxides. Almost all common contaminants (grease, oil, perspiration, dust, abrasive particles, and oxides) are effective barriers to braze metal flow. At brazing temperature, most of these contaminants either vaporize or outgas, and because gases expand when heated, they can prevent bonding over a large area when confined within the braze joint.

Regardless of the electrical conductivity of the electrodes or workpieces, it is important to position and maintain the electrodes so as to sustain maximum electrode-to-workpiece contact through the entire brazing cycle. In addition, although it is preferable for the electrode-to-workpiece contact area to equal that of the braze joint in order to achieve even heating, the contact area should be no less than half the area of the braze joint.

For high-conductivity electrodes, maximum contact area is an optimum condition because:

- ELECTRODE-TO-WORKPIECE INTERFACE RESISTANCE IS MINIMIZED, THEREBY PROLONGING ELECTRODE LIFE AND ELIMINATING LOCALIZED HOTSPOTS ON THE WORKPIECE
- CURRENT FLOW INTO THE WORKPIECE WILL BE MORE EVENLY DISTRIBUTED, THUS HEATING THE WORKPIECE MORE UNIFORMLY

For low-conductivity electrodes, maximum contact area is even more critical because the workpieces are heated only by conduction from the electrode surfaces.

Because molten braze filler metal tends to flow to the hottest region in the joint, uniform heating is vitally important in achieving a uniform brazed joint. Therefore, it is necessary that the shape of the electrodes conform closely to the contour of the workpieces.

Pressure on the workpieces must be controlled carefully in order to achieve a properly bonded joint. Thermal expansion (and, commonly, differential thermal expansion in dissimilar joints) of the workpieces and electrodes must be allowed for. On one hand, too much pressure can squeeze molten filler metal out of the joint. Excessive pressure can cause the formation of a complete fillet around the joint perimeter while little or no bonding exists within. On the other hand, insufficient pressure can allow an unacceptably thick layer of filler metal to remain in the joint, which can result in a low-strength brazement that could fail prematurely in service.

Resistance Brazing

Allen Cedilote, Industrial Testing Laboratory Services

Equipment and System Selection

Resistance brazing may be classified as either manual or automatic, with manual resistance brazing being by far the most widely used.

In both manual and automatic RB, the kinds and models of transformers that provide the power are the same as those used for resistance welding. In many cases that involve high-resistance workpieces, the electrodes are also the same as those used in resistance welding applications. Welding transformers for RB can be purchased with automatic current/voltage controls, timers, electrode motion and pressure controls, and even automatic parts-handling devices, presuming that the production run is sufficient to warrant the added investment and a complexity of process optimization.

For manual RB, electrodes are usually incorporated into tongs made of chromium-copper, silver-tungsten, or copper-tungsten (for high-resistivity workpieces), and graphite, molybdenum, or tungsten (for low-resistivity workpieces). Graphite is the most common material for high-resistance electrodes because of its low cost and easy machinability. In addition, because it is not wetted by molten braze filler metals, there is no danger that graphite electrodes will be brazed to the workpieces. However, hot graphite is attacked by atmospheric oxygen during the brazing process. Thus, graphite electrodes must be inspected often and dressed as needed in order to maintain good workpiece contact. Special oxidation-resistant grades are available from graphite suppliers.

There is no standard design for manual RB tongs. Most RB organizations design and fabricate their own. As a result, there is an enormous variety of manual RB tongs and electrodes. However, the various types do contain some common elements; for example:

- WATER-COOLED, QUICK-RELEASE ELECTRODE CLAMPS (USUALLY MADE OF COPPER OR COPPER-CHROMIUM)
- WATER-COOLED CABLES FROM THE TRANSFORMER TO THE TONGS
- NONCONDUCTIVE HANDLES
- INSULATION OF THE ELECTRODES FROM EACH OTHER
- GROUND-FAULT INTERRUPTER PROTECTION

- INSULATING SHIELDS TO PREVENT INADVERTENT CONTACT WITH HOT OR ELECTRICALLY ENERGIZED AREAS

Resistance Brazing

Allen Cedilote, Industrial Testing Laboratory Services

Metal Electrodes

Selection of electrode material for RB depends on the electrical conductivity of the workpieces to be joined, the design and dimensions of the joint, appearance requirements for the brazed product, susceptibility of the workpieces to damage or marking, pressure needed on the work, production quantity of brazed joints, and cost of reconditioning or replacing an electrode.

The materials used most frequently in RB are RWMA class 2 (chromium-copper), RWMA class 14 (molybdenum), and various grades of carbon-graphite and graphite. Other standard and special electrode materials are sometimes used for special applications.

Class 2 (chromium-copper), a general-purpose resistance welding electrode material with a minimum electrical conductivity of about 75% IACS, is usually used to make electrode holders and shanks of faced electrodes for RB.

Refractory metal electrodes include class 14 (molybdenum), which is intermediate in mechanical and electrical properties in that classification, having a nominal electrical conductivity of 30% IACS. This material and RWMA class 13 (tungsten), because of resistance to high temperatures and nonsticking characteristics, are the only common electrode materials that have long life in resistance brazing of copper and other highly conductive nonferrous metals (i.e., aluminum and precious metals). They are about equal in electrical conductivity.

Class 14 (molybdenum) is generally preferred because class 13 (tungsten) is harder to machine and is likely to develop radial cracks in service. For reasons of economy, common practice is to use facings, buttons, or inserts of the refractory metal instead of making the entire electrode of the refractory metal.

Special electrode materials are sometimes needed to meet the unusual requirements of specific RB applications. An electrode made of 60% Pt and 40% Rh provides long life in the high-speed mass-production RB of insulated copper wires to copper terminal pads clad with BCuP-5. This electrode can withstand the heating used to melt the polyurethane insulation on the copper wire, the contact with molten BCuP-5 filler metal, and the heating in air used for burning off insulation residues after each brazed connection is made. This electrode material can be used at temperatures approaching 925 °C (1700 °F).

Carbon Electrodes

Ordinarily, two general types of carbon electrodes are used in RB: carbon-graphite and electrographite (artificial graphite). These electrode materials are made by simultaneously heating and blending the finely divided raw materials with coal tar pitch, which serves as a binder.

The stock from which RB electrodes are made comprises a few of the many grades of carbon stock that are manufactured primarily for use in melting ferrous and nonferrous metals. Composition and properties of the commercial carbon electrode materials vary; no generally accepted industry standards and terminology exist. The properties of five grades that are generally typical of the materials used in carbon electrodes for resistance brazing are given in Table 1.

TABLE 1 PROPERTIES OF FIVE CARBON ELECTRODE MATERIALS USED IN RESISTANCE BRAZING

GRADE	ELECTRODE MATERIAL	ELECTRICAL RESISTIVITY		SCLEROSCOPE HARDNESS	FLEXURAL STRENGTH (MINIMUM)		APPARENT DENSITY	
		μΩ· mm	Ω· in.		mpa	ksi	g/cm^3	$lb/in.^3$
1	CARBON-GRAPHITE, HARD(A)	20	0.00080	70	24	3.5	1.74	0.0629
2	CARBON-GRAPHITE, HARD, OXIDATION RESISTANT(B)	20	0.00080	70	24	3.5	1.75	0.0632
3	CARBON-GRAPHITE, SOFT	19	0.00075	40	16.5	2.4	1.57	0.0567
4	ELECTROGRAPHITE(A)	11	0.00042	50	17.2	2.5	1.73	0.0625
5	ELECTROGRAPHITE, OXIDATION RESISTANT(B)	11	0.00042	50	17.2	2.5	1.75	0.0632

(A) THIS TYPE OF CARBON ELECTRODE MATERIAL IS ALSO FREQUENTLY USED IN AIR CARBON ARC CUTTING.

(B) SIMILAR TO THE ELECTRODE MATERIAL LISTED IMMEDIATELY ABOVE, BUT IMPREGNATED WITH A SMALL PERCENTAGE OF AN OXIDATION RETARDANT, USUALLY AN INORGANIC COMPOUND CONTAINING BORON OR PHOSPHORUS, FOR LONGER LIFE

Carbon-Graphite. The first three types of electrode materials listed in Table 1 are called carbon-graphite. They are made from mixtures of finely ground petroleum coke (carbon) and natural or artificial (electro) graphite with coal tar pitch. These electrode materials are extruded in suitable shapes and heated in an electric furnace at about 815 °C (1500 °F) to develop the desired properties shown in Table 1. The heating converts about half of the pitch to carbon; the remainder is driven off as gases.

The final properties can be varied from those shown by changing the proportions of the raw materials, the particle size, and the time and temperature of heating. Increasing the ratio of graphite to carbon in the mixture, prolonging the heating time, or increasing the temperature lowers resistivity, hardness, and strength. Density is influenced chiefly by particle size.

Oxidation resistance for some grades of carbon-graphite is improved, for longer electrode life, by impregnating the cured material with a small percentage of an oxidation retardant, usually an inorganic compound that contains boron or phosphorus. In Table 1, oxidation-resistant grades 2 and 5 are the same as grades 1 and 4, respectively, except for the presence of an additive of this type.

Electrographite Electrode Material. Carbon-graphite grades and electrographite materials are produced in the same way except that the extruded mixture of raw materials is heated in "beehive" furnaces at about 2480 to 2705 °C (4500 to 4900 °F) for approximately four weeks, thus converting the mixture to graphite (called artificial graphite or electrographite). Properties of a representative material of this type and of an oxidation-resistant or long-life impregnated form of the same material are given in Table 1. Resistivity, hardness, and flexural strength of electrographite electrode materials are substantially lower than for the hard carbon-graphite electrode materials.

Selection of Carbon Electrode Material. The general types of carbon electrode material shown in Table 1 (carbon, graphite, and electrographite) have almost completely replaced the formerly used straight-carbon types, which are made by heating finely ground petroleum coke and a binder at about 815 °C (1500 °F). The straight-carbon grades typically have an electrical resistivity of about 51.2 μΩ· mm (0.0020 Ω· in.) and a Scleroscope hardness of about 100. Machining of these materials is much more difficult and costly than that of carbon-graphite and electrographite.

The hard carbon-graphite types are general-purpose materials and are preferred for most RB with carbon electrodes because brazing temperatures can be reached with less current than when the less-resistive electrographite types are used. Electrographite is preferred for RB of metals that have a high surface resistance, particularly when one of the metals being joined is steel or another iron-base alloy. Soft carbon-graphite material combines high heating capacity with a low tendency to produce local hot spots on the workpieces, but has comparatively low wear resistance. The first and fourth grades in Table l are the same types of material ordinarily used in air-carbon arc cutting.

In RB with carbon electrodes, nonuniform current flow and resultant local overheating of the electrodes can shorten electrode life excessively. To prevent this, carbon electrodes must be tightly fitted into matching tapered adapters or clamped securely to the electrode holder making contact with the holder over as large an area as possible. Provision also must be made for adequate flow of cooling water in the electrode holder. In addition, some carbon brazing electrodes are electroplated or sprayed with a copper coating about 0.05 mm (0.002 in.) in thickness to reduce contact resistance against the electrode holder and to minimize internal temperature buildup in the carbon electrode.

Design of Electrodes

Commercially available resistance seam welding electrodes are used where the design and dimensions of workpiece and joint permit. The electrode tip is machined, where necessary, to provide a tip shape and face dimensions suitable for the work. Carbon electrodes, depending on the size and design of the work, are in the shape of either standard metallic electrodes or flat blocks that may be several inches in length and width (size is usually limited by ability to obtain uniform heating and water cooling or by the current capacity of the power source).

When a high-resistance or long-wearing electrode is required, it is often used in the form of facings, inserts, or buttons that are attached to electrode shanks or bodies made of a less-expensive material. Electrode design is developed to work with workpiece and joint design in eliminating the need for holding and locating fixtures or clamps wherever possible and in permitting rapid and easy loading and unloading of workpieces, filler metal, and flux. Provision for water cooling of electrode holders and electrodes generally is the same as in resistance welding.

Filler Metals

Of the large number of filler metals available, only a few are used extensively in RB (Table 2). Selection of filler metal for RB is similar to that for other brazing processes and is discussed in the Section "Procedure Development and Practice Considerations for Brazing and Soldering" in this Volume.

TABLE 2 COMPOSITION AND THERMAL PROPERTIES OF SELECTED FILLER METALS USED FOR RESISTANCE BRAZING OPERATIONS

AWS CLASS	UNS NUMBER	COMPOSITION, WT%						LIQUIDUS		SOLIDUS

Source: Ref 1

More attention is given in RB to selecting compatible filler metals having the lowest brazing temperature, because in RB, the maximum local temperature reached by the work must be kept as low as possible, while providing uniform heating of the faying surfaces and the filler metal. Fluidity of the filler metal is not critical in most RB, because the filler metal is

usually preplaced and the bond area is relatively large. The general types of filler metal usually selected for resistance brazing various classes of work metals are:

WORKPIECE METAL	FILLER METAL ALLOYS
STEEL, STAINLESS STEEL, HEAT-RESISTANT ALLOYS, COPPER, COPPER ALLOYS, NICKEL ALLOYS	SILVER (BAG TYPE)
ALUMINUM ALLOYS	AL-SI
COPPER AND COPPER ALLOYS	CU-P

These types of filler metal all have relatively low brazing temperatures (Table 3).

TABLE 3 SOLIDUS, LIQUIDUS, AND BRAZING TEMPERATURES FOR SELECTED RESISTANCE BRAZING FILLER METALS

FILLER METAL	SOLIDUS		LIQUIDUS		BRAZING TEMPERATURE	
	°C	°F	°C	°F	°C	°F
BCUP-2	710	1310	795	1460	730-845	1350-1550
BCUP-5	645	1190	800	1475	705-815	1300-1500
BAG-1A	625	1160	635	1175	635-760	1175-1400

Silver Alloys. Of the silver alloy (BAg type) group of filler metals, the two most often used are BAg-1 and BAg-1A, which are free-flowing alloys that permit the use of low brazing temperatures. In addition, their narrow melting ranges (-7 and -9 °C, or 20 and 15 °F, respectively) prevent liquation, making them insensitive to variations in the rate of heating or cooling. Their narrow melting ranges are also advantageous in step brazing. For making corrosion-resistantbrazed joints in stainless steel, BAg-3 and BAg-18 are preferred.

Aluminum-Silicon Alloys. Aluminum-silicon alloys (BAlSi type) are used in the RB of aluminum alloys. These low-melting alloys are available in sheet or wire form; BAlSi-2 and BAlSi-5 are also available as cladding on aluminum brazing sheet. Temperature must be controlled with special care in brazing of the lower melting brazeable aluminum alloys, such as wrought alloy 6151 (UNS A96151) and cast alloys 443.0 (UNS A04430) and 356.0 (UNS A03560), because the melting range of these filler metals approaches closely or overlaps the melting range of the work metal.

Copper-Phosphorus Alloys. Filler metals of copper-phosphorus alloys (BCuP type) are widely used for resistance brazing of copper and copper alloys. They are low-cost, general-purpose filler metals and have the special advantage of being self-fluxing on copper (by virtue of their phosphorus content), although flux is ordinarily needed when using them on copper alloys because phosphorus does not reduce metallic oxides other than those of copper. BCuP-5 is by far the most frequently used of the group.

In some applications on copper or copper alloys, the wider melting range, higher working temperature, and lower ductility of the BCuP filler metals make them less suitable than the BAg types. For example, in applications requiring higher ductility and corrosion resistance, silver brazing alloys are sometimes preferred to the BCuP filler metals for brazing of copper, despite the resulting need for fluxing. The difficulty in restricting flow of BCuP filler metals to joint surfaces may be a disadvantage.

Diffusion Brazing

W. Daniel Kay, Wall Colmonoy Corporation

Introduction

DIFFUSION BRAZING (DFB) is a process that coalesces, or joins, metals by heating them to a suitable brazing temperature at which either a preplaced filler metal will melt and flow by capillary attraction or a liquid phase will form *in situ* between one faying surface and another. In either case, the filler metal diffuses into the base metal until the physical and mechanical properties of the joint become almost identical to those of the base metal. Pressure may or may not be applied to accomplish this.

"Diffusion bonding," a term that can refer to either diffusion brazing or diffusion welding, is now considered to be a nonstandard term. Where diffusion brazing is required, it should be clearly specified, However, in the aerospace industry, diffusion brazing is still commonly referred to by such tradenames as Activated Diffusion Bonding (ADB), Activated Diffusion Healing (ADH), and Transient Liquid-Phase Bonding (TLP). In each case, the process is actually diffusion brazing.

Two critical aspects of DFB are:

- A *LIQUID* FILLER METAL MUST BE FORMED AND BECOME ACTIVE IN THE JOINT AREA.
- EXTENSIVE DIFFUSION OF FILLER METAL ELEMENTS INTO THE BASE METAL MUST OCCUR.

This diffusion process often results in the total loss of identity of the original brazed joint (Fig. 1).

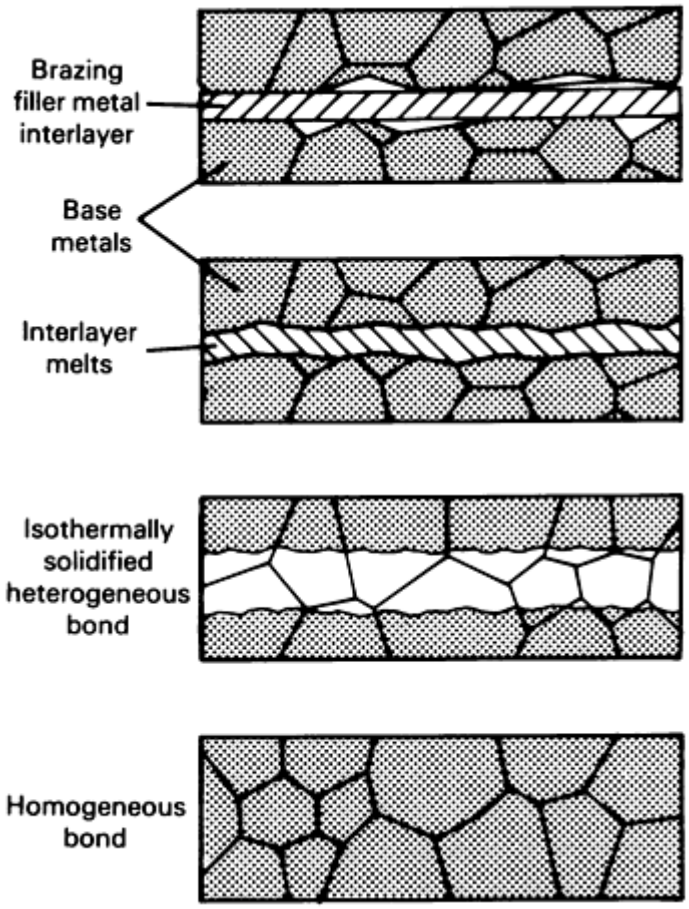

FIG. 1 DIFFUSION PROCESS RESULTING IN LOSS OF IDENTITY OF ORIGINAL BRAZED JOINT

Diffusion Brazing

W. Daniel Kay, Wall Colmonoy Corporation

Diffusion Brazing Processes

The most advanced diffusion brazing processes are used in the aerospace industry, particularly for brazements involving titanium, nickel, cobalt, and aluminum alloys. However, many similar and dissimilar metal combinations can be diffusion brazed, because diffusion is involved in all brazing processes, to a lesser or greater extent.

Although diffusion brazing is commonly performed in furnaces specifically set aside for brazing or heat treating, it is also possible to initially braze two components together by induction heating or by torch brazing, and then place the brazement into a furnace for the extended diffusion cycle. This cycle can range from 30 min to 80 h, or even longer.

As an example of a typical DFB process, a round bar of 304L stainless steel was diffusion brazed (end-to-end) to a round bar of pure copper in a furnace at 930 °C (1700 °F) for 60 min at temperature, using pure dry hydrogen as the atmosphere. The laying surface of the stainless steel was electrolytically plated with about 0.13 mm (0.005 in.) of pure silver. As this assembly was heated (without external pressure), the silver and copper diffused together to form a liquid eutectic filler metal alloy (72Ag-28Cu) in the butt joint at 780 °C (1435 °F), which metallurgically bonded the stainless steel and copper bars together permanently. When the brazement was subsequently heated in another furnace at 1040 °C (1900 °F), with a weight attached to the copper side of the part (in an effort to remelt the braze joint and take the brazement apart), it was found that the copper elongated until the pure copper portion of the part, rather than the brazed joint, failed. Diffusion had been complete enough that the remelt temperature of the brazement approached that of pure copper.

This example shows that, once the liquid has been distributed throughout the joint area, the assembly should be held at the brazing temperature long enough for one or more of the filler metal elements to adequately diffuse into the base metals (and vice versa). In this way, the mechanical properties of the brazed joint area become essentially identical to those of either or both of the base metals.

The amount of diffusion that occurs will be a function of:

- THE BRAZING TEMPERATURE
- THE LENGTH OF TIME THE PART IS HELD AT TEMPERATURE
- THE QUANTITY OF FILLER METAL AVAILABLE FOR DIFFUSION
- THE MUTUAL SOLUBILITY OF FILLER METAL AND THE BASE METALS

A fully diffused joint will lose all joint identity because of base-metal grain growth across the entire joint (Fig. 2).

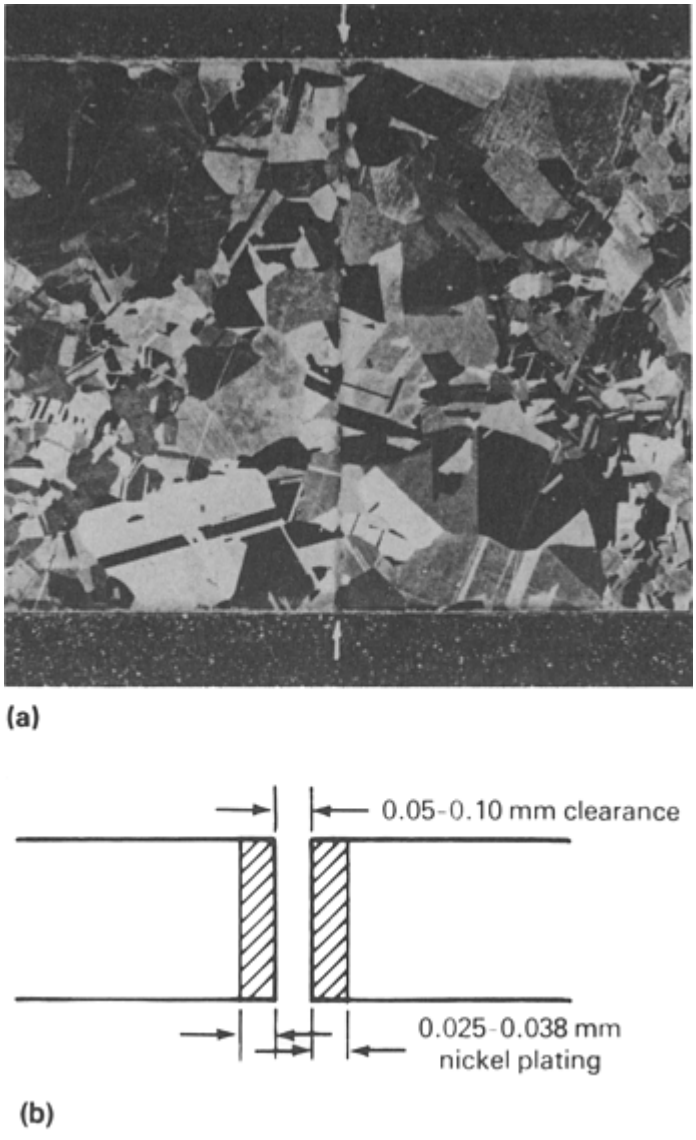

FIG. 2 DFB JOINT ILLUSTRATING HOW THE BRAZING FILLER METAL AND NICKEL PLATE DIFFUSED INTO THE BASE METAL, ALMOST OBLITERATING THE JOINT. SPECIMEN: NICKEL-PLATED NIMONIC 80A 6.4 MM (0.252 IN.) TENSILE TEST BAR MACHINED FROM RECTANGULAR BRAZED BLOCKS. BRAZING PROCEDURE: 30 MIN AT 1175 °C (2150 °F); NICROBRAZ 125 BRAZING FILLER METAL; AGED AFTER BRAZING. (A) MACROSTRUCTURE OF JOINT. 8×. (B) SCHEMATIC OF JOINT

When a brazement is to be made using either a preplaced sheet of filler metal or a layer of filler metal powder, it is wise to apply pressure to the assembly so that, when filler metal becomes molten, the gap between the two base metals is reduced. As an example of this process, a cobalt-base alloy was diffusion brazed at 1120 °C (2050 °F) in a vacuum furnace using a nickel-chromium-boron filler material in sheet form. The assembly was held at temperature for 8 h. Even though the solidus of the filler metal was only 970 °C (1780 °F), the braze joint completely lost its identity through diffusion, and the resulting remelt temperature was above 1370 °C (2500 °F). In this case, pressure was applied using simple weights on top of the part. Because the filler metal contained boron as a melting-point depressant, the diffusion of the boron out of the filler metal into the base metal caused the remelt temperature of the filler metal to rise. Because boron is also a very small atom, it very readily diffuses (as an interstitial atom) away from the joint as the temperature of the base metal rises.

Diffusion brazing is very advantageous for the effective joining of aerospace components that are intended for elevated-temperature service, such as jet engine hot-section parts. It is critical that they be able to perform well and safely at operating temperatures from 1040 to 1150 °C (1900 to 2100 °F). These objectives can be readily achieved when diffusion brazing is properly understood and used.

Diffusion Brazing

Exothermic Brazing

Donald W. Bucholz, IBM Federal Systems Corporation

Introduction

EXOTHERMIC BRAZING (EXB) is a process that utilizes the heat produced in a solid-state chemical reaction to melt a conventional filler metal or to produce molten filler metal as a product of the reaction.

When used to melt a conventional filler metal, exothermic brazing is similar to thermite welding (see the article "Thermite Welding" in this Volume) in that the heat required is derived from the chemical reaction, but it is different from thermite welding because only the heat is used. The brazing filler metal is not a component of the exothermic heat source and therefore does not include contaminants from the reaction.

When the EXB process is used to produce molten filler metal as a product of the reaction, an exothermic reaction occurs between two or more melting-point-depressant elements, which react to form a compound with a higher melting point. The result is an intermetallic compound that forms a heterogeneous filler metal. During this type of reaction, surface oxides are either displaced or disintegrated, which can eliminate the need for protective atmospheres or fluxes (Ref 1).

Exothermic Brazing

Donald W. Bucholz, IBM Federal Systems Corporation

Process Advantages and Disadvantages

Exothermic brazing is most frequently used to make brazed joints in remote locations, inaccessible areas, physically complex structures, or situations that require the application of localized heat for a brief period of time. The basic advantages of this process are:

- RAPID CYCLE TIME (20 TO 30 S)
- LOCALIZED APPLICATION OF HEAT
- SIMPLICITY AND PORTABILITY OF EQUIPMENT
- PREPLACEMENT OF FILLER METAL

Some disadvantages of the EXB process are:

- DIFFERING JOINT DESIGNS REQUIRE EXPERIMENTATION PRIOR TO ACTUAL PRODUCTION IN ORDER TO EFFECTIVELY BRAZE EXOTHERMICALLY
- SAFETY ISSUES THAT CONCERN HANDLING AND APPLICATION MUST BE THOROUGHLY EVALUATED WHEN USING IGNITABLE, HIGH-HEAT-PRODUCING MATERIALS
- FILLER METAL SELECTION IS LIMITED BY THE THERMODYNAMIC BEHAVIOR OF THE EXOTHERMIC MATERIAL

Types of Compounds

Exothermic compounds that generate enough heat to melt conventional filler metals have been developed for iron alloys, copper alloys, and refractory metals. Aluminum compounds that react and produce a heterogeneous filler metal can be used to join aluminum alloys.

The aerospace industry has utilized exothermic brazing to replace hydraulic fittings in corrosion-resistant steel tubing (AM-350 CRT). An example of this application using a commercial filler metal and an exothermic compound to braze a 25.4 mm (1 in.) outside diameter stainless steel tube with a 1 mm (0.04 in.) wall thickness has shown that a satisfactory braze joint can be made (Ref 2, 3). The exothermic compound in that example consisted of 30 g (1 oz) of 19.90% Mg, 51.84% NiO, 18.24% MnO, 4.24% Al, and 5.36% MnO_2.

Refractory metals exothermically brazed at approximately 1760 °C (3200 °F) with conventional filler metals, using either 24.9% B and 75.1% V_2O_5 or 19.8% B, 60.2% V_2O_5, 16.5% Ta_2O_5, and 6.8% Al as the exothermic compound, have shown minimal base metal recrystallization and braze filler metal/base metal interdiffusion (Ref 4).

Aluminum alloys have been brazed utilizing an exothermic compound consisting of powdered mixtures of: 3.5 g (0.12 oz) of 50% Al and 50% Mg; 10.0 g (0.35 oz) of 88% Al and 12% Si; and 13.5 g (0.48 oz) Al. The resulting intermetallic compound that forms the filler metal is composed of 27 g (0.95 oz) of 89.1% Al, 10.2% Mg_2Si, and 0.7% Si. More than a dozen of these types of exothermic brazing filler metals used with aluminum alloys are described in Ref 1 and 5.

Exothermic Brazing

Donald W. Bucholz, IBM Federal Systems Corporation

Equipment

The type of equipment used for exothermic brazing is shown in Fig. 1. The principal components are the joint itself, the brazing filler metal (if it is not a component of the exothermic compound), the exothermic compound, the igniter, the tubing sleeve insulation, and the container. Variations that utilize different joint designs, shielding gases, and external sources for preheating can also be used.

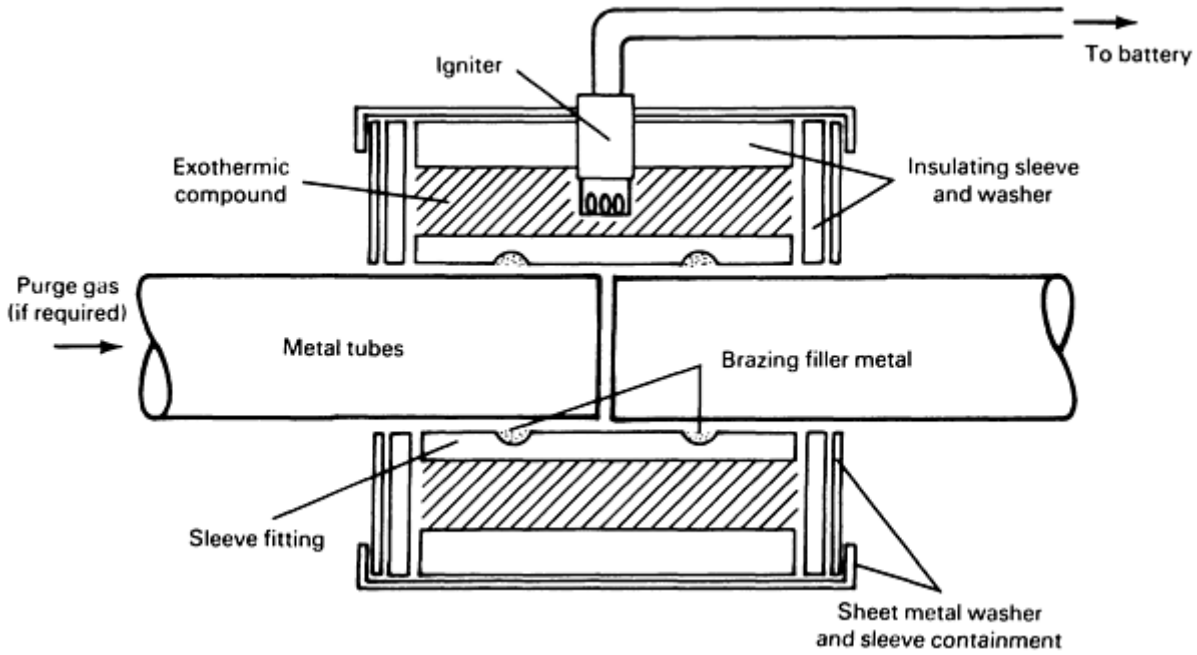

FIG. 1 TYPICAL ARRANGEMENT FOR EXOTHERMIC BRAZING OF TUBE. SOURCE: REF 2

A moderate amount of technical skill and knowledge of the fundamental principles, as well as empirical experience for the particular joining situation, are needed in order to make high-quality brazed joints. In addition to typical joint inspection methods and braze filler metal quality control requirements, exothermic brazing also can require lot control for exothermic compounds to ensure uniformity of performance.

Exothermic Brazing

Donald W. Bucholz, IBM Federal Systems Corporation

Procedure

When performing exothermic brazing, the standard steps that are followed in any other brazing process apply, such as joint design, alloy selection, and surface preparation. However, additional parameters must be considered: selection of exothermic compound, required quantity of exothermic compound, and brazing assembly configuration.

The typical effects of joint mass on the heat-up time and the mass of exothermic material that is required to achieve a specific temperature are shown in Fig. 2 and 3, respectively. The exothermic material is usually placed around or over the joint to be made, and an electric igniter is embedded in the exothermic compound. The assembly is typically insulated with ceramic or ceramic fiber and then covered and held in place with metal sheet or foil. The electrical leads of the igniter should be connected to a low-voltage battery. Once the assembly has been prepared, the battery and igniter circuit is closed, and the process runs to completion.

Brazing With Clad Brazing Materials

Sunil Jha, Michael Karavolis, Kevin Dunn, and James Forster, Texas Instruments, Inc.

Introduction

BRAZING is the preferred method for manufacturing complex assemblies such as heat exchangers, which contain a large number of joints (Ref 1). In the conventional plate-and-fin type of heat exchanger, the fins are brazed to the plates. Often, the brazing filler metal, which can be in the form of a foil, a paste, or a powder that has been consolidated into a sheet using a polymer carrier, is inserted between the plate and fin, and a multiple stack of plate, brazing foil, and fin is fixtured for brazing in a furnace. This complex assembly requires the precise fit of multiple components and the use of a flux, which allows the filler metal to "wet" the surfaces to be joined. To reduce part count and thereby simplify the assembly operation, the brazing filler metal can be clad to the plate material by a roll bonding technique.

This article focuses on clad brazing material, which is defined as any base material or alloy that is clad with an appropriate lower-melting-point brazing filler metal. The most common example is the aluminum-braze clad sheet that is used in the fabrication of aluminum heat exchangers (Ref 2). In these sheets, the aluminum brazing filler alloy (BAlSi series) is clad to the aluminum-base alloy by hot roll bonding. The aluminum-clad brazing sheets can be brazed in a variety of atmospheres, and are used in numerous applications.

Another commercial example of a clad brazing material is copper-clad stainless steel sheet, which is used in the fabrication of heat exchangers for automotive, electronic, and other applications. The copper layer acts as the brazing filler material. The clad brazing material can be formed by drawing, bending, stamping, or other metalworking processes. The formed parts can be assembled and brazed without using any additional filler metal in the joint. Clad brazing materials are frequently used as one member of an assembly, in which the mating piece is made from a brazeable alloy, so that the clad filler metal flows by capillarity to the joint area.

On a more limited scale, aluminum-clad titanium strips have been used to fabricate titanium heat exchangers for electronics applications. In addition, silver brazing alloy (BAg3) that is clad on copper is often used in the brazing of carbide tools (Ref 3). The copper core remains in the joint area and acts as a ductile member that plastically deforms during cooling of the brazed joint.

Cladding Materials

Clad brazing materials are produced as strips, using the roll bonding technique. The strips comprise a base metal that is clad with a brazing filler metal on either one or both sides. These products are used primarily in high-volume manufacturing operations, such as the production of heat exchangers, brazed bellows, and honeycomb structures. The use of a self-brazing sheet reduces the total part count, simplifies the assembly operation (because the brazing filler metal is always present on the core material), and reduces assembly time and, therefore, cost. In addition, there is no need for the application of flux, nor for its subsequent removal. This not only saves the initial purchase cost of the flux, but the waste-management cost that is associated with the disposal of the spent material.

Aluminum-braze clad products, copper-clad steel, and copper-clad stainless steel are the most commonly used clad brazing materials. Table 1 lists the typical clad brazing strip products that are used in the fabrication of compact heat exchangers for the automotive, truck, and aircraft industries.

TABLE 1 TYPICAL CLAD BRAZING STRIP PRODUCTS

MATERIAL	CLAD LAYER RATIOS	THICKNESS		TEMPER	TENSILE STRENGTH		0.2% YIELD STRENGTH		ELONGATION, %
		mm	in.		mpa	ksi	mpa	ksi	
C12200 COPPER CLAD TO 409 STAINLESS STEEL	10/80/10 5/80/15	0.51-0.76	0.020-0.030	ANNEALED	400	58	230	33	37
C12200 COPPER CLAD TO 304 L STAINLESS STEEL	13.5/86.5	0.51-0.30	0.020-0.012	ANNEALED	635	92	290	42	56
	10/80/10			ANNEALED	620	90	275	40	55
C12200 COPPER CLAD TO 1008 STEEL	10/80/10	0.38	0.015	NO. 4 TEMPER	380	55	290	42	35
C52400 PHOSPHOROUS BRONZE CLAD TO C10200	10/80/10	0.51	0.020	ANNEALED	275	40	97	14	48

The thickness of the brazing filler metal used in a clad brazing material can range from 0.050 to 2.54 mm (0.002 to 0.100 in.) and will represent 5 to 20% of the total strip thickness. This range of strip thickness covers the majority of applications in the heat-exchanger industry. Figure 1 shows a typical clad brazing strip of copper-clad stainless steel.

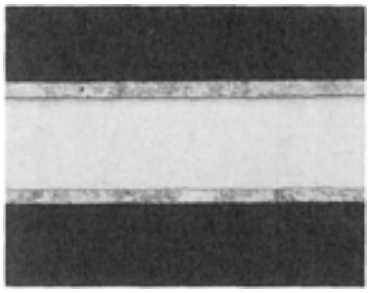

FIG. 1 PHOTOMICROGRAPH OF TYPICAL CLAD BRAZING MATERIAL, C12200 COPPER CLAD TO 304 L STAINLESS STEEL

Figure 2 compares the steps in using brazing preforms to fabricate a brazed assembly with the steps involved in using clad brazing materials. The latter is shown to be more efficient.

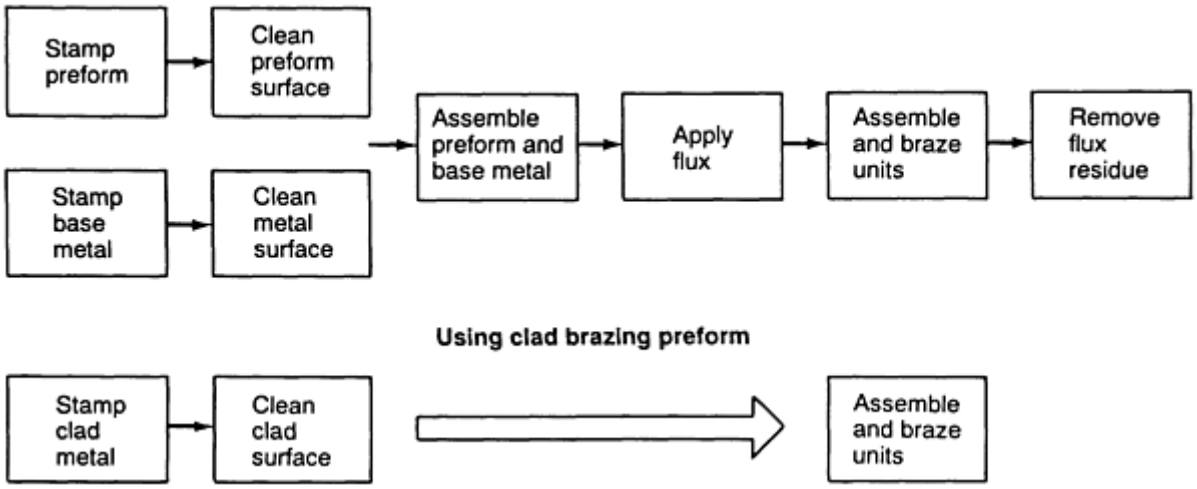

FIG. 2 COMPARISON OF BRAZING PROCESS USING BRAZING PREFORM VERSUS PROCESS USING CLAD BRAZING SHEET

Figure 3 depicts an automotive transmission fluid cooler that was assembled using clad brazing materials. A turbulator is brazed to a copper-clad stainless steel base and cover. The base and cover are formed from a stainless steel strip containing copper braze on one side. After brazing, the dimensional changes in this part are minimal, which is important when making a hermetically sealed heat exchanger.

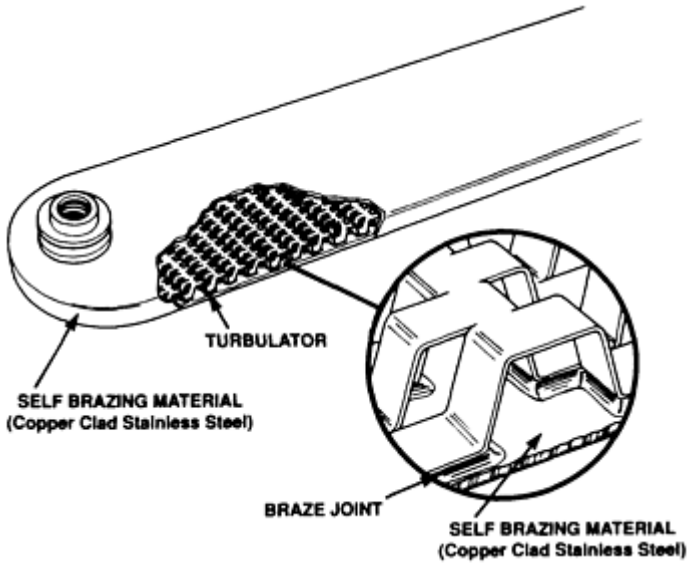

FIG. 3 HEAT EXCHANGER FABRICATED USING CLAD BRAZING ("SELF-BRAZING") MATERIALS

To fabricate clad brazing materials, the brazing filler metal must be ductile enough to be roll bonded to the base metal. The roll bonding technique is described in the article "Roll Welding" in this Volume and in Ref 4 and 5. A nickel brazing alloy that contains high levels of boron and silicon as melting-point depressants, such as the BNi-W series, is not available in thin-strip form, because these materials are brittle. Therefore, it cannot be roll bonded or processed by conventional metalworking methods.

The advantages of using clad brazing materials are that they:

- REDUCE THE TOTAL NUMBER OF PARTS THAT NEED TO BE ASSEMBLED
- ELIMINATE THE STAMPING AND ASSEMBLY COSTS ASSOCIATED WITH THE PRODUCTION OF A BRAZING FILLER METAL PREFORM
- ELIMINATE THE USE OF FLUXES AND REDUCING OR SURFACE-ACTIVATING ATMOSPHERES, BECAUSE ROLL BONDING ALLOWS THE BRAZING FILLER METAL TO METALLURGICALLY BOND TO THE SURFACES TO BE JOINED
- IMPROVE THE MANUFACTURING YIELD, BECAUSE PRECISE POSITIONING OF THE FILLER METAL IN THE JOINT AREA IS POSSIBLE
- ENHANCE DESIGN FLEXIBILITY, BECAUSE THE BRAZING FILLER METAL IS INTEGRAL WITH THE STRUCTURAL COMPONENTS THROUGH ALL MANUFACTURING STEPS, WHICH PERMITS THE DESIGN OF COMPACT, MORE COMPLEX, AND COST-EFFECTIVE ASSEMBLIES
- IMPROVE PROCESS REPEATABILITY, BECAUSE OF THE UNIFORMITY OF BRAZING FILLER METAL AND TIGHTER DESIGN TOLERANCES
- ELIMINATE HANDLING PROBLEMS WITH THIN AND WEAK FILLER METAL SHIMS, FOILS, OR PASTES

Brazing With Clad Brazing Materials

The design and manufacturing considerations associated with obtaining a good joint when using a clad brazing material are similar to those associated with producing joints when using conventional brazing techniques (Ref 6). Because the brazing filler metal is metallurgically bonded to the base metal, it acts as a protective (oxide-inhibiting) layer. This somewhat reduces the requirement for cleaning and fixturing before brazing, because the total part count is reduced. Similarly, the use of clad brazing materials often imposes a less-stringent requirement on the furnace atmosphere.

In the case of copper-clad stainless steel, the copper protects the surface of the stainless steel during heating. At the brazing temperature, it readily melts and flows to form the braze joint. Therefore, self-brazing materials often eliminate the need for pretreatments and fluxes to ensure adequate flow and wetting.

Clad brazing materials should not be used solely as a substitute material or as a joining method in an existing design that is based on conventional assembly techniques and placement of the filler metal. The greatest benefits of clad brazing materials are obtained when their use is comprehended in the basic design of the assembly and in the manufacturing process. The decision to use clad brazing material in the design stage of a heat exchanger allows greater design flexibility, tighter tolerances, and a more-robust process, because the design engineer does not need to allow spaces for wires or shims, or to specify the application method and handling procedure for the brazing filler metal. During the high-volume production of brazed assemblies that utilize clad brazing materials, the same amount of brazing filler metal is located at any given location every time.

Iron Soldering

Mark Cowell, Metcal, Inc.

Equipment

Hand soldering equipment can be broadly classified by its temperature control method. There are constant-voltage, variable temperature, and tip-temperature-controlled soldering iron types, each of which is described below.

Constant-voltage soldering irons are temperature-limited, but do not incorporate a temperature sensor. Temperature calibration of the tip is not possible, because these irons depend on the increasing resistance of the heating element to limit tip temperature. Line voltage fluctuations and ambient temperatures greatly affect the temperature of the soldering tip. A constant-voltage soldering iron is the least-expensive hand soldering tool. However, this type of soldering iron requires highly skilled operators to create reliable joints.

Variable-temperature soldering irons incorporate a temperature control device in the soldering handle. A control knob on the power source provides a means for the user to vary the tip temperature. When the soldering tip achieves the prescribed temperature, current to the heater is turned off. The tip cools to the lower temperature setpoint of the controller, and current to the heater is turned back on. Tip temperature calibration is possible with variable-temperature soldering irons. This type of iron can be adjusted so that its temperature is balanced with the thermal requirements of the joint. However, one of its drawbacks is that an unskilled or inattentive operator may leave the temperature at the highest setting, in an attempt to solder more quickly, damaging heat-sensitive components or printed circuit boards. Damage can also occur when the heat is too low and an operator stays on the termination too long while adding pressure.

Temperature-controlled irons incorporate a temperature sensor in the soldering tip. These soldering irons operate at a manufacturer's preselected temperature, and tip temperature calibration is not required. Tips are selected for their shape, as well as their operating temperatures. At the preselected temperature, either the resistance of the heating element changes or the current supplied to the heating element is turned off. The resulting reduction in heat generation stabilizes the tip temperature at its setpoint. Temperature-controlled soldering tips help ensure that the proper tip is used in a production environment, thus eliminating costly damage to printed circuit boards and components. This tool requires the least amount of operator training.

Iron Soldering

Mark Cowell, Metcal, Inc.

Soldering Iron Selection

When selecting a soldering iron, potential damage to the printed circuit board and its components must be considered. Damage can result from excessive joint temperatures or electrical overstress. Thermal damage can result from an iron that is not temperature controlled or is operated at too high a temperature, whereas electrical overstress results from the flow of electrical energy (leakage or electrostatic) when the iron is placed in contact with the component, which damages or weakens an electrical component. Military soldering standard MIL-STD-2000A and industry soldering standard IPC-S-815B cover the minimum soldering requirements in detail.

Figure 2 illustrates a typical soldering iron tip and joint thermal profile for repetitive joints. When an iron and tip have been properly selected, the tip temperature will decrease when the tip is placed in contact with the joint and solder is applied. When the temperature of the joint is from 28 to 55 °C (50 to 100 °F) greater than the solder liquidus temperature, the tip is removed from the joint. The tip temperature recovers (increases) to its setpoint as the solder joint cools.

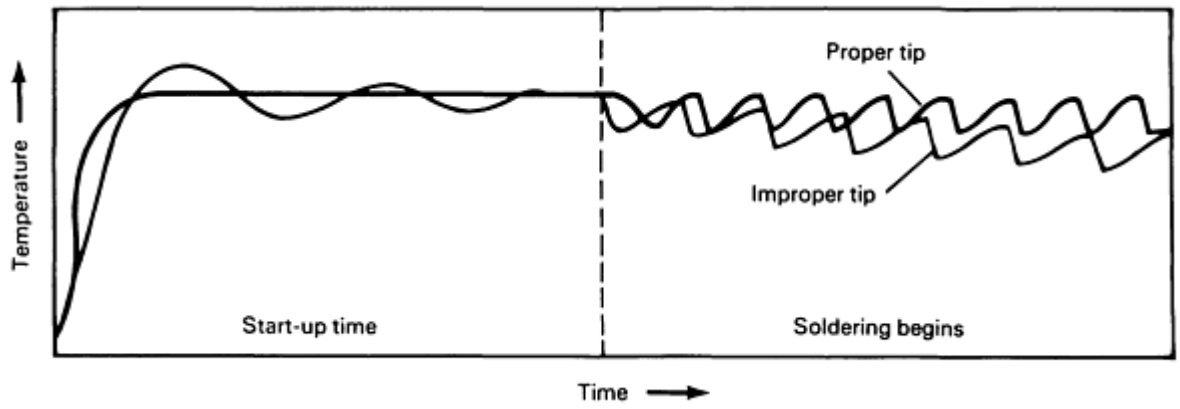

FIG. 2 TYPICAL SOLDERING IRON TIP AND JOINT THERMAL PROFILE

When a soldering iron is improperly selected, each successive joint connection decreases the working temperature of the tip. After several solder joints have been completed, the tool may be unable to form reliable joints. A properly selected soldering iron will stabilize the tip at a temperature that does not damage components, while providing a working temperature sufficient for soldering successive joints reliably.

Torch Soldering

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Introduction

TORCH SOLDERING (TS) utilizes a fuel gas flame as the heat source in the soldering process. The fuel gas is mixed with either air or oxygen to produce the flame, which is applied to the materials to be soldered until the assembly reaches the proper soldering temperature. Solder filler metal, which melts at temperatures below 450 °C (840 °F), is added to the assembly to bond it. Successful torch soldering is accomplished when parts are clean and fit together closely, and when oxides are not excessive.

Torch soldering is used in numerous industries that utilize a variety of base metals. It is most often used to produce a leak-tight assembly with some degree of mechanical strength. This process does have several advantages when compared with other metal-joining methods.

These advantages include:

- RELATIVELY LOW TEMPERATURES, WHICH RESULT IN MINIMAL DISTORTION AND HEAT DISCOLORATION OF THE SOLDERED ASSEMBLY
- FLEXIBILITY, SUCH THAT ONE TORCH CAN BE USED TO SOLDER A VARIETY OF ASSEMBLIES
- RELATIVELY INEXPENSIVE CAPITAL EQUIPMENT COST
- ABILITY TO SOLDER MOST BASE METALS AND BASEMETAL COMBINATIONS WITH AN APPROPRIATE FLUX
- LOCAL HEATING OF SMALL JOINTS ON LARGE ASSEMBLIES, WHICH PRECLUDES THE NEED TO HEAT THE ENTIRE ASSEMBLY
- PROCESS AUTOMATION, IN MANY CASES

The limitations of the process are that:

- A FLUX IS NEEDED BECAUSE THE PROCESS IS ACCOMPLISHED IN AIR, AND THIS FLUX OFTEN MUST BE REMOVED IN ORDER TO PREVENT PART CORROSION
- HIGHLY REACTIVE MATERIALS, SUCH AS TITANIUM AND MANY REFRACTORY METALS, CANNOT BE SOLDERED, BECAUSE NO SUITABLE FLUXES ARE AVAILABLE
- SOLDERED JOINTS DO NOT NORMALLY EXCEED THE STRENGTH OF THE PARTS BEING SOLDERED, THAT IS, THE PROCESS PRODUCES RELATIVELY WEAK JOINTS, WHEN COMPARED WITH BRAZED AND WELDED ASSEMBLIES

Torch Soldering

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Applications

Materials. Torch soldering is used extensively on copper, brass, and other copper alloys. Steel, stainless steel, aluminum, gold, and other metals, as well as many combinations of these, also can be soldered by this process.

Industries. The plumbing industry utilizes this process extensively on residential copper tubing for water lines, primarily because of its flexibility and ease of use. Soldered copper water lines provide leak-tight joints with the requisite strength. Torch heating is also used for liquid and gas conduit in industrial processing applications.

This process is also used by many other industries in assembly processes, such as the soldering of jewelry, aluminum heat exchangers, radiators, and pressure-sensing devices. Tube-to-fitting types of assemblies also are commonly torch soldered, as are butt and lap joints.

Torch Soldering

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Equipment

Torch. Typically, the equipment required for torch soldering is simple. Single torches are often used for hand soldering, whereas multiple torches can be used together on automated systems.

Gases. Fuel gas and air systems are frequently used for torch soldering because of the low heat requirements. The plumbing industry often utilizes a simple hand-held propane/air torch that is attached to the top of a small, rechargeable cylinder. Surrounding air is mixed with the propane from the cylinder in the appropriate ratio.

Gas/oxygen systems can also be used for torch soldering, although they produce more heat than gas/air systems. This amount of heat is not normally required for torch soldering.

A reducing flame--that is, a flame where excess fuel is present and surrounding air is used to complete combustion--is typically used when soldering. A reducing flame helps keep the assembly clean by reducing surface oxides.

Filler Metals. Many different filler metals are used in the torch soldering process. Tin-lead, tin-silver, and tin-antimony filler metals are commonly used on copper alloys, steel, and stainless steels. Zinc-aluminum is used exclusively on aluminum-base metals. The solders that are commonly used as filler metals are shown in Table 1.

TABLE 1 COMMON SOLDERS FOR TORCH SOLDERING

COMPOSITION	SOLIDUS TEMPERATURE		LIQUIDUS TEMPERATURE		COMMENTS
	°C	°F	°C	°F	
63SN-37PB	183	361	183	361	EUTECTIC COMPOSITION; MOST FLUID OF THE SNPB ALLOYS
40SN-60PB	183	361	238	460	LONG MELTING RANGE; GOOD FOR FILLING GAPS
96.5SN-3.5AG	221	430	221	430	FLUID SOLDER; STRONGEST OF LOW-TEMPERATURE SOLDERS
95SN-5SB	233	452	240	464	FOR COPPER- AND IRON-BASE ALLOYS; NOT FOR USE ON ZINC-BEARING ALLOYS, SUCH AS BRASS
98ZN-2AL	376	710	385	725	FOR SOLDERING OF ALUMINUM; USED EXTENSIVELY ON HEAT EXCHANGERS

Torch Soldering

Charles E. Fuerstenau, Lucas-Milhaupt, Inc.

Basic Heating Techniques

The key to torch soldering, as in all methods of heating, is to equally heat the components that need to be soldered. This may require directing the torch to a larger mass component of an assembly. Because the filler metal will flow to the hottest portion of an assembly, the flame should be applied so that the filler metal will flow in the intended direction. Also, movement of the torch is required to avoid overheating or burning the assembly.

Figure 1 shows the appropriate wire and torch placement for the soldering of tubing. Proper heating will result in the flow of filler metal through the joint, resulting in a fillet both inside and outside the joint. This ensures that a leak-tight joint has been produced.

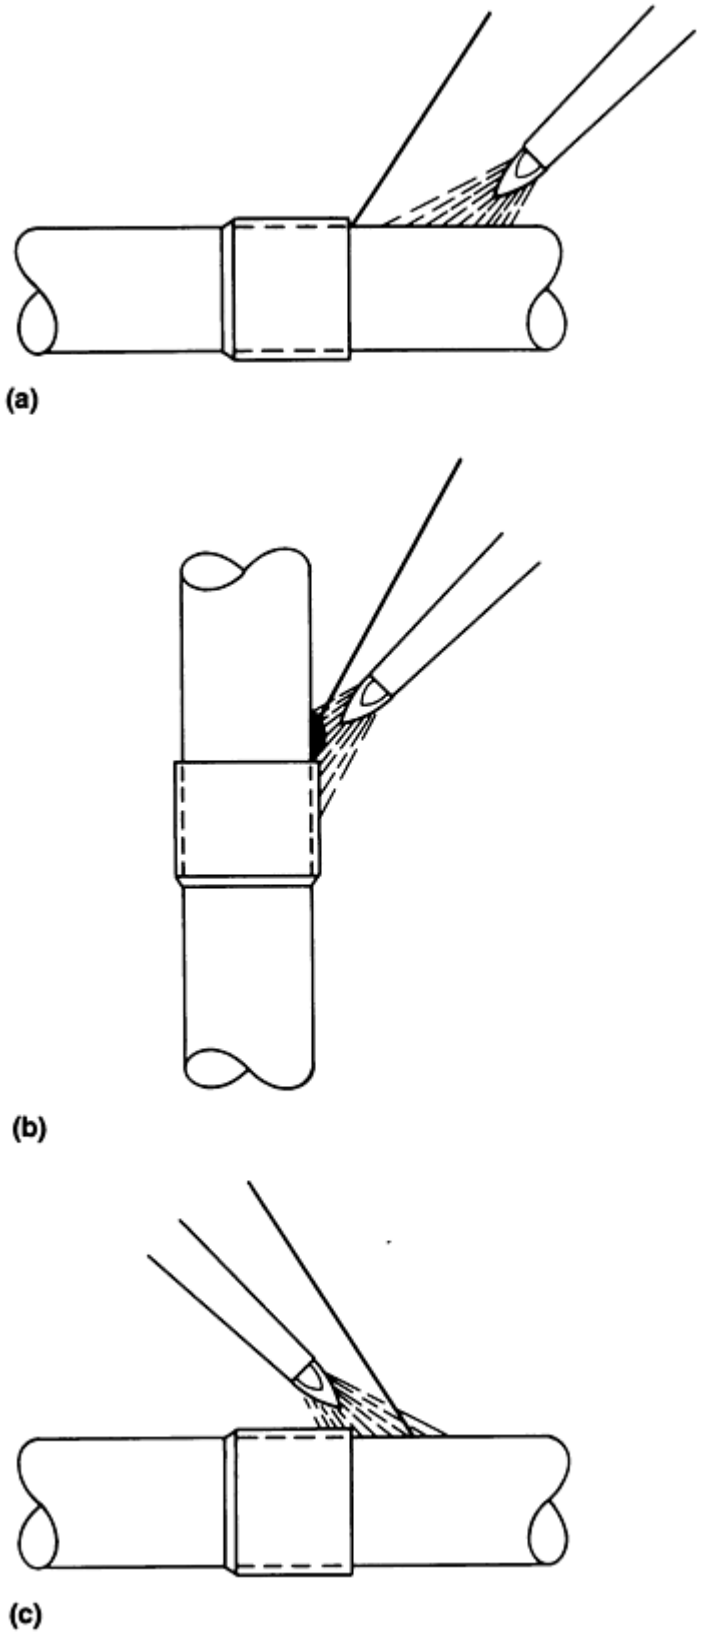

FIG. 1 EXAMPLES OF PLACEMENT OF FILLER-METAL WIRE AND FLAME. (A) AND (B) PROPER PLACEMENT. (C) POOR PLACEMENT

Torch soldering techniques are easy to learn when proper training and experience are provided.

Furnace and Infrared Soldering

Phil Zarrow, Synergistek Associates

Introduction

FURNACE SOLDERING (FS) encompasses a group of reflow soldering techniques in which the parts to be joined and preplaced filler metal are put in a furnace and then heated to the soldering temperature. Five reflow technologies are currently certified for use in surface-mount technology (SMT) applications:

- TYPE A: VAPOR PHASE
- TYPE B: AREA CONDUCTION (THAT IS, LINEAR CONDUCTION)
- TYPE C: HOT BAR
- TYPE D: CONVECTION AND CONVECTION/INFRARED (IR)
- TYPE E: LASER

Of these five methods, three are considered to be mass reflow techniques (Types A, B, and D), because all of the solderable interconnections on the surface of a printed wiring board (PWB) assembly are brought through the reflow heating cycle simultaneously.

Vapor-phase reflow, or condensation heating, had early prominence as an SMT reflow soldering method. A fluid that has a boiling point higher than the solder melting point is heated and the vapor is contained in a chamber, through which the PWB assembly is passed. Heat transfer is achieved through the heat of vaporization released by the fluid as it condenses on the PWB surface. The fluids are compatible with most substrate and device packaging materials. The process is relatively insusceptible to variances in component distribution and assembly densities. Additional information can be found in the article "Vapor-Phase Soldering" in this Volume.

Area conduction comprises multiple "hot-plates" with a substrate conveyance system. This method can also be combined with other energy-transfer techniques, including convection and infrared, when appropriate for specific applications.

Infrared heating technology has also been very successfully adapted to SMT reflow soldering. Area IR emitters, that is, radiant panels, and lamp radiant emitters that are arranged in arrays with reflectors are incorporated in a conveyorized oven to provide the source of heat. By using mid- to far-infrared emissions and presenting a large heated surface area to heat the resident atmosphere in the oven, the dual heat transfer technologies (that is, IR heat provided by the direct lamp heat and conduction-generated heat provided by the indirect heating of the atmosphere) can achieve a very controlled rate of heating, which is ideal for SMT reflow soldering.

IR reflow has continued to evolve. Emphasis has been placed on enhancing heat transfer through forced convection (class 3), also known as convection-dominant reflow soldering (Fig. 1 and 2). Convection evens out the "hot" and "cold" spots caused by different surface adsorptivity. The intent is to approach the beneficial near-equilibrium aspects of vapor-phase reflow, but with the multizone profile control that has been traditionally offered by the convection/IR method. This objective is driven by the more-complex soldering applications, in terms of assembly mass and surface geometries.

Reflow Profile

The heating cycle of the PWB assembly should be precisely controlled. The reflow profile is composed of four regions (Fig. 3):

- PREHEAT (PREBAKE)
- PREFLOW (SOAK)
- REFLOW
- COOLDOWN

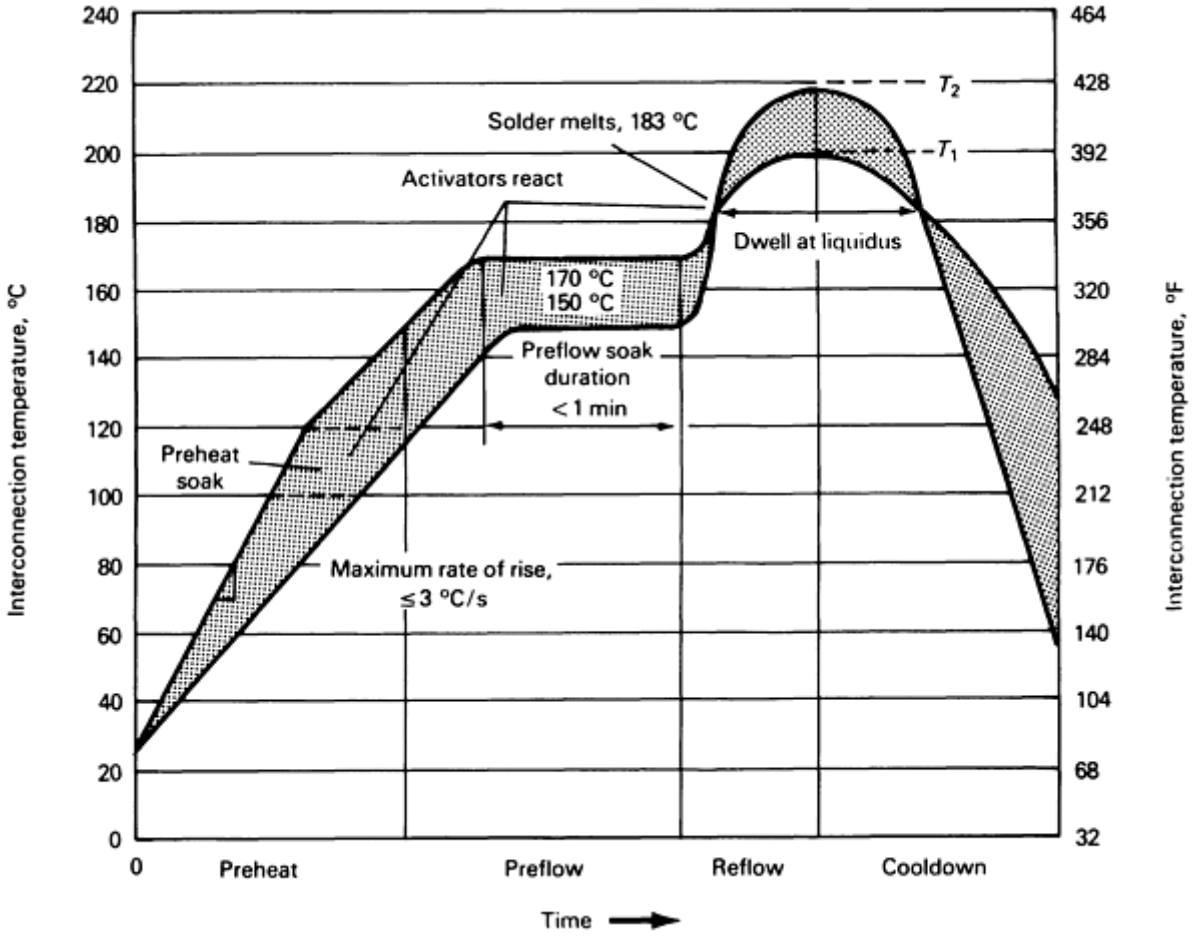

FIG. 3 PLOT OF INTERCONNECTION TEMPERATURE VERSUS ELAPSED TIME SHOWING FOUR REGIONS THAT CONSTITUTE REFLOW PROFILE. TOTAL ELAPSED TIME FROM PREHEAT TO COOLDOWN VARIES FROM 3 TO 6 MIN.

Preheat. As the PWB assembly enters the oven tunnel (at ambient temperature) and energy is introduced to the assembly, the heat transfer process begins. The interconnection temperature is brought up to approximately 100 to 120 °C (212 to 250 °F) to reduce the risk of thermal shock to the components and PWB delamination. The control of the rate of heating is most critical in the preheat portion of the profile. Many component manufacturers, particularly suppliers of ceramic capacitors, recommend a preheat rate of heating that is less than 4 °C/s (7 °F/s). The rate of heating should be based on the application, and the component complement should be considered.

Throughout the preheat stage, activators commence "scrubbing" and some solvents begin to evaporate. In certain solder paste formulations, some of the flux activators may begin oxide reduction at this stage.

Preflow. Before it attains reflow temperatures, the assembly is allowed to "soak" for a period of time. Those PWB assemblies that have polymer-base substrates require time to allow the transfer of heat throughout the assembly, in order to reduce thermal gradients. The remainder of the noncontributing solvents contained in the solder paste are driven off. As the temperature of the solderable interconnections are brought to just below the solder melting point, flux activators react with the surface to clean component and pad interfacing surfaces.

The temperature range and duration of this stage varies among flux types and the solder paste formulations that different manufacturers produce. Generally, rosin mildly activated (RMA) fluxes become fully activated in a preflow soak at temperatures between 150 and 170 °C (300 and 340 °F). Some RMA formulations achieve optimum results when the preflow soak is held to less than 1 rain (Fig. 3).

Some organic acid (OA) fluxes exhibit preflow characteristics that are similar to those of the RMA fluxes. Many OA formulations are optimized with a gradual slope in which temperature rises from approximately 100 to 170 ± 15 °C (212

to 340 ± 30 °F) (Ref 1). The duration of preflow is very critical to OA fluxes and will typically be approximately 1 min, although this will vary among different formulations (some manufacturers recommend minimizing the duration). If the preflow time interval is too long, paste oxidation and flux degradation can occur.

Reflow. As the temperature of the solder paste on the interconnect passes the melting point of the solder alloy and enters a molten state, the reflow portion of the process begins. With 63Sn-37Pb, a eutectic solder that represents the most commonly used alloy in SMT assembly, reflow occurs at 183 °C (361 °F). During the reflow stage, all solderable portions of the PWB assembly reach their desired peak temperatures. Most solder manufacturers recommend bringing the interconnect temperature to approximately 15 to 30 °C (27 to 54 °F) above the alloy melting point to ensure complete melting, as well as good solder flow, and to aid fillet formation. This is designated T_1 in Fig. 3. The supplier should be consulted to provide the actual temperature for a particular formulation.

The duration of time at which a solderable interconnect resides above the melting point of the solder paste is called the "dwell at liquidus." The liquidus dwell extends through the reflow portion of the profile and into the cooldown portion until the solder reaches solidus. This is the most critical portion of the reflow profile. Because these are the highest temperatures endured by the assembly during the process, the duration at these elevated temperatures should be minimized. Intermetallic growth occurs while the solder is in the molten state, as well as a result of diffusion over a period of time. A sustained liquidus dwell period essentially gives it a "head start." The longer the duration, the more intermetallic growth takes place. Because cooling the interconnection to below the solidus temperature is also part of this duration, the actual dwell for a particular application will be affected by the mass and surface geometry (and expediency of heat dissipation) of the assembly and the resulting thermal gradient.

Cooldown. As the assembly passes its peak temperature and leaves the heated tunnel, it begins to cool, eventually passing the point where the solder solidifies. Cooling can be aided by fans, blowers, inert gas curtains, refrigeration, normal exposure to ambient air, or a combination of several of these mechanisms. To avoid thermal shock to components, it is currently recommended that the rate of cooling not exceed -4 °C/s (-7 °F/s). However, rapid cooling does promote a finer grain growth in the joint and contributes to a stronger interconnect.

The actual time and temperature duration range for each zone not only varies among the different types of fluxes used in SMT soldering, but also among similar flux designation formulations of different manufacturers. The user should consult his supplier to obtain the actual time and temperature durations that are recommended for the specific solder paste being used. It is important to note that most fluxes have a fairly substantial "envelope" in terms of temperatures at the different stages. In some cases, however, actual duration can be more stringent.

Furnace and Infrared Soldering

Phil Zarrow, Synergistek Associates

Reflow Schedule

A reflow specification should be required for any facility that uses mass reflow techniques. This procedure should mandate the temperatures that the PWB assembly will be exposed to at the peak of the reflow cycle. The full peak liquidus temperature, T_1, is the minimum peak temperature that any solder and interconnection must be exposed to for proper joint formation and is a parameter of the reflow schedule. It is affected by factors such as solder paste alloy, metal content, particle size, flux, surface tension, and fluidity of the solder. As noted earlier, this value will vary among different formulations and should be specified by the solder paste manufacturer (see the section "Reflow Profile" in this article).

The most vulnerable component (MVC) maximum peak temperature is represented by the value T_2. It identifies the component that has the lowest thermal threshold and is most likely to be thermally damaged. The MVC might be an inserted component with a low material melting point (that is, an electrolytic capacitor), a plastic connector, a switch, a label, or some other heat-sensitive part or material. The lowest common denominator within the assembly will determine the highest temperature to which any part should be exposed. A buffer of -5 °C (-9 °F) should be taken from that threshold to establish the MVC temperature used in the specification.

In some applications, the MVC temperature might be determined by the internal heat sensitivity of an active device. Hence, the internal temperature tolerances should also be taken into consideration.

Processing in Inert Atmosphere

Reflow soldering in an inert atmosphere can, in some instances, be beneficial to improved wettability. However, implementing nitrogen in the reflow oven is being driven by two specific factors: "no-clean" fluxes and the bare copper assembly process.

No-clean (or low-residue) fluxes represent one solution to the search for alternatives to cleaning PWB assemblies with environmentally damaging chlorofluorocarbon (CFC) solvents. The result is the development of solder formulations that do not require cleaning.

A number of factors will ultimately affect feasibility for a given application. Besides external cosmetic appearance requirements, both solder joint quality and testability (in light of remaining residue) will be dictated by other user standards and requirements. Although some low-residue solder paste formulations that work well in ambient (oxygen-laden) atmosphere are available, many very low residue no-clean solder pastes require that reflow take place in an inert (N_2) atmosphere. Some no-clean solder paste formulations have been successfully tested at approximately 300 ppm of O_2, but the higher the concentration of inert atmosphere, the wider the process window. Optimum results, in terms of very low residue, have been attained with nitrogen atmosphere of less than 20 ppm O_2.

The bare copper assembly process has been prompted by the need for coplanarity on the PWB substrate when placing fine- pitch devices. Hot-air leveling of solder during PWB fabrication has not attained adequate levels of coplanarity when components of 0.51 mm (0.020 in.) pitch or finer are being attached. In the bare copper assembly process, the PWB is fabricated in the usual manner, except that the tin-lead solder coating is omitted. Instead, the substrate is coated with a sealant (that is, inhibitor) that prevents the copper from oxidizing. In assembly, solder paste deposition (screened or stencilled) and component placement are accomplished "as usual." During reflow, the sealant vaporizes between 100 and 120 °C (212 and 250 °F) (during the preheat stage), which exposes the copper to the solder paste. Because the copper is exposed, the furnace must contain an inert atmosphere to prevent excessive oxidation of the lands. Just how oxygen-free the oven atmosphere needs to be varies among users. Some obtain successful results in atmospheres composed of approximately 500 to 700 ppm O_2. The most stringent specification requires a nitrogen atmosphere with less than 50 ppm O_2 at any point in the process where the PWB assembly becomes elevated above 150 °C (300 °F).

Dip Soldering

Roy E. Beal, Amalgamated Technologies, Inc.

Introduction

DIP SOLDERING (DS) is accomplished by submerging parts to be joined into a molten solder bath. The molten bath can be any suitable filler metal, but the selection is usually confined to the lower melting point elements. The most common dip soldering operations use zinc-aluminum and tin-lead solders.

The molten bath can be heated by electricity or gas. The bath container is made from ceramic materials or a metal that is nonreactive to the filler metal used for dipping. The dip baths, which can range in size from very small to large, are used in a wide range of industries.

The process of dip soldering is simple to carry out. The joint areas are cleaned and then coated with an appropriate flux. The parts are then lowered into the molten filler metal and joining takes place by capillary attraction into the joints. The solder does not wet surfaces that are not coated with flux. Jigs and fixtures are normally essential to hold components at proper clearances for joining purposes and to maintain overall dimensions of the finished product. They should not be wetted by the solder. Furthermore, any substrates that must be submerged should be able to tolerate the solder temperature.

The molten bath supplies both the heat for raising the temperature of the part and the filler metal to make the joints. It is therefore important that the dip soldering pot capacity be large enough to allow heating of the part and joining without significantly reducing the temperature of the molten filler metal. For some applications, soldering pots are designed for specific production rates.

An advantage of the dip soldering process is the wide range of part sizes, shapes, and thicknesses that can be accommodated by the same apparatus and still result in satisfactory joints. Larger parts require a preheating operation in order to reduce thermal shock when the part enters the dip pot. The preheat also allows quicker attainment of equilibrium between the molten metal in the pot and the part being joined. Atmosphere protection of the dip soldering pot is necessary when the filler metal has oxidation tendencies. Surface oxides on the workpieces must be removed prior to dip soldering, because they can interfere with a proper joining operation.

Dip Soldering

Roy E. Beal, Amalgamated Technologies, Inc.

Applications

Dip soldering is used in job shops, as well as high-rate production situations. Therefore, the parts joined by dip soldering vary from individually designed products to mass-produced items. Dip soldering is ideal for the production of prototype engineered products, which are often made for test purposes. The process also can be used to join limited-production items for the automotive, aircraft, consumer, electronic, and other industries. High-production products are typically heat exchangers for automotive use, high-volume telecommunications equipment, and appliances.

Joints produced by dip soldering techniques are usually sleeve, lap, or T-joints that fill by capillary attraction. The parts to be joined are assembled with gaps appropriate to the particular filler metal surface tension and viscosity characteristics. The joint/fixture design must accommodate thermal expansion that is due to heating the entire substrate or part. Joint gaps also depend on the reactions of the molten filler metal with the material to be joined. For example, aluminum filler metals (or those with zinc, tin-zinc, or zinc-aluminum alloys) react more quickly with aluminum than a tin-lead solder will with copper and therefore require larger gaps for joining.

Equipment

Dip soldering equipment is very basic, comprising a bath made of metal or ceramic to hold the molten filler metal and a means to heat and control the molten filler metal temperature. In the radiator industry, job shops use gas heating with their pots for the sake of economy. Much equipment is made to operate electrically, either because of space considerations or because the pots are used in conjunction with other equipment on a production line that might be affected by a gas heating system. Some systems include a metal pump that raises the level of the liquid metal in areas smaller than the overall pot in order to ensure that no surface oxides are present during the dip operation. This type of equipment is used in automotive radiator manufacture. A typical installation is illustrated in Fig. 1.

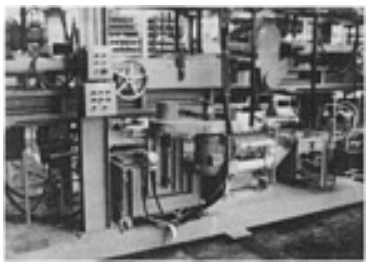

FIG. 1 DIP SOLDERING POT IN A RADIATOR PRODUCTION LINE

Dip Soldering

Roy E. Beal, Amalgamated Technologies, Inc.

Personnel

Solder pots are generally run by production personnel who should be trained to handle and care for equipment that contains molten metals. A substrate that has been raised to the soldering temperature represents a high-temperature hazard. Parts must be dry upon entering the dip solder pot to avoid splashes or explosions. Suitable protective wear (with guards, where possible) is necessary. Good ventilation is important, because of flux and, possibly, metal fumes. Generally, operators of tin-lead solder dip pots are now checked for lead content in the blood, because of possible health hazards.

Introduction

RESISTANCE SOLDERING (RS) is a soldering process in which the heat needed to melt the solder is developed by the resistance of the material when a large electrical current is supplied. Resistance soldering can be applied to electrically conductive materials that allow the passage of electric current. The process can be used for selective spot soldering of small components, for the soldering of closely placed parts on an assembly, or for heat restriction when necessary. It is similar in many ways to resistance brazing (see the article "Resistance Brazing" in this Volume).

When the current is applied, rapid local heating occurs, melting the solder. This molten solder wets the surface. As a result, the resistance in the material falls and the current increases, tripping a control. The heat rapidly dissipates into the surrounding area, and the solder quickly solidifies.

Resistance Soldering

Karl Lazar

Process Applications

The RS process can be used in all soldering operations and with all solderable metals. The only limitations are the thickness and the design of the parts to be soldered. Resistance soldering is used to join steels (for example, carbon, low alloy, and stainless) and nonferrous alloys (for example, aluminum and aluminum alloys, nickel and nickel alloys, and copper and copper alloys) up to 3.2 mm ($\frac{1}{8}$ in.) in thickness (Ref 1).

The RS process is suitable where:

- AN OPEN FLAME CONSTITUTES A POTENTIAL HAZARD IN THE WORKPLACE.
- THE HEAT NEEDED FOR SOLDERING MUST BE CONFINED TO A SPECIFIC AREA.
- THE OXIDATION ATTRIBUTED TO HEATING OF THE SOLDER MUST BE MINIMIZED.
- THE COMPONENTS TO BE JOINED ARE INACCESSIBLE WITH A CONVENTIONAL SOLDERING IRON.
- THE BEAD PRODUCED CAN BE ADAPTED TO AUTOMATED PROCESSING/MASS PRODUCTION METHODS.

Resistance Soldering

Karl Lazar

Equipment

Resistance soldering equipment typically consists of two electrodes that have been modified for use with a specific part configuration. These electrodes are made of a high-resistance electrical conductor (for example, carbon, graphite, or tungsten). The geometry of the electrode can assume any one or a combination of the following forms (Fig. 1):

- PENCIL
- TWIN-PENCIL
- ROLLER
- CLAMP
- PLIER-TYPE

The electrodes are connected to the transformer by oversized current-carrying conductors. The heart of the system is a heavy-duty, variable, step-down transformer designed to develop an output of 2 to 25 V_{ac} and a current of 5 to 500 A (Fig. 2). A footswitch, a timer, or an adjustable-resistance bridging device across the electrodes can be used to provide a method for the parts to reach the desired solder temperature and shutdown. This allows the solder to solidify and the parts to return to ambient temperature in a 4 to 6 s cycle.

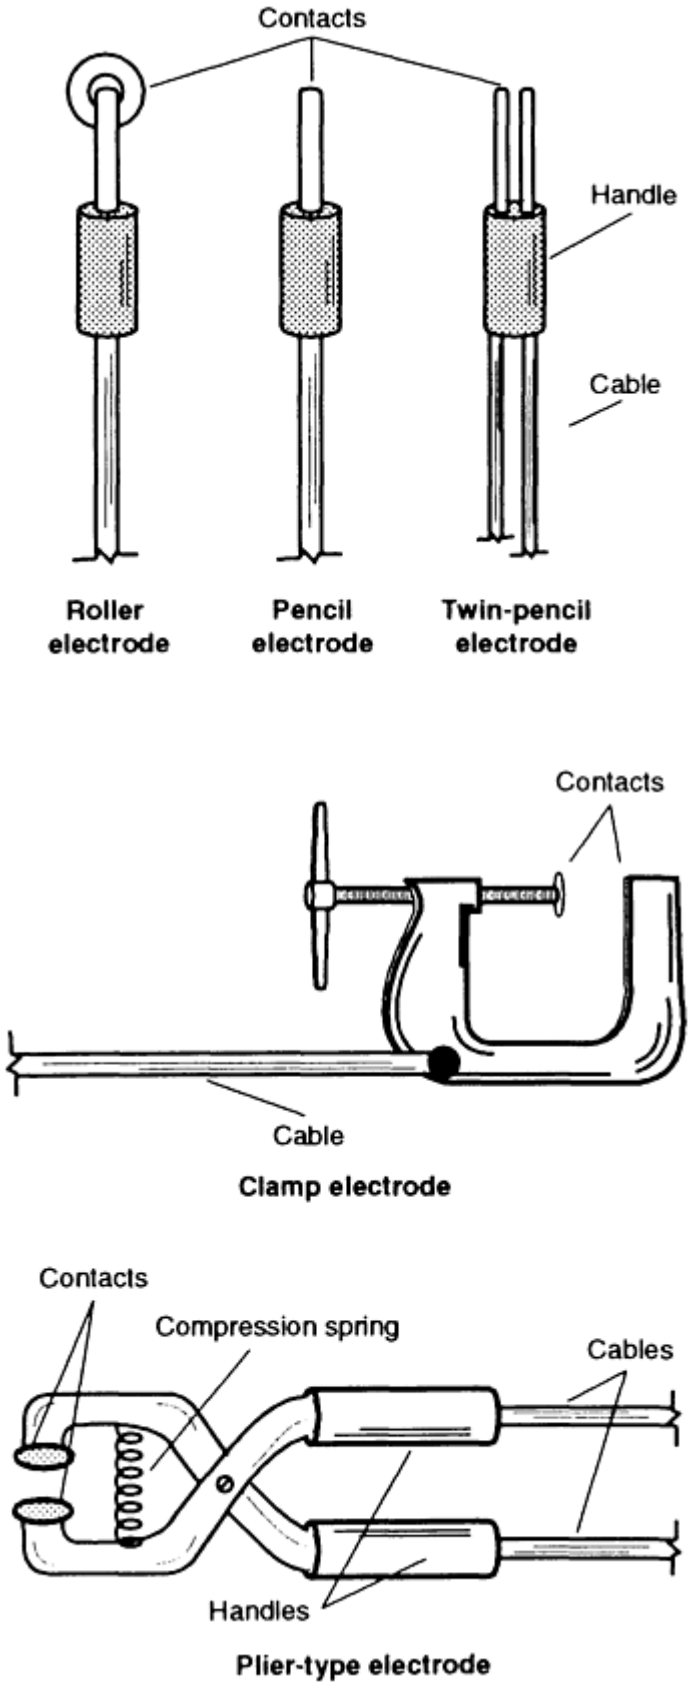

FIG. 1 TYPICAL ELECTRODE CONFIGURATIONS USED IN RESISTANCE SOLDERING APPLICATIONS

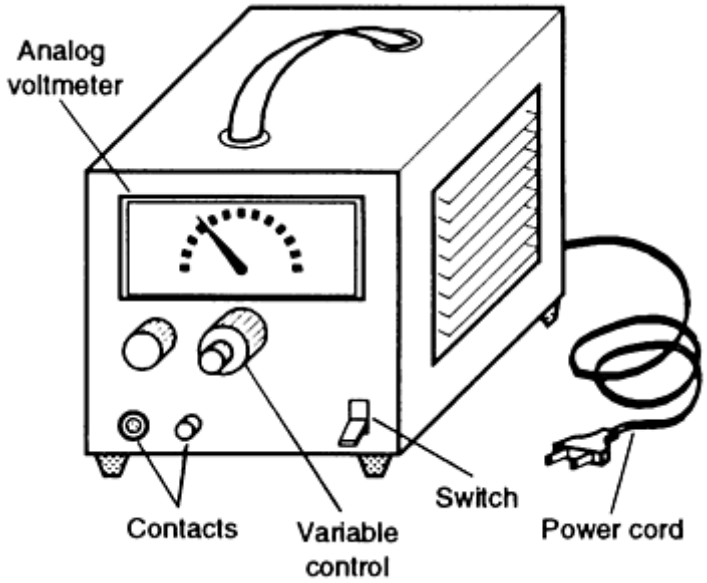

FIG. 2 TYPICAL VARIABLE STEP-DOWN TRANSFORMER WITH 2 TO 25 V OUTPUT (AT 5 TO 500 A CURRENT) USED IN RESISTANCE SOLDERING PROCESSING

Personnel Training

Soldering personnel with a strong basic training will need some additional special training to operate an RS system. The operator's function is to load and unload the parts and to maintain or replace the electrode heads when required. General soldering health and safety rules should be observed to avoid electrical shock and the potential for overheating solder to cause spatter. Typically, the engineer who originally designs the electrode heads is responsible for the equipment's initial start-up.

Resistance Soldering

Karl Lazar

Resistance Soldering Practice

The RS process requires preassembly of the workpiece components. Because the workpiece and the solder are integral parts of the current loop, care must be taken to ensure that the current path is not blocked by any foreign or nonmetallic substance. Hence, the preassembled workpiece requires a clean, deburred surface and the proper solder alloys (preform or in paste form). The use of wire solder and flux is not recommended because of the rapidity of heating and the potential hazard of electrical shock.

The preassembled workpieces are positioned in a grounded jig or clamp, and the movable electrode is brought in contact with the workpiece to complete the circuit. When the power is turned on, the operator waits for signs that the solder is starting to flow and then immediately turns the power off. When using automatic soldering equipment, the duration of the current flow is monitored by sensors that determine the length of the "on" cycle. As the workpiece cools, the solder

solidifies, and the workpiece is removed from the jig. The next assembly can then be placed in the jig. A properly designed movable electrode head allows multiple solder connections to be produced in a single operation.

Laser Soldering

Riccardo Vanzetti, Vanzetti Systems, Inc.

Introduction

INDUSTRIAL LASERS are able to deliver large amounts of heat with great precision and without contact, making them ideal for applications that have either a destructive nature, such as cutting or drilling, or a constructive nature, such as soldering or annealing.

The use of focused energy generated by either a CO_2 or a neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser continues to gain acceptance as a process for a number of operations requiring high-temperature injection with speed and precision. For example, in the electronics field, component soldering can be carried out one joint at a time with highly reliable results. Laser soldering uses the well-focused, highly controlled beam to deliver energy to a desired location for a precisely measured length of time.

Advantages of laser soldering are that it is a noncontact procedure; it avoids thermal stress by localizing heat input and confining it to the solder joint area; it reduces intermetallic compound formation, due to rapid joint formation which results in a more ductile joint; and it involves a fine grain size (due to rapid cooling), resulting in better fatigue properties. Disadvantages include low output rates, high power requirements, and high capital requirements.

This discussion focuses on two types of laser soldering operations, blind laser soldering and intelligent laser soldering, and the conditions under which their application is suitable. Key attributes of each system, relative to other types of soldering operations, are also identified.

Laser Soldering

Riccardo Vanzetti, Vanzetti Systems, Inc.

Blind Laser Soldering

The early configurations of production lasers were of the "blind" (no feedback) type. The system included a laser programmed for power, as well as length of heat injection time. The focal spot of the laser beam was brought to impinge on the target by moving either the target itself or the laser beam, or a combination of the two.

Among the vast array of currently available lasers, the preferred systems for industrial soldering applications are the CO_2 laser, which emits at a wavelength of 10.6 μm, and the Nd:YAG laser, which emits at a wavelength of 1.06 μm. The total energy emitted by these lasers (or by any laser, in fact) is in part absorbed by the target, in part reflected by the target, and the balance causes an instantaneous emission of highly energized atomic and subatomic particles from the target's

uppermost surface layer. The ratio of these three parts is a function of laser wavelength and of surface emissivity of the target. The latter, in turn, is a function of chemical composition, crystal structure, and degree of smoothness.

For all practical purposes, certain solder alloys are known to reflect about 74% of the energy from a CO_2 laser, but just 21% of the energy from a Nd:YAG laser. These figures are approximate, because the presence of fluxes and activators reduces the reflection factor. However, the Nd:YAG laser, when used for soldering, is more efficient.

In a blind system, the coordinates of the target, the power of the laser, the diameter of the beam at its focal point, the duration of the incident heat pulse, and other parameters must be preprogrammed and cannot be changed during the operation. Without a feedback mechanism, the quality of the work done by the laser can only be assessed after the operation has been completed.

This approach is adequate for highly repeatable production situations in which the targets are nearly identical to one another. Once the optimum settings for all variables have been established, uniformly good results can be expected. Care must be taken to avoid any process variations, such as changes in surface emissivity of the target or its contamination by a host of other factors, including solderability degradation from oxidation and handling.

However, blind laser soldering is less suitable in electronics applications, where components and the printed circuit pose a serious problem, because no two joints are identical. Although they might visually appear to be identical, their heat requirements can vary substantially. This is due to hidden differences in their heat-sinking efficiency, which is a function of the thermal mass of the subsurface elements connected to the joint. Especially critical is the diameter of the laser beam at the focal spot, because it must cover proportional areas of the elements to be joined, plus some of the solder material. This is why blind laser soldering seldom finds practical applications in the field of electronics. The most difficult applications involve fine pitch technology (FPT) and tape automated bonding (TAB), where the very small dimensions of the joints make the use of conventional soldering systems critical.

Key attributes of blind laser soldering are:

- *REPEATABILITY:* GOOD FOR LARGE PRODUCTION RUNS OF IDENTICAL PARTS, BUT POOR FOR PROCESSES THAT INVOLVE A NUMBER OF NONCONTROLLABLE ITEMS
- *SPEED:* FAST, WHEN COMPARED WITH ANY SOLDERING APPROACH IN WHICH JOINTS ARE MADE ONE AT A TIME
- *QUALITY:* GOOD, WHEN OPTIMIZED FOR LARGE PRODUCTION RUNS OF IDENTICAL CONDUCTORS AND PARTS
- *COST:* EXPENSIVE, WHEN COMPARED WITH MOST OTHER SOLDERING TECHNOLOGIES
- *SAFETY:* CRITICAL, BECAUSE SERIOUS BURNS AND EYE DAMAGE CAN RESULT IF SPECIAL PRECAUTIONS ARE NOT TAKEN
- *FLEXIBILITY:* POOR, BECAUSE ANY DRIFT OF THE MANY PROCESS VARIABLES WILL CAUSE DEFECTS, UNLESS THE PROGRAM IS MODIFIED ACCORDINGLY

Laser Soldering

Riccardo Vanzetti, Vanzetti Systems, Inc.

Intelligent Laser Soldering

Because solder joints can differ from one another in terms of thermal mass, emissivity, contamination, presence of internal thermal barriers, and heat-sinking efficiency, an infrared (IR) detector was added to create an "intelligent" laser soldering system. This system enables the precise control of heat input to the joint, because the IR "eye," constantly focused on the joint being heated, monitors its thermal radiation, and turns off the laser beam right after lead and pad substrates have been thermally soaked by the molten solder. The resulting solder joints are neither overexposed nor underexposed.

Figure 1, which depicts an intelligent system, shows two lasers with coaxial beams: a He-Ne 0.5 mW visible beam and a Nd:YAG 50 W "heating" beam emitting at a 1.06 μm wavelength. After traveling through an optical fiber, these two beams are focused on the solder joint to be formed. At the same time, the IR (thermal) radiation emitted by the heated solder joint is focused on the IR detector, which does not register the wavelength of the laser beams and therefore is not disturbed by their reflections. The visible image of the solder joint is picked up by a closed-circuit television camera and displayed on a television screen. These three optical signals are separated by dichroic mirrors in the optical head while the solder joints are brought, one at a time, under the focal spot of the system. The preprogrammed sequence is based on the *x* and *y* coordinates of each joint.

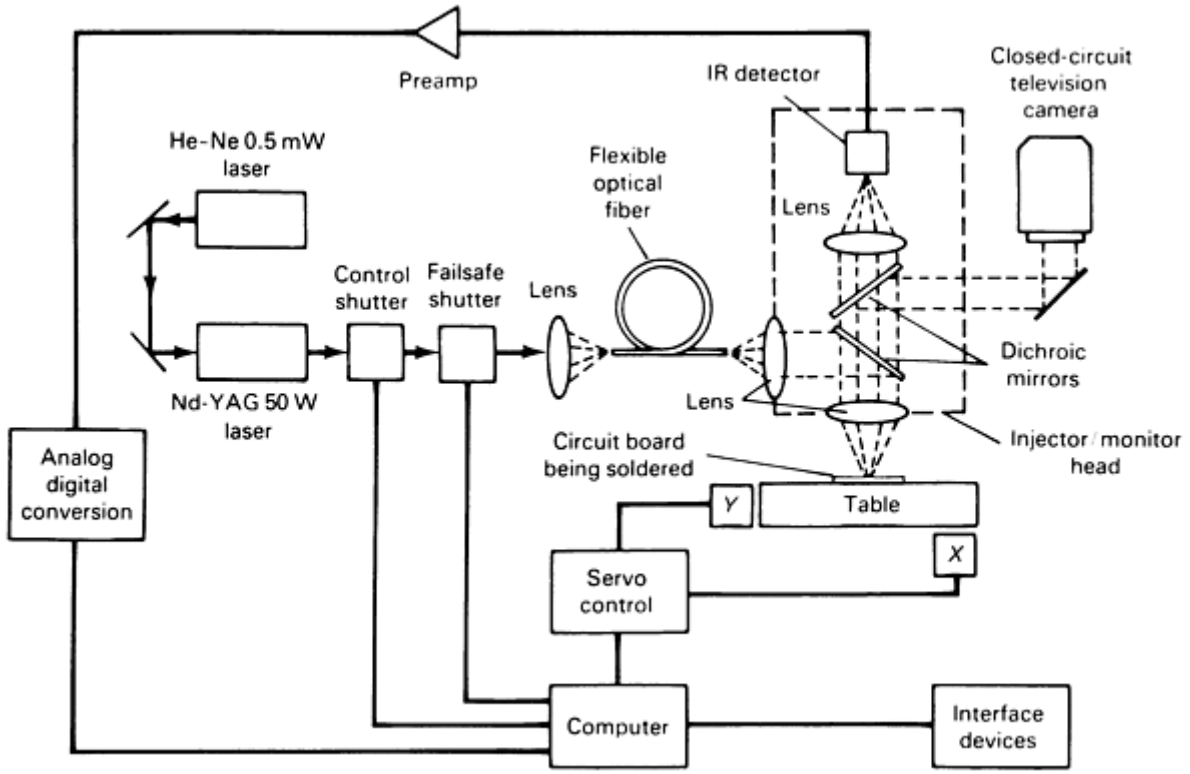

FIG. 1 SCHEMATIC OF INTELLIGENT LASER SOLDERING SYSTEM

The output of the IR detector is an analog signal that depicts, in real time, the radiation history of a spot on the surface of the solder joint during fabrication. This signal, called the "infrared signature" of the joint, is unique for every joint. The amplitude of the signal records the thermal radiation of the joint as it first rises during the heat injection by the laser and then as it decays after the laser is shut off. After the IR signature is turned into digital form, it is forwarded to the computer, which watches for the dip in the amplitude of the signal radiated by the joint, which pinpoints the transition from a solid to a liquid phase. At this point, the computer decreases the power of the laser for several milliseconds (the "dwell" phase) to allow adequate thermal soaking of the substrate. The laser is then turned off to allow the joint to quickly cool down to ambient temperature.

Figure 2 shows the theoretical signature of a typical good joint. The top curve is the radiation signal, as seen by the detector, and the lower curve is the temperature of the joint at each corresponding point in time. The sharp peak of the upper curve signals, with unequivocable precision, the instant when melting begins, so that the computer can initiate the laser control sequence, thus making it impossible to either overheat or underheat the joint. The resulting joint is free from defects such as excess intermetallics, nonreflowed solder, voids, cracks, or substrate damage.

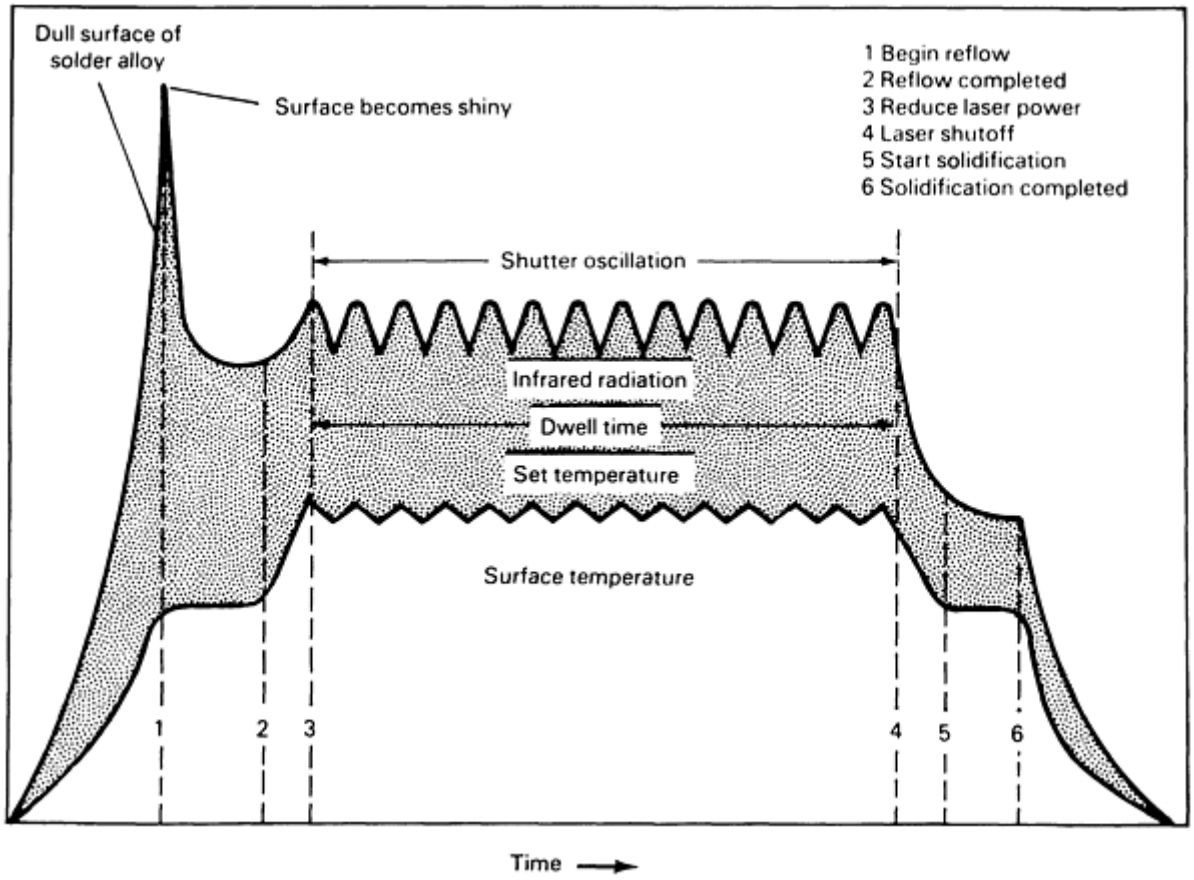

FIG. 2 THEORETICAL SIGNATURE OF A TYPICAL GOOD SOLDER JOINT

Key attributes of intelligent laser soldering are:

- *REPEATABILITY:* GOOD FOR ANY TARGET
- *SPEED:* FAST, WHEN COMPARED WITH ANY OTHER SOLDERING AND INSPECTION SYSTEM, BECAUSE THE IR SIGNATURE IS THE INSPECTION CERTIFICATE, AND IS AVAILABLE SIMULTANEOUSLY WITH THE COMPLETION OF THE JOINT
- *QUALITY:* GOOD FOR ANY TARGET
- *COST:* INEXPENSIVE, WHEN COMPARED WITH THE COST OF THE TWO SYSTEMS IT REPLACES, THAT IS, SOLDERING AND INSPECTION
- *SAFETY:* CRITICAL, BECAUSE SERIOUS BURNS AND EYE DAMAGE CAN RESULT UNLESS SPECIAL PRECAUTIONS ARE USED
- *FLEXIBILITY:* EXCELLENT, BECAUSE NO MATTER HOW DIFFERENT THE JOINTS ARE FROM ONE ANOTHER, EACH RECEIVES A CUSTOM DOSE OF THE LASER HEAT NECESSARY FOR OPTIMUM RESULTS

Hot Gas Soldering

Michael D. Frederickson, Electronics Manufacturing Productivity Facility

Introduction

HOT GAS SOLDERING is a process that is commonly used in applications where the workpiece thermal mass is small and the melting temperature of the solder is relatively low. The efficiency of heating large-mass substrates with hot gas is low, when compared with radiative or conductive methods of heating. The electronics industry utilizes hot gas soldering to reflow or melt solder in localized areas on circuit assemblies. A common application is the reworking or removal of electronic components.

Michael D. Frederickson, Electronics Manufacturing Productivity Facility

Process Characteristics

Characteristics of hot gas heating that are critical to its effectiveness in soldering are:

- FOCUS OF GAS FLOW
- GAS FLOW RATES (VELOCITY AND VOLUME)
- TEMPERATURE CONTROL
- GAS MEDIA OR CONSTITUENT

The focus of gas flow defines the area of localized heating, determines the efficiency rate of heating a defined area, and controls the excessive heating of adjacent areas. In most electronic applications, because the areas that need to reach the solder melting temperature are relatively small, confining thermal energy to a small area is critical. The focus of gas flow is usually controlled via nozzle design or the use of baffle plates. The nozzle collimates the gas stream to optimize the gas impingement across one or more solder interconnects, whereas the baffle plates attempt to block the gas from impinging on adjacent areas or on a component body directly. Common nozzle materials are stainless steel or quartz glass.

Gas flow rates primarily determine heat transfer efficiency (that is, the temperature and heating rate of the workpiece) and may affect the total area being heated. Insufficient gas flow will reduce the efficiency of thermal energy transfer, whereas excessive gas flow will disperse heat across the assembly, which may result in the overheating of adjacent areas. On some hot gas soldering systems, the flow rates are adjustable in both volume and velocity and can be used to establish the most appropriate heating profile for soldering. The selection of optimum flow rates usually depends on the gas temperature selected for the soldering process and on the size of the openings in the nozzle, as well as the configuration of the workpiece or circuit board.

The gas temperature also affects the heat transfer efficiency and ultimately the time required to form the solder interconnect. Typically, the gas is heated by passing it through a set of resistive heating elements. The usual temperature of interest for soldering process control is the temperature at the exit aperture of the nozzle. Because air is a poor heat conductor, the gas temperature will fall off rapidly as the distance from the nozzle to the solder interconnect increases. In electronics applications, the component body tends to heat more rapidly than the actual interconnect; therefore, excessive nozzle-exit temperatures with a high flow rate may thermally damage components or circuit boards.

Typical gas media used in hot gas soldering are air, nitrogen, and a nitrogen-hydrogen mix ($75N_2$-$25H_2$). Air is the most common gas used because of its ready availability and low cost. Nitrogen is sometimes used to minimize the oxidation of the component and board metallizations and to potentially improve solder wetting performance and interconnect reliability. In some cases, a nitrogen-hydrogen mixture is used to capitalize on its lower density relative to air. The lighter gases allow for the same heat transfer performance and inert nature, while reducing the force of the gas against the area being soldered. This reduction in the force of the gas decreases the dispersive effects upon impingement. In addition, some no-clean flux materials perform better in an inert atmosphere, such as nitrogen, during the soldering process.

Hot Gas Soldering

Michael D. Frederickson, Electronics Manufacturing Productivity Facility

Process Parameters

Heating profiles are established in hot gas soldering by using a combination of gas flow rates, gas temperatures, and time. Some systems use lower flow rates and higher temperatures, whereas others use higher flow rates and lower temperatures. The actual selection of flow rates and temperatures depends on the physical and dimensional characteristics of the item being soldered, as well as component mounting density. Figure 1 illustrates a thermal profile of a component being soldered and the temperature across adjacent components.

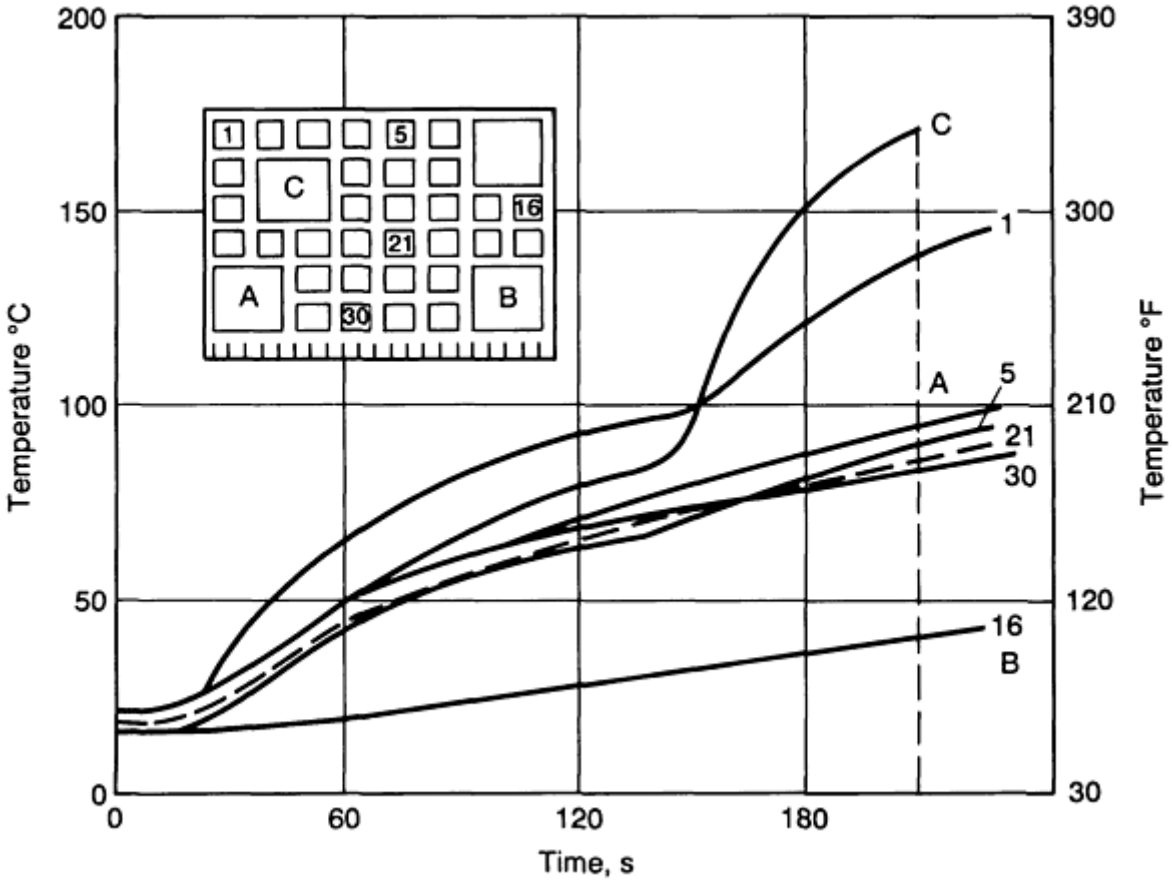

FIG. 1 TIME-TEMPERATURE RELATIONSHIP OF COMPONENT BEING SOLDERED (LINE C) AND ADJACENT COMPONENTS (LINES A AND B). LOCATIONS OF SPECIFIC SENSOR COMPONENTS ARE SHOWN IN INSET DIAGRAM.

Reliability concerns do exist when hot gas soldering techniques are used in electronics assembly. There is a potential for solder joint fracture when melting or reflowing a portion of a multi-leaded component. Fractures in solder joints occur when the joints are thermally cycled in use because of the induced stress caused by partially reflowing the component. If the hot gas process excessively heats adjacent components, causing a percentage of the interconnects on a component to reflow, then a residual stress may be established, which can significantly reduce the overall fatigue life of the solder interconnects. Therefore, gas flow rates and focus are critical to the overall reliability of the solder interconnects. The use of properly maintained equipment and trained operators should minimize these concerns.

Processing concerns also exist when using hot gas soldering in electronics assembly. Because this technique has inefficiencies relative to conductive and radiative methods, it is difficult to reflow solder joints that have large heat sinks. Therefore, an additional heating process may be needed to reduce the total hot gas heat energy required to reflow the solder interconnects. There are four methods of preheating the assemblies: oven bake, diffused hot gas, radiant, and conduction (edge rail or hot plate) heating. All methods are effective. However, the working time of assemblies preheated in an oven is very short. The selection of the preheating technique depends on the physical characteristics of the assembly being soldered and on the process equipment.

Induction Soldering

Paul T. Vianco, Sandia National Laboratories

Introduction

INDUCTION OR (RADIO FREQUENCY) HEATING is a versatile means of providing heat to the joint area. Heating is caused by electrical resistance to eddy currents induced in the workpiece. These currents are induced by the rapidly changing magnetic field generated by a coil supplied with an alternating current. The eddy currents are generated at the surface of the workpiece (skin effect) and diminish toward the interior. The depth of direct heating by eddy currents depends on the electromagnetic properties of the workpiece material, the frequency of the alternating current (higher frequency results in shallower penetration depth), and the power level of the magnetic field (i.e., the current in the coil).

The advantages of induction heating include the ability to supply heat uniformly over the entire joint area while maintaining a localized temperature rise so heat sensitive materials or devices neighboring the joint are not damaged. Induction heating is a compromise between global heating processes such as furnaces, which warm the entire part, and more concentrated heat sources, such as torches or soldering irons, which warm only a very localized area. A second advantage of induction heating is that the temperature rise can be very rapid, thereby limiting heat loss into the workpiece, oxidation of the substrate, and thermal degradation of the flux. Limitations that must be considered with the application of induction heating are the cost of the equipment and the need for specially trained personnel. These personnel are needed to ensure proper equipment setup so that efficient transfer (coupling) of energy between the coil and the workpiece take place.

In the induction process, heat energy is not delivered to the workpiece; instead, it is generated within the material by electromagnetic field coupling between the workpiece and the alternating current in the coil (i.e., the workpiece and the coil form an inductance-capacitance-resistance circuit with the power supply).

Induction Soldering

Paul T. Vianco, Sandia National Laboratories

Coupling Efficiency

The coupling efficiency is optimized over a narrow range of operating parameters (frequency, coil turns, coil proximity, etc.) per the given workpiece parameters (electromagnetic properties and part geometry). The first consideration regarding the use of induction heating in a soldering operation is the electrical and magnetic properties of the materials to be joined. First, the energy coupling is more efficient in ferromagnetic materials, that is, materials with large magnetic permeability values (e.g., iron, low-carbon steels, nickel, etc.). Permeability being the same, materials with higher electrical resistivity heat more efficiently than low-resistivity materials. Therefore, heating efficiency is optimized by joints having metals with large permeability and high electrical resistance as opposed to low-permeability, low-resistance metals (e.g., copper, brass, or aluminum). Figure 1 illustrates the energy input required to bring several ferrous and nonferrous materials to 188 °C (370 °F) (Ref 1). These differences become especially critical when joining dissimilar materials, where one part may heat up more quickly than the other.

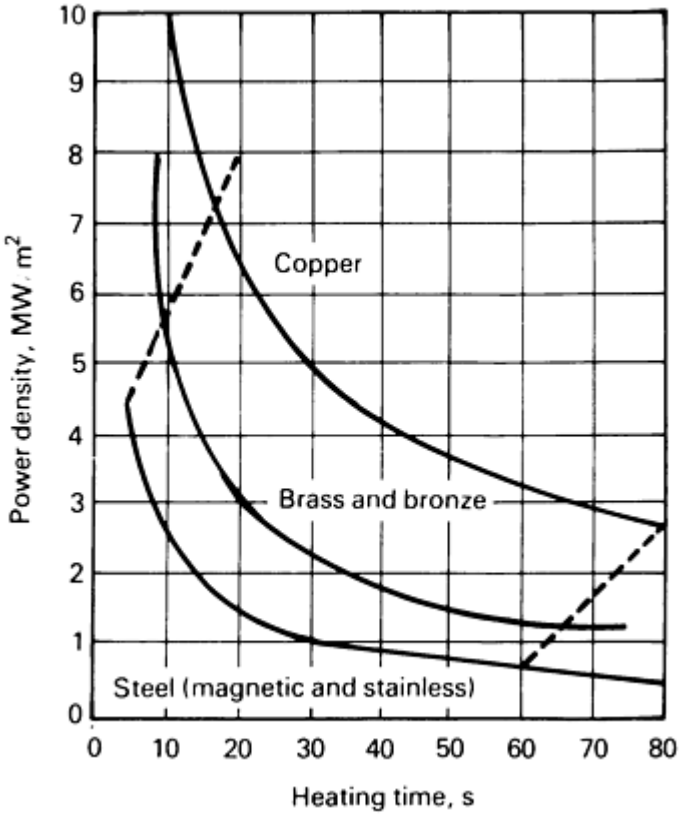

FIG. 1 POWER INPUTS AND HEATING TIMES FOR SELECTED FERROUS AND NONFERROUS MATERIALS. SOURCE: REF 1

Resistivity Effects. The coupling efficiency changes as the material warms up due to the temperature dependence of the electrical and/or magnetic properties. Resistivity increases with temperature for most metals and is the most important concern in nonmagnetic materials. Table 1 shows the resistivity changes in materials over the typical range of soldering temperatures. Unfortunately, changes to the overall coupling efficiency (and therefore heating rate) caused by resistance changes are not easily predicted because part geometry and penetration depth of the electromagnetic field have a synergistic effect.

Source: Ref 1

Curie Temperature Effects. In magnetic materials, a significant reduction in coupling efficiency occurs when the material passes through its Curie temperature upon heating (i.e., changes from ferromagnetic to paramagnetic). Curie points for iron and nickel are 770 °C (1418 °F) and 358 °C (676 °F), respectively (Ref 2). Clearly, only nickel would be of concern at soldering temperatures. The magnitude of the coupling loss depends strongly on the geometry of the part and the coil configuration. Lost coupling efficiency due to resistance or magnetic property variations can be regained by changes to the power supply frequency during the soldering procedure. However, in the case of the Curie transition, the exceptional heating rate of ferromagnetic materials can never be wholly recovered.

Temperature rise in the workpiece is also affected by the thermal mass of the part(s) as reflected by thermal conductivity, specific heat, and size of the part. Heat loss from the joint area due to thermal conductivity as well as excessive part size can lengthen heating times, making it difficult to uniformly heat joints containing dissimilar metals. Thermal mass is often expressed quantitatively by the product of the specific heat (c) and the material density (γ). Values of $c\,\gamma$ are given in Table 1.

Induction Soldering

Paul T. Vianco, Sandia National Laboratories

Workpiece Geometry

Induction heating is more efficient and more easily practiced on workpieces with simple, axis-symmetric geometries because they, in turn, require simple coil geometries. Electromagnetic energy is more easily coupled into the part due to closer proximity to the workpiece and the generation of a more uniform magnetic field. Uniformity, as well as field strength, improves as the number of turns in the coil is increased. A larger coil also provides a more uniform field but at the expense of delocalizing the heating area. Some sample coil configurations for typical part geometries are shown in Fig. 2. Finally, uniform heating of the workpiece can be achieved in relatively nonuniform magnetic fields by rotating the part within the coil.

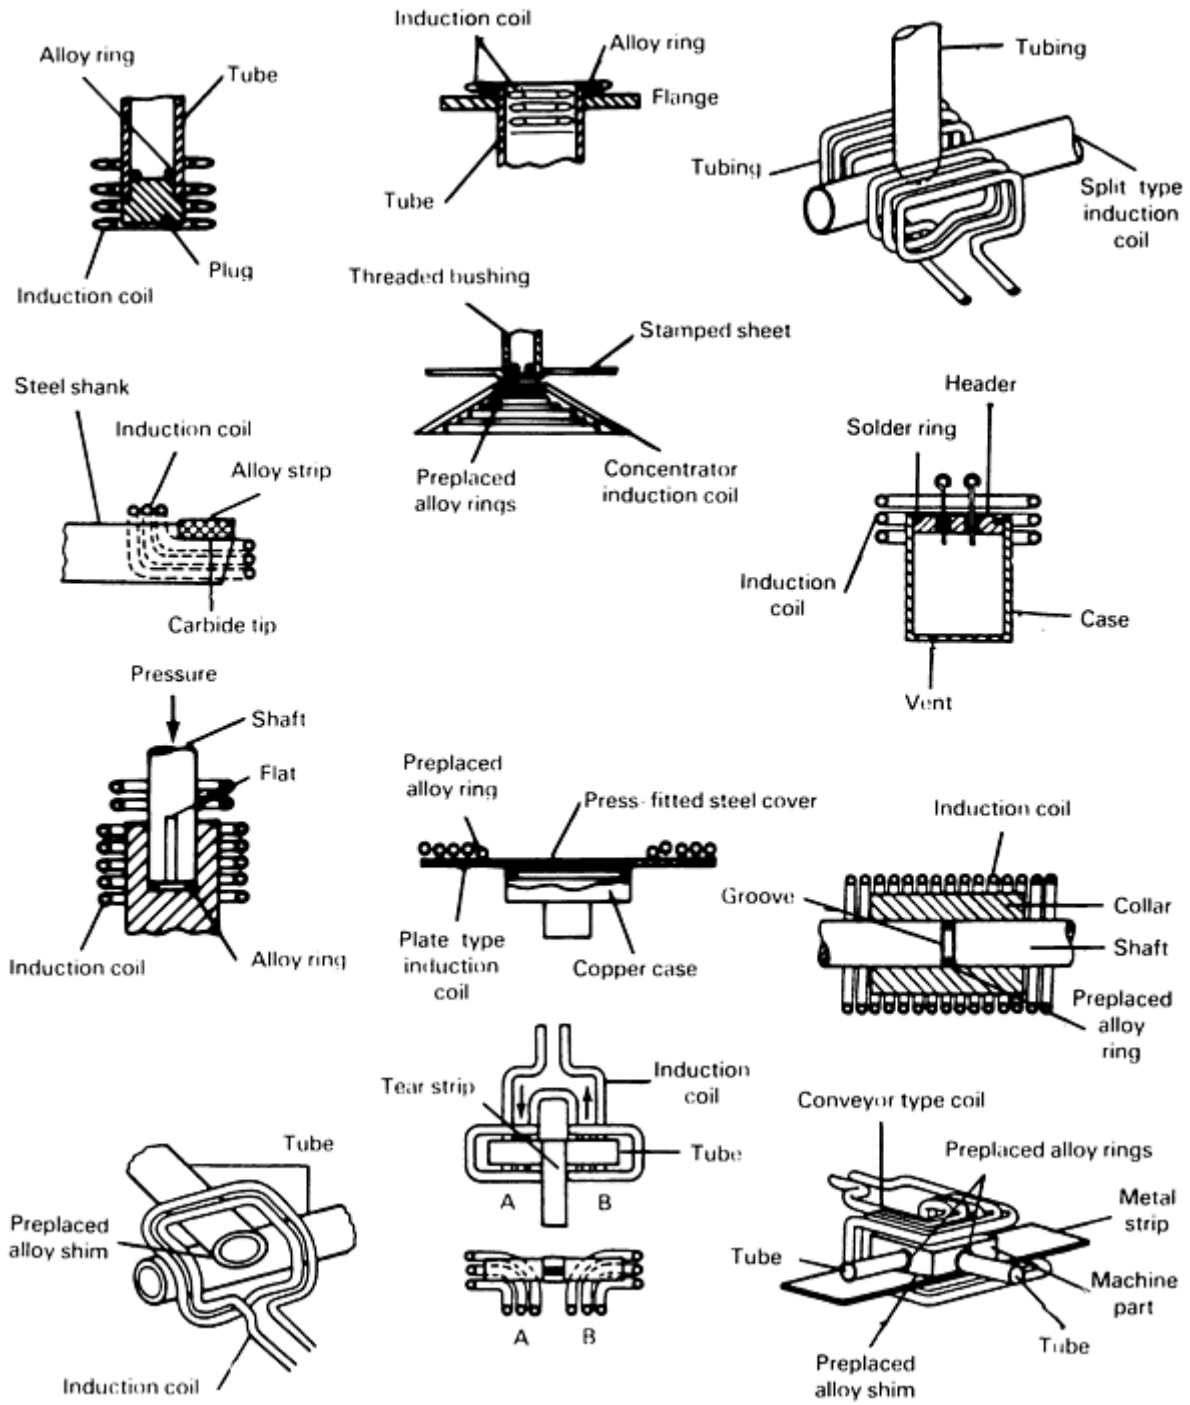

FIG. 2 COIL CONFIGURATIONS FOR TYPICAL JOINT SHAPES. SOURCE: REF 1

Use of induction heating becomes more limited as the workpiece geometry becomes complex. First, the placement of the coils about or near the joint area becomes more difficult. Secondly, corners and protrusive shapes in the magnetic field may develop hot spots caused by proximity to the coil or low thermal mass, thereby possibly damaging the material at those locations. To accommodate complex part configurations, coil shapes can be altered to vary the local magnetic field strength and hence change the localized heating of the part. For example, the overheating of a corner or protrusion can be reduced by locally decreasing the number of coil turns in that area or by positioning the coil farther from the workpiece. The opposite actions apply to part configurations with large thermal mass that require additional power input to prevent heat-sinking effects.

In addition to surrounding the part with the coil to maximize coupling, coils can be used as proximity sources for localized heating. In this technique, a coil (typically smaller than the part) is located next to the joint area to be heated. As

expected, the limited magnetic field intensity causes this technique to have very low coupling. The heating area can be extended by manually scanning the coil over a larger area (such as is done in torch heating).

1. P. SIMPSON, *INDUCTION HEATING,* MCGRAW-HILL, 1960

Preplaced Solder

Soldering by induction heating necessarily implies joints designed for the use of solder preforms or paste; these items are introduced into the joint area prior to applying heat. The amount of solder is much less than the mass of the parts, so the effect of the preform on the induction heating process is typically negligible. Space restraints, as well as the danger of electrical shock and severe burns, prohibit manual interaction with the workpiece during heating. Therefore, certain practices associated with the use of preplaced solder must be followed:

- AN ADEQUATE SUPPLY OF SOLDER ALLOY MUST BE PRESENT TO COMPLETELY FILL THE GAP.
- PROVISION MUST BE MADE FOR SOLDER FLOW THROUGH THE JOINT AND THE ESCAPE OF FLUX VOLATILES FROM THE JOINT.
- DESIGN CONSIDERATIONS MUST ALLOW FOR AN INCREASED PROPENSITY OF VOID FORMATION DUE TO LIMITED CAPILLARY FILL WITH PREPLACED SOLDER.
- FIXTURING THAT SECURES THE WORKPIECE DURING SOLDERING MUST MAINTAIN SUBSTRATE ALIGNMENT AND THE JOINT GAP SPECIFIED FOR THE FINAL PRODUCT.

Wetting of the parts can be enhanced by hot solder dipping or by electroplating a coating of tin-lead solder on the joint surfaces prior to final assembly. Although typically performed in air, induction soldering can also be practiced in inert atmospheres or in vacuum (e.g., localized cover gas blankets or more sophisticated equipment such as glove boxes and large chambers). Induction heating is well suited for robotic automation, including bench-top systems as well as larger-scale factory production lines. Monitoring the workpiece temperature by optical pyrometry can provide a feedback signal for real-time control of the induction power source, thereby improving reproducibility of the heating schedule parameters.

Induction Soldering

Paul T. Vianco, Sandia National Laboratories

Setup Parameters

The heating requirements of some simple workpiece geometries (and accompanying simple coil geometries) have been calculated, and performance parameters have been tabulated in charts (Ref 1). However, maximizing the energy coupled into a particular workpiece is more often the result of trial-and-error experiments with coil configurations, power supply frequency, and voltage. Nonoptimum coupling causes greater current to be drawn from the power supply to achieve the desired heating of the part, possibly exceeding the power capacity of the generator. Joints between dissimilar metals further lessen optimum coupling and diminish efficiency.

Although induction heating may require some trial-and-error efforts to optimize the process for a given product, some preliminary calculations can provide approximate design criteria from which to begin process development.

The first parameter required to set up an induction system is the power required to heat the workpiece(s). For localized heating, heat is lost to the remaining mass of the part as well as through radiation, conduction, and convection with the atmosphere. For a first-order approximation, ambient heat loss can be neglected, particularly with the relatively low temperatures necessary for soldering processes. However, conduction into the solid away from the joint area can be significant; moreover, the calculations to quantify the effect may be very complex. An estimate of the power, ***P***, required to heat a section of material can be determined from:

$$P = \frac{g\,c\Delta TV}{t} \qquad \textbf{(EQ 1)}$$

where V is the volume to be heated, c is the specific heat of the material, ΔT is the temperature rise, γ is the density of the material, and t is the time for the temperature increase to take place. Of course, the power rating of the induction heating equipment must be higher than that calculated in Eq 1 to account for coupling inefficiencies and the heat loss mechanisms noted above. The overall efficiency of induction heating nonferrous metals is 50 to 75%. Values are approximately 75% for magnetic metals that are below the Curie temperature (i.e., in the ferromagnetic state).

Selection of a power frequency depends on the type of soldering material and the size of the workpiece. Table 2 gives typical frequencies for the through-heating of nonferrous metals. The representative geometry is that of round bar. A similar range of values can also be used for magnetic materials below the Curie temperature. Heating the material above the Curie point requires a frequency increase to maintain reasonable power coupling, particularly as the part size increases (power input to the workpiece is proportional to the square root of the frequency). Frequency values at temperatures exceeding the Curie point are 3 to 10 kHz for part sizes of 5 to 40 mm (0.20 to 1.6 in.) diameter and 1 to 3 kHz for diameters of 40 to 150 mm (1.6 to 5.9 in.).

TABLE 2 FREQUENCIES FOR THE THROUGH-HEATING OF NONFERROUS METAL ROUND BARS

BAR DIAMETER		FREQUENCY, KHZ
mm	in.	
0-12	0-$\frac{1}{2}$	450
12-25	$\frac{1}{2}$-1	10 AND 3
25-75	1-3	1
>75	>3	50

A parameter of particular interest to induction heating is the penetration depth of heating (also called the skin depth), and this is denoted by the symbol δ. The skin depth is defined as the position in the solid away from the surface at which the magnitude of the magnetic field falls to approximately 37% of its value at the part surface. The skin depth is given by:

$$d = \frac{r}{pm\,f} \qquad \textbf{(EQ 2)}$$

where ρ is the resistivity of the part, $\rho$is the absolute magnetic permeability, and f is the frequency. The absolute permeability is equal to the product $\mu_r\mu_0$, where μ_r is the relative permeability of the material (e.g., pure iron = 18,000 and nonmagnetic copper = 1) and μ_0 is the permeability of "free space," which equals 1.257×10^{-6} V · s/m · A (a universal constant). Skin depth increases as the material resistivity increases and as the frequency decreases. For magnetic materials at temperatures below the Curie point, the value of μ_r is not a constant; it is dependent on the magnetic field intensity, H_0. For example, the value of μ_r for a low-carbon 1044 steel is $734{,}000/H_0^{0.92}$.

Induction Soldering

Paul T. Vianco, Sandia National Laboratories

Safety Concerns

The safety hazards accompanying the use of induction heating include electrical shock from contact with the coils as well as burns caused by the heated workpiece. A third hazard is the danger of steam explosion caused by arcing between the coil and the part. Typically, the heating coils are hollow copper tubing; they are cooled by the internal flow of water or a water-base coolant. The vapor cloud accompanying the spatter of flux during soldering can cause an electric arc that may puncture the copper tubing if the induction coil is close to the workpiece. Arcing can also be caused by movement of the coil windings through forces generated by the magnetic field. Water contacting the hot part produces an immediate, violent steam explosion. To prevent this occurrence, adequate clearance should be maintained between the coil and the part (typical minimum spacing is 6.4 to 13 mm, or 0.25 to 0.50 in.). Moreover, trial heating runs, in which the current is slowly increased to assess coil movement and part-to-coil shorting, should be performed prior to product assembly.

Wave Soldering

Paul T. Vianco, Sandia National Laboratories

Introduction

WAVE SOLDERING is one of the primary techniques for mass assembly of printed wiring boards involving through holes, surface mount devices, or a combination of these two technologies. A schematic of the wave soldering process is shown in Fig. 1. A solder "fountain" or "wave" is created by a pump located at the bottom of the solder pot; suitable baffles are mounted in the pot to direct the flow of solder into the desired configuration. The printed wiring board is placed onto a conveyor, which brings it into contact with the wave surface. Note from Fig. 1 that the circuit boards travel along the surface of the solder; molten alloy does not flow on top of the board. As the printed circuit board passes on the wave, the solder wets the surface-mount package leads, terminations, and exposed metal surfaces in the circuit board, and also fills plated through holes. This technique can produce several thousand solder joints in a matter of minutes.

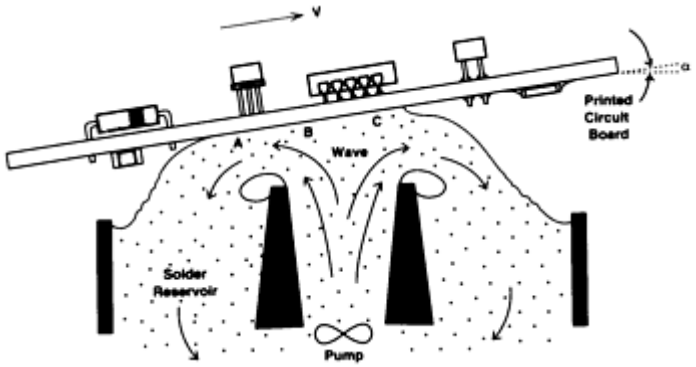

FIG. 1 SCHEMATIC OF THE WAVE SOLDERING PROCESS. THE THREE IMPORTANT PROCESS CONTROL REGIONS ARE THE ENTRY (A), THE INTERIOR (B), AND THE PEEL-BACK REGION (C).

The implementation of wave soldering for surface-mount technology requires that the devices be glued to the substrate prior to wave soldering. Moreover, the entire surface-mount package must be able to withstand contact with the flux and temperatures of the molten solder without a loss of reliability. Small-outline transistors and discrete components (chip resistors, capacitors, etc.) are readily attached by wave soldering; larger packages (e.g., leaded or leadless chip carriers) may be damaged by exposure to the harsh environments (flux and molten solder) as well as be more prone to solder defects (Ref 1).

The wave soldering technique encompasses a sequence of processes, all of which are typically contained in the same apparatus. First, the substrate receives a coating of flux. Flux application methods include:

- A WAVE TECHNIQUE SIMILAR TO THAT SHOWN IN FIG. 1
- COATING THE CIRCUIT BOARD BY A FLUX FOAM CREATED BY PASSING AIR OR NITROGEN THROUGH A FLUX BATH TO GENERATE THE FOAM (OR FROTH) ON THE BATH SURFACE
- DIRECTLY SPRAYING THE FLUX ONTO THE BOARD SURFACE

After flux is applied, the substrate is passed through a preheating stage. Warming the board promotes activation of the flux, accelerates the evaporation of volatiles from the flux (which can cause voids and solder balls by spattering upon contact with the hot solder bath), and reduces thermal shock to the substrate and devices when it passes onto the solder wave. Then, the circuit board contacts the solder wave for the formation of the joints. After passing the wave, the board cools through natural heat loss or, more quickly, by the use of forced air.

Design Considerations and Process Parameters

The successful assembly of a printed circuit board by the wave soldering technique relies on the proper process parameters and the layout of the board for the respective technology (through-hole, surface-mount, or mixed). The hole or via size (diameter) must permit adequate capillary filling by the molten solder and form the joint or to interconnect within the short time period (5 to 7 s) that the board contacts the wave. Holes with small diameters (<0.076 mm, or 0.003 in.) and long length joints with very thin gaps restrict the elimination of flux volatiles, causing voids and insufficient solder quantity. Excessively large holes (>1.0 mm, or 0.039 in.) and gaps (>0.40 mm, or 0.016 in.) decrease the capillary driving force of the solder to fill the volume and create the joint; in some cases, the solder simply drains from the hole under its own weight.

In addition to insufficient solder in holes and vias, other defects in wave-soldered products include bridges, icicles, and skips. Bridges are defects in which a quantity of solder forms a short across two conductors (leads, lands, or traces). A piece of solder that does not short two conductors, but rather hangs from one surface, is an icicle. Skips refer to the failure of solder in the wave to reach the metal surface and form the joint.

Design Considerations

Design considerations, such as the orientation of through-hole leads and surface-mount devices with respect to the direction of travel past the wave, as well as the proximity of packages to 0one another, can dramatically affect yields (Ref 1, 2). Figure 2 is a diagram showing the preferred orientation of through-hole and surface-mount packages.

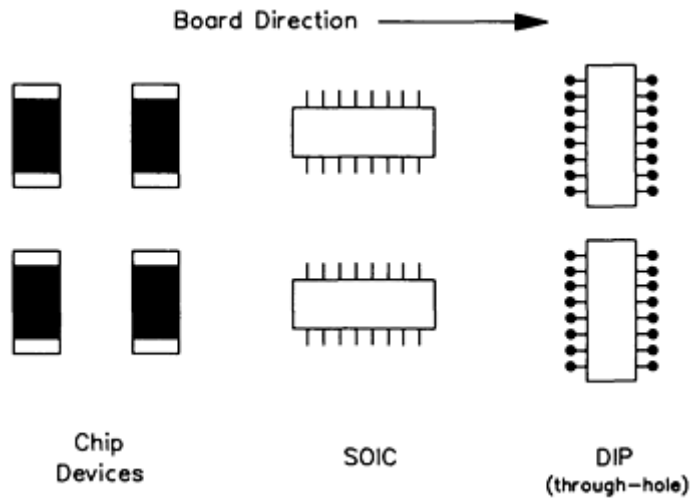

FIG. 2 SCHEMATIC OF PREFERRED DEVICE ORIENTATION FOR WAVE-SOLDERED ASSEMBLIES. SOIC, SMALL-OUT-LINE INTEGRATED CIRCUIT (SURFACE-MOUNT); DIP, DUAL-INLINE PACKAGE (THROUGH-HOLE)

Through-Hole Technology. In the case of through-hole assemblies, the leads on the side of a through-hole 16-pin dual-in-line package (DIP) should be oriented perpendicular to the travel direction of the conveyor to prevent bridging between them. Moreover, the bridging of leaded packages can be limited by maintaining the lead extension beneath the circuit board at less than 1.0 mm (0.039 in.). Leads that are too close to each other also increase the chances of solder bridges. Solder skips are less frequently observed on through-hole products (assuming adequate wettability of the metal surfaces) because the device package body is on the top surface, and therefore does not shadow joints from the wave.

Surface-Mount Technology. The circumstances of solder defect function are different for surface-mount technology because the entire package passes through the wave. Solder joint skips are more common because the package body can shadow nearby leads or terminations from contact with the wave, causing an inadequate supply of solder at the joint. Therefore, the joint areas of the package should be fully exposed to the wave, as suggested by Fig. 2. Packages with leads or terminations on all four sides experience an increased propensity for defects on the leads in the nonpreferred orientation. Also, the greater density of devices on surface-mount circuit boards increases the frequency of solder skips due to the closer proximity of the packages. Finally, the finer lead pitch used on surface-mount leaded and leadless (chip carrier) packages limits or prohibits their assembly on boards by wave soldering.

Process Parameters

The second factor critical to successful implantation of wave soldering of printed circuit boards is the process parameters. Process parameters can be divided into three groups: the fluxing operation, the solder wave properties, and the process schedule.

The fluxing operation not only includes the particular parameters (wave or foam height, spraying pressure, etc.) needed to ensure adequate flux supply to the board for solder wetting, but also the condition of the flux. In-line fluxing techniques (wave or foam) frequently use the same quantity of flux to process a large number of boards. Deterioration of the flux due to board contaminants, as well as loss of the flux vehicle, must be monitored to minimize defects in the final product. Specific gravity is used to indicate flux condition.

Low-solids fluxes are gaining popularity as a "no-clean" alternative to rosin-base fluxes, including their use in wave soldering. The low-solids contents (typically less than 5%) make these fluxes difficult to foam, so spray or wave applications are preferred (Ref 3). Tighter control of the flux chemistry, reduced solder pot temperatures (by 10 to 15 °C, or 18 to 27 °F), shorter solder dwell times (by 1 to 2 s), and the use of inert or reducing atmospheres (Ref 4) can reduce the number of defects.

Solder Wave Properties. The second process factor is the solder wave properties. The simple wave geometry (also called the T-wave) is shown in Fig. 1. Three regions of the wave are identified. The entry region (on the left with the board moving to the right) should be sufficiently turbulent to supply solder to all of the exposed metal surfaces and should permit the escape of flux volatiles that may cause voids in the joint. In the case of surface-mount assemblies, fluid motion must be sufficiently active to force solder close to the packages for adequate wetting of terminations and leads, thereby avoiding solder skips. The interior region of the wave acts as the heat source and solder supply to promote wetting of the substrate features. The exit or peelback region is the point at which the board leaves the wave and is critical in preventing solder bridge and icicle defects on the circuit board. For example, defects are reduced by having a smooth wave that separates very slowly from the board. This effect is achieved by matching the solder flow velocity with the speed of the circuit board (Ref 5) as well as by making adjustments to the wave configuration. Hot air knives positioned after the wave have been used to remove solder bridges and icicles prior to solidification of the solder.

Figure 3 shows several equipment modifications used to produce different wave geometries. The extended T-wave and lambda-wave modifications to the standard T-wave cause a smooth surface at the exit region to limit bridges, icicles, and the formation of excessive dross. The dual-wave configuration provides separate turbulent and smooth (laminar) waves to effect the desired solder joint qualities. Note that these modifications generally require that the circuit board laminate and devices withstand a longer period of contact with the molten solder.

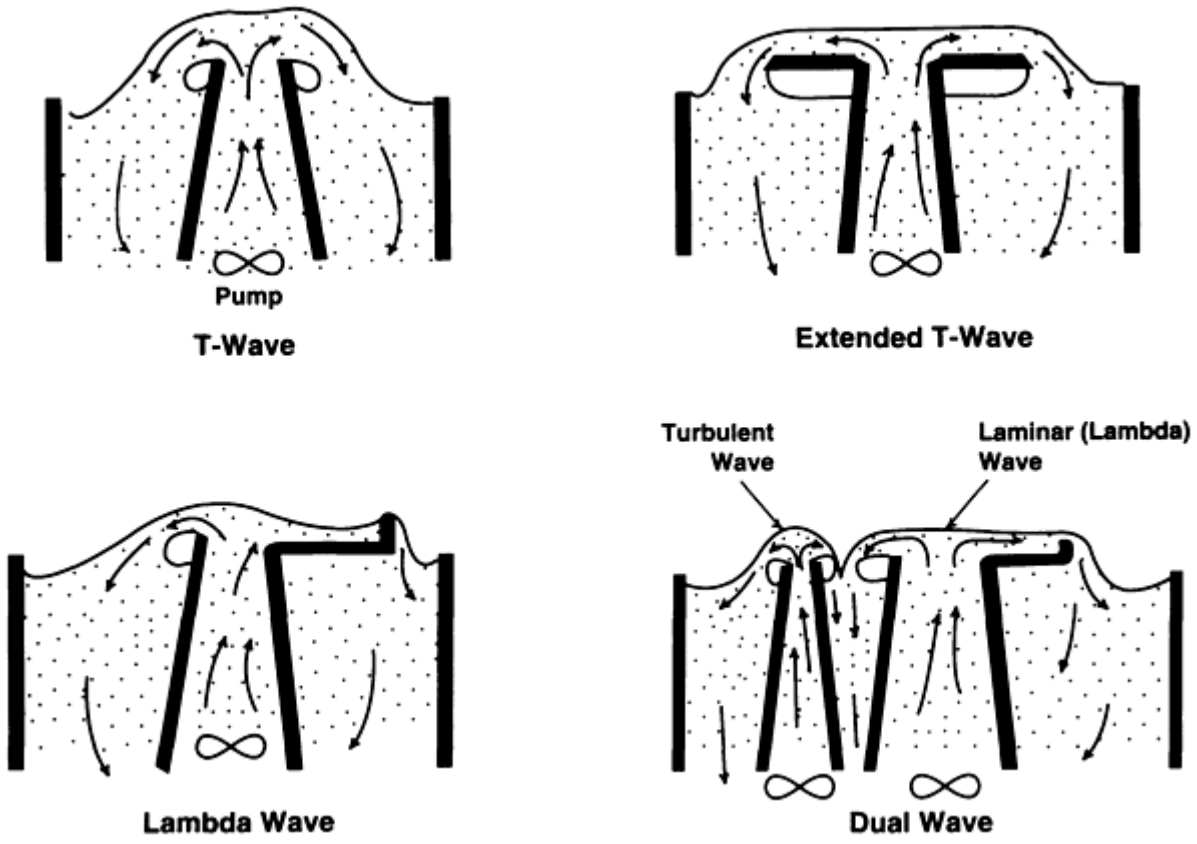

FIG. 3 EQUIPMENT MODIFICATIONS USED TO PRODUCE DIFFERENT WAVE GEOMETRIES. THE NOMENCLATURE DESCRIBES THE PROFILE GEOMETRY OF THE WAVE.

Dross formation tends to be high in wave soldering due to the large surface areas of solder exposed to the atmosphere (which is further aggravated by the turbulent flow of the solder in the pot). Dross particles can become embedded in the solder joints as well as disturb the peel back of the solder upon exiting the board. The use of inert atmospheres, reduced solder temperatures, and oils to cover the solder surface limit the formation of dross.

Solder temperatures are typically higher than those used in reflow processes. The higher temperatures are required to provide sufficient heat transfer to the substrate for adequate wetting as well as to reduce the solder surface tension to limit defects at the peel-back region. Solder pot temperatures are typically 50 to 80 °C (90 to 145 °F) above the liquidus temperature of the alloy; higher values are required for thicker substrates (e.g., multilayer or controlled-expansion substrates). The potential for damage to the laminate, including warpage and distortion as well as delamination of the conductor, increases with higher solder temperatures. Continuous processing with wave soldering equipment can cause a build-up of contaminants in the solder pot (e.g., nickel, copper, and gold from circuit board and lead finishes). See the article "Soldering in Electronic Applications" in this Volume for guidelines on acceptability limits for solder pot contamination.

In addition to the traditional tin-lead alloys, wave soldering has been adapted to other solders, including the eutectic tin-bismuth solder and the tin-lead-bismuth alloys (Ref 6).

Process Schedule. The third factor in the wave soldering technique is the process schedule, which includes the preheat zone temperature profile, the solder wave temperature, the conveyor tilt angle (α in Fig. 1, which affects the exit geometry of the board), and the conveyor speed. The conveyor speed determines the dwell time of the circuit board in the preheat zone and solder wave. Although specific settings depend on the type of equipment and the product being assembled, some general guidelines can be applied. First, the preheat stage should bring the board temperature to the range of 100 to 150 °C (210 to 300 °F). These temperatures provide suitable activation of the flux and lessen thermal shock to the circuit board (and devices) upon contact with the solder wave. The dwell time in the molten solder wave should be limited to 3 to 5 s. Dwell times at the molten solder temperature can reach 5 to 10 s for dual-wave systems. Time-temperature exposure limits for soldering processes are typically specified for devices and the laminate; manufacturer recommendations should

always be followed. Also, dwell times should be minimized to limit the leaching of conductor or lead finishes (e.g., copper, nickel, or gold) into the solder.

Wave Soldering

Paul T. Vianco, Sandia National Laboratories

Defects

Certain defect trends can be identified with particular process conditions (Ref 7). For example, voids and blowholes are more frequent at fast conveyor speeds and higher solder temperatures. These process conditions generate an excessively fast heating rate, which causes the rapid volatilization of the flux components and subsequent void formation. Rapid conveyor speed can be responsible for several other defects:

- AN INCREASED PROPENSITY FOR POOR FILLING OF HOLES AND VIAS CAUSED BY INSUFFICIENT DWELL TIME IN THE SOLDER WAVE. AS A RESULT, THE WETTING KINETICS MAY NOT FILL THE VOLUME (THIS IS FURTHER EXAGGERATED BY LOW SOLDER TEMPERATURES)
- THE PRESENCE OF SOLDER BRIDGES AND ICICLES DUE TO POOR MATCHING OF THE SUBSTRATE SPEED AND FLOW OF THE SOLDER WAVE AT THE PEEL-BACK REGION UPON BOARD EXIT
- CRACKING OF SURFACE-MOUNT CERAMIC CHIP CAPACITORS CAUSED BY THERMAL SHOCK

High solder pot temperatures and slow conveyor speeds (i.e., long dwell times) can create difficult-to-remove flux residues. Also, excessive warpage or distortion of the board results from inadequate support of the substrate by the conveyor system; this is particularly acute with thinner laminates, higher soldering temperatures, or longer dwell times (e.g., dual-wave systems). Thicker circuit boards (backplanes) may also warp due to the large thermal gradients through the thickness of the laminate due to inadequate preheating of the board.

Clearly, the various process parameters can interact to produce certain defects. Therefore, optimization experiments and statistical process control are required to obtain and maintain acceptable product yields. The qualitative guidelines cited above provide a first measure of correlating defects to process conditions for subsequent improvement to the assembly procedure.

Vapor-Phase Soldering

Dale L. Linman, Centech Corporation

Introduction

VAPOR-PHASE SOLDERING is a process of condensation heating, in which a product prepared for soldering is passed through or into a layer of saturated vapor. The vapor condenses on the relatively cool part, which transfers the latent heat of vaporization to the part and heats it rapidly and uniformly. The process reaches thermal equilibrium in a few seconds at a temperature that is only limited by the boiling point of the fluid used in the process. Typically, newer equipment utilizes a single perfluorocarbon fluid vapor layer, which does not contain chlorine or bromine and is environmentally safe. This fluid is also chemically inert, thermally stable, and has very low solvent action.

Although the process is used in a variety of heating applications, such as curing epoxies and polymers or stress relieving various platings, it is primarily useful when soldering surface-mounted components to various substrate materials. Because of the precise temperature control that this process offers (by virtue of a fixed boiling point), multilevel soldering is possible using up to three solder compositions with three different melting temperatures. Fluid temperatures that range from 100 to 265 °C (212 to 510 °F) are available. The most common fluid used boils at 215 °C (420 °F) and is used for 63-37 type solder, which melts at 183 °C (360 °F). A 30 °C (55 °F) differential is typical, to enable the heating process to proceed rapidly. Temperature precision also prevents the assembly from overheating.

Typical Materials

The typical materials that are joined by this process are solder-coated substrates made from various ceramic materials and G10 or FR4 epoxy laminates mated with surface-mounted components. Solder paste is typically applied to the substrate by screening, stenciling, or using *X-Y* dot placement. Components are then placed in the correct position in the solder paste, which temporarily holds them until they are soldered. The assembly is then passed through the vapor-phase setup, where the solder is melted, joining the components to the substrate. Typical surface-mount lead density is 1.25 mm (0.050 in.) on centers. Fine-pitch components as small as 0.38 mm (0.015 in.) on centers can also be processed. There is no inherent lead-pitch limitation in the vapor-phase process, because it is essentially an oxygen-free soldering process. Because of its uniformity, rapid heating, precise temperature control, and oxygen-free environment, the process is preferred for high-value assemblies. Also, because of the thermal capacity, ease of profiling, and forgiving nature of the process, it is also used when high throughput is required from limited floor space or when a large number of different types of boards need to be run in a given time period.

Equipment is normally configured for either batch or in-line operations (Fig. 1 and 2). The majority of machines available are of single-vapor design (Fig. 3). Earlier models had vertical access and used less-expensive fluid as a cover layer. These machines also lacked a preheating capability, which was found to be necessary in order to reduce the temperature differential at the point of solder melting. This measure prevents wicking and other undesirable characteristics that can develop when one part of a solder joint heats faster than the other. Both a preheating capability, typically provided by infrared panels, and a cooldown stage have been incorporated in newer models. The cooldown stage brings the solder joint through the liquidus phase more quickly (Fig. 4). This procedure reduces the time that the joint can form undesirable intermetallic layers and simultaneously improves the grain structure of the joint, thus improving its capability to withstand thermal cycling.

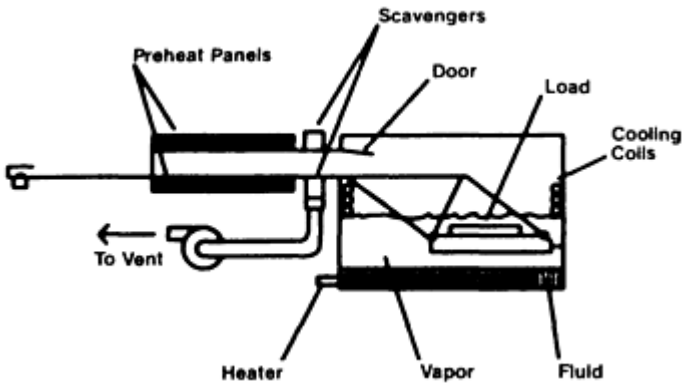

FIG. 1 PELLETIZED VAPOR-PHASE BATCH SYSTEM

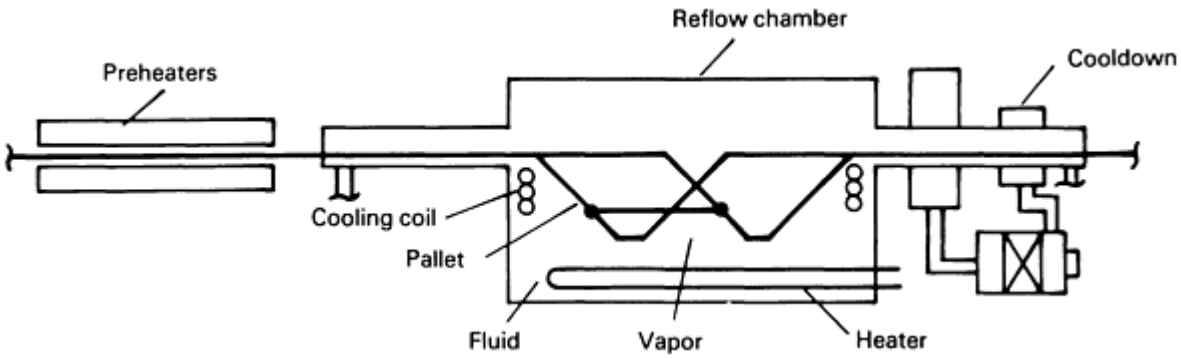

FIG. 2 THIRD-GENERATION VAPOR-PHASE REFLOW SYSTEM

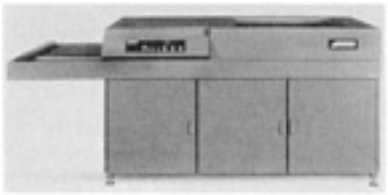

FIG. 3 SINGLE-VAPOR BATCH-TYPE EQUIPMENT

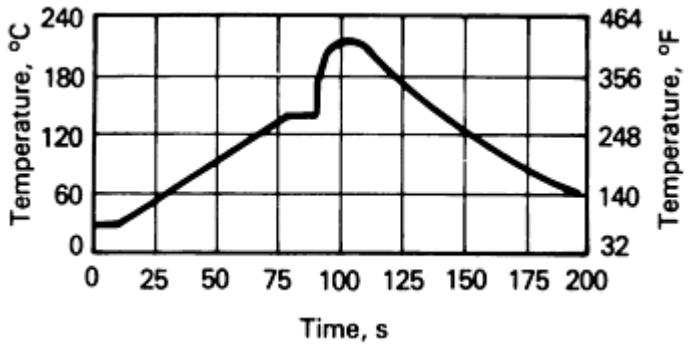

FIG. 4 THERMAL PROFILE

The stability of the vapor-phase process and its ease of profiling means that machine operators require little training. If the overall process is established correctly, then there are few elements that require adjustments. A smooth, vibration-free conveying mechanism enables defect-free soldering and assembly.

The proper setup procedure is to attach a thermocouple to a strategic location on the printed board, such as a sensitive component or a solder joint. Then, the board is processed to reach a preheat temperature of between 125 and 150 °C (255 and 300 °F) in 50 to 60 s. A desirable heating rate is approximately a 2 °C/s (4 °F/s) rise to within 100 °C (180 °F) of the reflow temperature. Major parameters are dwell time (batch machines), conveyor speed (in-line machines), and preheat panel temperature. Reflow time is established by observing the solder melt through the window in the chamber. In the batch machine, the dwell times can be set from those obtained and the process replicated. With in-line machines, the reflow time is established by the conveyor speed and the preheat temperature is adjusted with the panel temperature. Similar board assemblies can be processed using very similar profiles, which minimizes lost machine time due to the complex repetitive profiling that is common with other reflow methods.

Because vapor-phase soldering depends on the series of processes that precede it, every parameter leading to the actual soldering process must be carefully controlled to ensure a high yield. For example, thickness, viscosity, and location accuracy are just some of the parameters involved in solder paste application. Pad design and board layout are equally important to the process, as is the accurate placement of components. With proper controls, it becomes possible to solder with defect rates under 50 ppm using the vapor-phase process. Information on guidelines for parameter control can be obtained by contacting the Institute for Interconnecting and Packaging Electronic Circuits.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Introduction

THE SELECTION of materials for welded construction applications involves a number of considerations, including design codes and specifications where they exist. Mobile structures, such as automobiles and aerospace vehicles, have quite different materials requirements for weight, durability, and safety than stationary structures, such as buildings and bridges, which are built to last for many years. In every design situation, economics--choosing the correct material for the life cycle of the part and its cost of fabrication--are of great importance. Design codes or experience frequently offers an adequate basis for material selection; for new or specialized applications, however, the engineer encounters problems of an unusual nature and thus must rely on basic properties of the material, such as strength, corrosion or erosion resistance, ductility, and toughness. The properties of the various metallurgical structures associated with the thermal cycles encountered in the welding operation must also be included in the design process. The various subsections in this article offer guidance for material selection applications involving bridges and buildings, pressure vessels and piping, shipbuilding and offshore structures, aerospace systems, machinery and equipment, automobiles, railroad systems, and sheet metal. Material properties and welding processes that may be significant in meeting design goals are described.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Overview

Principles of Material Selection

Structural Integrity. Before a structure is initially placed in service, the properties of its materials of construction must be adequate to ensure that the structure will perform as intended. Its components must be strong enough to bear the loads that will be imposed. It must be capable of meeting various inspection and qualification tests required by the end user to measure base material and weld soundness, ductility, toughness, and strength.

Length of Service. The service environment is often the largest influence on material selection. Materials of construction rarely last indefinitely. One of the principal selection considerations is the intended length of service for the structure. The designer needs to choose materials that will meet the conditions imposed initially and that can adapt to possible changes in conditions during the life of the structure.

The length of service is often dictated by obsolescence. Military hardware fabricated during wartime is an example of structures with relatively high obsolescence and short service life. Rocket cases for the propulsion of space vehicles need

to last one launching. At the other end of the spectrum, hydroelectric projects have expected lifetimes of a century or longer.

Materials or components rarely reach the end of their useful lives at the same time. Although a hydroelectric project is designed to last 100 years, some components may reach the end of their expected lives in less time, either by obsolescence due to improved technology or by unavoidable wear. At the outset of the material selection process, the length-of-service criterion must take into consideration the following: inspectability for potential failure, ease of maintenance of areas subject to deterioration, and ease of replacement of obsolete or life-exhausted components.

Joining Process. The suitability of the materials for the fabrication process to be employed must be considered early in the selection process. Weldability is the property of a material that dictates its ease of joining. The term most often applies to various types of steels joined by arc welding processes. This property often determines whether preheat is needed for successful welding and whether some type of postweld heat treatment is required to restore properties degraded by the welding operation.

Although weldability usually relates to the joining of relatively thick plates, the choice of materials for sheet metal applications must also take the welding process into account. The thinner the metal, the more difficult it is to arc weld. Brazing, soldering, or resistance welding is often used to join thin sheet materials. Resistance welding is frequently employed in the assembly of automobile bodies, for example; however, this process may not perform as reliably on coated steels as it does on uncoated steels.

Design Codes. Material selection is often dictated by the codes by which the design is governed, but there is still frequently a choice of materials. For example, pressure vessel codes offer a choice of steels, depending on the service temperature. Structural codes for buildings and bridges allow the use of both plain carbon and low-alloy steels. However, the codes tend to narrow the choice of materials.

Economics. An overriding selection criterion is often cost. In the broadest sense, this can be determined by the price of the material. However, a designer must assess not only the unit cost of the selected material, but also the costs imposed by fabrication. Compared with unalloyed steel, a low-alloy steel may allow a structure to be built using 25% less steel at a nominal 15% increase in unit price, but the cost of fabrication, such as the need for preheat and postweld heat treatment, may outweigh the material saving. A more costly steel that does not require painting or other protection from atmospheric corrosion may be a more economical choice, if not for initial construction, then for the life of the structure.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Service Conditions

The service environment is a principal determinant in the selection of materials for welded construction applications. The physical, mechanical, and corrosion properties of a material must be considered (Table 1).

TABLE 1 PRINCIPAL ATTRIBUTES OF A MATERIAL

PHYSICAL PROPERTIES

- DENSITY
- MELTING POINT
- THERMAL EXPANSION
- ELECTRICAL CONDUCTIVITY
- FERROMAGNETISM

MECHANICAL PROPERTIES

- TENSILE STRENGTH
- IMPACT STRENGTH
- FATIGUE STRENGTH
- CREEP STRENGTH
- DUCTILITY
- HARDNESS
- FRACTURE TOUGHNESS
- ELASTIC LIMIT

CORROSION PROPERTIES

- GENERAL CORROSION
- PITTING ATTACK
- STRESS CORROSION
- EROSION
- CAVITATION
- OXIDATION

Ambient Temperatures and Pressures. Most welded structures are designed to work in normal atmospheric conditions. The properties of common materials are well known for such conditions, and ample data are available to assist the designer in material selection.

Elevated Temperatures. The chemical industry has many processes that operate at temperatures of 1000 °C (1830 °F) and higher. Fossil fuel electric power generation makes use of steam temperatures from 500 to 600 °C (930 to 1110 °F). At such temperatures, most steels will exhibit creep--that is, a gradual deformation in the direction of the principal stresses--and thus the creep strength of a material becomes the controlling property. Creep strength determines the unit stress allowed to minimize the rate of creep and hence the permanent distortion and ultimate failure of a component.

Materials operating at high temperatures are frequently exposed to corrosive, erosive, or oxidizing environments, which may determine the life span of a structure. The resistance of proposed materials of construction to these types of environments should be examined during the selection process.

In processes where heat transfer occurs, the thermal conductivity of a material becomes an important consideration. Allowance must be made in the design for the expansion and contraction of components during heating and cooling--phenomena related to the coefficient of thermal expansion of a material.

Low Temperatures. Most ferritic metals become brittle at low temperatures, losing their ability to deform plastically to adjust to localized stresses and to accept a sudden shock. Thus, materials for use at low temperatures must have good toughness, a property usually measured by the Charpy V-notch impact test. For low-temperature applications, as for elevated-temperature service, the physical properties of thermal conductivity and coefficient of expansion become important.

High Pressures. Structures intended to contain high pressures are usually weldments and are designed according to American Society of Mechanical Engineers (ASME) codes for pressure vessels and piping. Strength properties are of primary importance. The codes specify the unit stress allowed for pressure-containing components. In cylindrical vessels, the maximum stress is in the tangential (i.e., hoop) direction, and the axial stress is half the hoop stress. In its simplest form, hoop stress is determined by:

$$S = \frac{PD}{2T}$$

where S is unit stress, P is pressure, D is the diameter of the cylinder, and T is wall thickness.

The tensile strength of a material determines the allowable stress and is specified in the ASME codes. The codes for steels allow a stress in excess of two-thirds of the minimum yield strength but less than 90% of the minimum yield strength. The minimum wall thickness, T_m, is then determined by:

$$T_m = \frac{PD}{2S + P_v} + A$$

where the extra thickness allowance, *A*, provides for anticipated corrosion or wear, and the coefficient *y* is specified by the code and varies with the temperature of operation and the wall thickness relative to the diameter.

Vacuum Conditions. Materials that are selected for very-low-pressure applications are primarily concerned with the tightness of the joints to prevent leakage from the exterior higher (or ambient) pressures into the vacuum chamber. For welded containers, the properties of the weld metal are critical to ensure lack of defects, such as porosity, cracks, and microfissures.

Vacuum conditions exist in outer space. In such applications, the vacuum condition is on the exterior of the vessel, and design for pressure containment is similar to that described for high pressures. Material selection also requires consideration of dynamic loads experienced during launches (hence, toughness), density for light weight (as in aircraft and aerospace applications), and corrosive and erosive effects, especially for reentry into the atmosphere.

Underwater Applications. A wide variety of material properties are involved in the application of weldments under water. Corrosion resistance is frequently a major concern, especially in seawater. Ships and offshore drilling platforms are notable examples.

For ships and for piping operating in biologically active waters, microbiologic organisms pose an unusual problem in material selection. Barnacles that attach themselves to the hulls of ships greatly increase the resistance to propulsion. The use of copper cladding or paints containing copper-bearing compounds is one means of discouraging barnacle formation. In turbid waters, piping is sometimes attacked by microorganisms that form surface pits, causing cracks in areas of local tension stresses. Because high tensile stresses frequently occur in or adjacent to welds, failures of weldments in these conditions can be attributed to these organisms, even in materials that otherwise are considered corrosion resistant to such environments.

Corrosion, Erosion, and Oxidation. Corrosion generally refers to surface attack by aqueous solutions or organic chemicals in either the liquid or vapor phase. Erosion implies the mechanical removal of metal from the surface, sometimes by high-pressure impingement of a fluid, in which case it is termed cavitation. Oxidation commonly occurs in metals at elevated temperatures and results in the removal of metal in the form of oxides.

Data on the resistance of materials to deterioration in many of these environments are frequently available from handbooks and material suppliers. In the case of weldments, the performance depends largely on experience gained in a variety of applications. The weld metal has a structure distinctly different from that of the parent metal, and sometimes a different composition as well. An electrochemical potential may exist between the weld and parent metal structures, causing attack on one or the other (frequently the weld metal because of its lower surface area).

Corrosive attack in weldments often is attributed to stress-corrosion cracking (SCC). In the presence of chloride ions (even at levels of parts per million), high tensile stress zones in or adjacent to welds can cause failure in materials whose corrosion life in the absence of stress is more than adequate for a particular application.

The welds in components carrying fluids at high velocity may erode during service. Under such conditions, hardness is the critical property. Localized areas of components, such as valve seats and turbine blades, may be protected from erosion by applying a hard weld metal, known as hard surfacing. For more information, see the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume.

In high-temperature service, allowance must be made for the thinning of metal sections due to progressive oxidation. In some applications the initial oxide layer protects the underlying metal, and progress is arrested. Adjacent to welds, oxidation can form preferentially in the highly stressed zones adjacent to welds and progress through the wall, causing weakness and possible failure.

Fatigue. In weldments subjected to fluctuating stresses, the fatigue strength of a metal may be the primary consideration in material selection and design loads. In the absence of flaws, the fatigue strength of most metals used for dynamically loaded structures is considerably higher than that of the welds. Designs for such structures must take into consideration both service experience and laboratory experiments dealing with various types of welds.

Weld metal cracks (even fine microfissures), lack of penetration or lack of fusion at the interface, and geometric discontinuities on the surface (such as overlaps and undercuts) are the major causes of poor performance in fatigue tests of welds. In the absence of such flaws, the fatigue properties of the weld metal itself or of the weld heat-affected zone (HAZ) rarely need to be considered, even though these zones may be inferior compared with the wrought parent metals. Design allowances for fatigue of weldments primarily take into account potentially damaging flaws.

Effect of Weld Thermal Cycles

Thermal Excursions During Welding. The thermal cycles encountered during the welding operation must be considered when selecting material for weldments. To make a weld requires that temperatures in the fusion zone reach above the melting point of the metal. Zones adjacent to the fusion region reach varying peak temperatures, depending on their distance from the fusion zone. Each of these thermal cycles causes metallurgical changes that affect the properties of the metal.

In the weld metal itself, the dendritic structure formed during solidification in a single thermal cycle is similar to that of a casting. In multipass welding, which is common when arc welding thicknesses greater than 6.4 mm ($\frac{1}{4}$ in.), the weld metal will undergo several thermal cycles, a process that refines the dendritic structure and alters the weld properties.

Similarly, in the HAZs immediately adjacent to the weld, one or more heat cycles will be experienced, causing changes in properties. When selecting materials for welded construction, the properties of these HAZs must be considered.

Cooling from the peak temperatures causes residual stresses, most often of a magnitude matching the yield strength of the material. Residual stresses may add to the service stresses. In cases where residual stresses may influence the integrity of the structure during its life expectancy, the designer may specify a postweld heat treatment.

Postweld Heat Treatments. Many weldments are placed in service in the as-welded condition. Under certain circumstances, postweld heat treatments may be required, thereby changing the properties of the selected metal.

Stress relieving is a thermal cycle that takes a weldment up to a high temperature where its yield strength is substantially reduced, allowing localized plastic deformation of the highly stressed regions. In ferritic steels, most stresses are relieved by heating to a temperature of less than 720 °C (1330 °F) for carbon steels (note that alloy steel values are higher). This is below the temperature transformation of ferrite to austenite, known as the critical temperature. This softens the structures that have been hardened by fast cooling from above the austenite-forming temperatures. Such subcritical heat treatments are said to "temper" the steel.

To cause the structures to become more similar to that of the parent metal, a supercritical heat treatment is sometimes specified. The properties of such welds are then likely to be comparable to those of the parent metal, provided that the compositions are similar.

Bridges and Buildings

This section deals with large welded structures built of plain carbon steels--the tonnage items in the construction industry. These structures generally conform to established codes.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Material Selection

The four code-writing organizations listed in Table 2 specify the chemical compositions, tensile properties, and other pertinent characteristics of steels used for large welded structures. Most employ the steel specifications of ASTM.

TABLE 2 CODES FOR STEEL STRUCTURES

ORGANIZATION	TITLE	SPECIFICATION NO.
AMERICAN WELDING SOCIETY (AWS)	"STRUCTURAL WELDING CODE--STEEL"	D1.1
	"BRIDGE WELDING CODE"	D1.5
AMERICAN INSTITUTE OF STEEL CONSTRUCTION (AISC)	"DESIGN, FABRICATION, AND ERECTION OF STRUCTURAL STEEL FOR BUILDINGS"	. . .
AMERICAN ASSOCIATION OF STATE HIGHWAY AND TRANSPORTATION OFFICIALS (AASHTO)	"STANDARD SPECIFICATION FOR WELDING STRUCTURAL STEEL HIGHWAY BRIDGES"	. . .
AMERICAN RAILWAY ENGINEERS ASSOCIATION (AREA)	"MANUAL FOR RAILWAY ENGINEERING"	. . .

The "Structural Welding Code--Steel" (AWS D1.1) considers three classes of structures:

- STATICALLY LOADED (BUILDINGS)
- DYNAMICALLY LOADED (BRIDGES)
- TUBULAR (OFFSHORE AND ARCHITECTURAL)

Fifteen ASTM specifications are applicable to buildings, 13 to bridges, and 34 to tubular structures, including four of the American Petroleum Institute (API) and two of the American Bureau of Shipping (ABS). The six most commonly used ASTM specifications, applicable to all three classes, are:

NO.	TITLE
A 36	"SPECIFICATION FOR STRUCTURAL STEEL"
A 500	"SPECIFICATION FOR COLD-FORMED WELDED AND SEAMLESS CARBON STEEL STRUCTURAL TUBING"
A 501	"SPECIFICATION FOR HOT-FORMED WELDED AND SEAMLESS CARBON STEEL STRUCTURAL TUBING"
A 514	"SPECIFICATION FOR HIGH-YIELD STRENGTH, QUENCHED AND TEMPERED ALLOY STEEL PLATE, SUITABLE FOR WELDING"
A 572	"SPECIFICATION FOR HIGH-STRENGTH LOW-ALLOY COLUMBIUM-VANADIUM STEELS OF STRUCTURAL QUALITY"

A 588	"SPECIFICATION FOR HIGH-STRENGTH LOW-ALLOY STRUCTURAL STEEL WITH 50 KSI (345 MPA) MINIMUM YIELD POINT TO 4 IN. THICK"
A 852	"STANDARD SPECIFICATION FOR QUENCHED AND TEMPERED LOW-ALLOY STRUCTURAL STEEL PLATE WITH 70 KSI YIELD STRENGTH TO 4 IN. THICK"

These specifications vary considerably in properties important to notch sensitivity (toughness) and weldability. The summary in Table 3 provides a guide as to what to look for in these and other specifications referred to in the structural codes. The supplementary requirements in some of these specifications are useful to the designer and fabricator when evaluating the need for additional acceptance tests for unusual applications.

TABLE 3 PROPERTIES RELATING TO SELECTION FOR SERVICE OF ASTM STEELS APPROVED IN AWS D1.1-92

Includes only the seven steels approved for all three AWS structural classes: (1) statically loaded, (2) dynamically loaded, and (3) tubular designs.

