Hot and Cold Cracking

Hot cracking occurs during weld solidification and can occur in the weld metal or in the heat-affected zone (HAZ). Hot cracking is caused by low melting temperature constituents, in addition to tensile stress on the weld. Other names for hot cracking include microfissuring, solidification cracking, reheat cracking, and liquation cracking. In actual weldments, the tensile stress may come from external loads on the structure, the weight of the structure producing stress on the weld, solidification shrinkage stresses, or combinations of these.

Cold cracking (also known as hydrogen-induced cracking) is a cracking phenomenon that occurs after the weld has solidified (Ref 6). It is also referred to as delayed cracking, because cracking is often "delayed" for minutes, hours, or even longer, after the weld has solidified. Cold cracking is most often associated with the presence of hydrogen in hardenable steels. The ductility and toughness of the welded structure are greatly reduced by cold cracking. Requisites for cold cracking include tensile stress (external loading or residual stress from welding), a crack-susceptible microstructure (martensite), and the presence of hydrogen. Cold cracking can occur in the weld fusion zone or in the HAZ.

Several weldability tests for evaluating cracking susceptibility are described in this article. Most tests are used to evaluate susceptibility to one type of cracking: cold cracking, hot cracking, underbead cracking, or lamellar tearing. Some tests are useful for both hot and cold cracks. The applicabilities of each test are discussed within the descriptions of the test. The weldability tests discussed in this section are classified as self-restraint tests or externally loaded tests.

Self-Restraint Tests

Self-restraint tests utilize the restraint, or stress, within the specimen to cause weld metal or base metal cracking. No external loading of the specimen occurs. The specimen is designed to produce variable restraint on the weld joint, thus causing cracking.

Lehigh Restraint Test (Hot and Cold Cracks). The Lehigh restraint test is illustrated in Fig. 1. This test, developed at Lehigh University, uses a plate with slots machined into the sides and ends. A groove weld joint is machined along the centerline of the plate, and a single-pass weld is produced along this groove. The restraint from the plate and slots produces a weld with various levels of cracking.

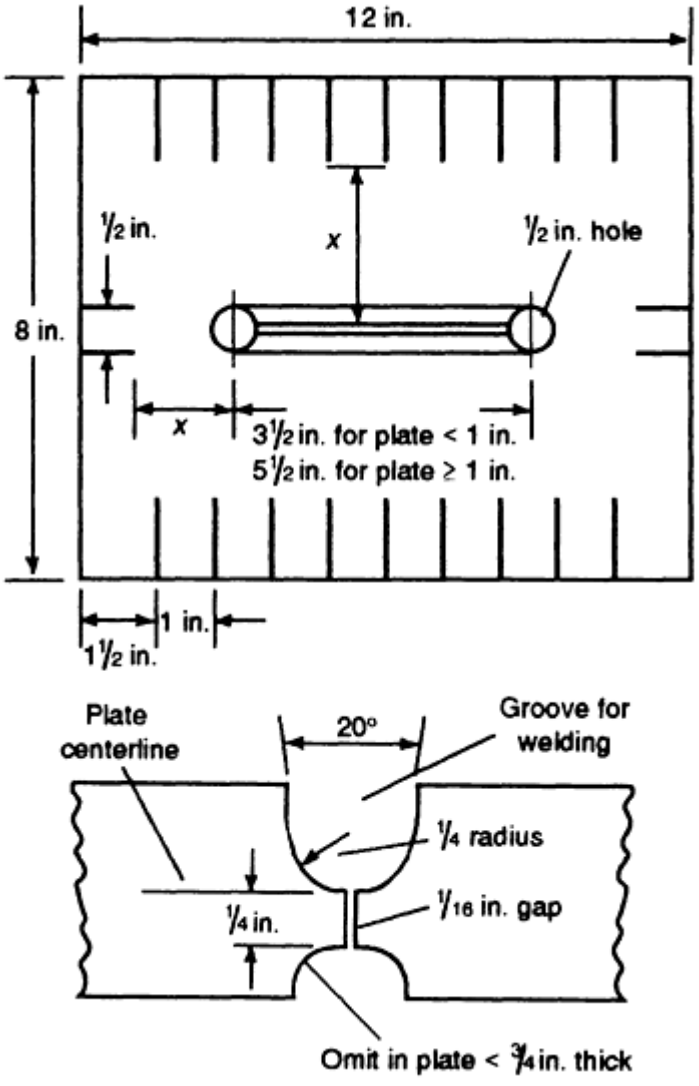

FIG. 1 SCHEMATIC SHOWING SLOTTED PLATE SPECIFICATIONS FOR LEHIGH RESTRAINT TEST. SOURCE: REF 8

This test compares quantitatively the degree of restraint at which cracking occurs in welds during cooling. The level of restraint is altered by changing the length of the slots (Ref 7). The restraint is quantified as 2*x*, where *x* is the distance from the centerline of the weld groove to the bottom of the slots. Numerous samples with different slot lengths are welded, and a threshold level of restraint is determined as the width that is just sufficient to cause cracking. Cracking can be evaluated by metallographic cross sections of the weld or by heat tinting and breaking open the weld to expose the cracked region. This test has also been used to evaluate reheat cracking in steels (Ref 7, 8, 9).

Keyhole Restraint Cracking Test (Hot and Cold Cracks). The Naval Research Laboratory (NRL) keyhole restraint crack test (Fig. 2) is a simplified version of the Lehigh test. The specimen is welded along the groove beginning at the open end and progressing toward the hole. This imposes a varying degree of restraint along the weld, with a maximum at the hole and a minimum at the edge where welding commenced. Cracks form at the hole and extend outward to a point where the restraint is low enough to arrest the crack growth. The crack length is the measure of crack susceptibility (Ref 8).

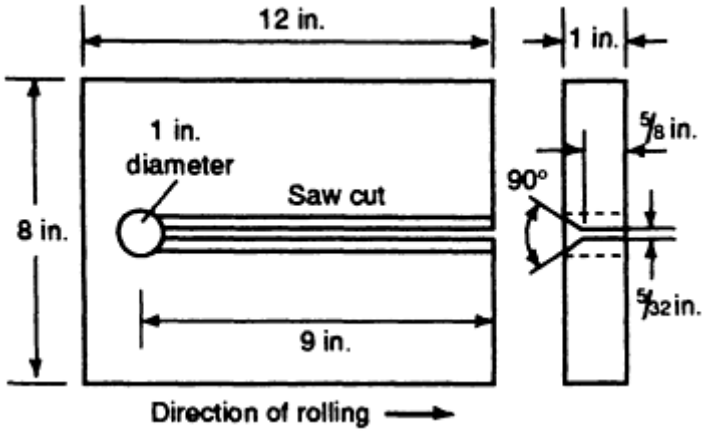

FIG. 2 PLATE SPECIFICATIONS FOR NRL KEYHOLE RESTRAINT TEST. SOURCE: REF 8

Houldcroft Crack Susceptibility Test (Hot Crack Test). The Houldcroft crack susceptibility test utilizes a design similar to the Lehigh test, but the slots vary in length from one end of the specimen to the other (Fig. 3). The Houldcroft test was developed for sheet steels. No weld joint is machined into the specimen, but rather a bead-on-plate, complete penetration weld (usually using the GTAW process) is made. Duplicate samples are produced, and the mean crack length of these specimens is used as an index of hot crack susceptibility (Ref 8).

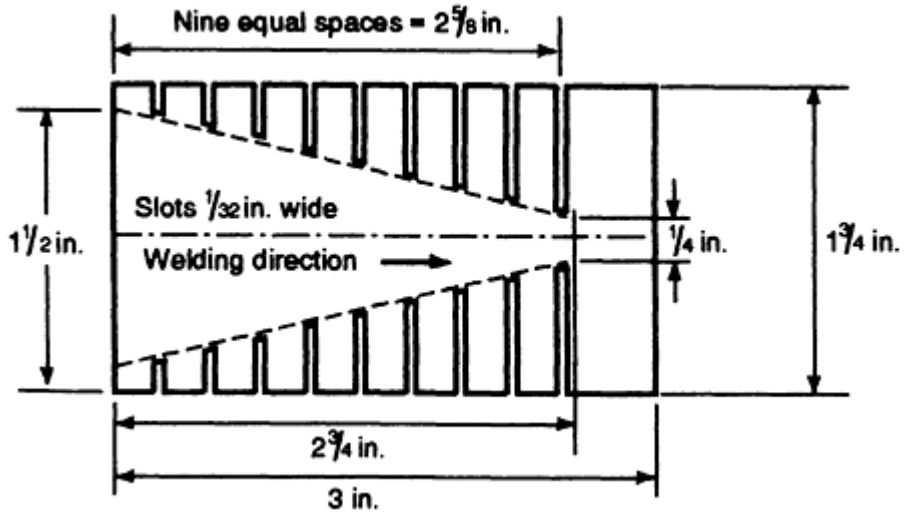

FIG. 3 SPECIMEN DIMENSIONS FOR HOULDCROFT CRACK SUSCEPTIBILITY TEST. SOURCE: REF 8

Keyhole Slotted-Plate Restraint Test (Hot Crack Test). A variation of the Houldcroft test for plate material is the keyhole slotted-plate restraint test (Fig. 4). This test was developed at Battelle and utilizes a groove weld, which begins at the low restraint end. Crack sensitivity is determined, in a manner similar to the Lehigh test, by the uncut width of the specimen at which the crack propagation ceases (Ref 8).

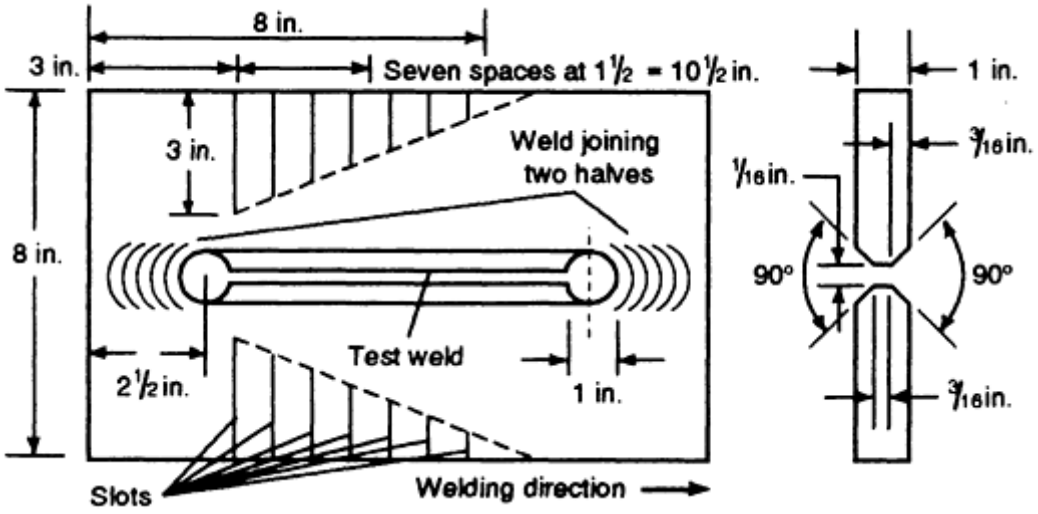

FIG. 4 SPECIMEN REQUIREMENTS FOR KEYHOLE SLOTTED-PLATE RESTRAINT TEST. SOURCE: REF 8

Tekken Test (Cold Crack Test). The Tekken Test, developed in Japan, uses several specimen dimensions and joint designs (Fig. 5). The Y joint provides more restraint than the U- or double-U joint designs. In these tests, preheat and welding parameters are varied to alter the stress state, rather than changing the specimen design. This test is used to evaluate HAZ cracks and underbead cracks.

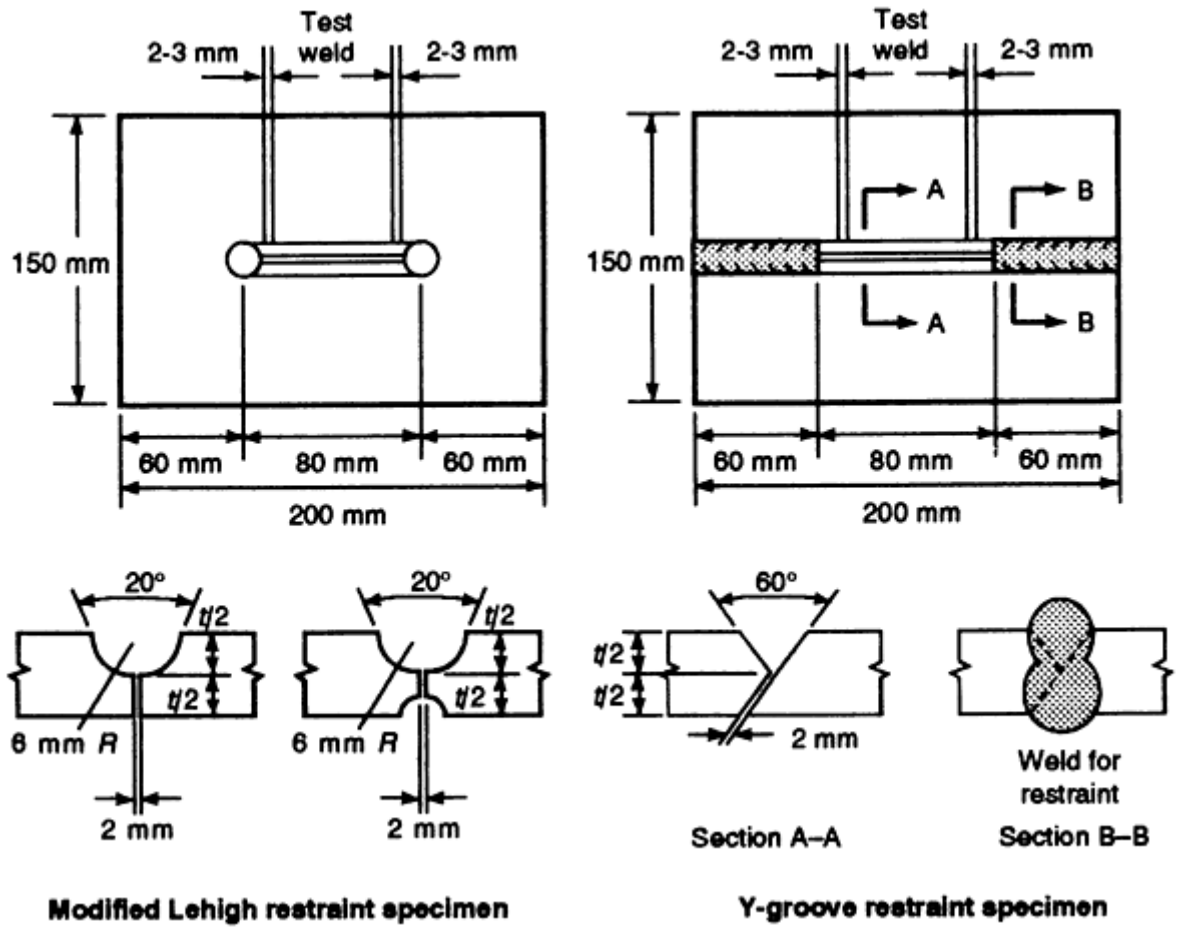

FIG. 5 SAMPLE SPECIFICATIONS FOR TEKKEN TEST. SOURCE: REF 9

Circular Patch Test (Cold and Hot Crack Test). The circular patch test (Fig. 6) utilizes a plate with a circular hole cut out and replaced by a patch. Both the plate and the patch have a weld joint machined into them. One or more weld passes are made in this circular groove, and cracking is detected by visual, radiographic, and/or liquid penetrant inspection. This test is used to generate and evaluate both hot cracks and cold cracks (Ref 8, 9).

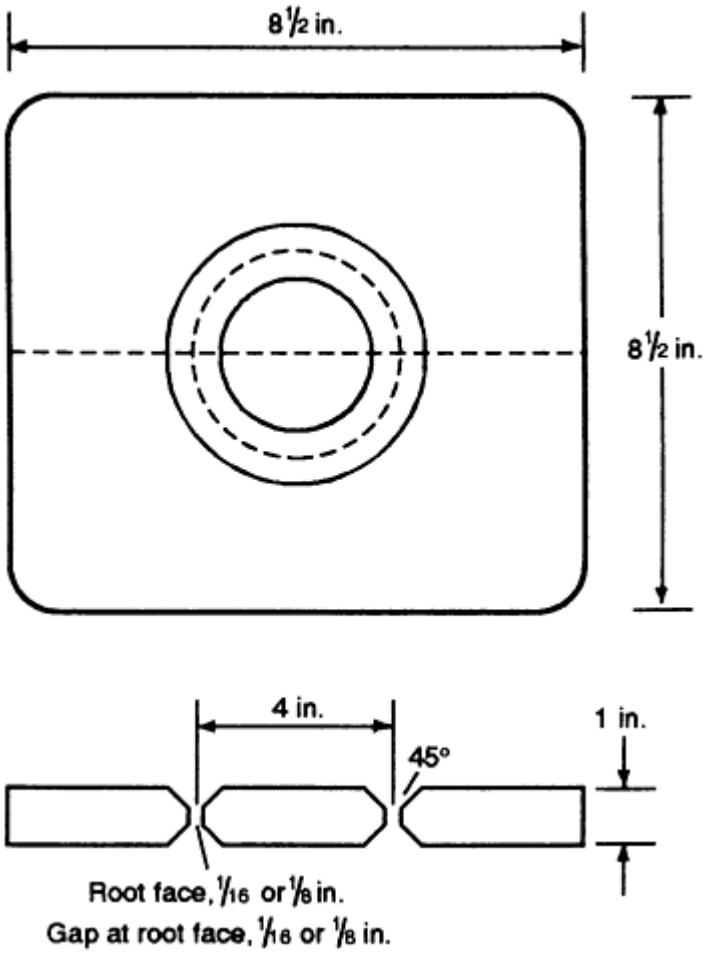

FIG. 6 PLATE SPECIFICATIONS FOR CIRCULAR PATCH TEST. SOURCE: REF 8

Navy Circular Patch Test (Cold and Hot Crack Test). The Navy circular patch test utilizes a much larger specimen (Fig. 7). This test is used for evaluating different electrodes on various base metals. A circular hole is cut in the plate, into which a patch is placed, with a backing ring to hold the plate and patch together. A multipass weld is made, one quadrant at a time, as shown in Fig. 7. Cracking evaluation is by visual, radiographic, and/or liquid penetrant inspection. Both hot cracks and cold cracks can be generated in this test (Ref 8).

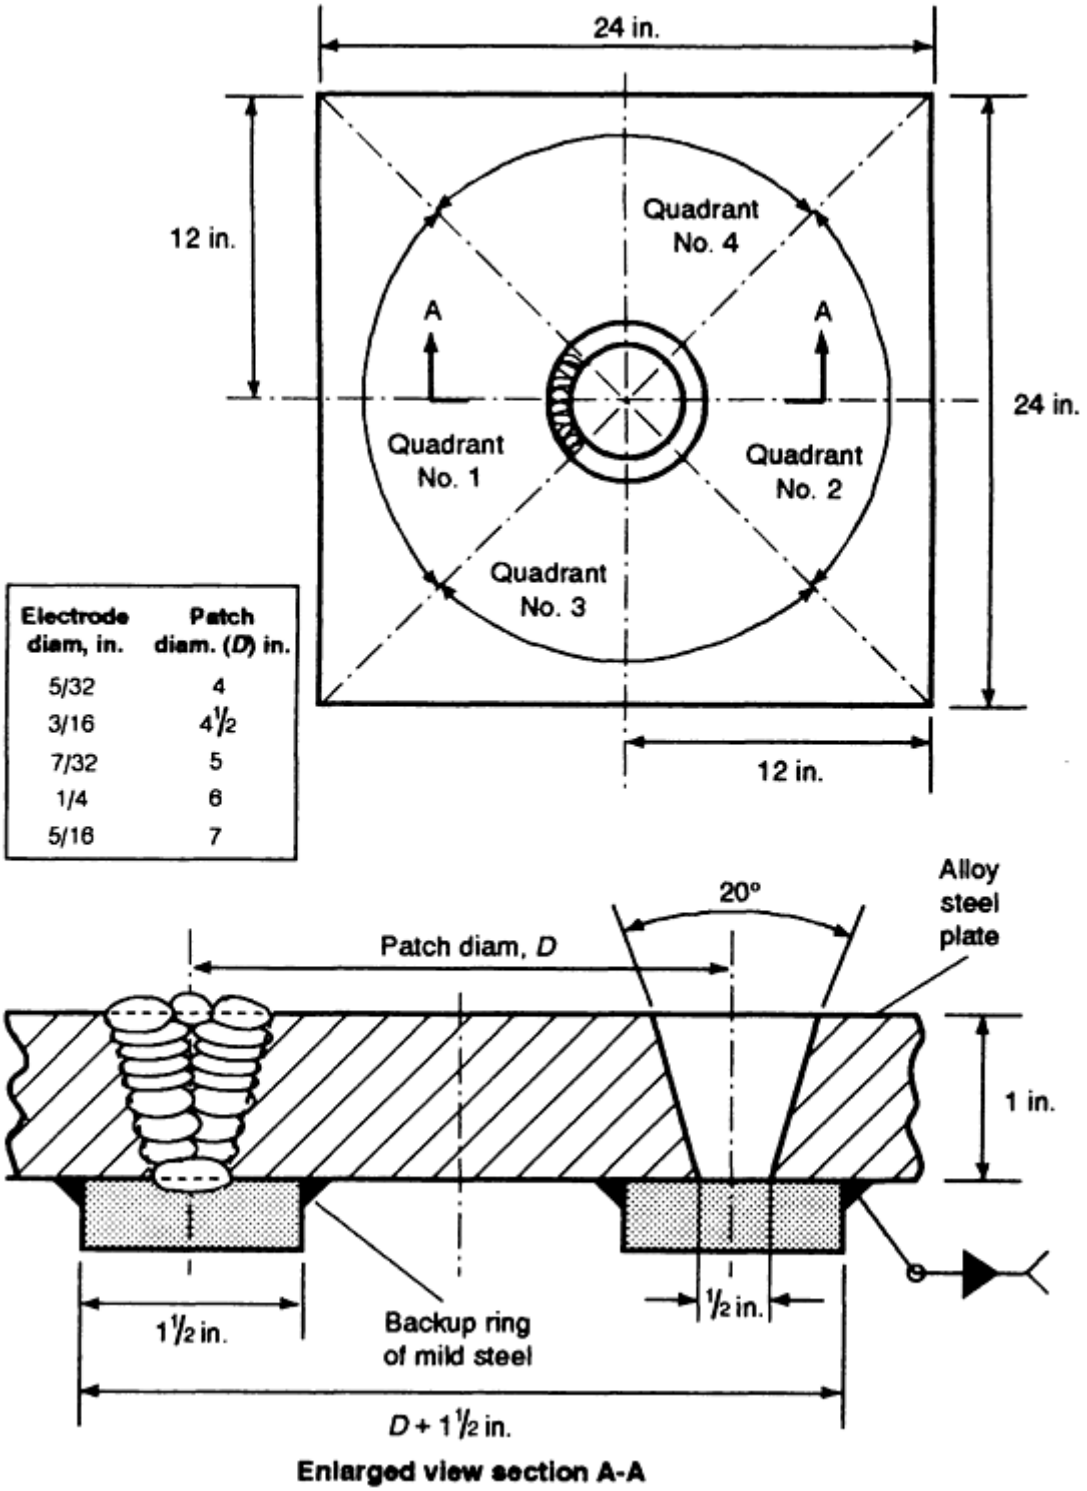

FIG. 7 PLATE REQUIREMENTS FOR NAVY CIRCULAR PATCH TEST. SOURCE: REF 8

Controlled-Thermal-Severity Test (Cold Crack Test). The controlled-thermal-severity test specimen consists of a square plate bolted and anchor welded to a larger rectangular plate (Fig. 8). After the anchor welds have cooled to room temperature, two test welds are made on the specimen. The fillet weld along the plate edges is made first. This weld, called the bithermal weld, has only two-dimensional heat flow. After this weld has cooled, the lap weld is made on the other edge of the top plate, near the center of the bottom plate. Because this weld has nearly three-dimensional heat flow, it is called a trithermal weld. The specimen is held for 72 h at room temperature, then the degree of cracking is determined by measuring crack length on three metallographic specimens cut from cross sections of the two welds.

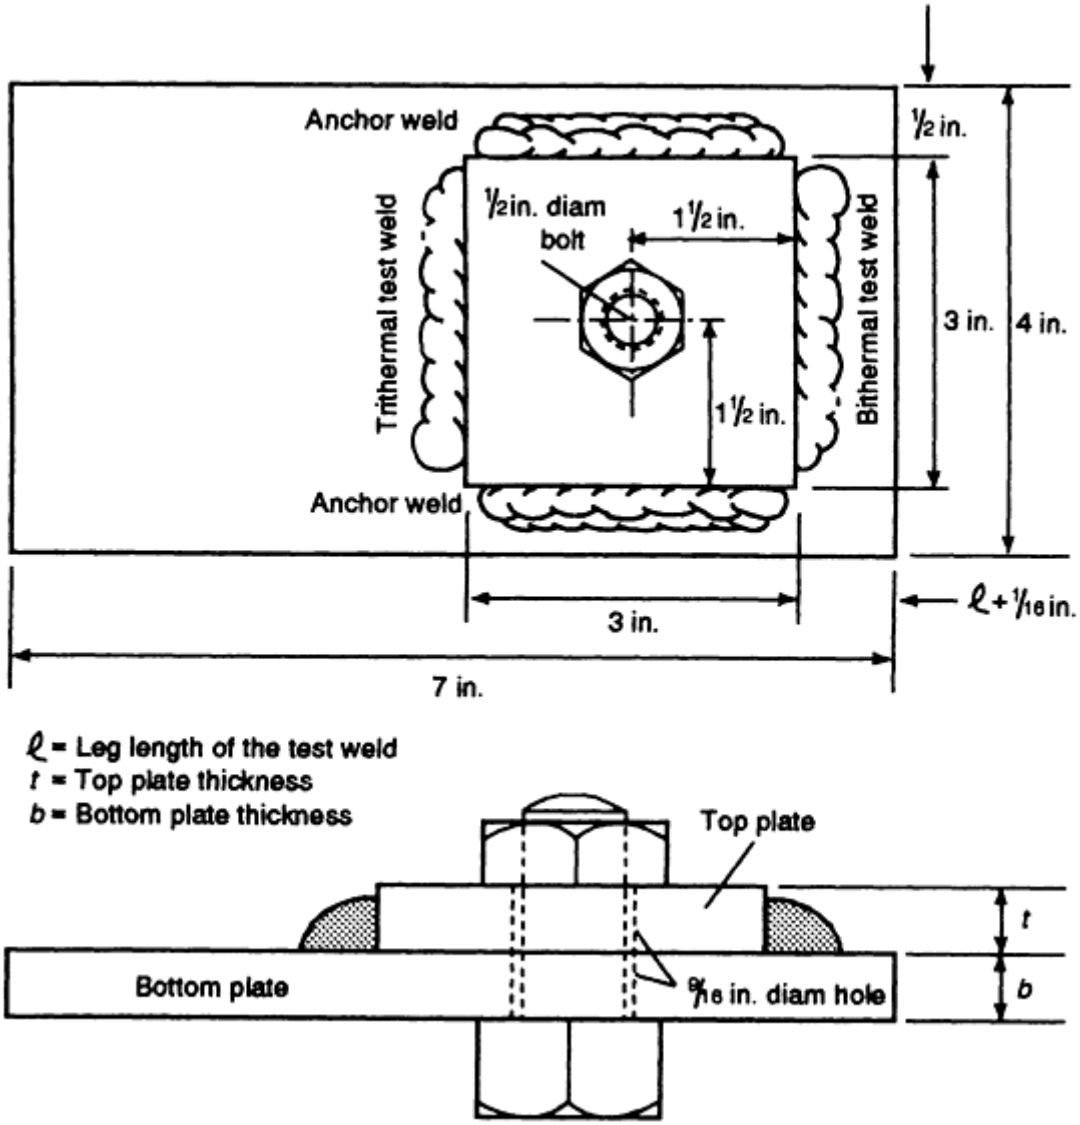

FIG. 8 PLATE DIMENSIONS FOR CONTROLLED THERMAL SEVERITY TEST. SOURCE: REF 8

Each specimen is assigned a thermal severity number (*TSN*) according to plate thickness using Eq 1 and 2. For bithermal welds:

$$TSN = 4(T + B) \qquad \textbf{(EQ 1)}$$

where *t* and *b* are the thicknesses of the top and bottom plates, respectively. For trithermal welds:

$$TSN = 4(T + 2B) \qquad \textbf{(EQ 2)}$$

A series of plate thicknesses, which provided varying cooling rates, are tested. The crack susceptibility of the base metal-filler material (welding wire or electrode) combination is determined by the minimum *TSN* that produces cracking. Controlled-thermal-severity testing is used to measure the cold crack sensitivity of steels under cooling rates controlled by the thickness of the plates and the differences in cooling rates between bithermal and trithermal welds. This test is primarily used to evaluate the crack sensitivity of hardenable steels (Ref 7, 9).

Cruciform Cracking Test (Cold Crack Test). The cruciform cracking test (Fig. 9) uses three plates that are surface ground along their interfaces to ensure consistent and reproducible fit-up. The ends are tack welded together to form a

double T-joint. Four test fillet welds are deposited in the sequence shown in Fig. 9, with complete cooling between passes. The specimen is held at room temperature for at least two days before stress relieving at about 620 °C (1150 °F) for 2 h (Ref 7). Cracking is determined by evaluation of metallographic cross sections of the four welds. The test data can be erratic and are very susceptible to sample preparation. Five to ten samples are typically required to provide reliable results for cracking sensitivity level (Ref 7, 8).

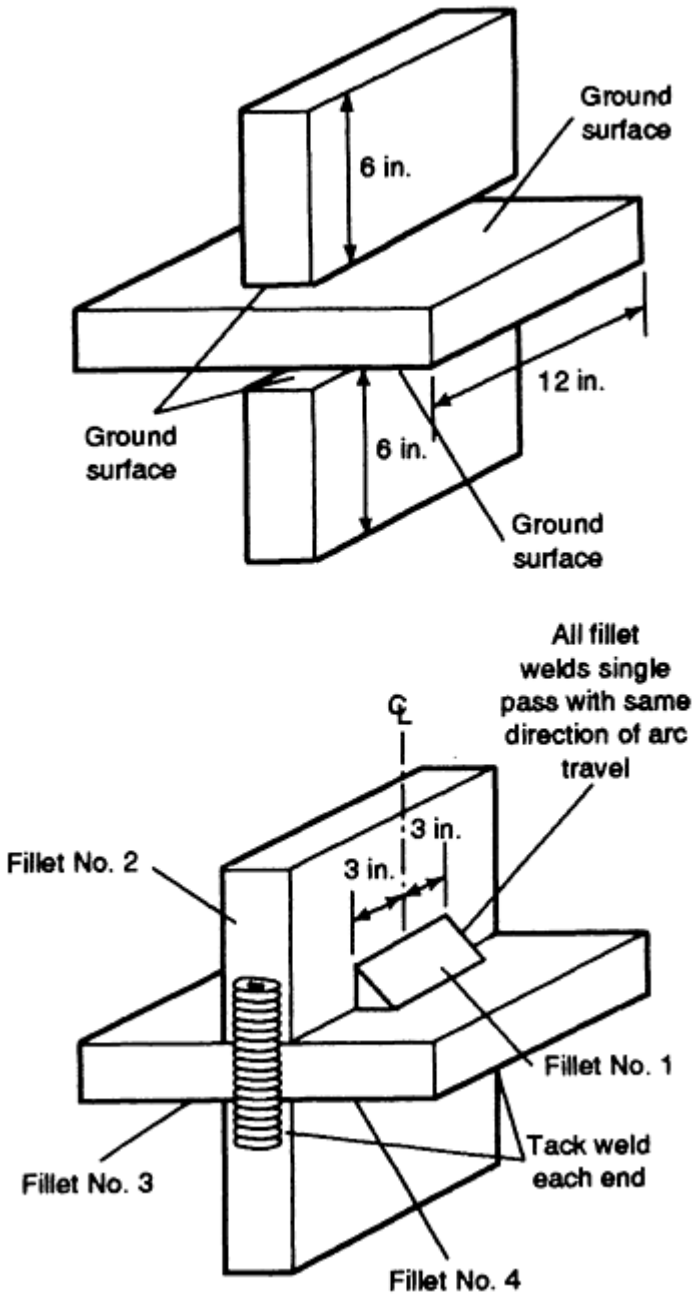

FIG. 9 SPECIFICATIONS FOR CRUCIFORM CRACKING TEST SPECIMENS. SOURCE: REF 8

Externally Loaded Tests

Externally loaded tests involve the application of an external load to the specimen during weld testing. This external load is typically varied to alter the stress state and thus the severity of cracking. This allows a more quantitative measure of stress than can be obtained from the self-restraint tests.

Implant Testing (Cold Crack Test). The implant test is used to evaluate hydrogen-induced cracking (HIC). A rod of the steel base metal to be tested is machined to the dimensions shown in Fig. 10, the end of the rod having either a circular groove or a helical groove machined into it (Ref 8). The rod is placed inside a hole in the center of a plate so the

top of the rod is flush with the top of the plate. A weld bead is made on the top surface of the plate and passes directly over the top of the rod. By making the weld over the rod, the groove in the rod is thus located in the coarse-grained HAZ, which is most susceptible to HIC.

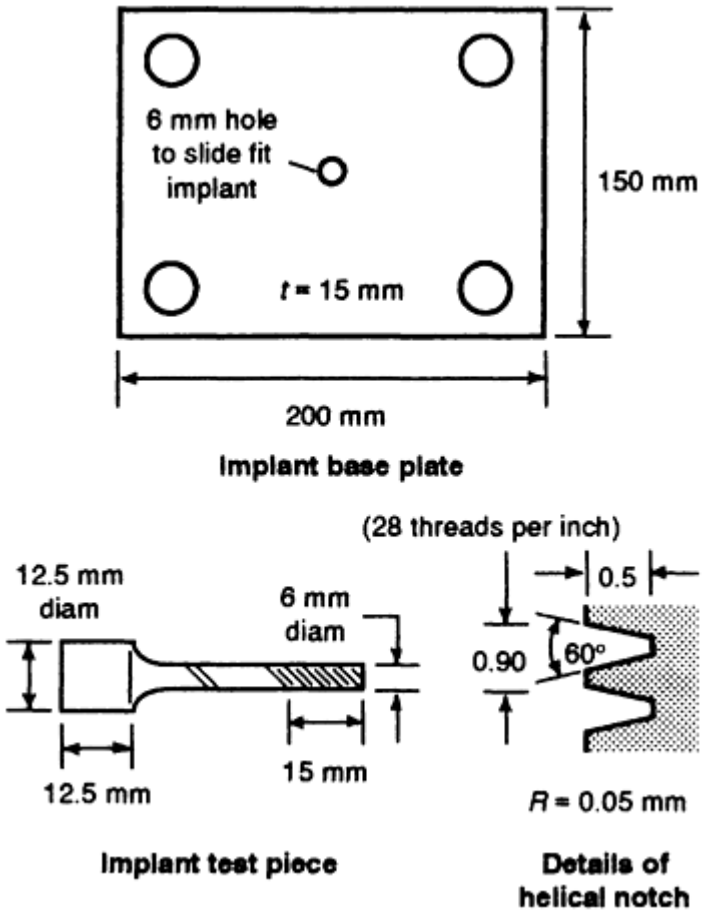

FIG. 10 SAMPLE SPECIFICATIONS FOR IMPLANT TEST SPECIMENS. SOURCE: REF 8

After welding (but within 60 s after weld completion), the test setup is placed in an apparatus that places a tensile stress on the rod, and this is maintained for 24 h, or until the weldment fails. Numerous samples are welded, then tested under different loads. The time to fail is plotted as a function of the loading stress. The crack susceptibility of the base metal is measured by the degree to which the failure stress is reduced with time.

Varestraint Test (Hot Crack Test). The Varestraint (variable restraint) test was developed at Rensselaer Polytechnic Institute (Ref 10). It is the most common test used to evaluate hot crack sensitivity. In this test, one end of a rectangular bar (typically 50 by 205 by 6.4 mm, or 2 by 8 by $\frac{1}{4}$ in.) is firmly mounted in a fixed position while the opposite end is attached to a hydraulic or pneumatic plunger (Fig. 11). A gas-tungsten arc weld is produced on the top side of the plate, along its longitudinal centerline, beginning at the unsupported end and moving toward the fixed end. When the welding arc reaches a predetermined location over a die block, the plate is bent to conform to the radius of the die block. This induces an augmented longitudinal strain on the welded surface of the specimen. The value of the strain is given approximately by:

$$e = \frac{t}{2R} \qquad \textbf{(EQ 3)}$$

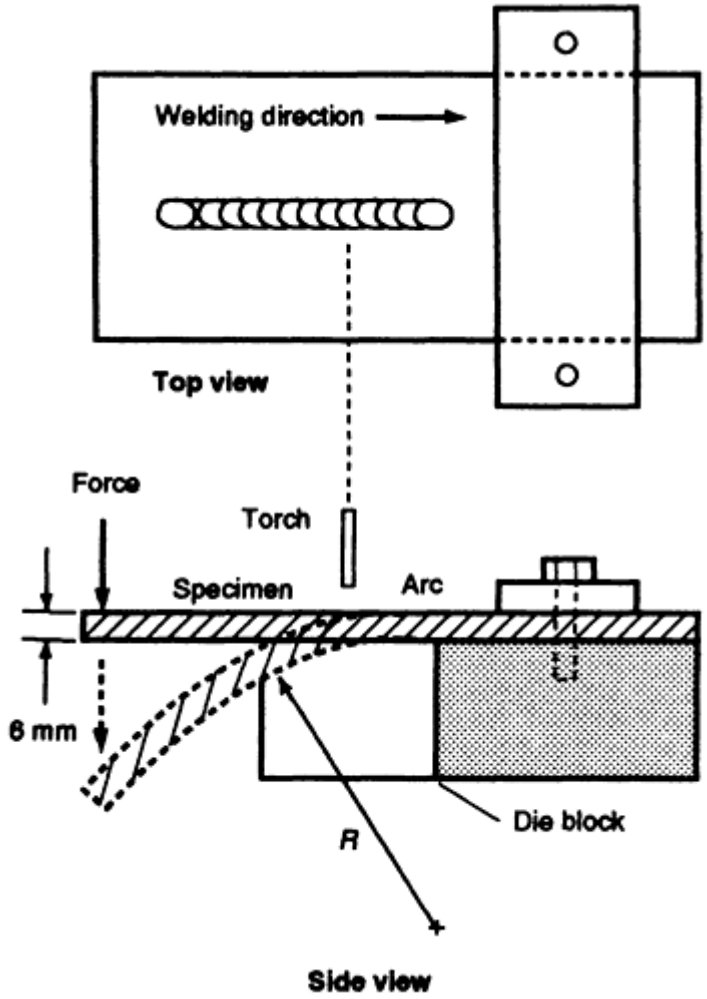

FIG. 11 SETUP AND SAMPLE SPECIFICATIONS FOR VARESTRAINT TEST. SOURCE: REF 7

Various die blocks with different radii can be used on samples of the same material to characterize the strain level at which cracking begins. Typically, for alloy evaluation, a single die block of known radius is used which will produce cracking in all samples. Hot cracks typically form radially along the trailing edge of the weld pool and in the HAZ. Duplicate samples of each alloy are tested, and mean values of total crack length, number of cracks, or maximum crack length are used as a quantitative means of base metal weldability (Ref 7).

The Varestraint test also has been used to test the hot crack susceptibility of filler material. By depositing filler wire on a plate (for example, with the gas-metal arc welding process) and then machining the specimen surface flush, a Varestraint test can be made using the GTAW process. This method has been used to evaluate the effect of base metal-filler material dilution on hot crack susceptibility.

The subscale Varestraint test uses a smaller sample (Fig. 12). This test uses the same testing equipment, but was developed for sheet material (Ref 11). Typical specimen size is 25 by 150 by 3.2 mm (1 by 6 by $\frac{1}{8}$ in.).

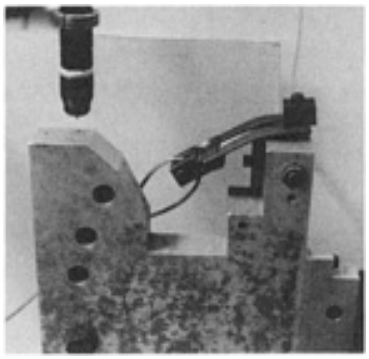

FIG. 12 PHOTO OF A TYPICAL SUBSCALE VARESTRAINT TEST APPARATUS. SOURCE: REF 11

Advantages of the Varestraint and subscale Varestraint tests are that they produce top surface cracks, both in the weld and the HAZ. Disadvantages are the cost of manufacturing or procuring the test equipment.