ASTM NO.	MAXIMUM CARBON CONTENT, %	TENSILE TEST REQUIREMENTS[(A)]	DEOXIDATION	SUPPLEMENTARY REQUIREMENTS
A 36	0.25-0.29 (FOR PLATE THICKER THAN 4 IN., OR 100 MM)	400-550 MPA (55-80 KSI); 250 MPA (36 KSI) MIN YP	NO RIMMED OR CAPPED STEEL FOR PLATE THICKER THAN 13 MM ($\frac{1}{2}$ IN.)	CHARPY V-NOTCH TESTING; SILICON KILLED, FINE-GRAIN PRACTICE
A 500	0.23-0.30	MIN TENSILE, THREE GRADES; 230, 290, 320 MPA (33, 42, 46 KSI) MIN YP	. . .	. . .
A 501	0.26-0.30	400 MPA (58 KSI) MIN TENSILE; 250 MPA (36 KSI) MIN YP	. . .	. . .
A 514	0.10-0.21 (15 PROPRIETARY COMPOSITIONS)	760-900 MPA (110-130 KSI) TO 65 MM (2.5 IN.) THICK; 690 MPA (100 KSI) MIN YP	FULLY KILLED, FINE-GRAIN PRACTICE	CLOSER THAN STANDARD FLATNESS
A 516	0.18-0.27	PLATES THICKER THAN 38 MM (1.5 IN.) NORMALIZED	KILLED, FINE-GRAIN PRACTICE	VACUUM TREATMENT; CHARPY V-NOTCH TEST; DROP-WEIGHT TEST[(B)]
A 572	0.21-0.26	MIN TENSILE, FOUR GRADES; 290-450 MPA (42-65 KSI) MIN YP	. . .	MAX TENSILE
A 588	0.15-0.20 (WEATHERING STEELS)	MIN TENSILE	FINE-GRAIN PRACTICE	MAX TENSILE; CHARPY V-NOTCH TEST; DROP-WEIGHT TEST(B); ULTRASONIC TEST

(A) YP, YIELD POINT.

(B) SEE ASTM E 208.

In general, the lower the carbon content and the finer the grain size of a steel, the better its notch toughness and weldability. The methods for achieving superior properties add to the unit price of the steel, so a designer striving for a low-cost structure tries to reduce steel cost, which is usually the most expensive single item in a job. This is especially true of static structures.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Environment

Low Temperatures. In the design of bridges, certain components merit special-toughness steel. Such components, termed fracture critical tension members (FCMs), would allow the bridge to collapse should they fail. The steel selection criteria are based on the minimum Charpy V-notch energy at a given temperature. For bridges financed in part by the Federal Highway Administration (FHA), the minimum winter temperature is the criterion used for the required Charpy V-notch energy at that temperature. A bridge located in the northern United States requires FCMs made with steel that exhibits the required minimum Charpy V-notch energy at a lower temperature than the same bridge constructed in the southern U.S.

The same FCM concept also applies for railroad bridges constructed under the codes established by AREA. The Charpy V-notch requirements for the three temperature zones defined by AREA codes are shown in Table 4. The required temperatures for measuring the Charpy V-notch energy are 21 °C (70 °F) for zone 1, 4 °C (40 °F) for zone 2, and -23 °C (-10 °F) for zone 3. Higher minimum Charpy V-notch values are required for weathering steels in heavier thicknesses. These values have been selected on the basis of extensive studies of steel structures, especially those of the Liberty ship failures during World War II.

TABLE 4 CHARPY IMPACT TEST REQUIREMENTS FOR WELDED STRUCTURAL STEEL: FRACTURE CRITICAL MEMBERS

ASTM	THICKNESS	MINIMUM AVERAGE ENERGY AND TEST TEMPERATURE		
		ZONE 1	ZONE 2	ZONE 3
A 36 OR A 709, GRADE 36	≤38 MM (≤1.5 IN.)	34 J (25 FT · LBF) AT 21 °C (70 °F)	34 J (25 FT · LBF) AT -12 °C (10 °F)	34 J (25 FT · LBF) AT 4 °C (40 °F)
	>38 TO ≤100 MM (>1.5 TO ≤4 IN.)	34 J (25 FT · LBF) AT -1 °C (30 °F)	34 J (25 FT · LBF) AT -7 °C (20 °F)	34 J (25 FT · LBF) AT -23 °C (-10 °F)
A 572, GRADE 50	≤38 MM (≤1.5 IN.)	34 J (25 FT · LBF) AT 21 °C (70 °F)	34 J (25 FT · LBF) AT -12 °C (10 °F)	34 J (25 FT · LBF) AT 4 °C (40 °F)
A 709, GRADE 50	>38 TO ≤50 MM (>1.5 TO ≤2 IN.)	34 J (25 FT · LBF) AT -1 °C (30 °F)	34 J (25 FT · LBF) AT -7 °C (20 °F)	34 J (25 FT · LBF) AT -23 °C (-10 °F)
A 588 A 709, GRADE 50 W	>38 TO ≤100 MM (>1.5 TO ≤4 IN.)	41 J (30 FT · LBF) AT -1 °C (30 °F)	41 J (30 FT · LBF) AT -7 °C (20 °F)	41 J (30 FT · LBF) AT -23 °C (-10 °F)
MINIMUM SERVICE TEMPERATURE		-18 °C (0 °F)	-34 °C (-30 °F)	-51 °C (-60 °F)

Earthquakes. Structures for locations subject to earthquakes should be designed to withstand the impact of such events. This is a constantly evolving technology. For up-to-date information, contact the Earthquake Engineering Research Center (EERC) at the University of California at Berkeley.

Atmospheric Corrosion. Steel structures that are to remain exposed to the atmosphere without painting or other surface protection can be constructed of a steel that forms an adherent oxide. Such steel is known as weathering steel and is covered by ASTM specification A 588. Corrosion resistance is provided by additions of approximately 0.35% Cu in most grades and/or small amounts of chromium or nickel in other grades. Weathering steels are suitable for resisting corrosion in air, but are not significantly better than other structural steels under water. In highway bridges where salt is used to control icing conditions, progressive corrosion is encountered, especially at expansion joints. A matching filler metal should be used to weld these steels, such as those with the designation "W" in the AWS specifications (e.g., E7018W in A5.5 or EW in A5.23).

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Fitness for Service

No structure is entirely free from flaws. Fitness for service is a term applied to an evaluation of the flaws found on inspection. The codes define the allowance for defects considered acceptable for the intended service.

Workmanship. Prior to assembly, the base metals are inspected for evidence of surface flaws that could impair the integrity of the structure. Before welding, the prepared edges are examined for discontinuities longer than 25 mm (1 in.). Such flaws must be removed and weld repaired before final assembly.

Distortion and shrinkage result from the welding operation. Permissible variations in the dimensions, straightness, and camber of structural members are defined in the codes. Peening of intermediate layers of multi-pass welds can be used to control distortion, but should be avoided on the weld surfaces.

Acceptable weld profiles are also defined as part of the workmanship standards of the codes for buildings and bridges. Unacceptable profiles, cracks, undercuts, overlaps, and other deficiencies are generally repaired by grinding the objectionable flaw and, if necessary, rewelding.

Inspection. Visual inspection is relied on for assessing workmanship criteria. In the construction of large structures, the general contract defines the extent of nondestructive testing of welds that may be required. Methods of nondestructive testing include radiography, ultrasonic testing, magnetic-particle inspection, and dye-penetrant inspection. For more information, see the article "Inspection of Welded Joints" in this Volume.

Radiography and ultrasonic testing allow examination of the full cross section of a weld. Flaws larger than 1% of the thickness, including cracks, lack of fusion, inclusions, and porosity can be detected by these techniques. X-ray analysis will detect only cracks substantially parallel to the impinging x-ray beam. Ultrasonic pulses can be introduced at an angle of 30 or 45° from the perpendicular to the plate surface, which permits a more complete inspection coverage of a weld.

Magnetic-particle and dye-penetrant methods are limited to the detection of defects on or near the surface. Dye penetrants can detect surface flaws only, whereas magnetic-particle testing can detect flaws slightly below the surface.

Flaw Assessment. The integrity and performance of welded structures depend heavily on the assessment of the significance of flaws identified during inspection. The discipline of fracture mechanics allows judgments to be made as to the likelihood of a flaw to cause a failure.

For static structures, the acceptance of a flaw of a given size that is found during inspection makes use of the material property evaluated by the crack-opening displacement (COD) test. Acceptance is based on the principle illustrated in Fig. 1. An example of the application of the COD test to flaw assessment is shown in Fig. 2.

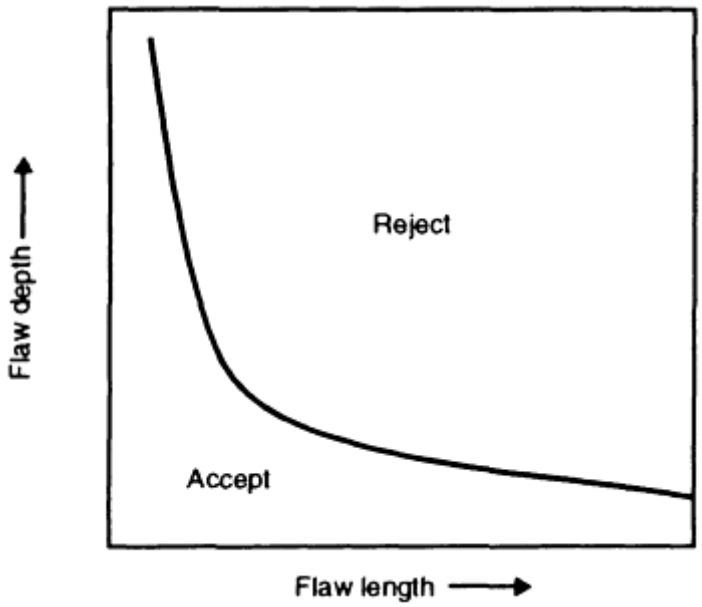

FIG. 1 SCHEMATIC OF AN ALLOWABLE FLAW-SIZE CURVE

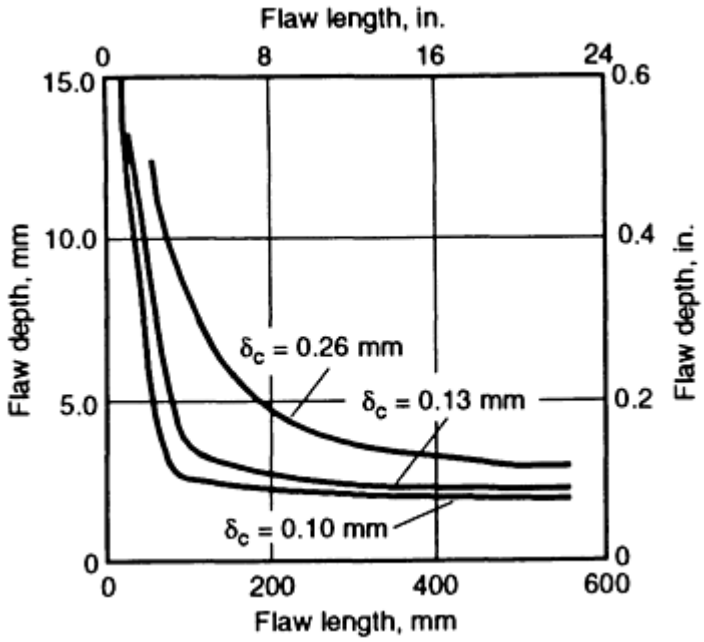

FIG. 2 ALLOWABLE FLAW SIZES DETERMINED FOR GIRTH WELDS IN PIPELINES CONSTRUCTED FROM API X70 STEEL, ASSUMING A COD VARYING FROM 0.1 TO 0.25 MM (0.004 TO 0.010 IN.), A FLOW STRESS OF 520 MPA (75 SKI), AND AN APPLIED STRESS OF 435 MPA (63 KSI). SOURCE: REF 1

Tolerance for Flaws. The inherent material properties of steels and welds that allow them to withstand the existence of flaws are measured by tensile testing (ductility), Charpy impact testing (toughness), and COD testing. For welds in FCMs, values of these measurements should be well above the minimum specification requirements. These tests are conducted on the welded joints prepared according to the specified qualification test procedures. An evaluation of ductility, toughness, and crack-opening displacement should be obtained on the weld metal, the HAZ, and the unaffected base metal.

Pressure Vessels and Piping

Codes and Specifications

The primary users of pressure vessels and piping are the chemical, petroleum, and electric power industries. While there are numerous codes, standards, and specifications that govern the selection of materials for pressure vessels and piping, the manufacture of boilers and pressure vessels in the United States falls under the general specification issued by ASME titled "Boiler and Pressure Vessel Code." This code is published in several parts. The rules governing the design of boilers are included in section I, "Power Boilers." The design rules for pressure vessels are included in section VIII, divisions 1 and 2, "Rules for Construction of Pressure Vessels." The materials requirements are included in section II, "Materials Specifications":

- PART A: FERROUS
- PART B: NONFERROUS
- PART C: WELDING RODS, ELECTRODES, AND FILLER METALS
- PART D: PROPERTIES

The ferrous (SA) and nonferrous (SB) ASME materials specifications were originally developed by ASTM and in most cases are identical. Thus, ASME specifications designated SA 204 and SB 467 may also be found as ASTM specifications A 204 and B 467, respectively.

In the United States, the AWS filler metal specifications are the primary guidelines used by the pressure vessel and piping industry. Here again, the ASME specifications (part C) are identical. The ASME specifications carry the initial designation SFA to correspond to the AWS specification designations starting with A; for example, SFA 5.5 is identical to AWS A 5.5. The AWS specifications are written to provide the specific chemical analysis of the filler material and the mechanical properties (minimum tensile and yield strengths) of the deposited weld metal.

Standards for pressure piping are covered by the American National Standards Institute (ANSI) document B31.1, "Code for Pressure Piping." This standard also applies to industrial pipelines and piping. Material selection is primarily from the ASTM and ASME materials specifications, although the API does provide a number of pipe specifications for material with yield strengths ranging from 170 to 760 MPa (25 to 110 ksi) and tensile strengths ranging from 275 to 860 MPa (40 to 125 ksi). The intended service temperatures, corrosion resistance, and fabricability are the primary considerations in the selection of materials for pressure vessels and piping.

Environment

Ordinary-Temperature Service (-30 to 345 °C, or -20 to 650 °F). The ASME, recognizing the fact that the ultimate strength of steels remains relatively constant over the temperature range from -30 to 345 °C (-20 to 650 °F), elected to set a safe maximum design stress of 25% of the ultimate tensile strength at temperatures over this temperature range. Consequently, the plain carbon steels are the most economical, with the popular grades being SA 515 ("Pressure

Vessel Plates, Carbon Steel, for Intermediate- and Higher-Temperature Service") and SA 516 ("Pressure Vessel Plates, Carbon Steel, for Moderate- and Lower-Temperature Service"). SA 516, a fine-grain, silicon-aluminum killed steel, is often preferred to SA 515, a coarse-grain, silicon killed steel, because of its better notch toughness characteristics.

A steam drum for an electric utility boiler fabricated from SA 515 grade 70 material is shown in Fig. 3. Where reduction in weight is important and operating pressures are high, the higher strength weldable steels are used, such as SA 302 ("Pressure Vessel Plates, Alloy Steel Manganese-Molybdenum and Manganese-Molybdenum-Nickel"). The quenched and tempered version of this steel, SA 533 (grade B, class 1), is used extensively in nuclear reactor vessels. Pertinent data for these materials are listed in Table 5. The specifications listed in Table 5 (and also Tables 6 and 7, to be discussed later) are for plate material. Similar ASME specifications exist for forgings, pipe, tube, and cast material.

FIG. 3 STEAM DRUM FOR AN SA 515 STEEL ELECTRIC UTILITY BOILER

Low-Temperature Service (-30 to -195 °C, or -20 to -320 °F). The commonly measured mechanical properties of steels, such as ultimate strength, yield strength, and elongation, do not always ensure freedom from failure at low temperatures, even when the design load is not exceeded. To ensure safe performance, the steel must be resistant to the initiation and propagation of a crack under all service conditions. Resistance to brittle crack initiation and propagation is commonly referred to as notch toughness or notch ductility. Factors that adversely affect notch toughness include cold working, strain aging, large grain size, increasing section thickness, and increasing the compositional contents of carbon, sulfur, phosphorus, nitrogen, and silicon. Beneficial factors include fine grain size, deoxidation, heat treatment, increasing the manganese and nickel contents, and decreasing the sulfur content. The notch toughness of a steel is also dependent on fabrication procedures, workmanship, and design details. Even the best design will contain some notch effects, and there will also be some imperfections in the highest level of workmanship. In the presence of these notches, the breaking strength of a pressure vessel and, more importantly, its failure mode (ductile or brittle) depend largely on the capacity of the steel at the root of some critical notch to yield plastically as the stress increases.

In thick sections, plain carbon steels produced according to fine-grain practice and normalized or quenched and tempered are used for service to -45 °C (-50 °F). Low-carbon high-nickel (e.g., 9% Ni) alloy steels are used for service down to -195 °C (-320 °F). Ferritic steels covered by ASME specifications are shown in Table 6. Austenitic chromium-nickel steels, aluminum, and special copper and aluminum-base alloys have been found to be particularly suitable for applications close to absolute zero. Because austenitic steels have a face-centered cubic (fcc) crystal structure, they retain their toughness to very low temperatures.

High-Temperature Service (345 to 815 °C, or 650 to 1500 °F). In the design of pressure vessels and piping, engineers and designers are confronted with the problem of selecting materials for a wide range of high-temperature service conditions. The chromium-molybdenum ferritic steels and austenitic stainless steels are generally used for design temperatures above 425 °C (800 °F). In addition to service temperature, corrosion resistance, and fabricability, the following conditions should be considered in high-temperature applications:

- POSSIBLE MAXIMUM TEMPERATURE
- TYPE AND SIZE OF LOAD
- EXPECTED LIFE OF THE STRUCTURE
- COST

Service experience and laboratory test data have established the normal temperature range of usage shown in Table 7 for the materials commonly used for high-temperature service. The allowable stresses in the ASME code, section VIII, division 1, for the low and high ends of the usage temperature ranges are also given in Table 7.

The following material properties must be taken into account in addition to the aforementioned service conditions:

- CREEP STRENGTH
- STRESS-RUPTURE LIFE
- DUCTILITY
- SHORT-TERM TENSILE PROPERTIES
- SURFACE STABILITY
- STRUCTURAL STABILITY
- THERMAL CONDUCTIVITY
- THERMAL FATIGUE
- THERMAL EXPANSION
- WELDABILITY
- HOT AND COLD WORKABILITY

All of these factors are important in arriving at the most suitable alloy for a given application.

Corrosion. Because of the many chemical compounds that may be encountered in pressure vessel and piping service, a discussion of corrosion is outside the scope of this section. However, there are two areas of concern in both the petrochemical field and the electric power industry: the effect of hydrogen absorption on materials properties and the possible metal loss due to steam/air oxidation.

High-Pressure, High-Temperature Hydrogen Service. Pressure vessels and piping exposed to hot high-pressure hydrogen may embrittle, crack, and ultimately fail without visible thinning of the metal or a superficially observable change in appearance of the exposed surfaces. A tool known as the Nelson diagram (Ref 3) is generally used to predict the behavior of alloy material in high-pressure, high-temperature hydrogen (Fig. 4). The Nelson diagram is based on actual service experience and indicates the temperature-pressure limits below which a material has not failed to date. Allowance must be made for temperature and pressure excursions that may occur over the design life of the component. Hydrogen can affect the mechanical properties of steel in two ways. Absorbed hydrogen causes a reduction in yield strength and impairs material toughness. More advanced attack, as manifested by fissuring and decarburization, is reflected in severely reduced tensile strength, ductility, and toughness.

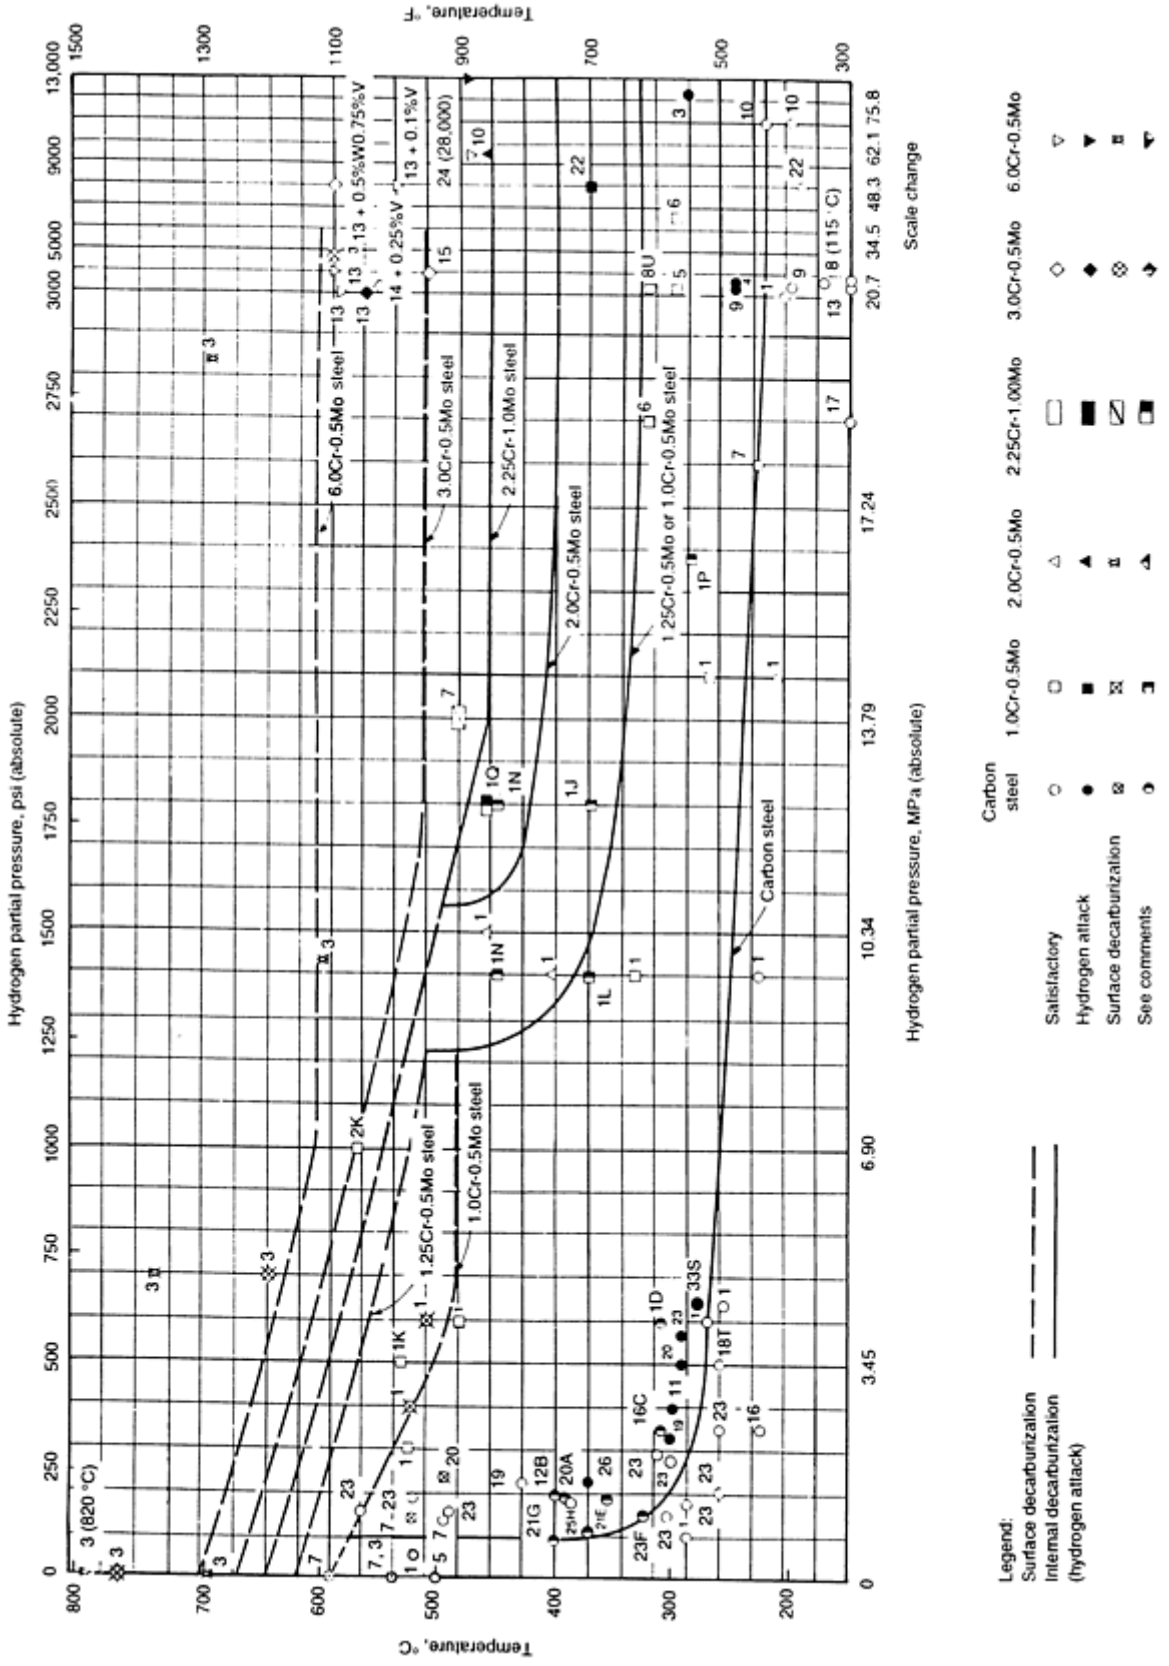

FIG. 4 NELSON DIAGRAM. 1, THE LIMITS DESCRIBED BY THESE CURVES ARE BASED ON ACTUAL SERVICE EXPERIENCE AND ON INFORMATION GATHERED BY API (REF 3). 2, AUTENITIC STAINLESS STEELS ARE GENERALLY NOT DECARBURIZED IN HYDROGEN AT ANY TEMPERATURE OR HYDROGEN PRESSURE. 3, THE LIMITS DESCRIBED BY THESE CURVES ARE BASED ON EXPERIENCE WITH CAST STEEL AS WELL AS ANNEALED AND NORMALIZED STEELS AT STRESS LEVELS DEFINED BY THE ASME CODE, SECTION VIII, DIVISION I. LINES REPRESENT THE UPPER LIMIT OF CONDITIONS FOR ACCEPTABLE USE OF THE ALLOY STEEL. SOURCE:

The recent trend in low-alloy steels for hydrogen service has been in the direction of steels of the chromium-molybdenum-vanadium type, such as 3Cr-1Mo-0.25V or 2.25Cr-1Mo-0.25V. For the most severe corrosive conditions, particularly those involving hydrogen sulfide (H_2S) in addition to hydrogen, austenitic steels of the 18Cr-8Ni type are used.

The National Association of Corrosion Engineers (NACE) standard MR-01-75 is the accepted reference in terms of materials and fabrication requirements for H_2S service. This standard specifies the materials and fabrication that are considered to provide satisfactory resistance to H_2S attack. Carbon steels for use in wet H_2S service are usually evaluated in accordance with NACE TM-01-77 (test solution) and TM-02084 (test method).

The relatively high cost of the austenitic steels frequently dictates the use of carbon or low-alloy steel vessels with applied corrosion-resistant cladding. In general, three methods of attaching the cladding to the backing plate are utilized: integral cladding, strip lining, and weld overlay cladding. Integrally clad plate is fabricated by hot rolling in a steel mill or by explosive cladding. Strip lining is applied by using long, narrow alloy sheet attached to the vessel by a continuous weld around the edges. Weld overlay cladding produces a continuous bonded layer of corrosion-resistant alloy on the base metal. Weld overlay cladding can be applied on irregular shapes, such as nozzles, thus avoiding dissimilar-alloy welds in the main pressure boundary.

Oxidation in Steam Service. In choosing a steel for service at elevated temperature, consideration must be given not only to its resistance to applied stress at temperature but also to its resistance to scaling, both of which decrease rapidly with increasing temperature above about 600 °C (1110 °F). Chromium, alone or in combination with silicon or molybdenum, contributes to increased resistance. For plain carbon steels, Fe_3O_4 is the only oxidation product and is stable until a temperature of 570 °C (1060 °F) is reached. Above 570 °C (1060 °F), FeO is the stable oxide phase and contributes to more rapid metal loss. The addition of chromium raises the temperature at which the Fe_3O_4/FeO transition occurs (see Table 8). Metal loss due to oxidation is of relatively little importance in heavy-wall pressure vessels; however, it deserves consideration in thinner-wall piping and in thinner low-pressure vessels.

TABLE 8 FE_3O_4/FEO TRANSITION TEMPERATURES

ALLOY	TEMPERATURE	
	°C	°F
0.5CR-0.5MO	590	1095
1CR-0.5MO	600	1110
1.25CR-0.5MO	605	1120
2.25CR-1MO	615	1140
5CR-0.5MO	625	1155

Other Factors Causing Degradation of Materials (Ref 4). Specific service conditions may degrade materials to an extent that requires replacement or retirement of components in the system. One of the more common failure modes in pressure vessels is SCC, which can be characterized as either intergranular (IGSCC) or transgranular (TGSCC), depending on the environment. Hydrogen-induced cracking (HIC) is another failure mechanism, again influenced by the localized stress condition.

Low-alloy steels in service at temperatures above 450 °C (850 °F) will suffer a loss in ductility due to temper embrittlement unless the composition is rigidly controlled. Phosphorus, tin, arsenic, and antimony are the principal elements that contribute to temper embrittlement.

The ductility of steels operating in the creep temperature range (generally above 480 °C, or 900 °F) suffers from a condition known as creep embrittlement. The loss in ductility is caused by the formation of small cavities in grain boundaries. In the presence of relatively low stress, the number of cavities grow and eventually link together to form microcracks, thus preventing the plastic deformation that is characteristic of ductile behavior. Sulfur is one of the elements that contribute to cavity formation and loss in ductility in creep service.

Fabricability

Fabrication operations can affect the performance of pressure vessels and piping in several ways: (1) cold forming operations may lead to strain aging, with a loss in toughness and ductility; (2) hot forming, unless carefully controlled, may produce undesirable changes in microstructure; (3) welding operations may produce an HAZ with reduced toughness and high hardness, and may also produce high tensile residual stresses that could lead to stress-rupture cracking (reheat cracking) during postweld heat treatment of susceptible materials.

Welding Process Selection. Considerations which govern the selection of a welding process are those that define the end use of a vessel, such as toughness, tensile properties, creep properties, and corrosion. There are also practical considerations, such as weldment size, equipment limitations, welding position, and access to the weldment area.

Two welding processes are primarily used: shielded metal arc welding (SMAW) and submerged arc welding (SAW). Other processes, such as electroslag welding, gas-tungsten arc welding, and gas-metal arc welding, are also used, but historically SMAW (see the article "Shielded Metal Arc Welding" in this Volume) and SAW (see the article "Submerged Arc Welding" in this Volume) have been dominant in vessel manufacture. A characteristic of both the SMAW and SAW processes is that they rely on the use of a flux to produce a slag over the molten weld pool, protecting it from atmospheric contamination. These fluxes vary significantly in formulation and operating characteristics and can modify the chemical composition, inclusion content, and microstructure of the final weld metal.

Weldability. Steels for pressure vessel fabrications are often classified as weldable based on composition, thickness, and need for preheat (see the article "Weldability Testing" in this Volume). Carbon and low-alloy steels are the most frequently used materials for pressure vessels; consequently, their weldability has received the greatest attention.

Preheating is utilized to prevent cracking, to permit diffusion of hydrogen from the weld and HAZ during and following welding, to reduce distortion, and to prevent loss of toughness and ductility. Preheating is also used to ensure that all traces of moisture have been removed from the surface of the material. Of the various schemes proposed for predicting preheating requirements, most are based on the carbon equivalent (C_{eq}). A variety of equations have been developed by various researchers for determining the C_{eq}, one of which has demonstrated that prevention of cracking due to hydrogen can be correlated with chemical composition in terms of a carbon equivalent formula of the form:

$$C_{eq} = C + \frac{Mn}{6} + \frac{Si}{24} + \frac{Ni}{40} + \frac{Cr}{5} + \frac{Mo}{4}$$

This formula was developed by Winn (Ref 5). A plot of carbon equivalents for a series of steel compositions used by Winn against preheat temperature is shown in Fig. 5. A linear relationship exists between the steel chemical composition, expressed by the carbon equivalent formula, and the minimum preheat temperature to avoid HAZ cracking.

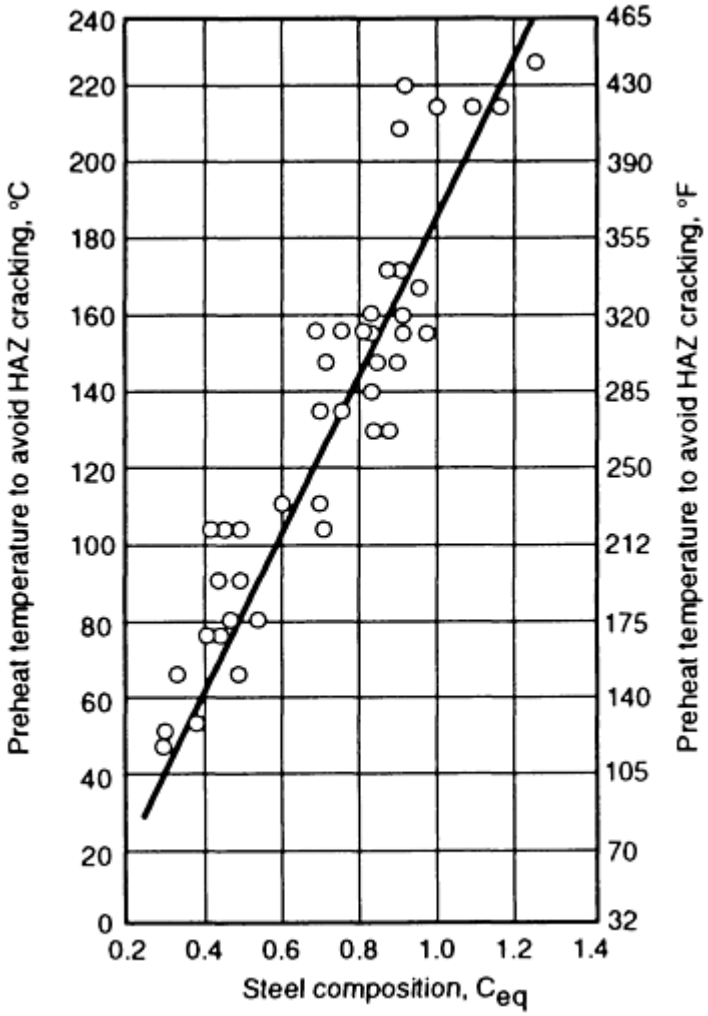

FIG. 5 CARBON EQUIVALENT VERSUS MINIMUM PREHEAT TEMPERATURE. THE BEST-FIT LINE SHOWN MAY BE REPRESENTED APPROXIMATELY BY: $T = 210(C_{EQ}) - 25$, WHERE T IS THE PREHEAT TEMPERATURE (°C).

The formula used by the International Institute of Welding (IIW) for judging the risk of underbead cracking and the resultant need for preheat is as follows:

$$C_{eq} = C + \frac{Mn}{6} + \frac{Cr + Mo + V}{5} + \frac{Ni + Cu}{15}$$

Regardless of the formula used, the C_{eq} values must be considered as approximations, because all factors affecting hardenability (e.g., section thickness, mass, restraint, grain size, and environmental effects) are not included.

Weld Zones. Based on work published by Savage, Nippes, and Szekeres (Ref 6), a typical weld consists of the composite zone, the unmixed zone, the weld interface, the partially melted zone, the HAZ, and the unaffected base metal (Fig. 6). All of these zones possess different mechanical properties, which are determined by the chemical compositions of the weld metal and the base metal. The preheat used, the weld energy input, and whether or not postweld heat treatment is specified also affect the resultant mechanical properties of the weldment.

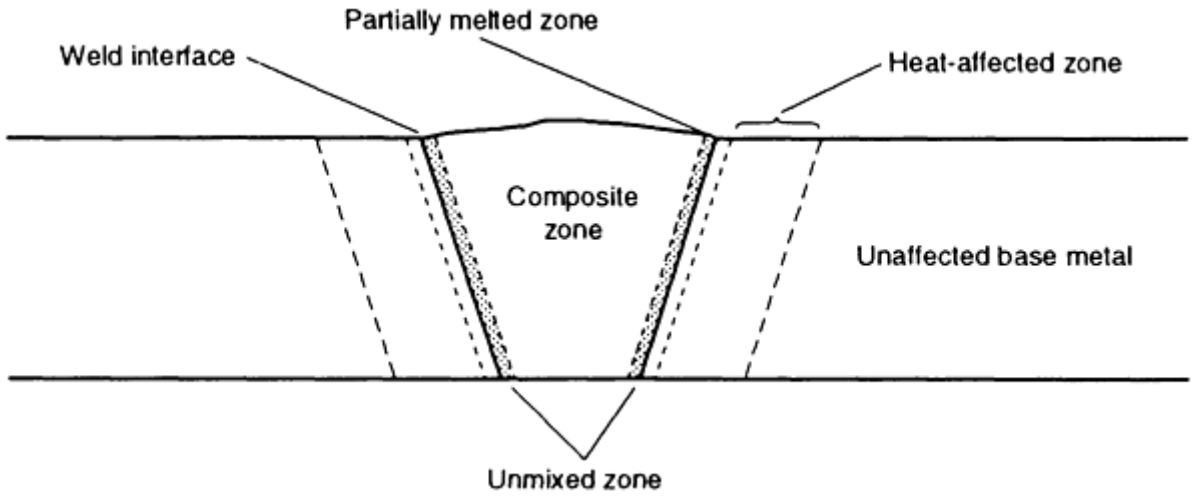

FIG. 6 TYPICAL ZONES ASSOCIATED WITH FUSION WELDS. SOURCE: REF 6

Postweld Heat Treatment. The circumstances under which the postweld heat treatment of pressure vessels is required are set forth in the ASME pressure vessel codes. They are determined primarily by the steel composition, thickness, specific fabrication operations, and intended service.

The principal beneficial effects of postweld heat treatment are the relief of residual stresses and the tempering action on the microstructures produced by the welding thermal cycles. Undesirable metallurgical phenomena may also be produced, such as temper embrittlement or cracking due to stress-rupture failures at grain boundaries.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Mechanical Properties of Weldments

Design Considerations. Some designers have tacitly assumed that a pressure vessel behaves as if it were manufactured from an isotropic material with the same properties throughout the vessel. Because of the presence of welded seams and welded attachments, however, no actual vessel fulfills this simple concept. Welds produce regions where the mechanical properties are considerably different from those of the base material. The stress-rupture life and the ductility at rupture may also be significantly different.

Weld Metal Strength. There is a tendency for weld metal to overmatch the parent metal in strength at ambient and low temperatures. While a slight overmatch is not harmful, excessive hardness in welds can cause greater susceptibility to weld cracking.

Creep of Welds in High-Temperature Service. Recent developments suggest that welded joints in some chromium-molybdenum steels are a potential source of weakness in creep. Vessels that have performed satisfactorily in service thus far may have safety factors lower than those suggested by present design rules. This arises from the mismatch of creep

properties in the different weld zones, especially in thick sections. In recognition of this fact, section III of the ASME code, "Nuclear Power Plant Components," has assigned stress-reduction factors to weldments operating in the creep range of temperatures.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Shipbuilding and Offshore Structures

The materials used for ships and offshore structures encounter a broad range of service conditions and must be capable of withstanding the rigors of weather and sea. With the advent of sophisticated communications systems, ships can often avoid heavy weather, whereas site-dependent offshore structures must be built to withstand any service condition that arises.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Ships

Steel ship structures are comprised of shell plating and shapes joined by welding. The structures vary considerably among various ship types, including small boats 10 to 25 m (30 to 80 ft) long to supertankers with lengths ranging from 100 to 400 m (330 to 1300 ft) or more. In between are container ships, liquefied natural gas (LNG) and liquefied petroleum gas (LPG) carriers, passenger ships, ore carriers, and others. Requirements for ordinary- and higher-strength steels according to the rules of the American Bureau of Shipping Rules (ABS) are given in Tables 9 and 10, respectively.

TABLE 9 ABS REQUIREMENTS FOR ORDINARY-STRENGTH HULL STRUCTURAL STEEL (≤50 MM, OR 2 IN., THICK)

(A) FOR ALL GRADES EXCLUSIVE OF GRADE A SHAPES AND BARS, THE SUM OF CARBON CONTENT AND ONE-SIXTH OF THE MANGANESE CONTENT IS NOT TO EXCEED 0.40%. THE UPPER LIMIT OF MANGANESE MAY BE EXCEEDED UP TO A MAXIMUM OF 1.65%, PROVIDED THAT THIS CONDITION IS SATISFIED. THE CONTENTS OF NICKEL, CHROMIUM, MOLYBDENUM, AND COPPER ARE TO BE DETERMINED AND REPORTED, AND WHEN THE AMOUNT PRESENT IS LESS THAN 0.02%, THESE ELEMENTS MAY BE REPORTED AS 0.02%.

(B) A MAXIMUM CARBON CONTENT OF 0.26% IS ACCEPTABLE FOR GRADE A PLATES $\leqslant$12.5 MM (0.5 IN.) AND ALL THICKNESSES OF GRADE A SHAPES AND BARS.

(C) GRADE D MAY BE FURNISHED SEMIKILLED IN THICKNESSES UP TO 35 MM (1.4 IN.), PROVIDED THAT STEEL >25 MM (1 IN.) THICK IS NORMALIZED. IN THIS CASE THE REQUIREMENTS RELATIVE TO MINIMUM SILICON AND ALUMINUM CONTENTS AND FINE-GRAIN PRACTICE DO NOT APPLY.

(D) IMPACT TESTS ARE NOT REQUIRED FOR NORMALIZED GRADE D STEEL WHEN FURNISHED FULLY KILLED, FINE-GRAIN PRACTICE.

(E) CONTROLLED ROLLING OR THERMOMECHANICAL CONTROLLED ROLLING OF GRADE D STEEL MAY BE CONSIDERED AS A SUBSTITUTE FOR NORMALIZING.

(F) GRADE D HULL STEEL THAT IS NORMALIZED, THERMOMECHANICAL CONTROLLED ROLLED, OR CONTROLLED ROLLED IN ACCORDANCE WITH [E] IS TO BE MARKED AB/DN.

(G) CONTROLLED ROLLING OR THERMOMECHANICAL CONTROLLED ROLLING OF GRADE E SHAPES AND THERMOMECHANICAL CONTROLLED ROLLING OF GRADE E PLATES MAY BE CONSIDERED AS A SUBSTITUTE FOR NORMALIZING.

(A) THE NUMBERS FOLLOWING THE GRADE DESIGNATION INDICATE THE YIELD POINT OR YIELD STRENGTH TO WHICH THE STEEL IS ORDERED AND PRODUCED IN KGF/MM^2. THE CHEMICAL COMPOSITION FOR ALL GRADES IS: 0.18% MAX C; 0.90-1.60% MN (GRADE AH THAT IS ≤12.5 MM, OR 0.5 IN., THICK MAY HAVE A MINIMUM MANGANESE CONTENT OF 0.70%); 0.04% MAX P; 0.04.% MAX S; 0.10-0.50% SI (GRADE AH PLATE THAT IS ≤12.5 MM, OR 0.5 IN., THICK AND ALL THICKNESSES OF AH SHAPES MAY BE SEMIKILLED, IN WHICH CASE THE 0.10% MIN SI DOES NOT APPLY; UNLESS OTHERWISE SPECIALLY APPROVED, AH PLATE >12.5 MM, OR 0.5 IN., THICK ARE TO BE KILLED WITH 0.10-0.50% SI); 0.40% MAX NI; 0.25% MAX CR; 0.08% MAX MO: 0.35% MAX CU; 0.05% MAX NB; 0.10 MAX V. NICKEL, CHROMIUM, AND MOLYBDENUM MAY BE REPORTED AS 0.02% WHEN THE AMOUNT PRESENT IS LESS THAN 0.02%. NIOBIUM AND VANADIUM NEED NOT BE REPORTED ON THE MILL SHEET UNLESS INTENTIONALLY ADDED.

(B) IMPACT TESTS ARE NOT REQUIRED FOR AH THAT IS ≤12.5 MM (0.5 IN.) THICK OR FOR ALUMINUM TREATED GRADE AH THAT IS ≤35 MM (1.4 IN.) THICK, NOR FOR FULLY KILLED FINE-GRAIN NORMALIZED GRADES AH OR DH THAT IS ≤50 MM (2 IN.) THICK.

(C) GRADES DH AND EH ARE TO CONTAIN AT LEAST ONE OF THE GRAIN-REFINING ELEMENTS IN SUFFICIENT AMOUNT TO MEET THE FINE-GRAIN PRACTICE REQUIREMENT.

(D) CONTROLLED ROLLING OR THERMOMECHANICAL CONTROLLED ROLLING OF GRADE D STEEL MAY BE CONSIDERED AS A SUBSTITUTE FOR NORMALIZING.

(E) CONTROLLED ROLLING OR THERMOMECHANICAL CONTROLLED ROLLING OF GRADE EH SHAPES AND THERMOMECHANICAL CONTROLLED ROLLING OF GRADE EH PLATES MAY BE CONSIDERED AS A SUBSTITUTE FOR NORMALIZING.

(F) THE MARKING AB/DHN IS TO BE USED TO DENOTE GRADE DH PLATES WHICH HAVE EITHER BEEN NORMALIZED, THERMOMECHANICAL CONTROLLED ROLLED, OR CONTROL ROLLED IN ACCORDANCE WITH APPROVED PROCEDURE.

(G) FOR DH TREATED WITH NIOBIUM OR VANADIUM, OR WHEN USED IN COMBINATION WITH ALUMINUM OR EACH OTHER. DH TREATED ONLY WITH ALUMINUM IS TO BE

NORMALIZED WHEN >25 MM (1 IN.) THICK.

Tankers and Container Ships. Large ocean-going tankers have been built with both single and double hulls, with the latter type becoming more popular due to environmental considerations and the belief that oil spills are more readily prevented by double-hull construction. However, most tankers in service today have single hulls. In the design of typical ships, 0 °C (32 °F) is normally assumed to be the lowest service temperature.

Material selection for single-hull tankers for a particular steel strength level is based on stress level, location, thickness, and toughness. A typical cross section of the shell and longitudinal bulkheads for a large tanker is shown in Fig. 7. Plating for various parts of the ship can be categorized as secondary, intermediary, and special application. The four corners of a ship and the deck and bottom plating in the way of the longitudinal bulkheads are usually highly stressed and are made from "special" steels with improved toughness properties. The side shell and areas close to the neutral axis of the ship are the least stressed, and thus the toughness of the steels employed is of "secondary" importance. The remaining deck and bottom of a tanker are moderately stressed and are constructed of intermediate-toughness steels.

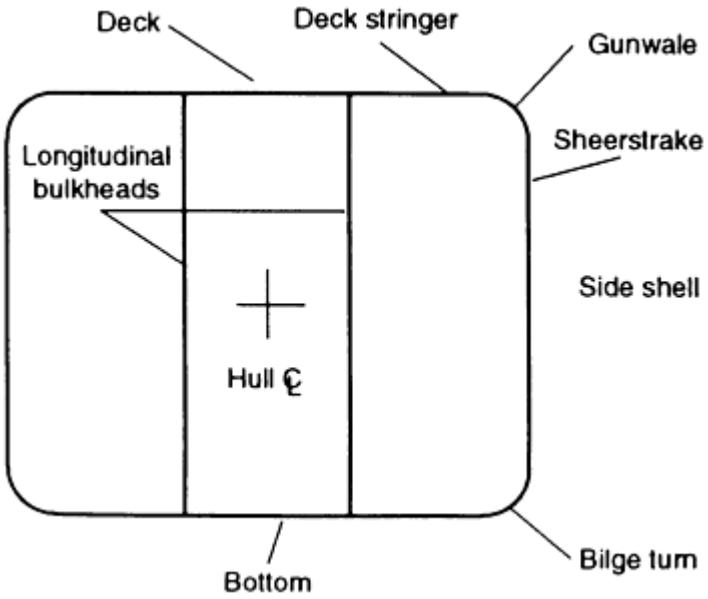

FIG. 7 MIDSHIP CROSS SECTION OF A LARGE TANKER, INDICATING SHELL PLATING AND LONGITUDINAL BULKHEADS.

The design considerations for tankers can also apply to container ships. However, because of the large cutouts on the deck that allow access for loading and unloading, the most critical structural area of a container ship is the box girder that connects the side shell to the deck. Major stresses are transmitted through this member, and thus the steels selected for these areas must have improved notch toughness.

Liquefied Natural Gas/Liquefied Petroleum Gas Ships. The minimum service temperature for most ships is approximately 0 °C (32 °F), and hull steels are selected and applied on this basis. Where temperatures below 0 °C (32 °F) are expected, application adjustments or selection of materials with superior low-temperature notch toughness must be considered. In the marine industry, low-temperature service is a significant factor in the design of ships carrying liquefied gases in bulk and of structures operating for prolonged periods in cold weather. Liquefied gases--both petroleum and natural--are transported in bulk by ship at temperatures ranging from -50 to -165 °C (-58 to -265 °F).

Steels for ship hulls are brittle at cryogenic temperatures. Thus, for safety reasons, it is essential to prevent the liquefied gas from contacting the steel hull and to minimize excessive conduction cooling of the hull. The primary requisite for the cargo tank material is high notch toughness at low temperature. Also, because shipboard tanks are subjected to dynamic loads resulting from ship motions, fatigue is another consideration.

Fracture mechanics concepts, which require knowledge of fracture toughness and fatigue crack-growth rate properties at low temperature, are frequently used in design. One design concept applied is "leak before failure," combined with a small-leak protection system. Utilizing this concept, a ship will be able to journey to an unloading and repair site before a detected flaw grows to critical size. Other systems are provided with large secondary containment barriers that can contain major leaks while permitting the ship to proceed to an unloading facility. All designs incorporate insulation to prevent excessive conduction cooling of the hull structure. For LNG containment systems, designed for cargo temperatures of -65 °C (-265 °F), external insulations of balsa, pearlite, polyurethane foam, and polyvinyl chloride foam have been used. For higher-temperature liquefied gases, such as LPG transported at a temperature of about -50 °C (-60 °F), some tanks have been internally insulated, which permits the use of less expensive tank structure materials than would be necessary with external insulation.

The worldwide adoption of International Maritime Organization (IMO) requirements for the carriage of liquefied gases by sea has unified material requirements for ships carrying cryogenic cargos in bulk. For the primary containment of such cryogenic cargos as LNG (methane) at a temperature of -165 °C (-265 °F), the most commonly selected materials have hexagonal close-packed (hcp) crystal structures; these include alloys such as 5083 aluminum, austenitic stainless steels, and 36% Ni steels, selected because of their superior low-temperature toughness properties. Nickel-bearing body-centered cubic (bcc) alloys, such as 9% Ni steels, have also been used, although less extensively.

The most important characteristic of the low-temperature mechanical behavior of ferritic steels is the ductile-to-brittle fracture transition. The transition occurs over a narrow temperature range for sharply notched specimens, and at temperatures below the transition, failure occurs by the brittle cleavage mode. This low-temperature embrittlement severely restricts the use of ferritic materials in cryogenic systems. Structural applications of ferritic materials are generally limited to environments where the service temperature remains above the ductile-to-brittle transition. The ferritic steels that are used for low-temperature applications usually contain nickel to improve low-temperature toughness. At the lower end of the cargo temperature range, austenitic alloys and 5083 aluminum are commonly used.

Table 11 indicates the service temperature specified in the ABS rules for each material. Austenitic stainless steel and 36% Ni steel are used for nonpressurized membrane tank designs. These alloys are provided in thin 0.5 to 1.5 mm (0.02 to 0.06 in.) sheets, usually corrugated to provide stiffness and allow for thermal expansion.

TABLE 11 MATERIALS FOR CRYOGENIC APPLICATIONS

MATERIAL	ASTM NO.	SERVICE TEMPERATURE	
		°C	°F
2% NI STEEL	A 203, GRADE A	-62	-80
	A 203, GRADE B	-59	-75
3% NI STEEL	A 203, GRADE D	-90	-130
	A 203, GRADE E	-79	-1L0
5% NI STEEL	A 645	-105(A)	-155(A)
9% NI STEEL	A 353	-196	-320
9% NI STEEL	A 553	-196	-320
AUSTENITIC STAINLESS STEEL	A 240	-196	-320
36% NI ALLOY	A 658	-196(B)	320(B)
ALUMINUM ALLOY	E 209, ALLOY 5083	-196	-320

(A) 5% NI STEEL MAY BE USED DOWN TO -165 °C (-265 °F) PROVIDED THAT IMPACT TESTS ARE CONDUCTED AT -196 °C (-320 °F).

(B) CHEMISTRY WILL BE SPECIALLY CONSIDERED FOR LOWERING THE COEFFICIENT OF EXPANSION.

For spherical pressurized tanks, 5083 aluminum alloy at a thickness of 40 to 60 mm (1.6 to 2.4 in.) is used to form tanks up to 35 m (115 ft) in diameter. The aluminum tank is attached to the steel hull by means of an explosion-bonded aluminum-to-steel plate; the tank connects to the aluminum side, and the steel side connects to the hull. This type of explosion-bonded plate is also used for connecting aluminum superstructures to steel decks.

ASM Committee on Material Requirements for Service Conditions*

Offshore Structures

Several important characteristics and operations of many offshore drilling units dictate the use of materials different from those used for ships, or restrictions on the application of similar materials. Much offshore exploration by mobile drilling or fixed units is carried out in areas where ambient air temperatures remain below 0 °C (32 °F) for long periods, such as in the Arctic. Toughness for these applications must be considered on the basis of the lowest expected steel temperature, because ferritic steels undergo a ductile-to-brittle fracture transition. The lowest steel temperature expected in service is estimated from meteorological data representing the coldest region in which the structure is designed to operate.

Toughness Versus Structural Application. In general, toughness testing of structural steel for offshore structures is conducted at a temperature below the minimum expected service temperature, the extent of the temperature increment being based on certain design criteria, such as anticipated stresses, stress concentrations, and redundancy of the structural member. For example, the ABS defines three structural categories to which different levels of toughness are assigned (see Table 12). The three categories are assigned to structural components based on consideration of the following: consequence of failure; redundancy of component; service experience with similar design; stress level, including stress concentration and restraint; fatigue; loading rate; and capability of inspection and repair in service.

TABLE 12 TEST TEMPERATURE FOR STEELS WITH A YIELD STRENGTH OF LESS THAN 415 MPA (60 KSI)

STRUCTURAL CATEGORY	DESCRIPTION	CHARPY V-NOTCH TEST TEMPERATURE
SECONDARY	LEAST CRITICAL: REDUNDANT	AT SERVICE TEMPERATURE
PRIMARY	MAIN STRUCTURAL MEMBERS THAT SUSTAIN PRIMARY TENSILE STRESS AND WHOSE FAILURE WOULD JEOPARDIZE THE SAFETY OF THE STRUCTURE	10 °C (18 °F) BELOW SERVICE TEMPERATURE
SPECIAL	MOST CRITICAL: FRACTURE CRITICAL MEMBERS THAT COULD EXPERIENCE RAPID LOADING AT POINTS OF STRESS CONCENTRATION	30 °C (55 °F) BELOW SERVICE TEMPERATURE

Absorbed energy obtained by a Charpy V-notch test is the most commonly used criterion for grading steels according to toughness. This criterion cannot be related directly to design, but is used as an expression of a toughness quality level.

Structural steel elements for offshore structures are often fabricated from cold-formed sections. As most structural steels are strain-age sensitive, it is important to evaluate the extent to which a given steel loses toughness after being cold strained. Outer fiber strains of less than 3% usually do not reduce toughness significantly. In general, at above 3% strain the material is either heat treated to restore the toughness or tested to determine that the poststrain toughness has not degraded below minimum acceptable values.

Quenched and Tempered Steels. Certain offshore drilling unit designs, especially the self-elevating type, make weight savings in the upper structure and the legs an important consideration in order to reduce the size and power requirements for lifting equipment and to aid stability. Therefore, high-strength quenched and tempered martensitic steels with yield strengths of approximately 700 MPa (100 ksi) find wider application in offshore structures than in ships. Areas subject to concentrated loads, such as openings for leg structures, cantilever overhangs for drilling booms, helicopter decks, and crane pedestals, are other locations on offshore drilling structures in which high-strength steels are commonly used.

Welding Process Selection

Welding has exclusively replaced riveting for joining structural steels in the fabrication of ships and offshore structures. In shipbuilding, welding permits large subassemblies to be built quickly and efficiently; these subassemblies are then welded together to form ship hulls.

Manual Welding. Shielded metal arc welding with stick electrodes, semiautomatic gas metal arc welding (GMAW), and flux-cored arc welding (FCAW) are all used in shipbuilding. These processes offer a high degree of versatility because of the portability of equipment and are commonly used for short weld runs and for erection welds.

Gravity-feed welding is used in the assembly of ships and offshore structures. It is carried out using contact or drag-type electrodes with tripod-type holding mechanisms, which allow welding to be done semiautomatically. An operator places the electrode in the holder and positions the holding mechanism, and welding progresses unrestricted until the electrode is consumed. Long electrodes enable welds more than 750 mm (30 in.) in length to be made with one electrode. Specific electrode diameters with proper current and voltage settings control the size of the deposited weld. One operator can handle two to six gravity-type devices at the same time.

This process has been largely employed for attaching stiffeners to plating by fillet welding. It is particularly attractive when the weld lengths are less than 3 m (10 ft), in which case the use of a fully automatic process may not be justified due to setup time, portability, and other considerations. Applications include internal stiffening of drilling-rig support columns and braces, as well as stiffening of decks.

Mechanized Welding. Submerged arc welding is used for making long, continuous butt welds to join plate panels or for joining stiffeners to plating by fillet welding. Modern shipyards that build large ships, especially tankers, where a considerable amount of flat panel work is required, have invested heavily in panel lines to further mechanize or automate the SAW process. Such panel lines are capable of making panel subassemblies up to about 20 m^2 (200 ft^2) in size.

One-side welding using SAW was introduced and perfected in Japan during the 1960s and early 1970s in connection with a massive tanker-building program for very large and ultralarge crude-oil carriers. In one-side welding, weld backing on the underside is provided by copper bars, ceramic forms, solid flux systems, or powdered flux held in place by various troughing systems.

Electroslag welding (ESW) and electrogas welding (EGW) have been used to make relatively long (more than 10 m, or 30 ft) continuous vertical erection welds in the side shells of large ships. These processes offer higher deposition and production rates than more conventional welding processes. The minimum plating thickness is about 19 to 25 mm ($\frac{3}{4}$ to 1 in.).

Consumable-nozzle ESW, a variation of the basic electroslag process, is used for making vertical butt welds in deck and bottom longitudinals and in heavy face plates of girders.

Oxyfuel Gas (OFG) and Plasma Arc Cutting. Oxyfuel gas cutting is used predominantly for cutting panels and stiffeners and for handfitting miscellaneous members. Plasma arc cutting has been used for mechanized cutting of plating up to about 12 to 20 mm (0.5 to 0.8 in.) thick. It offers the advantage of faster cutting speeds and less heat distortion as compared with gas cutting for thin plating. Because the significant tonnages of plating and shaping that must be cut or beveled for welding large ships, a high degree of mechanization has been introduced. Numerical control cutting permits panels up to about 2.5 by 15 m (8 by 50 ft) to be completely cut to size with appropriate cutouts, as well as edge beveling for welding to make large subassemblies.

Weld Considerations

The materials used for ship construction are generally ordinary-strength or higher-strength steels with a maximum yield strength of 355 MPa (52 ksi) (see Tables 9 and 10). For offshore drilling units and platforms, a variety of high-strength quenched and tempered steels with yield strengths up to 700 MPa (100 ksi) are also used. Weld filler metals should approximate the tensile and toughness properties of the base material; where materials of two different strengths or toughnesses are to be joined, the lower-strength or lower-toughness weld metal can be used.

Weld metal toughness is an important parameter in shipbuilding. Quantitative measurements of toughness are based on Charpy V-notch properties, and values comparable to those of the base materials are specified for weld metal. For offshore structures such as fixed platforms or drilling units, which must stay on station and encounter severe storms, winds, waves, and temperature fluctuations, toughness is also an important consideration. Materials and weld metals with yield strengths of up to 700 MPa (100 ksi) are commonly offered for tubular leg chord sections, braces, and rack material. The racks that form part of the leg chord are often 100 to 150 mm (4 to 6 in.) thick.

Hydrogen Cracking. When joining thick high-strength quenched and tempered steels, appropriate preheat and interpass temperatures are necessary to avoid HIC (see the article "Cracking Phenomena Associated with Welding" in this Volume). This condition is generally more prevalent in HSLA steels than in ordinary-strength steels, and its occurrence is generally proportional to the hardenability and tensile strength of the base material. Hydrogen cracks are usually found in the HAZ and can occur in both fillet- and butt-welded connections. Hydrogen cracking is often referred to as cold or delayed cracking because of the tendency for these cracks to occur and propagate after the weld has cooled to ambient temperatures. It is not uncommon for such cracks to be revealed hours or even days after welding, depending on the restraint conditions within the structure. For this reason, it is common practice to postpone the final nondestructive testing until several days after completing a weld.

Hydrogen sources in and around the arc atmosphere include moisture in the electrode coating, flux, gas, and base material and the presence of hydrocarbons, such as grease, paint, or oil. Moisture requirements for electrode coatings, along with storage and conditioning recommendations, are included in specifications and become more severe as strength levels increase. In SAW, where the flux is a common source of moisture, storage should be controlled to avoid moisture contamination from the atmosphere. Inadequate protection from hydrogen must be provided, especially in final erection or field welding applications, where hydrogen sources are more prevalent and where accessibility to the welded joint is less than ideal.

Lamellar tearing is the separation of steel plate underneath a weld in a plane generally parallel to the plate surface. It usually results from high through-thickness strains induced by weld shrinkage. These strains cause nonmetallic inclusions present in the steel to decohere. The resulting tears or cracks are planar in appear- ance, with some steplike characteristics. Welded connections joining two or more tubular sections are common in offshore structures. On several occasions, lamellar tearing has been observed in diaphragm plates used between two tubulars to simplify construction. Improvement in through-thickness properties is possible by using steels with fewer impurities or nonmetallic inclusions, lowering the permitted sulfur contents (typically 0.010% maximum), and treating the molten steel with rare earth elements, which combine with sulfur to form refractory sulfides that resist deformation at hot rolling temperatures. Another approach to eliminate lamellar tearing, and to simplify fabrication, is to use steel castings for the node connections. Centrifugally cast straight tubulars have also been proposed for offshore structural applications.

Lamellar tearing has been reported in sheer-strake-to-deck connections in ships. This problem can be eliminated by the use of gunwale connections. Lamellar tearing or cracking at welded connections is best avoided by the selection of a design that reduces the tendency for stressing through the thickness of the structural members.

In the construction of offshore drilling units and platforms, lamellar tearing presents a more acute problem because of the complexity of welded joints and connections. Sometimes joints may be unavoidably susceptible to lamellar tearing; in such cases, carefully planned welding sequences should be employed. It is common practice to use other than full-penetration welds; for instance, double-bevel partial-penetration T-welds are often used. Steel exhibiting the equivalent of 20% (minimum) reduction of area in a through-thickness tensile specimen (as per ASTM A 770) is considered to be less susceptible to lamellar tearing. Commonly used structural steels, including ABS hull steels, that meet the A 770 specification are available from some producers. Such steels have additional restrictions on chemistry and are produced using special melting practices.

Undermatching Weld Metal Strength. In some cases, weld metal that undermatches the base plates may be used in the fabrication and repair of high-strength steels, primarily for fillet welding and local repairs. The use of the lower-strength weld metal minimizes cracking tendency by providing a weld with reduced residual stresses and somewhat higher ductility. Such lower-strength filler metals are permitted when the strength level of the particular weld fulfills design requirements. When lower-strength covered electrodes are used to weld higher-strength materials, special precautions associated with welding the higher-strength materials are still required to prevent hydrogen cracking. When E80*xx* or E90*xx* electrodes are used to weld 700 MPa (100 ksi) yield strength material, such as ASTM A 514, the electrodes should be subjected to appropriate baking to reduce electrode-covering moisture to 0.15% maximum. This precaution should also be taken in the more common case where E7018-type electrodes are used to join high-strength steels (e.g., 700 MPa, or 100 ksi, yield strength) to lower-strength steels.

To summarize, in the following circumstances, the use of undermatching electrodes should be considered:

- *FILLET WELDING:* USE OF E9018 OR EVEN E8018 ELECTRODES FOR FILLET WELDING OF STEELS WITH A YIELD STRENGTH OF 700 MPA (100 KSI) IS A CONVENIENT WAY OF MINIMIZING CRACKING TENDENCY IN THE WELD METAL AND HAZ. ELECTRODES SHOULD BE BAKED TO A 0.15% MAXIMUM MOISTURE CONTENT.
- *REPAIR WELDING:* THE LOWER STRENGTH AND LOWER RESIDUAL STRESS ASSOCIATED WITH THE E9018 ELECTRODE MAKE IT THE ELECTRODE OF CHOICE FOR ISOLATED REPAIRS IN BUTT OR FILLET WELDS IN THE HIGHER-STRENGTH STEELS (700 MPA, OR 100 KSI, YIELD STRENGTH), PROVIDED THAT THE OVERALL STRENGTH OF THE STRUCTURE IS MAINTAINED TO MEET DESIGN REQUIREMENTS.

Aerospace

Aerospace systems push materials to the limits of their physical and mechanical properties. Therefore, it is important to optimize designs, which often involves consideration of nonmechanical fastening methods. Welding, brazing, soldering, and/or adhesive bonding are the only options in many aerospace structures. Whether the driving force is weight, leakproof seals, continuous load paths, or any number of other requirements, nonmechanical joining of materials is essential in the manufacture of aerospace systems. The list of materials used in the construction of such systems is quite large. This section will present an overview of mechanical and physical property considerations as they relate to joining.

Applications. The service requirements for a particular application will order the material properties. As shown in Fig. 8, material selection is based on a number of interrelated factors, including material properties, manufacturability, repairability, and availability (Ref 8). Because compromise is required to ensure optimal material selection, both the service requirements and the materials characterization must be thorough and complete. Design also plays an important role. For example, if a material is selected for a design using mechanical fastening, and nonmechanical joining is substituted as the manufacturing technique, the material and the design must be reevaluated. A design requiring mechanical fastening generally is not optimal for nonmechanical joining.

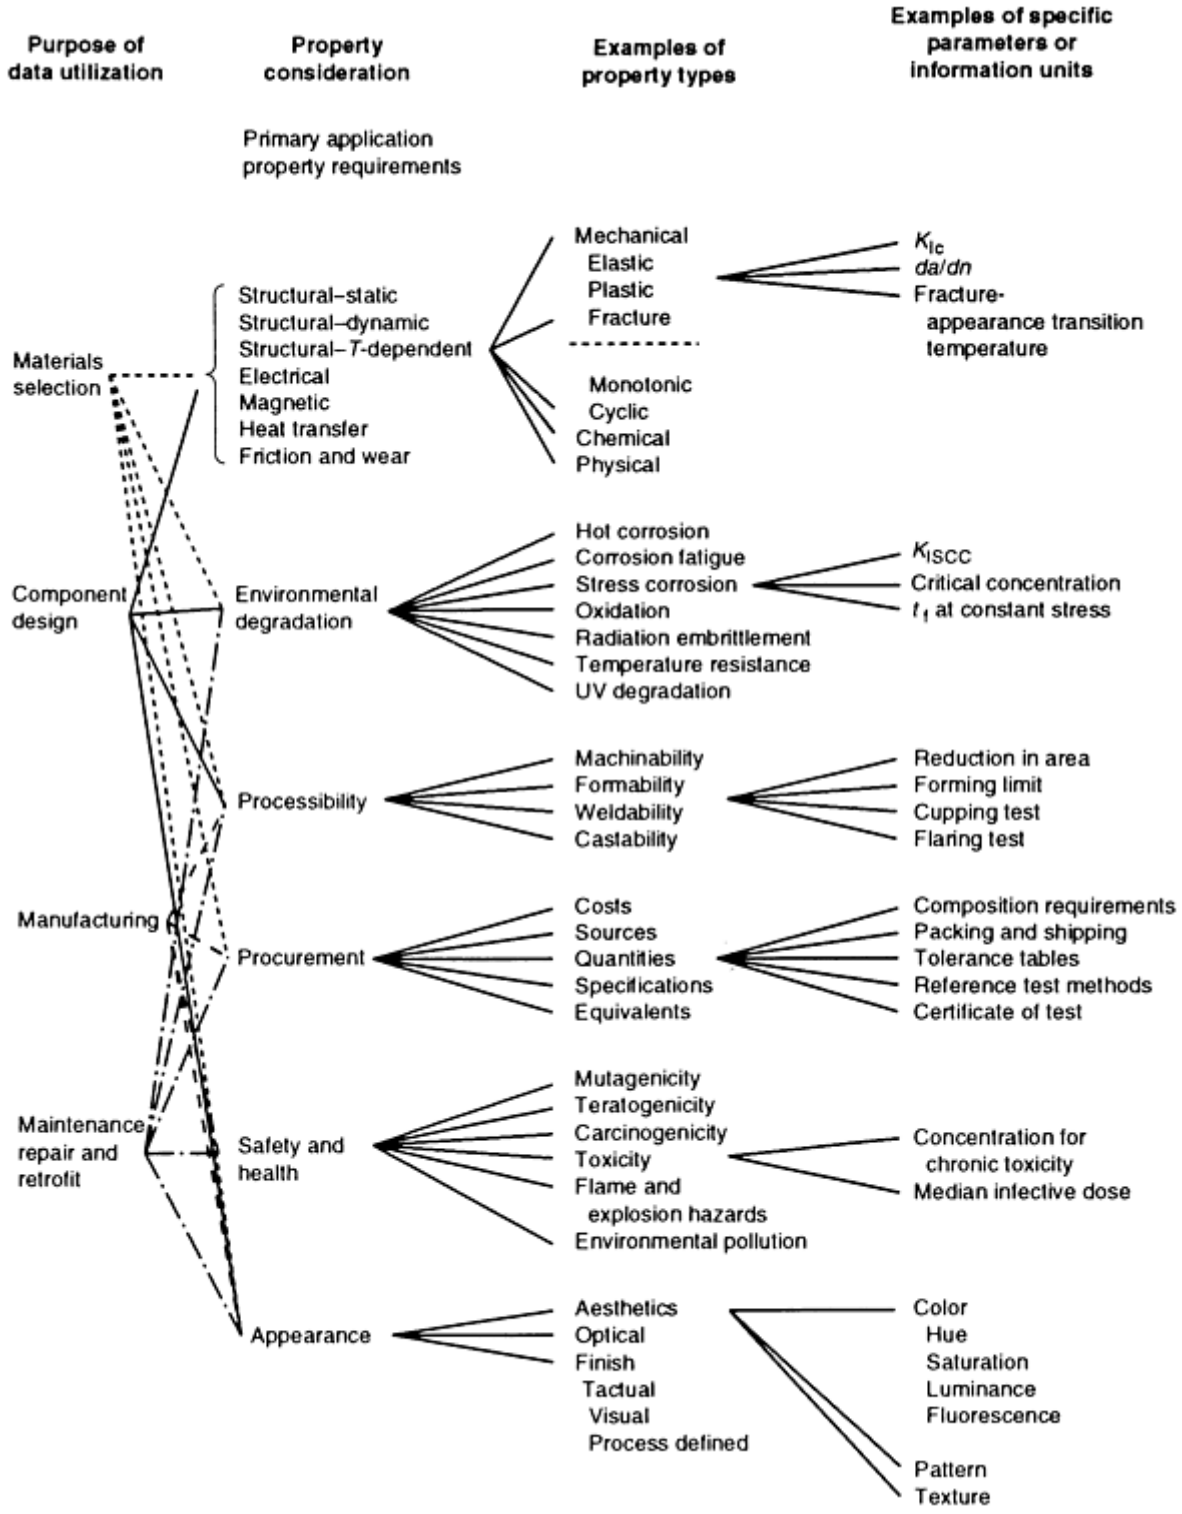

FIG. 8 INTERRELATIONSHIPS AMONG AEROSPACE DESIGN, MANUFACTURE, MAINTENANCE AND REPAIR, AND MATERIAL SELECTION. SOURCE: REF 8

Thermal Stability. A clear understanding of the material properties of importance for a given application is crucial to optimal material selection. For example, thermal stability, both metallurgical and physical, is a very important factor in elevated-temperature applications. Over time, microstructural thermal instability may alter mechanical properties, such as toughness, creep, or crack growth. The thermal stability of a material may be affected by a thermal joining process. Precipitation of unstable phases in the fusion zones of structural alloys, such as advanced titanium alloys, can be difficult to evaluate. Also, the tensile strength of high-strength aluminum alloys can be adversely affected during high-temperature

curing of adhesives if the aging temperature is exceeded for a sufficient length of time (Ref 9). Thermal stability can be maintained by ensuring proper material chemistry, heat treatment, joining process, joining consumable, and/or postjoining thermal treatments. Thermal instability may manifest itself as creep, cracking, buckling, and/or a reduction in corrosion resistance (Ref 4, 10, 11, 12). The corrosion properties of stainless steels may be severely impaired by elevated-temperature exposure, such as welding and brazing. The degradation referred to as sensitization can also reduce fatigue performance. Thermal stability has been used here as an example. A similar discussion could be presented for each property listed in Table 13.

Weight is an overriding concern in aerospace applications because of its adverse effect on performance and operational costs. Many decisions are based on the specific property of a material, such as those shown in Fig. 9. Specific properties are defined as the mechanical or physical property of the material divided by its density:

$$\frac{\textit{Material}\ \text{property}}{\text{Material density}} = \textit{specific}\ \text{property}$$

When using specific properties, one must be careful to fully characterize anisotropic materials. When considering a material for a nonmechanical joining application, an understanding of the effect of joining on these properties is essential. Joinability often is ignored during the development of aerospace materials (and materials in general) and can considerably inhibit their versatility during construction. Because compromise is the standard when selecting materials for a specific application, the effect of joining on properties must be considered.

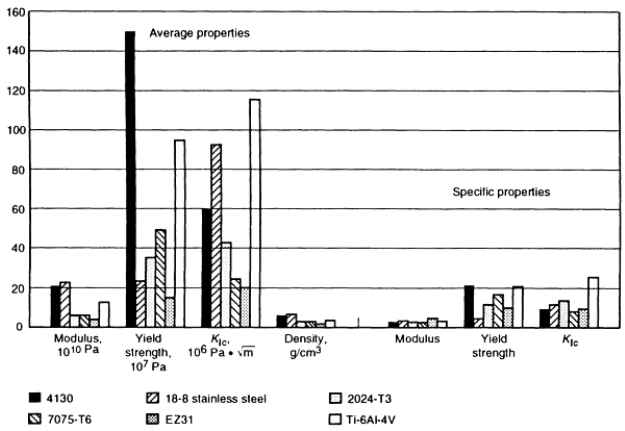

FIG. 9 AVERAGE VERSUS SPECIFIC PROPERTIES

Specifications. Aerospace materials are most often purchased to a military (MIL) or Aerospace Materials Specification (AMS). Some materials, such as A286, are available in standard and weldable grades. The weldable grade is formulated to reduce the tendency for microcracking. Filler metal specifications are provided by AWS or by the Society of Automotive Engineers (SAE) as Aerospace Materials Specifications.

Economics. Cost is another important material consideration. The cost of the raw materials is usually a small percentage of the cost of the end product in applications such as aerospace airframes and engine components, structures, and assemblies. The costs of some common materials as a function of volume production are presented in Fig. 10. However, material selection can have a significant cost impact in the areas of manufacturability and life-cycle costs (repairability and maintainability). The designation of materials must be as specific as possible to ensure maintenance of quality for joining applications (Ref 10, 11, 13). If multiple welds are to be performed on a given structure, the requirement for intermediate heat treatments or other processing steps must be considered. In large structures where full heat treatments are difficult because of distortion, the reduction in properties may require increased joint thickness, thereby increasing weight and complicating the manufacturing process.

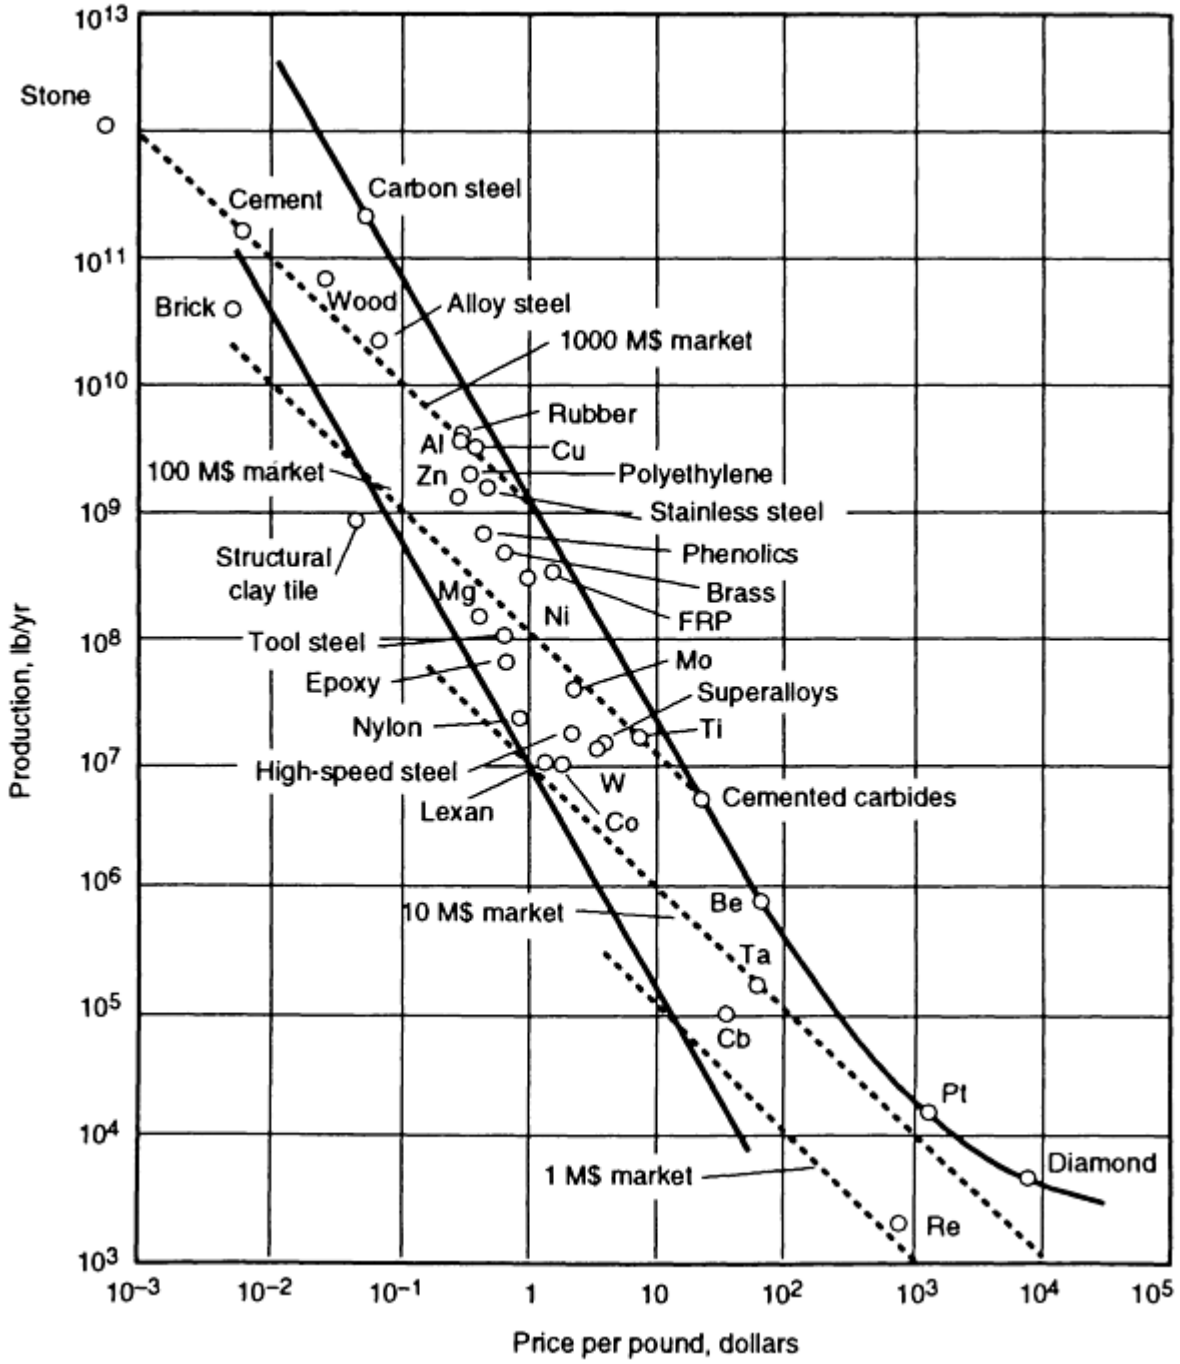

FIG. 10 COST VERSUS PRODUCTION FOR SEVERAL COMMON AEROSPACE MATERIALS. SOURCE: REF 8

Joining process selection and practice are influenced by material selection. For example, titanium requires vacuum or complete inert shielding (chambers with glove ports) to produce high-quality joints when elevated-temperature joining processes are used, which increases production costs in comparison with some other materials.

Finally, the environmental ramifications of joining must be considered when selecting a material. Toxic materials, such as beryllium, are sometimes used in aerospace structures because of their very high specific properties. However, when joining these materials, especially by welding, health and safety issues may drive manufacturing costs very high.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Joinability

Material Characteristics Related to Joining. Materials for aerospace use can be divided into two major categories: structural and engine, the latter being materials for elevated temperatures. There is considerable overlap, but it is instructive to examine materials from these points of view. Although the practice of welding of critical structural members in modern aircraft is small, but growing, the use of welding in missiles and space hardware has always been extensive. The joinability of aerospace materials takes on various definitions. Joint efficiency, cracking resistance, welding characteristics (such as flow), maintenance of corrosion resistance, and long-term metallurgical stability are all measures of joinability. Design, process, and consumable selection affect the joining characteristics of materials.

Dissimilar-materials joining muddies these definitions even further. For example, the welding of titanium to stainless steel is not recommended, but brazing these two materials together is possible. The usefulness of the hybrid braze would be determined by the service requirements. Joinability is often determined by standardized tests or by the ability of a material to meet certain mechanical or inspection requirements.

When evaluating joinability, it is important to consider the range of conditions to be experienced n production. For example, most material specifications allow a range of compositions. Because joinability may vary considerably as a function of chemistry, addressing these concerns prior to production will avoid costly rework.

The joinability of a material is influenced by the condition of the material when joined. For example, nickel-base superalloys should always be stress relieved prior to brazing to prevent stress cracking (Ref 14). Heat-treatable aluminum alloys are sometimes welded in the T4 condition and then postweld aged to the T6 condition to achieve more uniform properties in the weldment. Alpha-beta titanium alloys are sensitive to preweld heat treatment.

The thermal history can become very important during repair operations. If a material has been exposed to elevated temperatures or high loading in service, its joinability may be altered. In such instances, specialized testing may be required to ensure adequate joinability for repair operation.

The joinability of a material may be contingent on the postjoining operations, such as heat treatments. Many as-joined materials do not have the properties required for a particular application, but can be brought to an acceptable condition by a postjoining process. Postjoining thermal treatments can consist of full heat treatments (solution, intermediate, age), stress relief, or stabilization treatments (age). These can be localized or can be applied to the entire part. Other postjoining treatments include shot peening, machining, vibration stress relief, and sizing.

Base Materials. When characterizing the joinability of a material, it is important to consider the effect of joining on the base material as well as on the nexus (the actual joint; i.e., the fusion zone in welding). Nonthermal joining operations, such as room-temperature-cured adhesive bonding, may have no effect on the base material. In contrast, thermal

processes, such as brazing, soldering, and welding, can radically change material properties, especially near the nexus. Characterization of the affected base material can be difficult because of its size and makeup. For example, the HAZ in an electron beam weld in thick-section titanium may be as little as half the fusion-zone width. If the weld is on the order of 2.5 mm (0.10 in.) in width, the HAZ is only 1.25 mm (0.05 in.) in width. Locating a notch in the HAZ to evaluate fatigue or fracture toughness can be challenging. Moreover, if the HAZ is small enough, its effect on the service performance of the joint may be negligible, which signals a caution when service life is evaluated by using "simulated" HAZ microstructure. Joints of the same configuration as the production parts should be used whenever possible.

Filler Materials. The selection of filler materials is a critical factor that sometimes receives less than proper attention when joining aerospace materials (Ref 15). Filler materials are most often selected on the basis of chemistry match. However, other considerations sometimes take precedence, such as ferrite control in the welding of stainless steels, distortion/residual stress control for high-strength steels, optimization of elevated-temperature properties for nickel-base superalloys, and strength optimization in aluminum welding or optimization of environmental resistance in brazing and adhesive bonding.

Selection of filler materials for dissimilar-material joining requires careful consideration. Some brazing alloys contain melting-point depressants to allow brazing at temperatures lower than the operating environment (diffusion brazing). The effect of the formation of detrimental phases in the base materials is a factor when these alloys are used. Special corrosion or wear requirements will sometimes direct the use of a particular joining consumable.

Joining Techniques Other Than Fusion Welding. Process is another consideration in the joinability of aerospace materials. Alloys that are nonfusion weldable may be readily joined by other methods, such as friction, explosion, diffusion, brazing, or soldering.

Service Considerations. The joinability of materials is influenced by service requirements. A titanium weldment used for a missile fuselage or a wing support must have high strength, low fatigue crack-growth rates, and high toughness. Good corrosion resistance and thermal stability are also desirable. The properties of the weldments made from such material must reflect the base material requirements. On the other hand, an Inconel 626 weld used to build up a turbine blade tip may not have the same requirements as the turbine blade. Ease of welding and adequate elevated-temperature oxidation resistance are overriding concerns in this case. Because the tip buildup is not "structural" in nature and the consequences of failure not as severe as for the wing support, weldability is based on different criteria. Therefore, the joinability of a given material can vary depending on the end service requirements.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Damage Tolerance

Existence of Flaws. Damage tolerance is a design methodology often used for aerospace systems. The basic premise is that all structures contain inherent flaws. The effect of these flaws on flight safety depends on their geometry, growth rate at the service conditions, and critical size, and on the inspectability of the structure and the consequence of failure (Ref 16).

In the design of damage-tolerant structures, it is imperative that the relevant material properties, such as fatigue crack-growth rates, fracture toughness, and SCC, be well characterized. When applying damage-tolerant methodologies to structures joined by other methods than mechanical, unique considerations include:

- RESIDUAL STRESS EFFECTS
- PROPERTY GRADIENTS ACROSS THE JOINT
- INHERENT FLAWS, SUCH AS MICROFISSURES AND POROSITY
- LONG-TERM STABILITY
- CORROSION
- STRESS CONCENTRATIONS

These concerns are not well characterized for many of the materials and joining processes used in aerospace.

Finally, because the properties of the base metal may be altered nonuniformly during thermal joining, specialized testing may be required. For example, the crack-growth rate may be improved in the fusion zone of a weld, but the fracture toughness and SCC resistance may be reduced in the HAZ. All of these factors are important to the damage-tolerance analysis, and thus full characterization is required.

Inspection Criteria. For complex structures, the limiting factor may well be the inspectability of the joint. As a result, many welding specifications used for aerospace production, such as MIL-STD-2219 and AMS 2680, include defect allowable tables. When contractually requiring one of these standards, it is important to review the defect allowables to ensure that they are realistic for the application. Many unnecessary repairs are performed on welded structures because of improper defect criteria. As a result of the additional thermal cycles, the repairs may be more detrimental than the flaw in many materials. For many joining processes and materials combinations used in aerospace, the information necessary to perform a damage-tolerance analysis is not available; therefore, the defect criteria in the welding specifications are used, as this procedure is less expensive than developing the required data. Also, the effect of residual stress on fracture toughness and fatigue crack growth is difficult to evaluate with current damage-tolerance methodologies. Much work needs to be accomplished in this area.

Nondestructive examination (NDE) concerns require consideration of both the process and design limitations. Many times joints are designed without adequate attention to inspection requirements, often making effective NDE impossible due to inaccessibility.

Advanced Materials

Some materials used for aerospace systems present special problems in relation to joining. Among these materials are composites and intermetallics. Composite materials, including metal matrix and organic matrix, are used because of their increased stiffness, damping properties, and high specific properties. Composites present challenges when joined by any method, and much work is currently underway to establish their joinability. Maintenance of properties when using nonmechanical joining is difficult. Metal-matrix composites have been successfully joined by brazing, diffusion, and high-energy density welding. During the development of these materials, joinability was not a high priority and is thus limited.

The bond integrity between the fibers and the matrix of a composite greatly affects material properties. Special coatings are applied to the fibers to ensure adequate bonding. The stability of these coatings to a large degree determines joinability when using elevated-temperature processes. Coating schemes that optimize joinability should be addressed during materials development. A further challenge involves the attainment of material properties across the joint.

Intermetallics, such as Ti_3Al_2, offer very promising elevated-temperature properties. Limited studies to date concerning the fusion weldability of these materials indicate that tight control of base-metal chemistry, accurate regulation of heat input and cooling rate, and joint design to minimize residual stress are required to produce sound joints (Ref 17). Brazing offers some advantages, but may be limited by operating temperature unless suitable diffusion-bonding fillers can be developed. The joinability of these types of emerging materials will to a large degree determine their long-term usefulness in aerospace systems.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Machinery and Equipment

Welding plays an important role in the wide variety of structures broadly characterized as machinery and equipment. This section will discuss three categories: stationary equipment, such as presses, rolling mills, and machine tools; mobile equipment, such as cranes, earthmoving, and other construction equipment; and rotating components of machines. In all of these categories, the materials requirements for serviceability are distinctly different for the structural machine support parts and for those involving the machine-moving and working parts.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Applications

Stationary Equipment. The working parts of machine tools require stability. Massive cast iron or cast steel bases are used to provide a damping capacity, thus ensuring that cutting tools do not vibrate or chatter. In applications that use weldments, thick steel components are specified.

The principal design requirement for metalworking presses is adequate strength to counter the forces imposed during press operation. Weldments of various sections using both wrought and cast carbon steels offer adequate strength and rigidity. The elastic deflections of the components created by work forces affect the design, which must take into account the cyclical nature of the stress and hence the fatigue properties of the materials and welded joints.

Mobile Equipment. In the design of components for earthmoving and other construction equipment, static and dynamic loads are important factors, as are erosion, wear, weight, and ease of maintenance. The materials for each working part of such equipment must be considered separately.

As an example, booms used in mobile industrial cranes must be light in weight, yet rigid under load. Wear resistance is another important factor in this application.

Rotating Elements. Materials specified for the rotating parts of pumps, fans, compressors, and similar machinery have a wide variety of properties. For large rotating components, weldments are commonly required, sometimes employing different metals for improved performance in specific environments. Erosion, corrosion, and cavitation are often the

mechanisms that limit the lives of such machine elements. Critical surfaces are frequently weld surfaced with corrosion-resistant materials.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Design Considerations

Welds and members of weldments are sized to withstand the working stress and stress range induced by static and fluctuating loads. The magnitude of the fluctuation between maximum and minimum working stress is termed the working stress range. The magnitude of the static and fluctuating stresses is influenced by such factors as dead load, live load, type of operating mechanism, machine geometry, component size, shock or impact, accidental overloads, corrosion, wear misalignment, stress concentration, and weld joint design. The allowable stress and stress range must be greater than the expected working stress and stress range. The relationships among the various stresses, stress ranges, strengths, and loads are shown graphically in Fig. 11.

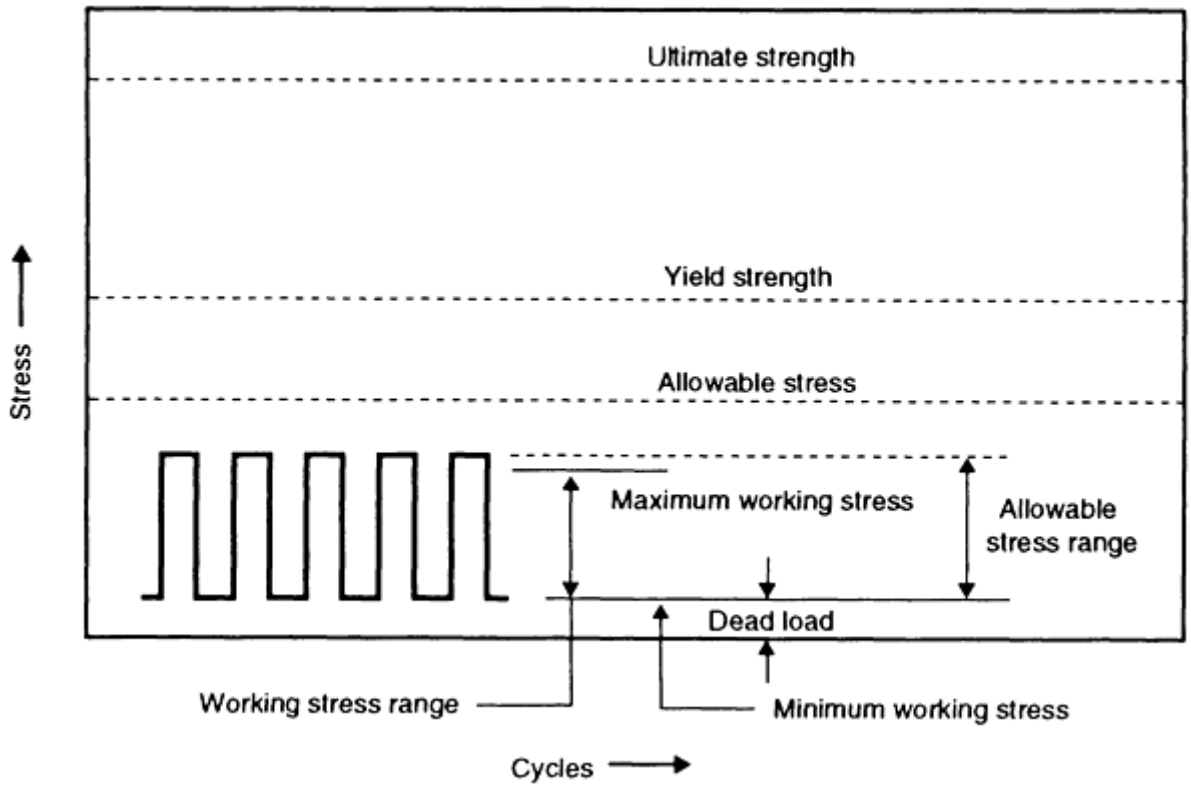

FIG. 11 STRESS RELATIONSHIPS RESULTING FROM STATIC AND FLUCTUATING LOADS

Allowable stresses in weld and base metals are usually specified by an applicable code or standard based on a history of satisfactory operating performance. In the absence of an industry standard, as in the case of most machinery and equipment, the determination of an allowable stress value is left to the discretion of the manufacturer or designer. In such case, the allowable stress (SA) is calculated by dividing the ultimate tensile strength (UTS) or yield strength (YS) by an appropriate factor of safety (FS) selected by the designer:

$$SA = \frac{UTS}{\text{FS}} \text{ or } \frac{\text{YS}}{\text{FS}}$$

The selection of an appropriate factor of safety to prevent failure from unpredictable causes is empirical and depends on industry data and the experience and judgment of the designer. Table 14 provides guidance in selecting a factor of safety, based on the ultimate tensile strength of the material. The assigned factors in Table 14 may be increased as warranted by safety, cost, plant utilization, and engineering judgment. Also, the assigned factors may be reduced if detailed analysis increases confidence in design factors, such as loading, material properties, and fabrication controls.

TABLE 14 FACTOR OF SAFETY SELECTION CRITERIA

CONDITION	ASSIGNED FACTOR OF SAFETY(A)
EXCEPTIONALLY RELIABLE MATERIALS USED UNDER CONTROLLABLE CONDITIONS AND SUBJECTED TO LOADS AND STRESSES THAT CAN BE DETERMINED WITH CERTAINTY. USED ALMOST INVARIABLY WHERE LOW WEIGHT IS A PARTICULARLY IMPORTANT CONSIDERATION	2.5-3
WELL-KNOWN MATERIALS, UNDER REASONABLY CONSTANT ENVIRONMENTAL CONDITIONS, SUBJECTED TO LOADS AND STRESSES THAT CAN BE DETERMINED	4-5
LESS TRIED OR BRITTLE MATERIALS UNDER AVERAGE CONDITIONS OF ENVIRONMENT, LOAD, AND STRESS	5-6
KNOWN MATERIALS THAT ARE TO BE USED IN UNCERTAIN ENVIRONMENTS OR SUBJECTED TO UNCERTAIN STRESSES	6-8

(A) FOR REPEATED LOADS, THE FACTORS SHOULD BE DOUBLED. FOR IMPACT LOADS. THE FACTORS SHOULD BE INCREASED AS WARRANTED.

When a design is analyzed using a mathematical model, it must be understood that subsequent calculations only approximate the working stress. With all models, various assumptions, limitations, and simplifications used to fit equations to the component model influence the accuracy of the calculations. (This is true even when using finite-element methods.) The calculated stress values that result from applying "good" theory to a "good" model are, at best, ballpark figures that give the design engineer a rational basis for making design decisions. For the most part, the allowable stress ranges specified in current standards for welded joints subjected to fatigue loading are based on testing of representative full-size welded joints in actual or mockup structures.

Static Loads. Nearly every machine is subjected to static and fluctuating loads; few useful machine structures have only static loads applied. Structures subjected to slowly applied loads, few cycles (less than 20,000) of loading, or nearly steady loads are considered statically loaded and are designed using rules that apply to static structures. These rules assume that localized areas of high stress due to stress concentrations are relieved by yielding of the highly stressed material to redistribute internal stresses.

Steels commonly used for welded construction of machinery and equipment have yield strengths of less than 700 MPa (100 ksi) and are listed in Table 15. Class I materials have the highest weldability, and class V have the lowest. Carbon and carbon-manganese steels--those class I and class II steels designated by the American Iron and Steel Institute (AISI), SAE, and ASTM--are the most commonly used materials for welded machinery and equipment. These steels do not require preheat unless the thickness is greater than 150 mm ($1\frac{1}{2}$ in.). High-strength low-alloy steels (classes III, IV, and V) allow the thickness and hence the weight of a machine structure subjected to high static loads to be reduced.

TABLE 15 WELDABILITY CLASSES OF STEELS USED IN MACHINERY AND EQUIPMENT

STEEL	TYPICAL MINIMUM YIELD	CARBON EQUIVALENT (C_{EQ})	SPECIFICATION

	STRENGTH		(MAX)[A]			
	MPA	KSI		AISI-SAE	ASTM	API
STRUCTURAL CARBON						
CLASS I	200-400	30-60	0.38	1005, 1006, 1008, 1010, 1012, 1015, 1016, 1017, 1018, 1020, 1021	. . .	. . .
CLASS II	240-380	35-55	0.48	. . .	A 36, A 38 (GRADE Y35), A 53 (GRADE B), A 106, A 131, A 139, A 374, A 500, A 501, A 516, A 524, A 529, A 570 (GRADES D, E), A 573	52 (GRADE B)
HSLA						
CLASS III	275-380	40-55	0.63	. . .	A 242, A 441, A 537 (GRADES A, E), A 572 (GRADES 42, 45, 50), A 588, A 618	5LX (GRADE 42)
CLASS IV	410-450	60-65	NOT SPECIFIED	. . .	A 572 (GRADES 60, 65)	. . .
QUENCHED AND TEMPERED						
CLASS V	620-700	90-100	0.74	. . .	A 514, A 517	. . .

(A) CARBON EQUIVALENT IS A MEASURE OF WELDABILITY. FOR UNALLOYED (STRUCTURAL) STEELS. C_{EQ} = %C + (MN/4) + (SI/4). FOR LOW-ALLOY STEELS, C_{EQ} = %C + (MN/6) + (NI/20) + (CR/10) + (MO/40) + (V/10).

The AISI and SAE carbon-manganese steels have carbon contents of less than 0.25% and manganese contents of less than 0.90% and are supplied to meet composition specifications that do not include mechanical properties. Unless verified by mechanical tests, an ultimate tensile strength of 380 MPa (55 ksi) and a yield strength of 190 MPa (27.5 ksi) should be used for design purposes. These steels have the highest weldability rating shown in the machinery welding specifications that classify steels according to weldability.

ASTM material specifications include mechanical property requirements that demand higher strength than the AISI and SAE carbon-manganese steels, and thus offer the opportunity to reduce thickness and weight for statically loaded conditions. The weldability of these higher-strength steels is lower, and they usually require higher preheat and low-hydrogen welding processes.

Allowable stress for statically loaded steel base metals can be determined from the equation given above after selecting a factor of safety. Allowable stress levels for statically loaded weld metal are presented in Table 16.

TABLE 16 ALLOWABLE STRESSES IN WELD METAL

TYPE OF WELD	STRESS IN WELD	ALLOWABLE STRESS	REQUIRED WELD STRENGTH LEVEL[A]
GROOVE WELDS WITH COMPLETE JOINT PENETRATION	TENSION NORMAL TO EFFECTIVE AREA	SAME AS BASE METAL	MATCHING WELD METAL SHALL BE USED.
	COMPRESSION NORMAL TO	SAME AS BASE METAL	WELD METAL WITH A STRENGTH LEVEL EQUAL

	EFFECTIVE AREA		TO OR ONE CLASSIFICATION (69 MPA, OR 10 KSI) LESS THAN MATCHING WELD METAL MAY BE USED.
	TENSION OR COMPRESSION PARALLEL TO WELD AXIS	SAME AS BASE METAL	WELD METAL WITH A STRENGTH LEVEL EQUAL TO OR LESS THAN MATCHING WELD METAL MAY BE USED.
	SHEAR ON EFFECTIVE AREA	0.27 × NOMINAL TENSILE STRENGTH OF WELD METAL, EXCEPT SHEAR STRESS ON BASE METAL SHALL NOT EXCEED 0.40 × YIELD STRENGTH OF BASE METAL.	
GROOVE WELDS WITH PARTIAL JOINT PENETRATION	COMPRESSION NORMAL TO EFFECTIVE AREA: JOINT NOT DESIGNED TO BEAR	0.45 × NOMINAL TENSILE STRENGTH OF WELD METAL, EXCEPT STRESS ON BASE METAL SHALL NOT EXCEED 0.55 × YIELD STRENGTH OF BASE METAL.	WELD METAL WITH A STRENGTH LEVEL EQUAL TO OR LESS THAN MATCHING WELD METAL MAY BE USED.
	COMPRESSION NORMAL TO EFFECTIVE AREA; JOINT DESIGNED TO BEAR	SAME AS BASE METAL	
	TENSION OR COMPRESSION PARALLEL TO WELD AXIS[B]	SAME AS BASE METAL	
	SHEAR PARALLEL TO WELD AXIS	0.27 × NOMINAL TENSILE STRENGTH OF WELD METAL. EXCEPT SHEAR STRESS ON BASE METAL SHALL NOT EXCEED 0.36 × YIELD STRENGTH OF BASE METAL.	
	TENSION NORMAL TO EFFECTIVE AREA	0.27 × NOMINAL TENSILE STRENGTH OF WELD METAL, EXCEPT SHEAR STRESS ON BASE METAL SHALL NOT EXCEED 0.55 × YIELD STRENGTH OF BASE METAL.	
FILLET WELDS	SHEAR ON EFFECTIVE AREA	0.27 × NOMINAL TENSILE STRENGTH OF WELD METAL	WELD METAL WITH A STRENGTH LEVEL EQUAL TO OR LESS THAN

	TENSION OR COMPRESSION PARALLEL TO WELD AXIS[B]	SAME AS BASE METAL	MATCHING WELD METAL MAY BE USED
PLUG AND SLOT WELDS	SHEAR PARALLEL TO FAYING SURFACES (ON EFFECTIVE AREA)	0.27 × NOMINAL TENSILE STRENGTH OF WELD METAL, EXCEPT SHEAR STRESS ON BASE METAL SHALL NOT EXCEED 0.36 × YIELD STRENGTH OF BASE METAL.	WELD METAL WITH A STRENGTH LEVEL EQUAL TO OR LESS THAN MATCHING WELD METAL MAY BE USED.

(A) FOR MATCHING WELD METAL, SEE TABLE 20.

(B) FILLET WELDS AND GROOVE WELDS WITH PARTIAL JOINT PENETRATION JOINING THE COMPONENT ELEMENTS OF BUILT-UP MEMBERS, SUCH AS FLANGE-TO-WEB CONNECTIONS, MAY BE DESIGNED WITHOUT REGARD TO THE TENSILE OR COMPRESSIVE STRESS IN THESE ELEMENTS PARALLEL TO THE AXIS OF THE WELDS.

Fluctuating Loads. Fatigue is the process of progressive localized damage that may result in cracks or complete fracture after a sufficient number of working stress fluctuations. Fatigue life is the number of stress fluctuations sustained to failure.

The fatigue design of welded joints is different from the "modified Goodman diagram" method used for plain (unwelded) machine and structural members. The fatigue life of plain base metal is a function of its tensile strength. Welded joints introduce stress concentrations in a structure, which reduces fatigue life. Examples of stress concentrations include weld ripple, undercut, crowned reinforcement, lack of penetration, slag inclusions, microcracks, and craters. The fatigue life of a steel welded joint is independent of base metal tensile strength. An ASTM A 36 steel weld joint has the same fatigue strength as a joint made from ASTM A 514 steel. The fatigue life of a steel weld joint is indirectly proportional to working stress range; that is, as the magnitude of working stress range increases, fatigue life decreases (see Table 17). The fatigue life of a steel weld joint is a function of the weld joint category, which in turn is a function of joint geometry, type of weld, direction of load application, and weld quality assurance (see Table 18 and Fig. 12).

(C) ALLOWABLE FATIGUE STRESS RANGE FOR TRANSVERSE PARTIAL-PENETRATION AND TRANSVERSE FILLET WELDS IS A FUNCTION OF THE EFFECTIVE THROAT, DEPTH OF PENETRATION, AND PLATE THICKNESS.

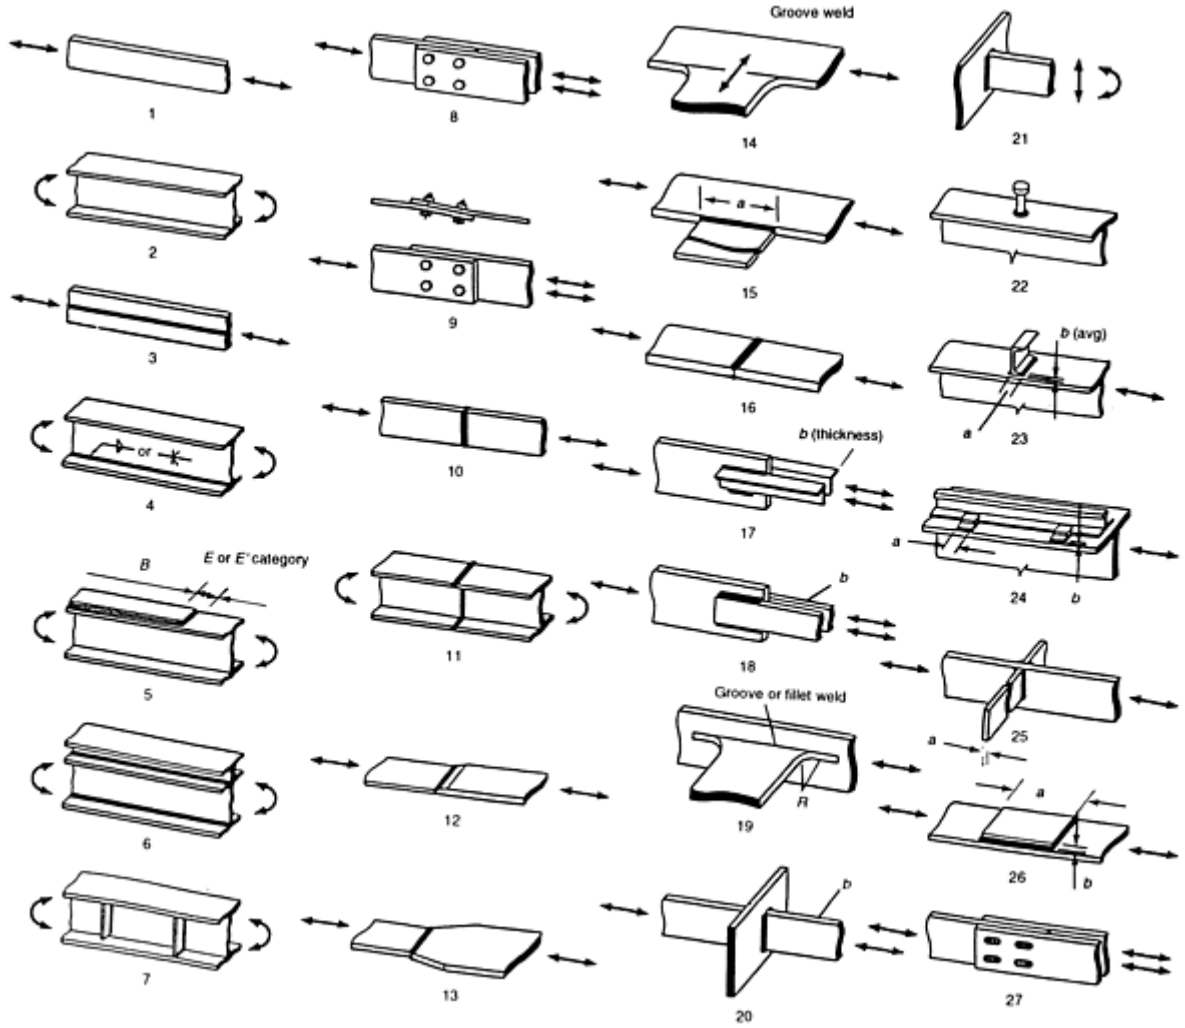

FIG. 12 ILLUSTRATIVE EXAMPLES OF THE STRESS CATEGORIES IN TABLE 18

The primary design requirement for some machine members can be rigidity. Such members, even when subjected to both static and fluctuating loads, are treated as statically loaded structures. Deflection under load is very small and the working stress is only 14 to 28 MPa (2 to 4 ksi). In this case, the weld need not be sized to carry the full load capacity of the member.

Loads are considered cyclic if the stress range exceeds 10% of the allowable stress range or if the total life cycles exceed 20,000. Care must be taken when selecting higher-strength materials, because the allowable stress range of welded joints is independent of material strength. The maximum allowable stress is higher for higher-strength steels, but the allowable stress range is the same. The use of higher-strength steels in cyclic load applications is beneficial only when the part is not welded or when the part is in a tensile prestress condition.

The materials listed in Table 15 are commonly used steels that are considered prequalified. Other steels, such as AISI 4340 and 4140, are also commonly used in machinery components, but are not prequalified. Weld procedure qualifications must be developed as required by the appropriate machinery weld specifications. Preheats for these high-hardenable steels must be above the martensitic start (M_s) temperature of 290 °C (550 °F) for AISI 4340 and 4140 to allow the formation of the more ductile bainitic structure and thus avoid brittleness and HAZ cracks. A low-hydrogen welding process is mandatory. The postheat temperature must be no higher than 28 °C (50 °F) below the hardening temper temperature incurred when the part was prehardened.

A table of welding practices applicable to most steels for machinery and equipment is available in Ref 18. Related AWS specifications are listed in Table 19.

D14.6	"WELDING ROTATING ELEMENTS OF EQUIPMENT"

Service Life. Material selection for machine tools, presses, and heavy rolling and forging equipment is usually governed by an indefinite life expectancy. The working parts (e.g., tools, hammers, forming or punching dies, and mill rolls) and the moving parts (e.g., motors, gears, and clutches) are subject to wear and may need to be either replaced or rebuilt. The basic equipment, however, should be constructed from materials that will last until the machine is retired due to obsolescence.

Obsolescence is also a design consideration in material selection for mobile equipment. Because of weight restrictions, however, material election must make use of the maximum load-carrying capacity of the principal components. The life of wear surfaces, especially in earth-moving equipment, is often enhanced by careful selection of weld surfacing materials.

Maintenance and repair of components must also factor into the material selection process. If it is known that parts will need replacement, access for this type of maintenance should be part of the design. If welds must be removed to provide access, necessitating rewelding, the weldability of the steel used for that part is important. A design that seems perfectly feasible during the initial fabrication of a component may present difficult, or even insoluble, problems during disassembly and reassembly for replacement or repair of a worn part.

Safety. Construction equipment is used in a variety of applications, some of which may endanger the operator or other workers at the site. The designer is responsible for ensuring that the material selected is appropriate for the intended use, making allowances for improper uses that cause stress higher than the rated load stress. Material selection should therefore be based on conservative estimates for components whose failure might jeopardize operators and others.

Economics. Machinery and equipment involve the same economic principles with regard to material choice as other types of welded structures. In most applications the unit cost of the material is a small percentage of the overall cost of the fabricated component or machine. Too often the driving force for low initial cost fails to consider the life-cycle cost of a machine. The cost of maintenance, repair, or replacement of components subject to failure or wear can in many cases justify the selection of more costly materials with longer life cycles. Pumps that handle corrosive liquids and dredges that handle erosive slurries are useful examples. Impellers and casings made of materials resistant to corrosion and erosion can add enormously to the utility of a pump over its anticipated life in comparison with materials that may require frequent replacement or rebuilding. In some cases, maintaining the efficiency of a machine component during its life by selecting materials with greater resistance to the environment will offset its cost. Life-cycle cost assessments should be applied to the choice of materials for machinery and equipment during the design phase.

Material Properties of Weldments

Assessment of the performance of welded components must include the ability of the various metallurgical structures to perform the tasks specified by the designer. These structures are broadly defined as the fusion zone and the heat-affected zone. The thermal excursions that occur during welding invariably result in residual stresses, which in some instances may add considerably to the service stresses encountered by a weldment. The effect of welds on the service-ability of weldments for machinery and equipment may influence material selection.

Heat-Affected Zone. In unalloyed steels, the properties of a region that has experienced one or more thermal excursions during welding are quite similar to those of the unaffected base metal. In low-alloy steels, especially those in weldability classes IV and V (Table 15), the HAZ becomes considerably stronger, harder, and less ductile. This impairs the ability of the metal to adjust to the strains imposed by static loads; moreover, the fatigue properties are degraded, lowering resistance to cyclic loads. When low-alloy steels are used for critical weldments in machinery, postweld heat treatments are employed to overcome most of these adverse effects. Preheat is necessary to permit these hardenable steels to overcome the effect of hydrogen, which can cause cracks in the HAZ during arc welding operations.

Fusion Zone. In an arc weld, the fusion zone comprises the amount of base metal that has been melted in addition to the filler metal that is fused by the arc. This is a cast structure distinctly different from the base material--which in wrought materials is usually a polycrystalline structure of more or less uniform size. The welding filler metals normally used for unalloyed carbon steels produce welds whose yield strength is generally higher in the as-deposited condition than that of the base metal. In most machinery applications, this higher strength is considered advantageous. Failures in static loading will therefore depend on the strength of the base metal, which the designer has chosen based on its known properties. Weld failures in statically loaded full-strength welds are thus unlikely, assuming that the welds meet specified workmanship standards.

Low-alloy steel welds of matching weld-metal composition are considerably stronger than the base metal. In these applications, it is often preferable to choose a filler metal of lower alloy content (especially carbon) to match, or even undermatch, the strength of the base metal. As long as the yield strength of the weld metal is not less than that of the base metal, static loads will not cause significant plastic deformation in the welds. Because filler metals are traditionally classified on the basis of the ultimate tensile strength of the welds that they produce, it is possible to use filler metal that is one classification lower in ultimate strength than the base metal. Generally, the yield strength of the lower-strength weld metal will more nearly match that of the base metal. Table 20 lists matching filler metal specifications.

TABLE 20 MATCHING FILLER METAL SPECIFICATIONS

BASE METAL[B]	WELDING PROCESS[A]			
	SMAW	SAW	GMAW	FCAW
CLASSES I AND II	AWS A5.1 OR A5.5 E60*XX* OR E70*XX*	AWS A5.17 F6*X* OR F7*X*-E*XXXX*	AWS A5.18 E70S-*X*	AWS A5.20 E60T-*X* OR E70T-1 (EXCEPT E*XX*T-2 AND E*XX*T-3)[C]
CLASS III	AWS A5.1 OR A5.5 E70*XX*[D]	AWS A5.17 F7*X*-E*XXXX*	AWS A5.18 E70S-*X*	AWS A5.20 E70T-*X* (EXCEPT E70T-2 AND E70-T3)[C]
CLASS IV[E]	AWS A5.5 E80*XX*[D]	AWS A5.23 F8*X*-E*XXX*	GRADE E80S[F]	GRADE E80T[F]
CLASS V	AWS A5.5 E110*XX*[D]	AWS A5.23 F11*X*-E*XXX*	GRADE E110S[F]	GRADE E110T[F]

Note: The use of the same type of filler metal having the next higher mechanical properties as listed in AWS specification is permitted.

(A) A FILLER METAL OF A LOWER STRENGTH MAY BE USED WHERE THE DESIGN ENGINEER HAS STIPULATED LESS THAN 100% JOINT EFFICIENCY.

(B) IN JOINTS INVOLVING BASE METALS OF DIFFERENT YIELD POINTS OR STRENGTHS, FILLER METALS APPLICABLE TO THE LOWER-STRENGTH BASE METAL MAY BE USED.

(C) IF TYPE 2 FILLER METALS ARE USED ON SUCCESSFULLY TESTED PROTOTYPE VEHICLES, THIS QUALIFIES THE USE OF TYPE 2 FILLER METALS FOR PRODUCTION.

(D) LOW-HYDROGEN CLASSIFICATION.

(E) WHEN WELDS ARE TO BE THERMALLY STRESS RELIEVED, THE DEPOSITED WELD METAL SHALL NOT EXCEED 0.05% V.

(F) FOR WELD METAL HAVING A MINIMUM SPECIFIED YIELD STRENGTH GREATER THAN 415 MPA (60 KSI), THE USER SHALL DEMONSTRATE THAT EACH COMBINATION OF ELECTRODE AND SHIELDING PROPOSED FOR USE WILL PRODUCE LOW-ALLOY WELD METAL HAVING THE MECHANICAL PROPERTIES LISTED. THE MECHANICAL PROPERTIES SHALL BE DETERMINED FROM A MULTIPLE-PASS WELD MADE IN ACCORDANCE WITH THE TEST REQUIREMENTS OF THE LATEST EDITION OF AWS A5.18 ("SPECIFICATION FOR MILD STEEL ELECTRODES FOR GAS METAL ARC WELDING") OR A5.20 ("SPECIFICATION FOR MILD STEEL ELECTRODES FOR FLUX CORED ARC WELDING"), AS APPLICABLE. WHEN AN APPLICABLE AWS FILLER METAL SPECIFICATION IS ISSUED, IT WILL TAKE PRECEDENCE OVER ALL OTHERS, AND TESTING BY THE USER WILL NOT BE REQUIRED. THE MECHANICAL PROPERTY TESTS REQUIRED FOR GRADES E110S. E100T, AND E110T SHALL BE MADE USING ASTM A 514 BASE METAL. WHEN REQUESTED, THE ELECTRODE MANUFACTURER SHALL FURNISH CERTIFICATION THAT THE ELECTRODE WILL MEET THE REQUIREMENTS OF CLASSIFICATION OR GRADE.

As-Welded Versus Postweld Heat-Treated Welds. Most welds used for machinery and equipment, including HSLA steels, are placed in service in the as-welded condition. Postweld heat treatment is usually specified to reduce residual stress and to attain dimensional stability when the weldment is to be machined after welding and the machining dimensional tolerances are small. Postweld heat treatment is sometimes specified to improve corrosion resistance in the welded area. The allowable stresses in specifications for components to be postweld heat treated are based on experience or on laboratory tests of the various types of weld joints.

High residual stresses remain in welds that have not undergone postweld heat treatment. In some cases, service loads added to the residual stresses in the weld area will cause sufficient distortion to present problems of dimensional misalignment. A stress-relief thermal treatment may be needed to overcome problems caused by residual stresses. Additional information is available in the article "Residual Stresses and Distortion" in this Volume.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Automobiles

Since its inception nearly a century ago, the automobile industry has relied heavily on joining technologies. Improvements in those technologies over the years have enabled improvements in automotive design--a constantly changing field driven by the ever-increasing demands of customers and governmental agencies. Customers want vehicles to meet criteria ranging from performance and function to appearance and styling; governmental agencies dictate that vehicles meet stringent safety and environmental standards. Producing automotive designs under such demands and constraints can often create difficulties in joining operations.

Service Conditions. The automotive design engineer must consider numerous types of service conditions. Structurally, a vehicle must be capable of withstanding on- and/or offroad service, must be crashworthy in order to meet Federal Motor Vehicle Safety Standards (FMVSS), and yet must possess an economy in terms of overall weight to meet Corporate Average Fuel Economy (CAFE) regulations. A vehicle must be able to withstand diverse environmental conditions,

ranging from the external environment (weather, electrolyte exposure, acid rain, etc.) to the internal environment (engine heat, fuels, lubricants, sealers, etc.), and must be watertight and airtight as well. Finally, all of this must be accomplished within the boundaries of cost-effective and manufacturable processes, including joining.

Welding Processes. The automobile industry utilizes a wide array of welding processes, materials, coatings, and designs. Given the many possible combinations of these factors, difficulties in the manufacturing process are inevitable. However, many problems can be avoided by exercising care in the initial design phase. By taking into account structural requirements (strength, crashworthiness, and fatigue resistance) as well as appearance requirements (corrosion resistance and finish), the design engineer can determine the most effective combination of materials and joining processes to fit the intended design and maximize performance.

Joining processes commonly used in the automotive industry include, but are not limited to, the following:

- RESISTANCE SPOT WELDING
- GAS-METAL ARC WELDING
- GAS-TUNGSTEN ARC WELDING
- FLUX-CORED ARC WELDING
- RESISTANCE PROJECTION WELDING
- STUD ARC WELDING
- LASER BEAM WELDING
- RESISTANCE SEAM WELDING
- BRAZING
- SOLDERING
- PLASTIC WELDING

These processes are applied and controlled either by the automotive industry itself or by suppliers within the industry. In either case, each joining technique should be governed by a reliable set of standards to ensure that the technique is properly defined and applied. The sections that follow will describe how the more commonly used joining techniques listed above are affected by the various material and mechanical factors encountered in the automotive industry.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Resistance Spot Welding

Resistance spot welding is the primary joining process used in automobile production. Its widespread use can be attributed to its many advantages. Specifically, the method is easy, cost effective, and, when properly applied, can produce structures with greater integrity than the sum of the individual welds. Therefore, RSW lends itself to the extremely high production volumes common in the automotive industry. Despite the obvious advantages of the spot welding process, adequate results cannot be achieved without special consideration of a number of factors that can ultimately affect the welded structure, including raw material coatings, processing fluids, raw material chemistry, joint design, joint sealers, and joint adhesives.

Steel Composition. Raw material chemistry is of primary importance in the design of a spot-welded structure. Most automotive applications use SAE 1008-1010 steel. This material has a low carbon equivalent, which makes it readily formable and weldable and relatively inexpensive and abundantly produced. However, low-carbon material is not used exclusively. Automobile manufacturers must reduce weight while retaining structural integrity. This has resulted in increasing use of high-strength steels, such as bake-hardenable, dual-phase, precipitation-hardenable, and martensitic steels. These materials are inherently more difficult to weld because of the residual elements added for solid-solution strengthening, but weldable grades are available. As a rule, welding of these materials requires increased heat input compared with low-carbon steel material.

Steel Thickness. In the design of a spot-welded joint, a critical factor is the combination of materials to be joined, along with their thicknesses. As the number of sheets to be welded increases, the difficulty of the welding operation also increases. Similarly, welding becomes more difficult as the ratio of material thicknesses between sheets becomes overly large. Flange size is another important factor. Flanges must be large enough to accommodate weld equipment constraints and required weld sizes. Too often, designers fail to consider these important yet simple manufacturing requirements.

Coated Steels. Due to consumer demand, the automobile industry has been striving in recent years to produce vehicles with greater corrosion resistance. For the most part, this demand has been met by the use of steels coated by galvanizing, aluminizing, prepainting, or laminating. Such coatings greatly enhance the corrosion resistance of the base material, but reduce its weldability. In general, spot welding of coated materials generally requires an increase in weld current and hold time. Greater electrode wear is also exhibited, which can ultimately affect the resultant welds.

Joint Sealers. Passenger comfort is always an overriding concern in the design of a vehicle; therefore, much attention is paid to the reduction of wind noise, fume intrusion, and water leakage. Body sealers, particularly weld-through sealers, are used to control these factors. Welding problems associated with the use of the sealers include reduced conductivity at the faying surface and increased fuming as the sealer is burned away at the weld. Solutions to these problems include increasing heat input to ensure proper welding and providing for adequate ventilation to remove fumes generated (although minimal) by the vaporized sealer.

Joint adhesives are used to enhance joint integrity. They are commonly used in conjunction with the spot welding process to improve joint shear strength. Similar to joint sealers, adhesives can cause problems in welding, which can be overcome by the methods described above.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Gas Metal Arc Welding

The GMAW process is widely used in the automotive industry to weld frames, brackets, body panels, and many other structural components. This method is easily applied (automated and manually) and lends itself well to high productivity at a relatively low cost; in addition, it allows most metals to be joined to themselves. Disadvantages include the fact that GMAW is sensitive to material chemistry, surface coatings, and joint design. When these factors are not considered in the initial design, weld quality problems, such as cracks, porosity, lack of fusion, and burnthrough, often result, which may affect the structural integrity of an assembly.

Steel Properties. In the automotive industry, a wide variety of steel chemistries are used to meet strength and durability requirements, ranging from low-strength plain carbon steels to high-strength alloys. To avoid GMAW problems associated with chemistry, the designer must take into account the compatibility of the materials to be joined as well as their individual chemistries. Both plain carbon and alloy steels with carbon equivalents of approximately 0.30 are generally considered to be weldable. Once the material chemistries have been established, the appropriate solid filler material must be chosen to produce a weld with characteristics similar to those of the base materials being joined. By taking these initial design steps, problems such as underbead cracking and weld-metal embrittlement can be avoided.

Surface Condition. The GMAW process is sensitive to surface impurities on the base material, such as corrosion, dirt, and oil. Surface coatings can also adversely affect the resultant weld. When improperly prepared surfaces are welded by this method, quality problems (typically porosity and cracking) are often observed. The solution involves simply removing the surface contaminants. Surface coatings are not dealt with as easily, for either the coating must be selectively removed from the weld joint or the welding parameters must be adjusted to reduce the effects of the off-gassing material. This is sometimes done through a trial-and-error process, but can be refined to produce sound welds. In addition, if the coatings are removed in the weld area, provisions must be made to reapply corrosion protection where necessary.

Joint Preparation. Joint designs for GMAW are quite important in the automotive industry. Joints must be designed in such a way as to minimize the amount of joint preparation necessary, yet produce a weld that will serve the intended purpose. Joint preparation is a time-consuming process, which is not desirable for high-volume vehicle production.

Therefore, naturally occurring joints that result from strategic part placement are preferred to prepared joints, such as groove welds, which often require extra processing steps.

Gas Tungsten Arc Welding and Flux-Cored Arc Welding

The GTAW process is well suited to handle thin-section welding with or without filler materials. The FCAW process can handle the same types of welding conditions as the GMAW process, despite the filler material differences (flux-filled wires versus solid wires, respectively). In terms of automotive applications, both processes involve considerations similar to those listed for the GMAW process.

Fasteners: Resistance Projection Welding and Stud Welding

The intricate assembly of an automobile requires that parts be securely fastened, yet the ease of manufacturing must not be compromised. In order to accomplish this task, projection-welded screws, nuts, and studs are often used. These fasteners must possess welds that can withstand the rigors of a production environment as well as endure the torquing operations in assembly. Types of service conditions that can affect the welding and subsequent use of these parts include:

- BASE METAL/FASTENER CHEMISTRY
- BASE METAL/FASTENER STRENGTH CHARACTERISTICS
- BASE METAL/FASTENER COATINGS
- BASE METAL CLEANLINESS PRIOR TO WELDING

Materials Properties. Selection of the correct base metal and fastener chemistries is extremely important to ensure compatibility at the weld interface and HAZs. In order to avoid exotic weld schedules, materials with carbon equivalents of approximately 0.30 are ordinarily used, as they are readily weldable. It should be noted that these types of welds result in a similar type of weld metal/HAZ transition as other joining processes; this fact must be recognized in the design of such weldments.

Base-metal strength and fastener strength characteristics can affect the ultimate mechanical joint integrity. Designs must reflect conditions where the base-metal strength is compatible with that of the fastener; otherwise, premature failures or insufficient mechanical joints may result. The different strength characteristics may be a result of chemistry, heat treatment, cold working, or simply section thickness.

Surface Condition. Projection-welded fasteners may also be affected by coatings present on the base material or the fastener. As described previously, the automotive industry utilizes different corrosion-resistant coatings on many areas of vehicles. Such coatings can affect projection or stud welds in several ways. If the base material is zinc coated or the fastener is coated with a corrosion-resistant plating, the arc characteristics of the welding process are much different than for bare materials. In either case, provisions must be made in welding schedules. Lastly, use of an antispatter/antifriction coating, such as Teflon, can also affect the welding process. Such coatings are being used increasingly to prevent production problems associated with weld spatter and expulsions generated by other processes.

Laser Beam Welding

Laser beam welding is an emerging technology that has shown promise for use in the automotive industry. Basically, the technique utilizes a high-power laser beam capable of penetrating deep into the weld joint. Laser welding offers high speed, precision, and flexibility to automotive applications. The resultant welds exhibit very small HAZs and are easily formed to final part configuration without weld degradation.

The diverse capabilities of the laser welding technique enable the user to produce parts with properties unattainable with common methods, such as resistance spot welding or GMAW. Laser welding is most often used to make lap and butt joints. It allows blanks to be fabricated through the welding of different-gage materials as well as materials with dissimilar coatings. After the welding operation, the parts can be formed to their final shape. This allows heavier-gage materials to be used in place of reinforced areas, thereby eliminating parts. Similarly, coated parts can be strategically placed in corrosion-prone areas, which eliminates the need to coat the entire assembly.

Despite the obvious advantages of laser welding, application of the technique requires care, especially with the types of materials used in automotive applications. Coated steels complicate the laser welding process, because the off-gassing of the lower-boiling-point material interferes with the maintenance of the weld keyhole. Once this keyhole is broken, the weld must be restarted, resulting in inferior quality. Joint edges and part alignment/fit-up are also common production problems when laser welding. They affect the continuity of the welding process by disrupting the laser beam or by deflecting the beam from the joint.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Other Joining Processes

Many other joining techniques are commonly used in the automotive industry, but to a lesser extent than those discussed above. Some of these processes include resistance seam welding, soldering, brazing, and plastic welding, each of which requires due care in its application to ensure the production of sound joints.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Railroad Equipment

The transporting of freight and passengers by railroads in the United States involves over 200,000 miles of track, 1,200,000 freight cars, 19,000 locomotives, and thousands of passenger vehicles (Ref 19). Welding is the major process used in the fabrication of railroad facilities and structures, as well as in their repair and maintenance. Practically all known welding processes are being used or have been applied to components used by the industry. This section will deal with freight cars, locomotives, and track.

ASM Committee on Material Requirements for Service Conditions*

Freight Cars

Freight car requirements vary considerably, depending on the type of load being carried. A variety of products are transported by rail, including various liquid and solid commodities. Some commodities must be kept at low temperatures and some at high pressures, and some are classified as hazardous. Public safety is always a key issue.

Many freight cars are in "interchange service," which means that they may be handled by any railroad. It also means that repair work may be done by a variety of shops throughout North America. Ease of repair welding is therefore a critical consideration in material selection.

It is not unusual to expect a freight car to last 40 years. Cars for interchange are designed for required service conditions, which for high-utilization cars may be up to 3 million miles of service. Freight cars must be able to sustain 4.5 MN (10^6 lbf) of squeeze and single-end impacts of 5.6 MN (1.25×10^6 lbf). Designs must include buff and draft forces of up to 3.5 MN (630,000 lbf) without exceeding the yield strength of the materials.

Freight cars are subject to a variety of cyclic stresses due to train action, track irregularities, and track hunting. Most failures are caused by fatigue crack propagation, with a lesser number caused by a single overspeed impact.

Types of freight cars in common use include tank, flat, gondola, box, hopper, and covered hopper cars. Of these, only tank and covered hopper cars have seen a net increase in number over the last 21 years (Ref 20). The largest increase has been in the use of covered hopper cars, which handle a variety of dry commodities that must be kept clean.

Tank cars consist of a tank, which is basically a pressure vessel, and an underframe, which provides connection to other cars and to the "trucks." Underframes may be continuous or may consist of attachments to the ends of the tank, with the tank being a structural member. Tank cars and covered hopper cars are often lined with epoxy, rubber, or other protective materials to prevent car body corrosion and/or contamination of the commodity being carried.

Specifications. Freight car construction is regulated by the Association of American Railroads (AAR). Tank car welding is covered by the AAR "Tank Car Specification." For other types of freight car welding, the AAR references the AWS "Railroad Welding Specification" (D15.1).

Design Considerations and Materials of Construction. With the type of welded construction employed on freight cars, the use of higher-strength materials does not improve fatigue resistance. Where fatigue is a significant factor, structural designs incorporating welding are based on carbon steel and HSLA steels with moderate strengths (usually 345 MPa, or 50 ksi, yield strength or less). For applications requiring high static strength and moderate fatigue resistance, quenched and tempered steels with yield strengths of 690 MPa (100 ksi) and high-strength controlled rolled steels with yield strengths of 550 MPa (80 ksi) have been used.

The most common steels used in the production of modern tank cars are ASTM A 516 grade 70 and AAR TC128 grade B (similar to ASTM A 612 grade B). For all pressure tank cars and for some nonpressure cars, these steels are used in the normalized condition. For general-purpose nonpressure cars, hot-rolled steel is used.

Certain components are exposed to severe wear conditions, including "truck" components as well as couplers and related wear plates. Wear materials used include plain high-carbon steel, quenched and tempered alloy steel, and austenitic manganese steel, which are attached by welding or by mechanical fasteners.

Some commodities warrant the use of stainless steel tanks or covered hopper cars, which are generally fabricated of AISI type 304 or 316 stainless steel. However, this constitutes a small percentage of the freight car business.

The empty car weight, or tare weight, is an important factor in determining the hauling capacity of a car. The tare weight is deducted from the total allowed weight (i.e., gross rail load) to determine the weight of commodity that can be loaded (i.e., load capacity). The energy used to haul the tare weight around is wasted fuel. For this reason, the use of aluminum

car bodies has recently become more popular, especially in coal-hauling service. The corrosion resistance of aluminum alloys is an added benefit. In some designs, the aluminum is mechanically fastened to the welded steel underframe, and little or no welding of the aluminum is required.

Freight cars generally consist of six components: tracks, brakes, underframes, draft components, safety appliances, and bodies. Figure 13 shows a side view of a general-purpose boxcar. A high percentage of the welding operation is performed in the underframes and the car bodies. Underframe components typically are from 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.) thick, but may be thicker for heavy-duty cars. Bodies vary from 3.2 to 7.8 mm ($\frac{1}{8}$ to $\frac{5}{16}$ in.) in thickness. Tank car tanks range from 11 mm ($\frac{7}{16}$ in.) to slightly more than 25 mm (1 in.) in thickness.

Welding Processes. The most common welding processes used in the manufacture of freight cars are FCAW, GMAW, and SAW. SMAW has been largely displaced by semiautomatic, mechanized, or automatic welding procedures. Seams in tank car tanks are produced primarily by SAW. Except for carbon and low-alloy steel tank car tanks, which are stress relieved, most freight car components are used in the as-welded condition.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Locomotives

Modern locomotives are diesel-electric, ranging from 0.75 to 3.3 MW (1000 to 4500 hp) in power and weighing as much as 181,000 kg (400,000 lb). The life of a locomotive is expected to be 20 years and with rebuild can be extended to as long as 40 years. Locomotives are generally owned by a railroad and remain within its control. Maintenance is normally done by the owners, but major overhauls and rebuilds are performed by remanufacturing specialists.

Design Considerations and Materials of Construction. The modern diesel-electric locomotive consists of welded components fabricated using the full range of welding processes. The basic components are the underframe, cab structures, engine, generator, tracks, traction motors, electrical cabinets, fuel tank, air compressor, and brake equipment. Components are fabricated from rolled plate, sheet metal, forgings, castings, and various shapes.

Locomotives must be able to withstand forces similar to those experienced by freight cars, including 4.5 MN (10^6 lbf) of squeeze. Buff and draft forces are transmitted through a self-supporting rigid underframe consisting of a fabricated draft gear pocket, "T" or "I" sills, and a bottom plate.

Materials used for fabrication of the main components of a locomotive are typically selected on the basis of good weldability in order to facilitate original construction and subsequent maintenance and rebuild. The underframe, fuel tank, traction motor frame, generator frame, and other structural steel components are fabricated from low-carbon steel containing less than 0.26% C, with and without added alloying. Typical tensile and yield strengths are 415 and 275 MPa (60 and 40 ksi), respectively. Weld filler metals used for these components include E70*xx*, ER70S-X, and E70T-X-type electrodes. Although higher-strength base materials do not improve high-cycle fatigue life, quenched and tempered steels with a tensile strength of 690 MPa (100 ksi) and normalized carbon-manganese steels with a tensile strength of 550 MPa (80 ksi) may be used when high static strength or weight reduction is an issue.

Diesel locomotive track frames are made of cast steel. Except for the application of wear plates, welding on cast steel truck frames is accomplished using E70-type electrodes. Wear plates made of medium-carbon, high-carbon, or austenitic manganese steels are welded using austenitic stainless steel electrodes.

With the exception of certain critical subassemblies (bolsters, center plates, and traction motor frames), which are stress relieved, most diesel locomotive structural fabrications are used in the as-welded condition.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Track

Rails are designed for strength and wear resistance. Locomotives and freight cars weighing up to 181,000 kg (400,000 lb) and riding on steel wheels create high bearing stresses, requiring very-high-strength rail material. Bearing stresses may be up to 2750 MPa (400 ksi).

Rail life averages 70 years. Replacement of rail is extremely expensive. Maintenance of high wear areas, such as switch points and rail ends, requires that repairs be made economically in the field. The desire for long, continuous rails necessitates the use of materials that allow butt welds to be made in the rail that have properties matching the unwelded rail.

Design Considerations and Materials of Construction. There are two categories of rail materials. The largest category by far is T-rail, typically of near-eutectoid composition (~0.8% C), which makes up the thousands of miles of railroad track. The much smaller category is austenitic manganese steel, which is used extensively in cast frogs. The welding practices for each type of material are very different. This section will address the metallurgical reasons for these differences. Welding is applied to T-rail for joining and repair purposes, and is applied to austenitic manganese steel solely for repair purposes.

The controlling feature for welding of near-eutectoid T-rail is hardenability--that is, its tendency to form transformation products such as martensite and bainite, rather than the preferred pearlite. Untempered martensite is unacceptable because of its possible embrittling effect on rail steel; near-eutectoid composition bainite and tempered martensite are avoided because of their poor wear resistance compared with pearlite of the same hardness.

Historically, rail steels have had carbon contents near 0.7 to 0.75%, with manganese contents of 0.85 to 0.95% and silicon levels of up to 0.5% maximum. The as-hot-rolled hardness generally has been near 240 to 270 HB. More modern conventional carbon rail steel has a slightly higher maximum manganese content (1.25%) and allows up to 0.25% Cr to be added to ensure as-hot-rolled hardness near 300 HB.

Metallurgical Characterization. The time-temperature-transformation (TTT) characteristics of steel control the type of transformation product that results from the welding process. A typical continuous cooling curve diagram for the older grades of conventional carbon rail steel is illustrated at the left in Fig. 14. In an effort to ensure that the transformation product resulting from welding is pearlitic, the maximum cooling rate through the transformation region generally must not exceed approximately 4 °C/s (7 °F/s). For rates up to this maximum level, transformation will take place entirely between the pearlite start and finish boundaries. However, should the cooling rates exceed approximately 4 °C/s (7 °F/s), it is possible that the cooling path will miss the nose of the pearlite finish boundary such that untransformed austenite will be available for transformation to bainite or untempered martensite at temperatures below 540 °C (1000 °F).

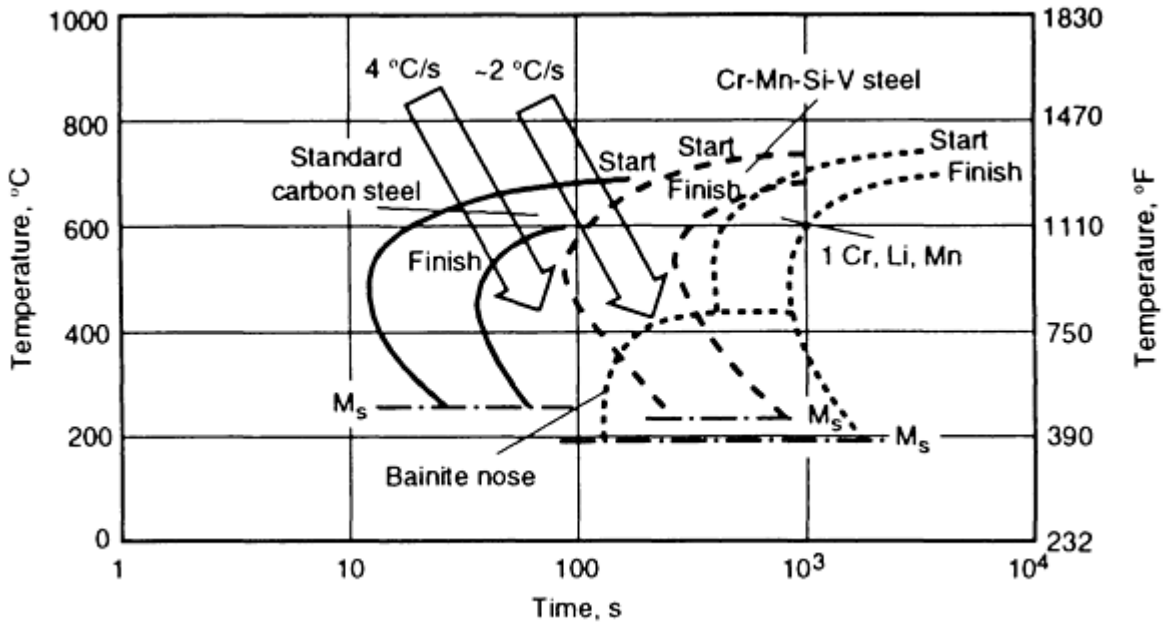

FIG. 14 TTT CHARACTERISTICS OF RAIL STEELS

Alloying additions are sometimes made to near-eutectoid rail steels in an effort to produce pearlite having a smaller spacing between the Fe_3C platelets during cooling following hot rolling; this yields superior hardness and greater wear resistance. The alloying additions most commonly used are the carbide formers: chromium, molybdenum, and vanadium. If added in sufficient amounts (1% Cr; 0.6 to 0.8% Cr and 0.20% Mo; or 1% Cr and 0.08% V), these types of alloy additions tend to increase hardenability significantly and in so doing shift the diagram to longer times. In fact, a specific bainite nose can be obtained (see Fig. 14).

Welding Thermal Cycles. One of the limitations of the alloy approach to strengthening is that a welding practice resulting in a cooling rate near 2 °C/s (3.6 °F/s) (which would be perfectly satisfactory for conventional carbon steel rail) would now lead to the formation of undesirable bainite or untempered martensite. Welding practices must be modified to slow the cooling rate to less than 2 °C/s (3.6 °F/s).

By and large, most rail welding is done to join rails into strings up to 440 m (1440 ft) in length. The most common practice for that purpose is flash butt welding utilizing either ac or dc current. This practice generally involves the use of a number of preheating cycles to heat the rail ends and control the subsequent cooling rate. When the rail ends have been sufficiently preheated, a flashing phase is initiated that removes oxidized metal and establishes a metal ion plasma in which forge welding of the rail ends can be accomplished. The forging operation ideally expels all liquid metal from the bond interface, such that the weld is in reality a solid-state bond.

Postweld Heating and Cooling Cycles. For significantly alloyed rail steels, adjustment of the preheat practice may not be sufficient to limit the final cooling rate. To this end, postheat cycles are applied after the forging cycle. The added expense of postheating has caused railroads to prefer the use of heat-treated carbon steel rails--both those achieving full section hardening and those in which only the head is hardened. These rails generally require no modification of the electric flash butt welding practice. However, a consequence of welding most heat-treated rails (except those classified as slack quenched) is the loss of the heat-treat strengthening in the weldment. This loss can lead to severe batter of the weldment under heavy wheel loads. Thus, some railroads have introduced a postweld air quench to refine the pearlite in weldments.

An alternative approach to air quenching is the use of head-hardened rails having their composition adjusted slightly to achieve slack quenching during the normal cooling after flash butt welding. Typically, such modified compositions will include increased silicon (up to 0.8%) and chromium (up to 0.5%) levels. After normal cooling, the hardness of the weldment will have returned to about the same level (~350 HB) as that of the head-hardened region of the rail. Although this approach works very well, the cost of the rail may be notably higher than that of conventional head-hardened rail. Neither air quenching nor slack quenching prevents the softening that occurs in the outer boundaries of the HAZs.

Other Welding Processes. Rails are also joined together in track by thermite welding--a metal casting process based on the reaction between aluminum powder and iron oxide (see the article "Thermite Welding" in this Volume). The resulting cast structure has low ductility and toughness compared with the hot-worked structure of a flash butt weld. The cooling rates typical of thermite welding are low in comparison with those of the flash butt process, so there generally is no need to alter standard welding practices for use with alloy rail.

Welding also is applied to near-eutectoid rail steels to repair battered and chipped rail ends, wheel burns, and worn and chipped switch points and frogs. Both arc welding and oxyfuel gas welding processes are possible, although arc welding is preferred. Either coated electrodes or flux-cored wire can be used. Electrodes may contain high nickel and manganese contents, and deposits are generally austenitic. Both longitudinal and transverse lay-down patterns have been employed.

Austenitic Manganese Steels. The nominal chemical composition range for austenitic manganese steel is 10 to 14% Mn and 1.0 to 1.4% C. The presence of such high levels of manganese stabilizes the high-temperature fcc austenite phase so that, with rapid cooling, the austenite is retained to room temperatures. The austenite has a relatively low yield strength that is not strongly influenced by carbon or manganese levels. However, its ultimate tensile strength, which is influenced by carbon or manganese levels, can be quite high in comparison with yield strength. This wide separation imbues the steel with a much higher work-hardening capacity than pearlitic rail steels. It is this high work-hardening capacity that makes manganese steels effective in resisting impact loads such as those occurring at railroad frogs. Although the high manganese content can delay the transformation of the high-temperature austenite phase to the room-temperature equilibrium phases (ferrite and carbides), it cannot completely suppress the transformation. If temperatures are elevated to 315 °C (600 °F) for very long periods or to temperatures 480 to 540 °C (900 to 1000 °F) for much shorter periods (a few minutes), the steel can become embrittled. The mechanism of embrittlement is the precipitation of carbides, usually along austenite grain boundaries. For this reason, repair welding must cease when the casting temperature reaches 315 to 370 °C (600 to 700 °F), and the parts must be allowed to cool to a more suitable range.

Sheet Metals

This section deals with a wide variety of sheet metal fabrications, excluding those discussed in previous sections of this article. Ductwork of many types, small and large appliances, containers, pharmaceutical and food processing vessels, and industrial and domestic kitchen equipment are examples of sheet metal applications.

Service conditions are the principal consideration in material selection for such applications. The material attributes listed in Table 1 are a useful starting point. If an application requires cold forming or deep drawing, the ductility of the material will be of primary importance. Corrosion properties are paramount in applications where the weldment will not be protected by some type of coating following fabrication. Mechanical properties figure prominently in designs for structural applications. Density becomes important in many applications for products where shipping weight is a factor. Fracture toughness, conductivity, and magnetic properties are rarely significant in sheet metal fabrications.

Weldability is extremely important in the material selection process, particularly when an application involves very thin sheet materials. The choice of welding process will be determined by the ability to weld thin materials without burnthrough. When dealing with sheet metals, the ability to make sound welds without burnthrough is often synonymous with weldability.

The weldability of sheet metals is vitally affected by the welding process selected, the manner of welding (manual, semiautomatic, or automatic), and the number of parts to be fabricated in a given manufacturing operation. This section will deal with material selection criteria as determined by the joining process to be employed.

Welding process selection is greatly influenced by the need to control distortion. Thinner material is inherently more difficult to weld because of the thermal cycles encountered in welded joints. Distortion is minimized by rigid fixturing and by use of high-energy rapid-travel-rate welding processes. Brazing or soldering allows lower peak temperatures to be used for joining, which is advantageous in distortion control. Materials with low heat conductivity, such as stainless steels, aggravate distortion problems. Warpage of materials during joining is one of the principal problems encountered in the fabrication of sheet metal by any of the joining processes that involve fusion of metal.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Joining Processes

Resistance Welding. Spot, seam, and projection welding are commonly used in sheet metal fabrications. The most commonly used material joined by these processes is low-carbon steel, although low-alloy steels, stainless steels, nickel, and copper-base alloys are also readily joined.

When an unalloyed carbon steel is suitable for an application, the carbon content is generally limited to 0.20% maximum. For products that are to be enameled after welding, the carbon content is usually kept below 0.04% to avoid blistering of the enamel. The designer can then take advantage of the enamel thickness in assessing the strength properties of the part, which will offset the relatively low strength of the very-low-carbon steel.

Spot welding and projection welding are advantageous for control of distortion, but are unsatisfactory for containment of fluids or for elimination of crevices. Seam welding can be suitable for fluid containment, but distortion is a greater problem and crevices continue to be present. As described in the section titled "Automobiles" in this article, joint sealants and adhesives can be used with the resistance welding processes, offering the possibility of fluid containment and crevice elimination.

Arc Welding. Developments over the past 20 years have greatly increased the application of arc welding in the fabrication of sheet metals. All of the arc welding processes are employed, although some are more suitable than others.

The simplest arc welding process is SMAW. For nonrepetitive parts, it is the preferred process and is suitable for thicknesses of most steels down to about 2 mm (0.080 in.). Covered electrodes down to 1.6 mm ($\frac{1}{16}$ in.) in diameter are available in most types of low-carbon, low-alloy, and stainless steels. Burnthrough is a problem with the thinner sheet metals, more so with stainless steel than with carbon steels because of its low thermal conductivity. The SMAW process is commonly used in job shops and for repairs. Fixturing for prevention of distortion and warpage is needed in cases where large, flat surfaces must be kept flat.

Manual welding with the gas-shielded arc welding processes (GMAW, FCAW, and GTAW) offers improved control of the arc energy, especially when using more sophisticated power sources with pulsed current controls. However, travel rate in manual welding is generally slow, so the distortion problem is similar to that encountered with SMAW. Automation of the process offers increased welding speed, use of fixtures with heat sinks for more rapid cooling, and higher productivity and quality.

High-energy-beam welding processes, such as electron and laser beam, offer even higher welding speed and lower distortion. Materials sensitive to atmospheric effects during welding, such as titanium and zirconium, are especially suited to electron beam welding in vacuum chambers or with an inert gas trailing shield. Laser welding is being increasingly used for unalloyed carbon steel sheet fabrication, because the process requires no protection from the atmosphere during welding and because relatively low-power laser equipment of nominal cost is adaptable for thin metal sections. Fully automatic welding systems are generally required for high-energy-beam welding processes.

Brazing and soldering are suitable joining methods for many sheet metal materials. The metal surfaces must be compatible with the liquid-phase joining material. For successful joining, both brazing and soldering depend on capillary action between the mating surfaces to cause flow of the liquid joining material. Oxides on the metal surface must be mechanically or chemically removed in many instances for the liquid metal to flow freely. Fluxes are frequently used to assist this flow process.

These joining processes are easily adaptable to manual low-volume fabrication using oxyfuel torches for the heat source. Job shops customarily use these methods for fabrication or repair. The lower joining temperature is a distinct advantage in that fusion of the base metals does not take place, minimizing distortion.

Soldering is commonly used to join galvanized steel and tin plate. The surface zinc or tin becomes alloyed with the solder during the fusion process and assists in establishing an adherent bond with the underlying steel. The coated surface adjacent to the joint is unaffected and is thus resistant to the service environment.

Brazing requires much higher temperatures and offers many more types of filler metals than soldering. A filler metal must be chosen not only for its ability to flow at the brazing temperature, but also for its compatibility with the service environment. The filler metal is distinctly different from the base metal and may set up electrochemical cells, causing localized corrosion adjacent to the joint.

Brazing and soldering are superior to resistance welding for producing crevice-free joints, but are usually less satisfactory than the arc welding processes for joints that require mechanical and corrosion-resistance properties comparable to those of the base metals.

Nonfusion Joining Processes. Bonding of metal surfaces can be accomplished in many metal systems without fusion. Diffusion bonding, ultrasonic welding, and similar techniques can be used to join very thin metals. These processes are particularly appropriate for the precious metals--for example, in making contacts to foils in electronic circuitry. They are economically unsuitable for continuous seams in liquid or gas containers.

Materials and Properties

Steels. Low-carbon steels are characterized by their considerable ductility at ambient temperatures, which becomes even higher at elevated temperatures. During the welding thermal cycle, plastic deformation occurs in the HAZ. Unless restrained by clamping devices or by the inherent shape of the piece, unwanted distortion in the weld area will result. The thinner the steel, the greater the distortion problem.

Fusion welds have greater strength and lower ductility than the base metal. If a sheet metal is to be cold formed after joining, this strength mismatch may need to be addressed in the design. Although the ductility of the weld is less than that of the base metal, it is usually adequate for most cold-forming operations. Distortion that forms during the welding operation can sometimes be ignored if the component is subsequently cold formed.

In corrosive or high-temperature environments, carbon steel weldments will perform in a manner generally comparable to that of the unaffected base metal. The cast structure of the weld is often less resistant to some environments than the wrought structure of the unaffected steel. Also, the welding process usually results in fine oxide inclusions in the weld, which are often less resistant to corrosion.

The higher strength of low-alloy steels does not offer the same advantages to sheet metal welding applications that it does to structural steel applications. Thinner sections might be possible by using the higher-strength steels, but distortion and weldability considerations usually make such choices uneconomical unless weight savings are critical.

Table 21 lists the principal ASTM specifications for weldable carbon and low-alloy sheet steels.

TABLE 21 PRINCIPAL ASTM SPECIFICATIONS FOR WELDABLE CARBON AND LOW-ALLOY SHEET STEELS

TYPE OF STEEL	PURPOSE	ASTM NO.	
		COLD ROLLED	HOT ROLLED
LOW CARBON	COMMERCIAL QUALITY	A 366	A 569
		A 794	A 659
	STRUCTURAL	A 611	A 570
	ENAMELING	A 424	A 424
	DEEP DRAWING	A 619	A 621
		A 620	A 622
CARBON-MANGANESE	ATMOSPHERIC CORROSION	A 606	A 606
	PRESSURE VESSELS	. . .	A 414
LOW ALLOY	HIGH STRENGTH	. . .	A 715
	NIOBIUM OR VANADIUM ADDED	A 607	A 607

Aluminum and aluminum alloy specifications for sheet metal are included in ASTM B 209. The low density of aluminum when compared with most metals makes aluminum sheet metal desirable for fabrications where weight savings are important. It is also useful for its adherent oxide, which makes it resistant to many environments at ambient temperatures.

The refractory oxide on the surface of aluminum becomes increasingly important as the thickness of the sheet is reduced. Gas-shielded arc welding processes, especially those using ac power, are essential to break down this adherent refractory aluminum oxide in order to make successful welds. Manual welding with covered electrodes is employed occasionally; oxyfuel welding is not suitable. Brazing and soldering are possible only with chemically active fluxes that dissolve the oxide layer.

The high thermal conductivity of aluminum can cause distortion. Gas-shielded arc welding processes overcome this problem by concentrating the arc energy sufficiently to cause fusion to occur. Electron beam welding is also suitable.

Aluminum alloys offer higher strength, which is especially important in applications where weight saving is a factor. Furthermore, their thermal conductivity is lower than that of pure aluminum, making fusion welding easier.

Distortion control is usually provided by rigid fixturing and backups. The metallic backup of the fixtures offers the advantage of heat sinks and backside weld contour control. Adding an inert backing gas often prevents oxidation of the molten weld pool.

Stainless Steel. The corrosion resistance of stainless steel is provided by chromium in an amount of at least 12%. When the content of nickel is greater than 8%, the austenitic form of iron becomes stable at ambient temperatures. The most frequently employed stainless steels for sheet metal fabrication contain 18% Cr and 8% Ni and are known as austenitic stainless steels. ASTM specifications normally used in stainless steel sheet metal applications are listed in Table 22.

TABLE 22 PRINCIPAL ASTM SPECIFICATIONS FOR WELDABLE STAINLESS STEEL SHEET

TYPE OF STEEL	PURPOSE	ASTM NO.
AUSTENITIC CHROMIUM-NICKEL	GENERAL REQUIREMENTS	A 480
	GENERAL PURPOSES	A 167
		A 240
	ARCHITECTURAL	A 666
	ROLL CLAD	A 264
DUPLEX CHROMIUM-NICKEL	GENERAL PURPOSES	A 240
FERRITIC CHROMIUM	GENERAL REQUIREMENTS	A 480
	GENERAL PURPOSES	A 240
		A 276
	ROLL CLAD	A 263

The austenitic stainless steels are extremely ductile and easily welded. The weld strengths, both yield and ultimate tensile, are generally higher than those of the base metal, but ductility remains high, permitting subsequent cold forming or straightening if necessary.

The thermal conductivity of stainless steels is about 30% less than that of carbon steels. The thermal cycles during welding cause plastic deformation to occur in the widely heated zones adjacent to the weld. Moreover, the coefficient of thermal expansion for stainless steels is about 30% greater than that of carbon steels. These two properties account for the even greater distortion problems encountered in the austenitic stainless steels compared with carbon steels. Therefore, rigid fixturing and heat sinks are essential when welding these alloys.

Stainless steels are principally used for their resistance to aqueous corrosion and for their strength and oxidation resistance at elevated temperatures. With regard to certain corrosive media, it is important to recognize that the thermal cycles during welding cause carbide precipitation to occur in the HAZ, with severe loss in corrosion resistance. This can be overcome by the use of low-carbon types (0.03% maximum) or those stabilized with titanium or niobium. The stabilized stainless steels are also stronger at elevated temperatures. The fluidity of the very-low-carbon stainless steels often affects the attainment of the desired weld profiles. This is particularly troublesome in autogenous GTAW when sulfur is unusually low (<0.010%).

Because many applications require avoidance of crevices at weld joints, arc welding is the preferred joining method. Shielding from the atmosphere during welding is essential, and while manual arc welding with covered electrodes is suitable for many applications, gas-shielded processes, especially those using inert gases, are useful in minimizing the oxidation of chromium and other essential alloying ingredients.

Butt joints in sheet metals are welded in a single pass. If the backside of the weld will be exposed in the finished weldment, it should have a suitable contour. Purging of the backside of the joint with an inert or inactive gas, usually

argon or helium, but sometimes nitrogen, is useful in producing the desired finish. Gas purging is often built into the distortion-control fixturing.

Austenitic stainless steel welds are almost invariably put into service in the as-deposited condition. The residual stresses associated with the welding operation can give rise to SCC in certain service environments. This situation can be substantially overcome by selecting one of the duplex stainless steels, which have structures of roughly half austenite and half ferrite. These steels contain less nickel than the austenitic stainless steels and provide corrosion resistance by the addition of molybdenum. Filler metals with matching compositions are available for the duplex stainless steels; more commonly, welds are made using an austenitic stainless steel filler metal, provided that the type is suitable for the service environment.

The ferritic stainless steels that contain little or no nickel are less suitable for sheet metal fabrications. Although they do not present the problems of the austenitic stainless steels in terms of low thermal conductivity and high coefficient of expansion, their metallurgical weldability is troublesome, forming constituents that have low ductility in the HAZs. Postweld heat treatments are required to restore ductility, which in practice complicate the distortion problem.

Other Metals and Alloys. ASTM specifications for weldable nonferrous sheet metals are listed in Table 23. Like the stainless steels, nickel-base alloys are commonly used in sheet metal weldments. The welding processes and controls are similar to those described for the austenitic stainless steels, although corrosion impairment due to carbide precipitation is not a concern. Unalloyed nickel, nickel-chromium alloys, and nickel-copper alloys are readily weldable, although their physical properties can affect distortion and burnthrough.

TABLE 23 PRINCIPAL ASTM SPECIFICATIONS FOR WELDABLE NONFERROUS SHEET METALS

MOLYBDENUM AND ITS ALLOYS	. . .	B 386

Copper and its alloys in sheet metal form are somewhat more difficult to weld. Unalloyed copper has a very high thermal conductivity. The tin-alloyed bronzes are much more easily welded, whereas suitable fusion welds are virtually impossible in the zinc-alloyed brasses. Copper-nickel alloys (both 10% and 30% Ni), on the other hand, are easily welded with many of the processes and controls cited for stainless steels.

Titanium is used in sheet metal fabrications for its superior corrosion-resistance properties in many environments. Gas shielding or vacuum environments are needed during the welding operation to protect against contamination of the weld zone by oxygen and nitrogen from the air. Gas-shielded arc welding processes are almost invariably used, because smooth contour welds free from crevices are usually demanded. These can be fabricated without resorting to vacuum chambers, provided that both sides of the weld at the welding arc and in the trailing solidifying weld regions are protected from the atmosphere.

Zirconium, niobium, and molybdenum and their alloys are occasionally produced in sheet metal form and are welded using the gas-shielded processes.

High-energy-beam welding processes are also adaptable to exotic metals and alloys. Electron beam welding in vacuum chambers is especially suited to joining these metals, the unit cost of which is high. The added equipment and fixturing costs can be justified by the reliable welds that are produced.

Coated Metals. Among the most commonly used coated sheet metals are galvanized steel and tin plate. As described above, soldering is a useful technique for joining these metals. Arc welding is possible, but it destroys the coating adjacent to the weld, thus negating the corrosion resistance for which the coated steel was specified. If arc welding is used on galvanized steel, good ventilation must be provided to protect the operator from zinc fumes.

In applications where the corrosion resistance offered by austenitic stainless steels is needed on only one side of a vessel, roll-clad steels are often an economical choice, especially for heavier-gage thicknesses. Distortion during welding is much less of a problem than with solid stainless steel because of the physical properties of the steel backing and its greater thickness. The welding of clad steels in thin sections is usually accomplished in a single pass using a higher-alloyed filler metal (e.g., type 309 for joining type 304 clad steel) to offset the effect of dilution with the unalloyed steel backing.

Painted sheet steels are commonly encountered in repair welding applications. Paints or other surface contaminants should be removed before welding to ensure sound joints.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Surface Finishing

Protective Coatings. Sheet metal weldments fabricated from unalloyed carbon steel are often more vulnerable to failure by corrosion or other environmental deterioration because of their relatively thin sections. Moreover, the welds themselves are frequently anodic to the base metal, causing corrosion failure in those regions. Suitable protective coatings, such as enamels, are often mandated for sheet steel weldments.

Postweld Finishing. Sheet metal fabrications frequently remain in the as-deposited condition, with only slag removal considered essential. This places a premium on smooth contours and good workmanship standards for meeting appearance criteria.

Appearance demands sometimes require the removal of all evidence of the weld. Grinding of the weld surface to blend with the base metal is often performed for appearance reasons or to remove notches for fatigue service applications. The amount of grinding can be substantially reduced if the welding process is intelligently selected and if the controls are carefully set forth in the fabrication specifications. Sheet metal fabrications in which the welds are to be ground smooth are more economically produced when the amount of weld reinforcement is kept to a minimum by appropriate welding process selection and controls.

Stainless steel sheet fabrications often require polishing to match the finish of the base metal. Polishing of the welds can be done either on the as-deposited finish or, if necessary, on the ground and blended finish.

Material Requirements for Service Conditions

ASM Committee on Material Requirements for Service Conditions*

Fabrication Codes and Specifications

Most of the requirements for sheet metal fabrications are set forth in user specifications or contractual documents. Aside from those considered in the preceding sections, few industry-wide codes are available. The American Welding Society publishes a specification titled "Structural Welding Code--Sheet Steel" (AWS D9.1) that covers the welding of low-carbon hot-rolled and cold-rolled sheet and strip steel with and without zinc coatings (galvanized steel). Qualification of welding procedures and welding operators is set forth in this specification.

Introduction to the Selection of Carbon and Low-Alloy Steels

Bruce R. Somers, Lehigh University

Introduction

CARBON AND LOW-ALLOY STEELS are welded more frequently than any other materials because of their widespread applications and good weldability. This versatility is principally due to the metallurgical characteristics of the iron-base system. The characteristics include the ability to undergo allotropic (that is, microstructural) transformations that allow the opportunity for hardening and strengthening through martensitic and bainitic transformations or precipitation mechanisms in addition to the ability to be readily alloyed with a wide variety of elements.

This Section of the Handbook will provide the reader with information about the suitability of these materials for particular types of assemblies. This Section will also provide in-depth metallurgical information about the response of these materials to welding conditions and microstructural evolution in the weld heat-affected zone (HAZ).

Introduction to the Selection of Carbon and Low-Alloy Steels

Bruce R. Somers, Lehigh University

Weldability

The articles in this Section focus on the weldability of carbon and low-alloy steels. The user should consider weldability as being divided into two general classes: (1) fabrication weldability and (2) service weldability.

Fabrication weldability addresses the question, "Can one join these materials by welding without introducing detrimental discontinuities?" The acceptability of these discontinuities depends on the application requirements for the particular weldment. The fabrication weldability of a steel may be adequate for a noncritical application. However, this same steel may not be recommended for a critical application, or special precautions, such as preheat, may be required when welding. Fabrication weldability deals primarily with discontinuities such as hydrogen-assisted cold cracks, hot cracks, reheat cracks, lamellar tearing, and porosity.

Service weldability addresses the question, "Will the finished weldment have properties adequate to serve the intended function?" An important aspect of service weldability is the comparison of HAZ properties with those of the unaffected base metal. Again, the acceptability of the service weldability depends on the intended application. The service weldability of a particular steel may be acceptable for an application where corrosion is of prime importance and toughness is secondary. However, the same steel may be unacceptable for an application where toughness is most important.

Service weldability involves the effect of the welding thermal cycle on the properties in the HAZ. Service weldability often determines the range of heat inputs allowable for a particular steel. Low heat inputs may introduce unacceptable low-toughness microstructures, as well as fabrication-weldability problems associated with cold cracking. High heat inputs can introduce coarse microstructures with both low toughness and low strength. The heat input alone does not control the resulting microstructure and HAZ properties, but the induced thermal cycle controls the microstructure and properties. Therefore, both heat input and thickness should be considered.

Introduction to the Selection of Carbon and Low-Alloy Steels

Bruce R. Somers, Lehigh University

Classification of Steels

The carbon and low-alloy steels discussed in this Section cover a wide variety of compositions and properties. Steels are most often classified according to their carbon and/or alloy content. The various classifications have become known under assorted designations, such as plain-carbon steel, carbon-manganese steel, medium-carbon steel, low-alloy steel, high-strength low-alloy steel, and microalloyed steel. Recently, a new classification of steel has introduced the steel-processing technique as a categorization factor. These steels, known by various designations, are most often described as thermal-mechanical-controlled processing (TMCP) steels. The boundaries between all the above classes are often diffuse, they frequently overlap, and they are sometimes arbitrary (Table 1).

TABLE 1 CARBON STEELS CLASSIFIED ACCORDING TO CARBON CONTENT

REF	CARBON, %			
	LOW-CARBON STEEL	MILD STEEL	MEDIUM-CARBON STEEL	HIGH-CARBON STEEL
1	≤0.15	0.15-0.30	0.30-0.50	0.50-1.00
2	≤0.15	0.15-0.35	0.35-0.60	0.60-1.0
3	<0.30	. . .	0.30-0.60	>0.6
4	≤0.30	≤0.25	0.30-0.60	0.60-1.00

The steels covered in this Section have been grouped into six general classes according to composition or processing:

- LOW-CARBON STEELS
- HIGH-STRENGTH LOW-ALLOY STEELS
- QUENCHED-AND-TEMPERED STEELS

- HEAT-TREATABLE LOW-ALLOY STEELS
- THERMAL-MECHANICAL-CONTROLLED PROCESSING STEELS
- CHROMIUM-MOLYBDENUM STEELS

There will be some overlap between these classifications because fabricators often use some steels in more than one heat-treated condition. Typical steel compositions in these classifications are given in Table 2.

TABLE 2 COMPOSITION AND CARBON EQUIVALENT OF SELECTED CARBON AND LOW-ALLOY STEELS

STEEL DESIGNATIONS			COMPOSITION, WT%										CARBON EQUIVALENT, %
AISI	ASTM	MIL-STD	C	Mn	P	S	Si	Ni	Cr	Mo	V	Nb	
LOW-CARBON STEELS

Low-carbon steels contain up to approximately 0.30 wt% C and up to about 1.65 wt% Mn. Most as-rolled steel used for welded applications consists of low-carbon steel. This group encompasses steels that can have wide variations in weldability. For example, it is possible to weld low-carbon steels with less than 0.15% C by most welding processes. It is also possible to weld low-carbon steels containing 0.15 to 0.30% C (sometimes termed mild steels) in thicknesses up to

25 mm (1 in.). However, thicker sections of these steels may require additional measures in order to produce successful welds.

High-strength low-alloy (HSLA) steels are designed to provide better mechanical properties than those of conventional carbon steels. These steels generally have yield strengths of 290 to 550 MPa (42 to 80 ksi). They are also generally of the carbon-manganese type, with very small additions of niobium and vanadium to ensure both grain refinement and precipitation hardening. The term microalloyed steels is often used in reference to these materials. Fabricators usually weld these steels in the as-rolled or the normalized condition. The weldability of most HSLA steels is similar to that of mild steel.

Recently, a new family of steels has been appearing in the literature under the designation HSLA steels. These are the low-carbon, copper-bearing age-hardening steels, also frequently referred to by their ASTM designations, A 710 or A 736 (Table 3); or by their military specification grade designation, HSLA 80 or HSLA 100 (MIL-S-24645). These steels are not truly low-alloy, because the copper, nickel, and chromium contents are all usually near 1%. However, the weldability of these materials is very good, mainly because of their low carbon contents (less than 0.06% C). These steels are usually used in the quenched-and-aged condition. Because of these two conditions, it is probably more appropriate to group these materials with the thermal-mechanical-controlled processing steels.

Quenched-and-tempered steels are heat treated to provide yield strengths of 345 to 1035 MPa (50 to 150 ksi). ASTM A 514 and A 517 are well-known examples of this category of steel. Other examples include the HY-80, HY-100, and HY-130 nickel-chromium-molybdenum steels covered by military specifications. Weldments fabricated from these materials generally do not need further heat treatment except for a postweld heat treatment (stress relief) in some special applications. For example, HY-100 and HY-130 require controls on the filler-metal carbon content, preheat/interpass minimums and maximums, heat input, and postweld soaks to achieve the desired military mechanical properties.

Advantages of HSLA Steels Over Selected Quenched-and-Tempered Steels. In certain situations, the U.S. Navy substitutes HSLA-80 for HY-80, and HSLA-100 for HY-100. One significant advantage of this substitution is the reduced welding preheat required for the copper age-hardening HSLA versus the HY steels. It should also be noted that HSLA-100 steel does not weld like a mild steel.

Heat-treatable low-alloy (HTLA) steels are usually reaustenitized, then quenched and tempered after welding. These are relatively hardenable steels that in their quenched-and-tempered condition develop yield strengths well above 965 MPa (140 ksi). Weld metals usually cannot develop acceptable combinations of strength and toughness at these levels in the as-welded or stress-relieved condition. Therefore, it is necessary to reaustenitize and then quench and temper the entire weldment after welding. These steels are often referred to by their AISI designations (for example, AISI 4140 and AISI 4340).

Thermal-mechanical-controlled processing (TMCP) steels are a relatively recent addition to the family of steels. These steels are generally produced with a combination of controlled rolling followed by accelerated cooling or in-line direct quenching. This processing allows the steelmaker to develop a combination of high strength and high toughness while maintaining good weldability. The weldability is good because the alloy content of these steels can be kept very lean, with carbon contents generally below 0.06 wt%. Yield strength levels as high as 700 MPa (100 ksi) and above are possible with these steels. Generally, they can be welded without preheat. However, at the high strength levels, preheat may be required in order to prevent cracking in the weld metal.

Chromium-molybdenum steels are extensively used for elevated-temperature applications in the power and petroleum refinery industries. The chromium content of these steels varies from 0.5 to 9%, and the molybdenum content from 0.5 to 1.0%. Typical compositional ranges for chromium-molybdenum steels are given in Table 2. They are usually supplied in the normalized-and-tempered or the quenched-and-tempered condition.

Because these materials have reasonable hardenability, adequate precautions must be taken to avoid hydrogen-assisted cold cracking. The service application frequently imposes additional requirements on the welding of these steels. For example, in the power industry, these materials are required for their creep resistance, and the weld metal and HAZ must provide adequate creep properties. The corrosion environment in refineries requires that the maximum HAZ hardness be limited to avoid corrosion cracking.

Relative Susceptibility of Steels to Hydrogen-Assisted Cold Cracking

Figure 1 illustrates where these classes of steel are located on a Graville diagram. Graville has suggested that the susceptibility to hydrogen-assisted cold cracking can be evaluated by calculating the carbon equivalent (CE) and comparing it to the carbon content (Fig. 1). Zone I steels have low carbon and low hardenability and are not very susceptible to cracking. Zone III steels have both high carbon and high hardenability, and all welding conditions will produce crack-sensitive microstructures. Therefore, to avoid hydrogen-assisted cold cracking in Zone III steels, the user must apply low-hydrogen procedures, including preheat and postweld heat treatment. Zone II steels have higher carbon levels with lower hardenability. Thus, it is possible to avoid crack-sensitive microstructures by restricting HAZ cooling rates. This can be accomplished through control of heat input and, to a minor extent, with preheat.

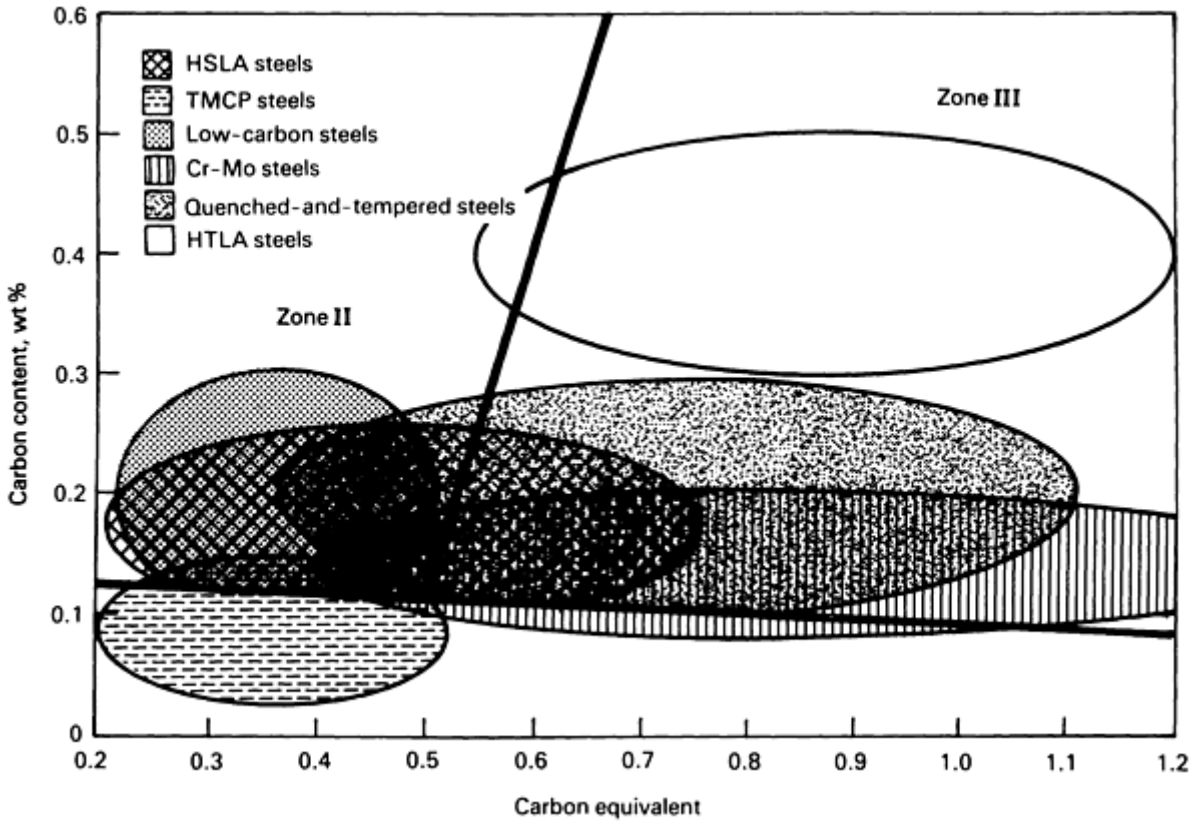

FIG. 1 GRAVILLE DIAGRAM SHOWING SUSCEPTIBILITY OF STEELS TO HYDROGEN-ASSISTED COLD CRACKING RELATIVE TO CARBON CONTENT AND CARBON EQUIVALENT (CE), WHERE CE = %C + (%MN + %SI)/6 + (%NI + %CU)/15 + (%CR + %MO + %V)/5. SUSCEPTIBILITY TO COLD CRACKING PROGRESSIVELY INCREASES AS STEELS MIGRATE FROM ZONES I TO II, TO III. SEE TEXT FOR EXPLANATION. SOURCE: REF 6

Figure 1 also shows that heat-treatable alloy steels, squarely in Zone III, require special considerations for welding. Chromium-molybdenum and quenched-and-tempered steels also require attention, as will some HSLA steels. As mentioned in the section "Low-Carbon Steels" of this article, low-carbon steels are readily welded except in thick sections, for which some precautions may be necessary. The TMCP steels have been specifically developed to lie in Zone I, and so their weldability is excellent. Although Fig. 1 represents only one aspect of weldability and there are many other considerations, the desired preference with regard to hydrogen-assisted cold cracking is to use steels that push the compositional envelope toward the lower-left corner of the Graville diagram.

Introduction

ARC WELDING is a process by which metals are joined by coalescence. In most cases, the process uses a compatible filler metal. Before a well-bonded joint can be produced, the joint surfaces must be heated above their melting temperatures in order to completely fuse with the weld metal. Although the metallurgical reactions that involve melting, solidification, and solid-state transformations may not be unusual, the temperatures and cooling rates observed are severe. Active gases also are present and can dissolve in the fused metal. Fluxes are introduced to alloy with and protect the weld metal.

Generally, joints are rigid and will restrain dimensional changes caused by shrinkage and solid-state transformations, producing residual stresses of yield-strength magnitude. Because the metallurgical changes do not occur under equilibrium conditions, and because the stresses are high, many of the reactions can take place in either or both the weld metal and the heat-affected zone (HAZ) of the plate and can produce defects that impair their soundness.

The intent of this article is to point out those defects. However, because of the tremendous variability of the welding processes, it is impossible to provide much detail about the exact mechanisms involved or the corrections that can be made. Furthermore, many corrective measures are self-evident once most defects are explained. One problem, which relates to hydrogen, is not so simple. Because this problem is becoming more relevant as more high-strength, low-alloy (HSLA) steels are being welded, the subject of hydrogen-induced cracking will be emphasized.

Influence of Welding on Steel Weldment Soundness

A. Lesnewich

Common Defects Associated with Arc Welds

Porosity is caused by the entrapment of small pockets of gas, particularly nitrogen and hydrogen, which typically have a higher solubility in molten, rather than solid, iron. During solidification, gases attempt to leave the weld metal. However, because of high solidification rates, some gas may become trapped. This entrapment depends both on the rate of gas dissolution and on the rate of weld-metal solidification. If the dissolution rate is high, gas bubbles have a chance to develop and escape before the metal solidifies. If the rate is very low the gas may remain in solution, which avoids porosity but allows other problems such as hydrogen-induced cracking or poor toughness. At intermediate rates, the gas can nucleate and, depending on the amount of gas dissolved in the weld metal and the weld-solidification rates, develop bubbles that become trapped. A very severe form of porosity, called worm holes, occurs when the rates of gas evolution and solidification are similar, causing elongated gas pockets to develop instead of essentially spherical bubbles.

Among the possible sources of hydrogen are moisture in fluxes, hydrocarbons in either wiredrawing lubricants or surface contaminants in the joint to be welded, and water leaks in gas-metal arc welding (GMAW) equipment. Nitrogen is gleaned from air that enters the arc regions as a result of poor shielding of the arc. With GMAW, this can happen when the gas flow rates are either so low that crossdraf ts displace the shielding or so high that the surrounding atmosphere is aspirated into the shielding gas. With the shielded metal arc welding (SMAW) process, this can happen because welders are not sufficiently skilled or use improper procedures that cause the arc length to be excessive.

Incomplete fusion can take a number of forms, such as inadequate joint penetration (Fig. 1), absence of root fusion, or lack of side-wall fusion (Fig. 2). These defects can be caused by: inadequate energy input to the weld, particularly insufficient current; excessive travel speed, which allows weld metal to flow ahead of the arc; or improper electrode angles or work positions.

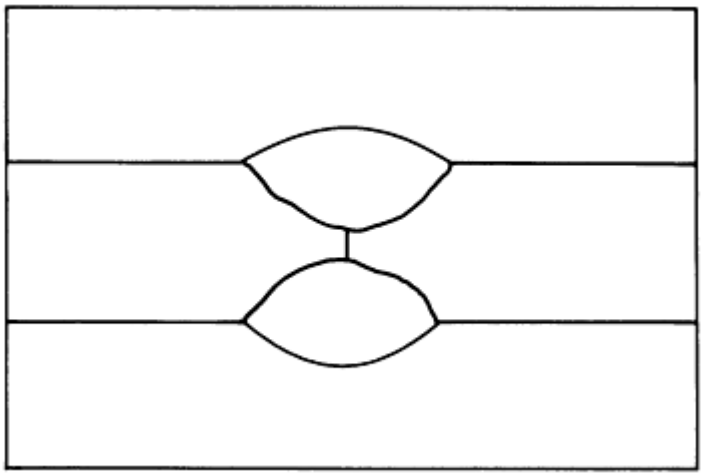

FIG. 1 INCOMPLETE PENETRATION OF WELD INTO BUTT JOINT

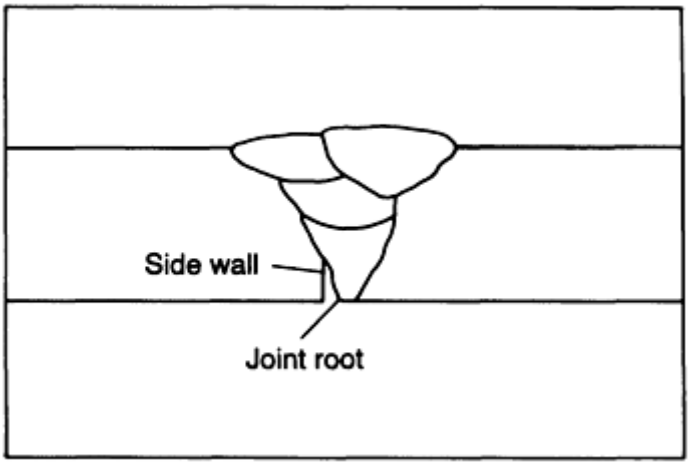

FIG. 2 INCOMPLETE FUSION OF WELD METAL TO SIDE WALL AND TO JOINT ROOT

Problems with joint penetration and root fusion commonly are due to the use of a joint design that is not proper for the welding process being used or to a disregard for the procedures that are intended to provide adequate penetration of the arc. In most cases, this would mean that the welding current is too low. However, in the case of the gas-shielded welding processes, it could mean that the wrong shield gas is being used. For example, with argon-rich gas mixtures, the penetration pattern is relatively shallow, with the exception of a fairly deep central "finger," which is shown in Fig. 3. Unfortunately, this finger generally is not positioned centrally and, therefore, cannot be relied upon. However, shield gas mixtures that are rich in helium or carbon dioxide are capable of a more uniform and deeper useful penetration pattern.

Poor root fusion that occurs when welding from one side requires either a modification in the joint design to allow better penetration or a change to welding from both sides of the plate.

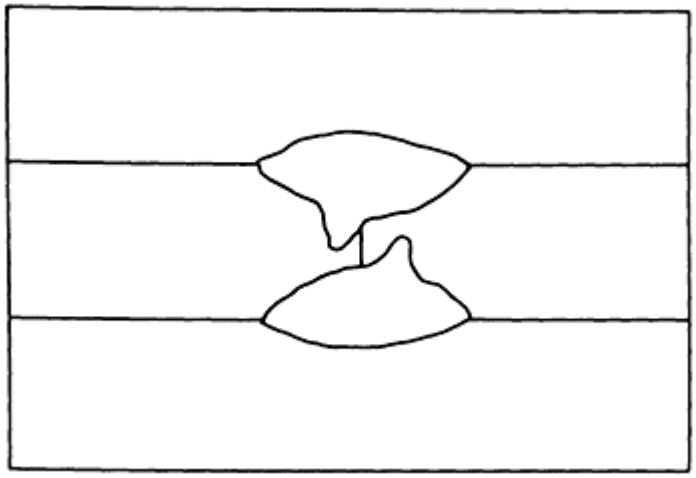

FIG. 3 OFF-CENTER PENETRATION OF CENTRAL CORE OF WELD USING ARGON SHIELD

In most cases, the lack of side-wall fusion between the weld metal and the joint occurs when proper procedures or manipulative techniques are not being used by welders. With the GMAW process, it can be due to using inappropriate variations, such as short-circuiting transfer, when welding heavy sections. Short-circuiting transfer is effective only at low energy levels, which makes it very suitable for welding sheet or thin plate in all positions. This is because the process is designed to provide little penetration and to quickly freeze weld metal. For that reason, the weld metal may not fuse the side walls of joints from which heat is extracted rapidly, that is, those thicker than 6 mm ($\frac{1}{4}$ in.). Both a spray arc with argon and a buried arc with carbon dioxide shielding will deposit welds that are too massive and fluid to be supported in the vertical or overhead positions. However, these processes are very effective for making welds in the flat or horizontal positions. On the other hand, the pulsed-arc variation with argon-rich shielding is very effective in all positions, offering both adequate penetration and control of the weld pool to prevent defects caused by poor side-wall fusion.

Hot cracks, also called centerline or solidification cracks (Fig. 4), are caused by the rejection of low-melting constituents along the centerline of restrained welds. They are called hot cracks because they develop immediately after welds are completed and, sometimes, while the welds are being made. If the welds are broken to expose these cracks, they are found to be blued, or heat tinted. These defects, which are often caused by sulfur and phosphorus, are more likely to occur in higher-carbon alloys. Nearly always, the base plate is their source. The susceptibility to cracking, based on weld composition, has been compared with empirical equations, such as:

$$UCS = 230\,C + 190\,S + 75\,P + 45\,NB - 12.3\,SI - 5.4\,MN - 1 \quad \textbf{(EQ 1)}$$

where the elemental values are given in percent. If the *UCS* value is less than 10, then the susceptibility to cracking is low, whereas a value higher than 30 means that this susceptibility is high, and a value between 10 and 30 means that the welding procedures become controlling.

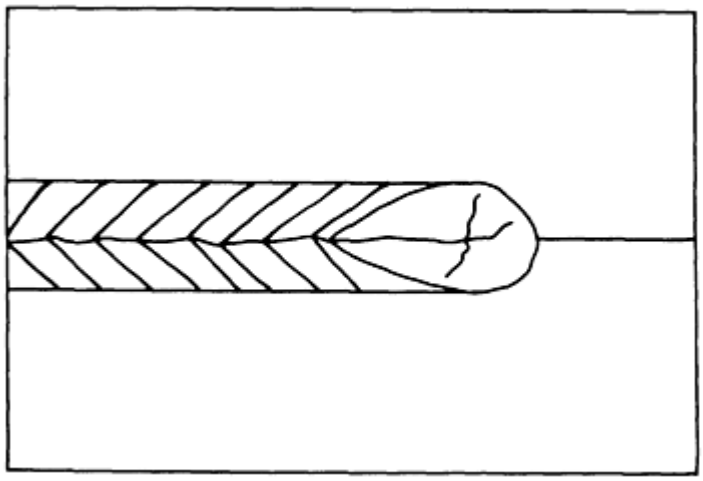

FIG. 4 HOT CRACK AND CRATER CRACKS IN WELD BEAD

Such defects are more likely to occur with welding processes or procedures that produce high dilution (that is, deep penetration). Another factor that contributes to centerline cracking is a sharp tear-drop profile of the weld crater, which is characteristic of high welding speeds. In these situations, the weld crater often develops shrinkage cracks, called crater cracks. Both the teardrop crater and deep penetration are produced with the submerged arc welding (SAW) process and the GMAW process using carbon dioxide shielding. The problem also may occur in fillet welds that are very concave, because their cross section might not be sufficient to tolerate the transverse stresses that are due to weld shrinkage.

In most cases, the problem can be prevented by keeping the combined phosphorus and sulfur levels below 0.06%. However, when welding highly restrained joints using high-strength steels, a combined level below 0.03% might be necessary. When the steels to be welded contain excessive amounts of sulfur or phosphorus, hot cracks can be avoided by:

- USING WELDING PROCESSES OR PROCEDURES THAT ARE NOT DEEPLY PENETRATING
- SELECTING TRAVEL SPEEDS THAT ARE SUFFICIENTLY SLOW TO PREVENT THE FORMATION OF TEAR-DROP CRATERS
- PROVIDING CONVEX BEAD PROFILES
- FILLING THE CRATERS AT THE END OF EACH BEAD

Lamellar tearing occurs in the base plate when stressed through its thickness and generally is found just below the HAZ (Fig. 5). It is associated with banded steels that contain thin layers of inclusions located beneath the plate surfaces. If the dirty steels must be used, the problem can be prevented by changing the joint design to minimize strain through the thickness of the plate at the weld.

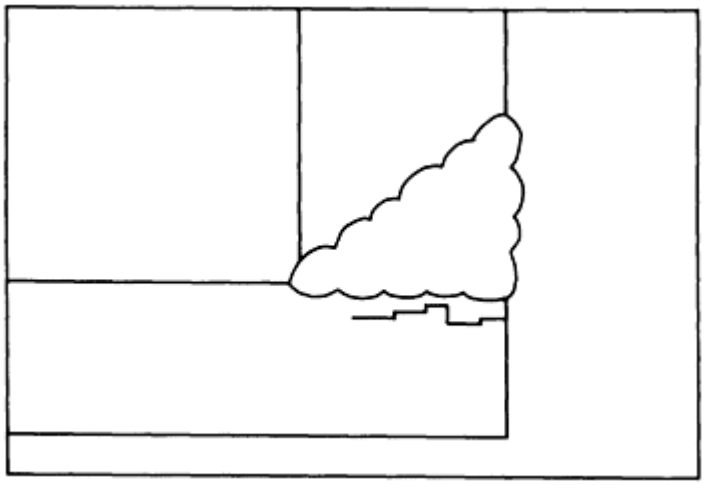

FIG. 5 LAMELLAR TEARING

An undercut is an irregular gouge that is generally found in the upper toe of a horizontal fillet weld. The base plate in that section of the weld shown on the left side of Fig. 6 had been melted by the arc, but not refilled by the weld metal. Most often, this defect is caused by improperly selected welding conditions such as the electrode angle, travel speed, and welding current. It is more likely to occur when attempting to make fillet welds with legs that are more than 8 mm (0.3 in.) in length. With the GMAW process, it also can occur when using an argon shield containing less than 2% oxygen. Undercut also can be found in welds made in the vertical position, where it is generally attributed to excessive weaving.

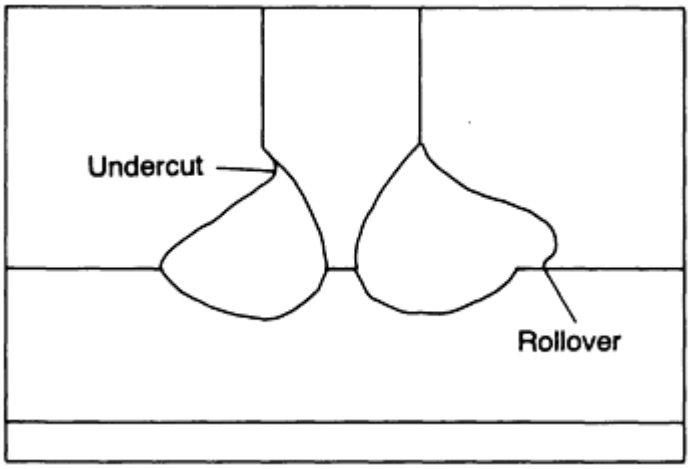

FIG. 6 UNDERCUT IN VERTICAL LEG OF FILLET WELD AND ROLLER IN HORIZONTAL FILLET WELD

A rollover, also called an overlap (Fig. 6), generally is associated with fillet welds and can be found when either the welding current is too low to properly fuse the base plate or the travel speed is too low to accept the amount of metal being deposited. Poor manipulation of the electrode during the SMAW process also can be a factor.

Inclusions are produced by slag that is trapped between weld passes. They originate as pieces of unfused fluxes that may be trapped in a joint, or as slag that is allowed to flow ahead of the arc and is covered by the weld, or as solidified slag that has not been removed between weld passes, or as heavy mill scale that has not been removed from a joint prior to welding. The problem is most common with the SMAW process because it can be aggravated by poor manipulative techniques on the part of the welder. The presence of inclusions can be anticipated when welding over highly crowned or rough welds because their edges are difficult to clean between passes or to penetrate during welding.

Prevention is possible by:

- TRAINING WELDERS TO DEPOSIT WELDS THAT HAVE PROPERLY FLAT PROFILES
- POSITIONING WELDS TO ALLOW HIGHER ENERGY AND MORE FLUID DEPOSITS TO BE MADE
- PREVENTING THE DEVELOPMENT OF RUST BETWEEN PASSES
- ENSURING THAT THE WELDS ARE PROPERLY CONDITIONED BETWEEN PASSES BY EITHER CLEANING OR GRINDING

Hydrogen-Induced Cracking

Hydrogen-induced cracking (HIC) is a phenomenon primarily associated with welds in low-alloy steels. Figure 7 depicts a typical crack, which was taken from the HAZ of a weld. The factors that contribute to HIC are the presence of hydrogen, high tensile stress, susceptible microstructures, temperatures between approximately 200 and -100 °C (400 and -150 °F), and time. At lower strength levels (approximately 485 MPa, or 70 ksi) HIC is most often observed as longitudinal cracks in the HAZ of the base metal, often called underbead cracking. At higher strength levels (approximately 830 MPa, or 120 ksi, and higher), transverse cracks can occur in the weld metal as well.

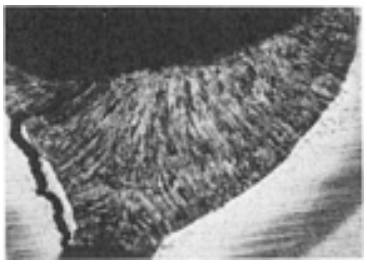

FIG. 7 PHOTOMICROGRAPH OF HYDROGEN-INDUCED CRACK IN HAZ OF WELD. 5×

The commonly used expression "hydrogen embrittlement" suggests that hydrogen impairs the toughness of welds, but that designation is a misnomer. Impact tests on material removed from the area between cracks show that the material exhibits levels of toughness equivalent to welds made in the absence of hydrogen and, of course, cracks. However, tensile ductility can be reduced because HIC can occur while the tensile test is in progress, which reduces the cross-sectional area of the test specimens. The resulting defects in the fractured surfaces are called "fisheyes."

Cold cracking is another expression that has been used to differentiate these cracks from the hot cracks that are found in weld metal and are produced by low-melting constituents that segregate during solidification. Delayed cracking is another term that has been used. It is descriptive because HIC might not occur for days or weeks. When HIC is anticipated, welds often are not radiographed for a week or more in order to allow the cracks to develop.

Mechanism. Hydrogen is a ubiquitous contaminant in all arc welding processes. It exists in the water that is unavoidable in fluxes, in the organic lubricants on the surfaces of filler wires, in the debris that collects in weld joints, and in the moisture in air that can be aspirated into the arc stream. Hydrogen has a much higher solubility in molten iron than it does in solid iron, and its solubility decreases with temperature in the solid state as well. The hydrogen solubility in iron as a function of temperature is shown in Fig. 8. The solubility above the liquidus at 1500 °C (2730 °F) is about 30 ppm by weight, but about 8 ppm in the solid state. At 400 °C (750 °F), its solubility drops to less than 1 ppm. The rates of weld-metal solidification are very high and, as a result, the hydrogen that has dissolved in the fused weld metal is retained.

Although that which does escape as gas often is trapped in the form of small bubbles or weld-metal porosity, a substantial amount does remain in the solidified weld metal as supersaturated hydrogen. The residue might appear to be insignificant, but it should be recognized that as little as 1 ppm of hydrogen can cause cracking problems in high-strength steels.

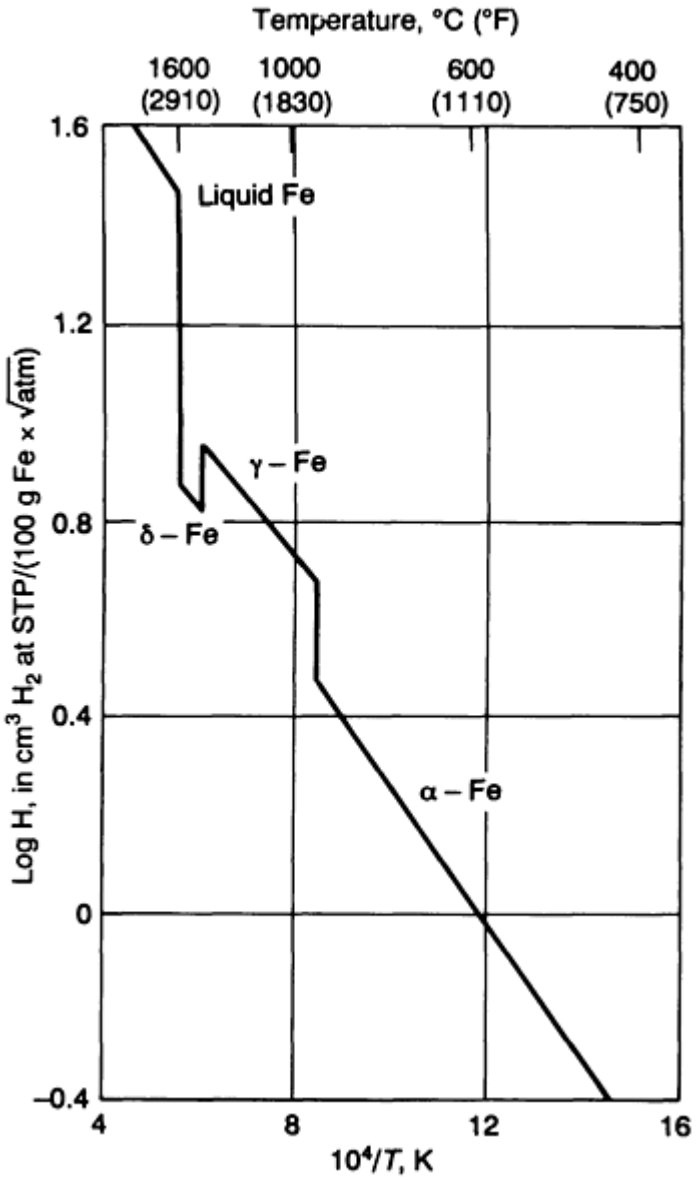

FIG. 8 EFFECT OF TEMPERATURE ON THE SOLUBILITY OF HYDROGEN IN IRON

During the cooling interval, the atomic hydrogen diffuses rapidly, with some going into the weld HAZ, some escaping to the air, and the rest remaining within the weld metal. Given the right conditions, these highly mobile atoms seek rifts and discontinuities in the metal lattice and concentrate at those points. In concert with the residual stresses in the lattice that are due to external restraint and volume changes caused by solidification and solid-state transformation, the hydrogen enlarges the discontinuities to form microcracks. The localized stresses are relieved abruptly as the atoms penetrate the fissures and become trapped as molecules. The resulting microcracks, which have sharp tips, also are associated with high stress concentrations at which additional atoms collect. Those stresses build up until they, too, are relieved as the crack is extended. This process of stress build up and relief by cracking continues until:

- THE CROSS-SECTIONAL AREA IS REDUCED SUFFICIENTLY TO CAUSE FAILURE.
- HYDROGEN ESCAPES IN A SUFFICIENT AMOUNT TO LOWER ITS CONCENTRATION BELOW THAT WHICH IS NEEDED FOR CRACKING TO PROCEED.

- UNDERBEAD CRACKS HAVE REDUCED THE RESIDUAL STRESSES IN THE WELD BELOW THAT LEVEL NEEDED FOR CRACKING TO PROCEED.

HIC does not occur spontaneously, but as discrete steps. The stepwise progression can be observed acoustically. In small specimens, its progression also can be monitored by measuring changes in resistance, as shown in Fig. 9. The lower portion of this illustration depicts the changes in resistance that occur after the process of HIC begins, as well as the way in which HIC progresses a step at a time until failure. The upper portion of Fig. 9 illustrates the sensitivity of HIC to the level of external stress. Failure occurs quickly when the stress on a specimen exceeds its tensile strength, whether or not hydrogen is present. However, when enough hydrogen is present, damage that is caused by HIC can be initiated with stresses well below the tensile strength. Given enough hydrogen and time, HIC can cause failure. Note that the time needed for initiating the cracks and leading to failure increases as the stress is reduced.

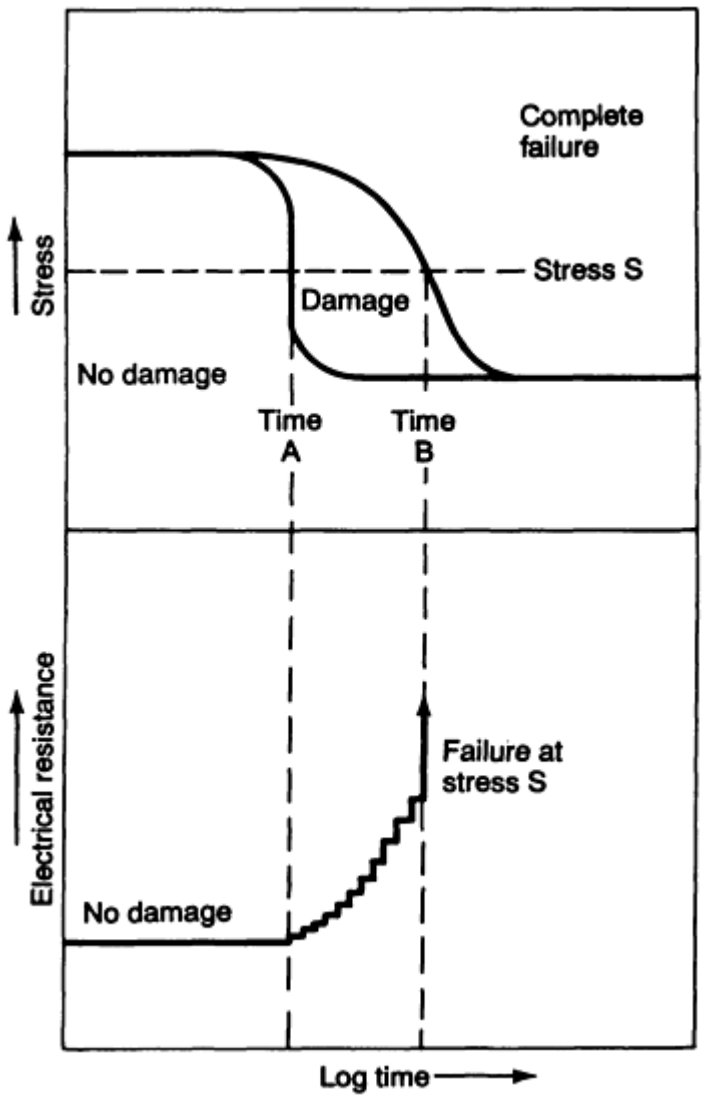

FIG. 9 DAMAGE CAUSED BY HIC, AS AFFECTED BY APPLIED STRESS. IN SMALL SPECIMENS, ELECTRICAL RESISTANCE INCREASES AS HYDROGEN-INDUCED CRACKS GROW.

Most important is the observation that HIC does not occur below a critical stress. In addition to the applied stress, the amount of hydrogen dissolved in the steel also plays an important role. With increasing hydrogen, less stress is needed to initiate HIC, and the times required for its initiation are reduced, as well. The interaction of these two variables, stress and hydrogen, on HIC is shown in Fig. 10. Note that both the time to initiate HIC and the critical stress below which failure will not occur are inversely proportional to the amount of hydrogen present in the steel.

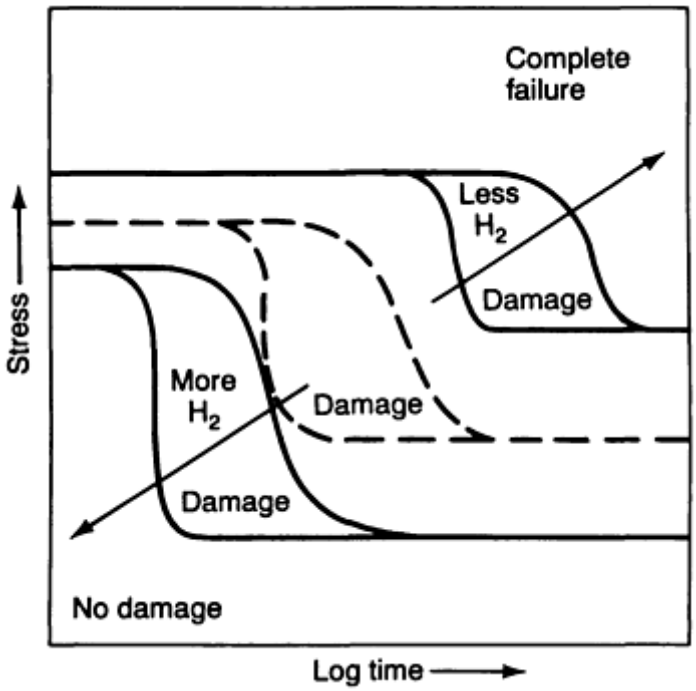

FIG. 10 EFFECT OF HYDROGEN AND STRESS ON DAMAGE CAUSED BY HIC. AS HYDROGEN INCREASES, LESS STRESS IS NEEDED TO CAUSE DAMAGE BY HYDROGEN-INDUCED CRACKS.

The third variable that affects HIC is the microstructure of the steel (either the weld metal or the HAZ). Twinned martensites, which occur in higher-carbon-content steels (above approximately 0.3% C), are the most troublesome, although the problem can occur with all acicular microstructures, including the bainites. This hypothesis might be flawed because the acicular microstructures are typical of those associated with high-strength steels, and higher stresses, in themselves, are an aggravating factor with HIC. However, as shown in Fig. 11, a steel with a relatively tolerant microstructure can exhibit a higher critical stress than a stronger steel with a sensitive microstructure. Note that the stronger steel is more sensitive to hydrogen with regard to both an earlier initiation time for HIC and a lower critical stress. Such behavioral differences have been observed between high-strength martensitic and weaker bainitic steels.

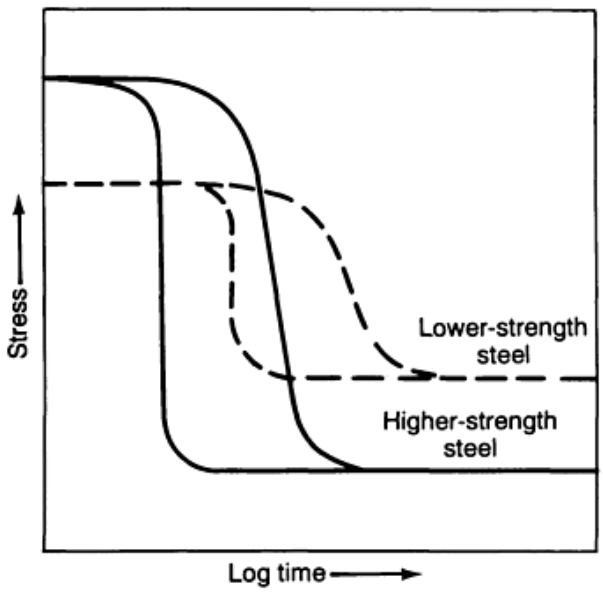

FIG. 11 EFFECT OF STEEL STRENGTH ON SUSCEPTIBILITY TO HIC DAMAGE. STRONGER STEELS CAN BE MORE SENSITIVE TO HYDROGEN, RESULTING IN LOWER CRITICAL STRESSES THAN THOSE EXHIBITED BY WEAKER

STEELS, WHICH ARE MORE TOLERANT.

Inclusions also are important. The toughness of HSLA steels is impaired by contaminants, particularly when in the form of inclusions. However, because inclusions can serve as sinks for hydrogen atoms, they also can have a beneficial effect. For this reason, some very high-purity steels have been shown to be surprisingly sensitive to HIC.

One should not conclude that welds need to be stressed externally in order to develop HIC. The differential shrinkage associated with fusion welding always produces residual stresses in weldments, and, with rare exceptions, those stresses are at least equivalent to the yield strength of the weakest component of the joint. Because most weld metals are stronger than the base metal, the residual stresses are close to the yield strength of the base plate. Often, it is possible to minimize the development of HIC in critical structures by selecting a weaker, or undermatching, weld metal to keep the residual stresses as low as possible. With some applications, such as those involving fatigue, a weaker but sound structure could be more suitable than one that contains HIC. However, given a sensitive microstructure and enough hydrogen, the critical stress can be very low, that is, substantially less than typical residual stresses. Therefore, if HIC is a problem, it will develop, in most cases, before a welded structure leaves the fabrication shop.

Another important observation that needs to be noted is that the mechanism of hydrogen-induced cracking is affected by temperature. The chances for HIC are minimal when temperatures exceed about 205 °C (400 °F). At higher temperatures, the hydrogen diffusion rates are too high to allow the atoms to concentrate at lattice defects or other sharp discontinuities in the weld. Because the mobility of hydrogen is essentially nil, HIC is unlikely to occur in welds cooled below -130 °C (-200 °F). The relevance of the different behaviors at temperatures above 205 °C (400 °F) will be discussed later.

Control of Hydrogen-Induced Cracks. In reviewing the metallurgical requirements for HIC, it is evident that a number of approaches might be taken to prevent its occurrence. They include reducing the residual stresses associated with a weldment; either avoiding acicular microstructures in the weld metal and HAZ or at least selecting those that are bainitic, rather than martensitic; reducing the amount of hydrogen dissolved in the weld metal during the welding operation; or allowing hydrogen to escape before it can cause damage. The most appropriate of these options will depend on the size of the component to be welded, the mechanical properties required, the service anticipated, the welding process to be used, and any cost constraints. In most cases, compromises have to be made and a combination of these approaches probably will prove to be most cost effective.

As mentioned earlier, the residual stresses in welds are generally equivalent to the yield strength of the weakest material in the joint. In joint configurations that introduce high triaxial stresses, the residual stresses can be significantly higher than the yield strengths. Although designers rarely use weaker materials just to reduce residual stresses, they should recognize that HIC can have a significant effect on the fatigue life of a structure. To accommodate weaker steels, a more-acceptable compromise might be to redesign the weldment to incorporate thicker sections. However, other approaches can be taken to gain full advantage of the strengths available in low-alloy steels without incurring HIC.

For the reasons mentioned earlier, the possibility of changing the microstructure of the weld metal or the HAZ is remote, unless given the option of selecting different alloys. In that case, the alloy that is most forgiving of HIC should be chosen.

Another method for reducing the residual stresses in welds is by using a postweld heat treatment at temperatures below the critical temperature. Because steels are weaker at higher temperatures, a significant reduction of residual stresses is possible by heating welds to a temperature at which plastic yielding can occur. For a steel with a tempered martensite structure, the most suitable choice for this heat treatment would be at or just below its original tempering temperature, which is generally close to 620 °C (1150 °F). This treatment is called stress relief annealing (SRA). For this treatment to be effective, the weldment must be placed in a suitably large furnace before its temperature drops below 205 °C (400 °F) and then, to prevent difficulties associated with distortion, heated and cooled slowly. Considering the temperatures and times needed for the SRA treatment, it is obvious that all of the diffusible hydrogen in the weld will escape. However, unless the stresses in a weld must be relieved for reasons other than the avoidance of HIC, SRA can prove to be a very expensive option.

Postheating does have a place in the scheme of preventing HIC. It is not necessary to reheat weldments to temperatures that are much higher than 205 °C (400 °F) in order to accelerate the escape of hydrogen and still avoid the temperature range within which HIC is likely. Such thermal treatments are excellent candidates for welded components that are small enough to be preheated in a furnace prior to welding and returned to the furnace immediately after welding for a period of

time that allows all of the hydrogen to escape. This approach is particularly important for very high strength alloys, such as SAE 4340, that are very sensitive to cracking problems associated with hydrogen.

Similar results are possible by slowing the rates at which welds are allowed to cool after welding. This provides more time for hydrogen to escape before temperatures drop below 205 °C (400 °F). Retarding the cooling rate also allows the transformation of austenite to softer microstructures that are less sensitive to HIC.

The cooling rates of arc welds are affected primarily by three factors: the temperature of the joint before welding begins, the arc energy input during welding, and the joint thickness. The initial temperature can be that of the shop in which the steel had been stored, or the temperature to which the weldment had been heated as the result of a previous weld by external methods (the interpass temperature), or the temperature to which the joint had been heated (the preheat temperature). As preheat temperatures are increased, the cooling rates decrease. The arc energy input is defined by the electrical energy dissipated by the arc and the speed at which the arc is moved along the joint. Higher arc energy inputs retard the cooling rate.

The joint thickness also affects cooling rates because much of the heat entering the joint is extracted by conduction into the body of the weldmerit. Conduction is at a maximum with three-dimensional cooling. This occurs when the joint is thicker than about 25 mm (1 in.). Conduction is less effective in thinner sections, that is, the weld cooling rate is inversely proportional to thickness. Although the cooling rates of thin sections are also influenced by radiation and convection, the effect is much less pronounced than that of conduction.

The variables described above can be incorporated into a single equation that allows calculations to be made of the rate at which welds cool at a specific temperature:

$$CR_T = C\frac{(T - T_0)^2}{E} \qquad \textbf{(EQ 2)}$$

where CR_T is the cooling rate at temperature T, C is a constant of proportionality (including an adjustment for plate thickness, if it is thinner than 25 mm, or 1 in.), T_o is the preheat or interpass temperature, E is the arc energy input, which is calculated as:

$$E = \frac{VI}{S} \qquad \textbf{(EQ 3)}$$

where V is the arc voltage, I is the welding current, and S is the arc travel speed. By combining the above two equations, a general expression for cooling rate is obtained:

$$CR_T = C\frac{(T - T_0)^2 S}{VI} \qquad \textbf{(EQ 4)}$$

This equation was developed for the purpose of predicting weld and HAZ microstructures in conjunction with continuous-cooling transformation diagrams. These diagrams allow the determination of the cooling rates above which strong martensites or bainites are ensured or below which they can be avoided. The same equation can be used to calculate the cooling rates at temperatures critical to the evolution of hydrogen and the avoidance of HIC.

The adjustment of welding procedures is accomplished by varying the current or the travel speed. Voltage is a strongly dependent variable that is determined by the welding process; the characteristics of the electrodes, fluxes, or shielding gases; and the current. It should not be viewed as a variable with which to control weld cooling rates.

The other method of retarding cooling rates, which is probably the most common method, is to control the preheat or interpass temperature of the joint prior to welding. Relatively small changes in those temperatures can exert strong effects on cooling rates at temperatures around 205 °C (400 °F), which is critical with regard to the onset of HIC. For example, by increasing the preheat temperature from 20 to 95 °C (70 to 200 °F), the cooling rate at 205 °C (400 °F) is reduced by approximately one third. By preheating to 150 °C (300 °F), the cooling rate is reduced by a factor of approximately ten, which is a very significant amount when fabricating high-strength steels that have little tolerance to HIC.

Unfortunately, preheating is expensive, it can affect the weld microstructures, and it can make working conditions unbearable for welders. Nevertheless, as Fig. 12 shows, a preheat is important for reducing HIC. The data plotted in Fig. 12 clearly show how a preheat affects the lower critical stress in the HAZ of HY-80 steel when welded with an E11018-M covered electrode. The ultimate tensile stress of this heat of HY-80 is approximately 760 MPa (110 ksi). However, with a 25 °C (78 °F) preheat, that is, room temperature, failure was caused by HIC in less than 10 min, at a stress level of only 480 MPa (70 ksi). The lower critical stress below which failure did not occur was only 415 MPa (60 ksi). By preheating to a temperature of 120 °C (250 °F), the critical stress was increased to 620 MPa (90 ksi), which is approximately the yield strength of the HY-80 steel, but still considered unsafe. To avoid HIC entirely, under the conditions used to produce the welds shown, the preheat temperature would need to exceed 150 °C (300 °F).

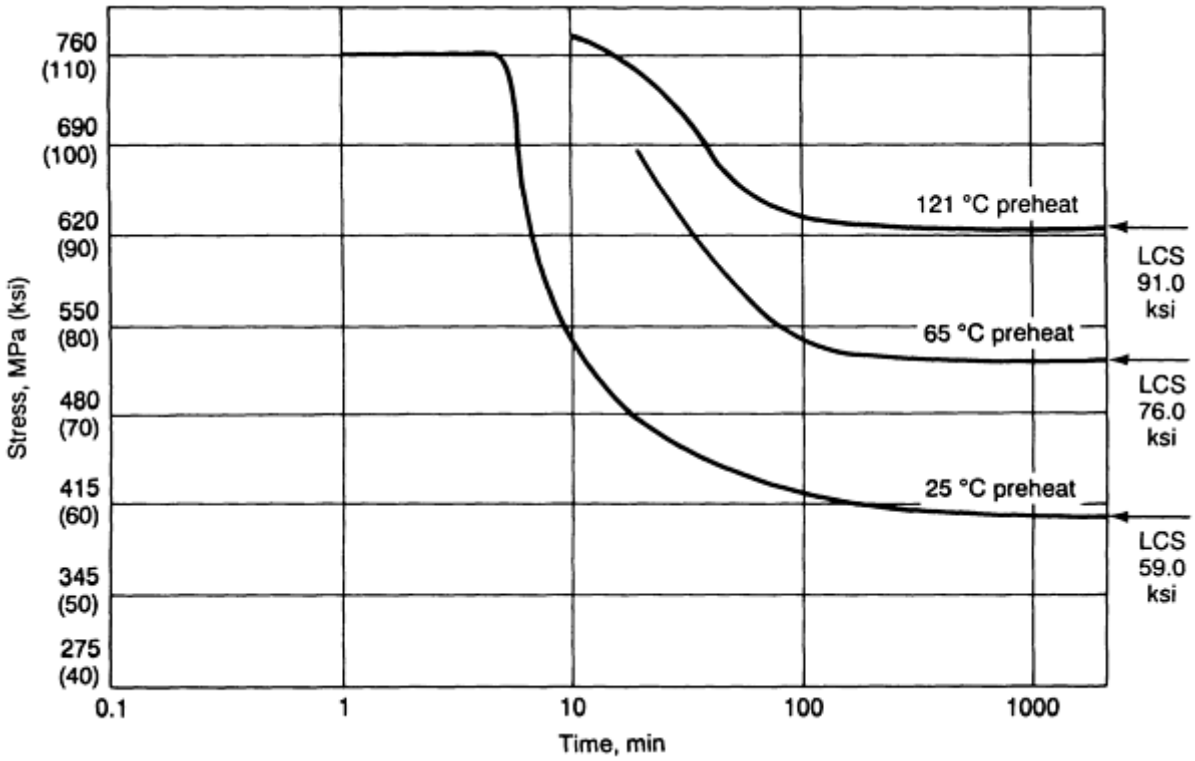

FIG. 12 EFFECT OF PREHEAT ON HIC SUSCEPTIBILITY. PREHEAT INCREASES CRITICAL STRESS NEEDED TO CAUSE HIC. LCS, LOWER CRITICAL STRESS

A number of approaches can be used to select the most appropriate temperature for preheating a steel to avoid HIC. Some approaches rely on empirically derived tables that list the steels and recommended welding procedures, including those for preheat and postheat. Another relates cracking tendencies quantitatively to the hardenability of the alloy steel, calculating it on the basis of the carbon equivalence. One such formula for carbon equivalence is given as:

$$CE = C + \frac{Mn}{6} + \frac{Si}{24} + \frac{Ni}{40} + \frac{Cr}{5} + \frac{Mo}{4} \qquad \textbf{(EQ 5)}$$

For applications that involve welds made with covered electrodes, the recommended preheat temperatures for steels having different carbon equivalencies are plotted in Fig. 13. Although considerable scatter is seen, the overall trend demonstrates a linear relationship between the carbon equivalence and the preheat temperature. For a quick approximation of the required preheat, the following relationship can be used:

$$T_O = 200\ CE \qquad \textbf{(EQ 6)}$$

where T_o is in °C.

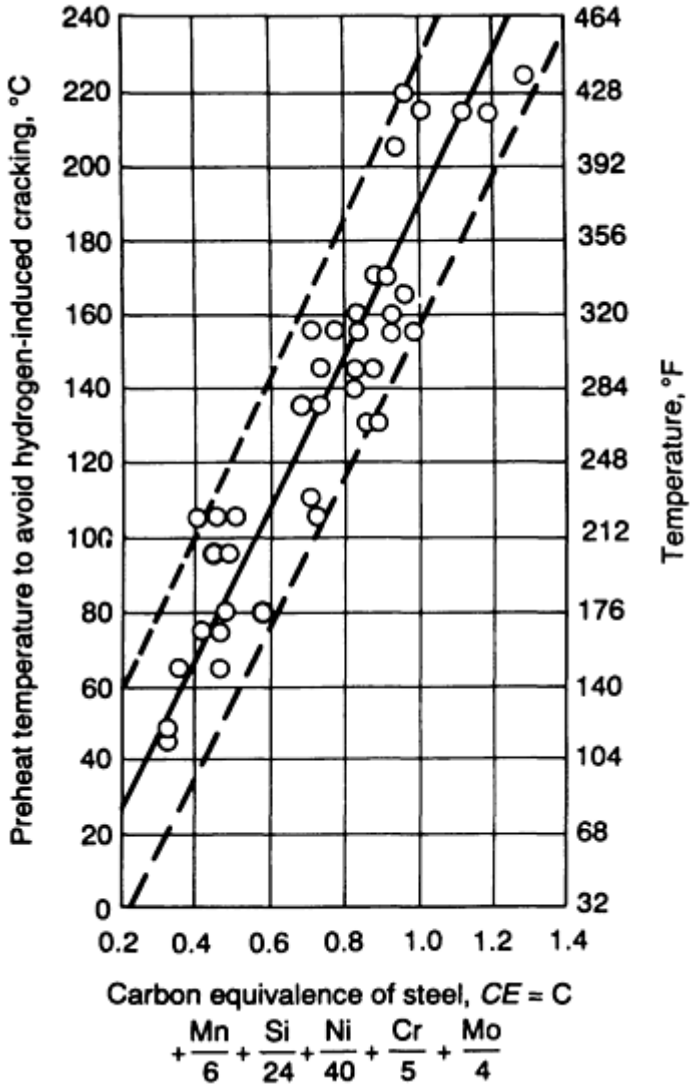

FIG. 13 EFFECT OF CARBON EQUIVALENT ON PREHEAT REQUIREMENTS. AMOUNT OF PREHEAT NEEDED TO PREVENT HIC IS PROPORTIONAL TO THE CARBON EQUIVALENT OF THE STEEL BEING WELDED

To include the scatter band that incorporates all of the data points, a more-precise interaction between the carbon equivalence and the preheat temperature can be shown as:

$$T_O = 210\ CE + 15/-45 \qquad \textbf{(EQ 7)}$$

The scatter band of 60 °C (108 °F) is quite large, which suggests that the upper portion be used for selecting suitable preheat temperatures with which to avoid potential problems. However, if metallurgical softening needs to be avoided, then the most appropriate course of action would be to rely on laboratory trials for determining the minimum effective level of preheat. Of course, such a determination would require that the energy input, the thickness of the joint, and the welding process also be considered.

Measurement of Hydrogen. Direct measurements of hydrogen in weld metal are difficult. Unless great care is taken to stop its escape from a weld before an analysis can be made, the amount found will not be representative of that which might have caused a crack to develop. This means that specimens must be designed to be analyzed quickly or supercooled in liquid nitrogen to stop the diffusion of hydrogen while awaiting analysis. The procedure recommended by the American Welding Society (AWS A4.386) measures the volume of hydrogen gas that escapes from a test weld approximately 75 mm (3 in.) in length. It is collected in either a eudiometer tube (in a mercury or glycerine bath) or in the isolation chamber of a gas chromatograph.

Indirect methods also have been used by measuring the sources of the hydrogen. For wires used in the GMAW and SAW processes, this can be done by measuring the hydrocarbons on their surface. Mass spectrometry can be used for the analysis. For the SMAW and SAW processes, the moisture adsorbed in the fluxes can be determined. Often, this is done by measuring weight loss after drying at high temperatures of approximately 400 to 425 °C (750 to 800 °F). The problem with indirect measurements is that the efficiency of transfer of the hydrogen to the weld from the wires or fluxes is difficult to predict. It can be very dependent on the welding procedures. Therefore, empirical results are used to relate the amount of hydrogen present in the welding materials to the HIC in the weldment. For this reason, a comparison among processes becomes very difficult. However, even the measurements of gas evolution can be faulted, because only the diffusible hydrogen is measured. Some remains in solution and some is trapped within weld defects or inclusions.

Importance of Welding Processes. The arc welding processes require a source of filler metal and methods for protecting and controlling the arc and the deposited metal. In almost all cases, the filler metals are provided in the form of rods, continuous wires, or continuous tubes. The surfaces of all of these materials are contaminated with residues of hydrogen-rich drawing lubricants. In the GMAW process, a shield gas is used for protection. For cored wires, a combination of shield gases and fluxes are used. The submerged-arc and covered-electrode methods involve only fluxes. All of the fluxes are sources of chemically combined or adsorbed water. The quantity of hydrogen dissolved in weld metal can vary, not only between but within processes. Some indication of the variability to be expected is shown in Table 1.

TABLE 1 EFFECT OF WELDING PROCESSES AND ELECTRODES ON HYDROGEN LEVELS IN WELDS

TYPE OF ELECTRODE	DIFFUSIBLE H_2, ML/100 G
GMAW SOLID WIRE	0-10
BASIC SMAW ELECTRODE	3-20
ACID SMAW ELECTRODE	20-40
SAW SOLID WIRE AND FLUX	4-20
GMAW CORED WIRE	3-30

Of all of the arc welding processes using consumable electrodes, the GMAW process is associated with the lowest hydrogen levels, the primary source being residual drawing lubricants on the wire surface. Totally dry wire is unacceptable, because it is difficult to feed. The amount of residual lubricant generally is not a problem with steels having yield strengths below 520 MPa (75 ksi). However, as the yield strengths approach 620 MPa (90 ksi), the residual lubricants become a potentially important factor if HIC is to be avoided, unless relatively high preheat temperatures can be used. When the yield strengths exceed 830 MPa (120 ksi), the residual lubricants must be kept as low as possible.

The importance of such residues is shown in Fig. 14, which summarizes the effects of hydrogen on HIC in welds that have a yield strength of 930 MPa (135 ksi) and shows how it can be minimized by controlling cooling rates. In this case, the cooling rates indicated were determined at 540 °C (1000 °F), a temperature close to that at which the weld metal transforms from austenite to martensite. The closed circles indicate the presence of HIC in the welds, whereas the open circles indicate sound welds. At the relatively rapid cooling rates of 28 °C/s (50 °F/s), 4 ppm of hydrogen on the wire surface is shown to have caused HIC. To be securely free of HIC, the hydrogen had to be maintained at levels below 3 ppm. By adjusting the welding procedures, preheat temperatures, or both, in order to retard the cooling rate at 540 °C (1000 °F) to less than 20 °C/s (35 °F/s), the tolerance for hydrogen on the wire was increased to 5 ppm.

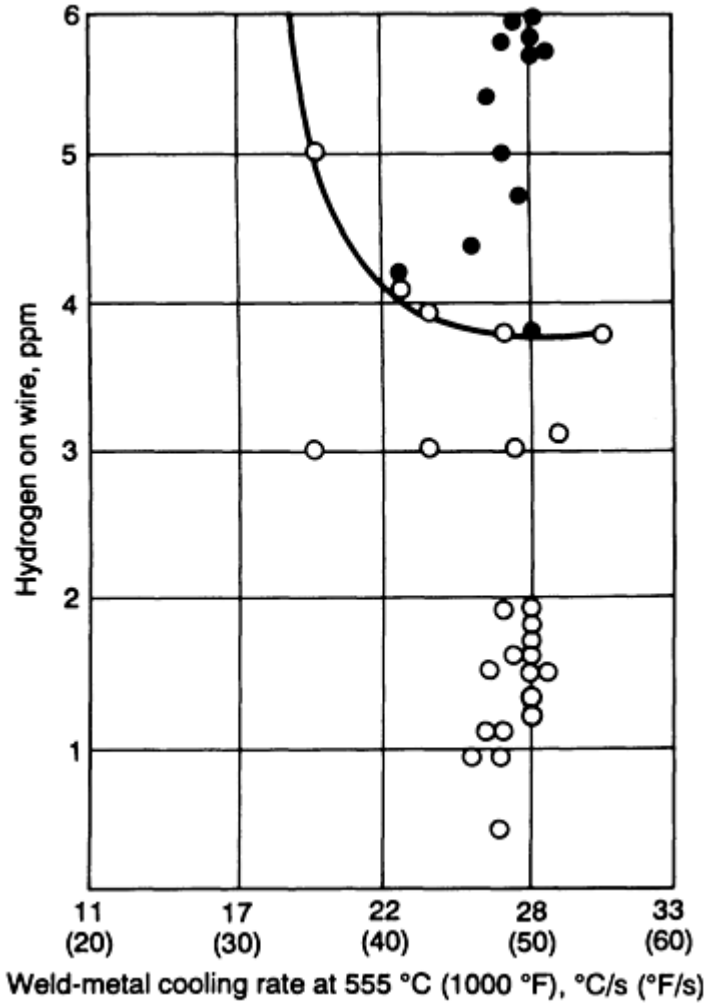

FIG. 14 INFLUENCE OF HYDROGEN PRESENT ON A WIRE SURFACE AND WELD-METAL COOLING RATE ON HIC. DATA ARE BASED ON GMAW WELD METAL WITH YIELD STRENGTH OF 930 MPA (135 KSI).

As mentioned earlier in the discussion of hydrogen measurements, it is difficult to predict the amount of hydrogen that will transfer to a weld from surface contaminants that are decomposed in the arc (or before reaching the arc), particularly when the levels are measured in single-digit parts per million. These levels are so low as to preclude the use of gas-evolution techniques to measure the hydrogen.

The higher tolerance for wire surface contaminants at lower cooling rates may be due as much to softer microstructures as it is to the escape of hydrogen. The effect of cooling rate on the tensile yield strength of these alloys is illustrated in Fig. 15. To retain high strengths, the higher cooling rates are essential. In this example, a very abrupt drop in strength is shown as the cooling rate drops below 10 °C/s (20 °F/s). Obviously, to obtain the strongest possible welds without encountering HIC, it is necessary to minimize the presence of any contaminants that contain hydrogen.

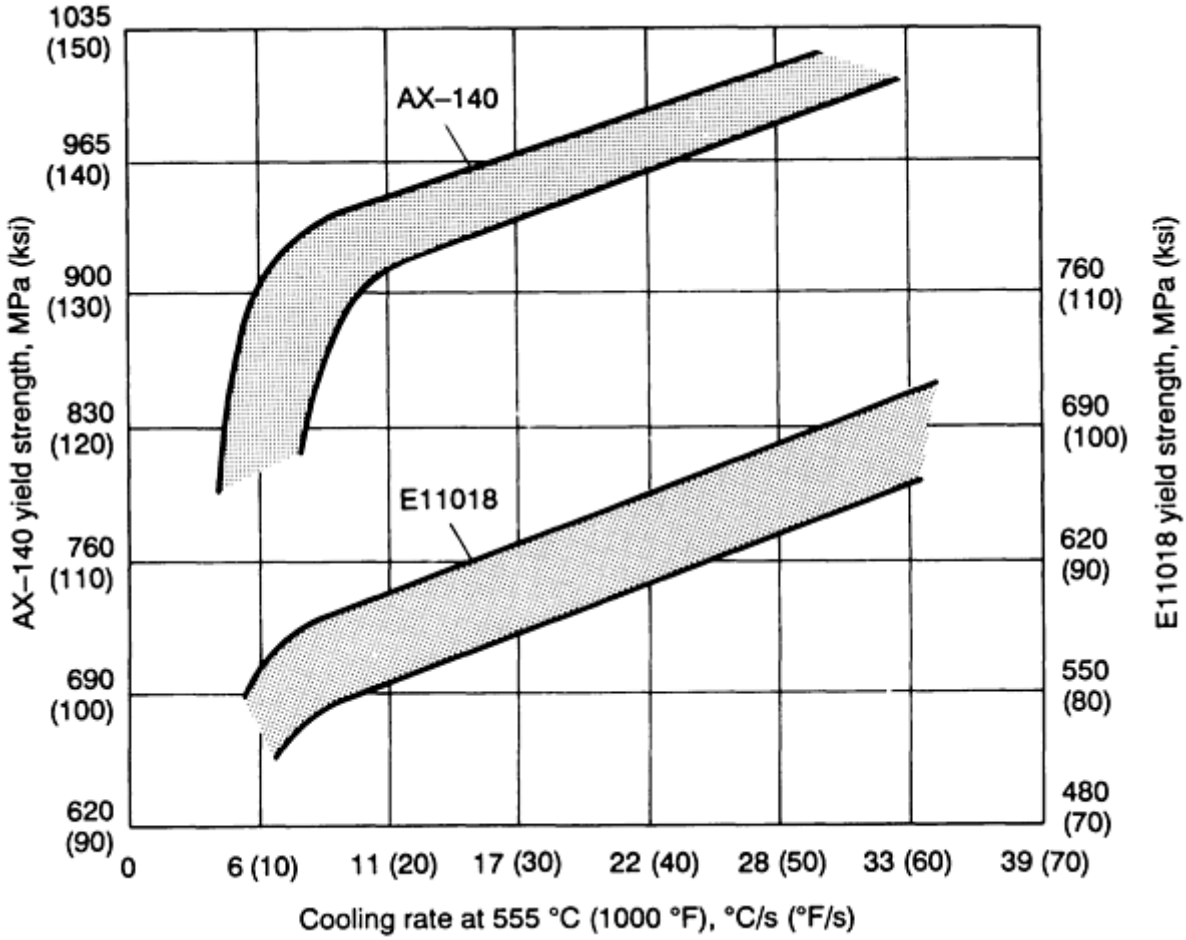

FIG. 15 EFFECT OF COOLING RATE ON STRENGTH OF HSLA STEEL WELD METAL. TENSILE YIELD STRENGTH OF HSLA STEEL WELD METAL IS AFFECTED BY THE COOLING RATE AT WHICH IT TRANSFORMS. DATA ARE BASED ON AX-140 GMAW AND E11018 SMAW FILLER METALS.

The attainment of such low levels of hydrogen is not possible with any of the other arc welding processes, because they require fluxes instead of shield gases for protection. Fluxes can absorb water. The data in Fig. 16 summarize the importance of moisture in a submerged arc flux on the cracking sensitivity of a Soviet weld metal that has a yield strength of 830 MPa (120 ksi). It demonstrates that diffusible hydrogen levels as low as 7 mL/100 g can drop the critical strength to 105 MPa (15 ksi). (Note that a hydrogen content of 1 ppm is equivalent to 1.11 mL/100 g). Even baking the flux to reduce the weld-diffusible hydrogen below 2 mL/100 g did not eliminate HIC. The critical stress remained below 415 MPa (60 ksi). It is evident that the welding conditions used for these submerged arc welds were not acceptable. Either this steel is unusually sensitive to hydrogen or the flux used is not capable of being dried sufficiently to reduce hydrogen contamination.

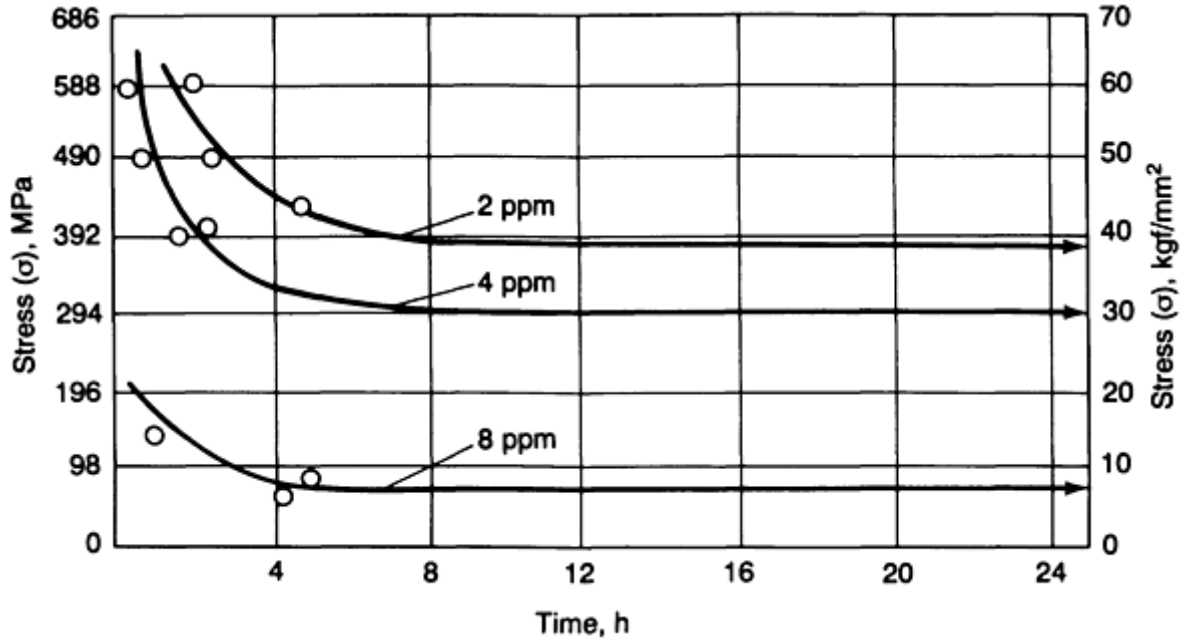

FIG. 16 EFFECT OF HYDROGEN ASSOCIATED WITH SUBMERGED ARC WELDS ON THE LOWER CRITICAL STRESS AND THE TIME NEEDED FOR HIC. FLUX AS RECEIVED, 4 PPM; FLUX BAKED, 2 PPM; FLUX MOISTENED, 8 PPM. DATA ARE BASED ON 30KH2N2M SOVIET STEEL WITH A YIELD STRENGTH OF 930 MPA (135 KSI).

Similar HIC problems are encountered in the SMAW process when weld strengths exceed 480 MPa (70 ksi). For this reason, low-hydrogen electrodes were developed specifically to minimize, if not prevent, these problems. Low-hydrogen electrode coatings are formulated without any organic materials, such as the cellulose that characterizes the EXX10 classes. These low-hydrogen coatings are baked at temperatures exceeding 425 °C (800 °F) to reduce residual moisture to a level of approximately 0.1 wt%. This is nearly the lowest practicable level, because the absence of moisture in a coating tends to make it brittle. The effect of baking on the residual moisture during initial manufacture is shown in Fig. 17. Even with careful control of formulations and baking, the moisture level of covered-electrode coatings cannot be reduced to levels sufficiently low to prevent HIC in steels having yield strengths higher than 830 MPa (120 ksi).

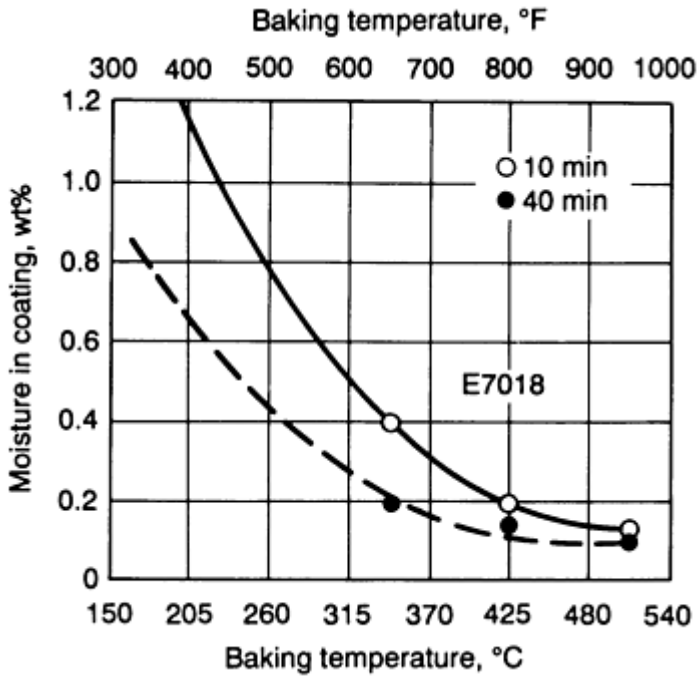

FIG. 17 EFFECT OF BAKING TIME AND TEMPERATURE ON MOISTURE IN E-7018 COVERED ELECTRODES

The moisture in low-hydrogen electrodes generally is specified as 0.2% max. This moisture level is what is expected to be found in coatings of commercial low-hydrogen electrodes, immediately after being removed from hermetically sealed containers. However, if exposed to humid, warm air, these electrode coatings will reabsorb moisture, as shown in Fig. 18. The rate of moisture pickup depends on the constituents in the coating. In some cases, reabsorbed moisture can reach levels exceeding 1%. For this reason, electrodes must be stored in heated ovens on hot and humid days and exposed to shop environments for only short times.

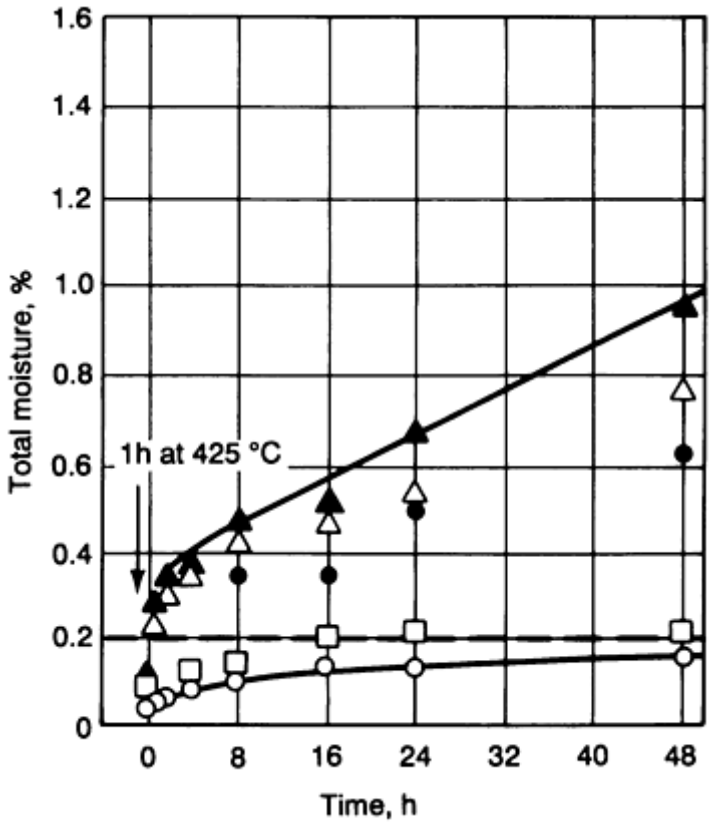

FIG. 18 MOISTURE ABSORPTION IN COVERED-ELECTRODE COATINGS WHEN EXPOSED TO MOIST, HUMID ENVIRONMENTS. THE AMOUNT ABSORBED DEPENDS ON THE ELECTRODE AND INCREASES WITH TIME. TEMPERATURE, 21 ± 3 °C (70 ± 5 °F); RELATIVE HUMIDITY, 65 ± 5%

Moisture-resistant coatings have been developed to counter the reabsorption problem. Their rates of reabsorption are typical of the lower curve shown in Fig. 13. Although they are quite safe when exposed to the relatively cool and moderately humid environment indicated, extra precautions are essential when welding in tropical conditions.

It is possible to salvage electrodes that have become "wet" by rebaking them at temperatures that approach those used during their manufacture. Typical results are shown in Fig. 19. Drying times of about 1 h are needed to recondition typical electrodes at approximately 400 to 425 °C (750 to 800 °F). Although rebaking can salvage electrodes that are inadvertently exposed to moist conditions, it should not be repeated. Covered electrodes are alloyed with metal powders that can be oxidized during rebaking operations. Therefore, the resulting alloys are leaner and weaker, as seen in Table 2.

TABLE 2 EFFECT OF REBAKING ON COMPOSITION AND STRENGTH

NUMBER OF	COMPOSITION, WT%	YIELD STRENGTH

BAKE CYCLES	C	MN	SI	MPA	KSI
1	0.069	1.54	0.39	723.3	104.9
2	0.064	1.46	0.37	714.3	103.6
3	0.066	1.45	0.37	688.8	99.9

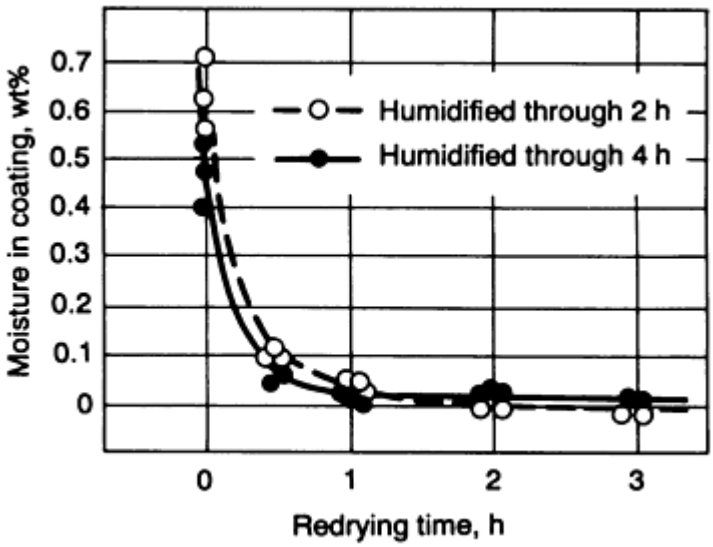

FIG. 19 EFFECT OF DRYING TIME ON MOISTURE ABSORBED BY COVERED ELECTRODES AFTER EXPOSURE TO MOIST ENVIRONMENTS. E11016 LOW-HYDROGEN TYPE ELECTRODE, 4 MM (0.16 IN.); REDRYING TEMPERATURE, 400 °C (750 °F)

Rebaking caused a loss in both manganese and silicon in the weld metal, resulting in a drop in the weld yield strength. These data were obtained after very controlled rebaking. Unfortunately, the same care is not always taken in shop environments. Significantly greater losses in the manganese and silicon contents, as well as mechanical properties, can be expected.

Influence of Welding on Steel Weldment Properties

C.C. Chen and Abe Pollack, Microalloying International, Inc.

Introduction

THE FUNDAMENTAL AND THE SPECIFIC FACTORS that control the properties of steel weldments in both the weld metal and heat-affected zone (HAZ) of carbon and low-alloy steels are described in this article. The influence of welding processes, welding consumables, and welding parameters on the weldment properties also will be discussed. The service properties of weldments in corrosive environments and subjected to cyclic loading will be considered, as well.

Influence of Welding on Steel Weldment Properties

C.C. Chen and Abe Pollack, Microalloying International, Inc.

Heat-Affected Zone

In terms of materials selection, the service characteristics of the HAZ should be emphasized more than those of the weld metal. This is because the metallurgical and mechanical properties of the HAZ are directly related to the selected base metal, even though they can be modified by welding parameters and postweld heat treatment (PWHT). It is also true that

any metallurgical and/or weldability problems associated with the HAZ characteristics will be more difficult to handle than those associated with the weld metal. Welding problems that occur in the weld metal can often be overcome by changing the welding electrode and/or other welding consumables. In contrast, problems with the HAZ sometimes can only be resolved by changing the base metal, which is often an excessively costly measure, or by changing the heat input.

Various empirical carbon equivalents have been developed and utilized to evaluate the weldability (hydrogen-induced cold-cracking tendency) of the base materials. In the United States and European countries, the International Institute of Welding (IIW) equation is most common:

$$CE(IIW) = C + \frac{Mn}{6} + \frac{Cu + Ni}{15} + \frac{Cr + Mo + V}{5} \qquad \textbf{(EQ 1)}$$

In Japan, the Ito-Bessyo (Ref 1) composition-characterizing parameter, P_{cm}, is more widely used. This carbon equivalent is considered to allow a more realistic assessment of the weldability of low-carbon steels, when compared with the IIW equation:

$$P_{cm} = C + \frac{Si}{30} + \frac{Mn + Cu + Cr}{20} + \frac{Ni}{60} + \frac{Mo}{15} + \frac{V}{10} + 5B \qquad \textbf{(EQ 2)}$$

Yurioka *et al.* (Ref 2) have also developed another carbon-equivalent number, CEN, which incorporates both the IIW carbon equivalent and the P_{cm}. The CEN is similar to the P_{cm} for steels with carbon levels that are less than 0.17%, and it follows the IIW formula at high carbon levels.

$$CEN = C + A(C)\left(\frac{Si}{24} + \frac{Mn}{6} + \frac{Cu}{15} + \frac{Ni}{20} + \frac{Cr + Mo + Nb + V}{5} + 5B\right) \qquad \textbf{(EQ 3)}$$

where A(C) equals 0.75 plus 0.25 tan*h* [20(C - 0.12)].

Although these carbon-equivalent expressions were initially developed to characterize the hydrogen cracking tendency for steel plates, they also have been utilized to assess the hardenability of steels based on their chemistry. Figure 1 illustrates the correlation between carbon equivalent, P_{cm}, and the martensite volume in both the coarse-grained region and the grain-refined region (Ref 3). As the P_{cm} increases, the martensite volume and hardness in both regions increase.

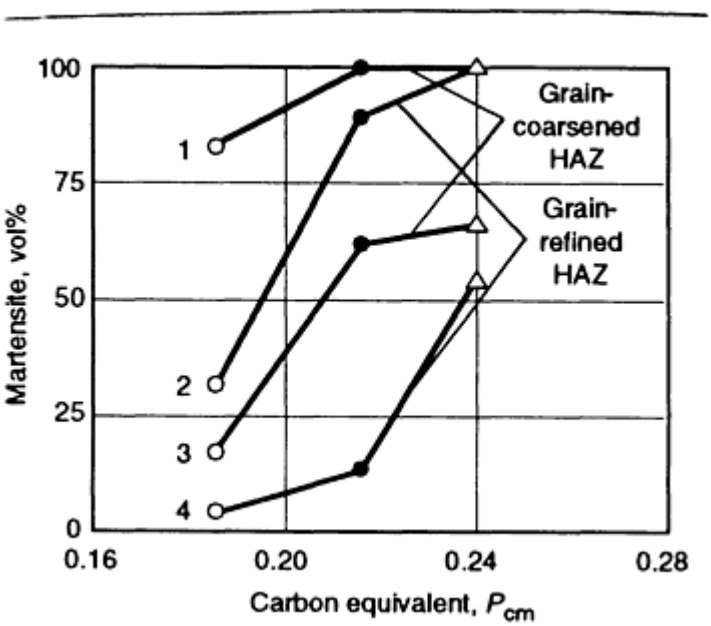

FIG. 1 RELATIONSHIP BETWEEN HAZ VOLUME FRACTION OF MARTENSITE AND THE P_{CM} CARBON EQUIVALENT

OF THERMALLY CYCLED SPECIMENS. FOUR THERMAL PROGRAMS ARE INCLUDED: (1) PEAK TEMPERATURE (T_P) ≈ 1350 °C (2460 °F), COOLING TIME FROM 800 TO 500 °C ($\Delta T_{8/5}$) = 3 S; (2) T_P ≈ 1000 °C (1830 °F), $\Delta T_{8/5}$ = 3 S; (3) T_P ≈ 1350 °C (2460 °F), $\Delta T_{8/5}$ = 13 S; (4) T_P ≈ 1000 °C (1830 °F), $\Delta T_{8/5}$ = 13 S. SOURCE: REF 3

Various regions in the HAZ of ferritic steels have been defined and characterized using a specific peak temperature of the HAZ weld thermal cycle in conjunction with an iron-carbon equilibrium phase diagram (Ref 4). These regions are the coarse-grained, grain-refined, intercritical, subcritical, and partly molten regions. However, the metallurgical behavior in the HAZ that undergoes rapid heating and cooling is a nonequilibrium process. Consequently, a continuous cooling transformation (CCT) diagram is more appropriately used to predict the microstructures in the HAZ.

The cooling rate is closely related to plate thickness, joint geometry, and welding heat input. The cooling rate that is often most critical in welding applications is that which falls between 800 and 500 °C (1470 to 930 °F). As the welding heat input is increased or the plate thickness is reduced, the cooling rate between these temperatures is reduced. (The effects of welding parameters on the HAZ cooling rate will be discussed in detail later in this article.)

The effects of major alloying elements in carbon and low-alloy steels on HAZ microstructure and toughness is summarized below (Ref 3).

Carbon has a tremendously important role in the overall hardness of welded steels. This can be clearly seen by its role in the carbon-equivalent and P_{cm}, equations. An increase in carbon level promotes the formation of lower-temperature transformation products, such as bainite and martensite, and leads to a significant reduction in HAZ cleavage resistance.

Manganese. In addition to solid-solution hardening, manganese can lower the transformation temperature of austenite to ferrite while providing strengthening effects by grain refinement. However, the level of manganese should be limited to minimize solidification segregation and microstructural banding.

Chromium is a solid-solution strengthener and carbide former. It increases the hardenability of steels and improves oxidation and corrosion resistance. The addition of chromium can be favorable in cases where the precipitation of chromium carbides suppresses the formation of ferrite side plates through a pinning effect.

Nickel is considered to have a beneficial effect on steel transformation, similar to that of manganese, by lowering the austenite transformation temperature. The addition of nickel also can improve toughness, as well as provide a solid-solution hardening effect.

Vanadium and niobium are added in small quantities in low-alloy steels to obtain the desired mechanical properties. By forming V(C,N) and Nb(C,N), the vanadium and niobium can retard the recrystallization and grain growth of austenite during rolling and normalizing. During fusion welding, especially with high heat input, V(C,N) and Nb(C,N) dissolve in the HAZ with peak temperatures greater than 1100 °C (2012 °F) and reprecipitate during slower cooling. The reprecipitation of V(C,N) and Nb(C,N) impairs the toughness of the HAZ.

Titanium, in the form of stable titanium nitride, has been found to prevent coarsening of the prior austenite grain in regions adjacent to the weld fusion boundary.

Weld Metal

The use of a filler metal is very common in many fusion-welding processes. When selecting the proper filler metal/electrode, the primary considerations are whether or not the weld metal can be produced defect-free and whether or not the weld metals are compatible with the base metal and can provide satisfactory properties. These characteristics are determined by the:

- CHEMISTRY OF THE ELECTRODES
- DILUTION OF THE BASE METAL
- FLUX SYSTEM OR SHIELDING GAS
- WELD-POOL SOLIDIFICATION AND SUBSEQUENT COOLING AND TRANSFORMATION

The selection of the proper filler metal is not based on matching the chemistry of the base metal. Rather, it is based on matching the weld metal and base metal service properties. Using a filler metal with a chemistry identical to that of the base metal may not provide the desired results, because the microstructures of the weld metal are entirely different from those of the base metal. For most carbon and low-alloy steels, the solidification and rapid cooling rate involved in fusion welding will result in a weld metal that has higher strength and lower toughness properties than the base metal when they are of the same chemistry. Consequently, the filler metal often contains a lower carbon level than the base metal. The strength of the weld metal is not improved by increasing the carbon content, but by adding the alloying elements that provide solid-solution or precipitation strengthening and modification of the microstructures (Ref 5).

The weld-metal microstructure in carbon and low-alloy steels contains a variety of constituents, ranging from blocky ferrite, to acicular ferrite, to bainite, to martensite. The effects of alloying elements and cooling on the weld-metal microstructure can be expressed in a schematic CCT diagram (Fig. 2), whereas the effects of alloying elements on the hardness and notch toughness of weld metal are illustrated in Fig. 3.

Dilution. The melting of base metal and the subsequent mixing with filler metal causes the final chemistry of the weld deposit to be between that of the base and filler metals. When a filler metal has the same chemistry as the base metal, the final weld-metal chemistry remains the same, theoretically. Depending on the amount of base metal that is melted and the amount of filler metal that is added, the final chemistry of the weld deposit can be approximated using the dilution equation:

$$Dilution, \% = \left(\frac{Weight \text{ of parent metal melted}}{\text{Total weight of used metal}} \right) 100 \qquad \textbf{(EQ 4)}$$

Figure 4 shows how factors such as joint configuration and edge preparation influence dilution. Welding processes and parameters that increase penetration can also increase dilution (Ref 7).

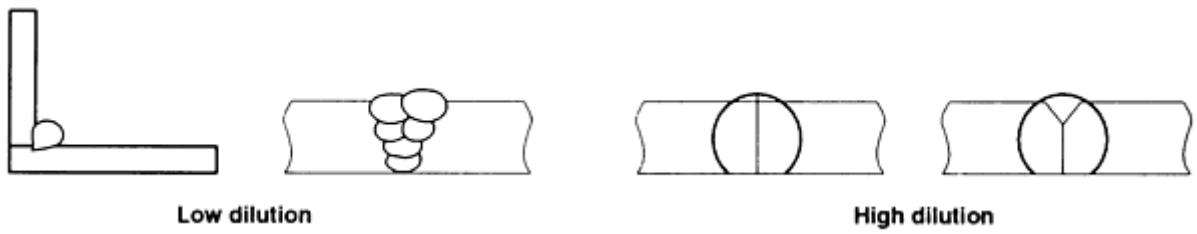

FIG. 4 DILUTION OF WELD DEPOSIT. SOURCE: REF 7

In a single-pass weld, certain element contents in the weld metal can be approximated using this formula: Specific element in weld metal equals (that element in the base metal multiplied by the dilution) plus (that element in the filler metal multiplied by [1 - dilution]).

In certain cases, greater dilution is favorable, considering the less-drastic change in mechanical and other properties across the fusion boundary. However, in applications involving weld cladding or weld surfacing, it is more desirable to

minimize the dilution. This is because filler metal contains more-expensive alloying elements tailored to impart specific weld-metal properties. When there are concerns that the base metal may introduce undesired impurities and/or alloying elements, then welding practices that lower the dilution are recommended. This also includes considerations for phosphorus and sulfur and for higher carbon and silicon contents, which adversely affect the properties of weld metal.

Single-Pass versus Multipass Welding

In terms of mechanical properties, especially toughness, multipass weld metal is usually better than single-pass weld metal for these reasons:

- THE REHEAT THERMAL CYCLE OF EACH SUBSEQUENT WELDING PASS NORMALIZES AND REFINES PORTIONS OF THE MICROSTRUCTURE IN THE PREVIOUS WELD METAL.
- SUBSEQUENT WELD RUNS TEMPER THE PREVIOUS WELD METAL AND REDUCE RESIDUAL STRESSES FROM PREVIOUS RUNS.
- THE TOTAL ENERGY INPUT PER PASS IS REDUCED, WHICH IS HELPFUL FOR LIMITING THE AMOUNT OF GRAIN GROWTH.
- PREVIOUS WELD PASSES PROVIDE A CERTAIN PRE-HEAT THAT SLOWS DOWN THE COOLING RATE OF THE SUBSEQUENT PASS.

Figure 5 shows that the weld-metal ductility (cross-sectional area) increases as the total grain-refined areas are increased (Ref 8).

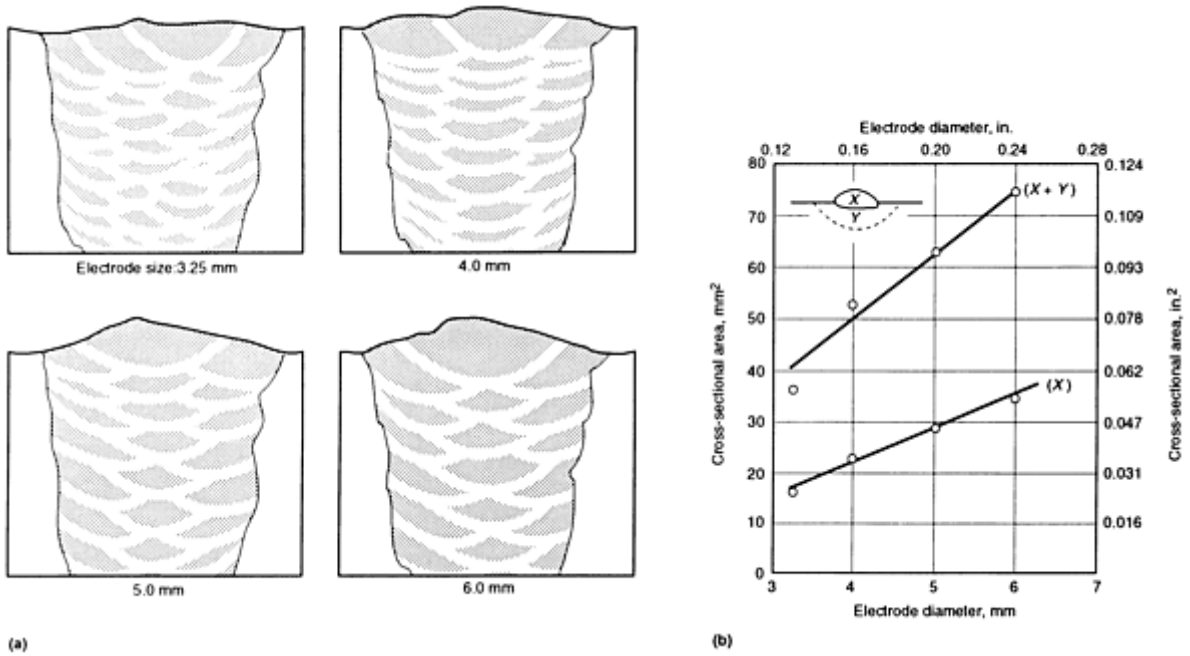

FIG. 5 EFFECT OF ELECTRODE SIZE ON AMOUNT OF RECRYSTALLIZED WELD METAL IN MULTIRUN WELDING. (A) CROSS SECTIONS AS A FUNCTION OF ELECTRODE DIAMETER; WHITE AREAS REPRESENT RECRYSTALLIZED WELD METAL. (B) GRAPHICAL REPRESENTATION. SOURCE: BASED ON REF 8

In contrast, when an active flux is used in submerged arc welding, the number of weld passes to be applied in a joint is limited. This is because there is a tendency for alloying elements (such as silicon and manganese) to build up during multipass welding, which impairs the fracture toughness values in the final weld pass.

Influence of Welding on Steel Weldment Properties

C.C. Chen and Abe Pollack, Microalloying International, Inc.

Steel Types and Weldability

The high-strength, low-alloy (HSLA) steels were designed to have improved mechanical properties and weldability, when compared with conventional carbon steels. These improvements are obtained through the addition of small amounts of alloying elements, such as niobium, vanadium, titanium, nitrogen, and carbon, which strengthen the ferrite, increase the hardenability, and control the grain size. Most of these steels are provided in the as-rolled, normalized condition, and some are provided in the precipitation-treated condition, as well. The finer grain size and greater amount of pearlite account for the greater strength and toughness of this group of steels. In addition, the lower carbon content (0.22% max) leads to good weldability. Figure 6 shows the CCT diagram for a titanium-boron HSLA steel (Ref 9).

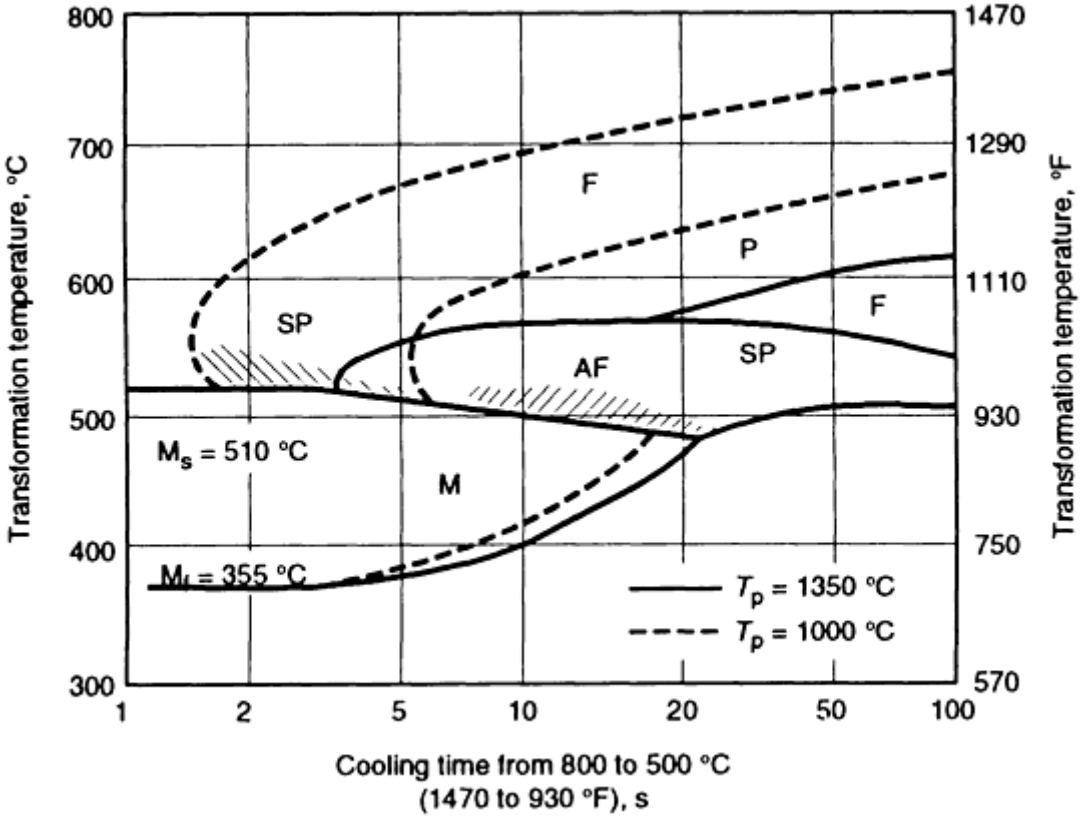

FIG. 6 CCT DIAGRAM FOR A TITANIUM-BORON MICROALLOYED STEEL. T_P, PEAK TEMPERATURE. SOURCE: REF 9

Generally, the weldability of HSLA steels is similar to that of mild steels (Ref 10). Although HSLA steels have good weldability, the consideration of preheating and controlling hydrogen in the welding process is still necessary to ensure a successful weldment. The embrittlement in the coarse-grained HAZ is one of the concerns during the welding of HSLA steels. This embrittlement is attributed to the slow cooling rate leading to the formation of undesirable microstructures, such as coarse ferrite side plates (Widmanstätten ferrite and upper bainite) and grain-boundary ferrite (Ref 3), especially at high-energy input levels.

For HSLA steels that contain niobium and vanadium, the weld metal and the HAZ will exhibit low notch toughness at high heat inputs, such as those used in the electroslag and submerged arc welding processes. This is because the high heat input increases the extent of coarse-grained HAZ. The associated low cooling rate in the HAZ reduces the scope for grain refinement and increases the likelihood of the precipitation of niobium and vanadium carbides, leading to embrittlement of the coarse-grained HAZ. The high heat input and the resulting greater dilution also brings the precipitation-hardening problem of niobium and vanadium carbides to the weld metal.

The use of steels with small additions of titanium (up to 0.04%) and nitrogen has been found to effectively minimize the grain growth in the coarse-grained HAZ (Ref 11). This is due to the greater stability of titanium nitride at the peak temperature experienced in coarse-grained regions (>1100 °C, or 2012 °F), where niobium and vanadium carbides are turned back into solution.

Low-carbon steels comprise two classes of steels, namely, low-carbon steels with a carbon content of less than 0.15% and mild steels with a carbon content between 0.15 and 0.30%.

For these low-carbon steels in the annealed condition, the major microstructure is relatively soft ferrite with scattered small carbide particles, whereas low-carbon steel in the hot-rolled or normalized condition has islands of pearlite. During fusion welding, the HAZ will undergo transformation from ferrite to austenite upon heating, and from austenite back to ferrite during cooling. At this carbon level, the hardening involved in the HAZ is approximately 10 HRC or less. However, when the weldment undergoes a cold-forming operation, it is recommended that the carbon content be limited

to 0.06%. The HAZ of steels with higher carbon contents may not have good ductility to accommodate the strain involved in cold forming (Ref 10).

When low-carbon steels are furnished as rimmed steels, their central core regions tend to contain concentrations of elements such as carbon monoxide and carbon dioxide, as well as elements such as sulfur and phosphorus, as a result of segregation during the rimming action. In addition, the gaseous species that result from the reaction between dissolved oxygen and carbon are also trapped in the central core region. During the welding operation, certain amounts of base metal will melt and mix with filler metal because of dilution. The high-temperature, molten weld pool provides conditions that allow the incomplete oxygen-carbon reaction to resume and trapped carbon monoxide and carbon dioxide to evolve. When the weld-pool solidification rate is too rapid for gaseous species to escape, their entrapment will lead to pores in the weld metal. Consequently, sufficient weld-pool deoxidation is the practical way of avoiding porosity problems when welding rimmed steels (Ref 10).

When low-carbon steels are furnished as killed steels, weld-metal porosity is no longer a problem during fusion welding. Instead, a viscous refractory slag sometimes forms on the weld-pool surface of the killed steels, which makes the flow of molten metal sluggish and weld-pool manipulation difficult. The slag becomes viscous when deoxidizers, such as the aluminum, titanium, and zirconium used in the steel-ingot killing practice, form oxides with relatively high melting temperatures. This problem with slag is more intensified for oxyacetylene welding, because of the low temperatures involved in that process. The common remedy is to select a filler metal that contains a sufficient amount of manganese and silicon to reduce the melting point and improve the flow of the slag (Ref 10).

Mild steels are also considered to be very weldable, and cold cracking is usually not a problem when the carbon content is less than 0.2% and the manganese content is less than 1.0%. Preheat, interpass temperature control, PWHT, or special welding procedures are usually not necessary when welding plate with thicknesses of 25 mm (1 in.) or less. The carbon content is usually higher in thicker plates in order to provide the required strength. In addition, the related HAZ cooling rate during the fusion welding of a thicker plate is higher. Consequently, when welding plate that is thicker than 25 mm (1 in.), or when the carbon and manganese contents are beyond 0.3 and 1.4%, respectively, proper caution and the use of low-hydrogen electrodes/fluxes is required to prevent hydrogen cracking (Ref 10).

A useful guideline in selecting carbon-manganese and microalloyed carbon-manganese steels with optimum weldability and toughness, as established by Dolby (Ref 4, 12), is provided below.

For carbon-manganese and microalloyed carbon-manganese steels with more than 0.1% C, use steel base materials with both a low-carbon content and a low-carbon equivalent, but high toughness properties. Select steels that are aluminum-treated to restrict the width of the coarse-grained region in the HAZ and minimize the free-nitrogen level (aluminum-nitride precipitates are relatively stable). The selected steels should be clean. The aluminum-treated or vacuum degassed steels will have lower sulfur levels. The calcium treatment for sulfide shape control will improve the mechanical properties in the through-thickness direction and reduce the lamellar tearing associated with liquidation cracking problems.

When using welding processes with high-energy input for the same base-metal carbon-manganese compositions, the addition of niobium and vanadium will lower HAZ toughness, because of the niobium and vanadium precipitations that occur during cooling and reheating.

Microalloyed steels with less than 0.1% C should have higher toughness and a reduced tendency for hydrogen cracking in the HAZ. Clean aluminum-treated steels with high toughness values should be selected for the reasons described above for carbon-manganese steels. The same precaution regarding welding processes with high-energy inputs, as mentioned above, also applies.

Low-alloy steels that have a low-carbon level should be selected. A high cleavage resistance can be obtained when the hardenability of the steels is sufficient to develop low-carbon martensite for the welding conditions used. Caution should be used in the PWHT of steels that have significant amounts of secondary precipitation-hardening alloying elements, such as vanadium and niobium. Care also should be given to the PWHT of steels that contain high amounts of residual elements such as antimony, phosphorus, arsenic, and tin.

Clean, aluminum-treated steels with high toughness values should be selected for the reasons described above for carbon-manganese steels. The same precaution regarding welding processes with high-energy inputs, as mentioned above, also applies.

Thermomechanically controlled process (TMCP) steels are recently developed steels that exhibit significantly improved strength and toughness properties and weldability. The new technology of using accelerated cooling makes it possible to achieve the same strength level as conventional controlled rolled steels at a lower carbon content (<0.06%). Instead of strengthening by increasing the carbon content, TMCP steels derive their strength and toughness from the very fine ferrite and second-phase microstructure (finely dispersed pearlite or bainite) that occur during the accelerated cooling of the manufacturing process. As a result of the reduction in carbon content and carbon equivalent, these steels significantly improve their resistance to hydrogen-induced cold cracking. Therefore, the concern with preheat, interpass temperature control, and PWHT during welding fabrication is not critical.

However, HAZ softening, especially at high heat inputs, is a concern, because the favorable microstructure of the TMCP steel is reverted during the slow cooling in the HAZ at high heat input levels. Figure 7 shows the hardness profiles in the HAZ of a TMCP steel welded using various heat inputs (Ref 13).

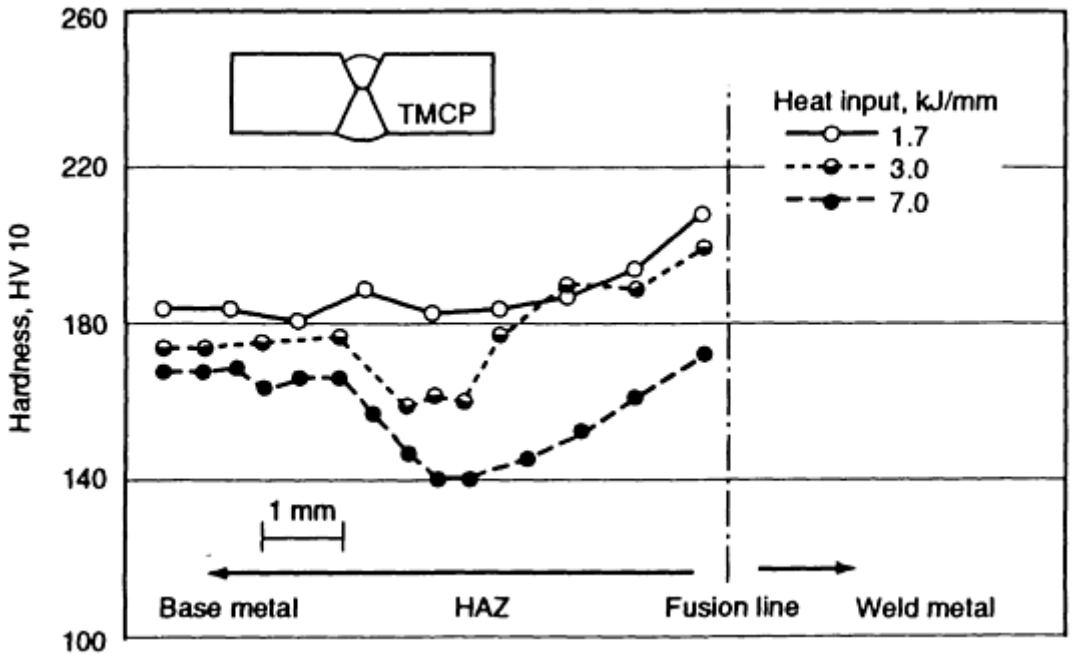

FIG. 7 VARIATION OF HARDNESS PROFILES IN HAZ OF TMCP STEEL WELDED WITH HEAT INPUT OF 1.7, 3.0, AND 7.0 KJ/MM (43, 76, AND 178 KJ/IN.). Chromium-molybdenum steels are relatively inexpensive materials, when compared with high-alloy steels used in the power and petrochemical industries, because of their oxidation resistance, elevated-temperature creep resistance, and sulfide corrosion resistance. The chromium content provides oxidation corrosion resistance, whereas the molybdenum content increases elevated-temperature strength. The presence of finely distributed stable carbide enhances the creep resistance. Because of the alloying element content and approximate 0.15% C level, these steels are air hardenable. Most of these steels are supplied in normalized and tempered or quenched and tempered condition.

The weldability of chromium-molybdenum steels is very similar to that of quenched and tempered and hardenable low-alloy steels. The major problem in the HAZ is cracking in the hardened coarse-grained region, as well as HAZ softening between Ac_1 and Ac_3. Reheat cracking during PWHT and long-term exposure in elevated-temperature service conditions also can cause severe problems. The appropriate preheat and interpass temperature should be selected, and low-hydrogen practice should be used. The recommended practice for welding these steels is provided in ANSI/AWS D 10.8-86.

Although a PWHT is not required for chromium-molybdenum steels with lower chromium contents and thinner gages, it is often conducted immediately after welding as part of the welding procedure. The PWHT of a chromium-molybdenum weldment is also referred to as a stress-relief heat treatment. Such a heat treatment is designed to relieve the residual stresses by a creep-relaxation process and to temper the as-welded hardened microstructures to improve the fracture

toughness of the HAZ and the weld metal. Additional beneficial effects of a PWHT are to allow for more dissipation of hydrogen in the weld region and to further reduce the likelihood of hydrogen-induced cold cracking.

Although a stress-relief treatment or PWHT is often used in chromium-molybdenum steel weldments, this type of steel is susceptible to either stress-relief cracking in the HAZ during such a treatment or reheat cracking during postweld reheating processes, including short-term exposure to elevated-temperature service environments. The temperature range for the occurrence of stress-relief/reheat cracking is between 500 and 700 °C (932 and 1292 °F). Although it is not clear, the cracking mechanism is believed to be related to the strengthening of the grain interior as a result of precipitation. Cracking occurs during reheating when the relatively soft grain boundaries that are free of precipitates cannot accommodate the plastic deformation during creep relaxation. A parameter known as the P_{SR} has been developed (Ref 14) to correlate the susceptibility of chromium-molybdenum steels to reheat cracking when the steels contain $\leq$1.5% Cr, $\leq$1.0% Cu, $\leq$2.0% Mo, and $\leq$0.15% V, Nb, and Ti:

$$P_{SR} = CR + CU + 2MO + 10V + 7NB + 5TI - 2 \qquad \textbf{(EQ 5)}$$

When P_{SR} is less than zero, the material is considered sensitive to reheat cracking. However, when there is more than 2% Cr, the tendency for cracking is eliminated.

Another parameter that takes into account the tramp elements that lead to grain-boundary embrittlement and increase the tendency for reheat cracking is the metal composition factor (MCF) (Ref 15):

$$MCF = SI + 2CU + 2P + 10AS + 15SN + 20SB \qquad \textbf{(EQ 6)}$$

A greater MCF also increases the susceptibility of chromium-molybdenum steels to reheat cracking.

The common welding practices that are used to reduce the likelihood for reheat cracking can be summarized as (Ref 5):

- REDUCE THE STRESS RISERS IN WELDMENT DESIGN.
- USE WELDING PRACTICES THAT MINIMIZE RESIDUAL STRESS, SUCH AS INCREASING THE PREHEAT TEMPERATURE AND REDUCING RESTRAINT.
- WHEN APPLICABLE AND NECESSARY, REDUCE WELD-METAL STRENGTH TO ACCOMMODATE THE PLASTIC DEFORMATION IN THE WELD METAL, AND REDUCE THE STRESS CONCENTRATION IN THE COARSE-GRAINED REGION.

Quenched and tempered steels (Q&T) steels are normally furnished in heat-treated conditions that involve austenitizing and/or quenching and tempering to obtain high-strength properties. The hardenability of Q&T steels is such that the HAZ consists of microstructures of low-carbon martensite and bainite. This type of as-welded HAZ microstructure has desirable mechanical properties that are close to those of the base metal. Consequently, these materials generally do not require a PWHT or stress-relief treatment, except in certain special situations.

Unlike other hardenable low-alloy steels in which high-energy input has to be used to avoid the formation of martensite in the HAZ, the use of Q&T steels requires that welding conditions include a cooling rate in the HAZ that is rapid enough to ensure the reformation of martensite and bainite microstructures. This is necessary because a HAZ cooling rate is too slow will cause the austenitized HAZ to transform into ferrite and a mixture of bainite and martensite. When proetectoid ferrite is undergoing transformation from austenite, the untransformed austenite will become enriched in carbon and will subsequently transform into hard and brittle bainite and martensite. This mixed microstructure of ferrite, bainite, and martensite leads to embrittlement of the coarse-grained HAZ. The slower the cooling rate, the greater the extent of embrittlement in the HAZ. When welding less-hardenable or thinner material, an even faster critical cooling rate (less heat input) is required to avoid transformation of brittle mixed microstructures (Ref 10).

Another concern with welding Q&T steels is the strict maintenance of low-hydrogen welding practice in order to prevent underbead cold cracking. A preheat is one of the most effective ways of reducing the tendency for cold cracking. However, a preheat also significantly reduces the cooling rate in the HAZ. Consequently, it should be applied in such a manner that a satisfactorily fast cooling rate can be achieved in the HAZ.

When welding Q&T steels with a higher strength level, the tendency for hydrogen cracking to occur in the weld metal increases. Consequently, the allowable moisture content in the electrode coating and flux, as well as the handling of these materials, become much more critical. For Q&T steels with a yield strength level under 483 MPa (70 ksi), a 0.4 wt% moisture content is the allowable limit in covered electrode, whereas for steels with a strength level above 690 MPa (100 ksi), the limit is 0.1 wt% (Ref 10). The use of a temper bead technique, as shown in Fig. 8, also can help avoid undesirable regions of high hardness and low toughness in the HAZ.

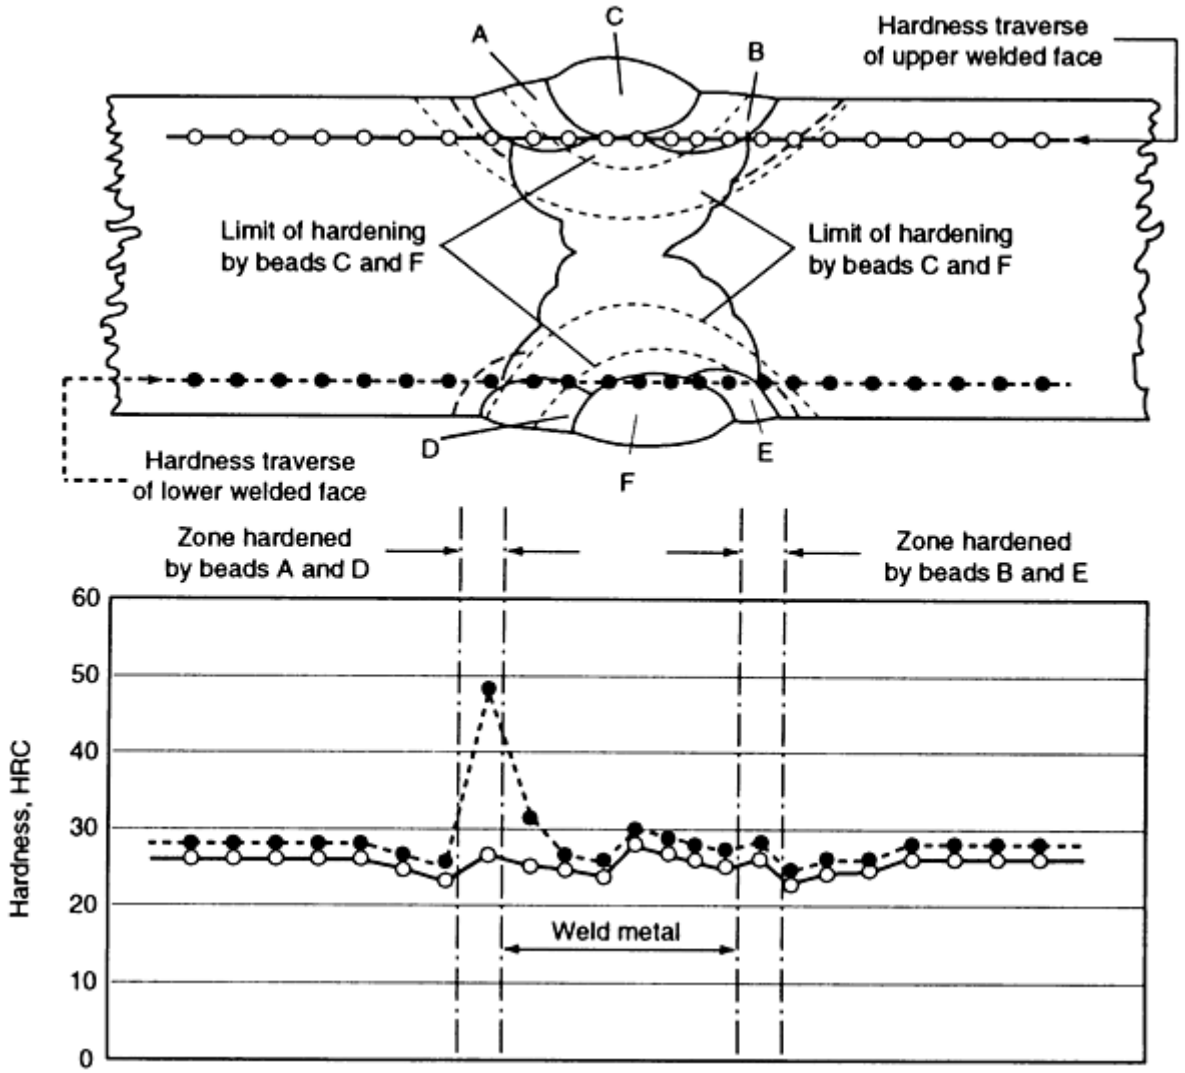

FIG. 8 TEMPERING BEAD TECHNIQUE FOR MULTIPASS WELDING OF A BUTT JOINT IN A Q&T ALLOY STEEL. HARDNESS VALUES FOUND BY UPPER AND LOWER TRAVERSES. DISTRIBUTION OF HARDNESS IS ALMOST IDENTICAL, EXCEPT FOR UNTEMPERED ZONE OF BEAD D, AT LEFT. SOURCE: REF 16

Multipass welding is a good practice when welding Q&T steels. In addition to the refining and tempering effects on the weld metal of the previous weld pass, the smaller heat input of multipass welding, compared to that of single-pass welding, can help achieve a fast cooling rate. When hydrogen cracking in weld metal is a concern, it is recommended that thin-layer multipass welding be used, along with soaking at the interpass temperature for a predetermined time before depositing the subsequent pass (Ref 17). Although this practice helps dissipate the hydrogen in the weld metal in each weld pass, productivity is decreased.

In Q&T steels, there is a softening region in the HAZ that is caused by a HAZ thermal cycle with a peak temperature between A_{c1} and A_{c3} (intercritical region). At temperatures below A_{c3} during heating, the carbides do not completely dissolve in the austenite. Therefore, the carbon level in the austenite is a lower concentration. During cooling, the unsaturated austenite transforms at high temperature and results in a microstructure with lower strength.

Weldment Considerations

Corrosion. Carbon and low-alloy steels used for structural applications are not commonly utilized in severe corrosion environments. However, they are used in moderate corrosive service conditions, such as those in oil refinery facilities and sour gas/oil pipelines. The presence of a weld often leads to a reduction in corrosion resistance because of these circumstances (Ref 6):

- COMPOSITIONAL VARIATIONS IN THE BASE METAL, HAZ, AND WELD METAL THAT RESULT IN A CONDITION FAVORING GALVANIC CORROSION
- PRESENCE OF WELDING RESIDUAL STRESSES THAT LEAD TO STRESS-CORROSION CRACKING
- PRESENCE OF WELD DISCONTINUITIES, SUCH AS SURFACE FLAWS, WHICH ACT AS PREFERENTIAL SITES FOR LOCAL CORROSION ATTACK

In a corrosive environment, the prevention of hydrogen-induced cracking (HIC) and sulfide stress-corrosion cracking (SCC) is of great importance.

Hydrogen-induced cracking, which has been observed in both high- and low-strength steels, even under nonstressed conditions, occurs primarily in the low-strength steels that are exposed to a hydrogen-containing environment. Because of

its rapid cooling and solidification, weld metal forms a structure of rendrites and has oxide inclusions dispersed in the form of fine globules. It has been confirmed that weld metals, even when used without a filler metal of special chemistry, do not develop HIC up to a maximum hardness of 280 HV. In comparison, HIC has been observed primarily in the base metal and HAZ (Ref 18, 19).

Stress-corrosion cracking is defined as a cracking phenomenon that occurs under sulfide-corrosive conditions when steel materials are subjected to stress. Steels that are to be used in environments containing hydrogen sulfide can be selected per Ref 20. According to this standard, a value of 22 HRC (248 Hv) is recommended as the hardness limit for steel line pipe used in sour-gas service.

In the case of a weldment, the HAZ generally becomes harder than the base metal, and, consequently, is more susceptible to SCC. In addition to the more susceptible microstructure, other factors that contribute adversely to SCC are weld residual stresses and the presence of the entrant angle of the weld cap as a stress raiser in the welded region.

When the welded joints are quenched and tempered or normalized, the HAZ disappears and the tendency for the previous HAZ to develop SCC is altered (Ref 18, 19). The SCC susceptibility is greater in the as-welded condition than in the Q&T (PWHT) condition.

Fatigue Strength of Weld Joints. Fatigue cracks in a welded structure under cyclic loading are often observed to develop at weld toe regions. This is because the weld toes are regions of stress concentration. The toes are the point at which the base metal and weld metal meet and where changes are greatest in both sections. More importantly, slag intrusions that result from a welding operation are often present at the weld toe regions.

Various methods have been utilized to improve the fatigue strength of welded structures by reducing the stress concentration in the regions of weld toes and weld reinforcements. These methods are (Ref 21, 22):

- REMOVING THE WELD REINFORCEMENT ON BOTH SIDES OF A BUTT JOINT BY MACHINING THE WELD TO THE LEVEL OF THE BASE METAL
- INCREASING THE RADIUS AND ENTRANT ANGLE OF WELD TOES BY MECHANICALLY GRINDING THE INTERSECTING REGIONS BETWEEN THE WELD AND THE BASE METAL
- CHANGING THE STATE OF THE SURFACE-WELD RESIDUAL STRESS BY THE MECHANICAL COLD WORKING OF THE WELD SURFACE AND THE BASE METAL AT THE WELD TOE REGIONS
- COATING AND/OR PAINTING THE WELDS AND BASE METAL TO PREVENT CORROSION IN THE REGION OF STRESS CONCENTRATION
- INCREASING THE TOE RADIUS AND WELD ENTRANT ANGLE BY ADDING A WELD BEAD ON BOTH SIDES OF THE REINFORCEMENTS USING A FILLER METAL WITH HIGH FLUIDITY
- USING WELDING CONDITIONS THAT WILL RESULT IN A GREATER WELD TOE RADIUS AND ENTRANT ANGLE
- REMELTING THE SURFACE IN THE WELD TOE REGIONS FOR FLATTENING AND SMOOTHING WELD PROFILES USING THE GAS-TUNGSTEN ARC WELDING PROCESS

Influence of Welding on Steel Weldment Properties

C.C. Chen and Abe Pollack, Microalloying International, Inc.

Effect of Welding Procedure on Steel-Weldment Properties

The American Welding Society defines a welding procedure as the detailed methods and practices that include all joint welding procedures involved in the production of a weldment (Ref 23). In a comprehensive review of the relationship between procedures and weldment properties, the conclusions described below were made (Ref 23).

First, for any welding process/steel combination, welding procedures have a predominant role, along with the electrode (if a filler metal is used), in determining the quality and mechanical properties of the weldment. However, these two variables (welding procedures and mechanical properties) do not have a direct cause-effect relationship.

Second, the mechanical properties of any metal are attributable only to its soundness, microstructure, and chemical composition, and to whether or not it is base plate, weld metal, vapor-deposited metal, electrodeposited metal, or any other type. The response of a metal to mechanical forces depends on its current state and not on the manner in which this state was created.

Third, metallurgical research has established relationships between mechanical properties and microstructure, such as the inverse relationship between grain size and strength, the difference in strength between pearlite and martensite, the embrittling effect of grain-boundary films, the deleterious effect of inclusions, and others. Conversely, there is no direct relationship between the current setting of a welding machine and the final properties of the weldment. Rather, the true cause and effect relationship is that:

- INCREASED CURRENT INTRODUCES MORE HEAT INTO THE ALLOY
- INCREASED HEAT AFFECTS THE STRUCTURE OF BOTH THE WELD METAL AND THE HAZ IN A PARTICULAR MANNER, DEPENDING ON THE ALLOY CHEMISTRY, PHASES THAT ARE PRESENT, AND OTHER FACTORS
- DIFFERENCES IN STRUCTURE PRODUCE DIFFERENT MECHANICAL PROPERTIES

Described below are the specific welding procedure factors that affect weldment properties.

Preheat Temperature

Preheating is the application of heat to the base metal immediately before welding, brazing, soldering, or cutting (Ref 24). The preheat temperature depends on many factors, such as the composition and mass of the base metal, the ambient temperature, and the welding procedure.

Preheating is used to:

- REDUCE SHRINKAGE STRESSES IN THE WELD AND ADJACENT BASE METAL, WHICH IS ESPECIALLY IMPORTANT WITH HIGHLY RESTRAINED JOINTS
- PROVIDE A SLOWER RATE OF COOLING THROUGH THE CRITICAL TEMPERATURE RANGE (APPROXIMATELY 879 TO 720 °C, OR 1600 TO 1330 °F), WHICH PREVENTS EXCESSIVE HARDENING AND LOWERS THE DUCTILITY OF BOTH THE WELD AND HEAT-

AFFECTED AREA OF THE BASE PLATE

- PROVIDE A SLOWER RATE OF COOLING DOWN TO 205 °C (400 °F), ALLOWING MORE TIME FOR ANY HYDROGEN THAT IS PRESENT TO DIFFUSE AWAY FROM THE WELD AND ADJACENT PLATE IN ORDER TO AVOID UNDERBEAD CRACKING

Gas torches, gas burners, heat-treating furnaces, electric-resistance heaters, low-frequency induction heating, and temporary furnaces are some of the preheating methods that are used. The selection of the method depends on several factors, such as the preheat temperature, the length of preheating time, the size and shape of the parts, and whether it is a one-of-a-kind or a continuous production type of operation.

For critical applications, the preheat temperature must be precisely controlled. In these cases, controllable heating systems are used, and thermocouples are attached directly to the part being heated. The thermocouple measures the exact temperature of the part and provides a signal to a controller, which regulates the fuel or electrical power required for heating. By accurately regulating the fuel or power, the temperature of the part being heated can be held to close limits. Most code work requires precise heat-temperature control. Preheat and interpass temperature requirements are described in the article "Welding of Carbon Steels" in this Volume and in ANSI/AWS D1.1-92.

The effect of preheat is illustrated by the data in Table 1. The analysis indicates that the extent to which the ductility and fracture-transition temperature are affected depends on the chemical composition of the steel. Changes in preheat temperature for the steel with 0.24% C were effective only above 120 °C (250 °F), whereas for the steel with 0.18% C, the changes were effective over the entire range from -12 to 260 °C (10 to 500 °F).

TABLE 1 EFFECT OF PREHEAT AND STRESS-RELIEF TREATMENT ON TRANSITION TEMPERATURE OF WELDED STEELS

CONDITION OF PLATE	19 MM ($\frac{3}{4}$ IN.) 0.18% C, SEMIKILLED STEEL				19 MM ($\frac{3}{4}$ IN.) 0.24% C, SEMIKILLED STEEL			
	DUCTILITY-TRANSITION TEMPERATURE		FRACTURE-TRANSITION TEMPERATURE		DUCTILITY-TRANSITION TEMPERATURE		FRACTURE-TRANSITION TEMPERATURE	
	°C	°F	°C	°F	°C	°F	°C	°F

Source: Ref 6

Interpass Temperature

The interpass temperature, which is involved in multipass welds, is represented by the minimum and maximum temperatures of the deposited weld metal and adjacent base metal before the next pass is started.

Usually, a steel that requires preheating to a specified temperature also must be kept at this temperature between weld passes. With many weldments, the heat input during welding is adequate to maintain the interpass temperature. On a massive weldment, it is not likely that the heat input of the welding process will be sufficient to maintain the required interpass temperature. If this is the case, then torch heating between passes may be required.

Once an assembly has been preheated and the welding begun, it is desirable to finish welding as soon as possible, in order to avoid the need for interpass heating.

Because the purpose of preheating is to reduce the cooling rate, it logically follows that the same slow cooling should be accorded all passes. This can only be accomplished by maintaining an interpass temperature that is at least equal to the preheat temperature. If this is not done, then each individual bead will be subjected to the same high quench rate as the first bead of a nonpreheated assembly.

The required minimum temperatures, based on specific steel, welding process, and plate thickness, should be heeded. When heat buildup becomes excessive, the weldment must be allowed to cool, but not below the minimum interpass temperature. The temperature of the welding area must be maintained within minimum and maximum interpass temperatures.

Postweld Heat Treatment

A PWHT is generally considered necessary for welds in thicker-section steels, in order to reduce the high as-welded residual stress levels and improve the toughness and defect tolerance of the joint. Many fabrication codes offer guidance on the duration and temperature of the PWHT, although some discrepancies between various codes exist. In assessing the time and temperature required to provide a suitable PWHT, it is necessary to know how such parameters will respond to various heat-treatment schedules.

In all heat treatments, with the possible exception of fusion, the heating rate and time can be specified. The maximum temperature is related to the composition of the steel, the holding time (at the maximum temperature) is related to the material thickness, and the cooling rate is related to the particular treatment and to the code. The rate of heating usually ranges from 149 to 177 °C (300 to 350 °F) per hour. The holding temperature is usually 2.4 min/mm (1 h/in.) of maximum thickness in order to provide uniform heating throughout. The cooling rate also ranges from 149 to 177 °C (300 to 350 °F) per hour, down to a specific temperature. In some cases, the cooling rate can be increased when the part has cooled to a temperature from 260 to 316 °C (500 to 600 °F). These rates of heating, holding, and cooling are usually part of the specification and must be followed explicitly.

Example 1: Effects of PWHT on the HAZ Properties of Welds in a Carbon-Manganese Grade Steel.

An investigation (Ref 25) of the effects of PWHT has reported the variation in HAZ properties (strength, hardness, and toughness) with different PWHT parameters. The tests were carried out on a 50 mm (2 in.) BS1501-225-490B-LT50 steel manufactured by the British Steel Corporation. The steel was a carbon-manganese grade that had been silicon killed and treated with aluminum and niobium. This grade was chosen because it is increasingly being used in pressure-vessel applications and is also similar to BS4360 grade 50E, a steel that is used in many off-shore fabrications and other structures. The submerged arc welding process was used with a heat input of approximately 3.4 kJ/mm (89 kJ/in.) of the fill passes. In addition, the effects of multiple PWHT cycles, which are often encountered in pressure-vessel fabrication or in cases where repairs have been made, have been investigated in the same manner.

Longitudinal tensile tests of the HAZ were conducted, and the data are plotted in Fig. 9(a). No significant effect that was due to multiple stress-relief cycles was noted in the HAZ regions. The values observed exceeded the plate minimum requirements. Adequate ductility and elongation values were observed at 600 °C (1112 °F). Figure 9(b) indicates no significant effect of PWHT time on the HAZ yield-stress tensile strength or ductility at this temperature. The data plotted in Fig. 9(c) indicated that only a minor reduction in yield stress and tensile strength were observed with increasing PWHT temperature. No significant effects on ductility were observed.

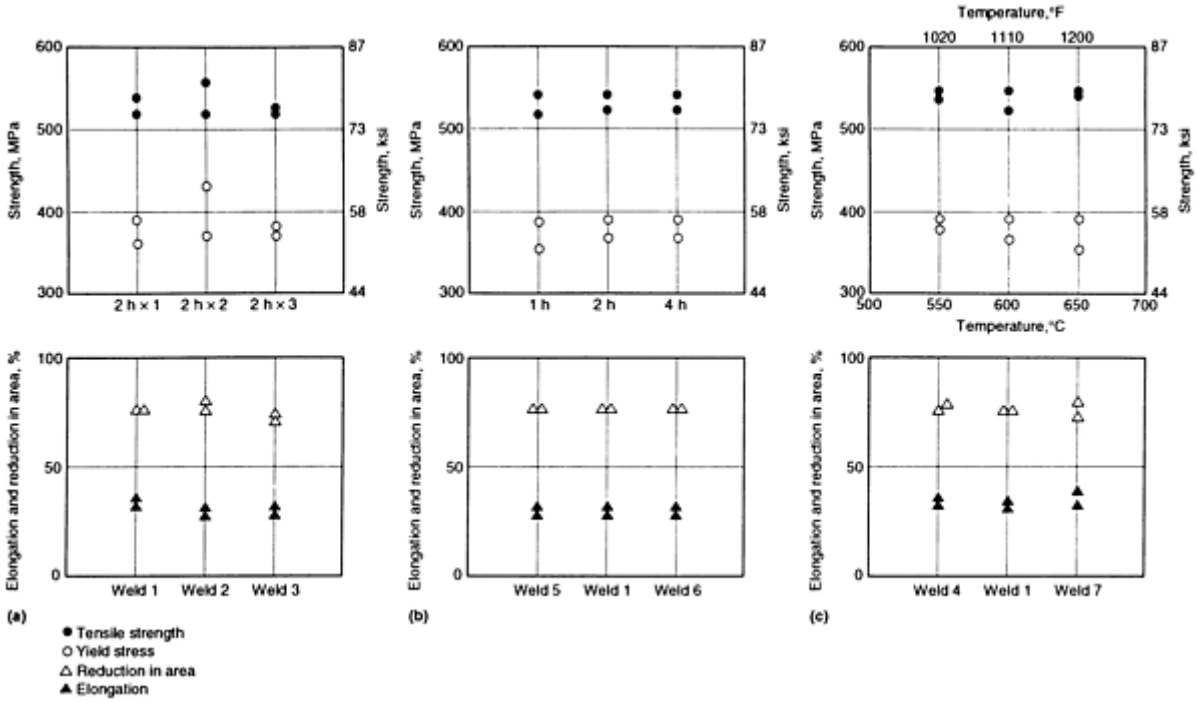

FIG. 9 EFFECT OF PWHT ON THE HAZ TENSILE PROPERTIES OF A CARBON-MANGANESE GRADE STEEL. (A) EFFECT OF MULTIPLE PWHT AT 600 °C (1112 °F), (B) EFFECT OF PWHT TIME. (C) EFFECT OF PWHT TEMPERATURE. SOURCE: REF 25

Charpy Tests. Five testing temperatures were chosen and three specimens were tested at each of the temperatures, which were -80 °C (-112 °F), -60 °C (-76 °F), -40 °C (-40 °F), -20 °C (-4 °F), and 0 °C (32 °F). For the welds, one specimen was taken from the first side of the HAZ, one from the second side of the HAZ, and one from the HAZ at the plate midthickness, which was associated with second-side welds. The data in Fig. 10 show that multiple PWHT cycles had only a marginal effect, in that a slight increase in the number of low values at low temperatures was observed at two and three cycles, particularly from specimens machined from the plate midthickness.

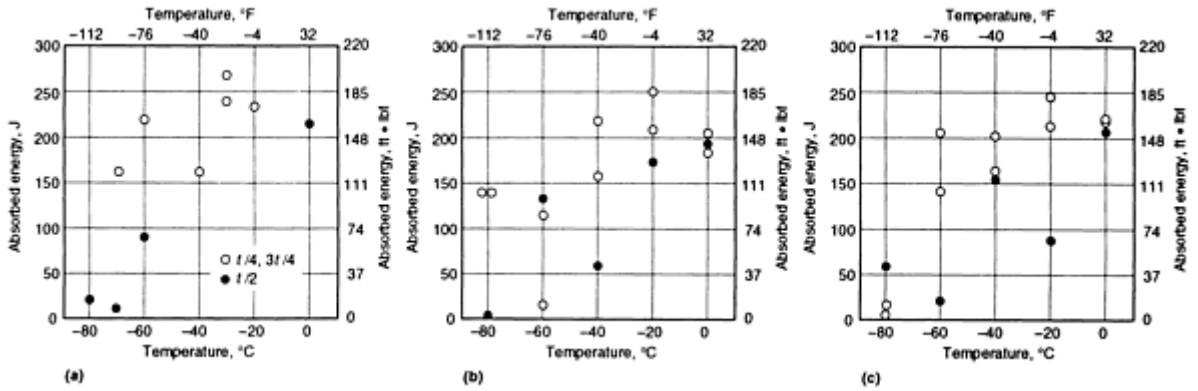

FIG. 10 EFFECT OF MULTIPLE PWHT CYCLES ON THE HAZ CHARPY V-NOTCH PROPERTIES OF A CARBON-MANGANESE GRADE STEEL. (A) WELD 1; PWHT, 1 × 2H. (B) WELD 2; PWHT, 2 × 2 H. (C) WELD 3; PWHT, 3 × 2 H. SOURCE:REF 25

Although extended PWHT has not led to an appreciable variation in HAZ Charpy properties from the $(\frac{1}{4})t$ and $(\frac{3}{4})t$ locations, a pronounced drop in absorbed energy levels has been observed after 4 h in specimens machined from the plate

midthickness. This is clearly shown in Fig. 11, from which the toughness at the plate midthickness appears to fall off with time, although this does not happen at the $(\frac{1}{4})t$ locations.

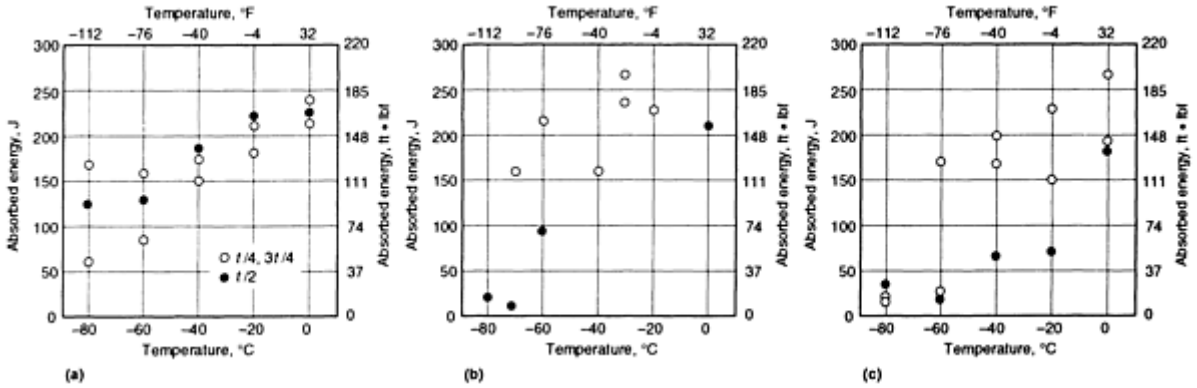

FIG. 11 EFFECT OF PWHT TIME AT 600 °C (1112 °F) ON THE HAZ CHARPY V-NOTCH PROPERTIES OF A CARBON-MANGANESE GRADE STEEL. (A) WELD 5; PWHT TIME, 1 H. (B) WELD 1; PWHT TIME, 2 H. (C) WELD 6; PWHT TIME, 4 H. SOURCE:REF 25

The effects of increasing the PWHT temperature are shown in Fig. 12, from which it is clear that no pronounced effect of temperature on toughness exists, except at the plate midthickness. Here, there seems to be a trend of increasing transition temperature with increasing PWHT temperature.

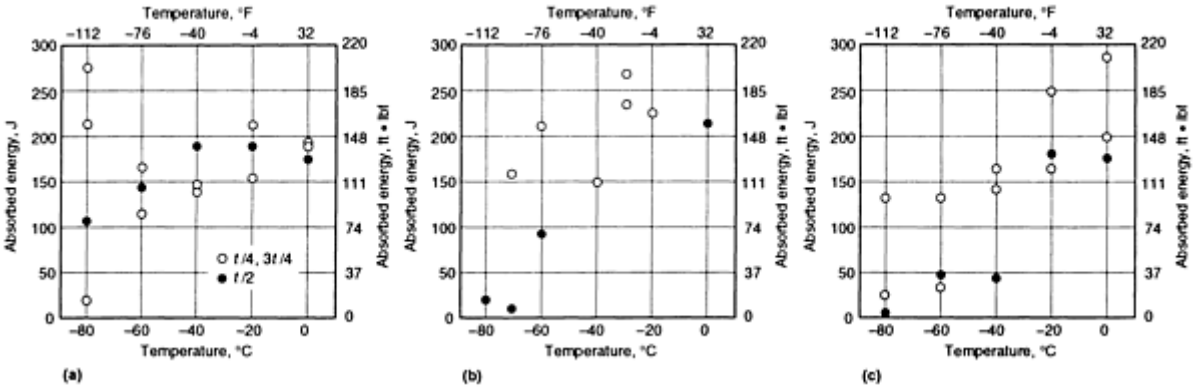

FIG. 12 EFFECT OF PWHT TEMPERATURE ON THE HAZ CHARPY V-NOTCH PROPERTIES OF A CARBON-MANGANESE GRADE STEEL. (A) WELD 4, 550 °C (1020 °F). (B) WELD 1, 600 °C (1110 °F). (C) WELD 7, 650 °C (1200 °F). SOURCE:REF 25

Hardness Survey. Hardness traverses were conducted in the macrosection from each weld after PWHT, reaching from the parent plate that was unaffected by the welding processes into the weld metal. Similar traverses were made on welds 1 and 2 in the as-welded condition. On each macrosection, three traverses were made at these locations: 3 mm (0.12 in.) below the surface of the first side; at the plate midthickness; and 3 mm (0.12 in.) below the surface of the second side. In all cases, a 98 N (10 kgf) load was used on a Vickers hardness machine.

The as-welded hardness data from welds 1 and 2 are shown in Fig. 13. Plate values were approximately 170 to 180 HV 10, and weld-metal values were 200 to 220 HV 10. Peak HAZ hardness was below 240 HV 10.

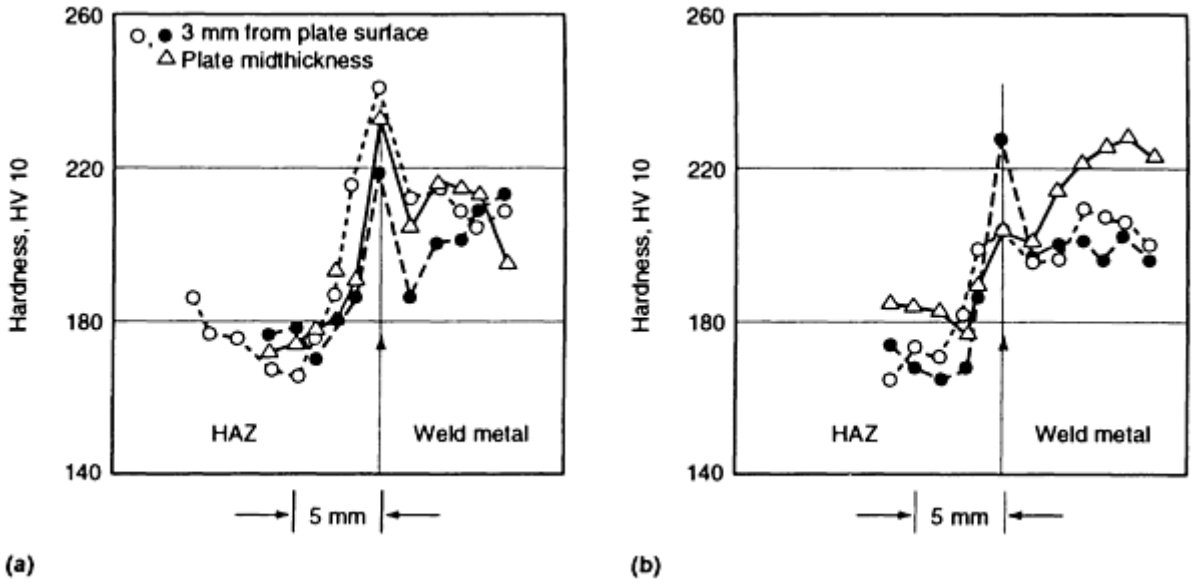

FIG. 13 AS-WELDED HARDNESS DATA FOR TWO WELDS IN A CARBON-MANGANESE GRADE STEEL. (A) WELD 1. (B) WELD 2. SOURCE: REF 25

The effect of multiple PWHT cycles is shown in Fig. 14. Multiple PWHTs had little influence on HAZ or plate hardness, where peak HAZ values of less than 240 HV were obtained and plate values were approximately 140 to 160 HV 10. In all welds, the hardness at the plate midthickness was slightly higher than it was at the surfaces, because of the presence of a segregated band, as is frequently observed in continuously cast steel.

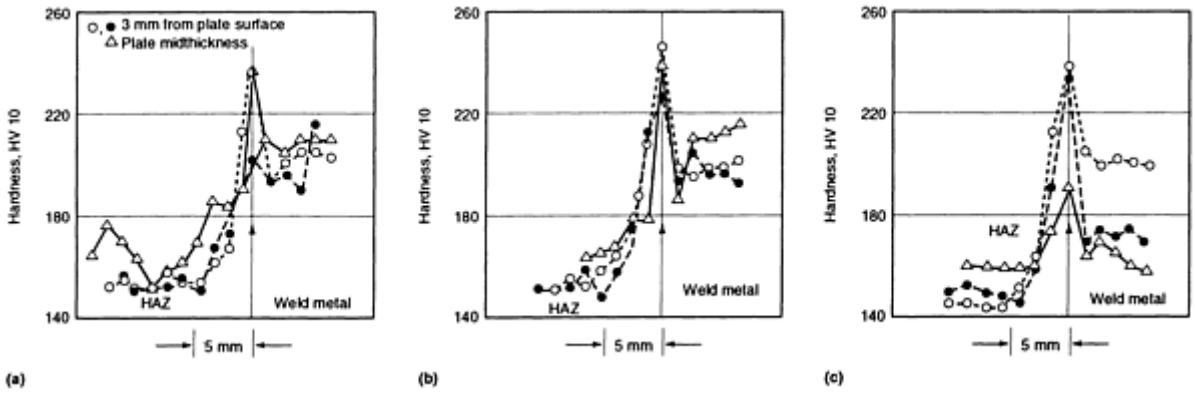

FIG. 14 EFFECT OF MULTIPLE PWHT CYCLES ON THE HARDNESS OF WELDS IN A CARBON-MANGANESE GRADE STEEL. (A) WELD 1; PWHT, 1 × 2 H. (B) WELD 2; PWHT, 2 × 2 H. (C) WELD 3; PWHT, 3 × 2 H. SOURCE: REF 25

Weld-metal hardness shows a more noticeable effect when exposed to multiple stress-relief cycles. Welds 1 and 2 had a fairly uniform hardness of approximately 200 HV, but after the third PWHT cycle, the weld-metal hardness levels dropped to 160 to 220 HV, with the lowest values appearing at the weld midthickness.

The values in Fig. 15 show only a slight reduction in HAZ hardness as PWHT time increases. Plate values are unaffected. The weld metal behaves in a nonsystematic manner. Values between approximately 190 and 210 HV 10 were observed after 1 h, increasing to approximately 200 to 220 HV 10 after 2 h, and decreasing to approximately 160 to 195 HV 10 after 4 h.

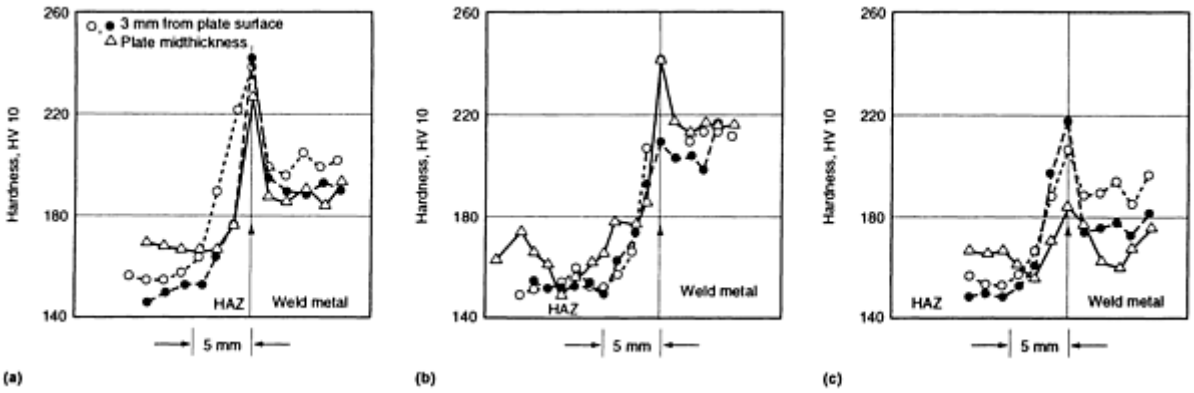

FIG. 15 EFFECT OF PWHT TIME AT 600 °C (1112 °F) ON THE HARDNESS OF WELDS IN A CARBON-MANGANESE GRADE STEEL. (A)WELD 5, 1 H. (B)WELD 1, 2 H. (C) WELD 6, 4 H. SOURCE: REF 25

Figure 16 shows that plate and HAZ hardness levels appear to be fairly insensitive to PWHT temperature. No obvious trends in the variation of hardness with temperature are apparent. However, a slight drop in plate hardness has been observed. Weld-metal hardness appears to decline after a 650 °C (1202 °F) PWHT, where values of approximately 180 to 190 HV 10 have been recorded. This compared with values of approximately 190 to 210 HV 10, which were recorded at 550 and 600 °C (1022 and 1112 °F).

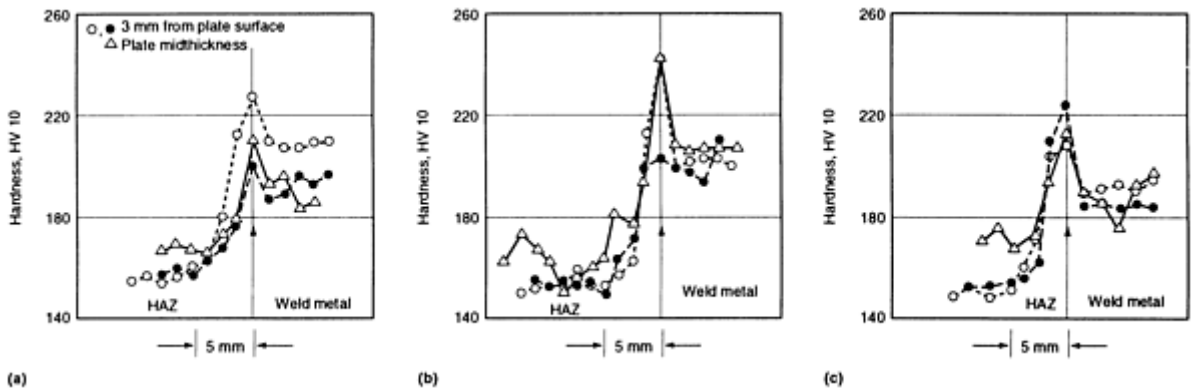

FIG. 16 EFFECT OF PWHT TEMPERATURE ON THE HARDNESS OF WELDS IN A CARBON-MANGANESE GRADE STEEL. (A) WELD 4, 550 °C (1020 °F). (B) WELD 1, 600 °C (1110 °F). (C) WELD 7, 650 °C (1200 °F). SOURCE: REF 25

It was concluded that increasing the PWHT time at 600 °C (1112 °F), whether by prolonging single treatments or by using multiple treatments, had little effect on the mechanized properties. In addition, increasing the PWHT temperature from 550 to 650 °C (1022 to 1202 °F) resulted in no significant drop in HAZ strength or hardness. However, evidence for a drop in the HAZ Charpy V notch-toughness at the plate midthickness with increasing temperature was found.

Heat Input

The welding process and procedure both influence the energy input used to made a weld. The greater the energy input, the slower the cooling rate. Heat input is a function of welding current, arc voltage, and travel speed. To increase the heat input, either the welding current should be increased or the travel speed should be reduced. Welding current is related to the process and the electrode size. Heat input is calculated by using the following formula:

$$HE = EI\frac{60}{S} \qquad \textbf{(EQ 7)}$$

where *HE* is the energy input in joules per linear measure of weld, *E* is the arc voltage in volts, *I* is the welding current in amperes, and *S* is the travel speed (linear measure) per minute.

By increasing the amperage or voltage, heat input increases, but by increasing the travel speed, heat input decreases. The voltage has a minor effect, because it varies only slightly, when compared with the other factors. The general higher input reduces the cooling rate. This must be used with caution, because with Q&T steels, too high a heat input will tend to soften the HAZ, and its strength level will be reduced.

In relatively low hardenability steels, it is possible to produce an unhardened HAZ by increasing the heat input. In higher-hardenability steels, the tendency toward cracking and the maximum hardness will be reduced by a slower cooling rate.

There are limits to the amount of heat input that can be used. In this case, preheating is used in order to reduce cooling rates.

Effect of Welding Process. Each welding process has a different thermal cycle. Figure 17 shows the time-temperature relationship of base metal taken immediately adjacent to welds made by two welding processes (Ref 26). The rate of heat rise, the maximum temperature, the time at high temperature, and the rate at which the metal cools are quite different for the shielded metal arc and the electroslag welding processes. Those processes with the highest concentration of heat will cause the temperature to both rise and fall much more rapidly. The curve shown for the shielded metal arc weld rises almost instantaneously, and the cooling rate of the base metal is a very steep slope, which indicates quick cooling. The curve for electroslag welding rises more slowly, is held at a high temperature for a fairly long time, and then decreases slowly. The temperature changes that occur during an arc welding operation are much quicker and more abrupt than for most metallurgical processes. The metallurgical reactions from the heat of welding do not follow the normal heat-treating relationships. The temperature changes with electroslag welding are more similar to those encountered in foundry metallurgy.

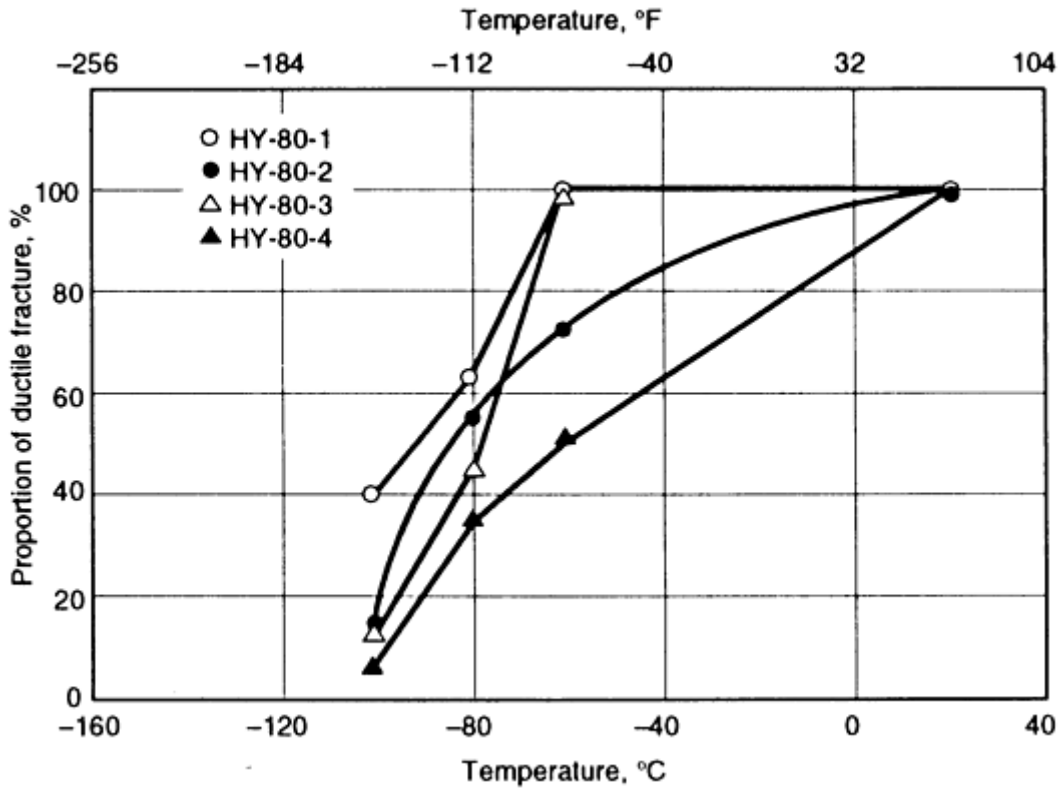

FIG. 17 PERCENT DUCTILE FRACTURE VERSUS TEST TEMPERATURE FOR THE SUBMERGED ARC BEND-IN-

Example 2: Effect of Heat Input on Properties of HY-80 and HSLA-80 Weld Metals.

Because the low-alloy Q&T steels are already in a heat-treated condition, any heating beyond a certain temperature will destroy the properties developed in them by the manufacturing process. A study (Ref 27) was conducted to assess the influence of composition and energy input on the structure and properties of single-pass submerged arc bead-in-groove welds produced on HY-80 and HSLA-80 steels.

Table 2 and 3 gives the chemical composition of the high-strength steels and the welding electrodes used in the study; Table 3 lists the welding conditions. The single-pass welds were produced at energy input levels of 1, 2, 3, and 4 kJ/mm (25, 51, 76, and 101 kJ/in.). The size of the machined grooves was increased to accommodate the increase in energy input, while maintaining the same level of dilution (50%) from the base plate.

Effect on HY-80 Tensile Properties. The weld-metal tensile results noted in Table 4 exhibited yield strengths that were greater than the targeted level of 56 MPa (81.9 ksi) with HY-80-1 weld deposited at 1 kJ/mm (25 k J/in.), which displayed very high yield strength and lower ductility. Upon increasing the energy input from 1 to 4 kJ/mm (25 to 101 kJ/in.), there was a pronounced decrease in yield strength (209 MPa, or 30 ksi) for the HY-80 welds.

TABLE 4 TENSILE PROPERTIES OF SUBMERGED ARC BEAD-IN-GROOVE WELDS DEPOSITED IN HY-80 STEEL FROM EXAMPLE 2

WELD NO.	ENERGY INPUT		YIELD STRENGTH		ULTIMATE STRENGTH		ELONGATION, %	REDUCTION IN AREA, %
	KJ/MM	KJ/IN.	MPA	KSI	MPA	KSI		
HY-80-1	1	25	875	127	1124	163	18	54
HY-80-2	2	50	745	108	930	135	24	59

HY-80-4	4	100	666	97	867	126	25	63

Source: Ref 27

Effect on HY-80 Charpy Properties. Charpy impact transition curves for HY-80 welds based on 5 × 10 mm (0.2 × 0.4 in.) subsized specimens and plots of the percentage of ductile fracture versus test temperature are shown in Fig. 12. The investigators noted that, for HY-80 welds, the lowest energy input weld displayed the lowest toughness values, despite ductile behavior at temperatures above -80 °C (-112 °F). Figure 12 shows the variation in proportion of ductile fracture for the series of HY-80 welds. For 2 and 4 kJ/mm (5 and 10 kJ/in.) welds, ductile fracture occurred at temperatures above -50 °C (-58 °F), with the transition to brittle cleavage fracture occurring below -50 °C (-58 °F). The 1 and 3 kJ/mm (25 and 75 kJ/in.) welds displayed fully ductile fracture at temperatures above -80 °C (-112 °F).

Effect on HSLA-80 Tensile Properties. Tensile property results (Table 5) show that the HSLA-80 welds displayed lower strengths and better ductilities than the HY-80 welds. A slight decrease (45 MPa, or 6.5 ksi) was observed for the HSLA-80 welds, compared with the pronounced decreased in yield strength (209 MPa, or 30 ksi) for the HY-80 welds.

TABLE 5 PROPERTIES OF SUBMERGED ARC BEAD-IN-GROOVE WELDS DEPOSITED IN HSLA-80 STEEL FROM EXAMPLE 2

WELD NO.	ENERGY INPUT		YIELD STRENGTH		ULTIMATE STRENGTH		ELONGATION, %	REDUCTION IN AREA, %
	kj/mm	kj/in.	MPa	ksi	MPa	ksi		
HSLA-80-1	1	25	640	93	806	117	25	64
HSLA-80-2	2	50	618	90	756	110	28	66
HSLA-80-3	3	75	607	88	720	105	27	65
HSLA-80-4	4	100	595	86	710	103	28	65

Source: Ref 27

Effect on HSLA-80 Charpy Properties. In the case of the HSLA-80 welds, only slight variations in notch toughness were observed, as plotted in Fig. 18. The weld metals deposited at energy inputs of ≤3 kJ/mm (75 kJ/in.) displayed ductile behavior down to -80 °C (-112 °F). The transition to cleavage fracture occurred at temperatures between -80 and -150 °C (-112 and -238 °F), as shown in Fig. 18. The superior toughness of the HSLA-80 weld metals was generally attributed to the combined effect of the acicular ferrite microstructure and the lower yield strength.

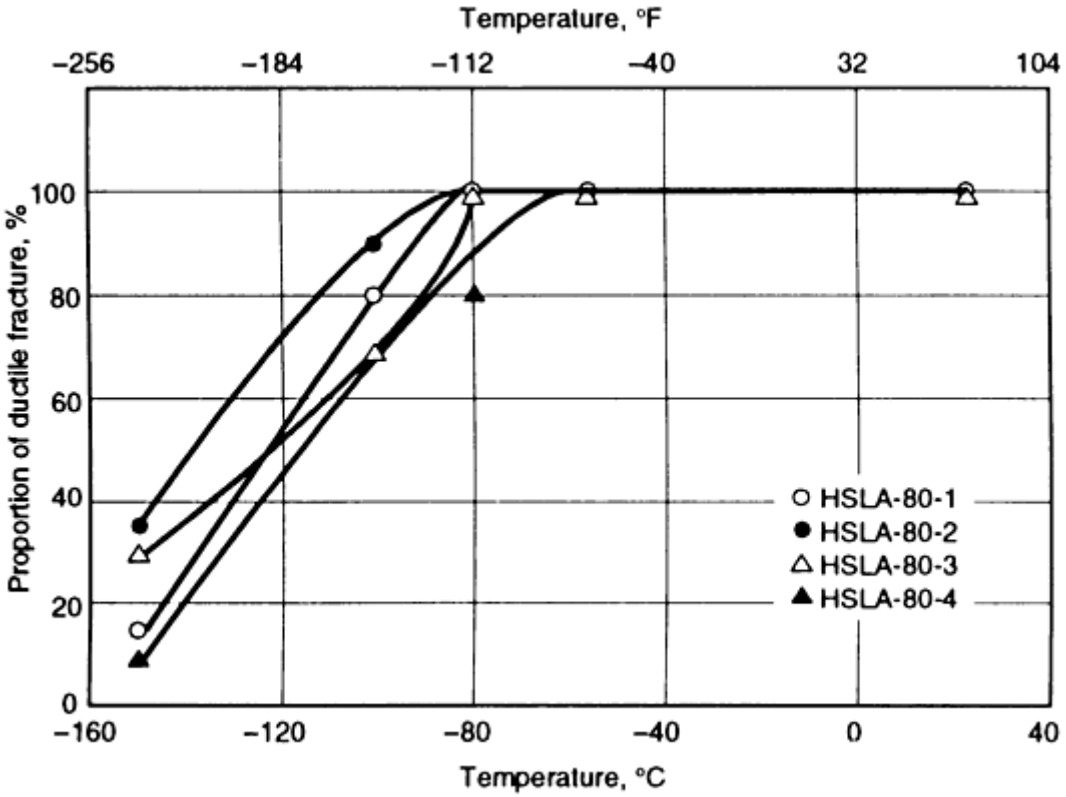

FIG. 18 PERCENT DUCTILE FRACTURE VERSUS TEST TEMPERATURE FOR THE SUBMERGED ARC BEAD-IN-GROOVE WELDS DEPOSITED IN HSLA STEEL. SOURCE: REF 27

With regard to the effect of heat input on weldment properties, the investigators concluded that:

- A PRONOUNCED DECREASE IN WELD-METAL YIELD STRENGTH AND REDUCTION IN HARDNESS WERE ALSO OBSERVED FOR THE HY-80 WELDS WITH INCREASING ENERGY INPUT. POOR LOW-TEMPERATURE NOTCH TOUGHNESS WAS DISPLAYED BY BOTH THE LOW- AND HIGH-ENERGY INPUT WELDS, WHEREAS CONSIDERABLE IMPROVEMENTS OCCURRED FOR THE 2 AND 3 KJ/MM (50 AND 75 K J/IN.) WELDS.
- THE NOTCH TOUGHNESS WAS RELATED TO THE PACKET SIZE AND THE RELATIVE STRENGTH OF THE MICROSTRUCTURES. THE EXCESSIVELY HIGH YIELD STRENGTH OF THE HY-80-1 WELD RESULTED IN LOW RESISTANCE TO BOTH DUCTILE AND CLEAVAGE FRACTURE, DESPITE FINE CLEAVAGE FACETS, WHICH CORRESPONDED CLOSELY TO THE MARTENSITIC PACKET SIZES (≤ 5 μM, OR 0.2 MIL). AT A HIGH-ENERGY INPUT, POOR TOUGHNESS OCCURRED, BECAUSE OF AN INCREASE IN THE PACKET SIZE FOR THE FULLY BAINITIC MICROSTRUCTURE.
- SUPERIOR NOTCH TOUGHNESS PROPERTIES WERE OBSERVED TO BE INDEPENDENT OF THE ENERGY INPUT FOR THE HSLA-80 WELDS AS A RESULT OF THE TRANSFORMATION TO A HIGH PROPORTION OF ACICULAR FERRITE WITH THE LOWER YIELD STRENGTHS.

Introduction to the Selection of Stainless Steels

John C. Lippold, Edison Welding Institute

Introduction

STAINLESS STEELS are an important class of engineering alloys used in both wrought and cast form for a wide range of applications and in many environments. Stainless steels are used extensively in the power generation, pulp and paper, and chemical processing industries, but are also chosen for use in many everyday household and commercial products. The widespread use of stainless steels and their importance in critical industrial technologies has led to considerable investigation of the weldability and service integrity of these steels. The purpose of the articles in this Section of the Handbook is to aid the reader in the selection of stainless steels based on these criteria.

Introduction to the Selection of Stainless Steels

John C. Lippold, Edison Welding Institute

Selection of Stainless Steels

Fundamentally, stainless steels are based on the iron-chromium, iron-chromium-carbon, and iron-chromium-nickel systems, but may contain a number of other alloying additions that alter their microstructures and/or properties. The "stainless" nature of these steels arises primarily from the addition of chromium in quantities greater than 12 wt%. This level of chromium ensures that a continuous layer of protective chromium-rich oxide forms on the surface. In practice, however, stainless steels may contain as little as 9 wt% Cr and be subject to general corrosion ("rusting") at ambient temperatures. Few stainless steels contain more than 30 wt% Cr or less than 50 wt% Fe.

Historically, stainless steels have been classified by microstructure and are described as ferritic, martensitic, austenitic, or duplex (austenitic and ferritic). In addition, a number of precipitation-hardenable (PH) martensitic and austenitic stainless steels exist and are normally classified separately as PH stainless steels. Cast versions of all of the microstructural variants exist, but their welding behavior is often unique relative to the corresponding wrought alloys. The articles in this Section are organized according to the categories of stainless steels described above.

In order to control microstructure and properties, a number of alloying elements are added to the basic iron-chromium, iron-chromium-carbon, and iron-chromium-nickel systems; these alloying elements include manganese, silicon, molybdenum, niobium, titanium, and nitrogen. In order to broadly describe the effect of composition on microstructure in a wide range of stainless steels, the concept of chromium and nickel equivalents was developed to normalize the effect of these alloying additions on microstructural evolution, relative to chromium and nickel. Plotting the chromium and nickel equivalents on opposing axes provides a graphic depiction of the relationship between composition and microstructure for stainless steel welds. The Schaeffler diagram (Fig. 1) has become known as the "roadmap" of stainless steels. The compositional ranges of the ferritic, martensitic, austenitic, and duplex alloys have been superimposed on this diagram.

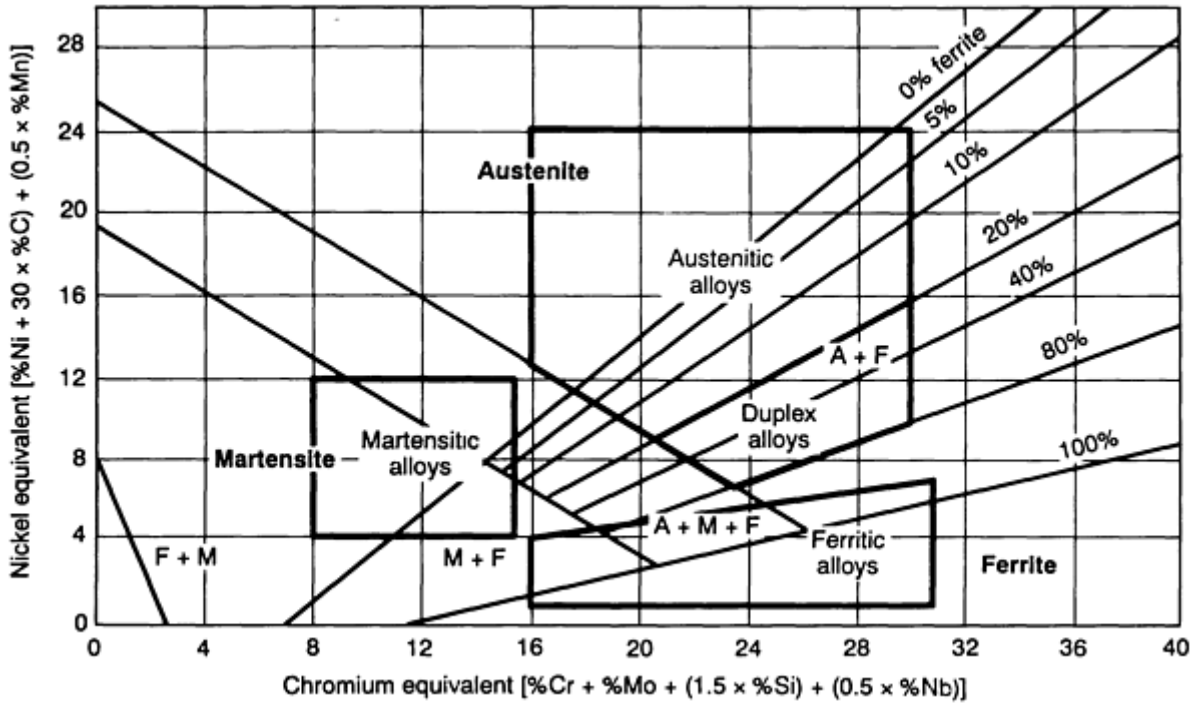

FIG. 1 SCHAEFFLER CONSTITUTION DIAGRAM FOR STAINLESS STEELS

The following articles describe the metallurgical aspects of welded stainless steels to be considered when selecting these materials for particular engineering applications and service conditions. Each article describes the microstructural evolution of the weld metal and the heat-affected zone, susceptibility to defect formation during welding, mechanical and corrosion properties, and weld process tolerance. In addition, each article lists the compositions and base metal properties for commercially available alloys. Information regarding filler metal selection and detailed process applications related to the joining of stainless steels can be found in the articles "Welding of Stainless Steels," "Brazing of Stainless Steels," and "General Soldering" in this Volume.

Selection of Wrought Martensitic Stainless Steels

J.R. Davis, Davis & Associates

Introduction

MARTENSITIC STAINLESS STEELS are essentially alloys of chromium and carbon that possess a body-centered cubic (bcc) or body-centered tetragonal (bct) crystal (martensitic) structure in the hardened condition. They are ferromagnetic and hardenable by heat treatments. They generally resist relatively mild corrosive environments.

The chromium content of these materials generally ranges from 11.5 to 18 wt%, and their carbon content can be as high as 1.2 wt%. The chromium and carbon contents are balanced to ensure a martensitic structure after hardening. Tables 1 and 2 list the chemical compositions for standard and nonstandard grades, respectively.