Another variation of this test is the trans Varestraint test, in which the sample is bent in a direction normal to the welding direction instead of the longitudinal direction. The loading in this test is tensile loading normal to the welding direction. This usually causes centerline cracks to form. The length of centerline cracks is used as a measure of hot crack susceptibility.

Spot Varestraint Test (Hot Crack Test). The spot Varestraint test is a modification of the Varestraint test; it is sometimes referred to as the TIG-A-MA-JIG test (Ref 10). In this test, a stationary welding torch is used to produce a gas-tungsten arc spot weld in the center of a rectangular sample (Fig. 13). The specimen size is typically 140 by 25 by 6.4 mm (5.5 by 1 by 0.25 in.). After the weld is established for a predetermined time, the test specimen is forced around a curved die block and the arc is extinguished. Hot cracks or hot tears form radially around the weld pool in the HAZ. The total crack length, maximum crack length, or strain level necessary to cause cracking is used as the measure of crack sensitivity. The spot Varestraint test is used mainly for evaluating susceptibility to HAZ hot cracking or liquation cracking (Ref 12).

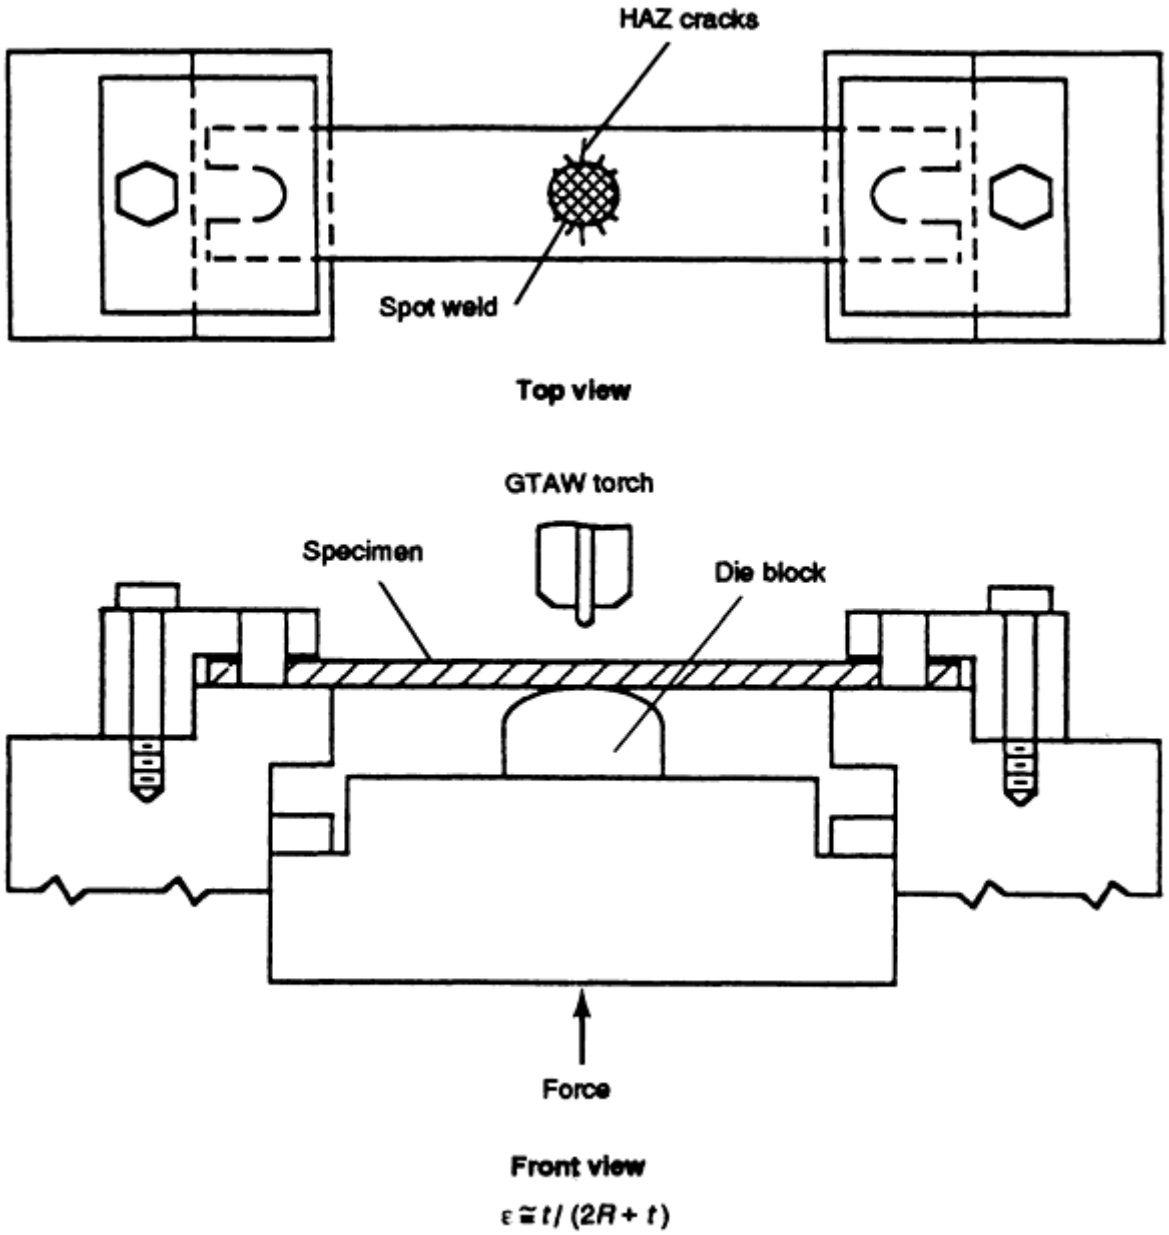

FIG. 13 SCHEMATIC SHOWING TOP AND FRONT VIEWS OF A SETUP USED IN SPOT VARESTRAINT TESTING. SOURCE: REF 12

One potential problem with the spot Varestraint test is that crater cracks often form, and they are difficult to distinguish from the other hot cracks. Also, extensive subsurface cracking often occurs, but cannot be detected without examination of metallographic cross sections. Reproducibility is difficult because slight variations often occur in welding conditions with the spot weld. A modified spot Varestraint test, developed at the University of Tennessee, moves the torch away from the pool prior to bending. This helps eliminate problems associated with crater cracks.

Sigmajig Test (Hot Crack Test). This test, developed at Oak Ridge National Laboratory, involves application of a transverse normal stress, σ, to a 50 by 50 mm (2 by 2 in.) sheet specimen (Fig. 14). An autogenous gas-tungsten arc weld is produced along the longitudinal centerline of the specimen. Numerous specimens are welded, with the stress being increased with each specimen, until centerline cracking occurs. A threshold stress level necessary to cause 100% cracking is used to quantify hot crack susceptibility (Ref 13). The advantages of this test are its usefulness for thin sheet, up to approximately 2.5 mm (0.1 in.).

Weldability Tests for Evaluating Weld Pool Shape, Fluid Flow, and Weld Penetration

Weld pool shape, fluid flow, and the subsequent weld penetration and weld profile are important characteristics in industrial welding applications. Improvements in material processing have resulted in alloys with much "cleaner" chemical analyses. Small changes in the amounts of certain trace elements have been shown to cause dramatic variations in weld pool shape and penetration (Ref 14). Predictable and reproducible weld shape and weld penetration are critical in many applications. As a result, several weldability tests have been developed to evaluate base material response characteristics. Although these tests are not as standardized as the others described above, they are becoming increasingly important, both for alloy development and for production welding applications.

Weld Penetration Tests. Individual companies have developed tests for evaluating the penetration behavior of base metals. A simple weld test utilizes a bar stock sample on which an autogenous gas-tungsten arc, bead-on-plate, partial-penetration weld is produced (Fig. 15). A single set of welding parameters and the same heat sinking are used to test different heats of the same base materials. After welding, the sample is metallographically cross sectioned and etched. Measurements are made of the weld bead width (*W*) and depth of penetration (*D*); from these dimensions, a depth-to-width ratio (*D*/*W*) is calculated.

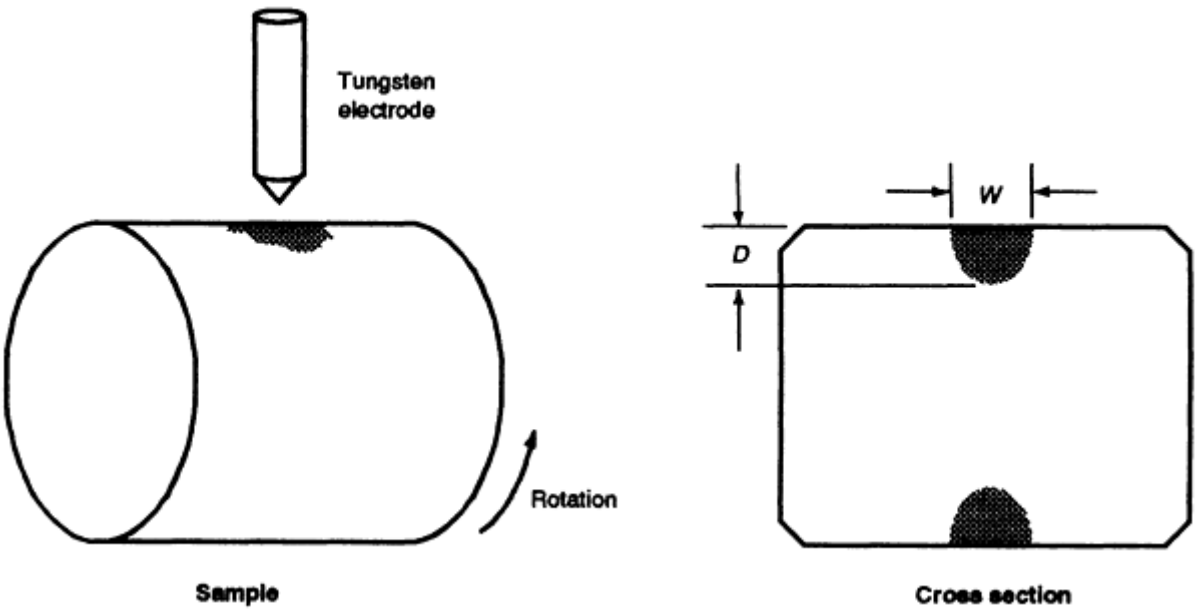

FIG. 15 POSITION OF WELD RELATIVE TO SOLID BAR STOCK IN PARTIAL PENETRATION WELD TEST. SOURCE: REF 14

The *D*/*W* ratio can be used to characterize the weld penetration characteristics of base materials and different heats of the same materials. For production applications, this provides information about the material response before components reach the production welding area. The advantage of this partial-penetration test is that measurements of the solidified weld bead are made. These data characterize the response of the material to all forces that affect weld bead shape, without the influence of a backside or underbead.

Full-penetration weld tests can also be used. These tests are applicable when the weldability test specimen is similar in geometry to the production weldment. However, full-penetration weld shape is complicated because, in some cases, three-dimensional heat flow applies, while in other cases, two-dimensional heat flow applies. Heat buildup on the backside,

weld joint shape, and-heat sinking dramatically affect the final weld shape. As a result, full-penetration weldability tests are useful only when the production geometry is used in the test (Ref 14).

Weld Pool Shape Tests. Weld pool shape is determined by a complex set of factors that include process and material variables (Ref 15, 16, 17). Pool shape determination is of interest for basic research and for production applications. Walsh, Campbell, and Savage (Ref 18) pointed out that determinations of pool shape based on metallographic cross sections are incomplete, and subject to error even in stationary welds. Any arc or weld pool motion that sweeps out a width or length greater than the instantaneous pool dimensions cannot be detected on metallographic cross sections. Many critical geometric features of the weld pool could be overlooked if a true three-dimensional measurement was not made.

Some work has been done to characterize the three-dimensional shape of weld pools (Ref 19, 20). However, techniques based on gravity and gunshots have drawbacks, principally lack of speed and contamination, respectively. A new weldability test, called an impulse decanting test, is shown in Fig. 16. This test utilizes a high-pressure jet of argon gas that is impulse-released through the bottom of a modified GTAW torch to decant, or expel, the liquid weld pool. A control box contains the necessary timing circuitry and system relays to extinguish the welding arc and fire the solenoid valve on an accumulator tank that holds the argon.

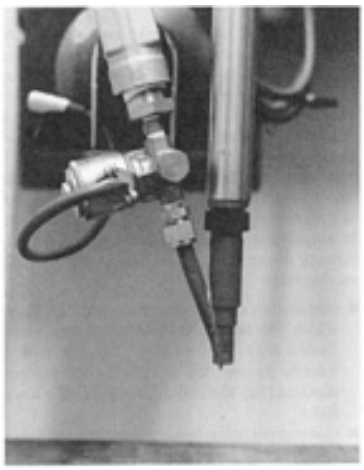

FIG. 16 TYPICAL SETUP USED TO MEASURE WELDABILITY USING THE IMPULSE DECANTING TEST. SOURCE: REF 11

The decanted weld pool shape can be evaluated by two methods:

- USING SILICONE RUBBER TO REPLICATE THE WELD POOL CAVITY
- VISUALLY MEASURING THE WELD POOL CAVITY DIMENSIONS ALONG THE SAMPLE TOP SURFACE, AND ALSO ON A METALLOGRAPHIC TRANSVERSE CROSS SECTION OF THE CAVITY

The silicone rubber replicas are the best method (Fig. 17), because they accurately provide the weld pool length, width, depth, volume, and surface area. This test method is extremely valuable to investigators of weld pool modeling.

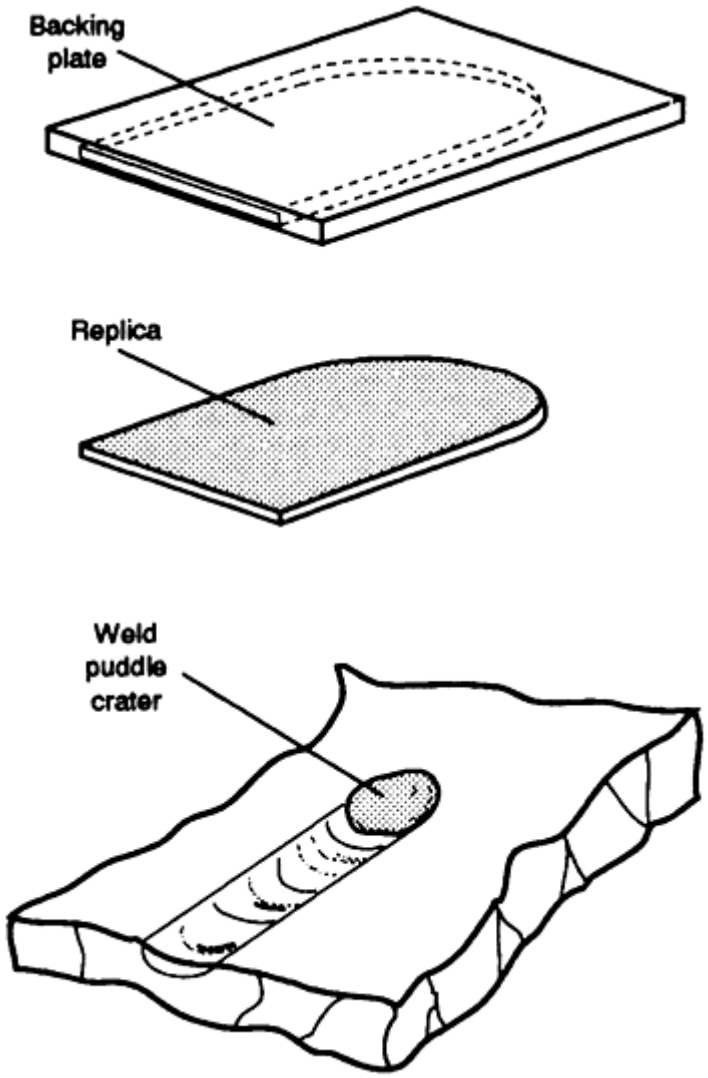

FIG. 17 SILICONE RUBBER REPLICATION TECHNIQUE USED TO EVALUATE DECANTED WELD POOL SHAPE. SOURCE: REF 21

Gleeble Testing

The Gleeble, a thermomechanical testing device, has been used in a wide range of applications involving study of a variety of material problems. These include, but are not limited to, studies of hot ductility (Ref 22, 23, 24, 25), mechanical properties of the weld HAZ (Ref 26, 27, 28, 29, 30, 31, 32, 33, 34, 35), continuous cooling transformation diagrams (Ref 36, 37, 38), stress relief cracking (Ref 39), precipitation kinetics (Ref 40), basic weldability (Ref 41, 42, 43, 44, 45), strain age cracking (Ref 46, 47), constitutional liquation (Ref 48), liquid metal embrittlement (LME) (Ref 49, 50), and solidification of austenitic stainless steel weldments (Ref 51, 52). The Gleeble system permits simulation of virtually any thermomechanical process. The device is used in a variety of applications and is in no way limited by its historical application to welding.

The Gleeble test method is shown schematically in Fig. 18. Stainless steel samples being tested under load and no-load conditions are shown in Fig. 19(a) and 19(b), respectively. The Gleeble is a fully computer interfaced system, readily programmed to provide reference signals for closed loop control of both thermal and mechanical operations. Heating is accomplished by the flow of low-frequency alternating current in the specimen, and heating rates up to 20,000 °C/s (36,000 °F/s) per second can be obtained (Ref 54). The feedback signal necessary for closed-loop control is normally obtained from a fine wire thermocouple percussion welded to the specimen surface. However, for temperatures above the operating limits of thermocouples, a radiation pyrometer can be employed at some sacrifice in the overall response time of the system.

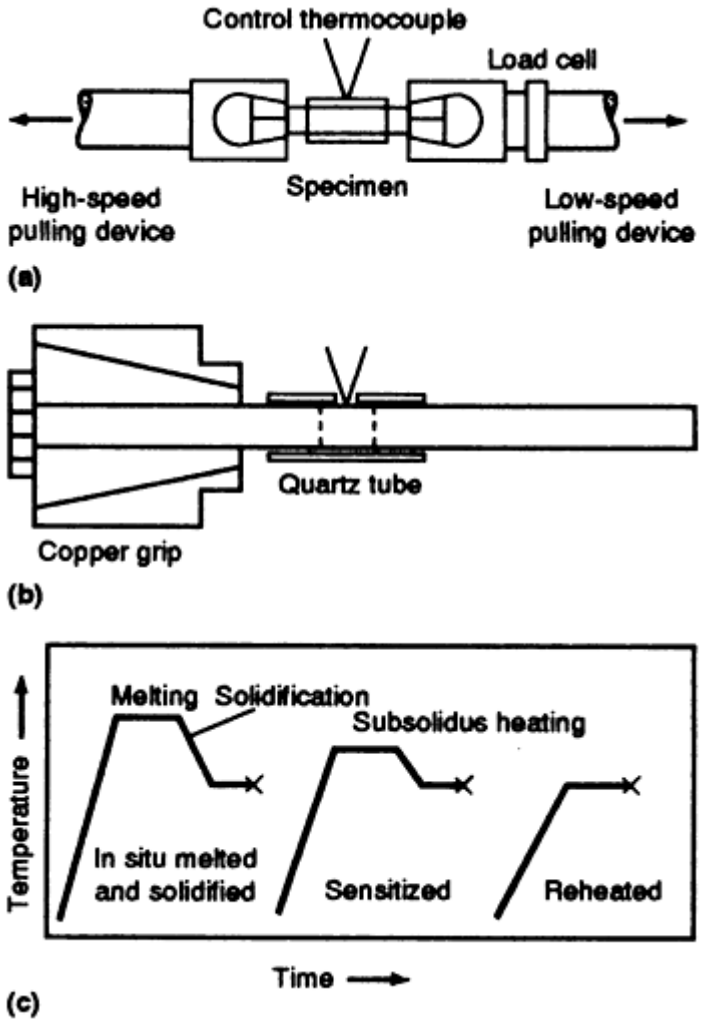

FIG. 18 GLEEBLE TEST METHOD. (A) PRIMARY COMPONENTS. (B) CLOSE-UP VIEW OF RESISTANCE HEATER. (C) PROGRAMMED THERMAL CYCLE. SOURCE: REF 53

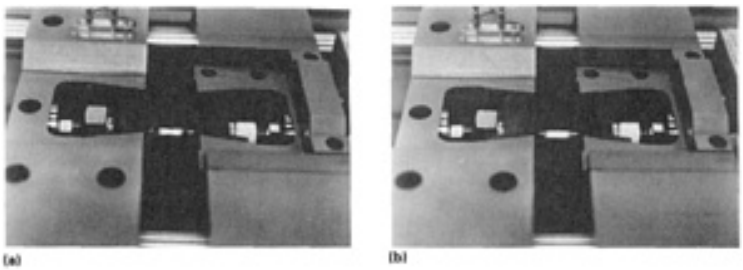

FIG. 19 GLEEBLE TESTING OF A 6 MM (0.236 IN.) DIAMETER STAINLESS STEEL BAR AT 1100 °C (2010 °F). (A) SAMPLE UNDER NO-LOAD CONDITION (NOTE UNIFORMITY OF REPRODUCIBLE THERMAL GRADIENT). (B) SAMPLE UNDER LOAD AT ELEVATED TEMPERATURES TO EVALUATE DUCTILITY

The Gleeble has a long and proven history as a tool for both the study of metallurgical phenomena at the research level and for materials testing to predict service behavior at the production level. A major advantage of the Gleeble is that it generates large volumes of microstructure that simulate small, hard-to-study regions in actual weldments.

Gleeble test samples take on an unlimited variety of sizes and shapes, based on material availability and project application. The following is a discussion of round bar samples, as they are the most typical samples studied. The concepts discussed can be extended to a variety of geometries.

A given test sample is a system in dynamic thermal equilibrium with its surroundings. Thus, to maintain any given temperature profile, heat is supplied by the electrical current passing through the specimen, and heat is lost by three mechanisms:

- CONDUCTION ALONG THE SPECIMEN ITSELF, IN WHICH THE HEAT IS TRANSFERRED TO THE WATER-COOLED JAWS. THE RATE OF THIS HEAT FLOW IS DIRECTLY PROPORTIONAL TO BOTH THE THERMAL GRADIENT AND THE THERMAL DIFFUSIVITY OF THE MATERIAL.
- CONVECTION IN THE GASEOUS ATMOSPHERE, WHICH REMOVES HEAT AND DISSIPATES IT TO THE SURROUNDINGS BY MIXING.
- RADIATION EMITTED BY THE SPECIMEN. THE AMOUNT OF HEAT LOST THROUGH THIS MODE IS PROPORTIONAL TO THE FOURTH POWER OF THE ABSOLUTE TEMPERATURE, AND THEREFORE BECOMES MORE IMPORTANT AT HIGH TEMPERATURES.

Thus, the thermal profile generated by a given peak temperature, jaw separation, specimen diameter, and material type is determined by a complex interplay of these mechanisms in establishing a thermal balance.

The Gleeble specimen may be treated as a uniform cylindrical bar with internal generation of heat. If convection and radiation losses are neglected, the principle of the conservation of energy leads to the following relationships for the instantaneous temperature distribution in the bar:

$$\frac{\partial T}{\partial t} = \frac{K}{r C_p} \nabla^2 T + \frac{t^2}{r C_p w^2 s} \qquad \textbf{(EQ 4)}$$

where C_p is the heat capacity at constant pressure; ∇ is the del operator; I is the current; ω is the area in cross section; σ is the electrical conductivity; K is the thermal conductivity; T is the temperature; ρ is the density; and t is the time.

If the system is simplified by limiting the heat flow to one dimension, Eq 4 becomes:

$$\frac{\partial T}{\partial t} = \frac{K}{r C_p} \frac{\partial^2 T}{\partial x^2} + \frac{t^2}{r C_p w^2 s} \qquad \textbf{(EQ 5)}$$

This relationship closely approximates the behavior of a resistance-heated specimen. If the temperature distribution within the bar is assumed to be steady state, Eq 5 reduces to the Poisson relation:

$$\frac{\partial^2 T}{\partial x^2} = \frac{-I^2}{K w^2 s} \qquad \textbf{(EQ 6)}$$

Therefore, if radiation and convection losses are ignored, the temperature distribution in the bar will be a parabolic one. This can be demonstrated by double integration of Eq 6 to obtain:

$$T(x) = \frac{-I^2}{K w^2 s} x^2 + c' + c'' \qquad \textbf{(EQ 7)}$$

The constants of c' and c'' can be determined for specific boundary conditions. Solutions to this equation exist in the literature (Ref 55) and have been applied to the determination of the lengths over which the temperature of the bar lies, between the maximum, T_{max}, and some arbitrary lower temperature, T_0. This length is given by the following:

$$L = L_o\left(\frac{\Delta T}{T_{\max} - T_o}\right)^{1/2} \qquad \textbf{(EQ 8)}$$

where L is the length at or above arbitrary temperature; L_0 is the jaw separation; T_0 is the temperature at the jaw; and ΔT is the difference between peak temperature and arbitrary temperature.

However, problems exist for this simplified treatment because experimental results do not fit the model well. Several factors contribute to this. The thermal conductivity, K, is not a constant, and being itself a function of temperature can be presented as:

$$K = K_0(1 - BT) \qquad \textbf{(EQ 9)}$$

where K_0 is the thermal conductivity at absolute zero if conductivity is treated linearly.

However, because the value of b is small, an average value of K can be used over a small range of temperatures without generating an excessively large error.

The mathematics of the system become more complex when treatments for either convection or radiation heat transfer are included. Heat loss by either mechanism will tend to flatten the parabolic profile predicted by Eq 7. Convection losses can be represented by adding a single term to the Poisson equation to obtain:

$$\frac{K}{rC_p}\frac{\partial^2 T}{\partial x^2} + \frac{-I^2}{rC_p w^2 s} - \frac{hg}{rC_p w}(T - T_o) = 0 \qquad \textbf{(EQ 10)}$$

where h is the convective heat transfer coefficient and γ is the dependent constant relative to geometry.

The inclusion of another temperature-dependent term makes the solution to the differential equation more complex, and leads to solutions involving hyperbolic functions. The addition of a term for radiation losses further complicates the solution because the radiative heat loss, Q_{12}, is proportional to the fourth power of absolute temperature:

$$Q_{12} = F_{12}\alpha(T_1^4 - T_2^4) \qquad \textbf{(EQ 11)}$$

where Q_{12} is the heat transfer from body 1 to body 2; F_{12} is the view factor, body 1 to body 2; T_1 is the temperature of body 1; and α is the Stefan-Boltzmann constant. The constants h, in the convective solution, and α, in the radiative solution, are small, and high temperatures are required before convection and radiation play a major role in determining the temperature profile in the bar.

Walsh, Savage and Cieslak (Ref 56) reported an empirical study of carbon and stainless steel that related test parameters to the extent of a uniform temperature region in Gleeble samples. They developed polynomial equations that describe longitudinal and radial thermal profiles that exist in test samples under a wide variety of operator-controlled conditions. At any particular peak temperature, a span in which the temperature lies within a specified percentage of the peak temperature can be generated by a judicious choice of operating conditions and specimen geometries.

Gleeble testing has been used to study a variety of phenomenon in electrically conductive materials. However, the discussion of its application to weldability testing will be limited to studies of hot cracking and hot ductility. Information about other applications of Gleeble testing is available in the References cited in this article.

Hot Ductility Testing. The development of high-performance materials and increasingly rigid standards for quality, coupled with the jux-taposition of very different materials in engineering assemblies, has led to significant increases in the difficulty associated with producing satisfactory weldments. The temperatures and steep thermal gradients associated with welding produce high stresses and complex transient stress patterns. These factors often combine to produce cracking in the weld and HAZ region. The rapid thermal cycle associated with the welding process produces a plethora of microstructures in the weld/HAZ region, and weld understood metallurgical transformations associated with heating and cooling become complex under the nonequilibrium conditions associated with the welding process.

Goodwin (Ref 57) has pointed out that hot cracking is an often-studied, yet poorly understood phenomena. Hot cracking results when a susceptible microstructure is subjected to tensile stresses, and it occurs while liquid and solid phases coexist. A successful hot cracking test must reproduce combinations of restraint and microstructure that can be used to differentiate the crack sensitivity of different materials (Ref 57). Several hot cracking tests are described in the section "Weldability Tests for Evaluating Cracking Susceptibility" in this article.

Borland (Ref 58) described features required of an ideal hot crack test--it should be inexpensive, simple, brief, directly correlatable to fabrication parameters and service conditions, reproducible, free from operator error, and applicable to all welding processes. In addition to these criteria, the test should also produce easily interpretable results, be amenable to modeling, be quantitative, and above all, be universally accepted (Ref 57). It is very difficult to conceive of a single test that could satisfy all these criteria; however, many investigators have found that the combination of Varestraint or Varestraint-like testing and Gleeble testing yields results that can be used to provide a state-of-the-art characterization of weldability. (The Varestraint test is described in the section "Varestraint Test (Hot Crack Test)" in this article.)

Gleeble testing provides a complete characterization of hot ductility related to hot crack susceptibility. In the Gleeble test, small cylindrical tensile samples are fractured during heating or during cooling from specified temperatures. Reduction-in-area and ultimate tensile strength data are used to generate strength and ductility curves upon cooling and upon heating. A number of factors are important to the test, including heating and cooling rates, peak temperatures, hold times, and stroke rates. A number of investigators have examined the effects of changes to these parameters and found that the peak temperature of the test is by far the most crucial. The magnitude of effects that changes to other parameters produce is a strong function of material and material condition.

Weiss, Grotke, and Stickler (Ref 25) discuss the physical metallurgy of hot ductility testing and the use of the Gleeble in studying alloy weldability. Hot cracking is caused by the presence of persistent liquid films on grain boundaries. These films are unable to accommodate strains that are produced by mechanical restraint and/or transient thermal distributions during cooling. Hot cracking will not occur unless a susceptible microstructure is exposed to critical level of restraint. Several characteristic temperatures that can be used to classify material weldability have been identified using the Gleeble. In hot ductility testing, the nil temperature (NDT) is the temperature upon heating at which the material ductility goes to zero; in essence, the temperature at which all surfaces are coated by a thin liquid layer. The nil strength temperature (NST) is the temperature upon heating at which the strength of a material drops essentially to zero; in essence, the temperature at which liquid layers thicken to the point that minimal capillarity exists. The ductility recovery temperature is the temperature upon cooling at which an arbitrary ductility is observed.

Investigators have used a wide variety of criteria to interpret hot ductility curves produced using the Gleeble. Nippes, Savage, and Grotke (Ref 23) published a classification of hot ductility curves encountered during testing of stainless steels and nickel-base alloys. The criteria most widely used include minimum arbitrary ductility, recovery rate of ductility, recovery rate of ultimate strength, zero-ductility range, and the presence of ductility dips (Ref 31). Kreischer (Ref 24) published a critical review of hot ductility testing and suggested that:

- WHEN THE NST IS USED AS THE PEAK TEMPERATURE IT PROVIDES MUCH MORE ACCURATE INDICATION OF HOT CRACK SUSCEPTIBILITY THAN THE NDT
- ALLOYS EXHIBITING HIGH DUCTILITIES UPON HEATING AND RAPID RECOVERY OF DUCTILITY UPON COOLING FROM THE NST ARE CRACK RESISTANT
- ALLOYS WITH HIGH TENSILE STRENGTH AT ELEVATED TEMPERATURES CAN BE CRACK RESISTANT DESPITE LOW DUCTILITIES
- ALLOYS WITH RELATIVELY LOW TENSILE STRENGTHS AT ELEVATED TEMPERATURE, IN CONCERT WITH ONLY MODERATE DUCTILITIES, ARE NORMALLY CRACK SENSITIVE

Lin, Lippold, and Baeslack (Ref 59, 60) have detailed a methodology for quantifying crack susceptibility using the Gleeble hot ductility test.

Brazeability and Solderability of Engineering Materials

S.D. Brandi, Escola Politécnica da Universidade de São Paulo, Brazil; S. Liu, Colorado School of Mines; J.E. Indacochea and R. Xu, University of Illinois at Chicago

Introduction

ANALYSIS of the brazeability and solderability of engineering materials requires the following considerations:

- JOINING PROCESS CHARACTERISTICS (TYPE AND CHARACTERISTICS OF HEAT SOURCE)
- CHEMICAL COMPOSITION OF BASE METAL
- CLEANING PREPARATION AND AFTER-PROCESS CLEANING
- CHEMICAL COMPOSITION OF FILLER METAL
- JOINT PROTECTION AGAINST OXIDATION (FLUX, BATH COMPOSITION, PROTECTIVE ATMOSPHERES)
- JOINT TEMPERATURE AND TIME
- JOINT DESIGN (JOINT GEOMETRY, JOINT CLEARANCE, JOINING POSITION)

Each one of these topics influences wetting and spreading behavior, joint mechanical properties, corrosion resistance, and residual stress levels.

Brazeability and Solderability of Engineering Materials

S.D. Brandi, Escola Politécnica da Universidade de São Paulo, Brazil; S. Liu, Colorado School of Mines; J.E. Indacochea and R. Xu, University of Illinois at Chicago

Process Applications and Requirements

The use of high-performance materials in advanced engineering and manufacturing places demanding requirements on joining processes such as brazing and soldering. Appropriate design of the joints and proper selection of joining processes and filler metals can increase the application of brazed and soldered joints in sophisticated mechanical assemblies, such as aerospace equipment, chemical reactors, and high-value electronic assemblies.

Soldering in the electronics field has undergone many dramatic changes since the first radios were built. Between the 1920s and 1940s, all interconnections were made using the point-to-point wiring method, and the solder joints were made with soldering irons. With the end of World War II and a greater demand for consumer electronics, mass soldering techniques such as dip soldering were developed. By the late 1950s, wave soldering was developed in England and introduced to the United States soon after; this technique is still widely used on printed wiring boards.

Brazing has also evolved significantly. The introduction of torch brazing, furnace brazing, and vacuum brazing has expanded the application of brazing to different material systems such as aluminum, stainless steel, superalloys, titanium, and ceramics.

Recent developments in aluminum brazing in the automotive industry include the application of noncorrosive fluxes in conjunction with a dry nitrogen atmosphere in a continuous mesh belt furnace. Under these conditions, only a small amount of flux is required for joint protection, so flux removal after brazing is not necessary. Many other automotive parts are furnace brazed, such as pollution control tubing, water pump impellers, torque converters, and so on. While the torque converter is usually brazed with a copper filler metal, a nickel filler metal is used when additional strength is required (for example, for dynamometer testing or other high-stress applications). Stainless steel automotive assemblies are brazed in a low-dew-point atmosphere such as cryogenic nitrogen, with an addition of 20 to 50 vol% of dry hydrogen.

The potential applications of brazing and soldering have increased both in volume and significance with the introduction of advanced structural ceramics. Much emphasis has been placed on the application of these ceramics in aerospace, automotive, and electronics applications. A complete characterization and understanding of the existing brazing and soldering techniques for joining dissimilar materials will contribute to the further development of these techniques and to the joining of ceramic materials reliably. Improved brazing and soldering technology will also result in the establishment of optimized design criteria and high-yield, low-cost manufacturing processes.

Aerospace Applications

Jet engine components such as turbines blades and stators with very thin section are assembled by brazing. The vanes can be hollow, with passageways for dynamic cooling during operation. Yet the brazements must be designed to withstand loads that the part will experience throughout its service life. In the modem aircraft engine industry, most brazing is carried out in vacuum or hydrogen, using specialized brazing cycles. Typically, large components are brazed in vacuum furnaces at 0.13 to 0.013 Pa (10^{-3} to 10^{-4} torr). Other parts of engine systems are brazed in continuous hydrogen furnaces and batch hydrogen furnaces.

The interest of the aerospace industries in structural ceramics centers on the potential application in gas turbine engines. The severe service conditions encountered within a gas turbine, and the desire of design engineers to increase operating temperatures for higher efficiency, make several of the properties of structural ceramics particularly attractive. High-temperature strength, low thermal expansion coefficient, dimensional accuracy, and corrosion resistance are some of these properties.

The silicon-base ceramics, such as Si_3N_4, SiC, or Sialon ($Si_{5.5}Al_{0.5}O_{0.5}N_{7.5}$), have been considered for gas turbine parts (including bearings, shroud rings, and turbine blades). The bearings may be found either as ceramic balls or rollers in conventional bearings or shells. The use of ceramics for shroud rings allows for high-temperature operation while maintaining tight control of shroud clearances on the blades, because of their low thermal expansion coefficients. In the case of present turbine blades technology, the operating temperatures are already close to the maximum temperature limit. Therefore, the high-temperature strength of these ceramics is particularly desirable.

Ceramic materials are more difficult to braze because they are not easily wet by the standard commercial filler metals. When joined to metals, the different thermal expansion coefficients may result in residual stress generation and cracking of the ceramic component. Ceramic-to-metal joints must be specially designed to alleviate the residual stress problem. Techniques such as metallization and ductile reactive metal fillers can be utilized to promote wettability and minimize stress-induced cracking in the ceramic component.

Braze joints for heat engine applications require good mechanical properties at high temperatures. Thus, the combination of base metal and filler metal in the joint must be thermally stable. The presence of intermetallics at the interface of base metal and filler metal should be minimized, and the filler metal should not undergo any type of strengthening or softening mechanism, such as precipitation hardening, order/disorder reactions, or precipitate coarsening. Wetting and spreading are important to avoid lack of filling, which will create stress concentrations and, consequently, the premature failure of the component.

Nuclear Applications

Because of the need of structural integrity at high temperatures for components used in nuclear applications, refractory metals are targeted for those applications. Joints of significant dimensions with properties that are adequate to meet requirements of strength, ductility, and corrosion resistance are required. Brazing has been widely accepted as the joining method to satisfy these requirements.

For the past 30 years engineers have been attracted to the inherent properties of ceramic materials for potential use in nuclear reactors, which involve high temperatures and corrosive environments. Fuel element structures were one of the first applications for which experimental assemblies were designed and fabricated using ceramic materials. To demonstrate the use of ceramic brazing in advanced fuel elements, one element was made entirely of Al_2O_3 and compartmented ceramic plates were brazed after loading with fuel (Fig. 1).

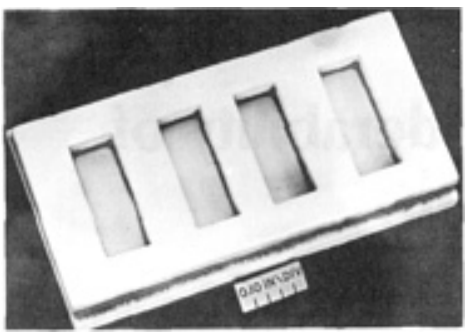

FIG. 1 ALUMINUM OXIDE COMPARTMENTED ASSEMBLY VACUUM BRAZED WITH 49TI-49CU-2BE (IN WT%) BRAZING FILLER METAL AT 980 °C (1795 °F) FOR 10 MIN

A BeO tubular assembly was also brazed, simulating a fuel bundle with ferrule spacers. The larger BeO tube diameters represent the fuel tubes, while the smaller tubes simulate the spacers. This assembly (Fig. 2) was brazed with the same brazing filler metal as the flat-plate assembly in Fig. 1 (vacuum, 1000 °C, or 1830 °F, for l0 min).

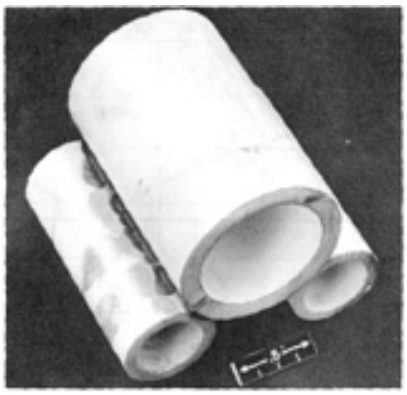

FIG. 2 BERYLLIUM OXIDE TUBULAR ASSEMBLY BRAZED WITH 49TI-49CU-2BE FILLER METAL

Another application is the advanced Tokamak fusion test reactor, being developed at Princeton University. The effort is aimed at achieving a commercially feasible magnetic-fusion reactor. In this reactor, large ceramic insulator rings are used to electrically insulate the vacuum-pumping and natural-beam injector system from the stainless steel vacuum vessel, in which the plasma is confined by surrounding magnetic fields.

The insulating rings for the fusion reactor are composed of ceramics, copper, and stainless steel, all of which must be brazed together successfully. To accomplish the task, titanium hydride was first applied to the ceramic mating surfaces, followed by silver-copper foil of 0.076 mm (0.003 in.) thick. The assembled parts, wrapped in titanium foil that acted as a getter to obtain a higher purity atmosphere, were then successfully brazed.

Heat Exchangers

Heat exchangers, particularly in the automotive industry. are fabricated from many different materials. such as copper. aluminum, copper-nickel alloys, steels, and titanium. Depending on the base metal selected, joint strength requirements, and assembly design, different brazing processes, such as torch, furnace, resistance brazing, and so on, can be used.