(C) GERMAN (DIN) SPECIFICATION

The most commonly used alloy within this stainless steel family is type 410, which contains about 12 wt% Cr and 0.1 wt% C to provide strength. The carbon level and, consequently, strength, increase in the 420, 440A, 440B, and 440C alloy series. The latter three alloys, in particular, have an increased chromium level in order to maintain corrosion resistance.

Molybdenum can be added to improve mechanical properties or corrosion resistance, as it is in type 422 stainless steel. Nickel can be added for the same reasons, as it is in types 414 and 431. When higher chromium levels are used to improve corrosion resistance, nickel also serves to maintain the desired microstructure and to prevent excessive free ferrite. The limitations on the alloy content required to maintain the desired fully martensitic structure restrict the obtainable corrosion resistance to moderate levels.

In the annealed condition, martensitic stainless steels have a tensile yield strength of approximately 275 MPa (40 ksi) and can be moderately hardened by cold working. However, martensitic alloys are typically heat treated by both hardening and tempering in order to yield strength levels up to 1900 MPa (275 ksi), depending on carbon level, primarily. These alloys have good ductility and toughness properties, which decrease as strength increases. Depending on the heat treatment, hardness values range from approximately 150 HB (80 HRB) for materials in the annealed condition to levels greater than 600 HB (58 HRC) for fully hardened materials (Fig. 1). Basic room-temperature properties of the martensitic types are given in Table 3. Typical physical properties of annealed martensitic stainless steels are listed in Table 4.

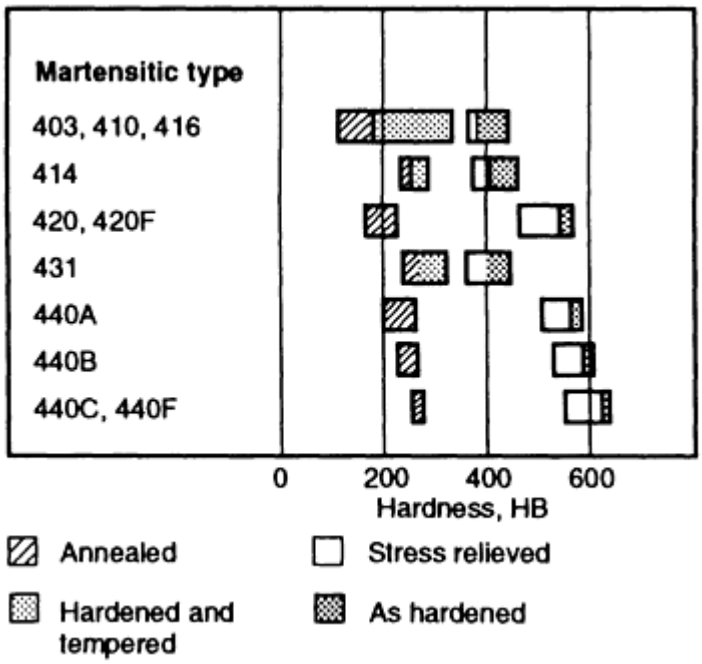

FIG. 1 RANGE OF HARDNESS IN VARIOUS MARTENSITIC STAINLESS STEELS

Martensitic stainless steels are specified when the application requires good tensile strength, creep, and fatigue strength properties, in combination with moderate corrosion resistance and heat resistance up to approximately 650 °C (1200 °F). In the United States, low- and medium-carbon martensitic steels (for example, type 410 and modified versions of this alloy) have been used primarily in steam turbines, jet engines, and gas turbines. Martensitic stainless steels are also used in petroleum and petrochemical equipment. Other applications for higher-carbon-level grades (type 440 grades) include cutlery, surgical and dental instruments, scissors, springs, valves, gears, shafts, cams, and ball bearings.

In Europe, these alloys have been used in similar applications. In addition, certain alloys, particularly 12Cr-1Mo-0.3V (HT9), have been widely used in elevated-temperature pressure-containment applications, including steam piping and steam generator reheater and superheater tubing used in fossil fuel power plants. The 12Cr-1Mo-0.3V alloy also has been investigated as a candidate material for the first wall of fusion reactors in both Europe and the United States (Ref 1, 2, 3, 4).

General Welding Characteristics

As mentioned above, the compositions of martensitic stainless steels are specifically formulated to render them amenable to a quench-and-temper heat treatment in order to produce high levels of strength and hardness. The response of martensitic stainless steels to the heattreat process is essentially the same as that of plain carbon or low-alloy steels, where maximum strength and hardness primarily depend on carbon content. Although the chromium level of approximately 11 to 18 wt% in martensitic grades is the same as in ferritic stainless steels, the higher carbon content of the martensitic grades results in a complete transformation from delta (δ) ferrite to austenite at high temperature (~980 °C, or 1800 °F), followed by a subsequent change to the hard martensite phase upon rapid cooling. The thermal cycle of heating and rapid cooling, which occurs within the confined heat-affected zone (HAZ) during welding, is equivalent to a quenching cycle.

The high-carbon martensitic structure that is produced is extremely brittle in the untempered condition. Cracking can occur when the heated weldment and the surrounding martensitic HAZ are unable to contract to the same degree and at the same rate as the weld metal. Preheat and postweld cooling rates are important vehicles for controlling these shrinkage stresses and will be further discussed later in this article. Because of their response to welding thermal cycles, martensitic stainless steels are considered to be the most difficult of the five stainless steel families to weld.

The extent to which HAZ hardening is present depends on the carbon content of the base metal. Higher carbon contents (>0.15%) will produce greater hardness and, therefore, an increased susceptibility to cracking. Thus, type 440A, B, and C stainless steels are not usually considered for applications that require welding, and filler metals are not readily available in type 440 compositions.

In addition to the problems that result from localized stresses associated with the volume change upon martensitic transformation, the risk of cracking will increase when hydrogen from various sources is present in the weld metal. Therefore, the use of low-hydrogen consumables is mandatory. Hydrogen-induced cold cracking in martensitic stainless steel weldments is also discussed in more detail later in this article.

Selection of Wrought Martensitic Stainless Steels

J.R. Davis, Davis & Associates

Weld Microstructure (Ref 2, 3, 4)

Detailed studies have been made on the transformation, tempering behavior, and resulting microstructures of martensitic stainless steel weldments. These studies were spurred by an interest in using 12Cr-1Mo-0.3V (HT9) martensitic stainless steel as a candidate material for the first wall/blanket of fusion-containment devices (Tokamaks), because of its improved resistance to swelling, low coefficient of thermal expansion (CTE), and high thermal conductivity relative to austenitic stainless steel (Ref 2).

During the welding of martensitic stainless steels, the fusion zone and that portion of the HAZ that is heated to a temperature higher than the austenitization temperature is transformed to a brittle, untempered martensite upon cooling to room temperature (Ref 4). Because the ductility, or fracture toughness, of the untempered martensite is inferior to that of the surrounding quenched-and-tempered microstructure, the material is unfit for service in the as-welded condition. Consequently, a postweld heat treatment (PWHT) must be employed to reduce the hardness and increase the toughness of the weld region. Recommended PWHT practices for martensitic stainless steels, including HT9, are described in the section "Specific Welding Recommendations" in this article.

The as-welded properties of the weld fusion zone and its response to PWHT can often be controlled by the appropriate choice of weld filler metal (Ref 4). However, the properties of the HAZ can be controlled only by the judicious selection of the welding process and process parameters, and by the use of a PWHT. As a result, the utilization of martensitic

stainless steels depends, to a large extent, on the ability of the user to understand and control the properties of the weld HAZ.

An extensive review of the microstructure and properties of the HAZ in martensitic HT9 weldments is provided by Lippold (Ref 2, 3, 4). In his studies, a variety of autogenous bead-on-plate gas-tungsten arc welds were evaluated using both light optical microscopy and microhardness techniques. Prior to welding, the base-metal plates were austenitized for 30 min at 1040 °C (1900 °F), followed by an air cool. Tempering was performed at 760 °C (1400 °F) for 1 h. The base-metal microstructure consisted of a mixture of tempered lath martensite and alloy carbides, as shown in Fig. 2.

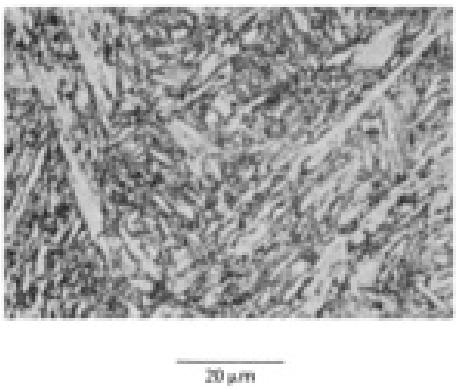

FIG. 2 QUENCHED-AND-TEMPERED BASE METAL (HT9) MICROSTRUCTURE, 22 TO 25 HRC. SOURCE: REF 2

The welding parameters used in these studies are listed in Table 5. The welding current was varied in the range from 100 to 225 A in order to produce weld heat inputs ranging from 0.71 to 2.13 kJ/mm (18 to 54 kJ/in.). The plates were clamped in a copper fixture during welding in order to stimulate the structural restraint experienced by actual components during fabrication.

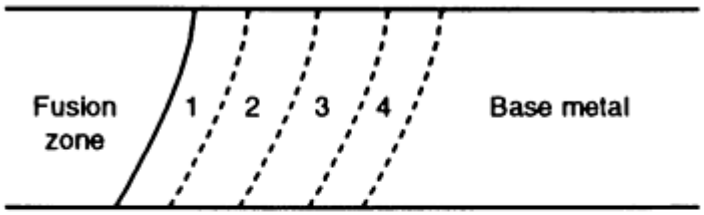
As shown in Fig. 3, the weld area consisted of the base metal (described above and shown in Fig. 2), the HAZ, and the fusion zone. Prior to tempering, the fusion zone microstructure comprised a mixture of untempered martensite and δ ferrite, as shown in Fig. 4.



Four HAZ regions:

1 γ + ferrite ⟶ martensite + ferrite
2 Coarse-grained γ ⟶ martensite
3 Fine-grained γ ⟶ martensite
4 Overtempered base metal

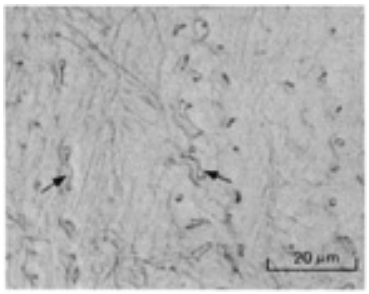

FIG. 4 AS-WELDED GAS-TUNGSTEN ARC FUSION ZONE MICROSTRUCTURE IN HT9 WELDMENTS. ARROWS INDICATE METASTABLE δFERRITE, WHICH CONSTITUTES APPROXIMATELY 2 TO 3 VOL% OF THE STRUCTURE. 1000×. SOURCE: REF 2

Four distinct regions were identified within the HAZ. These regions can be related to the phase fields on the iron-chromium-carbon equilibrium diagram shown in Fig. 5. The microstructures associated with these four regions are (Ref 4):

- *REGION 1,* WHICH IS A TWO-PHASE REGION ADJACENT TO THE FUSION LINE THAT CONSISTS OF UNTEMPERED MARTENSITE AND FERRITE. THE FERRITE FORMS ALONG PRIOR AUSTENITE GRAIN BOUNDARIES AS THIS REGION IS HEATED INTO THE AUSTENITE-PLUS-FERRITE PHASE FIELD (DESIGNATED 1 IN FIG. 3 AND 5).
- *REGION 2,* WHICH CONSISTS ENTIRELY OF UNTEMPERED MARTENSITE. AS THIS PORTION OF THE HAZ IS HEATED INTO THE HIGH-TEMPERATURE REGIME OF THE AUSTENITE PHASE FIELD, ALLOY CARBIDES FROM THE ORIGINAL BASE-METAL MICROSTRUCTURE COMPLETELY DISSOLVE, RESULTING IN A CARBIDE-FREE UNTEMPERED MARTENSITE THAT EXHIBITS A LARGE PRIOR AUSTENITE GRAIN.
- *REGION 3,* WHICH CONTAINS UNTEMPERED MARTENSITE INTERSPERSED WITH UNDISSOLVED ALLOY CARBIDES. BECAUSE THIS REGION EXPERIENCES A TEMPERATURE EXCURSION INTO THE LOWER REGIME OF THE AUSTENITE PHASE FIELD, CARBIDE DISSOLUTION IS INCOMPLETE AND THE PRIOR AUSTENITE GRAIN SIZE IS SMALLER RELATIVE TO REGION 2.
- *REGION 4,* WHICH CONSISTS OF TEMPERED MARTENSITE AND OVERAGED CARBIDES. IT APPEARS TO BE VIRTUALLY IDENTICAL TO THE BASE-METAL MICROSTRUCTURE.

Representative microstructures of these four regions are shown in Fig. 6.

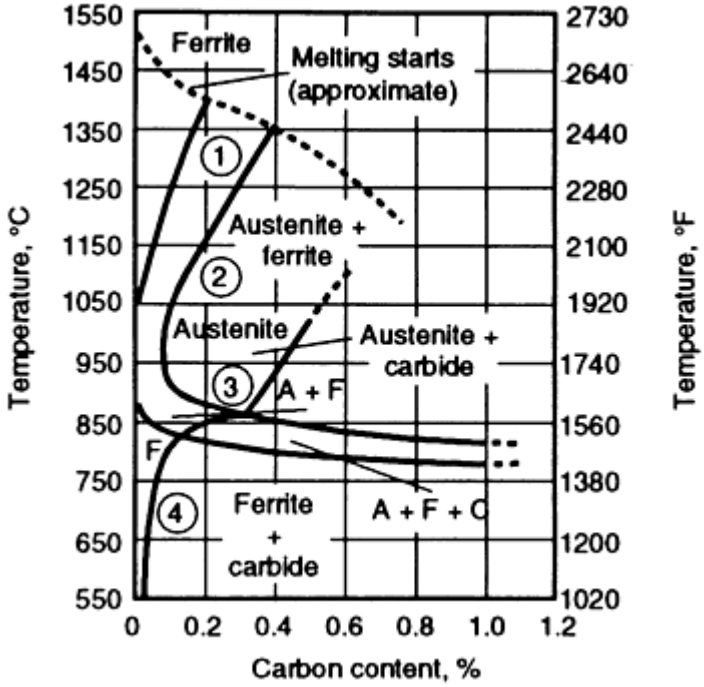

FIG. 5 IRON-CHROMIUM-CARBON PSEUDO-BINARY PHASE DIAGRAM FOR 12 WT% CR STEEL. CIRCLED NUMBERS REPRESENT THE FOUR HAZ REGIONS SHOWN IN FIG. 3 AND 6. SOURCE: ADAPTED FROM REF 5

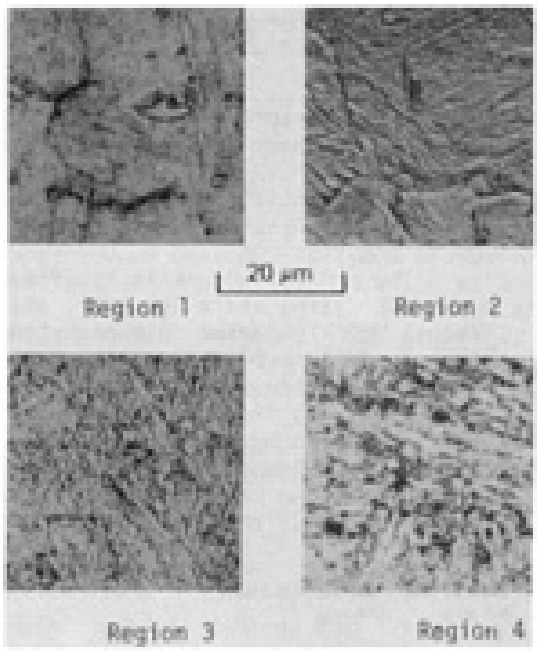

FIG. 6 GAS-TUNGSTEN ARC WELDED HAZ MICROSTRUCTURES IN HT9 WELDMENTS. SOURCE: REF 2

The microstructures in the HAZ can also be differentiated by means of a microhardness traverse, as shown in Fig. 7. The drop in hardness in Region 1 results from the presence of the softer ferrite phase situated at prior austenite grain boundaries within the untempered martensite matrix. The highest hardness in the HAZ occurs in the region where carbide dissolution is nearly complete. Because the hardness of the martensite is almost entirely a function of the carbon content of the prior austentite, Region 2 exhibits the peak HAZ hardness. Within Region 3, the carbon content of the austenite is

less, because of the incomplete dissolution of the carbides at lower austenitization temperatures. Therefore, the resultant microstructure, which consists of untempered martensite and residual carbides, is softer than the adjacent untempered microstructure (Region 2). The hardness decrease in Region 4 results from overtempering the base-metal microstructure at a temperature just below Ac_1 (the temperature at which austenite begins to form during heating), which is approximately 840 °C (1545 °F).

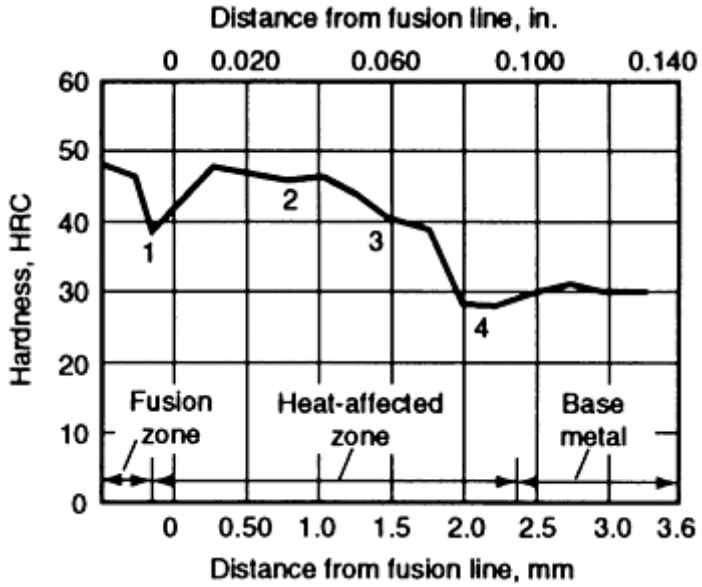

FIG. 7 MICROHARDNESS TRAVERSE ACROSS A GAS-TUNGSTEN ARC WELD IN HT9 STAINLESS STEEL (NO PREHEAT OR POSTHEAT TREATMENT). SOURCE: REF 3

Figures 8 and 9 demonstrate the effect of PWHT on the hardness and toughness, respectively, of the four HAZ regions described above. As shown in these figures, a PWHT of 760 °C (1400 °F) for 1 h produced superior results.

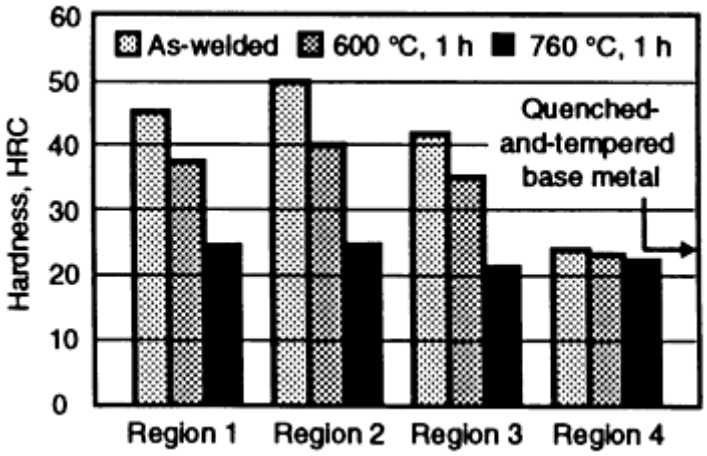

FIG. 8 HARDNESS AS A FUNCTION OF PWHT TEMPERATURE IN THE FOUR HAZ REGIONS OF HT9 WELDMENTS. SOURCE: REF 4

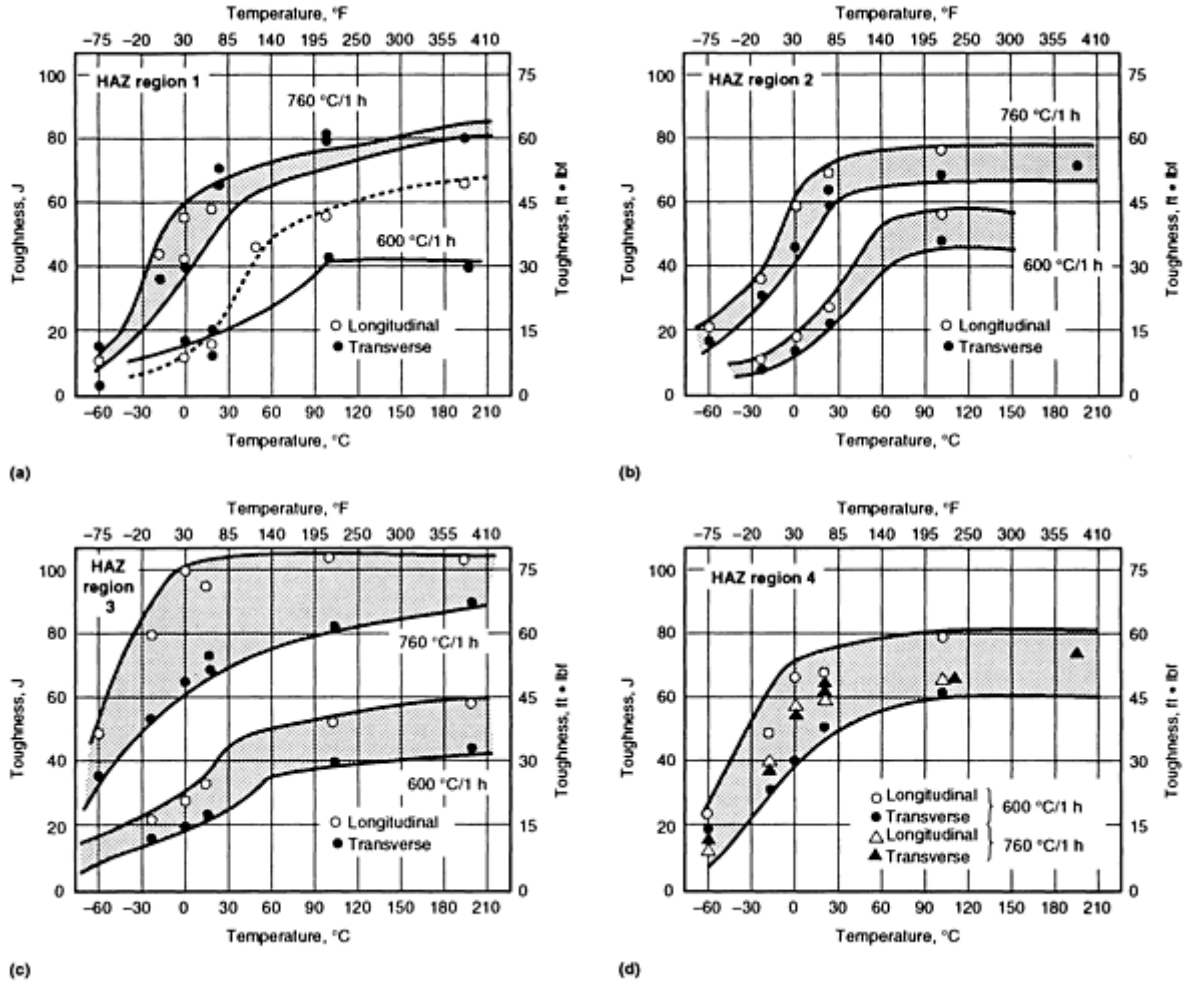

FIG. 9 EFFECT OF ORIENTATION AND PWHT ON THE TOUGHNESS OF HT9 WELDMENTS. (A) REGION 1. (B) REGION 2. (C) REGION 3. (D) REGION 4. SEE ALSO FIG. 3 AND 6. SOURCE: REF 4

Similar studies on HT9 have been carried out by Fenn and Jordan, with particular attention being given to δ ferrite formation (Ref 6). Maintaining a δ ferrite content that is as low as possible (< 10 vol%) is important, because a homogeneous martensitic structure that is free of δ ferrite islands results in a tougher weld. The investigations of these workers covered a variety of welding processes and a wide range of welding heat inputs, and involved real and simulated HAZ material.

Selection of Wrought Martensitic Stainless Steels

J.R. Davis, Davis & Associates

Weldability

Martensitic stainless steels can be welded in the annealed, hardened, and hardened-and-tempered conditions. Regardless of the prior condition of the steel, welding produces a hardened martensitic zone adjacent to the weld. In other words, the high-temperature HAZ will be in the "as-quenched" condition after welding, regardless of the prior condition of the material. In addition, the HAZ hardness is very much independent of the cooling rate over the temperature range experienced in common arc welding practices. This is evident from the isothermal transformation diagram shown in Fig. 10. Because such high hardness values render the material prone to cracking during fabrication, the selection of appropriate preheating levels and welding procedures is critical to the success of the welding process.

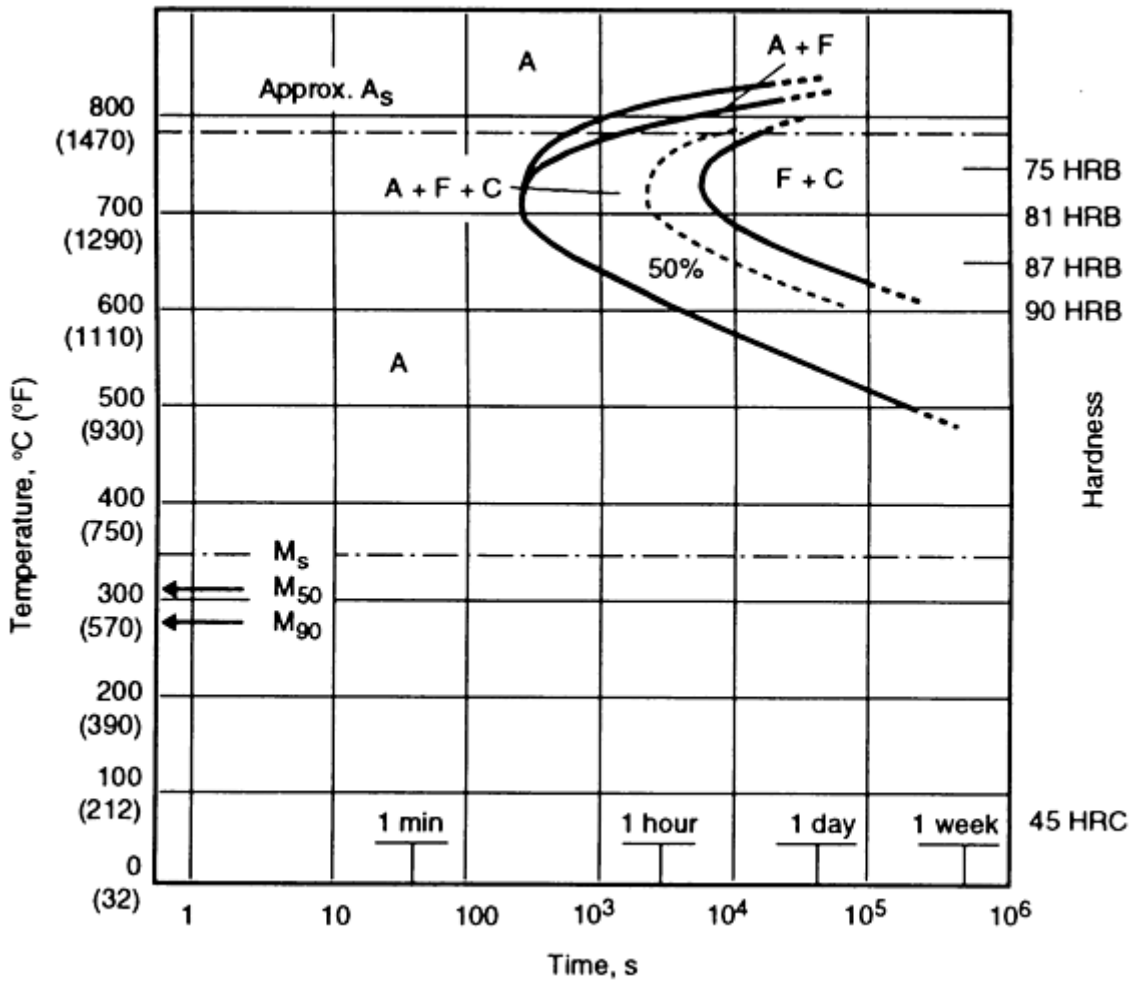

FIG. 10 ISOTHERMAL TRANSFORMATION DIAGRAM FOR TYPE 410 STAINLESS STEEL

Hydrogen-Induced Cold Cracking. Weld-area cracking in martensitic stainless steels is primarily due to the presence of hydrogen in the hardened structure (Ref 7). Hydrogen-induced cold cracks form in welds when the weldment is at or

near room temperature (typically, less than 150 °C, or 300 °F). Cracking may occur almost immediately or hours after cooling. In steel, cold cracks depend on the presence of a tensile stress, a susceptible microstructure, and sufficient hydrogen in the weld. Elimination of one or more of these factors greatly reduces crack susceptibility. The stress may arise from restraint by other components of a weldment or from the simple thermal stresses created by welding in a butt, groove, or "T" joint.

The susceptibility of the microstructure to cold cracking relates to the solubility of hydrogen and the possibility of supersaturation. Austenite, in which hydrogen is highly soluble, is least susceptible to cold cracking, and martensite, in which the solubility is lower, is most susceptible, because the rapid cooling necessary for the austenite-to-martensite transformation traps the hydrogen in a state of supersaturation in the martensite. Because the solubility of hydrogen in bcc martensite is low and diffusivity is high, austenitic filler metals are often selected to weld martensitic stainless steels. The discussion on filler metal selection later in this article provides more details.

The presence of hydrogen in a weld is generally due to moisture that is introduced in the shielding gas (or the electrode coating or flux), dissociated by the arc to form elemental hydrogen, and dissolved by the molten weld pool and by the adjacent region in the HAZ. In the supersaturated state, the hydrogen diffuses to regions of high stress, where it can initiate a crack. Continued diffusion of the hydrogen to the region of stress concentration at the crack tip extends the crack. This behavior means that hydrogen-induced cold cracking is time dependent--that is, time is needed for hydrogen diffusion--and the appearance of detectable cracks can be delayed until long after the weld has passed inspection. Additional information on the mechanisms of hydrogen cracking of weldments can be found in Ref 8 and 9.

For most commercial steels, the avoidance of hydrogen-induced cold cracking is based on the control of hydrogen (Ref 7). The sources of hydrogen (water, oils, greases, waxes, and rust that contains hydrogen or hydrates) should be eliminated. The hydrogen potential also can be minimized by using low-hydrogen, inert-gas welding processes, such as gas-tungsten arc welding (GTAW) or gas-metal arc welding (GMAW), or by paying stringent attention to consumable drying and baking for flux-shielded welding processes, such as shielded metal arc welding (SMAW) or flux-cored arc welding (FCAW). In addition, preheating must be applied to slow the rate of cooling. This allows more time for hydrogen to diffuse away from the weld area during cooling within the austenite range and, especially, following transformation to martensite.

Preheating is generally carried out in the temperature range from 200 to 300 °C (400 to 600 °F). In multipass welds, interpass temperatures must be maintained at the same level, and it is frequently beneficial to hold this temperature for some time after arc extinction to permit further hydrogen diffusion out of the joint. Postweld tempering is carried out to improve weld-area toughness. For higher-carbon steels (>0.2 wt% C), this process should be applied as soon as possible after welding to avoid the possibility of hydrogen-induced cracking from atmospheric corrosion. The weld must be cooled to a sufficiently low temperature to induce the austenite-to-martensite transformation (in principle, below the martensite completion point, M_f, as described below) prior to PWHT.

Material Composition and Selection of Preheat Temperature (Ref 10). The temperature at which austenite transforms to martensite upon cooling in martensitic stainless steels depends on material composition, particularly the carbon, manganese, nickel, chromium, and molybdenum contents. The martensitic start temperature, M_s, for such steels can be calculated using the following equation developed by The Welding Institute (Ref 11):

$$M_S = 540 - (497 \times \%C + 6.3 \times \%MN + 36.3 \times \%NI + 10.8 \times \%CR + 46.6 \times \%MO)\ ^\circ C \quad \textbf{(EQ 1)}$$

It should be noted that all of the elements listed above lower the M_s temperature.

Using Eq 1 for a type 410 stainless steel of the composition listed in Table 1, the M_s temperature is approximately 350 °C (660 °F). The temperature at which the transformation to martensite is complete, denoted by M_f, is approximately 100 °C (180 °F) below the M_s, that is, 256 °C (493 °F) for type 410. The preheat level should be below the M_f wherever possible, for example, 250 °C (480 °F) for type 410. However, if the M_f is less than about 150 °C (300 °F), as is the case with high-carbon (>0.2 wt% C) steels, it is not advisable to select a lower preheat level, because the embrittling effect of hydrogen can be significant at this temperature.

In most cases, the reason for choosing a preheat temperature below the M_f is to ensure that maximum transformation to martensite occurs. If this has not happened, then subsequent PWHT immediately after welding may be ineffective for two

reasons. First, the partially austenitic structure will retain hydrogen, which can lead to hydrogen cracking problems upon eventual cooling to room temperature, where untempered martensite with a high hydrogen concentration could form. Second, an isothermal transformation of the weld can take place during heat treatment, and the martensite that forms upon cooling to room temperature will be untempered and hard.

The major compositional factor influencing hydrogen-induced cold cracking is the material carbon content, because it determines the hardness of the transformed structure and its sensitivity to hydrogen embrittlement (Ref 7). Below levels of approximately 0.1 wt% C, and at least in thin sections (<5 mm, or 0.2 in.) it may be possible to weld without a preheat, if hydrogen levels are low. For materials with high carbon levels (above 0.2 wt% C), both a preheat and a PWHT are essential. Such materials are particularly difficult to weld, because the M_f temperature may be well below 150 °C (300 °F). In such cases, alloys are frequently welded with a preheat of 250 °C (480 °F), but are allowed to cool to an intermediate temperature of approximately 150 °C (300 °F) prior to a hydrogen release treatment or a full PWHT or both. For both low- and high-carbon martensitic stainless steels, it should be stressed that the weld should not be allowed to cool to room temperature after welding before either a full PWHT or a hydrogen release treatment is conducted.

Conventional martensitic stainless steels containing 12 wt% Cr and 0.15 wt% C have been successfully welded for many years, but a number of developments have reduced the risk of hydrogen-induced cold cracking. In terms of composition, this is best achieved by lowering the carbon content, except that this also reduces the hardenability of the material. Consequently, alloys that contain nickel have been produced in order to attain higher hardenability. The most common of these grades, particularly in Europe, is the 13Cr-4Ni-0.05C steels (Ref 12). Although the additional alloying reduces the M_s temperature, HAZ hydrogen-induced cold cracking resistance is substantially improved.

Selection of Wrought Martensitic Stainless Steels

J.R. Davis, Davis & Associates

Heat Treatment

Preheating is one of the most effective means of avoiding weld cracking in martensitic stainless steels. The preheating temperature usually ranges from 200 to 300 °C (400 to 600 °F). As discussed previously, the material composition (particularly the carbon content) affects the preheat temperature. The use of the M_s equation (Eq 1) is helpful in determining an acceptable preheat temperature.

Another consideration that influences preheating requirements is material thickness. As described above, the restraint imposed by material thickness is also one of the factors controlling hydrogen-induced cold cracking in any welded joint (Ref 10). If the weld metal or HAZ has been embrittled by the presence of hydrogen, then the level of restraint in the joint may determine whether cracking occurs. The general rule for joint thickness is that the thicker the material, the greater the

restraint, that is, the more material that is present, the greater the force opposing the dimensional changes in the weld area that is brought about through thermal and transformation stresses. In a repair weld situation that involves a groove, the restraint will be very high and a conservative approach is recommended. However, for a simple butt joint involving very thin material, for example, 3 mm (0.12 in.) or less, a preheat is generally considered unnecessary. This is particularly true with low-carbon (<0.10 wt% C) base metals. However, a preheating step is typically carried out.

Postweld Heat Treatment. The functions of a PWHT are to temper the martensite in the weld metal and HAZ, in order to reduce the hardness and increase the toughness, and to decrease residual stresses associated with welding. Postweld heat treatments used for martensitic stainless steels usually take one of two forms. The most common form involves tempering the weldment by heating it below the austenite-start temperature, A_s (Fig. 10). This is generally carried out at temperatures ranging from 650 to 750 °C (1200 to 1400 °F). The weldment should be held at temperature for a minimum of 1 h per inch of weld thickness (Ref 10). Another form of PWHT involves heating the weldment above the austenite-finish temperature, A_f, to austenitize the entire mass, and then cooling it back to just above room temperature, followed by a second heat treatment at a temperature below the A_s, in order to temper the metal to the desired properties. The latter PWHT is utilized only when matching filler metals are used and maximum joint toughness must be achieved.

In addition, a low-temperature PWHT is sometimes carried out to facilitate the diffusion of hydrogen from the joint and decrease the likelihood of hydrogen-induced cold cracking (Ref 10). This type of PWHT is carried out at, or slightly above, the preheat temperature range of, for example, 300 to 400 °C (550 to 750 °F). The 450 to 500 °C (840 to 930 °F) range should be avoided because it can compromise weld toughness.

Except for very small weldments or very-low-carbon base metals, martensitic stainless steels are not typically used in the as-welded condition. If a weldment of martensitic stainless steel must be used in the as-welded condition, then it is recommended that both autogenous welds and welds with matching filler metal be avoided.

Correlations of Heat Treatment and Carbon Content. The following correlations of preheating and PWHT practice with carbon contents and welding characteristics of martensitic stainless steels can be used:

- *CARBON CONTENT BELOW 0.10%:* NEITHER PREHEATING NOR PWHT IS REQUIRED EXCEPT FOR VERY HEAVY SECTIONS; MARTENSITIC STAINLESS STEELS WITH CARBON CONTENTS THIS LOW ARE NOT STANDARD
- *CARBON CONTENT 0.10 TO 0.20%:* PREHEAT TO 260 °C (500 °F); WELD AT THIS TEMPERATURE; SLOW COOL BELOW 65 °C (150 °F); TEMPER
- *CARBON CONTENT 0.20 TO 0.50%:* PREHEAT TO 260 °C (500 °F); WELD AT THIS TEMPERATURE; SLOW COOL BELOW 65 °C (150 °F); AUSTENITIZE AND TEMPER
- *CARBON CONTENT OVER 0.50%:* PREHEAT TO 260 °C (500 °F); WELD WITH HIGH HEAT INPUT; ANNEAL WITHOUT LETTING THE WELDMENT COOL BELOW 260 °C (500 °F); AUSTENITIZE AND TEMPER

Selection of Wrought Martensitic Stainless Steels

J.R. Davis, Davis & Associates

Filler-Metal Selection

On the basis of hydrogen-cracking risk, the use of austenitic filler metals is preferable to the use of martensitic consumables of "matching" composition, because the solubility of hydrogen in a bcc structure (martensite) is low and diffusivity is high, as noted earlier. This contrasts with the situation in fcc materials, such as austenite, where the

solubility is high and diffusivity is low (Ref 10). It follows that if a matching martensitic filler metal is employed, then the hydrogen introduced via the welding consumable (which occurs in every case, regardless of cleanliness) will diffuse into the adjacent HAZ, where it has the opportunity to embrittle the steel. However, if an austenitic filler metal is used, then the majority of hydrogen introduced through welding will remain in the austenitic weld metal, where its solubility is high. A high hydrogen concentration in the austenitic weld metal is unlikely to cause weld-metal hydrogen-induced cracking, because the embrittling effect of hydrogen is considerably less in a predominantly austenitic weld structure than it is in a martensitic one. Suitable austenitic filler metals used for welding martensitic stainless steels include AWS E/ER308, 309, and 310, or a duplex austenitic-ferritic filler metal, such as 312.

Matching filler metals are used when the strength of the weld metal must be similar to that of the base metal or when maximum weld toughness is specified. The availability of matching filler metals is a problem for some martensitic stainless steels. Only AWS E410 and 410NiMo types are available in covered-electrode form. These compositions, as well as AWS ER420, are available as solid wires. Chemical compositions of martensitic stainless steel filler metals are given in Table 6.

TABLE 6 ALL-WELD-METAL CHEMICAL COMPOSITIONS FOR MARTENSITIC STAINLESS STEEL FILLER METALS

AWS CLASSIFICATION	COMPOSITION, %

Specific Welding Recommendations

This section provides specific arc welding procedural recommendations for the more commonly welded martensitic stainless steels. The free-machining grades (types 416, 416Se, 420F, 440F, and 440FSe) are not included, because these enhanced-machining alloys are not recommended for welding. Weld data related to the welding of martensitic stainless steels are available from both alloy producers and manufacturers of welding equipment and consumables. For example, some of the data listed below were obtained from Carpenter Technology Corporation and from Sandvik. Such companies should be consulted prior to welding martensitic stainless steels.

Type 403 can be satisfactorily welded using AWS E/ER309 austenitic filler metal. If a martensitic consumable must be used, then either AWS E/ER410 or 410NiMo are acceptable. Parts should be preheated to at least 200 to 250 °C (400 to 450 °F) before welding to prevent cracking. Following welding, a PWHT of 650 to 750 °C (1200 to 1400 °F) should be conducted.

Because of the considerable cracking that can occur when welding thick sections (greater than 25 mm, or 1 in.) of type 403, a program designed to select the optimal filler metal to produce crack-free welds was conducted by Westinghouse Electric Corporation (Ref 13). This study compared the mechanical properties of AWS ER410 and 410NiMo gas-metal arc welds in 25 mm (1 in.) thick type 403 stainless steel (normalized and tempered to 585 MPa, or 85 ksi; 0.2% yield strength). Table 8 lists the welding parameters that were used in this study.

TABLE 8 PARAMETERS FOR GMAW OF TYPE 403 MARTENSITIC STAINLESS STEEL

	ELECTRODE	
	ER410NIMO	**ER410**

ARC CURRENT, A	460	420
TRAVEL SPEED, MM/S (IN./MIN)	3.8 (9)	5.0 (12)
ELECTRODE DIAMETER, MM (IN.)	2.38 ($\frac{3}{32}$)	2.38 ($\frac{3}{32}$)
SHIELDING GAS (ARGON), MM^3/S (FT^3/H)	600 (50)	600 (50)
PREHEAT, °C (°F)	NONE	200 TO 250 (400 TO 450)

Source: Ref 13

Weldments were tested using U-bend, tensile, stress-rupture, and Charpy V-notch tests. Results indicated that AWS ER410NiMo weldments exhibited superior tensile and impact properties (Fig. 11 and 12), but had lower stress-rupture values (Fig. 13).

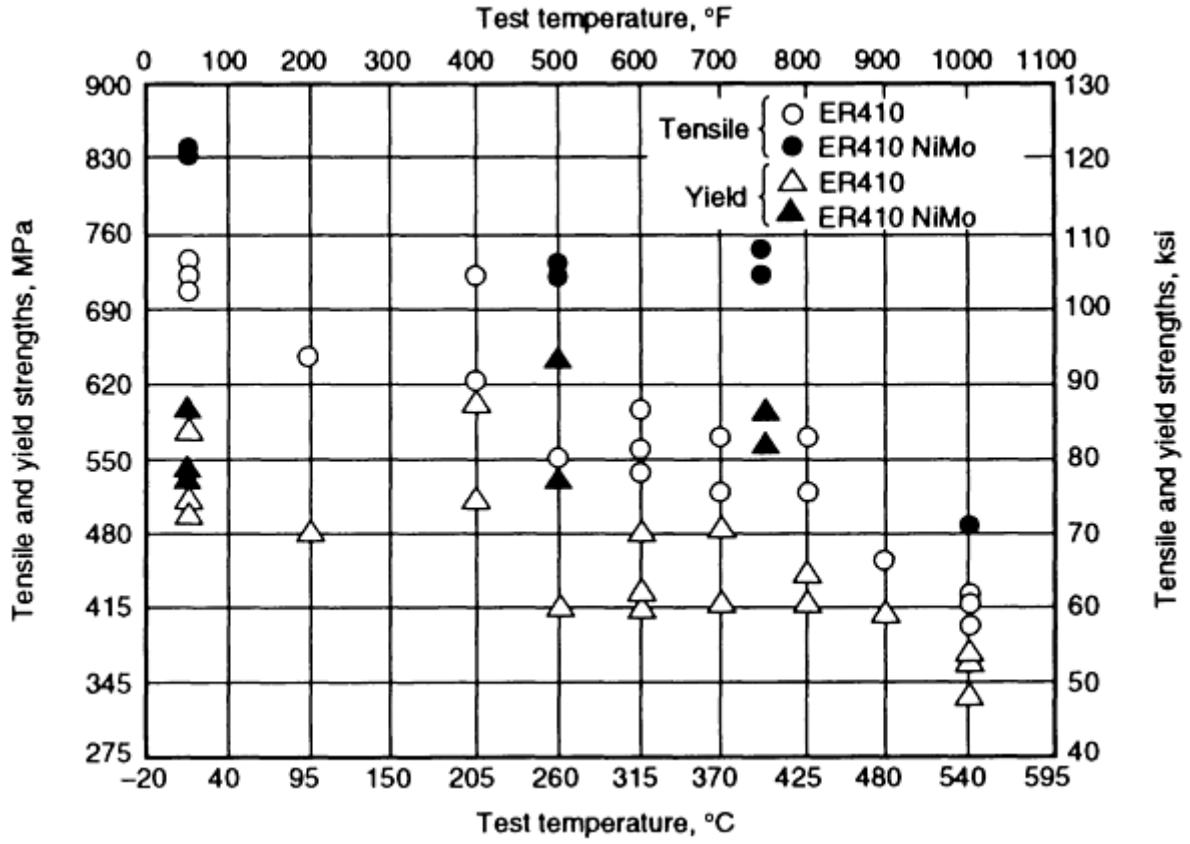

FIG. 11 STRENGTH VERSUS TEST TEMPERATURE FOR TWO MARTENSITIC STAINLESS FILLER METALS. SOURCE: REF 13

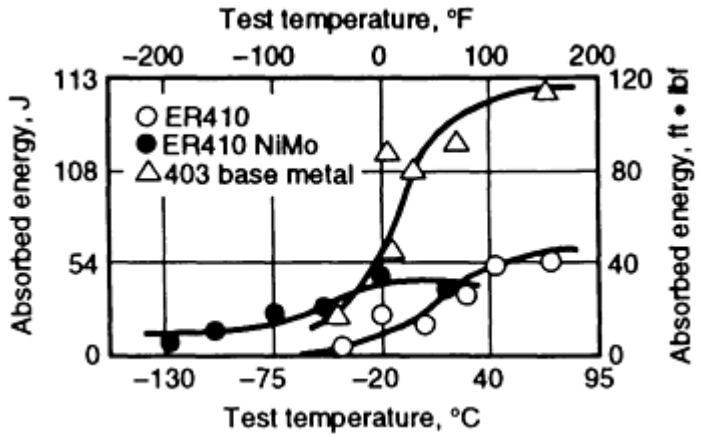

FIG. 12 CHARPY V-NOTCH VALUES VERSUS TEST TEMPERATURE FOR TWO MARTENSITIC STAINLESS STEEL FILLER METALS. SOURCE: REF 13

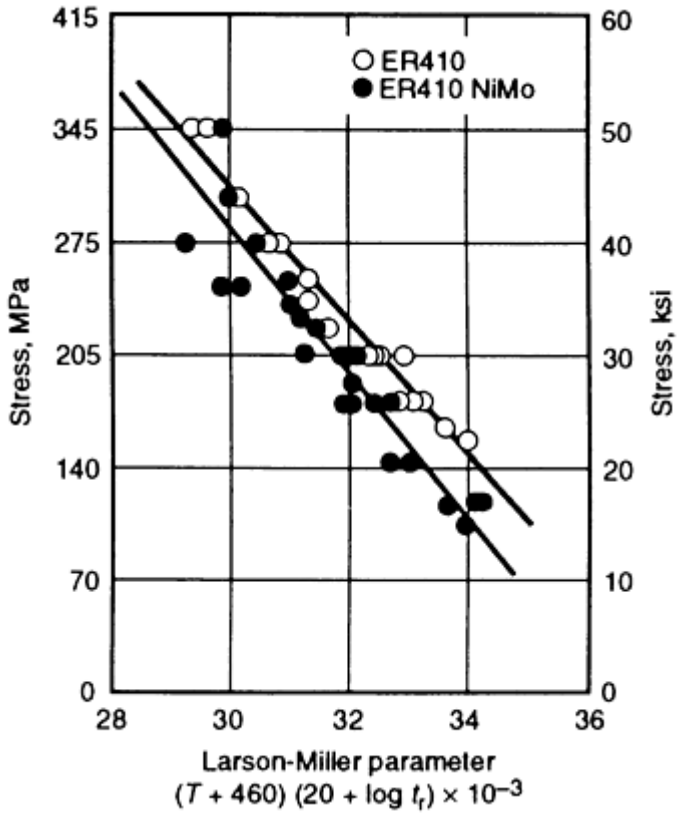

FIG. 13 RUPTURE STRESS AS A FUNCTION OF THE LARSON-MILLER PARAMETER FOR TWO MARTENSITIC STAINLESS STEEL FILLER METALS. SOURCE: REF 13

Type 410. The following recommendations for the arc welding of type 410 stainless steel are taken from Ref 10:

- PREHEAT TO 250 °C (480 °F) AND MAINTAIN THIS TEMPERATURE DURING WELDING. USE AN AUSTENITIC CONSUMABLE SUCH AS AWS E/ER308 OR 309. IF A STRONGER WELD IS DESIRED, AWS E/ER410 SHOULD BE USED.
- AFTER WELDING, ALLOW THE JOINT TO COOL TO THE PREHEAT TEMPERATURE, THAT IS, 250 °C (480 °F).
- BEFORE ALLOWING THE JOINT TO COOL TO ROOM TEMPERATURE, CONDUCT A TEMPERING OPERATION AT 720 °C (1330 °F) AND ALLOW APPROXIMATELY 1 H PER INCH OF THICKNESS, WITH A MINIMUM OF 1 H.
- COOL TO ROOM TEMPERATURE.

Type 414 can be welded using a filler metal of similar composition (AWS E/ER410 or 410NiMo) or an austenitic consumable (AWS E/ER309). Cracking is best prevented by preheating the part to at least 200 °C (400 °F) and maintaining that as a minimum interpass temperature. In addition, a PWHT that is in the range from 650 to 700 °C (1200 to 1300 °F) should be conducted.

Type 420. Satisfactory welds have been obtained in type 420 by preheating to a minimum of 200 °C (400 °F) before welding, followed by a PWHT of 675 to 750 °C (1250 to 1400 °F) (Ref 14). If a filler metal is required, then AWS ER420 should be considered when the mechanical properties of the weld are important. If the mechanical properties of the weld do not have to match those of the base metal, then AWS E/ER309 should be considered.

HT9 (12Cr-1Mo-0.3V) martensitic stainless steel can be welded using shielded-metal arc, gas-tungsten arc, or gas-metal arc welding processes (Ref 1). The joint should be preheated to a temperature between 200 and 400 °C (400 and 600 °F). In the case of multipass welds, an interpass temperature of 250 °C (480 °F) is specified to prevent the transformation to

untempered martensite that occurs upon cooling to room temperature. Finally, a PWHT in the temperature range from 740 to 780 °C (1365 to 1470 °F), for a period ranging from 30 min to 2 h, is required immediately following welding. If a filler metal is used, then consumables of matching composition should be selected.

Type 431 can be welded satisfactorily with most of the arc welding processes. If a filler metal is required, then one of a similar composition, such as AWS E/ER410, should be considered. An austenitic filler metal, such as AWS E/ER310, can also be used if the mechanical properties of the weld and the response to heat treatment are not required to be similar to those of the base metal. To prevent cracking of the weldment, it is necessary to preheat the base metal to a temperature between 200 and 300 °C (400 and 600 °F) and maintain a minimum interpass temperature of 200 °C (400 °F). After welding, the weldment should receive a PWHT at 650 °C (1200 °F).

Types 440A, B, and C. Because of their high carbon contents (0.6 to 1.2 wt% C, as listed in Table 1), these alloys are not generally considered to be weldable. However, successful welds using austenitic filler metals (AWS E312) have been made in type 440A stainless steel, which has the lowest carbon content of this group (0.60 to 0.75 wt% C). A case history outlining the proper gas-metal arc welding of type 440A stainless steel is given in the article "Welding of Stainless Steels" in this Volume.

Selection of Wrought Martensitic Stainless Steels

J.R. Davis, Davis & Associates

Non-Arc Welding Processes

Although arc welding processes (particularly GMAW, GTAW, and SMAW) are commonly used to join martensitic stainless steels, a variety of other joining methods also can be employed, such as laser- and electron-beam welding, resistance welding, flash welding, and friction welding. However, regardless of the method selected, a hard (untempered) weld microstructure results from the welding process, and the same PWHTs as those discussed above must be carried out.

Laser-Beam Welding. Although the lower heat input that is typical of laser welds results in faster cooling rates and steeper temperature gradients in the weld HAZ, the problems of high hardness and low toughness in the weld area persist. Lippold has studied the microstructure of laser-beam welded martensitic stainless steels (Ref 2). The microstructure along the fusion boundary consists almost entirely of untempered martensite. The HAZ consists of two distinct microstructural regions. The first region immediately adjacent to the fusion line consists entirely of untempered martensite and extends less than 0.25 mm (0.01 in.) from the fusion line. The microstructure that is more remote from the fusion line consists of untempered martensite and carbides. The as-welded hardness of both the fusion zone and HAZ range from 52 to 56 HRC. As a result, a postweld tempering treatment is necessary. Lippold has shown that the tempering response of martensitic stainless steel laser welds is similar to that of arc welded specimens. As shown in Fig. 14, tempering for 1 h at 800 °C (1470 °F) reduced the as-welded hardness of laser welds.

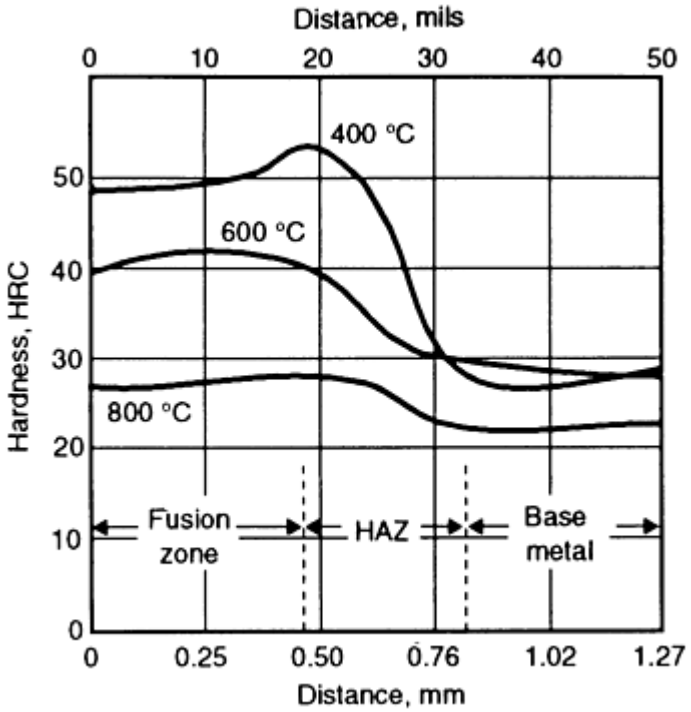

FIG. 14 TEMPERING BEHAVIOR OF HT9 LASER WELDS. SOURCE: REF 2

Lippold has also studied the effects of welding parameters on the quality of laser welds in HT9 martensitic steels (Ref 15). Laser welds were made in 6.35 mm (0.25 in.) thick HT9 plate using a variety of travel speed/focal length combinations at a constant power level of 6 kW. Welds made using low travel speed (1.27 mm/s, or 30 in./min), high heat input (0.47 kJ/mm, or 12 kJ/in.), and sharp focus produced sound welds. Welds performed at sharp focus with travel speeds ranging from 1.69 to 4.23 mm/s (40 to 100 in./min) and heat inputs decreasing from 0.35 to 0.14 kJ/mm (12 to 3.6 kJ/in.) exhibited scattered porosity and occasional centerline cracking that occurred during the final stages of solidification. Defocusing the laser beam relative to the plate resulted in welds containing severe porosity and centerline cracks. Microstructural and microhardness evaluation of the welds indicated that the region of highest hardness occurred in the HAZ immediately adjacent to the fusion line.

Laser-beam welds can be autogenous, or, alternatively, filler metals can be used. Martensitic stainless steels can be joined to each other or to dissimilar materials. For example, successful welds have been made between type 403 stainless steel and Inconel 600 using AWS A5.14 Class ENiCr-3 (Ni-20Cr-2.5Mn-2.25Nb) filler wire (Ref 16).

Electron-beam (EB) welding has been successfully conducted on modified 12 wt% Cr steels used for high-pressure, high-temperature components in power plants and in the chemical industry. In one study, EB welds were made to join 21 mm (0.83 in.) thick Fe-12Cr-1Mo plates (Ref 17). After tempering at 740 °C (1365 °F) for 2 h, the welds were investigated by Charpy V-notch and tensile tests at temperatures up to 550 °C (1020 °F). Impact properties of the EB welded joint were superior to those of submerged arc welded joints in the same alloy (Fig. 15) and exceeded those of the base metal. As is the case with laser-beam welds, the HAZ of the EB welds consisted of untempered martensite. A microhardness traverse across the weld revealed that the hardness in the fusion zone and HAZ region ranged from 300 to nearly 600 HV (30 to 55 HRC) (Fig. 16). Tempering subsequently lowered the hardness to below 300 HV.

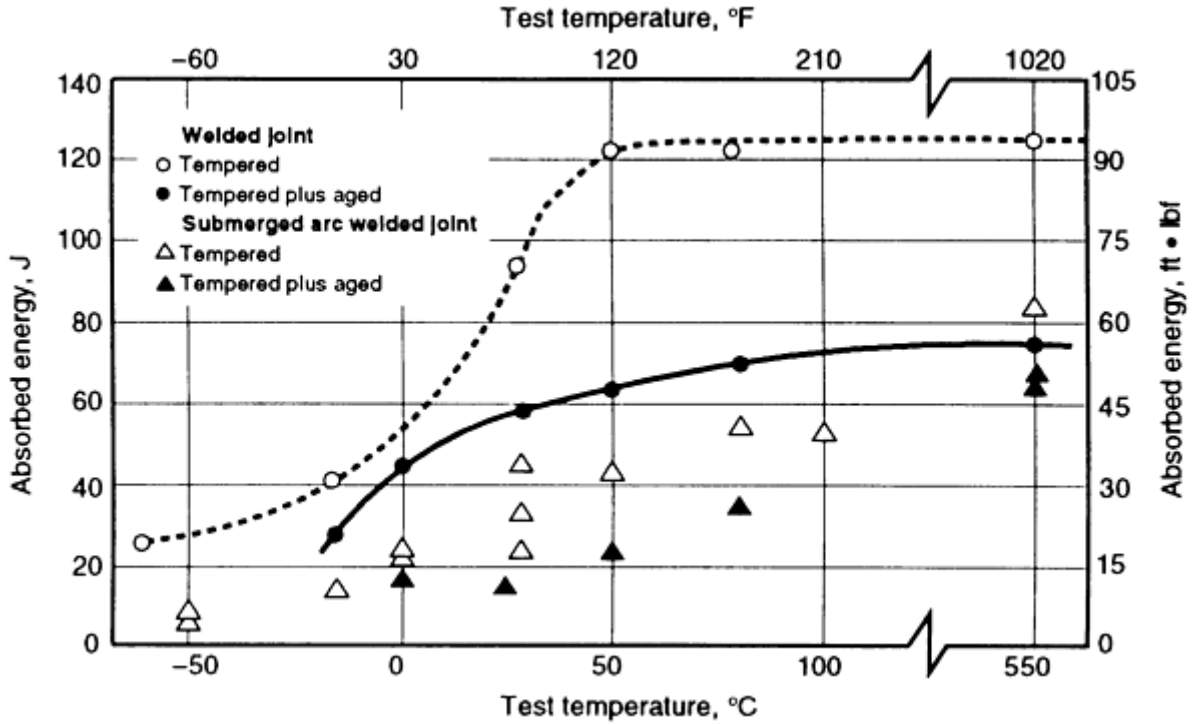

FIG. 15 CHARPY V-NOTCH DATA FOR WELD JOINTS OF EB WELDED ALLOY FE-0.2C-12CR-1MO PLATES, COMPARED WITH IMPACT DATA FOR SUBMERGED ARC WELDED JOINT USING A FILLER METAL SIMILAR TO FE-0.2C-12CR-1MO. Friction welding can be used to join martensitic stainless steels to themselves, as well as to other steels. As is the case with other welding processes, changes in hardness at and near the weld interface can be expected (Ref 18). Figure 17 shows changes in hardness of a welded joint made of JIS S45C (0.45 wt% C) carbon steel and type 440C stainless steel.

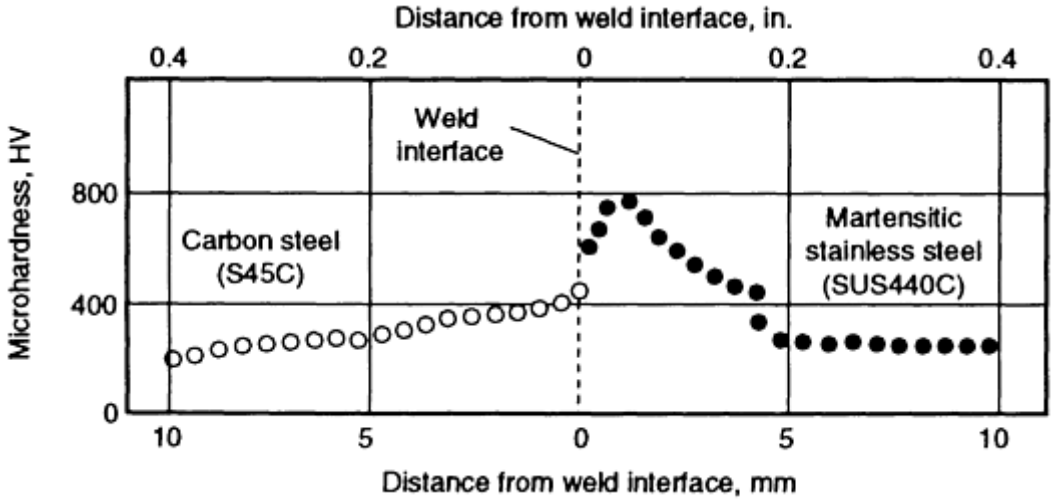

FIG. 17 CHANGES IN HARDNESS AT AND NEAR A FRICTION WELD INTERFACE. SOURCE: REF 18

Resistance Welding. Martensitic stainless steels can be spot welded in the annealed, hardened, or quenched-and-tempered conditions. Regardless of the initial base-metal hardness and the welding schedule, the HAZ adjacent to the weld nugget quenches to martensite. The hardness of the weld nugget and HAZ primarily depends on the carbon content of the steel, although it can be controlled somewhat with preheat, postheat, and tempering during the spot-welding cycle. The likelihood of cracking in the HAZ increases with the carbon content of the steel.

Flash Welding. As is the case with resistance spot welding, a hard HAZ is formed during the flash welding of martensitic stainless steels. This hard HAZ can be softened somewhat by a tempering cycle in the welding machine. A PWHT will produce welds with properties approximately equal to those of the base metal (Ref 19).

Selection of Wrought Ferritic Stainless Steels

K.F. Krysiak, Hercules, Inc.; J.F. Grubb, Allegheny Ludlum Corporation; B. Pollard; R.D. Campbell, Joining Services, Inc.

Introduction

FERRITIC STAINLESS STEELS comprise approximately one-half of the SAE-AISI-type 400-series stainless steels. These steels contain from 10.5 to 30% Cr along with other alloying elements, notably molybdenum. Ferritic stainless steels are noted for their excellent stress-corrosion cracking (SCC) resistance and good resistance to pitting and crevice corrosion in chloride environments.

Following a discussion on how ferritic stainless steels can be classified, this article will review the metallurgical characteristics of various ferritic grades as well as the factors that influence their weldability. Emphasis will be placed on arc welding processes. Additional information on ferritic stainless steels can be found in the companion article "Welding of Stainless Steels" in this Volume.

Selection of Wrought Ferritic Stainless Steels

K.F. Krysiak, Hercules, Inc.; J.F. Grubb, Allegheny Ludlum Corporation; B. Pollard; R.D. Campbell, Joining Services, Inc.

Classification of Ferritic Stainless Steels

The ferritic stainless steels can be classified into three groups. These include: Group I alloys, which are the standard ferritic stainless steels; Group II alloys, which are modified versions of the standard alloys; and Group III alloys, which contain very low interstitial element (carbon, nitrogen, and oxygen) contents or stabilizing elements for improved corrosion resistance and ductility in the as-welded condition.

Group I Alloys. Ferritic stainless steels of the 400-series Group I variety have been available for many years and are used primarily for their resistance to corrosion and scaling at elevated temperatures. Table 1 lists chemical compositions of standard-grade Group I ferritic stainless steels. While these alloys have useful properties in the wrought condition, welding is known to reduce toughness and ductility and corrosion resistance because of grain coarsening and formation of martensite (Ref 1). Welding these commercial grades usually requires preheat and postweld heat treatment. For these reasons, the application of the 400-series Group I ferritic stainless steels is not as extensive as it might otherwise be, compared with the 300-series austenitic stainless steels, which enjoy ease of weldability.

Group II Alloys. To overcome some of the difficulties and to improve weldability, several of the standard grade ferritics have been modified. These Group II ferritic stainless steels which contain lower levels of chromium and carbon, along with additions of ferrite stabilizers, are listed in Table 2. Applications of these alloys involve exposure to high temperatures, such as for quenching racks and annealing boxes, and also for tanks for agricultural sprays, transformer cases, and automotive applications.

(B) TYPICAL VALUE

For example, type 405, containing nominally 12% Cr, is made with lower carbon and a small aluminum addition of 0.20% to restrict the formation of austenite at high temperature so that hardening is reduced during welding. For maximum ductility and corrosion resistance, however, postweld annealing is necessary (Ref 2). Recommendations for welding include either a 430- or a 309-type filler metal, the latter being used when increased weld ductility is desired.

Type 409 is one of the most widely used ferritic stainless steels. This alloy, which has a titanium addition, is used extensively in automotive exhaust systems and is often welded using the resistance welding processes.

Group III Alloys. In the late 1960s and early 1970s, researchers recognized that highly alloyed (higher chromium and molybdenum contents) ferritic stainless steels possessed a desirable combination of resistance to general corrosion, pitting, and SCC (Ref 3, 4, 5, 6, 7, 8, 9, 10). These properties made them attractive alternatives to the 300-series austenitic stainless steels that are commonly plagued by failure as a result of chloride SCC. It was reasoned that by controlling the interstitial element content (carbon, C, nitrogen, N, and oxygen, O) of these new ferritic alloys, either by ultrahigh purity processing methods or by stabilization, the formation of martensite could be eliminated, as well as the need for preheat and postweld heat treatment, so that welds would be corrosion resistant, tough, and ductile in the as-welded condition. To achieve these results, electron-beam vacuum refining, vacuum and argon-oxygen decarburization (AOD), and vacuum induction melting processes were used. From this beginning, two basic ferritic stainless alloy systems evolved.

Ultrahigh-Purity Group III Alloys. Ferritic alloys that have an interstitial element (C + N) content less than 150 ppm are termed ultrahigh purity. Examples of these alloys, shown in Table 3, are available commercially. These alloys are produced by either electron beam vacuum refining, vacuum induction melting (VIM), or vacuum oxygen decarburization

(VOD). Plate is available up to 13 mm ($\frac{1}{2}$ in.) in thickness. Purity is especially important with the higher-chromium alloys because of the effect on ductility, toughness, and weldability. Although not mentioned in the chemistry specification for these alloys, oxygen and hydrogen are particularly harmful, and their levels must also be carefully restricted. A modest amount of niobium (columbium) is added to some of these alloys to preserve corrosion resistance in the welded condition.

(A) SINGLE VALUES ARE MAXIMUM UNLESS OTHERWISE STATED.

(B) TYPICAL VALUE

Intermediate-Purity Group III Alloys. When the (C + N) interstitial element content exceeds 150 ppm (but is less than 800 ppm), ferritic alloys are considered to be of intermediate purity. Alloys listed in Table 4 are available commercially and are produced typically by the AOD process. Because these steels have higher carbon and nitrogen contents, their ductility and toughness are inferior to those of the ultrahigh-purity alloys. For this reason, metal thickness is limited to a maximum of approximately 3 mm ($\frac{1}{8}$ in.) where toughness is adequate. In order to maintain acceptable corrosion resistance in the as-welded condition, titanium and/or niobium are added to tie up the carbon and nitrogen that otherwise would combine with the chromium to form chromium carbides and nitrides, which can lead to preferential intergranular attack in many environments. This form of attack is most readily observed in the weld heat-affected zone (HAZ). Although niobium and titanium are both stabilizers, they are not equivalent. Autogenous welds in titanium-containing alloys typically exhibit an equiaxed grain region near the weld centerline. Alloys stabilized only with niobium typically show a columnar weld structure with a sharply defined centerline and a propensity for weld cracking. To avoid this, one must: (1) keep the carbon content below 0.01%, (2) keep the niobium content below 0.1%, and (3) add titanium in amounts greater than 0.1%.

(A) SINGLE VALUES ARE MAXIMUM VALUES UNLESS OTHERWISE STATED.

(B) TYPICAL VALUE

Although it was claimed that the ultrahigh-purity alloys were costly to produce, many users found that the cost differential of similar alloys produced by the AOD melting practice was not economical enough to warrant purchase of these alloys in preference to similar alloys of ultrahigh purity, especially considering the inferior ductility and toughness of welded AOD-refined materials.

Metallurgical Characteristics

All of the ferritic stainless steels ideally possess the body-centered cubic (bcc) crystal structure known as ferrite at all temperatures below their melting temperatures (Fig. 1). Many of these alloys are subject to the precipitation of undesirable intermetallic phases when exposed to certain temperature ranges. The higher-chromium alloys can be embrittled by precipitation of the tetragonal sigma (σ) phase, which is based on the compound FeCr. Sigma phase has a lower temperature limit of formation (about 440 °C, or 825 °F). The σ solvus for the E-Brite alloy (see Table 3) is relatively low, probably less than 675 °C (1250 °F), and σ formation at low temperatures is sluggish. As a result, σ precipitation is rarely an issue for the E-Brite alloy during welding. The presence of increased chromium and molybdenum contents in other ultrahigh-purity ferritic stainless steels raises their σ solvus temperatures to approximately 1000 °C (1830 °F). Molybdenum also promotes formation of the complex cubic chi (χ) phase, which has a nominal composition of $Fe_{36}Cr_{12}Mo_{10}$. Sigma and χ phases are also stabilized by titanium. In the alloys other than E-Brite, these intermetallic phases form most rapidly at about 850 °C (1560 °F) and these alloys must consequently be cooled rapidly after annealing. Service exposure of welded ferritic alloys containing high levels of chromium and molybdenum should avoid these temperature ranges.

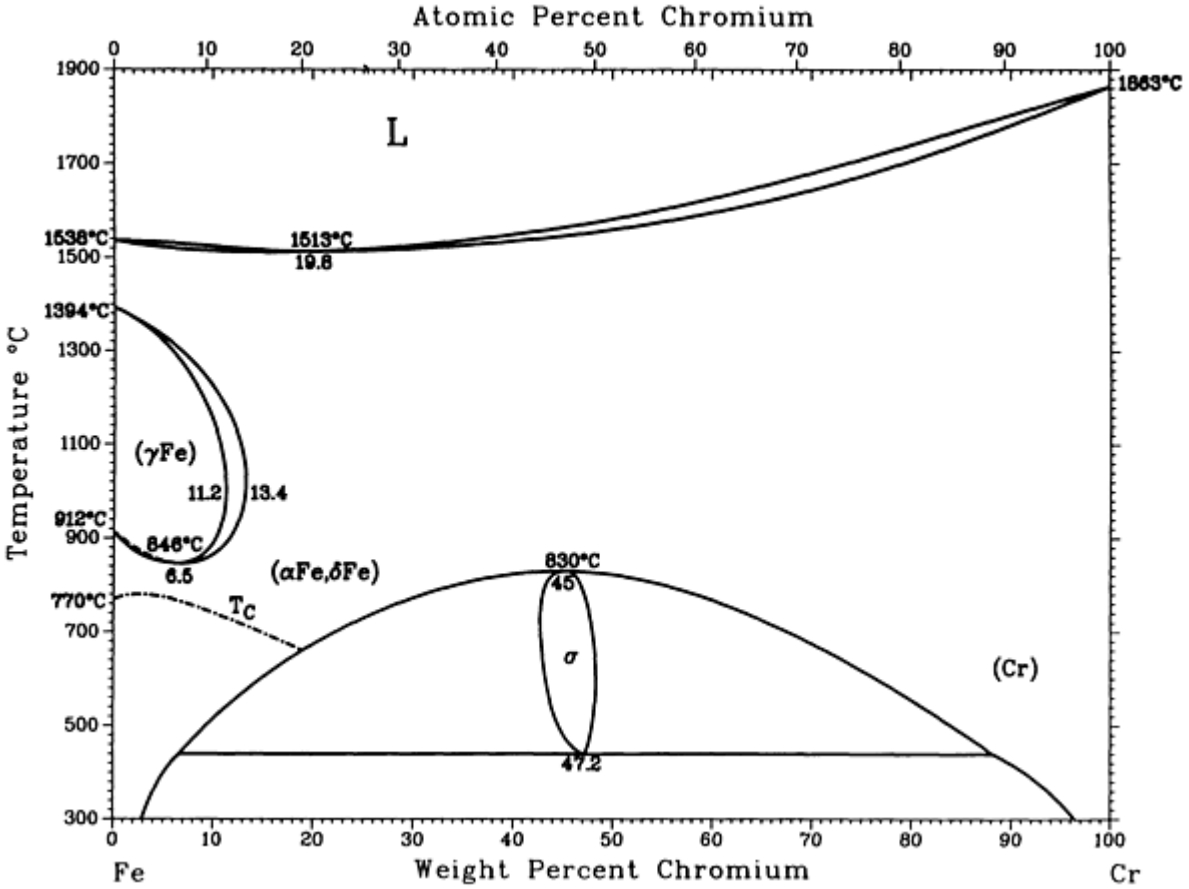

FIG. 1 THE IRON-CHROMIUM PHASE DIAGRAM. SOURCE: ASM/NIST PHASE DIAGRAM PROJECT

All of the ferritic stainless steels with chromium contents higher than 12% are also subject to embrittlement when exposed in the 370 to 550 °C (700 to 1200 °F) range. This embrittlement is most rapid at about 475 °C (885 °F) and is usually called "885 °F (475 °C) embrittlement." The rate of 475 °C (885 °F) embrittlement increases with increasing chromium plus molybdenum contents. It is generally agreed that the severe embrittlement which occurs upon long-term exposure at these temperatures is due to the decomposition of the iron-chromium ferrite phase into a mixture of iron-rich alpha (α) and chromium-rich alpha-prime (α') phases. This embrittlement is thus often called "alpha-prime embrittlement." Additional reactions such as chromium carbide and nitride precipitation may play a significant role in the more rapid, early stages of 475 °C (885 °F) embrittlement. Short-term heat treatments at 620 to 650 °C (1120 to 1210 °F) can often alleviate 885 °F embrittlement, and 885 °F embrittlement can always be cured by a full anneal heat treatment followed by rapid cooling.

The ferritic stainless steels have higher yield strengths and lower ductilities than austenitic stainless steels. Like carbon steels, and unlike austenitic stainless steels, the ferritic stainless alloys exhibit a transition from ductile-to-brittle behavior (Fig. 2) as the temperature is reduced, especially in notched impact tests. The ductile-to-brittle transition temperature (DBTT) for the ultrahigh-purity ferritic stainless steels is lower than that for type 430 and similar standard ferritic stainless steels. It is typically well below room temperature. The DBTT for the intermediate-purity stabilized ferritic stainless steels is similar to that for type 430 stainless steel. Since the DBTF decreases as metal thickness decreases, the stabilized alloys are available commercially only as sheet, strip, and light-wall tubing. The high-purity grades, because of their superior toughness, are available in thicker gages up to at least 6 mm ($\frac{1}{4}$ in.) plate. Nickel additions lower the DBTT and somewhat increase the thicknesses compatible with high toughness; nonetheless, with or without nickel, the ferritic stainless steels are not suitable for heavy-section applications.

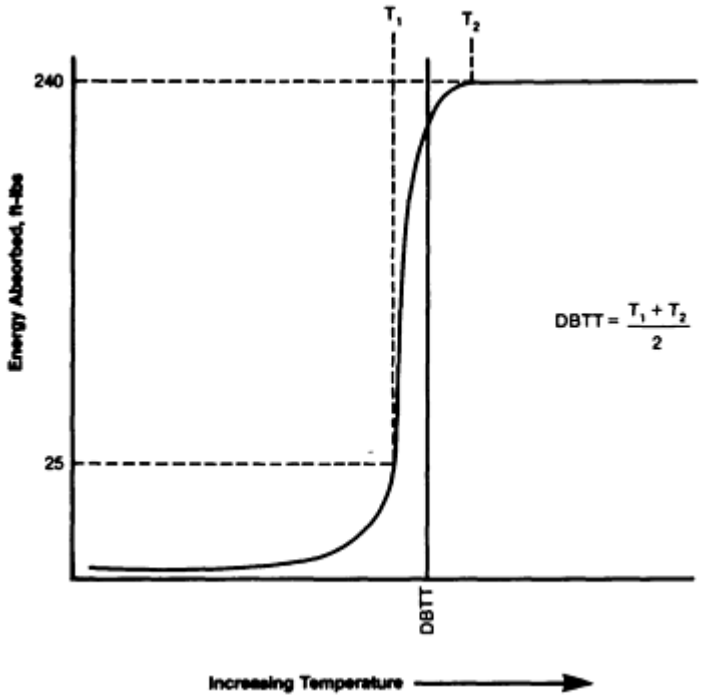

FIG. 2 SCHEMATIC OF THE DUCTILE-TO-BRITTLE IMPACT TOUGHNESS BEHAVIOR IN FERRITIC STAINLESS STEELS

In addition to the significant influence of section size (that is, thickness or mass) on the impact toughness of ferritic stainless steels, these alloys are cooling-rate sensitive (Ref 3). This effect is illustrated in Fig. 3. Depending on the cooling rate, precipitates of carbides and nitrides will tend to align along the grain boundaries or be randomly distributed in the matrix. Thus, grain size is an important factor relative to ductility and toughness. The finer the grain size, the higher the impact energy, just as in carbon or low-alloy steels.

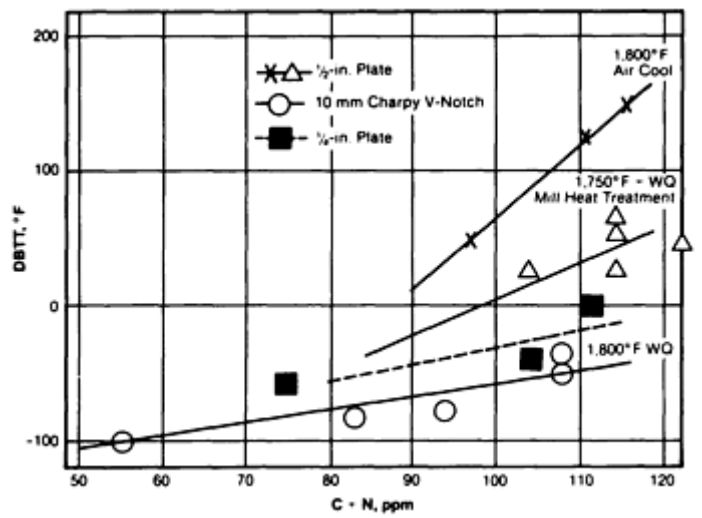

FIG. 3 THE DUCTILE-TO-BRITTLE TRANSITION TEMPERATURE (DBTT) AS A FUNCTION OF (C + N) CONTENT AND THERMAL TREATMENT. WC, WATER COOLED

Hunter and Eagar (Ref 11) investigated the mechanism of ductility loss in type 444 ferritic stainless steel (UNS S44400) welds stabilized with niobium and, in particular, titanium. It was found that stabilizing TiN or Nb(C,N) precipitates are

dissolved during the autogenous gas-tungsten arc welding process resulting in a finer distribution of precipitates in the weld metal during solidification than in the base metal. The fracture appearance transition temperature (FATT) was studied using an Olsen cup test and was found to increase by almost 200 °C (360 °F) leading to decreased room-temperature ductility. Such an increase in FATT was not explainable solely in terms of grain growth. It was proposed that these finer precipitates were likely to contain chromium as well as titanium and niobium. The combination of chromium with the nitrogen releases more free titanium, which may have an embrittling effect.

Earlier, Pollard (Ref 12) studied the ductility of ferritic stainless steel weld metal in the 26 to 35% Cr range. He concluded that the most practical methods for maximizing the ductility of welds in ferritic stainless steels in gage thicknesses of at least 6 mm ($\frac{1}{4}$ in.) are:

- KEEP THE LEVEL OF BOTH SUBSTITUTIONAL AND INTERSTITIAL ALLOYING ELEMENTS AS LOW AS POSSIBLE
- MAKE ADDITIONS OF STRONG CARBONITRIDE-FORMING ELEMENTS (LOGICALLY AS LOW AS POSSIBLE)

Weldability

The term "weldability" is defined here as meaning the ease with which sound welds can be made and the suitability of these welds to perform satisfactorily in service. It is necessary, therefore, that weldability include both the mechanical aspects, such as strength, ductility, and Charpy V-notch (CVN) impact toughness, and the corrosion aspects, such as resistance to intergranular attack (IGA), SCC, and general overall corrosion resistance.

The relative performance and weldability of ferritic alloys can best be determined by comparing the impact fracture behavior of these steels. Furthermore, impact testing of the HAZ as well as the weld should be included when qualifying both the welding procedure specification(s) and the welder for these materials. In addition to the CVN impact energy (which includes examination of the DBTT), the lateral expansion and percent shear fracture of CVN specimens also should be a part of a thorough analysis of weldability.

Over the years, two schools of thought have existed on how to weld the Group III ferritic stainless steels. One school recommends welding these alloys as one would the austenitics (this is not acceptable), and the other endorses using extra care and special techniques somewhat like those used to weld titanium. Extra care and special techniques are mandatory for Group III alloys. While the Group I alloys also require care, the welding of the Group II alloys is rather routine.

During the early to mid-1970s, a reluctance developed on the part of many users and fabricators to follow recommended procedures (Ref 13). As a result, many welds were produced that had inferior corrosion resistance, ductility, and impact

toughness. Because of these problems, the weldability of the new ferritics was explored by many (Ref 14, 15, 16, 17, 18, 19, 20).

The unique as-welded properties of the Group III ferritics have been made possible by obtaining either very low levels of impurities, including carbon, nitrogen, and oxygen (ultrahigh-purity Grade III alloys), and a careful balance of niobium and/or titanium to match the carbon, nitrogen, and oxygen contents (intermediate-purity Group III alloys). For these reasons, every precaution must be taken and welding procedures must be selected that optimize gas shielding and cleanliness to avoid pickup of carbon, nitrogen, oxygen, and hydrogen.

Autogenous welds in ferritic stainless steels exhibit relatively simple microstructures. The grain size gradually increases from the edge of the heat-affected zone (HAZ) to the fusion boundary. In unstabilized or niobium-stabilized welds, columnar grains extend from the fusion boundary to meet at well-defined centerline (Fig. 4). In titanium-stabilized or dual-stabilized welds (niobium and titanium), there is typically a transition from columnar grains near the fusion boundary to equiaxed grains near the weld centerline (Ref 23, 24). The former structure shows a greater tendency for hot cracking (Ref 47).

With lower chromium or high-carbon-content ferritic stainless alloys, such as types 409, 430, 434, 442, and 446, martensite formation during welding can occur as illustrated in Fig. 5. In the as-welded condition, the DBTT will easily be above room temperature with increased susceptibility to weld cracking during and after cooling from the molten state. Caution is advised when making welds under high restraint or in heavier section sizes. Preheat can be used under these conditions to slow the cooling rate and minimize stresses that can lead to cracking.

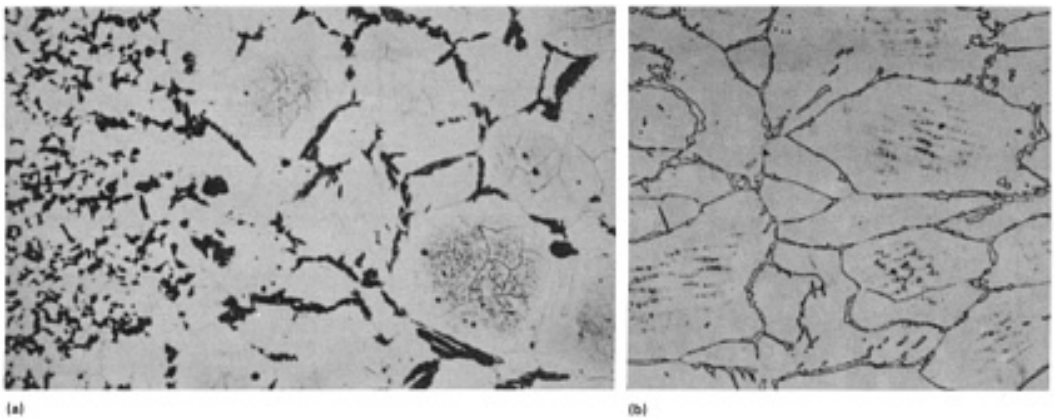

FIG. 5 GRAIN BOUNDARY MARTENSITE FORMATION IN A TYPE 430 FERRITIC STAINLESS STEEL GAS-TUNGSTEN ARC WELD. (A) FUSION ZONE. 100×. (B) HEAT-AFFECTED ZONE. 150×. SOURCE: REF 47, 48

A further word of caution is advised regarding selection of preheat and welding parameters. One must not forget that while higher heat inputs and preheats can reduce weld cracking in some ferritic stainless steels, grain growth in the weld HAZ can occur. Figure 6 shows grain growth in an ultrahigh-purity Fe-28Cr-2Mo alloy in the base metal and HAZ. Excessive grain growth can produce loss in fracture toughness, ductility, and corrosion resistance.

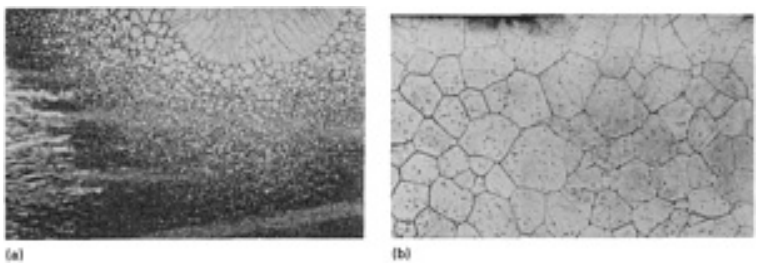

FIG. 6 CROSS SECTIONS OF PARTIAL PENETRATION GAS-TUNGSTEN ARC WELDS IN HIGH-PURITY FE-28CR-5MO FERRITIC STAINLESS STEEL. (A) WELD IN WARM-ROLLED SHEET. (B) WELD IN SHEET WHICH WAS PREWELD ANNEALED AT 1040 °C (1900 °F) FOR 60 MIN. ETCHED IN 40% NITRIC ACID ELECTROETCH. 11×

Under some conditions, annealing after welding can be performed to eliminate martensite, however the ferrite grains that have coarsened may grow even more. Generally annealing after welding is costly, can cause distortion, and usually is not practical in the field. Annealing of tubular products at the steel mill is the exception and is performed as standard procedure. This tube annealing is performed at high rates and is followed by quenching.

Regardless of which welding process is used, joint preparation and thorough solvent degreasing (using a solvent that does not leave a residue) on both sides of the joint (inside and outside) are of paramount importance.

Welding Processes

Gas-Tungsten Arc Welding (GTAW). When welding with the GTAW process, direct current electrode negative (DCEN), or straight polarity should be used. A tungsten-2% thoria electrode (AWS classification EWTh-2) with a tapered tip is recommended. Oxidation of the electrode tip or filler metal pickup are not acceptable as they reduce arc stability. When this occurs, welding must be stopped and the electrode redressed. To optimize weld quality, a gas lens collet body and the largest size ceramic nozzle should be used. With higher speed automatic processes, a trailing gas shield is recommended to prevent excessive oxidation of the weld bead.

Argon, helium, or mixtures of the two can be used for shielding. Only high-purity gas should be used. Standard welding grade gas may not be adequate because of cylinder contamination, and standard grade cylinders are not certified as to purity level. On full penetration welds or when welding thinner gages where oxidation of the back-side can occur, back gas shielding with a high-quality gas is mandatory. When welding the austenitic grades of stainless alloys, it is common to use nitrogen backing gas (usually to reduce costs, or enhance corrosion performance with these alloys). Nitrogen backing gas *must never be used* when welding ferritics because nitrogen pickup will cause severe embrittlement (loss of toughness and ductility) and loss of corrosion resistance. Inert backing gas should be used for at least two layers of deposited weld metal (3 mm, or $\frac{1}{8}$ in., minimum). Another common technique that is used when welding austenitics is to butt two pieces of metal together, weld from one side, then back grind the backside to sound metal and complete the joint. This procedure must *never* be attempted when welding ferritics because all of the contaminated metal may not be completely removed. The result is a defective, crack-sensitive ferritic weld.

To enhance weld quality and performance, especially for the Group III alloys, the following are recommended:

- THOROUGHLY DEGREASE THE WELD JOINT AND ADJACENT SURFACES BACK AT LEAST 50 MM (2 IN.) ON BOTH SIDES OF EACH JOINT MEMBER. THIS MUST ALSO INCLUDE THE WELD FILLER WIRE. WELDING SHOULD ONLY BE PERFORMED WITH CLEAN GLOVES. DIRTY AND SWEATY (DAMP) WELDING GLOVES MUST NEVER BE USED.
- KEEP THE WELDING TORCH AT RIGHT ANGLES TO THE WORK SURFACE WITHIN 15° OF VERTICAL TO PREVENT AIR ASPIRATION INTO THE INERT GAS SHIELD.
- GAS LENS SCREENS THAT BECOME CONTAMINATED WITH A DROP OR MORE OF WELD SPATTER MUST BE CHANGED IMMEDIATELY BECAUSE THE DISRUPTION OF GAS FLOW FROM THE TORCH NOZZLE CAUSES AIR ASPIRATION INTO THE MOLTEN WELD POOL. REMOVAL OF CONTAMINATED WELD METAL IS ADVISED. USUALLY, THE LENS MUST BE CHANGED.
- WEAVING THE ELECTRODE IS NOT PERMITTED, EXCEPT FOR A SMALL AMOUNT TO ALLOW GOOD SIDE-WALL FUSION AND TIE-IN. IT SHOULD BE NOTED THAT EXCESSIVE WEAVING CAUSES CONTAMINATION OF THE WELD POOL WITH A SUBSEQUENT LOSS IN FRACTURE TOUGHNESS, DUCTILITY, AND CORROSION RESISTANCE.
- WHEN WELDING, KEEP THE TIP OF THE FILLER WIRE WITHIN THE SHIELDING GAS ENVELOPE--ANOTHER REASON TO USE A GAS LENS AND AS LARGE A GAS CUP AS POSSIBLE. IF THE FILLER WIRE TIP BECOMES CONTAMINATED, EITHER BECAUSE IT TOUCHED THE TUNGSTEN ELECTRODE OR WAS WITHDRAWN OUTSIDE THE INERT GAS ENVELOPE, WELDING MUST STOP, THE TIP OF THE CONTAMINATED WIRE CUT BACK TO SOUND METAL, AND THE CONTAMINATED WELD, IF ANY, GROUND OUT, AND REPAIRED.
- ALL HOSE CONNECTIONS MUST BE OF GOOD QUALITY AND BE TIGHT TO PREVENT AIR INGESTION. CHECK ALL WATER SEALS IN THE TORCH. AIR DRAFTS IN THE WELDING AREA ARE TO BE AVOIDED TO PREVENT LOSS OF THE INERT GAS SHIELD. VERIFY THE INTEGRITY OF THE GAS SYSTEM WITH A WELD BUTTON TEST. THIS IS DONE BY STRIKING AN ARC ON A TEST PIECE OF E-BRITE PLATE OR OTHER HIGH-PURITY FERRITIC, ESTABLISHING A SMALL CIRCULAR POOL OF MOLTEN METAL APPROXIMATELY 13 MM ($\frac{1}{2}$ IN.) IN DIAMETER, EXTINGUISHING THE ARC, AND POSTPURGING AT LEAST SIX SECONDS OR MORE. THE WELD BUTTON MUST BE BRIGHT AND SHINY AND FREE OF ANY HEAT TINT. IF NOT, THE SOURCE OF CONTAMINATION MUST BE FOUND AND CORRECTED.
- PREPURGE THE TORCH BEFORE WELDING TO REMOVE AIR AND/OR MOISTURE WHICH HAS INFILTRATED INTO THE SYSTEM. POSTPURGE ALL WELD STOPS TO PREVENT CONTAMINATION. THE POSTPURGE TIME SHOULD BE SUFFICIENT SUCH THAT THE WELD STOP IS BRIGHT AND SHINY AND FREE OF ANY OXIDE HEAT TINT OR DISCOLORATION.
- A REMOTE CONTROL SHOULD BE USED TO ALLOW GRADUAL INCREASE AND DECREASE OF CURRENT WHEN INITIATING OR EXTINGUISHING THE ARC.
- AVOID OVERHEATING AND EMBRITTLING THE WELD BY MINIMIZING HEAT INPUT, AND IN MULTIPASS WELDS, BY KEEPING THE INTERPASS TEMPERATURE BELOW 95 °C (200 °F).
- WHEN HIGH-SPEED AUTOMATIC WELDING IS PERFORMED, A TRAILING GAS SHIELD IS RECOMMENDED.

Gas-Metal Arc Welding (GMAW). With the GMAW process, direct current electrode positive (DCEP), or reverse polarity, is used. The following methods of metal transfer across the welding arc are possible with GMAW:

- *SPRAY TRANSFER* IS CHARACTERIZED BY HIGH HEAT INPUT AND A FLUID WELD POOL. EXCESSIVE GRAIN GROWTH IS LIKELY IN THE WELD AND HAZ. SPRAY TRANSFER IS NOT USUALLY RECOMMENDED WHEN WELDING FERRITIC STAINLESS STEELS,

ALTHOUGH SOME STABILIZED GRADES APPEAR TO BE LESS SENSITIVE TO HEAT INPUT. HEAT INPUT CAN BE REDUCED WITH THE PULSED GMAW PROCESS, THUS OFFERING OUT-OF-POSITION WELDING.

- *GLOBULAR TRANSFER* IS CHARACTERIZED BY LOWER HEAT INPUT, BUT IS NOT NORMALLY USED BECAUSE OF EXCESSIVE SPATTER. SPATTER CAN BE MINIMIZED WITH PROPER CHOICE OF HIGH-PURITY SHIELDING GAS AND THE PROPER CHOICE OF POWER SUPPLY (FOR EXAMPLE, RAPID ARC POWER SUPPLIES THAT FEATURE CAPACITIVE DISCHARGE ELECTRONICS).
- *SHORT-CIRCUITING TRANSFER* FEATURES THE LOWEST HEAT INPUT OF ALL THE GMAW PROCESSES. HOWEVER, LACK OF FUSION DEFECTS ARE COMMON WITH SHORT-CIRCUITING TRANSFER IF PROPER TECHNIQUES ARE NOT FOLLOWED.

While grain growth can be controlled to some degree with higher weld travel speeds, lower interpass temperatures, and heat sinks, care must be taken to avoid weld defects such as lack of fusion and insufficient penetration. In some situations, the use of an austenitic filler metal can overcome the problem of weld grain growth because of the formation of a two-phase grain structure. However, the HAZ grain growth must not be forgotten when using one of these filler metals.

When welding ferritic and austenitic stainless steels with the GMAW process using one of the standard power supplies, pure argon shielding gas is usually not used because of arc instability which causes air to be aspirated into the arc. As a result, the weld pool becomes enriched in nitrogen and oxygen. In the DCEP mode, the arc wanders, seeking spots which are emissive in character, usually oxides. This erratic arc behavior causes a disruption of the laminar flow of the inert gas, resulting in air being aspirated into the gas envelope.

One way to solve the arc wander problem has been to add an oxidizing element to the inert gas. Argon with 2% oxygen (O_2) or with 2% carbon dioxide (CO_2) typically used to weld plain carbon steel, low-alloy steel, and austenitic stainless steel, has been recommended for ferritic stainless steels as well. While this seems to be satisfactory for the stabilized ferritics in Group II where the bulk of the applications are for automobile exhaust systems (type 409), these active, oxidizing shielding gases should *never* be used for the Group III higher-purity ferritics, stabilized or not, because of the dramatic effect on degrading toughness and ductility.

Still other investigators have shown that the arc wander problems associated with the GMAW process can be resolved by using an argon-helium mix, typically 75Ar-25He, and by ensuring that the inert gas is purified and free of contaminants such as air, moisture, and hydrocarbons. To further enhance operability and weld quality, a device covered in a U.S. patent (No. 5,081,334, Improved Gas Shielding," 14 Jan 1992) enables air and moisture to be excluded from entering the welding arc. By taking the high-purity inert gas system approach rather than using a gas mixture containing reactive gases (O_2 and CO_2), critical reactive alloying elements such as titanium, niobium, aluminum, and chromium are not removed by oxidation. In this way, arc wander is virtually eliminated and wetting action is enhanced. With this new technology stable GMAW has been attained with pure argon. This patent also has possible application in any welding process that uses a wire feed system.

Flux-cored arc welding (FCAW) functions essentially the same as GMAW, except that instead of the filler wire being solid, it is fabricated from a carbon steel, stainless steel, or nickel sheath that surrounds a core of alloying additions formulated to the desired weld deposit chemistry. Some FCAW consumables contain active fluxing ingredients while others do not. In some instances, suppliers recommend the use of a supplementary gas shield, and sometimes the consumable is self-shielding. It is important to know the operating characteristics of the wire and when to use supplementary shielding gas which usually gives better results. The advantages of using shielding gas purification as discussed for GMAW may apply here as well.

The FCAW process is not recommended for the Group III ferritic stainless steels because of the difficulty of maintaining alloy purity and because of the pickup of carbon, nitrogen, and oxygen. Flux-cored arc weld deposits are never as clean as those produced by solid wire, inert gas welding processes. For less critical applications, or where an austenitic filler metal can usually be used, FCAW may be possible.

Because FCAW operates in the spray arc mode, higher heat inputs will result, making grain growth a potential problem. Although higher travel speeds can be employed with lower interpass temperature and heat sinks, care must be used to avoid lack-of-fusion defects.

Shielded Metal Arc Welding (SMAW). When welding with the SMAW process, DCEP (reverse polarity) is typically used. Shielded metal arc weld deposits made with covered electrodes are never as tough as welds made with an inert gas shielded process. For this reason, covered electrodes with matching composition are not available for the Group III ferritic stainless steels. Basically, the problem is one of purity, because carbon, nitrogen, and oxygen are difficult to suppress without seriously hampering welding electrode operability.

Where covered electrodes are available, proper storage is essential to avoid any pickup of moisture. Improper storage of SMAW consumables resulting in moisture pickup usually leads to weld porosity, and in some cases hydrogen cracking.

For some ferritic stainless steels that must be used in the as-welded condition, and where postweld annealing is not practical or cost effective, a dissimilar welding electrode can be used. The choice varies from the high-chromium austenitic grades such as a type E310 or E310 ELC (which are fully austenitic) to a high-nickel alloy such as an ENiCrFe-2. Type E309 coated electrode (welds contain ferrite for resistance to hot cracking) and its low-carbon and higher-silicon variations have been used to advantage.

High-alloy austenitic weld metals do not flow as readily as the ferritic stainless steels. High-nickel alloy weld metal is particularly sluggish with shallow penetration. This behavior requires that the welder make adjustments in technique. This means the welder must use arc force and electrode manipulation to physically move the molten weld pool against the sides of the joint. Ferritic stainless steels have significantly higher melting temperatures than do the austenitic stainless steels or corrosion-resistant nickel-base alloys. When using austenitic filler metals to join ferritic stainless steel base metals, care must be exercised to ensure that sufficient heat has been applied to fuse the ferritic stainless steel base metal. Failure to follow these recommendations usually results in lack-of-fusion defects.

Depending on weld bead profile, slag entrapment can be a problem with some covered electrodes. If the slag does not chip out readily, grinding will be necessary. Trying to float out residual slag with successive molten weld passes is rarely successful. The net result is slag entrapment which readily shows up on radiographic inspection. It should be remembered that grinding, if it becomes excessive, can result in more heat input via additional weld passes and ultimately will cause grain growth. The net result could be a loss in HAZ toughness and ductility.

When welding ferritic stainless steels with the SMAW process, the following techniques are recommended:

- AS WITH ALL OTHER WELDING PROCESSES, WELD JOINT SURFACES SHOULD BE CAREFULLY CLEANED WITH SOLVENT (BOTH SIDES OF EACH JOINT MEMBER) TO REMOVE ANY CONTAMINANT SUCH AS OIL, GREASE, OR DIRT WHICH WOULD DEGRADE WELD PROPERTIES AND CORROSION RESISTANCE.
- THE ARC SHOULD BE STRUCK IN THE BEVEL OF THE WELD JOINT, AND NOT ON THE ADJACENT BASE METAL.
- A SHORT ARC SHOULD BE MAINTAINED TO AVOID THE FORMATION OF POROSITY AND TO MINIMIZE OXIDATION EFFECTS AND PICKUP OF OXYGEN AND NITROGEN.
- AVOID EXCESSIVE INCLINATION OF THE ELECTRODE (A MAXIMUM INCLINE OF 20° FROM THE VERTICAL IS GENERALLY SATISFACTORY).
- A SLIGHT WEAVE FOR TIE-IN AND FUSION IS ALLOWED PROVIDED IT IS NOT WIDER THAN THREE TIMES THE DIAMETER OF THE ELECTRODE CORE WIRE.
- CRATER CRACKS AT WELD STOPS MUST BE GROUND OUT TO SOUND METAL BEFORE PROCEEDING. DYE PENETRANT INSPECTION IS THE BEST WAY TO BE SURE ALL CRACKED MATERIAL HAS BEEN REMOVED.

Plasma arc welding (PAW) of ferritic stainless steels is very similar to GTAW and the same precautions and recommendations apply. Concern has been voiced about the use of hydrogen gas with PAW because of the possibility of weld metal cracking caused by the interaction of hydrogen in the weld metal and in high stress conditions. Gas-tungsten arc welding experience with type 409 indicates that hydrogen additions will cause embrittlement immediately after welding but most of the hydrogen diffuses out of the weld metal within 48 h and ductility is restored. The situation, however, is more critical with higher-chromium alloys.

An advantage of the PAW process is that the unique high-intensity arc produces a weld bead characterized by deep penetration and a HAZ narrower than that produced by the GTAW process. The net result is that less HAZ grain growth is possible with PAW than with GTAW.

Resistance Welding. Spot welding, seam welding, and flash welding processes can be used provided the loss in toughness can be tolerated. Seam welding has been used to fabricate panel coil-type heat exchanger surfaces. Whenever possible argon inert gas should be used to protect the weld joint or seam (back side included) to minimize oxidation and the pickup of nitrogen. Titanium-stabilized alloys appear to be more resistant to the effects of nitrogen pickup due to poor shielding than are the high-purity alloys. This is apparently due to the formation of a protective TiN film which covers the weld pool (Ref 26).

Other Welding Processes. Ferritic stainless steels can be readily welded using the electron beam process with hard vacuum. Friction welding and laser welding are also possible. Where practical, the molten zone should be protected with an inert gas shield.

Submerged arc welding (SAW) can be used to join some of the ferritic stainless grades; however, the high heat input with the process becomes troublesome because of undesirable grain growth in the weld HAZ. Choice of fluxes and control of residues become critical. Dilution can exceed 50%. Submerged arc welding is not suitable for the Group III alloys and generally would also not be suitable for most of the other alloys.

Selection of Welding Consumables

Welds in ferritic stainless steel base metals can be produced several ways: (1) autogenously (that is, without the addition of filler metal) (Ref 27), (2) with a matching filler metal composition, (3) with an austenitic stainless steel filler metal (Ref 25), or (4) using a high-nickel filler alloy (Ref 17). Table 5 lists some base metal-filler metal combinations for several ferritic stainless steels.

TABLE 5 TYPICAL FERRITIC BASE METAL-FILLER METAL COMBINATIONS

BASE METAL	COVERED ELECTRODE, BARE ROD, OR FILLER WIRE	APPLICATION
405	405 NB	AS-WELDED
	430	ANNEALED
	308(L), 309(L), 310(ELC)	AS-WELDED
409	430	ANNEALED
	308(L), 409, 409NB, 309LSI	AS-WELDED
429	208(L), 309(L), 310(ELC)	AS-WELDED
430	430	ANNEALED
	308(L), 309(L), 310(ELC)	ANNEALED OR AS-WELDED
439	430, 430TI	ANNEALED OR AS-WELDED
442	442	ANNEALED
	308(L), 309(L), 310(ELC)	AS-WELDED
446	446	ANNEALED
	308(L), 309(L), 310(ELC)	AS-WELDED
E-BRITE 26-1	ER26-1	AS-WELDED
	INCONEL 112, HASTELOY C-276, OR HASTELOY C-22	AS-WELDED
AL 29-4C	AL 29-4-2	AS-WELDED
AL 29-4	AL 29-4-2	AS-WELDED
AL-29-4-2	AL 29-4-2	AS-WELDED

Before selecting a welding consumable, consideration must be given not only to mechanical property requirements, especially weld ductility and toughness (including the weld HAZ), but also to the level of corrosion resistance required for the application. Autogenous welding may be considered for some of the high-purity Group III alloys such as E-Brite 26-1. The mill annealed product will have good mechanical properties and corrosion resistance, but if the interstitial levels of carbon, oxygen, and nitrogen are on the high side of the specification limits, the autogenous weld will not only exhibit poor ductility and toughness, but also poor corrosion resistance. To avoid this kind of a problem, material should be purchased with interstitial element levels on the low side of the specification range.

Filler metals of matching composition for the more common grades of Groups I and II ferritic stainless steels, such as types 409 and 430, are available as solid wire, metal cored, or fluxcored wire (both gas shielded and self-shielded), covered electrodes, and bare rod. Because of the reactivity of titanium and aluminum and poor transfer of these elements across the arc, the availability of consumables containing these elements is usually limited to bare wire or rod.

When nonstandard grade ferritic filler metals are not available, or because poor wire drawing characteristics make production prohibitive, metal-cored or flux-cored filler metals offer a solution. Weld metal properties should be qualified before purchase.

Welding consumables for the Group III alloys are available as matching composition in bare wire or rod form. Because Group III weldments are usually always used in the as-welded condition, it is strongly recommended that these filler metals be purchased having interstitials at the very low end of the alloy specification. For best ductility, toughness and corrosion performance, the (C + N + O) content should not exceed 120 ppm for the ultrahigh-purity grades (such as E-Brite 26-1, 29-4, and 29-4-2).

Because the Group III ferritics of intermediate purity rely on stabilization with titanium or titanium and niobium, welds have such poor toughness that welding with these filler metals is limited to very thin section sizes such as thin-walled pipe, tubing, or sheet. When better toughness is required of stabilized grades with a ferritic consumable, welding should be performed with an ultrahigh-purity filler metal containing very low levels of (C + N + O). It should be noted that ultrahigh-purity welding consumables require careful handling and processing to keep interstitials at these very low levels. Keeping them clean at the job site is also mandatory.

Austenitic stainless steel welding consumables are often used to join ferritic stainless steels to overcome poor weld ductility and toughness deficiencies and they do not display a DBTT like ferritics. Although weld metal grain growth is usually not a problem (because a two-phase mixture of austenite and ferrite forms), grain growth in the weld HAZ of the ferritic base metal must not be overlooked. Sometimes the application of an austenitic filler can be a problem because of the rather large discrepancy in thermal expansion between the two alloys. In this regard, problems can range from (1) cracking due to thermal stress, (2) sensitization and loss of corrosion resistance if the austenitic filler metal is not a low-carbon grade or stabilized with titanium or niobium (corrosion can also result because of the heat from multipass welds or some subsequent thermal treatment after welding), or (3) stress relief which may not be fully effective because of the thermal expansion differences.

High-nickel alloy welding consumables have also been used successfully to join ferritics, especially the Group III alloys to themselves as well as to carbon steel, 300-series stainless steels, duplex stainless steels, superaustenitic stainless steels, and nickel-base alloys. Examples of nickel-base filler metals that have been used successfully are ENiCrFe-2, ENiCrMo-3, ERNiCrMo-1, and ERNiCrMo-3. In addition to their outstanding corrosion resistance, these high-nickel filler metals have coefficients of thermal expansion that are similar to the ferritics they are joining. While they have worked well with E-Brite alloy, attempts to use them with the 3 to 4% Mo grades of ultrahigh-purity ferritics have occasionally been less successful (Ref 28). Formation of brittle intermetallic compounds at the fusion boundary has been encountered in some cases, but good welds can be produced (Fig. 7). Sound welds have been produced using duplex stainless steel filler metal, but corrosion resistance of such joints may not be adequate in some applications.

Welding Procedures and Weld Properties

Effect of Shielding Gas Purity on Weld Toughness (Ref 29, 30, 31, 32, 33, 34). The primary reasons for using shielding and backing gas are to protect the molten filler wire tip, the nonconsumable electrode (when used), the weld pool, and the solidified weld bead from atmospheric contamination. Researchers have shown that gas contaminants can cause cracking, varying degrees of weld bead oxidation, arc instability, and degradation of mechanical and corrosion properties. A particular gas or gas mixture might be used for enhanced arc stability, a particular mode of weld metal transfer, enhanced penetration or bead profile, its availability, or easier arc ignition.

Certainly, there is no question that quality welds require quality shielding. What is essential is that clean gas be maintained and delivered to the point of use. From a practical standpoint, some factors that have been identified as relating to "bad gas" and welding problems are:

- CONTAMINATED GAS CYLINDERS (BY MOISTURE/AIR)
- CONTAMINATED AND/OR LEAKING GAS MANIFOLD SYSTEMS
- DAMAGED, DEFECTIVE, OR LOOSE SHIELDING/BACKING GAS LINE FITTINGS
- INTRUSION OF CONTAMINANTS WHEN MIXING GASES

Achieving gas quality at the point of use can be elusive. Welding problems can show up with a single cylinder of gas or a series of cylinders. A manifold system can be particularly difficult to deal with because of its long length and numerous welding stations. As a result of poor gas quality, defects are produced which require repair, job completion can be delayed, and job quality may be compromised. What is needed is a portable, cost-effective system that will remove contaminants from the shielding gas and backing gas, not only when working in the shop, but also in the field.

Because ferritic stainless steels are sensitive to interstitial element contaminants, it is important that these elements be removed so as not to degrade properties such as ductility, toughness, and corrosion resistance. Impurities commonly found in gas cylinder or manifold systems are moisture, oxygen, hydrocarbons (such as oils from compressors), and carbon dioxide (when not intentionally added). Moisture in CO_2 gas is also a common problem.

While there are systems on the market that can eliminate gas contaminants to levels below one part per million (ppm), they have to rely on multicomponent, energy-intensive gettering. These systems are heavy, flow rates are usually restrictive, and they are not very portable. Another system relies on a resin that is a single rechargeable compound that can provide effective removal of a variety of impurities to less than 10 parts per billion (ppb), operates at room temperature, and is light and portable. The effects of using such a system on the impact properties of 6 mm ($\frac{1}{4}$ in.) thick E-Brite 26-1 alloy plate are shown in Fig. 8.

Hydrogen Embrittlement. Like other ferritic materials, the ferritic stainless steels are susceptible to hydrogen embrittlement. For this reason, the use of hydrogen-containing shielding gas should be avoided. Hydrogen can also be created from water, water vapor, or oils, and these should be rigorously excluded from the weld region. The presence of hydrogen in the weld can lead to cracking of the weld bead shortly after welding. It can also reduce ductility in uncracked welds. Hydrogen is often spontaneously outgassed from these alloys at room temperature and is readily lost during low-temperature (90 to 200 °C, or 200 to 400 °F) heat treatments (Ref 36). Hydrogen outgassing at room temperature, if it will occur, requires a few days to a few weeks. Surface films of oxides and/or nitrides can inhibit hydrogen outgassing, and it may be necessary to remove such films to facilitate hydrogen outgassing and restoration of ductility. Sensitivity to hydrogen is a function of alloy composition, microstructure, and strength. In general, the stabilized, high-chromium plus molybdenum materials, such as AL 29-4C alloy, are more sensitive than the high-purity, lower-chromium plus molybdenum materials, such as the E-Brite alloy.

Preheating. One of the main reasons for preheating is to reduce the temperature gradient between the weld area and the unaffected base metal. Any austenite which forms in nominally ferritic stainless steels will air harden to martensite even in heavy (>300 mm, or 12 in., diam) sections. Preheating light-gage sheet will not prevent the formation of martensite. It is also unlikely that enough preheat could be applied to produce any significant post-transformation tempering. Hydrogen may be a factor in situations involving high stress and restraint. When additional preheat time is allowed, the hydrogen can diffuse out safely. Ferritic stainless steels that would benefit from preheat would be the Group I types (430, 434, 442, and 446).

When required, a preheat in the range of 150 to 230 °C (300 to 450 °F) is usually sufficient. Section sizes of $\leq$6 mm ($\leq \frac{1}{4}$ in.) generally do not need preheat, but such parameters as joint design, restraint, welding process, cooling rate, and dissimilar metal combinations (different coefficients of thermal expansion), and base metal composition should be reviewed before making a final decision.

Preheat should not be used on the Group III alloys, especially the ultra-high purity steels. These alloys do not form martensite when welded, so no preheat is necessary. Furthermore, because these alloys have such low levels of impurities, excessive grain growth would occur, compared with the Group I and Group II alloys.

Postweld annealing is normally performed on the Group I ferritic stainless steels. The purpose is to transform any martensite that may have formed during welding into a wholly ferritic structure (usually containing some spheroidized carbides), or to remove effects of high-temperature embrittlement and improve corrosion resistance. Annealing under these conditions does not refine coarsened ferrite grains (some form of metal working is needed to achieve recrystallization and grain refinement).

When postweld annealing is required, the recommended temperature range is 790 to 850 °C (1450 to 1550 °F). At these temperatures consideration must be given to oxidation of the metal surface and distortion effects. Fixturing to prevent metal deformation may be required. Sigma, σ, and chi, χ, formation is typically not a problem with the Group I alloys.

Cooling from the annealing temperature must be done carefully. Furnace cooling to 600 °C (1100 °F) is usually specified to minimize distortion from handling. Rapid cooling through the temperature range of 565 to 400 °C (1050 to 750 °F) is necessary to avoid 475 °C (885 °F) embrittlement. Depending on section thickness, forced air cooling or water spray quenching is usually performed.

Group III ferritic stainless steels (ultralow interstitials and the stabilized grades), particularly the high-chromium, high-molybdenum alloys, are typically not annealed after welding because of the danger of precipitation of σ and χ phases in the temperature range of 550 to 900 °C (1020 to 1650 °F) unless the anneal is followed by a rapid quench. However, postweld annealing of welded tubes is common.

Corrosion Resistance. Investigators have determined that the loss of corrosion resistance of ferritic stainless steels after welding is caused by chromium depletion upon cooling from exposure to temperatures of 925 °C (1700 °F) (Ref 37, 38, 39, 40, 41, 42). Sensitization* due to chromium depletion occurs by holding or cooling through the temperature range of 425 to 700 °C (800 to 1300 °F). In the temperature range from 700 to 925 °C (1300 to 1700 °F), rapid diffusion of chromium in ferrite occurs, replenishing the chromium-depleted zones. For this reason, weldments which are annealed at 790 to 850 °C (1450 to 1550 °F) show good intergranular corrosion resistance despite the presence of intergranular precipitates of chromium-rich carbides and nitrides. Below 700 °C (1300 °F), little chromium diffusion occurs and corrosion resistance is not completely restored.

Conventional (Group I) 400-series ferritic stainless steels such as types 430, 434, and 446 are susceptible to intergranular corrosion and to embrittlement in the as-welded condition. Corrosion in the weld area generally encompasses both the weld metal and weld HAZ. Early attempts to avoid some of these problems involved the use of austenitic stainless steel filler metals; however, failure by corrosion of the HAZ usually occurred even when exposure was to rather mild media for relatively short periods of time.

Figure 9 shows an example of a saturator tank used to manufacture carbonated water at room temperature that failed by leakage through the weld HAZ of the type 430 base metal after being in service for only 2 months. This vessel, fabricated by welding with a type 308 stainless steel welding electrode, was placed in service in the as-welded condition. Figure 10 shows a photomicrograph of the weld/base metal interface at the outside surface of the vessel; corrosion initiated at the inside surface. Postweld annealing--at 785 °C (1450 °F) for 4 h in the case of type 430 stainless steel--restores weld area ductility and resistance to corrosion to that of the unwelded base metal.

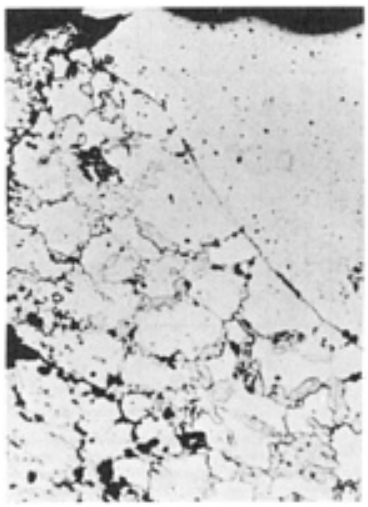

FIG. 10 PHOTOMICROGRAPH OF THE OUTSIDE SURFACE OF THE SATURATOR TANK SHOWN IN FIG. 9 SHOWING CORROSION AT THE FUSION LINE. SOURCE: REF 34

To overcome some of these earlier difficulties and to improve weldability, several of the standard grade ferritic stainless steels were modified. For example, type 405, containing nominally 12% Cr, is made with lower carbon and a small aluminum addition of 0.20% to restrict the formation of austenite at high temperature so that hardening is reduced during welding. For maximum ductility and corrosion resistance, however, postweld annealing is necessary. Recommendations for welding include either a 430- or a 309-type filler metal, the latter being used when increased weld ductility is desired.

As mentioned earlier in this article, researchers recognized that the high-chromium, high-molybdenum ferritic stainless steels possessed a desirable combination of good mechanical properties and resistance to corrosion. These properties made them attractive alternatives to the austenitic stainless steels, which often failed due to chloride SCC.

Reducing the total interstitial element levels in ferritic stainless steels improves weldability and corrosion resistance. Figure 11 shows the relationship of chromium content and (C + N) content on the combined properties of as-welded corrosion resistance and ductility. Table 6 lists this relationship separately for each property. As chromium content increases, the amount of (C + N) that can be tolerated for intergranular corrosion resistance increases. Conversely, for aswelded ductility, the amount of tolerable (C + N) is drastically reduced. Thus, at low chromium levels, as-welded corrosion resistance is the controlling factor; at high chromium levels, as-welded ductility is the factor that limits the use of high-chromium stainless steels.

TABLE 6 LIMITS OF INTERSTITIAL ELEMENT (C + N) CONTENT FOR ACCEPTABLE AS-WELDED INTERGRANULAR CORROSION RESISTANCE AND AS-WELDED DUCTILITY

Sample thickness: 2.5 mm (0.1 in.)

CHROMIUM CONTENT, WT%	INTERGRANULAR CORROSION RESISTANCE[(A)], PPM (C + N)	DUCTILITY[(B)], PPM (C + N)
19	60-80	>700
26	100-130	200-500
30	130-200	80-100
35	<250	<20

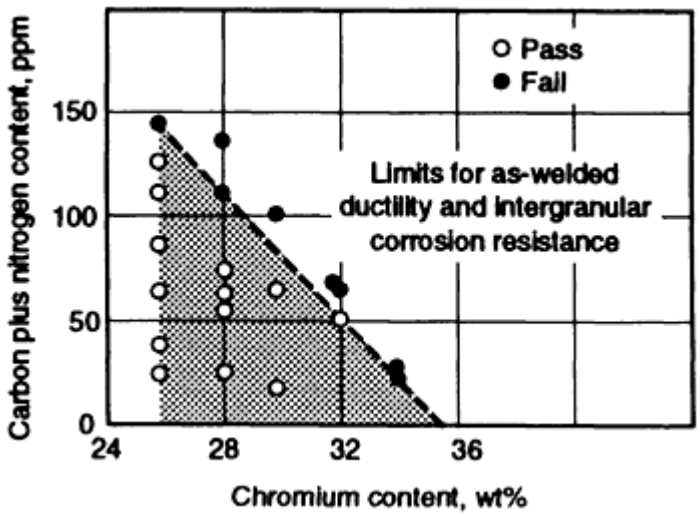

FIG. 11 THE EFFECT OF INTERSTITIAL LEVELS AND CHROMIUM CONTENT ON AS-WELDED DUCTILITY AND INTERGRANULAR CORROSION RESISTANCE. SOURCE: REF 43

To improve the corrosion resistance of ferritic stainless steels, two practical methods have been applied:

- *LOWER INTERSTITIAL LEVELS.* BECAUSE THE SOLUBILITY OF INTERSTITIAL ELEMENTS IS LOW IN FERRITE, NEW MELTING AND REFINING PRACTICES HAVE BEEN UTILIZED TO PRODUCE ULTRAHIGH-PURITY FERRITIC (GROUP III) STAINLESS ALLOYS LIKE THOSE SHOWN IN TABLE 3. WITH THESE LOW LEVELS OF CARBON AND NITROGEN, CHROMIUM CARBIDE AND NITRIDE PRECIPITATION CANNOT OCCUR TO A HARMFUL DEGREE, THUS AS-WELDED DUCTILITY AND CORROSION RESISTANCE ARE MAINTAINED

- *STABILIZATION OF CARBON AND NITROGEN.* THIS IS ACHIEVED BY THE ADDITION OF CARBIDE- AND NITRIDE-FORMING ELEMENTS WHICH ARE MORE STABLE THAN CHROMIUM CARBIDES AND CHROMIUM NITRIDES. TITANIUM AND/OR NIOBIUM ARE USED TO TIE UP THE CARBON AND NITROGEN IN THE MATRIX. STABILIZATION HAS PROVEN EFFECTIVE IN PREVENTING SENSITIZATION OF FERRITIC ALLOYS SUCH AS 18CR-2MO AND 26CR-1MO, AS WELL AS THE HIGHER CHROMIUM-MOLYBDENUM GRADES (REF 44). INVESTIGATORS HAVE SHOWN, HOWEVER, THAT IF EXCESSIVE AMOUNTS OF STABILIZER ARE USED BEYOND WHAT IS REQUIRED FOR CORROSION RESISTANCE, DUCTILITY AND ROOM-TEMPERATURE IMPACT PROPERTIES ARE DEGRADED (REF 15, 44, 45, 46).

It should also be pointed out that corrosion resistance can also be improved by following proper welding procedures and recommendations. As described previously, preheating (except to remove moisture) or postweld heat treating should not be performed. Postweld heat treatment is used only with the conventional ferritic stainless alloys. The following example illustrates the results of not following proper procedures.

Example 1. Leaking Welds in a Ferritic Stainless Steel Wastewater Vaporizer. A nozzle in a wastewater vaporizer began leaking after approximately 3 years of service with acetic and formic acid wastewaters at 105 °C (225 °F) and 414 kPa (60 psig).

Investigation. The shell of the vessel was gas-tungsten arc welded in 1972 from 6.5 mm ($\frac{1}{4}$ in.) E-Brite stainless steel plate. The shell measured 1.5 m (58 in.) in diameter and 8.5 m (28 ft) in length. Nondestructive examination included 100% radiography, dye-penetrant inspection, and hydrostatic testing of all E-Brite welds.

An internal inspection of the vessel revealed that portions of the circumferential and longitudinal seam welds, in addition to the leaking nozzle weld, displayed intergranular corrosion. At the point of leakage, there was a small intergranular crack. Figure 12 shows a typical example of the corroded weld. A transverse cross section through this weld characteristically displays intergranular corrosion with grains dropping out (Fig. 13). The HAZ next to the weld fusion line also experiences intergranular corrosion a couple of grains deep as a result of sensitization (Fig. 14).

FIG. 12 TOP VIEW OF A LONGITUDINAL WELD IN 6 MM ($\frac{1}{4}$ IN.) THICK E-BRITE STAINLESS STEEL PLATE SHOWING INTERGRANULAR CORROSION. THE WELD WAS MADE WITH MATCHING FILLER METAL. ABOUT 4×. SOURCE: REF 47

FIG. 13 INTERGRANULAR CORROSION OF A CONTAMINATED E-BRITE STAINLESS STEEL WELD. ELECTROLYTICALLY ETCHED WITH 10% OXALIC ACID. 200×. SOURCE: REF 47

FIG. 14 INTERGRANULAR CORROSION OF THE INSIDE SURFACE HAZ OF E-BRITE STAINLESS STEEL ADJACENT TO THE WELD FUSION LINE. ELECTROLYTICALLY ETCHED WITH 10% OXALIC ACID. 100×. SOURCE: REF 47

The evidence indicated weldment contamination; therefore, effort was directed at finding levels of carbon, nitrogen, and oxygen in the various components present before and after welding. The following are the average results:

ELEMENT	**CONTENT, PPM**
E-BRITE BASE PLATE	
C	6
N	108 (C + N = 114)
O	57
CORRODED LONGITUDINAL WELD	

C	133
N	328 (C + N = 461)
O	262
CORRODED CIRCUMFERENTIAL WELD	
C	34
N	169 (C + N = 203)
O	225
E-BRITE WELD WIRE	
C	3
N	53 (C + N = 56)
O	55
SOUND LONGITUDINAL WELD	
C	10
N	124 (C + N = 134)
O	188
SOUND CIRCUMFERENTIAL WELD	
C	20
N	106 (C + N = 126)
O	85

These results confirmed suspicions that failure was due to excessive amounts of nitrogen, carbon, and oxygen. To characterize the condition of the vessel further, subsize CVN impact tests were run on the unaffected base metal, the HAZ, and the uncorroded (sound) weld metal. These tests showed the following ductile-to-brittle transition temperatures:

SPECIMEN	**DUCTILE-TO-BRITTLE TRANSITION TEMPERATURE**	
	°C	**°F**
BASE METAL	40 ± 3	105 ± 5
HAZ	85 ± 3	180 ± 5
WELD	5 ± 3	40 ± 5

Comparison of the interstitial levels of the corroded welds, sound welds, base metal, and filler wire suggested that insufficient joint cleaning and faulty gas shielding were probably the main contributing factors that caused this weld corrosion failure. Discussions with the vendor uncovered two discrepancies. First, the welder was using a large, 19 mm ($\frac{3}{4}$ in.) inside diameter ceramic nozzle with a gas lens, but was flowing only 19 L/min (40 ft^3/h) of argon; this was the flow rate previously used with a 13 mm ($\frac{1}{2}$ in.) inside diameter gas lens nozzle. Second, a manifold system, found to be contaminated, was used to distribute pure argon welding gas from a large liquid argon tank to various satellite welding stations in the welding shop. The exact cause for the carbon pickup was not determined.

Conclusions. Failure of the nozzle weld was the result of intergranular corrosion caused by the pickup of interstitial elements and subsequent precipitation (sensitization) of chromium carbides and nitrides. Carbon pickup was believed to have been caused by inadequate joint cleaning prior to welding. The increase in the weld nitrogen level was a direct result of inadequate argon gas shielding of the molten weld puddle. Two areas of inadequate shielding were identified:

- IMPROPER GAS FLOW RATE FOR A 19 MM ($\frac{3}{4}$ IN.) DIAM GAS LENS NOZZLE
- CONTAMINATION OF THE MANIFOLD GAS SYSTEM (LEAKS)

In order to preserve the structural integrity and corrosion performance of the new Group III ferritic stainless steels, it is important to avoid the pickup of the interstitial elements carbon, nitrogen, oxygen, and hydrogen. In this particular case, the vendor used a flow rate of 23 to 28 L/min (50 to 60 ft^3/h) of argon for a 19 mm ($\frac{3}{4}$ in.) gas lens nozzle. As was mentioned previously in this article, the gas lens collet body is an important and necessary part of the torch used to weld these alloys. Failure to use a gas lens will result in a flow condition that is turbulent enough to aspirate air into the gas stream, thus contaminating the weld and destroying its mechanical and corrosion properties.

The manifold gas system also contributed to this failure. When a system such as this is first used, it is necessary to purge the contents of the manifold of any air to avoid oxidation and contamination. When that is done, the system functions satisfactorily; however, when it is shut down overnight or for repairs, air infiltrates back in, and a source of contamination is reestablished. Manifold systems are never fully purged, and leaks are common.

The contaminated welds were removed, and the vessels were rewelded and put back into service. Some rework involved the use of covered electrodes of dissimilar composition. No problems have been reported to date.

Recommendations. First, to ensure proper joint cleaning, solvent washing and wiping with a lint-free cloth should be performed immediately before welding. Also, a word of caution: Solvents are generally flammable and can be toxic. Ventilation should be adequate. Cleaning should continue until cloths are free of any residues.

Second, when GTAW, a 19 mm ($\frac{3}{4}$ in.) diameter ceramic nozzle with gas lens collet body is recommended. An argon gas flow rate of 28 L/min (60 ft^3/h) is optimum. Smaller nozzles are not recommended. Argon back gas shielding is mandatory at a slight positive pressure to avoid disrupting the flow of the welding torch.

Third, the tip of the filler wire should be kept within the torch shielding gas envelope to avoid contamination and pickup of nitrogen and oxygen (they embrittle the weld). If the tip becomes contaminated, welding should be stopped, the contaminated weld area ground out, and the tip of the filler wire that has been oxidized should be snipped off before proceeding with welding.

Fourth, a manifold gas system can be a problem when supplying shielding and backing gas. Individual argon gas cylinders (or individual liquid dewars) were found to provide good performance. A weld button spot test should be performed to confirm the integrity of the argon cylinder and all hose connections. In this test, the weld button sample must be absolutely bright and shiny. Any cloudiness is an indication of contamination. It is then necessary to check for leaks or to replace the cylinder. The best insurance is to purify the gas.

Fifth, it is important to remember that corrosion resistance is not the only criterion when evaluating these new ferritic stainless steels. Welds must also be tough and ductile, and these factors must be considered when making welds.

Lastly, dissimilar weld filler metals can be successfully used. To avoid premature failure, the dissimilar combination should be corrosion tested to ensure suitability for the intended service.

Weld toughness is an important property, and of great interest to the design engineer as well as the end user because of the influence of weld defects or notches on the performance of the material such as in a piping system or pressure vessel, especially under high strain rate conditions. Because ferritic stainless steels undergo a transition from ductile-to-brittle behavior as the temperature decreases (Fig. 2), researchers have been able to show rather good correlation between the DBTT and weldability. The common method used to measure DBTT is the CVN test.

Section size and thickness have a significant effect on the impact toughness of ferritic stainless steels (and all ferritic alloys). The effect of section size on DBTT is shown in Fig. 15. The thinner the material, the lower the DBTT.

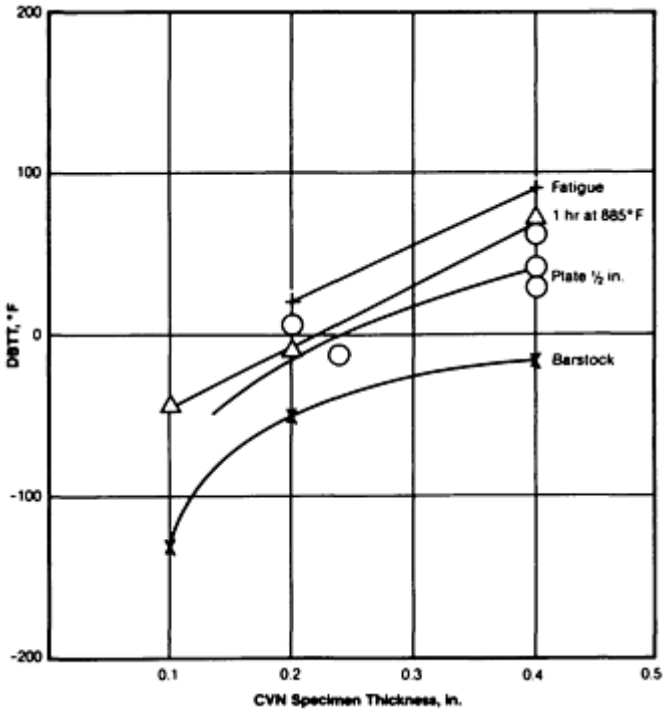

FIG. 15 IMPACT PROPERTIES AS A FUNCTION OF SECTION THICKNESS FOR XM-27 FERRITIC STAINLESS STEEL. SOURCE: REF 3

The cooling rate from peak welding temperatures is very important because toughness appears to be strongly related to the precipitation and morphology of carbides and nitrides. Even in ultrahigh-purity E-Brite 26-1, chromium nitrides have been observed (Ref 3). Depending on cooling rate, these precipitates will align along the grain boundaries or intragranularly within the matrix. For this reason, grain size is important. The finer the grain size, the more uniform the properties and the tougher the material.

Figure 16 illustrates the effect of carbon, nitrogen, and stabilizing elements on 26Cr-1Mo alloys. As shown in this figure, low interstitial levels correspond to lower DBTT values. Similar results are reported in Ref 4, 6, 44, 46, 48, and 49. It was further observed that notch brittleness was the result of the total interstitial element content (C + N), rather than the absolute value of each. Reducing the total interstitial element levels in ferritic stainless steels improves weldability and notch toughness. Another comparison is shown in Fig. 17. Here, the higher the purity of a 26Cr-1Mo alloy, the better the notch toughness and the lower the DBTT when compared to a 26Cr-1Mo alloy stabilized with titanium. Although the titanium-stabilized alloy was 3 mm ($\frac{1}{8}$ in.) thick compared to the 6 mm ($\frac{1}{4}$ in.) thick E-Brite plate, the ultrahigh-purity alloy had decidedly superior notch toughness (DBTT = -40 °C, or -40 °F, for E-Brite versus DBTT = +80 °C, or +175 °F, for 26-1 with titanium).

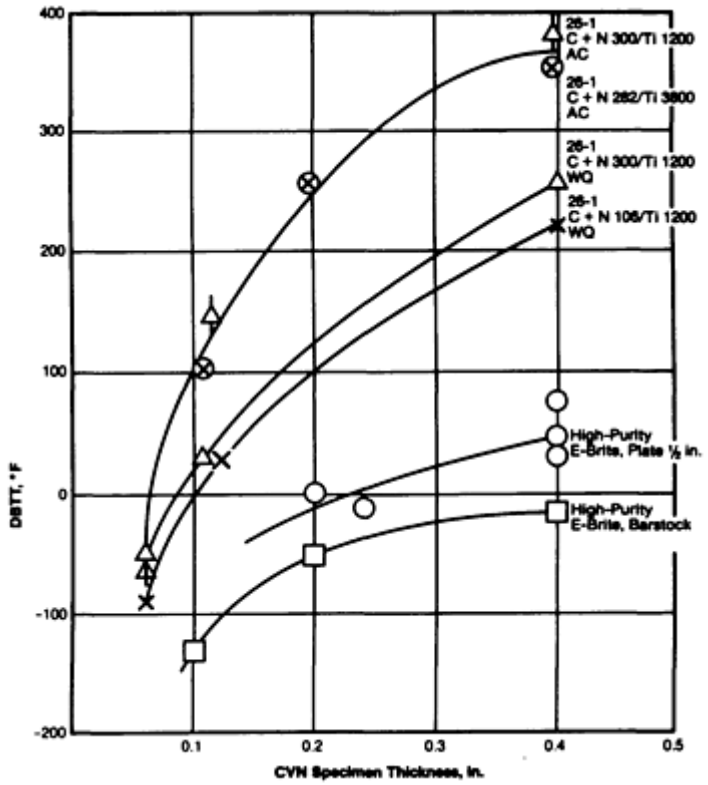

FIG. 16 EFFECT OF ALLOY PURITY (INTERSTITIAL ELEMENT CONTENT) AND STABILIZER CONTENT (VALUES GIVEN IN PARTS PER MILLION) ON THE DBTT OF FERRITIC STAINLESS STEELS. AC, AIR COOL; WQ, WATER QUENCHED. SOURCE: REF 3

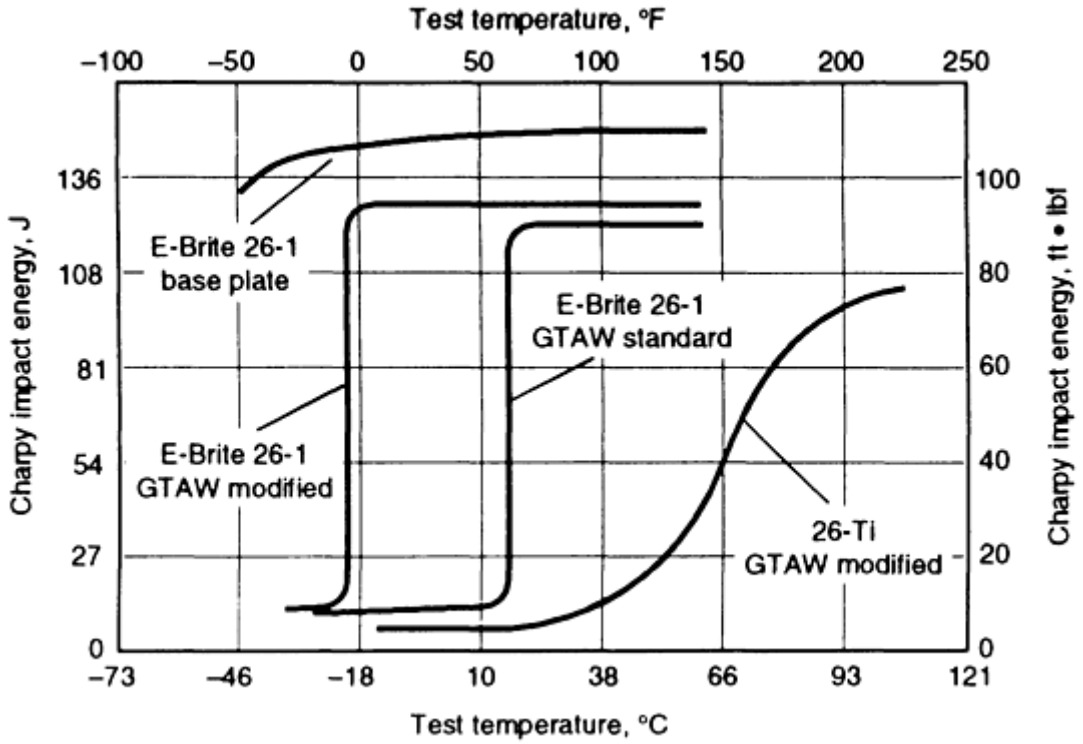

FIG. 17 NOTCH TOUGHNESS OF A GAS-TUNGSTEN ARC WELDED HIGH-PURITY FERRITIC STAINLESS STEEL (6 MM, OR $\frac{1}{4}$ IN., THICK E-BRITE 26-1 PLATE) VERSUS A TITANIUM-STABILIZED ALLOY (3 MM, OR $\frac{1}{8}$ IN., THICK

26-1 TI PLATE). SOURCE: REF 17

If the alloy thickness is reduced below 3 mm ($\frac{1}{8}$ in.), the stabilized grades start to display somewhat improved toughness. Because of the difficulty of measuring CVN impact toughness in those thin gages, weld ductility as measured by a bend test (see Table 6) or bend angle, was determined to be an acceptable method of measuring weldability. Under these conditions, stabilized ferritic stainless steels have excellent aswelded ductility when stabilizers are present in the minimum amounts necessary for stabilization, but the room-temperature impact properties suffer. When excessive stabilizing element(s) are present, weld ductility decreases as excess stabilizer content increases (Ref 50). If welding techniques are poor and shielding gas is contaminated, the amounts of stabilizer added to prevent sensitization and embrittlement may be insufficient to combine with all of the carbon and nitrogen. Oxygen pickup can also be detrimental. The result is loss of ductility, toughness, and corrosion resistance. Shielding gas purity must not be overlooked.

Dissimilar austenitic filler metals can be used to overcome the difficulties of higher than desired weld metal DBTT. Typical CVN toughness data are shown in Fig. 18.

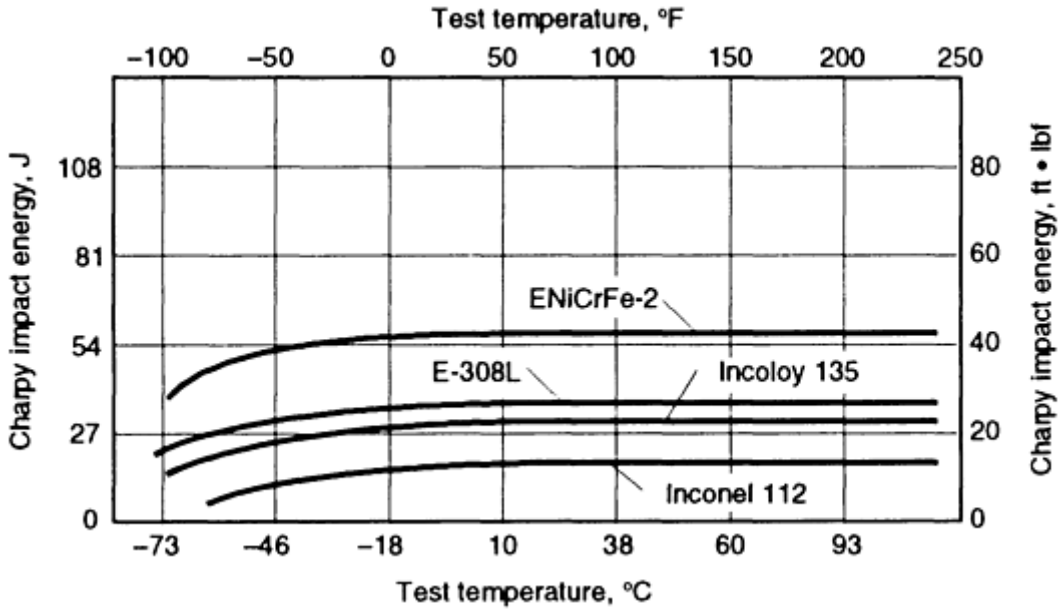

FIG. 18 CHARPY V-NOTCH TOUGHNESS OF SHIELDED METAL ARC WELDS MADE IN 6 MM ($\frac{1}{4}$ IN.) THICK E-BRITE 26-1 PLATE WITH DIFFERENT FILLER METALS. SOURCE: REF 17

Hot Cracking. Weld and HAZ hot cracking in the ferritic stainless steels is not as common a problem as with austenitic stainless steels. This is a result of the lower coefficient of thermal expansion of the ferritic stainless steels, as well as the greater solubility of sulfur and phosphorus in ferrite. However, excessive amounts of stabilizing elements have been shown to cause hot cracking as well as reduced ductility (Ref 25). Figure 19 shows hot cracks in the top surfaces of autogenous gas-tungsten arc welds in two type 444 ferritic stainless steel subscale varestraint test specimens. The stabilized alloys were found to be more susceptible to hot cracking than an alloy of similar composition with ultralow levels of impurities.

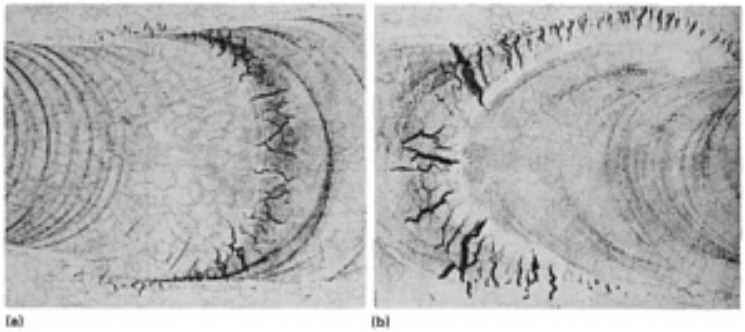

FIG. 19 TOP SURFACES OF SUBSCALE VARESTRAINT TEST GAS-TUNGSTEN WELDS IN TYPE 444 STAINLESS STEELS. (A) TITANIUM-STABILIZED (0.333% TI) TYPE 444 ALLOY. (B) NIOBIUM-STABILIZED (0.401% NB) TYPE 444 ALLOY. SOURCE: REF 25

The alloy which contained 0.40% Nb as a stabilizing element cracked more severely than the alloy which contained 0.333% Ti, but the worst cracking occurred in an alloy which contained both niobium (0.394%) and titanium (0.171%). The high-purity alloy which contained a total (C + N) content of 47 ppm (and no stabilizing elements), produced no hot cracks when tested under the same conditions. Although sulfur and phosphorus can also cause hot cracking in the ferritic stainless steels, the excess levels of niobium and titanium (above that necessary to tie up the carbon and nitrogen) are a more common cause of hot cracking. Thus, the stabilizing elements must be kept to the minimum practical levels to avoid hot cracking and reduced ductility.

Along with hot cracking, which is not often a problem for ferritic stainless steel welds, autogenous welds in alloys stabilized only with niobium often suffer from low ductility and poor toughness. In highly restrained situations, cracks may propagate in the weld along its length. For this reason, ferritic stainless steels of high or intermediate interstitial content stabilized only with niobium are rarely welded. (Titanium-free, stabilized ferritic stainless steels do, however, provide better brazeability and may be selected for brazed rather than welded applications.) Reduction of total interstitial element content to below approximately 0.02% largely eliminates this problem (Ref 51). Thus, the Group III ultra high purity alloys that contain niobium additions can be welded without fear of cracking. Addition of approximately 0.05% or greater titanium causes equiaxed grains to form near the weld centerline and yields improved weld properties (Ref 22). Thus, dual stabilized, intermediate purity Group III ferritic stainless steels are used to provide toughness in both the base metal and the weld regions.

Note cited in this section

* * SENSITIZATION OF FERRITIC STAINLESS STEELS DIFFERS FROM THAT OF AUSTENITIC STAINLESS STEELS BECAUSE OF THE LOWER SOLUBILITY OF (C + N) IN FERRITE AND THE MUCH GREATER (APPROXIMATELY 10^3 TIMES) DIFFUSION RATE OF (C + N) AND CHROMIUM IN FERRITE THAN IN AUSTENITE.

Selection of Wrought Austenitic Stainless Steels

John A. Brooks, Sandia National Laboratories; John C. Lippold, Edison Welding Institute

Introduction

AUSTENITIC STAINLESS STEELS exhibit a single-phase, face-centered cubic (fcc) structure that is maintained over a wide range of temperatures. This structure results from a balance of alloying additions that stabilize the austenite phase from elevated to cryogenic temperatures. Because these alloys are predominantly single phase, they can only be strengthened by solid-solution alloying or by work hardening. The exceptions are the precipitation-strengthened austenitic stainless steels that are discussed in the article "Selection of Wrought Precipitation-Hardening Stainless Steels" in this Section of the Volume.

The austenitic stainless steels were developed for use in both mild and severe corrosive conditions. They are also used at temperatures that range from cryogenic temperatures, where they exhibit high toughness, to elevated temperatures of nearly 600 °C (1110 °F), where they exhibit good oxidation resistance. Because the austenitic materials are nonmagnetic, they are sometimes used in applications where magnetic materials are not acceptable.

The most common types of austenitic stainless steels are the UNS S20000 and S30000 alloys (AISI 200 and 300 series). Within these two grades, the alloying additions, which are chosen to provide the desired properties at reasonable cost, can be considerably different. Furthermore, alloying additions and specific alloy composition can have a major effect on weldability and the as-welded microstructure. The AISI 300 series of alloys typically contain from 8 to 20% Ni and from 16 to 25% Cr. Minor alloying additions are approximately 1% Si (maximum), which is used as a deoxidizer; 0.02 to 0.08% C, which is used as an austenite stabilizer; and approximately 1.5% Mn, which is used both as an austenite stabilizer and as a sulfur and silicon compound former. A more-complete compositional range of common AISI 200- and 300-series alloys is shown in Table 1. The less common alloys, including some of the superaustenitic stainless steels, are identified in Table 2.

TABLE 1 COMPOSITIONS OF STANDARD AUSTENITIC STAINLESS STEELS

TYPE	UNS NO.	COMPOSITION, %[A]							
		C	Mn	Si	Cr	Ni	P	S	Other

(A) XM DESIGNATIONS IN THIS COLUMN ARE ASTM DESIGNATIONS FOR THE LISTED ALLOY.

(B) SINGLE VALUES ARE MAXIMUM VALUES UNLESS OTHERWISE INDICATED.

(C) NOMINAL COMPOSITIONS.

(D) UNS DESIGNATION HAS NOT BEEN SPECIFIED; THIS DESIGNATION APPEARS IN ASTM A 887 AND MERELY INDICATES THE FORM TO BE USED.

Depending on alloy composition, the austenitic stainless steels may solidify with a microstructure containing some retained ferrite at room temperature, as a result of welding. Weld cracking, of which the most common form is solidification cracking, can be another consequence of welding. Cracks can occur in various regions of the weld with different orientations, such as centerline cracks, transverse cracks, and microcracks in the underlying weld metal or adjacent heat-affected zone (HAZ). These cracks are due, primarily, to low-melting liquid phases, which allow boundaries to separate under the thermal and shrinkage stresses resulting from weld solidification and cooling. Other possible metallurgical consequences of welding are:

- THE PRECIPITATION OF INTERGRANULAR, CHROMIUM-RICH $M_{23}C_6$ CHROMIUM CARBIDES IN THE WELD HAZ, WHICH CAN LEAVE THESE REGIONS SENSITIVE TO CORROSION
- THE TRANSFORMATION OF WELD FERRITE TO SIGMA PHASE DURING ELEVATED-

TEMPERATURE SERVICE, WHICH CAN REDUCE DUCTILITY AND TOUGHNESS

These phenomena can be either minimized or eliminated through alloy selection, process optimization, or postweld heat treatment. In general, these alloys are very weldable. With an understanding of the evolution of the weld microstructure and the ability to control it, one can produce welds to meet a wide variety of service requirements.

Alloy Types. One of the most important decisions of engineering design is the selection of the appropriate stainless steel type for the desired application and service. The factors for selection are covered more thoroughly in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of the *ASM Handbook.* However, when the engineering design includes welding as a fabrication process, then alloy selection must consider weldability and weld performance.

An important criterion for alloy selection in welding applications may be to use low-carbon grades to prevent chromium carbide precipitation and sensitization to intergranular corrosion. On the other hand, additions of sulfur or selenium may be used to improve machinability, although these elements can result in severe weld hot-cracking problems and, thus, may not be suitable when welding is required.

In reviewing the composition of the alloys listed in Tables 1 and 2, one can see that a wide range of alloy additions exists, as well as a fairly wide range in composition within the specification of individual alloy types. These two factors can have major effects on the welding behavior of the different alloy types, in addition to heat-to-heat variations in weldability. One goal of this article is to provide an understanding of the effects of composition on welding behavior, and another is to provide guidance in the selection and welding of these materials.

General Welding Characteristics. The austenitic stainless steels are generally considered the most weldable of the stainless steels. Because of their physical properties, their welding behavior may be considerably different than those of the ferritic, martensitic, and duplex stainless steels. For example, the thermal conductivity of typical austenitic alloys is only approximately half that of the ferritic steels. Therefore, the weld heat input that is required to achieve the same penetration is considerably reduced. In contrast, the coefficient of thermal expansion (CTE) of austenite is 30 to 40% greater than that of ferrite, which can result in increases in both distortion and residual stress, because of welding. The molten weld pool of the austenitic stainless steels also tends to be more viscous, or "sluggish," than ferritic and martensitic grades. This impedes the metal flow and wettability of welds in these materials, which may promote lack-of-fusion defects.

A major concern, when welding the austenitic stainless steels, is the susceptibility to solidification and liquation cracking. As discussed below, these materials can be very resistant to these forms of high-temperature cracking, if the material is compositionally balanced such that the solidification behavior and microstructure is controlled to ensure that the weld metal contains more than 3 vol% ferrite.

In cases where fully austenitic welds are required, such as when the weld must be nonmagnetic or when it is placed in corrosive environments that selectively attack the ferrite phase, the welds will solidify as austenite and the propensity for weld cracking will increase. In some alloys, such as AISI 310 and the superaustenitic grades, all the allowable compositions within the specification range solidify as austenite when welded. To minimize cracking in these welds, it is generally advisable to weld with low heat input and under low constraint conditions.

Welds that are made at slower speeds and produce elliptical-, rather than teardrop-, shaped pools are also generally less susceptible to cracking. This effect is particularly pronounced when welding thin sheet, as in the production of thin-walled tubing. Residual elements, which form low-melting liquid phases that promote cracking, should be kept to a minimum. These elements include phosphorus, sulfur, boron, selenium, niobium, silicon and titanium. Small additions of oxygen and nitrogen are somewhat beneficial and are thought to affect the wetting characteristics of the liquid phases. However, high concentrations of these elements may promote porosity. Manganese also can reduce cracking susceptibility, primarily by tying up sulfur and silicon that would otherwise be available to form low-melting phases.

Microstructural Development

Although austenitic stainless steels are predominantly austenitic, they often contain small amounts of body-centered cubic (bcc) ferrite, particularly in the weld metal. This ferrite is often described as "delta" ferrite, because it forms at elevated temperatures and is distinguished from "alpha" ferrite, which is the low-temperature form in iron-base alloys. In this article, the term ferrite will refer to high-temperature delta ferrite, unless noted otherwise. These alloys also may contain martensite, although the presence of this phase is unusual and limited to special composition and temperature ranges, forming only as a result of plastic deformation (Ref 1).

The solidification behavior and microstructural development of the weld metal of these alloys are quite complex, and, until recently, were not well understood. In this class of alloys, weldability and subsequent weld performance are often directly related to weld microstructure. Thus, when welding these alloys, a general understanding of the welding metallurgy can be very beneficial in optimizing weld performance. Because chemical composition has the greatest influence on weld microstructure, a number of empirical relationships and constitution diagrams have been developed to predict microstructure based on actual or approximated composition. In all cases, the concept of chromium equivalence (Cr_{eq}) and nickel equivalence (Ni_{eq}) has been used to normalize the effect of various alloying additions on the ferrite-forming and austenite-forming potency, respectively. Considerable disagreement still exists regarding these equivalency relationships (Table 3) for austenitic stainless steels.

The Schaeffier diagram (Ref 2) was developed in the late 1940s in an attempt to predict weld microstructure for a wide range of stainless steels. This diagram was refined as the DeLong diagram (Ref 3), which pertained to the range of compositions associated with 300-series stainless steels and filler metals. In 1988, the Welding Research Council introduced a further improvement, when compared with the DeLong diagram, which was called the WRC-1988 diagram (Ref 4). This diagram was further modified in 1992 by adding copper to the Ni_{eq} formula. The WRC-1992 diagram (Fig. 1) allows the amount of weld-metal ferrite to be predicted using newly developed Cr_{eq} and Ni_{eq} formulas. The use of this diagram will be described later.

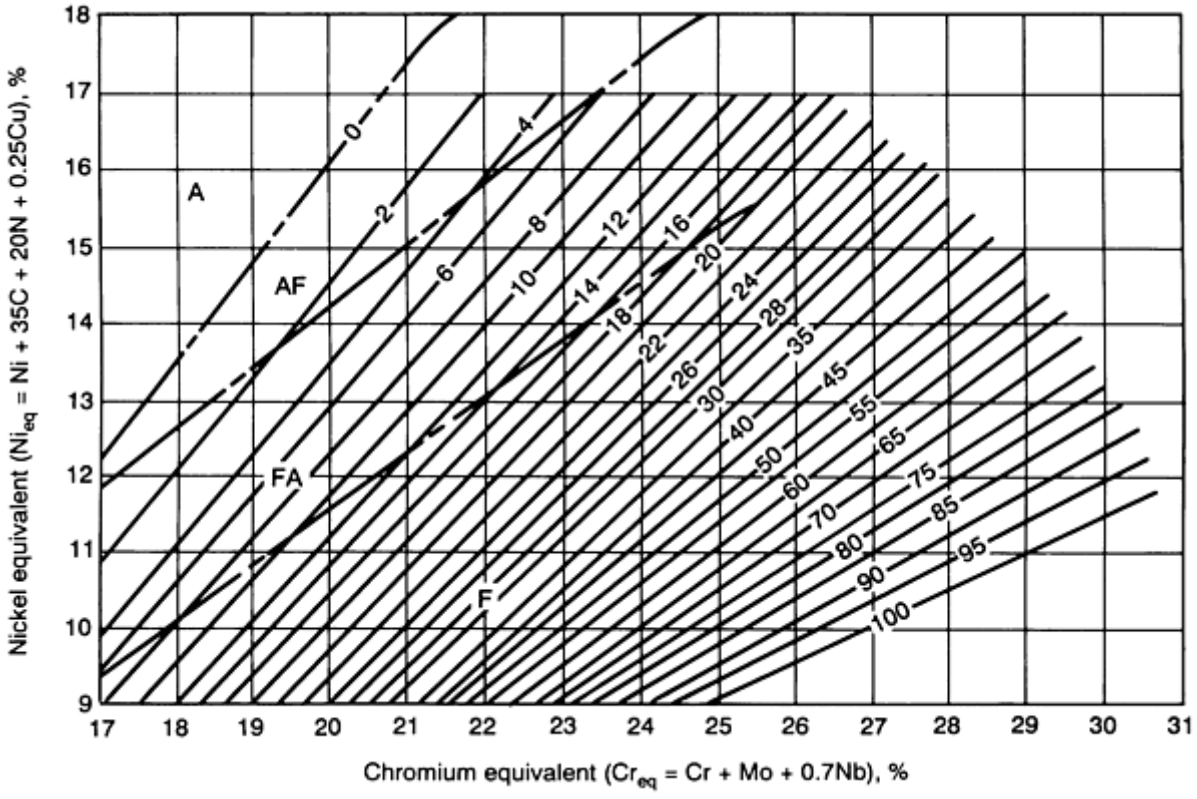

FIG. 1 WRC-1992 DIAGRAM FOR PREDICTING WELD FERRITE CONTENT AND SOLIDIFICATION MODE. SOURCE: REF 4

The following sections in this article summarize the important aspects of solidification behavior and microstructural evolution that dictate weld-metal ferrite content and morphology. An understanding of microstructural evolution and its ramifications in austenitic stainless steel welds is crucial, because it will dictate base- and filler-metal selection, as well as welding conditions.

Selection of Wrought Austenitic Stainless Steels

John A. Brooks, Sandia National Laboratories; John C. Lippold, Edison Welding Institute

Solidification Behavior

In austenitic stainless steels, the primary phase of solidification may be either austenite or ferrite. This is dictated predominantly by composition. It has been well documented (Ref 5, 6, 7) that welds that solidify as primary austenite are inherently more susceptible to weld solidification cracking than welds that solidify as primary ferrite. Thus, control of weld solidification behavior is critical to ensuring crack-free welds.

The iron-nickel-chromium ternary diagram assembled by Speich (Ref 8) can be used to discuss, in general terms, the solidification process. Figure 2 shows both liquidus and solidus surfaces. A eutectic trough extends to the ternary eutectic

composition of roughly 49Cr-43Ni-8Fe. A peritectic trough at Fe-4Ni extends into the diagram to about 75% iron, at which location the liquidus crosses the nickel-rich solidus, changing from peritectic to eutectic behavior (Ref 9).

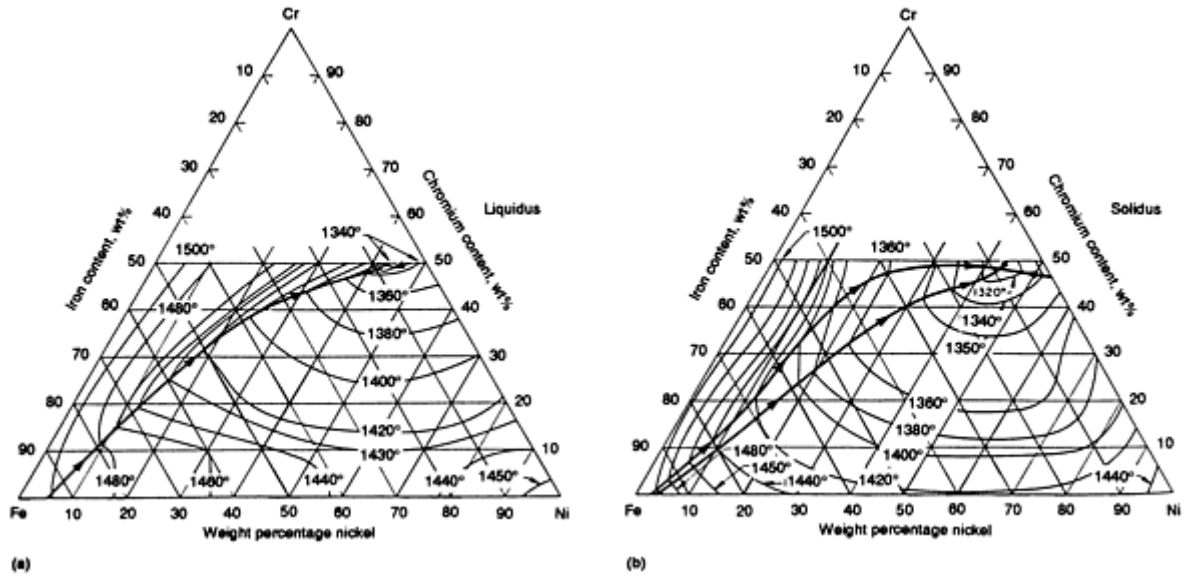

FIG. 2 PROJECTIONS OF (A) LIQUIDUS AND (B) SOLIDUS SURFACES, AS ISOTHERMAL CONTOURS ON IRON-NICKEL-CHROMIUM TERNARY DIAGRAM. TEMPERATURES SHOWN ARE IN °F. SOURCE: REF 8

In Fig. 2, it can be seen that for approximately 60 to 70% Fe, which is the iron content of many of the austenitic stainless steels, the liquidus lies along the chromium/nickel ratio of approximately 1.5. Compositions on the nickel-rich side of the liquidus will solidify as primary austenite, sometimes referred to as A-type solidification. Depending on composition, it may solidify with a small fraction of eutectic ferrite (AF-type solidification). Alloys on the chromium-rich side of the liquidus will solidify as primary ferrite with the peritectic or eutectic solidification of austenite (FA-type solidification). However, the solidification boundary between ferrite and austenite can be shifted, because of the nonequilibrium solidification conditions of welding. For compositions that are further from the peritectic/eutectic liquidus, the welds solidify completely as ferrite at higher chromium/nickel ratios (F-type solidification). The chromium/nickel ratio for single-phase ferrite solidification is often reported to range from 1.9 to 2.0.

A number of diagrams can be used to predict the primary phase of solidification based on the weld-metal composition. The WRC-1992 diagram (Fig. 1) can be used to predict solidification behavior, in addition to ferrite content. Note that this diagram contains four solidification regimes, designated as A, AF, FA, and F. The austenite-ferrite microstructural morphologies associated with these regimes are described below.

Solid-State Transformations and Ferrite Morphologies

The final weld microstructure is controlled by both the solidification behavior and the subsequent solid-state transformations. A number of schematics have been published (Ref 10, 11, 12, 13), such as the one by Brooks *et al.* (Ref 11) shown in Fig. 3, which depicts some of the general characteristics of microstructural development. However, a much wider variety of microstructures exists in actual welds. The vertical sections of the iron-nickel-chromium ternary diagram for 70% and 60% Fe (Fig. 4) are useful in discussing the solid-state transformations. As indicated by these diagrams, during the cooling of primary austenite welds (AF-type), some of the eutectic ferrite may transform to austenite. The primary ferrite-solidified welds that exhibit peritectic/eutectic behavior during the final stages of solidification (FA-type) typically solidify with a large fraction of ferrite (Fig. 3). During cooling through the $\delta + \gamma$ two-phase field, much of the ferrite transforms to austenite, with chromium partitioning to the ferrite and nickel partitioning to the austenite, leaving ferrite only within the very cores of the original dendrites. When only several percent of the original ferrite is retained, which is often referred to as skeletal, or vermicular, ferrite, it may be difficult to distinguish between it and the eutectic ferrite that results from primary austenite solidification, unless good metallographic techniques are used (Fig. 3a and b). However, the location of the ferrite is different. It resides within the core of the dendrites, in the case of FA-type solidification, rather than at the dendrite boundaries, in the case of AF-type solidification.

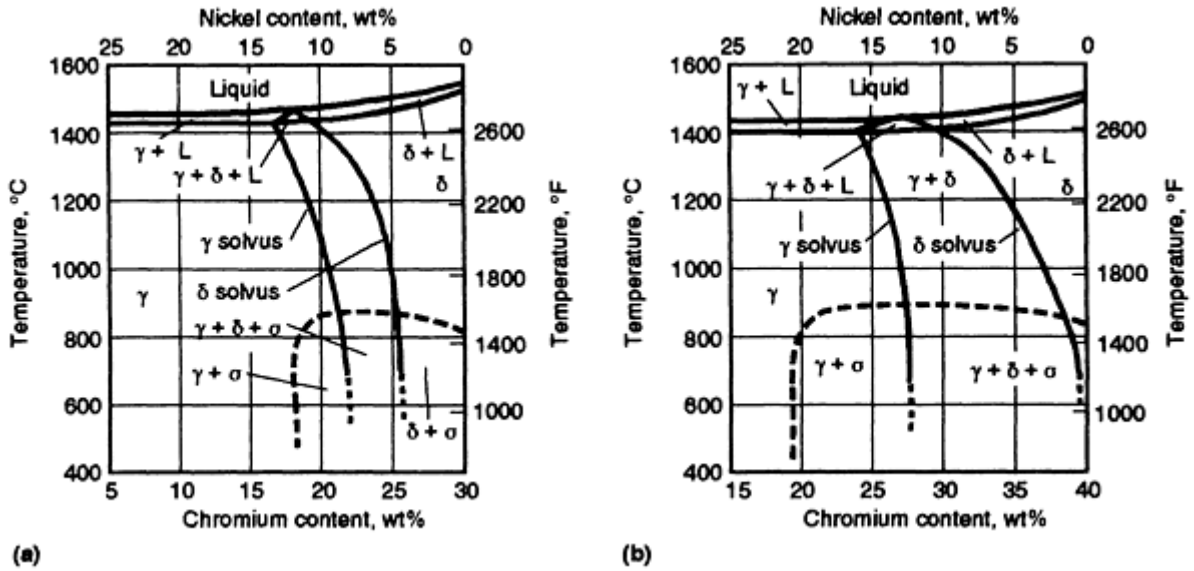

FIG. 4 VERTICAL SECTIONS OF IRON-NICKEL-CHROMIUM TERNARY DIAGRAM, AT CONSTANT IRON CONTENT. (A) 70% FE. (B) 60% FE. SOURCE: REF 14

At higher chromium/nickel ratios, other ferrite morphologies are often observed, such as the lathy structure shown in Fig. 5(c). It is generally reported that the skeletal and lathy ferrite morphologies are indicative of primary ferrite with the secondary solidification of austenite, but these ferrite morphologies can also exist in welds that solidify as single-phase ferrite, as shown in Fig. 3(c) and (d). At higher chromium/ nickel ratios, a Widmanstätten austenite structure can also form in welds that solidify as single-phase ferrite. It should be noted that the solidification and transformation behavior shown in Fig. 3 is dependent not only on composition, but also on cooling rate. Extremely high solidification and cooling rates, such as those encountered during electron-beam or laser-beam welding, may significantly alter the microstructure relative to that predicted using the WRC-1992 diagram. This behavior is described in the section "Solidification Behavior and Microstructure of High-Energy-Density Welds."

SOURCE: REF 15

Micrographs of the three-dimensional structure of several weld ferrite morphologies compiled by David (Ref 15) are shown in Fig. 5. Small amounts of ferrite along solidification cell boundaries of a primary austenite structure are shown in Fig. 5(a). This very cellular-appearing solidification structure is characteristic of welds that solidify as austenite and results primarily from the microsegregation of chromium and, to a lesser extent, nickel, along the solidification cell boundaries. Depending on alloy composition and welding conditions, final solidification may occur as a eutectic of ferrite and austenite. Figure 5(b) and (c) show ferrite along cell cores of primary ferrite structures, whereas Fig. 5(d) shows acicular ferrite or Widmanstätten austenite in a structure that solidified completely as ferrite. Additional details on solidification behavior and microstructural development are provided in Ref 11 and 16.

Alloying Effects on Solidification Behavior, Weld Microstructure, and Cracking Susceptibility. The relationship between solidification behavior and a composition factor, in terms of Cr_{eq}/Ni_{eq}, was established by Suutala and Moisio (Ref 17) using coefficients of: $Ni_{eq} = Ni + 0.3Mn + 22C + 14.2N + Cu$; and $Cr_{eq} = Cr + 1.37Mo + 1.5Si + 2Nb + 3Ti$ (see Table 3). A diagram (Fig. 6) was developed that delineates the four solidification types, A, AF, FA, and F, as described previously. Using their data, the demarcation between single-phase austenite solidification (A) and austenite solidification with the eutectic solidification of ferrite (FA) occurs at a Cr_{eq}/Ni_{eq} ratio of approximately 1.35. The transition to solidification as primary ferrite with the eutectic/peritectic solidification of austenite (FA) occurs at a Cr_{eq}/Ni_{eq} of approximately 1.5. This value has been found to be valid for most conventional 300-series alloys welded under normal arc-welding conditions. This ratio increases with increasing solidification velocity. At the lower bounds of primary ferrite, some regions may solidify as ferrite and others as austenite (Ref 18). In this case, the region where primary austenite is most commonly located is along the weld centerline, where the solidification velocity is maximum. This transition between primary austenite and primary ferrite is especially important, because of the strong relationship between solidification behavior and solidification-cracking susceptibility.

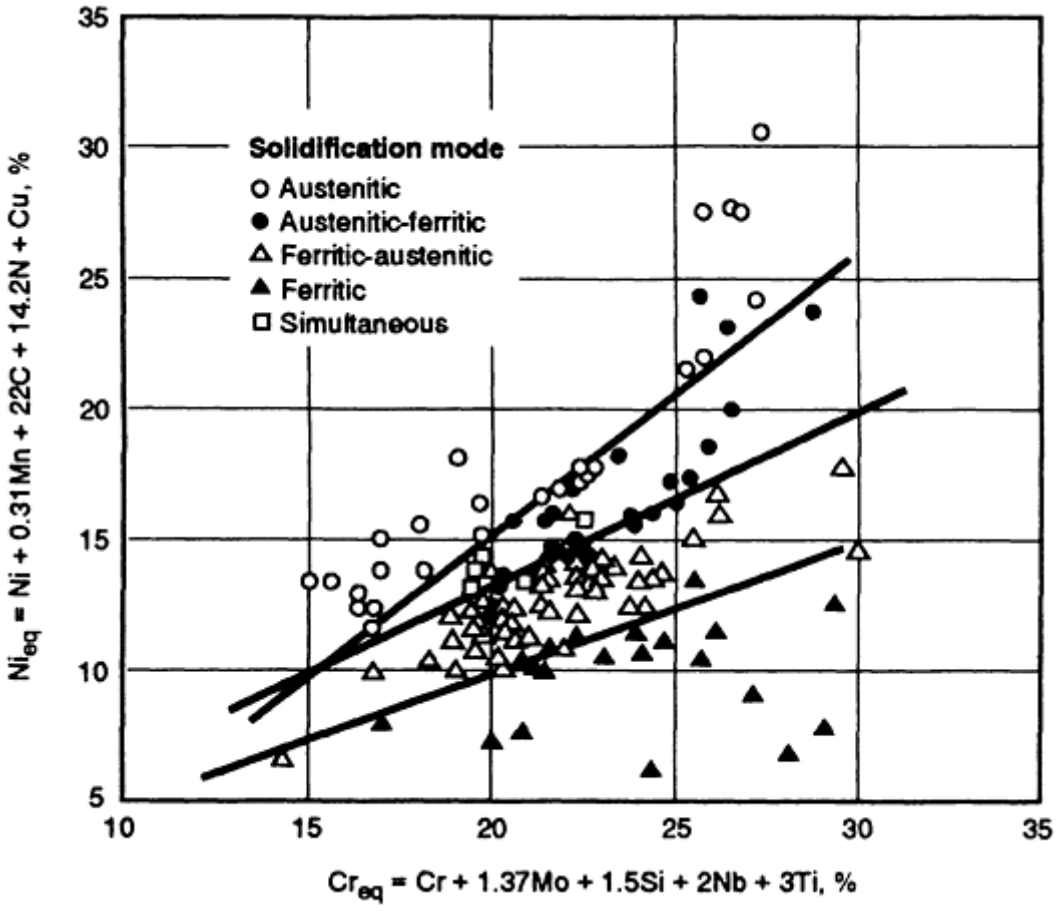

FIG. 6 SOLIDIFICATION MODE (EXPERIMENTAL) FOR VARIETY OF COMPOSITIONS, COMPARED ON BASIS OF CR_{EQ}/NI_{EQ} RATIO. SOURCE: REF 17

As indicated in Fig. 6, above a Cr_{eq}/Ni_{eq} ratio of approximately 1.95, solidification occurs as single-phase ferrite. However, other studies (Ref 13) indicate that single-phase ferrite solidification occurs at considerably lower Cr_{eq}/Ni_{eq} ratios, and that the ratio of approximately 1.95 may more closely correlate to microstructures containing Widmanstätten austenite.

Note that the Cr_{eq}/Ni_{eq} ratios defined above are valid only when using the Suutala and Moisio equivalency relationships. Corresponding ratios for delineating the solidification behavior by using the WRC-1992 equivalencies are somewhat different. However, discrepancies between the two diagrams exist, as is apparent for lean alloys or pure iron-nickel-chromium ternaries. For example, the transition from primary austenite to primary ferrite is reported to occur at a Cr_{eq}/Ni_{eq} ratio of 1.5 by Suutala and Moisio (Ref 17), versus 1.4 in the WRC diagram.

Takalo, Suutala, and Moisio (Ref 18) also described the solidification-cracking susceptibility of austenitic stainless steels by plotting their Cr_{eq}/Ni_{eq} ratios versus impurity content in terms of sulfur plus phosphorus. Their results are shown in Fig. 7. Note that a dramatic transition in cracking susceptibility occurs at a value of approximately 1.5. This transition represents the shift in solidification behavior from primary austenite to primary ferrite, as described above, and reinforces the importance of controlling solidification behavior in order to avoid weld solidification cracking.

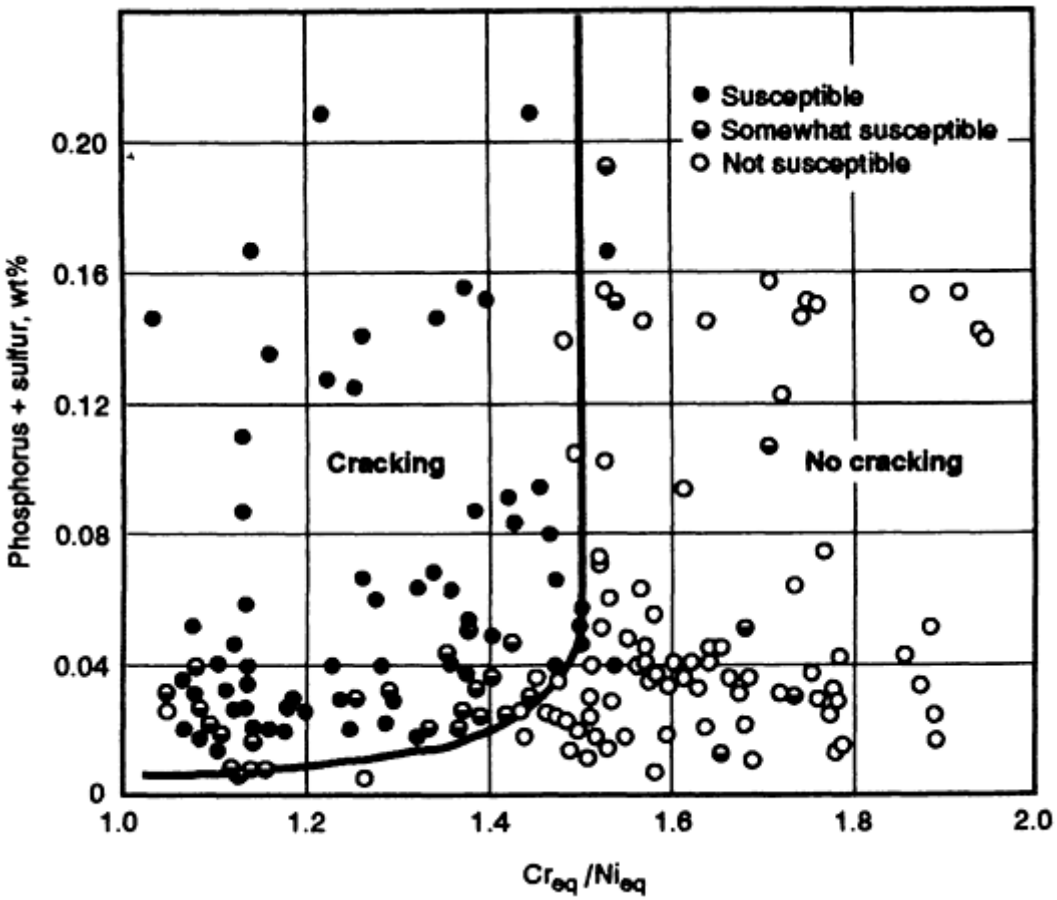

FIG. 7 RELATIONSHIP BETWEEN SOLIDIFICATION CRACKING SUSCEPTIBILITY AND CR_{EQ}/NI_{EQ} RATIO. BOUNDARY BETWEEN CRACKING AND NO CRACKING AT CR_{EQ}/NI_{EQ} = 1.5 CORRESPONDS TO CHANGE IN SOLIDIFICATION MODE FROM PRIMARY AUSTENITE BELOW 1.5 TO PRIMARY FERRITE ABOVE 1.5. SOURCE: REF 18

As noted previously, Schaeffler developed one of the first diagrams for predicting weld microstructures. This diagram is especially useful for predicting microstructures between dissimilar alloys using a tie line between the two alloy compositions and the appropriate alloy dilution. The diagram was developed using the shielded metal arc welding (SMAW) process, where the nominal nitrogen level was about 0.06 wt% and, as such, was not shown as an alloying addition. This diagram described the behavior of most of the alloys in use at that time, and is relatively accurate for most 300-series alloys when using conventional welding processes. The use of this diagram is discussed in more detail in the article "Welding of Stainless Steels." Other diagrams that have been developed, often using limited alloy compositional ranges, are reviewed in detail in Ref 19.

The WRC-1992 diagram, developed primarily with data from welds made by SMAW, is the most accurate diagram and is preferred in terms of the composition ranges for which it was established. In this diagram, the alloying elements have been limited to nickel, carbon, nitrogen, and copper in the Ni_{eq}, and to chromium, molybdenum, and niobium in the Cr_{eq}. However, the diagram is applicable for manganese contents up to 10%, molybdenum contents up to 3%, nitrogen contents up to 0.2%, and silicon contents up to 1%.

When the diagram is used for alloy systems containing significant amounts of alloying elements that have not been included in the diagram, predictions may be inaccurate. As discussed above, boundaries between the different solidification modes are also included on the diagram, although some disagreement exists with the boundaries established by other investigators. However, the most important boundary by far is the one separating primary ferrite from primary austenite solidification, in which some discrepancy still exists. The diagram does predict that the maximum amount of eutectic ferrite will not exceed a few percent, which is consistent with that observed in practice.

When using these diagrams to predict weld behavior, one must be aware that uncertainties in compositional analysis, as well as welding process and parameters, can affect predicted solidification behavior and ferrite content. One common occurrence in the welding of stainless steels is the possibility of nitrogen adsorption during welding when inadequate shielding is used. It is not uncommon that nitrogen levels of approximately 0.02% in the base material can be increased to values as high as 0.1%. This will significantly decrease ferrite content and may also result in a change in solidification mode from primary ferrite to primary austenite, which can have a drastic effect on weld solidification-cracking susceptibility. Thus, the nitrogen content of the deposited weld material must be used in making the predictions. However, with the use of the diagrams, magnetic measurements of ferrite number, and an understanding of weld microstructural evolution, one can reasonably predict the nature of the weld microstructure.

Selection of Wrought Austenitic Stainless Steels

John A. Brooks, Sandia National Laboratories; John C. Lippold, Edison Welding Institute

Measurement of Weld-Metal Ferrite

As described previously, weld-metal ferrite content significantly influences both the weldability and service performance of austenitic stainless steels. Weld-metal ferrite content can either be predicted using constitution diagrams, such as the WRC-1992 diagram (Fig. 1), or measured using instruments that take advantage of the ferromagnetic characteristics of the ferrite phase.

The term *Ferrite Number*, designated FN, has been adopted as a relative measure for quantifying ferrite content using standardized magnetic techniques (Ref 20). The FN approach was developed in order to reduce the large variation in ferrite levels determined on a given specimen when measured using different techniques by different laboratories. FN approximates the "volume percent ferrite" at levels below 8 FN. Above this level, deviation occurs, where the FN value exceeds the actual volume percent ferrite. For example, a weld metal with 16 FN contains approximately 13.8 vol%.

A number of instruments are commercially available for determining the ferrite content of welds, including the Magne gage, Severn gage, and ferrite scope (Ref 20). The Severn gage and ferrite scope are particularly applicable for use in the field or on the production floor. The ferrite scope is also useful in measuring ferrite on welds of small cross section, as is often the case with electron-beam welds. Calibration procedures for magnetic measurement techniques have been

recommended by the American Welding Society in AWS A4.2 (Ref 20). These procedures use either the thickness standards of the National Institute of Standards and Technology (NIST) or actual weld-metal standards that include certified levels of weldmetal ferrite.

However, it is important to understand that it is impossible to accurately determine the absolute ferrite content of austenitic stainless steel weld metals. Even on undiluted weld pads, ferrite variations from pad to pad must be expected, because of slight changes in welding and measuring variables. On a large group of pads made from one heat or lot, using a standard pad welding and preparation procedure, two sigma values indicate that 95% of the tests are expected to be within a range of approximately ±2.2 FN at about 8 FN. If different pad welding and preparation procedures are used, then these variations will increase. Variations are also introduced based on the composition of the ferrite. The magnetic attraction of the ferrite may vary significantly with chemical composition. Thus, for the same volume percent ferrite, the FN determined by magnetic instruments may vary for weld pads made using different filler materials.

Even larger variations in ferrite content may be encountered if the welding technique allows excessive nitrogen pickup, in which case the ferrite can be much lower than otherwise expected. A nitrogen pickup of 0.10% typically will decrease the FN by about 8.

Austenitic stainless steel base materials are intentionally balanced compositionally to produce inherently lower ferrite content than matching weld metals. This is done, in part, to facilitate the hot workability of the material during forging, extrusion, and rolling operations. For this reason, special attention is required when making autogenous welds if primary ferrite solidification is desired to prevent solidification cracking. In general, weld metal diluted with base metal will also be somewhat lower in ferrite than the undiluted weld metal. For example, this effect is commonly observed when welding types 304 or 304L base metals with ER308 or ER309 filler materials.

The agreement between the predicted and measured weld-metal ferrite content is also strongly dependent on the accuracy of the chemical analysis. Variations in the results of the chemical analyses encountered from laboratory to laboratory can have significant effects on the predicted ferrite level, particularly if these variations occur in the detection of carbon and nitrogen. It is not uncommon for predicted and measured ferrite levels to differ by as much as 4 to 8 FN.

Nitrogen-Strengthened Stainless Steels. The addition of nitrogen to austenitic stainless steels significantly improves the strength and pitting resistance of the alloy, and may also improve cryogenic toughness. These alloys may contain relatively high levels of manganese, because manganese increases the solubility of nitrogen in the austenite matrix, in addition to substituting for nickel as an austenite stabilizer.

In general, the weldability of these alloys is similar to the 300-series materials. The presence of ferrite in the as-deposited weld microstructure reduces weld-cracking susceptibility for the same reasons described previously. The prediction of weld-metal ferrite content in these alloys has historically been problematic, because the DeLong diagram did not adequately account for large concentrations of nitrogen and manganese. Both Espy and Hull developed equivalency relationships and predictive diagrams that better coped with high levels of nitrogen. The Espy diagram (Ref 21) represented a modification of the DeLong diagram and accounted for higher nitrogen and manganese levels. Hull (Ref 22) developed equivalencies (see Table 3) to predict ferrite levels in high-nitrogen, high-manganese stainless steels. The Ni_{eq} of 14.2 developed by Hull for nitrogen is significantly lower than the value of 20.0 used in the WRC-1992 diagram. However, the omission of manganese in the diagram is in agreement with the small Ni_{eq} assigned by Hull. Limited data suggest that the Hull and WRC-1992 diagrams are in fair agreement when predicting weld ferrite contents in these alloys with nitrogen contents as high as approximately 0.25%. At the higher nitrogen contents, one may expect that the WRC-1992 diagram would predict higher ferrite contents than that of the Hull diagram. From Table 3, it can be seen that Hammer and Svennson (Ref 23) used the same nickel equivalent developed by Hull.

Because of the high nitrogen contents of these steels, weld porosity may sometimes be encountered. The critical level of nitrogen, in terms of porosity problems, is lower for electron-beam welds made in vacuum (approximately 0.25%) than it is for welds made by gas-tungsten arc welding (GTAW), where porosity problems are usually not encountered at nitrogen levels less than approximately 0.35%.

Solidification Behavior and Microstructure of High-Energy-Density Welds

Differences exist between the solidification behavior and microstructures of high-energy-density welds, such as electron-beam and laser-beam welds, and more-conventional welds, such as shielded metal arc and gas-tungsten arc welds (Ref 12, 16, 24). These differences have been attributed to the rapid solidification velocities and cooling rates of the high-energy-density welds and, if not recognized, can have a drastic effect on weld quality and performance.

One characteristic of the high cooling rates during high-energy-density welding is a fine solidification cell size. However, changes in solidification behavior and solid-state transformation, compared with the behavior and transformation observed in gas-tungsten arc welds of the same alloy composition, can also occur. One of the most important effects of the rapid solidification rates of high-energy-density welds is a shift in the solidification transition from primary austenite to primary ferrite to higher Cr_{eq}/Ni_{eq} ratios than those encountered in conventional arc welds. A change in solidification mode from primary ferrite to primary austenite, which resulted in centerline cracking of an electron-beam weld in type 304L, is shown in Fig. 8. It must be recognized that similar changes in solidification mode from primary ferrite to primary austenite can occur along the centerline of welds made with the more-conventional welding processes, such as the GTAW process (Ref 25). This is especially common at higher welding speeds in materials with Cr_{eq}/Ni_{eq} ratios (Suutala and Moisio equivalents) slightly above 1.5.

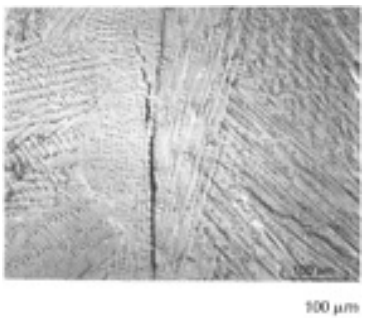

FIG. 8 SOLIDIFICATION CRACK IN ELECTRON-BEAM WELD ALONG WELD CENTER IN REGION WHERE SOLIDIFICATION OCCURRED AS PRIMARY AUSTENITE AS A RESULT OF HIGHER SOLIDIFICATION AND COOLING RATES

Several microstructures can also exist in high-energy-density welds that have not been reported in welds of more-moderate cooling rates. Basically, these microstructures consist of a single phase of either ferrite or austenite. An example of the single-phase austenite structure is shown on the right side of Fig. 9(a), where a carbon dioxide laser-beam weld was made over a gas-tungsten arc weld in an alloy of 23Cr-12Ni-balance Fe with a Cr_{eq}/Ni_{eq} ratio of 1.9 (Ref 26). These welds solidify as single-phase ferrite, but subsequently transform to approximately 100% austenite during cooling via a massive transformation. The gas-tungsten arc weld of this composition, shown to the left in Fig. 9(a), exhibits a typical two-phase microstructure with a FN of approximately 21.

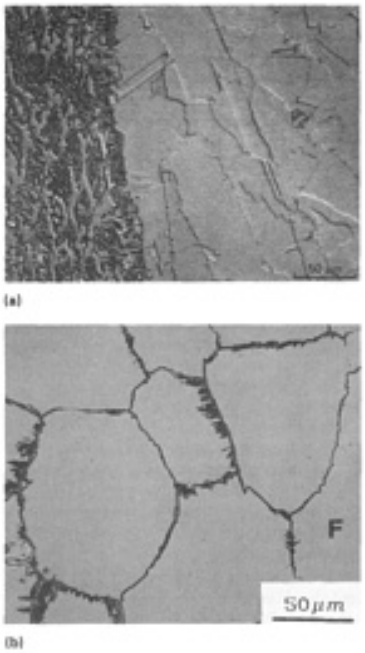

FIG. 9 MICROSTRUCTURES OF LASER-BEAM-WELDED AUSTENITIC STAINLESS STEELS. (A) GAS-TUNGSTEN ARC WELD SHOWN ON LEFT, WITH CO_2 LASER-BEAM WELD SHOWN ON RIGHT, IN ALLOY OF CR_{EQ}/NI_{EQ} = 1.8. LASER-BEAM WELD ON RIGHT IS SINGLE-PHASE AUSTENITE FORMED AS A PRODUCT OF MASSIVE TRANSFORMATION. (B) FERRITIC STRUCTURE FORMED IN LASER-BEAM WELD OF CR_{EQ}/NI_{EQ} = 2.0. SOURCE: REF 26, 27

Characteristics of the massively transformed austenitic structure are fairly small-faceted-appearing grain boundaries and little or no evidence of the cellular solidification that would result from microsegregation. This apparent lack of microsegregation may be due to the higher solute diffusivities in ferrite, as compared with austenite, which results in homogenization occurring during solidification and cooling and/or by reduced alloy partitioning occurring at the rapid solidification velocities (Ref 26, 27).

At high Cr_{eq}/Ni_{eq} ratios, high-energy-density welds can solidify completely as ferrite. However, because of suppression of the solid-state transformation of ferrite to austenite during the rapid cooling, a large fraction of the ferrite is retained at room temperature. This behavior has been reported in laser-beam welds of AISI 312. Microsegregation is also minimal in these welds, and the grain boundary region sometimes exhibits Widmanstätten austenites rather than the faceted grain structure of the massively transformed austenite. An example of this microstructure is shown in Fig. 9(b). In some applications, such as the containment of high-pressure hydrogen, for which the austenitics are highly suited, a weld that completely comprises ferrite would be unacceptable. With the massively transformed ferrite and the retention of ferrite at high Cr_{eq}/Ni_{eq} ratios, the composition range in which two-phase $\delta+\gamma$ microstructures exists in the high-energy-density welds is greatly reduced.

The shift from primary ferrite to primary austenite solidification at high solidification rates often leads to problems with weld cracking, as shown in the electron-beam weld in Fig. 8. Alloy selection based on solidification behavior predicted by the WRC-1992 diagram or that of Moisio and coworkers (Ref 17) may not be valid.

For example, a pulsed Nd:YAG laser-beam weld in a 316L alloy with a Cr_{eq}/Ni_{eq} (Suutala and Moisio equivalents) of approximately 1.6 is shown in Fig. 10. Solidification of this weld has occurred as primary austenite, with resultant solidification cracking. Reference to the Suutala and WRC-1992 diagrams indicate that solidification would occur as primary ferrite with conventional gas-tungsten arc welds and that the weld should contain approximately 6 FN.

FIG. 10 PULSED ND:YAG LASER-BEAM WELD EXHIBITING SEVERE SOLIDIFICATION CRACKING AS A CONSEQUENCE OF PRIMARY AUSTENITE SOLIDIFICATION, CR_{EQ}/NI_{EQ} = 1.6. SOURCE: REF 28

A modified Suutala diagram developed by Pacary *et al.* (Ref 28) (Fig. 11) shows the shift in solidification mode and associated cracking behavior of pulsed laser-beam welds. The critical cracking/no cracking demarcation shifts from the Cr_{eq}/Ni_{eq} ratio of approximately 1.48 (Suutala and Moisio equivalents) for conventional arc welding to approximately 1.7 for the pulsed laser-beam welds.

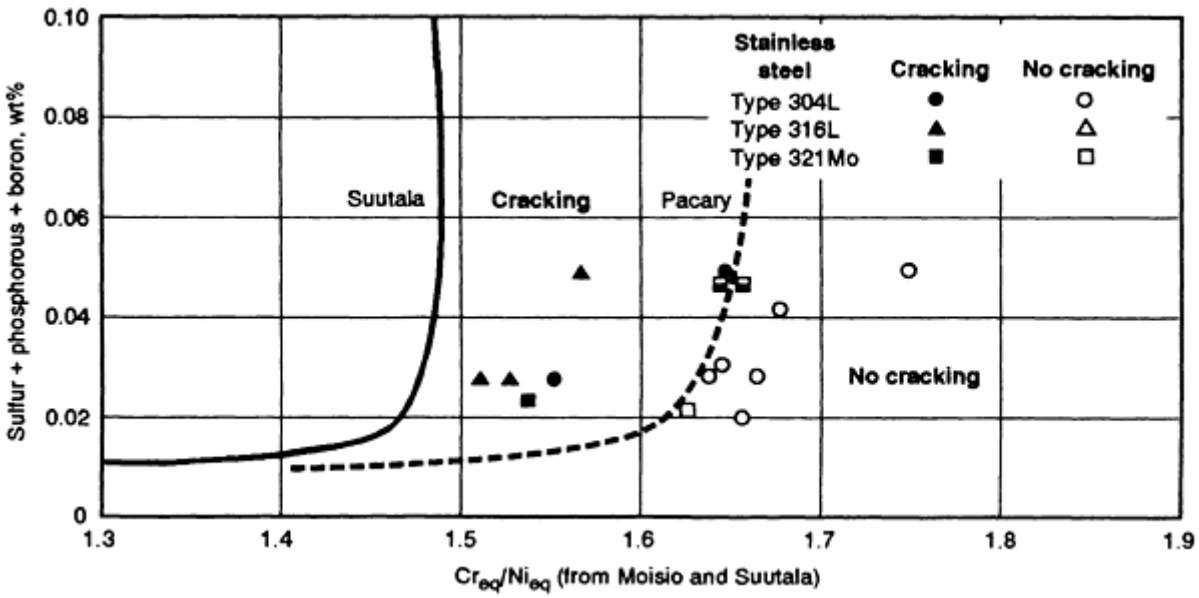

FIG. 11 DIAGRAM FOR PREDICTING WELD SOLIDIFICATION CRACKING SUSCEPTIBILITY OF PULSED LASER WELDS IN AUSTENITIC STAINLESS STEELS. NOTE WRC EQUIVALENTS ARE USED. SOURCE: REF 28

Katayama and Matsunawa (Ref 12) established the change in solidification using Schaeffler equivalents to also occur at the value of 1.7. These values are dependent on the welding process (for example, electron-beam and pulsed-Nd:YAG and carbon dioxide laser-beam welds), as well as on weld parameters (Ref 27). Because the pulsed-YAG technique produces the most rapid solidification interface velocities and cooling rates, the transition for this process should occur at the highest ratio. Thus, the selection of alloy compositions above the Cr_{eq}/Ni_{eq} ratio of approximately 1.7 (Suutala and Moisio equivalents) ensures solidification as primary ferrite and significantly reduces the risk of cracking, although higher accompanying ferrite content in the base material must also be expected.

Weld Defect Formation

Solidification cracking, which results from the formation of low-melting liquid films along grain boundaries during the last stages of solidification, is probably of greater concern to the welding engineer than is any other metallurgical defect in austenitic stainless steel welds. As discussed above, welds that solidify as primary austenite may be very susceptible to solidification cracking. This susceptibility is increased by elements that promote the formation of liquid phases. These elements include phosphorus and sulfur, which are often present as impurities, and silicon, niobium, titanium, and boron, which are sometimes present as minor alloying additions. In these welds, high manganese levels may be beneficial in reducing cracking, for example, by tying up sulfur and silicon. Several percent of eutectic ferrite may be somewhat beneficial in counteracting the detrimental effect of phosphorus and sulfur. However, because the amount of eutectic ferrite is alloy dependent and seldom exceeds several percent (see Fig. 1), it is not a practical solution for improving cracking resistance.

Cracking susceptibility is drastically reduced in welds that solidify as primary ferrite with the peritectic/eutectic solidification of austenite (FA-type), even at high levels of phosphorus and sulfur, as shown in Fig. 7. Welding electrodes such as 308L are specifically designed to produce a desired range of ferrite, and thus promote this solidification mode. In applications where no such filler metal is used and cracking is a concern, it may be necessary to limit composition ranges or to select heats of material that solidify in this mode. However, at the higher Cr_{eq}/Ni_{eq} ratios, where welds solidify completely as ferrite, and when the transformation of ferrite to austenite occurs at lower temperatures, cracking susceptibility again increases, but not to the extent of welds solidifying as austenite. The solidification-cracking behavior can thus be directly related to the structures shown in Fig. 3 and 5. The welds that solidify as ferrite and exhibit skeletal and lathy morphologies are very resistant to cracking, whereas cracking increases in welds that exhibit microstructures of Widmanstätten austenite.

Many rationales have been proposed to explain the cracking behavior of the austenitic stainless steel welds. The two that seem to be most consistent in explaining this behavior are related to the nature of the weld microstructure during solidification and the early stages of cooling.

During single-phase solidification, the fairly planar ferrite/ferrite or austenite/austenite grain boundaries that form are easily wet by low-melting liquids, often involving eutectics with phosphides and sulfides. If sufficient stresses and strains

are developed before these liquids are solidified, then solidification cracks can easily form and propagate. However, when solidification occurs as primary ferrite with the secondary solidification of austenite (FA-type), or if austenite is nucleated at the grain boundaries near the solidus temperature of welds solidifying completely as ferrite (F-type), then very irregular grain-boundary structures are formed. These ferrite/austenite boundaries that become potential crack paths are of lower energy than the grain boundaries of either of the single-phase structures. The resulting tortuous crack paths and/or the low-energy boundary configurations not readily wetted by the low-melting liquids are very resistant to the nucleation and propagation of cracks (Ref 29).

Thus, it can be seen that understanding and being able to identify solidification behavior are important in preventing solidification-cracking problems. Because increased solidification velocities and cooling rates shift the transition between primary austenite and primary ferrite to higher Cr_{eq}/Ni_{eq} ratios, this effect on weld cracking must be considered, as discussed in the section "Solidification Behavior and Microstructure of High-Energy-Density Welds." .

Heat-affected zone liquation cracking is occasionally observed in austenitic stainless steels, particularly in the stabilized grades (containing titanium and/or niobium). This cracking occurs as a result of the constitutional liquation of carbides, such as niobium carbide, in AISI type 347 alloy, resulting in grain-boundary liquation. HAZ cracking can also occur in other alloy types as a result of impurity segregation along HAZ grain boundaries. This form of cracking is always intergranular and located immediately adjacent to the weld fusion boundary. Occasionally, cracking is continuous across the fusion boundary into the weld metal.

Analogous to weld solidification cracking, alloys with a ferrite potential (predicted FN) above approximately 2 to 3 FN are generally resistant to HAZ liquation cracking (Ref 30). This results from the formation of ferrite along HAZ grain boundaries. HAZ cracking that is due to grain-boundary liquation also can be limited by minimizing heat input. Lower weld heat inputs result in steeper HAZ thermal gradients, thereby limiting the spatial extent over which cracking is possible.

Weld-metal liquation cracking is defined as HAZ cracking that occurs in weld metal. By definition, this form of cracking is associated with multipass welds. The cracking that occurs is sometimes referred to as "microfissuring," or underbead cracking, because the cracks are typically small and located adjacent to the interpass fusion boundary in the previously deposited weld metal. These defects are almost always associated with fully austenitic weld metal and are located along solidification grain boundaries or migrated grain boundaries.

Analogous to weld solidification cracking, weld-metal liquation cracking can generally be avoided by reducing the impurity levels in fully austenitic microstructures or by selecting filler metals that produce weld deposits containing more than approximately 3 FN.

Copper contamination cracking adjacent to austenitic stainless steel welds can also occur as a result of contact with copper or copper-bearing alloys, such as brass. This type of cracking is a form of liquid-metal embrittlement, whereby molten copper embrittles austenitic grain boundaries. Because copper melts at 1083 °C (1981 °F), this type of cracking caused by pure copper is only observed in regions of the weld (typically, the HAZ) that are heated near or above this temperature. Cracking is always intergranular and, normally, traces of copper or copper-rich material can be observed along the grain boundary.

This contamination can often be traced to copper weld fixturing, contact tips, or fabrication tools. The use of alternate fixturing, often incorporating chromium plating, and the prevention of copper abrasion normally eliminates the problem.

Ductility dip cracking occurs in the solid state and is typically associated with the HAZ or weld metal in highly constrained welds or thick sections. Such cracking occurs as a result of strain-induced grain-boundary precipitation, which limits mid-temperature ductility, but is much more common in precipitation-strengthened nickel-base alloys. However, this type of cracking has been observed in type 347 alloy, resulting from strain-induced precipitation of niobium carbides.

Weld porosity can result either from alloying additions (especially in the high-nitrogen alloys) or by contamination. In the Nitronic alloys, for example, nitrogen levels near the upper limit of 0.4% can result in porosity in gas-tungsten arc weld deposits, whereas lower levels (above approximately 0.25%) can result in excessive porosity in electron-beam welds (Ref 31). Porosity can also occur as a result of surface contamination, such as by oil and greases or undetected leaks in water-cooled welding torches or weld fixtures. Thus, surfaces should be thoroughly cleaned prior to welding. If wire

brushing is used, then the brushes should be made of stainless steel and dedicated to stainless usage, rather than made of steel, which can result in iron deposition and in-service corrosion.

Selection of Wrought Austenitic Stainless Steels

John A. Brooks, Sandia National Laboratories; John C. Lippold, Edison Welding Institute

Sigma-Phase Embrittlement

Sigma is a hard, brittle phase that can form in stainless steels when they are held in the temperature range from approximately 600 to 800 °C (1110 to 1470 °F). The sigma-phase compositional range shown in the vertical sections of Fig. 4 reveals that sigma can form over a wide range of compositions. The tendency for sigma-phase formation increases with increasing amounts of chromium, molybdenum, and silicon, and is reduced somewhat by nitrogen, nickel, and carbon. As a consequence of alloy partitioning during both solidification and the solid-state transformation of ferrite to austenite, ferrite is enriched in the alloying elements, which promotes the sigma phase, and depleted in the elements that retard its formation. Thus, ferrite in austenitic stainless welds is especially susceptible to sigma-phase formation. The sigma phase has been observed to nucleate preferentially at the ferrite-austenite interface in weld metal.

The transformation kinetics of ferrite to sigma has been studied by Vitek and David (Ref 32) in type 308 gas-tungsten arc welds (Fig. 12). They found that sigma started to form after approximately 15 h at 725 °C (1335 °F), and all the ferrite had transformed to sigma and $M_{23}C_6$ after approximately 3000 h.

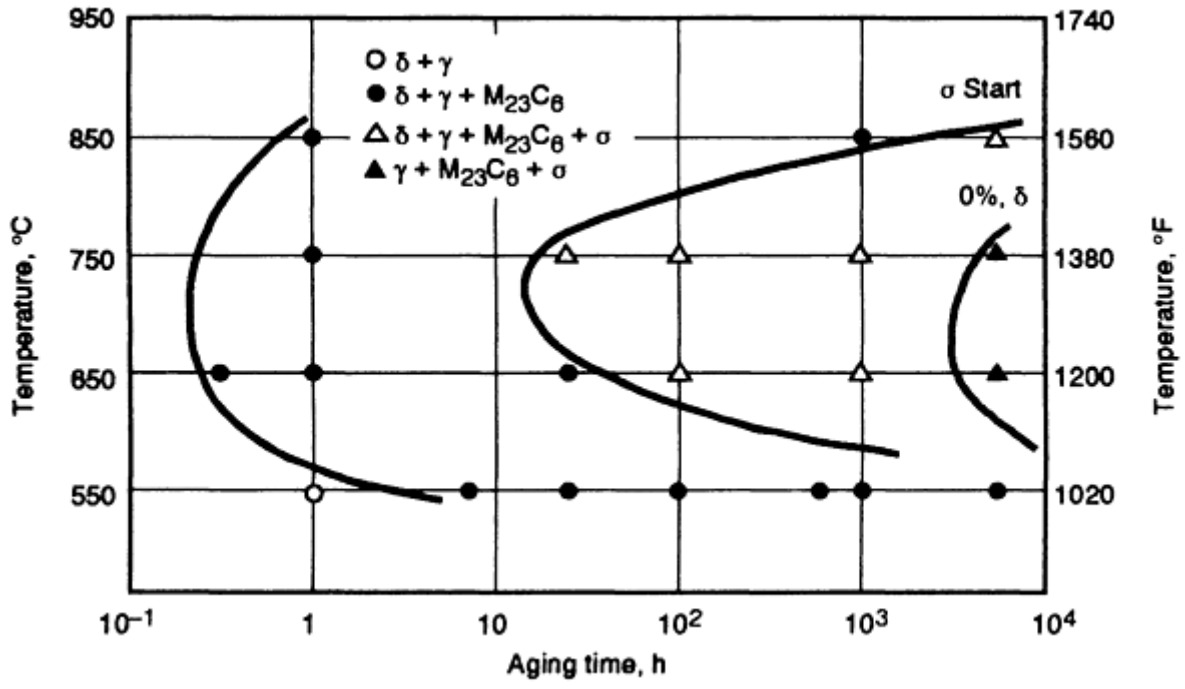

FIG. 12 TIME-TEMPERATURE TRANSFORMATION DIAGRAM FOR WELDED AND AGED TYPE 308L ALLOY GAS-

TUNGSTEN ARC WELDS. SOURCE: REF 32

The notorious effect of sigma phase is a decrease in ductility and toughness. When materials are to be used in elevated-temperature service, the effects of sigma formation must be considered. The sigma phase can be minimized by using filler materials that produce fully austenitic structures. However, even in these compositions, sigma formation can still occur, initiating in chromium-enriched interdendritic boundaries.

In cases where solidification cracking is a concern, some ferrite in the weld deposit is required. Weld-metal ferrite content should be controlled in the range from 3 to 8 FN to prevent the formation of a continuous network of ferrite. Because the chromium content of sigma is nearly double that of the weld ferrite, the potential maximum level of the sigma phase is always less than that of the original weld-metal ferrite.

Corrosion Behavior

Austenitic stainless steel weldments are often subject to corrosive attack. The nature of this attack is a function of weld thermal history, service temperature and environment, and stress level (both residual and applied). Four general types of corrosive attack have been reported:

- INTERGRANULAR ATTACK
- STRESS-CORROSION CRACKING
- PITTING AND CREVICE CORROSION
- MICROBIOLOGICALLY INFLUENCED CORROSION

Each phenomena and its effect on service integrity is discussed below.

Carbide Precipitation and Intergranular Corrosion. Austenitic stainless steel weldments have often been subject to intergranular attack (IGA). This behavior is particularly prevalent in chloride-beating aqueous environments, and it is usually typified by accelerated attack in the HAZ. The basis for this attack is related to a phenomenon known as sensitization, whereby exposure or slow cooling in the temperature range from 400 to 850 °C (750 to 1550 °F) promotes the formation of chromium-rich carbides ($M_{23}C_6$) along the austenite grain boundaries. This temperature range is commonly described as the "sensitization" temperature range, because exposure within it makes austenitic stainless steels particularly sensitive to IGA. An example of intergranular corrosion in the HAZ of a weld in type 316L NaOH reactor vessel is shown in Fig. 13.

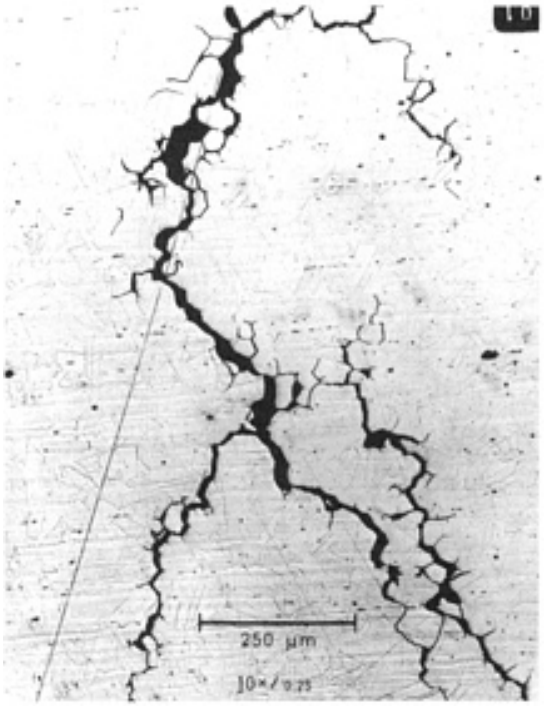

FIG. 13 CAUSTIC SCC IN THE HAZ OF A TYPE 316L STAINLESS STEEL NAOH REACTOR VESSEL. CRACKS ARE BRANCHING AND INTERGRANULAR.

Mechanistically, localized attack occurs immediately adjacent to the grain boundary, because of precipitation of the chromium-rich carbides in the boundary. Carbide formation depletes the adjacent matrix in chromium to a level generally estimated to be less than 12 wt% Cr. The severity of attack depends on the corrosive media, the time and temperature of exposure, and the composition and metallurgical condition of the steel.

Unfortunately, sensitization can be a by-product of the fusion-welding process. During welding, the weld HAZ experiences peak temperatures, ranging from the melting point to the ambient base-metal temperature, depending on the distance from the weld fusion boundary. Because heating and cooling in the weld HAZ is relatively rapid, regions of the HAZ that are heated to peak temperatures below about 650 °C (1200 °F) are immune to sensitization.

In addition, the HAZ region immediately adjacent to the fusion boundary is also resistant to sensitization, because carbon solubility is high at the peak temperatures achieved and cooling through the sensitization range is generally rapid enough to suppress carbide precipitation. This leaves a narrow region in the HAZ, somewhat removed from the fusion boundary, that will be heated into the sensitization temperature range. If the time within this temperature range is sufficient, then intergranular carbides will nucleate along austenite grain boundaries.

For a given thermal history, the level of precipitation and the associated degree of sensitization are approximately proportional to the carbon content of the austenitic stainless steel. Conventional austenitic stainless steels can retain a maximum of about 0.02 wt% C in solid solution over their service temperature range (up to 600 °C, or 1110 °F). Thus, as carbon content increases above this level, the driving force for carbide precipitation increases.

This can be illustrated by the time-temperature-precipitation (TTP) curves shown in Fig. 14 for an 18Cr-9Ni alloy. Because of this, low-carbon grades of stainless steel (the so-called L-grades) are preferred for corrosive service where weldments must be used in the as-welded condition. The use of "stabilized" alloys, such as types 321 and 347, which contain additions of titanium and niobium, respectively, are also effective in reducing susceptibility to IGA. Both titanium and niobium form stable carbides in the base metal that resist dissolution in the weld HAZ and/or at service temperatures in the sensitization range.

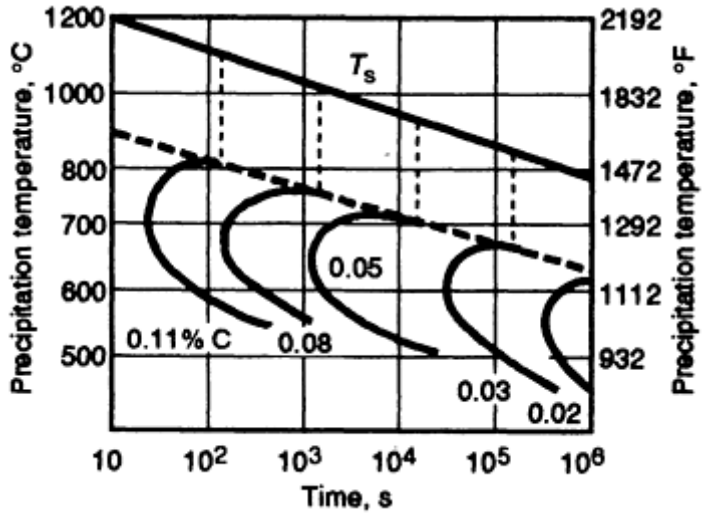

FIG. 14 TIME-TEMPERATURE PRECIPITATION CURVES FOR AN 18CR-9NI ALLOY WITH VARIOUS CARBON CONTENTS. SOURCE: REF 33

A phenomenon known as "knifeline" attack has been observed in the stabilized grades. However, its occurrence is associated with localized HAZ attack adjacent to the weld fusion boundary (Ref 34). Where temperatures exceed 1300 °C (2370 °F), niobium carbide and titanium carbide precipitates may dissolve and, upon reheating into the sensitization temperature range, chromium carbide ($M_{23}C_6$-type) precipitation occurs preferentially to the reformation of either niobium carbide or titanium carbide. Subsequent exposure to a corrosive medium may result in IGA that is extremely localized. In severe cases, it may often appear as if the weld has been cut out by a knife.

Weld metals containing even small amounts of delta ferrite are not generally susceptible to such severe sensitization as wrought material of similar composition. In ferrite-containing weld metal, carbide precipitation occurs more uniformly throughout the structure at the austenite-ferrite interphase boundaries. Because the ferrite phase has a relatively high chromium content (on the order of 25 wt% in a 18Cr-8Ni alloy), chromium depletion caused by carbide formation is not so significant. Consequently, weld metal is not generally susceptible to intergranular corrosion. However, fully austenitic weld metals may be susceptible to IGA when exposed to severely corrosive environments.

In general, it is possible to either minimize or eliminate IGA in austenitic stainless steel weldments by using one or more of these methods:

- USE A LOW-CARBON-CONTENT ALLOY, SUCH AS "L-GRADE" ALLOYS WITH CARBON CONTENTS ON THE ORDER OF 0.03 WT%.
- USE ALLOYS THAT ARE STABILIZED BY ADDITIONS OF NIOBIUM AND TITANIUM (SUCH AS TYPES 347 AND 321).
- ANNEAL THE MATERIAL PRIOR TO WELDING TO REMOVE ANY PRIOR COLD WORK (COLD WORK ACCELERATES CARBIDE PRECIPITATION).
- USE LOW WELD HEAT INPUTS AND LOW INTERPASS TEMPERATURES TO INCREASE WELD COOLING RATES, THEREBY MINIMIZING THE TIME IN THE SENSITIZATION TEMPERATURE RANGE.
- IN PIPE WELDING, WATER COOL THE INSIDE DIAMETER AFTER THE ROOT PASS, WHICH WILL ELIMINATE SENSITIZATION OF THE INSIDE DIAMETER CAUSED BY SUBSEQUENT PASSES.
- SOLUTION HEAT TREAT AFTER WELDING. HEATING THE STRUCTURE INTO THE TEMPERATURE RANGE FROM 900 TO 1100 °C (1650 TO 2010 °F) DISSOLVES ANY CARBIDES THAT MAY HAVE FORMED ALONG GRAIN BOUNDARIES IN THE HAZ. FOR LARGE STRUCTURES, THIS APPROACH IS USUALLY IMPRACTICAL.

The IGA of the weld HAZ has also been observed at service temperatures well below the classic sensitization temperature range. This behavior, often called low-temperature sensitization (LTS), typically occurs after years of service exposure at temperatures below 400 °C (750 °F), even in low-carbon grades. Mechanistically, it is proposed (Ref 35) that carbide embryos form along grain boundaries in the weld HAZ and then grow to form chromium-rich carbides in service. Corrosive attack occurs via the chromium-depletion mechanism described previously. In order to combat LTS, either stabilized alloys or alloys containing higher nitrogen contents (such as type 316LN) are substituted for conventional or L-grade materials.

The stress-corrosion cracking (SCC) of austenitic stainless steels may occur when an alloy is subjected simultaneously to a tensile stress and a specific corrosive medium. The important variables affecting SCC are temperature, environment, material composition, stress level, and microstructure. Crack propagation may be either transgranular or intergranular, depending on the interaction of these variables. Intergranular stress-corrosion cracking (IGSCC) can occur even though the alloy is insensitive to intergranular corrosion. The presence of residual tensile stresses in the HAZ may accelerate corrosion attack and cracking, particularly along sensitized grain boundaries.

Transgranular SCC is also observed in austenitic stainless steels. This form of cracking is usually indigenous to chloride environments (seawater), but may also occur in caustic media. The ions of the halogen family (fluorine, chlorine, bromine, and iodine) are largely responsible for promoting transgranular SCC. Of the halides, the chloride ion causes the greatest number of failures. Figure 15 shows an example of transgranular SCC in type 316 stainless steel. Note that cracking has initiated at the toe of the weld, probably because of the high residual stress level at that location.

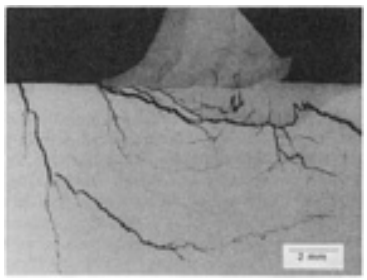

FIG. 15 TRANSGRANULAR SCC THAT HAS INITIATED NEAR THE TOE OF A WELD IN TYPE 316L ALLOY

Methods for controlling SCC include:

- A STRESS-RELIEVING OR ANNEALING HEAT TREATMENT TO REDUCE WELD RESIDUAL STRESSES
- SUBSTITUTION OF MORE-RESISTANT HIGH-NICKEL ALLOYS, HIGH-CHROMIUM FERRITIC STAINLESS STEELS, OR DUPLEX STAINLESS STEELS, THE LATTER OF WHICH HAVE BEEN DESIGNED SPECIFICALLY TO MINIMIZE SCC
- REDUCTION OF CHLORIDE AND OXYGEN CONTENTS FROM THE ENVIRONMENT, BECAUSE THESE TWO ELEMENTS, IN COMBINATION, ARE RESPONSIBLE FOR MOST SCC FAILURES IN AUSTENITIC STAINLESS STEELS

Pitting, Crevice Corrosion, and Microbiologically Influenced Corrosion. Localized attack in the weld metal or HAZ may occur in the form of pitting or crevice corrosion, particularly in aqueous, chlorine-bearing environments.

Microbiologically influenced corrosion (MIC) often occurs preferentially in the weld metal of austenitic stainless steels (Ref 36, 37). This curious form of attack is restricted to aqueous environments containing microbes that attach to the surface of the weld. In pipe welds, pitting from MIC often initiates at the weld fusion line and proceeds into the weld metal. Sensitized HAZs also are common regions of attack, although the most preferred site of attack seems to be the weld metal. Attack is a strong function of pitting resistance of the material and is thus more common in type 304 alloy, than in type 316.

The surface condition seems to have a large effect on MIC. Machining and grinding conducted on the inside of piping is thought to increase susceptibility to MIC by introducing rough surfaces for easy attachment by microbes and residual stresses, as well as localized metallurgical changes and corrosion pitting.

Superaustenitic Stainless Steels

The superaustenitic stainless steels represent a special class of austenitic stainless steels that contain high levels of nickel, molybdenum, and, in some cases, nitrogen. These alloys are designed for severely corrosive environments. They provide improved resistance to SCC, pitting, and crevice corrosion, relative to the standard 300 series of austenitic alloys. Higher nickel contents improve chloride SCC resistance, whereas molybdenum and nitrogen provide improved pitting and crevice corrosion resistance. In general, these alloys are compositionally balanced to ensure fully austenitic microstructures. The compositions of selected commercially available superaustenitic alloys are shown in Table 2.

The weldability of most of these alloys is similar to that of fully austenitic grades of conventional stainless steel. Because these welds solidify as austenite and exhibit fully austenitic (no ferrite) microstructures, solidification cracking may be a problem in highly restrained joints. Typically, these alloys contain extremely low impurity levels, thus minimizing the likelihood of cracking.

The segregation of molybdenum in 6% Mo alloys during weld solidification has been reported to reduce corrosion resistance (Ref 38), particularly in severe pitting environments. The cell or dendrite cores in these alloys may exhibit molybdenum contents as low as 4.2 wt%, resulting in localized pitting attack at these sites. As a result, autogenous welding or the use of matching filler materials is normally avoided when severe service environments are anticipated. The use of molybdenum-containing, nickel-base filler materials, such as alloy 625 (AWS ERNi-CrMo-3), alloy C-276 (AWS ERNiCrMo-4), or alloy C-22 (AWS ERNiCrMo-10), is often recommended in order to avoid pitting. Precautions must be taken to prevent the formation of an unmixed zone adjacent to these overalloyed weld metals, because this region may have the same susceptibility to corrosive attack as autogenous weld metal does. Much more detail is provided in Ref 39.

Mechanical Properties

Austenitic stainless steels exhibit moderate strength and excellent toughness and ductility. Because of these properties, austenitic filler materials are often used in dissimilar combinations with carbon steels and ferritic and martensitic stainless steels. The weld properties of austenitic stainless steels are essentially similar to those of the annealed base material. Typical base-metal properties for austenitic stainless steels are listed in Table 4. Weld-metal properties are described in the article "Welding of Stainless Steels" in this Volume.

(A) FOR FORGED SECTIONS 127 MM (5 IN.) AND OVER, THE TENSILE STRENGTH SHALL BE 485 MPA (70 KSI).

Weld geometry and alloy composition also affect weld properties. Most weld tensile properties are determined using specimens transverse to the weld direction. Because failure often occurs outside the weld metal, only minimum tensile strength values can be determined and no weld-metal ductility data are generated. Impact toughness data are much more accurate, because a notch can be placed in the weld metal. HAZ mechanical property data are essentially nonexistent. Because the HAZ undergoes high temperatures during welding where carbide dissolution and grain growth can occur, it would be expected that this region may exhibit slightly lower strength than the annealed base metal.

In welds containing ferrite, the ferrite provides second-phase strengthening with a concomitant decrease in ductility. Thus, for an autogenous weld, the actual properties may vary somewhat from heat to heat in the same manner as the ferrite content. Typically, the tensile strength of welds is fractionally higher than the annealed wrought properties of similar compositions. However, the elongation and impact properties are reduced on the order of 30%. In multipass welds of thicker sections, warm working that results from the large strains encountered during cooling of subsequent passes can also result in significant increases in yield strengths and variations in strength from the top to the bottom of the weld deposit.

Nitrogen is a strong solid-solution strengthener and, thus, its increase or decrease in the welding process may also affect weld properties. In wrought materials, each addition of approximately 0.01% N results in an approximate increase of 5.5 to 7 MPa (0.8 to 1 ksi) in yield strength. Thus, from a conservative standpoint, weld strength is often considered to be the same as that of the annealed base material.

Weld properties may be significantly influenced by service temperature. At elevated temperatures, carbide, nitride, and intermetallic formation may reduce mechanical and corrosion properties. At cryogenic temperatures, the strain-induced martensite transformation from austenite can result in reduced toughness and ductility, relative to those properties in the homogeneous single-phase base material. In cases where filler metal is added, ASTM specifications provide minimum requirements. The reader is referred to the article "Welding for Cryogenic Service" in this Volume to obtain information on mechanical properties at cryogenic temperatures.

Weld penetration characteristics of austenitic stainless steels are generally poor, relative to ferritic and martensitic grades, because of the low thermal conductivity of the austenite. In addition, large heat-to-heat variations in weld penetration can occur when welding austenitic stainless, especially in autogenous welds or the root pass of multiple-pass gas-tungsten arc welds. These penetration variations have been attributed primarily to minor elements affecting the surface-tension-driven fluid flow within the weld pool (known as the Marongoni effect) (Ref 40).

The elements that influence penetration tend to be surface active and include sulfur, selenium, and oxygen. When present in sufficient quantity, these elements tend to increase weld penetration. However, other elements can have synergistic effects. Aluminum combined with oxygen can mitigate the effect of oxygen. Thus, high levels of aluminum can decrease penetration. For example, heats of type 304L alloy with low sulfur contents (0.001 to 0.003 wt%) may have a weld depth-to-width ratio of only 0.25, whereas the same material, but with a sulfur content of 0.01 wt%, welded under identical conditions, will exhibit a depth-to-width ratio higher than 0.5. Increased surface-oxygen content that results from wire brushing may also result in increased depth-to-width ratios in materials that otherwise have low penetration characteristics. However, this method is not often practiced, because of problems with reproducibility.

In autogenous welds, penetration control is best achieved by the proper selection of base materials. The addition of hydrogen and helium to argon shielding gas may help to compensate for poor penetration. For example, 98Ar-2H_2 and Ar-5H_2 are commonly used in the manufacture of welded tubing to increase penetration at high travel speeds. Trimixes of argon, helium, and H_2 may also be used to increase weld penetration.

Weld Thermal Treatments

Preheat and Interpass Heat Treatments. Because the austenitic stainless steels do not experience a martensitic transformation upon cooling, there is generally no benefit derived from the use of preheat or interpass temperature control during multipass welding. In fact, these thermal treatments may actually increase the degree of sensitization by reducing cooling rates and allowing more time for carbide precipitation. Preheat and interpass heating can also increase distortion and cracking susceptibility.

Postweld heat treatment (PWHT) is often required to relieve residual stresses in austenitic stainless steel weldments, particularly in thick sections. Because the CTE value and the elevated-temperature yield and creep strengths of austenitic materials are significantly greater than for ferritic materials, the magnitude of residual stresses is generally larger. Although the effect of residual stresses from welding is typically not as severe as when less-ductile materials are used, they may still affect mechanical properties and corrosion behavior. PWHT is particularly critical when machining must be performed after welding, because significant distortion may occur.

Perhaps of greatest concern, however, is the influence of residual stress on SCC resistance. As described in the section "Corrosion Behavior" in this article, high levels of residual stress associated with the weld may severely reduce SCC resistance in chlorine-beating and caustic environments.

Stress relieving can be performed over a wide range of temperatures, depending on the amount of stress relaxation required. Time at temperature ranges from about 1 h per inch of section thickness at temperatures above 650 °C (1200 °F) to 4 h per inch of thickness at temperatures below 650 °C (1200 °F). Because of the high CTE value and low thermal conductivity of austenitic stainless steels, cooling from the stress-relieving temperature must be slow. Because the stress-relieving temperature range overlaps the sensitization temperature range, the stress-relieving temperature must be compatible with the extent of acceptable carbide precipitation and with the required amount of corrosion resistance. Nonstabilized stainless steels cannot be stress relieved in the sensitizing range without sacrificing corrosion resistance. Extra-low-carbon grades are affected much less, because sensitization is more sluggish. Stabilized grades exhibit minimal chromium carbide precipitation tendencies.

Higher stress-relief temperatures can be used for fully austenitic weld metals. For weld metals that contain ferrite, stress-relief temperatures above 650 °C (1200 °F) may result in weld embrittlement via sigma formation.

For austenitic stainless steels, the estimated percentages of residual stresses relieved at various temperatures at the times previously noted are 85% stress relief at 845 to 900 °C (1550 to 1650 °F) and 35% stress relief at 540 to 650 °C (1000 to 1200 °F). The data compiled by Cole and Jones (Ref 41) in Table 5 show specific time-temperature combinations that represent a compromise between the degree of stress relieving and carbide precipitation, which can lead to reduced corrosion resistance and ductility.

Selection of Wrought Duplex Stainless Steels

David N. Noble, ARCO Alaska, Inc.

Introduction

WROUGHT DUPLEX STAINLESS STEELS (DSS) are two-phase alloys based on the iron-chromium-nickel system. These materials typically comprise approximately equal proportions of the body-centered cubic (bcc) ferrite and face-centered cubic (fcc) austenite phases in their microstructure and are characterized by their low carbon content (<0.03 wt%) and additions of molybdenum, nitrogen, tungsten, and copper (Ref 1). Typical chromium and nickel contents are 20 to 30% and 5 to 10%, respectively. The specific advantages offered by DSS over conventional 300 series stainless steels are strength (about twice that of austenitic stainless steels), chloride stress-corrosion cracking (Cl SCC) resistance, and pitting corrosion resistance (Ref 2). These materials are used in the intermediate temperature range (about -60 to 300 °C, or -75 to 570 °F) where resistance to acids and aqueous chlorides is required. The weldability and welding characteristics of DSS are somewhat better than those of ferritic stainless steels, but generally not as good as austenitic materials.

Wrought DSS development in the 1970s and 1980s was particularly rapid, although the steels had been available in a number of compositions for several decades, particularly in the form of castings (Ref 3). Early grades were alloyed with approximately 18% Cr, about 4 to 6% Ni, and sometimes with molybdenum. Current commercial grades contain between 22 and 26% Cr, 4 to 7% Ni, up to 4.5% Mo, and 0.7% Cu and W, and are alloyed with 0.08 to 0.35% N (Ref 4). Continual modifications to the alloy compositions have been made to improve corrosion resistance, workability, and weldability. In particular, nitrogen additions have been effective in improving pitting corrosion resistance and weldability.

The current commercial DSS can be loosely divided into four generic types. With increasing corrosion resistance these alloy groups are:

- FE-23CR-4NI-0.1N
- FE-22CR-5.5NI-3MO-0.15N
- FE-25CR-5NI-2.5MO-0.17N-CU
- FE-25CR-7NI-3.5MO-0.25N-W-CU

As with 18-8 austenitic stainless steels, DSS are also frequently referred to by their chromium and nickel contents to describe the alloy class. The alloys listed above are then described as 2304, 2205, 25% Cr, and 2507, respectively. The last alloy class is also frequently termed "super" duplex stainless steel.

The performance of DSS can be significantly affected by welding. Due to the importance of maintaining a balanced microstructure and avoiding the formation of undesirable metallurgical phases, the welding parameters and filler metals employed must be accurately specified and closely monitored. The balanced microstructure of the base material (that is, equal proportions of austenite and ferrite) will be affected by the welding thermal cycle. If the balance is significantly altered and the two phases are no longer in similar proportions, the loss of material properties can be acute. Because the steels derive properties from both austenitic and ferritic portions of the structure, many of the single-phase base material characteristics are also evident in duplex materials. Austenitic stainless steels have excellent weldability and low-temperature toughness, whereas their Cl SCC resistance and strength are comparatively poor. Ferritic stainless steels have high resistance to Cl SCC but have poor toughness, especially in the welded condition. A duplex microstructure with high ferrite content can therefore have poor low-temperature notch toughness, whereas a structure with high austenite content can possess low strength and reduced resistance to Cl SCC (Ref 5). The high alloy content of DSS also renders them susceptible to formation of intermetallic phases from extended exposure to high temperatures. Extensive intermetallic precipitation may lead to a loss of corrosion resistance and sometimes to a loss of toughness (Ref 6).

Selection of Wrought Duplex Stainless Steels

David N. Noble, ARCO Alaska, Inc.

Base Material Properties

Microstructure. Duplex stainless steel parent materials have approximately equal proportions of austenite and ferrite, with ferrite comprising the matrix. Representative base material microstructures are shown in Fig. 1 and 2. Both exhibit a ferritic matrix with austenite islands of various morphologies. The wrought structure in Fig. 1 (a) parallel to the rolling direction has a pronounced orientation. The transverse view in Fig 1 (b) shows the austenite islands "end-on." The plan view in Fig 1 (c) also has some directionality but it is not as pronounced as in Fig. 1(a). A cast microstructure (Fig. 2) is coarser and displays a different morphology of austenite than that observed in the wrought plate.

Alloy Grades. There are several types of DSS that have slightly different chemical compositions to cover the range of possible applications. The effects of chromium, nickel, molybdenum, and nitrogen on corrosion resistance are well understood and apply to most grades of stainless steels. The additional requirement of the alloying elements in the DSS base metal is to ensure that a balanced microstructure at room temperature is developed.

The DSS alloying additions are either austenite or ferrite formers. As the names suggest, certain elements will favor a higher proportion of austenite and others will favor ferrite. This is achieved by extending the temperature range over which the phase is stable. Among the major alloying elements in DSS, chromium and molybdenum are ferrite formers, whereas nickel, carbon, nitrogen, and copper are austenite formers (Ref 7, 8). The balance of austenite and ferrite formers will dictate the base material microstructure. Constitutional diagrams, such as the WRC-1992 diagram (Fig. 3) can be used for estimating the weld metal ferrite content in welds and developing appropriate base material compositions (Ref 8).

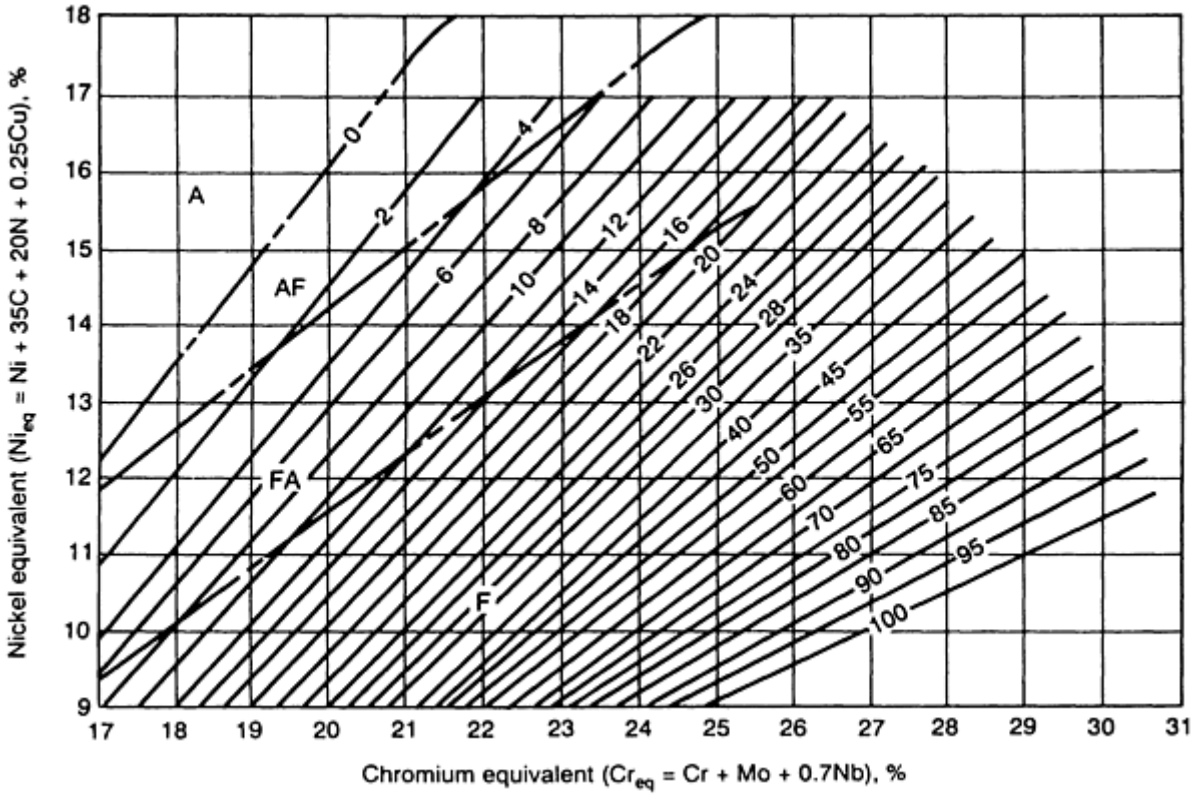

FIG. 3 WRC-1992 DIAGRAM FOR PREDICTING FERRITE CONTENT IN STAINLESS STEELS. FERRITE CONTENT IS GIVEN BY THE FERRITE NUMBER (FN), WHERE 100 FN IS APPROXIMATELY EQUAL TO 65 VOL% FERRITE. BOUNDARIES DENOTING A CHANGE IN SOLIDIFICATION MODE (A, PRIMARY AUSTENITE; AF, AUSTENITIC-FERRITIC; FA, FERRITIC-AUSTENITIC; F, PRIMARY FERRITE) ARE ALSO SHOWN (INDICATED BY DOTTED LINES). SOURCE: REF 8

Composition also plays a major role in the corrosion resistance of DSS. Pitting corrosion resistance is most easily affected. To determine the extent of pitting corrosion resistance offered by the material, the pitting resistance equivalent (PRE) is commonly used. This concept was proposed in the 1970s to characterize alloy resistance to pitting in chloride solutions (Ref 9). The PRE is calculated by adding the weight percentages of elements that affect pitting corrosion resistance, namely chromium, molybdenum, and nitrogen, then normalizing them with respect to the effect of 1% Cr. There are several formulas, which principally vary in the coefficient used for nitrogen, from 13 to 30. The PRE may also include negative coefficients for sulfur and phosphorus (Ref 10, 11). The most commonly used formula for pitting resistance equivalent is:

$$PRE = \%CR + 3.3(\%MO) + 16(\%N) \qquad \textbf{(EQ 1)}$$

The four types of DSS can also be classified by their PRE values. These range from 24 for the Fe-23Cr-4Ni-0.1N steel without molybdenum to over 40 for the Fe-25Cr-7Ni-3.5Mo-0.25N-Cu-W "super" grades. A minimum PRE value of 40 is often used to define the "super" DSS grades.

The chemical composition ranges of wrought DSS are given in Table 1, with the corresponding UNS numbers and PRE range for each. ASTM product specifications, in which the UNS numbers are referenced, are reported in Table 2. Some commercial grades of DSS, relevant composition ranges, and closest UNS numbers are given in Table 3.

Mechanical and Physical Properties. The high yield strength of DSS offers designers the use of thin-wall material with adequate pressure-containing and load-bearing capacity. This can lead to major reductions in weight and welding time. The yield strength of the Fe-22Cr-5.5Ni- 3Mo-0.15N grade is 450 MPa (65 ksi) minimum, which is double that of austenitic stainless steels and significantly higher than that of ferritic stainless steels. Base material hardness varies dependent upon processing route and extent of cold working, but it generally averages about 260 HV 10 (25 HRC) for the Fe-22Cr-5.5Ni-3Mo-0.15N grade (Ref 2). Details of room-temperature tensile properties and hardnesses for each grade are given in Table 4, and the physical properties are reported in Table 5.

(A) UNLIKELY TO CHANGE SIGNIFICANTLY RELATIVE TO GRADE

The parent metal toughness down to approximately -100 °C (-150 °F) is good, but the weld metal and heat-affected zone (HAZ) are commonly much less tough and are frequently the limiting factor in DSS application. The parent metal will undergo a slight ductile-to-brittle transition (Fig. 4) but the change is not as marked as in other steels with bcc matrices. These alloys are not suitable for cryogenic applications.

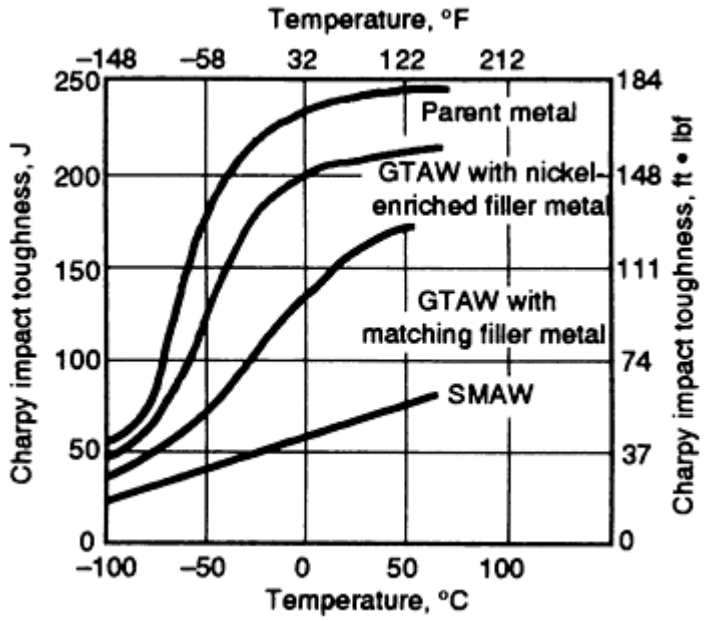

FIG. 4 PLOT OF CHARPY IMPACT TOUGHNESS VERSUS TEMPERATURE FOR FE-22CR-5.5NI-3MO-0.15N DSS BASE METAL AND WELDS PRODUCED WITH GAS-TUNGSTEN ARC WELDING (GTAW) AND SHIELDED METAL ARC WELDING (SMAW) PROCESSES. SOURCE: REF 2

The high alloy content and the presence of a ferritic matrix render DSS susceptible to embrittlement and loss of mechanical properties, particularly toughness, through prolonged exposure to elevated temperatures. This is caused by the precipitation of intermetallic phases, principally σ phase, χ phase, and η phase (Laves phase) (Ref 6). For this reason, the upper temperature of application is typically approximately 280 °C (535 °F) for parent material and 250 °C (480 °F) for welded structures (Ref 4). The more highly alloyed steels (for example, the Fe-25Cr-5Ni-2.5Mo-0.17N-Cu and Fe-25Cr-7Ni-3.5Mo-0.25N-Cu-W grades) are the most susceptible to the formation of these detrimental phases. Figure 5 shows the phases that can be formed in DSS, the approximate temperature range over which they will develop, and the effects of alloying elements on the transformation kinetics.

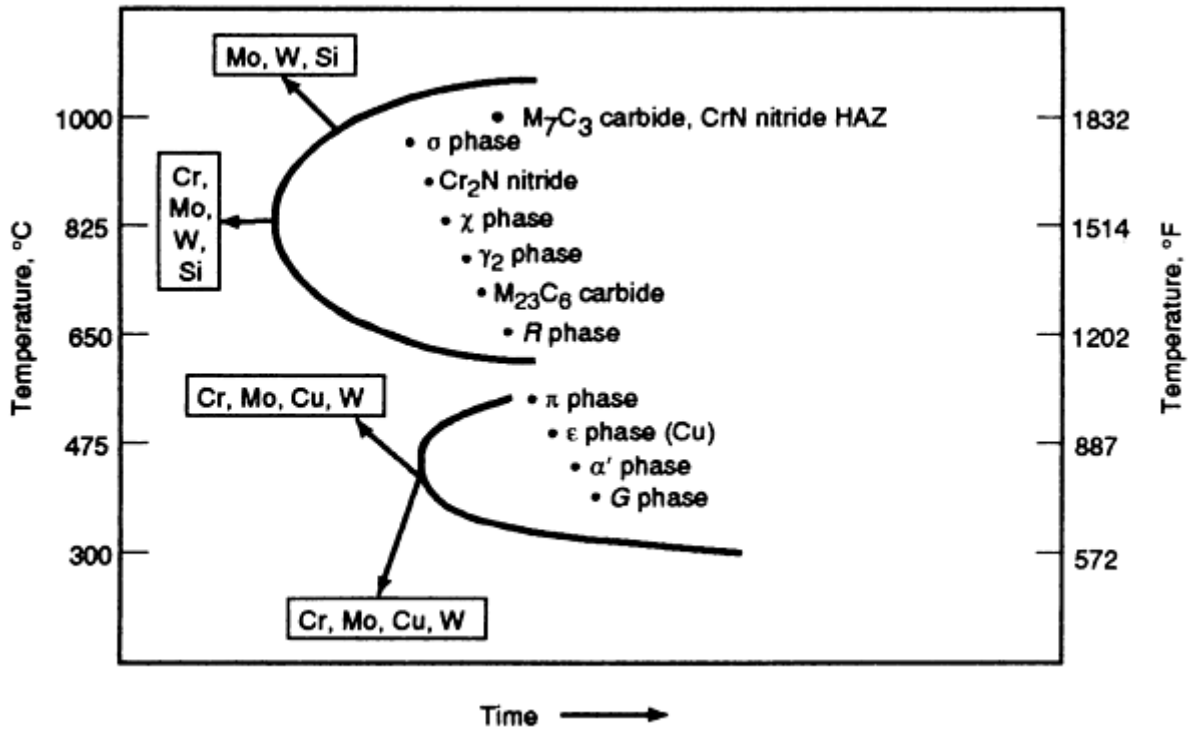

FIG. 5 TIME-TEMPERATURE TRANSFORMATION DIAGRAM SHOWING EFFECT OF ALLOYING ELEMENTS ON PRECIPITATION REACTIONS. SOURCE: REF 6

Corrosion Resistance. Duplex stainless steels were principally developed for their improved resistance to Cl SCC. Compared with conventional austenitic grades, they are clearly superior (Fig. 6). The more highly alloyed DSS are more resistant to Cl SCC than those with lower alloy contents.

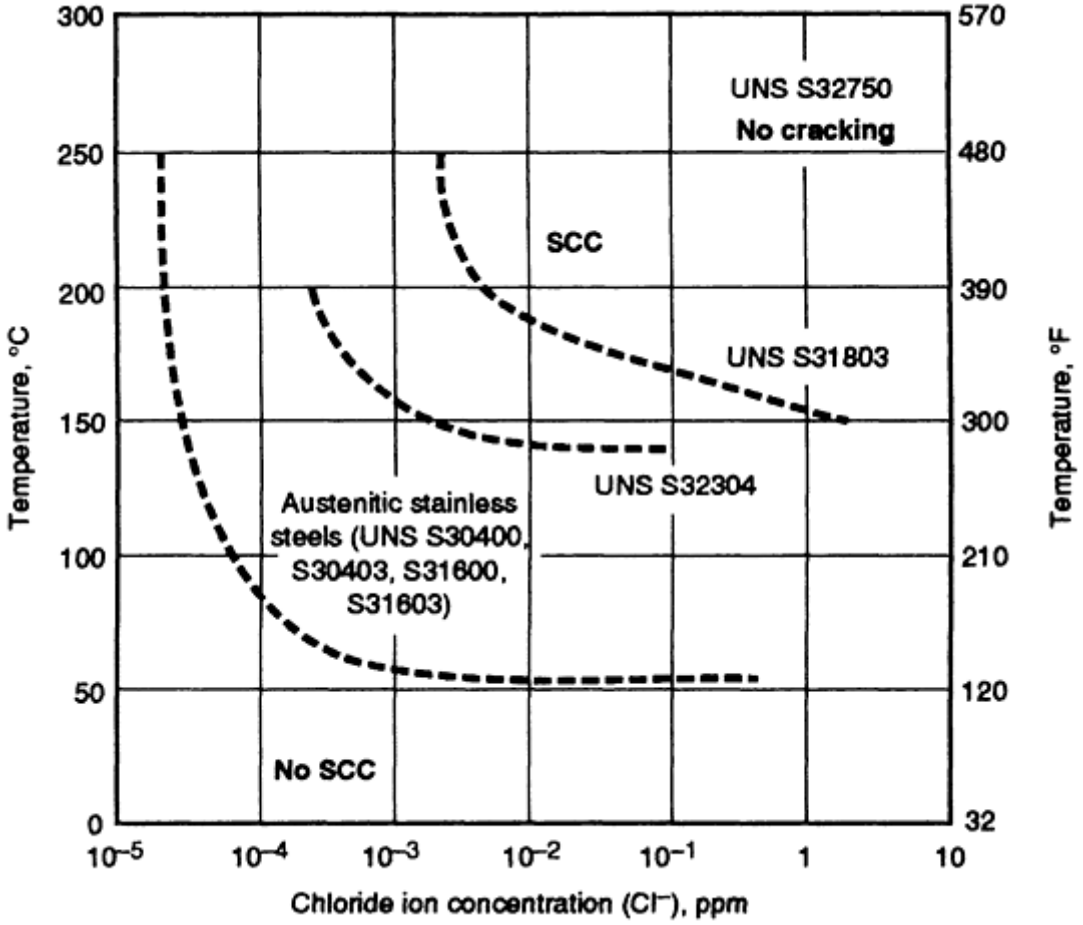

FIG. 6 STRESS-CORROSION CRACKING RESISTANCE OF SELECTED DUPLEX STAINLESS STEELS (S31803, S32304, AND S32750) RELATIVE TO AUSTENITIC STAINLESS STEELS (S30400, S30403, S31600, AND S31603) AS A FUNCTION OF TEMPERATURE AND CHLORIDE CONCENTRATION IN NEUTRAL O_2-BEARING SOLUTIONS (APPROXIMATELY 8 PPM). TEST DURATION WAS 1000 H. APPLIED STRESS WAS EQUAL TO YIELD STRENGTH. SOURCE: REF 2

Pitting corrosion resistance and general corrosion in acids are also generally acceptable (Fig. 7, 8) but these materials are susceptible to cracking in H_2S/Cl^- environments (Ref 12, 13, 14, 15). The tolerable H_2S limit for each grade depends on additional environmental factors (such as pH, temperature, chloride ion concentration, and so on) and is therefore not easily identified. Nevertheless, H_2S partial pressures of typically from 3.5 to 10 kPa (0.5 to 1.5 psi), dependent upon grade, have been reported as maxima for sour (H_2S-containing) service limits (Ref 16, 17). Regardless of H_2S partial pressure and chloride ion concentration, resistance to H_2S/Cl cracking appears to reach a minimum at about 60 to 100 °C (140 to 212 °F) (Ref 18).

When considering corrosion performance, the effect of alloy partitioning within the microstructure is important. Even in base material that has undergone a soaking heat treatment at over 1000 °C (1830 °F), the austenite and ferrite phases will contain different amounts of the alloying elements. The ferrite will generally be highest in chromium and molybdenum, whereas the austenite will be richer in nickel and nitrogen (Ref 19). This imbalance in composition between the phases may translate into a difference in corrosion behavior, particularly pitting resistance. Significant differences in the PRE values have been reported between the ferrite and austenite phases in base material (Ref 19).

Applications

Duplex stainless steels have found widespread use in a range of industries, particularly the oil and gas, petrochemical, pulp and paper, and pollution control industries. They are commonly used in aqueous, chloride-containing environments and as replacements for austenitic stainless steels that have suffered from either Cl SCC or pitting during service (Ref 20). The more highly alloyed grades (that is, the "super" DSS) are resistant to oxygenated or chlorinated sea water (Ref 21). The leaner alloy materials are not resistant to live sea water and will suffer from pitting. Several grades have been used for transportation of wet, CO_2-containing gas where carbon would have suffered general corrosion (Ref 22). Table 6 gives a list of DSS grades and typical applications.

TABLE 6 TYPICAL APPLICATIONS OF DUPLEX STAINLESS STEELS

GRADE(S)	APPLICATION
S31803, S32760, S32750, S32550	TUBING FOR HEAT EXCHANGERS IN REFINERIES, CHEMICAL INDUSTRIES, PROCESS INDUSTRIES, AND OTHER INDUSTRIES USING WATER AS A COOLANT; KRAFT PAPER DIGESTERS
ALL	HEAT EXCHANGERS, CHEMICAL TANKERS, CHEMICAL REACTOR VESSELS, FLUE GAS FILTERS, ACETIC AND PHOSPHORIC ACID HANDLING SYSTEMS, OIL AND GAS INDUSTRY EQUIPMENT (MULTIPHASE FLOW LINES, DOWNHOLE PRODUCTION TUBULARS, COMMONLY COLD WORKED)
S32304	DOMESTIC WATER HEATERS AND WHERE PITTING RESISTANCE IS NOT OF OVERRIDING IMPORTANCE
S32750, S32760, S32550	PIPE FOR SEAWATER HANDLING AND FIREFIGHTING SYSTEMS, OIL AND GAS SEPARATORS, SALT EVAPORATION EQUIPMENT, DESALINATION PLANTS, GEOTHERMAL WELL HEAT EXCHANGERS, HUMAN BODY IMPLANTS (S32550 MAY SUFFER SLIGHT PITTING AND CREVICE CORROSION IN SEAWATER SERVICE)

Microstructural Development

Factors Controlling Microstructure. By assuming a duplex stainless steel contains 68% Fe and 32% alloying elements (comprising nickel and chromium, but representing austenite and ferrite formers, respectively), the 68% Fe pseudo-binary phase diagram can be used to explain the microstructural transformations that occur during heating and cooling (Fig. 9).

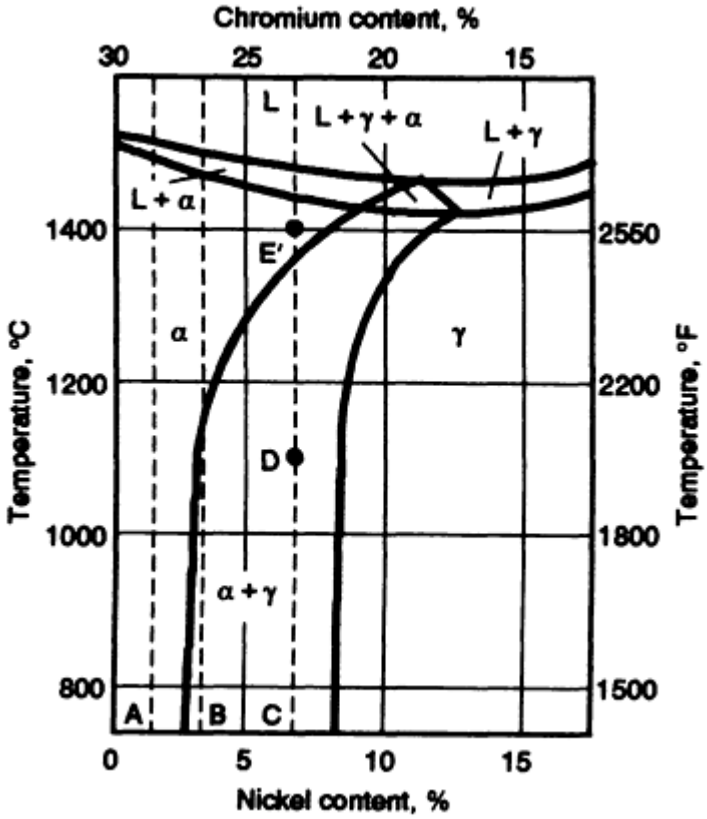

FIG. 9 PSEUDO-BINARY DIAGRAM AT CONSTANT IRON SECTION (68 WT% FE) OF THE FE/CR/NI TERNARY SYSTEM. SEE TEXT FOR DEFINITION OF LINES A, B, AND C AND POINTS D AND E. SOURCE: REF 9

Composition. With approximately 30% Cr and 2% Ni (composition indicated by line A), the steel will solidify completely to ferrite and remain ferritic down to room temperature. As the chromium content decreases and the nickel content increases, an alloy containing 28% Cr and 4% Ni, indicated by line B, will solidify as ferrite, remain fully ferritic until about 1200 to 1300 °C (2190 to 2370 °F), and then enter the dual-phase field (denoted by $\alpha + \gamma$). A two-phase microstructure will be developed and maintained down to room temperature. Because the composition of alloy B lies to the far left of the dual-phase field, a microstructure rich in ferrite would be anticipated. Current commercial DSS with 25% Cr are more likely to contain about 7% Ni, indicated by line C, which upon cooling enters the dual-phase field at a much higher temperature, thereby allowing more time for the diffusion-driven solid-state transformation from ferrite to austenite. An alloy with composition C will solidify as ferrite and be fully ferritic for a narrow temperature range prior to entering the dual-phase field. It should be noted that alloys A, B, and C will solidify primarily as ferrite and will have ferritic matrices.

Heat Treatment. The sequence of phase transformation in DSS upon cooling is (Fig. 9):

$$\text{LIQUID} \rightarrow \text{LIQUID} + \text{FERRITE} \rightarrow \text{FERRITE} \rightarrow \text{FERRITE} + \text{AUSTENITE} \qquad \textbf{(EQ 2)}$$

The solid-state transformation from ferrite to austenite is considered to be diffusional (Ref 23) and therefore affected by time and temperature. Very rapid cooling from a temperature at which the steel is fully ferritic will result in suppression

of the ferrite-to-austenite transformation and retention of a predominantly ferritic structure. The temperature range over which the transformation from ferrite to austenite occurs is highly dependent upon composition and grade (Fig. 9), but is typically from 1200 to 800 °C (2190 to 1470 °F). For this reason, a $\Delta T_{12\text{-}8}$ cooling rate term has been used when characterizing a DSS thermal cycle (Ref 24, 25). A longer $\Delta T_{12\text{-}8}$ will result in more transformation from ferrite to austenite. In a weld of given thickness, longer $\Delta T_{12\text{-}8}$ values can be achieved by a higher heat input weld. The $\Delta T_{12\text{-}8}$ term has been employed in an effort to identify critical cooling rates necessary to develop acceptable austenite content in weld heat-affected zones to achieve the desired mechanical and corrosion resistance properties. The critical $\Delta T_{12\text{-}8}$ for phase transformation is independent of material thickness, unlike heat input, but is highly dependent on alloy composition.

Low-temperature thermal cycles will not affect the austenite/ferrite balance, but they will control the extent of intermetallic phase precipitation. These steels should undergo rapid cooling (that is, water quenching) through the precipitation temperature range to develop optimum properties. For welds, water quenching is usually not necessary or practical, but some means of forced cooling may be beneficial for productivity and quality reasons, particularly for multipass welds in the high-alloy grades (Ref 26, 27).

To produce the necessary base material microstructure, an isothermal heat treatment is carried out at a temperature at which the steel is dual phase, approximately 1050 to 1100 °C (1920 to 2010 °F), or point D in Fig. 9 (Ref 28). To avoid the formation of intermetallic phases during cooling, water quenching from the soaking temperature is necessary.

Morphology. Wrought DSS base material microstructures have a pronounced orientation of austenite islands in the ferritic matrix, parallel and transverse to the rolling direction, as a result of the hot and cold working following casting (Fig. 1). The cast microstructure (Fig. 2) is very different, and more similar to that observed in weld metal and the HAZ.

During the weld thermal cycle, the HAZ adjacent to the fusion line will become fully ferritic at temperatures above the austenite-to-ferrite transition temperature (point E in Fig. 9). Grain growth will occur and, regardless of the extent of austenite transformation that occurs during subsequent cooling, the coarse prior ferrite grain boundaries will still be apparent (Fig. 10). Very rapid cooling from the fully ferritic phase field will retard austenite reformation in the HAZ, and result in a predominantly ferritic structure, also shown in Fig. 10. When cooled more slowly, the austenite will form initially on the ferrite grain boundaries and then within the ferrite grains along preferred crystallographic planes in a manner similar to the cast material.

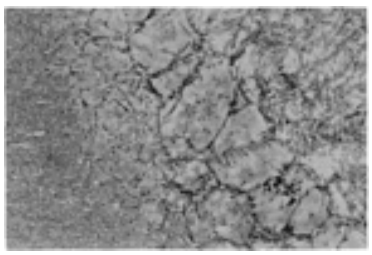

FIG. 10 PHOTOMICROGRAPH OF A FE-22CR-5.5NI-3MO-0.15N DSS WELD AREA SHOWING ELONGATED PARENT PLATE MORPHOLOGY, A COARSE GRAIN HEAT-AFFECTED ZONE HIGH IN FERRITE, AND COLUMNAR WELD METAL GRAINS. SPECIMEN ELECTROLYTICALLY ETCHED IN 40% NAOH. 30×. COURTESY OF THE WELDING INSTITUTE

The HAZ in Fig. 10 is relatively wide and has a high ferrite content. Such a structure may lead to poor low-temperature notch toughness and reduced corrosion resistance. Nitrogen levels in the base steel are being steadily increased to improve weldability and to avoid the formation of structures similar to that shown in Fig. 10; some DSS contain as much as 0.35 wt% N (Ref 4). A higher nitrogen level will increase the temperature at which ferrite begins to transform to austenite on cooling (Ref 6). This reduces the width of the transformed HAZ by limiting to a narrow temperature range the extent of the fully ferritic phase field. It also encourages more austenite reformation by starting the transformation at a much higher temperature. The recent grades of DSS, which typically have minimum 0.20 wt% N, develop a very narrow HAZ in which the transformed region is often difficult to distinguish.

The sequence of transformation reactions in the weld metal is the same as for the HAZ, but due to the solidification pattern, the macroappearance is different and columnar grains are more typical (this can be seen on the top left of Fig.

10). Duplex weld metal grain growth is epitaxial, with the large prior ferrite grains in the HAZ dictating weld metal grain size and orientation. Austenite again forms preferentially on the grain boundaries, and intragranular austenite forms along preferred crystallographic planes as the weld metal continues to cool (Fig. 11).

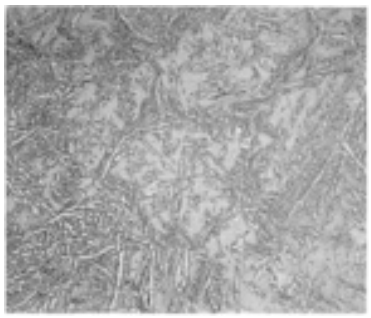

FIG. 11 PHOTOMICROGRAPH OF DSS WELD METAL WITH AUSTENITE LATHS (WHITE) AT PRIOR FERRITE GRAIN BOUNDARIES AND ALONG PREFERRED CRYSTALLOGRAPHIC PLANES IN A FERRITIC MATRIX. SAMPLE ELECTROLYTICALLY ETCHED IN 40% NAOH. 100×. COURTESY OF THE WELDING INSTITUTE

Precipitates are often difficult to observe and require precise etching techniques and experience with the type of microstructure. Due to its highly detrimental effect on corrosion resistance and toughness and relative ease of formation, the most commonly investigated precipitate in DSS is σ phase, an Fe(Cr,Mo) intermetallic. Sigma will initially precipitate at phase boundaries in the ferrite phase and will then grow into the ferrite phase, which is richer in chromium and molybdenum. Only a small amount of σ precipitation is required to reduce mechanical and corrosion properties.

Welding and Weldability

Duplex stainless steel weldability is generally good, although it are not as forgiving as austenitic stainless steels or as prone to degradation of properties as fully ferritic stainless steels. The current commercial grades are low in carbon (less than 0.03 wt%), thereby essentially eliminating the risk of sensitization and intergranular corrosion from carbide precipitation. The base material and filler metals also have low sulfur and phosphorus levels (less than 0.03 wt%), which in combination with the ferritic solidification reduce the likelihood of solidification cracking (hot cracking). Hydrogen cracking (cold cracking) resistance is also good due to the high hydrogen solubility in the austenite (Ref 29) and the high percentage of austenite in the matrix. Nevertheless, solidification cracking and hydrogen cracking can occur in duplex alloys, and some precautions are necessary.

Preheat is generally not recommended for DSS, but may sometimes be specified in low-nitrogen grades, because thick sections and low heat input welding processes may, in combination, develop highly ferritic heat-affected zones (Ref 30). For the more highly alloyed DSS, a preheat can be highly detrimental and reduce corrosion resistance and mechanical properties.

Postweld heat treatment (PWHT) is not commonly used except in autogenous welds or welds with a filler metal composition that exactly matches the base steel. Although not always necessary, particularly if a nickel-enriched filler metal is used, it is common to postweld heat treat DSS welded pipe after longitudinal seam welding. The PWHT will largely be for the purpose of restoring the correct phase balance and redissolving unwanted precipitates. Postweld heat treatment temperatures of about 1050 to 1100 °C (1920 to 2010 °F) are used, depending on grade, followed by the same heat treatment applied to the base material during solution annealing--usually water quenching (Ref 31). The heat treatments commonly used for structural steels (for example, 550 to 600 °C, or 1020 to 1110 °F) (Ref 32) are totally inappropriate for duplex alloys and should never be considered.

Interpass Temperature Control. The need for interpass temperature control depends on alloy grade and composition. The more highly alloyed grades should have tighter interpass control. For the Fe-22Cr-5.5Ni-3Mo-0.15N steels, interpass temperatures of 150 to 200 °C (300 to 390 °F) are typical, whereas for the Fe-25Cr-7Ni-3.5Mo-0.25N-(Cu-W) steels, temperatures as low as 70 °C (160 °F) have been recommended (Ref 33).

Welding practices employed for austenitic stainless steels (for example, cleanliness, use of a backing gas, avoidance of contamination with carbon steel, and so on) should also be adopted for DSS. The backing gas most commonly used is pure argon. However, the use of a backing gas without nitrogen can lead to nitrogen loss from the molten weld nugget (Ref 34) with probable loss in corrosion performance and toughness. Because of this, argon/nitrogen mixed gases for shielding and backing have been explored (Ref 35), and generally the corrosion resistance of welds produced with these gases has been superior to that of welds made with nitrogen-free gases. Pure nitrogen may also be used as a backing gas (Ref 2), but a concern exists that too much nitrogen may be picked up, thereby significantly affecting the phase balance locally by promoting the formation of austenite.

Open root gaps are commonly used in manual DSS welding to limit the extent of dilution from the base material, because extensive base metal dilution will negate the effect of the nickel over-alloying in the filler metal. To control the problems of too little austenite and intermetallic phase formation, associated with too-low and too-high heat inputs, respectively, DSS welding procedures typically specify a "window" of allowable heat inputs. For the highly alloyed and heat-sensitive super DSS, stringer beads are commonly specified, particularly in the hot pass (that is, weld pass immediately following the root), and in some cases in split hot passes (that is, two hot passes side by side). The technique of using a low heat input hot pass has led to the use of the term "cold" pass (Ref 33).

Welding procedure qualification generally follows the mechanical property test requirements of a major code, for example, ASME Section IX (Ref 36) or API 1104 (Ref 37). There are also several tests (specifically phase balance assessment, microstructural examination, and a pitting corrosion test) used for DSS weldment evaluation that are not typically employed for other stainless steels.

Phase-Balance Assessment. The phase balance test measures the amount of austenite and ferrite present in the microstructure and is similar to tests used to measure ferrite in austenitic weld metals. However, the testing requirements are usually more exhaustive for duplex alloys and will typically call for assessment of the ferrite content in the HAZ and weld metal. and possibly at several through-thickness locations (Ref 38). The amount of ferrite in a duplex structure can be specified and measured in two ways. Percentage ferrite is measured by manual point counting or image analysis. These methods measure the area fraction of ferrite and austenite exposed on the surface of a sample under examination. The values are reported as a volume fraction, thereby linking the surface area measurement on one plane to the overall volume fraction in the sample. Percentage ferrite requirements are typically 35 to 65% and are applied to weld metal and the HAZ.

The alternative method uses the ferromagnetic properties of the ferrite to measure its proportion in the matrix. The Ferrite Number (FN) system used for austenitic stainless steel weld metals (where the ferrite content is measured by attraction of a spring-loaded magnet) was not originally developed for high ferrite levels, such as those in duplex alloys, and was only calibrated to about 28 FN (Ref 39). Furthermore, the variations in iron content between the various duplex grades affected the magnetic attraction for a given phase balance (Ref 40). Because no reliable magnetic attraction system had been fully developed and proven at the time duplex alloys were seeing widespread industrial application, most specifications required ferrite percentage measurements. However, changes to the FN measuring system have now been made so that all ferrite levels in duplex alloys can be recorded, and the system has been shown to be more reliable. To achieve the extended range, counterweights were added to the spring-loaded magnet (Ref 40). Specification requirements for weld metals are typically 50 to 90 FN. A rule-of-thumb conversion from FN to percentage is:

$$0.70(\text{FN}) = \%\ \text{FERRITE} \qquad \textbf{(EQ 3)}$$

Measurement of ferrite content in DSS, however, is seldom currently performed with a magnetic measuring technique and is more commonly referred to in terms of percentage.

There are also some limitations to the application of the FN measuring system in certain regions of the weld. The measurement tool applies well to large areas of finely dispersed ferrite, such as in the weld metal, but it cannot accurately measure small areas that may have locally high ferrite levels (for example, the weld HAZ). It also may provide inaccurate readings in base material measurements due to the effect of magnet deflection toward the relatively coarse base material ferritic matrix.

Microstructural Examination. Optical microstructural examination is included to determine whether extensive phase precipitation has occurred (for example, σ-phase, carbides, nitrides, and so on), and specifications frequently call for the absence of any deleterious phases. However, the interpretation of DSS microstructures is so difficult that one cannot make a definitive assessment, especially without experience in studying similar structures. Detecting small proportions of precipitates by optical means is also relatively difficult.

Pitting Corrosion Test. The pitting corrosion test most commonly used for qualifying DSS is a modification of the ASTM G 48 Practice A ferric chloride test (Ref 41). Other tests are available (for example, potentiostatic critical pitting temperature tests in 3 or 15% NaCl, and others involving the use of CO_2), but the ASTM G 48 test has been shown to detect material with substandard properties and is preferred to most other common test techniques (Ref 42). The test solution is not representative of most service conditions in that it is highly acidic, oxidizing, and has a high chloride concentration, but the test is relatively easy to perform and can distinguish between good and bad welds. As used on DSS, the test involves the immersion of a welded coupon into a 10% $FeCl_3 \cdot 6H_2O$ solution for a duration of between 24 and 72 h at a temperature from 15 to 70 °C (60 to 160 °F), depending on material grade and specification requirements. Test assessment can be by direct weight loss, visual observation of pitting, weight loss per unit of exposed area, or corrosion rate. The procedure as laid out by ASTM was not designed for DSS weldment testing, and although it has been adapted in a number of ways, its interpretation still presents difficulties (Ref 43).

Filler Metal Requirements. For most DSS grades there are two types of filler metals:

- MATCHING COMPOSITION FILLER METALS
- FILLER METALS THAT ARE SLIGHTLY OVERALLOYED, PRINCIPALLY WITH RESPECT TO NICKEL

The matching filler metal is used where a PWHT is performed, whereas welds made with the filler metal enriched with nickel are used in the as-welded condition. The weld metal microstructure from a composition exactly matching that of the parent steel will contain a high ferrite content. The increase in nickel is made to improve the as-welded phase balance and increase austenite content. The ferrite content of a weld made with a nickel-enriched consumable would decrease significantly if it underwent a PWHT. It may suffer from slightly reduced weld metal strength and could also be more susceptible to σ phase formation during heat treatment (Ref 44). The nickel level in the enriched weld metal will be approximately 2.5 to 3.5% greater than in the base material (for example, for the Fe-22Cr-5.5Ni-3Mo-0.15N DSS base material containing 5.5% Ni, the filler metal will comprise 8.0 to 9.0% Ni, depending on consumable manufacturer and form). Nominal filler metal compositions for the Fe-22Cr-5.5Ni-3Mo-0.15N grade of DSS, proprietary names, and the American Welding Society classifications, where appropriate, are reported in Table 7.

(A) MAXIMUM.

(B) PENDING

The higher alloy filler metals are sometimes used for welding a less alloyed base material (for example, a DSS filler metal with 25% Cr could be used for the root run in a Fe-22Cr-5.5Ni-3Mo-0.15N base metal). This is usually done to improve root weld metal corrosion resistance and thereby pass the qualification test requirements. In most cases, this does not lead to loss of mechanical properties; indeed, the more highly alloyed filler metal in the case above is likely to have greater strength.

To avoid all the requirements for weld metal phase balance and microstructural control necessary with duplex filler metals, nickel-base consumables (for example, AWS A 5.14 ERNi-CrMo-3) have been used. The yield strength, however, is slightly below that of the more highly alloyed grades, and the lack of nitrogen and the presence of niobium in the filler metal may contribute to unfavorable metallurgical reactions and the formation of intermetallic precipitates and areas of high ferrite content in the HAZ (Ref 45, 46).

Cracking Behavior. Duplex stainless steels can suffer from weld metal hydrogen cracking and solidification cracking (Ref 47, 48), but HAZ cracking has not been reported in practice and is considered highly unlikely to develop. Hydrogen cracking from welding and in-service hydrogen pickup has been observed (Ref 49). The duplex microstructure provides a combination of a ferritic matrix, where hydrogen diffusion can be fairly rapid, with intergranular and intragranular austenite, where the hydrogen diffusion is significantly slower, thereby acting as a barrier to hydrogen diffusion. The net effect appears to be that hydrogen can be "trapped" within ferrite grains by the surrounding austenite, particularly where it decorates the prior ferrite grain boundaries. Due to these characteristics, low-temperature hydrogen release treatments are not effective, and the hydrogen is likely to remain in the structure for a long period (Ref 49). Whether cracking actually develops will depend upon a number of factors, including the total amount of trapped hydrogen, the applied strain, and

the amount of ferrite and austenite in the structure. Weld metal hydrogen content from covered electrodes can be relatively high, and levels up to 25 ppm have been reported (Ref 50).

The problem of weld metal hydrogen cracking in practice must not be overstated. The reported incidences of hydrogen cracking in DSS have been restricted to cases in which the alloy has been heavily cold worked or weld metals have seen high levels of restraint or possessed very high ferrite contents in combination with very high hydrogen levels as a result of poor control of covered electrodes or the use of hydrogen-containing shielding gas. Indeed, other studies have shown how resistant DSS weld metals are to hydrogen cracking, even with consumables intentionally humidified (Ref 51), and that hydrogen-containing backing gases can be employed without producing cracking (Ref 2). There is no doubt an effect of hydrogen on the ductility of DSS, and to avoid fabrication-related cracking problems, high-hydrogen-potential welding processes, such as shielded metal arc welding, should be controlled by careful storage and use of electrodes, and by ensuring that the weld metal phase balance is within acceptable limits.

Solidification cracking in DSS has not been reported as a commercial problem, but it has been witnessed in laboratory-made high heat input submerged arc welds (Ref 48). Cracking occurs at the solidification grain boundaries and has the appearance of running through the austenite phase. This is due to the subsequent solid-state transformation that occurs, in which the austenite forms predominantly on the prior ferrite grain boundaries. The solidification cracking susceptibility is not great, however, and weldability cracking tests have shown that the performance of DSS is similar to that of austenitic stainless materials with approximately 3 to 5 FN (Ref 52). Resistance to HAZ liquation cracking is also reportedly similar to type 304 stainless steel (Ref 53) and unlikely to develop in practical welding situations.

Loss of Properties. The weld is usually the part of a system with reduced corrosion resistance and low-temperature toughness, and therefore in many cases it is the limiting factor in material application. Welding primarily affects pitting corrosion, stress corrosion, and Charpy toughness.

Pitting corrosion resistance can be affected by many features of the welding operation, including:

- LOCALIZED SEGREGATION OF ALLOYING ELEMENTS TO THE DIFFERENT CONSTITUENT PHASES IN THE MICROSTRUCTURE, PRODUCING AREAS LEAN IN MOLYBDENUM AND CHROMIUM
- INCORRECT FERRITE/AUSTENITE PHASE BALANCE
- FORMATION OF NITRIDES OR INTERMETALLIC PHASES
- LOSS OF NITROGEN FROM THE ROOT PASS
- PRESENCE OF AN OXIDIZED SURFACE ON THE UNDERSIDE OF THE ROOT BEAD

The extent to which the reduction occurs depends on which of these factors are active and to what degree. Partitioning of alloying elements between the austenite and ferrite occurs in the weld metal, with chromium, molybdenum, and silicon partitioning to the ferrite and carbon, nickel, and nitrogen to the austenite (Ref 19, 54). The effect is not so apparent in as-deposited weld metals, but it becomes more significant as a result of reheating a previously deposited weld pass. The effect is also exacerbated by higher welding heat inputs (Ref 4, 54).

Weld metal and HAZ microstructures with very high ferrite contents are also less resistant to pitting attack than am balanced structures. This is largely because predominantly ferritic structures are more prone to chromium nitride precipitation, which locally denudes the chromium concentration and lowers resistance to pitting attack.

Nitrogen loss in the root pass may reduce weld metal corrosion resistance. Up to 20% loss of nitrogen has been reported for gas-tungsten arc welds (Ref 34), and nitrogen-bearing backing gases have been explored and used in limited applications (Ref 35).

Cleanliness of the root side purge gas may also affect pitting resistance. Figure 12 shows the effect of reducing oxygen content in an otherwise pure argon purge gas and its beneficial effect on pitting resistance. Also shown is the apparent benefit of using a reducing gas (NH_{10}), which would significantly reduce the tendency for oxide formation and leave the underbead appearance very shiny (Ref 55).

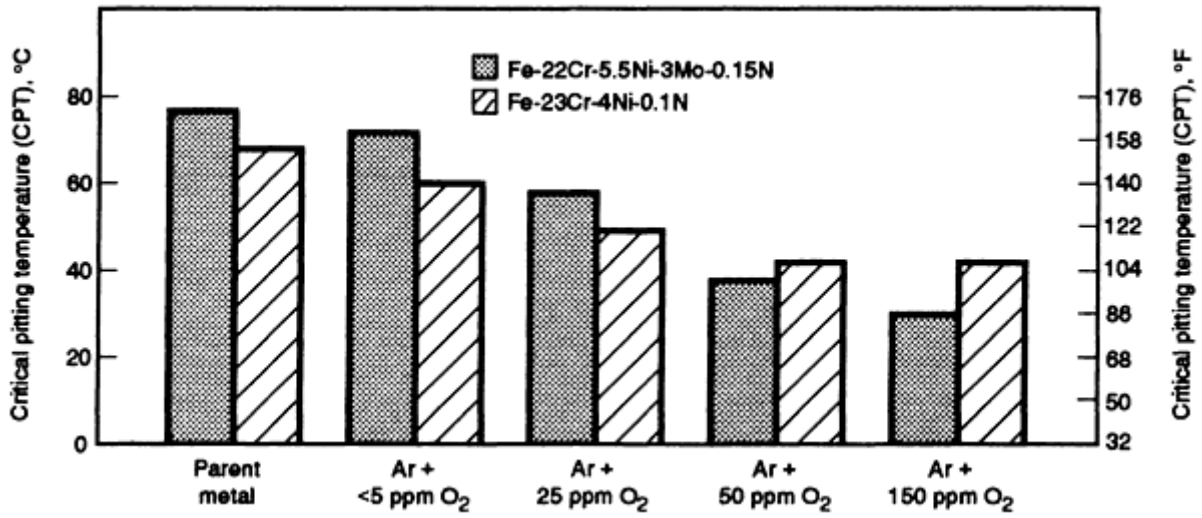

FIG. 12 PLOT OF PITTING TEMPERATURE VERSUS OXYGEN CONTENT OF BACKING GAS FOR FE-22CR-5.5NI-3MO-0.15N AND FE-23CR-4NI-0.1N DUPLEX STAINLESS STEELS TESTED IN 3% NACL AND 0.1% NACI SOLUTIONS, RESPECTIVELY, BOTH AT ANODIC POTENTIAL OF + 300 MV. SOURCE: REF 55

The net effect on pitting corrosion resistance may be observed by applying the ASTM G 48 pitting corrosion test to welds and base material with the same PRE value, then assessing the reduction in critical pitting temperature (that is, the temperature at which pitting in the ferric chloride solution is first observed). The difference is approximately 20 °C (35 °F), as reported in Fig. 13, thereby quantifying the effect of reduced weld metal properties. Figure 13 also shows that the use of a super DSS filler metal with a PRE value of about 40 on a Fe-22Cr-5.5Ni-3Mo-0.15N parent steel (which typically has a PRE value of about 33 to 35) will improve the weld metal pitting corrosion resistance, as assessed by the ASTM G 48 test, to approximately match that of the base material.

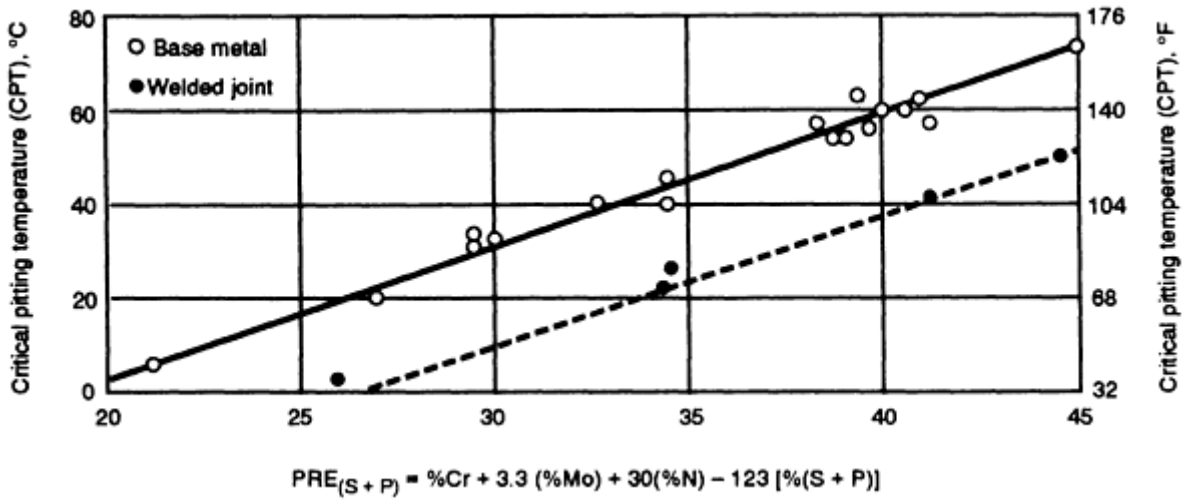

FIG. 13 PITTING CORROSION RESISTANCE OF BASE METAL RELATIVE TO WELD METAL PLACED IN 6 WT% $FECI_3$ SOLUTION FOR 24 H DURATION PER ASTM 6 48 (METHOD A). SOURCE: REF 11

Resistance to CI SCC does not appear to be affected significantly by welding per se (Ref 56). Nevertheless, welds are likely regions of attack for CI SCC due to the presence of high stresses and the structural inhomogeneity present at the weld. If localized pitting is a necessary precursor for CI SCC, the effects described above will also ultimately affect Cl SCC resistance.

There are three main causes of poor weld metal toughness:

- VERY HIGH FERRITE CONTENT
- PRESENCE OF INTERMETALLIC PHASES OR NITRIDES
- HIGH WELD METAL OXYGEN CONCENTRATION

Predominantly ferritic microstructures with a coarse grain size, as may be developed in a weld HAZ, have poor low-temperature notch toughness. Their performance is similar to that of ferritic stainless steels, and they may undergo low energy cleavage fracture. The Fe-25Cr-5Ni-2.5Mo-0.17N-Cu and super DSS are more susceptible to embrittlement through intermetallic phase precipitation, due to their increased kinetics of formation (Ref 57), and heat input and interpass temperature control are advised. Welding processes that produce high weld metal oxygen contents also produce welds with lower toughness, mainly due to the size and distribution of nonmetallic inclusions. Gas-shielded processes have the least oxygen potential and generally exhibit superior Charpy toughness properties (Fig. 14).

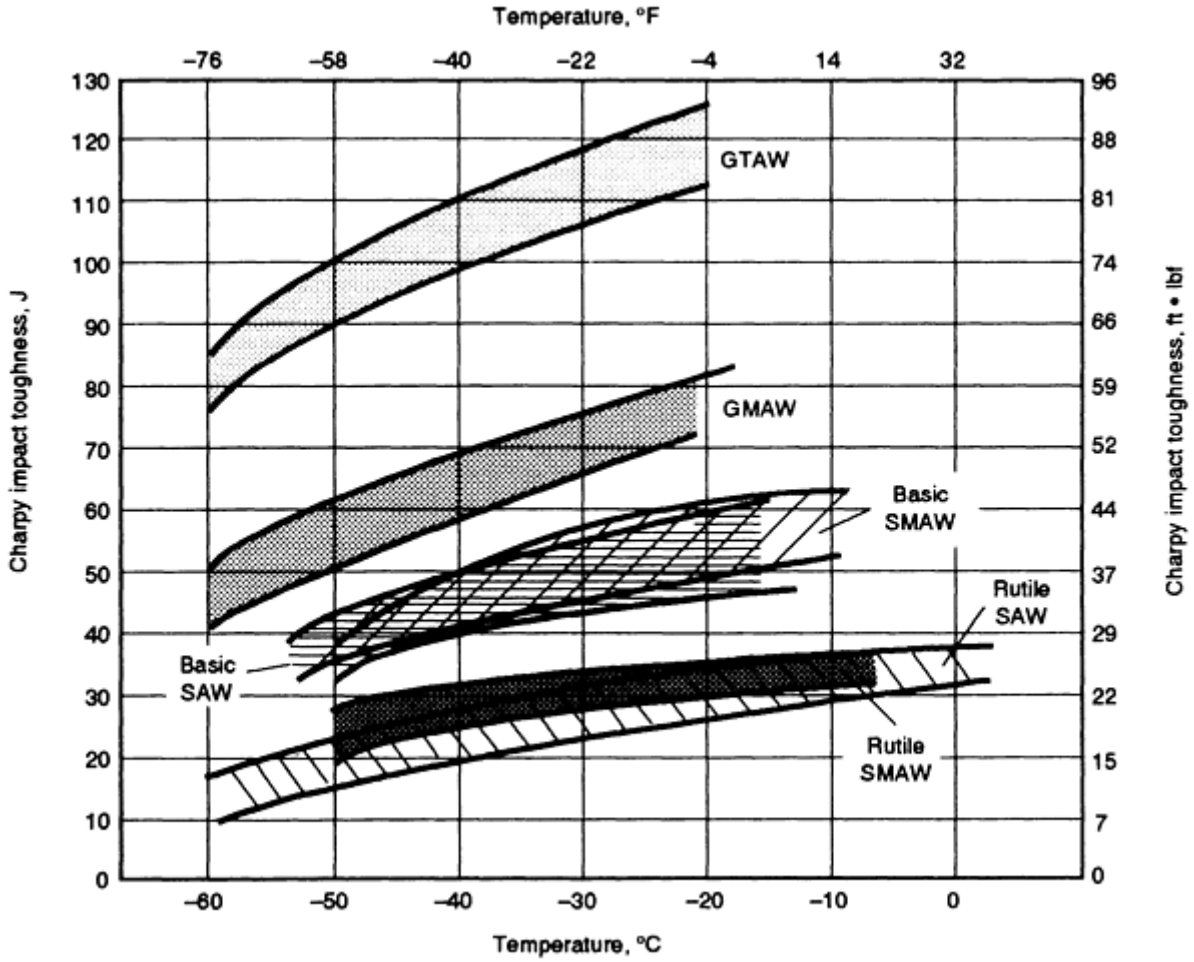

FIG. 14 PLOT OF CHARPY V-NOTCH TOUGHNESS VERSUS TEMPERATURE AS A FUNCTION OF WELDING PROCESS FOR UNS S32760 ALLOY. THE TERMS "BASIC" AND "RUTILE" REFER TO LIME-BASED AND TITANIA-BASED ELECTRODE COATINGS USED WITH SAW AND SMAW. SOURCE: REF 58

Selection of Wrought Duplex Stainless Steels

David N. Noble, ARCO Alaska, Inc.

Applicable Welding Processes

Fusion Welding. Nearly all of the arc welding processes that are employed for other stainless steels can be used with duplex alloys, except where the process characteristic is to weld autogenously, such as electron-beam welding and laser-beam welding. In such circumstances a PWHT is nearly always necessary to restore the correct phase balance to the weld metal and remove any undesirable precipitates. There are few reported differences in corrosion resistance between welding processes, but the nonmetallic inclusion distribution would be anticipated to have an effect. In most instances of pipe welding, where access is from one side only, gastungsten arc welding is almost exclusively employed for the root pass (Ref 22). This provides a controllable, high-quality root bead that dictates the final corrosion performance of the weld. The inert gas on the backside of the weld can also be more closely controlled with this process. Aside from this preference, process selection will probably be dictated more by the availability of consumable form and economic and logistic considerations than by desired properties for the particular welding process. Welds in DSS have been made by all the major fusion welding processes and have performed satisfactorily. However, in a very few cases, the final application may necessitate the stipulation of a particular welding process. Where exceptional low-temperature toughness is required, gasshielded processes may be specified because they produce higher weld metal toughness properties than flux-shielded processes (Fig. 14). Some consumable forms have not yet been fully developed for all grades of DSS. Nevertheless, gas-tungsten arc welding, shielded metal arc welding, submerged arc welding, flux-cored arc welding, and gas-metal arc welding are commonly used with success for most alloy classes.

Additional information is available in the article "Welding of Stainless Steels" in this Volume.

Solid-State Welding Processes. Few studies have been made of the solid-state welding characteristics of DSS. Explosive welding has been applied to overlaying of tube sheets and similar items (Ref 2). Corrosion and mechanical properties are presumed to be similar to parent material. Friction welding of DSS has shown that the corrosion resistance of a friction weld zone can be significantly better than that of a corresponding arc weld in the same material (Ref 34). This is attributed to the absence of fusion and the related effects that can result (that is, segregation and nitrogen loss).

The bond line will, however, experience high temperatures, and some degree of transformation of the austenite to ferrite would be anticipated. Very rapid cooling will then probably suppress reformation of austenite, and a structure high in ferrite could result. There is ongoing effort to establish whether solid-state welding processes offer significant advantages over fusion processes. The lack of a fused zone is potentially attractive to the welding of alloys that are prone to localized segregation effects.

Selection of Wrought Precipitation-Hardening Stainless Steels

B. Pollard

Introduction

PRECIPITATION-HARDENING (PH) STAINLESS STEELS are iron-chromium-nickel alloys with corrosion resistance superior to that of the hardenable 400 series stainless steels and yield strengths of 585 to 1795 MPa (85 to 260 ksi). These high strengths are obtained by precipitation hardening a martensitic or austenitic matrix with one or more of the following elements: copper, aluminum, titanium, niobium (columbium), and molybdenum. Precipitation-hardening steels can be grouped into three types--martensitic, semiaustenitic, and austenitic--based on their martensite start and finish (M_s and M_f) temperatures and resultant behavior upon cooling from a suitable solution treatment temperature.

The martensitic PH steels, such as 17-4PH, have M_f temperatures just above room temperature so that they transform completely to martensite upon air cooling from the solution treatment temperature and thus are martensitic in the annealed condition. Hardening is accomplished by a single aging treatment of 1 to 4 h at 480 to 620 °C (900 to 1150 °F).

The semiaustenitic PH steels, such as 17-7PH, have compositions that are balanced so that their M_s temperatures are well below room temperature. Therefore, they are predominantly austenitic upon cooling from the solution treatment temperature and are highly ductile and readily formed in that condition. After forming, transformation to martensite is accomplished by a conditioning treatment, which raises their M_s and M_f temperatures by precipitating carbon and alloying elements from solution. If a low conditioning temperature is used (730 to 760 °C, or 1350 to 1400 °F), the M_f temperature is raised to the vicinity of room temperature and transformation to martensite is complete upon cooling. If a high conditioning temperature (930 to 955 °C, or 1710 to 1750 °F) is used, less carbon is precipitated, the M_f temperature remains below zero, and refrigeration is required to accomplish transformation to martensite. However, since the martensite produced in this manner contains more carbon, it is of higher strength than that produced by transformation at lower temperatures. Transformation may also be accomplished by cold working. In all cases, the martensite structure is then hardened by aging at a temperature in the range of 455 to 565 °C (850 to 1050 °F) for 1 to 3 h.

The austenitic PH steels, such as A-286, have M_s temperatures so low that they cannot be transformed to martensite. Strengthening is obtained by the precipitation of intermetallic compounds in an austenitic matrix.

The chemical compositions of the PH steels presently produced in North America are presented in Table 1. A detailed treatment of aging in PH stainless steels is beyond the scope of this article because many different precipitation hardening phases are involved. Table 2, which was compiled from Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, and 15, lists the phases produced in martensitic, semiaustenitic, and austenitic PH grades. However, certain aging characteristics are common to most PH stainless steels. For martensitic and semiaustenitic types, maximum strengthening is obtained by aging at 455 to 510 °C (850 to 950 °F). Higher temperatures increase ductility and toughness but reduce both the maximum strength level and the time required to attain it. Typical aging curves for selected martensitic and semiaustenitic PH steels aged at 480 °C (900 °F) and 510 °C (950 °F) are shown in Fig. 1(a) and 1(b), respectively (Ref 16 17, 18, 19, 20).

For any alloy, a wide range of properties can be obtained by varying the heat treatment practice. However, certain standard heat treatments for which mechanical property data are available am generally used. These are summarized in Table 3. The corresponding mechanical properties are presented in Table 4.

(I) UP TO AND INCLUDING 150 MM (6 IN.)

The standard aging times used for aging temperatures of 480 and 510 °C (900 and 950 °F) are such that most steels so heat treated are in the fully aged or slightly overaged condition, whichever gives the best combination of strength and ductility. PH 15-7 Mo stainless steel is unusual in that it has the best combination of strength and ductility when slightly underaged. Material aged at temperatures above 510 °C (950 °F) and, therefore, in a significantly overaged condition, is used when greater ductility or toughness is required. Precipitation in austenitic PH steels is markedly slower than in martensitic or semiaustenitic PH steels. For example, 16 h at 720 °C (1325 °F) is required to produce near-maximum hardening in A-286.

The problems likely to be encountered in welding PH steels are different for each group, but similar for different steels within a group. Therefore, the weldability of the steels within each group can be best understood by first considering the welding of a typical steel from that group, which is invariably also the steel for which the most welding data are available. The weldability of other steels within the same group can then be understood by comparison with the "typical" steel.

Welding Martensitic PH Steels

Following a brief description of the solidification characteristics and microstructures of martensitic PH stainless steels, this section reviews welding parameters for types 17-4PH, 15-5PH, PH13-8 Mo, Custom 450, and Custom 455. Tables 1, 2, 3, and 4 list properties and heat treatment recommendations for these materials. Additional information can be found in the article "Welding of Stainless Steels" in this Volume.

Microstructural Evolution

There have been no systematic studies of the solidification of welds in PH stainless steels, but since the mechanisms involved are the same as for the standard austenitic stainless steels, the primary solidification mode can be predicted for a specific composition by using equations that were originally developed by Suutala and have since been modified by the addition of an aluminum term and higher values for the carbon and nitrogen equivalents. These equations are (Ref 21):

$$CR_{EQ} = \%Cr + 1.4(\%Mo) + 1.5(\%Si) + 2(\%Nb) + 2.5(\%A1) + 3(\%Ti)$$

$$NI_{EQ} = \%Ni + 0.3(\%Mn) + 35(\%C) + 20(\%N) + \%Cu$$

Calculated values of the Cr_{eq}/Ni_{eq} ratios for typical PH steels are given in Table 5. According to Suutala, a Cr_{eq}/Ni_{eq} greater than 1.55 is required for primary ferrite solidification (Ref 22). Therefore, the calculated values for the Cr_{eq}/Ni_{eq} ratio indicate that all the martensitic PH stainless steels except Custom 455 solidify as primary δ-ferrite. Upon cooling, nearly all this ferrite first undergoes a transformation to austenite, which subsequently transforms to martensite at temperatures close to ambient. Custom 455 solidifies as primary austenite, which transforms to martensite upon cooling to ambient temperature. Although the as-welded fusion zone microstructures of welds in martensitic PH steels made without filler metal or with a matching filler metal are predominantly martensitic, they may also contain a few percent of δ-ferrite in the untempered martensitic matrix (Fig. 2a). The morphology of this δ-ferrite is summarized in Table 5. The δ-ferrite in welds made with moderate-to-high heat inputs may be intercellular or vermicular. Intercellular ferrite is formed as part of a divorced δ-γ eutectic, which is a result of segregation during the last stages of primary austenite solidification, while vermicular ferrite constitutes the untransformed cores of the primary ferrite dendrites. Very high cooling rates, such as may be experienced by welds made at high speeds in sheet material, suppress the transformation of δ-ferrite to austenite and promote the formation of acicular austenitic-ferritic structures, the austenite content of which subsequently transforms to martensite.

In the as-welded condition, the heat-affected zones of welds in martensitic PH steels are distinguishable from the base metal by grain growth and an increased amount of ferrite in the high-temperature region close to the fusion line.

Postweld solution treatments reduce the residual δ-ferrite content and refine the prior-austenite grain size of both the fusion and heat-affected zones (HAZ). Aging, likewise, simultaneously tempers the martensite and precipitates the age-hardening particles in the fusion zone, HAZ, and base metal. However, these particles are too small to observe by optical microscopy. Aging may also reform up to 10% austenite at temperatures of 540 to 620 °C (1000 to 1150 °F), the amount increasing with aging temperature.

17-4PH Stainless Steel

Weldability. 17-4PH stainless steel is typical of the martensitic PH stainless steels. Its weldability is superior to that of the standard austenitic stainless steels because, due to its low carbon content, it does not require preheat to prevent cracking in thicknesses up to 100 mm (4.0 in.) (Ref 23 , 24, 25). The welding conditions used for arc welding 17-4PH stainless steel are essentially the same as those used for joining the standard austenitic stainless steels. However, neither welds nor base metal have the high ductility of the austenitic stainless steels, so care must be taken to avoid the presence of stress raisers (Ref 23 24, 25). One common form of stress raiser is the built-in notch at the root of a partial penetration weld. If design requirements dictate partial-penetration welds, the initiation of cracks at the root of the weld can be avoided by making the root pass with a ductile, low-strength filler metal such as type 308L, and then completing the balance of the weld with a matching high-strength heat-treatable filler metal.

Arc Welding. Gas-tungsten arc, gas-metal arc, and shielded metal arc welding processes have all been used extensively for joining 17-4PH stainless steel (Ref 23, 24, 25). Typical mechanical properties of arc welds in 17-4PH are presented in Table 6. The choice of welding process has little effect on the strength of welds after postweld heat treatment (PWHT),

but does affect the weld metal cleanliness and resultant ductility and toughness (Ref 23). Gas-tungsten arc welds have the highest and shielded metal arc welds the lowest quality. However, shielded metal arc welds are generally satisfactory for all but the most critical applications.

(D) NOTCH IN TRANSVERSE FACE OF WELD METAL.

Base-Metal Condition for Welding. Depending on the thickness and level of restraint, 17-4PH stainless steel can be welded in the annealed (A) or overaged (H1100 or H1150) conditions. The welding of material in conditions H900 through H1075 is generally not recommended. Material up to 25 mm (1.0 in.) thick can usually be welded in condition A provided that the weld is not very heavily restrained. Highly restrained welds or welds in heavier sections are best welded in conditions H1100 or H1150.

Filler Metals. Type 630 covered electrodes and filler wires, which deposit weld metal that closely matches 17-4PH base metal in composition and heat treatment response, are used when high-strength welds are required. Austenitic filler metals, such as type 308L, can be used for joining 17-4PH when high strength is not required in the joint. Welds made with austenitic filler metals are less susceptible to hydrogen embrittlement than those made with martensitic filler metals and may be used in the as-welded condition.

Postweld Heat Treatment. In the as-welded condition, the weld metal and the high-temperature regions of the HAZs of welds in 17-4PH stainless steel have structures consisting primarily of untempered martensite plus a small amount of ferrite (Fig. 2a). Weldments exhibit an aging peak in the HAZ and a weld metal hardness that is only slightly less than that of the base metal in condition A (Fig. 3a). Weldments in 17-4PH stainless steel are not usually put into service in the as-welded condition except for repair welds where PWHT is impractical. In order to obtain weld properties approximating those of the base metal, PWHT is necessary. For single-pass welds made with the base metal in condition A, a simple aging treatment of 1 to 4 h at 480 to 620 °C (900 to 1150 °F) is usually sufficient. It simultaneously hardens the weld metal, HAZ, and base metal and lowers the residual stresses associated with the weld. Because only slight overaging occurs in the portion of the HAZ that is heated into the aging temperature range during welding (Fig. 3a), joint efficiencies of 97 to 100% are obtained (Ref 25).

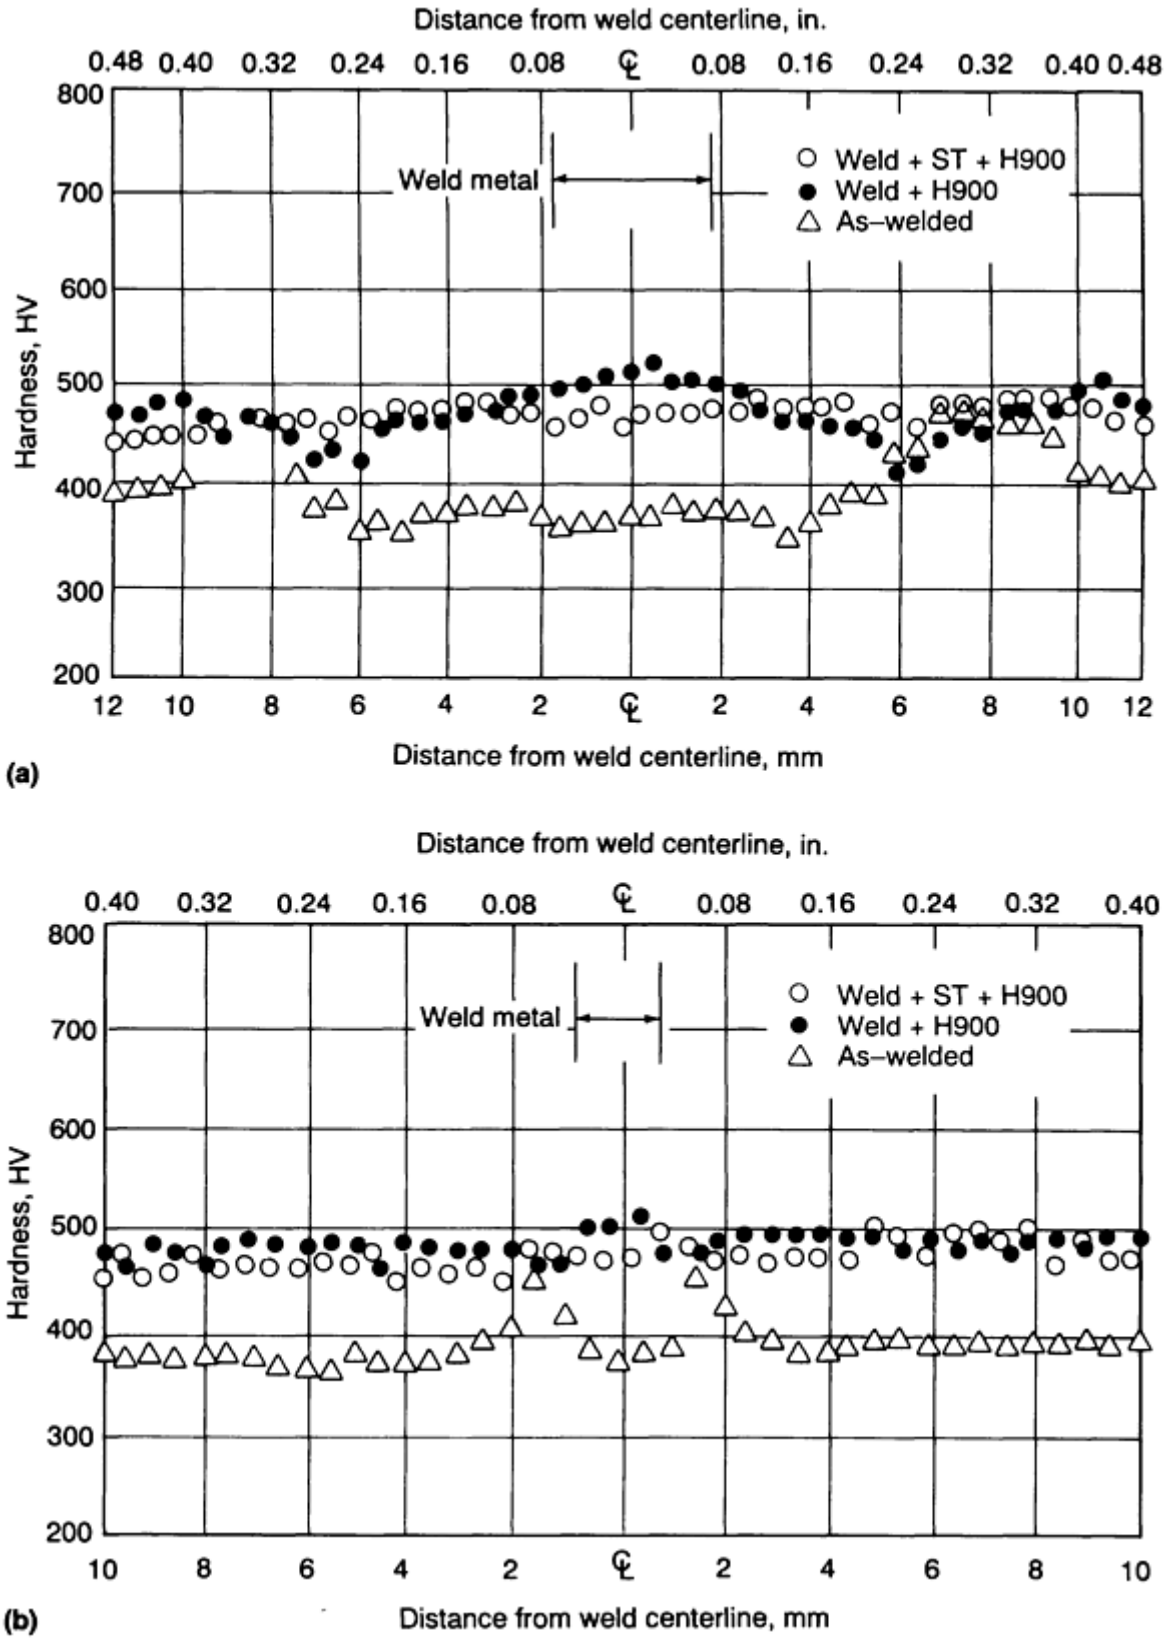

FIG. 3 MICROHARDNESS PROFILES OF AS-WELDED AND POSTWELD HEAT-TREATED WELDS IN 17-4PH MADE WITH (A) PAW AND (B) EBW PROCESSES. SOURCE: REF 26

In multipass welds, the repeated heating from the deposition of successive beads may leave a variation in structure from bead to bead that will result in nonuniform response to the aging treatment. Consequently, in the aged condition, weld

yield and ultimate tensile strengths are only about 65% and 80 to 90%, respectively, of the base-metal values (Ref 25). Solution treating the weld before hardening reduces the weld metal and HAZ ferrite contents and improves weld metal uniformity and response to heat treatment. As a result, weld strength increases to 80 to 90% and 90 to 95%, respectively, of the base-metal yield and ultimate tensile strengths. For welds made with the base metal in the overaged condition, solution treatment is required if it is desired to heat treat the weldment to a higher strength level. In general, if the weld deposit is less than 13 mm (0.5 in.) in thickness, fairly good tensile properties can be obtained even if the solution treatment is omitted prior to aging. However, the toughness of the weld metal decreases with aging temperature above 540 °C (1000 °F), probably due to an unfavorable carbide morphology. Therefore, if weld deposits are 13 mm (0.5 in.) or greater in thickness and a postweld solution treatment is not feasible, an age-hardening temperature of 550 °C (1025 °F) or lower is suggested (Ref 25).

Electron-beam (EB) welding is used for joining 17-4PH stainless steel when precision welds with maximum strength and minimum distortion are required. Welding parameters are similar to those used for welding the standard austenitic stainless steels and the same considerations as in arc welding apply to the choice of base-metal condition for welding. The most important characteristic of an EB weld is the total heat input, which is only about 20% of that of a comparable arc weld (Ref 26). As a result, the HAZ is much narrower (Fig. 3b) and the weld metal is finer grained and has a lower ferrite content. Furthermore, since an EB weld is usually a single-pass weld, the weld-metal structure does not exhibit the inhomogeneities of a multipass arc weld. Consequently, the mechanical properties of EB welds are generally superior to those of arc welds, particularly in regard to fracture toughness (Ref 27). Typical mechanical properties of EB welds in 17-4PH are presented in Table 7. Postweld aging alone results in joint efficiencies of 95 to 100% (Ref 26, 28) and total elongation values only slightly lower than those of the base metal; however, the toughness of welds in the H900 condition is low (Ref 26). Re-solution treating before aging has little effect on weld strength but markedly increases the toughness of welds aged at 480 °C (900 °F). However, it produces only a small increase in toughness for welds aged at higher temperatures.

15-5PH Stainless Steel

15-5PH stainless steel differs from 17-4PH in that its composition is balanced so that its structure is ferrite-free and material for bar and forging billets is vacuum arc remelted. As a result, the transverse ductility and toughness of 15-5PH stainless steel are superior to those of 17-4PH. However, its weldability is essentially the same as that of 17-4PH and the same welding processes and procedures are used. A matching 15-5PH filler wire (AMS 5826) is available for critical applications but it is most often welded with type 630 (17-4PH) covered electrodes or filler wire. Postweld heat treatment and weld mechanical properties are essentially identical to those for 17-4PH.

Autogenous welds in 15-5PH stainless steel contain less δ-ferrite than those in 17-4PH. Sufficient δ-ferrite is normally formed to prevent weld solidification cracking in GTA welds. However, the rapid cooling rates that are characteristic of EB and laser welding can produce welds with little or no δ-ferrite, which are susceptible to weld solidification cracking if welded with excessively high welding speeds (Ref 29). The strengths of defect-free EB welds in 15-5PH are similar to those in 17-4PH, but the fracture toughness is higher (Table 7).

PH13-8 Mo Stainless Steel

PH13-8 Mo stainless steel is vacuum induction melted plus vacuum arc remelted. It is ferrite-free and is used where high fracture toughness is required in heavy sections. Weldability is similar to 17-4PH stainless steel and the same procedures are used. It can be welded with the same processes, although covered electrodes for SMA welding are not available. Gas-tungsten arc and GMA welds can be made using a matching filler wire (AMS 5840). Although the final weld metal microstructure is ferrite-free (Fig. 2b), PH13-8 Mo has excellent resistance to weld solidification cracking because it solidifies as δ-ferrite and has low sulfur and phosphorus contents (Ref 30). After postweld solution treating and aging, the yield strengths and Charpy V-notch (CVN) impact energies of multipass GTA welds in PH13-8 Mo stainless steel are 96 to 100% and 50 to 100%, respectively, of the base-metal values (Fig. 4a), the difference between weld- and base-metal properties being greatest for aging temperatures above 540 °C (1000 °F). In heavy sections, PH13-8 Mo stainless steel is often joined by EB welding. After PWHT, EB welds have joint efficiencies of virtually 100% and their fracture toughness is approximately the same as that of the base metal (Ref 31).

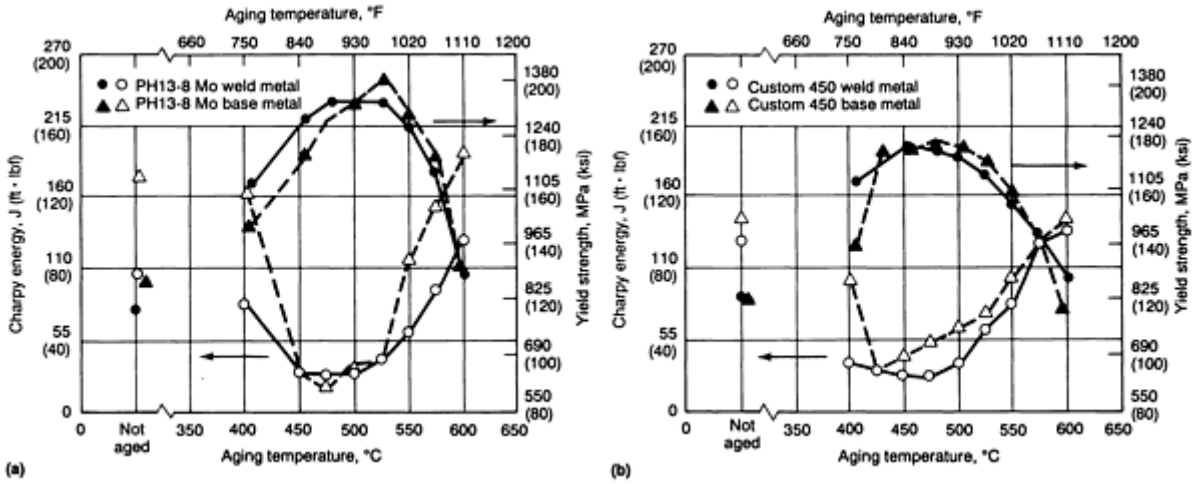

FIG. 4 EFFECT OF AGING TEMPERATURE ON THE YIELD STRENGTH AND CHARPY V-NOTCH IMPACT ENERGY OF (A) PH13-8 MO AND (B) CUSTOM 450 BASE METAL AND WELD METAL. GTA WELDS MADE IN 13 MM (0.50 IN.) THICK PLATE (CONDITION A) WITH MATCHING FILLER METALS. CLOSED SYMBOLS REPRESENT YIELD STRENGTH VALUES; OPEN SYMBOLS REPRESENT IMPACT VALUES. SOURCE: REF 30

Custom 450 Stainless Steel

The composition of Custom 450 stainless steel is balanced so that base metal, HAZ, and weld metal are essentially fully martensitic. In most respects, its weldability is similar to that of 17-4PH, and it can be joined using the same welding processes and procedures (Ref 32). A matching filler wire (AMS 5763) is usually used for GTA and GMA welding Custom 450 and is essential if the weldment is to be used without PWHT. A type 630 (17-4PH) filler wire or coated electrode can be used for joining Custom 450 if the weldment is postweld aged or solution treated and aged.

Custom 450 stainless steel is often used in condition A when only moderate strength is required. Material welded in this condition has acceptable weld properties in the as-welded condition, but CVN impact energy is substantially increased by a postweld solution anneal at 1040 °C (1900 °F) (Ref 32). Higher strength levels are obtained by postweld aging or solution treating and aging. After postweld solution treating and aging, the yield strengths of multipass GTA welds in Custom 450 are 98 to 100% of the base-metal values. Weld metal CVN impact energy increases with aging temperature from about 50% of the base-metal value for welds aged at 480 °C (900 °F) to 100% for welds aged at 565 °C (1050 °F) as shown in Fig. 4(b).

Custom 455 Stainless Steel

Custom 455 stainless steel is vacuum induction melted plus vacuum arc remelted and is completely martensitic. It is joined primarily by GTA welding and a Custom 455 filler metal is available for multipass welds. Procedures are similar to those used for 17-4PH, but a lower postweld solution treatment temperature (815 to 845 °C, or 1500 to 1550 °F) is used. In small sections, joint efficiencies of 80% are obtained by postweld aging only and 100% by solution treating and aging the weldment (Ref 33, 34). In large sections, joint efficiencies in excess of 85% are possible (Ref 19).

Welding Semiaustenitic PH Steels

As shown in Tables 1, 2, 3, and 4, semiaustenitic PH stainless steels include types 17-7PH, PH15-7 Mo, AM-350, and AM-355. As with the previous section on martensitic PH stainless steels, both microstructural evolution and weld parameters associated with semiaustenitic PH steels are described. The article "Welding of Stainless Steels" in this Volume should also be consulted.

Microstructural Evolution

The semiaustenitic PH steels have a primary δ-ferritic solidification mode and, on cooling, the δ-ferrite partially transforms to austenite by a Widmanstätten reaction. This austenite is stable down to ambient temperature so the as-welded structure of the fusion zone consists of austenite in a ferrite matrix (Fig. 2c). With the exception of AM-355, the percentage of retained ferrite in semiaustenitic PH welds is substantially higher than for welds in martensitic PH steels.

Postweld conditioning treatments destabilize the austenite so that it transforms to martensite at ambient or subzero temperatures. Subsequent aging simultaneously tempers the martensite and precipitates the strengthening particles, which are not visible by optical microscopy. The final fusion zone microstructure, therefore, consists of areas of retained ferrite in a tempered martensitic matrix. If a low conditioning temperature is used, carbide particles may also be observed at the ferrite-martensite interfaces.

In the as-welded and, to a lesser degree, the postweld heat-treated conditions, the HAZ is distinguishable from the base metal by an increase in grain size and ferrite content in the high-temperature region close to the fusion line.

17-7PH and PH15-7 Mo Stainless Steels

Weldability. 17-7PH and PH15-7 Mo stainless steels are typical of the semiaustenitic PH steels. As-deposited welds made without filler metal have weld metal and HAZ structures that are predominantly austenitic (Fig. 2c). This ductile structure is not susceptible to cold cracking, so 17-7PH and PH15-7 Mo are readily welded in any condition without preheat and without the need for critical control of interpass temperature or cooling rate (Ref 24, 35). However, autogenous 17-7PH weld metal is not fully austenitic, but rather contains about 25% δ-ferrite versus 10 to 15% in the base metal. Likewise, autogenous PH15-7 Mo weld metal may contain up to 40% δ-ferrite versus 15% in the base metal. The δ-ferrite content of the weld metal is determined primarily by composition, but high values are also promoted to a lesser degree by thicker weld beads, higher welding currents, and higher welding speeds. A large volume fraction of δ-ferrite can make the weld metal susceptible to hot cracking and reduce the ductility of the weld metal in the heat-treated condition. If necessary, the δ-ferrite content of the weld metal can be reduced by the addition of an appropriate filler metal.

Filler Metals. Filler wires are available for 17-7PH (AMS 5824) and PH15-7 Mo (AMS 5812) stainless steels. The compositions of these wires have been adjusted so as to produce deposits with lower δ-ferrite contents than would be produced by the base-metal compositions while still responding correctly to the age-hardening treatment (Ref 24, 35). Covered electrodes are not available for 17-7PH and PH15-7 Mo stainless steels because excessive oxidation of aluminum would occur in the arc. However, type 630 (17-4PH) covered electrodes have been used successfully for joining 17-7PH. To obtain adequate heat treat response with this filler metal, welding conditions that produce high dilution and a compromise PWHT practice are required (Ref 24). A heat treatment of 870 °C (1600 °F) for 90 min is used to simultaneously solution treat the type 630 weld metal and condition the 17-7PH base metal (Ref 35). The weld is then refrigerated at -75 °C (-100 °F) for 8 h and aged at 510 to 595 °C (950 to 1050 °F) for 1 h, depending on the properties required. Standard iron-chromium-nickel filler metals, such as types 308, 308L, 309, and 347, can also be used for joining 17-7PH and PH15-7 Mo, but the weld metal will not respond to heat treatment in the same manner as the base metal. Response to heat treatment will depend on the ratio of austenite-to-ferrite-forming elements in the filler metal and the amount of dilution by the base metal. In most instances, weld strength will be much lower than that obtained with a matching filler metal, but ductility and toughness will be higher.

Gas-Tungsten Arc Welding. Because 17-7PH and PH15-7 Mo stainless steels are used primarily as sheet and strip, they are most frequently joined by GTA welding. Preheating and postheating are not required to prevent cracking, but the

selection of welding conditions requires more care than for the standard austenitic stainless steels. Helium gas is preferred over argon for shielding the arc because helium minimizes the formation of a continuous aluminum oxide film on the surface of the weld pool (Ref 23). Particular care should be taken to provide efficient shielding of the weld pool in order to minimize loss of aluminum. Inert gas shielding should also be used on the underside of full penetration welds to protect the weld root. Welding speeds typically are of the order of 5 mm/s (12 in./min) (Ref 35). Higher welding speeds can cause porosity at the fusion line. Welding currents and weld-pass sequence should be selected to minimize the weld cross-sectional area.

Gas-metal arc welding is used for joining 17-7PH and PH15-7 Mo in heavy sheet and plate thicknesses. A mixture of 75He-25Ar is the most widely used shielding gas. Welding conditions are otherwise similar to those used for the standard austenitic stainless steels.

Postweld Heat Treatment. As-deposited welds in 17-7PH and PH15-7 Mo steels have a structure of austenite plus ferrite that is of much lower strength than the hardened base metal. A PWHT is, therefore, essential if a weld strength similar to the base-metal strength is required. The effects of PWHT on the tensile properties of GTA welds in 17-7PH and PH15-7 Mo steels are presented in Table 8; corresponding welding conditions are given in Table 9. The joint efficiencies of welds postweld hardened to the RH950 or TH1050 conditions without reannealing are 100% with weld reinforcement and 95 to 98% without it. Postweld reannealing before hardening has negligible effect on weld strength but increases weld ductility.

Resistance Welding. Spot and seam welding have been used extensively for joining 17-7PH and PH15-7 Mo steels. For good results, particular attention should be given to the surface cleanliness of the steel. Surfaces to be joined should be free of oil, grease, dirt, and heat treating scale. Welding schedules should use longer weld times, lower weld currents, and electrode forces 10 to 20% higher than those normally used for the standard austenitic stainless steels (Ref 24). The best mechanical properties are obtained by welding just before or after final hardening. This practice produces weld nuggets with a tough austenitic microstructure. The tensile strength normal to the weld interface is a maximum for this condition, and the shear strength is not significantly lower than for nuggets in the hardened condition (Ref 35).

Sound flash butt welds can be produced in 17-7PH and PH15-7 Mo stainless steels, but ductility may be low as a result of ferrite stringers in the base metal being bent parallel to the weld interface (Ref 35).

AM-350 and AM-355 Stainless Steels

Weldability. AM-350 and AM-355 differ from 17-7PH and PH15-7 Mo stainless steels in that they do not contain aluminum. Martensitic transformation provides their major strengthening mechanism with an additional but smaller contribution from the precipitation of Cr_2N or an isostructurally similar phase during tempering (Ref 12). The absence of any reactive elements makes the weldability of AM-350 and AM-355 as good as that of the standard austenitic stainless steels and superior to that of 17-7PH. Although these steels are most often joined by GTA and GMA welding, they can be joined by any of the processes used for the standard austenitic stainless steels, including submerged arc, electron-beam, laser-beam, and resistance welding (Ref 34, 36, 37). Like 17-7PH and PH15-7 Mo, these steels may be welded in the annealed or hardened conditions and neither preheat nor special precautions with regard to interpass temperature or cooling rate are necessary. However, PWHT must be used if maximum weld strength is required.

Annealed AM-350 base metal contains 10 to 15% δ-ferrite, and welding produces even higher levels in autogeneous weld metal and the high-temperature portion of the HAZ. In the subzero cooled and tempered (SCT) condition, the final structure consists of islands of ferrite surrounded by carbides in a tempered martensitic matrix. In contrast, the composition of AM-355 is balanced so that the base metal contains less than 5% δ-ferrite in condition H (solution treated at 1065 °C, or 1950 °F) and 0% ferrite in the equalized plus overaged and tempered (EOT+) condition, and welding does not increase the ferrite content to any significant extent.

Filler Metals. An AM-355 filler wire (AMS 5780) with a composition identical to that of the base metal is available for joining AM-355. Likewise, a matching AM-350 filler wire (AMS 4774) is available for welding AM-350, but the AM-355 filler wire is usually preferred for this material because it gives slightly higher weld strengths after PWHT (Ref 36). The AM-355 filler wire can also be used with a proprietary flux for submerged arc welding. AM-355 covered electrodes have been developed for SMA welding but may not be readily available.

Postweld Heat Treatment. Joint efficiencies of 90 to 100% can be obtained by PWHT of AM-350 and AM-355 welds (Ref 36). The PWHT for welds in AM-350 consists of annealing at 930 °C (1710 °F) (condition L) and cooling rapidly to

room temperature, followed by subzero cooling to -75 °C (-100 °F) and tempering at 455 or 540 °C (850 or 1000 °F) (condition SCT).

Unlike AM-350, AM-355 must have a suitably prepared microstructure prior to the condition L treatment in order to minimize intergranular precipitation during this treatment. The required microstructure is produced by a prior heat treatment which involves carbide solution annealing for 1 to 3 h at 1040 °C (1900 °F), cooling rapidly enough to room temperature to avoid intergranular carbide precipitation in the temperature range 870 to 650 °C (1600 to 1200 °F), and subzero cooling to -75 °C (-100 °F). The subzero cooling causes a partial transformation to martensite and, during subsequent heat treatments in the carbide precipitation range, carbides precipitate in the former martensitic areas in preference to the grain boundaries. After this treatment, AM-355 weldments are annealed at 915 to 970 °C (1675 to 1775 °F), subzero cooled to -75 °C (-100 °F), and tempered at 455 or 540 °C (850 or 1000 °F) (condition SCT).

Resistance Welding. AM-350 and AM-355 can be spot welded either before or after the hardening treatment using similar conditions as for standard austenitic stainless steels. Postweld heat treatments (for example, condition SCT) produce a moderate increase in tensile shear strength, but also a corresponding decrease in cross-tension strength. Consequently, the best combination of tensile shear and cross-tension strength is obtained by welding in the hardened condition and not postweld heat treating (Ref 24, 37).

Welding Austenitic PH Steels

Weldability and welding recommendations for A-286 and JBK-75 austenitic PH stainless steels are discussed below. Tables 1, 2, 3, and 4 list properties and heat treatments for these steels. As noted previously, additional information can be found in the article "Welding of Stainless Steels" in this Volume.

A-286 Stainless Steel

Weldability. A-286 stainless steel is highly alloyed and since welds solidify entirely as austenite (Fig. 2d), they are susceptible to hot cracking in both the fusion zone and HAZ (Ref 38, 39, 40, 41, 42). Solidification cracking in the fusion zone results from the formation of a low-melting-point Laves-phase eutectic at the grain boundaries, which is produced by the segregation of titanium and other solutes during the last stages of solidification (Ref 40, 42). This phase is enriched

in titanium, nickel, silicon, and molybdenum and depleted in iron and chromium (Ref 40). The same phase is also responsible for HAZ cracking (Ref 39, 40, 41, 42). However, in the HAZ, the Laves-phase eutectic is formed by the constitutional liquation of (Ti,Mo)(C,N) inclusions (Ref 41, 42). Constitutional liquation is a result of the rapid, nonequilibrium heating conditions typical of arc welding, which cause the carbonitrides to decompose more rapidly than their constituent elements can diffuse into the matrix. The result is the formation of solute-rich zones of eutectic composition (and hence low melting point) around the decomposing carbonitrides. This liquid then wets the grain boundaries, and the grains are pulled apart by shrinkage stresses as the weld cools. Of the residual elements normally present in A-286, silicon and boron have been found to have the greatest effect on hot cracking in both the fusion zone and HAZ (Ref 40, 41, 42).

The ease with which crack-free arc welds can be produced in A-286 depends on the grade of material, weld-section thickness, amount of restraint, the welding process used, the welding procedure, and the choice of filler metal. Both regular and welding grades of A-286 are produced. The welding grades (AMS 5858 and AMS 5895) have lower limits on manganese, silicon, sulfur, and phosphorus than the regular grades and exhibit greater resistance to hot cracking. Whenever possible, they should be specified in preference to the regular grades for applications that involve welding. Although A-286 is classified as a difficult-to-weld material, it can be joined successfully by GTA, EB, and resistance welding if the correct procedures are used.

Gas-Tungsten Arc Welding. When GTA welding A-286, the best results are obtained with the base metal in the solution treated condition, low-heat inputs, and minimum restraint (Ref 24, 34). Autogenous crack-free GTA welds can be produced in thin sheet, but welds in thick sheet and plate require filler metal. A stringer bead technique should be used for multipass welds in heavy sections.

The choice of filler metal depends on the application. The regular A-286 filler wires (AMS 5804) have lower limits on sulfur and phosphorus contents but are otherwise similar in composition to the base metal. Deposits made with these wires are the most prone to hot cracking, so they have been used primarily for single-pass welds (Ref 34). Premium quality A-286 filler wires (AMS 5805) with lower carbon, manganese, silicon, phosphorus, and boron contents and limits on oxygen, nitrogen, and hydrogen levels are also available. These wires are produced from vacuum induction melted material by wire rolling instead of drawing (Ref 43, 44). They produce high-purity deposits that are less susceptible to hot cracking than those made using the regular filler wires and are used for critical applications such as jet engine repairs.

Dissimilar metal filler wires are the usual choice for multipass welds if a matching filler metal is not essential because they exhibit greater resistance to hot cracking than A-286 weld metal. Hastelloy W has been used extensively for joining A-286 (Ref 24, 43). It has excellent resistance to hot cracking, but its stress-rupture strength is substantially lower than that of A-286 weld metal and it is not suitable for many high-temperature environments. Type 310 filler metal has been used for joining A-286 plate (Ref 24). It has very good corrosion resistance in many media but is nonhardening. AMS 5675 (AWS A5.14 Class ERNiCrFe-6) filler metal is significantly less crack sensitive than A-286 and is age hardenable, but it does not quite match the strength of A-286.

Postweld Heat Treatment. Typical tensile properties of welds in A-286 are presented in Table 10. A-286 weld metal does not age harden as rapidly or to the same extent as the base metal. A PWHT of 725 °C (1335 °F) for 48 h is required to increase the yield and ultimate tensile strengths to 93% and 89%, respectively, of the base-metal values (Ref 45). However, aging is much more rapid if the weld is first solution treated (Ref 46). For example, solution treating at 1080 °C (1975 °F) for 2 h and aging at 725 °C (1335 °F) for 16 h increases the yield and ultimate tensile strengths to 94% and 97%, respectively, of the base-metal values. If a high-temperature solution treatment is not feasible, weld strength can be increased by using a low-temperature multistep heat treatment consisting of 725 °C (1335 °F), 4 h plus 650 °C (1202 °F), 5 h plus 725 °C (1335 °F), 44 h (Ref 45). This heat treatment raises the yield and ultimate tensile strengths to 99% and 93%, respectively, of the base-metal values.

(C) ESTIMATED FROM HARDNESS

Electron-Beam Welding. Although EB welding is a low-heat input process compared to arc welding, the use of EB welding does not guarantee freedom from hot cracking. However, crack-free EB welds can be made in A-286 if heat input, welding speed, and restraint are low. A-286 can be EB welded in both the solution treated and hardened conditions. However, resistance to hot cracking is greater in the solution treated condition. EB welds in A-286 are usually made without filler metal. In the as-welded condition, weld strength is about the same as for GTA welds in the same condition, but postweld aging is more effective in increasing weld strength than for GTA welds in A-286. For example, the yield and ultimate tensile strengths of EB welds made in 3.2 mm (0.128 in.) thick A-286 in the solution treated condition has yield and ultimate tensile strengths of 98% and 88%, respectively, of the base-metal values after aging at 720 °C (1330 °F) for 16 h (Ref 47).

Resistance Welding. A-286 stainless steel can be joined by resistance spot and seam welding in both the soft and hardened conditions, but the welds, as with those made by other fusion welding processes, are susceptible to hot cracking. However, some hot cracking can be tolerated in spot and seam welds since cracking of up to 5 vol% of the weld nugget has little effect on static or cyclic weld strength if it is concentrated at the center of the weld nugget (Ref 48). Hot cracking can be reduced or eliminated by using electrode forces significantly higher than those used for the standard austenitic stainless steels (Ref 24, 48). Welding conditions that slow down the cooling rate (for example, downsloping the weld current) have also been recommended as a means of eliminating cracking (Ref 48). Limited data suggest that longer weld times and lower weld currents than those used for standard austenitic stainless steels may also be beneficial.

Spot welds made in hardened material without PWHT have the best combination of shear and cross-tension strengths (Ref 37).

Seam welds in A-286 are also susceptible to hot cracking. Limited data indicate that the best results are obtained with a lower wheel speed, lower weld current and longer (on plus off) time than are generally used for the standard austenitic stainless steels. Increased electrode force and continuous (rather than interrupted) weld current may also be used to prevent cracking (Ref 49).

Little information is available on welding conditions for flash butt welding A-286 because these conditions vary from machine to machine and application to application. However, A-286 is routinely joined by flash butt welding with excellent results. After postweld aging at 720 °C (1325 °F), weld properties are virtually equal to those of the base metal (Ref 50).

JBK-75 Stainless Steel

JBK-75 is a modification of A-286 with the low carbon, manganese, silicon, and boron contents of welding grade A-286 plus a higher nickel content. The beneficial effect of the higher nickel content is explained by the concept of shrinkage brittleness (Ref 51). According to this concept, during the last stages of solidification, a minimum amount of eutectic liquid is required to fill all the dendritic fissures formed by the eutectic films. If a critical, subminimum amount of eutectic forms, severe cracking occurs. On the other hand, if only a very small amount of eutectic forms, no cracking occurs because enough solid boundaries are present to withstand the shrinkage stresses. Therefore, the beneficial effect of the high nickel content of JBK-75 is due to it increasing the amount of eutectic formed so that any microfissures which nucleate are self-healing. Consequently, JBK-75 has greater resistance to hot cracking than A-286 and can be GTA welded in heavier sections without cracking.

Mechanical properties of GTA welds in JBK-75 are presented in Table 10. Hardness measurements indicate that the weld ultimate tensile strength (UTS) is only about 70% of the base-metal value after postweld aging at 725 °C (1335 °F) for 24 h (Ref 52). Higher weld- and base-metal strengths and a joint efficiency, based on the UTS, of about 78% are obtained by a double aging treatment consisting of 725 °C (1335 °F), 24 h plus 650 °C (1200 °F), for 24 h. Homogenizing at 950 °C (1740 °F) before aging also increases weld-metal strength but simultaneously reduces the strength of the base metal. For example, a heat treatment consisting of 950 °C (1740 °F) for 24 h plus 725 °C (1335 °F) for 24 h produces a hardness of 30 HRC, which is equivalent to a UTS of about 965 MPa (140 ksi) in both the weld and base metal.

Selection of Cast Stainless Steels

Michael J. Cieslak, Sandia National Laboratories

Introduction

THE DEVELOPMENT OF CASTING TECHNOLOGY has been driven by two distinct engineering perspectives. The first involves the potential economy of cast hardware relative to totally machined wrought parts. Complex, nearnet shapes can be produced by a variety of casting processes, including sand casting, investment casting, and centrifugal casting (used almost exclusively for making tubular products). Casting also can be an extremely effective way of producing very large parts.

The second perspective is associated with metallurgical realities. Many alloys have been developed for which there are no true wrought counterparts. The chemical composition and microstructure of these alloys is such that deformation processing of large ingots into wrought product forms would be problematic. In addition, the very nature of the cast microstructure, which in general is composed of large grains, can provide benefits in high-temperature creep applications.

Some common examples of stainless steel castings include valve and pump bodies, compressor wheels, propellers, turbine impellers, large pipe elbows, heat treating fixtures, and food, paper, and chemical processing equipment. Extensive reviews on the properties and applications of cast stainless steels can be found in Ref 1, 2, 3, and 4.

Acknowledgement

This work was performed at Sandia National Laboratories, supported by the U.S. Department of Energy under contract number DE-AC04-76DP00789.

Selection of Cast Stainless Steels

Michael J. Cieslak, Sandia National Laboratories

Stainless Steel Casting Alloys

Categories. Unlike the case of wrought alloy designators, cast stainless steels are not grouped according to microstructural types, but by the intended service environment. The general classification of stainless steel castings places these alloys in one of two categories: corrosion-resistant alloys and heat-resistant alloys. The corrosion-resistant alloys have been designed primarily for service environments involving aqueous or liquid-vapor corrosives at temperatures generally less than 315 °C (600 °F). Use at extended temperatures up to 650 °C (1200 °F) in selected environments may also be considered.

The heat-resistant alloys have been designed for use in service environments exceeding 650 °C (1200 °F) where aqueous corrosives do not exist. At these elevated temperatures, oxidation, sulfidation, and carburization/decarburization are the environmental effects of consequence. High-temperature mechanical strength, creep and stress-rupture resistance, and microstructural stability are the engineering requirements for these alloys. The high-temperature alloys are most readily distinguished from the corrosion-resistant alloys on the basis of carbon content (although other alloying elements may also vary considerably in response to service needs) with the high-temperature alloys containing 0.20 to 0.70 wt% C and the corrosion-resistant alloys generally containing less than 0.20 wt% C.

Nomenclature. Cast stainless steels are most often specified on the basis of composition using the designation system of the High Alloy Product Group of the Steel Founders' Society of America. (The High Alloy Product Group has replaced the Alloy Casting Institute, or ACI, which formerly administered these designations.) The first letter of the designation indicates whether the alloy is intended primarily for liquid corrosion service (C) or high-temperature service (H). The second letter in either group of alloys indicates an approximate ratio of nickel-to-chromium with the ratio increasing in alphabetical order. (As the nickel content increases, the second letter of the designation progresses through the alphabet from A to Z.) The number immediately following the hyphen indicates the carbon content of the alloy in hundredths of a weight percent (also known as "points" of carbon). For the corrosion-resistant alloys, the carbon content indicated is the maximum allowable for the alloy. For the heat-resistant alloys, the carbon content identified is the midpoint with an allowable range of ± 0.05 wt%. Finally, if further alloying elements are present, these are indicated by the addition of one or more letters as a suffix. Thus, the designation of CF-8M refers to an alloy for corrosion-resistant service (C) of the 19Cr-9Ni type with a maximum carbon content of 0.08% that contains molybdenum (M). Figure 1 graphically shows the range of nickel and chromium contents in several grades of corrosion-resistant and heat-resistant alloys identified by the aforementioned designation system. Tables 1 and 2 list the chemical compositions of the common corrosion-resistant and heat-resistant alloys, respectively.

(A) TYPE NUMBERS OF WROUGHT ALLOYS ARE LISTED ONLY FOR NOMINAL IDENTIFICATION OF CORRESPONDING WROUGHT AND CAST GRADES. COMPOSITION RANGES OF CAST ALLOYS ARE NOT THE SAME AS FOR CORRESPONDING WROUGHT ALLOYS; CAST ALLOY DESIGNATIONS SHOULD BE USED FOR CASTINGS ONLY.

(B) MAXIMUM UNLESS A RANGE IS GIVEN. THE BALANCE OF ALL COMPOSITIONS IS IRON.

(C) SULFUR CONTENT IS 0.04% IN ALL GRADES EXCEPT: CG-6MMN, 0.030% S (MAX); CF-10SMNN, 0.03% S (MAX); CT-15C, 0.03% S (MAX); CK-3MCUN, 0.010% S (MAX); CN-3M 0.030% S (MAX), CA-6N, 0.020% S (MAX); CA-28MWV, 0.030% S (MAX); CA-40F, 0.20-0.40% S; CB-7CU-1 AND -2, 0.03% S (MAX). PHOSPHORUS CONTENT IS 0.04% (MAX) IN ALL GRADES EXCEPT; CF-16F, 0.17% P (MAX); CF-10SMNN, 0.060% P (MAX); CT-15C, 0.030% P (MAX); CK-3MCUN, 0.045% P (MAX); CN-3M, 0.030% P (MAX); CA-6N, 0.020% P (MAX); CA-28MWV, 0.030% P (MAX); CB-7CU-1 AND -2, 0.035% P (MAX).

(D) MOLYBDENUM NOT INTENTIONALLY ADDED.

(E) CF-3A, CF-3MA, AND CF-8A HAVE THE SAME COMPOSITION RANGES AS CF-3, CF-3M, AND CF-8, RESPECTIVELY, BUT HAVE BALANCED COMPOSITIONS SO THAT FERRITE CONTENTS ARE AT LEVELS THAT PERMIT HIGHER MECHANICAL PROPERTY SPECIFICATIONS THAN THOSE FOR RELATED GRADES. THEY ARE COVERED BY ASTM A 351.

(F) NB, 8 × %C MIN (1.0% MAX); OR NB + TA × %C (1.1% MAX).

(G) FOR CN-7MS, SILICON RANGES FROM 2.50 TO 3.50%.

Welding and Weldability of Cast Stainless Steels

Welding and Welding Processes. In general terms, there are two situations in which welding of stainless steel castings is required. One of these occurs before the casting ever leaves the foundry. Casting defects, such as hot tears, shrinkage cavities, and cold shuts, are often observed in stainless steel castings. Certain specifications preclude the acceptance of these castings for service use without repair. Fusion welding is an appropriate method for repair of these casting defects. The defects, identified through one of several possible procedures (for example, dye penetrant, radiography, or ultrasonic inspection), are removed by machining or grinding, leaving a clean joint surface onto which weld filler metal is added to produce a sound final product. For small, near-surface defects, autogenous welds (that is, no filler metal added) may be sufficient to eliminate the defects. A special case of repair welding is known by the term "upgrading." An "upgraded" casting is one that has been selectively welded in order to achieve a higher level of product specification acceptance.

The second situation requiring welding involves joining of the casting to other hardware, cast or wrought, as part of an engineering design. In this circumstance, the design rules for welding are similar to those for wrought alloys, as discussed in the articles on wrought stainless steels that appear in this Section of the Handbook. Any of the fusion welding processes can be successfully employed in the welding of castings. Most common are the arc welding processes, especially autogenous and filler-metal-added gas-tungsten arc welding, shielded metal arc welding, and gas-metal arc welding. Fabrication involving the use of extremely large castings may employ electroslag welding as the only reasonable economic choice. Other processes, such as electron-beam welding, laser-beam welding, and plasma arc welding, are also appropriate choices in many instances. A wide range of filler metals exists for joining of the various casting alloys. The choice depends on the specifics of the situation and whether the weld will be to a similar or dissimilar alloy. The use of matching filler metal is generally suggested when welding like alloys. Where a matching consumable is not available, common choices are 308L and 316L for the low-nickel-content corrosion-resistant austenitic alloys. For the higher-nickel-content corrosion-resistant and heat-resistant alloys, appropriate choices may be consumables (bare electrodes for gas-tungsten arc welding and gas-metal arc welding) such as 20Cb-3 (AWS ER320/ER320LR) and nickel alloys such as C-276 (AWS ERNiCrMo-4), Alloy 625 (ERNiCrMo-3), and Inconel alloys 82 (AWS ERNiCr-3), 92 (AWS ERNiCrFe-6), and 182 (AWS ERNiCrFe-3).

Metallurgical Considerations. Castings are metallurgically more complex than wrought alloys. Segregation during dendritic solidification can lead to local variations in both chemical composition and microstructure. The vast majority of the heat-resistant alloys will terminate solidification with the formation of a eutectic-like carbide constituent that remains upon cooling of the casting to room temperature. This microstructural constituent helps to augment the creep resistance of this group of alloys. Subsequent heat treatment of these alloys is not common.