Temperature and humidity control within the atmospheres of space vehicles, space stations, and space suits can be realized with condensing heat exchangers. By use of the plate-fin design, units with high efficiency at minimum mass and volume may be tailored close to actual system requirements. Stainless steel cores, brazed together in vacuum with nickel-base filler metals, are used to meet these requirements.

A variety of ceramic materials have been considered for use in heat exchange systems, such as the main heat transfer surfaces (tubes, plates, and so on), seals, tube sheets, and insulation. They have been used primarily in these critical zones in an effort to minimize cost over metallic counterparts. Heat exchanger designs have ranged from all-ceramic to ceramic-metal hybrids with varying numbers of ceramic components. These parts are commonly brazed with ductile active metal fillers.

Brazeability/solderability in this application is related mainly to the corrosion resistance of the joint. The filler metal should be more noble than the base metal to minimize galvanic corrosion in the joint. Wetting and spreading are also important to prevent crevices that may generate crevice corrosion, especially when the environment has chloride ions in solution. The flux should be easily removed to avoid residues that can accelerate the corrosion rate in the joint.

Electronic Packaging

Filler metal compositions and forms for soldering have experienced significant changes to meet the needs of a growing number of process techniques and applications, from simple wires to foils, preforms, and pastes. The first electronic solder was 50Sn-50Pb wire, traditionally used by plumbers. Today, the selection of materials has expanded to eutectic tin-lead solders, neareutectic (60Sn-40Pb) solders, and ternary (62.5Sn-36.1Pb-l.4Ag) alloys in the form of foils, preforms, and pastes. Although the main emphasis has remained on the Sn-Pb eutectic and near-eutectic alloys, other alloys, such as the indium and gold-tin eutectics, have also been developed for more specialized applications.

Flux technology has also evolved. Environmental regulations have placed emphasis on the development of new flux types. Extensive work has been done with organic acids, that can be removed with aqueous media or low-residue fluxes which have eliminated cleaning altogether.

The use of mass soldering techniques has increased the need for adequate solderability of substrates. The large throughput of high-production-rate processes prohibits the repair of defective solder joints. In addition, modern components are more heat-sensitive. Lower soldering temperatures and less mechanical working have made it necessary to maintain the highest solderability to ensure a metallurgically sound and reliable joint on the first pass.

The service performance of a solder joint is a strong consideration in modem electronics. Many environments, such as aircraft avionics, telecommunications systems, dishwashers, and automobiles, impose a regular thermal cycle on the electronic equipment that results in thermal-mechanical strains. Failure by fatigue or creep becomes inevitable if the joint design is incorrect or if the joint has defects due to poor manufacturing control.

Solderability in this application describes the formation of a joint by adequate wetting of the entire surface by the molten solder to achieve good electrical contact. Base-metal dissolution by the molten solder should be minimized by processing variables (time, temperature, filler metal composition). The flux should promote the oxide removal and protect the molten solder against oxidation to prevent "cold weld," which may cause a misfunction of the electronic component.

Dissimilar Material Joints

Industrial machinery construction and electronic components fabrication require the joining of materials that exhibit highly different properties. An example is the joining of ceramics with metals that have quite different melting points and coefficients of thermal expansion. Various processes have been developed to join dissimilar materials. Usually the selection of the joining technique will depend on the materials used and on the specified joint properties. For instance, to obtain high mechanical strength or good heat resistance, the reaction layer must consist of high-melting-temperature products. For good dielectric properties, the reaction layer must contain oxide compounds. The use of vitreous phases in the interlayer may provide chemical resistance and high puncture-proofness. Presently, processes such as sintering of interfaces, spraying and sintering of coatings, and depositing of layers by chemical vapor deposition, soldering (metal-metal and metal-ceramic), and infiltration (joints of composite materials) are applied in joining dissimilar materials. In developing processes to join dissimilar materials, one must consider and solve such problems as wettability, chemical reactivity of the base materials and filler metals to be bonded under specific processing conditions, and the effect of the joining processes on the stress state in the joint during production and during operation.

Brazeability and Solderability of Engineering Materials

Materials Selection

Brazing and soldering are joining processes performed at temperatures below the base material solidus temperature. To fill the joint, the liquid filler metal must spread through the joint gap by capillarity or coat the substrate by spreading. Capillarity and spreading are related to the balance of surface tensions, which determines the wetting and spreading behavior of a liquid on a solid. Both wetting and spreading are results of interfacial reactions (physical and chemical reactions). The influence of material selection, joint design, and surface conditions on the mechanical properties and corrosion resistance of a brazed joint will be discussed below.

There is no precise definition of brazeability and solderability of a material. These properties are related to how easily a material can be joined, how closely a joint can fit its design function (mechanics, corrosion, electrical contact, and so on), and the most suitable joining process. As an example, in electronic applications solderability involves not only the soldering process characteristics but also the effect of heating on the electronic component characteristics.

Wetting and Spreading. Wetting is a surface phenomenon related to the balance of the solid-liquid surface tension, γ_{sl}, the solid-vapor surface tension, γ_{sv}, and the liquid-vapor surface tension, γ_{lv}. The contact angle, θ, between the solid and the liquid is defined in equilibrium conditions as the angle between the vectors that represents the liquid-vapor surface

tension and the solid-liquid surface tension. The relationship between the contact angle and the surface tensions is given by the Young-Dupré equation:

$$\gamma_{LV} \cdot \cos\theta = \gamma_{SV} - \gamma_{SL} \qquad \textbf{(EQ 1)}$$

A liquid is said to wet a solid when the contact angle is less than 90°. In this case, for constant γ_{lv} the solid-vapor surface tension is greater than the solid-liquid surface tension. On the other hand, if the solid-vapor surface tension is lower than the solid-liquid surface tension, the contact angle is greater than 90° and the liquid will not wet the solid. Figure 3 shows a wetting and a nonwetting system in a joint. In neither case did a reaction layer form between the solid and the liquid.

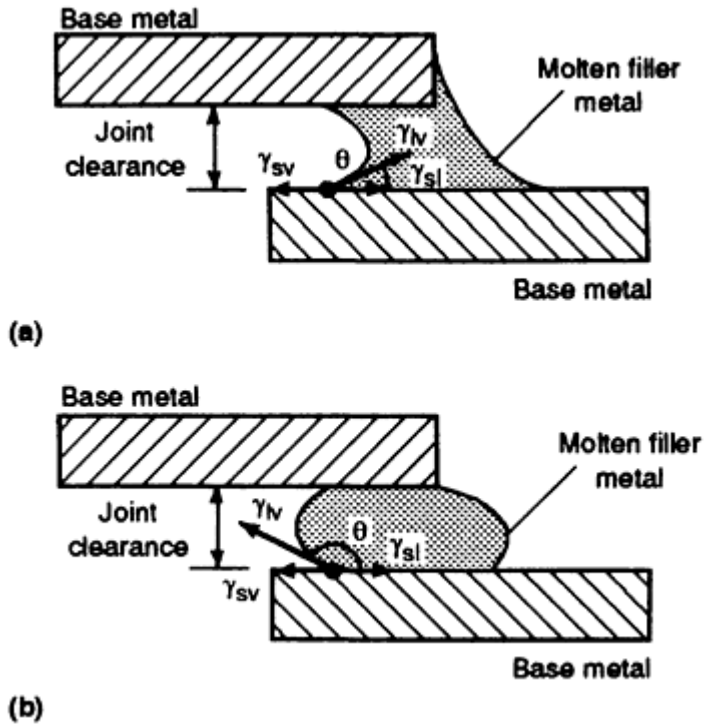

FIG. 3 SCHEMATIC SHOWING RELATIONSHIP OF CONTACT ANGLE TO SURFACE TENSION. (A) WETTING SYSTEM. (B) NONWETTING SYSTEM

Spreading is a dynamic process related to the contact angle θ and can be described as an increase in the liquid surface and the interfacial area, ΔA, with time. Based on Fig. 4, a liquid is said to completely spread over a solid surface when the contact angle tends to 0° (Fig. 4a). Alternatively, spreading is considered to proceed when the liquid surface area increases to a maximum, even if θis greater than 0° (Fig. 4b). Rate of spreading can be inhibited by the liquid inertia and/or the liquid viscosity.

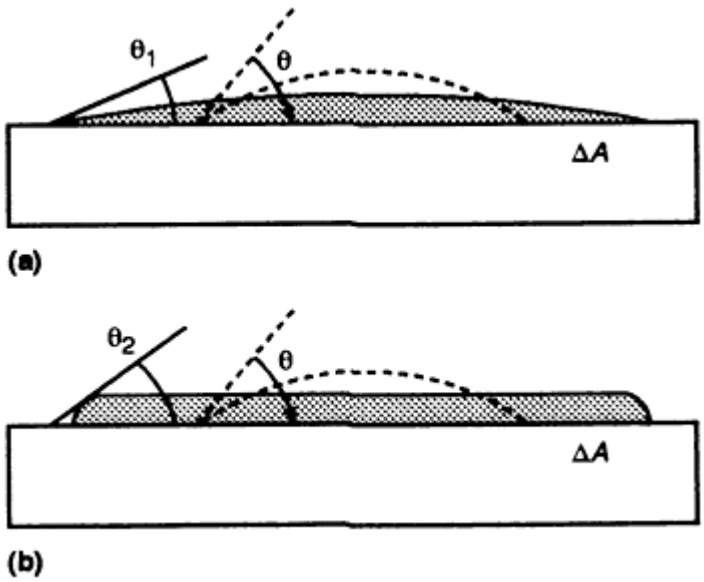

FIG. 4 SCHEMATIC SHOWING A LIQUID SPREADING THROUGH A SOLID SURFACE WITH θ< 90°. (A) θ_1 0°. (B) $\theta_2 = \theta_{EQUIL}$

From Eq 1, $\gamma_{lv} \cdot \cos \theta$can be considered as a resistance force that opposes a liquid to wet a solid, and ($\gamma_{sv} - \gamma_{sl}$) is a driving force for wetting. If $\gamma_{lv} \cdot \cos \theta$ is greater than ($\gamma_{sv} - \gamma_{sl}$), no wetting or spreading will occur. So it is important to decrease $\gamma_{lv} \cdot \cos \theta$and/or to increase ($\gamma_{sv} - \gamma_{sl}$) by means of a flux, a filler metal, or a suitable brazing atmosphere. γ_{lv} and γ_{sv} decrease when a deoxidation reaction takes place at the liquid and solid surfaces. γ_{sl} can be reduced by promoting a deoxidation reaction via alloying elements in the filler metal (such as phosphorus in BCuP filler in contact with a copper substrate), formation of a reaction layer, or adsorption of a chemical element at the solid-liquid interface. Figure 5 shows the effect of the atmosphere and filler metal composition on the surface tensions for a Cu-BCuP system.

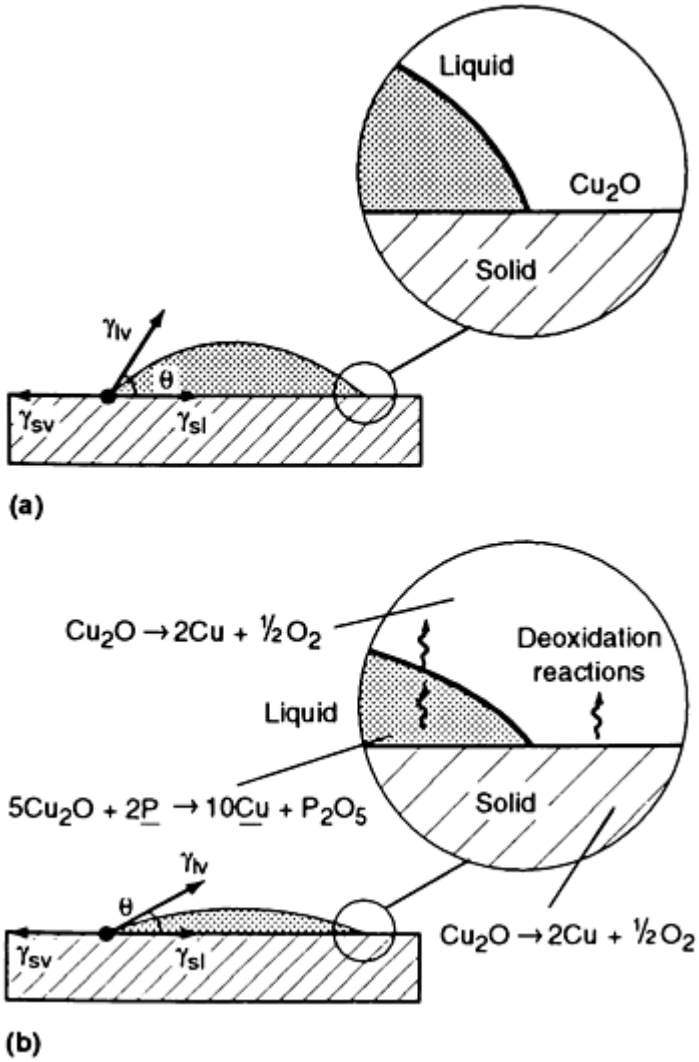

FIG. 5 SCHEMATIC SHOWING EFFECT OF THE SURROUNDING MEDIUM AND THE COMPOSITION OF THE FILLER METAL ON THE WETTING AND SPREADING BEHAVIOR OF COPPER-BCUP SYSTEM. (A) NEUTRAL OR OXIDIZING MEDIUM. (B) DEOXIDIZING MEDIUM

Interfacial Reactions. During brazing, the molten filler metal often reacts with the base metal. The product is a reaction layer that is sometimes too thin to be observed by optical microscopy. In fact, this layer modifies the wetting and spreading behavior of the liquid filler metal in contact with the base metal. Figure 6 shows the interfacial reaction during the brazing process.

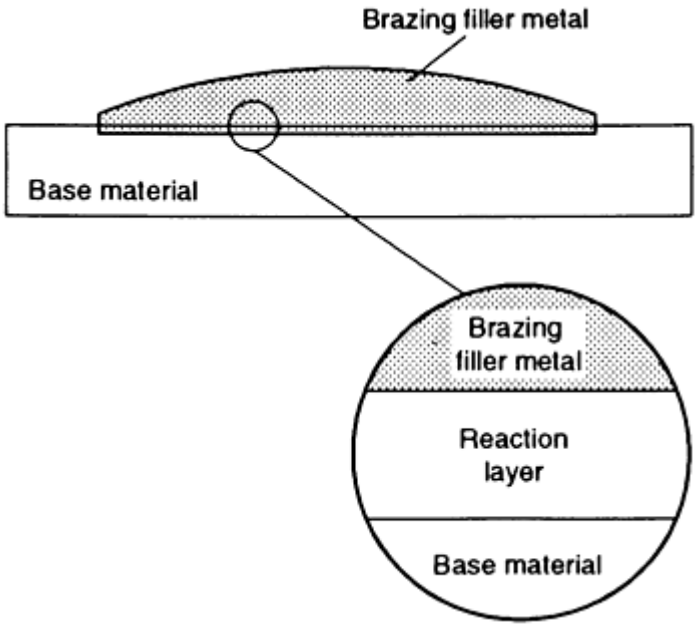

FIG. 6 REACTION LAYER FORMATION DURING THE BRAZING PROCESS

When an interfacial reaction occurs between the base metal and the liquid filler, the free energy of the reaction per unit area and unit time (ΔG_r) should be included in Eq 1, as follows:

$$\gamma_{SV} - (\gamma'_{SL} - \Delta G_R) = \gamma_{LV} \cdot \text{COS}\ \theta \qquad \textbf{(EQ 2)}$$

Due to a change in the solid-liquid interface by a chemical reaction, γ'_{sl} is lower than γ_{sl} of Eq 1. The variables γ'_{sl} and ΔG_r will increase the driving force for wetting. If the driving force is greater than $\gamma_{lv} \cdot \cos\ \theta$, spreading will occur until the liquid has reacted completely with the solid. This concept can be illustrated by the results of a sessile drop experiment in copper-silver systems, shown in Fig. 7.

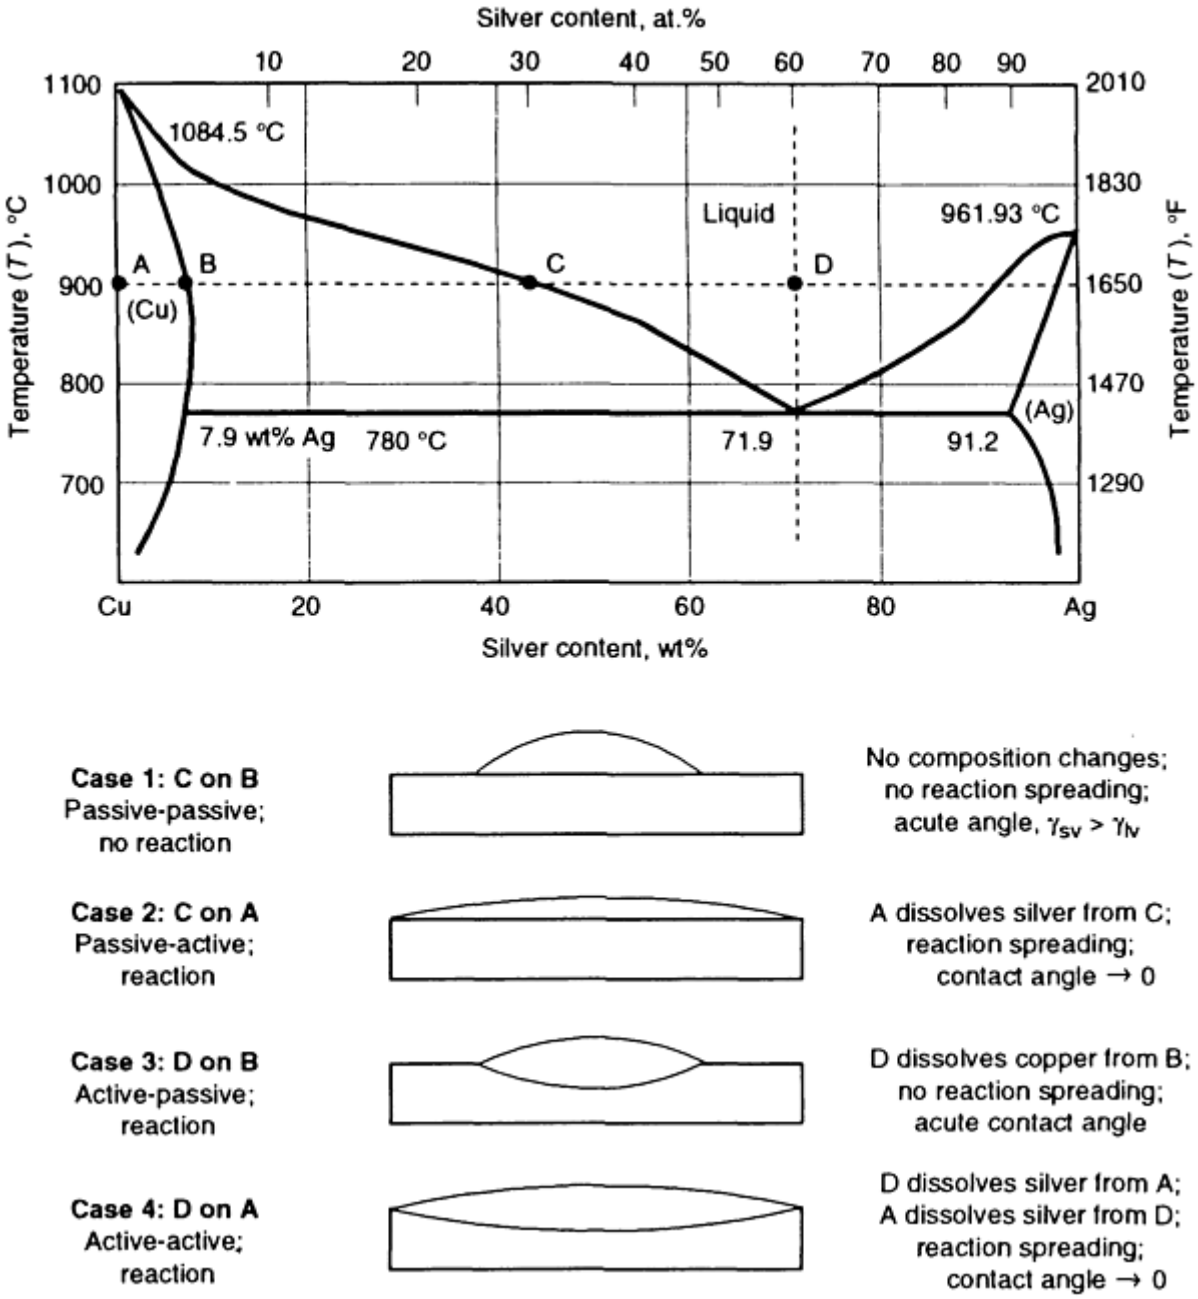

FIG. 7 RESULTS OF A SESSILE DROP TEST TO ANALYZE SPREADABILITY AS A FUNCTION OF THE SOLID AND LIQUID COMPOSITION. SOURCE: REF 1

Cases 1 and 2 in Fig. 7 show that no spreading occurred. In case 1 the solid and the liquid are in equilibrium (points B and C), and no composition change can occur as long as the brazing temperature is maintained. In case 3 the liquid dissolves copper from the solid to reach the equilibrium composition (point C). In both cases the chemical composition of the solid remains the same. This means that in cases 1 and 3 the solid has a passive behavior with respect to the liquid. On the other hand, cases 2 and 4 show the solid as the active element in the system. In other words, the chemical composition of solid A changes up to B, based on the phase diagram. In case 2, a spreading reaction occurs (that is, silver from the liquid diffuses into the solid and changes the composition at the solid-liquid interface). In case 4, both solid and liquid are active and a spreading reaction is expected to occur. It is important to point out that wetting will occur in all four cases, but only in cases 2 and 4 is spreading expected to take place.

Depending on the mechanical properties of the base metal and the filler metal, the mechanical behavior of the reaction layer may determine the strength of the braze joint. If a solid solution is formed, the reaction layer may be as tough as the base metal and the filler metal. On the other hand, if a brittle intermetallic compound is produced, the interfacial region

may degrade the joint properties. Phase diagrams are good tools to estimate the compatibility between the filler metal and the base metal.

Liquid Filler Flowability. Joint clearance is an important factor in the brazeability or solderability of a joint. Table 1 shows the recommended joint clearance at brazing temperatures for different filler metal groups. The BAlSi and BMg filler metals require larger clearances, while the BCu, BAu, BAg, and BCuP filler metals require smaller gaps. This difference can be related to the difficulty with which the first two filler metal groups wet and spread over a solid surface. The flowability of a liquid filler metal on a solid surface is related to the equilibrium conditions expressed through Eq 2, the dynamic properties such as liquid viscosity, and interfacial reaction kinetics, if applicable. So it is desirable that a filler metal has:

- HIGH WETTABILITY AS DESCRIBED BY EQ 2
- LOW VISCOSITY
- FASTER INTERFACE REACTION KINETICS

Figure 8 shows the effect of the chemical composition of a binary alloy on its viscosity. The eutectic composition will have the lowest viscosity. Filler metals with large solidification ranges tend to have higher viscosities. Notice that the chemical composition of the filler metal may change during brazing or soldering due to a dissolution reaction or an intermetallic formation. This will also affect the liquid flowability.

TABLE 1 RECOMMENDED JOINT CLEARANCE FOR SELECTED FILLER METALS AT BRAZING TEMPERATURE PER AWS B2.2 SPECIFICATION

AWS FILLER METAL CLASSIFICATION	FLUX OR BRAZING ATMOSPHERE	JOINT CLEARANCE[A]	
		mm	in.
BAG, BVAG	FLUX	0.05-0.12	0.002-0.005
	BRAZING ATMOSPHERE	0.00-0.05	0.000-0.002
BAU, BVAU	FLUX	0.05-0.12	0.002-0.005
	BRAZING ATMOSPHERE	0.00-0.05	0.000-0.002
BALSI	FLUX	0.05-0.21[B]	0.002-0.008[B]
	BRAZING ATMOSPHERE	0.21-0.25[C]	0.008-0.010[C]
BCUP	FLUX OR FLUXLESS	0.025-0.12	0.001-0.005

BMG	FLUX	0.10-0.25	0.004-0.010

(A) CLEARANCE ON THE RADIUS WHEN RINGS, PLUGS, OR TUBULAR MEMBERS ARE INVOLVED. ON SOME APPLICATIONS IT MAY BE NECESSARY TO USE THE RECOMMENDED CLEARANCE ON THE DIAMETER TO PREVENT EXCESSIVE CLEARANCE WHEN ALL THE CLEARANCE IS ON ONE SIDE. AN EXCESSIVE CLEARANCE WILL PRODUCE VOIDS. THIS IS PARTICULARLY TRUE WHEN BRAZING IS ACCOMPLISHED IN A HIGH-QUALITY ATMOSPHERE (GAS PHASE FLUXING).

(B) FOR A LAP LENGTH OF ≤ 6.35 MM ($\leq \frac{1}{4}$ IN.).

(C) FOR A LAP LENGTH OF >6.35 MM ($> \frac{1}{4}$ IN.)

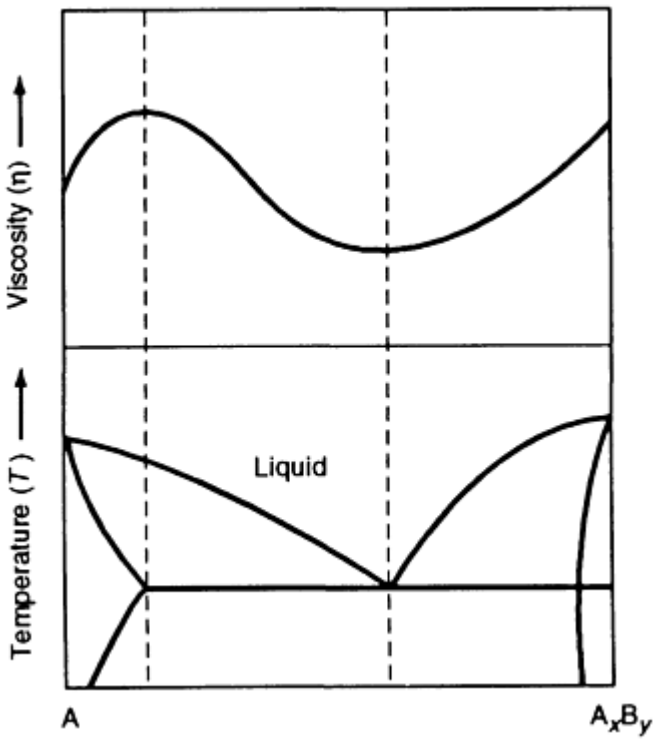

FIG. 8 EFFECT OF THE CHEMICAL COMPOSITION OF A BINARY ALLOY ON ALLOY VISCOSITY. SOURCE: REF 2

Joint design also affects filler metal flow. Figure 9 shows two different groove geometries for brazing with preplaced filler metals. In the case of a groove with sharp edges (Fig. 9a), the filler metal melts and starts to wet and spread through the groove surface. At the corner, however, the abrupt change in wall angle produces a barrier to the liquid's continued flow. Nearly all the liquid metal will accumulate at the corner, so that only a smaller amount of the molten filler is available to form the braze joint. On the other hand, the groove in Fig. 9(b) is designed to assist liquid filler flow to the outer joint surface by specifying a radius at the corner. Smooth changes in angles are preferred, to promote a more uniform flow of the liquid filler metal.

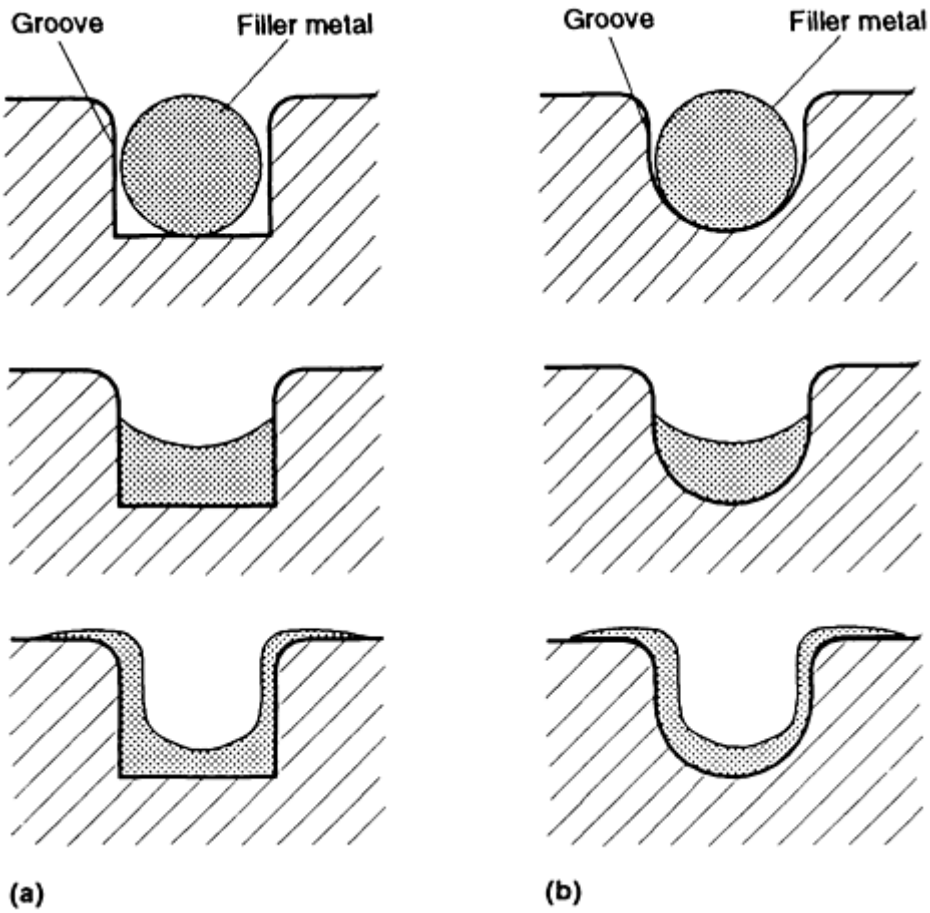

FIG. 9 EFFECT OF GROOVE GEOMETRY ON THE SPREADABILITY OF A PREPLACED FILLER METAL. (A) GROOVE WITH SHARP EDGES AND RECTANGULAR BOTTOM. (B) GROOVE WITH RADIUSED CORNERS AND SEMICIRCULAR BOTTOM WALL

Brazing position will also affect the flow rate of the liquid filler metal. A horizontal joint position is expected to offer a better flow characteristic than a vertical joint design. This is due to the gravitational field action in the vertical joint. The flow equation for the vertical and horizontal gaps are, respectively:

$$\frac{dh}{dt} = \frac{1}{4}\sqrt{\frac{g_{lv}.d.\cos q}{h.t}} \qquad \textbf{(EQ 3)}$$

$$\frac{dh}{dt} = \frac{1}{2}\sqrt{\frac{g_{lv}.d.\cos q}{h.t}} \qquad \textbf{(EQ 4)}$$

where h is the filler metal penetration in the joint, d is the joint clearance, η is the molten filler metal viscosity, t is brazing time, γ_{1v} is the surface tension between liquid and vapor, and θ is the wetting angle.

Joint Clearance. The effect of joint clearance on the behavior of a joint is about the same whether the joint is brazed or soldered. When shear strength is plotted as a function of joint clearance (Fig. 10), three different regions can be identified. At small clearances, region 1, the joint strength decreases as the clearance diminishes. The number of pores and the lack of joint filling caused by improper flow of the molten filler metal may be responsible for the lower shear strength observed. Surface discontinuity and/or entrapped flux are other factors that contribute to the joint performance. If intermetallic compounds form at the interface, a small joint clearance will invariably result in a higher volume fraction of brittle compounds, which degrade the joint properties.

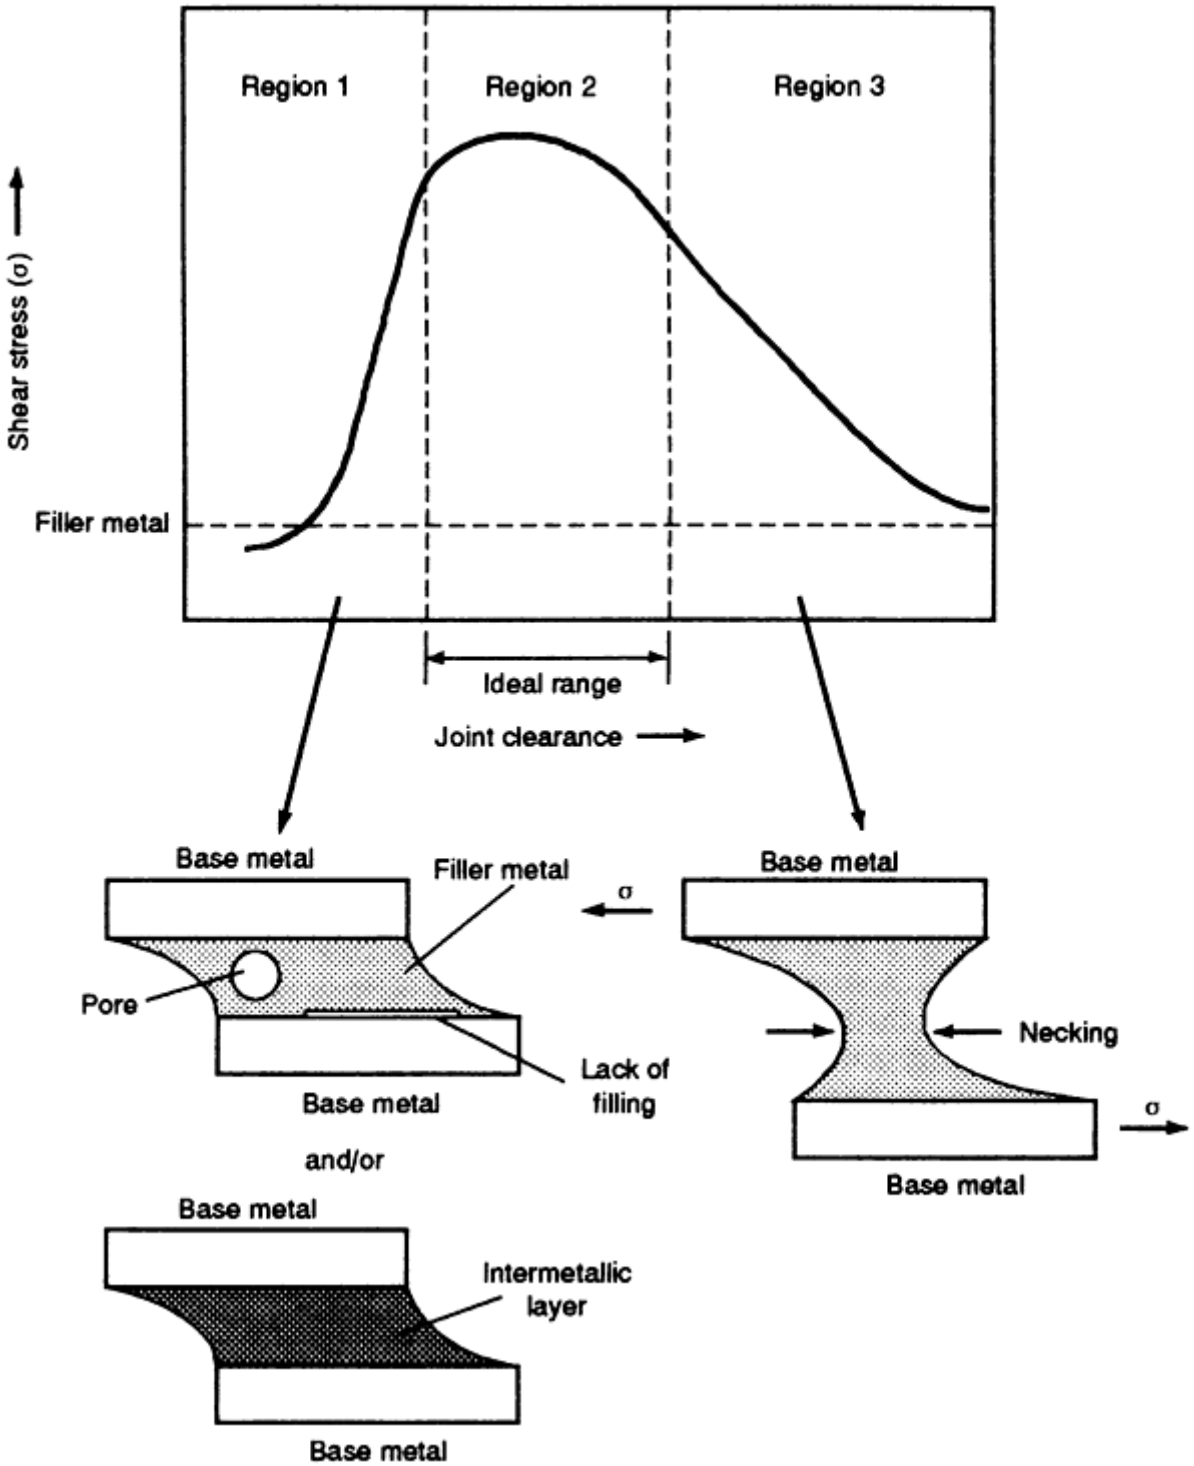

FIG. 10 EFFECT OF JOINT CLEARANCE ON THE STRENGTH OF A BRAZEMENT

With clearances indicated in region 2, the joint strength increases to a value close to that of the base metal, but only in the case of brazing. This increase in strength is due to a constraint generated by the base metal in the filler metal. As the clearance further increases, region 3, the constraint in the filler metal decreases and the mechanical properties of the filler metal will determine the strength of the joint. The lack of joint filling and the presence of voids can also affect the properties in this region.

Mutual Dissolution and Erosion. In the presence of the liquid filler metal, base metal dissolution can occur. Depending upon the mutual solubility of the base metal and the filler metal, excessive dissolution or erosion can result. Additionally, the alloying elements found in the filler metal may migrate into the base metal through solid-state diffusion or liquid

metal grain boundary penetration. Figure 11(a) shows a phase diagram that suggests complete solubility of the filler metal (fm) and the base metal (bm). The amount of base metal dissolution expected in the system represented by Fig. 11(a) will be higher than that expected in the eutectic phase diagram shown in Fig. 11(b). The effect of dissolution depends on the kinetics of the reaction. One example of mutual solubility is the brazing of nickel-base alloys with pure copper. The copper-nickel phase diagram is similar to Fig. 9(a).

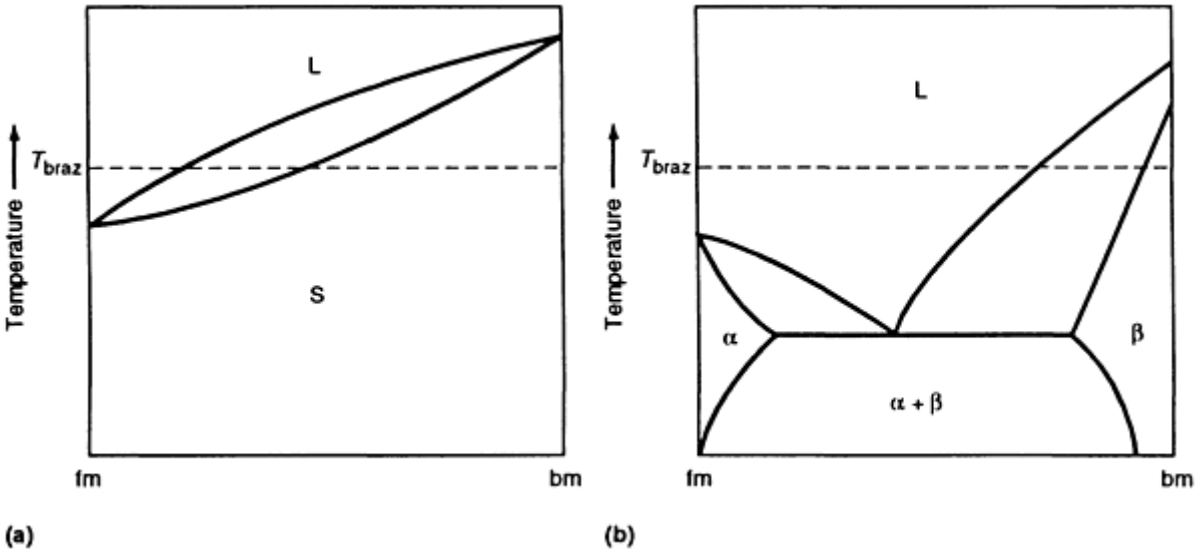

FIG. 11 HYPOTHETICAL PHASE DIAGRAMS BETWEEN FILLER METAL AND BASE METAL. (A) COMPLETE SOLUBILITY OF FILLER METAL AND BASE METAL. (B) EUTECTIC PHASE

Liquid penetration through grain boundaries may increase with decreasing mutual solubility. Copper is known to cause hot shortness in steel because of its limited solubility in steel (0.3 wt% at 590 °C, or 1095 °F) which favors the grain boundary liquid penetration.