Many of the lower-nickel-content corrosion-resistant alloys (for example, CF-3, CF-8M, and CB-7Cu) will have a duplex microstructure consisting of ferrite islands in a matrix of either austenite or martensite. Postcasting solution heat treatments used to prepare corrosion-resistant alloys for service are insufficient to homogenize the microstructure. The inhomogeneous microstructure of both groups of alloys will tend to promote relatively wide areas of partial melting adjacent to the fusion zone when compared with similar wrought alloys.

Martensitic Stainless Steel Castings. Special considerations exist for the welding of martensitic stainless steel castings (CA-6NM, CA-15, CA40, and CB-7Cu-1, and CB-7Cu-2). Quench cracking and a marked reduction in mechanical properties (especially ductility and impact toughness) may result from the welding of these alloys. Corrosion resistance may also be detrimentally affected by the thermal cycle that the material undergoes in the fusion zone and heat-affected-zone (HAZ) of welds.

Suggested welding practice often calls for the preheating and postheating of most of the martensitic alloys. Alloys CA-15 and CA-40 require preheating temperatures in the range of 200 to 315 °C (390 to 600 °F) and a postweld heat treatment (PWHT) temperature range of 610 to 760 °C (1130 to 1400 °F). Alloy CA-6NM requires a preheat temperature range of 100 to 150 °C (210 to 300 °F) and a PWHT temperature range of 590 to 620 °C (1095 to 1150 °F). The higher preheating temperatures should be used when welding thicker sections and higher carbon compositions of these alloys.

The PWHT for these alloys is a tempering operation intended to restore ductility and toughness at the expense of strength and hardness. Because of the broad range of potential tempering temperatures, a wide range of PWHT properties are possible.

Alloy CB-7Cu (1 and 2) has no suggested preheat temperature, but a range (480 to 590 °C, or 895 to 1095 °F) of PWHT temperatures is recommended. In the case of this alloy, the PWHT is an aging operation. In order to recover properties in the welded product, a full solution anneal (1040 °C, or 1095 °F, oil quench), followed by aging, is required. Direct aging without solution annealing will not fully restore preweld properties. The higher aging temperatures result in the lowest strength but also provide the highest ductility and toughness.

Welding Defects. The two most serious problems encountered in the welding of stainless steel castings, either during the repair of casting defects or for subsequent attachment to other structures, are solidification hot cracking and heat-affected zone (HAZ) hot cracking. Figure 2 shows a prototypical hot crack extending both into the fusion zone and the HAZ of a casting alloy. Both of these phenomena involve separation of grain boundaries due to the presence of a wetting liquid phase and sufficient mechanical imposition.

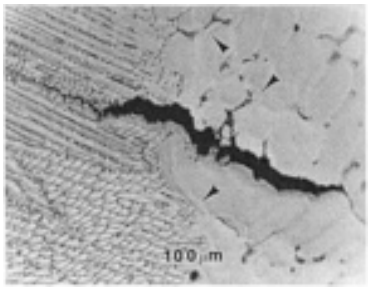

FIG. 2 OPTICAL MICROGRAPH OF THE FUSION LINE REGION IN A CAST CORROSION-RESISTANT AUSTENITIC STAINLESS STEEL. NOTE THE HOT CRACK EXTENDING BOTH INTO THE FUSION ZONE (LEFT) AND BACK INTO THE PARTIALLY MELTED REGION OF THE HAZ. ARROWS INDICATE REGIONS OF PARTIAL MELTING.

Studies (Ref 5, 6, 7, 8, 9) have indicated that wholly austenitic stainless steel casting alloys are more susceptible to the formation of these types of defects than are duplex ferrite plus austenite alloys. In particular, Cieslak (Ref 7, 8) and Cadden (Ref 9) have shown that CF-8M alloys (being prototypic of a wide range of low-nickel corrosion-resistant casting alloys) having welds that solidify with ferrite as the primary solidification phase are much more resistant to hot cracking than are alloys that solidify with austenite as the primary solidification phase.

Table 3 lists the chemical compositions and ferrite content of a series of CF-8M castings used in a study of weldability (Ref 8). Figure 3 shows the fusion zone hot cracking susceptibility of these alloys determined using the Varestraint test at $\frac{1}{2}$ % applied strain. The alloys that solidified as primary austenite (γ) were more susceptible to cracking than those which solidified as primary ferrite (δ). With the exception of heat number 7, the primary ferrite alloys did not experience any cracking under this set of experimental conditions. The high level of sulfur (0.032 wt%) and phosphorus (0.046 wt%) were identified as being responsible for the greater cracking sensitivity in heat number 7. This particular observation was important for establishing that ferrite content alone was not a sufficient criterion to preclude the possibility of hot cracking in duplex alloys.

(A) THE BALANCE IS IRON.

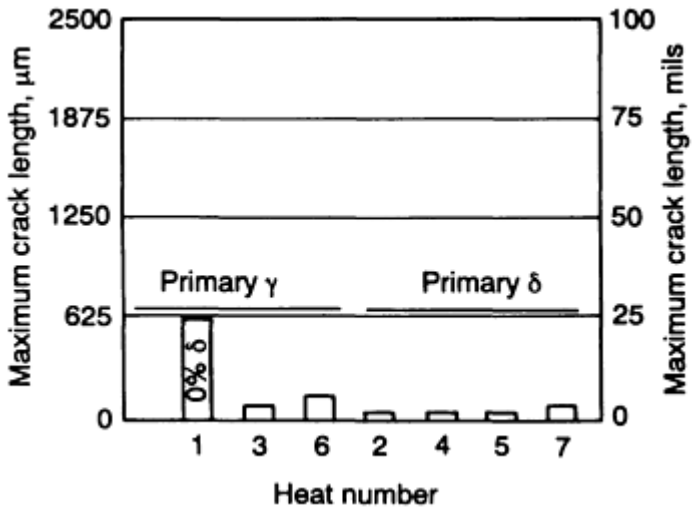

FIG. 3 VARESTRAINT TEST RESULTS ON SEVERAL HEATS OF CF-8M CORROSION-RESISTANT ALLOY. TESTS WERE RUN AT $\frac{1}{2}$ % AUGMENTED STRAIN USING AN ENERGY INPUT OF APPROXIMATELY 2.7 KJ/MM (69 KJ/IN.). SEE TABLE 3 FOR HEAT NUMBER CHEMICAL COMPOSITIONS.

In the same investigation, the hot cracking sensitivity of the heat-resistant alloy HK-40 was also examined. This alloy solidifies as primary austenite and terminates solidification with a eutectic-like Cr_7C_3 carbide constituent. This is prototypical solidification behavior of a wide range of heat-resistant stainless steel casting alloys. It was found that cracking was exacerbated by low carbon content (0.38 wt%), and high levels of combined sulfur and phosphorus (>0.026 wt%). Silicon addition also had a detrimental effect on cracking susceptibility when either carbon content was low or sulfur or phosphorus was high. It was observed that hot cracks could be "healed" by the carbide eutecticlike constituent, suggesting that higher carbon contents in alloys of this type could be helpful in minimizing this type of defect. Similar results have been found for 16Cr-35Ni (HT type) (Ref 10) and high-carbon-content alloys such as 25Cr-20Ni (the cast equivalent of wrought type 310 containing up to 0.2 wt% C) (Ref 11).

A study of the weldability of alloy CN-7M identified sulfur, phosphorus, and silicon as being detrimental to the hot cracking resistance of this high-nickel-content (29 wt% Ni) corrosion-resistant alloy (Ref 12). Specifically, silicon was found to promote the formation of an M_6C carbide eutecticlike constituent associated with intergranular hot cracked regions. For a discussion of the hot cracking susceptibility of a wide range of corrosion-resistant and heat-resistant casting alloys, along with microstructural analysis of the cracking behavior, a review of the work of Cadden (Ref 9) is suggested.

In many studies examining both the fusion zone and HAZ hot cracking behavior of stainless steel casting alloys, the presence of sulfur and phosphorus has universally been identified with increased cracking susceptibility. To a somewhat lesser extent, so have silicon and niobium. Carbon can also be detrimental, although not all studies have reached the same conclusion. It can be said that if there is sufficient carbon present to result in the formation of terminal-stage, eutectic-like constituents, then the hot cracking susceptibility will increase up to the point where the level of carbon promotes eutectic healing. Eutectic healing may eliminate the hot cracking problem, but the reduction in ductility with increasing carbon content can limit the utility of the weld joint for an engineering application (Ref 10).

Each of these elements appears to increase cracking susceptibility in two possible ways. The first is by promoting the formation of low-melting-point constituents, and the second is by acting as a surfactant which promotes wetting of solidifying grain boundaries. As discussed elsewhere in this Volume (see, for example, the articles in this Section of the

Handbook that describe wrought stainless steels), either phenomenon will promote an increased tendency toward fusion zone or HAZ hot cracking.

A specific concern in the welding of corrosion-resistant stainless steel castings is the production of a sensitized microstructure. Sensitization occurs in stainless steel alloys when chromium-rich phases--$M_{23}C_6$ carbides, sigma (σ), chi (χ), and Laves phases--precipitate during exposure to temperatures between 400 and 900 °C (750 and 1650 °F). The precipitation of these constituents can result in a local depletion of chromium (and also molybdenum), lowering the corrosion resistance to a point where corrosion-induced failure of the casting can result. Primary among the phases of concern is the $M_{23}C_6$ carbide (with M being primarily chromium). Precipitation of carbides at grain boundaries can occur during the fusion welding cycle at sites in both the HAZ and the fusion zone. Because the kinetics of precipitation are proportional to the carbon concentration, low-carbon grades (such as CF-3 or CF-3M) have been developed that can experience welding without producing a sensitized microstructure.

A final metallurgical consideration involves the welding of castings that have seen extended service at relatively high temperatures. For a variety of reasons, castings may have to be rewelded sometime during their service lifetime. This can pose a difficult problem if the temperature environment has modified the alloy microstructure so that additional constituents are present that adversely affect alloy ductility. It is always preferable to heat treat the casting to remove these unwanted microstructural features. This process may require solutionizing at temperatures above 1000 °C (1830 °F) and may be impractical for large castings. If solution heat treatment is not an option, then special care must be taken to ensure that the new weld joint design will have the lowest possible level of inherent restraint.

Weld Parameters. From an understanding of the metallurgical behavior of stainless steel casting alloys given above, general rules for fusion welding can be inferred. Low-heat-input processes are almost universally suggested. For alloys that are far from homogeneous, a high-heat-input process would produce flatter thermal gradients outside of the fusion zone, creating a wider zone of partial melting and a greater microstructural sensitivity to HAZ hot cracking. The greater total shrinkage strain associated with the solidification of a large (high-energy-input) weld can create a restraint situation more likely to result in fusion zone solidification cracking. The flatter thermal gradients of higher-energy-input welds reduce the cooling rates through the carbide precipitation temperature range, resulting in a higher likelihood of a sensitized structure in the corrosion-resistant alloys.

For the same reasons, low interpass temperatures are generally employed in the welding of these alloys. Interpass temperatures below 200 °C (400 °F) are common. For critical applications (especially among corrosion-resistant alloys), interpass temperatures of less than 150 °C (300 °F) are often specified. Spraying castings with water between passes is not uncommon for the austenitic corrosion-resistant alloys (Ref 4).

Preheating of castings prior to welding is almost never required and generally not suggested, at least for the corrosion-resistant alloys, because the sensitization impact of such processing is similar to the use of high-energy-input welding parameters. In the case of heat-resistant alloy castings, preheating can be used to reduce the magnitude of thermal shrinkage strains, but again this benefit comes at the expense of a wider zone of partial melting. There is no known formula for preheating temperature and welding parameters for a given alloy that can ensure the preclusion of welding defects. Because of this technological limitation, the use of preheating prior to welding of these alloys is questionable.

Postweld solutionizing of corrosion-resistant alloys is always recommended. For the heat treatable alloys (for example, CB-7Cu), a complete solutionizing and aging heat treatment is recommended to reestablish baseline properties. Where PWHT is not possible, it is even more important to weld using low-heat-input parameters.

Where direct fusion welding is not appropriate, as in the case of an extremely hot-crack-sensitive casting, other approaches might prove useful. One option is to "butter" the area of the crack-sensitive casting to be joined, using a consumable of a less crack-sensitive material. This "buttering" involves surfacing the casting locally with a consumable before fabricating the actual weld joint. With no joint present during the buttering operation, the restraint on the solidifying surface pass and the underlying HAZ of the casting can be quite small and defects (fusion zone and HAZ hot cracks) may be avoided. This surfaced area can be built up slowly to a thickness where it can then be prepared as a joint for subsequent welded attachment. Additional information on buttering can be found in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume. As another option, an insert of a less hot-crack-sensitive alloy can be inertia or friction welded onto the mating surface of the hot-crack-sensitive casting. This insert could then be prepared for subsequent fusion welding to the required structure. These options are contingent upon the availability of consumable materials that are acceptable in the service environment.

Dissimilar Welds With Stainless Steels

Joel G. Feldstein, Foster Wheeler Energy Corporation

Introduction

THE WELDING OF DISSIMILAR AUSTENITIC STAINLESS STEELS to each other is fairly common practice. When suitable welding procedures and filler metals are employed, most austenitic stainless steels can also be welded satisfactorily to several other classes of weldable steel, including ferritic and precipitation-hardening stainless steels, carbon steels, and low-alloy steels.

As a general rule, the weld metal should be at least equal in strength and corrosion properties to the poorest component in the joint. Additionally, there should be no intermetallic compounds or other phases to degrade the properties of the weld metal. Further, the microstructure must be resistant to cracking. An austenitic microstructure with a Ferrite Number (FN) of 5 to 10 has been shown to be highly resistant to cracking. If a fully austenitic weld metal occurs, satisfactory resistance to cracking can be achieved in certain applications by using a filler metal of high manganese content or a nickel-base alloy.

Dissimilar Welds With Stainless Steels

Joel G. Feldstein, Foster Wheeler Energy Corporation

Welding Dissimilar Austenitic Stainless Steels

In general, the deposited weld metal composition should nearly match the base metal composition when welding different austenitic stainless steels to themselves. However, it is not uncommon to weld different austenitic stainless steels, such as types 304 and 347, to each other or to a nickel-base alloy using a filler metal that differs in chemical composition from both base metals provided the weld metal will have suitable corrosion resistance or mechanical properties (or both) for the required service. Generally, the alternate filler metal should be more highly alloyed than the base metal, but the ferrite content of the resulting weld metal should be considered for corrosion or high-temperature service. Some filler metals may give too high a ferrite content, particularly the high-chromium, low-nickel types, such as type 312. Recommended filler metals for welding dissimilar austenitic stainless steels are given in Table 1. Additional information on stainless steel filler metals can be found in the article "Welding of Stainless Steels" in this Volume.

Dissimilar Welds With Stainless Steels

Joel G. Feldstein, Foster Wheeler Energy Corporation

Welding Austenitic Stainless Steels to Carbon or Low-Alloy Steels

In joining austenitic stainless steel to carbon or low-alloy steel for service applications involving exposure to temperatures not exceeding 370 °C (700 °F), it is good practice to use a stainless steel filler metal with a total alloy content high enough to prevent the formation of martensite in the weld after dilution by the base metal and to preserve residual amounts of ferrite to minimize the possibility of hot cracking resulting from welding under severe restraint. Dilution is the change in chemical composition of a welding filler metal caused by the admixture of the base metal or previously deposited weld metal in the deposited weld bead. It is normally measured by the percentage of base metal or previously deposited weld metal in the weld bead. Dilution control, which is of primary concern when joining dissimilar metal combinations, is described in detail in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume.

The Schaeffler diagram is particularly useful when examining what filler metal is suitable for joining dissimilar metals. The example in Fig. 1 shows the joining of a carbon steel (point A) to a type 304 austenitic stainless steel (point B) using type 309 as the filler metal (point D). Point C shows what the composition of the weld metal would be if these items were joined without a filler metal. If we assume that each base metal is fused to the same extent, point C will lie halfway between A and B. Because the welding is done using type 309 filler metal, the composition of the weld metal will lie along the line CD, depending on the degree of dilution. At point E a suitable weld metal composition is obtained, that is, an austenitic structure with 8 to 9% ferrite (Ferrite Number). This weld metal will be crack resistant, in contrast to that obtained at point C, which is very sensitive to cracking because of martensite formation. Types 309 and 309L (25Cr-12Ni) filler metals are most widely used for joining carbon or low-alloy steel to austenitic stainless steel; they normally contains about 8 to 15 FN. Types 304Cb, 309Mo, 309MoL, and 312 (29Cr-9Ni) are progressively more strongly ferritic. Satisfactory welds are also obtained with nickel-chromium-iron filler metal and these filler metals allow the service temperature to exceed 370 °C (700 °F) and minimize some stress relieving problems.

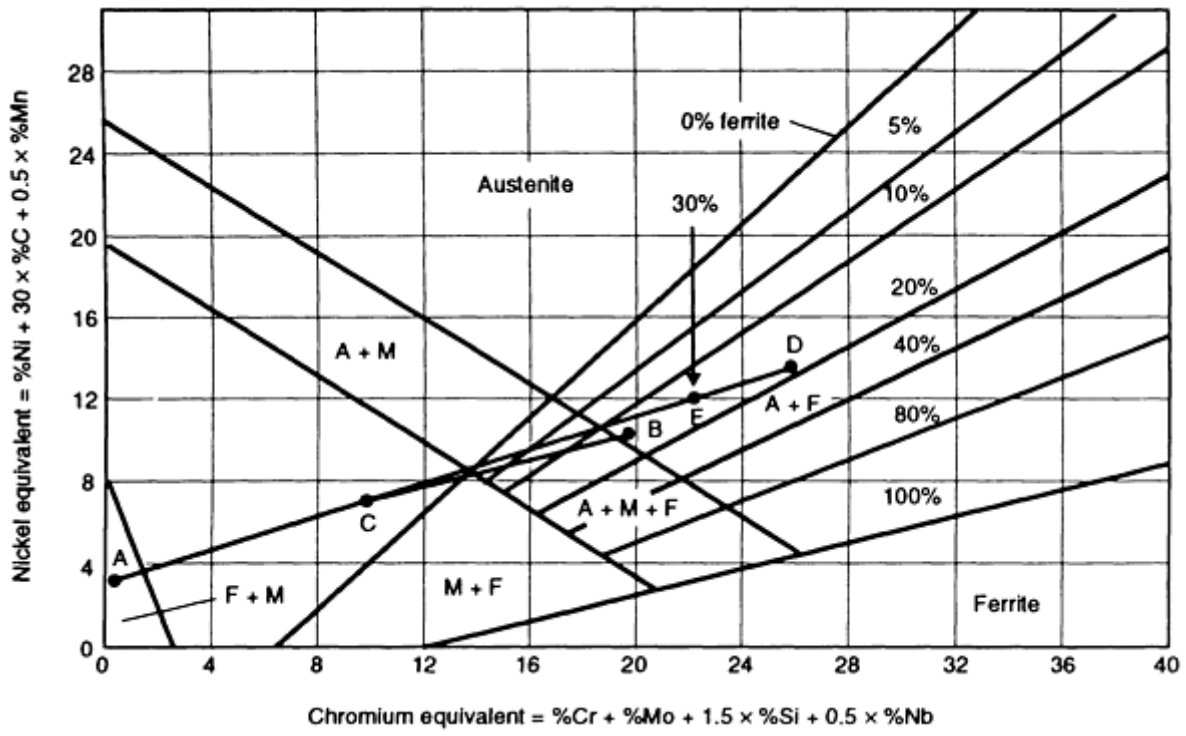

FIG. 1 THE SCHAEFFLER DIAGRAM USED FOR PREDICTING WELD MICROSTRUCTURE USING TYPE 309 TO JOIN

TYPE 304 STAINLESS STEEL TO CARBON STEEL. SEE TEXT FOR DETAILS.

Although the Schaeffler diagram is still widely used to predict the ferrite content of dissimilar metal weld deposits, more recently developed diagrams have increased the scope and accuracy of FN prediction in stainless steel weld metal and related dissimilar metal joints. These include the DeLong diagram, which is described later in this article, and the Welding Research Council 1988 and 1992 diagrams (WRC-1988 and WRC-1992). A review of each of the aforementioned diagrams can be found in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume.

Specific Welding Practices. In joining austenitic stainless steel to carbon steel, it is good practice to first surface, or "butter," the carbon steel with a layer of type 309 or other suitable stainless steel weld metal, so that the portion of the weld (on the carbon steel member) where difficulties are most likely to occur is deposited with stainless steel filler metal while there is little restraint on the weld metal. Thus, following deposition and inspection of the buttered surface, the joint between the stainless steel member and the surfaced layer becomes a stainless-to-stainless joint that can be welded using a conventional stainless steel filler metal. The deposition of carbon steel or low-alloy steel filler metal on austenitic stainless steel should be avoided whenever possible because it can result in hard, brittle weld deposits.

A procedure for joining stainless steel to carbon steel or stainless steel to stainless-clad carbon steel is shown in Fig. 2. This procedure is widely used in the welding of stainless steel pipe to carbon steel, low-alloy steel, and stainless-clad carbon steel. Weld cladding procedures are described later in this article.

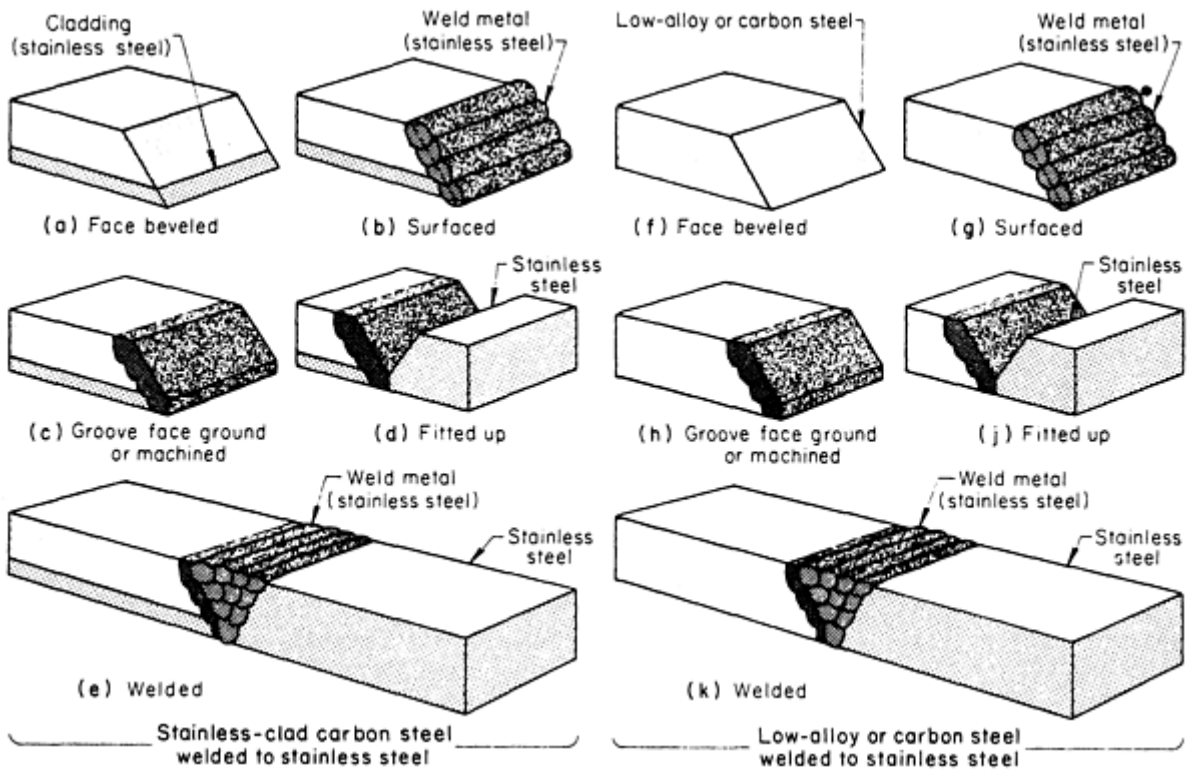

FIG. 2 PROCEDURES FOR JOINING AUSTENITIC STAINLESS STEEL TO STAINLESS-CLAD CARBON STEEL, CARBON STEEL, AND LOW-ALLOY STEEL. STAINLESS-CLAD, LOW-ALLOY, OR CARBON STEEL EDGES ARE BEVELED FOR WELDING (A AND F). AN OVERLAY (OR "BUTTERING" LAYER) OF STAINLESS STEEL FILLER METAL IS APPLIED TO THE BEVELED EDGE (B AND G). THE LAYER IS MACHINED OR GROUND TO REQUIRED DIMENSIONS AND STRESS RELIEVED, IF REQUIRED (C AND H). THE COMPONENTS ARE FITTED UP FOR WELDING (D AND J). THE WELD IS COMPLETED, USING THE FILLER METAL NORMALLY USED FOR WELDING THE STAINLESS STEEL MEMBER OR THAT USED FOR THE SURFACING PASS ON STAINLESS-CLAD LOW-ALLOY OR CARBON STEEL (E AND K).

In depositing the surface layer, dilution of the stainless steel weld metal by carbon steel, which can cause cracking of the weld, can be minimized with the following practices. If the cladding on stainless-clad steel is type 304 stainless steel, types 309 and 309L should be used for the surfacing layer. After depositing the surfacing layer, the component is stress relieved, if necessary. The final weld between the solid stainless steel and the surfaced stainless-clad steel or carbon steel can be made either with the filler metal normally employed for welding the solid stainless steel member or with the one that was used for the overlay.

In another method, a short stainless steel transition member is welded to the carbon steel or stainless-clad carbon steel member prior to stress relieving and final welding. This method ensures protection of the carbon steel base metal from the effect of final welding, and stress relieving can be done while there is little restraint on the joint. This method, however, is more costly than the procedure for producing a surfacing layer.

In a third method, the workpiece interface (stainless steel and carbon steel or stainless steel and stainless-clad carbon steel) is beveled and fitted, leaving a root opening at the joint that is then welded with a filler metal of sufficiently high alloy content to prevent cracking of the weld after dilution by the carbon steel. The welding procedure should be controlled to hold penetration to a minimum. A disadvantage of this method is that the joint is under restraint both during welding and local stress relieving. Although often used, this method is the least desirable of the three.

Dissimilar Welds With Stainless Steels

Joel G. Feldstein, Foster Wheeler Energy Corporation

Welding of Ferritic and Martensitic Stainless Steels to Carbon and Low-Alloy Steels

When welding ferritic or martensitic stainless steel to carbon or low-alloy steel for general service (not high-temperature service), the use of austenitic stainless steel or nickel-base (NiCrFe) filler metal can produce welds of suitable quality if correct welding procedures are followed. (If an austenitic stainless steel or NiCrFe filler metal cannot be used, a filler metal similar to the stainless steel base metal is usually specified.) Two methods are commonly employed. The first involves surfacing both members of the joint, using suitable preheat and postheat treatments as required, and then making a weld between the buttered surfaces without preheat or postheat. Filler metals (such as type 309) that are sufficiently high in alloy content to minimize the effects of dilution by carbon steel, or straight-chromium grades of stainless steel (400 series) are widely used with this method. Penetration into the base metal should be kept to a minimum. The second method involves depositing the filler metal directly on the surfaces of the two members of the joint without using a separate surfacing layer. Dilution of the weld metal by both base metals must be kept under close control while the restrained joint is being welded.

Dissimilar Welds With Stainless Steels

Joel G. Feldstein, Foster Wheeler Energy Corporation

Welding Austenitic-Stainless-Clad Carbon or Low-Alloy Steels

To preserve its desirable properties, stainless-clad plate can be welded by either of the two following methods, depending on plate thickness and service conditions.

- THE UNCLAD SIDES OF THE PLATE SECTIONS ARE BEVELED AND WELDED WITH CARBON OR LOW-ALLOY STEEL FILLER METAL. A PORTION OF THE STAINLESS STEEL CLADDING IS REMOVED FROM THE BACK OF THE JOINT AND STAINLESS STEEL FILLER METAL IS DEPOSITED.
- THE ENTIRE THICKNESS OF THE STAINLESS-CLAD PLATE IS WELDED WITH STAINLESS STEEL FILLER METAL.

When the non-stainless portion of the plate is comparatively thick, as in most pressure vessel applications, it is more economical to use the first method. When the non-stainless portion of the plate is thin, the second method is often preferred. When welding components for applications involving elevated or cyclic temperatures, the differences in the coefficients of thermal expansion of the base plate and the weld should be taken into consideration.

All stainless steel deposits on carbon steel should be made with filler metal of sufficiently high alloy content to ensure that normal amounts of dilution by carbon steel will not result in a brittle weld. In general, filler metals of type 308, 316, or 347 should not be deposited directly on carbon or low-alloy steel. Deposits of types 309, 309L, 309Cb, 309Mo, 310, or 312 are usually acceptable, although type 310 is fully austenitic and is susceptible to hot cracking when there is high restraint in a welded joint. Thus, welds made with type 310 filler metal should be carefully inspected. Welds made with types 309 and 312 filler metals are partially ferritic and therefore are highly resistant to hot cracking.

The procedure most commonly used for making welded joints in stainless-clad carbon or low-alloy steel plate is shown in Fig. 3. Stainless steel filler metal is deposited only in that portion of the weld where the stainless steel cladding has been removed, and carbon or low-alloy steel filler metal is used for the remainder. The backgouged portion of the stainless steel cladding should be filled with a minimum of two layers of stainless steel filler metal (Fig. 3e); an additional layer is recommended if a high weld reinforcement at the cladding surface can be tolerated.

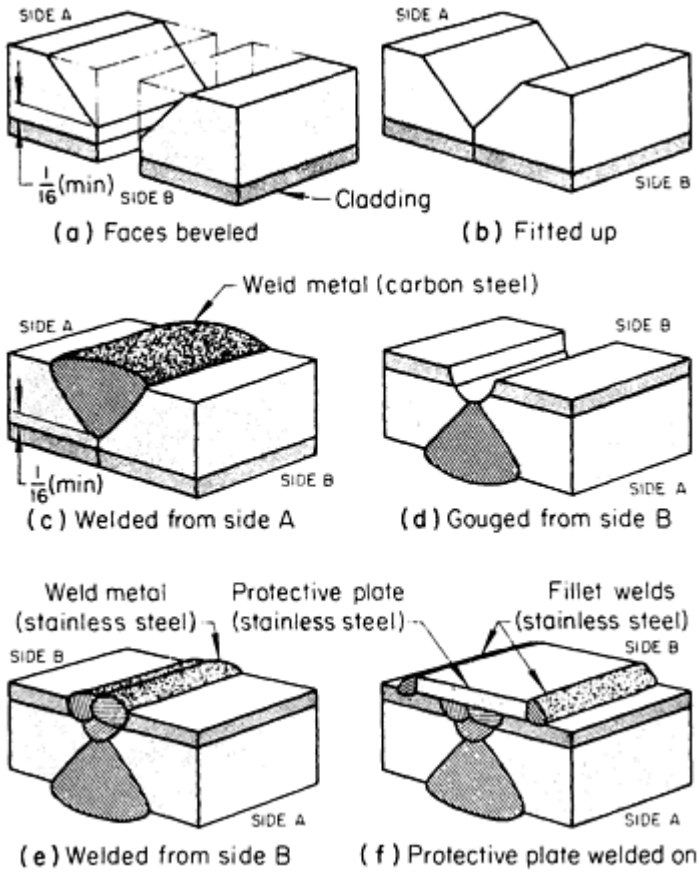

FIG. 3 PROCEDURE FOR WELDING STAINLESS-CLAD CARBON AND LOW-ALLOY STEEL, USING STAINLESS STEEL FILLER METAL ONLY IN PORTION OF JOINT FROM WHICH CLADDING WAS REMOVED. (A) AND (B) THE CLAD PLATES ARE MACHINED FOR A TIGHT FIT-UP, WITH THE BOTTOM OF THE WELD GROOVE NOT LESS THAN 1.6 MM ($\frac{1}{16}$ IN.) ABOVE THE STAINLESS STEEL CLADDING. (C) CARBON STEEL FILLER METAL IS DEPOSITED FROM SIDE A (A LOW-HYDROGEN FILLER METAL IS USED FOR THE FIRST PASS), TAKING CARE NOT TO PENETRATE CLOSER THAN 1.6 MM ($\frac{1}{16}$ IN.) TO THE CLADDING. (D) STAINLESS STEEL CLADDING ON SIDE B IS BACKGOUGED UNTIL SOUND CARBON STEEL WELD METAL IS REACHED. (E) THE BACKGOUGED GROOVE IS FILLED WITH STAINLESS STEEL WELD METAL IN A MINIMUM OF TWO LAYERS. (F) WHEN REQUIRED FOR SEVERELY CORROSIVE SERVICE, A PROTECTIVE STRIP OF STAINLESS STEEL PLATE MAY BE

FILLET WELDED TO THE CLADDING TO COVER THE WELD ZONE.

If the cladding is of type 304 stainless steel, the first layer of stainless steel weld metal should be of type 309 or 312. Subsequent layers of weld metal can be of type 308. If the cladding is of type 316, the first layer is deposited with type 309 Mo filler metal and the subsequent layers with type 316. When the cladding is of type 304L or type 347, the welding procedure must be carefully controlled to obtain the desired weld metal composition in the outer layers of the weld. Chemical analysis of sample welds should be made before joining of clad plates intended for use under severely corrosive conditions.

In some applications, a narrow protective plate of wrought stainless steel of the same composition as the cladding is welded over the completed weld (Fig. 3f) to ensure uniformity of corrosion resistance. The fillet welds joining the protective plate to the cladding should be carefully inspected after deposition. These welds, of course, are made with stainless steel filler metal.

Figure 4 illustrates an alternative method (method A) of welding clad plate in which a carbon or low-alloy steel weld joins the carbon steel portion of the plate and the use of stainless steel filler metal is limited to replacement of the cladding that was removed prior to making the carbon or low-alloy steel weld. This method is more expensive than the method described in Fig. 3 because of the cost of removing a larger portion of the cladding and depositing more stainless steel filler metal. Because there is no danger of alloy contamination from the cladding layer, method A in Fig. 4 permits the use of faster welding processes, such as submerged arc welding in depositing the carbon steel weld.

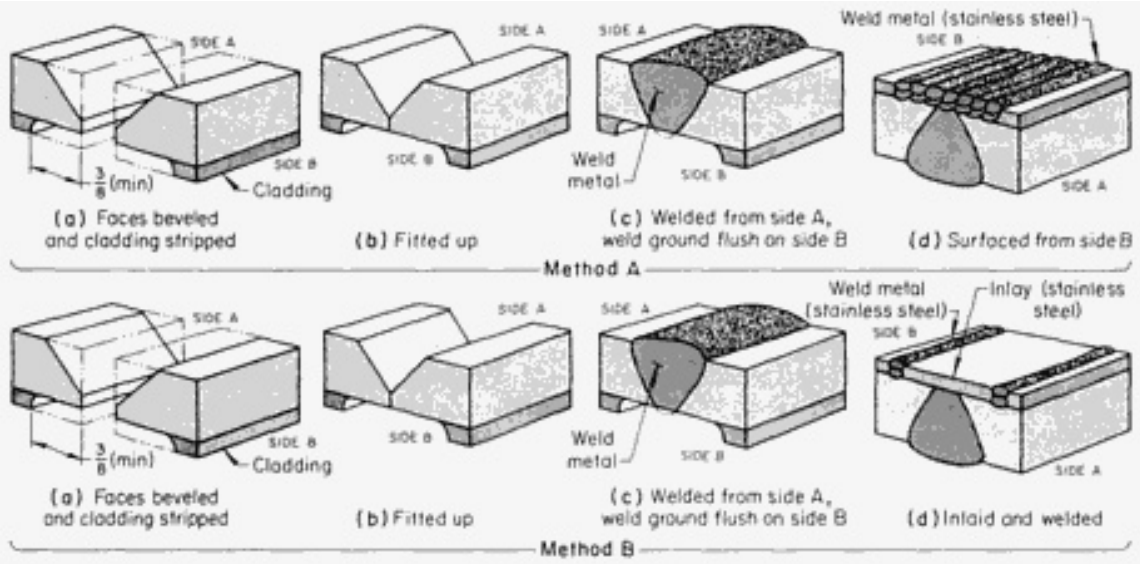

FIG. 4 ALTERNATIVE PROCEDURES FOR JOINING STAINLESS-CLAD CARBON AND LOW-ALLOY STEEL PLATE INVOLVING DIFFERENT TECHNIQUES FOR REPLACING PORTIONS OF THE STAINLESS STEEL CLADDING REMOVED BEFORE WELDING THE CARBON OR LOW-ALLOY STEEL SIDE. THE JOINT IS PREPARED BY BEVELING SIDE A AND REMOVING A PORTION OF THE STAINLESS STEEL CLADDING FROM SIDE B TO A MINIMUM WIDTH OF 9.5 MM ($\frac{3}{8}$ IN.) FROM EACH SIDE OF THE JOINT, AND THE JOINT IS FITTED UP IN POSITION FOR WELDING. USE OF A ROOT GAP (NOT SHOWN) IS PERMISSIBLE (A AND B, METHODS A AND B). CARBON STEEL FILLER METAL IS DEPOSITED AND THE ROOT OF THE WELD IS GROUND FLUSH WITH THE UNDERSIDE OF THE CARBON STEEL PLATE (C, METHODS A AND B). THE AREA FROM WHICH CLADDING WAS REMOVED IS SURFACED WITH AT LEAST TWO LAYERS OF STAINLESS STEEL WELD METAL (D, METHOD A), OR AN INLAY OF WROUGHT STAINLESS STEEL CAN BE WELDED IN PLACE (D, METHOD B).

In depositing the stainless steel weld metal, the first layer must be sufficiently high in alloy content to avoid cracking as a result of normal dilution by the carbon steel base metal. A stringer bead technique should be employed; penetration must be held to a minimum. If the proper weld metal composition is not achieved after the second layer has been deposited, a portion of the second layer should be ground off and additional filler metal should be deposited to obtain the desired

composition. Figure 4(d) of method B shows an alternative procedure in which the exposed carbon steel weld on side B is covered by welding an inlay of wrought stainless steel to the edges of the cladding.

The most common method of joining stainless steel-clad carbon or low-alloy steel plate with a weld that consists entirely of stainless steel is shown in Fig. 5. This method is most frequently used for joining thin sections of stainless-clad plate. The same basic welding procedure is followed for both the butt and comer joints shown in Fig. 5. After the plate has been beveled and fitted up for welding, a stainless steel weld is deposited from the carbon steel side, using a filler metal sufficiently high in alloy content to minimize difficulties (such as cracking) resulting from weld dilution and joint restraint. Types 309 and 312 filler metals are suitable for this application.

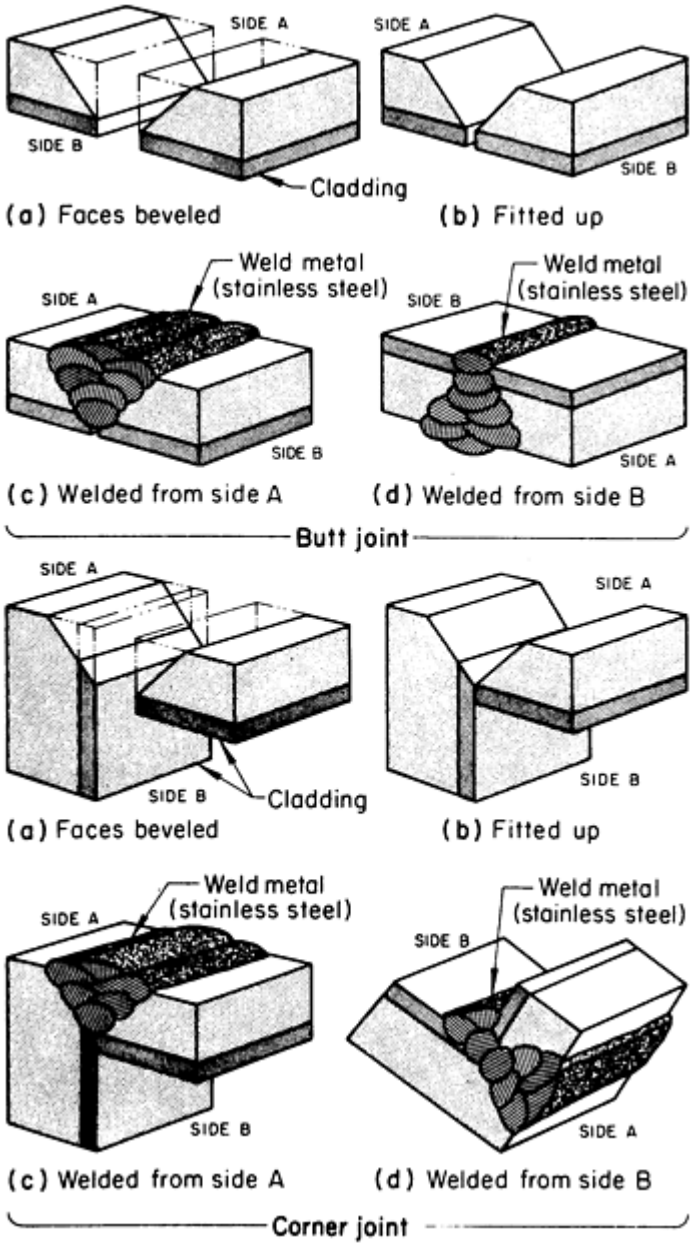

FIG. 5 PROCEDURES FOR WELDING V-GROOVE BUTT AND CORNER JOINTS IN STAINLESS-CLAD CARBON OR LOW-ALLOY STEEL PLATE, USING STAINLESS STEEL FILLER METAL EXCLUSIVELY. THE CLAD PLATES ARE BEVELED AND FITTED UP (A AND B, BUTT AND CORNER JOINTS). THE ROOT OF THE WELD IS CLEANED AND GOUGED, IF NECESSARY, BEFORE DEPOSITING STAINLESS WELD METAL FROM THE STAINLESS STEEL SIDE (D, BUTT AND CORNER JOINTS).

After the stainless steel weld has been deposited from the carbon steel side (Fig. 5c), the root of the weld is cleaned by brushing, chipping, or grinding, as required, and one or more layers of stainless steel filler metal are deposited (Fig. 5d).

The filler metal composition should correspond to that normally employed to weld the type of stainless steel used for the cladding. If the cladding is type 304, the final layer of weld metal should be type 308. If the cladding is type 316, it may be necessary to backgouge before deposition of the final weld metal layers to ensure that the proper weld metal composition is obtained at the surface of the weld.

Joel G. Feldstein, Foster Wheeler Energy Corporation

Cladding Austenitic Stainless Steel to Carbon or Low-Alloy Steels

Weld cladding involves the deposition of a relatively thick layer of weld metal by an arc welding process to impart a corrosion- or oxidation-resistant surface (see the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume). Materials of interest for cladding carbon or low-alloy steels include types 308, 309, 310, 316, 320, and 347. The exact chemical composition of a weld overlay depends on the composition of the cladding metal (determined from undiluted weld metals), the composition of the base metal, and dilution, and can be calculated if these variables are known. The chromium-nickel austenitic stainless steels, however, often contain more than one phase in the as-deposited structure. These materials are primarily austenitic with varying amounts of ferrite, martensite, and σ phases determined by the composition and cladding conditions.

The amounts of ferrite and martensite present in the austenitic structures can be estimated from a DeLong constitutional diagram similar to the one shown in Fig. 6. Chromium (ferrite formers) and nickel (austenite formers) equivalents are calculated from the following equations:

CHROMIUM
EQUIVALENT = %CR + %MO + 1.5(%SI) + 0.5(%NB)
NICKEL
EQUIVALENT = %NI + 30(%C) + 0.5(%MN) + 30(%N)

These values are then plotted and the percentages of phases present are read directly from the diagram. Care should be taken in this technique, however, because the as-clad microstructure also depends on cooling rate. Cooling rates can vary significantly, depending on cladding conditions. Another method of quickly determining the phases present is by using magnetic measuring devices. Austenite is nonmagnetic, whereas ferrite and martensite are ferromagnetic. When properly calibrated in accordance with AWS A4.2, these instruments can quickly give an indication of the amount of magnetic phase present. However, one should be aware that excessive dilution can result in martensite in the cladding, which will give a false high FN value when using a magnetic instrument.

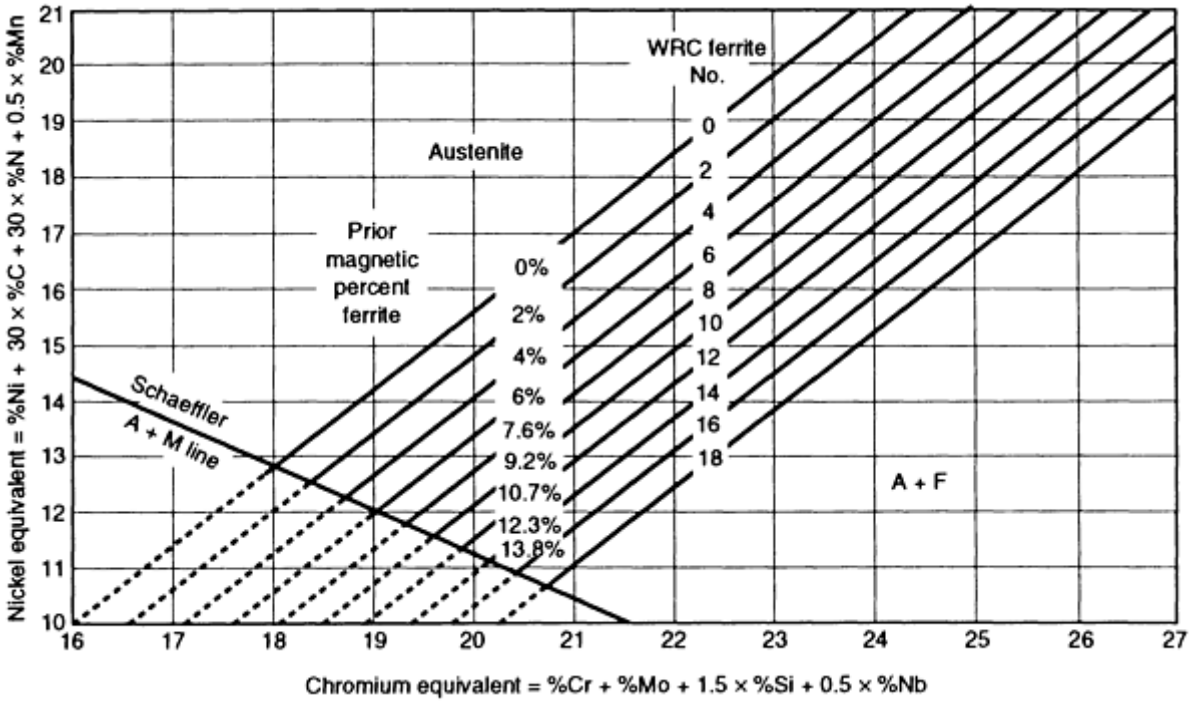

FIG. 6 THE DELONG DIAGRAM USED FOR PREDICTING WELD MICROSTRUCTURE. SEE TEXT FOR DETAILS.

Sigma phase is not common in as-clad structures but can occur where high-heat-input processes are used. It forms most readily from ferrite phase, but can also form from austenite in high-chromium areas. The transformation to σ phase occurs in the temperature range 500 to 900 °C (930 to 1650 °F), with longer times at these temperatures producing larger amounts of σ phase. The percentage of σ phase can be determined only by metallographic techniques.

Fully austenitic overlays are generally susceptible to hot cracking, which can occur upon solidification or reheating by a subsequent overlay pass (microfissures). Solidification cracks are generally very large and can be found by visual or dye-penetrant examination. However, microfissures are often subsurface and difficult to detect by conventional nondestructive examination techniques. For the austenitic stainless steels, the tendency for hot cracking is greatly reduced by the presence of a small amount of δ-ferrite in the structure. The amount of ferrite required to eliminate hot cracking varies from material to material, but it is generally recognized that a 4 or 5 FN minimum in the as-clad structure is sufficient for most austenitic stainless steel cladding alloys.

Finally, stainless steel cladding materials are susceptible to sensitization (precipitation of chromium carbides in grain boundaries that leaves chromium-depleted adjacent areas). Sensitization can occur when unstabilized stainless steels are heated in the range of 430 to 820 °C (800 to 1500 °F) either during stress relief or in service. The best way to inhibit these problems is to use low-carbon grades (such as type 308L or 309L) or stabilized grades (such as type 347) of austenitic stainless steels that are not readily sensitized. Also, finer microstructures produced by the lower-heat-input processes improve corrosion resistance for all grades. Additional material on weld sensitization can be found in the article "Corrosion of Weldments" in this Volume as well as in *Corrosion,* Volume 13 of the *ASM Handbook.*

Selection and Weldability of Conventional Titanium Alloys

W.A. Baeslack III, The Ohio State University; J.R. Davis, Davis and Associates; C.E. Cross, Martin Marietta Astronautics Group

Introduction

TITANIUM is a low-density element (approximately 60% of the density of steel) that can be highly modified by alloying and deformation processing. Titanium is nonmagnetic and has good heat transfer properties. Its coefficient of thermal expansion is somewhat lower than that of steels and less than half that of aluminum. Titanium and its alloys have melting points higher than those of steels, but maximum useful temperatures for structural applications generally range from 425 to 540 °C (800 to 1000 °F). More recently developed alloys such as IMI-834 or Ti-1100 have temperature limits approaching 600 °C (1100 °F). Titanium has the ability to passivate, and thereby exhibits a high degree of immunity to attack by most mineral acids and chlorides. Titanium is nontoxic and generally biologically compatible with human tissues and bones. The combination of high strength, stiffness, good toughness, low density, and good corrosion resistance provided by various titanium alloys at very low to moderately elevated temperatures allows weight savings in aerospace structures and other high-performance applications. The excellent corrosion resistance and biocompatibility coupled with good strengths make titanium and its alloys useful in chemical and petrochemical applications, marine environments, and biomaterials applications.

Titanium and its alloys are used primarily in two areas of application where the unique characteristics of these metals justify their selection: corrosion-resistant service and specific strength-efficient structures. For these two diverse areas, selection criteria differ markedly. Corrosion applications normally utilize low-strength unalloyed titanium mill products fabricated into tanks, heat exchangers, or reactor vessels for chemical-processing, desalination, or power-generation plants. In contrast, high-performance applications typically utilize high-strength titanium alloys in a very selective manner that depends on factors such as thermal environment, loading parameters, available product forms, fabrication characteristics, and inspection and/or reliability requirements. As a result of their specialized usage, alloys for high-performance applications normally are processed to more stringent and costly requirements than unalloyed titanium for corrosion service.

Historically, titanium alloys have been used instead of iron or nickel alloys in aerospace applications because titanium saves weight in highly loaded components that operate at low to moderately elevated temperatures. Many titanium alloys have been custom designed to have optimum tensile, compressive, and/or creep strength at selected temperatures and, at the same time, to have sufficient workability to be fabricated into mill products suitable for specific applications. During the past four decades, various compositions have had transient usage, but one alloy, Ti-6Al-4V, has been consistently responsible for about 50% of industry application. Ti-6Al-4V is unique in that it combines attractive properties with inherent workability (which allows it to be produced in all types of mill products, in both large and small sizes), good weldability (which allows the mill products to be made into complex hardware), and the production experience and commercial availability that lead to reliable and economic usage. Thus Ti-6Al-4V has become the standard alloy against which other alloys must be compared when selecting a titanium alloy for a specific application.

Strength, fatigue-crack growth rate, and fracture toughness, plus manufacturing considerations such as welding and forming requirements, normally provide the criteria that determine the alloy composition, structure (alpha, near-alpha, alpha-beta, or metastable beta), heat treatment (some variant of either annealing or solution treating and aging), and level of process control selected or prescribed for structural titanium alloy applications. Detailed information on the selection and properties of wrought, cast, and powder metallurgy titanium alloys can be found in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of the *ASM Handbook.*

In the present article, emphasis will be placed on the physical metallurgy of titanium and titanium alloys and their microstructural response to fusion welding conditions. A companion article, which immediately follows in this Section of the Handbook, describes welding characteristics of advanced high-temperature and high fracture toughness alloys, titanium-matrix composites, and ordered intermetallic (titanium aluminides) alloys. Additional information on filler metal and shielding gas selection can be found in the article "Welding of Titanium Alloys" in this Volume.

Selection and Weldability of Conventional Titanium Alloys

W.A. Baeslack III, The Ohio State University; J.R. Davis, Davis and Associates; C.E. Cross, Martin Marietta Astronautics Group

Physical Metallurgy (Ref 1)

Titanium undergoes an allotropic phase transformation at about 885 °C (1625 °F), changing from a close-packed hexagonal crystal structure (alpha phase) to a body-centered cubic crystal structure (beta phase). The transformation temperature (beta transus, or the completion of transformation to beta on heating) is strongly influenced by the interstitial elements oxygen, nitrogen, and carbon (alpha stabilizers), which raise the transformation temperature; by hydrogen (beta stabilizer), which lowers the transformation temperature; and by metallic impurity or alloying elements, which may either raise or lower the transformation temperature.

Depending on their microstructure, titanium alloys fall into one of four classes: alpha, near-alpha, alpha-beta, or metastable beta. These classes, which are described below, denote the general type of microstructure after processing. An alpha alloy will contain only trace amounts of beta phase. A near-alpha alloy will contain limited beta phase and may appear microstructurally similar to an alpha alloy. An alpha-beta alloy will consist of alpha and retained or transformed beta. A metastable beta alloy will tend to retain the beta phase on initial cooling to room temperature but will precipitate fine alpha phase during heat treatment.

Effects of Alloying Elements. The role of the interstitial elements oxygen, nitrogen, and carbon was described above. The principal effect of an alloying element in titanium alloys is its effect on the alpha-to-beta transformation temperature and the resulting microstructure and properties (Fig. 1).

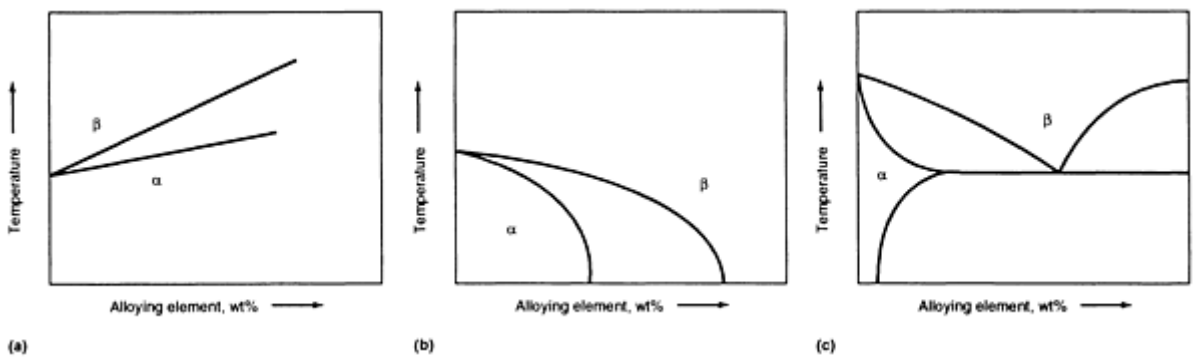

FIG. 1 EFFECT OF ALLOYING ELEMENTS ON TITANIUM MICROSTRUCTURE. (A) ALPHA STABILIZER (FOR EXAMPLE, ALUMINUM AND OXYGEN). (B) BETA STABILIZER (FOR EXAMPLE, VANADIUM AND NIOBIUM). (C) BETA STABILIZER PLUS ($\alpha + \beta$) STRENGTHENER (FOR EXAMPLE, COPPER AND IRON)

Tantalum, vanadium, niobium, and molybdenum are beta isomorphous with body-centered cubic titanium. Titanium does not form intermetallic compounds with the beta isomorphous elements. Eutectoid systems are formed with chromium, iron, copper, nickel, palladium, cobalt, manganese, and certain other transition metals. These elements have low solubility in alpha titanium and decrease the transformation temperature. They usually are added to alloys in combination with one or more of the beta isomorphous elements to stabilize the beta phase and prevent or minimize formation of intermetallic compounds, which might occur during service at elevated temperature.

Zirconium and hafnium are unique in that they are isomorphous with both the alpha and beta phases of titanium. Tin and aluminum have significant solubility in both alpha and beta phases. Aluminum increases the transformation temperature significantly, whereas tin lowers it slightly. Aluminum, tin, and zirconium are commonly used together in alpha and near-alpha alloys. In alpha-beta alloys, these elements are distributed approximately equally between the alpha and beta phases. Almost all commercial titanium alloys contain one or more of these three elements because they are soluble in both alpha and beta phases, and particularly because they improve creep strength of the alpha phase. Many more elements are soluble in beta titanium than in alpha. Beta isomorphous alloying elements are preferred as additions because they do

not form intermetallic compounds. However, iron, chromium, manganese, and other compound formers sometimes are used in beta-rich alpha-beta alloys or in metastable beta alloys, because they are strong beta stabilizers and improve hardenability and response to heat treatment. Nickel, molybdenum, and palladium improve corrosion resistance of unalloyed titanium in certain media. The approximate chemical composition ranges and effects of some alloying elements used in titanium can be summarized as follows (Ref 2):

ALLOYING ELEMENT	CONTENT, WT%	EFFECT ON STRUCTURE
ALUMINUM	2-7	α STABILIZER
TIN	2-6	α STABILIZER
VANADIUM	2-15	β STABILIZER
MOLYBDENUM	2- 13	β STABILIZER
CHROMIUM	2-12	β STABILIZER
COPPER	-3	β STABILIZER (α AND β STRENGTHENER)
ZIRCONIUM	2-8	IMPROVES CREEP STRENGTH
SILICON	0.05-1	IMPROVES CREEP STRENGTH

Secondary Phases and Martensitic Transformations. The basis for microstructural manipulation during elevated-temperature processing of titanium alloys centers around the beta-to-alpha transformation that occurs in these alloys during cooling. This transformation can occur by nucleation and growth, or it can occur martensitically, depending on the alloy composition and the cooling rate. The martensitic product is usually hexagonal close-packed and is designated alpha prime (α'). There also is an orthorhombic martensite, designated alpha double-prime (α"), which forms in alloys that contain higher concentrations of refractory elements such as molybdenum, tantalum, or niobium. Essentially all thermomechanical processing is conducted above the M_s temperature for either alpha prime or alpha double-prime. Alloys that contain enough beta-stabilizing elements to depress the M_s temperature below room temperature can be rapidly cooled to retain the metastable beta phase. More detailed information on the physical metallurgy and phase transformations associated with titanium alloys can be found in Ref 3.

A graphic illustration of the microstructural transformations that can occur in an alpha-beta alloy (Ti-6Al-4V) is shown in Fig. 2. As can be seen, the morphology (shape/location) of the phase changes with prior treatments. The alpha phase may remain relatively globular (equiaxed), but the transformed beta (martensites or alpha) may be very acicular or elongated. The amount of equiaxed alpha and the coarseness or fineness of the transformed beta products will affect alloy properties. For example, the fine, predominantly alpha-prime structures in rapidly cooled near-alpha and alpha-beta alloy weldments exhibit high strength levels that can become even higher after low-temperature postweld heat treatment. However, as the microstructure coarsens due to a reduced weld cooling rate or increased postweld heat treatment temperature, yield and ultimate tensile strengths decrease. See the section "Effect of Postweld Heat Treatment" in this article for additional information on the effects of PWHT on structure-property relationships.

Classification of Titanium Alloys

When classifying unalloyed and alloyed titanium, it is common to group the materials as:

- UNALLOYED, OR COMMERCIALLY PURE (CP) TITANIUM
- ALPHA AND NEAR-ALPHA ALLOYS
- ALPHA-BETA ALLOYS
- METASTABLE BETA ALLOYS

Table 1 lists compositions and tensile properties of some of the more common grades. Of the alloys listed in Table 1, Ti-6Al-4V is the most widely used titanium alloy, accounting for about 50% of total titanium production. Unalloyed grades comprise about 25% of production, and all other alloys combined comprise the remaining 25%.

(A) SEMICOMMERCIAL ALLOY; MECHANICAL PROPERTIES AND COMPOSITION LIMITS SUBJECT TO NEGOTIATION WITH SUPPLIERS.

(B) MECHANICAL PROPERTIES GIVEN FOR ANNEALED CONDITION; MAY BE SOLUTION TREATED AND AGED TO INCREASE STRENGTH.

(C) MECHANICAL PROPERTIES GIVEN FOR SOLUTION TREATED AND AGED CONDITION; ALLOY NOT NORMALLY APPLIED IN ANNEALED CONDITION. PROPERTIES MAY BE SENSITIVE TO SECTION SIZE AND PROCESSING.

(D) PRIMARILY A TUBING ALLOY; MAY BE COLD DRAWN TO INCREASE STRENGTH.

Unalloyed titanium products, which have minimum titanium contents ranging from about 98 to 99.5 wt%, are usually selected for their excellent corrosion resistance, especially in applications where high strength is not required. These materials are also used because they are highly formable and weldable. Yield strengths of unalloyed (commercially pure) grades (see Table 1) vary from 170 MPa (25 ksi) to 480 MPa (70 ksi) simply as a result of variations in the interstitial and impurity levels. Oxygen and iron are the primary variants in these grades; strength increases with increasing oxygen and iron contents. If the iron content is above about 0.05%, preferential corrosive attack of weld metal can occur in nitric acid solutions (Ref 4). Welds are particularly vulnerable because of the acicular nature of any retained beta phase that is stabilized by the iron. Galvanic cells between the beta and the contiguous alpha phase initiate corrosion of the weld metal. This behavior is not true for the base metal, where retained beta is finely divided and discontinuous, and corrosive attack is slight. Filler metal with low iron content should be used, and all sources of iron contamination during preparation and welding should be avoided.

Alpha and Near-Alpha Alloys. Alpha alloys that contain aluminum, tin, and/or zirconium are preferred for high-temperature as well as cryogenic applications. Alpha-rich alloys generally are more resistant to creep at high temperature than alpha-beta or metastable beta alloys. The extra-low-interstitial alpha alloys (ELI grades) retain ductility and toughness at cryogenic temperatures, and Ti-5Al-2.5Sn-ELI has been used extensively in such applications.

Unlike alpha-beta and metastable beta alloys, alpha alloys cannot be strengthened by heat treatment. Generally, alpha alloys are annealed or recrystallized to remove residual stresses induced by cold working. Alpha alloys have good weldability because they are insensitive to heat treatment. They generally have poorer forgeability and narrower forging-temperature ranges than alpha-beta or metastable beta alloys, particularly at temperatures below the beta transus. This poorer forgeability is manifested by a greater tendency for center bursts or surface cracks to occur, which means that small reduction steps and frequent reheats must be incorporated in forging schedules.

Alpha alloys that contain small additions of beta stabilizers (Ti-8Al-1Mo-1V or Ti-6Al-2Nb-1Ta-0.8Mo, for example) sometimes have been classed as "super-alpha" or "near-alpha" alloys. Although they contain some retained beta phase, these alloys consist primarily of alpha and behave more like conventional alpha alloys than alpha-beta alloys.

The alpha and near-alpha alloys have good weldability because of their good ductility (Ref 4). Welding operations have little effect on the mechanical properties of annealed material in the heat-affected zone. However, the strength of cold-worked material in the weld heat-affected zone is decreased as a result of heating. Therefore, these alloys are normally welded in the annealed condition. Stress relieving of weldments is commonly recommended.

Alpha-beta alloys contain one or more alpha stabilizers or alpha-soluble elements plus one or more beta stabilizers. These alloys retain more beta phase after solution treatment than do near-alpha alloys, the specific amount depending on the quantity of beta stabilizers present and on the heat treatment.

Alpha-beta alloys can be strengthened by solution treating and aging. Solution treating usually is done at a temperature high in the two-phase alpha-beta field, and is followed by quenching in water, oil, or other suitable quenchant. As a result of quenching, the beta phase present at the solution treating temperature may be retained or may be partly transformed during cooling by either martensitic transformation or nucleation and growth. The specific response depends on alloy composition, solution treating temperature (beta-phase composition at the solution temperature), cooling rate, and section size. Solution treatment is followed by aging, normally at 480 to 600 °C (900 to 1100 °F) to precipitate alpha and produce a fine mixture of alpha in the retained or transformed beta phase. Transformation kinetics, transformation products, and specific response of a given alloy can be quite complex; a detailed review is provided in Ref 3.

Solution treating and aging can increase the strength of alpha-beta alloys 30 to 50%, or more, over the annealed or over-aged condition. Response to solution treating and aging depends on section size; alloys relatively low in beta stabilizers (Ti-6Al-4V, for example) have poor hardenability and must be quenched rapidly to achieve significant strengthening. For Ti-6Al-4V, the cooling rate of a water quench is not rapid enough to significantly harden sections thicker than about 25 mm (1 in.). As the content of beta stabilizers increases, hardenability increases. For some alloys of intermediate beta-stabilizer content, the surface of a relatively thick section can be strengthened, but the core may be 10 to 20% lower in hardness and strength. The strength that can be achieved by heat treatment is also a function of the volume fraction of beta phase present at the solution treating temperature. Alloy composition, solution temperature, and aging conditions must be carefully selected and balanced to produce the desired mechanical properties in the final product. Table 2 summarizes typical heat treatments for alpha-beta alloys.

TABLE 2 SUMMARY OF HEAT TREATMENTS FOR ALPHA-BETA TITANIUM ALLOYS

HEAT TREATMENT DESIGNATION	HEAT TREATMENT CYCLE[(A)]	MICROSTRUCTURE
DUPLEX ANNEAL	SOLUTION TREAT AT 50-75 °C (90-135 °F) BELOW T β, AIR COOL AND AGE FOR 2-8 H AT 540-675 °C (1000-1250 °F)	PRIMARY α, PLUS WIDMANSTÄTTEN α - β REGIONS
SOLUTION TREAT AND AGE	SOLUTION TREAT AT ~40 °C (70 °F) BELOW T β, WATER QUENCH AND AGE FOR 2-8 H AT 535-675 °C (995-1250 °F)	PRIMARY α, PLUS TEMPERED α ' OR A β - α MIXTURE
BETA ANNEAL	SOLUTION TREAT AT ~15 °C (30 °F) ABOVE T β, AIR COOL STABILIZE AT 650-760 °C (1200-1400 °F) FOR 2 H	WIDMANSTÄTTEN α - β COLONY MIXTURE
BETA QUENCH	SOLUTION TREAT AT ~15 °C (30 °F) T β, WATER QUENCH AND TEMPER AT 650-760 °C (1200-1400 °F) FOR 2 H	TEMPERED α '
RECRYSTALLIZATION-ANNEAL	925 °C (1700 °F) FOR 4 H, COOL AT 50 °C/H (90 °F/H) TO 760 °C (1400 °F), AIR COOL	EQUIAXED α WITH β AT GRAIN-BOUNDARY TRIPLE JOINTS
MILL ANNEAL	α - β HOT WORK PLUS ANNEAL AT 705 °C (1300 °F) FOR 30 MIN TO SEVERAL HOURS AND AIR COOL	INCOMPLETELY RECRYSTALLIZED α WITH A SMALL VOLUME FRACTION OF SMALL β PARTICLE

(A) T β IS THE β TRANSUS TEMPERATURE FOR THE PARTICULAR ALLOY IN QUESTION. IN MORE HEAVILY β -STABILIZED ALLOYS SUCH AS TI-6AL-2SN-4ZR-6MO OR TI-6AL-6V-2SN, SOLUTION TREATMENT IS FOLLOWED BY AIR COOLING. SUBSEQUENT AGING CAUSES PRECIPITATION OF α PHASE TO FORM AN α - β MIXTURE.

Welding alpha-beta alloys may significantly change their strength, ductility, and toughness characteristics as a result of the thermal cycle to which the alloy is exposed (Ref 4). The low ductility of most alpha-beta alloy welds is caused by phase transformations in the weld metal or the heat-affected zone, or both (see the section "Weld Microstructure" below). Alpha-beta alloys can be welded with unalloyed titanium or alpha-titanium alloy filler metal to produce a weld metal that is low in beta phase. This improves weld ductility. However, this procedure does not overcome the low ductility of the heat-affected zone in alloys that contain large amounts of beta stabilizers.

Ti-6Al-4V has the best weldability of the alpha-beta alloys. This weldability can be attributed to two principal factors. First, the alpha-prime martensite which forms in Ti-6Al-4V is not as hard and brittle as that exhibited by more heavily beta-stabilized alloys, such as Ti-6Al-6V-2Sn. Secondly, Ti-6Al-4V exhibits a relatively low hardenability, which allows the formation of higher proportions of the more desirable Widmanstätten alpha plus retained beta microstructure even at relatively high weld cooling rates.

Due to its single-phase mode of solidification (i.e., absence of low-melting-point eutectics), Ti-6Al-4V is also highly resistant to solidification- and liquation-related cracking. However, the occurrence of solid-state cracking and the formation of porosity can be encountered during welding. Fortunately, these defects are not metallurgically inherent in Ti-6Al-4V, but rather originate from readily correctable deficiencies in preweld cleaning of the workpieces and shielding of the weld zone from atmospheric contamination.

Alpha-beta alloys that are highly beta stabilized, such as Ti-6Al-2Sn-4Zr-6Mo and Ti-6Al-6V-2Sn, have limited weldability. They tend to crack when welded under high restraint or when minor defects are present in the weld zone (Ref

4). The resistance to cracking may be improved by preheating in the range of 150 to 175 °C (300 to 350 °F) and then stress-relieving immediately after welding.

Metastable beta alloys are sufficiently rich in beta stabilizers (and lean in alpha stabilizers) that the beta phase can be completely retained with appropriate cooling rates. These alloys are metestable, and precipitation of alpha phase in the metestable beta is a method used to strengthen the alloys. Metestable beta alloys contain small amounts of alpha-stabilizing elements as strengthening agents.

As a class, metestable beta alloys offer increased fracture toughness over alpha-beta alloys at a given strength level (Ref 2). However, metastable beta and beta alloys require close control of processing and fabrication steps to achieve optimal properties. In the past, metestable beta alloys had rather limited applications, such as springs and fasteners, where very high strength was required.

In recent years, however, metestable beta alloys have received closer attention because their fracture toughness characteristics respond to the increased need for damage tolerance in aerospace structures. In addition, some metastable beta alloys containing molybdenum have good corrosion characteristics. Metastable beta alloys also exhibit:

- BETTER ROOM-TEMPERATURE FORMING AND SHAPING CHARACTERISTICS THAN ALPHA-BETA ALLOYS
- HIGHER STRENGTH THAN ALPHA-BETA ALLOYS AT TEMPERATURES WHERE YIELD STRENGTH (INSTEAD OF CREEP STRENGTH) IS THE APPLICABLE CRITERION
- BETTER RESPONSE TO HEAT TREATMENT (SOLUTION TREATMENT, QUENCHING, AND AGING) IN HEAVIER SECTIONS THAN THE ALPHA-BETA ALLOYS

Most metastable beta alloys are weldable in either the annealed or the heat-treated condition (Ref 4). These alloys include Ti-13V-11Cr-3Al, Ti-8Mo-8V-3A1-2Fe, and Ti-15V-3Al-3Cr-3Sn alloys. Welded joints have good ductility but relatively low strength in the as-welded condition. They are used most often in this condition because the welded joint can respond differently to heat treatment than the base metal and have low ductility after aging. Aging can take place if the welds are exposed to elevated temperatures in service.

General Welding Considerations (Ref 5)

Titanium has a strong chemical affinity for oxygen, and a stable, tenacious oxide layer forms rapidly on a clean surface, even at room temperature. This behavior leads to a natural passivity that provides a high degree of corrosion resistance (Ref 6). The strong affinity of titanium for oxygen increases with temperature, and the surface oxide layer increases in thickness at elevated temperatures (Fig. 3). At temperatures exceeding 500 °C (930 °F), its oxidation resistance decreases rapidly, and the metal becomes highly susceptible to embrittlement by oxygen, nitrogen, and hydrogen, which dissolve

interstitially in titanium. Therefore, the melting, solidification, and solid-state cooling associated with fusion welding must be conducted in completely inert or vacuum environments. The fusion welding processes most widely used for joining titanium are gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), plasma arc welding (PAW), laser-beam welding (LBW), and electron-beam welding (EBW); each of these processes are discussed later in this article. With the arc and laser welding processes, protection of the weld zone can be provided by localized inert-gas shielding. Complete enclosure in a protective chamber of the high vacuum environment associated with the electron-beam welding process inherently provides better atmospheric protection. In addition to proper shielding, welded component cleanliness (including filler metals) is necessary to avoid weld contamination.

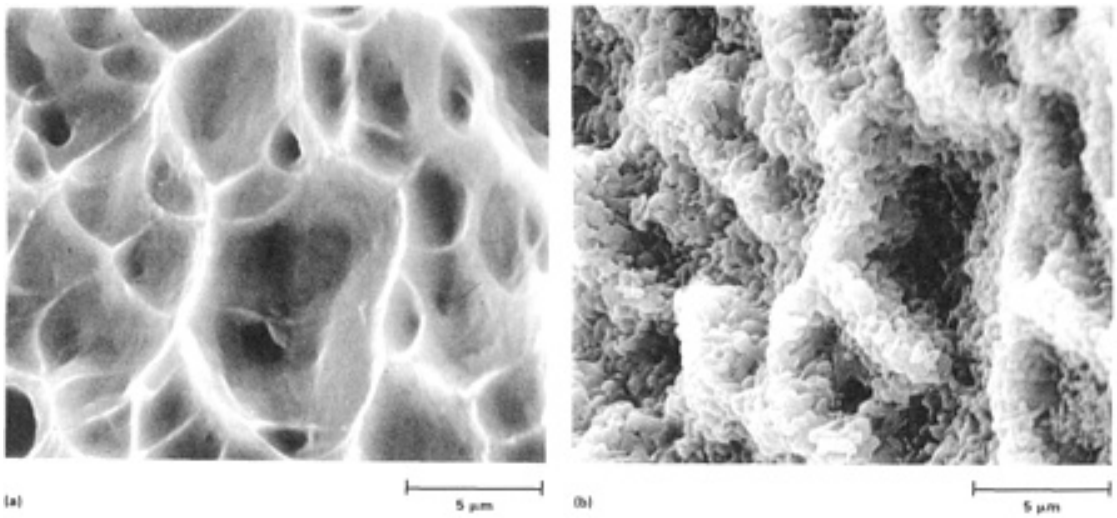

FIG. 3 EFFECT OF A 15 MIN 800 °C (1470 °F) AIR EXPOSURE ON A FRACTURE SURFACE OF AN ANNEALED TI-6AL-6V-2SN ALLOY. (A) FRACTURE APPEARANCE BEFORE EXPOSURE. (B) THE IDENTICAL FRACTURE SURFACE AFTER EXPOSURE; THE OXIDE BUILDUP IS SO GREAT THAT IT IS IMPOSSIBLE TO IDENTIFY THE FRACTURE MODE. COURTESY OF V. KERLINS, MCDONNELL DOUGLAS ASTRONAUTICS COMPANY

The welding of thin-to-moderate section thicknesses in titanium alloys can be accomplished using all of the aforementioned processes. The GTAW process offers the greatest flexibility for both manual and automatic application at minimum capital investment. If production volume is large, the high capital investment required for LBW and EBW systems can be acceptable, based on higher welding rates and improved productivity. For titanium plate thickness exceeding about 5 mm (0.20 in.), the high-energy density processes are the most efficient. Plasma are welding, for producing welds up to about 15 mm (0.6 in.) thick, and EBW, which can readily generate single-pass welds in plates over 50 mm (2 in.) thick, are used in current aerospace practice. In addition to thickness requirements, complex geometries may require manual welding or the use of extensive fixturing. The automatic welding of extremely large components may also prove difficult, particularly with the EBW process.

Residual stresses in titanium welds can greatly influence the performance of a fabricated aerospace component by degrading fatigue properties, while distortion can cause difficulties in the final assembly and operation of high-tolerance aerospace systems. Thus, the use of high-energy-density welding processes to produce full-penetration, single-pass autogenous welds, rather than multipass conventional arc welding, is desirable to minimize these difficulties.

Several important and interrelated aspects of welding phenomena contribute to the overall understanding of titanium alloy welding metallurgy. These factors include melting and solidification effects on weld microstructure, postweld heat treatment effects, and structure/mechanical property/fracture relationships. Each of these are described below as well as in several excellent review articles (Ref 5, 7, 8, 9).

Weld Microstructure

The microstructure of the weldment and the extent to which it differs from the thermomechanically processed base material is strongly influenced by the thermal cycle of welding. Two characteristics that are vitally important are the size and shape of the prior-beta grains and the phase transformations that take place during weld cooling. These characteristics are described for both alpha-beta (Ti-6Al-4V) and metastable beta alloys in this section. Also described are weld defects (macrosegregation, microsegregation, and solidification defect formation) and the effects of postweld heat treatment on welded titanium structures.

Alpha-Beta Alloys

Prior-Beta Grain Size. Mechanical properties of composite weld structures in titanium alloys depend on structural characteristics of each weld region, which in turn depend on the specific thermal cycle(s) imposed during welding and on subsequent postweld heat treatment. As the weld macrographs in Fig. 4, 5, 6, and 7 illustrate, the weld fusion zone in titanium alloys is characterized by coarse, columnar prior-beta grains that originate during weld solidification. The size and morphology of these grains depend on the nature of the heat flow that occurs during weld solidification.

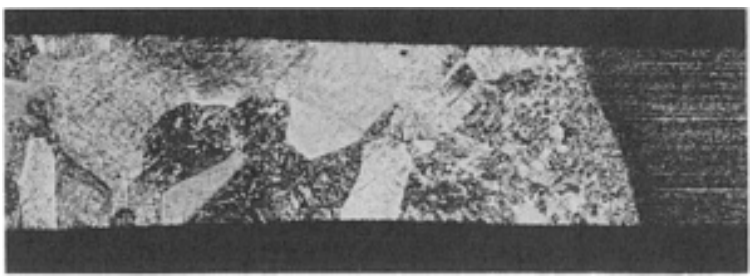

FIG. 7 MACROGRAPH SHOWING MULTIDIRECTIONAL BETA GRAIN MORPHOLOGY IN A TI-6AL-4V GAS-TUNGSTEN ARC WELD. 30×. COURTESY OF THE WELDING INSTITUTE

Under simple, uniaxial heat flow, such as occurs in a spot weld, the beta grains nucleate epitaxially on beta grains in the base-metal substrates and solidify preferentially in a direction parallel to the maximum temperature gradient (i.e., parallel to the welding electrodes) until they impinge at a horizontal weld centerline (Fig. 4). Under two-dimensional heat-flow conditions characteristic of full-penetration plasma-arc, laser-beam, and electron-beam welds, the columnar beta grains solidify inward from the base metal in a direction nearly parallel to the sheet or plate surface, ultimately impinging to form a vertical grain boundary at the weld centerline (Fig. 5 and 6). Three-dimensional or mixed two-dimensional/three-dimensional heat-flow conditions, such as those present in single-pass and multipass gas-tungsten arc and gas-metal arc weldments, promote the formation of more complex, multidirectional beta grain morphologies (Fig. 7).

The fusion-zone beta grain size depends primarily on the weld energy input, with a higher energy input promoting a larger grain size. Due to epitaxial grain growth, the fusion-zone beta grain size may also depend on the beta grain size in the near heat-affected zone (HAZ) directly adjacent to the fusion line. This latter effect of base metal grain size is most significant in the welding of extremely coarse-grained cast or beta-annealed alloys, as shown in Fig. 6 for an electron-beam weld produced in a coarse-grained forging. Because weld mechanical properties, particularly ductility, can be degraded by a coarse prior-beta grain size, it is important to maintain as fine a grain structure as possible by minimizing the weld energy input.

As indicated above, appreciable beta grain growth occurs in the near HAZ directly adjacent to the weld fusion line, where peak temperatures range from between the alloy solidus down to the beta transus (approximately 995 °C, or 1825 °F, for Ti-6Al-4V). As in the fusion zone, the extent of this growth increases with energy input into the weld zone. Consequently, this region can vary markedly in width, being almost unresolvable in electron-beam and laser-beam welds and yet being several beta grains wide in gas-tungsten arc welds (Fig. 5 and 7). Further from the fusion line, temperatures below the beta transus are encountered, which promote transformation of alpha phase in the mill-annealed microstructure to various proportions of the high-temperature beta phase. The presence of even small quantities of alpha phase at peak temperatures in the weld thermal cycle is sufficient to prevent beta grain growth, thereby contributing to the improved ductility of this region as compared with the coarser-grained fusion zone and near HAZ.

During the past two decades, numerous investigators in the former Soviet Union and in the United States have evaluated methodologies for promoting beta grain refinement in titanium alloy fusion welds. This work, which has recently been reviewed (Ref 10), utilized principally electromagnetic stirring techniques and inoculation with rare-earth (RE) elements and titanium "microcooler" particles to promote nonepitaxial heterogenous nucleation of beta grains during solidification and thereby provide a refined fusion zone grain structure. Several of these approaches have been effective in refining the beta grain structure, and correspondingly improving fusion zone mechanical properties. Figure 8 shows the equiaxed prior-beta grain structure in the fusion zone of a gas-tungsten arc weld produced in a Ti-6Al-4V joint using titanium powder microcooler additions. Despite the success of these techniques, particularly in thin sheet materials, their commercial application has been extremely limited, particularly in the United States.

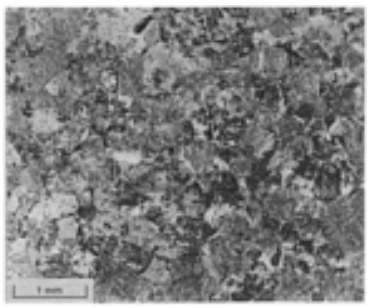

FIG. 8 PHOTOMICROGRAPH SHOWING EQUIAXED PRIOR-BETA MICROSTRUCTURE IN THE FUSION ZONE OF A TI-6AL-4V WELD JOINT. GTAW PROCESS UTILIZED TITANIUM MICROCOOLER ADDITIONS. 12×

Phase Transformations. In addition to prior-beta grain size, weld zone mechanical properties in Ti-6Al-4V are significantly influenced by the manner in which the high-temperature, body-centered-cubic beta phase transforms on cooling to the low-temperature, hexagonal-close-packed phase. Characteristics of this "transformed-beta" microstructure depend principally on the cooling rate from above the beta transus temperature, which is correspondingly influenced by the welding process, process parameters, and other welding conditions (such as workpiece geometry and fixturing). In the near-HAZ regions, high cooling rates associated with low-energy-input welding processes such as laser-beam, electron-beam, and resistance welding (100 to 10,000 °C/s, or 180 to 18,000 °F/s), promote transformation of beta to alpha-prime martensite. This extremely fine, acicular transformation product exhibits high strength and hardness but relatively low ductility and toughness. At the lower cooling rates associated with gas-tungsten arc or plasma-arc welding (10 to 100 °C/s, or 18 to 180 °F/s), a coarser structure of Widmanstätten alpha plus retained beta, or a mixture of this structure and alpha-prime, is produced, which exhibits yield and tensile strengths superior to those of the mill-annealed base metal and a ductility and toughness greater than those of an entirely martensitic microstructure. In the far HAZ, microstructures are comprised of primary alpha phase originating from the base-metal microstructure in a matrix of transformed beta.

The weld microstructure and mechanical properties may also be influenced by postweld heat treatment, with specific postweld heat treatment effects depending on the heat treatment time and temperature and on the as-welded microstructure. See the section on the "Effect of Postweld Heat Treatment" in this article.

Metastable-Beta Alloys

The weld HAZ and fusion zone beta grain macrostructures in metastable-beta titanium alloys are essentially identical to those observed in alpha-beta alloys. Due to the appreciable beta-stabilizer content in metastable-beta titanium alloys, and the relatively slow diffusivity of these elements, the high-temperature beta phase is retained on weld cooling to room temperature (although athermal transformation to omega phase may occur in certain alloys) (Ref 11, 12). Subsequent postweld aging heat treatment at temperatures ranging from about 450 to 650 °C (840 to 1200 °F) promotes the precipitation of fine alpha phase both intragranularly and along prior-beta grain boundaries. Through proper control of the aging temperature and time, a wide range of base metal and weld zone strength/ductility combinations can be achieved. The relatively uniform precipitation of extremely fine alpha phase during low-temperature aging (482 °C, or 900 °F, for 24 h), as shown in Fig. 9(a) and (b) for gas-tungsten arc weld fusion zone in Beta C, promotes high fusion zone hardness and strength (UTS, ultimate tensile strength, of 1382 MPa, or 200 ksi) and low ductility (2.5% elongation). An increased aging temperature promotes coarser alpha precipitation, softening (UTS of 1121 MPa, or 163 ksi), and an increase in ductility (8.0% elongation), as shown in Fig. 9(c) and 9(d) for the gas-tungsten arc weld fusion zone in Beta C aged at 593 °C (1100 °F) for 8 h. It should be noted that in contrast to alpha-beta alloys, residual microsegregation from weld solidification can influence alpha precipitation on aging, particularly for low-temperature aging heat treatments (Fig. 9).

Welding Defects

In many alloy systems, weldability is determined by the capability of the alloy to produce a weld that is free of discontinuities or defects. Defects that may be encountered when welding titanium alloys include:

- SOLIDIFICATION SEGREGATION (MACROSEGREGATION AND MICROSEGREGATION)
- SOLIDIFICATION CRACKING
- CONTAMINATION CRACKING
- HYDROGEN EMBRITTLEMENT

- SUBSOLIDUS (DUCTILITY DIP) CRACKING
- POROSITY

Macrosegregation in weldments is defined as segregation that extends over distances of several grain diameters. In titanium alloy fusion weldments, macrosegregation occurs primarily in the form of transverse solute banding (Ref 5). These solute-enriched or solute-depleted bands normally appear as curvilinear contours on the polished and etched weldment surface and are attributed to thermal variations in the weld pool, which periodically change the solid-liquid interface velocity. Transverse solute banding has occurred using both arc and high-energy welding processes. Studies on solute redistribution in Ti-6Al-4V gas-tungsten arc welds found distinct metallographic evidence of transverse solute banding. Electron microprobe analysis determined the bands resulted from vanadium and aluminum segregation (Ref 13).

The effect of macrosegregation on subsequent beta phase decomposition during cooling depends on the extent of segregation residual at the transformation temperature and the local alloy chemistry. Solute diffusion that occurs after solidification and prior to solid-state phase transformations reduces the magnitude of macrosegregation. In near-alpha and alpha-beta alloys, little effect of macrosegregation has been reported. However, in the more heavily beta-stabilized alloys, strong macrosegregation effects have been observed (Ref 14). This effect is shown in Fig. 10 for a gas-tungsten arc weld fusion zone produced between the alpha-beta alloy Ti-6Al-4V and the metastable-beta alloy Ti-15V-3Cr-3Al-3Sn. Transverse solute bands in the weld fusion zone, which were found to be depleted in the beta stabilizers vanadium and chromium, transformed to martensite while the remaining more heavily beta-stabilized regions were retained as beta phase during weld cooling. A similar effect of macrosegregation due to transverse-solute banding and incomplete mixing was recently observed for dissimilar-alloy laser welds produced between Ti-6Al-4V and the metastable-beta alloys Beta-C and Beta-21S (Ref 15, 16).

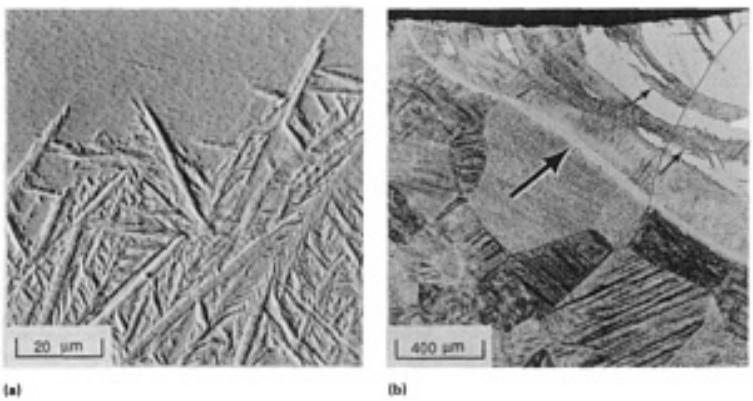

FIG. 10 LIGHT (A) AND SCANNING ELECTRON (B) MICROGRAPHS SHOWING MARTENSITICALLY-TRANSFORMED TRANSVERSE-SOLUTE BANDS (SMALL ARROWS) IN DISSIMILAR ALLOY GAS-TUNGSTEN ARC WELD BETWEEN TI-6AL-4V AND TI-15V-3AL-3CR-3SN SHEETS. LARGE ARROW IN (A) INDICATES FUSION LINE.

It should be pointed out, however, that the degradation of weld integrity, structure, or properties due to macro- and/or microsegregation is generally not significant in titanium alloys due to the limited extent of segregation of common alloying elements and the appreciable diffusional homogenization of alloying elements during weld cooling through the beta-phase field. This significant effect of alloying element homogenization on cooling through the beta-phase field has been recently demonstrated by lnoue and Ogawa (Ref 17) for gas-tungsten arc welds in Ti-6Al-4V using liquid tin quenching experiments that allowed analysis of the "as-solidified" fusion zone solidification structure. They observed in gas-tungsten arc welds produced in Ti-6Al-4V that the segregation of vanadium and iron to dendrite interstices disappeared at a very early stage of weld cooling following the completion of weld solidification due to their high diffusivity in the beta phase at high temperatures.

Microsegregation. The nonequilibrium solidification conditions experienced during fusion welding result in a breakdown of the advancing solid-liquid interface into cellular, cellular-dendritic, and dendritic substructures (Ref 5). This interface breakdown in commercial titanium alloy welds is associated with the segregation of alloying elements on

an intercellular or interdendritic scale. Microsegregation is much more evident in metastable-beta titanium alloy weldments than in alpha-beta weldments. This behavior is due primarily to the appreciably higher alloying levels (and therefore higher absolute compositional differences in segregated regions) and the absence of a transformed structure in the completely retained-beta fusion zone. As indicated earlier, local variations in beta-stabilizer content due to microsegregation can affect the alpha-phase precipitation response during subsequent postweld heat treatment.

Microsegregation effects have also become significant in the joining of advanced, elevated-temperature titanium alloys that contain rare earth elements for dispersoid strengthening (Ref 17). Figure 11 shows the fusion zone of a laser weld in a rapidly-solidified, powder metallurgy Ti-8Al-2.8Sn-5.4Hf-3.6Ta-1Y-0.2Si (wt%) alloy. The segregation of yttrium to dendrite interstices during weld solidification promotes the nucleation and growth of yttrium-enriched dispersoids in these regions both during the final states of solidification and possibly in the solid-state during cooling. Similar segregation of yttrium and dispersoid formation would be expected in gas-tungsten arc welds, but with a coarser grain and dispersoid size.

FIG. 11 TRANSMISSION ELECTRON MICROGRAPH OF LASER WELD FUSION ZONE IN RAPIDLY-SOLIDIFIED/POWDER METALLURGY TI-8AL-2.8SN-5.4HF-3.6TA-1Y-0.2SI ALLOY SHOWING YTTRIUM-ENRICHED DISPERSOIDS (INDICATED BY ARROWS) LOCATED ALONG SOLIDIFICATION SUBSTRUCTURE BOUNDARIES. SOURCE: REF 17

Solidification Cracking (Ref 9). Relative to many other structural alloys, such as aluminum alloys and many austenitic stainless steels, titanium alloys are generally not considered susceptible to fusion zone solidification cracking. Studies have demonstrated, however, that under severe conditions of restraint, solidification cracking along columnar beta grain boundaries can occur (Ref 18). Centerline cracking in a gas-tungsten arc welded alpha-beta alloy Ti-6Al-6V-2Sn is shown in Fig. 12. Recent work by Prokhorov *et al.* (Ref 19) has further evaluated the solidification cracking of Ti-6Al-4V using a weldability test in which a gas-tungsten arc weld is strained during the welding operation. They reported the formation of solidification cracks oriented along the welding direction and a quantitative susceptibility comparable to some steels, and concluded that solidification cracking must be considered when designing joints in Ti-6Al-4V structural components. However, this observation generally conflicts with the well-known excellent cracking resistance of this alloy, and suggests that their test imposed an excessive strain condition not representative of that experienced during conventional arc welding.

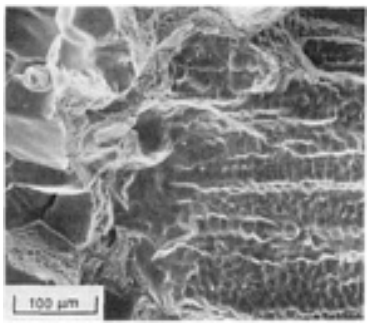

FIG. 12 SEM FRACTOGRAPH SHOWING SURFACE OF FUSION ZONE SOLIDIFICATION CRACK IN GAS-

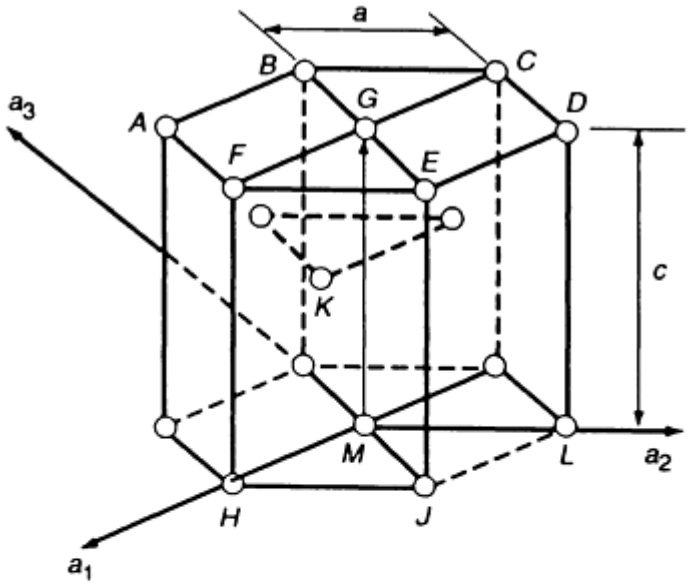
Due to an absence of second-phase dispersoids or precipitate particles, or impurities at grain boundaries, conventional titanium alloys are also generally very resistant to HAZ or weld metal liquation cracking. However, recent welding trials on selected rare earth dispersion-strengthened titanium alloys have indicated that the liquation of these particles in the weld HAZ can occur, with this liquid subsequently wetting adjacent beta grain boundaries. Although cracking along these boundaries has not been observed, it may be expected in the arc welding of these alloys under conditions of high weld restraint.

Contamination Cracking. When titanium is exposed to air, moisture, or hydrocarbons at temperatures exceeding 500 °C (930 °F), it will readily pick up oxygen, nitrogen, carbon, and hydrogen. These small atoms of the interstitial elements will enter the crystal lattice in monatomic form and will migrate to interstitial sites (sites located between titanium atoms). The presence of these interstitial elements serves to inhibit plastic deformation and increase strength, but with a substantial loss in ductility. If contamination levels exceed a certain amount, cracking may ensue from the stresses generated during welding. Levels of oxygen on the order of 3000 ppm in the weld have been known to result in transverse cracking (Ref 20). The alpha phase is particularly susceptible to contamination cracking. The hexagonal crystal lattice of alpha-titanium is distorted by the presence of interstitial atoms. In particular, the *c*/*a* ratio is increased (Fig. 13), which results in a reduced number of active slip planes from three (prism, pyramidal, and basal) down to one (prism or pyramidal) (Ref 21). Slip planes are crystallographic planes upon which dislocations move to achieve plastic deformation.



Basal plane (0001) – *ABCDEF*
Prism plane (10$\bar{1}$0) – *FEJH*
Pyramidal planes
Type I, order 1 (10$\bar{1}$1) – *GHJ*
Type I, order 2 (10$\bar{1}$2) – *KJH*
Type II, order 1 (11$\bar{2}$1) – *GHL*
Type II, order 2 (11$\bar{2}$2) – *KHL*
Diagonal axis [11$\bar{2}$0] – *FGC*

FIG. 13 DIAGRAM OF THE UNIT CELL FOR A HEXAGONAL CLOSE-PACKED CRYSTAL SHOWING BASAL, PRISM, AND PYRAMIDAL PLANES. THE *C/A* RATIO OF THE UNIT CELL FOR ALPHA-TITANIUM IS AFFECTED BY THE PRESENCE OF INTERSTITIAL ATOMS.

Contamination cracking can be avoided by minimizing exposure of the molten weld pool and the heated weld region to interstitial elements. This practice is accomplished by:

- THOROUGHLY DEGREASING THE JOINT PRIOR TO WELDING
- PROVIDING SUFFICIENT INERT GAS SHIELDING TO THE TORCH, TRAILING SHOE, AND BACK SIDE OF THE JOINT
- USING SHIELDING GAS WITH A SUFFICIENTLY LOW DEW POINT

When titanium is oxidized, it assumes different colors depending on alloy content and the degree of oxidation. These colors range from silver to straw, to blue, to white (severe oxidation). While the presence of a blue or white oxide serves as a good indicator that unacceptable contamination has occurred, its absence is no guarantee that the weld is interstitial free.

Hydrogen Embrittlement. While hydrogen can play a role in contamination cracking as discussed above, it can also lead to a more insidious type of defect known as hydrogen embrittlement, or hydrogen delayed cracking. One mechanism proposed for this problem involves the precipitation of titanium hydrides in the vicinity of cracks (Ref 22). If it is assumed that a microcrack is present in the weldment, it follows that hydrogen atoms will diffuse to the crack tip, where a triaxial stress state produces large interstitial sites (holes) in the lattice. These large interstitial sites can more easily accommodate the hydrogen atoms.

Once a critical concentration of hydrogen is reached, titanium hydrides will precipitate ahead of the crack tip (Fig. 14). Hydrogen may also diffuse to the crack to form diatomic gas, increasing pressure within the crack and increasing the load at the crack tip. Eventually the hydrides will rupture, allowing the crack to advance. Upon rupture, the hydrides will redissolve and hydrogen will diffuse to the new crack tip, thus reinitiating the sequence. This cycle may repeat many times, each cycle resulting in a small advancement of the crack.

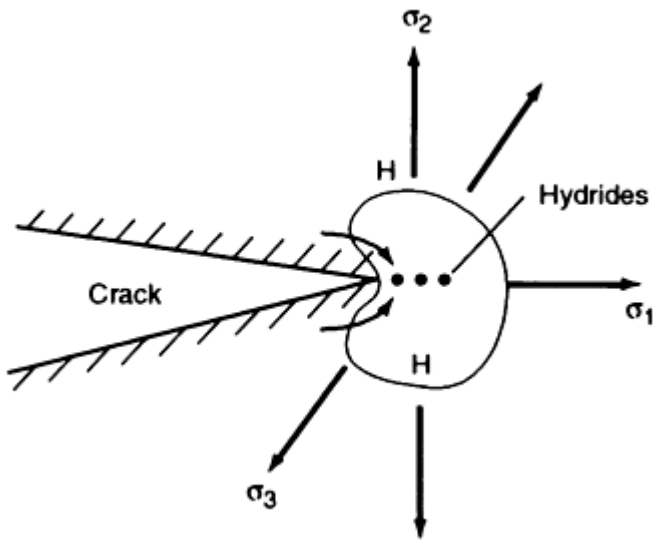


FIG. 14 SCHEMATIC DIAGRAM SHOWING HOW HYDROGEN ATOMS MAY DIFFUSE TO A CRACK TIP IN A TITANIUM WELDMENT TO FORM TITANIUM HYDRIDES

Because the hydrogen embrittlement sequence requires diffusion of hydrogen, the rate of crack advancement depends on time and temperature. Hours, days, or months may pass following welding before significant cracking is observed. This problem can be avoided by minimizing exposure of the weld to hydrogen (hydrocarbons and moisture). Hydrogen concentrations on the order of 200 ppm are known to cause cracking problems (Ref 15), although the combined presence of other interstitials (for example, oxygen or nitrogen) may lower this tolerance limit. The inert shielding gas should have a dew point of at least -50 °C (-60 °F) (34 ppm H_20). Welding-grade argon or helium gas (grade 4.5 with 50 ppm impurities) may not always satisfy this requirement. Also, the use of postweld heat treatment is beneficial because it relieves residual stress, thus reducing the driving force for crack advancement.

Subsolidus Cracking. Certain alloy compositions and microstructures have been found to be susceptible to a severe ductility loss (ductility dip) in a temperature range from about 750 to 850 °C (1380 to 1560 °F) on cooling from temperatures above the beta transus. In particular, alpha-beta alloys that contain niobium rather than vanadium as a beta-stabilizing element are more susceptible to this form of cracking. Microstructures having alpha films at prior-beta grain boundaries, with coarse Widmanstätten alpha colonies, are also more prone to subsolidus cracking.

Lewis *et al.* (Ref 23) utilized a Gleeble system and a typical gas-tungsten arc weld thermal cycle to evaluate the sensitivity of several near-alpha and alpha-beta titanium alloys to this phenomenon. The results of their analysis indicate that Ti-6211 (Ti-6Al-2Nb-1Ta-0.8Mo) exhibits the largest ductility dip and will be the most likely to crack during weld cool down, provided that the welding stresses are high enough (Fig. 15). Ductility dip cracks are intergranular, but show signs of microplasticity (ductile dimples) when examined at high magnification. They are believed to occur due to volumetric differences as a result of the beta-to-alpha transformation. It has been proposed that when the prior-beta grains transform to alpha, the grain boundaries are loaded in tension, causing rupture within grain boundary alpha films (Ref 24).

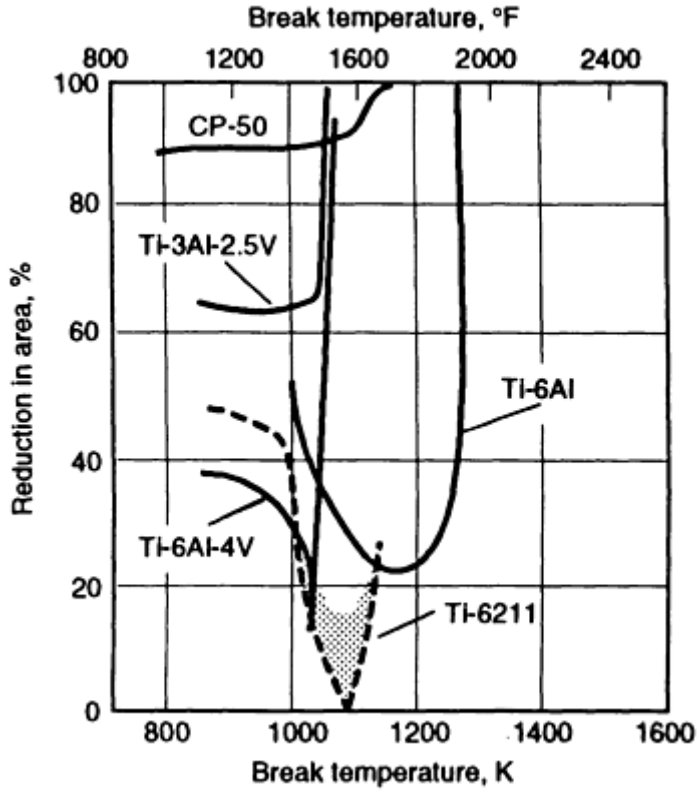

FIG. 15 DUCTILITY VERSUS TEMPERATURE FOR FIVE TITANIUM ALLOYS WITH VARYING ALUMINUM CONTENTS. SHADED AREAS INDICATE EXCESSIVE DATA SCATTER. SOURCE: REF 23

Considerable additional work has been performed in order to understand the origin of ductility-dip weld cracking in titanium alloys (Ref 25, 26, 27, 28). It is important to note, however, that difficulties with the occurrence of such defects in actual welds have not been reported in the literature, and therefore the potential for their formation is quite limited and may be encountered only under conditions of extreme restraint and for certain cooling rates.

Weld metal porosity originates at the trailing edge of the weld pool, where interstitial elements (oxygen or hydrogen) are partitioned between dendrites during solidification (Fig. 16). Partitioning occurs because of the large drop in oxygen (or hydrogen) solubility when transforming from liquid to solid.

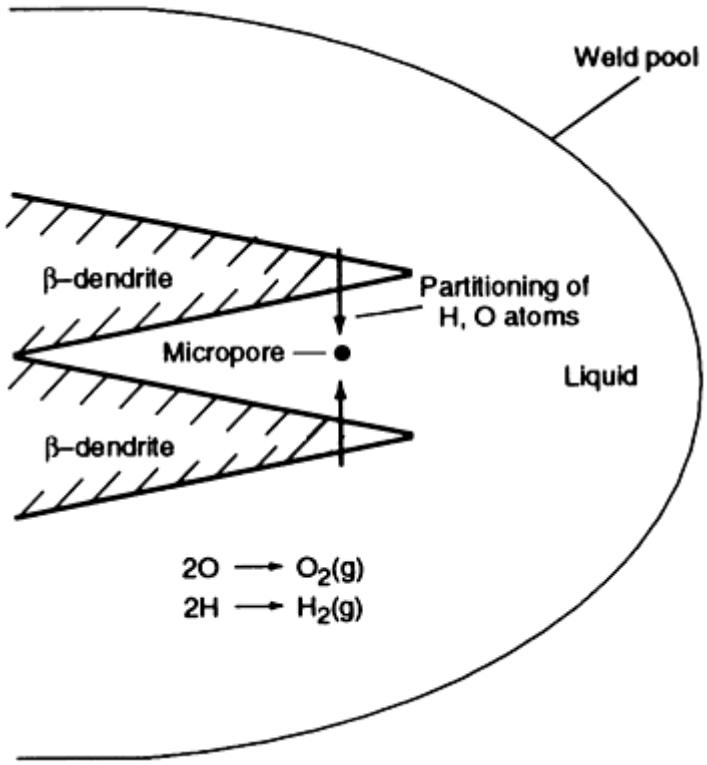

FIG. 16 SCHEMATIC DIAGRAM SHOWING HOW MICRO-PORES ARE NUCLEATED BETWEEN BETA-TITANIUM DENDRITES DURING WELD SOLIDIFICATION

As the concentration of monatomic oxygen (or hydrogen) in the interdendritic liquid reaches a critical concentration, micropores (~1 μm diam) of diatomic gas are nucleated. In order to nucleate, these micropores must overcome atmospheric pressure, liquid head pressure, and liquid/gas surface tension (Ref 29). Once nucleated, these micropores will either become entrapped interdendritically or will coalesce into larger pores (up to 3 mm, or 0.12 in., diam). These macropores will either become enveloped by the advancing solid/liquid interface or they will work their way to the weld pool surface and escape under buoyancy forces.

Avoiding porosity requires that the molten weld pool be protected from exposure to oxygen or hydrogen during welding. This means that the joint must be thoroughly degreased prior to welding and that adequate inert gas shielding with a low dew point must be provided. Porosity can occur at lower impurity levels than is required for contamination cracking, although the existence of porosity implies the possibility of contamination or hydrogen cracking. Porosity is also affected by process parameters and welding position. Welding at slow travel speeds favors the escape of gas pores, as does welding in the flat or vertical-up position.

Effect of Postweld Heat Treatment

Titanium alloy weldments are postweld heat treated for (Ref 5):

- RELIEF OF RESIDUAL STRESSES IMPARTED DURING THE WELDING OPERATION
- MODIFICATION OF THE METASTABLE WELD ZONE MICROSTRUCTURE
- COMPLETION OF THE SECOND STEP IN A TWO-STEP BASE METAL HEAT TREATMENT
- STABILIZATION OF THE MICROSTRUCTURE FOR WELD STRUCTURE APPLICATIONS AT ELEVATED TEMPERATURES

Numerous investigators have studied the influence of postweld heat treatment on the structure and properties of titanium alloy welds (Ref 30, 31, 32, 33, 34, 35). The structures commonly encountered include: alpha and hexagonal martensite in

near-alpha and linear alpha-beta alloys, alpha and orthorhombic martensite in heavily beta-stabilized alpha-beta alloys, and retained beta in metastable-beta alloys.

Alpha and Alpha-Beta Alloys. Heat treatment of rapidly cooled welds in near-alpha and alpha-beta alloys at relatively low temperatures (between about 450 and 600 °C, or 840 and 1110 °F), which are commonly employed for stress relief, age the martensitic structure and can further increase its strength and decrease its ductility and toughness. At higher postweld heat treatment temperatures, which are limited to about 760 °C (1400 °F) for large fabricated structures, tempering of the martensite and subsequent coarsening of the resultant alpha phase promote softening of the fusion zone with concurrent increases in ductility and toughness. Microstructures comprised of Widmanstätten alpha plus retained beta, which are produced at slower weld cooling rates, are influenced to a lesser extent by postweld heat treatment at these low-to-moderate temperatures. However, welds exhibiting these microstructures are still normally postweld treated to relieve residual stresses.

Metastable Beta Alloys. In contrast to near-alpha and alpha-beta alloys, metastable-beta alloys can undergo appreciable structural changes at the lower temperatures. In the as-welded condition, the alloy exhibits a retained beta microstructure that contains athermal omega, an extremely fine phase that is unresolvable with light microscopy. On aging isothermally at 480 °C (900 °F), extremely fine alpha forms intergranularly and in a continuous manner at beta grain boundaries. As the heat treatment temperature is increased to 565 °C (1050 °F) and to 650 °C (1200 °F), both alpha structures coarsen appreciably. From a practical standpoint, the post-weld heat treatment of welded structures is difficult and expensive because inert shielding is required at temperatures above about 500 °C (930 °F). Additionally, the loss of strength at temperatures approaching the beta transus limits the capability to maintain weld tolerances unless complex fixturing is employed.

Table 3 lists the temperature ranges used for stress-relieving titanium alloy weldments. Postweld heat treatments that employ high temperatures (exceeding 800 °C, or 1470 °F) with water quenching followed by an aging treatment between 350 to 500 °C (660 to 930 °F) have also been developed for near-alpha and alpha-beta alloys (Ref 36). Tensile properties of postweld heat-treated titanium weldments are given in Table 4.

Selection and Weldability of Conventional Titanium Alloys

W.A. Baeslack III, The Ohio State University; J.R. Davis, Davis and Associates; C.E. Cross, Martin Marietta Astronautics Group

Titanium Weldment Structure/Property Relationships (Ref 5, 9)

Macro- and microstructural characteristics of weldments in titanium alloys, as influenced by weld solidification, cooling rate, and postweld heat treatment, significantly influence weldment mechanical properties. In the welding of thin sheet materials for aerospace applications, the principal properties of interest are room- and elevated-temperature tensile properties and *S-N* fatigue characteristics. For welds produced in plate materials for either aerospace or marine applications, fracture toughness and fatigue-crack growth rate properties also become important.

Tensile Properties. The strength across an arc weld is determined by the strength of the weakest link in the composite weld region, which consists of the fusion zone, the near HAZ (where the peak temperature exceeded the beta transus temperature), and the far HAZ (where peak temperatures were below the beta transus). In the United States, sheet products of near-alpha or alpha-beta titanium alloys are most commonly welded in a mill-annealed condition (Table 2). In all but extremely slowly cooled manual arc welds, the fine alpha or alpha-prime martensite structures produced in the weld fusion zone and near-HAZ regions exhibit hardnesses and strengths above that of the affected base metal, and transverse weld failures consequently occur in the base metal (Table 4). Although these welds exhibit 100% joint efficiency, the ductility of the weld zone as measured by longitudinal-weld-oriented bend or all-weld-metal tensile tests

may be unacceptably low, particularly in rapidly cooled arc welds in the more heavily beta-stabilized alloys (for example, Ti-6Al-6V-2Sn, CORONA 5, and Ti-6Al-2Sn-4Zr-6Mo), which contain hard martensitic microstructures within a coarse prior-beta grain macrostructure. As shown in Table 4 for gas-tungsten arc welds in the near-alpha alloy Ti-6Al-2Sn-4Zr-2Mo-0.1Si and the alpha-beta alloy CORONA 5, the tempering of martensite in the weld zone and ultimate coarsening of the alpha + beta microstructure result in a decrease in strength but an increase in ductility with increasing heat treatment temperature.

Arc welds produced on near-alpha and alpha-beta base metals that have been solution heat treated and aged to high strength may exhibit weld zones exhibiting strengths below that of the base metal; consequently, transverse tensile fracture would occur preferentially in these regions. For example, the strength and ductility of weldments produced in Ti-6Al-4V that has been solution heat treated and aged to high strength levels are highly dependent on the weld zone structure. The completely martensitic microstructures exhibited in electron-beam and laser-beam welds having high depth-to-width ratios are sufficiently strong to promote base-metal fracture in the solution heat treated and aged base metal. However, the softer Widmanstätten plus retained-beta microstructures exhibited by the more slowly cooled gas-tungsten arc and plasma arc welds may promote preferential fracture in the weld zone at low macroscopic elongation.

As expected, the tensile properties of weldments in metastable-beta titanium alloys differ considerably from those of near-alpha and alpha-beta alloys. If arc welds are produced in solution-annealed base material, joints commonly fracture in the base metal because of a slightly higher strength in the weld metal due to oxygen pickup or the initiation of second-phase precipitation if cooling rates are sufficiently slow. Following postweld heat treatment, the presence of a coarse beta grain structure in the fusion zone combined with the formation of alpha preferentially along these grain boundaries (in addition to precipitation homogeneously within the beta grains) can promote fracture in the fusion zone at lower ductilities. As shown in Table 4 for the metastable-beta titanium alloy Ti-15V-3Al-3Sn-3Cr, postweld heat treatment significantly increases the fusion zone strength versus the as-welded condition. As indicated, this strength is maximum for low aging temperatures and decreases with an increase in aging temperature.

Figure 17 plots longitudinal weld tensile data for a variety of alloys. The most desirable weldment characteristic is the highest strength level that exhibits adequate ductility. Therefore, alloys and welding conditions would be selected that offer properties near the upper boundary of the scatter band shown in Fig. 17. Within the high-strength regions shown on such diagrams, the metastable beta and richer alpha-beta alloys show the most promise (Ref 7).

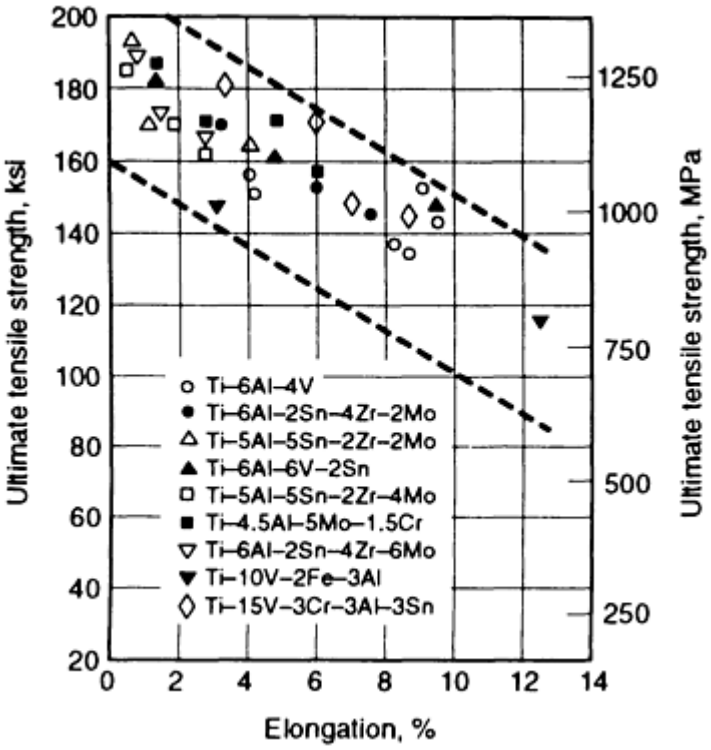

FIG. 17 LONGITUDINAL WELDMENT TENSILE DATA FOR COMMERCIAL TITANIUM ALLOYS. SOURCE: REF 7

The fracture toughness of suitably heat-treated titanium alloy weldments is generally equivalent or superior to that of the alpha-beta processed base material. The good fracture toughness of the fine Widmanstätten plus grain-boundary alpha microstructure in the weld fusion zone and HAZ is consistent with the good toughness of microstructurally similar beta-processed titanium alloy microstructures. Figure 18 shows fracture toughness versus ultimate-tensile strength for heat-treated electron-beam and plasma arc welds in wrought CORONA 5 base plate. Note that the values fall well within the scatterband of data for base-metal alloys exhibiting a lenticular alpha morphology (Ref 37).

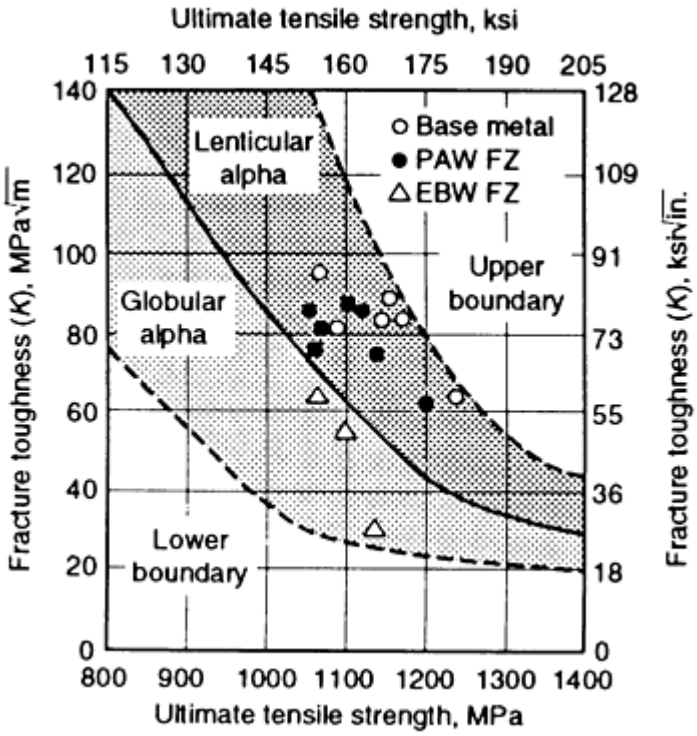

FIG. 18 FRACTURE TOUGHNESS VERSUS ULTIMATE TENSILE STRENGTH FOR CORONA 5 BASE METAL AND POSTWELD HEAT TREATED ELECTRON-BEAM AND PLASMA-ARC WELD FUSION ZONE REGIONS. SOURCE: REF 37

Fracture toughness is also markedly influenced by the interstitial content of the weld metal. When selecting a titanium alloy for a fracture-toughness-critical application, the use of extra-low interstitial (ELI) grades of base metal and consumable are recommended.

Lewis *et al.* (Ref 38) investigated the influence of boron on the dynamic tear toughness of gas-tungsten arc weldments in Ti-6Al-2Nb-1Ta-1Mo and found that welds containing a high boron content of 0.005 wt% exhibited toughness levels 40% below those containing 0.001 wt% B (boron can be introduced as an impurity in master alloys or during processing of welding wire). They attributed this difference to the occurrence of a beta + TiB to alpha peritectoid reaction during weld cooling in the alloy with a high boron content, which provided nucleation sites for alpha platelets. The absence of this transformation in low-boron weldments allowed greater undercooling of the beta phase and transformation to a martensitic structure.

Fatigue Properties. Generally, *S-N* fatigue properties of weld structures in the alpha-beta alloys such as Ti-6Al-4V and Ti-6Al-6V-2Sn are similar to that of the base material if the weld zones are free of defects such as porosity and undercut. Failure in transverse-oriented specimens occurs in the base metal remote from the weld zone. This greater resistance to crack initiation of these composite weld structures relates to the higher strength levels of the weld regions because the large prior-beta grain/transformed beta microstructures, which characterize these regions, generally exhibit reduced resistance to cyclic crack initiation compared to equiaxed-alpha type base metal structures. Studies of *S-N* fatigue properties of electron-beam-welded ELI CORONA 5 indicated that fatigue properties of all-fusion-zone specimens and transverse-weld specimens are comparable to those of the base metal over a range of stresses, even when fracture was initiated by weld porosity (Ref 35). Results from these studies are shown in Fig. 19.

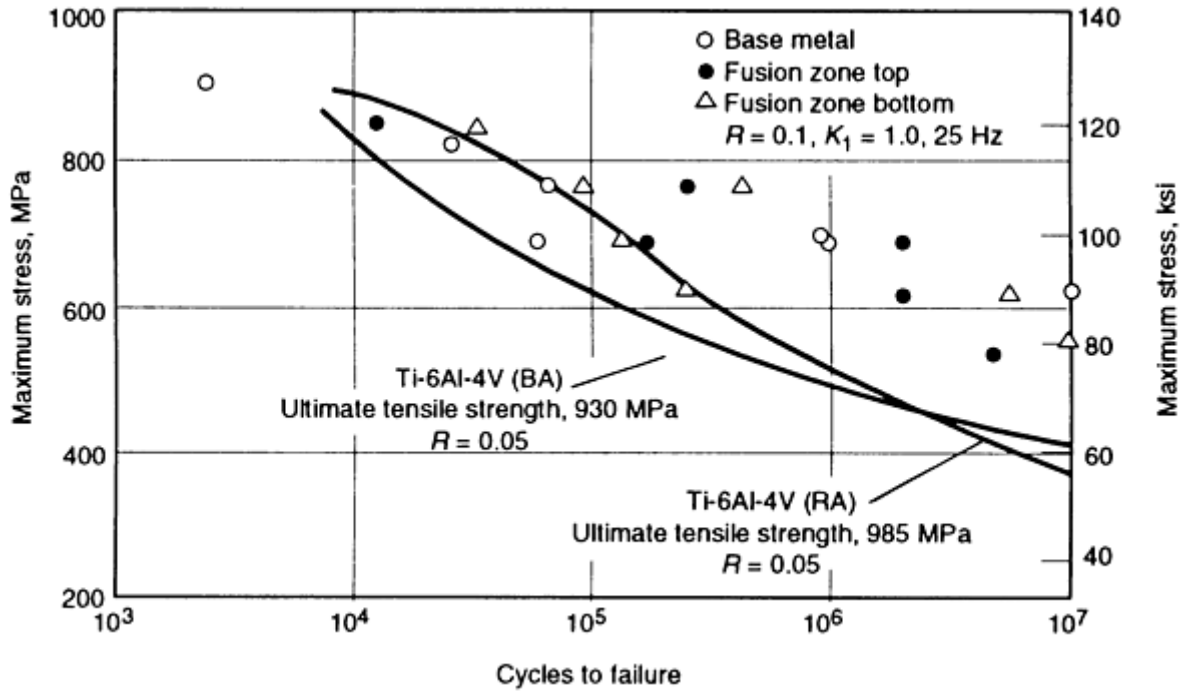

FIG. 19 AXIAL TENSION FATIGUE DATA FOR POSTWELD HEAT TREATED ELI CORONA 5 BASE METAL AND ELECTRON-BEAM-WELDED SPECIMENS COMPARED TO BETA-ANNEALED (BA) AND RECRYSTALLIZED ANNEALED (RA) TI-6AL-4V. SOURCE: REF 35

Although, as indicated above, equivalent weld zone and base-metal fatigue properties can be obtained, lower weld zone axial fatigue properties are commonly observed in actual practice. This is particularly true with high-energy-density welding processes (Fig. 20). This behavior is attributed to the presence of fine porosity, often unresolvable by radiography, and of other defects such as undercuts or underfills in fusion welds, or lack of bonding regions at the weld interface in solid-state diffusion or friction welds. As with tensile properties, the axial fatigue behavior of welds produced in solution heat treated and aged base metals depends on both the weld integrity and the strength of the weld zone.

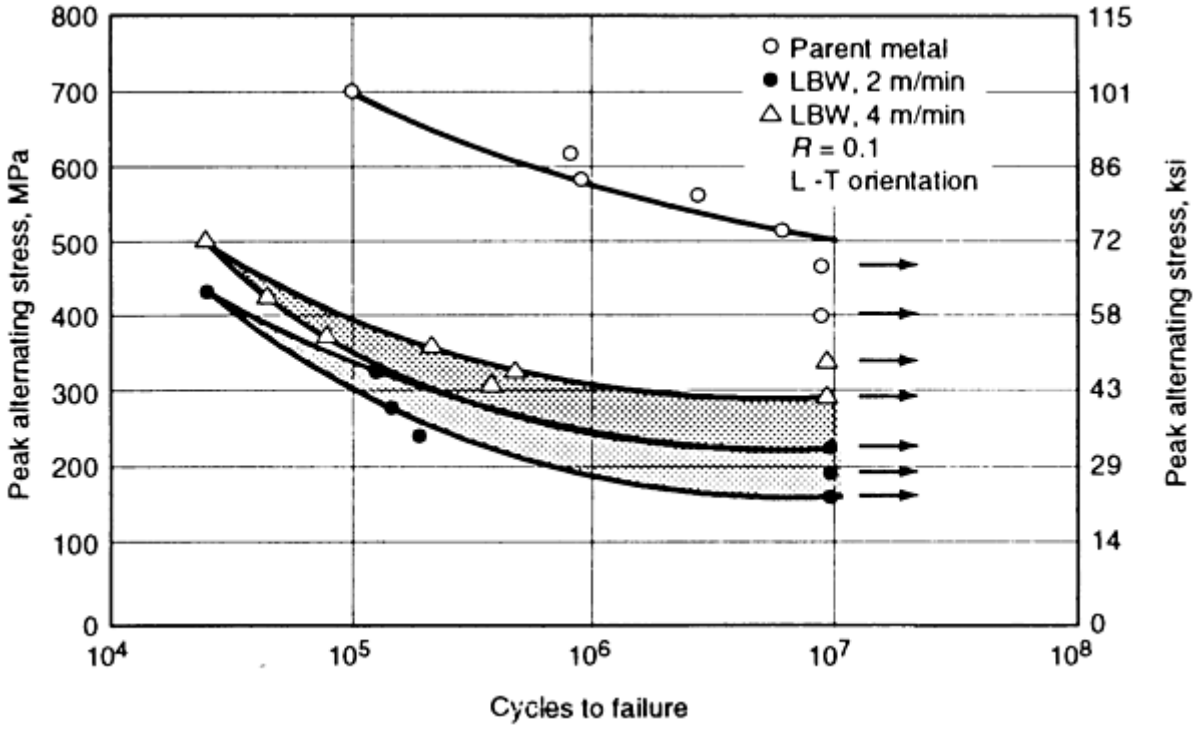

FIG. 20 *S/N* FATIGUE CURVES FOR LASER-BEAM WELDS IN 4 MM (0.16 IN.) TI-6AL-4V SHEET PRODUCED AT 2 AND 4 M/MIN (0.6 AND 1.2 FT/MIN). TESTED IN AS-WELDED CONDITION. FRACTURE INITIATED AT WELD UNDERCUT. BASE METAL PROPERTIES ARE PROVIDED FOR COMPARATIVE PURPOSES. SOURCE: REF 39

It should be noted that poor axial fatigue properties also can limit the application of lap joints produced in titanium using resistance, diffusion, and ultrasonic welding. In the case of resistance welds, the mechanical notch at the perimeter of the weld nugget, the presence of a brittle martensitic microstructure, and residual stresses can promote early fatigue crack initiation and low fatigue life. Although the metallurgical structure and residual stresses can be modified through process control, the presence of a notch is inherent to a lap joint and subject to less modification.

With the increased application of damage-tolerant design criteria, fatigue crack growth rate data for weldments are of increased importance. A comparison of fatigue-crack propagation rates between gas-tungsten arc, laser-beam, and electron-beam welds in Ti-6Al-4V and Ti-15V-3Al-3Cr-3Sn was made by Pao *et al.* (Ref 40). Their results indicated that the average fatigue crack growth rates through the postweld heat treated weld zones did not differ appreciably with the welding process (Fig. 21), although the scatter bands were narrower for the high-energy density versus the arc welding processes (Fig. 22). For Ti-6Al-4V, they found the average crack growth rates to be lower than that in the base metal, while in Ti-15V-3Al-3Cr-3Sn they found nearly equivalent base metal and weld metal crack growth rates (Fig. 21).

Selection and Weldability of Conventional Titanium Alloys

W.A. Baeslack III, The Ohio State University; J.R. Davis, Davis and Associates; C.E. Cross, Martin Marietta Astronautics Group

Welding Process Application

Titanium and its alloys can be welded by a wide variety of conventional fusion and solid-state processes, although titanium's chemical reactivity typically requires special procedures and precautions. In the United States, fusion welding of titanium is performed principally by inert gas-shielded arc welding and high-energy-beam welding processes. To date, the commercial joining of titanium alloys using flux-based processes (for example, submerged arc welding, flux-cored arc welding, and electroslag welding) has not been shown to be competitive due to requirements for costly high-purity fluoride-base fluxes. However, recent studies on submerged arc welding of 25 mm (1 in.) thick titanium alloy plate indicate that it is possible to weld heavy sections using a flux composed of 85% calcium fluoride, 10% strontium chloride, and 3% lithium chloride (Ref 41). Tensile and corrosion properties of the weld were equal to that of the base plate material; however, the coarser weld grain structure did not provide adequate toughness.

Additional information on the welding processes described below can be found in the Section "Joining Processes" in this Volume.

Gas-tungsten arc welding (GTAW), in which the heat of welding is provided by an arc maintained between a nonconsumable tungsten electrode and the workpiece, is the most widely used process for joining titanium sheet. In general, gas-tungsten arc welds can be produced manually (in complex joint geometries or for weld repair) and automatically in sheet up to about 3 mm (0.125 in.) in thickness without joint preparation or filler metal additions. For welding of greater thicknesses, suitable joint preparation and the cold or hot-wire addition of a filler metal are required. Although conventional GTAW equipment can be used for welding of titanium alloys, the heated metal in the weld zone must be shielded from the atmosphere to prevent pickup of oxygen and nitrogen, which can be deleterious to weld mechanical properties. Such protection is best provided by welding within a rigid or collapsible plastic chamber that has been evacuated and purged with argon, although local shielding is also suitable for many welding operations. Typical parameters for welding of Ti-6Al-4V by GTAW are shown in Table 5.

TABLE 5 WELDING PARAMETERS FOR GAS-TUNGSTEN ARC WELDING OF TI-6AL-4V

MATERIAL THICKNESS[A]		TUNGSTEN ELECTRODE DIAMETER		FILLER ROD DIAMETER		NOZZLE SIZE ID		SHIELDING GAS FLOW		WELDING CURRENT[B]	NUMBER OF PASSES	TRAVEL SPEED[C]	
mm	in.	mm	in.	mm	in.	mm	in.	m^3/h	ft^3/h			mm/min	in./min

6.35	0.25	3.2	1/8	3.2	1/8	16	5/8	0.76	30	275-320	2	205	8
9.52	0.375	3.2	1/8	3.2	1/8	19	3/4	0.99	35	300-350	2	150	6
12.7	0.50	3.2	1/8	4.0	5/32	19	3/4	1.13	40	325-425	3	150	6

Note: Tungsten used for the electrode; first choice 2% thoriated EWTh2, second choice 1% thoriated EWTh1. Use filler metal one or two grades lower in strength than the base metal. Adequate gas shielding is essential not only for the arc, but for heated material also. Backing gas is recommended at all times. A trailing gas shield is also recommended. Argon is preferred. For higher heat input, on thicker material use argon-helium mixture. Without backing or chill bar, decrease current 20%.

(C) PER PASS

Gas-metal arc welding (GMAW), in which the heat of welding is provided by an arc maintained between a consumable electrode and the workpiece, is more cost-effective than GTAW for the welding of titanium plate over 13 mm (0.5 in.) in thickness. However, the application of GMAW to titanium has been restricted by poor arc stability, which promotes appreciable spatter during welding, thereby reducing weld quality and overall process efficiency. Typical welding parameters for welding of Ti-6Al-4V by GMAW are given in Table 6.

Plasma arc welding (PAW) is an extension of the GTAW process in which the arc plasma is constricted by a nozzle, thereby increasing its temperature and energy density as compared with the more diffuse GTAW arc. This higher energy density provides greater penetration capabilities, allowing the production of full-penetration, keyhole square-butt welds in thicknesses up to 13 mm (0.5 in.). Typical welding parameters for PAW of Ti-6Al-4V are given in Table 7.

Electron-beam welding (EBW) involves melting of the base metals to be joined by the impingement of a focused beam of high-energy electrons. This process has been widely used in the aerospace industry for producing high-quality welds in titanium plate ranging from 6 to more than 75 mm (0.25 to more than 3 in.) in thickness. Advantages of EBW welding include high depth-of-penetration, minimum joint preparation, a narrow weld HAZ, low distortion, and excellent weld cleanliness as welding is performed in a high vacuum. Disadvantages of the EBW process include high capital equipment cost and high weld cooling rates, the latter of which promote formation of undesirable martensite in the weld zone. Table 8 lists typical welding parameters used in the EBW of Ti-6Al-4V. Tensile and fracture toughness data for Ti-6Al-4V are shown in Table 9.

TABLE 8 TYPICAL OPERATING PARAMETERS FOR ELECTRON-BEAM WELDING OF TI-6AL-4V

Laser-Beam Welding (LBW). During the past decade, LBW has become increasingly competitive as a joining process for titanium sheet and thin plate. In LBW, melting of the workpieces is produced by the impingement of a high-intensity, coherent beam of light. Because the laser beam can be readily transmitted through air, the LBW process offers significant practical advantages over conventional EBW, which requires welding in a high vacuum. However, the LBW process is more limited than EBW from the standpoint of joining thick titanium plate, with 15 kW required to produce a full-penetration weld in 13 mm (0.5 in.) thick Ti-6Al-4V. As expected, considering similarities in the heat sources, the metallurgical and mechanical properties of laser-beam and electron-beam welds are quite similar. Table 10 presents typical parameters for LBW of Ti-6Al-4V. Weld properties of laser-beam welded Ti-6Al-4V are given in Table 11.

Resistance welding is a process in which heat is produced by resistance to the flow of high electrical currents (5 to 10 kA) across the interface between two contacting surfaces. At sufficiently high current levels, melting is induced at the interface and a weld fusion zone (i.e., weld nugget) is created. At lower current levels, welding of the faying surfaces occurs entirely by a solid-state deformation or diffusion welding mechanism. Resistance welding is most commonly used to join sheet and can produce either discrete, individual spot welds or continuous, overlapping seam welds. The resistance welding parameters employed for titanium are generally comparable to those used for austenitic stainless steels, due to similarities in thermal conductivity between the two materials. As expected, the production of high-quality resistance welds requires careful cleaning of the sheet surfaces prior to welding. However, the rapid thermal cycles employed and the self-contained nature of the weld zone generally preclude the necessity for inert-gas shielding during welding. Table 12 presents typical parameters for resistance spot welding of Ti-6Al-4V.

Diffusion welding is a solid-state joining process that is finding increased application for the fabrication of complex titanium alloy components. Diffusion welding (or bonding) of titanium involves four basic steps: (1) development of intimate physical contact between the faying surfaces through deformation of asperity peaks (surface roughness) by yielding and creep at low pressures and high temperatures, (2) formation of a metallic bond, (3) diffusion across the faying surface, and (4) grain growth across the original weld interface. Prerequisites for accomplishing these steps include a clean and smooth surface combined with a low applied pressure to promote steps 1 and 2, and moderate-to-high temperatures to promote steps 3 and 4. Titanium alloys are ideal for diffusion welding because titanium exhibits a high solubility for oxygen, which promotes dissolution of surface oxides at elevated temperatures. In addition, the yield and creep strengths of titanium are low at welding temperatures, thereby enhancing stages 1 and 2 of the diffusion welding process. Diffusion welding of Ti-6Al-4V is generally performed at temperatures ranging from about 900 to 950 °C (1650 to 1740 °F), at pressures ranging from 1.3 to 13.8 MPa (200 to 2000 psi), and for times ranging from about 1 to 6 h. In combination with superplastic forming, diffusion welding has been utilized to produce a wide variety of complex Ti-6Al-4V shapes, such as honeycomb panels for aerospace applications.

Other Weld Processes. A wide variety of more specialized welding processes have been used to join titanium, including flash-butt welding, continuous-drive and inertia friction welding, ultrasonic welding, and explosive welding. In general, these processes have been effective, producing defect-free joints with properties that depend principally on the cooling rates from high temperatures and the characteristics of the resulting transformed-beta microstructure.

Special Welding Precautions and Requirements. Production of high-quality welds in titanium and titanium alloys requires meticulous preweld cleaning of the workpiece and consumables and adequate gas shielding to prevent atmospheric contamination. Mill-annealed titanium sheet and plate are generally supplied in a condition that requires only

the removal of surface grease, oil, and dirt. Such cleaning is normally accomplished by wiping with or dipping in a nonchlorinated solvent such as acetone or methyl-ethyl-ketone (MEK). Materials that exhibit a light oxide scale as a result of heat treatment below about 600 °C (1110 °F) or that contain entrapped oil from machining operations should be pickled for 5 to 10 min in a solution of 30 to 40% nitric acid and 4 to 5% hydrofluoric acid in water at a temperature between 20 and 70 °C (68 and 160 °F). Heavier oxide scales resulting from high-temperature heat treatment or thermomechanical processing may require cleaning in a molten salt bath or mechanical removal, followed by pickling. Pickled pieces should be rinsed in water, dried, and either directly welded or wrapped in clean plastic. All handling should be performed with clean white gloves. Weld contamination can also result from filler metal that has become dirty due to inadequate storage or careless handling prior to or during the welding operation. Degreasing the filler rod or wire is generally sufficient to eliminate contamination problems originating from these sources.

Effective shielding of the weld zone from the atmosphere during welding is extremely important in ensuring maximum weld ductility and toughness and in reducing the potential for solid-state weld cracking. Optimum shielding conditions are provided by welding within a permanent or collapsible clear plastic enclosure that has been evacuated and purged with argon (dew point, -24 °C, or -11 °F). Alternatively, localized trailing and backing shields can be used, particularly for automatic welding of simple joint geometries (for example, automatic butt welding of sheet). Use of localized shielding for manual welding of complex parts, although feasible, requires specially designed shielding fixtures and generally is not recommended. Fortunately, evidence of titanium weld contamination is readily apparent by discoloration of the weld surface, with a change from bright silver to straw, to magenta, to blue, with a gradual increase in the level of contamination. Severe contamination is associated with a white or gray powdery-appearing weld surface, and is often accompanied by solid-state cracking in the weld metal. In many high-performance applications, a bright silver color is required, although a light straw color may be accepted in less-critical applications.

Because titanium alloy welds are commonly used in fatigue-critical applications, a stress relief operation is generally required following welding. Specific stress-relief temperatures and times depend on the base-metal microstructure (Table 3). In order to prevent property degradation, stress relieving should be performed on components free of surface contamination and in an inert or vacuum environment.

Weld Design Criteria and Limitations. Designers of titanium welded structures must consider both welding process applicability and the physical characteristics and mechanical properties of the welds. From a welding process stand-point, an efficient design will utilize a welding process optimally suited to a particular material thickness and joint configuration. Such process suitability is also based on component size and shape (for example, whether the component will fit in an available EBW chamber, or whether the entire part can be suitably protected from the atmosphere during GTAW or PAW), the cost of producing the weld (including both capital equipment and operating costs), and postweld processing requirements.

The design of titanium welded structures is also influenced by the characteristics and mechanical properties of a joint produced by a particular welding process. Physical characteristics of the weld, including undercut or underfill in fusion welds, upset in solid-state welds, and weld distortion are important considerations, because these characteristics affect not only the physical dimensions of the component but also joint mechanical properties. Obviously, the mechanical properties of the joint, as influenced by the integrity and metallurgical structure of the weld zone, are the principal considerations in weld design. As indicated above, low fusion zone ductility and toughness in rapidly cooled welds, and poor axial fatigue behavior in welds containing defects, are important characteristics of welds that may influence the design of the welded component.

Welding Specifications. The American Welding Society has published two specifications related to welding of titanium. AWS Specification 5.16, "Specification for Titanium and Titanium Alloy Bare Welding Rods and Electrodes," provides requirements for titanium and titanium-alloy welding rods for use with GTAW and GMAW processes (see the article "Welding of Titanium Alloys" in this Volume for filler metal compositions). Although the basic specification principally covers filler metal chemical composition requirements, a rather lengthy appendix presents additional general information on welding of titanium, including toughness data for alpha-beta titanium alloy welds. AWS Specification D10.6, "Recommended Practices for Gas Tungsten-Arc Welding of Titanium Pipe and Tubing," is specific to single-phase alpha alloys.

Numerous additional specifications developed by the government and by industry discuss the procedural aspects of the welding of titanium and set forth minimum weld quality and mechanical property requirements. These specifications may be quite general or very specific, describing in detail the fabrication or weld repair of an individual component.

Selection and Weldability of Advanced Titanium-Base Alloys

David H. Phillips, Edison Welding Institute

Introduction

ADVANCED TITANIUM-BASE ALLOYS can generally be categorized as having conventional (terminal phase), intermetallic, or titanium-matrix composite structures. Conventional alloys can be further subdivided, on the basis of the amount of beta phase that is present, into four families: near-alpha, alpha-beta, near-beta, or metastable-beta (Table 1). Intermetallics that are based on titanium most commonly include alpha-2, gamma, and orthorhombic systems. Although the phrase titanium-matrix composite covers a potentially wide range of matrix materials and either continuous or discontinuous reinforcements, the most common composite used is continuous silicon-carbide-reinforced Ti-6Al-4V. This article will describe the physical metallurgy of each alloy category and its families, followed by a brief discussion on the weldability of each.

The physical metallurgies of selected alloys from each family are described below.

Near-Alpha Alloys. The alloy Ti-1100 was developed in response to a requirement for higher creep properties in Ti-6242S. It was determined that, by adjusting the tin and molybdenum compositions and adding silicon, significant improvements to the creep properties could be realized (Ref 1). Because it was developed for a maximum use temperature of 595 °C (1100 °F), it was named Ti-1100. The processing of this alloy usually involves a final beta forge, followed by an 8-h stabilization at 600 °C (1110 °F). This results in a fully transformed acicular structure, which is the proper microstructure for most applications.

The near-alpha alloy IMI-834 was developed for applications requiring a better balance of creep and fatigue properties. Because fully transformed microstructures are not ideal, in terms of fatigue, IMI-834 was developed to facilitate processing into a duplex microstructure. This was achieved by adding carbon, which stabilizes the alpha phase, thus

increasing the size of the alpha-beta phase field. As a result, although careful control is required, a duplex microstructure can be achieved through subsequent alpha-beta processing (Ref 2). The microstructure typically contains 15% primary alpha. Niobium was added to increase oxidation resistance during high-temperature exposures, and silicon was added to improve strength and creep resistance.

Alpha-Beta Alloys. The need for titanium alloys with higher levels of toughness led to the development of Corona 5. This alpha-beta titanium alloy has intermediate strength and exceptionally high fracture toughness. In order to achieve the latter property, this alloy is typically processed high in the alpha-beta phase field, which results in an alpha and beta microstructure containing moderately high aspect ratio primary alpha particles. One of the principal attractions of this alloy is that its strength level can easily be adjusted by modifying the dispersion of the fine alpha (transformed beta) phase (Ref 3).

Near-Beta Alloys. Ti-10V-2Fe-3Al, which is considered to be a relatively high-strength near-beta alloy, can be processed for either high strength and medium toughness or moderate strength and high toughness. It is typically solution treated and aged, which results in a mostly transformed alpha and beta microstructure.

Metastable-Beta Alloys. The Beta 21S alloy was developed primarily as a material that had acceptable high-temperature properties and oxidation resistance, could be readily cold rolled, and was age hardenable. These features (primarily the cold rollability) make it an excellent candidate as a matrix material for titanium-matrix composites. Base-metal processing usually involves the hot and cold working of the ingot to form billet or strip product, followed by solution annealing, cold forming to near-net shape, resolution annealing, and then aging. The fine alpha platelets that precipitate during the aging process provide increased strength in the alloy. The resultant microstructure contains the fine alpha platelets in a beta-phase matrix.

Beta C is a metastable-beta alloy that can be processed and heat treated to provide an excellent combination of yield and tensile strengths, ductility, fracture toughness, and fatigue strength (Ref 4). The alloy contains the beta-isomorphous elements molybdenum and vanadium, as well as the sluggish beta-eutectoid element chromium at levels that depress the beta transus temperature to approximately 750 °C (1380 °F) and promote retention of the high-temperature beta phase down to room temperature upon air cooling. A solution heat treatment, followed by aging, promotes the precipitation of a fine distribution of alpha phase in the beta-phase matrix.

Intermetallics. Titanium intermetallics consist primarily of the titanium aluminides alpha-2 and gamma, as well as the orthorhombic plus beta types of alloys. The aluminides, as shown on the titanium-aluminum phase diagram of Fig. 1, consist of two alloy families: alpha-2, which is based on the Ti_3Al intermetallic, and gamma, which is based on the titanium-aluminum intermetallic. These alloys offer greater stiffness and improved specific creep resistance, and they are capable of extending the use temperature range of conventional titanium alloys. The orthorhombic alloys contain large amounts of niobium, which promotes formation of the orthorhombic phase, Ti_2AlNb.

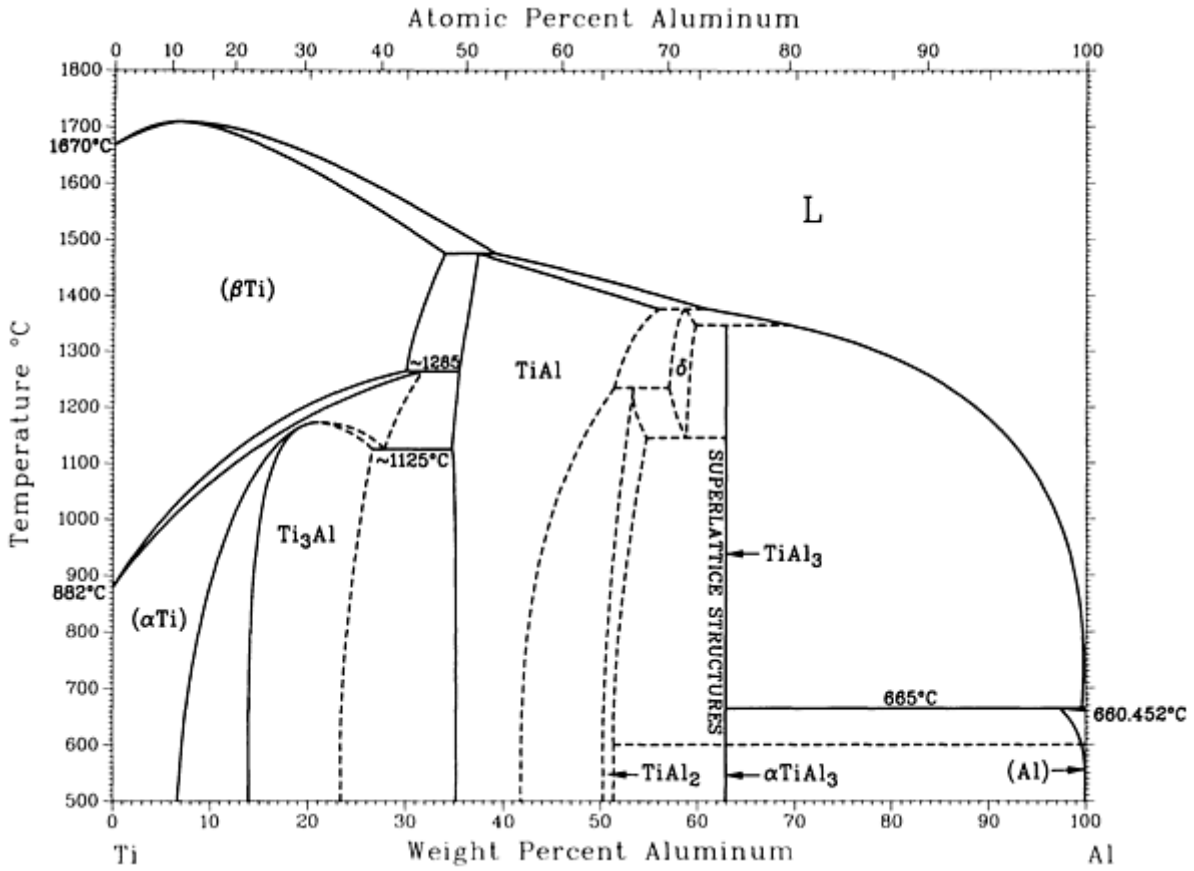

FIG. 1 TITANIUM-ALUMINUM PHASE DIAGRAM. SOURCE: REF 5

Alpha-2 alloys represent a growing family of intermetallics that contain from 14 to 25 at.% aluminum, which places them in the Ti_3Al phase field of Fig. 1. They usually contain beta-stabilizing elements, such as niobium and molybdenum, to promote beta-phase retention and ductility. These alloys are typically alpha-beta processed, resulting in a microstructure similar to that of conventional alloys, which consists of islands of equiaxed primary alpha-2 in a matrix of transformed beta. When compared with conventional titanium alloys, alpha-2 alloys offer higher temperature capabilities (from 100 to 150 °C, or 180 to 270 °F, higher), but have reduced room-temperature toughness and ductility properties (3 to 6% elongation).

The gamma alloy family, which is growing even more rapidly than the alpha-2 alloy family, typically contains from 45 to 52 at.% aluminum, which places these alloys primarily in the gamma phase field, with some overlap in the gamma/alpha-2 phase field. This results in a range of alloy microstructures, including single-phase gamma (TiAl) and duplex structures containing varying amounts of alpha-2 phase (Ti_3Al). Duplex microstructures are generally preferred, because of their higher ductility. Alloying elements such as niobium, chromium, vanadium, tantalum, manganese, and molybdenum are added in small amounts (generally from 2 to 4 at.%) to improve properties such as room-temperature ductility and oxidation resistance. The gamma alloys are more difficult to thermomechanically process than are the alpha-2 alloys, primarily because of their very high strengths at elevated temperatures. Accordingly, compared to alpha-2 alloys, the gamma alloys offer temperature capabilities that are from 100 to 150 °C (180 to 270 °F) higher. They also are known to suffer from low fracture toughness and ductility, although aggressive alloy development programs are currently attempting to improve these properties.

Orthorhombic alloys represent a new class of alloys based on the orthorhombic and beta phases. These alloys offer temperature capabilities similar to those of the alpha-2 alloys, but with higher ductilities and toughness at low temperatures. Although these alloys are similar to alpha-2 alloys, a higher niobium content results in an orthorhombic extension of the hexagonal lattice. The large amounts of niobium also result in a highly stabilized beta phase, compared with alpha-2 alloys. Processing is similar to that used with other titanium alloys. Forging is typically conducted below the beta transus temperature, resulting in a two-phase orthorhombic plus transformed-beta microstructure. A direct age then can be subsequently applied to develop properties.

Titanium-Matrix Composites. Although many titanium matrix/fiber combinations are currently being evaluated by aerospace companies and titanium producers, the most popular composite consists of a conventional Ti-6Al-4V or Ti-6242 matrix with layers of continuous silicon-carbide fibers. The layers can be either unidirectional or cross-ply. Two manufacturing techniques can be used: a foil/fiber/foil approach, in which layers of monolithic foil and fiber sets are either vacuum hot pressed or hot isostatically pressed to form the composite, or a plasma-spray approach, in which the composite is built up by sequentially winding individual layers of fibers and then spraying the monolithic layers, followed by consolidation using either vacuum hot pressing or hot isostatic pressing.

Selection and Weldability of Advanced Titanium-Base Alloys

David H. Phillips, Edison Welding Institute

Weldability

There are many weldability (fusion welding) concerns associated with advanced titanium alloys. These differ appreciably from the weldability concerns that are characteristic of steels, such as hydrogen cracking, or of superalloys, such as strain age or liquation cracking. The weldability problems associated with advanced titanium alloys are related to their microstructural sensitivity to high heat input and rapid cooling rates. These thermal excursions, which are characteristic of many welding processes, can result in excessive beta grain growth and the formation of undesirable solid-state transformation products. The affected microstructures typically suffer from poor ductility and toughness. Such effects can be minimized, however, through proper welding practices, such as those discussed below.

Conventional Alloys. Each of the four families previously identified are described below in terms of weldability.

The near-alpha alloy Ti-1100 is generally considered to be a very weldable alloy, because of its high ductility. However, the excellent creep resistance of this alloy also means that high residual stresses will be developed when welding, especially with thick sections. These stresses may have to be relieved by a postweld heat treatment following welding, in order to avoid cracking.

The near-alpha alloy IMI 834 is also considered to be weldable, but the weld fusion zone and heat-affected zone (HAZ) may be void in primary alpha phase. These regions may not retain a good balance of creep and fatigue properties, for which IMI 834 is designed.

Alpha-Beta Alloys. The Corona 5 high-toughness alloy can be successfully welded, but it requires carefully controlled cooling rates, as well as postweld heat-treatment conditions. Excessively high cooling rates can result in the formation of orthorhombic martensite, a structure that exhibits inferior strength and fracture toughness. The aging of this martensite at low and intermediate postweld heat-treatment temperatures results in high strength, but low ductility and fracture

toughness. However, through proper cooling and postweld heat treating, a fine alpha-beta fusion zone and HAZ microstructure that exhibits good mechanical properties can be created.

Near-Beta Alloys. The Ti-10V-2Fe-3Al alloy is very weldable in the heat-treated condition. Tensile and fracture toughness values that are near those of the base metal can be achieved with as-welded Ti-10V-2Fe-3Al.

Metastable-Beta Alloys. Although metastable-beta titanium alloys, such as Beta 21S, are generally considered to be weldable, cooling rates should be kept relatively high, and the weld fusion zone size should be minimized to avoid the formation of coarse columnar beta fusion zone grains and large beta HAZ grains, both of which can degrade ductility (Ref 6). If a relatively fine as-welded grain structure can be achieved, then moderate weld strength and high ductility can be achieved. Postweld heat treating to precipitate the alpha phase can significantly increase weld tensile strengths, but at the expense of ductility. Higher postweld aging temperatures may result in the formation of significant amounts of alpha phase along the beta grain boundaries, which changes the fracture mode, but does not necessarily degrade the properties.

Like Beta 21S, the Beta C alloy is considered to be highly weldable, but the fusion zone and HAZ beta grain size should be minimized (Ref 4). As-welded structures are characterized by low strength and high ductility. Relatively low postweld aging treatments can significantly increase strength levels, but ductility levels will be reduced, compared with those of the base metal, because of the large beta grain size and fine alpha phase distribution. Figure 2 shows a Beta C gas-tungsten arc weld microstructure, which reveals the large beta grain size. Higher postweld aging cycles coarsen the alpha phase, which reduces the strength but increases the ductility. As with Beta 21S, the higher aging temperatures can result in significant grain boundary alpha formation, which changes the fracture mode, but does not necessarily degrade the properties.

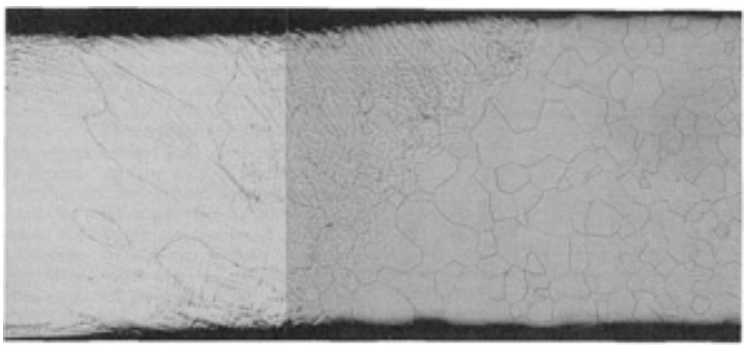

FIG. 2 MICROSTRUCTURE OF AS-WELDED GAS-TUNGSTEN ARC WELD IN BETA C SHEET

The intermetallic alloys are currently in the early stages of development. As a result, only limited weldability studies have been conducted to date. However, cursory fundamental studies have provided some indication of their weld sensitivities, and are discussed below.

Alpha-2 alloys form a similar weld and HAZ to many conventional alpha-beta titanium alloys. However, because of limited ductility and notch sensitivity, alpha-2 alloys are susceptible to solid-state fusion zone and HAZ cracking. Preheating to reduce residual stress and promote a more-ductile fusion zone and HAZ microstructure may be required in order to eliminate cracking. Weldability can also be improved by minimizing the size of the weld fusion zone and maximizing the cooling rate through the use of high-energy-density welding processes, such as laser-beam or electron-beam welding. Although this has the effect of retaining the metastable-beta phase, which can then be postweld heat treated, cracking may also occur during the heat treatment. Figure 3 shows cracking in the root of an alpha-2 electron-beam weld.

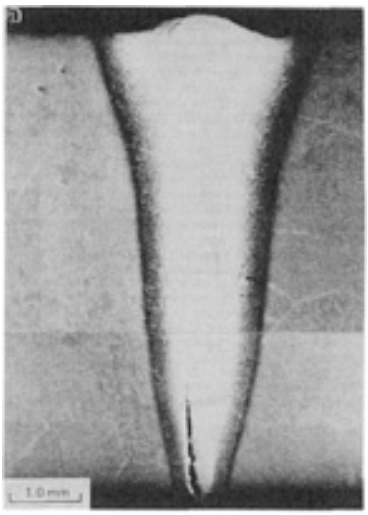

FIG. 3 CRACKING IN ALPHA-2 ELECTRON-BEAM WELD

Gamma Alloys. The gamma fusion zone and weld HAZ microstructures are significantly different from those of other titanium alloys. Depending on the weld process and metallographic technique used, the HAZ adjacent to the fusion zone can be nearly indistinguishable from the base-metal microstructure. Excessive grain growth does not appear to be an issue with gamma weldments. Because of low ductility and a high modulus, gamma alloys are very susceptible to weld fusion zone and HAZ cracking, resulting in the requirement for a weld preheat or controlled cooling.

Orthorhombic alloys are more ductile than the alpha-2 and gamma alloys, and are therefore easier to weld. Because of high beta-phase stabilities, a large retained-beta-phase HAZ will result from welding. Postweld heat treatments may be required to achieve an optimum combination of properties.

Titanium-Matrix Composites. The weldability issues relative to the monolithic titanium alloys also apply to titanium-matrix composites, with the additional complication of fiber/matrix interaction. Although some fiber damage from the welding process should not significantly degrade the properties, the damage should, of course, be minimized, where possible. Joint design is especially critical with titanium-matrix composites. The selection of a joining process is also critical, where processes such as brazing, solid-state diffusion welding, or transient liquid phase bonding may be required to minimize fiber damage. These processes eliminate or minimize base-metal melting that would damage the fibers.

Selection and Weldability of Heat-Treatable Aluminum Alloys

Richard P. Martukanitz, Applied Research Laboratory, Pennsylvania State University

Introduction

THE HEAT-TREATABLE ALUMINUM ALLOYS provide good strength and toughness in engineering applications while maintaining the low density and corrosion resistance of aluminum. These attributes allow the heat-treatable alloys to be used in a wide variety of applications, which include the aerospace, transportation, shipbuilding, tankage, piping, and appliance industries. The majority of these alloys are easily welded by the conventional arc welding processes (gas-metal arc and gas-tungsten arc welding), resistance spot and seam welding processes, as well as the high-energy processes (laser-beam and electron-beam welding).

However, these alloys also possess certain characteristics inherent to all aluminum alloys that must be considered during welding (Ref 1). Aluminum possesses a tenacious oxide that not only prevents corrosion, but may also impair welding if not minimized. This is achieved by mechanically or chemically removing heavy oxides prior to welding and using cathodic cleaning during direct current electrode positive (DCEP) gas-metal arc welding (GMAW) or alternating current gas-tungsten arc welding (GTAW). The high thermal conductivity of aluminum alloys requires the use of higher heat input for welding when compared to ferrous alloys. This requires greater welding current during arc welding of aluminum alloys. The high coefficient of thermal expansion of aluminum may also result in greater distortion when compared to ferrous alloys. Hence, aluminum is typically arc welded using high currents and high travel speeds. When in the liquid state, aluminum alloys possess a high solubility for hydrogen and very low solubility after solidification. Hence, proper cleaning and shielding must be utilized to ensure the production of welds free of gas porosity. Finally, aluminum alloys, and particularly the heat-treatable alloys, are sensitive to weld cracking. This condition is most easily avoided by proper filler and base alloy selection and adequate filler metal dilution. Anticipation of these characteristics and general knowledge of these materials allow the heat-treatable aluminum alloys to be readily welded.

Selection and Weldability of Heat-Treatable Aluminum Alloys

Richard P. Martukanitz, Applied Research Laboratory, Pennsylvania State University

Description of Heat-Treatable Aluminum Alloys

Designation Systems. The mechanical, physical, and chemical properties of aluminum alloys depend upon composition and microstructure. The addition of selected elements to pure aluminum greatly enhances its properties and usefulness. Because of this, most applications for aluminum utilize alloys having one or more elemental additions. The major alloying additions used with aluminum are copper, manganese, silicon, magnesium, and zinc. The total amount of these elements can constitute up to 10% of the alloy's composition (all percentages given in weight percent unless otherwise noted). Impurity elements are also present, but their total percentage is usually less than 0.15% in aluminum alloys. The two most commonly used methods of increasing the strength of aluminum alloys are to disperse alloying elements in solid solution and cold work the alloy, or to dissolve the alloying elements into solid solution and precipitate them throughout the alloy's matrix as strengthening particles (Ref 2). Alloys in which the first method applies are referred to as the work-hardenable alloys, and the latter method describes the precipitation-hardenable or heat-treatable alloys.

The designations used throughout North America for wrought aluminum alloys involve four digits, with the first digit indicating the major alloying additions, such as 6061 alloy representing the 6*xxx* alloy series. Aluminum casting alloy designations also involve four digits and may be proceeded by a letter to distinguish impurity levels or modifications of an original classification, such as A356.0 casting alloy. It should be pointed out that the fourth digit, which is separated from the others by a decimal point, indicates the product form (ingot or casting). The designations representing the heat-treatable wrought aluminum alloys are the 2*xxx* series (A1-Cu), the 6*xxx* series (Al-Mg-Si), and the 7*xxx* series (Al-Zn). The various combinations of alloying additions and strengthening mechanisms used for wrought aluminum alloys are shown in Table 1. The 8*xxx* aluminum alloy series denotes "other" major alloying constituents and may be found in both the work-hardenable and precipitation-hardenable classes of alloys. Table 2 provides the nominal composition of some of the common heat-treatable aluminum alloys (Ref 3). Included in Table 2 are compositions of selected heat-treatable casting alloys (Ref 4) and the recently commercialized aluminum-lithium alloys (Ref 5). Welding characteristics of aluminum-lithium alloys are described in the article "Selection and Weldability of Aluminum-Lithium Alloys" in this Volume.

In commercial product forms, such as aluminum sheet, plate, extrusions, and forgings, these alloys have also undergone varying degrees of mechanical working at ambient and elevated temperatures. It is the combination of alloying additions and thermal-mechanical processing that imparts the desired characteristics to the product. Common considerations in designing alloy compositions and processing practices are strength, toughness, and resistance to corrosion.

The temper designation, which follows the alloy designation, is used to describe the thermal and mechanical processing history of the material. The common temper designations for aluminum alloys utilize an H to denote work-hardening, a T to describe various heat-treatment sequences, or an O to represent annealed material. The most common product forms of the heat-treatable alloys dictate the use of either the T or O tempers, such as 6061-T6 or 6061-O. One or more numbers may follow the T to indicate the specific sequence of thermal treatments. Table 3 summarizes the numerical designations used to describe the specific heat-treating sequences of the T-tempers (Ref 6). Additional information on systems for designating aluminum and aluminum alloys can be found in the article "Alloy and Temper Designation Systems for Aluminum and Aluminum Alloys" in Volume 2 of the *ASM Handbook.*

Metallurgy. Wrought alloys that constitute heat-treatable (precipitation-hardenable) aluminum alloys include the 2*xxx*, 6*xxx*, 7*xxx*, and some of the 8*xxx* series alloys. They develop their maximum strength from appropriate solution, quenching, and precipitation treatments. The precipitation mechanism requires alloying elements with appreciable solid solubility in aluminum at elevated temperatures, but with limited solubility at lower temperatures. The solution heat treating operation, which involves heating the alloy to an elevated temperature, allows the alloyed elements to form a solid solution with aluminum. The temperature is then quickly reduced by quenching the material in water to create a supersaturated solid solution. A lower-temperature precipitation process, also referred to as artificial aging, is then used to precipitate strengthening phases throughout the metal in a controlled fashion. The driving force for precipitation is the supersaturation present after quenching.

This procedure is illustrated using the partial phase diagram for the aluminum-copper system in Fig. 1. Superimposed on the phase diagram are the temperature ranges used for solution heat treating and precipitation heat treating for a composition representing an aluminum alloy containing 4.0% Cu. Increasing the temperature of the 4.0% Cu alloy to 525 °C (980 °F) causes the copper to form a solid solution. When quenched to room temperature, the solid solution becomes supersaturated. If allowed to become stable, this condition is referred to as a T4 temper. Aging the alloy at a temperature of 175 °C (350 °F) causes nucleation and growth of strengthening precipitate. After solution heat treating and aging, the alloy condition is described as being in the T6 temper.

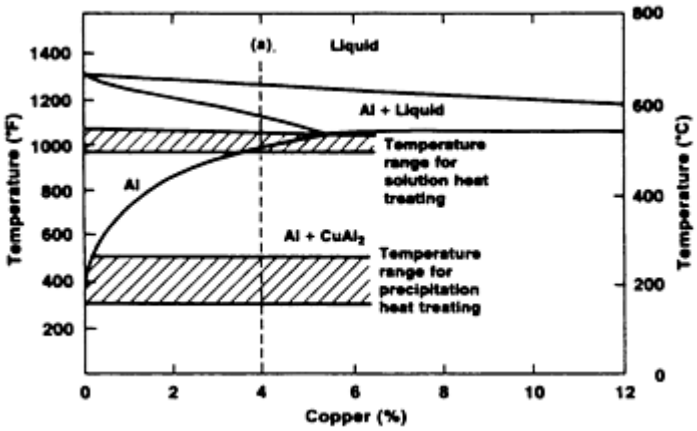

FIG. 1 PARTIAL PHASE DIAGRAM FOR THE ALUMINUM-COPPER SYSTEM SHOWING TEMPERATURE RANGES FOR SOLUTION AND PRECIPITATION HEAT TREATING

Many times these strengthening precipitates are not the equilibrium phases, such as $CuAl_2$ for the case of the 4.0% Cu alloy, but metastable phases. The metastable precipitates that form are determined by the time and temperature of the precipitation heat treating practice. The precipitation sequence for the aluminum-copper system is shown below:

$$\text{SOLID SOLUTION} \rightarrow \text{GP1} \rightarrow \text{GP2} + \theta'' \rightarrow \theta' \rightarrow \theta \quad (CuAl_2) \qquad \textbf{(EQ 1)}$$

In this system, strengthening is due to the formation of localized concentrations of copper atoms forming Guinier-Preston zones (GP1 and GP2) that are structurally coherent with the aluminum matrix. At longer aging times and higher aging temperatures the number of Guinier-Preston zones increase and lead to increased strength; the maximum strength is regarded as the peakaged condition. At still higher temperatures or longer times the Guinier-Preston zones are replaced by the noncoherent, metastable precipitates (θ" and θ'). The decrease in the amount of Guinier-Preston zones formed and the loss of particle coherency result in a subsequent reduction of strength, termed the overaged condition. Figure 2 shows the relationship between strength and precipitate formation during aging of an aluminum 4.0% Cu alloy at 190 °C (375 °F) and 130 °C (265 °F) (Ref 7).

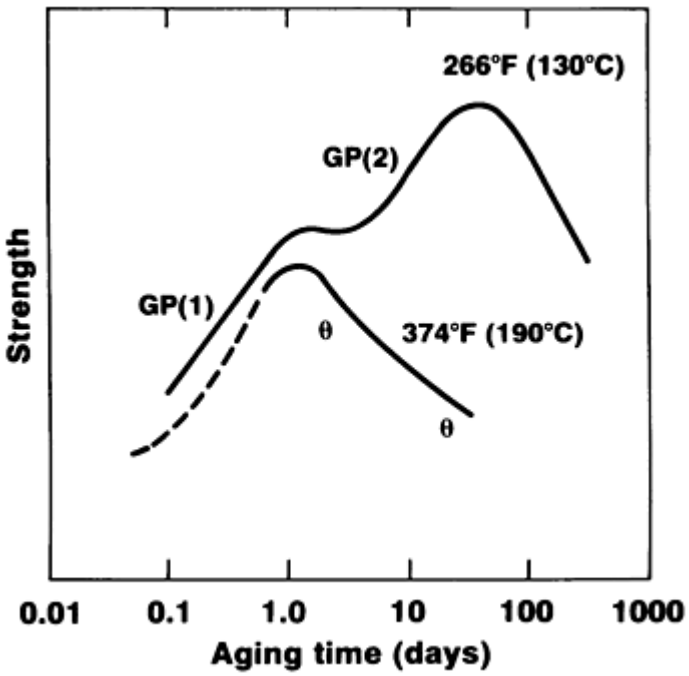

FIG. 2 RELATIONSHIP BETWEEN STRENGTH AND PRECIPITATE FORMATION DURING AGING OF AN AL-4CU ALLOY. SOURCE: REF 7

Characteristics and Applications. Alloying additions and subsequent thermal and mechanical processing dictate characteristics such as strength, toughness, and corrosion resistance of the heat-treatable aluminum alloys. However, it is usually the combination of these properties, that is, strength versus toughness, that is controlled, depending on application requirements. The utility of the heat-treatable aluminum alloys is greatly enhanced by the wide variety of product forms available. This includes sheet, plate, rod, bar, extruded shapes, forgings, and castings.

The 2*xxx* series alloys, having copper as the primary alloying addition, possess high strength but somewhat lower corrosion resistance than most other aluminum alloys. Many of these alloys also possess relatively good elevated-temperature strength. Magnesium is also added to the 2*xxx* series alloys for increased strength but results in greater weld crack sensitivity. Alloy 2024 is one of the highest strength 2*xxx* alloys and is used extensively in the aircraft industry; however, the 1.5% nominal Cu content of 2024 hinders its weldability due to increased weld crack sensitivity. Alloys having controlled levels of magnesium, such as 2014, 2219, and 2519, are utilized for applications requiring good weldability. Generally, these alloys provide good machinability, but less formability, than other heat-treatable aluminum

alloys. Some applications of the 2*xxx* alloys are aircraft skin sheet, automotive panels, ballistic armor, and forged and machined components.