Vapor Pressure. The vapor pressure of an element increases with increasing temperature. Furthermore, decreasing the surrounding pressure, such as in a vacuum, further increases the vaporization loss. This will cause variations in the chemical composition of the filler metal. As a consequence, the flowing behavior of the filler metal can be impaired. Metal vaporization may also promote porosity formation in the joint. Figure 12 summarizes the relationship between joining temperature, furnace pressure, and metal vapor pressure. Using silver as an illustration, the equilibrium vapor pressure at 1000 °C (1830 °F) is 13 Pa (10^{-1} mm Hg). If the furnace pressure is lower than 13 Pa (10^{-1} mm Hg), silver will vaporize. The loss due to vaporization is critical for soldering, especially when joined under vacuum.

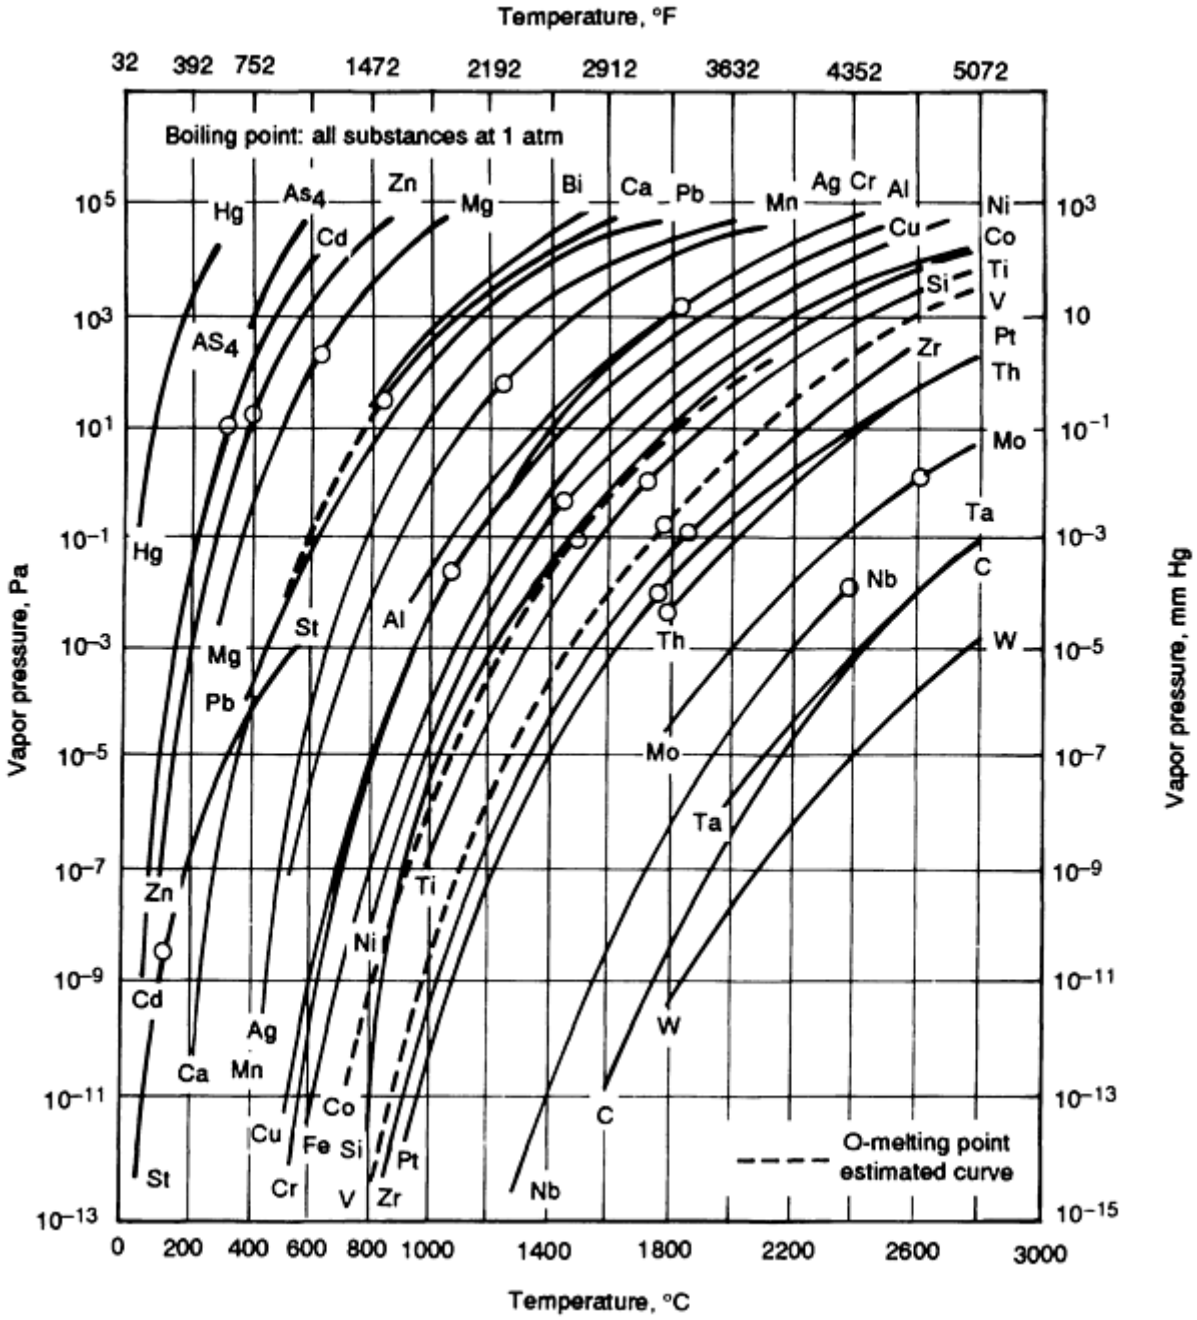

FIG. 12 VAPOR PRESSURE AS A FUNCTION OF TEMPERATURE. SOURCE: REF 3

Vapor pressure of metallic elements is particularly important in vacuum tube applications. The presence of high vapor pressure elements in the filler metal is restricted because of potential contamination inside the tube. The American Welding Society (AWS) filler metal specification for vacuum brazing limits the amount of high vapor pressure elements in the alloys. For elements that have vapor pressures higher than 13 μPa (10^{-7} torr) at 500 °C (930 °F), such as magnesium, antimony, potassium, sodium, lithium, thallium, sulfur, cesium, rubidium, selenium, tellurium, strontium, and calcium, the maximum allowed concentrations are 0.001 and 0.002 wt% for grades 1 and 2, respectively. In addition, the total sum of high vapor pressure elements, including zinc, cadmium, and lead, is limited to 0.010 wt%.

Fluxes and Atmospheres Selection. The major functions of fluxes in brazing and soldering are to remove oxides from the base metal surface by a reduction and/or dissolution reaction, to protect the clean surface from reoxidation, and to modify the surface tension of the molten metal. These functions can be achieved through chemical reactions that are, in general, thermally activated.

Chemical reactions typically occur between the surface oxide and the active components of the flux. The surface oxide can undergo a reduction reaction that results in the formation of a soluble compound, as exemplified below:

$$(MO)_{SURF} + (FLUX) \rightarrow M_{SURF} + O + \ldots \quad \textbf{(EQ 5)}$$

$$(MO)_{SURF} + (FLUX) \rightarrow M_{SURF} + (MO \cdot FLUX)_{VEHICLE\ SOLUB.} \quad \textbf{(EQ 6)}$$

$$\rightarrow M_{SURF} + (MO \cdot VEHICLE)_{FLUX\ SOLUB.} \quad \textbf{(EQ 6A)}$$

where MO is the metal oxide, M is the metal, and O is oxygen. The subscript *surf* indicates that the reaction is located at the surface. (MO · flux) and (MO · vehicle) represent metal oxides dissolved in the flux or vehicle. Equation 5 represents a reduction of a surface oxide by a flux, resulting in a metal at the surface plus the evolution of oxygen. Equations 6 and 6a(a) represent a reduction of a surface oxide by a flux succeeding in a metal at surface and the oxygen soluble in the vehicle flux (Eq 6) or in the flux (Eq 6aa).

The chemical activity of a flux is strongly dependent on temperature and on the properties of a flux, such as thermal stability, activation temperature, and deactivation temperature, that characterize the activation temperature range. Suitable joining processes require that the flux components be stable throughout the joining cycle. They should not evaporate or decompose. For example, in applications in which the boiling point of the flux vehicle is lower than the joining temperature, the flux is thermally stable and able to protect the clean surface from reoxidation. On the other hand, the flux vehicle may have a high boiling point and remain intact on the part surface. The liquid flux vehicle assists the flux solder to act as a physical barrier that ensures protection of the clean surface against reoxidation.

The activation temperature range is defined as the temperature range at which a flux reaches its maximum chemical activity. The deactivation temperature is the temperature at which the flux breaks down and is no long active. It is important that the joining temperature remains slightly higher than the minimum activation temperature for maximum activity. Figure 13 shows two temperature ranges. The first one corresponds to the maximum flux chemical activity and dissolution and reduction reactions. The second corresponds to the breakdown of the fluxes and a loss of flux chemical activity.

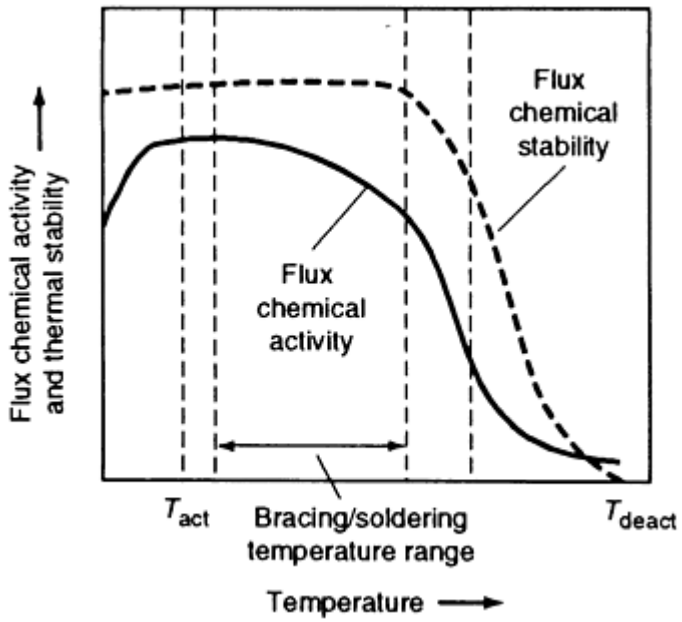

FIG. 13 EFFECT OF TEMPERATURE ON FLUX CHEMICAL ACTIVITY AND FLUX THERMAL STABILITY

Fluxes are not designed to remove grease, oil, dirt, or paint from the part surface. Thus, the joint surface must be free of these contaminants prior to joining.

Another common practice in brazing is the use of protective atmospheres. Combustion gases of different compositions, reducing gases such as NH_3 and hydrogen, and inert gases such as argon and nitrogen are typical examples of the gases used. In the case of combustion gases, the oxygen and carbon potentials of the gases determine the oxidation and reduction behavior of the alloying elements and surface oxides. Thermodynamic calculations can also be carried out to relate these potentials to the partial pressures of CO and CO_2. The water vapor content, similar to that of CO_2, is usually expressed as the dew point of the gas.

In the case of a hydrogen-rich atmosphere, it is the hydrogen-oxygen reaction alone that controls the oxidation-reduction behavior of the filler metal and base metal. For a particular brazing atmosphere and dew point, a threshold temperature must be reached to start to reduce the surface oxides that cover both the base metal and filler metal. This temperature is specific for each metal-metal oxide system and is related to the oxide stability.

Figure 14 shows the metal-metal oxide equilibria in pure hydrogen atmospheres. In this diagram the region under a metal-metal oxide curve represents the conditions under which the metal oxide can be reduced by hydrogen. For example, brazing a stainless steel at 925 °C (1700 °F) in a hydrogen-rich atmosphere can be successfully performed only if the dew point is lower than -43 °C (-45 °F). In this case the thermodynamic conditions are favorable to reduce the chromium oxide which will promote good wetting and spreading.

Additional Metallurgical Considerations. Exposure to brazing temperatures can also result in base metal embrittlement. These embrittling conditions must be taken into consideration in the design of a brazed joint and brazing process parameters. Soldering occurs at lower temperatures than brazing, so embrittlement seldom happens in the base metal of a soldered joint because it is thermally activated. Embrittlement in the base metal can be caused by second-phase precipitation, hydrogen embrittlement, or the brazing of dissimilar metals.

Second-Phase Precipitation. The most common embrittlement phenomenon is second-phase precipitation of carbides at grain boundaries. Plain steels with low carbon contents can be embrittled by the precipitation of a cementite (Fe_3C) film at the grain boundary. For a steel with 0.02 wt% C, this phenomenon occurs at approximately 400 °C (750 °F).

Ferritic and austenitic stainless steels can have their corrosion behavior and toughness impaired by chromium carbide precipitation between 450 to 850 °C (750 to 1560 °F). This precipitation forms a chromium-depleted zone around the carbides and along the grain boundaries, which decreases the corrosion resistance of the alloy. This phenomenon is called sensitization. For the austenitic stainless steels, a low-carbon steel or a stabilized steel should be chosen to avoid the loss in corrosion resistance. Higher chromium diffusivity in the ferritic stainless steels results in a narrower chromium-depleted zone than that observed in the austenitic stainless steels. Thus, a heat treatment can remove the chromium-depleted zone and restore corrosion resistance. However, the toughness of the ferritic stainless steels will not be recovered by heat treatment.

Aluminum-magnesium alloys can experience an Al_3Mg_2 grain boundary precipitate that decreases the corrosion resistance of the alloy. In this case the difference between the corrosion potentials of the precipitate and the matrix increases the corrosion rate at the matrix-precipitate interface. Depending on the conditions, intergranular corrosion may take place, followed by stress-corrosion cracking.

Hydrogen Embrittlement. Hydrogen can cause severe embrittlement in many different materials. It can diffuse faster at room temperature and may cause a delayed embrittlement, mainly in steels. This type of embrittlement is not important for soldering.

In steels, hydrogen embrittlement occurs when four conditions are met: favorable microstructure (martensite, bainite, ferrite), hydrogen level, residual stress, and low temperature (<<100 °C, or 212 °F). These four conditions should be kept in mind when choosing a brazing procedure for steels. For example, steel brazing in a hydrogen-rich atmosphere may be inappropriate due to hydrogen pickup during joining.

Two mechanisms have been proposed for hydrogen embrittlement in nonferrous alloys: water vapor buildup and hydride precipitation. If an alloy has oxides precipitated along the grain boundaries, hydrogen will diffuse toward the oxides and may react with them to form water vapor. The pressure built up because of water vapor at the grain boundaries can separate the boundaries and promote embrittlement of the alloy. This is the case with electrolytic tough pitch copper that is brazed in a hydrogen-rich atmosphere.

Refractory metals such as titanium, zirconium, niobium, tantalum, tungsten, and molybdenum are very susceptible to the presence of interstitial elements (hydrogen, nitrogen, oxygen, and carbon). These interstitials distort the metal lattice, causing a strong interstitial solid solution hardening that diminishes the toughness of these metals. In a body-centered cubic (bcc) lattice, the solubility of the interstitial elements is reduced, which may result in the precipitation of the carbides and nitrides in these metals. In the case of hydrogen, a hydride will precipitate. The brazing conditions should be carefully selected to avoid interstitial pickup and the formation of a second interstitial-based phase during brazing.

Brazing of Dissimilar Materials. When different materials are brazed together, the possibility of intermetallics formation and the effect of the mismatch between the coefficients of thermal expansion must be considered. The formation of intermetallics was described above. The mismatch between the coefficients of thermal expansion generates residual stresses that influence the mechanical properties of the joint. Ultimately, fracture may occur, depending on the residual stress level. This effect is particularly important in the case of metal-to-ceramic brazing, in which the thermal expansion coefficients are very different. Table 5 presents some physical properties for selected materials.

(A) SUBLIMATION POINT.

(B) 5% POROSITY.

(C) 2% POROSITY

The strain developed during heating and cooling by mismatch of thermal expansion coefficients can be evaluated using Eq 7.

$$\Delta\varepsilon = \Delta\alpha \cdot \Delta T \qquad \textbf{(EQ 7)}$$

where $\Delta\varepsilon$ is the strain variation, $\Delta\alpha$ is the thermal expansion coefficient mismatch, and ΔT is the temperature variation below solidus temperature. However, more in-depth computations using finite-element analysis should be performed to identify stress concentrations as a function of the joint configuration.

In the case of a silicon nitride (Si_4N_3) part being joined to an austenitic stainless steel component at 1325 K (1925 °F) using a filler metal with a solidus temperature of 1298 K (1877 °F), the value of the strain is estimated at 16.7×10^{-3} (thermal expansion coefficient mismatch = 16.7×10^{-6} K). Correspondingly, a stress of 5.078 GPa (much higher than the strength of silicon nitride) is generated. Based on this estimation, it is very likely that cracks will nucleate and propagate in the brittle ceramic material. The actual value of the stress is, however, lower than the value calculated by Eq 7 once the metal deforms and the stress developed in the joint is alleviated.

One technique for decreasing the residual stress level in the joint is to perform brazing with a soft, ductile metal interlayer. In this case the interlayer will deform and will accommodate the residual stresses generated by the mismatch between the coefficients of thermal expansion. Figure 15 shows this technique.

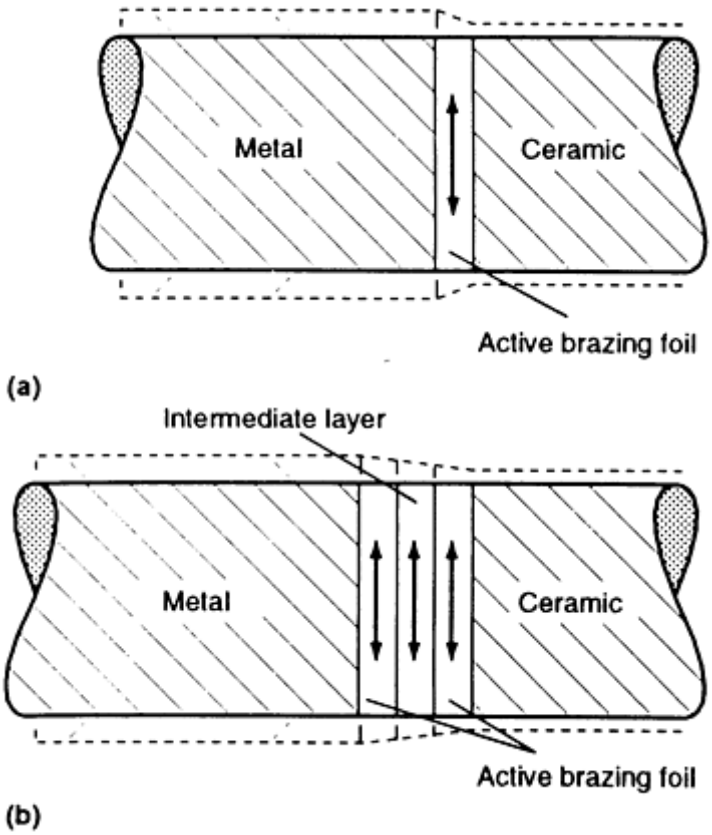

FIG. 15 ADDITION OF SOFT DUCTILE METAL INTERLAYER TO REDUCE RESIDUAL STRESSES IN A JOINT. (A) WITHOUT INTERLAYER. (B) WITH INTERLAYER

The mismatch in the strength may also generate a stress concentration in the joint under applied loads. In this case, assuming the same load and a metal-ceramic joint, the deformation in the ceramic is lower than that in the metal. Thus, as a result of the different deformation ($\varepsilon_{metal} - \varepsilon_{ceramic}$), a stress concentration is created at the interface, as shown in Fig. 16.

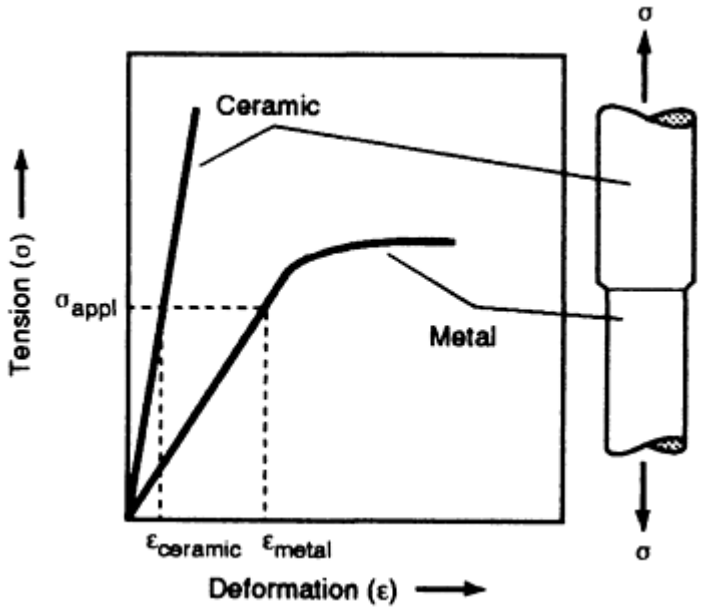

FIG. 16 STRESS CONCENTRATION AS A FUNCTION OF MISMATCHED STRENGTH

Brazeability and Solderability of Engineering Materials

S.D. Brandi, Escola Politécnica da Universidade de São Paulo, Brazil; S. Liu, Colorado School of Mines; J.E. Indacochea and R. Xu, University of Illinois at Chicago

Brazing and Soldering Characteristics of Engineering Materials

To continue the discussion on brazeability and solderability of engineering materials, the joining process characteristics will be discussed. More detailed information about practices for brazing and soldering specific materials is available in the Section "Procedure Development and Practice Considerations for Brazing and Soldering" in this Volume.

All brazing and soldering processes consist of a cleaning operation, a filler metal addition, and a heating and cooling cycle. In some processes the material is heated faster than in others, which may require different temperature and time control. The faster the joining process, the lower the probability that intermetallics will be formed and the narrower the heat-affected zone (HAZ) in the base metal. On the other hand, fast heating may lead to high residual stress levels.

Depending on the joining process characteristics (heating and cooling cycles, joint design, protection of the joint, and so on), the mechanical and corrosion behavior could be different for brazed or soldered joints of the same base metal and filler metal. Figure 17 presents the thermal experience of a joint prepared using three different heating methods. Curve A

represents induction or resistance heating, characterized by faster heating and cooling. Torch heating is generally more diffused and performed at a slower rate. As a result, base metal heating is more extensive, as shown by curve B. The thermal performance of furnace heating is described by curve C, where uniform heat in both base metal and joint is achieved.

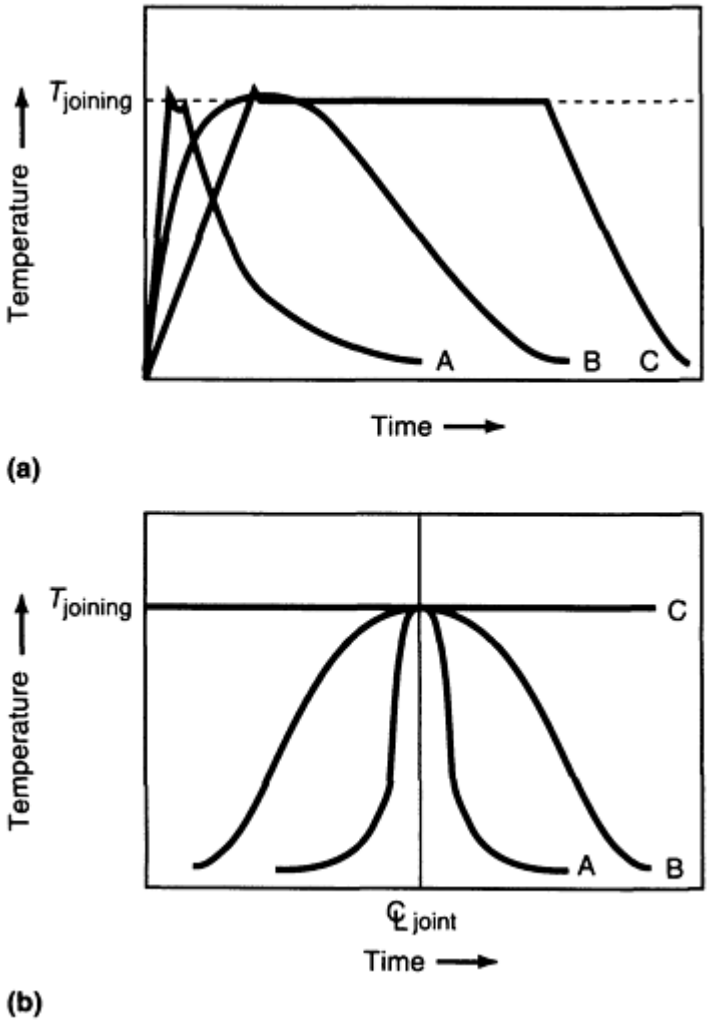

FIG. 17 THERMAL PERFORMANCE OF A JOINT AS A FUNCTION OF HEATING METHOD. (A) THERMAL CYCLE. (B) TEMPERATURE DISTRIBUTION. A, INDUCTION OR RESISTANCE HEATING; B, TORCH HEATING; C, FURNACE HEATING

The heating method is chosen according to base metal and filler metal characteristics, base metal-filler metal interaction, joint geometry, quality, cost, and productivity. Tables 6 and 7 summarize the common heating methods for brazing and soldering different materials.

Low-Carbon Steels, Low-Alloy Steels, and Tool Steels

Brazing of low-carbon steels, low-alloy steels, and tool steels is a common practice. In this article, low-carbon steel is defined as a carbon steel with a maximum carbon content of 0.1 wt% and with silicon and manganese within the usual range. Low-alloy steels include not only the steels with a maximum total alloy content of 5.0 wt%, but also the high-strength low-alloy steels (microalloyed steels). Tool steels are high-alloy steels designed for high hardness and wear resistance. Tool steels can be further divided into two groups: carbon tool steels and high-speed tool steels. The mechanical properties of carbon tool steels depend mainly on the carbon content, which lies between 0.6 and 1.4 wt%. The high-speed tool steels are generally lower in carbon content, and their mechanical properties are mainly achieved by alloying elements such as tungsten, molybdenum, chromium, and vanadium. These elements are carbide formers. These carbides may affect the wetting and spreading behaviors of the braze alloy at the microstructural level. They also change the characteristics of iron oxide, making wetting and spreading more difficult.

Because each type of steel has a different set of mechanical properties, the brazing procedure for these steels should be determined as a function of the process characteristics and possible deterioration in material properties due to heating. In particular, the type of heating and heating cycle control (temperature and time), the kind of quenching medium (oil, water, air, and so on), and the optimal brazing conditions (filler metal type, flux or atmosphere type, cleaning conditions, joint geometry, fixtures, and so on) must be considered.

Low-carbon and low-alloy steels can be brazed by all brazing processes, but torch, furnace, induction, and dip brazing are most commonly used. Torch brazing of low-alloy steels should be performed with a neutral or slightly reducing flame, to minimize thermal effects on the base metal, filler metal, and flux. However, this process does not offer accurate temperature control, and excessive grain growth may occur. On the other hand, furnace brazing generally offers more

accurate temperature and brazing cycle control. The chemical composition of the atmosphere, if not adequately controlled, may lead to decarburization or hydrogen pickup, which eventually will degrade the steel properties.

The presence of surface oxides on steels affects the wetting of the molten filler metal. In general, surface oxides on low-carbon and low-alloy steel can be easily removed by means of a flux or atmosphere during brazing. AWS specification B2.2 recommends different brazing conditions for steels that have more than 1.0 wt% Cr and for those that contain aluminum and/or titanium. These three elements change the characteristics of the iron oxide on the surface. They increase the adherence of the oxides and decrease the diffusivity of oxygen in the oxide layer. Thus, the flux or brazing atmosphere must be able to reduce these oxides and promote wetting.

Carbon and low-alloy steels can be brazed with BCu, BAg, and RBCuZn filler metals. These filler metal groups present brazing temperature ranges of 1095 to 1150 °C (2000 to 2100 °F), 620 to 900 °C (1145 to 1650 °F), and 910 to 982 °C (1670 to 1800 °F), respectively. Based on the brazing temperature range, two different brazing techniques can be performed (Fig. 18). If the brazing temperature is higher than the austenitization temperature, A_1, of the steel (Fig. 18a and b), brazing can be done together with the first part of the heat treatment. In other cases, the brazing process may require lower temperatures so it can be performed simultaneously with the first or secondary tempering of the steel (Fig. 18c).

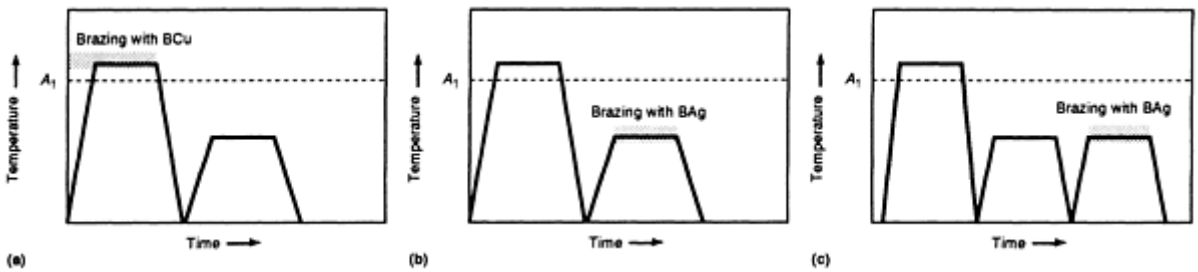

FIG. 18 INCORPORATION OF BRAZING OPERATION INTO HEAT TREATMENT CYCLE. (A) DURING AUSTENITIZATION PROCESS (BCU FILLER METAL). (B) DURING AUSTENITIZATION PROCESS (BAG FILLER METAL). (C) DURING TEMPERING PROCESS. A_1, AUSTENITIZATION TEMPERATURE

As a lower temperature process, soldering is related more to wetting phenomena than to microstructural changes in the steels. As with brazing, surface preparation and flux selection are fundamental to achieving a sound joint. Low-carbon and low-alloy steels present good solderability if the surfaces of the steels are properly cleaned and an aggressive flux is used.

Common filler metals used to solder steel belong to the tin-lead alloy group, with 20 to 50 wt% Sn. Because iron forms two intermetallics with tin, FeSn and Fe_2Sn, the amount and distribution of these intermetallics may impair the soundness of the joint. To minimize the presence of intermetallics, a solderable protective layer, such as copper and nickel, should be used. These layers present a limited intermetallic formation and can improve the solderability. The nickel layer must be protected from excessive oxidation by an overcoat of gold.

Tool steels having higher hardenability than the low-carbon, low-alloy steels, and the usual microstructure is tempered martensite with a fine dispersion of carbides. This microstructure is susceptible to thermal gradients, which may result in thermal cracking. During cooling, depending on the size of the component, the outer part transforms to martensite with volumetric expansion while the core remains untransformed and at a higher temperature. Together with different thermal expansion coefficients, this phase transformation may induce residual stresses and cracking in the transition region (between transformed and untransformed microstructure). Therefore, the heating and cooling of tool steels should be carefully controlled to minimize thermal gradients throughout the component.

Tool steels can be brazed by most brazing processes. However, torch brazing should be used carefully because of the lack of control in heating. As a result, thermal cracking is quite common. Induction brazing can be performed if a ductile metal insert is placed in the joint. The soft metal reduces the residual stresses generated and minimizes the cracking tendency. A composite filler metal (for example, copper-silver-copper sandwich) can be used to balance the shear stresses generated

during brazing. As indicated previously, furnace brazing presents the best temperature control, but the composition of the furnace atmosphere must be regulated to avoid decarburization of the base metal.

The filler metal groups are similar to those used to braze low-carbon and low-alloy steels. Some tool steels may have a higher chromium content, so the fluxes must be specially designed to promote wetting in spite of the oxidation potential of chromium.

Soldering of tool steel is not commonly done due to a lack of relevant applications.

Stainless steels are designed for better corrosion and oxidation resistance than ordinary steels. Chromium is responsible for this improvement. However, as the amount of chromium increases, the surface oxide changes from an $FeO/Fe_3O_4/Fe_2O_3$ to a more stable Cr_2O_3, which is difficult to wet. The presence of titanium, aluminum, manganese, and silicon in the stainless steels further modifies the nature of the surface oxide. The flux or the joining atmosphere must be able to promote reduction or dissolution of the oxide layer and enhance wetting and spreading behavior.

Stainless steels are often divided into five groups: austenitic, ferritic, martensitic, precipitation-hardened, and duplex. Filler metal selection will depend on the particular application:

- SERVICE CONDITIONS SUCH AS TEMPERATURE, STRESSES, AND ENVIRONMENT
- HEAT TREATMENT (ESPECIALLY FOR MARTENSITIC AND PRECIPITATION-HARDENING STAINLESS STEELS)
- BRAZING PROCESS CHARACTERISTICS (INCLUDING THERMAL CYCLE CONTROL)
- WETTING AND SPREADING BEHAVIOR
- METAL DISSOLUTION AND EROSION OF THE BASE METAL
- SECOND-PHASE PRECIPITATION (CARBIDES, σ PHASE)
- COST

Austenitic stainless steels exhibit good corrosion resistance, except in chloride-content environments. According to AWS specification B2.2, the austenitic and austenitic-alloyed-with-titanium stainless steels are classified into two groups. All other stainless steel groups are classified as one.

Corrosion resistance of an austenitic stainless steel is impaired by sensitization, which is a precipitation of chromium carbides along the grain boundaries when slowly heating or cooling the steel through the temperature range of 450 to 850 °C (750 to 1560 °F). The amount of precipitation depends on the temperature, time, carbon content, grain size, degree of plastic deformation, and the amount of stabilizers such as titanium and niobium. If not controlled, the heating cycle during brazing may sensitize the base metal. Based on Fig. 17, the best thermal experience to avoid sensitization is induction or resistance brazing (curve A). Furnace brazing (curve C) can give good results if joining is carried out at a temperature higher than the sensitization range, followed by a fast cooling.

Often the base metal that is susceptible to sensitization can be substituted with a low-carbon or a niobium-stabilized stainless steel, without the need to qualify a new brazing procedure (according to AWS B2.2).

Galvanic corrosion may also occur because of the potential difference between the base metal and the filler metal. In the case that the filler metal is less noble than the base metal, it will corrode faster and result in a crevice, which will further accelerate the corrosion process. A lack of joint filling (promoted by poor wetting) or void formation may also create a crevice that will corrode with or without galvanic action.

The chromium-nickel stainless steels are prone to stress-corrosion cracking (SCC). During brazing, the filler metal may penetrate along the grain boundaries of the base metal and form a grain boundary network of the filler metal. This grain boundary penetration, associated with tensile stresses and/or cyclic stresses and an aggressive medium, may promote stress-corrosion cracking. An example of stress-corrosion cracking at room temperature occurs when a sensitized austenitic stainless steel is exposed to fluorides (residual from brazing fluxes). Thus, cleaning after brazing is as important as the brazing operation to increase the life of brazed components.

Austenitic stainless steels have considerably higher coefficients of thermal expansion and lower thermal conductivities than other steels. The combination of these physical properties generally results in large distortions in a brazement. In the

case of localized heating, the broad heat source that heats up a large region may also induce plastic deformation in a large region, which generates residual stresses during cooling. For example, torch brazing of stainless steels should be used carefully when distortion is an important factor.

Stainless steels can be brazed using BCu, BAg, BNi, BCo, BPt, BPd, and BAu filler metal groups. Table 8 shows some filler metals and respective service temperatures of the brazement.

TABLE 8 BRAZING TEMPERATURES AND SERVICE TEMPERATURES FOR FILLER METALS USED IN THE BRAZING OF STAINLESS STEELS

Source: Ref 6

Stainless steels can be soldered using a nickel solderable coating and a gold protection finish to eliminate the need for harsh cleaning treatment.

Ferritic stainless steels usually have less chromium than austenitic grades. Sensitization is faster and at a slightly lower temperature range when compared with austenitic grades. So, the same brazing procedure should be followed to braze ferritic grades. A heating at the sensitization temperature range may eliminate the chromium-depleted zone, during or after brazing.

Ferritic stainless steel brazements are subjected to interfacial corrosion when brazed with some BAg alloys. A filler metal containing nickel can be used to minimize the corrosion rate. A special filler metal, BAg-21, was designed to braze AISI 403 ferritic stainless steel and reduce this corrosion attack.

Because the strength of ferritic grades is drastically reduced above 815 °C (1500 °F), special fixtures must be designed to maintain the shape of the component if brazing is to be performed at higher temperatures.

Martensitic and Precipitation-Hardening Stainless Steels. The brazing of a martensitic or a martensitic-type precipitation-hardening steel is similar to that of a martensitic low-alloy steel. The techniques shown in Fig. 18 can also be applied to these steels. The difference between the coefficients of thermal expansion of a transformed and an untransformed microstructure in a component must be considered to avoid residual stresses and subsequent cracking during cooling.

Some martensitic and precipitation-hardening stainless steels contain aluminum and titanium, which require special fluxes or a suitable atmosphere (dry H_2) to promote wetting. The hydrogen-rich atmosphere may cause hydrogen embrittlement of the martensitic stainless steels.

Duplex stainless steels generally contain a mixed microstructure of 50% ferrite and 50% austenite. They have better corrosion resistance than other stainless steels, and they have better mechanical properties than the austenitic and ferritic grades.

Few published data related to duplex stainless steel brazing are available. Compared with the austenitic grades, however, the duplex grades have higher chromium contents, so wetting and spreading problems may be expected.

Duplex stainless steels are susceptible to several embrittlement mechanisms, particularly chromium carbide formation, σ-phase precipitation, and 475 °C (885 °F) embrittlement. They all impair the corrosion resistance and the toughness of these steels. The effects of chromium carbide precipitation were discussed above. In many aspects, σ-phase precipitation is similar to sensitization in that it generates a chromium-depleted zone and occurs at almost the same temperature range (450 to 900 °C, or 840 to 1650 °F). Small amounts of σ phase (~1%) can reduce Charpy V-notch absorbed energy by 50%. Sigma phase also increases by at least eight times the corrosion rate of duplex stainless steels. To avoid σ-phase precipitation, brazing should be performed at high temperatures, greater than 950 °C (1740 °F).

The 475 °C (885 °F) embrittlement occurs in the ferrite phase at a temperature range from 300 and 500 °C (570 to 930 °F). It is characterized by the formation of a chromium-rich phase (α'), which causes a precipitation-hardening effect in the ferritic phase and, as a consequence, decreases the toughness of the steel. The presence of α' may also impair the corrosion resistance of the steel.

Duplex stainless steels also experience strength loss at temperatures near 1000 °C (1830 °F). Special fixtures must be designed to maintain the shape of the component during brazing.

Cast Irons

The brazing of gray, ductile, and malleable cast irons differs from the brazing of steel in two principal respects: special precleaning methods are necessary to remove graphite from the surface of the iron; and the brazing temperature is kept as low as feasible to avoid reduction in the hardness and strength of the iron. The processes used for brazing cast irons are the same as those used for steel--furnace, torch, induction, and dip brazing.

Because most cast irons are brazed at relatively low temperatures, the filler metals used are almost exclusively silver brazing alloys. Of these silver alloys, BAg-1 is most often used for brazing of cast iron, principally because it has the lowest brazing temperature range. A fluoride-type flux such as AWS type 3A is usually used with BAg-1 filler metal. Soldering of cast iron is not usual.

Relatively high silicon content and sand inclusions on as-cast surfaces have some adverse effects on the brazeability of cast iron. These effects, however, are less significant than the adverse effect of graphite, which is present in all gray, ductile, and malleable cast irons. Graphite has essentially the same effect on machined joint surfaces as on as-cast surfaces. Although gray, ductile, and malleable irons all have lower brazeabilities than carbon or low-alloy steels, the three types of iron are not equal in brazeability.

Malleable iron is generally considered the most brazeable of the three types of cast iron, largely because the total carbon content is somewhat lower (seldom over 2.70 wt%) and, therefore, graphitization is less. Brazeability is also enhanced because the graphite occurs in the form of approximately spherical nodules that are easier to remove or cover up (as by abrasive blasting). Also, malleable iron is lower in silicon than the other types of cast iron and thus is less graphitized, which makes it better suited for brazing.

Ductile iron and gray iron can have nearly the same composition. However, the graphite particles in ductile iron are spheroidal rather than flake-shaped. The spheroidal shape is more favorable for brazing. Gray iron, which is characterized by large flakes of graphite, is the most difficult type of cast iron to braze. Until the development of electrolytic salt-bath cleaning, brazing of gray iron was considered impractical.

A number of methods have been tried for preparing cast iron surfaces for brazing; most of them have been only partly successful. Abrasive blasting with steel shot or grit has proved reasonably successful for preparing the surfaces of ductile and malleable iron castings, but it is seldom suitable for preparing surfaces of gray iron casting. Electrolytic treatment in a molten salt bath, alternatively reducing and oxidizing, has been the most successful method for surface preparation and is applicable to all graphitic cast irons. Ordinary chemical cleaning methods, such as degreasing, detergent washing, or acid pickling, have the distinct disadvantage of not removing surface carbon, which interferes with bonding.

Before any procedure for cleaning is adopted, tests should be made by cleaning samples of the iron intended for use in the castings to be brazed, fluxing the samples, and applying filler metal (preferably on a smooth, flat surface). The samples are then heated to the pre-established brazing temperature, cooled, and examined visually. If the samples show that the filler metal has not uniformly wetted the test piece, the surface is not sufficiently clean.

Aluminum Alloys

Brazing of aluminum alloys was made possible by the development of fluxes that disrupt the oxide film on aluminum without harming the underlying metal and filler metals (aluminum alloys) that have suitable melting ranges and other desirable properties, such as corrosion and mechanical resistance. The aluminum-base filler metals used for brazing aluminum alloys have liquidus temperatures much closer to the solidus temperature of the base metal than those for brazing most other metals. For this reason, close temperature control is required in brazing aluminum. The brazing temperature should be approximately 40 °C (70 °F) below the solidus temperature of the base metal.

The non-heat-treatable wrought aluminum alloys, such as the 1*xxx*, 3*xxx*, and 5*xxx* (low-magnesium) series, have been brazed successfully. Alloys that contain higher magnesium contents are more difficult to braze by the usual flux methods because of poor wetting and excessive penetration by the filler metal. Filler metals that melt below the solidus temperatures of most commercial, non-heat-treatable wrought alloys are available.

The most commonly brazed heat-treatable wrought alloys are those of the 6*xxx* series. The 2*xxx* and 7*xxx* series of aluminum alloys have low melting points and therefore are not normally brazeable. Alloys 7072 (used as a cladding material only) and 7005 are the few exceptions. Alloys that have solidus temperatures above 595 °C (1100 °F) are easily brazed with commercial binary aluminum-silicon filler metals. Higher-strength, lower-melting-point alloys can be brazed with proper attention to filler metal selection and temperature control, but the brazing cycle must be short to minimize penetration by the molten filler metal. Sand and permanent mold casting alloys with high solidus temperatures are brazeable.

Commercial filler metals for brazing aluminum are aluminum-silicon alloys containing 7 to 12 wt% Si. Brazing fillers with lower melting points are attained, with some sacrifice in resistance to corrosion, by adding copper and zinc. Filler metals for vacuum brazing of aluminum usually contain magnesium.

The optimum brazing temperature range for an aluminum-base filler metal is determined by the melting range of the filler metal, the amount of molten filler metal needed to fill the joint, and the mutual solubility between the filler metal and the base metal.

Filler metals for separate application from the base metal to be brazed are available as wire and sheet.

Most filler metals are used for any of the common brazing processes and methods. Two alloys, 4004 and 4104, have been developed exclusively for use in fluxless vacuum brazing. They contain additions of magnesium and magnesium-bismuth, respectively, with a brazing temperature range of approximately 590 to 605 °C (1090 to 1120 °F). Similarly, a proprietary mixture of filler metal BAlSi-4 (alloy 4047) in powder form and a chemical compound is used exclusively with dip brazing. The manufacture of filler metal in sheet and wire forms becomes more difficult as the silicon content increases. Only BAlSi-2 (alloy 4343), BAlSi-4 (alloy 4047), and alloy 4004 are available as sheet.

Brazing of aluminum to other alloys should be performed only after considering the differences between:

- COEFFICIENTS OF THERMAL EXPANSION, WHICH CAN AFFECT THE RESIDUAL STRESS LEVEL AND CHANGE THE CLEARANCE OF THE JOINT
- THERMAL CONDUCTIVITIES, WHICH CAN GENERATE DIFFERENT HEATING RATES
- CORROSION RESISTANCES OF ALUMINUM AND THE OTHER MATERIAL, WHICH CAN GENERATE A GALVANIC CORROSION
- MECHANICAL PROPERTIES

Brazing of Aluminum to Ferrous Alloys. The steel component should be protected from oxidation during preheating and brazing to aluminum. In dip brazing, oxidation can be prevented by dipping unheated parts into molten flux, but this procedure has limited application because it is likely to cause warping and misalignment of the components.

Plated or coated steel can be brazed to aluminum more readily than bare steel. Copper, nickel, or zinc electroplates and aluminum, silver, tin, or hot dip zinc coatings are used to promote wetting of the steel and to minimize formation of brittle aluminum-iron compounds, thus producing a more ductile joint.

Brazing of aluminum to copper is difficult, because of the low melting temperature, 548 °C (1018 °F), of the aluminum-copper eutectic and its extreme brittleness. The eutectic is formed due to the dissolution of aluminum during

brazing. By heating and cooling rapidly, however, it is possible to make reasonably ductile joints for applications such as copper inserts in aluminum castings for electrical conductors. The usual filler metals and fluxes for aluminum-to-aluminum brazing can be used. Silver alloy filler metals, BAg-1 and BAg-1a, can also be used if heating and cooling are rapid (to minimize interdiffusion). Hot dipping the copper surfaces with solder or silver alloy filler metal improves wetting and permits shorter time at brazing temperatures. An example of brazing aluminum tubing to copper tubing is to use a transition tubing of steel with aluminum coating on one end of the tubing. The aluminum-coated end of the tubing is brazed to the aluminum, and the other end is silver brazed to the copper tubing.

Brazing of Aluminum to Other Nonferrous Metals. Aluminum-silicon filler metals are unsuitable for brazing aluminum to uncoated titanium because of the formation of brittle intermetallic compounds (titanium-aluminum and titanium-silicon). Titanium can be hot dip coated with aluminum, however, and then brazed to aluminum with the usual aluminum filler metals.

Under adequate conditions, nickel and nickel alloys are no more difficult to braze to aluminum than ferrous alloys. They can be brazed directly or precoated with aluminum. Although Monel alloys can be wetted directly, brazed joints are likely to be brittle; thus, Monel alloys are preferably precoated with aluminum.

Beryllium can be wetted directly by aluminum brazing alloys. Magnesium alloys can be brazed to aluminum, but the brazed joints have limited usefulness because of the extremely brittle aluminum-magnesium phases that form at the interface.

Soldering of aluminum and aluminum alloys is relatively simple. Compared with brazing, soldering presents advantages such as little loss of base metal temper, minimal distortion, and easy removal of flux. Aluminum is soldered at a minimum of 110 °C (200 °F) below the solidus temperature of the base metal.

Wetting and spreading are affected by the presence of an oxide at the faying surface of the joint. The nature of the aluminum oxide is different from alloy to alloy. The heat-treatable alloys present a more tenacious oxide that is more adherent and more difficult to remove. The oxides of the non-heat-treatable alloys are less tenacious and easier to remove. The action of a corrosive flux is enough to disrupt and displace the oxide layer in a non-heat-treatable aluminum alloy. However, the oxide layer of a heat-treatable alloy must be removed by chemical or mechanical means before soldering.

Solderability of aluminum alloys is influenced by alloying elements of the base metal. Generally, purer aluminum alloys are easily soldered. Table 9 presents the solderabilities of aluminum alloys. Analyzing this table, one can see that alloys of groups 1*xxx*, 3*xxx*, and 6*xxx* have good solderabilities.

TABLE 9 SOLDERABILITY OF ALUMINUM ALLOYS

ALLOY GROUP	TYPICAL ALLOY	SOLDERABILITY
1*XXX* (COMMERCIAL PURITY OR HIGHER)	1060	GOOD
	1100	GOOD

(A) SUSCEPTIBLE TO INTERGRANULAR PENETRATION BY SOLDER.

(B) SOLDERABLE ONLY WITH ABRASION OR ULTRASONIC TECHNIQUES.
(C) SOLDERABILITY GREATLY AFFECTED BY COMPOSITION.

Solderability is primarily affected by two alloying elements, magnesium and silicon. The presence of magnesium in an aluminum alloy not only reduces the wettability (more than 1 wt% Mg) but also increases the intergranular penetration (more than 0.5 wt% Mg). Magnesium content up to 1.0 wt% does not reduce the flux effectiveness, so it does not affect wetting and spreading of the molten filler metal. Alloys with less than 1.0 wt% Mg can be soldered with all flux types. Between 1.0 and 1.5 wt% Mg, the low-temperature organic-type flux is not effective to remove the surface oxide of the faying surface. When the amount of magnesium exceeds 1.5 wt%, the corrosive flux does not work either. Silicon plays the same role. Thus, if the amount of silicon is higher than 4.0 wt%, all flux types are ineffective. To solve this problem, a fluxless technique such as abrasion or ultrasonic soldering should be utilized.

Typical solders used for aluminum are shown in Table 10. The corrosion resistances of the filler metals are rated in this table. Solders that melt below 260 °C (500 °F) are called low-melting-point solders. Those that melt between 260 and 370 °C (500 and 700 °F) are called intermediate-melting-point solders. Those that melt between 370 and 440 °C (700 and 820 °F) are called high-melting-point solders.

(A) SOLDERS WITH ONLY ONE TEMPERATURE GIVEN ARE EUTECTICS.

(B) VG, VERY GOOD; G, GOOD; F, FAIR; P, POOR.

(C) C, CORROSIVE; OC, ORGANIC CORROSIVE; O, ORGANIC.

Aluminum alloys can be soldered to all usual metals and nonmetallic materials. However, loss of corrosion resistance should be expected. The high-melting-point solders are suitable for soldering mild steel, stainless steel, nickel, copper, brass, zinc, and silver directly to aluminum. Magnesium, titanium, zirconium, niobium, tantalum, molybdenum, and tungsten may be soldered if they are plated with a solderable metal coating such as silver.

Copper and Copper Alloys

Most coppers and copper alloys can be brazed satisfactorily using one or more of the conventional brazing processes: furnace, torch, induction, resistance, and dip brazing. Their brazeabilities are rated from good to excellent.

Brazing of Tough Pitch Coppers. Tough pitch coppers are subject to embrittlement when heated at temperatures above 480 °C (900 °F) in reducing atmospheres containing hydrogen. Phosphorus-deoxidized and oxygen-free coppers can be brazed without flux in hydrogen-containing atmospheres without risk of embrittlement, provided self-fluxing filler metals (BCuP series) are used.

The coppers, including those that contain small additions of silver, lead, tellurium, selenium, or sulfur (generally no more than 1 wt%), are readily brazed with the self-fluxing BCuP filler metals, but wetting action is improved when a flux is used and when a sliding motion between components is provided while the filler metal is molten. Precipitation-hardenable copper alloys that contain beryllium, chromium, or zirconium form oxide films that impede the flow of filler metal. To ensure proper wetting action of the joint surface by the filler metal, beryllium copper parts, for example, should be freshly machined or mechanically abraded before being brazed. Removal of beryllium oxide from joint surfaces requires the use of a high-fluoride-content flux.

Brazing of Red and Yellow Brasses. Red and yellow brasses are readily brazed with a variety of filler metals. Flux is normally required for best results, especially when the zinc content is above 15 wt%. Low-melting filler metals should be used to avoid dezincification of the yellow brasses. If added to red brass or yellow brass, lead forms a dross on heating that can seriously impede wetting and the flow of filler metal. Consequently, in brazing leaded brasses, the use of a flux is mandatory to prevent dross formation in the joint area.

Brazing of Tin-Containing Brasses. Tin-containing brasses, which include admiralty brass, naval brass, and leaded naval brass, contain up to 1 wt% Sn and may contain other alloying elements, such as lead, manganese, arsenic, nickel, and aluminum. Except for the aluminum-containing alloys, these brasses are readily brazed; they have greater resistance to thermal shock and are less susceptible to hot cracking than the high-lead brasses. For proper wetting, brasses that contain aluminum require a special flux.

Brazing of Phosphor Bronzes. Phosphor bronzes contain small amounts of phosphorus, up to approximately 0.25 wt%, added as a deoxidizer. Although susceptible to hot cracking in the coldworked condition, alloys in this group have good brazeability and are adaptable to brazing with any of the common filler metals that have melting temperatures lower than that of the base metal. The use of a flux is generally preferred. To avoid cracking, parts made from phosphor bronzes should be stress-relieved at approximately 290 to 345 °C (550 to 650 °F) before brazing. Silicon bronzes, which contain up to about 3.25 wt% Si, when applied in a highly stressed condition, are susceptible to hot shortness and stress cracking by molten filler metal. To avoid cracking, the alloys should be stress-relieved at about 290 to 345 °C (550 to 650 °F) before brazing.

Because of the formation of aluminum oxide on the surface, aluminum bronzes are generally considered difficult to braze. The oxide, which inhibits the flow of filler metal, cannot be reduced in dry hydrogen. However, alloys containing 8 wt% Al or less are brazeable, provided AWS type 4 flux is used to dissolve the aluminum oxide. Use of the low-melting, high-silver filler metals is recommended for these bronzes.

Brazing of Copper Alloys to Other Alloys. Copper and copper alloys can be brazed to other alloys. Some characteristics to consider are: coefficients of thermal expansion, thermal conductivities, corrosion behavior, and mechanical properties.

Copper nickels, which may contain from about 5 to 40 wt% Ni, are susceptible both to hot cracking and to stress cracking by molten filler metal. The silver alloy filler metals (BAg series) are preferred for brazing these alloys. In general, the use of filler metals containing phosphorus should be avoided, because the copper nickels are susceptible to the formation of brittle nickel phosphides at the interface. Nickel silvers (brasses that contain up to about 20 wt% Ni but do not contain silver) are highly susceptible to hot cracking and should be stress-relieved at about 290 °C (550 °F) before being brazed. They should be heated and cooled uniformly because of their low thermal conductivity.

Most of the alloys belonging to any one of the above groups can be brazed to an alloy of another group. However, to achieve compatibility, some compromise may be required in the selection of brazing temperature, filler metal, and flux. For example, if a copper component is to be brazed to a component made of aluminum bronze, the brazing temperature should be predicated on the lower melting temperature of the bronze, and a suitable flux should be selected to accommodate the bronze.

Soldering of Copper and Copper Alloys. Copper and copper alloys are among the most frequently soldered engineering materials. The copper oxide is easily disrupted and displaced by most flux types. The presence of alloying elements such as beryllium, chromium, silicon, and aluminum modifies the nature of the oxide, making it more tenacious. For these alloys, a special flux is recommended to remove the oxide from the surface and enhance the solderability of these base metal groups.

The most common solders for copper are tin- or lead-base solders. Tin can react with copper and form two intermetallic phases, Cu_6Sn_5 and Cu_3Sn, at the solid-liquid interface. As the thickness of this reaction layer increases, the mechanical behavior of the joint became impaired. Therefore, a thin intermetallic layer is desirable. The kinetics of intermetallic phase growth are controlled by the amount of tin and other elements in the solder, the soldering temperature, and time. Thus, to minimize the thickness of the intermetallic phase, a low-tin solder or a short soldering time should be utilized. Another way to minimize the intermetallic formation is to use a barrier coating, such as nickel, silver, or gold. These copper-tin intermetallics may also cause a dewetting phenomenon. Dewetting is defined as the withdrawal of molten solder from a surface that was previously wetted. If the solderable surface is not well protected during soldering, the intermetallic can oxidize and the dewetting phenomenon takes place.

Nickel-Base Alloys

In the selection of a brazing process for a nickel-base alloy, the characteristics of the alloy must be carefully considered. The nickel-base alloy family includes alloys that differ significantly in physical metallurgy (such as precipitation-strengthened versus solid-solution strengthened) and in process history (such as cast versus wrought). These characteristics can have a profound effect on their brazeability.

Precipitation-hardenable alloys present several difficulties not normally encountered with solid-solution alloys. Precipitation-hardenable alloys often contain appreciable (greater than 1 wt%) quantities of aluminum and titanium. The oxides of these elements are almost impossible to reduce in a controlled atmosphere (vacuum, hydrogen). Therefore, nickel plating or the use of a flux is necessary to obtain a surface that allows wetting by the filler metal.

Because these alloys are hardened at temperatures of 540 to 815 °C (1000 to 1500 °F), brazing at or above these temperatures may alter the alloy properties. This frequently occurs when using silver-copper (BAg) filler metals, which occasionally are used on heat-resistant alloys.

Liquid metal embrittlement is another difficulty encountered in brazing precipitation-hardenable alloys. Many nickel-base, iron-base, and cobalt-base alloys crack when subjected to tensile stresses in the presence of molten metals. However, liquid-metal-induced cracking of these alloys is usually confined to the silver-copper (BAg) filler metals. If precipitation-hardenable alloys are brazed in the hardened condition, residual stresses are often high enough to initiate cracking.

Oxide dispersion-strengthened alloys (ODS) are powder metallurgy (P/M) alloys that contain stable oxide, evenly distributed throughout the matrix. The oxide does not go into solution in the alloy, even at the liquidus temperature of the matrix. However, once the oxide particles are rejected into the molten matrix (for example, during fusion welding), they cannot be redistributed evenly in the matrix on solidification. Therefore, these alloys are usually joined by brazing. There are two commercial alloy classes of ODS alloys: the dispersion-strengthened nickel, and the mechanically alloyed Inconel MA 754, Inconel MA 6000, and Incoloy MA 956.

Inconel MA 754, dispersion-strengthened nickel alloys, and dispersion-strengthened nickel-chromium alloys are the easiest to braze of the ODS alloys. Vacuum, hydrogen, or inert atmospheres can be used for brazing. Prebraze cleaning consists of grinding or machining with a solvent that evaporates without leaving a residue. Generally, brazing temperatures should not exceed 1315 °C (2400 °F) unless demanded by a specific application that has been well examined and tested. The brazing filler metals for use with these ODS alloys usually are not classified by AWS. In most cases, the brazing filler metals used with these alloys have brazing temperatures in excess of 1230 °C (2250 °F); these filler metals include proprietary alloys based on nickel, cobalt, gold, or palladium.

Inconel MA 6000 is a nickel-base ODS alloy that is also γ'-strengthened. The number of alloying elements plus the γ' precipitation presents a formidable challenge to the joining of this alloy. Inconel MA 6000 has a solidus temperature of 1300 °C (2372 °F); therefore, the brazing temperature should be no higher than 1250 °C (2280 °F). Additionally, because 1230 °C (2250 °F) is the γ' solution treatment temperature, it becomes important to carefully select the brazing filler metal and to heat treat the assembly after brazing. The BNi, BCo, and specially formulated filler metals have been used in this alloy. Inconel MA 6000 is used for its high-temperature strength and corrosion resistance; unfortunately, the passive oxide scale that provides good corrosion resistance also prevents wetting and flow of brazing filler metal. Therefore, correct cleaning procedures are very important.

The brazeability of these alloys is affected by the chromium content, oxide dispersion, and the manufacturing process of the component. Chromium forms a stable and adherent oxide that impairs the wetting and spreading of the molten filler metal. The oxide dispersion also may affect the wetting and spreading behavior since an oxide is not easily wettable. The P/M manufacturing process can introduce some porosity in the component, which will act as a barrier to molten metal flow.

Heat-Resistant Alloys

Heat-resistant alloys are frequently referred to as superalloys because of their strength, oxidation resistance, and corrosion resistance at elevated temperatures. Superalloys can be subdivided into two categories: conventional cast and wrought alloys, and P/M products. Powder metallurgy products may be produced as conventional alloy compositions and as ODS alloys. Almost any metal or nonmetallic can be brazed to these heat-resistant alloys if it can withstand the heat of brazing.

The American Welding Society has classified several gold-base, nickel-base, and cobalt-base brazing filler metals that can be used for elevated-temperature service. In addition, there are many that are not classified by AWS. It should be noted that for lower service temperatures, copper (BCu) and silver (BAg) brazing filler metals have been used for many successful applications.

Generally, heat-resistant alloys are brazed with nickel-base or cobalt-base alloys containing boron and/or silicon, which serve as melting-point depressants and as oxide-reducing agents. In many commercial brazing filler metals, the levels are 2 to 3.5 wt% B and 3 to 10 wt% Si. Phosphorus is another effective melting-point depressant for nickel and is used in filler metals from 0.02 to 15 wt%. It is also used where good flow is important in applications of low stress, where temperatures do not exceed 760 °C (1400 °F). Chromium is often present to provide oxidation and corrosion resistance. The amount may be as high as 20 wt%, depending on the service conditions. Higher amounts, however, tend to lower brazement strength.

Cobalt-base filler metals are used mainly for brazing cobalt-base components, such as first-stage turbine vanes for jet engines. Most cobalt-base filler metals are proprietary. In addition to boron and silicon, these alloys usually contain chromium, nickel, and tungsten to provide corrosion and oxidation resistance and to improve strength. As discussed in the section "Stainless Steels" of this article, the presence of chromium in higher amounts affects the wetting and spreading behavior of the flux during brazing.

Titanium and Titanium Alloys

Titanium is one of the chemical elements that reacts readily with oxygen to form an adherent and stable oxide. This oxide gives titanium and titanium alloys excellent corrosion resistance. Properties such as corrosion resistance, light weight, and high strength make titanium especially attractive in aerospace and chemical applications.

On cooling, pure titanium undergoes an allotropic transformation from β(bcc) to α(hcp) at 882.5 °C (1621 °F). Some alloying elements stabilize the α phase, others, the β phase. Figure 19 shows the αand β stabilizers and their effects on a binary phase diagram. In this case, α and β represent a solid solution and γ represents an intermetallic compound. Table 11 shows the classification for some commercial titanium alloys according to the prevailing microstructure.

The β alloys present a ductile-to-brittle transition temperature (DBTT). Thus, depending on the temperature, β alloys can be brittle. On the other hand, α alloys have no DBTT. These characteristics determine some applications of the two alloys. The α alloys have, in general, good strength, toughness, and creep resistance, and they are suitable for cryogenic applications. The β alloys are not designed for low-temperature applications, but they present good formability and a high

strength-to-weight ratio. The α+ βalloys are also formable with high room-temperature strength and moderate elevated-temperature strength. The volumetric fraction of β in these alloys is between 10 to 50%, but alloys with over 20 vol% β phase are not joinable.

Titanium and titanium alloys are not directly solderable due to the formation of an adherent stable oxide.

Commercially Pure Titanium, α and Near-α Titanium Alloys. Because these alloys are not strengthened by heat treatment, the brazing thermal cycle has little effect on their mechanical properties. The filler metals used to braze titanium and titanium alloys are shown in Table 12. During brazing there is a dissolution of the base metal and a diffusion of the alloying elements toward the base metal and/or the filler metal. These phenomena will form a reaction layer, which may consist of brittle titanium intermetallics. Titanium can combine with copper, nickel, aluminum, and silver to form intermetallics. The first three intermetallics (titanium-copper, titanium-nickel, and titanium-aluminum) are harder and have a lower ductility than a titanium-silver intermetallic. Therefore, the filler metal should have a lower amount of these elements, or the brazing process should be as fast as possible, to minimize the intermetallic formation.

Titanium and titanium alloys are very resistant to corrosion. The filler metal should be selected carefully to avoid galvanic corrosion.

Titanium and its alloys are usually brazed by induction or furnace processes with a protective atmosphere. The brazing atmosphere is usually a vacuum with less than 13 mPa (10^{-4} torr) or an inert atmosphere with dew point lower than -55 °C (-70 °F). Vacuum brazing with filler metals that contain silver or gallium must be performed with an argon back pressure to avoid the vaporization loss of these elements.

In induction brazing, the chemical elements of the filler metal must alloy readily with titanium, due to the fast heating cycle. However, furnace brazing requires a filler metal with a chemical composition that does not alloy excessively with titanium, due to longer periods at elevated temperatures. Torch brazing is not usually done because special fluxes and a skilled operator are required.

β and α+ β titanium alloys can be strengthened by heat treatment. The basic heat treatment consists of heating in a single-phase field (β alloys) or in a two-phase field (α + βalloys), followed by a quenching. The aging is performed between 480 and 650 °C (900 and 1200 °F). During aging, α or other compounds will precipitate in a β matrix, increasing the strength and toughness of the alloy. Thus, the thermal cycle during brazing may affect the mechanical properties of the base metal. The β alloys should be brazed at a temperature close to the solubility temperature. Brazing at higher temperatures will reduce the ductility of these alloys. The α + β alloys should be brazed at a temperature below the α-to-β transition temperature. Table 13 shows the α-to-β transition temperature for some titanium alloys.

The fixture material for brazing a titanium alloy should be chosen carefully to avoid contamination or solid-state bonding between them. For example, nickel forms an eutectic with titanium at 940 °C (1725 °F) and can be bonded to titanium at approximately 816 °C (1500 °F). Thus, a physical contact between titanium alloys and nickel-containing alloys, such as austenitic stainless steels, should be avoided.

Cobalt-Base Alloys

The brazing of cobalt-base alloys is readily accomplished with the same techniques used for nickel-base alloys. Because most of the popular cobalt-base alloys do not contain appreciable amounts of aluminum or titanium, brazing atmosphere requirements are less stringent. Several cobalt-base alloys can be brazed in either a hydrogen atmosphere or a vacuum. Filler metals are usually nickel-base alloys, cobalt-base alloys, or gold-palladium compositions. Silver or copper brazing filler metals may not have sufficient strength and oxidation resistance in many high-temperature applications. Although cobalt-base alloys do not contain appreciable amounts of aluminum or titanium, an electroplate or flash of nickel is often used to better promote wetting of the brazing filler metal.

Cobalt alloys, much like nickel alloys, may become susceptible to liquid metal embrittlement or stress-corrosion cracking when brazed under residual or dynamic stresses. This frequently is observed when using silver or silver-copper (BAg) filler metals. Liquid metal embrittlement of cobalt-base alloys by copper (BCu) filler metals occurs with or without the application of stress; therefore, BCu filler metals should be avoided when brazing cobalt.

Refractory Metals

The mechanical properties of the refractory metals are affected markedly by their DBTT behavior, recrystallization temperature, and reactions with carbon and selected gases. These characteristics must be considered when procedures for

brazing refractory metals are established. The strength and ductility of the refractory metals are adversely affected by microstructural changes that occur when the recrystallization temperatures of these metals are exceeded.

The recrystallization temperature range also varies with alloying additions, interstitial content, fabrication method (including degree of cold working), and time at temperature. Some applications permit brazing with brazing filler metals that melt below the recrystallization temperature range. Other applications require the use of brazing filler metals that melt above this temperature range. As a result, a joint must be designed to accommodate the loss in mechanical properties associated with recrystallization.

The environment in which the refractory metals are brazed is determined by the reactivity of these metals with oxygen, hydrogen, carbon, and nitrogen, and the effect of these elements on the mechanical properties of the refractory metals. All of the refractory metals react with oxygen at moderately elevated temperatures, but they form different types of oxides. Niobium and tantalum form hard adherent oxides at temperatures above 205 and 400 °C (400 and 750 °F), respectively. On the other hand, molybdenum and tungsten form volatile oxides at temperatures above 400 and 510 °C (750 and 950 °F), respectively. In either case, the surfaces of the refractory metals must be protected from oxidation during brazing to ensure wetting by the braze filler metal. Also, these metals must be coated with an oxidation-resistant material, such as nickel or silver plating, if they are exposed to air at elevated temperatures. For such service conditions, the brazing filler metal must be compatible with both the base metal and the coating.

Niobium is used mainly for nuclear and aerospace applications. As a result, research has been directed toward the development of brazing filler metals with characteristics that are compatible with the base metal and its intended use. For example, brazing filler metals have been developed to produce joints that are resistant to liquid alkali metals, such as sodium, and that possess useful properties at 705 to 815 °C (1300 to 1500 °F). The base metal Nb-lZr has been vacuum brazed at 1250 °C (2280 °F) with the Ti-28V-4Be brazing filler metal.

Other niobium alloys--for example, D-43 (Nb-10W-IZr-0.1C), Cb-752 (Nb-10W-2.5Zr), and C-129Y (Nb-10W-11Hf-0.07Y)--have been successfully brazed with two brazing filler metals (B120VCA and Ti-8.5si) at 1455 °C (2650 °F).

Molybdenum. Copper-base and silver-base brazing filler metals can be used to braze molybdenun for low-temperature service. For high-temperature applications, molybdenum can be brazed with gold, palladium, and platinum filler metals, nickel-base filler metals, reactive metals, and refractory metals that melt at lower temperatures than molybdenum. It should be noted, however, that nickel-base alloys have limited applicability for high-temperature service, because nickel and molybdenum form an intermetallic compound that melts at 1315 °C (2400 °F). Two binary brazing filler metals (V-35Nb and Ti-30V) have been evaluated for use with the Mo-0.5Ti molybdenum base metal.

Molybdenum alloy TZM (0.5Ti-0.08Zr-Mo) has also been successfully vacuum brazed at 1400 °C (2550 °F) with molybdenum powder added to the Ti-8.5Si brazing filler metal. Molybdenum has an extremely low coefficient of thermal expansion, which should be considered in the design of brazed joints, particularly when molybdenum is joined to other metals.

Tantalum. Nickel-base brazing filler metals (such as the nickel-chromium-silicon filler metals) have been used to braze tantalum. Tantalum forms a homogeneous solid solution with nickel at concentrations up to 36 wt% with the liquidus temperature reducing from 1450 to 1350 °C (2640 to 2460 °F). These brazing filler metals are satisfactory for service temperatures below 982 °C (1800 °F). Copper-gold alloys with less than 40 wt% Au can be used as brazing filler metals. When gold is added in amounts between 40 to 90 wt%, the alloys tend to form brittle age-hardening compounds. Because tantalum and its alloys are usually used for elevated-temperature applications (1650 °C, or 3000 °F, and above), only a few brazing filler metals have been developed. Most of the brazing filler metals currently available for tantalum are in powder form, which is difficult to work with at elevated temperatures. New powder brazing filler metals (for example, Hf-7Mo, Hf-40Ta, and Hf-19Ta-2.5Mo) are being developed for tantalum as foil-type brazing filler metals.

Tungsten can be brazed in much the same manner as molybdenum and its alloys, using many of the same brazing filler metals. Brazing can be accomplished in a vacuum or in a dry argon, helium, or hydrogen atmosphere. To some extent, the selection of the brazing atmosphere depends on the brazing filler metal used. For example, brazing filler metals that contain elements with high vapor pressures at the brazing temperature cannot be used effectively in a high vacuum.

Ceramic Materials

Ceramic materials can be joined by two different methods: by metallization of the ceramic surface or by using a ductile active filler metal. In the first method, a coating of a metal such as molybdenum and manganese is used as a transition between the ceramic and metal. It may be followed by a nickel coating to improve the wetting and spreading of the filler metal. The disadvantage of this method is that the heating, cycles used to sinter these coatings can crack the ceramic substrate. In the second method, an active metal in the filler reduces the ceramic to promote the bond between a metal and a ceramic. This filler metal should be ductile to relieve the residual stresses built up during cooling. A uniform heating of all components, such as in furnace joining, should be used to minimize the presence of cracking due to thermal stresses.

Graphite. Brazeability of graphite is strongly influenced by the presence of impurities, such as oxygen and moisture, and by pore size and pore distribution. Data from Table 5 indicate that graphite has a low coefficient of thermal expansion and low strength; these properties make joining graphite to other engineering materials a difficult task. A metal with a coefficient of thermal expansion close to that of graphite (for example, tungsten, molybdenum, tantalum, and zirconium), should be chosen as a transition piece. Graphite is also difficult to wet, so a coating or a filler metal with a strong tendency to form carbide must be used to form the joint. Sometimes, a ductile metal such as copper is used to decrease the residual stress developed in the joint.

At least two commercially available filler metals are used to join graphite. One has a nominal chemical composition of 68Ag-27Cu-4.5Ti (in wt%) with a solidus temperature of 830 °C (1525 °F) and a liquidus temperature of 849 °C (1560 °F). The other filler metal has a chemical composition of 70Ti- 15Cu- 15Ni (in wt%) with a solidus temperature of 910 °C (1670 °F) and a liquidus temperature of 960 °C (1760 °F).

Figure 20 shows a sandwich technique for brazing graphite to an austenitic stainless steel. The filler metal is 68Ag-27Cu-4.5Ti with alternate layers of copper and molybdenum to match as closely as possible the coefficients of thermal expansion of graphite and stainless steel. A special fixturing system was designed to create compression in the joint to compensate for the mismatch in the coefficients of thermal expansion.

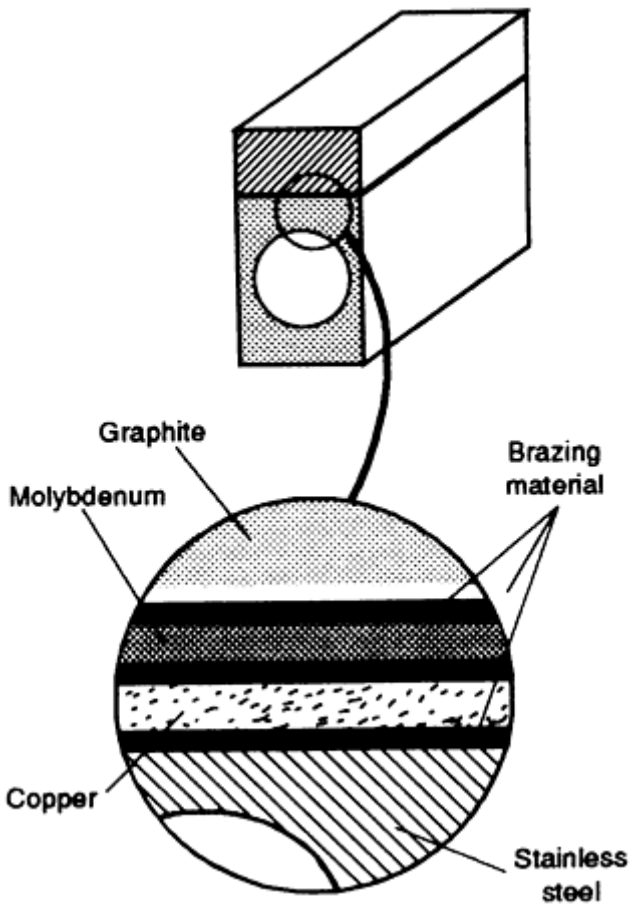

FIG. 20 APPLICATION OF SANDWICH TECHNIQUE TO BRAZE GRAPHITE TO AN AUSTENITIC STAINLESS STEEL WITH 68AG-27CU-4.5TI FILLER METAL. SOURCE: REF 10

Another example of graphite brazing also used transition inserts of gradient composition. In this case, graphite was joined to a nickel-base alloy, and the transition piece consisted of seven rings of tungsten-nickel-iron alloys. The first ring contained 97.5 wt% W to match the coefficient of thermal expansion of graphite, and the last ring contained 40 wt% W to match the coefficient of thermal expansion of the nickel-base alloy.

Carbides. The discussion of carbide brazing will be divided into two parts: brazing of carbide tools and brazing of silicon carbide (ceramic).

Carbide Tools. This group includes tungsten carbide with cobalt binder (3 to 25 wt%); tungsten carbide plus titanium and tantalum carbides, or niobium carbide with cobalt binder; titanium or tantalum carbides plus tungsten carbide with nickel or cobalt binder; chromium carbides with nickel or cobalt binders, and other carbide combinations.

Filler metals from the BAg group have been used to perform the carbide-to-steel joining. The filler metals that contain nickel (BAg-3, BAg-4, and BAg-22) promote a better wettability, because nickel improves the wettability in carbide-metal systems. RBCuZn-D and BCu have also been used, particularly where a post-braze heat treatment is required. Filler metals BAg-23 or 52.5Cu-38Mn-9.5Ni have been used when the brazements will be subjected to elevated temperature or additional wetting, as in the case of brazing titanium-base or chromium-base carbides.

In the case of tungsten-base carbide, the use of composite filler metal (consisting of a sandwich of two layers of a silver-base filler metal and a copper shim) has been reported. The ductile copper layer deforms during brazing to decrease the residual stress generated in the joint. A wider joint requires a thicker copper shim. Figure 21 shows this technique.

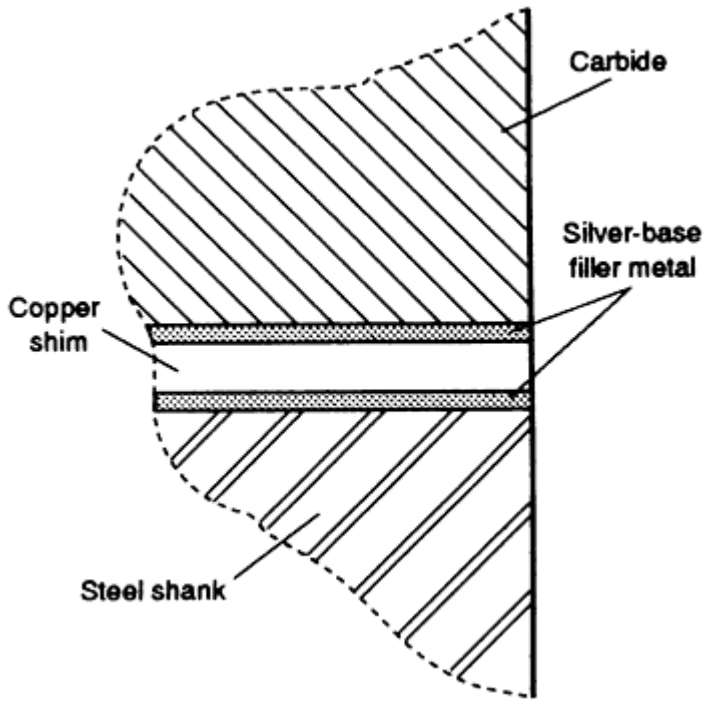

FIG. 21 USE OF COMPOSITE BRAZING FILLER METAL (TWO LAYERS OF SILVER-BASE FILLER METAL AND A COPPER SHIM) TO JOIN TUNGSTEN CARBIDE TO STEEL

Joint design is important in carbide tool brazing. The mismatch in the coefficients of thermal expansion must be taken into account and to avoid cracking during brazing, which decreases tool life. Figure 22 shows some optimum tool joint designs. In each set, the right-most drawing represents an improved design with longer expected tool life.

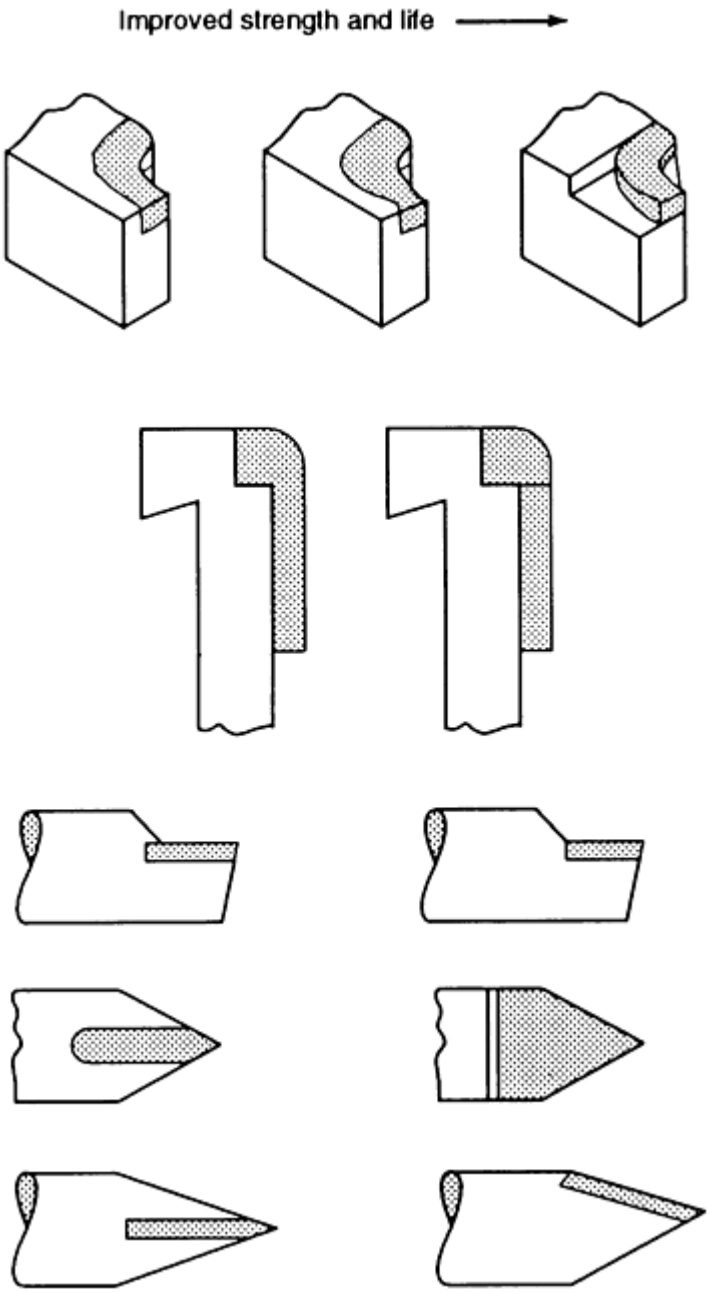

FIG. 22 JOINT DESIGNS TO OPTIMIZE STRENGTH AND TOOL LIFE OF BRAZED CARBIDE TOOL ASSEMBLIES. IN EACH SET, THE RIGHT-MOST DRAWING REPRESENTS AN IMPROVED DESIGN.