The 6*xxx* series alloys containing magnesium and silicon provide moderate strengths and good corrosion resistance in relation to other heat-treatable aluminum alloys. Because they are easily extruded, they are available in a wide range of structural shapes, as well as sheet and plate products. The versatility of these alloys is represented in 6061, which is one of the most commonly used aluminum alloys. Typically, the 6*xxx* alloys have good formability and good weldability. The 6*xxx* series alloys are used in autobody sheet, structural members, architectural panels, piping, marine applications, screw machine stock, and many other applications.

The 7*xxx* series provides the highest strength of all aluminum alloys, although this claim is being challenged by the recently developed aluminum-lithium alloys. High strength in the 7*xxx* alloys is achieved by alloying additions of zinc, magnesium, and often copper, combined with controlled thermal and mechanical processing. Copper, in combination with zinc and magnesium in the 7*xxx* series alloys, increases strength but hampers weldability due to increased susceptibility to weld cracking. Alloy 7075, containing nominally 5.6% Zn, 2.5% Mg, and 1.6% Cu, is a common alloy of this system having a propensity for weld cracking. Alloys 7004, 7005, and 7039 were designed for applications requiring high strength and good weldability. These alloys have limited amounts of copper that reduce the sensitivity to weld cracking. One important characteristic of the 7*xxx* series is the ability of the heat-affected zone (HAZ) in these alloys to naturally age, or become precipitation-strengthened at room temperature, after welding. Because of this, weld properties continue to improve for up to 30 days after welding. These alloys typically provide good machinability and adequate formability. Applications for the 7*xxx* alloys include aircraft construction, truck trailers, railcars, and armor plate.

Selection and Weldability of Heat-Treatable Aluminum Alloys

Richard P. Martukanitz, Applied Research Laboratory, Pennsylvania State University

Welding of Heat-Treatable Aluminum Alloys

As stated earlier, the heat-treatable aluminum alloys possess characteristics inherent to all aluminum alloys that must be considered before successful welding can be employed. These characteristics include a tenacious oxide, high thermal conductivity, high coefficient of thermal expansion, solidification shrinkage almost twice that of ferrous alloys, relatively wide solidification-temperature ranges, and high solubility of hydrogen when in the molten state. The first two items may be addressed by weld pretreatment and processing conditions--proper weld pretreating to minimize the oxide and welding at high currents and high travel speeds to ensure that adequate penetration is utilized. However, the remaining characteristics, if not carefully considered, may result in the production of welds of unacceptable quality. The high coefficient of thermal expansion and solidification shrinkage, combined with the relatively wide solidification-temperature range, makes these alloys susceptible to weld cracking. The high solubility of hydrogen in molten aluminum can result in gas porosity unless proper precautions are heeded. In addition, the degree of degradation of the HAZ for these alloys may differ markedly, depending upon weld processing conditions. An understanding of these aspects yields welds in the heat-treatable aluminum alloys having excellent joint properties.

Crack Sensitivity during Welding

Weld cracking in aluminum alloys is of concern due to aluminum's relatively high thermal expansion, large change in volume upon solidification, and wide solidification-temperature range. The weld crack sensitivity of heat-treatable aluminum alloys is especially of concern due to the greater amounts of alloying additions used for these alloys. Because of the detrimental effect of weld cracks on joint properties, the weldability of aluminum alloys is defined as its resistance to weld cracking. Weld cracking in aluminum alloys may be classified into two primary categories based on the mechanism responsible for cracking and crack location. Solidification cracking takes place within the weld fusion zone and typically appears along the center of the weld or at termination craters. Liquation cracks occur adjacent to the fusion zone and may or may not be readily apparent.

Solidification cracking, or hot tearing, occurs when high levels of thermal stress and solidification shrinkage are present while the weld pool is undergoing various degrees of solidification. The hot tearing sensitivity of any given aluminum alloy is influenced by a combination of mechanical, thermal, and metallurgical factors (Ref 8). The degree of restraint of welded assemblies plays a significant role in crack sensitivity by increasing the stress on the solidifying weld. Hot tearing occurs within the weld fusion zone and is affected by weld-metal composition and welding parameters. High heat inputs, such as high currents and slow welding speeds, are believed to contribute to weld solidification cracking (Ref 9). It follows that processes that result in minimal heat input, such as electron-beam welding, reduce weld crack sensitivity. The primary method for eliminating cracking in aluminum welds is to control weld-metal composition through filler alloy additions. Crack sensitivity, determined experimentally as a function of weld composition, is shown in Fig. 3 for various binary aluminum systems (Al-Li, Al-Si, Al-Cu, Al-Mg, and the quasibinary Al-Mg_2Si) (Ref 10, 11, 12, 13, 14, 15).

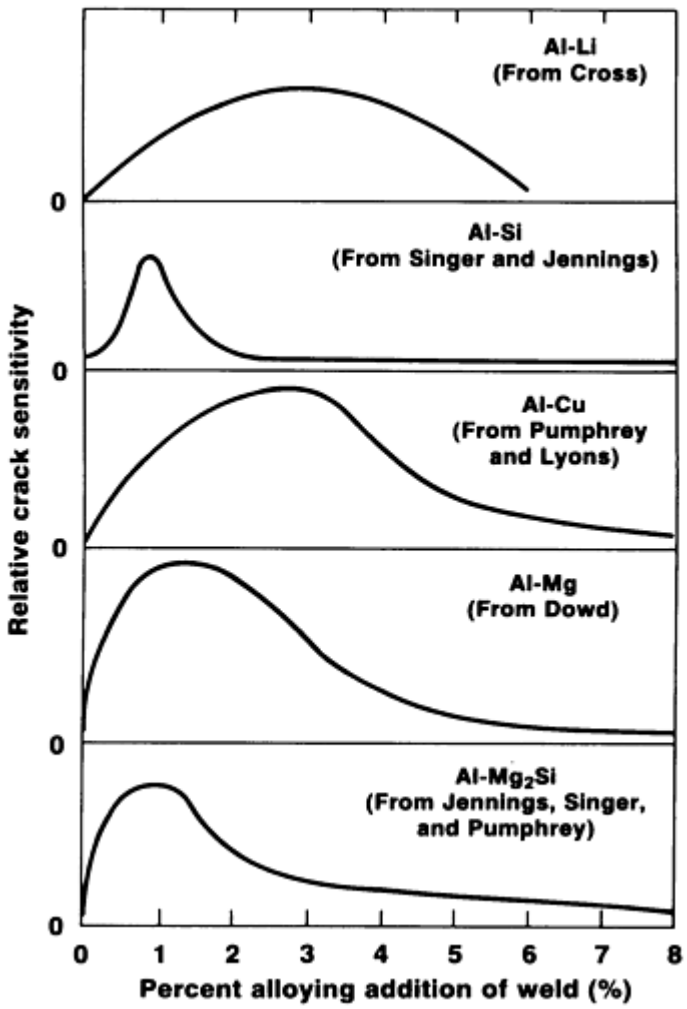

FIG. 3 RELATIVE CRACK SENSITIVITY VERSUS WELD COMPOSITION FOR VARIOUS BINARY ALUMINUM SYSTEMS. SOURCE: REF 10, 11, 12, 13, 14, 15

Although most commercial aluminum alloys are not strictly binary systems, crack-sensitivity curves based on binary systems are still useful in selecting a filler alloy to minimize weld crack sensitivity. In complex alloy systems, minor alloying additions may impact crack sensitivity by widening the temperature range in which a coherent solidifying structure is formed. This effect is shown in Fig. 4, which describes the weld crack sensitivity of two commercial quaternary aluminum systems (Al-Zn-Mg-Cu and Al-Mg-Si-Cu) and a ternary system (Al-Cu-Mg) (Ref 16, 17, 18). In all cases, the curves show the dramatic effect of minor alloying additions, such as copper or magnesium, on weld crack sensitivity. Several high-strength, precipitation-hardenable aluminum alloys rely on complex alloying additions to develop properties; however, these additions dramatically increase weld crack sensitivity. The most notable examples are alloys 2024 (Al-4.4Cu-1.5Mg) and 7075 (Al-5.6Zn-2.5Mg-1.6Cu). Increased weld crack sensitivity may also result when welding dissimilar aluminum alloys to produce weld compositions that widen the coherency temperature range, such as welding 2*xxx* series to 5*xxx* series alloys (Al-Cu alloys to Al-Mg alloys).

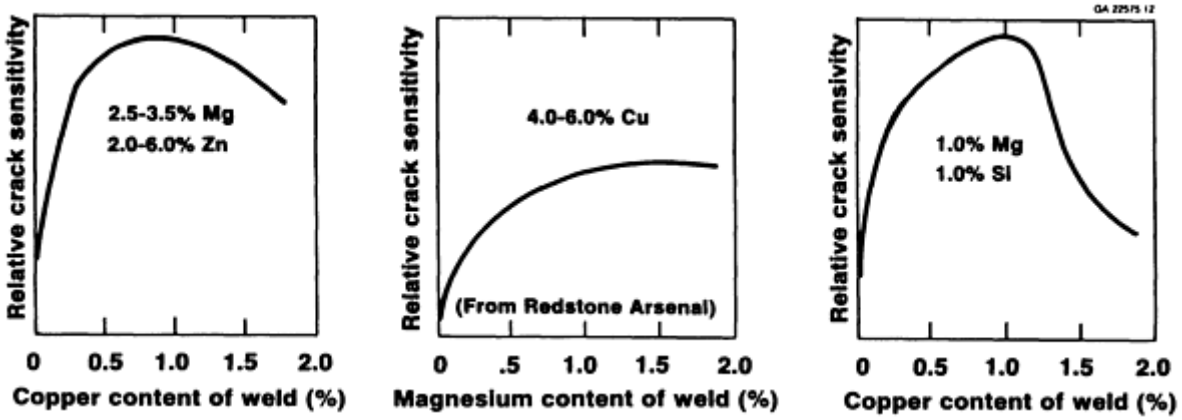

FIG. 4 WELD CRACK SENSITIVITY OF TWO COMMON QUATERNARY ALUMINUM ALLOY SYSTEMS (AL-MG-ZN-CU AND AL-MG-SI-CU) AND A COMMON TERNARY SYSTEM (AL-CU-MG). SOURCE: REF 16, 17, 18

Liquation Cracking. An important element of the HAZ for precipitation-hardenable alloys is the thin boundary layer adjacent to the fusion zone that is referred to as the partially melted region. This region is produced when eutectic phases or constituents that have low melting points (melting points below the melting point of the bulk material) liquate, or melt, at grain boundaries during welding (Ref 19). It occurs in precipitation-hardenable alloys because of the relatively large amount of alloying additions available to form eutectic phases. During welding, these phases liquate and, if sufficient stress is present, may be accompanied by tears. Under extreme conditions, continuous cracks may form along the fusion zone interface. As expected, higher heat input widens the partially melted region and makes it more prone to cracking. An example of cracks formed in this region for alloy 6013-T6 welded with 5356 filler alloy is shown in Fig. 5 (Ref 20). Filler alloy composition greatly affects whether cracks form in this liquated region (Ref 21 and 22). Filler alloys that have low-solidification temperatures provide less susceptibility to liquation cracks, since the solidification shrinkage strains occur at lower temperatures. This allows healing, or solidification, of the partially melted region to occur prior to solidification shrinkage strains.

Porosity during Welding

Porosity in aluminum weldments occurs when hydrogen gas is entrapped during solidification (Ref 23 and 24). Hydrogen has an appreciable solubility in molten aluminum and a low solubility in the solid. Figure 6 shows the solubility of hydrogen in pure aluminum at temperatures representing the solid and liquid states (Ref 25).

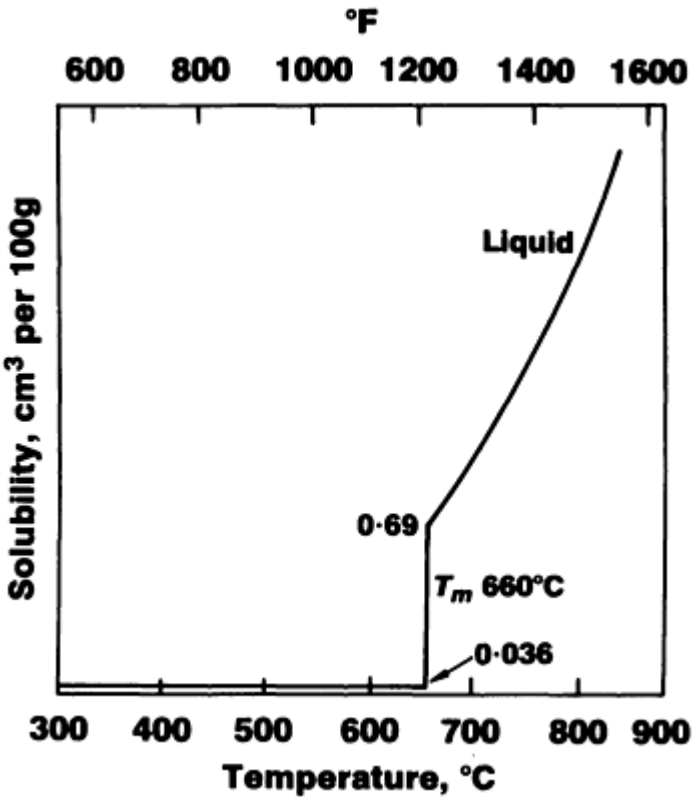

FIG. 6 HYDROGEN SOLUBILITY IN PURE ALUMINUM. SOURCE: REF 25

Hydrogen is absorbed into the molten pool during welding because of its high solubility, and it forms gas pores upon solidification due to the decrease in solubility. It is this difference in solubility that is the driving force for porosity formation (Ref 26). Once a gas bubble forms, it may be expelled from the weld by natural buoyancy or forced convection within the molten pool. Redistribution of hydrogen during solidification may also act to push pores ahead of the solidifying front. Therefore, the welding position and weld parameters may dramatically alter the amount of porosity found in solidified welds.

The expulsion of hydrogen pores may be described by the pore's buoyancy velocity and welding speed. If the solidification front is moving at a lower velocity than the pore's buoyancy velocity, gas pores may escape (Ref 27). Lower welding speeds create slower solidification fronts and favor expulsion of gas pores. Welding position may either help or hinder the expulsion of pores. In general, vertical-up welding of aluminum produces the least porosity because the solidifying pool provides easy escape of gas pores. Converse]y, overhead welding produces the greatest amount of porosity because float direction and pool convection patterns cause pores to be entrapped in the weld root during solidification.

The sources of hydrogen present in the welding system depend on the particular welding process. In arc welding these sources are: (1) hydrogen from the base metal, (2) hydrogen from the filler metal, and (3) hydrogen within the shielding gas (Ref 28). This is illustrated in Fig. 7 for GMAW. Hydrogen from the base metal may be attributed to the surface in the form of hydrocarbons (lubricants) and hydrated oxides, or it may be internal, as with castings and aluminum powder-metallurgy (PM) parts. Filler metal hydrogen is in the form of hydrocarbons (lubricants) or hydrated oxides on the surface of the filler. Hydrogen in the shielding gas is due to moisture contamination within the gas or aspiration of moist air into the gas system due to defective gas lines and couplings. A dew-point determination of the shielding gas may provide an indication of moisture contamination. Normally, a dew-point measurement of -50 °C (-60 °F) or below, measured at the gas cylinder outlet, is considered sufficient gas quality (Ref 29).

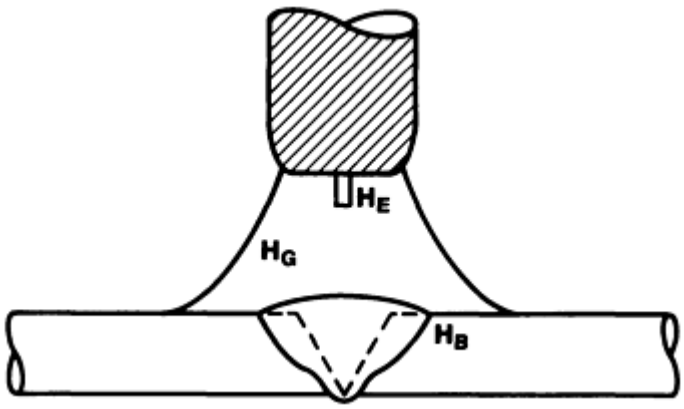

FIG. 7 SOURCES OF HYDROGEN IN GAS-METAL ARC WELDING. H_G, HYDROGEN FROM SHIELDING GAS; H_E, HYDROGEN FROM ELECTRODE; H_B, HYDROGEN FROM BASE METAL. SOURCE: REF 28

In the case of GMAW of aluminum wrought products, the filler electrode, shielding gas, and base-metal surface contaminants may contribute to gas porosity. In the case of welding aluminum castings or PM parts, internal hydrogen of the base metal typically governs pore formation (Ref 30). Because porosity in aluminum welds is attributed to a source of hydrogen contamination within the welding system, preventative measures may be taken to ensure sound welds. This begins with proper precleaning of the parts to be welded. Mill and machining lubricant must be removed by solvent degreasing before welding. Stainless steel wire brushing of the joint to remove thick mill oxides is recommended just prior to welding. During GTAW of aluminum, alternating current with sufficient electrode-positive polarity provides excellent arc cleaning action to remove surface oxides. For GMAW, procurement of quality electrodes and proper electrode storage are necessary to minimize porosity. In all cases, maintenance of gas hoses, regulators, and auxiliary equipment is required to produce porosity-free welds.

HAZ Degradation

A HAZ is created adjacent to the fusion zone and results in a degradation of base-metal properties. This degradation is caused by microstructural modifications associated with elevated temperatures experienced in this zone. For heat-treatable aluminum alloys, the HAZ is distinguished by dissolution or growth of precipitates. The response in the HAZ of 2*xxx* aluminum alloys follows dissolution, whereas the primary modification for the 6*xxx* alloys is growth of precipitates (Ref 31, 32, 33). Although the nature of these HAZs may differ, they are all diffusion-controlled and thermally dependent (Ref 34). A common method of determining the width and extent of the HAZ is by measuring the hardness across this zone. Hardness profiles for gas-tungsten arc welds of two common heat-treatable alloys, 2219-T87 and 6061-T6, are shown in Fig. 8 (Ref 35). A hardness profile for the work-hardenable alloy 5456-H116 is also shown in Fig. 8 for comparison.

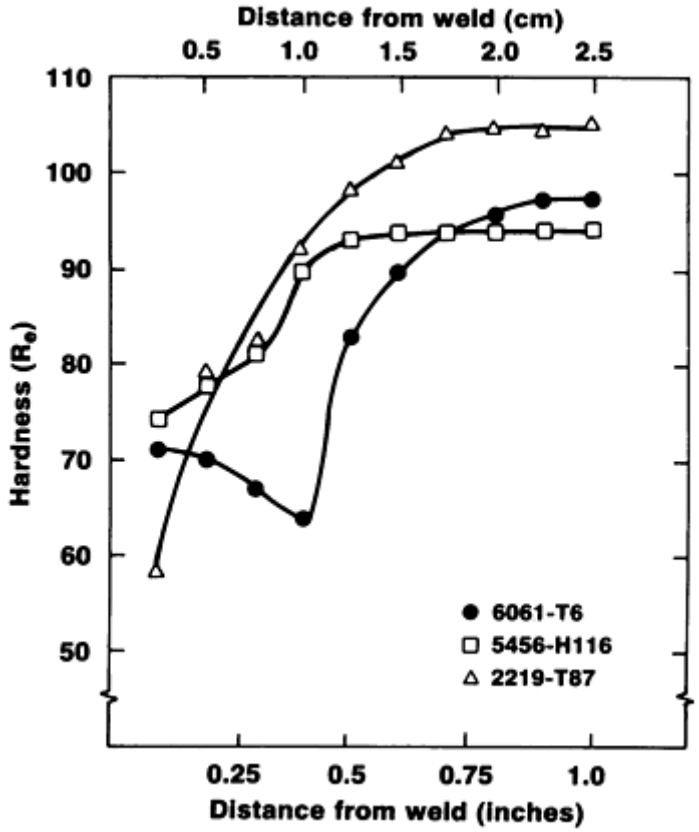

FIG. 8 HARDNESS PROFILES ACROSS THE HAZ OF GAS-TUNGSTEN ARC WELDS ON 3.2 MM (0.125 IN.) THICK 2219-T87, 5456-H116, AND 6061-T6 MADE USING CONSTANT HEAT INPUT. SOURCE: REF 35

The hardness profile for 2219-T87 exhibits dissolution of precipitates. The strengthening particles for these alloys are Guinier-Preston zones, which are metastable precipitates. The solvus curves for these phases are superimposed on the partial aluminum-copper phase diagram in Fig. 9 (Ref 31). When the temperatures in the HAZ exceed the various solvi, the respective phases are dissolved. At positions close to the fusion zone, higher temperatures are experienced and greater dissolution of strengthening phases occurs. This results in a continual decrease in strength in the HAZ of aluminum-copper alloys and is illustrated in Fig. 8 for 2219-T87 alloy.

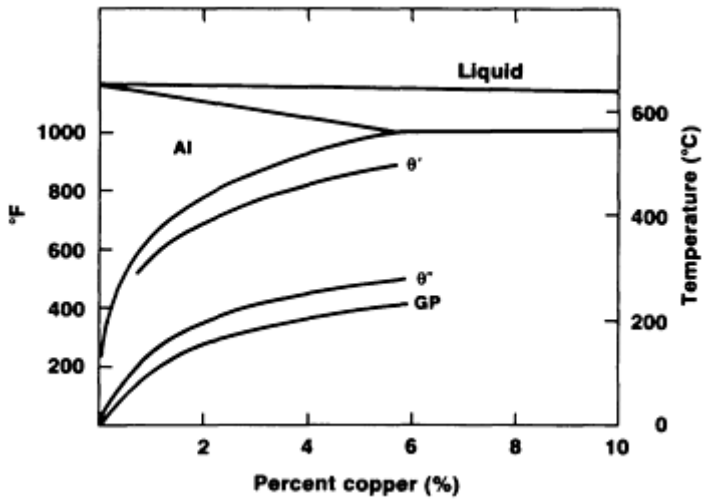

FIG. 9 PARTIAL PHASE DIAGRAM FOR THE ALUMINUM-COPPER SYSTEM SHOWING METASTABLE PHASE SOLVI. SOURCE: REF 31

The hardness profile for the HAZ of 6061-T6 is representative of the 6*xxx* series alloys and is governed by a growthlike transformation of precipitate. This system also exhibits a precipitation sequence of metastable precipitates, with the principal strengthening phases occurring early in the sequence in the form of Guinier-Preston zones. The transformation of these precipitates at elevated temperatures occurs in a smooth, continuous fashion and is closely akin to growth (Ref 31). The result is the formation of nonstrengthening phases. Due to the competing nature of the diffusion rate and supersaturation with increasing temperatures, the transformation proceeds at the greatest rate when temperatures are between 290 and 425 °C (550 and 800 °F) (Ref 36, 37, 38). The minimum hardness value for 6061-T6 in Fig. 8 represents the position in the HAZ that experiences temperatures within this range. This minimum has also been referred to as the overaged zone for these alloys. At higher temperatures, indicative of positions close to the fusion zone, particles are dissolved into solid solution and upon cooling may precipitate as strengthening phases. This contributes to the slight increase in hardness that typically occurs near the fusion zone for the 6*xxx* series alloys.

Effect of Heat Input on the HAZ. Because the metallurgical transformations of the HAZ of aluminum alloys are thermally dependent, the welding process and parameters determine the extent of base-metal degradation. High heat input and preheating increase both the degree and width of the HAZ. This is especially true for the precipitation-hardenable aluminum alloys and is illustrated for 6061-T6 welds made using various heat inputs in Fig. 10 (Ref 39). Thus, the HAZ degradation of the heat-treatable alloys can be reduced by employment of multipass welding, close control of interpass temperature, and elimination of preheating. The highest weld strengths for these alloys are achieved when interpass temperatures do not exceed 65 °C (150 °F) and welding heat input is minimized.

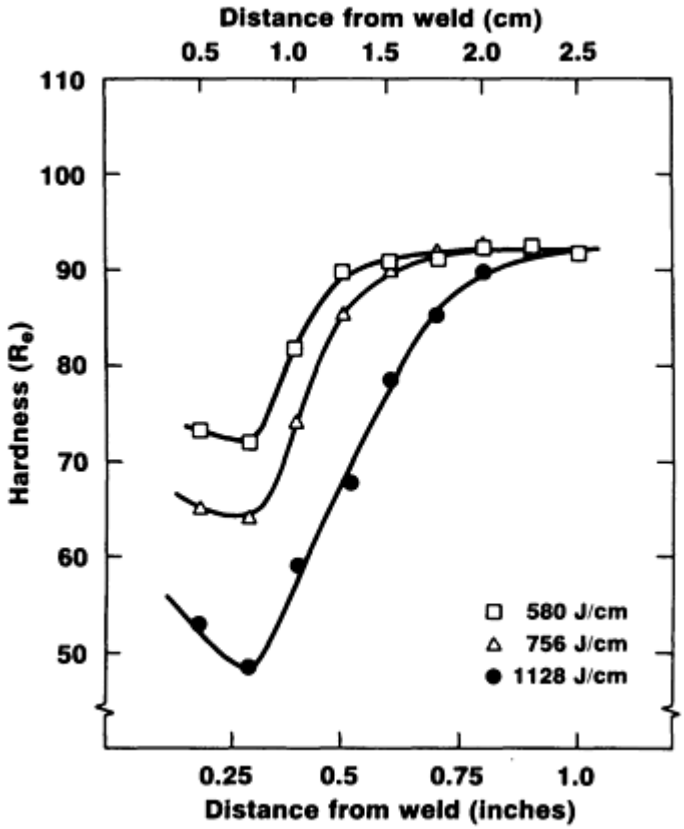

FIG. 10 HARDNESS PROFILES OF THE HAZ OF GAS-TUNGSTEN ARC WELDS ON 6061-T6 USING VARIOUS HEAT INPUTS. SOURCE: REF 39

Postweld Heat Treatment and the HAZ Postweld thermal heat treatments can also be used to improve the strength of the HAZ for heat-treatable alloys. This may involve complete postweld solution heat treating and aging or postweld aging only. Although the recovery of strength in the HAZ after postweld aging is less than postweld solution heat treating and aging, there are advantages to postweld aging only. Temperatures used for postweld aging are much lower than postweld solution heat treating, and postweld aging does not involve water quenching that imposes residual stresses and distortion to welded assemblies. However, great strides have been made in the development and application of polymer quenchants that reduce the amount of distortion observed after quenching and may complement the use of postweld solution heat treating and aging.

Figure 11 depicts hardness profiles of the HAZ for 6061-T4 and 6061-T6 starting material in the as-welded and postweld aged conditions (Ref 40). A dramatic recovery of strength in the HAZ is observed when welding 6061-T4 and postweld aging. Postweld thermal treatments may be used to recover strength in the HAZ of the heat-treatable alloys; however, when 6061-T6 is postweld aged, strength in the HAZ is increased while strength in the unaffected base metal is decreased. This is due to overaging of the 6061-T6 base metal; therefore, T4 or T3 material should be utilized when postweld aging the precipitation-hardenable alloys. The 7*xxx* series alloys possess the ability to naturally age (age at room temperature) in the HAZ. The recovery of strength is similar to postweld artificial aging, but because of the relatively low-temperature aging, the time is substantial. Usually, a period of 14 days is required for improving the HAZ strength of the 7*xxx* series alloys by natural aging.

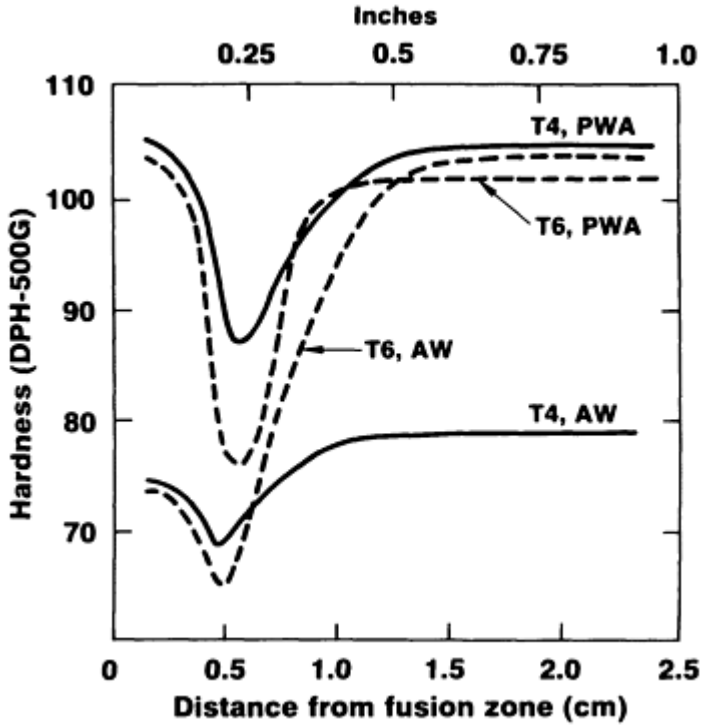

FIG. 11 HARDNESS PROFILES OF THE HAZ FOR 6061-T4 AND T6 STARTING MATERIALS IN THE AS-WELDED (AW) AND POSTWELD AGED (PWA) CONDITIONS. SOURCE: REF 40

Selection and Weldability of Heat-Treatable Aluminum Alloys

Richard P. Martukanitz, Applied Research Laboratory, Pennsylvania State University

---

Filler Alloy Selection and Properties of Welds

Although the selected base alloy and welding process greatly influence the characteristics of aluminum joints, the filler alloy plays a significant role in establishing a number of important weld properties for hem-treatable aluminum alloys. Of foremost concern is the weldability of a particular base alloy and filler alloy combination, which is defined as its susceptibility to weld cracking. Shear strength of a fillet weld, response to postweld heat treatments, and color match after anodizing are other attributes that are highly governed by the filler alloy used to produce the weld in heat-treatable aluminum alloys. Properties such as joint strength, ductility, toughness, and corrosion resistance across the weld are also dictated by the base alloy and filler alloy combination selected. The filler alloy selection chart in the article "Welding of Aluminum Alloys" in this Volume (see Table 14 in that article) provides a comprehensive guide for selecting the proper filler metal. Recently a knowledge-based system using computer software has also been constructed to allow greater interaction in selecting aluminum base metal and filler metal alloys for welding (Ref 41).

Filler Alloy Selection and Weld Crack Sensitivity

Weld crack sensitivity is most easily controlled by influencing the composition of the weld. This is achieved by selecting the proper filler alloy and ensuring adequate dilution of the filler alloy to the weld. Generally, joint designs that increase filler metal dilution (for example, square groove with gap as opposed to no gap) are beneficial in reducing the tendency for cracking. The principal filler alloys for welding aluminum are the 1*xxx* (1100), 2*xxx* (2319), 4*xxx* (4043, 4047, 4145, and 4643), and 5*xxx* (5154, 5183, 5356, 5554, 5556, and 5654) series. Nominal compositions of aluminum filler alloys are shown in Table 4 (Ref 42). Most of these alloys are high in solute to reduce crack sensitivity. Because of their narrow solidification temperature range, the 4*xxx* series filler alloys provide excellent insensitivity to weld cracking but are not applicable for welding all aluminum-base alloys. Because of the formation of large amounts of brittle magnesium-silicide (Mg_2Si), the 4*xxx* series filler alloys are not applicable for welding the 7*xxx* series alloys containing appreciable amounts of magnesium. Table 5 shows the filler alloys recommended for welding various base alloys to minimize sensitivity to weld cracking.

TABLE 4 NOMINAL COMPOSITION OF ALUMINUM FILLER METAL ALLOYS

ALLOY	COMPOSITION, WT%						
	Si	Cu	Mn	Mg	Cr	Ti	OTHER

Notes: (1) Service conditions such as immersion in fresh or salt water, exposure to specific chemicals, or a sustained high temperature (higher than 65 °C, or 150 °F) may limit choice of filler metals Filler alloys 5356, 5183, 5556, and 5654 are not recommended for sustained elevated-temperature service. (2) Recommendations in this table apply to gas-shielded arc welding processes. For gas welding, only 1100, 1188, and 4043 filler metals are ordinarily used. (3) All filler metals are listed in AWS specification A5.10. (4) Where no filler metal is listed, the base metal combination is not recommended for welding.

Source: Ref 43

(A) REFERS TO 7005 EXTRUSIONS ONLY (X-PREFIX STILL APPLIES TO SHEET AND PLATE).

(B) BASE METAL ALLOYS 5652 AND 5654 ARE USED FOR HYDROGEN PEROXIDE SERVICE. 5654 FILLER METAL IS USED FOR WELDING BETH ALLOYS FOR LOW-TEMPERATURE SERVICE (65 °C, OR 150 °F, OR BELOW).

(C) 4043 MAY BE USED FOR SOME APPLICATIONS.

(D) 4047 MAY BE USED FOR SOME APPLICATIONS.

(E) 4145 MAY BE USED FOR SOME APPLICATIONS.

(F) 5183, 5356, OR 5556 MAY BE USED.

(G) 1100 MAY BE USED FOR SOME APPLICATIONS.

(H) 2319 MAY BE USED FOR SOME APPLICATIONS.

(I) 5183, 5356, 5554, 5556. OR 5654 MAY BE USED. IN SOME CASES THEY PROVIDE IMPROVED COLOR MATCH AFTER ANODIZING TREATMENT, HIGHEST WELD QUALITY, AND HIGHER WELD STRENGTH 5554 IS SUITABLE FOR ELEVATED TEMPERATURE SERVICE.

(J) FILLER METAL WITH THE SAME ANALYSIS AS THE BASE METAL IS SOMETIMES USED.

Weld Strength and Ductility

The strength and ductility of welds in aluminum alloys are determined by a number of parameters. These may include base alloy and temper, filler alloy, welding process and parameters, use of postweld heat treatments, joint type, principal loading condition, and the presence of weld defects. As described earlier, metallurgical transformations in the HAZ of heat-treatable aluminum alloys result in a degradation of strength in this region. The degree of degradation may be related to heat input used to produce the weld. Processes that provide higher travel speeds minimize the degradation in the HAZ and typically result in higher weld strength. Postweld heat treatments may be used to recover the loss of strength in the HAZ. Postweld solution heat treating and aging provides the greatest improvement in joint strength; however, this practice requires the use of a cold-water quench that may impart unacceptable part distortion. Postweld aging, which is a lower-temperature treatment, results in a moderate improvement in joint strength and does not require water quenching. It is also appropriate to comment on the effects of loading that distinguish the properties of welded joints. The transverse tensile strength of a butt weld provides a relative indication of joint strength in service, although butt welds may also undergo multiaxial loading that hinders direct comparison to tabular data representing uniaxial behavior. In the case of fillet welds, the transverse or longitudinal shear strength (depending on the principal loading condition) obtained from shear test specimens may be used to ascertain joint performance. The strength and ductility of groove welds in the as-welded condition, the postweld aged only condition, and the solution heat treated and aged (artificially and naturally aged) condition are described in the article "Welding of Aluminum Alloys" in this Volume. Transverse and longitudinal shear strengths of fillet welds are also listed in the aforementioned article. Additional information on properties of aluminum weldments can be found in Ref 44 and 45.

Figure 12 displays strength profiles across gas-tungsten arc welds of 2219-T87 and 6061-T6 alloys. The 2219-T87 alloy was welded with 2319 filler alloy and the 6061-T6 was welded with 4043 alloy. The strength profile of the work-hardenable alloy 5456-H116 welded with filler alloy 5356 is also shown in the figure for comparison. The strength values in Fig. 12 are approximations obtained by converting hardness measurements using the empirically derived relationship for aluminum alloys (Ref 46):

$$UTS = 10,66 - 19,42 \ln\left(1 - \frac{HRE}{109}\right) \qquad \textbf{(EQ 2)}$$

where UTS is the ultimate tensile strength in ksi, and HRE is the Rockwell hardness using the E-scale.

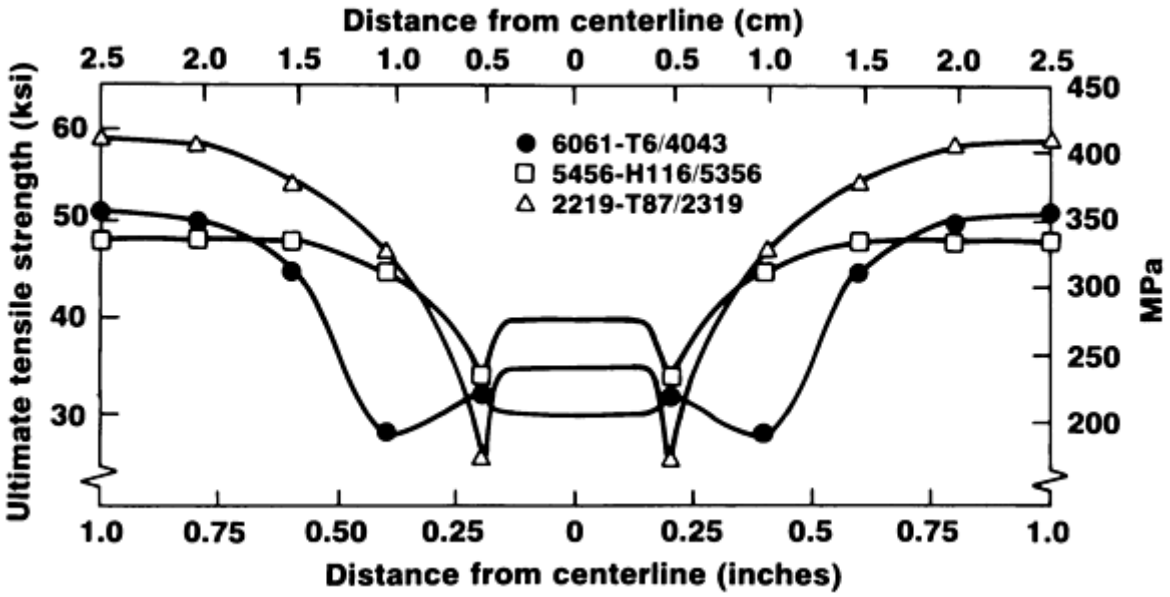

FIG. 12 STRENGTH PROFILES ACROSS ALTERNATING CURRENT GAS-TUNGSTEN ARC WELDS ON 3.2 MM (0.125 IN.) THICK 2219-T87 USING 2319 FILLER ALLOY, 6061-T6 USING 4043 FILLER ALLOY, AND 5456-H116 USING 5356 FILLER ALLOY. SOURCE: REF 35

It is evident from Fig. 12 that the degradation of strength associated with the HAZ usually dictates the strength of the joint for aluminum alloys. This is not true when weldments have been postweld heat treated, because the fusion zone may not respond to these treatments to the same degree as the HAZ.

The 2*xxx* series alloys exhibit the lowest ductility of the precipitation-hardenable alloys. This is due to the formation of brittle, copper-bearing eutectic phases at grain boundaries near the fusion zone interface. The 6*xxx* and 7*xxx* series alloys display good weld ductility. Postweld solution heat treating and aging of the heat-treat-able alloys or postweld aging only, usually decreases weld ductility.

Corrosion Resistance of Welds

Many of the heat-treatable aluminum alloys can be welded without reducing the resistance of the assembly to corrosion. However, because welding generates residual tensile stresses and modifies the parent metal structure, some alloys may have their resistance to corrosion lowered by welding. Corrosion of aluminum weldments is usually localized or preferential in nature and depends on the base alloy, filler alloy, and HAZ structure. The corrosion potential variations determined by electrode potential measurements across 2219 and 7039 weldments are shown in Fig. 13. The corrosion potential variations across the weld of the work-hardenable alloy 5456 are also shown in Fig. 13. The corrosion potentials of various base and filler alloys are also described in the article "Welding of Aluminum Alloys" in this Volume.

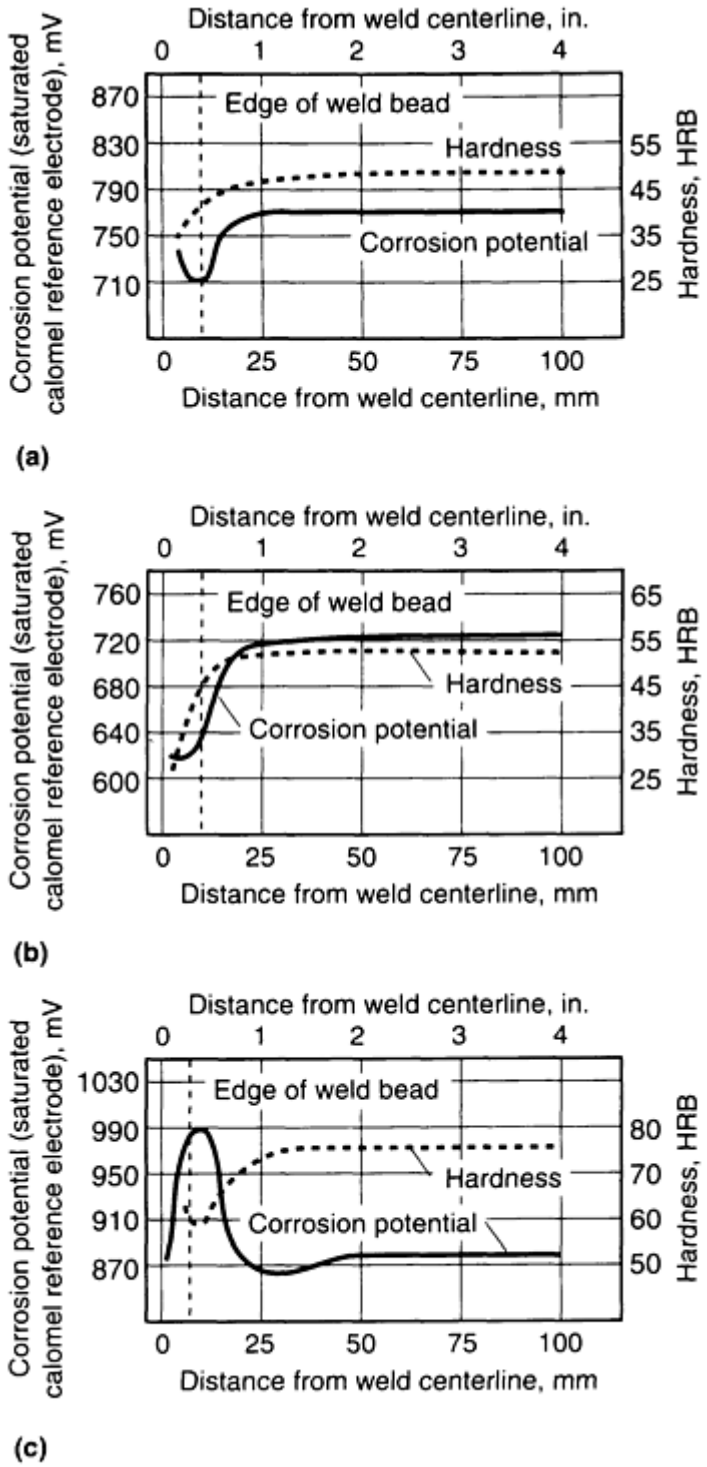

FIG. 13 PLOT OF CORROSION POTENTIAL AND HARDNESS LEVELS VERSUS DISTANCE FROM WELD CENTERLINE FOR SELECTED ALUMINUM ALLOYS. (A) ALLOY 5456-H321 (5556 FILLER METAL; DCRP-MIG WELD PRODUCED IN THREE PASSES). (B) 2219-T87 (2319 FILLER METAL; DCSP-TIG WELD PRODUCED IN TWO PASSES). (C) 7039-T651 (5183 FILLER METAL; DCRP-TIG WELD PRODUCED IN TWO PASSES). DCRP, DIRECT CURRENT REVERSE POLARITY; DCSP, DIRECT CURRENT STRAIGHT POLARITY. COURTESY OF ALCOA LABORATORIES

The 6*xxx* series alloys are highly resistant to localized corrosion after welding. The weldable alloy 2219 of the 2*xxx* series also exhibits good corrosion resistance after welding. The corrosion potential for 2219-T87 weldments produced using 2319 filler metal is shown in Fig. 13 and depicts a lower corrosion potential in the weld area as compared to the unaffected base metal. The weldable 7*xxx* series alloys produce greater sensitivity to corrosion after welding (Ref 47). In this case, the structural transformation of the HAZ due to the heat of welding makes the HAZ anodic to either the 5*xxx*

weld metal or the unaffected base metal. This mechanism is also shown in Fig. 13 for 7089-T651 welded with 5183 filler metal. The highly anodic, small area of the HAZ will pit and corrode in the presence of an electrolyte to protect both the weld metal and the much larger unaffected base metal. Postweld solution heat treating and aging of the 7*xxx* series alloys will improve their corrosion resistance; however, aluminum-magnesium filler alloys containing more than 3.5% Mg should not be used when postweld heat treating because the fusion zone can be sensitized to stress-corrosion cracking (Ref 48).

Wrought alloys usually have greater resistance to stress-corrosion cracking in the longitudinal orientation (direction of working) than in the transverse orientation or in the short-transverse orientation (through the thickness). Because of this, welding of the 7*xxx* series alloys near a base-metal edge may result in a tensile stress in the short-transverse direction sufficient to cause stress-corrosion cracking in the exposed edge. "Buttering" the edge with weld metal provides compressive stress at the edge and overcomes the stress-corrosion cracking problem. Finally, paint protection or metallizing with selected aluminum alloys can be used to reduce the general corrosion sensitivity of heat-treated aluminum weldments.

Other Joint Characteristics

Other joint characteristics may be of importance, depending upon the service requirements of the welded assembly. These may include characteristics that can affect the structural performance of the assembly, such as strength and toughness at the service temperature, as well as aesthetic qualities, such as joint color match after anodizing. Aluminum alloys are compatible with all known cryogenics; base-metal strength and weld strength generally increase at cryogenic temperatures (Ref 49 and 50). The 2*xxx* series heat-treatable alloys, as well as the work-hardenable 5*xxx* series alloys, display a good combination of strength and ductility at low temperatures. Alloy 2219 is used extensively for cryogenic applications requiring high strength and good weldability. Toughness of welds in aluminum alloys is defined as the ability of the joint to absorb energy by deformation rather than fracture catastrophically. Fracture toughness in aluminum alloy welds is typically not determined by Charpy impact tests but may be reasonably obtained by tear or tension tests involving notched specimens (Ref 51, 52, 53). Based on results of these tests, welds of 2219 and 7039 possess good notch toughness, although it must also be mentioned that welds representing the work-hardenable alloys of the 5*xxx* series also exhibit good toughness.

Although the weld and base-metal strengths of the heat-treatable aluminum alloys, particularly the 2*xxx* series, fare well at elevated temperatures up to 150 °C (300 °F), caution must be observed when selecting filler alloys for welded assemblies functioning at these temperatures. Elevated-temperature service for aluminum welds is usually defined as service at sustained temperatures above 65 °C (150 °F). Sustained elevated-temperature service of welds containing high amounts of magnesium may result in increased sensitivity to stress-corrosion cracking due to the formation of Mg_2Al_3 at grain boundaries. Therefore, most welded applications involving sustained elevated-temperature service dictate the use of filler alloys that do not contain magnesium. An exception is the use of filler alloy 5554 (containing approximately 2.7% Mg) when welds of 6*xxx* series alloys at sustained elevated temperatures also require good color match after anodizing. Typically, 2319 filler alloy is used in welds on 2*xxx* series base alloys that require good color match after anodizing. When good color match after anodizing is desired for welds in the 6*xxx* or 7*xxx* series base alloys, filler alloys of the 5*xxx* series containing magnesium are utilized. High levels of silicon in the weld when using the 4*xxx* series filler alloys result in darkening of the fusion zone in comparison to the base metal after anodizing.

Selection and Weldability of Non-Heat-Treatable Aluminum Alloys

C.E. Cross, Martin Marietta Astronautics Group; M.L. Kohn, FMC Corporation

Introduction

NON-HEAT-TREATABLE ALUMINUM ALLOYS constitute a group of alloys that rely solely upon cold work and solid solution strengthening for their strength properties. They differ from heat-treatable alloys in that they are incapable of forming second-phase precipitates for improved strength (see the article "Selection and Weldability of Heat-Treatable Aluminum Alloys" in this Volume). As such, the non-heat-treatable alloys cannot achieve the high strengths characteristic of precipitation-hardened alloys. For example, the yield strength of precipitation-hardened alloy 7075-T6 (505 MPa, or 73 ksi) is significantly greater than that of cold-worked and solution-strengthened alloy 5083-H32 (230 MPa, or 33 ksi).

The absence of precipitate-forming elements in these low- to moderate-strength non-heat-treatable alloys becomes a positive attribute when considering weldability, because many of the alloy additions needed for precipitation hardening (for example, copper plus magnesium, or magnesium plus silicon) can lead to liquation or hot cracking during welding. In addition, joint efficiencies are higher in non-heat-treatable alloys because the heat-affected zone (HAZ) is not compromised by the coarsening or dissolution of precipitates. This obviates the need for thick joint lands or postweld heat treatment and favors the use of welded structures in the as-welded condition.

Selection and Weldability of Non-Heat-Treatable Aluminum Alloys

C.E. Cross, Martin Marietta Astronautics Group; M.L. Kohn, FMC Corporation

Alloy Classification and Typical Applications

Non-heat-treatable wrought aluminum alloys can be placed into one of three groups using standard Aluminum Association designations:

ALLOY NUMBER	ALLOY ADDITION
1*XXX*	AL (99% MINIMUM PURITY)
3*XXX*	AL-MN
4*XXX*	AL-SI
5*XXX*	AL-MG

Nominal compositions for common non-heat-treatable alloys are given in Table 1.

TABLE 1 COMPOSITION OF WROUGHT NON-HEAT-TREATABLE ALUMINUM ALLOYS

1*xxx* Alloys. The 1*xxx*-series alloys are of commercial purity (>99% Al) and are used where thermal/electrical conduction or corrosion resistance becomes paramount over strength in design considerations (for example, alloy 1100 is used for sheet metal work, fin stock and chemical equipment). Alloys with purity levels greater than 99.5% are used for electrical conductors (for example, alloy 1350).

3*xxx* Alloys. The 3*xxx*-series alloys are used in applications where added additional strength and formability are needed, in addition to maintaining excellent corrosion resistance (for example, alloy 3004 is used for sheet metal work, storage tanks, and beverage containers). Typical applications include cooking utensils, pressure vessels, and building products (siding, gutters, and so on). These alloys get their strength from cold work and fine $(Mn,Fe)Al_6$ dispersoids that pin grain and subgrain boundaries. There is also a small degree of solid solution strengthening from both manganese and magnesium.

4*xxx* Alloys. Apart from their use as welding filler material (see the section "Filler Alloy Selection" in this article), the 4*xxx*-series alloys have limited industrial application in wrought form.

5*xxx* Alloys. The 5*xxx*-series alloys are used in cases where still higher strengths are required; this strength is achieved from large quantities of magnesium in solid solution. More importantly, magnesium promotes work hardening by lowering the stacking fault energy, thus reducing the tendency for dynamic recovery. Applications for 5*xxx*-series alloys include automobile and appliance trim, pressure vessels, armor plate, and components for marine and cryogenic service. The ballistic analysis of alloy 5083 is given in the section "Weld Properties" of this article.

While these alloys normally exhibit good corrosion resistance, care must be taken during processing to avoid formation of continuous β-Mg_3Al_2 precipitates at grain boundaries, which can lead to intergranular corrosion. This can occur in heavily cold-worked, high-magnesium alloys exposed to temperatures from 120 to 200 °C (250 to 390 °F). Alloy 5454 possesses the highest magnesium content suitable for sustained elevated temperatures and has become the standard alloy used for truck bodies for hot oil or asphalt applications, and storage tanks for heated products.

Temper Designations. Appropriate heat treatments and temper designations for non-heat-treatable alloys include a solution anneal (O temper) and a cold-worked condition (H1 temper). When the cold work achieved during processing is more than desired, a partial anneal can be used to reduce strength (H2 temper). When dealing with 5*xxx*-series alloys, it is common to use a low-temperature heat treatment (H3 temper) to stabilize the microstructure and prevent intergranular corrosion. This treatment involves heating to 120 °C (250 °F), resulting in partial recovery and making properties less susceptible to change with time.

When working with H-type tempers, a second digit is used to indicate the degree of cold work:

RELATIVE HARDNESS	TEMPER DESIGNATION
FULL HARD	**H18**
$\frac{3}{4}$ HARD	**H16**

$\frac{1}{2}$HARD	**H14**
$\frac{1}{4}$**HARD**	**H12**

A more thorough and complete description of non-heat-treatable alloys and tempers is given in Volume 2 of the *ASM Handbook* (Ref 2).

Selection and Weldability of Non-Heat-Treatable Aluminum Alloys

C.E. Cross, Martin Marietta Astronautics Group; M.L. Kohn, FMC Corporation

Filler Alloy Selection

Filler alloys used to join non-heat-treatable alloys can be selected from one of three alloy groups:

ALLOY NUMBER	ALLOY ADDITION
1*XXX*	**AL (99% MINIMUM PURITY)**
4*XXX*	**A1-SI**
5*XXX*	**AL-MG**

Commonly used filler alloys include 1100, 1188, 4043, 4047, 5554, 5654, 5183, 5356, and 5556. Nominal compositions for selected filler alloys are included in Table 1. Selecting the best filler alloy for a given application depends on the desired performance relative to weldability, strength, ductility, and corrosion resistance. In general, the filler alloy selected should be similar in composition to the base metal alloy. Thus, a 1*xxx* filler alloy is recommended for joining 1*xxx*- or 3*xxx*-series base metal alloys. Similarly, 5*xxx* filler alloys are used to join 5*xxx*-series base metal alloys. An exception to this rule is encountered when weldability becomes an issue. Weldability of non-heat-treatable aluminum alloys can be measured in terms of resistance to hot cracking and porosity.

Hot Cracking. Problems with hot cracking are encountered when welding under highly constrained conditions or when welding certain alloys that are highly susceptible to cracking. Such is the case when welding 5*xxx* alloys that have a low-range magnesium content ($\frac{1}{2}$ to $2\frac{1}{2}$ wt% Mg) where, according to the crack susceptibility curve (Fig. 1), a peak in susceptibility occurs. To avoid cracking, use of a high-magnesium filler alloy is recommended.

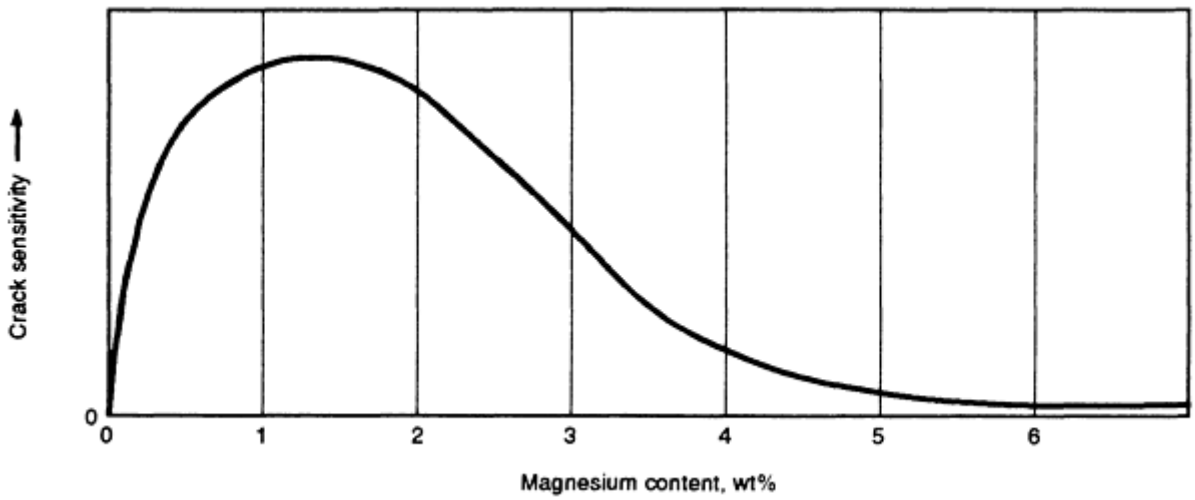

FIG. 1 PLOT OF HOT CRACKING SENSITIVITY VERSUS MAGNESIUM CONTENT TO SHOW PEAK IN SUSCEPTIBILITY OBTAINED FOR ALUMINUM-MAGNESIUM (5*XXX*) ALLOYS. SOURCE: REF 3

Similar problems may be encountered when 1*xxx* fillers are used to join 5*xxx* alloys (or vice versa), or when welding dissimilar metal alloys such as alloys 1100 and 5083, where mutual dilution may result in low magnesium levels. Electron-beam welding or laser-beam welding can also result in cracking when magnesium, a high-vapor-pressure alloying element, is boiled off. The problem is aggravated when welding in a vacuum environment. An example of a center-line hot crack produced when electron-beam welding alloy 5083 is shown in Fig. 2, where magnesium levels were measured to be approximately 3 wt% in the vicinity of the crack, based on microprobe analysis. This was an autogenous weld made in a hard vacuum (0.13 mPa, or 10^{-6} torr).

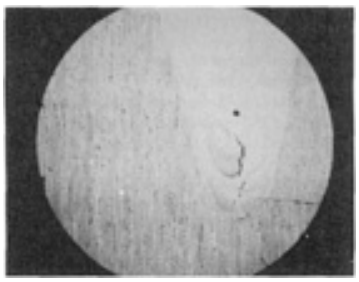

FIG. 2 CENTERLINE HOT CRACK PRODUCED IN AUTOGENOUS ELECTRON-BEAM WELDED ALLOY 5083

Another approach to be taken when hot cracking persists is to use 4*xxx* fillers. These aluminum-silicon alloys have exceptional resistance to cracking, due in part to their abundance of liquid eutectic available for back-filling (Ref 4). However, their use should be avoided when welding high-magnesium alloys (>3 wt%) because of embrittlement from excessive Mg_2Si precipitation. Other drawbacks include low joint ductility and nonmatching color when anodized. Weldability will improve with increased silicon content (for example, alloy 4047 versus alloy 4043), but the disadvantages discussed above will likewise become more predominant.

Porosity. Non-heat-treatable aluminum alloys are susceptible to hydrogen-induced weld metal porosity, as are all aluminum alloys in general. This porosity forms during solidification due to the abrupt drop in hydrogen solubility when going from liquid to solid. Porosity can best be avoided by minimizing hydrogen pickup during welding. This can be accomplished through proper joint preparation (that is, removal of hydrocarbons), use of high-grade (low-dew-point) shielding gas, and careful storage of filler wire (that is, protection from exposure to moisture and oil). It has been determined that welding filler wire is often the primary source of hydrogen contamination. The 5*xxx*-series filler alloys, in particular, are susceptible to the hydration of surface oxides, which can result in porosity (Ref 5).

In summary, guidelines for filler alloy selection when welding non-heat-treatable alloys are:

BASE METAL	FILLER METAL
1*XXX*	**1*XXX*, 4*XXX***
3*XXX*	**1*XXX*, 4*XXX***
5*XXX* (LOW MAGNESIUM)	**5*XXX*, 4*XXX***
5*XXX* (HIGH MAGNESIUM)	**5*XXX***

Selection and Weldability of Non-Heat-Treatable Aluminum Alloys

C.E. Cross, Martin Marietta Astronautics Group; M.L. Kohn, FMC Corporation

Weld Properties

When non-heat-treatable alloys are welded, microstructural damage is incurred in the HAZ. Unlike the case of heat-treatable alloys, whose strengthening precipitates may dissolve or coarsen, the HAZ damage in non-heat-treatable alloys is limited to recovery, recrystallization, and grain growth. Thus, loss in strength in the HAZ is not nearly as severe as that experienced in heat-treatable alloys. (An example of this is shown in the hardness traverses of Fig. 8 in the article "Selection and Weldability of Heat-Treatable Aluminum Alloys" in this Volume, where alloy 5456 is compared against alloys 6061 and 2219.) For this reason, 5*xxx*-series alloys are popular for use in welded pressure vessels where reasonable joint strengths can be obtained in the as-welded condition without the need for post-weld heat treatment.

The weld metal of non-heat-treatable aluminum alloys is typically the weakest part of the joint and is the location of failure when the joint is loaded in tension. This is in contrast to most heat-treatable aluminum alloys, where the heat-affected zone often is the weakest link. The weld metal microstructure of the non-heat-treatable alloys consists of columnar, epitaxial grains with a cellular or columnar-dendritic substructure that has interdendritic eutectic constituents-primarily $(Fe,Mn)Al_6$ for 1*xxx* and 3*xxx* alloys; Si for 4*xxx* alloys; and Mg_3Al_2 for 5*xxx* alloys.

Joint efficiencies for several non-heat-treatable alloys are compared in Table 2. It should be noted that joint efficiency is highest for annealed plate (approaching 100%) and decreases continuously with the degree of cold working. Also shown in Table 2 is the effect of composition and cold work on plate properties. The two 5*xxx*-series alloys shown exhibit significant improvement in strength over 1*xxx*- and 3*xxx*-series alloys, a reflection on the strengthening ability of magnesium. Likewise, 5*xxx*-series alloys with higher magnesium content have higher strength (for example, alloy 5083 versus alloy 5050). This same trend is observed for weld metal strength. For example, a weld made on high-magnesium alloy 5083 (4% Mg) is much stronger than a similar weld made on alloy 5050 (1% Mg).

TABLE 2 EFFECT OF VARIATIONS IN TEMPER AND FILLER ALLOY ON NON-HEAT-TREATABLE ALUMINUM GAS-METAL ARC WELDMENT PROPERTIES

BASE ALLOY AND TEMPER	PLATE PROPERTIES					FILLER ALLOY	WELD PROPERTIES					JOINT EFFICIENCY, %[A]

(A) JOINT EFFICIENCY = (UTS OF WELD)/(UTS OF PLATE), WHERE UTS STANDS FOR ULTIMATE TENSILE STRENGTH.

The correspondence between plate and joint strength does not apply to temper. For the high-magnesium alloy 5083 plate, no increase in joint strength is observed when welding an annealed versus a cold-worked temper (see Table 2). Likewise, filler metal selection has little effect on joint strength, as shown in Table 2. However, it is clear that use of a 4*xxx* filler does result in ductility loss. Also, filler alloys high in iron, silicon, or manganese (for example, filler alloy 5183) will have greater amounts of eutectic constituents, which will result in lower weld ductility. Even so, non-heat-treatable alloy welds exhibit significantly better ductility in comparison to similar heat-treatable welds.

Example 1: Use of Welded Alloy 5083 in Ballistic Applications.

An important application for heavy-gage alloy 5083 is the construction of tactical military vehicles. The hulls and turrets of Army vehicles such as the M113 armored personnel carrier, the M2/M3 infantry and cavalry fighting vehicles, the M109 self-propelled howitzer, and the Marine Corps AAV7A amphibians all consist of welded 5083 aluminum structures. There are also a myriad of brackets, clips, and so on, welded to the hulls and turrets, although not normally fabricated to ballistic requirements.

Aluminum alloys considered for use as armor include alloys 5083, 7039, and 2519. Alloys 7039 and 2519 are weldable and heat-treatable, capable of yield strengths exceeding 330 MPa (48 ksi). However, alloy 2519 weldments have failed rigorous ballistic shock tests (MIL-STD-1946, discussed below), even though the base material exhibits excellent ballistic and mechanical properties. Alloy 7039 possesses superior ballistic properties compared to alloy 5083, but it suffers from a tendency to delaminate and to exhibit stress-corrosion cracking. Alloy 5083 weldments have passed ballistic weld tests, and they possess the necessary resistance to corrosion.

In the MIL-STD-1946 ballistic test, a weldment is subjected to impact by a blunt-nose 75 mm (3 in.) aluminum projectile, fired at a velocity specified according to material thickness and alloy composition. Butt-welded specimens are struck no more than 13 mm ($\frac{1}{2}$ in.) from the weld centerline. Corner joints are struck so that the center of the impact projectile is

within 50 ± 13 mm (2 ± $\frac{1}{2}$ in.) from the weld toe on its back side. Welds are considered acceptable when the total length of cracking generated is less than 305 mm (12 in.).

An offset double-V configuration of the butt joint is commonly used in ballistic applications (Fig. 3). This results in solid metal backing for both welds and allows for a slip fit between adjoining plates, thereby simplifying the fit-up of large, heavy plates.

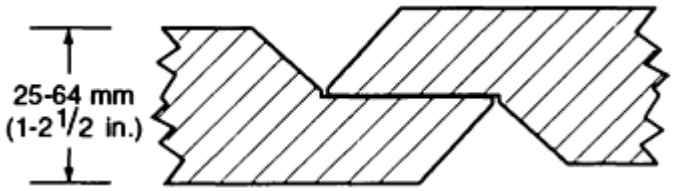

FIG. 3 OFFSET DOUBLE-V JOINT CONFIGURATION USED TO WELD THICK SECTION ALUMINUM ARMOR PLATE

Selection and Weldability of Dispersion-Strengthened Aluminum Alloys

K. Sampath, Concurrent Technologies Corporation; W.A. Baeslack III, The Ohio State University

Introduction

CONVENTIONAL HIGH-STRENGTH ALUMINUM ALLOYS produced via ingot metallurgy (I/M) processing contain precipitate particles that interact with moving dislocations, thus providing high strength at room temperature. However, when these alloys are exposed to elevated temperatures, the precipitate particles undergo dissolution and/or coarsening,

thereby reducing the strength of the base alloy. This behavior precludes the use of these alloys for elevated-temperature applications. In recent years, advances in two broad powder metallurgy (P/M) technologies--rapid solidification (RS) and mechanical alloying (mechanical attrition)--have enabled the development of a new family of high-strength aluminum alloys for elevated-temperature applications (Ref 1).

These new high-strength P/M aluminum alloys depend primarily on dispersion strengthening. Unlike the precipitate particles in I/M aluminum alloys, the dispersoid particles resist dissolution and/or coarsening when the alloys are exposed to elevated temperatures. In addition to high strength, these dispersion-strengthened aluminum alloys exhibit light weight, appreciable ductility, excellent fracture toughness, and resistance to stress-corrosion cracking (Ref 2). These alloys also exhibit coefficients of thermal expansion and galvanic properties comparable to those of conventional structural aluminum alloys (Ref 2). In view of the above properties, these dispersion-strengthened aluminum alloys are considered candidate materials to replace conventional high-strength aluminum alloys and titanium alloys used in the manufacture of selected aerospace components such as fan and compressor cases; vanes and blades in gas turbine engines; and fins, winglets, and rocket motor cases of missiles (Ref 3). Use of these alloys is expected to increase the thrust-to-weight ratio of gas turbine engines and allow significant improvements in the performance characteristics of advanced aircraft and weapons systems.

High-strength aluminum alloys produced via RS-P/M technology am primarily based on hypereutectic aluminum-iron compositions, although other alloys based on aluminum-chromium-zirconium, aluminum-manganese, aluminum-titanium, and aluminum-beryllium systems are also under various stages of development and/or evaluation (Ref 1). The dispersion-strengthened aluminum alloys produced via mechanical alloying contain a fine distribution of oxides, oxynitrides, and/or carbides in a fine-grain α-aluminum matrix. The α-aluminum matrix may additionally be strengthened by solid-solution strengthening or work hardening (Ref 1). Although many dispersion-strengthened aluminum alloys produced via mechanical alloying do not exhibit strength comparable to that of the conventional high-strength I/M aluminum alloys at room temperature, these alloys exhibit a minimal decrease in strength with increasing temperature (Ref 1).

The twofold purpose of this article is: (1) to guide users in the selection and application of welding processes and conditions for the joining of dispersion-strengthened aluminum alloys, based primarily on an understanding of the weldability of the material; and (2) to provide specific examples of material responses to welding conditions, chiefly by highlighting the microstructural development in the weld zone. In view of the limited number of publications available on the weldability and metallurgical response of this broad class of alloys, this article refers exclusively to the metallurgy and weldability of alloys based on the aluminum-iron system that are produced using various RS-P/M processing techniques.

Metallurgy of RS-P/M Aluminum-Iron-Base Alloys

Table 1 shows a list of selected dispersion-strengthened aluminum-iron-base alloys produced via RS-P/M processing. These alloys contain ternary and quaternary additions of transition and rare earth metals such as molybdenum, nickel,

cerium, vanadium, and silicon. These alloy additions exhibit low solid-solubility and low solid-state diffusivity in α aluminum (Ref 4), and consequently they tend to form thermally stable dispersoid particles. However, these alloy compositions are characterized by a wider freezing range (typically in excess of 300 °C, or 540 °F) than most aluminum alloys. Conventional I/M processing of these compositions produces equilibrium or near-equilibrium microstructures containing coarse Al_3Fe-type primary intermetallic particles in a coarse α-aluminum matrix. Such microstructures exhibit poor ductility and cannot be used for structural engineering applications. In contrast, RS processing of these novel chemistries suppresses the formation of Al_3Fe-type primary intermetallic particles. It instead produces particulates exhibiting refined metastable microstructures, such as an Al-Al_6Fe-type microeutectic and/or a solute-supersaturated dendritic aluminum. In other words, RS processing conditions produce refined hypoeutectic-type microstructures from hypereutectic melts. The occurrence of these metastable hypoeutectic-type microstructures is attributed to the following two characteristics of RS processing techniques: (1) subdivision of the melt into particulates isolates potential nucleants and produces nucleant-free particulates that undergo nonequilibrium solidification (Ref 5); and (2) the rapid cooling rate does not provide sufficient reaction time for a potential nucleant to produce the equilibrium microstructure (Ref 6).

Subsequent thermomechanical processing of the rapidly solidified particulates produces a consolidated product with a unique "engineered" microstructure consisting of submicron-size dispersoid particles in an extremely fine-grain (<1 μm) α-aluminum matrix. During thermomechanical processing, the as-solidified hypoeutectic-type microstructures undergo solid-state phase transformations and produce fine dispersoid particles in an α-aluminum matrix. These particles result from the low-equilibrium solid-solubility limit of the alloy addition, and they consist of both the stable, "non-shearable," incoherent θ(Al_3Fe-type) dispersoid particles and metastable, "shearable," partially coherent θ' (Al_3Fe-type) dispersoid particles. The ternary and quaternary alloy additions promote the formation of complex metastable and stable dispersoid particles, and they reduce the surface free energy or the lattice misfit between the dispersoid particles and the α-aluminum matrix (Ref 2, 4, 7, 8). The partially coherent particles exhibit a spherical morphology and provide excellent resistance to fracture or crack initiation. These microstructural features provide excellent thermal stability and superior mechanical properties, including high strength and ductility, both at room temperature and at elevated temperatures up to 345 °C (650 °F). Because RS-P/M processing results in microstructures finer than the resolution limit of light microscopy, transmission electron microscopy (TEM) is often required to resolve the distribution and morphology of the microstructural constituents. Figures 1(a) and 1(b) compare a light micrograph of alloy AA8009 with a TEM micrograph. Figures 1(c) and 1(d) show the TEM micrographs of Al-8Fe-4Ce and Al-9Fe-3Mo-1V alloys. The volume fraction of the dispersoid particles in these representative alloys typically ranges from 15 to 35%.

Selection and Weldability of Dispersion-Strengthened Aluminum Alloys

K. Sampath, Concurrent Technologies Corporation; W.A. Baeslack III, The Ohio State University

Weldability Issues

Although a variety of fusion welding and solid-state welding processes and techniques are available to join the conventional I/M aluminum alloys (Ref 12), several weldability issues, including the absence of compatible filler metals, preclude the application of many conventional welding processes and methodologies to the joining of dispersion-strengthened aluminum alloys. In particular, weldability issues related to weld solidification behavior, formation of hydrogen-induced porosity in the weld zone, and high-temperature deformation behavior of these alloys affect the selection and application of both fusion and solid-state welding processes.

Weld Solidification Behavior

The application of high-strength dispersion-strengthened aluminum alloys in the manufacture of specific aerospace structural components, where weight savings are critical for mission range and performance, will require the application of welding processes and procedures that optimize weld joint efficiency and minimize weld reinforcement. Because the high strength of the base alloy is due to the unique engineered microstructure obtained through RS-P/M processing, welding processes and procedures must re-create high-performance microstructures similar to the base alloy microstructures, and/or retain the superior base alloy microstructure in the weld zone. Since the wide freezing range of these alloys will tend to promote hypereutectic solidification and equilibrium or near-equilibrium microstructures, fusion welding conditions that promote RS or hypoeutectic-type solidification within the fusion zone will be required to re-create high-performance microstructures in the fusion zone. Welding conditions such as high energy density and minimum energy input, that increase the temperature gradients in both the fusion zone and the heat-affected zone (HAZ) and increase the overall weld cooling rate, will be required to minimize the widths of the partially melted region and the HAZ. Such welding conditions can be expected to facilitate the occurrence of plane front solidification, promote microstructural refining in the fusion zone, and minimize the extent of microstructural coarsening in the HAZ.

Alternatively, fusion welding conditions that provide minimum energy density and a shallow temperature gradient in the fusion zone can be expected to produce a wider HAZ and a wider partially melted region near the fusion boundary with the base metal. Depending on the local solidification conditions, this partially melted region can solidify to an equilibrium or near-equilibrium structure containing coarse intermetallic particles in a coarse-grain α-aluminum matrix. Coarse intermetallic particles can be expected to localize stress concentrations, thereby reducing the ductility and fracture toughness of the weldment. A distribution of coarse intermetallic particles can also be expected to be less effective at strengthening the matrix, especially at elevated temperatures.

Hydrogen-Induced Fusion Zone Porosity

The weldability of the dispersion-strengthened aluminum alloys is also limited by the hydrogen content of the base alloy. Hydrogen content in excess of 1 mL/100 g of aluminum is believed to produce excessive fusion zone porosity. Porosity in the fusion zone often reduces weld static strength and fatigue properties. Porosity occurs in aluminum alloy fusion welds mainly due to the rejection of hydrogen during weld solidification. It is related to the presence of hydrogen in the base alloy, filler metal, and the atmosphere and to the high ratio of solubility of hydrogen absorbed in the weld to the solubility limit of hydrogen at the melting point. The dispersion-strengthened aluminum alloys produced via RS-P/M processing often exhibit a residual hydrogen content in excess of 1 to 5 mL/100 g of aluminum and therefore show an increased tendency to form fusion zone porosity. Depending on the specific RS processing technique employed to produce the dispersion-strengthened aluminum alloy, the surface of the rapidly solidified particulates forms oxide layers to varying degrees (Ref 4, 7). During subsequent consolidation and handling, these surface oxides tend to hydrate. Decomposition of these hydrated oxides during fusion welding produces porosity in the weld fusion zone. Additionally, these oxides may

serve as heterogeneous nucleation sites during fusion zone solidification, thereby limiting the extent of undercooling and promoting hypereutectic solidification conditions and the formation of equilibrium microstructures.

Controlling the Hydrogen Content. Three approaches are available to control the residual hydrogen content in RS-P/M aluminum alloys:

- USE VACUUM OR OTHER COMPLETELY INERT PROCESSING STEPS DURING RS PROCESSING AND CONSOLIDATION.
- DEGAS THE RAPIDLY SOLIDIFIED PARTICULATES PRIOR TO CONSOLIDATION, EITHER IN VACUUM OR IN OTHER INERT CARRIER GASES (DEPURITIVE TREATMENTS).
- DEGAS THE CONSOLIDATED PRODUCT (DIFFUSION CONSIDERATIONS NORMALLY RESTRICT THIS TREATMENT TO SHEETS AND PLATES) PRIOR TO FUSION WELDING.

The use of vacuum or other complete inert processing steps during RS processing and consolidation will minimize the formation of surface oxides and thereby control consequent hydrate formation. Degassing of either the rapidly solidified particulates or the consolidated products is aimed at removing or reducing the residual hydrogen to an acceptable level, preferably below 1 mL/100 g of aluminum. The critical factors that contribute to effective degassing are temperature, time, environment, and the product size and shape. Degassing treatments are effective only at temperatures in excess of 530 to 550 °C (990 to 1020 °F). Unfortunately, the use of such high temperatures often decomposes the metastable base alloy microstructure and/or promotes microstructural coarsening, thereby irreversibly degrading the mechanical properties of the base material (Ref 13).

Alternatively, despite a higher hydrogen content in the RS-P/M aluminum-base alloy, the occurrence of fusion zone porosity can be minimized by using welding techniques that increase the total pressure during welding. Since the equilibrium solubility of hydrogen in molten aluminum is governed by Sievert's law, the solubility of hydrogen in aluminum near the boiling point of aluminum can be decreased by reducing the partial pressure of hydrogen (that is, by increasing the total pressure). Depending on the specific characteristics of the fusion welding process, welding techniques that provide increased total pressure will reduce the partial pressure of hydrogen in the welding atmosphere and thereby reduce the level of fusion zone porosity. Increased total pressure is also believed to minimize the nucleation of hydrogen bubbles (Ref 14). However, such welds will contain excessive hydrogen, either in solution or as fine-size pores not detectable using conventional nondestructive evaluation techniques.

Applicable Welding Processes. The above weldability considerations show that RS-P/M aluminum-base alloys characterized by a low residual hydrogen content (<1 mL/100 g of aluminum) can be joined using fusion welding methods. As mentioned before, the absence of compatible fillers restricts the choice to essentially autogenous welding processes, while a need to recreate high-performance microstructures further limits that choice to high-energy-density welding methods such as capacitor-discharge welding, electron-beam welding, and laser welding. In fact, considering the effects of laser wavelength on the weldability of aluminum alloys, the application of the pulsed Nd:YAG laser welding process is preferred because this process provides 1.06 μm wavelength radiation, which is more efficiently absorbed by the base alloys than the 10.6 μm wavelength CO_2 laser radiation.

Fusion welding of base alloys with higher residual hydrogen will require the use of weld pretreatment or other special techniques to control hydrogen content in the weld atmosphere. In fact, one company that manufactures high-strength aluminum alloys containing iron, vanadium, and silicon additions has developed material pretreatments that can enhance joining and provide acceptable welding procedures (with minimal porosity) for resistance spot welding, gas-tungsten arc welding (GTAW), laser-beam welding, and vacuum brazing of these alloys (Ref 15).

The RS-P/M aluminum-base alloys characterized by a higher residual hydrogen content (>1 mL/100 g of aluminum) will require the use of solid-state welding methods such as conventional friction welding, inertia friction welding, or linear friction welding. These solid-state welding processes employ relative motion of the parts to be joined under an axial force to generate frictional heat at the weld interface. During the initial stages of welding, the interface becomes plastic (softened) due to frictional heating. When adequate heating (softening) of the interface is obtained, the relative motion is slowed down and a forging force is applied to produce the weld joint. The forging force produces localized plastic deformation and expels the heated material from the interface (as a flash around the weld joint), thereby enabling the formation of a weld joint between nearly unaffected base metals. In this regard, the weldability of the dispersion-strengthened aluminum alloys is influenced by the effects of welding process conditions and parameters on the high-temperature deformation characteristics, and subsequent microstructural development in the weld zone of these alloys.

Since these solid-state welding processes preclude melting and solidification, these welds tolerate higher levels of residual hydrogen. Further, the absence of melting at the faying surfaces during these processes prevents solidification-related discontinuities, such as cracking, and enables joining with dissimilar materials. However, despite the inherent ability of solid-state welding processes to produce high-integrity weld joints, such processes are only selectively applicable in view of specific limitations on component size, cross-sectional shape, weld joint design, and difficulties in evaluating the weld joint integrity using conventional nondestructive evaluation techniques. Application of joining processes such as brazing or diffusion welding using interlayers may potentially circumvent the aforementioned weldability issues related to the dispersion-strengthened aluminum alloys.

Selection and Weldability of Dispersion-Strengthened Aluminum Alloys

K. Sampath, Concurrent Technologies Corporation; W.A. Baeslack III, The Ohio State University

Fusion Welding

Fusion welding studies on dispersion-strengthened aluminum alloys have focused on the use of GTAW, with and without the addition of filler wire; resistance spot welding; and autogenous welding using capacitor-discharge, electron-beam (EB), and pulsed Nd:YAG laser welding processes. These studies have related welding conditions to their effects on weld microstructure and mechanical properties.

Gas-Tungsten Arc Welding. Autogenous butt welding of 1.6 mm (0.06 in.) thick Al-10Fe-5Ce alloy sheets using the GTAW process has resulted in excessive porosity in the fusion zone (Ref 13). However, vacuum pretreating the base alloy sheets for 20 h at 400 °C (750 °F) prior to GTAW using direct current electrode negative and helium gas shielding conditions reduced the level of porosity in the weld zone significantly. Unfortunately, this pretreatment also resulted in an 8% decrease in the tensile strength of the base alloy due to microstructural coarsening.

The same investigation evaluated the application of three conventional, unmatched filler wire additions--ER4043 (Al-5Si), ER4047 (Al-12Si), and ER5356 (Al-5Mg)--to the gas-tungsten arc weld pool. The results indicated that the ER5356 filler metal provided virtually porosity-free weld deposits following the vacuum pretreatment of the base alloy. Transverse weld tensile testing of the gas-tungsten arc welds produced using the ER5356 filler wire additions and vacuum pretreatment showed the joint efficiency to increase from 55% at room temperature to about 81% at 315 °C (600 °F). Despite an acceptable weld joint efficiency at elevated temperature, the transverse weld tensile testing revealed low (1%) ductility. Weld microstructure characterization showed that the minimal ductility was related to the presence of brittle, acicular intermetallics near the fusion boundary with the base metal. The formation of these brittle intermetallics is evidently related to the occurrence of near-equilibrium weld solidification conditions.

Capacitor-Discharge Welding. Compared to the gas-tungsten arc weld in the Al-10Fe-5Ce alloy, the microstructural characterization of autogenous capacitor-discharge welds produced in 6.4 mm (0.25 in.) cylindrical specimens of an Al-8Fe-4Ce alloy showed that the extremely rapid heating and cooling rates obtainable in this process can allow the generation of rapidly solidified, size-refined fusion zone microstructures (Ref 10, 16). In addition, this investigation revealed that increasing the forge pressure during the final bonding stage minimized fusion zone porosity. Transmission electron microscopy characterization of a moderately cooled capacitor-discharged weld in Al-8Fe-4Ce alloy showed fine-size acicular intermetallic particles in an extremely fine dendritic α-aluminum matrix, along with a minimal distribution of spherical intermetallic particles (Fig. 2). Although the microstructural features of the weld zone were similar to those of the RS-P/M base alloy microstructure, the relatively fine weld zone microstructures showed a higher hardness than the base alloy.

Electron-Beam and Laser-Beam Welding. Table 2 shows the weld parameters and weldment characteristics of autogenous EB and pulsed Nd:YAG laser welds produced in a low-hydrogen (<1 mL/100 g of aluminum) Al-8Fe-2Mo alloy. These welds showed only occasional evidence of fusion zone porosity (Ref 17, 18, 19). Evaluation of room-temperature weld mechanical properties of the EB welds produced in 1.27 mm (0.05 in.) thick Al-8Fe-2Mo alloy sheet showed a high weld joint efficiency of 73%, corresponding to 19.3 J/mm (490 J/in.) weld energy input, and preferential failure along the weld interface with the base material at minimal weld ductility. In comparison, transverse weld tensile testing of the EB weld, produced in 0.65 mm (0.026 in.) thick Al-8Fe-2Mo alloy sheet using 4.5 J/mm (114 J/in.) energy input determined 88% weld joint efficiency, appreciable weld ductility, and preferential failure in the weld HAZ. These observations indicate that reducing the energy input shifted the area most susceptible to failure from the fusion boundary region to the base metal. In fact, scanning electron microscopy examination of the fracture surfaces showed that the preferential failure along the weld interface was invariably related to the presence of acicular intermetallic particles in the fusion boundary region (Fig. 3).

Microscopic examination of the low-energy-input EB weld showed that reducing the weld energy input minimized or eliminated the occurrence of acicular intermetallic particles within the fusion zone and produced refined α-aluminum dendrites (Ref 18). Coincident with the elimination of the acicular intermetallic particles near the fusion boundary, a relatively light-etching region was observed within the weld zone. Transmission electron microscopy examination of these regions revealed α-aluminum growth structures around coarse-size intermetallic particles (Fig. 4). In fact, TEM examination of a keyhole-type EB weld produced in a 2.5 mm (0.10 in.) thick RS-P/M Al-8Fe-1.7Ni alloy showed a similar microstructure at the weld center, one that contained primary Al_3Fe-type intermetallic particles nucleating an α-aluminum sheath around the primary particles (Ref 21). The α-aluminum sheath structure changed to a lamellar eutectic structure. In contrast to this structure, the fusion boundary region of this weld showed an epitaxially grown, extremely fine Al/Al_6Fe-type coupled-eutectic structure.

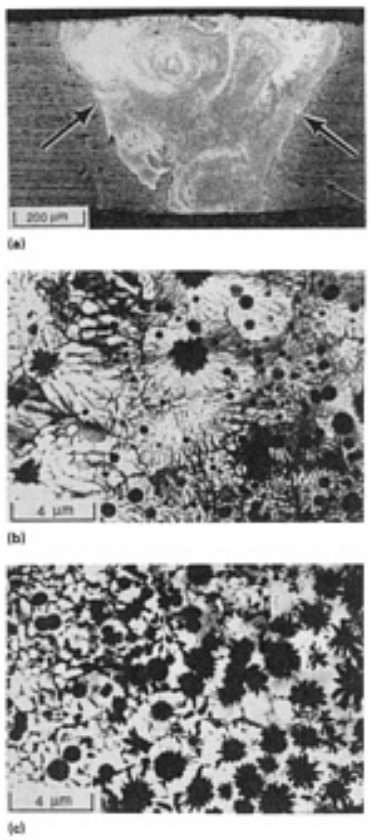

FIG. 4 ELECTRON-BEAM WELD (ENERGY INPUT 4.5 J/MM, OR 114 J/IN.) IN 0.65 MM (0.026 IN.) THICK AL-8FE-2MO SHEET. Compared with the EB welds, autogenous pulsed Nd:YAG laser welding studies on 1.27 mm (0.05 in.) thick Al-8Fe-2Mo alloy sheet using a higher-energy-density (power density $>10^6$ W/mm^2) welding condition showed that the transverse weld joint efficiency could be improved to 100% (Ref 19). The longitudinal weld bend ductility was also comparable with that of the RS-P/M base alloy. Transmission electron microscopy examination of the fusion boundary region showed that the pulsed Nd:YAG laser welding conditions produced a matrix consisting of a columnar-dendritic α-aluminum structure with a uniform distribution of fine Al_6Fe-type spherical intermetallic particles and solute-rich particles at the dendrite interstices (Fig. 5). The pulse overlap region of the weld zone showed microstructures very similar to those observed in the EB welds, albeit on a structurally finer scale. The low overall weld energy input resulted in a narrow HAZ with the base metal and only minimal structural coarsening (Ref 21, 22).

Development of Weld Microstructure. The occurrence of different types of weld zone microstructures and significant differences in weld mechanical properties underscore the effects of welding process conditions and parameters on weld microstructure development. Specifically, distinct variations in the morphology and population density of the intermetallic particles within the weld zone occur as the weld energy input is decreased and/or as the energy density (power density) is increased. An analysis based on peak temperature distribution during fusion welding indicated that despite the use of high-energy-density welding processes, these welds likely contained undissolved base metal dispersoid particles within the bulk fusion zone (Ref 20). A weld solidification analysis based on this premise showed that the subsequent microstructure development within the fusion zone occurs as one of the following three different types, depending on local thermal conditions--principally cooling rate and temperature gradient--that depend on welding process condition and parameters:

- *TYPE A:* AL_3FE-TYPE INTERMETALLIC PARTICLES IN A MATRIX OF DENDRITIC A ALUMINUM WITH INTERDENDRITIC LAMELLAR OR DIVORCED EUTECTIC
- *TYPE B:* AL_3FE-TYPE INTERMETALLIC PARTICLES THAT ACT AS GROWTH CENTERS FOR DENDRITIC α ALUMINUM WITH INTERDENDRITIC LAMELLAR OR DIVORCED EUTECTIC
- *TYPE C:* AL_6FE-TYPE INTERMETALLIC PARTICLES ENTRAPPED IN A MATRIX OF DENDRITIC α ALUMINUM WITH INTERDENDRITIC DIVORCED EUTECTIC

Depending on local weld solidification conditions, the above three types of microstructures can be observed at different regions within the same weld.

Figures 6, 7, and 8 show Al-Al_3Fe pseudobinary phase diagrams to illustrate possible solidification events that promote the formation of type A, type B, and type C microstructures, respectively. In these diagrams, C_O represents the nominal composition of the alloy, and C_O' represents the effective composition of the melt (containing undissolved base metal dispersoid particles) prior to the onset of weld solidification, T_E is the equilibrium (Al-Al_3Fe) eutectic temperature and T'_E is the metastable (Al-Al_3Fe) eutectic temperature. In Fig. 6 and 7, C''_O represents the composition of the melt at which the solidification mode changes from hypereutectic to hypoeutectic with respect to the metastable eutectic composition.

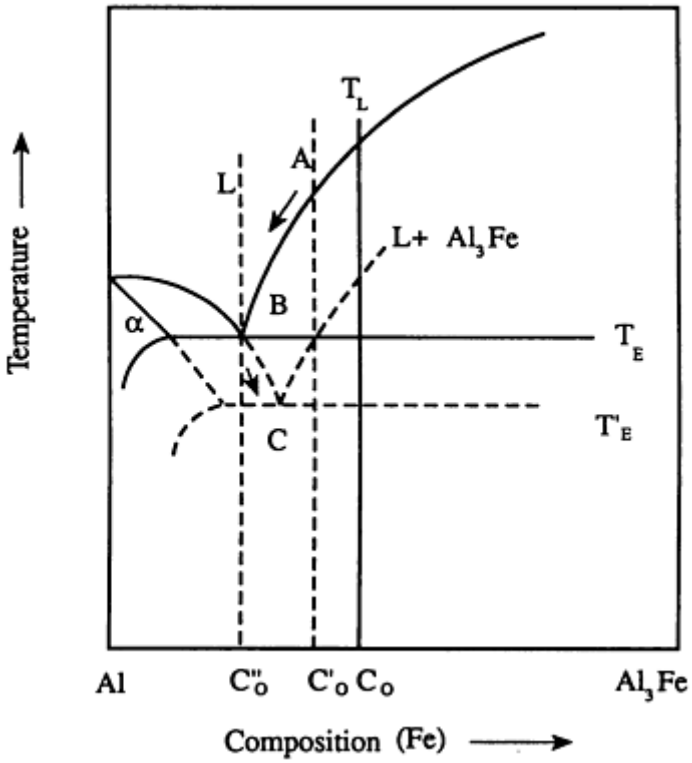

FIG. 6 AL-AL_3FE PSEUDOBINARY PHASE DIAGRAM ILLUSTRATING THE SEQUENCE OF SOLIDIFICATION EVENTS LEADING TO THE FORMATION OF TYPE A MICROSTRUCTURE. SOURCE: REF 20

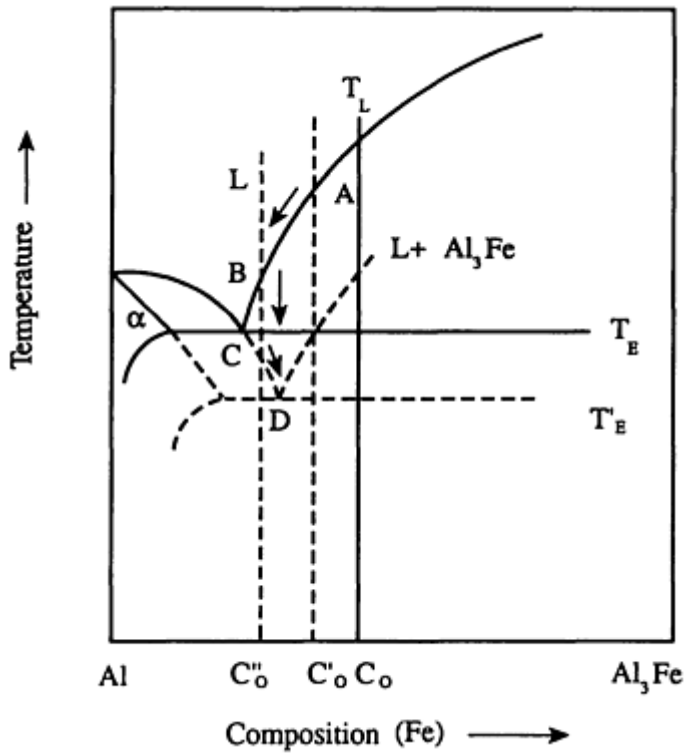

FIG. 7 AL-AL_3FE PSEUDOBINARY PHASE DIAGRAM ILLUSTRATING THE SEQUENCE OF SOLIDIFICATION EVENTS LEADING TO THE FORMATION OF TYPE B MICROSTRUCTURE. SOURCE: REF 20

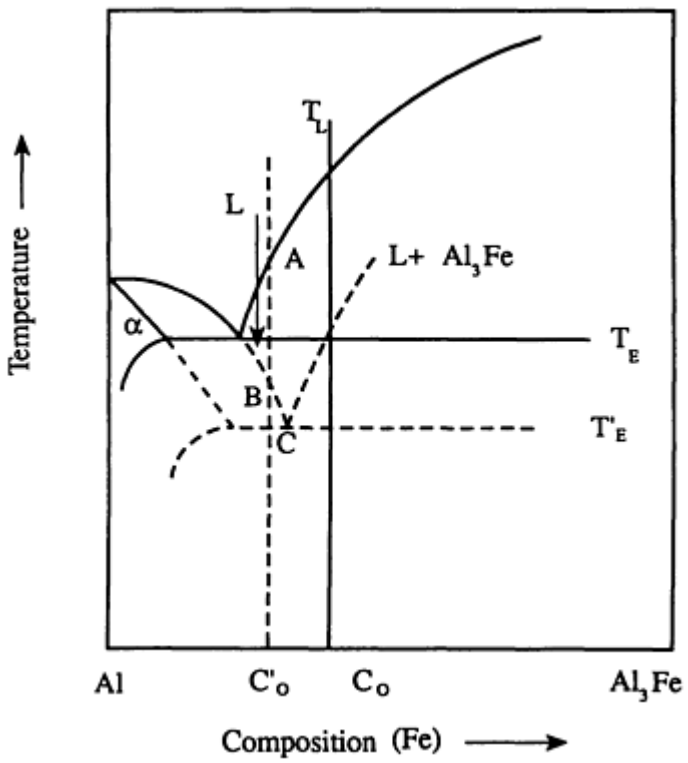

FIG. 8 AL-AL_3FE PSEUDOBINARY PHASE DIAGRAM ILLUSTRATING THE SEQUENCE OF SOLIDIFICATION EVENTS LEADING TO THE FORMATION OF TYPE C MICROSTRUCTURE. SOURCE: REF 20

The Type A Microstructure is a near-equilibrium microstructure and occurs within the fusion boundary region of high-energy-input welds. As shown in Fig. 6, the type A microstructure appears to occur in three stages. Initially, the undissolved base metal dispersoid particles grow in a relatively stagnant liquid region into randomly oriented, primary intermetallic particles and promote solute depletion in the remaining melt (from A to B). Since the primary intermetallic particles have a poor nucleation potency for α aluminum, solute depletion in the melt promotes the epitaxial growth of columnar-dendritic α aluminum from base metal α(from B to C). Further, since the α-aluminum solidification initiates from the fusion boundary at relatively low solidification velocities, the local solidification conditions promote appreciable structural coarsening and produce relatively coarse α-aluminum dendrites. Solute partitioning accompanying the α-aluminum growth promotes a solute-rich melt at the interdendritic regions, which undergoes terminal solidification to a metastable Al/Al_6Fe-type lamellar eutectic at the α-aluminum dendrite interstices (at C). These types of microstructures are commonly observed throughout the fusion zone in gas-tungsten arc weldments produced in these alloy types (Ref 13).

The Type B Microstructure contains both stable and metastable microstructural constituents. This structure is associated with high-energy-input welding conditions and is commonly observed within the central weld zone. As shown in Fig. 7, this microstructure appears to form with the growth of Al_3Fe-type intermetallic particles (from A to B). Due to high weld cooling rates, considerable undercooling occurs (from B to C) subsequent to the initial growth of the primary intermetallic particles, which allows the growth of supersaturated α-aluminum dendrites (from C to D). The occurrence of a metastable α-aluminum growth structure also indicates that the composition of the melt surrounding the equiaxed intermetallic particles was essentially hypoeutectic relative to the metastable eutectic composition. With the growth of the α-aluminum, the composition of the remaining melt in the dendrite interstices is enriched with solute elements. It ultimately reaches the metastable eutectic composition and undergoes terminal (metastable) eutectic solidification (at D). In view of the fine size of the interdendritic region, solute-rich particles are formed in this region instead of a regular lamellar eutectic (Ref 23).

The formation of the metastable α-aluminum growth structure around the primary intermetallic particles is attributed to catalytic nucleation. Catalytic nucleation of α aluminum occurs when the lattice disregistry between the potential nucleant and αaluminum is reduced below 10% (Ref 24). Since the supersaturation of solute elements in aluminum shows a negative deviation from Vegard's law and reduces the lattice parameter of α aluminum (Ref 25), improved lattice registry between the primary intermetallic particles and the metastable α aluminum, along with shallow temperature gradients in the central fusion zone, is considered responsible for the occurrence of the equiaxed-dendritic α-aluminum growth structure.

The Type C Microstructure is essentially a metastable growth structure and is associated with the extremely high-energy-density, low-energy-input welding conditions. Similar to the type A near-equilibrium microstructure, the type C metastable microstructure starts from the fusion boundary region with the base metal, by epitaxial solidification of α(or coupled eutectic) from base metal α in the fusion boundary. As shown in Fig. 8, the epitaxial growth of the α-aluminum grains appears to occur at significantly high undercoolings, possibly at temperatures slightly above the metastable eutectic temperature. Evidently, the coupled eutectic growth structures occur when the undercooling is below the metastable eutectic temperature.

The epitaxially grown α-aluminum grains entrap the undissolved dispersoid particles as solidification proceeds along a relatively steep temperature gradient across the advancing solid-liquid interface. The spherical morphology of the intermetallic particles is attributed to the high fusion zone cooling rate (in excess of 10^5 °C/s, or 1.8×10^5 °F/s), which does not provide adequate time for the growth of the undissolved base metal dispersoid particles. The steep temperature gradients in this region promote solidification of the melt to a columnar-dendritic substructure with fine intermetallics or solute-rich particles partitioning to the dendrite interstices. Coincident with the growth of the metastable α aluminum, the remaining melt is enriched with solute elements, which undergo final solidification to fine particles due to the relatively fine size of the interdendritic regions (Ref 23).

Epitaxial solidification generally indicates local wetting of the fusion boundary and minimal melt undercooling. However, epitaxially grown type C microstructures in the fusion boundary suggest that despite a readily wettable substrate, metastable growth structures in the weld fusion zone can likely occur from the combined effects of a minimal nucleation barrier for the metastable phase, a steep temperature gradient that restricts the growth of the stable phase, and perhaps a minimal difference in the level of undercooling required to allow the growth of metastable structures. In fact, although the nucleation of Al_3Fe occurs at less than 8 °C (14 °F) undercooling in aluminum-iron melts, the nucle tion of Al_6Fe is favored at undercoolings in excess of 10 °C (18 °F) (Ref 26).

Solid-State Welding

The solid-state welding studies on RS-P/M aluminum-iron-base alloys are mostly limited to the application of conventional friction welding, inertia friction welding, or linear friction welding methods to produce similar or dissimilar metal welds in cylindrical specimens. In general, these studies evaluated the effects of weld axial force on the structure, mechanical properties, and fracture behavior of the friction welds. These studies include similar welds between Al-9Fe-4Ce and Al-9Fe-7Ce alloys, dissimilar welds between Al-9Fe-4Ce and I/M 2024-T351 (Ref 27), similar welds between AA8009 alloy (Ref 9), similar welds between FVS1212 alloy (Ref 28), dissimilar welds between FVS1212 alloy and I/M

2024-T351 (Ref 29), similar welds between Al-9Fe-3Mo-1V alloys (Ref 30), and dissimilar welds between Al-9Fe-3Mo-1V alloy and I/M 2024-T351 (Ref 11). The similar welds exhibit a uniform flash around the weld joint, the amount of the flash increasing with the weld axial force. The dissimilar welds, however, show a nonuniform flash around the weld joint. The alloy with the higher strength at elevated temperatures (RS-P/M base alloy) forms a minimal flash compared to the alloy with a higher strength at room temperature (I/M 2024-T351 alloy).

Light and analytical electron microscopy examinations of the interface region (weld center) in inertia friction welds have shown extensive high-temperature plastic deformation in the heat-and-deformation zone. This plastic deformation was generally beneficial in effectively homogenizing the base metal microstructure. The plastic deformation often promoted the fracture of coarse, acicular dispersoid particles present in selected base alloys (Ref 11, 30). However, the fine spherical dispersoid particles commonly observed in AA8009 alloy were relatively unaffected by the level of plastic deformation occurring in the weld zone and usually did not show any evidence of coarsening or fracture (Ref 9). Further, in welds produced using a low axial force, nonuniform deformation at the weld outer periphery resulted in the formation of dispersoid-lean, coarse-grain regions with a hardness appreciably lower than that of the base alloy. The application of a sufficiently higher axial force extruded out this softened region as weld flash, thereby preventing the hardness degradation across the weld zone (Fig. 9). Results of transverse weld tensile testing were generally consistent with the microstructural observations, showing that weld joint efficiency up to 95% of the base metal tensile strength can be obtained in welds produced using high axial force.

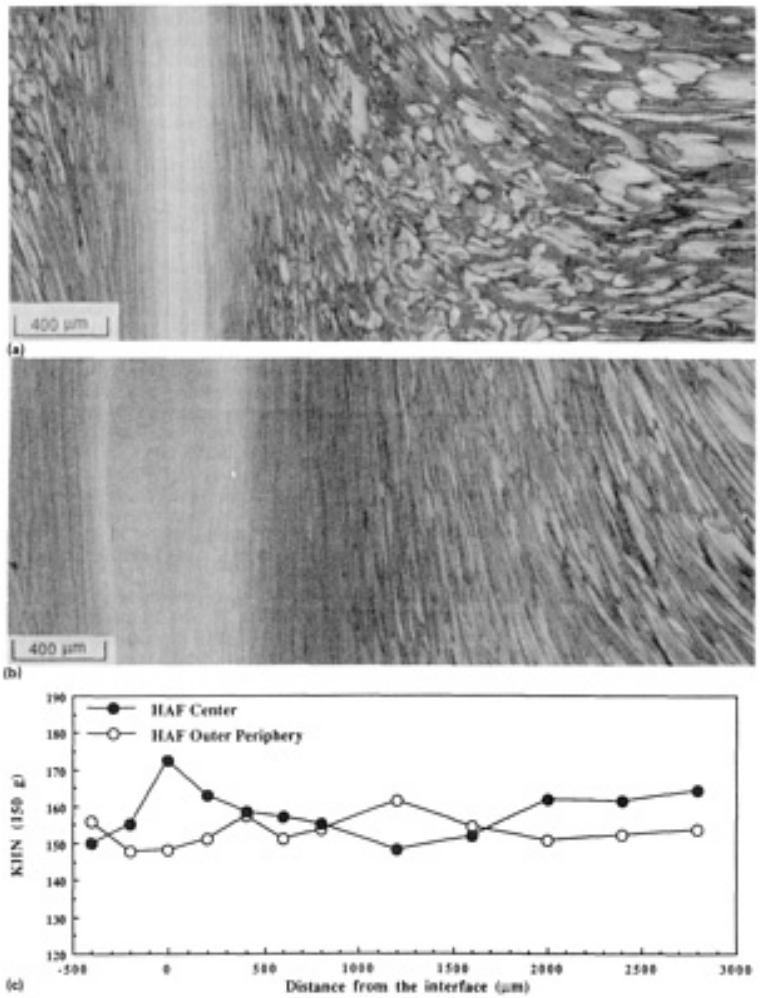

FIG. 9 LIGHT MICROGRAPHS OF AN INERTIA-FRICTION WELD IN AA8009 ALLOY PRODUCED USING HIGH AXIAL FORCE. (A) CENTER. (B) OUTER PERIPHERY. (C) CORRESPONDING KNOOP HARDNESS TRAVERSE. SOURCE: REF 9

Unlike the microstructure of the inertia friction welds, linear friction welds (produced in similar welds between FVS1212 alloy and dissimilar welds between FVS1212 alloy and I/M 2024-T351) showed appreciable coarsening of the α-

aluminum grains and the base metal dispersoid particles resulting from a somewhat slower weld thermal cycle and less forging force (Ref 29). Appropriate optimization of welding parameters to provide rapid weld thermal cycles is expected to minimize the microstructural coarsening in the weld zone.

Diffusion Welding

Diffusion welding of RS-P/M aluminum-iron-cerium alloy was investigated using electroplated silver interlayers (Ref 31). Temperature-time and temperature-pressure diffusion welding parameter zones were developed for an A1-9Fe-4Ce alloy and showed that it was possible to perform diffusion welding operations at temperatures up to 600 °C (1110 °F) without structural support. Although poor joint efficiencies were obtained for welds produced at low pressures, an increase in pressure and the promotion of deformation at the weld interface promoted joint efficiencies of up to 70%. The weld interface regions were characterized by the presence of a silver-aluminum intermetallic and occasional Kirkendall porosity.

Selection and Weldability of Aluminum-Lithium Alloys

C.E. Cross and W.T. Tack, Martin Marietta Astronautics Group

Introduction

ALUMINUM-LITHIUM alloys constitute the most recently developed group of high-performance wrought aluminum alloys intended for use primarily in aircraft and aerospace structures. Because aluminum alloys account for a large portion of the structural weight of most aerospace structures, designers can use the higher elastic modulus, lower density, and, in some cases, higher strength and fracture toughness of aluminum-lithium alloys to reduce structural weight. Another benefit is that the use of aluminum-lithium alloys does not require changes in manufacturing equipment, design methods, or fabrication techniques. In particular, aluminum-lithium alloys have been found to be readily weldable, a characteristic that is uncommon with other high-strength aluminum alloys such as 7075 and 2024.

The purpose of this article is to provide a guide to the welding of aluminum-lithium alloys that are now available commercially. Tabular data are provided for alloy composition, density, and modulus; tensile properties of plate; and tensile properties of weldments. There is limited information in the open literature regarding many of the newer alloys; therefore, some of these tables are incomplete. Weld properties are also characterized in terms of aging response, microstructure, and corrosion resistance.

A detailed and more thorough discussion of aluminum-lithium alloy weldability can be found in two review articles by Pickens (Ref 1, 2). An attempt is made here to give a very concise overview of the subject, including pertinent information from more recent conference proceedings not available for publication in previous reviews. With the fast-accumulating bank of information regarding aluminum-lithium weldments, design engineers can now begin to select and utilize aluminum-lithium alloys based on well-established behavior and property data.

Selection and Weldability of Aluminum-Lithium Alloys

C.E. Cross and W.T. Tack, Martin Marietta Astronautics Group

Commercial Alloys

Classification. Aluminum-lithium alloys can be divided into two groups: aluminum-lithium-magnesium ternary and aluminum-lithium-copper-magnesium quaternary alloy systems. These alloy groups are shown schematically in Fig. 1 with accompanying alloy designations and primary strengthening phases associated with each alloy. In addition to the solid-solution strengthening effects of alloying additions, the important strengthening phases δ' (Al_3Li), S' (Al_2CuMg), and T_1 (Al_2CuLi) are formed upon aging and are dependent on alloy composition (Ref 3, 4).

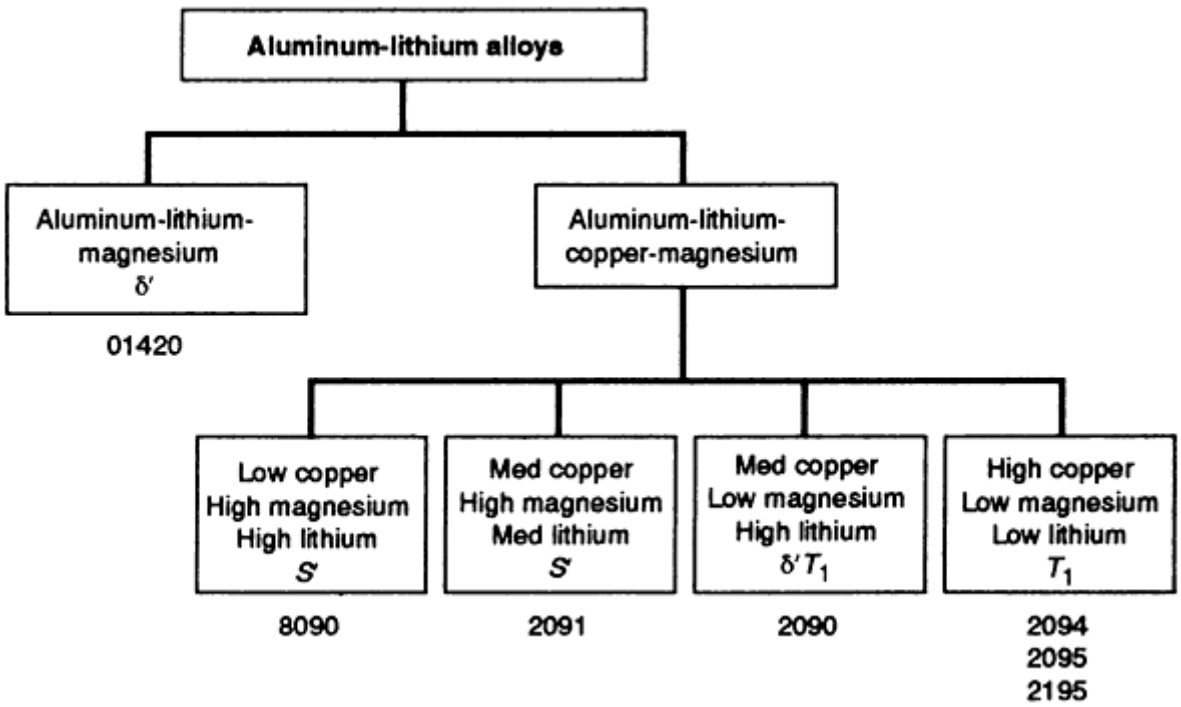

FIG. 1 SCHEMATIC OF TERNARY AND QUATERNARY ALUMINUM-LITHIUM ALLOY SYSTEMS SHOWING PRIMARY STRENGTHENING PHASES AND CORRESPONDING COMMERCIAL ALLOY DESIGNATIONS

Properties. Of the specific alloy compositions shown in Table 1, the high copper/magnesium ratio of alloy 2090 and the Weldalite 049 family of alloys (2094, 2095, 2195) results in the precipitation of T_1, which is the most potent strengthening phase in this alloy system (Ref 4, 5, 6). Accordingly, these alloys possess higher yield strengths than other aluminum-lithium alloys (Table 2). At lower copper/magnesium ratios, the *S*' phase is favored, and lower strengths are achieved (e.g., alloys 8090 and 2091). In the absence of copper, the δ' phase becomes predominant, resulting in even lower strength (e.g., Soviet alloy 01420). Density increases with copper content and decreases with lithium and magnesium contents; thus, alloy 01420 has the lowest density and the Weldalite 049 alloys have the highest densities. The elastic modulus tends to increase with lithium content; alloys 8090 and 2090 have the highest moduli in the aluminum-lithium-copper-magnesium alloy group.

Zirconium is added to most aluminum-lithium alloys to form β'-Al_3Zr or α'-Al_3(Zr,Li) dispersoids; these dispersoids serve to inhibit recrystallization and nucleate the δ' phase giving improved strength and toughness (Ref 3, 12, 13). However, the presence of these dispersoids also leads to an inherent tendency toward texturing and subsequent anisotropic behavior (Ref 14). The β' phase may also act to promote grain refinement during solidification in both ingots and welds (Ref 15). Silver is added to the Weldalite 049 alloys to assist in precipitate nucleation (Ref 2).

Applications. Because of their good weldability, high strength, and accompanying high fracture toughness, the Weldalite 049 alloys have been considered as candidates to replace alloy 2219 in welded propellant tank applications, for example, the Space Shuttle external tank (Ref 14, 16). In this case, the weight savings gained from using a high-strength alloy (enabling the use of thinner sections) allows for a larger launch payload, which, in turn, offsets any additional cost in material. Weight savings can also be achieved by taking advantage of the high specific modulus of aluminum-lithium alloys (8090 and 2090 in particular) for use in stiffened or compression-loaded structures. Alloy 8090 has been successfully used in a welded tubular structure constructed with over 400 manual welds (Ref 17). Future applications may include welded skirt assemblies for space launch vehicles and other compression-loaded structures.

Selection and Weldability of Aluminum-Lithium Alloys

C.E. Cross and W.T. Tack, Martin Marietta Astronautics Group

Weldability

Porosity. Weld metal porosity can form in aluminum alloys when monatomic hydrogen is partitioned interdendritically during solidification. A sufficient amount of hydrogen must be partitioned so that the interdendritic liquid becomes supersaturated, thus increasing the drive for pore nucleation. In order for diatomic gas pores to form, pore nuclei must overcome atmospheric pressure, surface tension, and liquid head pressure (Ref 18). Lithium-containing aluminum alloys exhibit a higher than normal propensity for weld metal porosity, although this does not appear to be due to any inherent

thermodynamic property. Lithium has been shown to increase the solubility of hydrogen in aluminum for both solid and liquid phases such that less hydrogen is partitioned during solidification in comparison with other aluminum alloys (Ref 19). The observed tendency to form porosity in aluminum-lithium alloys may, however, be due to higher initial amounts of hydrogen in the weld pool, making it easier to reach the threshold concentration needed for pore nucleation.

Hydrogen can enter the weld pool from the base plate, from hydrated oxides or hydrocarbons on the plate surface, and from moisture in the shielding gas. Similar in behavior to aluminum-magnesium alloys, aluminum-lithium alloys are particularly susceptible to the formation of hydrated oxides (Ref 20). Thus, preweld joint preparation requires special attention to avoid porosity. A thorough removal of mill scale at the weld joint, by means of dry machining or chemical milling, is required. In a review of Soviet literature (Ref 1), it was reported that a marked drop in porosity in alloy 01420 weldments could be achieved by removing 0.05 mm (0.002 in.) from the joint surface prior to welding. It has become common practice in the welding of all aluminum-lithium alloys to dry machine approximately 0.25 mm (0.01 in.) off abutting surfaces as well as top and bottom plate surfaces, 25 to 50 mm (1 to 2 in.) from the centerline, on both sides of the joint. It is also considered good practice to weld within a few hours of machining and to degrease immediately prior to welding.

Another factor affecting weld quality and porosity entrapment is the weld cover gas, which is typically argon, helium, or a mixture of the two. It has been determined that low levels of oxygen impurity (less than 300 ppm) must be maintained to produce acceptable welds in alloy 2090 (Ref 21). In this same study, normal welding-grade bottled gas was found to vary from between 100 and 300 ppm O. Thus, in-line gas purifiers (getter or sieve type) or oxygen sensors at the welding torch may be necessary if shielding gas of consistently high quality cannot be supplied. Also, when making through-thickness welds, as in a keyhole welding process, backside shielding must be used to prevent excessive oxidation and the occurrence of porosity.

Hot cracking occurs when low-melting, eutectic liquid films are torn apart at the trailing edge of the weld pool during solidification. The hot cracking susceptibility of any aluminum-lithium alloy, or any aluminum alloy in general, appears to be related to its copper and magnesium contents and may involve an aluminum-copper-magnesium eutectic (Ref 22). Alloys with high copper and low magnesium (e.g., alloy 2219) are weldable, as are alloys with low copper and high magnesium (e.g., alloy 5083). It is alloys containing large amounts of both copper and magnesium--for example, conventional high-strength aerospace alloys such as 2024 and 7075--that encounter problems with weldability. With aluminum-lithium alloys, the formation of strengthening precipitates such as T_1 does not require large quantities of both copper and magnesium, and thus weldability can be maintained without compromising strength.

The relationship between copper and magnesium contents and weldability is demonstrated in the weldability index of Fig. 2. This index was obtained by superimposing modern alloy compositions on an existing crack susceptibility (castability) diagram generated by Pumphrey and Moore in 1948 for aluminum-copper-magnesium ternary alloys (Ref 23). In Fig. 2, it is predicted that aluminum-lithium alloys with high copper and low magnesium contents (e.g., alloys 2094 and 2090) should have good weldability. On the other hand, alloy 2091, an aluminum-lithium alloy with intermediate amounts of both copper and magnesium, is predicted to be less weldable. Weldability predictions made using this index do not account for the effect lithium has on copper or magnesium solubility, nor do they account for the use of filler alloys to modify weld metal composition. Nevertheless, this index has proven useful in aluminum-lithium base metal and filler alloy development by predicting trends in weldability behavior with variations in alloy composition.

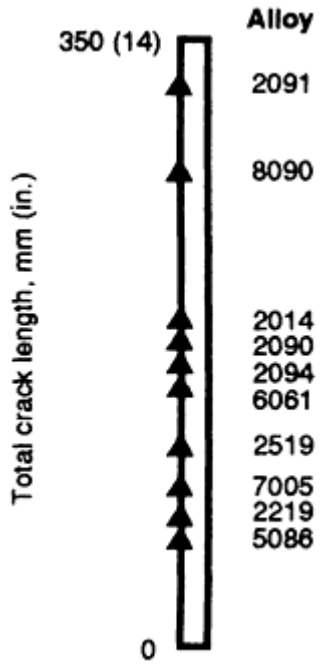

FIG. 2 PUMPHREY-MOORE CRACKING INDEX BASED ON CASTABILITY DATA OBTAINED FROM ALUMINUM-COPPER-MAGNESIUM ALLOYS. SOURCE: REF 25

Filler Metal Selection. Filler metal alloys used to join aluminum-lithium alloys are selected to give acceptable weldability and, at the same time, to optimize mechanical properties. Alloy 2319 has typically been used to join the high-copper alloys (e.g., alloys 2090, 2094, 2095, and 2195). Low-copper, high-magnesium alloys (e.g., alloy 8090) call for the use of a high-magnesium filler metal such as alloy 5356. Alloys that are difficult to weld (e.g., alloy 2091) require the use of an aluminum-silicon filler metal such as alloy 4043. Aluminum-silicon filler metal alloys provide excellent weldability, but are not normally used due to their characteristic low toughness and low ductility and their inability to respond to aging. Experimental aluminum-lithium filler metal alloys have been developed and show promise for future applications where high filler metal dilutions are required (Ref 24).

In a recent weldability study, a trans-Varestraint test was used to compare aluminum-lithium alloys with conventional aluminum alloys (Ref 25). Tests were performed using an applied strain of 0.5%, appropriate filler metal alloys at 30% filler dilution, and a gas-tungsten arc welding process operated at welding currents selected to achieve constant penetration for each alloy tested. Results of this study are shown in Fig. 3; alloy 2219 appears to be the most weldable and alloys 2090 and 2094 the least weldable of those alloys investigated. However, extensive weld development programs (Ref 10, 14, 26) have demonstrated that these aluminum-lithium alloys can be easily welded in practice with little concern for cracking. Weldability tests can provide a relative rating among alloys; they cannot be used to predict real-world behavior.

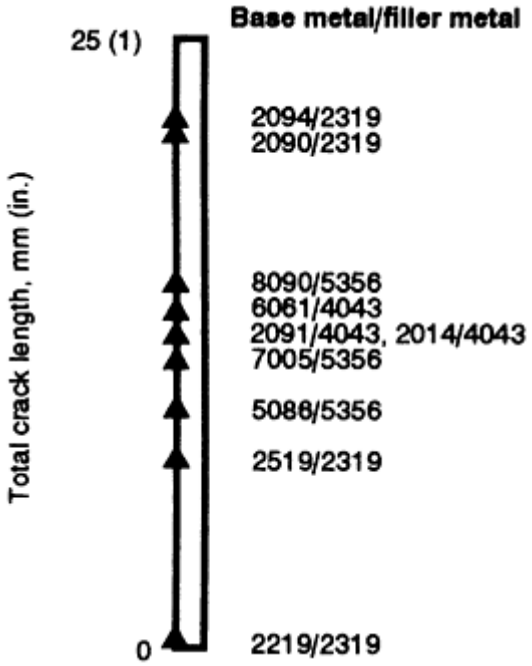

FIG. 3 TRANS-VARESTRAINT WELDABILITY DATA FOR ALUMINUM ALLOYS. SOURCE: REF 25

As shown in Fig. 4, the weldability of alloys 2090 and 2094 can be improved using high-silicon filler metal alloys (e.g., alloy 4047), although this is not normally deemed necessary or desirable (Ref 25, 27). Figure 4(b) shows that the use of a 2319 filler metal results in less cracking than a 4043 filler metal when welding alloy 2090. The same is not true when welding alloy 2094 (Fig. 4a). Alloy 2090 is much leaner in copper than alloy 2094, and thus it responds more to the use of a high-copper filler metal alloy. It should be noted that results from two different weldability tests are displayed in Fig. 4, and the magnitude of cracking is different for each test.

Selection and Weldability of Aluminum-Lithium Alloys

C.E. Cross and W.T. Tack, Martin Marietta Astronautics Group

Weld Characterization

Joint Strength. Although the tensile properties of many wrought aluminum-lithium alloys are exceptionally high, the strength of the welded joints in these alloys is limited by the strength of the solidified weld metal. Even though joint strengths are higher than those found in conventional aluminum alloys, joint efficiencies on the order of 50% are to be expected for the high-strength aluminum-lithium alloys.

A comparison of gas-tungsten arc, variable polarity plasma arc, and gas-metal arc weldment properties for aluminum-lithium alloys, taken from numerous sources, is given in Table 3. Alloy 2094 is found to have the highest joint strength (372 MPa, or 54 ksi, ultimate strength), which corresponds to a 38% improvement over alloy 2219 weldments (269 MPa, or 39 ksi, ultimate strength) (Ref 10). Alloy 01420 is found to have the lowest weld strength (241 MPa, or 35 ksi, ultimate strength).

High-energy-density welding processes have also been used successfully to join aluminum-lithium alloys. Electron-beam welding has been used to join alloys 8090, 2090, and 2094; tensile strength results for electron-beam weldments are given in Table 4. Typically, a slight improvement in strength above arc welding properties is to be expected because of a finer microstructure, narrower fusion zone, and better response to natural aging. Similarly, good results for laser-beam-welded alloy 2090 have been reported (Ref 34, 35).

TABLE 4 TRANSVERSE TENSILE PROPERTIES FOR ELECTRON-BEAM-WELDED ALUMINUM-LITHIUM ALLOYS IN THE AS-WELDED CONDITION

	MPA	KSI	
8090-T6	317	46	**33**
2090-T8	324	47	**27**
2094-T8	**434**	**63**	**2**

Postweld Aging. The Weldalite 049 alloys have been observed to naturally age in both the weld metal and the heat-affected zone (HAZ). It is important to wait a sufficient time (typically 30 days) between welding and proof or tensile testing to allow for precipitate stabilization, thereby ensuring accurate characterization of joint properties. In addition, postweld solution heat treatment and artificial aging, although not practical for large structures, have been found to significantly increase the strength of high-copper alloy gas-tungsten arc weldments; by using these postweld treatments, an ultimate tensile strength of 400 MPa (58 ksi) has been obtained with alloy 2090 (Ref 36) and 510 MPa (73 ksi) with alloy 2094 (Ref 37).

Ductility and Toughness. If the weld metal is significantly lower in strength than the base metal, when the weldment is plastically deformed, most of the strain will be concentrated in the weld metal. Such is the case for high-strength aluminum-lithium alloys, where hardness traverses for both alloy 2090 and 2094 have confirmed a steep gradient in strength in the HAZ between weld metal and base metal (Ref 31, 38). Typically, joint ductility measured over a 50 mm (2 in.) gage length will be 2 to 4% even though the actual weld metal ductility approaches 10 to 12%.

Fracture toughness is an important criterion in the design of welded tanks for aerospace applications. Also, an increase in toughness with decreasing temperature is particularly desirable for cryogenic tanks because it allows proof testing to be performed at room temperature, a much more feasible and economical procedure. Weld toughness values have been measured for alloy 2090 gas-tungsten arc (dual torch, variable polarity) weldments using a surface crack tension test. K_{Ie} values increasing from 30 MPa/ $\sqrt{m}$ at room temperature to 34 MPa/ $\sqrt{m}$ at 73 K have been reported, which is an improvement over similar measurements for alloy 2219 (19 to 24 MPa/ $\sqrt{m}$) (Ref 31). It should be noted that these are not plane-strain toughness values, and their magnitude is sensitive to precrack geometry.

Fatigue. Initial results from an ongoing study involving alloy 2095 weldments (Ref 39) have shown that fatigue growth resistance is higher in both the weld metal and HAZ when compared with the base metal. For precracks placed in the HAZ, there is a tendency for cracks to grow to the fusion line, where the fatigue crack growth rate is greater. In both the weld metal and HAZ (unconstrained condition), the general tendency is for the fatigue crack growth rate to increase with increasing stress ratio ($\sigma_{min}/\sigma_{max}$).

Microstructure. The high strength of aluminum-lithium weld metal is due to a combination of fine grain size and precipitate formation. This unexplained tendency for fine grains, as small as 10 μm in diameter (equiaxed), has been noted elsewhere (Ref 40). Constitutional undercooling by lithium has been ruled out as a possible cause (Ref 41). The tensile fracture of alloy 2094 weldments has been found to be intergranular, associated with a band of fine grains located along the fusion line (Ref 31, 42). Based onphase equilibria, two eutectic constituents are likely present in aluminum-lithium-copper weld metal: θ(Al_2Cu) and T_B ($Al_{15}Cu_8Li_2$) (Ref 43). Weld metal precipitates δ' and β' have been identified in alloy 2090 in the as-welded condition, and platelike precipitates, believed to be T_1, have been observed upon aging (Ref 36).

Corrosion. A study involving corrosion potential measurements taken across weldments (through base metal, HAZ, and weld metal) has identified certain aluminum-lithium alloy compositions as being susceptible to galvanic attack in a saline environment (Ref 44). In particular, two experimental alloys with high lithium content (2.9 wt% Li and 3.0 wt% Cu), welded with either 2319 or 4043 fillers, displayed a narrow region within the HAZ that was highly anodic to both base metal and weld metal. This behavior was attributed to the formation of the equilibrium δ(AlLi) phase and resulted in severe pitting in the HAZ. In contrast, a 2090-type alloy showed a continuously increasing (cathodic) potential when going from base metal to weld metal and was resistant to pitting attack. This behavior was attributed to the absence of the δ phase due to a higher copper-lithium ratio.

Selection and Weldability of Aluminum Metal-Matrix Composites

Thomas J. Lienert, The Ohio State University; Charles T. Lane, Duralcan USA; Jerry E. Gould, Edison Welding Institute

---

Introduction

THE PURPOSE of this article is to review the current understanding of the joinability of aluminum metal-matrix composites (Al-MMCs).* Unfortunately, the joining of Al-MMCs is not a mature technology, and many important details

are not well understood. Relatively little work has been directed toward furthering the understanding of Al-MMC joining. Much of the work has been either proprietary or protected for national security reasons and is not available in the open literature.

Although much of the early work on Al-MMCs, including that on joining, concentrated on continuous fiber types, most of the present work is focused on discontinuously reinforced (particle or whisker) Al-MMCs, because of their greater ease of manufacture, lower production costs, and relatively isotropic properties. The most commonly used reinforcement materials in discontinuously reinforced aluminum (DRA) composites are silicon carbide (SiC) and aluminum oxide (Al_2O_3). Consequently, this article focuses on composites that incorporate these specific materials. A review of Al-MMC joining technology up to 1975 is provided in Ref 1.

Note

* * AL-MMCS ARE NORMALLY SPECIFIED ACCORDING TO A NOMENCLATURE DEVELOPED BY THE ALUMINUM ASSOCIATION (AA) AND LATER ADOPTED BY THE AMERICAN NATIONAL STANDARD INSTITUTE (ANSI 35.5-1992). IN THIS SPECIFICATION, THE MATRIX ALLOY IS LISTED FIRST, FOLLOWED BY THE REINFORCEMENT MATERIAL, AND THEN THE VOLUME PERCENT AND SHAPE OF REINFORCEMENT, EACH SEPARATED BY A SLASH. THE HEAT TREATMENT DESIGNATION, IF USED, IS PLACED AFTER THE ENTRY FOR PERCENT AND SHAPE OF REINFORCEMENT. FOR EXAMPLE, $6061/AL_2O_3/15_P$-T6 REFERS TO AN AL-MMC WITH A 6061 AL ALLOY MATRIX THAT HAS BEEN HEAT-TREATED TO THE T6 CONDITION AND IS REINFORCED WITH 15 VOL% AL_2O_3 PARTICLES. A 15_W DESIGNATION WOULD INDICATE REINFORCEMENT IN WHISKER (W) FORM. THIS NOMENCLATURE WILL BE USED THROUGHOUT THE ARTICLE.

Selection and Weldability of Aluminum Metal-Matrix Composites

Thomas J. Lienert, The Ohio State University; Charles T. Lane, Duralcan USA; Jerry E. Gould, Edison Welding Institute

General Joining Considerations

The effective integration of Al-MMCs into useful structures and devices often requires that they be joined to similar and dissimilar materials. As a result, the ultimate utility of Al-MMCs hinges on the ability to effectively join them within reasonable economic constraints. As with all aluminum products, appropriate cleaning before joining and proper shielding during joining are necessary to avoid hydrogen contamination and the subsequent formation of porosity. However, the weldability of Al-MMCs differs markedly from that of monolithic aluminum alloys, because of the presence of the reinforcement. The addition of reinforcement to the aluminum matrix acts to modify several physical and chemical properties, which in turn greatly affect the weldability of Al-MMCs. Thus, an understanding of the weldability of Al-MMCs must include a thorough knowledge of the effects of the various interactions between matrix and reinforcement.

Viscosity Effects. The welding of Al-MMCs differs from the welding of monolithic aluminum alloys in that the weld pool of the composite contains a solid phase, because the reinforcement does not necessarily melt at welding temperatures. Thus, in the strictest sense, the composite weld pool is actually a partially melted zone. The most obvious effect of the presence of the reinforcement is the increased viscosity of the Al-MMC weld pool (Ref 2). This weld pool does not flow and wet as readily as that of monolithic aluminum alloys. Mass transfer is limited, because of the viscous nature of the MMC weld pool. Therefore, heat flow by convection in the weld pool is believed to be less effective than it is in aluminum alloys. Consequently, conductive heat flow through the aluminum alloy matrix is thought to play a larger than normal role in determining the temperature distributions and cooling rates in and around the weld pool of Al-MMCs.

The differences in heat flow in the MMC, relative to monolithic aluminum alloys, can affect the resulting microstructures and the stress distributions in the MMC weld.

Chemical Reactions. From a thermodynamic standpoint, Al-MMCs are nonequilibrium materials. Because a chemical potential difference exists between the matrix and the reinforcement, chemical reactions may occur. The contact between liquid aluminum and the reinforcement during joining can lead to the formation of unplanned or undesirable phases. The new phases may form at the matrix-reinforcement interface or they may entirely consume the original reinforcement.

For example, Al_4C_3 will spontaneously form when joining silicon carbide- or graphite-reinforced Al-MMCs by one of the following reactions:

$$3SIC(S) + 4AL(L) \leftrightarrow AL_4C_3(S) + 3SI_{AL} \quad \textbf{(EQ 1)}$$

$$3C(S) + 4AL(L) \leftrightarrow AL_4C_3(S) \quad \textbf{(EQ 2)}$$

where (*s*) and (*l*) represent solid and liquid, respectively.

Studies of the thermodynamics of Eq 1 and 2 show that the standard free energy, $\Delta G°$, of the reaction becomes increasingly negative (that is, the reaction proceeds further to the right) with increasing temperature and that the addition of silicon to the aluminum alloy matrix, which increases the activity of the silicon, aids in limiting the formation of Al_4C_3 during joining (Ref 3). The formation of Al_4C_3 creates concern for two reasons. First, its presence (in a very coarse or clustered form) is associated with a decrease in the mechanical properties of Al-MMCs. Second, it will readily dissolve in aqueous environments, resulting in formation of porosity and a loss of integrity to the weld.

Some control of the Al_4C_3 microstructure and, thus, the joint properties of silicon carbide- or graphite-reinforced Al MMCs can be achieved by tailoring the joining process. For these two types of composites, the integrated time at temperature above the matrix liquidus experienced by the composite during joining should be minimized, in order to limit the formation of Al_4C_3. Thus, joining should be performed using either a solid-state joining process or a fusion-welding process that can provide rapid thermal cycles with low heat inputs. Alternatively, a matrix alloy (or filler metal) with a high silicon content should be chosen, if possible, for the MMC.

A second type of chemical reaction occurs in aluminum-magnesium composites reinforced with Al_2O_3, where a magnesium spinel ($MgAl_2O_4$) is formed by the following reaction:

$$3MG + 4AL_2O_3 \leftrightarrow 3MGAL_2O_4 + 2AL \quad \textbf{(EQ 3)}$$

The formation of copper spinel ($CuAl_2O_4$) by similar reactions has also been reported in aluminum-copper alloy composites reinforced with Al_2O_3. The formation of these spinels is known to enhance wetting of the reinforcement by the aluminum, which limits or mitigates the agglomeration of the aluminum oxide into large clusters. The presence of the spinels at the interface does not appear to markedly change the mechanical properties of the weld.

Effects on Solidification. The third type of matrix-reinforcement interaction occurs during the solidification of discontinuously reinforced aluminum composites (Ref 4). Below a certain critical solidification rate, the reinforcement is pushed ahead of the solidification front. Because the reinforcement is pushed to the last areas to solidify, the uniformity of its distribution is governed by solidification conditions. The collection of reinforcement in front of the interface locally hinders heat flow and mass transport and causes a decrease in the extent of microsegregation, which diminishes the amount of terminal solidification phase(s) that forms. Furthermore, the modification of the amount and distribution of the terminal solidification phase(s) appears to improve the resistance of at least some Al-MMCs to solidification cracking. Modifications to microsegregation can also occur in continuous fiber reinforced Al-MMCs when solidification occurs along the small capillaries formed between the fibers. Both the pushing of reinforcement and the decrease in microsegregation can have an effect on the final microstructure and the properties of Al-MMC welds.

Weld Preparation. The standard methods of weld preparation are generally suitable for Al-MMCs, although a few modifications should be adopted. Because of their ceramic reinforcement, most MMCs are very wear resistant. Thus, standard steel-cutting tools and saw blades are ineffective for preparing the joint. Solid carbide (speed <100 m/min, or 330 ft/min) or diamond-tipped and diamond-plated tools (speed >400 m/min, or 1310 ft/min) are recommended for all

beveling and back gouging. Feeds that are greater than 0.3 mm/tooth (0.012 in./tooth) should be used for cutting tools, whereas constant, medium-heavy pressures should be used for saws.

Although the lower coefficient of thermal expansion (CTE) of the MMC will reduce the tendency of the joint to close ahead of the arc, the root gap and included angle of the joint should still be increased slightly to allow for the reduced fluidity of the composite weld pool.

The welding processes used for Al-MMCs can be characterized by the state of the matrix during welding. Several fusion-welding processes have been used to join these composites, including gas-tungsten arc welding (GTAW), gas-metal arc welding (GWAW), laser-beam welding (LBW), electron-beam welding (EBW), and resistance welding (RW). In addition, friction welding (FRW), transient liquid phase (TLP) bonding, and capacitor discharge welding (CDW) also have been used. Details on each process are provided below.

Fusion-Welding Processes

Arc Welding. The metallurgy of arc welding, more so than other joining processes, is akin to a casting process. Aluminum is melted, undergoes mixing, and then resolidifies. The microstructure of the weld, including its defects, is not dissimilar to that of an aluminum casting. Unfortunately, this "recasting" process can significantly degrade the microstructure and properties of most MMCs.

In terms of equipment and consumables, the arc-welding practice for Al-MMCs is substantially similar to that for aluminum alloys. When one considers that from 75 to 90 vol% of the MMC is aluminum, it becomes apparent that the basic rules for equipment and filler-metal selection still apply. The constant-current power supply is still recommended for most welding, although constant voltage is preferred for some automated welding. Argon is generally the preferred shielding gas, except in the usual cases where it is either mixed with or replaced by helium. Filler metals are usually matched to the matrix alloy of the composite and the service requirements of the weld.

For example, the alloy 6061 is typically welded with ER4043 or ER5356. These filler metals would be appropriate for a composite that has 6061 as its matrix. In the case of $6061/Al_2O_3/10_p$, the ER5356 is used for its ability to keep the reinforcement wetted. In the case of $6061/SiC/15_w$, the ER4043 would be preferred for its assistance in suppressing the Al_4C_3 reaction. The extra silicon in ER4045 or ER4047 may be even more effective in this regard. However, the near-eutectic composition of the resulting weld metal is unsuitable for postweld solution heat treatments because of the coarsening of the silicon phase (Ref 5).

Primary silicon will precipitate in significant amounts only if the silicon content of the melt is greater than 12.6%, or the cooling rate is sufficiently high at a lower silicon level to prevent eutectic formation. Although 4047 contains 11 to 13% Si, the weld pool contains less, owing to dilution by the base material being welded (6061 has only 4% Si). Arc welds do

not cool rapidly enough to precipitate primary silicon from a hypoeutectic aluminum-silicon solution. Finally, primary silicon *enhances* properties if it is small and well-refined versus large and coarse.

The GTAW process is the original inert-gas arc-welding process developed for aluminum. Its low, controlled heat input is ideal for thin sections and complex shapes. The control of heat input is especially important for welding silicon carbide-reinforced wrought alloys. For most applications, the GTAW process is used with alternating current (ac), and the arc balance is adjusted to favor either cleaning or penetration. A cleaning arc can help minimize reactions between the reinforcement and matrix by reducing heat input. However, dilution of the composite into the weld pool is also decreased. Thus, some welds do not have homogeneous microstructures and do not reflect the properties of the parent material.

An arc set for cleaning is capable of breaking up the thin surface oxides that exist on the surface of a typical aluminum weld pool. However, in the case of a metal-matrix composite, the skin is stabilized by the ceramic particles (diluted from the base material), which are held at the pool surface by buoyancy forces and surface tension. A cleaning arc does not register properly on this "shielded" surface and tends to "skitter" along the joint. Formation and advancement of the weld pool is difficult, and some surface melting adjacent to the weld bead may occur.

For most Al-MMCs, a balanced, or penetrating, arc is preferred, because it is more focused and forces heat into the weld pool and joint, rather than melting the adjacent base material. The increased specific heat makes feeding the filler wire significantly easier and results in an improved bead profile. The degree of penetrating balance will depend on the geometry of the joint and the preferred technique of the welder.

Another effect of the particle-stabilized oxide skin is the dull appearance of the weld-pool surface. In fact, the initial formation of the weld pool is difficult to discern, and welders may overmelt the area while waiting for a bright pool to form. This is further complicated by the fact that the work area is not as well illuminated, because of the reduction in reflected light from the arc. Welders should watch the area under the arc for a "slumping" of the surface or another indication that subsurface melting is present. Feeding the filler rod into the weld pool early will accelerate pool formation, increase its fluidity, and partially dissipate the oxide skin. However, the pool will not become bright, like an unreinforced aluminum weld pool does, and the welder should begin advancing the weld as soon as he can feed in the filler.

An example of this procedure is a single-pass butt weld on 6.35 mm (0.25 in.) thick plate of Al-MMC. A series of different Al-MMC extrusions was prepared with a 30° edge bevel (60° included angle) and a 1.6 mm (0.06 in.) root land. After degreasing and scrubbing with a clean stainless steel brush, the plates were fixtured to a grooved stainless steel backing bar using a 1.6 mm (0.06 in.) root gap. The power supply was set for 22 V and 325 A, maximum, with the ac balance towards penetration (a setting of 5, where 3 equals balance for a range of 0 to 10). A 2.4 mm (0.094 in.) filler rod of ER5356 was fed into the weld at 23.3 mm/s (0.917 in./s) as the automatic cold-wire feed traveled at 25.8 mm/s (1.02 in./s). The shielding gas of 100% argon was metered at 16.5 L/min (35 ft^3/h).

The resulting welds passed the bead appearance, radiography, and tensile requirements for 6061, as described in AWS D1.2-90. Typical as-welded properties are listed in Table 1, and a cross section of a representative weld is shown in Fig. 1. Note the smooth bead contour, minimal porosity, and even distribution of particles in the weld.

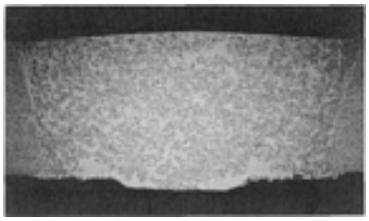

FIG. 1 MICROSTRUCTURE OF GAS-TUNGSTEN ARC WELDED 6061/AL_2O_3/10_P (6.35 MM, OR 0.25 IN., PLATE)

The GMAW process is preferred for most production welding, because of its high deposition rate and ease of automation. A root gap of 1 to 2 mm (0.04 to 0.08 in.), in conjunction with a temporary grooved backing bar, is recommended for single-sided welds, because of the lower fluidity and reduced penetration of the composite weld pool. A root gap is also preferred for double-sided welds; the root should be thoroughly back gouged before welding the second side. Joint openings range from 60° for single-V to 90° for double-V butt welds with root lands of 10 to 20% of the plate thickness. For multipass welds, it is recommended that the weld be vigorously scrubbed with a clean stainless steel wire brush between passes to remove any dewetted reinforcing phase, condensed magnesium oxide (a black, powdery residue), or other contaminants.

This procedure is illustrated by a multipass butt weld on a 19 mm (0.75 in.) plate of 6061/Al_2O_3/20_p-T6 (Ref 7). The extrusion was prepared with a 30° edge bevel (60° included angle) and a 3.2 mm (0.16 in.) root land. After degreasing and scrubbing with a clean stainless steel brush, the plates were fixtured to a grooved, stainless steel backing bar using a 1.6 mm (0.06 in.) root gap. A constant-current, dc, inverter-type power supply was set for 305 A and 26 V_{dc}, electrode positive (DCEP). The four passes were made at different travel speeds. The root pass was made at 384 mm/min (15 in./min) to keep the arc at the leading edge of the weld pool and ensure good root penetration. The speed was slowed to 252 mm/min (10 in./min) during the second pass to ensure good side-wall fusion. Capping passes (third and fourth) were made at 354 mm/min (14 in./min). A 1.6 mm (0.06 in.) filler wire of ER5356 was used with 100% argon shielding metered at 23.6 L/min (50 ft^3/h).

Typical as-welded properties are listed in Table 2, and a representative microstructure from the fusion zone is shown in Fig. 2. In this figure, the base material is to the right and the weld is on the left. There are no visible reaction products at the particle interface, and the dilution of the particles from the base material is relatively even, with minimal agglomeration.

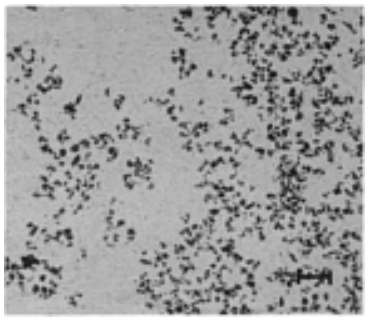

FIG. 2 MICROSTRUCTURE OF GAS-METAL ARC WELDED 6061/AL_2O_3/20_P

Laser-Beam Welding of Silicon Carbide-Reinforced Al-MMCs. Several researchers have attempted to limit the formation of aluminum carbide during fusion welding by employing welding processes, such as LBW, that can produce very rapid thermal cycles. Fully dense, crack-free welds have been produced with both continuous wave (CW) and pulsed carbon dioxide LBW processes, as well as the pulsed Nd:YAG process. The rapid thermal cycles made possible by these processes result in uniform distribution of reinforcement and a very fine grain size.

In one study, CW carbon dioxide laser-beam welds were produced on cast A356 (Al-7Si-0.3Mg)/SiC/15_p discontinuously reinforced aluminum at 1.0 and 1.5 kW and travel speeds ranging from 2.3 to 5.8 m/min (90 to 230 in./min) (Ref 8). These conditions resulted in heat inputs of 15.7 to 39.4 kJ/m (400 to 1000 J/in.). Pulsed Nd:YAG laser-beam welds were made on the same composite at an average power of 200 W with pulse energies that varied from 5 to 20 J. All welds were autogenous bead-on-plate welds.

The fusion zone of the CO_2 laser-beam welds made in this study exhibited three distinct regions (Fig. 3). The upper central region (region 1) contained large amounts of Al_4C_3 and silicon in the aluminum alloy matrix, with little remaining SiC. This region was spike-shape and encompassed less than 25% of the weld cross section. The Al_4C_3 in this region was not continuous with any silicon carbide, and it was relatively long (up to 45 μm, or 1.8 mil). The width of region 1 did not change with variations in heat input, and it was shown to be approximately the same size as the focused beam diameter. This suggests that region I is associated with the high temperatures of the weld keyhole, where the beam and material interact.

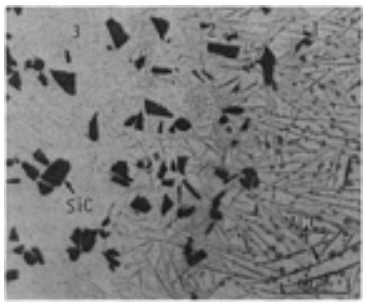

FIG. 3 MICROSTRUCTURE OF CO_2 LASER-BEAM WELD ON A356/SIC/15_P (UNETCHED)

The central region of the CO_2 laser-beam welds was surrounded by a very narrow region (region 2) in which the SiC had partially reacted to form Al_4C_3 and silicon, in accordance with Eq 1. The nucleation and growth of tiny needles of Al_4C_3 from the SiC in the partially reacted zone are evident. These needles, which are straight and relatively short, show an orientation relation with the silicon carbide.

Surrounding the partially reacted zone was a large region (region 3) in which the SiC appeared to be unreacted. This unreacted zone constituted approximately 70% of the total weld volume. Similar phenomena were also observed in the pulsed Nd:YAG laser-beam welds.

Other experiments showed that the extent of aluminum carbide formation in pulsed carbon dioxide laser-beam welds on a cast A356/SiC/15_p composite could be modified by changes in welding parameters. In one study, the size and quantity of Al_4C_3 was observed to increase proportionally with laser specific energy (Ref 9). In another experiment, measurements were made of the strength and ductility of pulsed carbon dioxide laser-beam welds made at a peak power of 3.2 kW and at duty cycles ranging from 50 to 91% (Ref 10). The laser processing resulted in increased strength in most of the welds, relative to the coarse-grained base material, despite the formation of a large amount of Al_4C_3. The presence of other phases, such as $Al_4Si_2C_5$ and MC-type carbides, in the pulsed CO_2 laser-beam welds was also reported.

Whereas LBW experiments have shown that the Al_4C_3 microstructure can be modified by varying process parameters, it appears that LBW is incapable of producing welds that are free of Al_4C_3. Experimental observations and physical data suggest that the laser energy is preferentially absorbed by the SiC, because of its greater absorptivity, relative to aluminum, at the laser wavelengths. The increased energy absorption results in local superheating of the SiC and surrounding areas and promotes Al_4C_3 formation. In summation, it appears that the LBW processes may have limited potential in joining silicon carbide-reinforced Al-MMCs.

Laser-Beam Welding of Aluminum Oxide-Reinforced Al-MMCs. Few LBW studies on aluminum oxide-reinforced Al-MMCs have been reported. It appears that the Al_2O_3 reinforcement also preferentially absorbs the impinging laser energy. The carbon dioxide LBW process was used on a 6061/Al_2O_3/20_p composite produced by powder metallurgy (Ref 11). Initial attempts at welding resulted in cutting of the samples. However, acceptable welds were ultimately produced when the shims of 5083 and 4047 filler wire were placed in the joints.

Similar problems were reported by other researchers on a 6061/aluminum oxide/20_p composite produced via ingot metallurgy (Ref 12). They attributed the difficulty to an unstable plasma above the weld pool and attempted to improve weldability with plasma control. Sound welds with a uniform distribution of reinforcement were produced by placing a small gas nozzle close to the weld area to blow away the plasma material. The quality of the welds was found to strikingly depend on the direction of the suppression gas flow, relative to the welding direction, and on nozzle positioning. Optimum welding conditions were realized when the flow was opposite to the welding direction and the end of the nozzle was inclined upward by 5° to the horizontal. The gas pressures at the nozzle ranged from 70 to 275 kPa (10 to 40 psi). Based on this study, LBW offers some potential for joining aluminum oxide-reinforced Al-MMCs.

Electron-Beam Welding of Silicon Carbide-Reinforced Al-MMCs. The EBW process appears to have potential for joining at least some silicon carbide-reinforced Al-MMCs. A follow-up study to the LBW work described in Ref 6 determined that EBW can be used successfully to join the same cast discontinuously reinforced aluminum (A356/SiC/15_p) without the formation of large amounts of Al_4C_3 (Ref 13). Like LBW, the EBW process is capable of producing rapid thermal cycles. However, the physics of beam-material interaction differs for the two processes. Heating during LBW results from the absorption of photons by the substrate, whereas heating during EBW occurs by the transfer of kinetic energy to the atoms of the substrate via collisions with the high-energy electrons of the beam. In this study, CO_2 laser-beam and electron-beam welds were produced at identical energy inputs, travel speeds, and focused beam diameters. The use of EBW resulted in sound welds with a uniform distribution of reinforcement and a fine grain size. The electron-beam welds exhibited orders of magnitude less Al_4C_3 than the laser-beam welds made using the same parameters. The electron-beam welds made at 85 mm/s (200 in./min) with sharp beam focus contained almost no Al_4C_3. Electron-beam welds made at slower speeds and/or with defocused beams contained somewhat more Al_4C_3.

The different mechanisms of energy transfer in EBW and LBW appear to affect the final weld microstructures of silicon carbide-reinforced Al-MMCs and, thus, the weld properties, despite the fact that both welding processes allow for rapid thermal cycles with low overall heat input.

Unfortunately, EBW cannot be successfully applied to all silicon carbide-reinforced Al-MMCs. For example, attempts at EBW on a wrought 2014/SiC/15_p MMC resulted in cutting of the sample. It is not known whether the problem resulted from the manufacturing process (powder metallurgy) or was inherent to the material.

Transient liquid-phase (TLP) bonding has proven fairly successful in joining Al-MMCs. The process employs a filler material or interlayer to produce a transient liquid layer at the interface to be joined. Solidification of the joint occurs isothermally, by diffusion. The advantage of TLP bonding of Al-MMCs involves the lower peak-processing temperatures, compared with the temperatures used in other fusion-welding processes. The lower processing temperatures result in less damage to the engineering properties of the composite in and around the joint. However, there is a concern for damage to the properties of the composite base material during processing, because the thermal cycles for TLP bonding hold the entire assembly at temperatures near the solidus for a longer time, relative to the other fusion-welding processes.

Transient liquid-phase bonding processes for Al-MMCs are controlled by several parameters, including surface finish, type and thickness of interlayer or filler metal, processing time and temperature, and clamping pressure on the joint. The surface aluminum oxides must be removed from the samples to facilitate wetting of the substrate by the interlayer. The choice of the correct combination of processing parameters is critical in avoiding such problems as reinforcement enriched or depleted zones and Kirkendall porosity. In general, the thinnest interlayer possible should be used to allow for the shortest processing times and a narrow liquid zone. Additionally, the lowest possible temperatures should be used to limit damage to the material properties of the composite. Although the application of pressure can aid in improving interlayer-substrate contact, excess pressure can lead to expulsion of the liquid zone, which results in reinforcement-rich areas at the joint line.

Silicon Carbide-Reinforced Al-MMCs. Transient liquid-phase bonding with gold and aluminum-silicon-magnesium interlayers has been used to join two 6061/SiC/25_p composite sheets (Ref 14). Based on thermomechanical simulation studies, a process window of time-temperature combinations that would not produce damage to the properties of the base material was developed. The window ranged from 30 min at 565 °C (1050 °F) to 10 min at 580 °C (1075 °F). A 0.025 mm (0.001 in.) gold interlayer was shown to produce better results than the aluminum-silicon-magnesium material. Optimum conditions of 30 min at 567 to 580 °C (1053 to 1075 °F) were reported for the gold interlayer. Three distinct zones were observed in the vicinity of the bond interface: a particle-enriched zone, a diffuse flow zone that showed a pattern of material flow, and the undisturbed base material. No mention was made of the formation of Al_4C_3 for these conditions. Low tensile joint efficiencies (<30%) were attributed to voids at the joint interface.

Aluminum Oxide-Reinforced Al-MMCs. The joining of a 6061/Al_2O_3/15_p Al-MMC using TLP bonding also has been reported (Ref 15). Three types of interlayers demonstrated an ability to join the material: gold, copper, and Al-12Si. The bonding experiments were performed in vacuum (1.3×10^{-8} Pa, or 10^{-10} torr) on mechanically cleaned samples using a clamping pressure of less than 70 kPa (10 psi). Joining with a 25 μm (1 mil) thick interlayer of gold at 580 °C (1075 °F) for 130 min produced the strongest bonds. The joints had a 323 MPa (47 ksi) yield strength and a 341 MPa (49 ksi) ultimate tensile strength with a joint efficiency of 95%. Joining with a 125 μm (0.005 in.) thick layer of Al-12Si at 585 °C for 20 min yielded bonds with nearly identical properties; however, the bond line contained residual filler material, as well as voids. A 25 μm (0.001 in.) thick layer of copper produced bonds with much lower strengths. An increase in volume fraction of the reinforcement was observed near the bond lines of joints made with gold and copper. Increased loading of reinforcement was not observed for bonds made with the Al-12Si.

The brazing of a 6061 MMC reinforced with 5, 10, and 15 vol% short Al_2O_3 fibers using aluminum-silicon and aluminum-manganese interlayers has been studied (Ref 16). However, the reported bonding temperature range of 580 to 610 °C (1075 to 1130 °F) suggests that TLP bonding may have actually occurred. A 150 μm (0.006 in.) thick sheet of Al-10Si was used for joining, as well as a 140 μm (0.0056 in.) thick sheet of Al-1.5Mn clad with 20 μm (800 μin.) of Al-10Si on each side. The bonding time for each test was 10 min at a vacuum of 6.7 mPa (5×10^{-5} torr). Bonding the composite to itself proved easier than joining the composite to a monolithic 6061 alloy. The tensile strengths for the similar material bonds of 5% aluminum oxide fiber material exceeded 230 MPa (33 ksi). The joint efficiencies of these bonds were not reported.

Resistance Welding and Forge Welding

Both resistance welding and forge welding are quite adaptable to a range of discontinuously reinforced aluminum composites. As described previously, problems associated with welding these materials typically have two causes. For the silicon carbide-reinforced Al-MMCs, the high temperatures and relatively long times at temperatures permit dissolution of the carbides and subsequent precipitation of detrimental phases (Al_4C_3). For the aluminum oxide-reinforced Al-MMCs, similar conditions allow the individual reinforcing particles to agglomerate, which reduces material performance. Both resistance and forge welding processes have rapid thermal cycles that may limit these problems. Particular aspects of these processes are described separately below.

Resistance Welding. Virtually all available work concerning the resistance welding of MMCs has been done using the resistance spot welding technique. An example of a cross section of a spot weld made on an A359 (Al-9Si-0.3Mg)/SiC/10_p is shown in Fig. 4. Aluminum MMCs are generally spot welded using conditions similar to those for conventional aluminum alloys. However, these materials typically require substantially less current (about half) for welding. This is likely due to an increase in bulk resistivity associated with the addition of the particles. The spot weld in Fig. 4, which shows a full-size nugget, does not show any of the Al_4C_3 plates seen in the fusion zones of the laser welds. Rather, a uniform distribution of the SiC particles is noted.

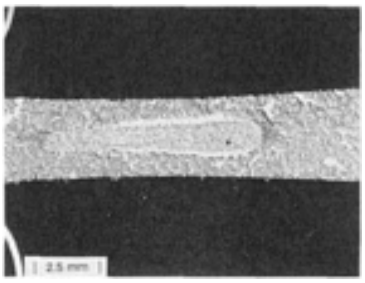

FIG. 4 RESISTANCE SPOT WELD ON A359/SIC/10$_p$

It is believed that the minimal reaction of the SiC to form Al_4C_3 is due to two factors. First, in resistance welds, the temperature of the liquid nugget only barely exceeds the melting point of the material (Ref 17), providing little, if any, driving force for the reaction. Second, temperature excursions above the liquidus are relatively short, typically less than 0.1 s, which minimizes any potential reaction.

Spot welds on discontinuously reinforced aluminum composites do show some redistribution of the reinforcement in the fusion zone (Fig. 4). Typically, the fusion zone is relatively free of the reinforcement near the fusion line, with an increased density of the reinforcement near the center of the weld. It is possible that this redistribution of the composite is the result of macroscopic liquid flow during solidification, but the effect is still under study. The effect of this reinforcement-free zone on the mechanical performance of the weld is not known.

Friction Welding. Both silicon carbide- and aluminum oxide-reinforced Al-MMCs have been friction welded using continuous-drive and inertia machines (Ref 18, 19). Friction welding is a solid-state process and does not require melting. Thus, it is not hampered by the melting and solidification concerns described previously. An examination of friction welds on these materials typically shows a distribution of reinforcement particles similar to that in the base material. There is, however, concern with the development of high in-process torques associated with these processes. High torques, particularly during stopping, can cause debonding of the matrix and the reinforcement, resulting in cracking near the bond line. In addition, stringers, if present in the material, can "open up" under the influence of these resultant torques.

Compared to conventional aluminum alloys, discontinuously reinforced aluminum composites require about double the applied force. This is because the reinforcement particles substantially increase the flow stress of the composite, even at high temperatures, preventing metal flow.

Inertia friction welding studies on an A356/SiC/20$_p$ and an A359/SiC/20$_p$ have been performed (Ref 18). Both similar and dissimilar material welds to a monolithic 6061-T651 aluminum alloy were produced over a range of flywheel speeds and axial pressures. High joint efficiencies (greater than 70%) were realized when high flywheel speeds and high axial pressures, relative to those used for monolithic aluminum alloys, were employed for the similar material welds. The joint efficiencies of the dissimilar welds were less than 70%, relative to the composite base material.

Flash-butt welding, another nominally solid-state process, has also been found to be effective for joining these materials (Ref 20). The flash welding of conventional aluminum alloys is typically characterized by very fast flashing rates and upset velocities. Similar approaches are recommended for the flash welding of Al-MMCs. Other process features that contribute to weld quality are the use of shielding gases during flashing (minimizing bond-line oxidation) and dc power for flashing. The dc power appears to provide a finer flash, resulting in higher thermal gradients in the workpiece.

Capacitor discharge welding is a generic term relating to all resistance-welding processes that supply energy to the workpiece by the discharge of charged capacitors. Variations on this process range from spot welding to small-scale butt welding. Generally, capacitive discharge welding processes are characterized by extremely rapid discharge rates (on the order of 5 to 25 ms) and subsequent rapid thermal cycles. In terms of suppressing chemical reactions in silicon carbide-reinforced Al-MMCs, the capacitive discharge processes offer considerable potential.

Work on the capacitive discharge welding of Al-MMCs has been reported (Ref 21). The capacitive system used in this work was basically a forge-butt welding process. Specifically, the system used oriented parts in a butt configuration, with the ends separated by a projection on one of the surfaces. A force was then applied to the workpieces and the energy from the discharging capacitors introduced. The result was surface melting, followed by impact and forging of the components. This work has shown that Al_4C_3 formation can be precluded on several types of silicon carbide-reinforced Al-MMCs. Consistent with the other resistance-welding processes, the short exposure times and rapid cooling rates (approximately 10^6 °C/s, or 2×10^6 °F/s) were responsible for the retention of the SiC.

General Welding Characteristics of High-Temperature Materials

A.C. Lingenfelter, Lawrence Livermore National Laboratory

Introduction

HIGH-TEMPERATURE ALLOYS are generally recognized as being those alloys that are used at temperatures of 540 °C (1000 °F) and above. These alloys exhibit some combination of high strength at temperature; resistance to environmental attack (including nitridation, carbonization, oxidation, and sulfidation), excellent creep resistance, creep rupture strength, toughness, and metallurgical stability; useful thermal expansion characteristics; and resistance to thermal fatigue and corrosion. This article addresses the general welding characteristics common to both solid-solution-strengthened and precipitation-hardened nickel-, iron-, and cobalt alloys. The remaining articles in this Section focus on characteristics of nonferrous high-temperature materials.

Table 1 is a reasonably inclusive list of the alloys that have found application as high-temperature materials and that have demonstrated some degree of weldability. (It should be noted that the refractory metals and alloys that are applied at high temperature are not listed in Table 1; information about these materials can be found in the article "Special Metallurgical Welding Considerations for Refractory Metals" in this Section of the Handbook.) Many of the alloys listed in Table 1 are general-purpose materials that find application in a full temperature range, from cryogenic temperatures on up. In addition, certain of these alloys may be used for their corrosion resistance or some other property not associated with high-temperature application. These considerations make it difficult to precisely estimate the amount of material used specifically for high-temperature applications, although a rough estimate would be of the order of 30,000 tons/year (27,000 tonnes/year). Most of the alloys listed are produced as wrought products; however, some cast materials appear on the list, and cast versions of many of the wrought alloys are produced.

Applications of these materials include:

- HEAT TREATMENT FIXTURES AND FURNACE PARTS
- HEATING ELEMENTS USED FOR DOMESTIC OR INDUSTRIAL APPLICATIONS
- NUCLEAR AND FOSSIL FUEL POWER PLANT COMPONENTS (BOTH ROTATING PARTS AND STRUCTURAL COMPONENTS SUCH AS PIPING AND PUMP HARDWARE)
- GAS TURBINE ENGINE COMPONENTS (AGAIN, BOTH ROTATING PARTS AND THE STATIC STRUCTURAL MEMBERS)
- PYROCHEMICAL AND PYROMETALLURGICAL PROCESSING EQUIPMENT, PARTICULARLY WHERE HIGH TEMPERATURE IS COMBINED WITH HIGH STRESS AND/OR AN AGGRESSIVE ENVIRONMENT
- ENVIRONMENTAL REMEDIATION EQUIPMENT SUCH AS THAT USED TO PROCESS STACK GASES, RECUPERATORS USED TO RECOVER WASTE HEAT, AND INCINERATORS OR OTHER HARDWARE USED FOR HIGH-TEMPERATURE DESTRUCTION OF WASTE

A.C. Lingenfelter, Lawrence Livermore National Laboratory

General Welding Characteristics of High-Temperature Alloys

As with all materials, successful welding of high-temperature alloys requires a thorough understanding of the metallurgy of the individual alloys involved. Strengthening of these alloys is achieved by the precipitation of a finely dispersed age-hardening constituent in the matrix of the alloy and/or by the addition of solid-solution-strengthening alloy additions in the matrix. In addition, the strength of these materials can be significantly increased by careful control of their thermomechanical history. Hot-working finishing temperatures can be lowered below the recrystallization temperature of the alloy, resulting in the retention of the hot/cold work introduced in the final hot-working operations. This retained strain energy significantly increases the strength of the material, particularly when combined with subsequent aging heat treatments. Yield strengths in excess of 1380 MPa (200 ksi) are possible with at least a few of these alloys.

Effect of Welding on Performance and Properties. The thermal cycle(s) introduced by the welding process can significantly alter the physical properties of the base material in the region of the weld. The heat of welding can result in the solutioning of age-hardening constituents on other precipitates such as delta phase or carbides, which define the strength, ductility, corrosion resistance, grain size, or other properties of the material. Temperatures immediately adjacent to the weld will reach and exceed the recrystallization temperature, resulting in grain growth and elimination of the retained strain energy from thermomechanical processing. These effects can significantly alter the properties of the weld heat-affected zone (HAZ).

The interaction of the alloy with the welding process can introduce micro- and, in some cases, macrofissuring in the base metal, either in the as-welded condition or as a result of subsequent heat treatment. Variables such as grain size, chemical composition, and level of restraint have been linked to the sensitivity of materials to base metal fissuring.

Applications that require good creep strength and resistance to creep rupture frequently require that the material be in a grain-coarsened condition. Applying a high-energy-input welding process to a coarse-grain material can frequently result in HAZ micro- or macrofissures. The addition of elements such as boron and zirconium to enhance stress rupture life and ductility has been shown to increase fissuring sensitivity. Fortunately, many of these materials have inherently good ductility, and the micro- or macrofissures, although undesirable, may not detract from the useful service of the material. Each case needs to be evaluated on the basis of the fitness-for-service requirements of the particular application.

Heat Treatment. Postweld heat treatment is required for most age-hardenable materials so that they can develop their full strength and physical property potential. Yield-strength-level residual stresses are introduced by the welding thermal cycle. Direct age hardening of some of these alloys after welding can result in strain age cracking; this is particularly a problem with the aluminum/titanium-hardened alloys, which exhibit a very rapid age-hardening response. Because of the relaxation resistance of these alloys, the yield-strength-level stresses can result in short-time stress rupture failures. Preweld heat treatments, which put the material in a condition that promotes stress relaxation (generally an overaged condition), as well as postweld heat treatment cycles, which stress relieve the structure prior to the age-hardening treatment, can serve to minimize or eliminate the strain age cracking problem.

Alloys with very high hardener contents, such as cast IN-713C, were once considered unweldable because of their susceptibility to strain age cracking. However, IN-713C has been successfully repair welded by preheating the material into or slightly above the age-hardening temperature range before welding and by applying the appropriate postweld heat treatment to avoid cracking.

The sluggish aging response of the niobium-hardened alloys, such as Inconel 718, helps them avoid the strain age cracking problem. Direct aging of such alloys, while possible in most instances, needs to be evaluated where highly restrained conditions are imposed.

In some cases, non-age-hardenable solution-strengthened materials exposed to high postweld temperatures--whether from a postweld heat treatment or the application environment--experienced base metal macrofissuring. These instances generally occurred with highly restrained heavy-section weldments made in grain-coarsened base materials. Again, the apparent cause is the inability of the base metal to relax the yield-strength-level residual stress prior to suffering a short-time stress rupture failure.

For additional information about the heat treatment response of high-temperature materials, see the article "Postweld Heat Treatment of Nonferrous High-Temperature Materials" in this Section of the Handbook.

Effect of Contaminants on Weld Soundness. High-temperature alloys must be clean and free of machining oils and other contaminants if welds free of defects are to be achieved. Introducing contaminants to the fusion zone can lead to fissuring and porosity.

The presence of low-melting elements and alloys in the HAZ can lead to fissuring. This problem has been noted with the presence of copper, brass, and lead, to name a few. The low-melting material becomes liquid in the HAZ as the arc passes and the liquid penetrates the grain boundary. This grain boundary penetration reduces the strength of the boundary and, coupled with yield-strength-level stress, leads to microfissuring. Care must be taken when using copper chills and tooling not to deposit the copper on the surface of the base material. Lead can cause weld metal fissuring if introduced even in minute quantities to the fusion zone. Unfortunately, lead/brass/copper hammers are commonly used in shops to "adjust" the position of metal parts in the tooling. Instances have been noted where this practice resulted in weld heat-affected zone and/or weld fusion zone fissuring.

Most of the high-temperature alloys have excellent oxidation resistance because they develop a tightly adhering refractory oxide on the surface of the material. This is a highly useful property from an application standpoint, but it can lead to problems such as trapped oxide in the weld metal and lack-of-fusion defects at the weld metal/parent metal interface if the surface of the material to be welded is not free of oxide. The oxide cannot be removed by simple wire brushing; the metal surface may appear to be clean after brushing, but the oxide has only been polished. An aggressive abrasive grinding operation is needed to positively remove the oxide. Less-than-ideal inert gas protection can allow the formation of an oxide film on the surface of the deposited weld metal. Care needs to be taken to remove this oxide before multipass welding to avoid the problems of entrapped oxide and lack-of-fusion defects.

Welding Metallurgy of Nonferrous High-Temperature Materials

R.G. Thompson, University of Alabama at Birmingham

Introduction

THE PHYSICAL METALLURGY of nonferrous high-temperature materials that affects weldability centers on the precipitates used for age hardening (γ' and γ'') and those associated with solidification and solidification segregation (primarily, Laves and carbides). Age hardening creates problems associated with strain-age (that is, reheat) cracking, while carbides and Laves phases can initiate melting and cause cracking of heat-affected zone (HAZ) grain boundaries. The weldability of these alloys generally affects both the fabricator, who must weld complicated assemblies, and the foundry, which must make repair welds to salvage expensive castings. Thus, weldability problems are not solved by designating some alloys weldable and others unweldable. Weldability solutions are often needed for both weldable and unweldable alloys.

Welding Metallurgy of Nonferrous High-Temperature Materials

R.G. Thompson, University of Alabama at Birmingham

Strain-Age Cracking

Cracking is sometimes found in age-hardenable alloys that are slowly cooled or reheated through the hardening temperature range in the presence of residual or applied stress in a constrained condition. The rate of hardening is of primary importance relative to the heating or cooling rate through the hardening temperature range. For cracking to occur, the thermal cycle must allow sufficient hardening for the imposed stress to cause cracking. Of equal importance is the

imposed stress, which must be sufficient in magnitude to initiate cracking. When these two phenomena occur simultaneously, they can result in severe cracking.

The root of the strain-age cracking problem from the metallurgical viewpoint is γ' precipitation. The nominal composition of γ' is Ni_3Al. However, the precise composition is even more complex. A typical γ' precipitate in alloy 731 is:

$$(NI_{0.884}CO_{0.070}CR_{0.032}MO_{0.008}\ V_{0.003})_3(AL_{0.632}TI_{0.347}\ V_{0.013}CR_{0.006}MO_{0.002})$$

A typical range of heat treatments for hardening nickel superalloys is given in Table 1.

TABLE 1 TYPICAL HEAT TREATMENT PARAMETERS FOR HARDENING NICKEL-BASE SUPERALLOYS

TREATMENT	**TEMPERATURE**		TIME, H
	°C	**°F**	
HOMOGENIZE AND HOT ISOSTATIC PRESSING	NEAR SOLIDUS		**1-20**
SOLUTION ANNEAL	925-1150	1700-2100	**1-5**
UPPER AGE HARDENING	815-980	1500-1800	**10-25**
LOWER AGE HARDENING	**650-815**	**1200-1500**	**10-20**

After welding, the residual stress is relieved, and the maximum strength is obtained by a solution anneal and aging heat treatment. Problems arise when the welded structure is heated through the aging temperature range on its way to the solution temperature. Strain-age weldability is dependent on both the rate and the magnitude of γ' precipitation (Ref 1). Figure 1 shows a plot of weldability as a function of the (Ti + Al) content. Titanium and aluminum are the γ' strengtheners in many superalloys. When the (Al + Ti) level exceeds some critical value, strain-age cracking becomes a significant problem. The base metal can be effectively protected against strain-age cracking by welding in the overaged condition. This prevents aging during reheating.