Silicon carbide can usually be brazed using a titanium-base filler metal according to the following reaction:

$$SiC + Ti_{fm} \rightarrow TiC_i + \underline{Si}_{fm} \qquad \textbf{(EQ 8)}$$

The subscripts *fm* and *i* denote the filler metal and interface, respectively. Commercial silver-titanium, silver-copper-titanium, and silver-copper-indium-titanium alloys can be used as filler metals to join silicon carbide to silicon carbide or to other alloys. The amount of copper in the filler metal must be controlled, because copper dissolves silicon from silicon carbide to form a copper-silicon alloy and graphite and changes the characteristics of the ceramic material close to the joint.

Some experimental results show that a Ni-13.4Cr-40Si (in at.%) filler metal can also be used to braze silicon carbide to silicon carbide components with good results. On the other hand, an experimental filler metal Fe-34Si (in at.%) used to join silicon carbide to Inconel 600 showed extensive chemical reaction with formation of low-melting-point silicides.

To increase the work temperature range of brazed silicon carbide components, a filler metal with higher solidus temperature is needed. Ni-50Ti (in at.%) has been reported to perform well. Table 14 presents some filler metals commonly used to braze silicon carbide.

TABLE 14 FILLER METALS COMMONLY USED IN SILICON CARBIDE BRAZING APPLICATIONS

BRAZING FILLER METAL SYSTEM	COMPOSITION, WT%					SOLIDUS TEMPERATURE		LIQUIDUS TEMPERATURE		BRAZING TEMPERATURE

Oxide ceramics such as Al_2O_3, ZrO_2, and MgO are not easily wetted. Consequently, an active element must be present in the filler metal to reduce the oxide. Titanium is the active element most frequently added in the filler metals, although zirconium, niobium, aluminum, chromium, and vanadium have also been used. The oxide reduction by titanium is represented by:

$$M_xO_y + y\underline{Ti}_{fm} \rightarrow yTiO_i + x\underline{M}_{fm} \qquad \textbf{(EQ 9)}$$

Depending on the brazing system, a dissolution reaction may occur instead of the reduction of the oxide ceramics. In the case of the Al_2O_3-Cu-Cu_2O system, a spinel $CuAlO_2$ is reported to form at the interface. This spinel makes the metal/ceramic transition to promote a good bond between both types of material.

The nature of the oxide formed at the ceramic oxide-filler metal interface is very important to the wetting and spreading of the molten filler metal and to the integrity of the joint. The metallic-type conductivity and metallic-ionic bonding of titanium gives it a metallic characteristic. On the other hand, Ti_2O_3 has only ionic bonding, giving it a typical ceramic characteristic.

To protect the titanium in the filler metal against "premature" oxidation or other reactions during the joining, a high vacuum or an inert atmosphere (that is, non-nitrogen) is recommended. Table 15 shows active brazing conditions for some oxide ceramics.

Nitride Ceramics. Nonoxide ceramics are more easily reduced by chemical reactions than oxide ceramics. Thus, the brazing techniques developed for oxide ceramics should be used judiciously in joining nonoxide ceramics.

Joining of nitrides using a glass bonding agent or by active metal brazing has been reported. A glass bonding agent such as $70SiO_2$-$27MgO$-$3Al_2O_3$ (in wt%) is used to join Si_3N_4. Si_2N_2O is formed at the ceramic-glass interface to promote the joining.

Active brazing of nitrides follows the same principles as outlined in the section "Oxide Ceramics" in this article. An active element reduces the ceramic at the interface between the ceramics and the molten filler metal. The general equation for a nitride reduced by a titanium-rich filler metal is:

$$M_xN_y + y\underline{Ti}_{fm} \rightarrow yTiN_i + x\underline{M}_{fm} \qquad \textbf{(EQ 10)}$$

TiN is formed at the filler metal-nitride interface, and it has a character similar to TiO in promoting wetting. Depending on which active metal is contained in the filler metal, a silicide or an aluminide may form first at the interface. In the case of copper-niobium filler metal for silicon nitride joining, niobium silicide may form before the niobium nitride. Table 16 shows some typical brazing conditions for the nitride ceramics.

(A) SHEAR TEST.

(B) FOUR-POINT BEND TEST

The presence of these compounds, as a reaction layer, is necessary to promote wetting and spreading and to make a good bond between ceramic and metal. The growth of the reaction layer is affected by brazing temperature, time, reactivity,

and the amount of active element in the filler metal. Thus, the joining conditions should be carefully controlled to produce a thin layer and promote the optimum mechanical behavior of the joint.

Arc Welding of Carbon Steels

Ronald B. Smith, The ESAB Group, Inc.

Introduction

CARBON STEELS are defined as those steels containing up to 2% C, 1.65% Mn, 0.60% Si, and 0.60% Cu, with no deliberate addition of other elements to obtain a desired alloying effect. Tables 1(a) and 1(b) list some of the common grades of carbon steel that are covered in this article. The weldability of these steels greatly depends on their carbon and manganese contents and impurity levels.

(A) SINGLE VALUES ARE MAXIMUMS.

(B) SINGLE VALUES ARE MINIMUMS.

(C) *T*, PLATE THICKNESS.

(D) SILICON CONTENT VARIES WITH DEOXIDATION PRACTICE USED.

At low carbon levels (less than 0.15% C), the steels are nonhardening and weldability is excellent. The bulk of the steels in this carbon range are used for flat-rolled products (sheet and strip), which may contain up to 0.5% Mn. Most of these steels are now aluminum-killed, continuous-cast product supplied in the cold-rolled and annealed condition. The lower available oxygen in the killed sheet makes it easier to arc weld without porosity formation. Typical uses for these steels are automobile body panels, appliances, and light-walled tanks.

In the range of 0.15 to 0.30% C, the steels are generally easily welded, but because hardening is a possibility, precautions such as preheating may be required at higher manganese levels, in thicker sections, or at high levels of joint restraint. Much of the steel in this carbon range is used for rolled structural plate and tubular products. These steels are generally killed or semi-killed and are usually supplied in the hot-rolled condition. The presence of surface scale (iron oxide) from the high-temperature rolling process increases the likelihood of porosity formation during welding and may require the use of welding electrodes with higher levels of deoxidizers, or removal of the scale prior to welding. Some carbon steel plate may be heat-treated (normalized or quenched and tempered) to enhance properties. In such cases, careful selection of the welding consumable must be made in order to match the base metal properties. Welding heat input may have to be controlled so as not to diminish the properties in the heat-affected zone (HAZ) of the base metal, or postweld heat treatment may be necessary to restore the strength and/or toughness of the HAZ.

Medium-carbon steel--steel that contains 0.30 to 0.60% C--can be successfully welded by all of the arc welding processes, provided suitable precautions are taken. The higher carbon content of these steels, along with manganese from 0.6 to 1.65%, makes these steels more hardenable. For this reason, they are commonly used in the quenched and tempered condition for such applications as shafts, couplings, gears, axles, crankshafts, and rails. Because of the greater likelihood of martensite formation during welding, and the higher hardness of the martensite formed, preheating and postheating treatments are necessary. Low-hydrogen consumables and procedures should also be used to reduce the likelihood of hydrogen-induced cracking. The higher strength level of these steels may require the use of an alloyed electrode to match the base metal properties. It may also be necessary to postweld heat treat the part in order to restore the strength and/or toughness of the HAZ.

Higher-carbon steel--steel that contains 0.60 to 2.00% C--has poor weldability because of the likelihood of formation of a hard, brittle martensite upon weld cooling. Steels of this type are used for springs, cutting tools, and abrasion-resistant applications. Low-hydrogen consumables and procedures, preheating, interpass control, and stress relieving are essential if cracking is to be avoided. Austenitic stainless steel electrodes are sometimes used to weld high-carbon steels. These electrodes will reduce the risk of hydrogen-induced cracking but may not match the strength of the high-carbon steel base metal.

The 11*xx* and 12*xx* series steels contain large amounts of sulfur, phosphorus, or lead for improved machinability. Both series are difficult to weld because of solidification cracking and porosity formation.

Carbon steel castings can be made in the same wide range of compositions as the wrought types. The major differences are that castings are always fully killed (0.3 to 1.0% Si) and are generally heat-treated. For a given composition, the weldabilities of the cast and wrought carbon steels are similar. Casting defects are often repaired by welding. Care in the selection of a welding electrode is required if the casting is to be heat-treated. Low-alloy steel electrodes are frequently used because they match the casting properties better after heat treatment. Low-hydrogen electrodes and procedures are commonly used, depending on casting size and carbon content.

Arc Welding of Carbon Steels

Ronald B. Smith, The ESAB Group, Inc.

Weldability Considerations for Carbon Steels

As a group, the carbon steels are among the most weldable of materials, yet they are susceptible, to one degree or another, to:

- HYDROGEN-INDUCED CRACKING
- SOLIDIFICATION CRACKING
- LAMELLAR TEARING
- WELD METAL POROSITY
- WELD METAL AND HAZ MECHANICAL PROPERTY VARIATIONS

Additional information about the weldability of carbon steel is available in the Section "Selection of Carbon and Low-Alloy Steels" in this Volume.

Hydrogen-Induced Cracking (Ref 1, 2)

Hydrogen-induced cracking (also referred to as cold cracking, delayed cracking, or underbead cracking) is the most serious problem affecting weldability. Any hardenable carbon steel is susceptible. This type of cracking results from the combined effects of four factors:

- A SUSCEPTIBLE ("BRITTLE") MICROSTRUCTURE
- THE PRESENCE OF HYDROGEN IN THE WELD METAL

- TENSILE STRESSES IN THE WELD AREA
- A SPECIFIC TEMPERATURE RANGE, -100 TO 200 °C (-150 TO 390 °F)

Hydrogen-induced cracking occurs after weld cooling (hence the term cold cracking) and is often delayed for many hours while atomic hydrogen diffuses to areas of high tensile stress. At microstructural flaws in a tensile stress field, the hydrogen changes to its molecular form, causing cracking. Cracking may occur in the HAZ or weld metal, and it may be longitudinal or transverse (Fig. 1). For carbon steels, cracking is more likely to occur in the HAZ because carbon steel electrodes are usually low in carbon and the weld metal is generally not hardenable. Exceptions would be if a highly alloyed electrode were being used, if the weld metal were made more hardenable by dilution of carbon from the base material, or in certain submerged arc welds where the use of excessive arc voltage and active fluxes results in high manganese and/or silicon pickup from the flux (see the section "Submerged Arc Welding" in this article).

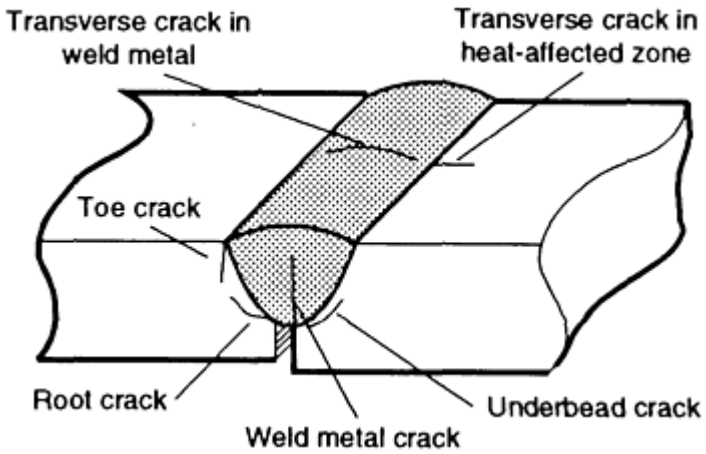

FIG. 1 SCHEMATIC SHOWING LOCATION OF HYDROGEN-INDUCED CRACKS IN CARBON STEEL WELDMENTS. SOURCE: REF 1

Cracks in the HAZ are most often longitudinal. Underbead cracks lie more or less parallel to the fusion line. They do not normally extend to the surface and may therefore be difficult to detect. Underbead cracks will form at relatively low stress levels in martensite when high levels of hydrogen are present.

Toe cracks and root cracks start in areas of high stress concentration. Cracking may therefore occur in less susceptible microstructures or at relatively low hydrogen levels. This type of cracking is often delayed while the necessary hydrogen diffuses to the area.

Transverse cracking in the HAZ is less common. It will occur in high-carbon martensite under conditions of high longitudinal stresses (for example, outside fillet welds on heavy plate).

Weld metal cracks may be longitudinal or transverse. Longitudinal cracks start due to stress concentrations at the root of the weld. Transverse cracking starts at hydrogen-containing defects subject to longitudinal stresses. Weld metal cracks do not always extend to the surface. In submerged arc weld metal made with damp fluxes, a unique crack morphology known as chevron cracking can occur. Here the cracks lie at 45° to the weld axis.

One of the serious problems with hydrogen-induced cracking is the difficulty in detecting the presence of a crack. The delayed nature of some of the cracks demands that inspection not be carried out too soon, especially in welds that will have external stresses applied when put in service. Because some of the cracks do not extend to the surface, they are not detectable by visual inspection methods (for example, liquid penetrant, or magnetic particle inspection, which requires the defect to be near the surface). Radiography is most sensitive to volumetric flaws, and it may not detect cracks that are too fine or of the wrong orientation. Ultrasonic inspection is capable of detecting the crack if the operator knows where to look. Given the difficulty in detecting hydrogen-induced cracks and the possibility of this cracking leading to in-service failure, it is prudent to observe the precautions necessary to avoid cracking in the first place.

Susceptible Microstructures. A susceptible microstructure is any hard, brittle transformation product formed in the HAZ or weld metal. Martensite is by far the most susceptible microstructure found in carbon steels. In all but high-carbon steel weld zones, the martensite, when formed, is usually mixed with other, less susceptible transformation products (for example, pearlite). Nevertheless, these mixed microstructures are susceptible to cracking, depending on the level of hardening. Martensite itself may be more or less susceptible, depending on its carbon content. Higher-carbon martensite is harder, more brittle, and more susceptible to cracking. Figure 2 shows the effect of carbon content on the hardness of carbon steel for various percentages of martensite formed upon rapid cooling.

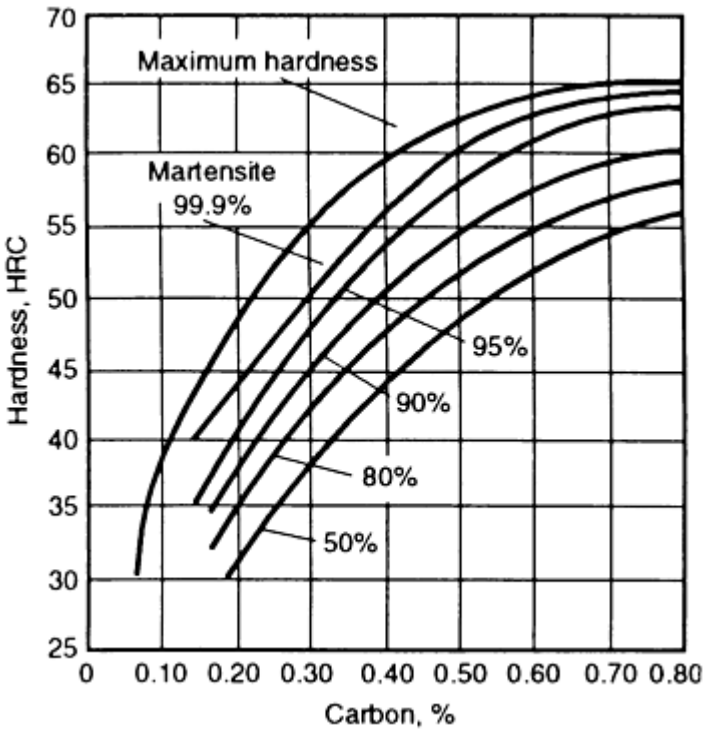

FIG. 2 PLOT OF HARDNESS VERSUS CARBON CONTENT AS A FUNCTION OF MARTENSITE FORMATION IN CARBON STEEL THAT HAS COOLED RAPIDLY

The hardenability of the steel also increases as the carbon content increases. Figure 3 presents hardenability curves for five carbon steels (as determined by end-quench tests). As the cooling rate (top scale) decreases, the lower-carbon steels show a more rapid decline in hardness (that is, less martensite is being formed at the slower cooling rates). Higher carbon steels are more likely to form martensite upon cooling, and the martensite formed will be harder and thus more susceptible to hydrogen-induced cracking.

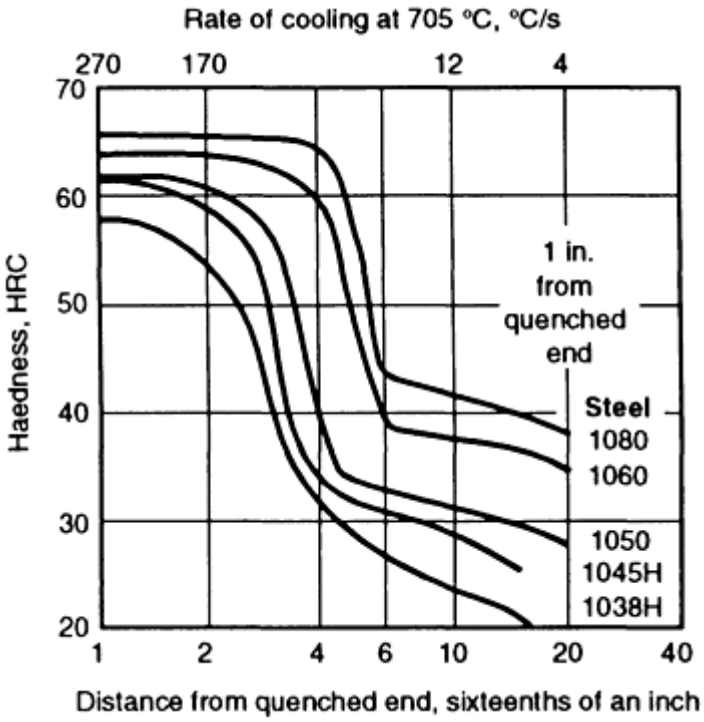

FIG. 3 HARDENABILITY CURVES FOR FIVE CARBON STEELS AS DETERMINED BY END-QUENCH TESTING

Martensite formation is also a function of grain size. The HAZ adjacent to the fusion line will have large austenite grains, which more readily form martensite than smaller grains.

Presence of Hydrogen in Weld Metal. The exact role that hydrogen plays in cold cracking is unknown, but its presence is necessary for this type of cracking to occur. Hydrogen is generally introduced into the weld area during welding. The sources are:

- MOISTURE IN THE FLUX COATING OF SHIELDED METAL ARC WELDING ELECTRODES, IN SUBMERGED ARC FLUXES, OR IN THE CORE OF FLUX-CORED ELECTRODES
- HYDROGEN-CONTAINING LUBRICANTS LEFT ON THE SURFACE OF WIRE ELECTRODES OR IN THE SEAMS OF CORED ELECTRODES
- HYDROGEN-CONTAINING COMPOUNDS OR RESIDUES LEFT ON THE PLATE SURFACE (THESE CAN INCLUDE GREASE, OIL, PAINT, RUST, AND SO ON)
- LEAKING WATER-COOLED TORCHES, BROKEN GAS LINES, OR HIGH MOISTURE IN THE SHIELDING GAS
- ASPIRATION OF MOISTURE-LADEN AIR INTO THE WELD AREA

The principal source of hydrogen is the welding consumable.

Hydrogen, ionized to its atomic form by the intense heat of the arc, is very soluble in liquid iron. This solubility decreases with decreasing temperature. Rapid cooling (in a weld, for example) can result in significant supersaturation of atomic hydrogen in the solidified metal. Because atomic hydrogen diffuses relatively easily through ferrite, a certain amount of the initial hydrogen present when the weld has cooled to ambient temperatures will subsequently diffuse out of the weld metal. This diffusible hydrogen, whose exit from the weld metal is accelerated by higher temperatures, may be measured using standardized test methods (such as those outlined in AWS A4.3). The results, measured in mL of hydrogen per 100 g of weld metal, give an indication of the amount of hydrogen potentially available to induce cracking. These tests are now widely used to measure diffusible hydrogen and to classify arc welding electrodes.

The distribution of hydrogen in the weld metal and HAZ and the subsequent susceptibility to cold cracking is a function of the phase transformations that take place upon cooling. Three examples are described below.

HAZ Hardens but Weld Metals Do Not. If the HAZ hardens (transforms to martensite) but the weld metal does not (for example, welding a medium-carbon steel with a low-carbon, mild-steel electrode), the weld metal undergoes transformation to a ferritic structure at relatively high temperatures. Because hydrogen diffuses easily in ferrite, it will diffuse to and migrate across the fusion boundary into the still-austenitic HAZ, which has a higher solubility for hydrogen but a lower diffusivity. At a much lower temperature, the HAZ transforms to martensite. The area near the fusion boundary is highly concentrated in hydrogen. Cracking may then occur.

Weld Metal More Hardenable than Base Material. If the weld metal is more hardenable than the base material (for example, highly alloyed electrode picks up substantial carbon from a carbon steel base plate), the HAZ transforms first. The weld metal, which is austenitic, will retain the hydrogen. When the weld metal transforms, it will be in the presence of high hydrogen, which may lead to cracking in the weld metal. The HAZ, which is low in hydrogen, will not crack.

No Lower Temperature Transformation in Austenitic Weld Metal. If an austenitic filler metal is used to weld a hardenable base metal (for example, high-carbon steel), there is no lower temperature transformation in the weld metal, which remains austenitic with a high tolerance for hydrogen. Little hydrogen migrates across the fusion boundary, and so the HAZ transforms to martensite with a low hydrogen content and cracking is avoided.

Once hydrogen is present in a hardenable microstructure, the exact mechanism by which it engenders cracking is unknown. The hydrogen is thought to diffuse to defects and areas of triaxial stress, where it interacts with tensile stress to enlarge and extend discontinuities.

Tensile Stresses in Weld Area. The stresses that a weldment is subjected to may be either externally or internally generated. External stresses are those applied when the weld is put in service. Internal, or residual, stresses are those that arise from the welding process, due mainly to thermal gradients, unequal thermal expansion and contraction of the base metal and weld metal, and volume changes resulting from phase transformations during cooling. The residual stresses can be reduced by unrestrained movement of the parts being welded, thermal treatments, and proper weld design.

Movement of the parts can be actual physical displacement or an elastic or plastic deformation. An example of the former would be offsetting the parts prior to welding and allowing them to rotate into the desired final position. An example of the latter is the use of a lower strength ferritic filler metal or of an austenitic filler metal to weld a medium- or high-carbon steel. The weaker, more ductile weld metal of these deposits is able to absorb some of the stress (by elastic or plastic deformation) and reduce the level in the more vulnerable HAZ.

Any condition that limits the movement of welded parts will increase the residual stresses and the likelihood of hydrogen-induced cracking. Thicker, more massive plates, high clamping pressure, or rigid surrounding structures reduce the freedom of motion of the welded parts and result in high residual stresses. Thicker, more massive weld structures also cool faster because of the large heat sink, thus increasing the likelihood of martensite formation. The use of preheat to reduce the risk of martensite formation will also reduce and delay the onset of maximum residual stresses (and allow more time for hydrogen to escape). Postweld stress relief reduces residual stresses by heating the weldment to a temperature at which the yield point drops low enough for plastic flow to occur, thus relaxing the stresses.

Joint designs that reduce the volume of weld metal needed will result in lower residual stresses. The smallest groove angles and root openings that allow good access should be used. The smallest fillet weld size that meets shear strength requirements should be used. The presence of notches or gaps in the weld joint will also increase the incidence of cracking because they produce a localized concentration of stress. Accumulation of relatively low levels of hydrogen in these areas may be sufficient to cause cracking.

Temperature Range for Hydrogen-Induced Cracking. Hydrogen-induced cracking will not normally occur outside of the temperature range of -100 to 200 °C (-150 to 390 °F). Below -100 °C (-150 °F), the hydrogen probably diffuses too slowly to reach a critical concentration in a susceptible area, while above 200 °C (390 °F) the hydrogen diffuses so rapidly out of the weld area that it does not have time to reach a critical accumulation.

Prevention of Hydrogen-Induced Cracking. The major preventative measures to avoid cold cracking are:

- PREHEAT, INCLUDING MAINTENANCE OF PROPER INTERPASS TEMPERATURE

- HEAT INPUT CONTROL
- POSTWELD HEAT TREATMENT
- BEAD TEMPERING
- USE OF LOW-HYDROGEN PROCESSES AND CONSUMABLES
- USE OF ALTERNATE FILLER MATERIALS (FOR EXAMPLE, AUSTENITIC ELECTRODES)

Preheating of the weld area is the most effective and widely used method for avoiding hydrogen-induced cracking. Its primary function is to reduce the weld metal cooling rate so that transformation to martensite is avoided or reduced below a certain critical level. The slower cooling also gives hydrogen more time to diffuse out of the weld area and delays the onset of maximum residual stresses. Many specifications and codes require the use of specific preheat and interpass temperatures for welding hardenable steels. AWS D1.1 (Ref 3) and CSA W59 (Ref 4) specify minimum preheat and interpass temperatures for various thicknesses of structural carbon steels (Table 2). Table 3 gives suggested preheat and postheat treatments for steels. Various methods are also available that allow one to determine the required preheat by taking into account the steel composition, restraint level, and hydrogen level. These methods are discussed in the section "Methods for Determining Preheat/Heat Input" in this article. Some are available as software packages. For example, PREHEAT is a software package from The Welding Institute that is based on BS 5135 (Ref 6) and is available from the Edison Welding Institute.

TABLE 2 RECOMMENDED PREHEAT AND INTERPASS TEMPERATURES FOR SELECTED THICKNESSES OF STRUCTURAL CARBON STEELS

(A) WELDING SHALL NOT BE DONE WHEN THE AMBIENT TEMPERATURE IS LOWER THAN -18 °C (O °F). TEMPERATURE OF -18 °C (0 °F) DOES NOT MEAN THE AMBIENT ENVIRONMENTAL TEMPERATURE BUT THE TEMPERATURE IN THE IMMEDIATE VICINITY OF THE WELD. THE AMBIENT ENVIRONMENTAL TEMPERATURE MAY BE BELOW -18 °C (0 °F) BUT A HEATED STRUCTURE OR SHELTER AROUND THE AREA BEING WELDED COULD MAINTAIN THE TEMPERATURE ADJACENT TO THE WELDMENT AT -18 °C (0 °F) OR HIGHER. WHEN THE BASE METAL IS BELOW THE TEMPERATURE LISTED FOR THE WELDING PROCESS BEING USED AND THE THICKNESS OF MATERIAL BEING WELDED, IT SHALL BE PREHEATED (EXCEPT AS OTHERWISE PROVIDED) IN SUCH MANNER THAT THE SURFACES OF THE PARTS ON WHICH WELD METAL IS BEING DEPOSITED ARE AT OR ABOVE THE SPECIFIED MINIMUM TEMPERATURE FOR A DISTANCE EQUAL TO THE THICKNESS OF THE PART BEING WELDED, BUT NOT LESS THAN 75 MM (3 IN.) IN ALL DIRECTIONS FROM THE POINT OF WELDING. PREHEAT AND INTERPASS TEMPERATURES MUST BE SUFFICIENT TO PREVENT CRACK FORMATION. TEMPERATURE ABOVE THE MINIMUM SHOWN MAY BE REQUIRED FOR HIGHLY RESTRAINED WELDS. FOR A 514, A 517, AND A 709, GRADES 100 AND 100W STEEL, THE MAXIMUM PREHEAT AND INTERPASS TEMPERATURE SHALL NOT EXCEED 205 °C (400 °F) FOR THICKNESS UP TO 38.1 MM ($1\frac{1}{2}$ IN.) INCLUSIVE, AND 230 °C (450 °F) FOR GREATER

THICKNESS. HEAT INPUT WHEN WELDING A 514, A 517, AND A 709 GRADES 100 AND 100W STEEL SHALL NOT EXCEED THE STEEL PRODUCER'S RECOMMENDATION.

(B) IN JOINTS INVOLVING COMBINATIONS OF BASE METALS, PREHEAT SHALL BE AS SPECIFIED FOR THE HIGHER STRENGTH STEEL BEING WELDED.

(C) ONLY LOW-HYDROGEN ELECTRODES SHALL BE USED WHEN WELDING A 86 OR A 709 GRADE 36 STEEL MORE THAN 25.4 MM (1 IN.) THICK FOR DYNAMICALLY LOADED STRUCTURES.

(D) WHEN THE BASE METAL TEMPERATURE IS BELOW 0 °C (32 °F), THE BASE METAL SHALL BE PREHEATED TO AT LEAST 21 °C (70 °F) AND THIS MINIMUM TEMPERATURE MAINTAINED DURING WELDING.

(E) NONE.

(F) AMERICAN PETROLEUM INSTITUTE (API) SPECIFICATION.

(G) AMERICAN BUREAU OF SHIPPING (ABS) SPECIFICATION.

(H) ALL GRADES.

(I) ALL CLASSES.

(J) PREHEAT IS NOT REQUIRED FOR THE BASE METAL. PREHEAT FOR E80XX-X FILLER METAL SHALL BE AS FOR GROUP C; FOR HIGHER STRENGTH FILLER METAL TREAT AS GROUP D.

(A) RANGES ARE INCLUSIVE.

(B) AMBIENT ABOVE -12 °C (10 °F).

(C) DUE TO LEAD CONTENT, MANUFACTURING OPERATIONS INVOLVING ELEVATED TEMPERATURES IN THE RANGE OF THOSE ENCOUNTERED IN GAS CUTTING OR WELDING SHOULD BE CARRIED OUT WITH ADEQUATE VENTILATION.

(D) HOLD AT TEMPERATURE FOR 1 H AFTER WELDING IS COMPLETED.

Particular care must be exercised when dealing with weldments made at low heat inputs (high cooling rates). Tack welds are usually short, low-heat-input welds that cool rapidly. The first pass of a multipass weld in a large structure may be made at low heat input (to avoid bum-through) or on a relatively cold workpiece. Again, cooling rates may be high. It is essential that proper preheat be used under these circumstances, because the likelihood of martensite formation is much greater, given the rapid cooling rates.

Heat input control can also be used to reduce the cooling rate. The use of a higher heat input to slow cooling may not always be commensurate with good welding practice. For example, the resultant bead size may be too large, or the welding parameters (current, voltage, travel speed) needed to achieve the required heat input level may be outside the operating window of the electrode.

Postweld heat treatment may involve holding the completed weld at or near the interpass temperature for a period of time sufficient to allow hydrogen to escape the weld area. This temperature should be above the temperature range where cracking occurs (approximately 200 °C, or 390 °F).

If the interpass and postweld soak temperature are held above the martensite start temperature, M_s, for a sufficient length of time, isothermal transformation to a less susceptible microstructure will occur (for example, bainitic structure with some ferrite). A tempered martensite, however, will generally have better toughness than the isothermal transformation product, so this procedure should be used only when a stress relief is not possible.

The use of a proper postweld treatment may allow a reduction in the preheat temperature because both treatments serve the same purpose (that is, reducing the weld metal cooling rate). A lower preheat will increase operator comfort.

In the event that martensite formation cannot be avoided (as may be the case in a medium- to high-carbon steel), or when joint restraint is high, it is advisable to postweld heat treat the weldment to produce a less brittle, tempered martensite. The weldment should be held at or near the interpass temperature until postweld heat treatment can be done. This will reduce the possibility of cracking before the postweld heat treatment. Postweld heat treating of carbon steels is normally performed in the 600 to 650 °C (1110 to 1200 °F) range. The soak time is usually 1 h/in. of the thickest member. Many codes (for example, the ASME Boiler and Pressure Vessel Code) define when postweld heat treatment is to be done. Figure 4 can also be used as a guide for determining when postweld heat treatment should be done.

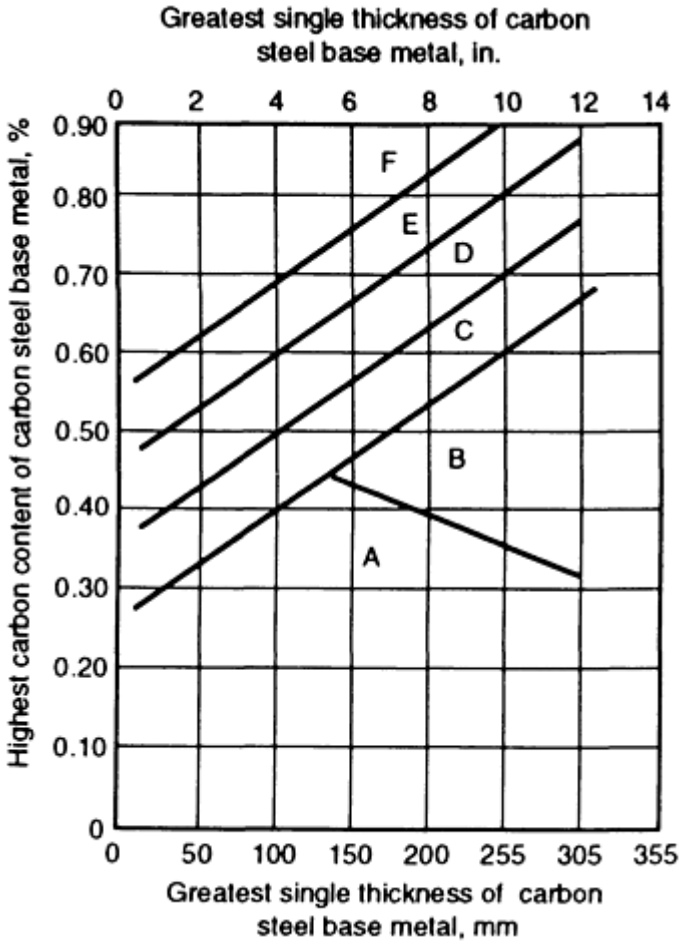

FIG. 4 PLOT OF BASE-METAL CARBON CONTENT VERSUS BASE-METAL THICKNESS OF CARBON STEELS TO SHOW DEGREE OF STRESS RELIEF REQUIRED. A, POSTWELD HEATING IS SELDOM REQUIRED. B, POSTWELD HEATING IS REQUIRED ONLY FOR DIMENSIONAL STABILITY, AS WHEN PARTS ARE TO BE FINISH MACHINED AFTER WELDING. C, POSTWELD STRESS RELIEF IS HIGHLY DESIRABLE FOR REPETITIVELY LOADED OR SHOCK-LOADED STRUCTURES AND FOR RESTRAINED JOINTS HAVING A THICKNESS GREATER THAN 25 MM (1 IN.). D, POSTWELD STRESS RELIEF IS REQUIRED FOR ALL REPETITIVELY LOADED OR SHOCK-LOADED STRUCTURES, FOR ALL RESTRAINED JOINTS, AND FOR ALL THICKNESSES OVER 50 MM (2 IN.); IT IS ALSO DESIRABLE FOR STATICALLY LOADED STRUCTURES. E, POSTWELD STRESS RELIEF IS RECOMMENDED FOR ALL APPLICATIONS; NO INTERMEDIATE COOLDOWN SHOULD BE PERMITTED FOR RESTRAINED STRUCTURES OR FOR BASE METAL HAVING A THICKNESS GREATER THAN 50 MM (2 IN.). F, SAME AS E, EXCEPT HAZARDS ARE GREATER

Bead Tempering. In a multipass weld, the underlying weld metal is subjected to repeated thermal cycles. This extends the time for hydrogen to diffuse out of the weld area, and it tempers any martensite that may have previously formed. Each bead also provides the preheat for the subsequent weld pass. The final bead and the HAZ it creates will not receive this same benefit. If the base metal is crack-sensitive, the final bead should be placed so that the HAZ does not form in the base metal (Fig. 5).

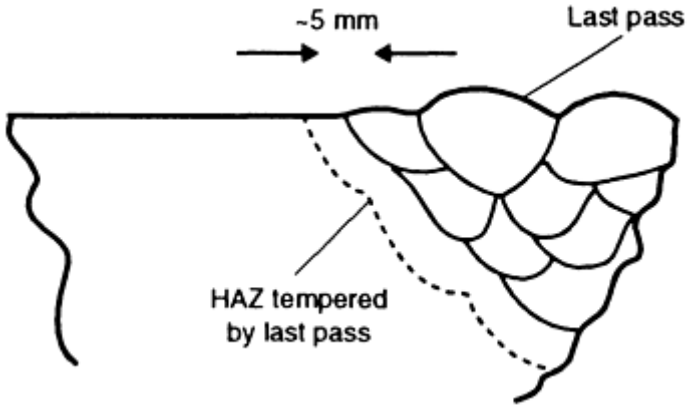

FIG. 5 BEAD TEMPERING. THE LAST BEAD IS PLACED SO ITS HAZ IS FORMED IN THE WELD METAL RATHER THAN IN THE MORE HARDENABLE BASE METAL. SOURCE: REF 1

Use of Low-Hydrogen Processes and Consumables. The principal source of weld metal hydrogen is the welding consumable(s). Careful selection of low-hydrogen consumables or low-hydrogen processes (such as gas-metal arc welding) can greatly reduce hydrogen pickup. This is especially important with medium- to high-carbon steels, in which the formation of a hard, brittle martensite is more likely. Many new specifications (for example, AWS A5.*x* filler metal specifications) now provide methods for consumable classification based on the diffusible hydrogen levels of their deposited weld metals. A standardized procedure is prescribed for measuring the diffusible hydrogen (for AWS specifications, this is AWS A4.3, while in many other parts of the world ISO 3690 is used). Designators are then used to indicate the maximum hydrogen level that an electrode will produce. The AWS uses a logarithmic scale; the International Institute of Welding method uses a linear system (Table 4).

TABLE 4 CLASSIFICATION OF CONSUMABLES RELATIVE TO THE DIFFUSIBLE HYDROGEN LEVELS OF THEIR DEPOSITED WELD METALS

SPECIFICATION	HYDROGEN LEVELS AT INDICATED DESIGNATIONS, ML/100 G		
	VERY LOW	LOW	HYDROGEN-CONTROLLED
AWS	<4[A]	<8[B]	<16[C]
IIW	<5	<10	<15

(A) H4.
(B) H8.
(C) H16

The extension of the AWS series down to diffusible hydrogen levels of less than 2 mL/100 g is feasible (for example, for gas-metal arc welding, flux-cored arc welding, or submerged arc welding). In both systems, an electrode that produces hydrogen in excess of the maximum, 16 mL/100 g (or 15 mL/100 g), is not considered hydrogen-controlled.

Use of Alternate Filler Materials. Often, the use of a softer, more ductile weld metal can help to absorb some of the high residual stresses in the weld area. The use of a lower-strength carbon steel electrode with greater ductility will reduce the high residual stresses in the HAZ and reduce the likelihood of cracking in the HAZ. Care must be exercised to be sure the decreased weld metal strength does not compromise the usefulness of the welded structure.

In higher carbon steels, austenitic weld metals are often used. They not only help reduce the stress level in the HAZ, but they also absorb and hold weld metal hydrogen. Austenite has a higher solubility for hydrogen, and the relatively low diffusivity of hydrogen in austenite ensures that little hydrogen will diffuse into the more susceptible HAZ. Caution must also be exercised here. The strength of the austenitic deposit will be lower than that of a carbon or alloy steel deposit. The austenitic filler material should be selected carefully to avoid other problems (for example, solidification cracking).

Methods for Determining Preheat/Heat Input. It is common practice to find preheat information by using published tables (for example, WRC Bulletin No. 326) or tables in applicable codes (for example, AWS D1.1). There are also various methods available that allow the fabricator to determine the necessary preheat (and/or heat input) by taking into account the effect of important variables such as steel composition, amount of restraint, and hydrogen level. Many codes, such as AWS D1.1 (Ref 3), Canadian Standard W59 (Ref 4), and British Standard 5135 (Ref 6), provide methods that the fabricator can use to determine preheat and/or heat input. The method used depends on the hardenability of the steel.

For lower hardenability steels, a hardness control method is used. The basis of this method is that welding conditions can be chosen that will give cooling rates slow enough to avoid the formation of a hard, brittle microstructure in the HAZ. Critical hardness levels, below which cracking is unlikely to occur, have been established. For high-hydrogen consumables, this critical hardness value is 350 HV, while for low-hydrogen consumables (<10 mL/100 g of diffusible hydrogen) it increases to 400 HV.

The cooling rate required to keep the HAZ hardness below the critical value is a function of the composition of the steel (this can be seen in Fig. 2). A carbon equivalent (CE) is used as an indicator of the hardenability of the steel. If the CE is known, Fig. 6 can be used to determine the cooling rate necessary to avoid cracking. Then the heat input and, if necessary, preheat to produce that cooling rate can be determined by using published data for various plate thicknesses. This is done graphically in AWS D1.1 (Ref 3) and CSA W59 (Ref 4) for determining the heat inputs necessary to make crackfree fillet welds without the need to preheat. Figure 7 is an example for submerged arc fillets with 13 mm ($\frac{1}{2}$ in.) flanges. Reference 7 (upon which specification BS 5135 is based) provides a more thorough treatment that allows one to determine the required heat inputs and, if necessary, preheat. An example of the graphical presentation is given in Fig. 8. Knowing the carbon equivalent, one can determine an energy input/preheat combination for a variety of plate thicknesses. The hardness control method is used for carbon steels up to CE = 0.6.

For higher hardenability steels, a hydrogen control method is used. Even slow cooling rates cannot prevent the formation of hard, brittle microstructures. In order to avoid cracking, a hydrogen control method is used. The hydrogen control method consists of holding the weld at an elevated temperature, above the range where cracking occurs, so that hydrogen can diffuse out of the weld area more rapidly. This method requires a preheat, an interpass temperature to maintain the heat, and a postweld soak to hold the heat after welding. Both AWS D1.1 (Appendix XI) (Ref 3) and CSA W59 (Appendix P) (Ref 4) provide a hydrogen control method that was designed for low-alloy steels and that may yield conservative results for carbon steels. Reference 7 provides a variety of data for different grades of steel. Figure 9 can be used for medium-carbon steels with up to 0.45% C.

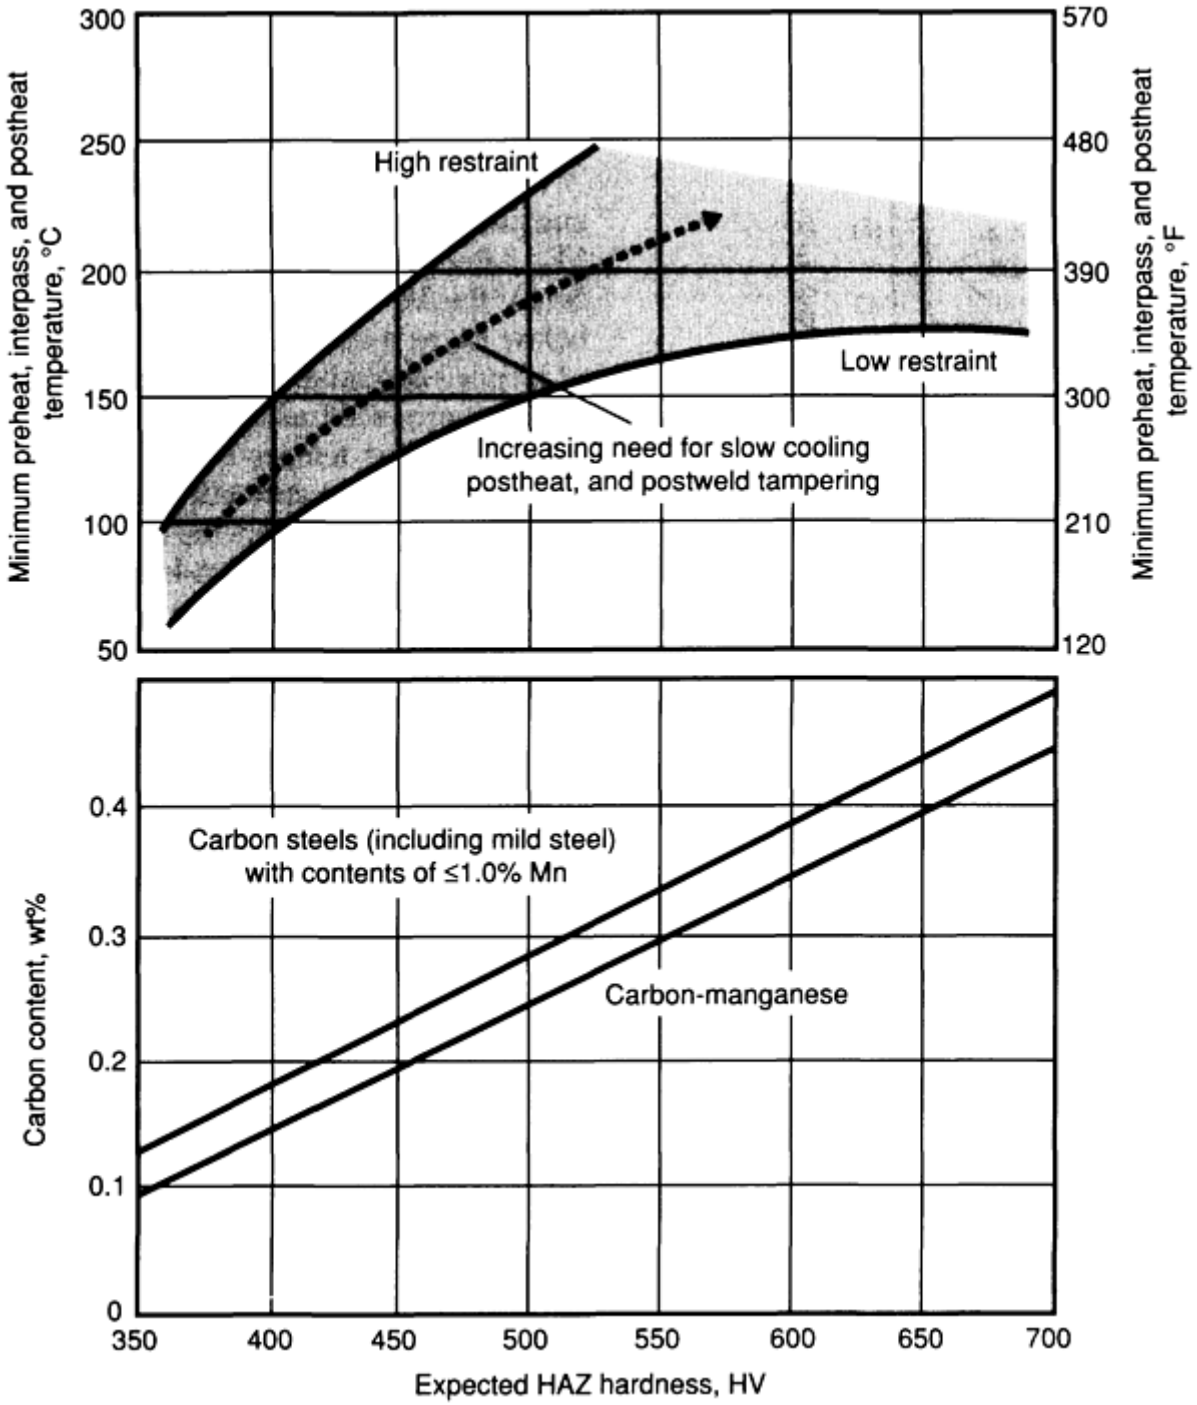

FIG. 9 PLOT FOR SELECTING PREHEAT, INTERPASS, AND POSTWELD SOAK TEMPERATURES FOR FULLY HARDENED CARBON STEELS USING HYDROGEN CONTROL METHOD. SOURCE: REF 7

Medium-carbon steels are often stress-relieved, especially at higher carbon levels, at higher restraint, and for welds exposed to shock or fatigue loading. When stress relief is not possible, an isothermal transformation method may be used. The use of this method requires knowledge about the isothermal transformation characteristics of the steel. By maintaining preheat, interpass, and postweld soak temperatures above the M_s for a sufficient length of time, a nonmartensitic microstructure is formed. This microstructure (usually bainite) will be less susceptible to hydrogen-induced cracking than martensite, but more susceptible than tempered martensite. For this reason, stress relieving is preferred when it can be done.

When even minimal preheat cannot be used with medium- or high-carbon steels, the use of an austenitic filler material should be considered. However, it should be noted that an austenitic filler cannot meet the yield strength requirements of a medium- or high-carbon steel. The high solubility of hydrogen in the austenitic weld metal and the slow diffusion rates limit the amount of hydrogen in the HAZ. At higher base-plate carbon levels (>0.4% C), a 150 °C (300 °F) preheat is recommended to reduce cracking tendency.

For high-carbon steels, the preheat, interpass, and postweld temperature should be equal to the M_s. After welding, the weld should be cooled below the M_s (60 to 70 °C, or 110 to 125 °F, below M_s as a minimum) to reduce the amount of retained austenite. A double temper treatment is then introduced as an additional heat treatment. The first temper treatment converts the remaining retained austenite to martensite. The second treatment tempers the martensite.

Overview of Hydrogen-Induced Cracking in Carbon Steels. The following guidelines apply to hydrogen-induced cracking in carbon steels.

Carbon steels with less than 0.2% C are generally not susceptible to cracking, and precautions are usually unnecessary.

Mild steels can be welded with hardness control methods. Up to CE of 0.40, cooling rates can be controlled by energy input, and preheat is usually not necessary except for thick plates. Above CE of 0.40, preheat is required except in thin sections. The use of low-hydrogen consumables is recommended at higher carbon and manganese levels and will reduce preheat requirements at all carbon equivalents. A heat-treated mild steel may require a low-alloy steel weld metal to match its properties. The resultant weld metal itself may be susceptible to hydrogen-induced cracking, and suitable precautions should be taken (such as using the hydrogen control method based on weld metal composition). Low-hydrogen consumables should be used.

Medium-carbon steels up to CE = 0.6 can be welded with hardness control methods. Above CE = 0.6, hydrogen control methods (preheat, interpass, and postweld soak) should be used with low-hydrogen consumables. Stress relief is recommended at high carbon levels (>0.45% C), for highly restrained welds, or for welds subjected to fatigue or shock loading. When stress relief is not possible, the isothermal transformation method should be considered.

High-carbon steels require preheat equal to the martensite start temperature, followed by a double temper. When tempering or isothermal transformation is not possible, the use of an austenitic filler material should be considered. Procedure testing for each specific application of high-carbon steel welding is essential.

Solidification Cracking

Solidification cracking occurs at high temperature, at the terminal stages of solidification. The cracks are easily recognized because they usually follow the weld centerline, although they do not always come to the surface. The cracks often appear towards the end of the weld, due to stresses arising from the thermal field. The crack surfaces are heavily oxidized, and dendritic structures can often be found upon examination with scanning electron microscopy.

Solidification cracks arise due to the formation of low melting compounds at grain boundaries. When a coherent solid network forms upon solidification, stresses start to build across the weld due to shrinkage. The low melting compounds remain molten, and the grain boundaries rupture under the shrinkage stresses. The conditions that control the extent of solidification cracking are the amount of impurities, the shape of the weld, and the stress level.

Impurities. Sulfur and phosphorus are the main causes of solidification cracking in carbon steel weld metal. Both will segregate to grain boundaries and form low melting compounds. In the case of sulfur, this is FeS, which tends to form a continuous film at the grain boundaries. The addition of a sufficient amount of manganese to the weld metal will cause MnS to form in preference to FeS. Manganese sulfide solidifies at a higher temperature and forms as globules, a morphology much less prone to cracking. Figure 10 shows the ratio of manganese to sulfur necessary to avoid cracking. Carbon also has a very strong effect, with the cracking tendency increasing with carbon content. At higher carbon levels, increasing the manganese-to-sulfur ratio is less effective, and it is more beneficial to lower the carbon content to avoid cracking. The effect of carbon is believed to be related to the phase, δ-ferrite or austenite, that forms upon solidification. At lower carbon contents, δ-ferrite, which has a relatively high solubility for sulfur and phosphorus, is the primary phase formed. As the carbon content increases, more austenite is formed upon solidification. Because austenite has a low solubility for sulfur and phosphorus, more of these impurities are rejected upon solidification and tend to build up at interdendritic boundaries.

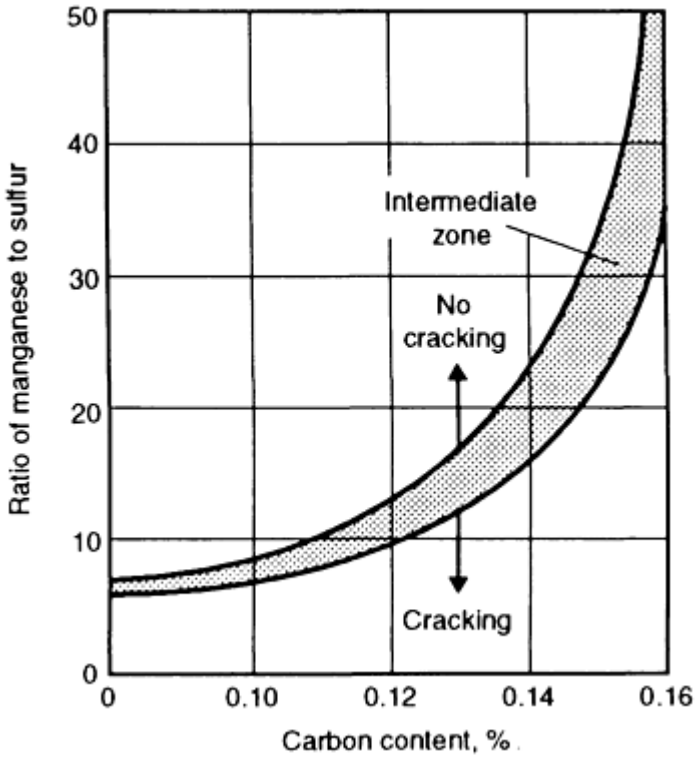

FIG. 10 EFFECT OF MANGANESE-TO-SULFUR RATIO AND CARBON CONTENT ON SOLIDIFICATION CRACKING TENDENCIES IN CARBON STEEL WELD METAL. SOURCE: REF 8

Welding consumables are kept deliberately low in sulfur and phosphorus to avoid problems. Base plates are the primary contributors of these impurities. Any high-dilution welding procedure or process (for example, submerged arc welding) will promote the pickup of impurities.

The shape of the weld bead and the solidification grain structure also affect solidification cracking (Fig. 11). Concave weld beads have a greater tendency to crack because their outer surface is stressed in tension. A slightly convex bead is always preferred. Deep narrow beads also have a greater tendency to crack. The depth-to-width ratio (d/w) should always be between 0.5 and 0.8.

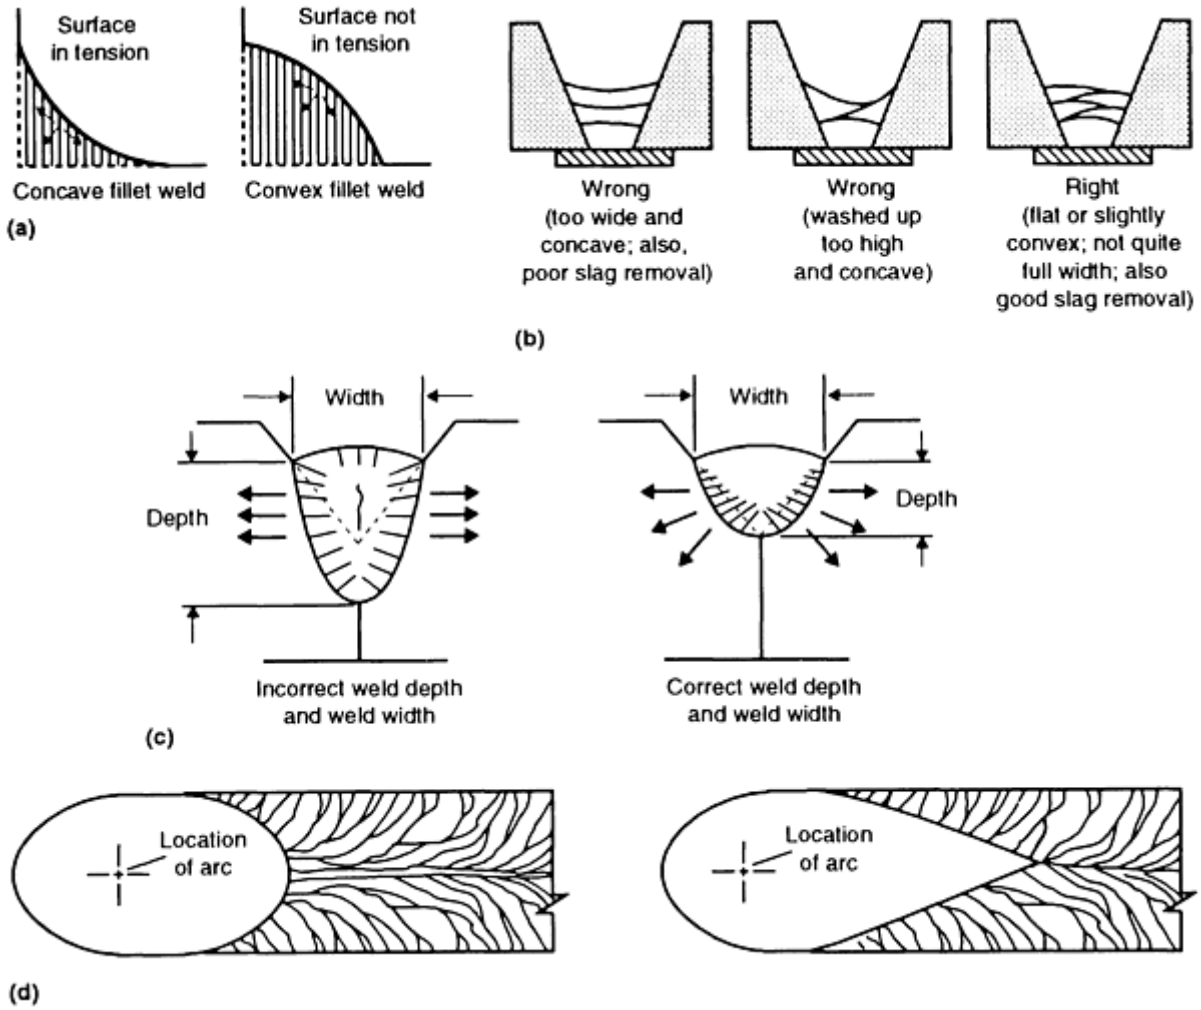

FIG. 11 EFFECT OF WELD BEAD SHAPE AND SOLIDIFICATION PATTERN ON SOLIDIFICATION CRACKING. (A) AND (B) CONCAVE VERSUS CONVEX BEAD SHAPES. SLIGHTLY CONVEX BEAD SHAPES ARE PREFERRED. (C) PREFERRED DEPTH AND WIDTH OF WELD BEAD. DEEP, NARROW BEADS SHOULD BE AVOIDED. (D) EFFECT OF TRAVEL SPEED ON CRACKING POTENTIAL. HIGH TRAVEL SPEEDS (TEARDROP-SHAPED PUDDLE, ON RIGHT) RESULT IN MORE CENTERLINE SEGREGATION AND A GREATER CHANCE OF CRACKING. SOURCE: REF 9, 10

High travel speeds tend to cause the dendrites growing from either side of the weld to meet head on. This results in heavy segregation of impurities at the weld centerline and a greater likelihood of centerline cracking. Teardrop-shaped puddles, which produce this type of solidification pattern, should be avoided if the weld metal is susceptible to hot cracking.

Weld Configuration. The greater the restraint in a joint, the greater the likelihood of solidification cracking. Particular care must be taken with root beads. They are generally small, highly diluted beads (a problem if the steel is high in carbon, sulfur, or phosphorus) that can be subjected to very high stresses. Concave weld beads should be avoided here also. A convex bead gives a better stress distribution and increases the throat dimension, thus providing more cross-sectional area to carry the stresses. A slight offset of the plates (Fig. 12) and freedom for them to move will reduce the residual stresses. If no offset is used, a gap at the root should be provided to allow for shrinkage movement. When welding higher-carbon steels, a low-carbon electrode will reduce the weld metal carbon level and decrease the likelihood of cracking.

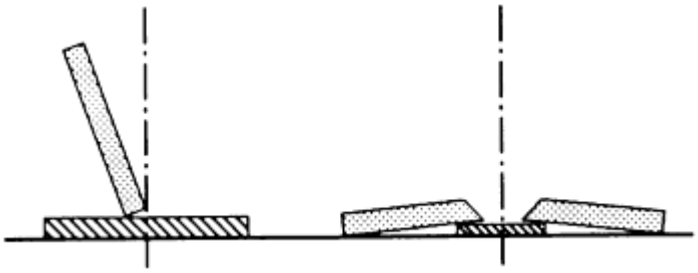

FIG. 12 DESIGN FOR OFFSETTING PLATES THAT ALLOWS THEM TO MOVE INTO FINAL POSITION, THEREBY REDUCING RESIDUAL STRESSES. SOURCE: REF 11

Welding of Free-Machining Steels. SAE-AISI series 11*xx* and 12*xx* steels are a particular problem because they contain high amounts of sulfur, phosphorus, or lead for improved machinability (see Tables 1(a) and 1(b)). The 11*xx* series steels are all resulfurized. The 12*xx* series steels are resulfurized and rephosphorized. The letter "L" after the first two numbers in any steel designation indicates the presence of lead.

All of these steels are susceptible to solidification cracking because of the high sulfur and phosphorus contents. High sulfur contents can also cause weld metal porosity. Lead can cause weld metal porosity or embrittlement, but the main concern is toxic fumes. Special precautions are required to ensure good ventilation during the welding of leaded steels.

When free-machining steels must be welded, a low-hydrogen consumable with a basic slag system is recommended. Low hydrogen will reduce the formation of hydrogen sulfide porosity, while the basic slag system reduces the sulfur and phosphorus content of the weld metal. Shielded metal arc welding electrodes such as E7015, E7016, and E7018 are preferred because they are the basic electrodes that produce the least base plate dilution. For gas-shielded flux-cored electrodes, E70T-5 and E71T-5 types are preferred over T-1 electrodes. Self-shielded flux-cored electrodes of the T-4, T-7 and T-8 types are recommended. Low currents should be used with all electrodes in order to minimize base plate dilution.

There is no guarantee that these precautions will eliminate the problem. Sometimes the best that can be achieved is a reduced level of cracking and/or porosity. The best advice is not to weld free-machining steel at all. Welding specifications can state that no component in a welded assembly should be produced from these materials. Overall, this will lead to the lowest total cost for the welded assembly.

Lamellar Tearing

Lamellar tearing is a form of cracking that occurs in the base metal beneath the weld (Fig. 13). It is caused by a combination of high, localized stresses from weld contraction and poor through-thickness ductility in the steel. The tearing is initiated by the separation of the interface between inclusions and metal (delamination) or by fracture of an inclusion itself. The cracks enlarge by linkage of delaminations in the same plane and by shear steps that join cracks on different planes. The controlling factors in lamellar tearing are:

- QUANTITY AND MORPHOLOGY OF NONMETALLIC INCLUSIONS (USUALLY SULFIDES OR SILICATES)
- MAGNITUDE OF THE INDUCED STRESSES NORMAL TO THE PLATE SURFACE

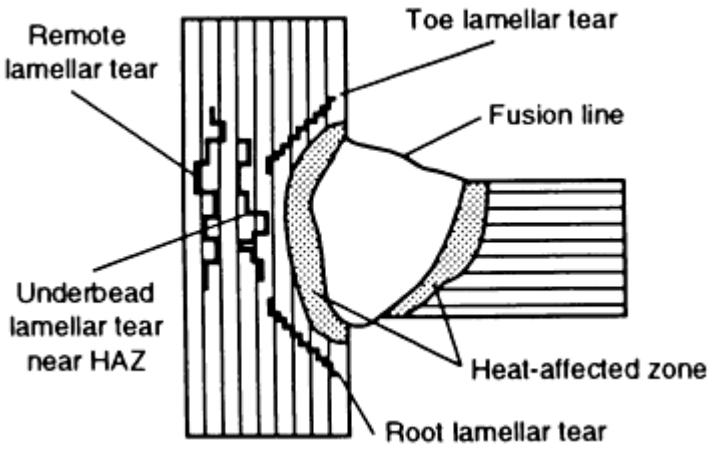

FIG. 13 ORIENTATION OF LAMELLAR TEARS IN A BASE METAL BELOW THE WELD. SOURCE: REF 4

During the hot rolling of plate, the inclusions become elongated in the rolling direction and tend to flatten out parallel to the surface of the plate. The ductility in the through-thickness direction is reduced because the bond between the inclusions and steel is much weaker than the steel itself. If the quantity of inclusions is high and if they have been sufficiently flattened during hot rolling, the steel may fail under high stresses in the thickness direction.

The magnitude of the induced stresses depends on the joint design, the degree of restraint imposed on the joint, the plate thickness, the orientation of the weld, and the size of the weld. Restrained corner or T-joints are the most susceptible to lamellar tearing because the fusion boundary is roughly parallel to the plate surface (Fig. 14) and through-thickness contraction stresses are high. Lamellar tearing in butt welds is rare. Thick-plate, high-imposed restraint (for example, rigid clamping) and large weld beads all increase residual stresses and the likelihood of tearing.

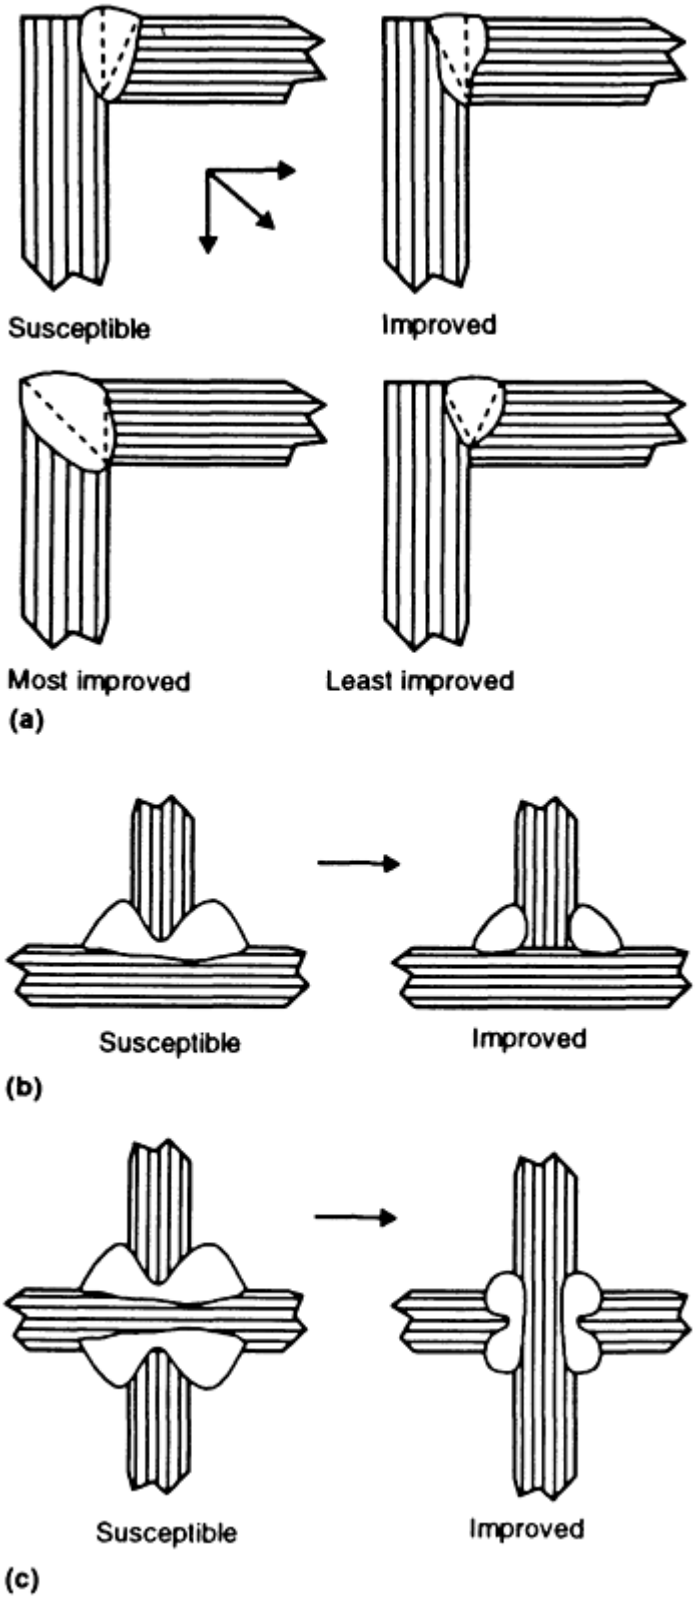

FIG. 14 METHODS USED TO REDUCE LAMELLAR TEARING. (A) ANGLING THE WELD FUSION LINE TO AVOID SHRINKAGE STRESSES IN THE THROUGH-THICKNESS DIRECTION. (B) USE OF SMALLER PARTIAL-PENETRATION WELDS TO REDUCE JOINT RESTRAINT. (C) PLACEMENT OF WELDING BEADS ON THE THINNER PLATE (WHEN WELDING PLATES OF DIFFERENT THICKNESSES) SO THAT SMALLER BEADS CAN BE USED. SOURCE: REF 4

Hydrogen has also been found to increase susceptibility to lamellar tearing. For this reason, a moderate preheat is sometimes beneficial in reducing the tendency to lamellar tearing. The use of low-hydrogen consumables is also beneficial.

Steps to avoid lamellar tearing include:

- USE OF PLATE MATERIAL WITH IMPROVED THROUGH-THICKNESS PROPERTIES. A REDUCTION IN OXYGEN CONTENT (BY ALUMINUM KILLING, FOR EXAMPLE) OR A REDUCTION IN SULFUR CONTENT WILL REDUCE THE AMOUNT OF INCLUSIONS IN THE STEEL. SULFUR UNDER 0.01% WILL GREATLY REDUCE THE RISK OF LAMELLAR TEARING. SULFIDE SHAPE CONTROL, THROUGH THE ADDITION OF RARE EARTHS OR CALCIUM TREATMENT DURING STEELMAKING, WILL ALTER THE INCLUSION MORPHOLOGY FROM STRINGERS TO DISCONTINUOUS GLOBULES.
- CHANGE THE JOINT DESIGN TO MINIMIZE THROUGH-THICKNESS CONTRACTION STRESSES (SEE FIG. 14 FOR EXAMPLES).
- USE LOWER-STRENGTH WELDING CONSUMABLES. THIS WILL ABSORB AND REDUCE SOME OF THE THROUGH-THICKNESS STRESS.
- IN EXTREME CASES, THE SURFACE OF THE PLATE MAY BE GROUND OR MACHINED TO A LEVEL BELOW WHERE LAMELLAR TEARING IS ANTICIPATED. THE AREA CAN THEN BE BUTTERED WITH WELD METAL AND THE ATTACHMENT WELD CAN BE MADE.

Porosity

Porosity in carbon steel weld metal may result from excessive amounts of carbon monoxide, nitrogen, hydrogen, or hydrogen sulfide remaining in the weld pool upon solidification.

Carbon monoxide is formed when oxygen combines with carbon in the weld puddle. The oxygen may come from the arc atmosphere, the welding consumables (especially fluxes), or the steel base material. Rimmed and capped steels contain low silicon (<0.05%) and high oxygen. When these types of steels are welded, the carbon and oxygen from the steel will react to form carbon monoxide, unless there is sufficient deoxidizer in the weld metal to prevent it. This deoxidizer (usually silicon) must come from the welding consumable. Higher levels of deoxidizer in the welding electrode are required when welding rimmed and capped steels. A killed steel is fully deoxidized during manufacture by the addition of silicon and/or aluminum or by vacuum treatment. Because it is the least costly, silicon (0.15 to 0.30%) is often used, although aluminum killing is becoming much more common. Killed steels are much less prone to carbon monoxide porosity, and consumables with a lower silicon level may often be used to weld them. A semikilled steel (0.05 to 0.10% Si) has a behavior that is intermediate to the rimmed and killed steels. It is important that the fabricator realize what deoxidation practice was used on the base material, especially for processes like autogenous gas-tungsten arc welding where no filler material is used.

The surface condition of the base material can also affect porosity levels. Millscale (iron oxide) or rust (hydrated iron oxide) adds additional oxygen to the weld puddle. Higher levels of deoxidizers in the consumables will be needed to prevent carbon monoxide porosity.

Nitrogen in the weld metal is most often the result of poor shielding. The amount of pickup will be increased by the use of excessive voltage (longer arc length), excessive travel speeds (effectively outrunning the shielding), broken electrode coatings, or unstable arc conditions (such as arc blow). A nitrogen-containing residue may be left on the surface of plasma cut plate when nitrogen is used as a cutting gas. Grinding of the surface may be necessary to avoid weld metal porosity.

Hydrogen has numerous sources, including atmospheric moisture, welding consumables (especially fluxes), and plate contaminants. The major source of hydrogen is the welding consumable. Hydrogen sources and pickup were discussed more fully in the section "Hydrogen-Induced Cracking" in this article.

Hydrogen sulfide is formed when high-hydrogen weld metal combines with high-sulfur (>0.04%) base plate. This type of porosity was discussed in the section "Welding of Free-Machining Steels" in this article.

There are many potential causes of porosity, too numerous to be covered in this article. Detailed information is available in the Section "Fusion Welding Processes" and the article "Overview of Weld Discontinuities" in this Volume.

Arc Welding of Carbon Steels

Ronald B. Smith, The ESAB Group, Inc.

Process Selection

All of the arc welding processes are suitable for welding carbon steels. Choosing the best process to use for a particular application must take into account not only the material characteristics (sensitivity to porosity or cracking and the required mechanical properties), but also the details of the joint (plate thickness, joint design, welding position, and location) and weld economics (deposition rates and efficiencies, cost of labor, cost of consumables, capital cost of equipment, number of spare parts required, operator skills or training needed, set-up, and cleanup cost, and so on). There are many excellent reviews (Ref 9, 11, 12, 13) that discuss process selection and cost calculation details. Table 5 provides a brief guide that can be used to select a process for welding carbon steels.

TABLE 5 PROCESS SELECTION GUIDELINES FOR ARC WELDING CARBON STEELS

PARAMETERS	**SMAW**	**GMAW**	**FCAW**	**GTAW/PAW**	**SAW**	**EGW/ESW**	SW
USABILITY	VERY ADAPTABLE, ALL-POSITION PROCESS. CAN BE USED OUTDOORS. GIVES EXCELLENT JOINT ACCESSIBILITY. VERY PORTABLE. CAN BE USED ON CARBON STEELS DOWN TO 18 GAGE. JOINT PREPARATION IS REQUIRED ON THICKNESSES OVER 3.2 MM ($\frac{1}{8}$ IN.). UNLIMITED UPPER THICKNESS BUT OTHER PROCESSES (GMAW, FCAW, OR SAW) ARE USUALLY MORE ECONOMICAL.	AN ALL-POSITION PROCESS IN THE SHORT-ARC OR PULSED MODE. MODERATELY ADAPTABLE, BUT USE LIMITED OUTSIDE WHERE LOSS OF SHIELDING IS POSSIBLE. USABLE ON STEEL DOWN TO <0.25 MM (0.010 IN.) THICK. ABOVE 4.8 MM ($\frac{3}{16}$ IN.), REQUIRES JOINT PREPARATION. NO UPPER LIMIT OF PLATE THICKNESS.	ALL-POSITION PROCESS. EQUIPMENT SIMILAR TO GMAW, BUT SELF-SHIELDED VERSION HAS BETTER PORTABILITY AND IS USABLE OUTDOORS. MINIMUM PLATE THICKNESS IS 18 GAGE. FOR SELF-SHIELDED MATERIAL ABOVE 6.4 MM ($\frac{1}{4}$ IN.), REQUIRES JOINT PREPARATION. WITH CO_2 SHIELDING, MATERIALS ABOVE 13 MM ($\frac{1}{2}$ IN.) REQUIRE JOINT PREPARATION. THERE IS NO UPPER LIMIT ON PLATE THICKNESS.	AN ALL-POSITION PROCESS WITH FAIR JOINT ACCESSIBILITY. LIMITED OUTDOOR USE. CAN WELD VERY THIN MATERIAL IN ALL POSITIONS; GTAW--<0.13 MM (0.005 IN.) MIN. THICKNESS, JOINT PREP. OVER 3.2 MM ($\frac{1}{8}$ IN.) PAW--<0.13 MM (0.005 IN.) MIN. THICKNESS, JOINT PREP OVER 6.4 MM ($\frac{1}{4}$ IN.). NO UPPER LIMIT ON THICKNESS BUT OTHER PROCESSES ARE MORE EFFICIENT.	LIMITED TO FLAT AND HORIZONTAL POSITION. SEMI-AUTOMATIC VERSION HAS SOME ADAPTABILITY BUT PROCESS IS MOST OFTEN MECHANIZED AND HAS LIMITED PORTABILITY. MINIMUM MATERIAL THICKNESS IS 1.6 MM ($\frac{1}{16}$ IN.) (MECHANIZED). JOINT PREPARATION IS REQUIRED ON MATERIAL ABOVE 13 MM ($\frac{1}{2}$ IN.) THICK. THE PROCESS LENDS ITSELF TO WELDING THICK MATERIALS.	LIMITED TO VERTICAL OR NEAR-VERTICAL. O.K. OUTSIDE. FAIR PORTABILITY. EGW USED ON PLATE 9.5 TO 102 MM ($\frac{3}{8}$ TO 4 IN.) THICK. ESW USED ON PLATE 19 TO 900 MM ($\frac{3}{4}$ TO 36 IN.) HICK.	**ALL-POSITION. O.K. OUTSIDE. FAIR PORTABILITY. USED ON PLATE 1.0 MM (0.04 IN.) AND ABOVE. NO JOINT PREPARATION REQUIRED.**
COST FACTORS	A LOW-DEPOSITION-RATE PROCESS (UP TO 9 KG/H, OR 20 LB/H) WITH LOW DEPOSIT EFFICIENCY (TYPICALLY 65%).	DEPOSITION RATES (TO 16 KG/H, OR 35 LB/H) ARE HIGHER THAN SMAW. DEPOSITION EFFICIENCY (90-	DEPOSITION RATES (UP TO 18 KG/H, OR 40 LB/H) ARE HIGHER THAN GMAW. DEPOSITION EFFICIENCIES (80-90%) ARE LOWER	LOW DEPOSITION RATES (UP TO 5.4 KG/H, OR 12 LB/H) BUT HIGH DEPOSITION EFFICIENCY (99%). IF AUTOMATED,	DEPOSITION RATES ARE VERY HIGH (OVER 45 KG/H, OR 100 LB/H WITH MULTIWIRE SYSTEMS). DEPOSITION EFFICIENCY IS 99%	HIGH JOINT COMPLETION RATE. HIGH DEPOSITION EFFICIENCY (SOLID WIRES--99%, CORED WIRES LOWER).	**EQUIPMENT COST IS MODERATE.**

	LOW OPERATOR FACTOR. EQUIPMENT COST IS LOW AND SPARE PARTS ARE MINIMAL. WELDING SPEEDS ARE GENERALLY LOW. HOUSEKEEPING IS REQUIRED TO DESLAG AND DISPOSE OF FLUX AND ELECTRODE STUBS.	95%) AND OPERATOR FACTOR (TYPICAL 50%) ARE ALSO HIGHER. EQUIPMENT AND SPARE PARTS COST ARE MODERATE TO HIGH (PULSED-ARC POWER SUPPLIES ARE HIGHER COST). WELDING SPEEDS ARE MODERATE TO HIGH (BURIED ARC CO_2 CAN WELD AT OVER 2540 MM/MIN (100 IN./MIN). CLEANUP IS MINIMAL.	BUT OPERATOR FACTORS (50%) ARE SIMILAR TO GMAW. EQUIPMENT COST IS MODERATE. GOOD OUT-OF-POSITION DEPOSITION RATES CAN BE ACHIEVED WITH CONVENTIONAL POWER SOURCES. WELDING SPEEDS ARE MODERATE TO HIGH. SLAG AND SPATTER REMOVAL AND DISPOSAL IS REQUIRED.	THE OPERATOR FACTOR IS HIGH. EQUIPMENT AND SPARE PARTS COST IS MODERATE TO HIGH, DEPENDING ON COMPLEXITY (PAW IS SLIGHTLY MORE EXPENSIVE). CLEANUP IS GENERALLY UNNECESSARY DUE TO NO FLUX OR SPATTER.	BUT THAT DOES NOT INCLUDE THE FLUX (A 1:1 FLUX-TO-WIRE RATIO IS COMMON). BECAUSE THE PROCESS IS USUALLY MECHANIZED, OPERATOR FACTORS ARE HIGH. COST IS MODERATE FOR SINGLE-WIRE SYSTEMS. HIGH WELDING SPEEDS ARE ACHIEVABLE. HIGHER HOUSEKEEPING COSTS RESULT FROM THE NEED TO HANDLE THE SLAG AND UNFUSED FLUX.	HIGH OPERATOR FACTOR. HIGH EQUIPMENT AND SET-UP COST.	
WELD METAL QUALITY	STRONGLY DEPENDENT ON THE SKILL OF THE WELDER. LACK OF FUSION OR SLAG INCLUSIONS ARE POTENTIAL PROBLEMS. THE RELATIVELY SMALL BEADS USUALLY RESULT IN A HIGH PERCENTAGE OF REFINING IN MULTIPASS WELDS, AND VERY GOOD TOUGHNESS IS ACHIEVABLE WITH SOME	VERY GOOD QUALITY. POROSITY OR LACK OF FUSION CAN BE A PROBLEM. LESS TOLERANT OF RUST AND MILLSCALE THAN FLUX-USING PROCESSES. VERY GOOD TOUGHNESS IS ACHIEVABLE.	GOOD QUALITY. WELD METAL TOUGHNESS IS FAIR TO GOOD (BEST WITH BASIC ELECTRODES). SLAG INCLUSIONS ARE A POTENTIAL PROBLEM.	HIGH QUALITY, BUT REQUIRES CLEAN PLATE. EXCELLENT TOUGHNESS POSSIBLE DUE TO SMALL BEAD SIZE (HIGH REFINED WELD METAL, FINER GRAIN SIZE).	VERY GOOD. GOOD WELD METAL TOUGHNESS IS POSSIBLE. HANDLES RUST AND MILLSCALE WELL WITH PROPER FLUX SELECTION. HIGH-DILUTION PROCESS.	LARGE COLUMNAR GRAIN STRUCTURE RESULTS IN ONLY FAIR TOUGHNESS. HIGH DILUTION OF BASEPLATE (UP TO 35% FOR EGW, UP TO 50% FOR ESW).	**MINIMAL WELD SIZE. USUALLY FINE-GRAINED DUE TO FAST COOLING. WELD STRUCTURE IS AS CAST.**

	ELECTRODES.						
EFFECT ON BASE METAL	LOW HEAT INPUTS CAN CAUSE RAPID HAZ COOLING. FLUX COATINGS ARE A POTENTIAL SOURCE OF HYDROGEN.	GENERALLY A LOW-HYDROGEN PROCESS.	FLUX CORE CAN CONTRIBUTE HYDROGEN.	A LOW-HYDROGEN PROCESS. LOW HEAT INPUTS CAN CAUSE RAPID HAZ COOLING.	HIGHER HEAT INPUTS CAN RESULT IN LARGE HAZ AND POSSIBLE DETERIORATION OF BASEPLATE PROPERTIES (ESPECIALLY QUENCHED AND TEMPERED PLATE). FLUX IS A SOURCE OF HYDROGEN.	HIGH HEAT INPUT RESULTS IN LARGE HAZ AND GRAIN GROWTH. NOT RECOMMENDED FOR QUENCHED AND TEMPERED STEELS UNLESS REHEAT TREATMENT IS TO BE DONE. SLOW WELD COOLING ALLOWS HYDROGEN TO ESCAPE WELD AREA.	**CAUSES RAPID COOLING OF HAZ.**
GENERAL COMMENTS	**VERY VERSATILE, LOW-COST PROCESS. ESPECIALLY STRONG ON NON-ROUTINE OR REPAIR JOBS. USUALLY NOT ECONOMICAL ON STANDARD THICK WELDS OR ON REPETITIVE JOBS THAT CAN BE MECHANIZED.**	**RELATIVELY VERSATILE. EQUIPMENT MORE COSTLY, COMPLEX, AND LESS PORTABLE THAN SMAW. EASILY MECHANIZED. A CLEAN PROCESS WITH HIGHER DEPOSITION RATES AND EFFICIENCIES THAN SMAW.**	**RELATIVELY VERSATILE (SELF-SHIELDED VERSION CAN BE USED OUTSIDE). HIGHER DEPOSITION RATES THAN GMAW (HIGHER FUMES ALSO). WELDS EASILY OUT-OF-POSITION. READILY MECHANIZED.**	**EXTREMELY GOOD WELDS IN ALL POSITIONS. REQUIRES MORE PREPARATION. LOW DEPOSITION RATES LIMIT PROCESS TO THINNER PLATES.**	**A HIGH-DEPOSITION, HIGH-PENETRATION PROCESS, BUT THIN MATERIAL CAN BE WELDED AT HIGH SPEEDS. EASILY MECHANIZED. NATURAL FOR WELDING THICKER PLATES. HOUSEKEEPING AND POSITION LIMITATION CAN BE A PROBLEM.**	**HIGH JOINT COMPLETION RATE, BUT LIMITED TO VERTICAL. USED MAINLY ON LONG VERTICAL WELDS. HIGH HEAT INPUT CAN LIMIT BASEPLATES.**	**SPECIALIZED PROCESS FOR ATTACHING STUDS TO STEEL PLATE. USUALLY MORE ECONOMICAL THAN DRILLING AND TAPPING.**

SMAW, shielded metal arc welding; GMAW, gas-metal arc welding; FCAW, flux-cored arc welding; GTAW, gas-tungsten arc welding; PAW, plasma arc welding; SAW, submerged arc welding; EGW, electrogas welding; ESW, electroslag welding; SAW, stud arc welding

The effect of the welding process on carbon steel base metal is a function of the heat input (and cooling rate) imposed by the process and the amount of hydrogen contributed. Low-heat-input processes, such as gas-tungsten arc welding (GTAW), plasma arc welding (PAW), shielded metal arc welding (SMAW), short-arc gas-metal arc welding (GMAW), and stud welding (SW), result in a narrow, rapidly cooled HAZ. Greater care needs to be exercised when using these processes to weld hardenable carbon steels. On the other hand, a higher-heat-input process, like electrogas welding (EGW), will produce a much wider HAZ, produce more grain coarsening, and may cause a deterioration in the properties of heat-treated carbon steels. Heat input limits or a process change may be necessary when welding quenched and tempered carbon steels.