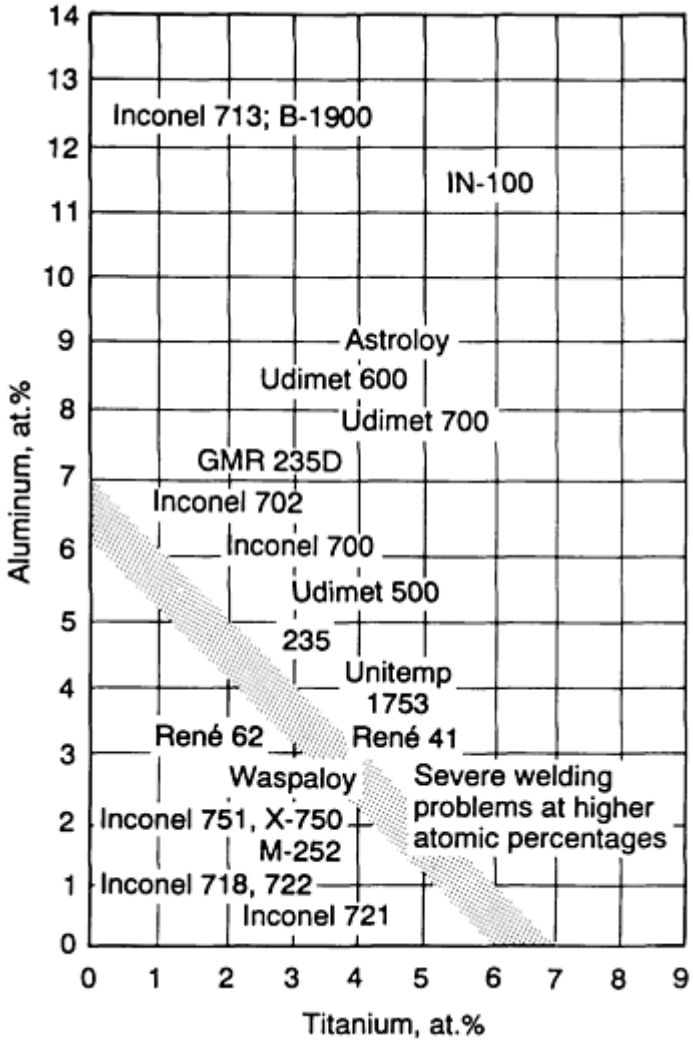

FIG. 1 PLOT OF ALUMINUM CONTENT VERSUS TITANIUM CONTENT TO INDICATE COMMERCIAL NICKEL-BASE ALLOYS THAT PRESENT WELDABILITY PROBLEMS WHEN (AL + TI) CONTENT EXCEEDS 6%. SOURCE: REF 1

Unfortunately, the HAZ cannot be protected in a similar manner. The welding process invariably produces a HAZ thermal cycle, which puts some of the age-hardening constituents into solution. During slow cooling or reheating these constituents can reprecipitate, age harden, and produce a crack-susceptible condition in the HAZ. This will be the case regardless of the preweld heat treatment.

Alloy 718 does not undergo strain-age cracking (Ref 2). The age hardening develops around a Ni_3Nb, γ", precipitate. The γ" precipitates at a much slower rate than the γ'. This allows alloys to be heated into the solution temperature range without suffering aging and the resultant strain-age cracking. Figure 2 compares the aging rates of several γ' alloys with those of alloy 718, which is strengthened with the γ" precipitate. Hardening is retarded in the γ" alloys, and they offer great latitude in methods for heating and cooling parts.

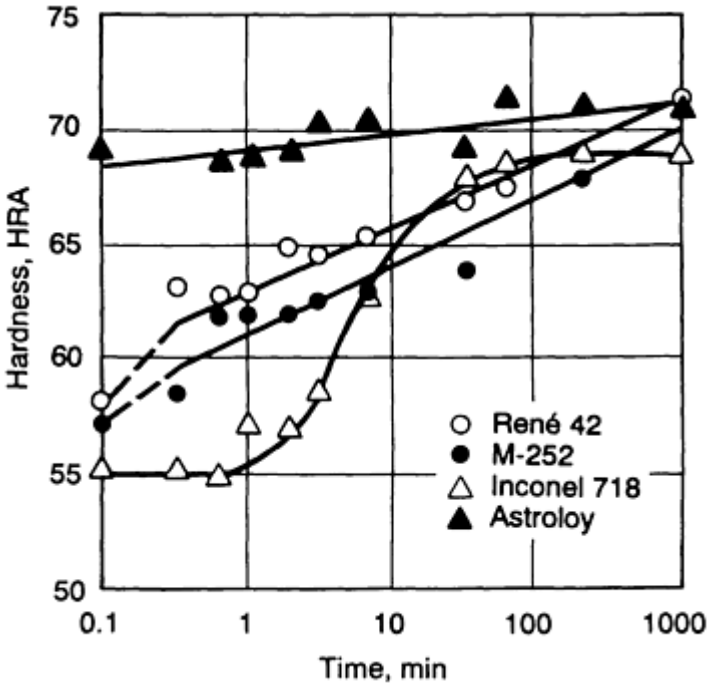

FIG. 2 PLOT OF HARDNESS VERSUS TIME TO SHOW AGE-HARDENING KINETICS OF SELECTED NICKEL-BASE ALLOYS. SOURCE: REF 3

Welded structures that require corrosion resistance but not high strength often will not need postweld heat, and can thus avoid strain-age cracking. However, if they are placed in service at elevated temperature, they may still crack during the initial heat-up cycle.

Strain-Age Cracking Susceptibility Curves. The circular-patch test is a high-restraint weld test that can be used to evaluate the sensitivity of an alloy to strain-age cracking. The test, when used with thermal treatments, can be used to produce crack-susceptibility C-curves. These are so named because of the characteristic "C" shape of the temperature-time space that separates the cracked from the uncracked behavior of this rate process. Figure 3 shows that, for a given C-curve behavior, different heating rates can produce cracked or uncracked plates. Figure 4 shows alloy chemistry variations that can affect the crack sensitivity of a given alloy.

HAZ Liquation Cracking. Phases that form during solidification, such as MC carbides and Laves phases, have the potential to initiate melting in the HAZ during welding and spread along the grain boundaries (Fig. 5). The melting, often termed liquation, occurs because of a reaction between the dissolving precipitate and the matrix. When this melting is accompanied by sufficient thermal stress, cracks can form along the HAZ grain boundaries, and extend into the fusion zone. Such cracking may be termed liquation cracking, hot cracking, or microfissuring. A number of alloy systems are known to experience liquation cracking; some are listed in Table 2.

TABLE 2 CONSTITUTIONAL LIQUATION IN MULTICOMPONENT SYSTEMS

Liquid metal is invariably associated with the HAZ except in the unusual case of very pure, single-element metals. This is so because the HAZ stretches from the base metal to the edge of the fusion zone and will include all or part of the mushy zone (a pure metal has no mushy zone). This liquid is almost always found along the grain boundaries (Fig. 6). The few exceptions are alloys that have miscibility gaps, such as leaded brass. These alloys can have liquid from the low-melting-point phase, such as lead, which does not wet the grain boundaries. Such nonwetting behavior is associated with alloys where the solute is insoluble in the parent phase. It can be concluded that most engineering alloys contain a HAZ during welding that has a mushy zone full of intergranular liquid.

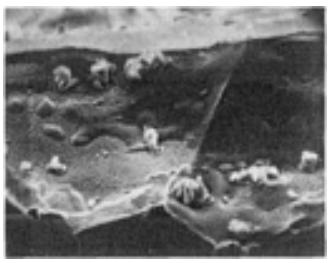

FIG. 6 INTERGRANULAR FRACTURE SURFACE SHOWING PARTIAL INTERGRANULAR WETTING WITH BOTH SOLID-SOLID AND LIQUID-LIQUID BONDING. 500×

The mushy-zone liquid generally does not contribute to poor weldability, because during the normal course of solidification it is always open to the fusion zone. The fusion zone acts as a source of liquid to backfill or heal shrinkage or cracks that might form.

Metallurgically, liquation cracking occurs when an alloy containing a susceptible second phase is heated at such a rate that the second phase cannot dissolve before the alloy reaches a system solidus that causes melting. This melting will invariably occur at the interface between the precipitate and the matrix, as can be shown with an analysis of the appropriate phase diagram. The molten liquid will spread along the grain boundaries if its solute is soluble in the matrix or if there is sufficient impurity to enhance wetting (Ref 10). This liquation can occur below the system solidus and thus be located remotely from the HAZ mushy zone. Such a location prevents backfilling and promotes liquation cracking. The fact that liquation from precipitates can extend well away from the fusion zone not only increases the chance of liquation cracking but also increases the potential length of the crack, accentuating the stress intensity of the crack.

Metallurgical evaluation of HAZ liquation reveals three stages of microstructural and compositional evolution (Fig. 7). An initial stage develops where the liquating precipitate is in contact with the liquid. In a later stage of evolution, the precipitate is completely liquated, but the intergranular liquid is stable and may even be growing. Finally, the intergranular liquid begins to solidify and may retract from the grain boundary.

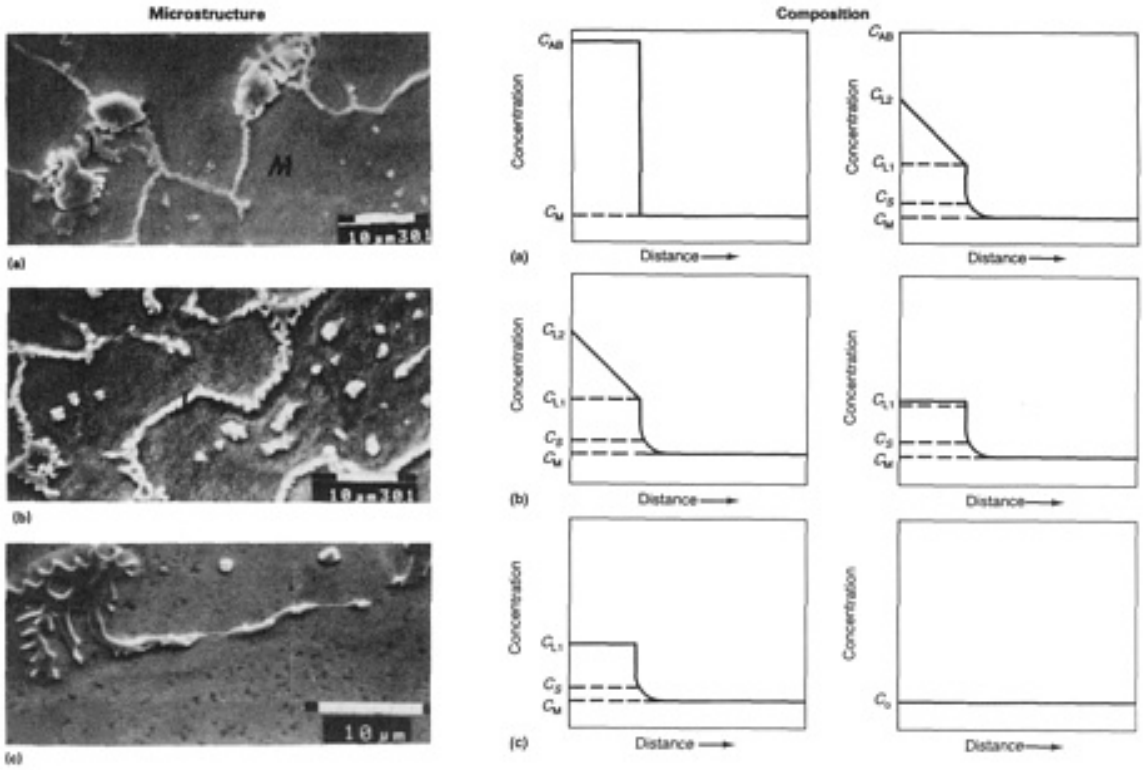

FIG. 7 THREE STAGES OF HAZ LIQUATION SHOWN RELATIVE TO THE TYPICAL TRANSFORMATION IN MICROSTRUCTURE AND COMPOSITION OF NICKEL-BASE ALLOY 718. (A) STAGE 1: PRECIPITATE LIQUATION. (B) STAGE 2: ELIMINATION OF COMPOSITION GRADIENT. (C) STAGE 3: SOLIDIFICATION

Parameters Affecting Liquation Cracking

Grain Size. A large grain size promotes liquation cracking (Ref 11), as shown in Fig. 8. This can be understood in several ways. When the HAZ begins to accumulate strain from residual stress, grain boundary sliding is one mechanism

that operates to accommodate the strain. Large grain size does not accommodate the strain as readily as smaller grain size, and the potential for crack initiation at grain boundary triple points, and therefore liquation cracking, is increased (Ref 13). Another effect of grain size occurs when precipitates liquate and the liquid spreads along the boundaries. Material of large grain size will accumulate a thicker layer of liquid for a given amount (volume fraction) of precipitate, because larger grains have less grain boundary surface area (Ref 14). The thicker liquid layer takes longer to resolidify during cooling, as has been shown in alloy 718 (Ref 11) and through computer simulations (Ref 14, 15). Anything that increases the life of the intergranular liquid relative to the onset of residual stress accentuates liquation cracking.

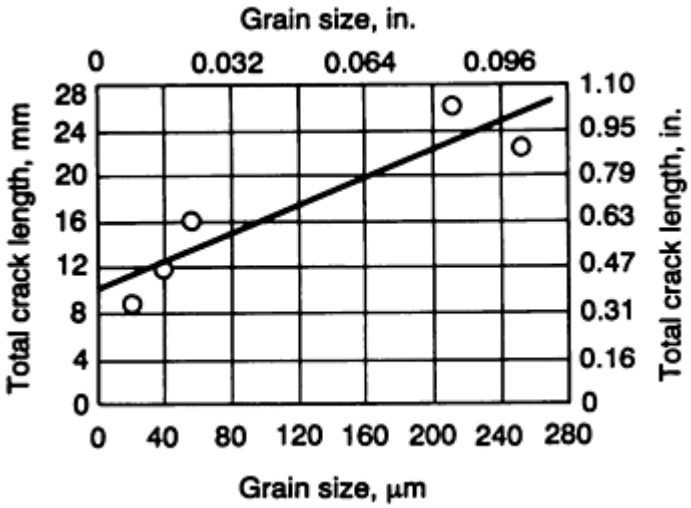

FIG. 8 PLOT OF TOTAL CRACK LENGTH VERSUS GRAIN SIZE TO SHOW EFFECT OF MICROFISSURING IN ALLOY 718 WHEN EVALUATING NICKEL-BASE ALLOY WITH SPOT VARESTRAINT TEST. SOURCE: REF 12

Liquation cracking is sensitive to the amount and location of second-phase precipitates. The size of precipitates in the HAZ, as well as the location relative to the position of grain boundaries, changes during the welding thermal cycle. Precipitates, especially those susceptible to constitutional liquation, dissolve during the thermal cycle (Ref 16).

Constitutional liquation can be illustrated with the simple binary eutectic shown in Fig. 9(a). Alloy C_O has a certain volume fraction of second-phase particles, AB, at room temperature. When the alloy is rapidly heated to a temperature, *T,* above the binary eutectic temperature, T_E, there may be insufficient time for complete dissolution of AB. Therefore, at temperatures above T_E, the AB phase is still present. Dissolution of AB above T_E takes place by the formation of a liquid phase that subsequently resolidifies in accordance with phase diagram requirements. The concentration gradients in the matrix adjacent to the AB particle are shown in Fig. 9(b). The terms C_{L1} and C_{L2} are the concentrations of liquid in equilibrium with γ and AB, respectively, at temperature *T.* The term C_S is the concentration of γ in equilibrium with liquid, and C_M is the concentration of the γ matrix in equilibrium with the AB particle at room temperature.

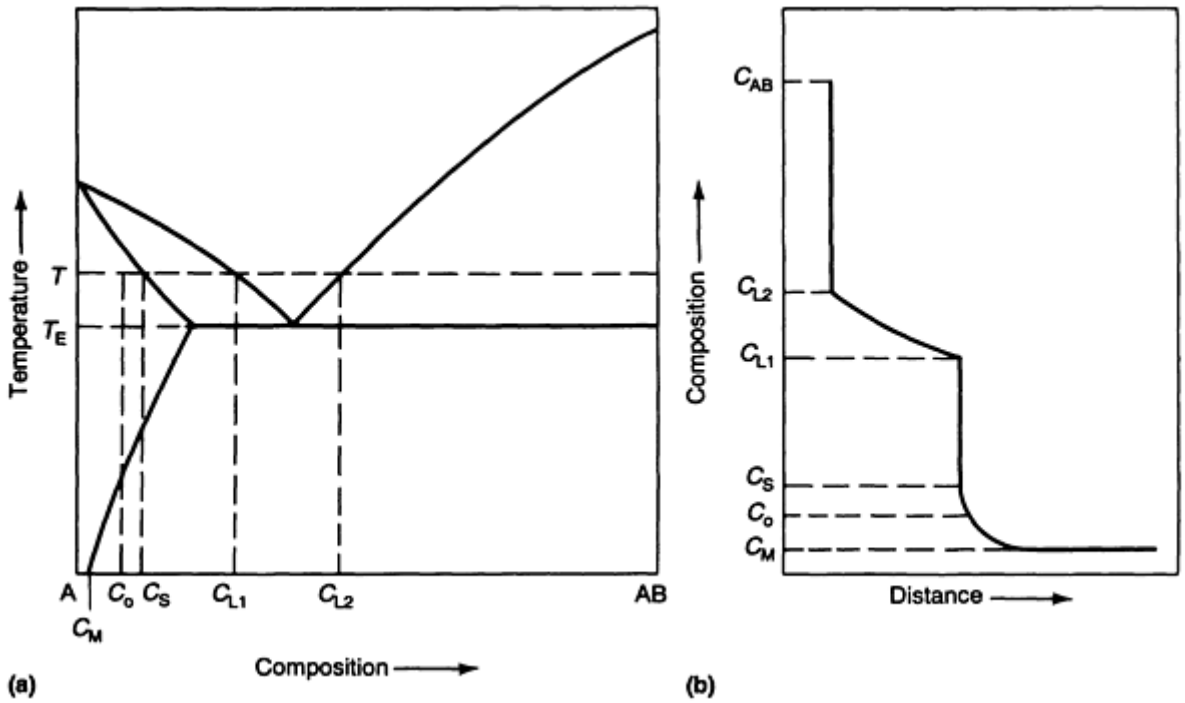

FIG. 9 EFFECT OF TEMPERATURE AND DISTANCE ON LIQUATION IN A BINARY SYSTEM. (A) CONSTITUTIONAL LIQUATION OF AB PARTICLES. (B) CONCENTRATION GRADIENTS IN FRONT OF THE LIQUATING AB PARTICLE

Behavior of NbC Dissolved in Nickel (Ref 16). A computer simulation of NbC dissolved in nickel is shown in Fig. 10. Some precipitates dissolve completely and disappear, while others become small and lose their attachment to the grain boundary. This is shown by computer simulation in Fig. 11, where *R* is the fraction of initial grain boundary precipitates remaining on the HAZ grain boundaries during heating.

Amount of Liquating Precipitate. A large amount of liquating precipitate can have both positive and negative effects relative to liquation cracking. On the negative side, a large amount of liquation produces a thicker layer of intergranular liquid. Just as for large-grain-size metal, a thicker layer takes longer to solidify and accentuate liquation cracking. However, on the positive side, a larger amount of liquation produces a wider path for backfilling from the mushy zone and thus can help heal cracking. This would be especially effective for liquation that occurs at a temperature near the bulk solidus. Because wrought alloys and many cast alloys are metallurgically designed to minimize liquation-type precipitates, the initial amount of precipitates is low (0.5 to 2.0 vol% for both wrought and cast alloy 718). Increasing an initially small amount of precipitate increases liquation cracking (Ref 11). Thus, using large amounts of precipitate to reduce liquation cracking would seem prudent only under closely guarded conditions where the precipitate is well connected to the HAZ mushy zone.

Finally, a more sophisticated analysis of the effect of precipitate volume fraction on liquation cracking must take into account the rate at which the precipitates dissolve before liquation (because all precipitates that liquate below the solidus try to dissolve first). While a large volume fraction of precipitates may be present in the HAZ before welding, those precipitates may disappear quickly during heating. Thus, the rate of precipitate dissolution and the welding thermal cycle must be known to predict the effect of precipitate volume fraction on cracking.

Type of Precipitate. Two types of precipitates liquate in the HAZ:

- CONSTITUTIONALLY LIQUATING PRECIPITATES (REF 7)
- EQUILIBRIUM MELTING PRECIPITATES (REF 12)

Constitutionally liquating precipitates can begin melting below the bulk solidus because their liquation is tied to the fact that the alloy has been forced to support their existence beyond some equilibrium limit. Such nonequilibrium processing can result from two factors: (1) a rapid heating rate that takes a normally low-temperature phase above its equilibrium stability temperature or (2) coring-type segregation during casting. Coring-type segregation causes the system to create a nonequilibrium phase (such as Laves phase in alloy 718) or an overabundance of an equilibrium phase (such as MC carbides). Both the nonequilibrium phase and the excessive fraction of the equilibrium phase can constitutionally liquate (Ref 4).

Equilibrium Melting Precipitates. The equilibrium phase melts when heated above its solidus temperature, producing HAZ liquid.

Precipitates Versus Liquation Cracking. The two types of precipitates described above are different relative to liquation cracking because their melting ranges are different relative to the mushy zone. Because equilibrium precipitates will always liquate at or above the bulk solidus, they will be connected with the mushy zone and have access to large volumes of liquid for backfilling and healing. The nonequilibrium precipitates will have the potential to liquate below the bulk solidus and thus be separated from backfilling liquid from the larger mushy zone. These nonequilibrium precipitates will have a greater potential for liquation cracking.

Solidification carbides such as MC carbides can be present in overabundance due to coring during solidification. Thus, they can be present in the nonequilibrium form but with a melting range that spans the subsolidus to the bulk liquidus. The liquation of the carbides should produce a continuous path to the mushy zone and thus provide a network for backfilling and healing cracks. However, the liquation of an MC carbide produces such great local solute enrichment at the groin boundary that the resolidification of these boundaries can be greatly delayed. This delay in resolidification separates them from the bulk solidification of the mushy zone and makes these boundaries potential sites for liquation cracking.

Impurities and Heat Treatment. Impurity metallic elements have long been the subject of intergranular-cracking investigations (Ref 17, 18, 19, 20, 21). Some elements (for example, sulfur, phosphorus, antimony, arsenic, bismuth, and tin) concentrate in the grain boundaries of various systems. Other elements (for example, boron), affect intergranular properties (for example, stress rupture strength).

Elements that have been identified as potential sources of liquation cracking are sulfur, phosphorus, boron, and lead. It has been suggested that if the impurity level restrictions shown below are observed, increased liquation cracking will not be observed (Ref 20):

ELEMENT	COMPOSITION, WT% (MAXIMUM)
SULFUR	**0.015**
PHOSPHORUS	**0.015**
SILICON	**0.02**
OXYGEN	**0.005**
NITROGEN	**0.005**

Some researchers separate the behavior of impurities into two groups: (1) those that are present as precipitates (for example, borides, sulfides, and so on) and (2) those that are not precipitated but are enriched at the grain boundary and the precipitate interfaces due to segregation. The latter category would also include elements such as boron and sulfur. However, the state in which the impurities reside is often debatable, and the issue here is their effect on HAZ hot cracking. Thus, no attempt will be made to differentiate between impurity precipitates or segregation.

Liquation is not necessarily caused by impurities. Impurities magnify the problem by:

- INCREASING THE WETTING OF THE INTERGRANULAR LIQUID (REF 11)
- DEPRESSING THE SOLIDUS TEMPERATURE
- FORMING LOW-MELTING-POINT PRECIPITATES/EUTECTICS
- INCREASING THE AMOUNT OF LIQUID PRESENT ON THE GRAIN BOUNDARIES

Sulfur and carbon provide a unique case. When the carbon content is increased in alloy 718, the amount of carbide and the potential for liquation cracking both increase (Fig. 12). If the sulfur content is increased, the potential for liquation cracking also increases about the same amount for both carbon levels (Fig. 12). One reason for the increased cracking susceptibility with sulfur is that the sulfur becomes trapped between the carbide and the matrix during casting (Table 3).

A high sulfur level reduces the solidification temperature of the carbide and appears to increase the wetting of the intergranular liquid in the HAZ during cooling (Ref 22).

STEP-COOLED	**0.1**	**2.20**

Source: Ref 21

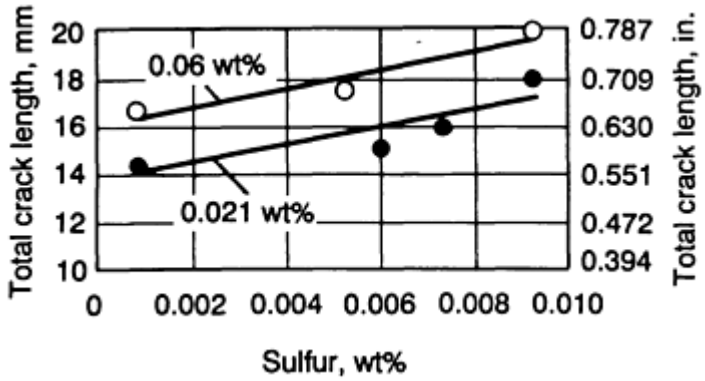

FIG. 12 PLOT OF TOTAL CRACK LENGTH VERSUS SULFUR CONTENT AS A FUNCTION OF TWO SELECTED BULK CARBON LEVELS TO SHOW MICROFISSURING SUSCEPTIBILITY OF CAST ALLOY 718. SOURCE: REF 11

Impurities may also affect the response of liquation cracking to heat treatment. Heat treatment has been shown to have either an adverse or a beneficial effect on liquation cracking (Ref 5, 23, 24). This has been shown for alloy 718 (Fig. 13) to be a function of carbon content. This effect might be partially explained by the change in impurity distribution (in this example, sulfur) during heat treatment (Ref 21, 25). As given in Table 3, sulfur moves from the carbide matrix interface onto the grain boundaries during age-hardening treatment. Simultaneously, liquation cracking increases during heat treatment. Conversely, the solution-anneal heat treatment cleans the grain boundary of any residual sulfur and reduces the potential for liquation cracking. Many other metallurgical events occur simultaneously during these heat treatments, and it has not been shown conclusively which of these events (if not all) affect cracking.

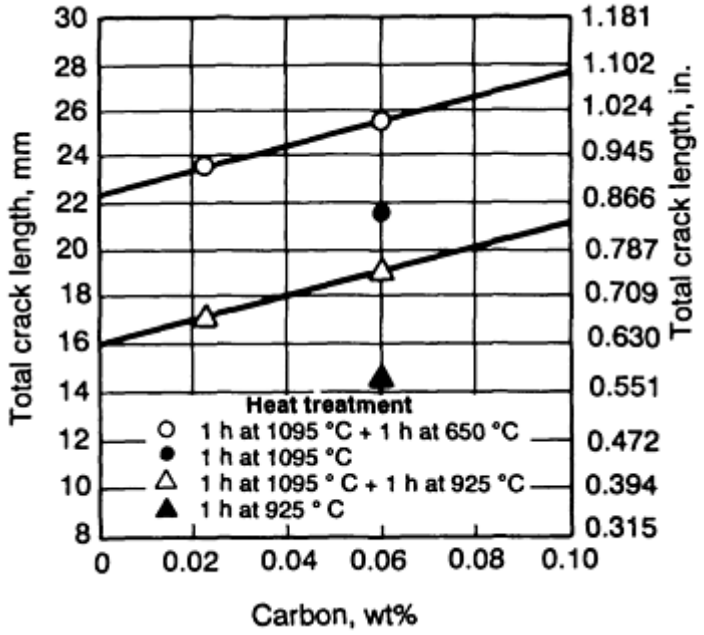

FIG. 13 PLOT OF TOTAL CRACK LENGTH VERSUS CARBON CONTENT AS A FUNCTION OF SELECTED HEAT TREATMENTS FOR CAST ALLOY 718 CONTAINING 0.009% S TO SHOW MICROFISSURING SUSCEPTIBILITY OF THE MATERIAL

Reducing Susceptibility to Liquation Cracking. Welding parameters and fabrication sequence can often be adjusted to reduce the possibility of liquation cracking. In addition, there are several metallurgical conditions that minimize HAZ liquation cracking:

- GRAIN SIZE SHOULD BE MINIMIZED
- IF PRECIPITATES ARE DESIRED FOR GRAIN SIZE CONTROL, SOLIDIFICATION PRECIPITATES SUCH AS MC CARBIDES SHOULD BE USED. THESE WILL MINIMIZE LIQUID PENETRATION INTO THE HAZ AND PROMOTE BACKFILLING AND HEALING OF CRACKS, BECAUSE THEIR LIQUATION TEMPERATURE IS SIMILAR TO THAT OF THE MUSHY ZONE
- THE AMOUNT OF PRECIPITATE THAT LIQUATES SHOULD BE MINIMIZED. IF A PARTICULARLY DIFFICULT CRACKING PROBLEM CANNOT BE RESOLVED ANY OTHER WAY, THEN INCREASING THE AMOUNT OF PRECIPITATE MAY PRODUCE ENOUGH LIQUATION TO INITIATE BACKFILLING FROM THE MUSHY ZONE AND PROMOTE HEALING OF CRACKS
- IMPURITY CONTENT SHOULD BE MINIMIZED
- WELDING SHOULD TAKE PLACE WHEN THE ALLOY HAS UNDERGONE SOME COMBINATION OF THE SOLUTIONED AND/OR HOMOGENIZED CONDITIONS, FOLLOWED BY RAPID COOLING (DIRECT QUENCHING SHOULD BE AVOIDED). THESE HEAT TREATMENTS MINIMIZE IMPURITY CONCENTRATION ON THE GRAIN BOUNDARIES

Postweld Heat Treatment of Nonferrous High-Temperature Materials

Steven C. Ernst, Haynes International, Inc.

Introduction

THE NONFERROUS HIGH-TEMPERATURE ALLOYS discussed in this article are based on nickel and on cobalt. These alloys can be generally categorized as either solid-solution strengthened or precipitation strengthened. The former category is not appreciably strengthened by heat treatment and is considered non-heat-treatable, whereas the latter category is typically used in the age-hardened or heat-treated, condition. It is important to distinguish between these two classes of alloys when considering postweld heat treatment. In general, alloys that contain significant amounts of age-hardening elements, such as aluminum, titanium, and niobium, are heat treatable. The compositions of selected nickel- and cobalt-base alloys in these two categories are shown in Table 1.

TABLE 1 NOMINAL COMPOSITION OF SELECTED NICKEL-BASE AND COBALT-BASE HIGH-TEMPERATURE ALLOYS

Postweld Heat Treatment of Nonferrous High-Temperature Materials

Steven C. Ernst, Haynes International, Inc.

Types of Postweld Heat Treatment

Stress relieving is a process used to reduce residual welding stresses prior to further fabrication or service. An important result of a good stress-relief heat treatment is dimensional stability of a weldment during high-temperature service. Typical stress-relieving temperature ranges are less than those required for annealing or recrystallization. Accordingly, stress relieving can result in deleterious effects to the microstructure and corresponding mechanical properties. When considering a postweld stress-relief heat treatment, it is important to recognize these effects so that a suitable compromise can be made between dimensional stability and mechanical properties.

Annealing is a process performed above the recrystallization temperature to promote maximum softness in an alloy. This heat treatment is also effective at relieving residual welding stresses. Annealing should be conducted after welding age-hardenable alloys in highly restrained conditions. This annealing requires high heating rates to reduce the probability of strainage cracking.

Solution annealing is a high-temperature anneal carried out above the secondary carbide solvus. Because that temperature is significantly higher than the recrystallization temperature, significant grain coarsening can occur. The carbide dissolution and coarse grain structure can be beneficial to high-temperature rupture life.

Solution treating and quenching is a process used with precipitation-strengthened alloys to dissolve the principle aging phases and carbides formed during welding and to produce a supersaturated solid solution at room temperature. This heat treatment will put the weldment in optimum metallurgical condition for subsequent age hardening.

Aging treatments are performed in the intermediate temperature range, allowing precipitation of the strengthening phase(s) from the supersaturated solid solution. The aging response may not necessarily be uniform in all regions of a weldment because of segregation effects that occur during weld solidification.

Steven C. Ernst, Haynes International, Inc.

Postweld Heat Treatment of Solid-Solution-Strengthened Alloys

Solid-solution-strengthened alloys normally do not require postweld heat treatment to achieve or restore optimum mechanical properties. Postweld heat treatment is sometimes used to provide stress relief. Complete stress relief can be achieved with full solution anneal, which also gives the alloy an optimal metallurgical condition. Solution annealing will eliminate any prior cold work by recrystallization and will dissolve secondary $M_{23}C_6$-type carbides that may have formed upon cooling during welding. Typical solution annealing temperatures for solid-solution-strengthened alloys are given in Table 2. The time required can range from a few minutes to about an hour, followed by rapid quenching in water or air. A popular calculated time is 140 s/mm (1 h/in.) of cross-section thickness.

TABLE 2 TYPICAL SOLUTION ANNEALING AND MILL ANNEALING TEMPERATURES FOR SOLID-SOLUTION-STRENGTHENED ALLOYS

ALLOY	**SOLUTION ANNEALING TEMPERATURE RANGE**		MINIMUM TEMPERATURE FOR MILL ANNEALING	
	°C	**°F**	**°C**	°F

HAYNES 230	1165-1245	2125-2275	1120	**2050**
HAYNES 188	1165-1190	2125-2175	1120	**2050**
HAYNES 25 (L-605)	**1175-1230**	**2150-2250**	**1040**	**1900**

In cases where stress relief is needed and a fine grain size is required, mill annealing is effective. The mill annealing heat treatment is similar to solution annealing. However, the lower temperatures involved are not sufficient to dissolve secondary carbides that may have precipitated intergranularly during welding. The mill annealing treatment may not develop the stress rupture properties in the weldment to their full potential. Examples of minimum mill annealing temperatures are given in Table 3.

In terms of optimizing metallurgical structure, mechanical properties, and stress relief, annealing treatments are the best postweld heat treatments for solid-solution-strengthened alloys. When large or complex structures are involved, the high annealing temperatures can result in distortion problems during the heat treatment. In many cases, the best decision may be to completely avoid postweld heat treatment. If stress relief is mandatory, but the high annealing temperatures are not tolerable, a lower temperature may be used at the expense of the metallurgical condition. Some fabricators conduct stress relieving at a temperature about 100 °C (180 °F) above the intended service temperature to avoid distortion during service. A partial stress relief can be accomplished for many alloys in the range from 450 to 900 °C (840 to 1650 °F), concomitant with embrittlement caused by extensive precipitation of carbides and topologically close-packed (TCP) phases. Additionally, the weldment may display poor creep-rupture characteristics in service following a stress relief heat treatment in the 450 to 900 °C (840 to 1650 °F) temperature range. The magnitude of stress relief and property degradation vary for each alloy and stress-relief temperature. These factors should be carefully considered if stress relief is to be performed below the minimum mill annealing temperature.

Postweld Heat Treatment of Nonferrous High-Temperature Materials

Steven C. Ernst, Haynes International, Inc.

Postweld Heat Treatment of Precipitation-Strengthened Alloys

The precipitation-strengthened alloys are typically used in the solution-treated and aged condition. Solution treatment can be performed either above or below the γ' solvus temperature, depending on the desired microstructure. In wrought material, aging results in a homogeneous distribution of γ' and intergranular, secondary-type carbides. The γ' distribution in weld metal may or may not be homogeneous because of the segregational effects of weld solidification. In this situation, the weld metal may not strengthen to the same degree as the base metal. A two-step aging treatment that involves a stabilization followed by a lower-temperature aging treatment can be used in some cases. The stabilization heat treatment involves the formation of $M_{23}C_6$ carbides plus γ', which forms from a reaction between metal carbides (MC) and the matrix. Examples of typical solution treatment and aging cycles are shown in Table 3. For further information, see the article "Heat Treating of Superalloys" in *Heat Treating,* Volume 4 of the *ASM Handbook.*

The major problem that occurs when postweld heat treating the precipitation-hardenable alloys is strain-age cracking. The susceptibility of an alloy to strain-age cracking tends to increase with an increasing aluminum and titanium content. Alloys that contain niobium as a hardening element exhibit a sluggish aging response and are therefore less sensitive to strain-age cracking. Strain-age cracking is more prevalent in highly restrained weldments or in the presence of high residual stresses. Cracking is caused by the combination of stress, precipitation strengthening, and the volumetric contraction associated with γ' precipitation. Guidelines to follow to avoid strain-age cracking include:

- MINIMIZE RESIDUAL AND THERMALLY INDUCED STRESSES BY USING THE APPROPRIATE JOINT DESIGN, WELDING PROCESS, AND FILLER METAL.
- HEAT AS RAPIDLY AS POSSIBLE THROUGH THE REGION OF AGING TEMPERATURES WHEN STRESS-RELIEF ANNEALING.
- MINIMIZE HEAT INPUT DURING WELDING TO AVOID PARTIAL MELTING OF GRAIN BOUNDARIES ADJACENT TO THE FUSION LINE.
- HEAT TREAT IN AN INERT ATMOSPHERE IF POSSIBLE; THE PRESENCE OF OXYGEN TENDS TO INCREASE INTERGRANULAR EMBRITTLEMENT, WHICH CAN RESULT IN CRACKING.
- TO AVOID POSTWELD STRAIN-AGE CRACKING, ALWAYS STRESS-RELIEF ANNEAL BEFORE AGING. FOR HEAVY-SECTION WELDMENTS IN ALUMINUM-TITANIUM AGED

MATERIALS, MULTIPLE STRESS-RELIEF ANNEALS MAY BE NECESSARY DURING WELDING.

- AVOID WELDING ON MATERIAL WITH ROUGH OR POOR SURFACE CONDITIONS.

Special Metallurgical Welding Considerations for Nickel and Cobalt Alloys and Superalloys

S.D. Kiser, Inco Alloys International, Inc.

Introduction

THE DESIGN ENGINEER who wishes to use a welded structure for demanding service faces a challenging dilemma. On the one hand, the materials involved and the deposited weld metal must exhibit sufficient ductility to withstand the severe thermal cycle imposed by fusion welding. On the other hand, many applications demand that specimens taken from a qualification welded assembly be capable of passing 2*t* 180° side-bend testing (where *t* is the material thickness). This test requires 20% elongation of the outer fibers of the bend specimen. After welding, some applications for which the weldment is designed may demand different properties.

Most solid-solution (nonprecipitation-hardening) nonferrous alloys exhibit sufficient ductility to meet the above requirements. The weld fabrication of these materials is straightforward in that they usually do not require preheat or postheat, and interpass temperature control during welding normally is not critical.

The precipitation-hardenable materials are different from the above alloys in that they generate a second phase when exposed to temperatures for specified times in a particular range. They further distinguish themselves by exhibiting superior mechanical properties after being precipitation treated (aged). These materials are usually welded in the annealed (or solution-annealed) condition and are heat treated to precipitate the second phase as a final or near-final production step.

Both the solid-solution and the precipitation-hardening groups of alloys are typically austenitic (that is, the atoms of their basic structures fit together in a face-centered-cubic arrangement, often referred to as γphase). The precipitation-hardening alloys form a second phase, γ', as a result of controlled heat treatment. The development and dispersion of this second phase are made possible by additions of aluminum, titanium, and niobium. The γ' phase imparts great stiffness to these materials at room temperature and up to the upper limit of their aging-temperature ranges. When used at service temperatures above their aging ranges, these materials lose strength rapidly as a result of the agglomeration of their second phase. This condition, commonly referred to as overaging, results in relatively large γ' particles.

A subset of the precipitation-hardenable high-temperature materials is the secondary-carbide-strengthened materials. These alloys have an austenitic structure like the above groups, but do not contain sufficient alloy content to precipitate γ' phase. Instead, they contain generous additions of carbide-forming elements such as chromium, niobium (also forms γ"), and a supersaturating amount of carbon. These materials are primarily used as centrifugally cast tubes. They enjoy reasonably good weldability in the as-cast condition, but usually require special precautions for welding after they have been in service.

A final group of exceptionally strong high-temperature metals is the mechanically alloyed materials. These metals combine the high strength of the precipitation-hardened alloys by use of γ' strengthening up to about 705 °C (1300 °F) with dispersion strengthening with yttrium oxide (Y_2O_3) up to 1315 °C (2400 °F). These materials are produced by a combination of the mechanical forging of powder particles in a ball mill, followed by hot working and a 1315 °C (2400 °F) thermal treatment (Fig. 1). Joining these materials requires special precautions.

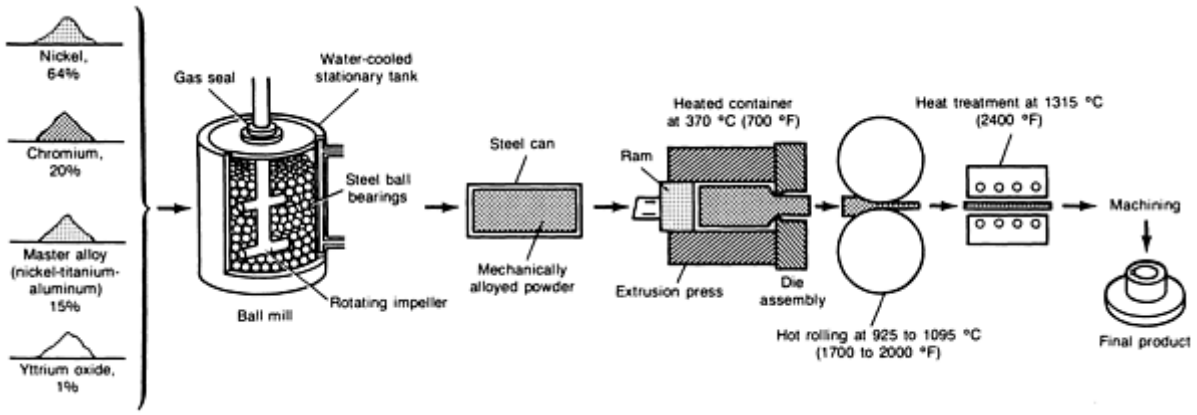

FIG. 1 SCHEMATIC SHOWING TYPICAL PROCESS OPERATIONS USED IN THE PRODUCTION OF MECHANICALLY ALLOYED OXIDE-DISPERSION-STRENGTHENED PRODUCTS

In many demanding applications, it is necessary to design components made of different materials. The process of making such assemblies often requires the welding of dissimilar metals, the welding of diffusion-bonded materials, and sometimes weld overlay cladding and even thermal spraying. These types of unusual welding and spraying applications require special knowledge and treatments that may have been developed specifically for each material.

Finally, in the service life of nearly every welded structure, there arises a need for alteration or repair. In many cases it becomes necessary to splice new materials into old. Most of the above materials require special conditioning before repair welding.

Special Metallurgical Welding Considerations for Nickel and Cobalt Alloys and Superalloys

S.D. Kiser, Inco Alloys International, Inc.

Solid-Solution Nickel Alloys

These materials have good weldability and are often used in the as-welded condition. The alloys are usually formed by additions to nickel of chromium, cobalt, molybdenum, iron, and sometimes small amounts of aluminum, silicon, and niobium (Table 1). While they do not develop abnormally high strength levels like the other groups, these alloys provide attractive creep resistance in conjunction with good thermal-fatigue resistance. Under moderate loading, alloys of this group can be used up to temperatures approaching 1150 °C (2100 °F). Typical applications are welded containers and fixtures for thermal processing, and headers and manifolds for chemical and petrochemical processing.

The potential problem in welding these materials is grain size. As grain size increases, weldability decreases. In some applications, a minimum grain size is specified for maximum creep resistance. The compromise normally implemented is to limit welding processes to those methods that use lower heat input (Ref 1).

Precipitation-Hardenable Nickel Alloys

These materials are characterized by their distinctively high strength at room temperature through about 705 °C (1300 °F). They range in alloy content from the virtually pure nickel-aluminum Alloy 301 to nickel-copper Alloy K-500 through the nickel-chromium-iron Alloy 718 through the low-expansion nickel-iron Alloy 909. They enjoy the commonality of γ' strengthening by heat treatment because of additions of aluminum, titanium, and niobium. Table 2 lists selected precipitation-hardening alloys and their chemistries.

Most of these alloys have good weldability in the annealed condition. Because of this, most are formed, machined, and welded in the annealed condition. They are then reannealed after welding, and then aged, to obtain the desired properties.

Postweld Strain-Age Cracking (PWSAC). Because all these types of materials are at least somewhat prone to PWSAC, little welding is performed in the aged condition if the weldment is to be re-heat treated or put in elevated-temperature service. Postweld strain-age cracking occurs in precipitation-hardenable alloys when cold-work stresses,

weld-induced residual stresses, and the stress imparted by aging exceed the yield strength (and available ductility) of the material. The result is an instantaneous, catastrophic failure by cracking (Fig. 2).

FIG. 2 PWSAC FAILURE IN ALLOY X-750 INDUCED BY RESIDUAL WELDING STRESS AT A 50 MM (2 IN.) THICK JOINT. ALLOY WAS WELDED IN THE AGE-HARDENED CONDITION AND RE-AGED AT 705 °C (1300 °F) FOR 20 H AFTER WELDING.

Those alloys whose γ' phase is formed predominantly by nickel-aluminum-titanium age more rapidly than those using niobium. As a result, these alloy are more prone to PWSAC.

Alloy 718. In an effort to improve the weldability of precipitation-hardenable alloys, niobium was substituted for large amounts of aluminum and titanium. The result was nickel-chromium-iron Alloy 718, which showed greatly improved resistance to PWSAC. With Alloy 718, thicknesses up to 3.2 mm ($\frac{1}{8}$ in.) could be welded in the aged condition and directly re-aged without cracking. This combination of very high mechanical properties and fabricability has earned Alloy 718 a prominent spot in the aerospace industry.

Alloy 713C. Some precipitation-hardenable alloys often require welding in the aged condition. Alloy 713C, for example, is a nickel-chromium alloy with very high levels of aluminum and titanium that is used for gas-turbine vanes. It is normally produced as a casting that precipitation hardens during cool down. It is considered nonweldable by fusion processes. However, experience has shown that blade and vane tips can be restored by fusion welding with a nonhardenable filler metal (ERNiCrMo-3) without cracking (Ref 2). Thus, crack-free welds can sometimes be accomplished in very-difficult-to-weld materials where residual shrinkage stresses can be kept low and cooling rates are slow. Both conditions occur naturally when welding on an edge.

Alloy 301. Preliminary work has shown similar results when welding on nickel-aluminum Alloy 301 in the aged condition. This alloy exhibits high mechanical properties and very good thermal conductivity. It finds use in cooled glass molds and plastic extrusion equipment. It can be readily welded in the aged condition--fully restrained--when the recommended ductile ERNi-1 filler metal is added. Also, autogenous, low-stress welds (on an edge) can be made at high travel speeds without cracking. However, when fully restrained, autogenous welds are made in forging stock at 200 to 250 mm/min (8 to 10 in./min) travel speed, the cooling rate is so rapid that the aluminum-rich weld pool contains numerous large solidification cracks. Decreasing the travel speed to decrease the cooling rate allows crack-free autogenous welds to be made.

Low-Coefficient-of-Expansion Alloys. For the next group of precipitation-hardening alloys, the same guidelines apply (that is, to weld in the annealed condition). In this group of alloys, the chromium has been removed in order to maintain a low coefficient of thermal expansion. The fabrication sequence includes welding, annealing, heat treating, and in some cases coating. The coating applied is usually an oxidation-resisting ceramic coating.

Alloy 909. The most prominent member of this group is nickel-iron Alloy 909. It is primarily used for seals and rings in aircraft turbines. Its low coefficient of expansion allows close-tolerance designs, which increase the fuel efficiency of gas-turbine engines.

Mechanically Alloyed Products. The final group of precipitation-hardening alloys to be discussed merits the name superalloys. Mechanically alloyed products have a remarkable advantage over conventional materials in elevated-temperature stress-rupture strength. This advantage is gained by the combination of precipitation hardening and dispersion strengthening. Neither concept is revolutionary, but the combination of the two using the ball mill is. As shown in Fig. 1, various ingredients are added to the ball mill as metallic and intermetallic powders. Extended processing times of approximately 10 h in the mill cause the particles to become metallurgically homogeneous. This process is similar to the step of incorporation in Du Pont's early approach to making homogenous particles of gunpowder, each containing the correct ratio of charcoal, sulfur, and potassium nitrate.

Homogenization in the mill is followed by either hot rolling or extrusion. The form is then thermally treated at 1315 °C (2400 °F) to produce the exceptional strength characteristics. Tables 3 and 4 list the chemical compositions and selected properties for mechanically alloyed products.

Figure 3 shows the dramatic advantage in strength of mechanically alloyed products over the conventional dispersion-strengthened and cast nickel-base alloys. Unfortunately, making these materials weldable is difficult. While they can undergo diffusion bonding or brazing with little loss in properties, fusion welding produces a softened heat-affected zone (HAZ). This behavior is caused by the agglomeration of the dispersoid Y_2O_3. In addition, it is not possible to produce a weld that has properties similar to those of the alloys. Thus, for most applications, the mechanically alloyed products are joined mechanically, or diffusion bonded, or brazed.

Creep-Resistant Secondary Carbide-Strengthened Alloys Welded with Nickel Alloys

This group of alloys has become extremely popular in the chemical and petrochemical industries for the processing of hydrocarbon compounds. Such alloys are typically fabricated in the as-cast condition after being produced in a rotating, water-cooled mold. This production method, which incorporates rapid cooling, allows a supersaturated solution of carbon (0.40 to 0.45%) in nickel, chromium, and iron to retain the carbon in solution. This condition allows sufficient ductility in the as-cast condition to provide good weldability by most fusion processes.

Formation of Secondary Carbides. Once the assembly has been fabricated, it is normally put into service at temperatures of 760 to 1095 °C (1400 to 2000 °F). At these temperatures, the chromium (and sometimes niobium) combines with the carbon in a solid-state diffusion process that results in the precipitation of secondary carbides. These secondary carbides provide a tremendous strengthening effect for the intended high-temperature service. Figure 4 compares the stress-rupture strength of a typical centrifugal-cast carbide-strengthened alloy with that of a widely used nickel-alloy welding product that is needed to attain approximately equal strength. It is interesting to note that welds made in these alloys with near-matching composition welding products suffer failure at less than half the rupture life of welds made with ERNiCrCoMo-1 type welding products (Ref 3). (See Table 1 for the approximate chemical composition of ERNi-CrCoMo-1, identified as N06617.) In addition, transverse stress-rupture specimens welded with near-matching composition products routinely fail in the weld itself, while those welded with ERNiCrCoMo-1 products typically fail in the alloy casting.

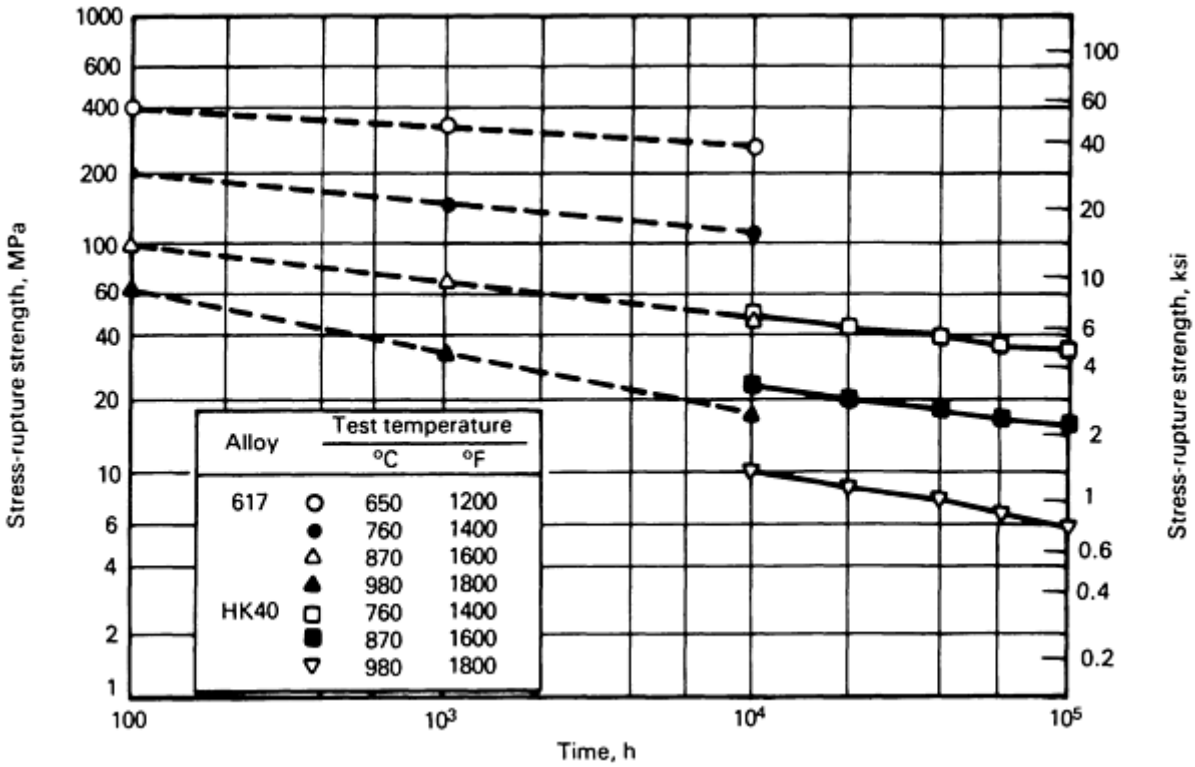

FIG. 4 STRESS-RUPTURE STRENGTH OF ALLOY 617 FILLER METAL RELATIVE TO CENTRIFUGAL-CAST CARBIDE-STRENGTHENED ALLOY HK40

Effect on Weldability. As might be expected, once these alloys have precipitated their secondary-phase carbides, their weldability decreases. Like the precipitation-hardenable, γ'-strengthened alloys, these materials undergo a drastic reduction in room-temperature ductility as a result of carbide precipitation. This result usually means that a secondary carbide-strengthened alloy cannot be welded by fusion processes immediately after service. It is customary to use a resolutioning heat treatment for used tubes in preparation for welding. Parts are exposed to 1095 to 1205 °C (2000 to 2200 °F) for several hours, usually followed by a forced-air cool (Ref 4). This practice restores ductility to near asproduced levels, and allows successful fusion welding without cracking of the base metal.

Castings. Most of the above-mentioned carbide-strengthened castings have good weldability in the proper thermally treated condition. Likewise, most of the solid-solution and precipitation-hardened nonferrous materials in previous sections can be produced as castings. Further, the weldability of these castings may be good if they are produced using clean foundry conditions and clean charge (raw) materials. However, castings are usually made to near-finished dimensions and do not require further hot working as wrought materials do. As a result, many castings do not have the good hot ductility and malleability of wrought materials, characteristics that contribute greatly to good weldability. Thus, a casting may be produced and delivered as a finished part if it simply solidifies from the liquid state without cracking.

In many cases, the customer may attempt to weld fabricate the casting into a larger design only to encounter HAZ cracking in the casting. Analysis usually discloses objectionable levels of low-melting-temperature elements as contaminants. Once the casting has been delivered, and welding difficulties discovered, options to produce good weldments are limited. Best results are obtained by using very low heat input, some-times coupled with buttering or overlaying joint surfaces before welding them together.

An alternate approach that generally yields successful results is for the buyer to specify in purchase documents that the casting must be weldable. To avoid sharply increased prices in quotations for castings, the buyer should not tightly specify chemical limits for damaging contaminating elements. Rather, a simple fusion weldability test can be written into the purchase specifications. Such a test is usually not seen as rigorously expensive to the foundry, and it ensures that the fabricator will get a weldable casting. The weldability test is usually a gas tungsten-arc weld made with no filler metal added on a ground surface of the casting (or testpiece). Amperage and travel speed are usually specified, along with

length of weld. A testing method, usually liquid-penetrant inspection, is employed to detect weld and HAZ discontinuities. Generally, the start and stop are excluded from inspection, and cause for rejection is any linear indication.

Special Metallurgical Welding Considerations for Nickel and Cobalt Alloys and Superalloys

S.D. Kiser, Inco Alloys International, Inc.

Special Welded Product Conditions

Dissimilar Metals. The welding of dissimilar metals has been amply discussed (Ref 5, 6, 7). The materials discussed in this article have reasonably good dissimilar weldability provided the dissimilar alloy is not too different in liquidus and solidus temperatures and other characteristics important to sound weldments. For instance, nearly all the materials previously mentioned can be readily joined to steel, high-strength low-alloy (HSLA) steels, stainless steels, and other nickel alloys. A high-temperature nickel alloy filler metal is often used to make such dissimilar joints. Design and filler metal selection criteria usually include strength, corrosion resistance, and dilution tolerance of the filler metal for the elements present in the metals to be joined. In some cases, special design consideration is given to selecting filler metals with a specific coefficient of thermal expansion, thermal conductivity, electrical resistivity, and thermal fatigue resistance (Ref 8).

An example of a filler-metal-added dissimilar weld for high-temperature service can be found in hydrogen furnaces. In many applications, centrifugal-cast, secondary-carbide-strengthened furnace tubes are welded to collection headers of UNS 08800 using ERNiCrCoMo-1, to achieve a combination of strength, ductility, and corrosion resistance. An example of a successful autogenous dissimilar weld is the weld used in the manufacture of internal combustion engine turbochargers. In some of these, the difficult-to-weld Alloy 713C is friction-welded to an HSLA steel shaft such as 4340. Such a design economically uses the high-strength precipitation-hardenable alloy only where its high-temperature strength and corrosion resistance are needed.

Clad Metals and Overlays. A similar set of considerations also applies to filler metal selection for welding clad materials and for overlay cladding by welding. First, the materials selected must be capable of being mixed during welding without resulting cracks, and second, the resulting weldment must perform well in the intended service.

In overlay cladding and the welding of clad materials, the alloy contribution of the substrate to the final weld composition must be considered. For instance, if a one-layer overlay on steel is desired to have a minimum of 50 wt% Ni and 15 wt% Cr, and the chosen welding process yields 20 wt% dilution, then a filler metal with approximately 70 wt% Ni and 20 wt% Cr must be selected. In this case, ERNiCr-3 filler metal, which has 18 to 22 wt% Cr and 67 wt% (min) Ni, would yield a single-layer overlay chemistry of 16 wt% Cr and 54 wt% Ni.

Likewise, if two clad plates are to be welded together, it is usually desirable that the weld have a slightly richer alloy content than the cladding. In order to achieve this condition, a welding product of considerably higher alloy content than the cladding must be selected to allow for the dilution by the substrate. For example, refineries often use steel tubing with the inside surface clad with UNS08825 for elevated-temperature resistance to H_2S. This alloy cladding contains 42 wt% Ni, 20 wt% Cr, 3 wt% Mo, and 1 wt% Ti. In order to achieve a slightly enriched weld composition, it is welded using ERNiCrMo-3, which contains 60 wt% Ni, 22 wt% Cr, and 9 wt% Mo.

Outside-Diameter Clad Tubing. A more complex application is needed for butt welding boiler tubing made from UNS08800 that had been outside-diameter clad with a 45Cr-55Ni nickel alloy for resistance to molten salt and fuel-ash corrosion. The substrate was welded using ERNiCr-3 to develop sufficient stress-rupture strength, and the weld was

capped with two layers of a proprietary near-matching filler metal using a low-dilution-rate process. (A crack-free higher-chromium filler metal was unavailable.) In this application, the filler metal chosen for welding the substrate had to provide the necessary strength after having been diluted by the substrate and had to be compatible with the capping weld layers. Because both materials were nickel-chromium types, the procedure went smoothly, and the tubing has given nearly 20 years of service in a demanding corrosive environment.

Repair welding, or welding after service, has been briefly addressed in some previous sections of this article. It has also been thoroughly discussed in the literature (Ref 9). Primarily, the same fabrication requirements must be met; namely, a sound weld must be produced that is capable of giving usable service in a given environment. If service conditions such as corrosion have rendered the material unweldable, the corrosion layers must be removed or neutralized. The precipitation-hardenable alloys and the secondary-carbide-strengthened alloys usually must have weldability restored by thermal treatment before repair is attempted.

In some cases, the usefulness of a part can be restored without a 100% joint-efficient weld design. In the example of worn turbine blades, greatly extended service can be attained by repair welding without reannealing by using a lower-strength but more ductile filler metal.

In yet other applications only a small part of a welded assembly may have become inoperative due to corrosion or tertiary creep. In these situations, it is highly desirable to remove the damaged portions, remove corrosion deposits, restore weldability if necessary, and select a suitable filler metal. Then, the assembly can be successfully repaired with a proven welding procedure to provide the desired extension in service life.

Alternatively, corrosion attack such as oxidation or carburization may have completely penetrated the full thickness of all parts. In such cases, attempts to repair the weld will be unsuccessful. In addition, the formation of extensive creep voids or thermal-fatigue cracking may have permeated the materials to such an extent that repair welding is impossible. In these cases, good diagnostic analysis is important for preventing wasted effort when attempting to repair parts that cannot be salvaged.

Special Metallurgical Welding Considerations for Refractory Metals

Bryan A. Chin, Probal Banerjee, Jiayan Liu, and Shaofeng Chen, Auburn University

Introduction

THE REFRACTORY METALS, which include niobium (also called columbium), tantalum, molybdenum, tungsten, and rhenium, have the highest melting temperatures and lowest vapor pressures of all metals, except osmium and iridium. The refractory metals are readily degraded by oxidizing environments at moderately low temperatures, a property that has restricted the applicability of the metals in low-temperature or nonoxidizing high-temperature environments.

This article is limited to a discussion of special metallurgical considerations during the fusion welding of refractory metal alloys. These alloys are discussed in order of decreasing weldability: tantalum, niobium, rhenium, molybdenum, and tungsten.

Special Metallurgical Welding Considerations for Refractory Metals

Bryan A. Chin, Probal Banerjee, Jiayan Liu, and Shaofeng Chen, Auburn University

Tantalum Alloys

Tantalum is a refractory metal that readily reacts with atmospheric gases, especially at high temperatures. This metal melts at 3000 °C (5430 °F), has a body-centered cubic (bcc) structure, and does not undergo an allotropic transformation. It also exhibits excellent corrosion resistance to a wide spectrum of reagents. However, it oxidizes readily at temperatures above 343 °C (650 °F).

Carbon, oxygen, nitrogen, and hydrogen actively react with tantalum, typically forming intermetallics that lead to weld embrittlement. Although tantalum and its alloys are generally considered to have the best weldability of the refractory metals, the formation of these brittle intermetallics makes it difficult to weld to most structural metals. Processes used for joining tantalum alloys include gas-tungsten arc welding (GTAW), solid-state diffusion bonding, friction welding, resistance welding, brazing, and explosion bonding (Ref 1). Trailing shields help reduce atmospheric contamination due to the active nature of tantalum.

Effect of Microstructure

The fusion zones generally contain large grains and, in the absence of hafnium, cellular substructures (Ref 2). The proportion of large grains is higher in alloys with low alloy contents, because of a narrow freezing range (Ref 3) and a single-phase structure. Metallographic sections along the cell growth direction typically consist of nearly parallel grain boundaries. However, transverse sections show hexagonal cells. Increasing alloy content produces a more delineated substructure (Ref 2). Extensive carbide precipitation at grain boundaries can lead to severe embrittlement after a silicide coating procedure in certain weld configurations in Ta-10W alloy (Ref 4).

Ductility. Differences in grain size or cell size do not appear to strongly affect ductility, but material quality, or impurity concentration, does have an influence. High interstitial contents in the alloys can lead to a large concentration of micropores. Only in special carbon-containing Ta-5W-2.5Mo alloys does weld hardness influence ductility (Ref 2). Ductility is reduced in surface-ground welded specimens. Welds in Ta-5W-2.5Mo and Ta-10W-2.5Mo have excellent bend ductility at room temperature.

The GTAW process results in an increase in sheet bend transition temperature in Ta-8W-2Hf, Ta-10W, and Ta-9.6W-2.4Hf-0.01C (T-222), with the highest increase being in the T-222 material (Ref 3). With an increasing tungsten content, alloys become brittle at room temperature (Ref 2). A postweld heat treatment of 1 h at 816 °C (1500 °F) can significantly reduce the 2*t* bend transition temperature for welds produced by the GTAW process. The bend transition temperature is the lowest temperature below which cracking develops in a weld bent at a radius of 2*t* (twice the thickness of the sheet) with an angle of at least 90 °. Welds produced by electron-beam welding (EBW), however, have slightly higher transition temperatures (Ref 2). Under elevated-temperature exposure, there is considerable grain growth, which reduces the cellular fusion zone substructure. This leads to an increased impurity concentration at grain boundaries. In alloys susceptible to impurities, elevated-temperature exposure leads to a decrease in ductility. Generally, total metallic alloy contents of less than 10 at.% produce ductile welds, whereas alloy contents of greater than 13 at.% produce brittle welds (Ref 2).

Tensile Properties. A postweld heat treatment of 1 h at 816 °C (1500 °F) reduces the susceptibility of tantalum-tungsten-molybdenum alloys to premature tensile failure (Ref 2). Joint efficiencies of welds in wrought material are lower than those of welds in recrystallized materials. However, room-temperature tensile strengths of welds in wrought material are higher than those of welds in recrystallized material. The tensile strengths of welds drop very sharply above 1649 °C (3000 °F). Tensile strengths decrease with an increase in tungsten content, whether testing is conducted at room temperature or at elevated temperatures. In general, tensile strengths decrease exponentially with an increase in testing temperature (Ref 3) (Fig. 1).

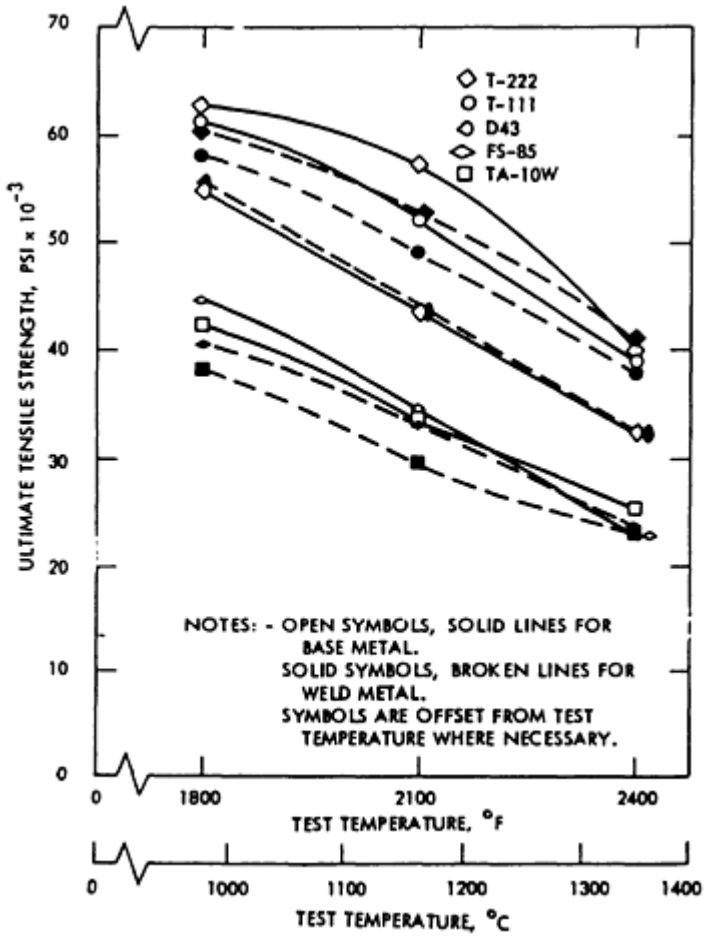

FIG. 1 ELEVATED-TEMPERATURE TENSILE STRENGTH OF ANNEALED BASE METAL AND TANTALUM ALLOY ARC WELDS. SOURCE: REF 3

Effect of Interstitial Impurities

Interstitial impurities can strongly influence the properties of welded tantalum materials. The average weld bend ductility is lower for gas-tungsten arc welds in low-interstitial-content materials. Generally, tantalum alloy sheet must have a low interstitial level (less than 100 ppm) to be weldable. Carbon contents of less than 100 ppm or hydrogen contents of less than 17 ppm do not significantly affect weld ductility (Ref 2).

Effect of Welding Conditions

Welding conditions can also be used to control properties in tantalum and its alloys. In low-interstitial-content sheets, arc travel speed and energy input do not appear to influence ductility. In high-interstitial-content sheets, ductility is better at high travel speeds (12.7 to 31.75 mm/s, or 30 to 75 in./min) and low energy inputs (98 to 118 J/mm, or 2500 to 3000 J/in.) (Ref 2).

Effect of Arc Oscillations

Arc oscillation has been found to reduce the columnar structure in the fusion zone (Ref 5), which promotes ductility. However, there is an optimum frequency that produces an equiaxed structure. If this frequency (10 Hz) is exceeded, then elongated grains result (Ref 5, 6).

Increased energy input results in larger heat-affected zone (HAZ) grains and fewer nucleation sites for fusion zone grains (Ref 2). There is an increase in hardness at the areas of metal deposition and at the HAZ in gas-tungsten arc welded tantalum (Ref 7).

Special Metallurgical Welding Considerations for Refractory Metals

Bryan A. Chin, Probal Banerjee, Jiayan Liu, and Shaofeng Chen, Auburn University

Niobium Alloys

Niobium and its alloys are often selected for high-temperature use in fabricated systems. They can be easily welded by the GTAW, EBW, and laser-beam welding (LBW) processes, either autogenously or with matching filler metals in inert atmospheres. In special cases, resistance welding (RW), plasma arc welding (PAW), hot pressure welding (HPW), and explosion welding (EXW) can be considered.

Atmospheric contamination is a major cause of the embrittlement of niobium alloy welded joints. To avoid significant increases in the ductile-to-brittle transition temperature (DBTT) of welds (caused by interstitial contamination), welding atmospheres should have less than 600 ppm oxygen, 300 ppm nitrogen, and 150 ppm hydrogen.

Effect of Welding Atmosphere. Niobium and its alloys can be welded using an inert gas shield or a vacuum chamber. A vacuum-purged chamber backfilled with argon and helium is recommended for better-quality welds that are free from air contamination.

Effect of Microstructure. The DBTT of welds is also influenced by microstructural changes resulting from weld thermal cycles. The size of the HAZ and grain growth in this zone are major factors that affect the ductility of welds. Welding conditions that tend to increase the size of the HAZ, as well as the grains within it, will result in an upward shift in the transition temperature of welds. Furthermore, alloys with different strengthening mechanisms respond differently to weld heat input.

The solid-solution alloys, such as Nb-1Zr and Nb-10W-10Ta (SCb-291) show a continuous ductility loss with an increasing HAZ size and fusion zone grain size. A heat input limit, above which ductility impairment occurs, exists for solid-solution plus dispersion-strengthened alloys, such as Nb-10W-2.5Zr (Cb-752), Nb-27Ta-10W-1Zr (FS-85), Nb-10W-1Zr-0.2C (D-43), and Nb-5Mo-5V-1Zr (B-66). To reduce the tendency of grain growth in the HAZ and fusion zones, a high-energy-density welding process, such as EBW, is often more advantageous than GTAW.

Effect of Welding Conditions. The alloy Nb-1Zr can be easily welded using arc welding and EBW processes. The alloy B-66 has a hot tearing tendency during arc welding, which makes both manual and automatic welding more difficult. High-speed arc welding of Nb-10W-10Hf + Y (C-129Y) will cause gross shrinkage defects in the welds. Welds of D-43Y have the tendency to hot tear along the weld centerline and crack during welding. This factor, in conjunction with unmodified D-43, tends to produce high porosity in the weld.

Several alloys are temperature limited with respect to thermal stability. Welds of D-43 tend to lose strength with increasing aging time and temperature. Design stresses need to be reset for long-term applications of welded joints at temperatures above 1095 °C (2000 °F). During high-temperature aging, SCb-291 and B-66 welds gradually lose ductility, because of grain growth in both the weld and the HAZ.

Special Metallurgical Welding Considerations for Refractory Metals

Bryan A. Chin, Probal Banerjee, Jiayan Liu, and Shaofeng Chen, Auburn University

Rhenium Alloys

The weldability of rhenium is better than that of tungsten and molybdenum, but is slightly less than that of tantalum. Rhenium welds typically demonstrate a large degree of ductility. The only problem that can be encountered is porosity, which often occurs from welding a powder metallurgical product. It has been proposed that tungsten and molybdenum be alloyed with rhenium to improve both room-temperature ductility and weldability. The binary alloy of molybdenum with 50% rhenium can be easily welded using the GTAW and EBW processes. The welds retain nearly the same strength as the base metal and have good ductility.

Special Metallurgical Welding Considerations for Refractory Metals

Bryan A. Chin, Probal Banerjee, Jiayan Liu, and Shaofeng Chen, Auburn University

Molybdenum Alloys

Molybdenum and its alloys can be welded by the GTAW and EBW processes (Fig. 2), as well as most other welding methods. However, the weldability of molybdenum and its alloys is marginal, because of a high DBTT in the welded and recrystallized zones. Furthermore, the DBTT of molybdenum welds is significantly increased after the GTAW and EBW processes.

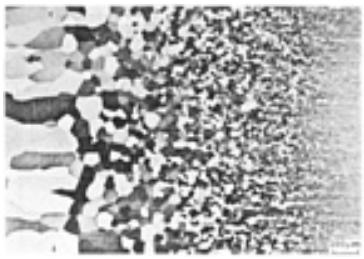

FIG. 2 WELD AND HAZ IN ELECTRON-BEAM WELDED TZM; ARROWS INDICATE FUSION LINE. SOURCE: REF 8

Effect of Welding Conditions. Heat input is a major factor influencing the ductility of welds. Electron-beam welding with relatively low heat input results in a lower DBTT than that obtained from the GTAW process. A high melting point, in conjunction with low ductility, also make molybdenum susceptible to failure by thermal impact during welding. Therefore, weldability can be improved by a weld preheat. If their DBTT values are below the ambient temperature, then molybdenum and most of its alloys with low DBTT values can be welded without a preheat. Alloys with high DBTT values must be preheated above their respective transition temperatures to avoid cracking during welding. Postweld annealing for stress relief helps improve weld ductility. The brittle behavior is principally the result of the large grain size in the HAZ and fusion zone. By reducing the grain size difference between the parent and weld metals through heat treatment, significant increases in ductility can be achieved. TZM (Mo-0.5Ti-0.1Zr) welds are not inherently as brittle as other molybdenum alloys (Ref 8).

Effect of Interstitial Impurities. Molybdenum and tungsten both have extremely low solubility limits for interstitials such as oxygen, nitrogen, and carbon (1 ppm or less). Of these three, oxygen is particularly harmful to ductility. Just several parts per million are enough to raise the DBTT from well below the ambient temperature to well above it. To prevent interstitial contamination, welding in vacuum or in an inert-gas-filled chamber is recommended. A high-purity shield gas is effective in promoting ductile joints.

Hot cracking and weld porosity represent other problems that can arise when welding powder metallurgy alloys. These problems often occur even when the welds are made in high vacuum. Large amounts of oxygen and other gases that are generally contained in the powder metallurgy base metal will react with the molybdenum during welding, leading to embrittlement.

Bryan A. Chin, Probal Banerjee, Jiayan Liu, and Shaofeng Chen, Auburn University

Tungsten Alloys

Tungsten and tungsten alloys can be joined by welding (GTAW and EBW), brazing, diffusion bonding, and other joining techniques. Tungsten and its alloys are generally considered to have poor weldability, when compared with other refractory metals, such as niobium and tantalum. Welding problems encountered with tungsten and its alloys are generally traceable to physical metallurgy and properties. Chemical changes that are due primarily to atmospheric contamination during heating and cooling and microstructural changes that are due to thermal cycling can result in grain growth, hardening, and embrittlement. Embrittlement can often be traced to recrystallization and oxygen ingression along grain boundaries.

Of the refractory metals, tungsten has the highest modulus and melting point. This high melting point results in greater than normal cooling time intervals after joining and a large range of cooling temperatures over which sizeable thermal strains can be generated, because of differential thermal expansion and contraction. High elastic modulus, high yield strength, and resistance to plastic flow lead to a rapid rise in residual stress with an increase in thermal strain. High residual stresses are commonly encountered in tungsten welds. If the welds are made under restraint, then they may crack during cooling.

Effect of Alloy Production Technique. The weldability and properties of tungsten strongly depend on the process used to make the tungsten. Porosity and entrained gases in powder metallurgy tungsten products will result in weld porosity. This porosity usually concentrates along the fusion boundary. To a lesser extent, welds of chemical vapor deposition (CYD) tungsten products will show porosity along the fusion line and in the HAZ (Ref 9). Welds of arc cast tungsten materials can be made porosity free if proper welding procedures are followed. Tungsten weld embrittlement can be caused by contamination and/or recrystallization.

Effect of Interstitial Impurities. Tungsten, which is composed of a bcc crystal lattice, is sensitive to the presence of interstitial atoms such as carbon, oxygen, and nitrogen. Because the solubility of these elements in tungsten is very low, their embrittling effects are much greater. Tungsten has a particularly high affinity for carbon and oxygen, readily forming carbides (WC) and oxides (WO_2).

Carbon, oxygen, and nitrogen dramatically increase the bend ductility transition temperature and DBTT, as shown in Fig. 3. Typical sources of these contaminants are moisture/impurities in the shielding gas, surface films on the base metals and/or filler metals, and oils on the components being welded. Use of either a vacuum or an inert atmosphere chamber consisting of specially purified shielding gas (argon, helium, or combinations of the two) is necessary to control contamination.

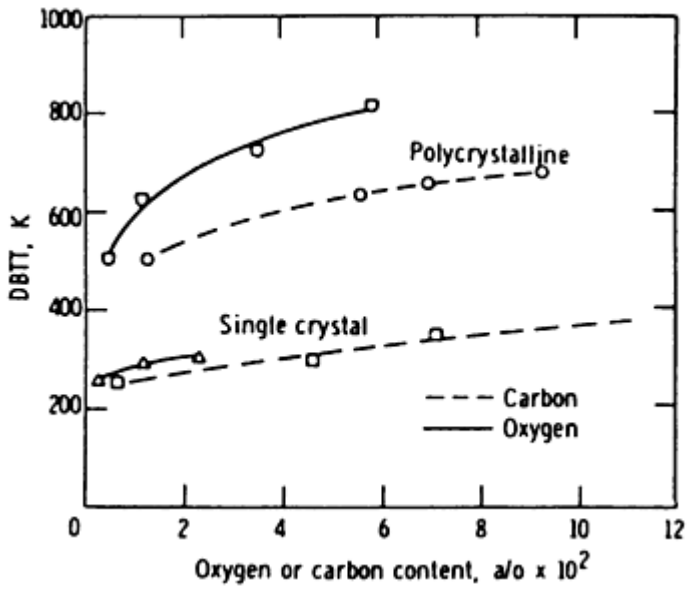

FIG. 3 EFFECTS OF OXYGEN AND CARBON ON DBTT OF TUNGSTEN. SOURCE: REF 10

Effect of Microstructure. Recrystallization and grain growth in the HAZ (Fig. 4) is another effect that can also contribute to embrittlement. Increasing grain size reduces the tensile strength, ductility, and toughness of tungsten alloys. Coarse grains in the HAZ have been found to increase the DBTT. The effect of grain size on DBTT is shown in Fig. 5. The effect of coarse grains on weldment ductility may be minimized by using a low heat input and by choosing proper welding procedures and parameters that limit recrystallization and grain growth effects. The EBW process can be used to obtain an extremely narrow HAZ. This technique has been shown to minimize embrittlement that is caused by recrystallization and grain growth.

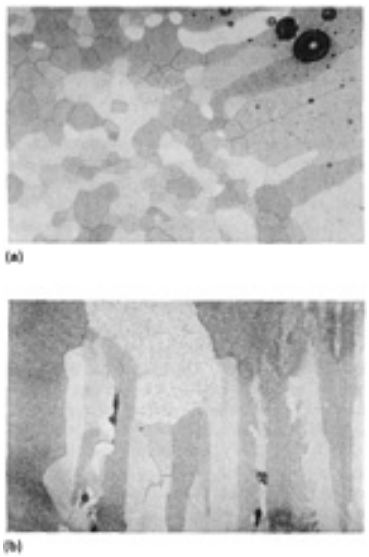

FIG. 4 COARSE GRAINS IN HAZ. 65×. (A) POWDER METALLURGY TUNGSTEN; POROSITY SHOWN ALONG FUSION LINE. (B) CVD TUNGSTEN

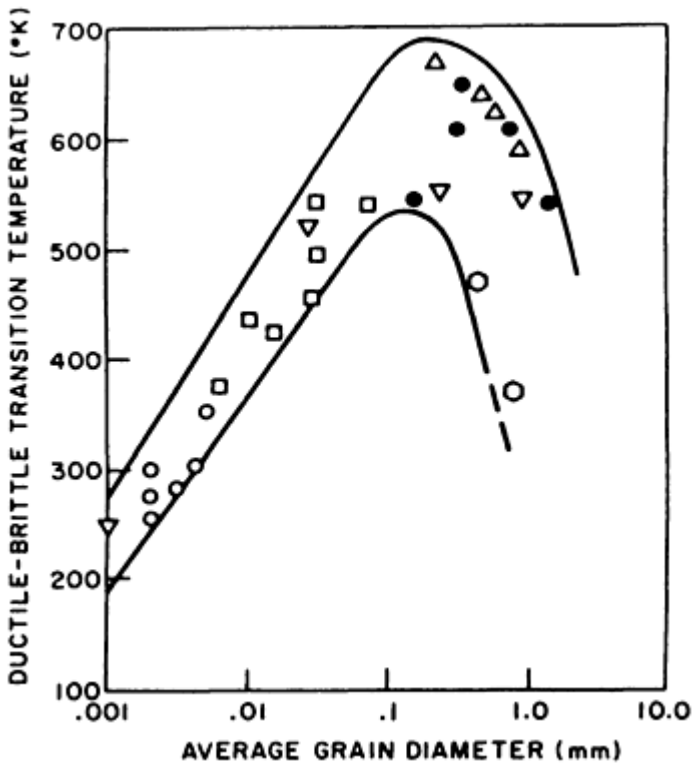

FIG. 5 EFFECT OF GRAIN SIZE ON DBTT OF TUNGSTEN. SOURCE: REF 10

Weld cracking usually can be avoided by preheating to above the DBTT. Welding tungsten-rhenium alloys or using the EBW process makes it possible to avoid preheat requirements. When CVD tungsten is welded, cracks are usually found in the columnar grain boundaries in the HAZ, having been caused by the growth and coalescence of small pores on the grain boundaries.

Introduction to the Selection of Nonferrous Corrosion-Resistant Materials

S.J. Matthews, Haynes International, Inc.

Introduction

CORROSION has a tremendous cost impact on our industrial society, estimated to be on the order of $170 billion/year. There are many different forms of corrosion, and the interested reader is referred to *Corrosion,* Volume 13 of the *ASM Handbook*, for a detailed description of the subject. Improvement in corrosion performance of a component or structure can be achieved through proper design, surface protection, proper material selection, or combinations of all three parameters. This Section of the Handbook will address weldability and material selection issues associated with nonferrous corrosion-resistant alloys.

Stainless steel, as its generic name implies, has been a traditional material employed to resist corrosion. However, some corrosion service is so harsh that even stainless steels do not perform adequately. In the chemical process industry, for example, the manufacture of phosphoric, acetic, hydrochloric, and sulfuric acids requires highly corrosion-resistant materials. A boiling 1% HCI solution, for example, can totally dissolve type 316 stainless steel during laboratory corrosion testing. For many applications, nickel-base alloys are called upon to resist certain severe corrosion environments.

Pure nickel has good resistance to reducing environment corrosion and is an excellent base upon which to build corrosion-resistant alloys. The atomic size, outer-shell electron configuration, and face-centered cubic (fcc) crystal structure of nickel make this element amenable to solid-solution alloying with elements such as iron, copper, chromium, tungsten, and molybdenum. Each of these alloying elements can contribute unique corrosion resistance to specific forms of corrosion attack, such as chloride pitting, galvanic corrosion, and stress-corrosion cracking. A wealth of empirical evidence and experience is available regarding the effects of alloying elements, individually and cumulatively, on corrosion resistance in aqueous environments (Ref 1).

Because industrial corrosion environments are diverse and complex, very few alloys can be expected to resist all forms of corrosion. Hence, numerous different nickel-base alloys have evolved over the last 50 years, each with a different combination of alloying elements to serve a particular niche in the corrosion market. It is not the intent of this Section to cover all nonferrous corrosion-resistant alloys on the market today. Rather, this Section has been organized into three different groupings of corrosion-resistant alloys; the information contained in these articles should also apply to similar alloys not listed. The first article addresses a family of materials that includes pure nickel, nickel-copper alloys, nickel-chromium alloys, and nickel-chromium-iron alloys. Monel and Inconel alloys are well-known members of this group of alloys. The next article addresses families of nickel-base alloys containing appreciable amounts of molybdenum. Molybdenum additions to nickel substantially improve resistance to nonoxidizing acid environments. Hastelloy alloys are typical of alloys belonging to this category of materials. In the last article, weldability and material selection issues associated with corrosion-resistant materials not based on nickel are discussed. These materials include cobalt-base corrosion-resistant alloys and commercially pure titanium, zirconium, and tantalum.

Introduction to the Selection of Nonferrous Corrosion-Resistant Materials

S.J. Matthews, Haynes International, Inc.

Corrosion Performance

Information presented in these articles about corrosion performance should be treated as generalized claims. Potential material users are advised to seek actual laboratory corrosion data or field test experience from the material producer

before selecting alloys for actual use. When communicating with a corrosion material specialist for the purposes of selecting alloys, it is important to identify five environmental parameters:

- CHEMICAL NATURE OF THE AQUEOUS (OR GASEOUS) ENVIRONMENT, INCLUDING IMPURITIES
- TEMPERATURE
- PH
- HALIDE CONCENTRATION (THAT IS, PRESENCE OF CHLORIDE OR FLUORIDE IONS)
- REDOX POTENTIAL (IF KNOWN)

Redox potential refers to the electrolytic nature of the aqueous environment. It determines whether the system is "oxidizing" or "reducing" to the exposed material and has an important influence on proper material selection.

Selection of Nickel, Nickel-Copper, Nickel-Chromium, and Nickel-Chromium-Iron Alloys

Donald J. Tillack, D.J. Tillack and Associates

Introduction

THE NICKEL-BASE FAMILY OF ALLOYS was developed in the early 1900s, and significant amounts of nickel began to be used in engineering materials in the 1920s. Although nickel was discovered by a Swedish scientist in 1751, them were no useful applications of the element until the late 1800s.

In nature, nickel is found in two basic forms: in lateritic deposits (as oxides) and in a nickel-sulfide ore. Usually, nickel is found in combination with copper and numerous other elements. The ratio of nickel to copper in these ore bodies is normally 2:1. Therefore, it is not too surprising that the first major alloy based on a nickel-containing ore was composed of 67% nickel and 33% copper. This is also the same composition, roughly, of Monel alloy 400, which was patented in 1906 and first melted and cast commercially in the United States in 1921 by the International Nickel Company. Subsequently, numerous alloys that could be used in a wide variety of applications were developed.

The Monel composition was used extensively in corrosion-resisting applications early in its history, because stainless steel had not yet been invented. Kitchen and food preparation equipment, in particular, were made from "Monel metal," because of its corrosion resistance, ease of cleaning, and attractive appearance.

The consumption of high-nickel-content corrosion-resistant alloys grow at an impressive rate during the postwar years. The cost of nickel alloys was high after World War I and high cost per unit weight continues to be a primary concern in the present use of these alloys. Although these alloys are more expensive than some other materials, their high performance generally makes them cost effective in the long run. Although the current annual consumption of nickel alloys is a small fraction of the steel consumption total, the numbers are still impressive. In 1990, it was estimated that the Western nations consumed approximately 40×10^9 g (89×10^6 lb) of solid-solution corrosion-resistant nickel, nickel-copper, nickel-chromium, and nickel-chromium-iron alloys. Most (85%) were wrought products.

Because of their relatively high cost, these alloys are usually only specified when lower-cost alloys are unable to withstand the environment or are not strong enough. Often, the combination of these two criteria is the reason that nickel alloys are specified. No other alloy system combines the qualities of strength, environmental resistance, weldability, formability, and availability more completely than the nickel-base alloy family.

The compositions of some of the popular, commercially available, solid-solution wrought nickel, nickel-copper, nickel-chromium, and nickel-chromium-iron alloys are given in Table 1. This list does not include the molybdenum-rich alloys nor the precipitation-hardened alloys. The former are covered in the article "Selection of Nickel-Base Corrosion-Resistant Alloys Containing Molybdenum" in this Section of the Volume. The latter are described in the Section "Selection of Nonferrous High-Temperature Materials" in this Volume.

TABLE 1 COMPOSITIONS OF SELECTED NICKEL-BASE CORROSION-RESISTANT ALLOYS

ALLOY	COMPOSITION, WT%								
	Ni	Cr	Fe	Cu	C0	Si	Al	Ti	Mo

800	32.5	21	46	. . .	0.05	0.5	0.3	0.3	. . .
825	42	21	30	. . .	0.03	0.2	0.1	0.9	3

The commercially pure nickel grades are used extensively in applications that utilize their corrosion resistance, such as caustic service areas and food handling equipment, and in applications that utilize their electronic or magnetic characteristics, such as transducers. Alloy 201 has a low carbon content and is used in applications above 315 °C (600 °F), where long time exposure would cause the precipitation of embrittling graphite in alloy 200.

The nickel-copper alloys are used extensively in seawater applications, because of their excellent resistance to corrosion, cavitation, and erosion. Other significant applications include their use in the presence of chlorinated solvents, sulfuric acid, and alkalies. Typical industrial applications include valves and pumps, propeller shafts, marine fixtures and fasteners, chemical processing equipment, process vessels and piping, and heat exchangers.

The nickel-chromium alloys are used in severely corrosive environments at elevated temperatures, as well as at lower temperatures. Typical applications include furnace muffles and retorts, carburizing baskets, nuclear reactor components, thermocouple protection tubes, radiant furnace tubes, and chemical and food processing equipment.

The nickel-chromium-iron alloys are typically used in oxidizing and carburizing applications because of their resistance to these environments and their high strength. Typical applications include furnace components, heat exchangers and process piping, electric range heating-element sheathing, extruded tubing for ethylene and steam methane reforming furnaces, and chemical processing equipment.

All of the nickel-base alloys are resistant to sigma formation (that is, a hard, brittle, non-magnetic intermetallic intermediate phase with a tetragonal crystal structure) and to stress-corrosion cracking. They are austenitic throughout the range of temperatures in which they are normally used. This metallurgical stability enables designers to specify these alloys with the confidence that exposure to service temperatures will not cause premature structural damage to the materials.

The nickel and nickel-copper alloys are generally easier to fabricate than steels of the same thickness. The nickel-chromium and nickel-chromium-iron alloys are stronger than most steels, but can be formed with modest changes in

technique. For example, their spring-back is greater, but if these alloys are overbent slightly more than normal, they can usually be formed on the same equipment that is used for steels. The nickel-base alloys can be work hardened more quickly than steels and require anneals more frequently during forming operations.

Selection of Nickel, Nickel-Copper, Nickel-Chromium, and Nickel-Chromium-Iron Alloys

Donald J. Tillack, D.J. Tillack and Associates

General Welding Characteristics

Thermal Conductivity. Nickel is quite conductive and copper is extremely conductive. However, the addition of chromium or iron decreases the thermal conductivity of nickel or nickel-copper. Conductivity, whether thermal or electrical, always decreases when the solvent accepts solute atoms, as in alloying. The data in Table 2 illustrate this fact. Note that nickel has a thermal conductivity value of 75 W/m · K (45 Btu/ft · h · °F) and copper (not shown in Table 2) has a value of 391 W/m · K (225 Btu/fi · h · °F), but alloy 400, which contains roughly two-thirds nickel and one-third copper, has a lower thermal conductivity value (22 W/m · K, or 13 Btu/ft · h · °F) than either nickel or copper.

TABLE 2 PROPERTIES OF SELECTED NICKEL-BASE CORROSION-RESISTANT ALLOYS

ALLOY	DENSITY, G/CM^3	MELTING RANGE		COEFFICIENT OF THERMAL EXPANSION(A), 10^{-6}/K	THERMAL CONDUCTIVITY		ELECTRICAL RESISTIVITY, 10^{-8} Ω/M
		°C	°F		W/M^2·K	BTU/FT^2 · H · °F	
1020 CARBON STEEL(B)	7.9	1470-1530	2680-2790	12	46	27	19
304 STAINLESS STEEL(B)	8.0	1390-1450	2535-2640	17	16	9.3	72
200	8.9	1435-1502	2615-2735	14	75	44	9
201	8.9	1435-1502	2615-2735	14	79	46	8
400	8.8	1299-1349	2370-2460	16	22	13	51
600	8.4	1354-1413	2470-2575	14	15	8.7	103
601	8.1	1301-1368	2375-2495	15	11	6.4	119
690	8.2	1343-1377	2450-2510	14	12	7	115
800	7.9	1357-1385	2475-2525	16	12	7	99
825	8.1	1371-1399	2500-2550	15	11	6.4	113

(A) IN RANGE FROM 20 TO 260 °C (68 TO 500 °F).

(B) DATA PROVIDED FOR PURPOSE OF COMPARISON

Thermal conductivity plays an important function during welding because it influences heat flow and the amount of heat required to melt material into the weld puddle. A base material composition with a high level of thermal conductivity will conduct heat away from the fusion zone and therefore requires slightly more heat input during welding than would an alloy with low thermal conductivity, which retains the local heat of welding for a longer time.

The nickel-base alloys vary considerably in their thermal conductivity characteristics. The nickel-chromium and nickel-chromium-iron alloys have values lower than those of both the carbon steels and the austenitic stainless steels, whereas nickel and the nickel-copper alloys have values considerably higher than those of the steels.

The electrical resistivity of a material is especially important in the welding process itself, because the melting rate of an electrode or wire is influenced by the electrical characteristics of the material (Table 2). Usually, solid-solution alloys are not very good electrical conductors because the solute and solvent atoms are of different sizes, which distorts the crystal lattice structure of the material and impedes the passage of electrons. The alloys that are composed primarily of one element, such as 1020 steel and nickel-base alloys 200 and 201, have the lowest electrical resistivity values of the alloys listed in Table 2.

The thermal expansion characteristics of a material are important because the heat that is applied to weld joints causes localized expansion and/or contraction during heating and/or cooling. A material with a greater thermal expansion value will expand and contract more during the welding operation, thus creating a greater amount of stress on the weld joint. This is particularly important when the weld deposit is marginally crack sensitive. It is also a consideration when dissimilar metals are welded together, especially when them is a large difference in expansion characteristics. The section "Dissimilar Welding" in this article provides more details on this topic. The nickel-base alloys have thermal expansion values that are between those of carbon steel and the austenitic stainless steels, as shown in Table 2.

Liquidus-Solidus Temperature. The cracking resistance of a material is often associated with the difference in the liquidus and solidus temperatures, particularly when stress is involved. When a highly restrained structure is welded, considerable stress is generated during the welding operation. If a material has a relatively large spread between its liquidus and solidus temperatures, then there is more time that the material is in a vulnerable situation in terms of cracking. However, a material with a relatively narrow liquidus-solidus range will cool down fairly rapidly through the temperature range, and there will be less time for stress-related cracking to occur. This example assumes that other factors that influence cracking, such as grain size or structural mass, are equal. Table 2 lists the liquidus-solidus temperatures, or melting ranges, of several solid-solution nickel alloys.

Selection of Nickel, Nickel-Copper, Nickel-Chromium, and Nickel-Chromium-Iron Alloys

Donald J. Tillack, D.J. Tillack and Associates

Welding Metallurgy

The heat-affected zone (HAZ) is discussed below in terms of grain boundary precipitation, grain growth, and hot cracking.

Grain Boundary Precipitation. Grain boundaries are the weak link in a microstructure that is exposed to elevated temperature, whether that exposure occurs during service or, in the case of welding, during the thermal cycles that are part of the welding operation. Precipitates that form in the grain boundaries can vary in size and composition and can be either harmful or beneficial. Intermetallic compounds, such as carbides, act as barriers to grain growth and can be very beneficial. Intergranular carbides in alloys 600 and 690 can also deter stress-corrosion cracking during high-purity water exposure in nuclear reactor steam generator primary side environments (Ref 1).

Grain Growth. Generally, it is easier to make defect-free welds in material with a relatively fine grain size, because there is less of an undesirable element concentration that contributes to grain boundary cracking in a fine-grain network. With larger grains, there are fewer grain boundaries and the deleterious elements are more concentrated in them. However, it is not always possible to have a fine-grain structure to weld. Most high-temperature applications, for example, need a large grain size material to ensure elevated-temperature creep and rupture strength.

Even when a fine-grain material is welded, grain growth will occur in the HAZ. The width of this grain growth band depends on numerous variables, such as the welding process used, the heat input and travel speed, and the heat transfer characteristics of the base material. The electron-beam (EB) welding process, for example, will produce a narrower HAZ and a smaller band of grain growth than the gas-metal arc welding (GMAW) process.

Hot Cracking. In terms of constitutional liquation, HAZ fissures are seldom a problem in the nickel or nickel-copper alloys, but they have been the subject of considerable study in nickel-chromium and nickel-chromium-iron alloys.

Such fissures have been observed in alloy 600, for example, when relatively high heat inputs puts (2.4 MJ/m, or 45×10^3 J/in., and higher) were used. These fissures are typically narrow, linear intergranular separations that are perpendicular to the direction of weld travel. Fissures have been found in the HAZ of welds made by the GMAW, gas-tungsten arc welding (GTAW), and EB welding processes. An example of a typical fissure found in a nickel-chromium HAZ is shown in Fig. 1.

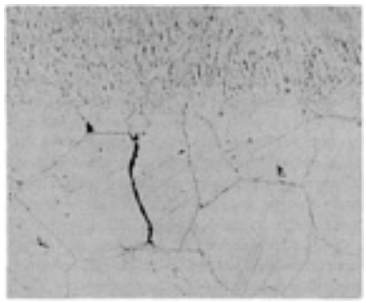

FIG. 1 PHOTOMICROGRAPH SHOWING A HEAT-AFFECTED ZONE MICROFISSURE IN A NICKEL-CHROMIUM ALLOY. SPECIMEN IS A GMAW 44.4 MM (1.75 IN.) PLATE. ELECTROLYTIC PHOSPHORIC ACID ETCHANT, 75×

Grain boundary liquation is one of the proposed mechanisms that causes fissuring (Ref 2). Grain boundary liquation occurs when a phase or particle causes the grain boundary to melt at a temperature below the bulk melting point. Because the liquated grain boundary has practically no strength, separation at the liquated grain boundary can occur, causing the fissure.

Constitutional liquation was proposed as a mechanism for hot cracking by Savage in 1959 and was described in detail in subsequent papers (Ref 3). In this theory, a relatively stable second-phase particle begins to dissolve during nonequilibrium, or rapid, heating and forms an intermediate phase with the matrix, which has a solidus temperature that is lower than that of either the second-phase particle or the matrix. In alloy 600, some experimenters have identified the precipitation of Cr_7C_3 at the grain boundary as the second-phase particle around which constitutional liquation occurs.

Chemical segregation at a grain boundary can also cause grain boundary liquation. Boron and sulfur are two elements that form lower melting point eutectics that can contribute to HAZ fissuring. Manganese segregation in alloy 600 has been identified as forming a binary compound (Mn-38Ni) with a 1000 °C (1832 °F) solidus temperature, which is considerably below the bulk melting range of the alloy.

Several approaches can be made to minimize the occurrence of HAZ fissuring, including the control of:

- HEAT INPUT DURING WELDING
- MICROSTRUCTURE, TO OBTAIN FAIRLY SMALL GRAIN SIZES
- CHEMISTRY, TO MINIMIZE THE AMOUNT OF DELETERIOUS MINOR ELEMENTS THAT ARE KNOWN TO CONTRIBUTE TO FISSURING

There are many minor elements that can contribute to HAZ fissuring in nickel-base alloys, including some that are intentionally added to enhance properties. Although these elements are considered minor because they are present in small amounts, they are far from being minor in their effect on fissuring. These elements include, but are not limited to, sulfur, phosphorus, lead, boron, zirconium, tin, zinc, selenium, tellurium, antimony, bismuth, silver, and gold. Boron and zirconium are two elements that are intentionally added to nickel-base alloys to enhance hot workability and elevated-temperature strength, but they can be detrimental during welding operations. More details on the effects of many of these elements are provided later in this article.

The fusion zone of autogenous welds is discussed below in terms of sensitivity to porosity formation, hot-cracking susceptibility, and microsegregation.

In terms of sensitivity to porosity, the nickel-base alloys can be divided into two groups: those that contain chromium and those that do not. Chromium has a natural affinity for the gases that form during the welding operation, notably oxygen, nitrogen, and hydrogen. Because the nickel and nickel-copper alloys lack chromium, they are sensitive to porosity formation during autogenous welding. Therefore, the protection of the weld puddle during melting and solidification is critical to the achievement of porosity-free autogenous welds in these two alloy classes. Dry torch gases and adequate gas protection are necessities. Although the use of filler metals helps in porosity control, because of the additions of gas-absorbing elements such as titanium and aluminum, proper precautions are still necessary.

Porosity control is much easier in the nickel-chromium and nickel-chromium-iron alloys because of their high chromium levels. This is not meant to imply that gas coverage is not important when autogenously welding the chromium-containing alloys, but it certainly is not as critical, compared with nickel and nickel-copper alloys.

Hot-Cracking Susceptibility. Hot cracking, or fissuring, is a grain boundary related mechanism that can occur, primarily, in the nickel-chromium and nickel-chromium-iron families of alloys. Although the nickel and nickel-copper alloys are not immune to this phenomenon, there have been more occurrences in the chromium-bearing nickel-base alloy materials.

A study of the weldability of alloy 800 (Ref 4) found that reducing the aluminum plus titanium content to extremely low levels (<0.06%) essentially eliminated hot cracking. It was noted that when normal levels of these elements were present, segregation of titanium and aluminum resulted in grain-boundary embrittlement and banding that was sufficiently severe to exhibit liquation during heating through a weld cycle. There also appeared to be a strong association between sulfur and titanium in the discrete inclusions observed in sulfur-bearing alloys.

Microsegregation. When a weld solidifies, an inhomogeneous dendritic structure forms. Solidification begins with the highest-melting-point liquid and continues until the whole structure is solid. A condition called microsegregation, or coring, occurs during this solidification process, and areas of the solidified microstructure can have great differences in composition. This becomes a problem in corrosion situations where an alloy was chosen for its particular resistance to corrosion. For example, because the dendritic weld material can have vastly different chromium and molybdenum levels, preferential corrosion may initiate and propagate at those areas of the microstructure that are lean in the element responsible for providing the corrosion resistance.

Microsegregation cannot be eliminated in a weld, but it can be minimized by judicious selection of welding parameters, such as the control of heat input. High-temperature heat treatments for several hours can partially equalize the composition gradients by diffusion. Cold working the weld structure, followed by annealing, can also break down this microsegregation, if the component lends itself to this type of treatment. Thin-sheet welds can be planished, for example. In addition to improving the corrosion resistance of the welds, cold working and annealing the weld area also increases weld ductility. Figure 2 illustrates how a dendritic weld structure can be reduced by cold working and annealing. After a 20% cold reduction followed by an anneal, the cast structure of the weld has been refined substantially and the wrought grain structure can be seen easily.

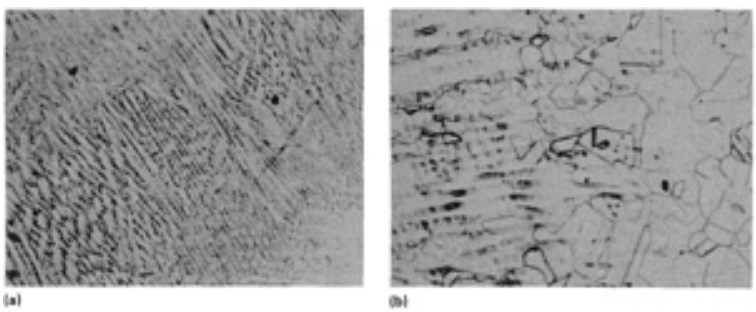

FIG. 2 MICROSTRUCTURES OF ALLOY 400 (UNS N04400) WELDED WITH FILLER METAL 60. (A) AS WELDED; CYANIDE PERSULFATE ETCHANT, 70×. (B) WELDED, PLUS 20% COLD REDUCTION, PLUS ANNEAL AT 871 °C (1600 °F)/2 H; CYANIDE PERSULFATE ETCHANT, 150×. SOURCE: REF 5

Unmixed Zone. For many years, it was assumed that there was complete mixing in the weld pool and that the composition of a fusion weld was homogeneous throughout. Now it is known that there are areas adjacent to the fusion line where mixing does not occur. This unmixed zone has been the subject of considerable research and is of concern to corrosion engineers because of the adverse effect that a cast base-metal structure can have on weld-associated corrosion. These zones are base material undiluted by filler metal and are, essentially, narrow bands of autogenous welds situated on the fusion line. Figure 3 shows an unmixed zone (Ref 6). There is a greater tendency for unmixed zones to be present in nickel-base welds, compared with steel and stainless steel welds. The sluggish nature of the molten nickel alloy weld metal tends to deter complete mixing during welding.

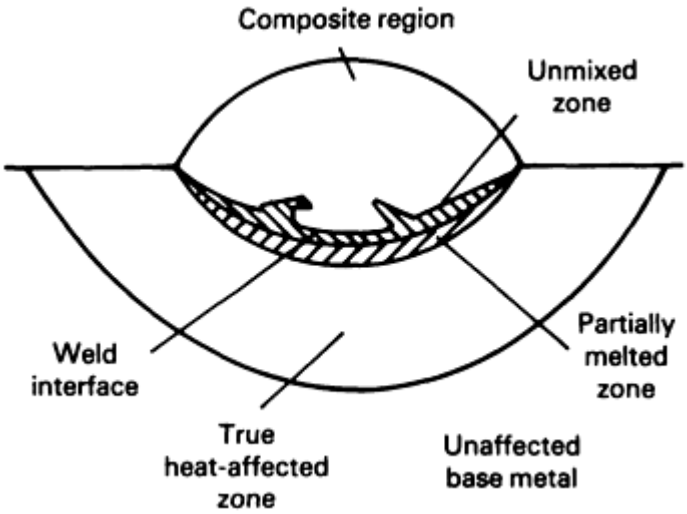

FIG. 3 SCHEMATIC SHOWING LOCATION OF UNMIXED ZONE IN A SOLIDIFIED WELDMENT. SOURCE: REF 6

These unmixed zones can be reduced or practically eliminated by controlling the welding procedures to ensure adequate mixing of the weld pool during welding. As an example, excessively fast travel speed promotes the formation of these zones. Slowing the travel speed and adjusting the other welding parameters to compensate for the slower travel speed will do a great deal to minimize the formation of unmixed zones.

The effects of alloying elements on the weldability of nickel-base alloys are described below.

Copper forms a complete series of solid-solution alloys with nickel and has little effect on the weldability of nickel. Metallurgically, the binary high-nickel-content alloys that contain from 15 to 40% Cu behave much like commercially pure nickel when welded. The nickel-copper alloys have about the same susceptibility to embrittlement by elements such as sulfur as does commercially pure nickel. The need for alloying to control gaseous porosity is not significantly reduced in the nickel-copper alloys, compared to that required for commercially pure nickel. As copper is increased up to the range of the copper-nickel alloys, such as 70Cu-30Ni and 80Cu-20Ni, the alloy behaves more like a copper alloy and reduced amounts of deoxidizers can be used. The presence of copper changes the high-temperature solubility of carbon to the point where graphitization is not encountered.

The chromium addition in alloys of commercial importance does not exceed the limit of solid-solution alloys and presents an attractively narrow freezing range. Chromium has the ability to form stable oxides and nitrides, which in turn greatly reduce the tendency for weld porosity, compared to that encountered in commercially pure nickel and nickel-copper welds. The chromium-bearing alloys are more susceptible than other high-nickel-content alloys to hot cracking when other elements, notably silicon, are present. For example, the hot-cracking susceptibility of a nickel-base weld metal containing 15% Cr is sharply increased as silicon increases from a few tenths of a percent to 1% and higher, whereas levels on the order of 1% Si are relatively innocuous in nickel and nickel-copper alloys.

Iron is commonly present in the nickel-chromium alloys, such as alloy 600, in amounts up to 8 wt%. It is not intended to enhance mechanical properties or weldability, but is added as a ferroalloy, along with other additives, and helps keep the cost of these alloys down. Up to this level, iron is not believed to appreciably effect welding behavior. As the amount of iron increases to the composition range of nickel-chromium-iron alloys (such as alloy 800, which contains about 46% Fe),

the alloy becomes increasingly hot-crack sensitive. When steel is melted into a high-nickel-content alloy weld, such as in an overlay or in dissimilar metal welding, there is some reason to believe that residual elements such as sulfur and phosphorus, which are normally present in more abundant quantities in steel than in nickel-base alloys, are more damaging to the properties of the weld than the iron itself.

Carbon is usually present in nickel and high-nickel-content weld metals in amounts ranging from 0.01 to 0.15 or 0.20%. The effect of carbon is a major concern with commercially pure nickel. The limit of carbon solubility in the temperature range from 371 to 649 °C (700 to 1200 °F) is about 0.02 to 0.03%. During welding, any graphitic carbon present in the HAZ is dissolved and held in a super-saturated solution as the metal rapidly cools. Subsequent exposure to the temperature range from 371 to 649 °C (700 to 1200 °F) causes carbon to precipitate in the form of intergranular graphite. Unwelded high-carbon commercially pure nickel would be similarly embrittled in this temperature range by carbon migration to the grain boundaries, but it would require a much longer time. Therefore, when the wrought commercially pure alloys are to be used at temperatures above 371 °C (700 °F), a maximum of 0.02% carbon is used, as in alloy 201. In weld metal, titanium is added to tie carbon up in the form of titanium carbide, thus preventing the formation of graphitic carbon.

In the nickel-base alloys, copper alters solubility to the point where graphitic embrittlement is not encountered up to carbon levels of 0.15 to 0.20%. The carbon content in nickel-copper alloys does have an effect on hot-cracking tendencies when iron is present. For example, nickel-copper alloys with over 0.20% C can tolerate only about 5% Fe; hot cracking may result at higher levels. Low-carbon nickel-copper alloys with less than 0.10% C can tolerate up to about 30 wt% Fe.

In nickel-chromium alloys, carbon combines with chromium to form chromium carbides, unless titanium or columbium are present to form their respective carbides. Although chromium depletion may occur in the HAZ of welds, as it does with the iron-base alloys in the absence of titanium or columbium, it is only in extremely corrosive media that corrosion resistance is impaired.

Manganese was considered to be relatively unimportant to welding metallurgy for many years. It is now well established that in both the nickel-chromium and nickel-copper alloys, manganese is beneficial in minimizing fissuring and in preventing hot cracking in welds of heavy sections, as well as in cases where excessive iron dilution may be encountered. Additions of up to 9 wt% Mn have been used in some commercially available welding electrodes.

Magnesium in wrought materials forms a stable high-melting-point magnesium sulfide preferentially to the extremely low-melting-point nickel-nickel sulfide eutectic. In welding, magnesium in the base metal serves to prevent hot cracking in the HAZ.

Silicon may be present in nickel-base alloys in amounts ranging from 0.01% to 4.0%. However, it is generally considered to have an adverse effect on welding because it increases the tendency for hot cracking. Therefore, wrought materials generally have less than 1% Si. The adverse behavior is associated with a eutectic melting that is more damaging to weld metal than to base metal. Pure nickel is most resistant, followed by nickel-copper alloys. Nickel-chromium alloys are the least resistant to the effects of silicon.

Both titanium and aluminum can be added to the weld metal and the base material to promote age hardening. In smaller amounts, the addition of titanium to nickel and nonchromium-bearing nickel-base alloys helps control gas porosity. Aluminum is added to wrought alloys as a deoxidizer. If substantial amounts of titanium and aluminum are added, the sensitivity of the weld metal to hot cracking increases.

Boron amounts that range from 0.003 to 0.10% improve the high-temperature mechanical properties of certain wrought and cast nickel-base alloys. These alloys are usually intended for elevated-temperature service, where grain boundary strengths are enhanced by boron additions. Unfortunately, boron contents of 0.03% or higher have a grossly damaging effect on weldability. At higher boron levels, the weld metal and HAZ are extremely hot-crack sensitive and considerable care must be exercised with respect to heat input and stress levels.

Zirconium acts similarly to boron in nickel-base alloys by promoting hot cracking in the weld metal and HAZ. However, the tolerance for zirconium is somewhat higher than it is for boron.

Sulfur is perhaps the most damaging of all elements that are involved in the welding metallurgy of nickel and high-nickel-content alloys. Sulfur is particularly damaging to nickel because of its extremely limited solid solubility and because of a nickel-nickel sulfide eutectic reaction that occurs at 649 °C (1200 °F).

Sulfur is different from most other elements that adversely affect weldability because it affects both the HAZ and the weld metal. Penetration occurs at the weld HAZ area that is heated above a threshold temperature while being in contact with sulfur-bearing material. The threshold temperature varies from 316 °C (600 °F) for pure nickel to about 649 °C (1200 °F) for chromium-bearing alloys. Magnesium and manganese are alloying additions that are used to control the effects of sulfur. Unusual diligence is required when handling the nickel-base alloys to avoid contamination from sulfur-containing compounds, which can include such commonly used materials as machining lubricants, marking crayons, temperature-indicating sticks, and shop dirt. Figure 4 shows the type of cracking that can occur when a sheet of alloy 200 is wiped with a dirty cloth containing sulfur compounds and then welded.

FIG. 4 SULFUR EMBRITTLEMENT OF A JOINT IN ALLOY 200 (UNS N02200). PRIOR TO WELDING, THE CRACKED SIDE OF JOINT WAS WIPED WITH DIRTY CLOTH ON WHICH SULFUR-CONTAINING RESIDUE HAD ACCUMULATED.

Lead causes hot shortness in high-nickel-content weld metal at about the same level as sulfur does. The metallurgical explanation of the subversive effect of lead is very similar to that of sulfur. In practice, lead contamination is less common than sulfur contamination, but probably only because there are fewer common sources of lead-containing contaminants in fabricating shops than there are sources of sulfur-containing contaminants.

Phosphorus can exhibit an effect similar to lead and sulfur in high-nickel-content weld metals. The solubility of phosphorus is quite limited and undergoes a eutectic reaction at about 871 °C (1600 °F). Severe weld metal cracking has been attributed to as little as a few hundredths of a percent of phosphorus.

Postweld Heat Treatment

Postweld heat treatments are usually not required for the non-precipitation-hardenable nickel and nickel-base alloy weldments. For example, the ASME boiler and pressure vessel code for unfired pressure vessels does not require postweld heat treatment, except as agreed upon between the user and the manufacturer. However, a dissimilar weldment between a nickel-base alloy and a steel is postweld heat treated because the steel side of the joint requires it. In this case, the heat treatment will normally have little consequence on the nickel-base alloy. Table 3 lists the typical annealing temperatures for many of the solid-solution nickel-base alloys.

TABLE 3 TYPICAL ANNEALING TEMPERATURES FOR CORROSION-RESISTANT NICKEL, NICKEL-COPPER, NICKEL-CHROMIUM, AND NICKEL-CHROMIUM-IRON ALLOYS

All alloys air cooled or water quenched

ALLOY	UNS NO.	TEMPERATURE[A]

(A) ±14 °C (±25 °F)

In certain environments, it has been beneficial to perform a postweld heat treatment on some of the nickel-base alloy weldments. Alloys 200, 201, and 600 receive this treatment for caustic service applications, as does alloy 400 for hydrofluoric acid service applications. The recommended heat treatment procedures for these materials in these service environments are given in Table 4.

TABLE 4 RECOMMENDED HEAT TREATMENT PROCEDURES FOR SELECTED NICKEL-BASE CORROSION-RESISTANT ALLOYS

ALLOYS 200 AND 201 FOR CAUSTIC SERVICE
1. HOLD AT 704 °C (1300 °F) FOR A MINIMUM OF 0.5 H/25.4 MM (L IN.) OF THICKNESS
2. DETERMINE THE HEATING AND COOLING RATES, WHICH WILL VARY WITH THE SHAPE OF THE PART. COMPLEX SHAPES WITH NONUNIFORM THICKNESSES SHOULD HAVE HEATING AND COOLING RATES OF 111 °C (200 °F)/H. SHAPES WITH UNIFORM THICKNESSES CAN USE FAST HEATING AND AIR COOLING
ALLOY 600 FOR CAUSTIC SERVICE
1. HOLD AT 899 °C (1650 °F) FOR A MINIMUM OF I H/25.4 MM (1 IN.) OF THICKNESS OR AT 788 °C (1450 °F) FOR A MINIMUM OF 4 H/25.4 MM (1 IN.) OF THICKNESS
2. DETERMINE HEATING AND COOLING RATES PER GUIDELINES FOR ALLOYS 200 AND 201
ALLOY 400 FOR HYDROFLUORIC ACID SERVICE
1. HOLD AT 593 °C (1100 °F) FOR A MINIMUM OF 0.5 H/25.4 MM (1 IN.) OF THICKNESS
2. DETERMINE HEATING AND COOLING RATES PER GUIDELINES FOR ALLOYS 200 AND 201

Although determining the rates of heating and cooling after postweld heat treating is seldom a problem with the solid-solution nickel-base alloys, the cooling rate should generally be at least as fast as the rate of an air cool. When there are

large differences in cross-sectional areas in a welded structure, the heating and cooling rates may have to be controlled in order to minimize the distortion that might occur with a rapid rate of heating or cooling. Such structures could experience enough distortion to cause fit-up or assembly problems, particularly if a too-rapid cooling rate causes excessive stresses that are due to the mass differences in the structure.

The usual precautions regarding furnace atmosphere and temperature control should be followed when postweld heat treating these alloys. Because cracking caused by contaminants is always a concern, all surfaces should be thoroughly cleaned prior to being postweld heat treated.

Special Metallurgical Welding Considerations

Dissimilar welding of plate-to-plate, clad, and weld overlay cladding specimens are described below.

Plate-to-Plate. There can be drastic consequences related to complex metallurgical considerations when butt welding plates of different composition. The composition of the weld deposit is controlled not only by the filler metal, but by the amount of dilution from the two base metals. Many different dissimilar-metal combinations are possible, and the amount of dilution varies with the welding process, the operator technique, and the joint design.

In many cases, more than one welding product will satisfy the requirement of metallurgical compatibility. Selection should be based on the strength required, service environment, or the cost of the welding product. Table 5 lists the recommended filler metals to use when welding numerous dissimilar metal combinations.

(A) PRECAUTION IS REQUIRED TO MINIMIZE COPPER DILUTION IN THE WELD, BECAUSE OF THE HIGH CHROMIUM LEVEL OF ALLOY 690. "BUTTERING" THE COPPER OR COPPER-NICKEL SIDE OF THE JOINT WITH NICKEL WELD METAL PRIOR TO WELDING MAY BE ADVISABLE.

The selection of the welding product involves extra considerations when dissimilar materials are being welded. In addition to dilution factors, the thermal expansion of the two metals being joined and of the filler metal should be reviewed in order to achieve a weld that will not fail prematurely.

In the power industry, for example, an austenitic stainless steel and a low-alloy steel represent a common joint. The expansion rate of the stainless steel side is higher than that of the low-alloy side (see Table 2). If this joint were welded with a stainless steel electrode, then both the weld and the stainless steel side of the joint would expand and contract during heating and cooling at the same rate, thus putting stress on the low-alloy side of the weld. Because the low-alloy steel has less strength than the stainless steel, the shifting of stress to this side of the joint is undesirable and could lead to premature fatigue or stress failure.

On the other hand, if a nickel-base alloy filler metal were used to weld this combination, both the weld and the low-alloy side of the joint would expand and contract together during temperature swings in the service environment and any stresses induced would be shifted to the stainless steel side of the joint, which is stronger than the low-alloy side. This would result in a longer service life for this weld.

Clad Material. Most clad specimens consist of a highly alloyed material, such as a nickel-base alloy, clad to a less-expensive material, usually steel. The nickel-base alloy provides corrosion resistance, whereas the steel, which usually constitutes at least 80% of the total thickness, provides backing strength and reduced costs. Because clad steels are frequently joined by welding, it is important to ensure that any weld joint surface that is exposed to corrosive media is at least as corrosion resistant as the cladding. This requirement influences both joint design and welding technique.

Butt joints should be used whenever possible. Figure 5 shows recommended designs for two thickness ranges. Both designs include a small edge of unbeveled steel above the cladding to protect the cladding when the steel is welded. The steel side should be welded first, using a low-hydrogen welding product. It is important to avoid cladding penetration during the first welding pass. Dilution of the steel weld with the nickel-alloy cladding can cause the deposit to crack. The clad side of the joint should be prepared by grinding or chipping, and it should be welded using the welding product that is recommended for solid sections of the cladding alloy. The weld metal will be diluted with steel. To maintain corrosion resistance, at least two layers should be applied, although three or more layers are preferable.

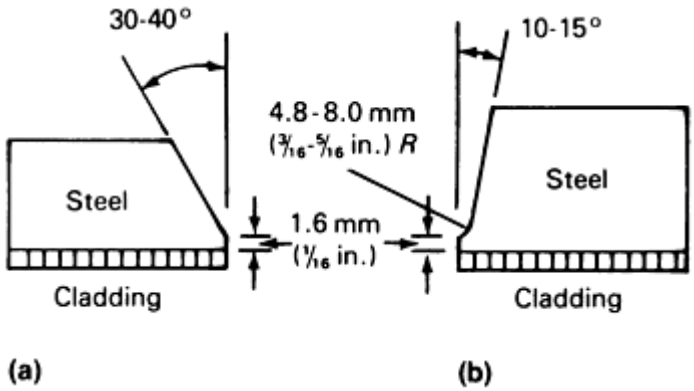

FIG. 5 JOINT DESIGNS FOR CLAD STEEL. (A) MATERIAL OF 4.8 TO 16 MM ($\frac{3}{16}$ TO $\frac{5}{8}$ IN.) THICKNESS. (B) MATERIAL OF 16 TO 25 MM ($\frac{5}{8}$ TO 1 IN.) THICKNESS. SOURCE: REF 7

The strip-back method is sometimes used instead of the procedure described above. The cladding is removed from the vicinity of the joint, as shown in Fig. 6. The remaining steel is then welded using a standard steel joint design and technique, and the nickel-alloy cladding is reapplied by weld overlaying. The advantage of the strip-back method is that it eliminates the possibility of cracking caused by steel weld metal penetration into the cladding (Ref 7).

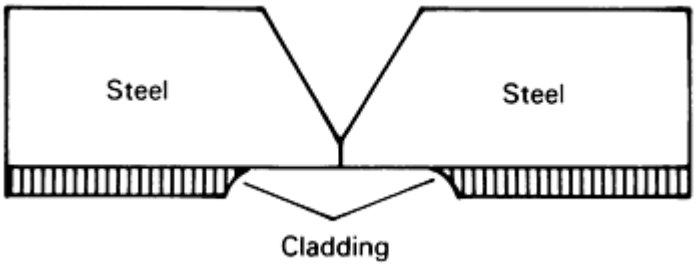

FIG. 6 STRIP-BACK METHOD OF JOINT PREPARATION. SOURCE: REF 7

Some joints, such as those in closed vessels or tubular products, are accessible only from the steel side. In such cases, a standard steel joint design is used, and the cladding at the bottom of the joint is welded first with nickel-base alloy weld metal. After the cladding is welded, the joint can either be completed with nickel-base alloy weld metal or a barrier layer of carbon-free iron can be applied and the joint completed with steel weld metal. If the steel thickness is 8.0 mm ($\frac{5}{16}$ in.) or less, it is generally more economical to complete the joint with nickel-base alloy weld metal.

Weld Overlay Cladding. Nickel-base alloy weld metals are readily applied as overlays on carbon steels, low-alloy steels, and other materials. The cleanliness of the surface to be overlaid is extremely important. All oxides and foreign materials must be removed prior to welding to ensure crack-free results and to minimize the possibility of oxide inclusions in the deposited weld metal. If the material being overlaid has a high sulfur or phosphorus content, then cracking is possible in the deposited nickel-base alloy weld layer. If this occurs, then the cracked layer should be ground or machined away and another layer deposited.

This sacrificial layer approach is just one solution to this situation. Other approaches would be to deposit the first layer with a more-tolerant weld metal composition or, if possible, to design the structure with a lower sulfur/phosphorus base material. Using a welding process and welding parameters that minimize dilution also is very helpful in avoiding problems in this type of situation.

Welding of Castings. Many of the wrought solid-solution nickel alloys discussed in this article have equivalent cast compositions that are modified slightly to enhance castability and properties. The largest modification usually is the increase in silicon content, which unfortunately has an adverse effect on weldability. It is not unusual to find silicon levels that exceed 1.5% in cast nickel-base alloys. Depending on other influences, such as restraint, amount of other minor elements, and the welding process used, this level of silicon may result in weld cracking. When welding surface defects that occurred during the casting process, which is a common welding procedure with castings, most welding methods can be used with most of the solid-solution nickel-base alloy castings.

Repair Welding. The solid-solution nickel-base alloy system does not undergo drastic metallurgical changes during either thermal cycling or exposure to commonly encountered service temperatures, as do many of the ferrous alloys. This is a definite benefit when it becomes necessary to repair weld a component. Except for exposure to surface-modifying environments, such as carburization, nickel-base alloys generally retain their excellent weldability, even after prolonged service exposure. In those cases where a general condition renders a component unusable, such as overall carburization or oxidation attack, very little can be done to repair weld the part. However, if a localized area fails, then there usually is a good chance that a repair weld can salvage the component.

There are occasions when a carburized area is the site of a failure, and if the carburization was not the primary reason for the failure, then sometimes the localized area can be ground free of the carburized layer and a successful repair weld made. If the carburization did-cause the failure, then localized repair welding would probably result in only a short extension of component life, because failure in another area of the carburized surface would undoubtedly occur quickly. This example illustrates how inspection and examination of the component is an important aspect when deciding whether or not to make a weld repair. Once the decision has been made that repair welding is feasible, an area of the component should be ground clean and a test weld made to determine whether the material can be successfully welded. If this test is positive, then the component should be thoroughly prepared by grinding the surface, if necessary, and cleaning it prior to

actual repair welding. If groove welding is necessary, then the previously described precautions concerning joint design should be followed in order to provide room for electrode manipulation.

Selection of Nickel-Base Corrosion-Resistant Alloys Containing Molybdenum

S.J. Matthews, Haynes International, Inc.

Introduction

THE FAMILY OF nickel-base corrosion-resistant (CR) alloys containing molybdenum are described in this article both in terms of a historical perspective and an alloy utilization viewpoint. Table 1 gives the nominal chemical compositions of the most widely used materials in this family, but is not all inclusive. Although other molybdenum-bearing nickel-base alloys exist, the information presented below is relative to the joining of similar alloys.

TABLE 1 NOMINAL COMPOSITION OF SELECTED MOLYBDENUM-BEARING NICKEL-BASE CORROSION-RESISTANT ALLOYS

ALLOY TYPE	ALLOY	UNS NO.	COMPOSITION, WT %										
			Ni	Co	Fe	Cr	Mo	W	Mn	Si	C	Cu	OTHERS

Alloy C Family. Hastelloy alloy C, developed in the early 1930s, is the grandfather of the nickel-chromium-molybdenum family of corrosion-resistant materials. Advances in process metallurgy and corrosion research has prompted the evolution of various C-type alloys. The minimum carbon content of the original alloy C composition was limited to about 0.05% C by the arc melting practices of the time.

The nickel-chromium-molybdenum alloys proved to be extremely important in the chemical processing industry, because they provided corrosion resistance over a wide range of reducing and oxidizing environments. However, grain boundary precipitation of carbides in the as-welded condition required a postweld solution heat treatment to restore optimum corrosion resistance. The deleterious effect of both carbon and silicon on corrosion resistance led to the development of alloy C-276.

An important factor in this new alloy was the development of a reliable quantitative method for determining susceptibility to intergranular attack in the original C-type alloy and the newer C-276 and C-4 alloys (Ref 1). The introduction of the argon-oxygen decarburization (AOD) process in the late 1960s made the production of alloy C-276 commercially viable. The maximum carbon content of alloy C-276 is 0.01% C with typical production compositions of about 0.005% C (Ref 2). Unfortunately, the optimum corrosion resistance of alloy C-276 was found to be hampered by the precipitation of an intermetallic compound rich in molybdenum and tungsten. The alloy is particularly susceptible to μ-phase formation when exposed to temperatures ranging from 650 to 1095 °C (1200 to 2000 °F).

Advances in alloy development theory, specifically the concept of electron vacancy number (N_v), led to the evolution of alloy C-4 in 1975. Alloy C-4 is essentially a tungsten-free, low-carbon, low-silicon ternary alloy of nickel, chromium, and molybdenum. Secondary carbide precipitation was further controlled by the addition of titanium to stabilize residual carbon that was not totally removed by AOD refining. Unfortunately, the removal of tungsten in order to reduce μ-phase precipitation also reduced the resistance of the alloy to localized corrosion attack, namely pitting and crevice corrosion (Ref 2).

A relatively recent (1985) development in the alloy C family is alloy C-22. Because it was recognized that molybdenum and tungsten had an opposing role to chromium in reducing versus oxidizing acid environments, alloy C-22 was developed with the proper balance of both elements to achieve versatility in a wide range of corrosive environments. The reduction of the molybdenum and tungsten content in alloy C-22, versus alloy C-276, also resulted in improved thermal stability (that is, resistance to intermetallic compound formation). An example of an alloy C-type application is in the lining of inlet and outlet ducts that are associated with the flue gas desulfurization (FGD) systems being installed by electric power utility companies.

Alloy B Family. Hastelloy alloy B-2 is unique in that it contains essentially no chromium, an element common to nearly all other CR alloys (Ref 3). It was originally developed to resist hydrochloric acid in all concentrations up to the boiling point and is used in many applications involving the production of this acid, as well as acetic acid and other chemicals. The alloy also resists sulfuric acid and pure phosphoric acid. Without chromium, however, this alloy is vulnerable to corrosion attack in reducing acids when oxidizing salts such as ferric or cupric chloride are present, even in the parts-per-million range.

Not unlike the old alloy C, which required postweld heat treatment to restore optimum corrosion properties, alloy B (the predecessor to alloy B-2) was improved by the evolution of a low-carbon (0.02% C maximum) and low-silicon version (0.08% Si maximum). Alloy B-2 is close to being a commercially "pure" binary alloy of nickel and molybdenum. It has a face-centered cubic (fcc) crystal structure and is quite ductile in the solution-annealed condition (that is, 60% room-temperature tensile elongation). However, the alloy forms intermetallic phases, Ni_3Mo and Ni_4Mo, with modest exposure

to the intermediate temperature range from 595 to 850 °C (1100 to 1560 °F). Precipitation of these intermetallic compounds can render alloy B-2 quite brittle. For example, its room-temperature ductility can drop to less than 5% elongation if it is exposed to 760 °C (1400 °F) for a period of 10 min.

A third-generation B-type alloy has recently been developed. Its composition was specially formulated to provide improved thermal stability while retaining the corrosion resistance of alloy B-2. This means that the reaction kinetics that drive the formation of Ni_3Mo and Ni_4Mo have been significantly retarded, greatly improving the fabricability of this family of alloys.

The alloy G family of alloys has excellent resistance to phosphoric acid and has been used in wet-process phosphoric acid evaporators, agitator shafts, pumps, and in the handling of superphosphoric acid (76% P_2O_5). Alloys G-3 and G-30 are newer versions of predecessor alloy G. Alloy G-3 is a lower-carbon version (0.015% C maximum versus 0.05% C maximum) and, hence, has improved resistance to heat-affected zone (HAZ) carbide precipitation. Improved resistance to hot cracking and improved weld metal bend ductility were also achieved by reducing the niobium plus tantalum content from nominally 2.0% (alloy G) to 0.5% maximum (alloy G-3). Alloy G-30 is a high-chromium (30% Cr) alloy designed to possess even greater resistance to HAZ corrosion attack. Recognizing that the phenomenon of sensitization involves not only the type and amount of HAZ precipitation, but also the depleted zones associated with the precipitates, the resistance of alloy G-30 to HAZ corrosion degradation is achieved by higher available chromium, even in the depleted zones. Alloy G-30 resists highly oxidizing acids such as the nitric plus hydrofluoric acid mixtures used in metal pickling baths and in nuclear waste reprocessing.

Selection of Nickel-Base Corrosion-Resistant Alloys Containing Molybdenum

S.J. Matthews, Haynes International, Inc.

General Welding Characteristics

Because of similarities in heat capacity, density, and other physical properties, the welding characteristics of the alloys described in this article are quite similar to austenitic stainless steels. The major differences between these alloys and stainless steel are lower thermal expansion, lower thermal conductivity, and higher electrical resistivity. Generally, solidus temperatures are about 55 °C (100 °F) lower than type 304 stainless. Table 2 summarizes the comparative physical properties relevant to welding and joining operations.

Welding Processes. Gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), and shielded metal arc welding (SMAW) processes are commonly used to join this family of CR alloys.

A filler metal that matches the composition of the base material is usually recommended when welding the nickel-chromium-molybdenum CR alloys. Other processes, such as plasma arc welding (PAW), resistance spot welding (RSW), laser-beam welding (LBW), electron-beam welding (EBW), and friction welding, can be used. The plasma arc cutting process is commonly used to cut alloy plate into desired shapes and to prepare weld angles. Oxyacetylene cutting is not recommended, nor is the use of oxyacetylene welding (OAW) and submerged arc welding (SAW). Oxyacetylene welding is not recommended because of the possibility of carbon pickup from the flame, whereas submerged arc welding is not recommended because of its high heat input, chromium loss across the arc, and silicon pickup from the welding flux.

Generally, welding heat input is controlled in the low-to-moderate range. Wide weave beads are not recommended. Stringer bead welding techniques, with some electrode manipulation, are preferred. The nickel-chromium-molybdenum alloy weld metal is not as fluid as carbon steel and does not flow out as readily to "wet" the sidewalls. Therefore, the welding arc and filler metal must be manipulated so as to place the molten metal where it is needed. In addition to sluggishness, the penetration pattern of this alloy type is less than that of a typical carbon or stainless steel weld, and incomplete fusion is more likely to occur. Therefore, care must be taken to ensure that the groove opening is wide enough to allow proper torch or electrode manipulation and proper placement of the weld bead.

Cleaning, Edge Preparation, and Fit-Up. Proper penetration of the weld angles is a very important part of welding these nickel-base CR alloys. It is necessary to condition all thermal cut edges to bright, shiny metal prior to welding. This is particularly important if air arc gouging is being used, because of the possibility of carbon pickup from the carbon electrode.

In addition to the weld angle, a 25 mm (1 in.) wide band on both the top and bottom (face and root) surface of the weld zone should be conditioned to bright metal with about an 80-grit flapper wheel or disk. This procedure is particularly important for the SMAW of alloy B-2. If the mill scale is not removed, then the B-2 alloy welding flux can interact with it and cause cracking at the toe of the weld in the base material.

The welding surface and adjacent regions should be thoroughly cleaned with an appropriate solvent prior to any welding operation. All greases, oils, cutting oils, crayon marks, machining solutions, corrosion products, paints, scale, dye-penetrant solutions, and other foreign matter should be completely removed.

Stainless steel wire brushing is normally sufficient for interpass cleaning of GTAW and GMAW weldments. The grinding of starts and stops is recommended for all fusion welding processes. When the GMAW process is used, light grinding may be necessary between passes prior to wire brushing, depending on the composition of the shielding gas. Slag removal during SMAW will require chipping and grinding, followed by wire brushing.

Preheating the nickel-molybdenum and nickel-chromium-molybdenum alloys is not required. A preheat is generally specified as room temperature (typical shop conditions). Interpass temperature should be maintained below 95 °C (200 °F). Auxiliary cooling methods can be used to control the interpass temperature. Water quenching is acceptable. However, care must be taken to avoid contaminating the weld zone with traces of oil from shop air lines, grit/dirt from soiled water-soaked rags, or mineral deposits from hard water used to cool the weld joint. The safest way to maintain a low interpass temperature is to allow the assembly to cool naturally. When attaching hardware to the outside of a thin-walled vessel, it is good practice to provide auxiliary cooling to the inside (process side) to minimize the extent of the HAZ.

Selection of Nickel-Base Corrosion-Resistant Alloys Containing Molybdenum

S.J. Matthews, Haynes International, Inc.

Welding Metallurgy

Heat-Affected Zone. The phenomenon of HAZ grain boundary sensitization is addressed in the article "Selection of Austenitic Stainless Steels" in this Volume. However, it should be noted here that the solid solubility of carbon is considerably lower in nickel-base alloys than in stainless steels. The net effect is that during the welding of low-carbon nickel-molybdenum and nickel-chromium-molybdenum CR alloys, HAZ grain boundary precipitation is still a potential reality, despite the relatively low carbon content of these alloys. The amount and severity of precipitation will depend on the cooling rate through the intermediate temperature range from 1000 to 600 °C (1830 to 1110 °F). Some heat-to-heat variations in grain boundary precipitation have also been observed during simulated HAZ studies in alloy B-2 (Ref 4). The adverse effects of minor grain boundary precipitation depend on the severity of the corrosive environment. For example, the maximum corrosion penetration after testing in boiling 10% hydrochloric acid (HCl) varied little for simulated heat-affected zones in alloy B-2. However, when harsher autoclave testing environments were used (20% HCl at 150 °C, or 300 °F), penetration by corrosion increased as the simulated HAZ cooling rate decreased from 20 to 120 s through the critical intermediate temperature range (Ref 4). Despite these laboratory findings, most low-carbon nickel-molybdenum and nickel-chromium-molybdenum alloys have been put into corrosion service in the as-welded condition with good results. Occasionally, poor results are encountered. Metallographic examination of the corroded part will usually reveal evidence of grain boundary precipitation in the heat-affected zone (Fig. 1).

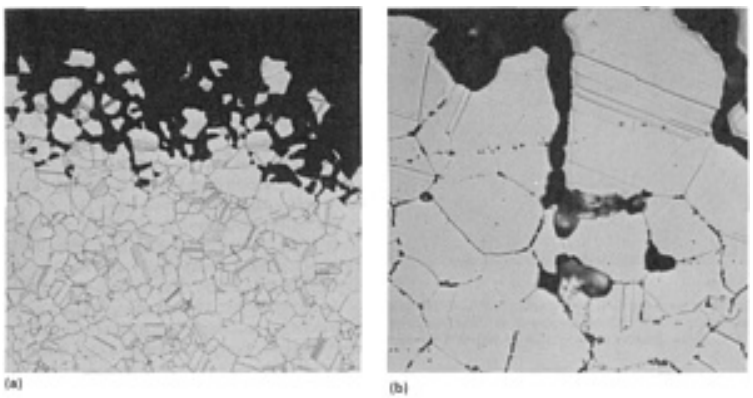

FIG. 1 PHOTOMICROGRAPHS SHOWING CORROSION ATTACK IN HASTELLOY C-276 (UNS N10276) CAUSED BY GRAIN BOUNDARY PRECIPITATION IN THE HEAT-AFFECTED ZONE OF THE WELD. THE SAMPLE WAS TAKEN FROM A PIPE REMOVED AFTER 18 MONTHS OF SERVICE IN A HYDROCHLORIC ACID VAPOR ENVIRONMENT IN A CHEMICAL PLANT. SAMPLE WAS ETCHED IN HCL AND OXALIC ACID. (A) 75×. (B) 375×

Aside from the possibility of grain growth, few other metallurgical HAZ problems have been reported for these alloys. HAZ hot cracking, especially of the type created by constitutional liquation of primary carbide particles, is not a problem with these alloys.

Fusion zone welding metallurgy of the nickel-molybdenum and nickel-chromium-molybdenum alloy family is important, because base materials are usually welded with filler metals of matching composition and because these alloys can be welded autogeneously (no filler added), as in the case of welded tubular products. Three issues should be considered in terms of the fusion zone:

- EFFECT OF WELD METAL SEGREGATION ON CORROSION RESISTANCE
- PROPENSITY TO FORM POROSITY
- SOLIDIFICATION HOT-CRACK SENSITIVITY

Segregation. Because of the segregation of solute elements upon solidification (principally molybdenum, which segregates to the cellular dendritic boundaries of the fusion zone), it is generally accepted that the corrosion resistance of the weld metal will be marginally less than that of the more homogeneous wrought base material. Differences in corrosion performance, however, depend heavily on the severity of the corrosion environment. In mild corrosion environments, little difference is observed. In severe environments, the fusion zone may be preferentially attacked, as illustrated in Fig. 2, a cross section of an as-welded alloy B-2 coupon exposed for about 1 year in a chemical plant process stream. Figure 3(a) is a high-magnification view of the surface attack on alloy B-2 weld metal when tested for 96 h in 20% HCl at 150 °C (300 °F) in an autoclave. Under these conditions, corrosion attack appears to be the most aggressive at the dendrite cores (molybdenum lean). Figure 3(b) shows the lack of corrosion attack on weld metal from a specially devised overalloyed B-type filler material (Ref 5). This alloy consists of 42% Mo, rather than the nominal 28% Mo. The higher-molybdenum nickel alloy solidifies as a nonequilibrium hypoeutectic structure consisting of a metastable α phase, with Ni_3Mo and NiMo in the interdendritic regions. In this case, despite solidification segregation, the dendrite core regions are sufficiently saturated with molybdenum to resist preferential fusion zone attack.

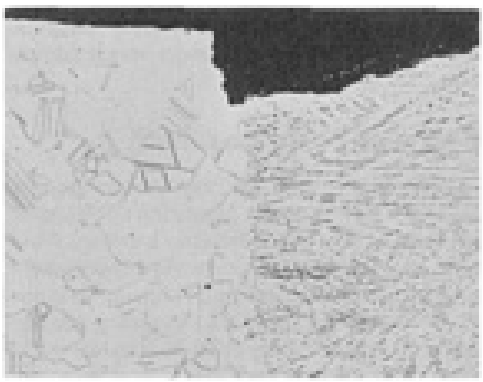

FIG. 2 METALLOGRAPHIC CROSS SECTION SHOWING PREFERENTIAL FUSION ZONE ATTACK IN HASTELLOY B-2 (UNS N10665). SAMPLE WAS A WELDED COUPON PLACED IN A CHEMICAL PLANT PROCESS STREAM FOR APPROXIMATELY 1 YEAR. HYDROCHLORIC AND CHROMIC ACID ETCH. 75×

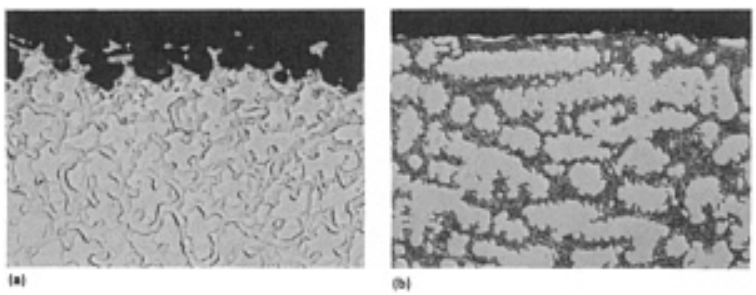

FIG. 3 METALLOGRAPHIC CROSS SECTIONS OF THE CORRODED SURFACE OF WELD DEPOSITS ON HASTELLOY B-2 (UNS N10665) AFTER TESTING IN AN AUTOCLAVE AT 150 °C (300 °F) FOR 96 H IN A 20% HCL ENVIRONMENT. (A) NI-28MO (UNS N10665) ALLOY FILLER METAL. 375×. (B) NI-42MO FILLER METAL. 375×. BOTH SAMPLES WERE ETCHED IN HYDROCHLORIC AND CHROMIC ACID. SEE TEXT FOR EXPLANATION.

It should be noted that although the microstructure of the Ni-42Mo material in Fig. 3(b) offers high corrosion resistance, the alloy is characterized by limited weld ductility (Ref 6). However, the use of overalloyed filler metals as a solution to preferential weld metal corrosion attack has been demonstrated elsewhere. For example, alloy C-22 (22% Cr) has been used successfully to refurbish corroded welds in an alloy C-276 (16% Cr) pulp and paper mill bleach-mixing device. Alloy G-30 (30% Cr) is also a logical choice as an overalloyed filler for certain alloy G-3 components.

Porosity. Recognizing that the solubility of gas is greater in the liquid state than in the solid state, the subject of weld porosity is relevant to fusion zone discussion. The three most logical origins of gas-generated porosity are carbon monoxide, hydrogen, and nitrogen. However, in welding the low-carbon nickel-molybdenum and nickel-chromium-molybdenum alloys, the cause of porosity is not believed to be from the formation of carbon monoxide. As long as there is a residual silicon or aluminum content in the weld deposit, the oxygen potential is too low for the formation of carbon monoxide. In order to produce a carbon monoxide "carbon boil" during welding, it would be necessary first to deplete all the aluminum, silicon, and any other deoxidizers that may be present.

Gas hole formation can be caused by hydrogen evolution. As is well known, even the smallest amount of water will be reduced by metal deoxidizers, releasing a sufficient volume of gas to create porosity. Hydrocarbons can also dissociate and go into solution. The lower the carbon content of the alloy, the more likely it is to pick up hydrogen from hydrocarbons. These reactions are favored as the carbon content of the alloy decreases. Gas hole formation that is due to hydrogen can be minimized by the well-known methods of keeping the joint area and the weld filler metal dry and oil-free. This approach is especially true when welding with coated electrodes. The ceramic coating ingredients can absorb sufficient moisture in humid weather to cause potential problems. It is because of this behavior that unused electrodes should be stored in a warm oven (110 °C, or 230 °F, minimum).

The third and only other possible cause of gas hole formation is nitrogen. As is well documented in the literature, a large quantity of nitrogen is capable of being picked up by the molten metal during arc welding processes whenever the gas in the arc contains any nitrogen. Nitrogen pickup from air, for example, might prove to be a problem whenever the weld pool is improperly shielded. Different alloys would be expected to have different susceptibilities to nitrogen-induced porosity. The ability of the solidified matrix plus secondary solid phases to hold or carry nitrogen is the primary difference between alloys. Alloys with a greater nitrogen-carrying capacity are apparently less susceptible to nitrogen-induced porosity. For example, a nickel-chromium alloy would be less susceptible to nitrogen porosity than pure nickel because of the increased solubility of nitrogen. Furthermore, because alloy B-2 contains no chromium, it possesses a lower nitrogen solubility than alloy C-22, and, thus, would be more prone to nitrogen porosity.

Hot-Crack Sensitivity. The final fusion zone issue is hot-crack sensitivity. Hot cracking of C-type alloys during solidification has been studied in depth by researchers equipped with sophisticated microanalysis equipment (Ref 7). Solidification hot cracking, as generated by the varestraint hot-cracking device, was found to increase as the tendency to form intermetallic secondary solidification constituents increased. In terms of general weldability ranking, alloy C-4 was found to be the least sensitive to solidification cracking, followed by alloy C-22, and then alloy C-276. It should be noted that all of the low-carbon nickel-chromium-molybdenum alloys of the C family are characterized by high weld metal ductility. Hot-cracking problems have rarely been reported under actual fabrication conditions.

Postweld Heat Treatment

Because of their very low carbon contents (<0.02% C), the newer-generation CR alloys do not require heat treatment after welding. However, for certain critical corrosion environments, proper postweld annealing will maximize corrosion resistance of the HAZ. Annealing can also be performed to reduce residual stresses, which play a role in the susceptibility to stress-corrosion cracking in some environments. Annealing can be used to increase the corrosion resistance of the weld fusion zone by promoting diffusion of some elements.

Corrosion-resistant alloys are usually supplied in the mill-annealed condition, unless otherwise specified. The mill-annealing procedure has been designed to place the material in the optimum condition with respect to ductility and corrosion resistance. During fabrication of a vessel or component, several operations or conditions may require an anneal. For example, following any hot-forming operation, a reanneal of the material should be done to restore ductility and corrosion properties. Annealing is also performed after cold working to restore ductility. Generally, annealing is not required if the total cold work is below 7% outer fiber elongation. In general, the only heat treatment that is acceptable for these alloys is a full solution anneal. Table 3 lists the proper heat-treating temperatures and type of quench. Intermediate temperatures commonly used for stress-relieving steels, stainless steels, and other alloys are not effective and could promote precipitation that would be detrimental to corrosion resistance.

TABLE 3 SOLUTION ANNEALING TEMPERATURES FOR CORROSION-RESISTANT NICKEL-BASE ALLOYS CONTAINING MOLYBDENUM

Data are applicable for either water quench (WQ) or rapid air cool (RAC) quench.

ALLOY	UNS NO.	TEMPERATURE	
		°C ± 14°	°F ± 25°
B-2	N10665	1065	1950
C-4	N06455	1065	1950
C-22	N06022	1120	2050
C-276	N10276	1120	2150
G-3	N06905	1150	2100
G-30	N06030	1175	2150
N	N10003	1175	2150

Before heat treatment, grease, graphite, and other foreign materials must be removed from all surfaces. Tube products may require special care for complete removal of these contaminants from interior surfaces. Carburization of these materials at the heat-treating temperatures can reduce corrosion resistance, and sulfur embrittlement can cause severe cracking. Proper control of the temperature and time cycle are also critical. A flexible set of rules governing soaking-annealing time is generally followed, because of the many variations in furnace type, furnace operation, facilities for loading and unloading the furnace, and so on. The temperature should be monitored using thermocouples attached to the piece being annealed. The actual holding time should begin to be measured when the entire section is at the specified annealing temperature. It is important to remember that the center of a section does not reach the solutioning temperature as soon as the surface.

Normally, hold time should be in the range from 10 to 30 min, depending on section thickness. Thin-sheet components are held at the shorter time, whereas heavier sections are held at the longer time. Shorter annealing times can be used if the sole purpose is to remove the effect of cold work. Longer annealing times might be required if the objective is to promote homogenization of the fusion zone.

Rapid cooling is essential after solution heat treatment to prevent the precipitation of secondary phases and the resultant lowering of the corrosion resistance of these alloys. Water quenching is recommended on material thicker than 9.5 mm

($\frac{3}{8}$ in.). Although rapid air cooling can be used on sections thinner than 9.5 mm ($\frac{3}{8}$ in.), water quenching is preferred. The time from the furnace to the quench tank or to the start of rapid air cooling must be as short as possible (less than 3 min).

The requirements for proper annealing of alloy B-2 (UNS 10665) are quite demanding. In addition to the guidelines established above, the following factors should be considered very carefully. It is strongly recommended that the part being heat treated be charged into a furnace that is at the annealing temperature, and that the heating rate be as fast as possible. In addition, the thermal capacity of the furnace should be large to allow the temperature of the furnace to recover quickly after the part is charged into it. These steps are designed to shorten the time in the intermediate temperature range from 595 to 815 °C (1100 to 1500 °F). Extended exposure (greater than 15 min) at these intermediate temperatures can cause intergranular cracking because of phase transformations, especially if the part is in the cold-worked condition. Under certain conditions, shot peening prior to heat treatment may be beneficial to the elimination of residual tensile stresses. For example, it has been observed that shot peening the knuckle radius and straight flange regions of a cold-formed head prior to heat treatment can help reduce intermediate temperature intergranular cracking by lowering the residual stress patterns at the surface of the cold-formed component.

Other Welding Situations

Welding of dissimilar metals to nickel-base CR alloys does not present a problem in most cases. The nature of nickel as a "forgiving" solvent element renders most industrially encountered dissimilar metal combinations as metallurgically compatible. Filler materials designed to join the nickel-base side of the joint are usually recommended.

When joining a nickel-base alloy to a ferrous alloy (for example, mild steel or a stainless steel), electrodes of the nickel-base alloy should be used as filler metal, rather than steel or stainless electrodes, because excess superheat caused by melting temperature differences (Table 2) will tend to aggravate the HAZ on the nickel-base side of the joint.

The joining of clad plate (that is, steel plate that has been explosion clad or roll clad with a thinner nickel-base CR alloy) has been successfully performed. However, proper welding procedures need to be developed to ensure minimum iron dilution in the weld zone facing the corrosion environment.

The welding of cast CR alloys presents no unusual problems, as long as the integrity of the casting is sound (that is, free from shrinkage cavity and inclusions). Welding is often used to repair casting defects. Generally, the defective area is thoroughly removed by grinding, which eventually forms a cavity. The prepared cavity should be dye-penetrant inspected to ensure that all objectionable defects have been removed and then thoroughly cleaned prior to welding repair. Because these alloys have low-penetration characteristics, the ground cavity must be broad enough and have sufficient sidewall clearance in the weld groove to allow weld rod/weld bead manipulation. It is not recommended to heal cracks or wash out defects by autogeneously remelting weld beads or by depositing additional filler metal over the defect.

Repair welding of wrought alloy components and structures is accomplished using a similar technique. The good thermal stability of low-carbon CR alloys is such that solution annealing of material that has been in corrosion service for many years is generally not required prior to repair welding. In these situations, the repair is usually required because of accelerated corrosion of a localized area. The selection of higher-alloyed filler metals for such repairs should be considered.

Selection of Nickel-Base Corrosion-Resistant Alloys Containing Molybdenum

Selection of Cobalt-, Titanium-, Zirconium-, and Tantalum-Base Corrosion-Resistant Alloys

S.J. Matthews, Haynes International, Inc.

Introduction

A GREAT VARIETY of nonferrous corrosion-resistant (CR) alloys are available in the market. The common nickel-base corrosion-resistant alloys are covered in the preceding articles in this Section of the Handbook. This article will provide information about non-nickel-base alloys; however, no attempt will be made here to cover all such materials. The interested reader is referred to *Corrosion,* Volume 13 of the *ASM Handbook,* for information on the corrosion of specific alloy systems. The four corrosion-resistant materials of commercial significance that are briefly addressed here are based on:

- COBALT
- COMMERCIALLY PURE TITANIUM
- ZIRCONIUM
- TANTALUM

S.J. Matthews, Haynes International, Inc.

Cobalt-Base CR Alloys

Cobalt behaves much like nickel in terms of active-passive behavior in aqueous corrosion systems. Chromium additions reportedly are more effective in imparting passivity to cobalt than to nickel (Ref 1). Cobalt-chromium CR alloys typically contain sufficient additions of nickel or iron, which serve to stabilize the face-centered cubic (fcc) crystal structure and increase the stacking, fault energy of the fcc phase. Molybdenum and tungsten additions act as solid-solution strengtheners and enhance the corrosion resistance of cobalt-base alloys in nonoxidizing media. Cobalt-base CR alloys have been used in the pulp and paper, agrichemical, and chemical process industries in applications such as valves, pumps, nozzles, screw conveyors, and other components that are characterized by harsh environments aggravated by both corrosion and wear. Electrogalvanizing rolls are an example of a component exposed to both of these conditions. Cobalt-base CR alloys represent the premium materials for this application. The nominal composition of some cobalt-base corrosion-resistant alloys are given in Table 1.

TABLE 1 NOMINAL COMPOSITION OF SELECTED COBALT-BASE CORROSION-RESISTANT ALLOYS

ALLOY	UNS NO.	COMPOSITION, WT %							
		CO	Cr	Ni	Fe	Mo	W	C	N
ULTIMET	R31233	BAL	26	9	3	5	2	0.06	0.08
ALLOY 25	R30605	BAL	20	10	3 MAX	. . .	15	0.10	. . .
ALLOY 150	. . .	BAL	28	. . .	21	. . .	. . .	0.05 MAX	. . .
MP35-N MULTIPHASE	R30035	BAL	20	35	. . .	10	. . .	. . .	. . .

Weldability Characteristics. The fusion-welding characteristics of fcc-stabilized cobalt-base alloys are virtually identical to those of nickel-base alloys, because of similarities in melting range and physical properties. The only welding procedural idiosyncrasy of cobalt-base alloys relative to nickel is the potential for heat-affected zone (HAZ) cracking caused by copper surface contamination. Even minuscule amounts of copper inadvertently transferred to the surface of a sheet or plate will cause cracking if the contaminated surface corresponds to a HAZ of a subsequent weld (Ref 2). Cracking is caused by liquid-metal embrittlement (LME). Copper and cobalt are relatively insoluble in each other and form a classic LME couple (Ref 3). Nickel and copper exhibit 100% solid solubility; hence, nickel-base alloys are not prone to copper contamination cracking in the HAZ. Copper jigs and fixtures, especially those used in sheet welding, are a potential source of copper contamination. Chromium or nickel plating of copper fixtures will minimize the potential for inadvertent copper transfer when welding cobalt alloys.

Cobalt-base CR alloys are generally welded using a filler-metal composition that matches the composition of the base material. Like low-carbon nickel-base CR alloys, cobalt alloys have relatively good resistance to fusion-zone (FZ) solidification cracking. The lower the carbon content, the greater the resistance to hot cracking. Boron is particularly deleterious as a residual trace element and can cause welding problems.

Cobalt-chromium CR alloys with relatively low nickel or iron content (for example, UNS alloy R31233, Table 1) exhibit unique mechanical property characteristics in the as-welded condition. Weldments are characterized by high strength and low ductility, because of stress-induced localized transformation from a fcc crystal structure to a hexagonal close-packed (hcp) structure (Ref 4). The transformation products are not visible in optical photomicrographs (Fig. 1). Instead, thin-film electron microscopy is required to detect the hcp phase.

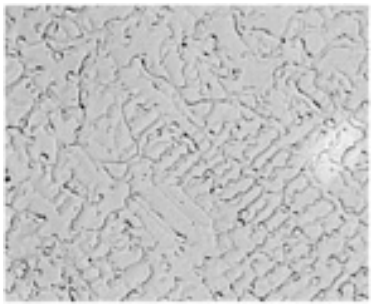

FIG. 1 TYPICAL WELD METAL MICROSTRUCTURE OF ULTIMET ALLOY (UNS R31233) OBTAINED WITH GMAW DEPOSIT WHEN SHORT-CIRCUITING MODE OF TRANSFER IS USED. SAMPLE WAS ETCHED WITH HCL AND OXALIC ACID. 500×

Tensile data comparing room-temperature elongation of weldments versus castings and annealed base material are given in Table 2. Castings generally have less residual stress in the as-cast condition than do weldments; hence, the observed difference in ductility. Table 2 also shows that a full postweld anneal at 1120 °C (2050 °F) will reduce the yield strength and improve the ductility of a welded structure. A postweld heat treatment is recommended, especially if the cold forming of a weldment after welding is a required part of the fabrication sequence.

TABLE 2 TENSILE PROPERTIES OF WELDED COBALT-BASE CORROSION-RESISTANT ALLOY UNS R31233 RELATIVE TO WROUGHT AND CAST PRODUCTS AT ROOM TEMPERATURE

PRODUCT FORM	CONDITION	YIELD STRENGTH AT 0.2% OFFSET		ULTIMATE TENSILE STRENGTH		ELONGATION, %
		MPa	ksi	MPa	ksi	
PLATE	ANNEALED	545	79	1020	148	36
CASTINGS[A]	AS CAST	395	57	770	112	35
WELD METAL[B]	AS WELDED	585	85	850	123	18

Titanium-Base CR Alloys

Commercially pure (CP) titanium offers excellent corrosion resistance in most environments, except those media that contain fluoride ions. Titanium is more corrosion resistant than stainless steel in many industrial environments, and its use in the chemical process industry has been gradually increasing (Ref 5). Titanium has a density approximately one-half that of nickel- or cobalt-base alloys, and its cost effectiveness relative to these alloys is generally calculated using the cost per unit weight, the difference in density, the corrosion allowances, and other performance factors.

Titanium has moderate strength, good ductility, and excellent weldability relative to the more complex aerospace α-β titanium alloys. Various grades of CP titanium are classified on the basis of mechanical properties and interstitial impurities. In general, variations in strength are produced by differences in impurity content, primarily the interstitial elements (that is, oxygen, nitrogen, and carbon) and iron. As the content of these elements increases, strength also increases.

Titanium that is intentionally alloyed with trace amounts of palladium or molybdenum and nickel is also used to provide corrosion-resistant service. For example, the Ti-0.2Pd alloy and the Ti-0.3Mo-0.8Ni alloy are characterized by improved crevice corrosion resistance, as well as improved corrosion resistance in reducing environments.

Weldability Characteristics. Corrosion-resistant titanium materials are generally welded with matching filler-metal compositions. Welded joints will have essentially the same corrosion resistance as the base metal. However, any iron contamination of the weld metal that exceeds even 0.05% Fe will cause accelerated corrosion attack in nitric acid or in other strongly oxidizing solutions. Therefore, it is imperative that all potential sources of iron contamination be avoided. Steel wire brushes should not be used for interpass cleaning of titanium weldments.

Titanium is a single (α) phase material with a hcp crystal structure. However, an allotropic transformation occurs at temperatures above approximately 870 °C (1600 °F), where α transforms to a body-centered cubic (bcc) β phase. Accordingly, the heat-affected zone of CP titanium weldments will be characterized by large β grains, which form at high temperatures during welding but transform back to an acicular and serrated α phase upon cooling to room temperature.

Commercially pure titanium alloys are not heat treatable, that is, they do not develop significant differences in properties after heat treatment. However, a postweld anneal in the temperature range from 650 to 760 °C (1200 to 1400 °F) or a postweld stress relief from 480 to 595 °C (900 to 1100 °F) might be warranted for purposes of maintaining dimensional stability during subsequent machining operations. A postweld heat treatment may also improve resistance to stress-corrosion cracking (SCC), depending on the configuration of the weldment and the intended corrosion-resistant service.

The welding metallurgy of titanium and titanium alloys is discussed in greater depth in the Section "Selection of Nonferrous Low-Temperature Materials" in this Volume. Additional information can be found in the article "Welding of Titanium Alloys" in this Volume.

Zirconium- and Tantalum-Base CR Alloys

The metals and alloys based on zirconium and tantalum have weldability characteristics similar to those of titanium. They readily react with oxygen and form very stable oxides. Like titanium, they have high solubilities for oxygen, nitrogen, and hydrogen at elevated temperatures. Small amounts of dissolved oxygen and nitrogen significantly increase the hardness of the metal, whereas dissolved hydrogen reduces toughness and increases notch sensitivity. Therefore, these metals must be welded or brazed in a shield of high-purity inert gas or in a vacuum (Ref 6).

Unalloyed zirconium is similar in characteristics to titanium, except that its density is about 50% higher. Like titanium, zirconium has a hcp crystal structure (α phase) up to approximately 865 °C (1590 °F), and it transforms to a bcc structure (β phase) above this temperature.

Zirconium is resistant to corrosive attack by most acids, strong alkalies, and some molten salts. Its corrosion-resistant behavior is due to the formation of a stable, dense, adherent, and self-healing zirconium oxide film on the metal surface. Zirconium is used for corrosion applications in the petrochemical, chemical process, and food processing industries. Zirconium alloys are also used in the nuclear industry for pressurized water reactor components, because of their low thermal neutron absorption characteristics.

Zirconium is readily welded using the same processes and procedures as titanium. Residual welding stresses are generally low because of its low modulus of elasticity. Zirconium also has a low coefficient of thermal expansion, which contributes to low distortion during welding. In addition, inclusions in welds are usually not a problem, because zirconium has a high solubility for its own oxide. Although some porosity is possible in zirconium welds, it can usually be minimized by properly adjusting welding parameters and by following sound welding practices with respect to precleaning and proper shielding during the welding process.

Additional information is available in the article "Welding of Zirconium Alloys" in this Volume.

Tantalum is a very dense (over 3.5 times the density of titanium) CR material. It is an inherently soft, fabricable metal that has a very high melting temperature, approximately 3000 °C (5400 °F). It has a bcc crystal structure, with no allotropic transformation at elevated temperature. Unlike many bcc metals, tantalum retains good ductility to very low temperatures, and exhibits a ductile-to-brittle transition temperature (DBTT) of approximately -250 °C (-420 °F).

Tantalum has excellent corrosion resistance to a wide variety of acids, alcohols, chlorides, sulfates, and other chemicals. For this reason, it is widely used for chemical equipment that operates at ambient temperatures.

Tantalum oxidizes in air above approximately 300 °C (570 °F) and is attacked by hydrofluoric, phosphoric, and sulfuric acids, and by chlorine and fluorine gases at temperatures above 150 °C (300 °F). Tantalum also reacts with carbon, hydrogen, and nitrogen at elevated temperatures. Because of the high per unit weight cost of tantalum and its high density, the cost effectiveness of this material has been increased by using clad, explosion clad, or resistance-welded clad products.

Like zirconium, tantalum is also readily welded by the processes and procedures used for titanium. The joining of tantalum-clad plate requires special procedures and precautions and is beyond the scope of this article.

Weldability Testing

Richard D. Campbell, Joining Services, Inc.; Daniel W. Walsh, California Polytechnic State University

Introduction

THIS ARTICLE describes many of the various weldability tests that have been developed through the years. Some of these tests are used extensively, while others find limited application. The purposes of this article are to briefly describe these tests, to show what material characteristics they provide, and to present some advantages and limitations of each. This discussion is limited to tests used to evaluate the weldability of base materials.

Additional Tests Used in Welding (Service Tests). This article does not cover the basic tests used for weld qualification, as specified in the numerous welding codes and standards. The tests for welding procedure qualification are used to establish the properties of the welded assembly (including any filler material) and determine that the weldment is capable of providing the required properties for the intended applications. Tests for welder performance qualification are intended to establish the ability of the welder to deposit sound weld metal. Examples of these tests are given in Table 1; information about these tests can be found in the Section "Joint Evaluation and Quality Control" in this Volume. These are often termed service tests because they measure the properties of the weldment under servicelike conditions.

TABLE 1 TYPICAL TESTS REQUIRED IN VARIOUS WELDING CODES AND STANDARDS FOR WELDING PROCEDURE QUALIFICATION AND WELDER PERFORMANCE QUALIFICATION

DESTRUCTIVE TESTS
MECHANICAL TESTS
TENSILE TESTS
GUIDED BEND TESTS
CHARPY V-NOTCH IMPACT TOUGHNESS TESTS
DROP WEIGHT NOTCH TOUGHNESS TESTS
FILLET WELD BREAK, SHEAR, OR FRACTURE TESTS
STUD WELD BEND OR TORQUE TESTS
METALLOGRAPHIC TESTS
MACROEXAMINATION TESTS
MACROETCH TESTS
MICROEXAMINATION TESTS
NONDESTRUCTIVE TESTS
VISUAL INSPECTION

LIQUID PENETRANT INSPECTION
MAGNETIC PARTICLE INSPECTION
RADIOGRAPHIC INSPECTION

Tests to evaluate the mechanical or corrosion properties of weldments are described in detail in several sources (Ref 1, 2). Other Volumes of the *ASM Handbook* present the basics of mechanical testing (Ref 3), metallographic techniques and etchants (Ref 4), and nondestructive testing methods (Ref 5).

This article does not cover tests for weld metal or weld wire. These tests, such as chemical analysis or mechanical testing of the deposited weld metal, are used to evaluate the properties of the weld filler material. Welding tests of filler material, such as spark tests, are performed to evaluate the welding characteristics of the wire.

Weldability Testing

Richard D. Campbell, Joining Services, Inc.; Daniel W. Walsh, California Polytechnic State University

General Characteristics of Weldability Tests

Weldability is defined as "*the capacity of a material to be welded under the imposed fabrication conditions into a specific, suitably designed structure and to perform satisfactorily in the intended service*" (Ref 6). The weldability tests described in this article are used to evaluate the effects of welding on such properties and characteristics as:

- BASE-METAL AND WELD-METAL CRACKING
- BASE-METAL AND WELD-METAL DUCTILITY
- WELD PENETRATION
- WELD POOL SHAPE AND FLUID FLOW

Because weldability testing is used to evaluate the welding characteristics of the base materials, many of these weldability tests are laboratory or research tests rather than "production" tests. Weldability tests are used extensively during alloy development. However, many are also used during weld procedure development to ensure the weldability of base materials before production commences. Each test is designed to evaluate a susceptibility to a specific weldability problem.

Obviously, the best tests evaluate the actual service conditions. However, because this is expensive and often impossible, standardized weldability tests and test methods have been developed. These tests evaluate various responses of the base material to different welding conditions or simulated welding conditions. Most of these tests utilize simple geometries and configurations, and loading conditions are typically simple and uniform. Thus, none of these tests duplicates the actual service conditions of a real weldment. Instead they provide a baseline for comparisons of base material responses.

The various weldability tests provide information on alloys, welding processes, and welding procedures. Data generated can be compared to data produced under the same testing conditions on other heats of material or to data produced with other welding processes or procedures (Ref 7). All of these tests provide qualitative information in that they are used to sort different materials or heats of the same materials, processes, procedures, and thermal cycles. None of these tests have any quantitative "acceptance" limits, such as the yield strength requirements of a specific alloy when tensile tested (Ref 7).

All weldability tests involve either actual welding or simulated welding. Those involving actual welding require that the test coupons be produced using an actual welding process. An example of this type of test is Varestraint hot crack testing using the gas-tungsten arc welding (GTAW) process. Simulated welding tests involve the application of heat through means other than welding, with or without loading. An example is Gleeble testing, in which a test specimen is resistance heated to simulate a weld heat-affected zone (Ref 7). Excellent reviews of various weldability tests are provided in Ref 8 and 9.

Weldability Tests for Evaluating Cracking Susceptibility

The majority of weldability tests have been developed to evaluate the susceptibility of the base materials (and any added filler material) to cracking. The purpose of these tests is to reduce or to eliminate the formation of these defects during fabrication or service. Cracking can be in the form of hot cracking, cold cracking, or lamellar tearing. Detailed information about these defects is available in the article "Cracking Phenomena Associated With Welding" in this Volume. Table 2 presents a comparison of several weldability tests for cracking susceptibility, their applications, and resultant types of data.

TABLE 2 WELDABILITY TESTS USED TO EVALUATE SUSCEPTIBILITY TO CRACKING

TEST	FIELDS OF USE	CONTROLLABLE VARIABLES	TYPE OF DATA	SPECIALIZED EQUIPMENT	RELATIVE COST
LEHIGH RESTRAINT TEST	WELD METAL HOT AND COLD CRACKING, ROOT CRACKING, HAZ HYDROGEN CRACKING, STRESS-RELATED CRACKING	JOINT GEOMETRY, PROCESS, FILLER METAL, RESTRAINT LEVEL, HEAT INPUT, PREHEAT	CRITICAL RESTRAINT, OR % HINDERED CONTRACTION	NONE	COSTLY MACHINING