The arc welding processes that employ flux or flux-containing consumables contribute hydrogen to the weld area if the consumables are not adequately dried or protected from moisture. Examples are SMAW, flux-cored arc welding (FCAW), and submerged arc welding (SAW). Each of these processes offers low-hydrogen consumable types that should be used when welding hardenable carbon steels. Procedures are available, or will soon be available, in AWS electrode specifications to allow classification of arc welding electrodes based upon the weld metal diffusible hydrogen produced. This is a safe approach to use when welding hardenable carbon steels, because there can be wide variations between electrodes, even in the so-called "low-hydrogen" processes.

Weld metal properties as a function of process are a bit more complex. Not only are the heat input and hydrogen contributions important, but also the amount of base metal dilution, rust and scale tolerance, and pickup of atmospheric gases. The high-heat-input processes, particularly EGW, and electroslag welding (ESW) will result in large columnar grains and resulting lower toughness. The lower-heat-input processes (particularly GTAW, PAW, and SMAW) produce finer grain size. For a given weld chemistry, the higher-heat-input processes will produce a weaker weld deposit because of the formation of coarser, high-temperature transformation products. Hydrogen-induced cracking is generally not as serious a problem in weld metal as it is in the HAZ, because weld metal is usually low in carbon. Excessive carbon pickup (by dilution) or the use of an alloyed electrode would make the weld metal more vulnerable.

High dilution processes (for example, SAW and EGW) will incorporate a large amount of base metal into the weld. In square-butt submerged arc welds, over 60% of the weld metal can be diluted base metal. Obviously, this has a major effect on the properties of the weld metal. It also illustrates the importance of conducting procedure qualification testing to determine the actual mechanical and chemical properties of the production joint. The pickup of impurities (for example, sulfur, phosphorus, or nitrogen) from the base plate could lead to problems such as solidification cracking, porosity, or toughness deterioration.

The tolerance of the process to plate contaminants, such as rust, scale, or organic compounds (oil, grease, and so on) can be important. The nonflux processes are generally less tolerant of rust and scale. Processes such as GTAW, GMAW, and PAW are particularly sensitive and require clean plate. The submerged arc process is sensitive to porosity caused by organic compounds. In the open arc processes, the compounds can be vaporized by the heat of the arc before steel melting occurs. In submerged arc welding, the flux blanket acts to block the radiant heat from the arc, and the compound becomes incorporated in the weld metal.

Pickup of nitrogen and oxygen can also cause problems. Porosity is one outcome; toughness deterioration is another. Figure 15 shows the levels of weld metal oxygen and nitrogen produced by several arc welding processes. The GTAW and PAW processes produce the lowest gaseous impurity level. The arc in both of these processes is short and extremely stable, and the shielding gases (for example, argon or argon-helium mixtures) are inert and make no contribution. GMAW deposits are higher in both oxygen and nitrogen. A longer, less stable arc allows a greater chance of pickup. The use of Ar-O_2, Ar-CO_2, or CO_2 shielding gases also raises the oxygen level of the weld metal.

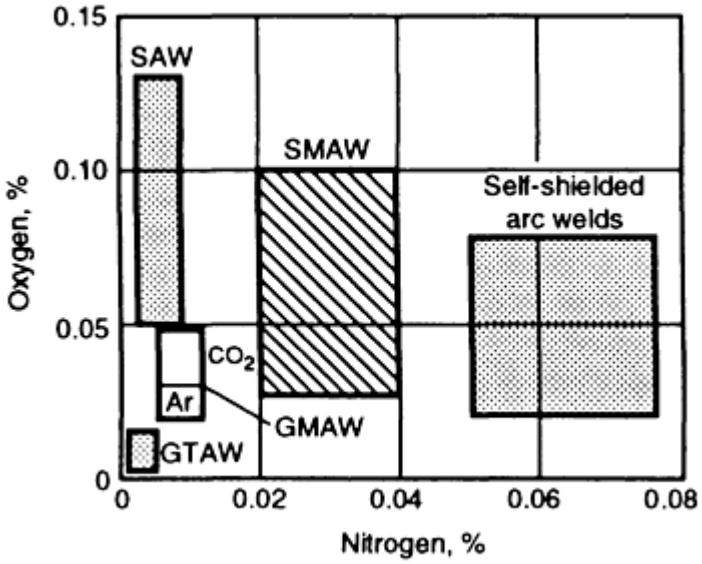

FIG. 15 TYPICAL OXYGEN AND NITROGEN LEVELS OBTAINED IN WELD METAL FROM SELECTED ARC WELDING PROCESSES. SOURCE: REF 14

The flux-using processes (that is, SMAW, FCAW, and SAW) can all pick up oxygen from decomposition of metal oxides contained within the flux. More basic flux systems produce lower oxygen levels. The two open arc, self-shielded processes (that is, SMAW and self-shielded FCAW) do not produce an even, well-directed gas shield. As a result, aspiration of air is higher than with the externally gas-shielded processes. Strong denitriders (for example, aluminum) are added to self-shielded flux-cored wires to counteract this pickup. Some submerged arc welds are more prone to nitrogen pickup when alternating current (ac) power is used.

All of the arc welding processes are susceptible to aspiration of air when long arc lengths (excessive arc voltages) are used. A longer arc length increases the time of exposure of the molten drops on transfer and increases the likelihood of gaseous impurity pickup.

Ronald B. Smith, The ESAB Group, Inc.

Welding Consumable Selection and Procedure Development

When choosing a welding consumable, the following should be considered:

- MECHANICAL PROPERTIES REQUIRED

- WELDABILITY CONSIDERATIONS
- PERFORMANCE FEATURES NEEDED OR DESIRED

Codes or customer specifications may define the mechanical properties required. Some codes will specify the types of electrodes to be used, while others limit the selection to certain products from certain manufacturers who have performed tests to qualify their products. If this information is not available, then it is customary to try to match or slightly exceed the base plate strength. There may be conditions where an undermatching weld metal strength is actually preferred--this is a function of the weld design and type of loading. The toughness level and other properties (for example, hardness) are dictated by service conditions and are more difficult to define. Code requirements can be used as guidelines.

Weldability considerations (that is, potential cracking or porosity problems in carbon steel) should then be assessed. A medium-carbon steel, for instance, will require a low-hydrogen consumable, preheat, and perhaps a postweld heat treatment to avoid hydrogen-induced cracking. The effect of this treatment on candidate consumables should be considered.

Certain performance features may be necessary, or at least desired. They allow the welding to be performed more economically. These types of choices are more frequently made with the flux-using processes where the formulations are designed to do certain things (for example, weld out-of-position, at high travel speeds, or at high deposition rates). Even nonflux processes require choices. For example, for GTAW of very thin steel tubing an ER70S-2 electrode (which contains some aluminum) produces a more viscous puddle that is easier to control out-of-position.

Once a consumable is chosen, a suitable process and procedure must be specified. American Society for Quality Control (ASQC) Standard Q91 (or ISO 9001) treats welding as a special process because the results cannot be fully verified by subsequent inspection and testing of the product. Therefore, documented work instructions, monitoring and control of process, approval of process and equipment, and criteria for workmanship shall be stipulated. In addition, ASQC Standard Q94 requires verifying the results of this special processing and determining to what extent equipment, environments, and operators are able to affect these final desired results.

In welding, the documented work instruction is usually referred to as a welding procedure specification (WPS) or just welding procedure (Fig. 16). In some fabrication specifications (for example, AWS D1.1), the WPS can be prequalified if it is specified within certain guidelines, such as equipment settings and methods. In other fabrication specifications, the WPS must be qualified, usually with the rules of the qualification standard such as the ASME Boiler and Presser Vessel Code Section IX or MIL STD 248. In all cases, a welding procedure specification that addresses all the important process variables must be documented. If these variables change, then a new WPS may have to be prepared to reflect these changes. Whether the WPS must be requalified when revised always depends on which variables are being revised. The qualification standard will identify which changes require requalification.

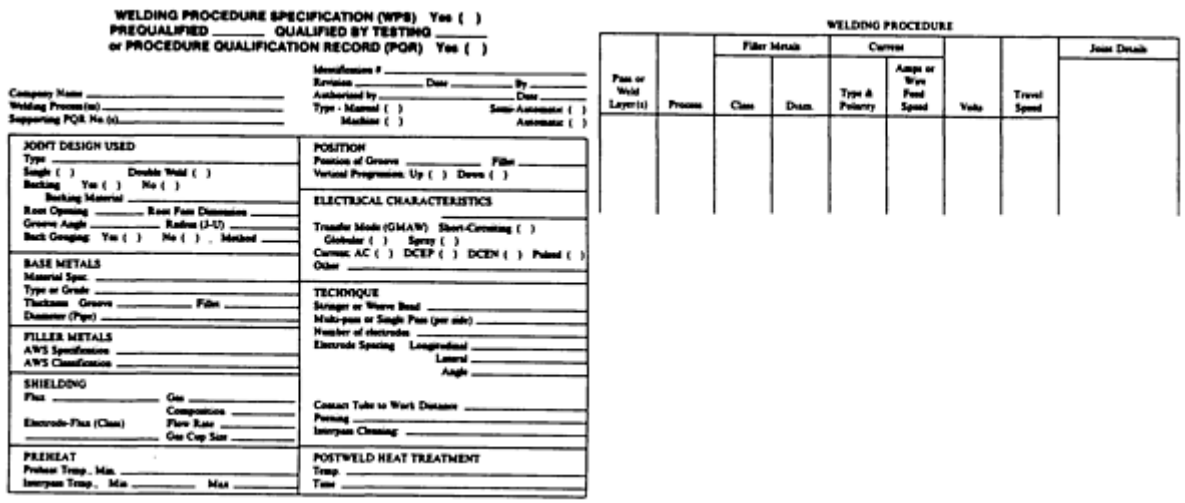

FIG. 16 WELDING PROCEDURE SPECIFICATION FORM. SOURCE: REF 3

All welding procedure specifications must be qualified by actual mechanical testing of welds made in accordance with the WPS. If this testing fails to meet the requirements of a customer or code, then a new WPS must be prepared and tested. Detailed information about procedure qualification is available in the article "Weld Procedure Qualification" in this Volume and in Ref 15.

Once a welding procedure specification is prepared, then the welding operators who will be applying this process should establish through testing that they are proficient in its application. This testing of worker proficiency is usually termed a welder or welding operator performance qualification test. Again, the qualification specification will outline the guidelines in which the welder or welding operator can be qualified with each test. As long as the worker continues to perform within those guidelines on a periodic basis without significant faults, the worker's qualification remains in effect. If the worker does not use the process for an extended period of time, uses it outside the guideline limits for performance qualification, or fails to achieve acceptable quality, then disqualification may occur with further training and testing as a corrective action, if deemed necessary. Repeated disqualification may necessitate reassignment to a less-skilled job. Adequate records are required to show continuity of process application for each qualified worker within the certifying organization.

Shielded Metal Arc Welding

Shielded metal arc welding is widely used for joining all classes of carbon steels. Detailed information is available in the article "Shielded Metal Arc Welding" in this Volume.

A wide variety of electrode types exist, each designed to work in a specific way and each possessing unique characteristics. Proper electrode selection is essential to achieve good welding performance and weld quality. AWS A5.1 (covering carbon steel electrodes) (Ref 16) and A5.5 (covering low-alloy steel electrodes) (Ref 17) are widely used to classify SMAW electrodes suitable for welding carbon steels. The low-alloy steel versions are used to weld higher carbon steels when higher strength is required.

E60XX electrodes (415 MPa, or 60 ksi, minimum tensile strength) are suitable for welding carbon steels containing up to about 0.3% C. They are not made with low-hydrogen coatings and should not be used to weld hardenable steels, especially under conditions of high joint restraint.

E70XX electrodes (485 MPa, or 70 ksi, minimum tensile strength) are suitable for steels with a wide range of strength values. The E7015, E7016, E7018, E7018M, E7028, and E7048 types are low-hydrogen electrodes and may be used in situations where hydrogen-induced cracking is a possibility. Table 6 summarizes some of the features and characteristics of the different carbon steel electrode types (see the Section "Fusion Welding Procedures" in this Volume or the appendices of Ref 16 and 17 for a more thorough discussion).

TABLE 6 CARBON STEEL ELECTRODES FOR SMAW WELDING APPLICATIONS

ELECTRODE	COATING TYPE	POSITION[A]	CURRENT TYPE	MINIMUM IMPACT ENERGY (CHARPY V-NOTCH)		GENERAL COMMENTS	APPLICATIONS
				J	J · LBF		
E6010	HIGH-CELLULOSE SODIUM	ALL	DCEP	27[B]	20[B]	GOOD PENETRATION. DIRECT FORCEFUL ARC. HIGH WELD METAL HYDROGEN.	**USED ON ALL TYPES OF JOINTS**
E6011	HIGH-CELLULOSE POTASSIUM	ALL	DCEP, AC	27[B]	20[B]	SIMILAR TO 6010 EXCEPT THAT IT HAS A MORE STABLE ARC AND IS SLIGHTLY LESS PENETRATING	**USED ON ALL TYPES OF JOINTS**
E6012	HIGH-RUTILE SODIUM	ALL	DCEN, AC	[C]	[C]	LOWER PENETRATION, HIGHER TRAVEL SPEEDS	**THIN SHEET METAL**
E6013	HIGH-RUTILE POTASSIUM	ALL	DCEN, DCEP, AC	[C]	[C]	HIGHER TRAVEL SPEEDS, LOWER PENETRATION. BETTER ON AC THAN E6012.	**THIN SHEET METAL**
E7014	RUTILE, IRON POWDER	ALL	DCEN, DCEP, AC	[C]	[C]	HIGHER-DEPOSITION-RATE VERSION OF E6013	**INCLINED AND SHORT FILLETS**
E6019	IRON OXIDE, RUTILE POTASSIUM	ALL	DCEN, DCEP, AC	27[D]	20[D]	MEDIUM-PENETRATION FLUID SLAG, ONLY SMALLER DIAMETER USED OUT-OF-POSITION (NO VERTICAL DOWN)	**MULTIPASS WELDS (TO 25 MM, OR 1 IN.), SOME OUT-OF-POSITION USE**
E6020	HIGH-IRON OXIDE	HF FLAT	DCEN, AC DCEN, DCEP, AC	[C]	[C]	SPRAY-LIKE ARC, HEAVY FLUID SLAG	**DOWNHAND WELDING OF THICKER PLATE**
E7024	RUTILE, IRON POWDER	HF, FLAT	DCEN, DCEP, AC	[C][E]	[C][E]	VERY HIGH-DEPOSITION-RATE VERSION OF E7014. THICK COATING OF FLUX. GOOD ARC CHARACTERISTICS.	**FILLETS AT HIGH TRAVEL SPEEDS. GRAVITY WELDING.**
E6027	HIGH-IRON OXIDE, IRON POWDER	HF FLAT	DCEN, AC DCEN, DCEP, AC	27[B]	20[B]	MEDIUM PENETRATION. HIGH-DEPOSITION-RATE VERSION OF E6020.	**FLAT FILLETS OR GROOVE WELDS**
E7027	HIGH-IRON OXIDE, IRON POWDER	HF FLAT	DCEN, AC DCEN, DCEP, AC	27[B]	20[B]	HIGHER TENSILE VERSION OF 6027	**SAME AS 6027**
LOW-HYDROGEN ELECTRODES							
E7015	LOW-HYDROGEN SODIUM	ALL	DCEP	27[B]	20[B]	THE ORIGINAL LOW-HYDROGEN ELECTRODE, NOT WIDELY USED TODAY	**USED ON ALL TYPES OF JOINTS WHERE LOW HYDROGEN IS NEEDED**

E7016	LOW-HYDROGEN POTASSIUM	ALL	DCEP, AC	27[B][F]	20[B][F]	SIMILAR TO E7015, BUT A MORE STABLE ARC	**USED ON ALL TYPES OF JOINTS WHERE LOW HYDROGEN IS NEEDED**
E7018	LOW-HYDROGEN POTASSIUM, IRON POWDER	ALL	DCEP, AC	27[B][G]	20[B][G]	MODERN LOW-HYDROGEN ELECTRODE. BETTER ARC AND OPERATING CHARACTERISTICS.	**USED ON ALL TYPES OF JOINTS, ESPECIALLY WHEN LOW HYDROGEN IS NEEDED**
E7018M	LOW-HYDROGEN IRON POWDER	ALL	DCEP	68[B]	50[B]	A LOW-MOISTURE VERSION OF 7018	**JOINING CARBON STEELS TO HIGH-STRENGTH LOW-ALLOY STEELS**
E7028	LOW-HYDROGEN POTASSIUM, HIGH-IRON POWDER	FLAT, HF	DCEP, AC	27[D]	20[D]	E7018 WITH HIGH IRON POWDER, HIGH DEPOSITION RATES	**HIGH TRAVEL SPEEDS ON FILLETS AND GROOVE WELDS**
E7048	**LOW-HYDROGEN POTASSIUM, IRON POWDER**	**FLAT, OH, HORIZONTAL, V-DOWN**	**DCEP, AC**	**27[B]**	**20[B]**	**SIMILAR TO E7018 WITH EXCELLENT VERTICAL-DOWN WELDING CHARACTERISTICS**	**VERTICAL DOWN WELDING**

(A) HF, HORIZONTAL FLAT; OH, OVERHEAD; V, VERTICAL.

(B) AT -30 °C (-20 °F).

(C) NOT REQUIRED.

(D) AT - 20 °C (0 °F).

(E) 7024-1 SPECIFICATIONS: 27 J (20 FT · LBF) AT -20 °C (0 °F).

(F) 7016-1 SPECIFICATIONS: 27 J (20 FT · LBF) AT -45 °C (-50 °F).

(G) 7018-1 SPECIFICATIONS: 27 J (20 FT · LBF) AT -45 °C (-50 °F)

Low-Alloy Steel Electrodes. Most low-alloy steel electrodes have low-hydrogen coatings (EXX15, EXX16, and EXX18), but some may not. Because low-alloy steel electrodes are used to weld higher-carbon, more hardenable steels, it is recommended that only the low-hydrogen versions be used. Consideration should also be given to the hydrogen-induced cracking tendencies of the low-alloy steel weld metal, especially if it is heavily diluted with carbon from the baseplate. The low-hydrogen electrodes have been specially formulated and processed to give low coating moistures. It is important that they be stored and handled properly in order to avoid moisture absorption. Once removed from their storage cans, they should be held in a vented oven at 110 to 150 °C (230 to 300 °F). If the electrodes have absorbed excessive moisture, they can be restored by baking at 250 to 425 °C (480 to 800 °F) for 1 to 2 h (consult the manufacturer of the electrode for the exact temperature).

Because SMAW is a lower-heat-input process and cooling rates can be high, it is especially important to control hydrogen when welding higher-carbon steels. The newer revisions of the AWS specifications will have optional procedures for choosing electrodes on the basis of the weld metal diffusible hydrogen produced.

Gas-Metal Arc Welding

Detailed information about this process is in the article "Gas-Metal Arc Welding" in this Volume. The process is unique in that it operates in a number of different modes, each with its own distinct method of metal transfer, using different shielding gases, operating at different heat input levels, and having different penetration (dilution) characteristics. The resultant weldment properties may vary significantly, depending on the mode used. For this reason, it is important to be cautious about generalizations regarding the process and to perform procedure qualifications.

Electrodes for GMAW are available as solid-or metal-cored wires. AWS A5.18 (Ref 19) classifies carbon steel filler metals. AWS A5.28 (Ref 18) classifies low-alloy steel electrodes, used to weld medium- and high-carbon steels where a higher-strength deposit is needed. Compositions of GMAW electrodes are given in Table 7. Mechanical property requirements are given in Table 8.

(A) CARBON DIOXIDE SHIELDING GAS. THE USE OF CO_2 FOR CLASSIFICATION PURPOSES SHALL NOT BE CONSTRUED TO RESTRICT THE USE OF ARGON-CO_2 OR ARGON-O_2 SHIELDING GAS MIXTURES. A FILLER METAL CLASSIFIED WITH CO_2 WILL ALSO MEET THE REQUIREMENTS OF THIS SPECIFICATION WHEN USED WITH ARGON-CO_2 OR ARGON-O_2 MIXTURES.

(B) FOR EACH INCREASE OF ONE PERCENTAGE POINT IN ELONGATION OVER THE MINIMUM, THE YIELD STRENGTH, OR TENSILE STRENGTH, OR BOTH MAY DECREASE 7 MPA (1 KSI) TO A MINIMUM OF 485 MPA (70 KSI) FOR THE TENSILE STRENGTH AND 400 MPA (58 KSI) FOR THE YIELD STRENGTH.

(C) SUBJECT TO AGREEMENT BETWEEN SUPPLIER AND PURCHASER.

(D) PWHT, POSTWELD HEAT TREATED IN ACCORDANCE WITH AWS A5.28-79.

(E) TENSILE STRENGTH SHALL BE CONSISTENT WITH THE LEVEL PLACED AFTER THE "ER" OR "E" PREFIX; E.G., ER90S-G SHALL HAVE 620 MPA (90 KSI) MINIMUM ULTIMATE TENSILE STRENGTH.

(F) AT -30 °C (-20 °F).

(G) AT -20 °C (0 °F).

(H) NOT REQUIRED.

(I) AT -45 °C (-50 °F).

(J) THE LOWEST AND THE HIGHEST VALUES OBTAINED SHALL BE DISREGARDED FOR THIS TEST. TWO OF THE THREE REMAINING VALUES SHALL BE GREATER THAN THE SPECIFIED 27 J (20 FT · LBF) ENERGY LEVEL; ONE OF THE THREE MAY BE LOWER BUT

SHALL NOT BE LESS THAN 20 J (15 FT · LBF). THE COMPUTED AVERAGE VALUE OF THE THREE VALUES SHALL BE EQUAL TO OR GREATER THAN THE 68 J (20-FT · LBF) ENERGY LEVEL.

(K) AS-WELDED IMPACT PROPERTIES.

(L) AT -60 °C (-80 °F).

(M) REQUIRED IMPACT PROPERTIES AFTER POSTWELD HEAT TREATMENT (SEE AWS A5.28-79).

(N) AT -75 °C (-100 °F).

(O) IMPACT PROPERTIES FOR THE ER100S-1, ER100S-2, ER110S-1, AND ER120S-1 SHALL BE OBTAINED AT TEST TEMPERATURE SPECIFIED IN THE TABLE ±1.7 °C (± 3 °F). THE LOWEST AND THE HIGHEST IMPACT VALUES THUS OBTAINED SHALL BE DISREGARDED FOR THIS TEST. TWO OF THE THREE REMAINING VALUES SHALL BE GREATER THAN THE SPECIFIED 68 J (50-FT · LBF) ENERGY LEVEL; ONE OF THE THREE MAY BE LOWER BUT SHALL NOT BE LESS THAN 54 J (40 FT · LBF); THE COMPUTED AVERAGE VALUES OF THESE THREE SHALL BE GREATER THAN THE SPECIFIED 68 J (50-FT · LBF) LEVEL.

Carbon steel electrodes are welded using CO_2, argon-oxygen, or argon-CO_2 shielding gases. Concern about welding fume levels has led to the increased use of the argon-base shielding gases. The low-alloy steel electrodes are commonly welded with argon-oxygen (2 to 5% O) or argon-CO_2 (5 to 12% CO_2) to avoid the loss of alloy during arc transfer. For carbon steel metal-cored electrodes, argon-CO_2 or argon-oxygen mixtures are used. The performance of welds is generally enhanced at higher argon levels.

The major difference between the carbon steel electrodes is the deoxidizer content. As the oxygen level of the molten weld pool increases, so must the deoxidizer level in the welding electrode if excessive porosity is to be avoided. The sources of oxygen are CO_2 or O_2 in the shielding gas, rust or millscale on the plate surface, and the baseplate oxygen (left from the deoxidation practice employed during steel manufacture. The ER70S-3 (1.1Mn-0.55Si) electrodes are the most widely used type, because of low cost, but they also have the lowest deoxidizer level. When welding rimmed steels with CO_2 shielding gas, porosity may be a problem. In that case an ER70S-4 (1.3Mn-0.75Si) electrode would do a better job. When heavier rest or scale is present or when high current welds are made (more baseplate dilution), it may be necessary to use an ER70S-6 (1.7Mn-0.9Si) electrode, which will tolerate most conditions, including high-speed welding. The ER70S-7 (1.8Mn-0.6Si) electrodes also have a higher deoxidizer level, better bead shape, and higher strength compared to ER70S-3 electrodes. The ER70S-5 (1.2Mn-0.5Si-0.7Al) electrodes, which contain high aluminum for deoxidation, are not readily available and are rarely used.

The ER70S-2 (low carbon, 1.2% Mn, 0.6% Si) electrodes contain small amounts of aluminum, titanium, and zirconium. Because these are strong deoxidizers, the ER70S-2 electrodes also produce good-quality welds at high weld puddle oxygen levels. The aluminum content makes the weld puddle more viscous, and this electrode is suitable for out-of-position welding because of ease of control. The low carbon content, and the fact that aluminum, titanium, and zirconium are strong denitriders, also make this electrode ideal for root passes. The highest weld quality is obtained when shielding gases higher in oxygen or CO_2 content are used. The viscous nature of the weld puddle can lead to an entrapment of gas that creates weld porosity. Higher oxygen and carbon dioxide components in the shielding gas improve puddle fluidity and minimize porosity levels.

Low-alloy electrodes contain sufficient deoxidizers to avoid porosity on relatively clean plate, but the silicon levels are kept low so as not to decrease toughness. An exception is ER80S-D2 electrodes, which contain higher silicon and can therefore be used with CO_2 or Ar-25CO_2 shielding.

Metal-cored electrodes may also be used. They produce higher deposition rates for a given heat input than do solid electrodes. Some users also claim that they provide a better bead profile and less chance of burn-through in root passes.

The GMAW process is considered a low-hydrogen process, but hydrogen can vary, depending on wire lubricant levels. Revisions of AWS A5.18 (Ref 18) and A5.28 (Ref 19) will include optional provisions for specification based on weld metal diffusible hydrogen.

Flux-Cored Arc Welding

Flux-cored arc welding may be used with or without an external shielding gas (see the article "Flux-Cored Arc Welding" in this Volume). Electrodes for flux-cored arc welding are classified under AWS A5.20 (covering carbon-steel electrodes) (Ref 20) and AWS A5.29 (covering low-alloy steel electrodes) (Ref 21).

Gas-shielded electrodes are designed to be used only with an external shielding gas (usually CO_2 or Ar-CO_2). The characteristics of these electrodes are given in Table 9. The majority of these electrodes are rutile-base and have excellent operating characteristics. The larger diameter versions (2.0 mm, or $\frac{5}{64}$ in., and larger) are used for flat and horizontal fillet welding, usually with CO_2 shielding gas. High penetration (high dilution), high heat inputs, and high deposition rates are characteristic of these electrodes. The T-1 group of large-diameter wires are used for single- and multiple-pass welding. The T-2 group contains higher levels of deoxidizer (manganese and silicon) to handle rust, scale, or rimmed steels, and is designed primarily for single-pass welding.

Source: Ref 20, 21

The smaller diameter (1.6 mm, or $\frac{1}{16}$ in., and under) rutile-base electrodes are used in all positions. They are widely used because of the ease of use and the high deposition rates possible when out-of-position. Carbon dioxide shielding or Ar-CO_2 shielding is used. The Ar-CO_2 mixture (typically with 20 to 25% CO_2) gives better operating characteristics and less loss of elements during arc transfer. Many electrodes are specifically designed to work in one gas or the other, so manufacturer recommendations should be followed. The weld metal toughness of these electrodes can vary from fair to very good. Newer, microalloyed versions, both carbon and low-alloy steel, are capable of achieving good low-temperature toughness and low-hydrogen characteristics. Small quantities of titanium and boron are added to modify transformation characteristics and promote the formation of acicular ferrite. The quantities of titanium and boron transferred to the weld metal are critical. The use of the recommended shielding gas and tight control of welding variables (especially arc voltage) are necessary to achieve optimum results. There is the possibility of solidification cracking with excessive amounts of boron in the weld metal.

The basic electrodes (T-5 types) do not have operating characteristics as good as those of the rutile types, but they are capable of producing excellent low-temperature toughness and low diffusible hydrogen. They are mainly used for multipass welding or where resistance to cracking (both hydrogen-induced and solidification) is required. Some smaller-diameter versions can be used for out-of-position welding, but the performance features are inferior to those of rutile-base electrodes.

Self-shielded electrodes are designed to be used only without a shielding gas. The weld metal is protected from atmospheric contamination by denitriders, deoxidizers, and gas formers in the core. Compared to the gas-shielded types, the self-shielded electrodes require closer control of welding parameters to achieve consistent results. This is because the balance of denitriders/deoxidizers to atmospheric gases, N_2 and O_2, is critical to performance and weld metal mechanical properties. An increase in arc length, for instance, will reduce the transfer of aluminum and titanium to the weld metal, but it will increase the amount of nitrogen and oxygen absorbed. This interaction with the atmosphere also makes weld metal hydrogen levels more dependent on atmospheric moisture. Self-shielded electrodes can be classified as being either controlled-hydrogen or low-hydrogen, provided that welding parameters, including proper electrode stickout parameters are maintained. These electrodes also have the special ability to make quality welds, even in windy conditions.

T-3 and T-10 Types. Self-shielded electrodes are differentiated according to the intended application and the mechanical properties achieved. The T-3 types are single-pass electrodes for use on sheet metal and plate under 5 mm (0.2 in.) thick. The fast travel speeds and high cooling rate of a thicker material result in poor weld metal ductility. The T-

10 types are also designed for high-speed, single-pass welding. They operate at lower travel speeds, but the deposit is less hardenable and they are not limited by plate thickness.

The T-4, T-7, and T-11 types are intended for single-pass or multipass applications, but none of them is required to meet minimum weld metal toughness levels. The T-4 and large diameter T-7 types are for horizontal and flat use. Both produce high deposition rates, but the T-7 is capable of higher travel speeds. The T-11 electrodes have very good operating characteristics and are frequently used for out-of-position welding of thin plate and gage materials. The higher hardenability of the T-11 deposit may require preheat when welding plate over 19 mm ($\frac{3}{4}$ in.) thick.

T-6 and T-8 Types. T-6 electrodes are intended for single-pass and multipass welding where good toughness is needed in the flat and horizontal position. T-8 electrodes provide good toughness single-pass or multipass welds in all positions. The T-8 slag system forms the basis for many of the higher-toughness, low-alloy steel electrodes.

Gas-Tungsten Arc and Plasma Arc Welding

These two processes are so similar that they can be treated together. Their main use on carbon steels is for welding thinner material components (especially thin-walled tubing) and for making root passes in pipe joints. (Detailed information is available in the articles "Gas-Tungsten Arc Welding" and "Plasma Arc Welding" in this Volume.) Both processes produce very clean, high-quality weld metal because of the use of inert shielding gases and a tightly-controlled arc. Each is considered a low-hydrogen process, with the major contribution coming from the filler material, if one is used. Heat inputs are relatively low, so care must be exercised when welding hardenable carbon steels.

A choice must be made whether to use a filler material or to weld autogenously (without a filler material). Generally, thin carbon steels are welded autogenously up to 3 mm ($\frac{1}{8}$ in.) thick (for GTAW) or 6 mm ($\frac{1}{4}$ in.) thick (for PAW) unless a metallurgical problem precludes the use of either process. If the baseplate sulfur or phosphorus levels are high, then a low-carbon, high-manganese filler material may have to be used to prevent solidification cracking. High oxygen levels in the steel (rimmed) will require a high-deoxidizer-containing filler material to counteract porosity. Consumable inserts are sometimes used in root-pass welds. These inserts are of a specific steel composition (some have compositions equal to the filler wires) and are preplaced in the root of weld. They are melted and become part of the root-pass weld metal. Their use generally results in more consistent weld-bead fusion and underbead formation. Consumable inserts are covered in AWS A5.30-79 (Ref 22).

Filler metals for GTAW or PAW joining of carbon steels are the same as those used for GMAW (see Tables 7 and 8). The same guidelines prevail (that is, higher oxygen weld puddles require higher deoxidizer levels in the filler material). Because much of the welding is done-out-of-position or in root passes, the ER70S-2 filler rod is very popular. This is due to its viscous, easier-to-control weld puddle and to the low carbon level that reduces the likelihood of solidification cracking in root beads. Manual GTAW or PAW processing is normally done with straight length rods. Spooled or coiled product is used for mechanized setups.

Submerged Arc Welding

Submerged arc welding is a high-current process capable of high heat input, high penetration, high rate of travel, and high deposition rates (see the article "Submerged Arc Welding" in this Volume).

The high heat inputs associated with this process lead to slow weld metal cooling rates. The presence of a flux blanket tends to slow down the rate of cooling even more. This promotes formation of microstructures less susceptible to hydrogen-induced cracking and allows longer times for hydrogen to escape. Excessive heat inputs, however, can result in low strength and perhaps low toughness in the weld metal and HAZ.

High penetration results in high baseplate dilution. It is not uncommon to have over 60% dilution in one- or two-pass, square butt welds. This addition of base material must be taken into consideration when selecting procedures and consumables to meet specific mechanical property requirements. Procedure tests should always be run. Impurities in the baseplate (for example, sulfur, phosphorus, oxygen, and nitrogen) can lead to problems in heavily diluted weld metal.

High travel speeds increase the probability of solidification cracking, especially in small, more diluted root passes. Under such circumstances, special attention should be paid to baseplate chemistry (carbon, sulfur, and phosphorus) and bead shape control.

Consumable selection involves choosing both a flux and an electrode. They are an interactive pair that together determine the properties of the weld. Fluxes and electrodes for welding carbon steels are classified under AWS A5.17 (carbon steels) (Ref 23) and AWS A5.23 (low-alloy steels) (Ref 24). Solid electrodes are classified on the basis of chemistry. The flux/electrode combination is classified on the basis of weld metal mechanical properties (tensile and Charpy V-notch) and, for low-alloy electrodes only, deposit chemistry. Preliminary selection based on mechanical properties is thus fairly easy. Procedure tests should always be run, because production welding conditions rarely match the AWS test procedures (which are low-dilution, moderate-heat-input welds).

Flux Selection. Selection for performance features is more difficult. Performance characteristics are largely determined by the flux. Past experience or manufacturer recommendations can be used. Caution must be exercised in the selection of a flux.

Active fluxes (those that contain, and contribute to the weld metal, significant amounts of silicon and manganese) are designed to tolerate high weld puddle oxygen. Their use is mainly for single- or limited-pass welding on scaled or rusty plate. In the absence of oxides, the deoxidizers enter the weld metal and may cause excessive hardness. Therefore, their use may be limited on multipass welds. Transfer of metals from the flux to the weld metal is enhanced at higher arc voltages, where more flux is consumed per unit of electrode. Close control of arc voltage is required with active fluxes, or weld metal cracking might occur. Low-alloy steel electrodes should not be used with active fluxes.

Neutral fluxes (those that contain and contribute no or low amounts of silicon and manganese) are not as tolerant to rust and millscale and are intended for welding on clean plate or in multipass welding.

Intermediate Activity Fluxes. Some fluxes have intermediate activity. This provides them with some tolerance to rust and millscale, and it allows their use for multipass welding with less probability of excessive manganese and silicon pickup.

Wall Neutrality Number Method. The appendices of AWS A5.17 (Ref 23) and A5.23 (Ref 24) describe a method, the wall neutrality number, that may be used to quantify the activity of a flux.

Basic fluxes are generally used for multipass welding where good low-temperature toughness is required.

Acid fluxes generally have better performance features than basic fluxes. Acid fluxes deslag more easily and may give better visual bead appearance. However, overall performance may be lacking due to silicon pickup or carbon depletion in heavier thicknesses.

Flux Storage. Submerged arc welding can be a low-hydrogen process if the fluxes are properly stored and handled. Flux exposed to the atmosphere can pick up moisture, especially under humid conditions. This moisture can be removed by drying the flux. The manufacturer should be consulted for proper procedures. Heated flux hoppers, which hold the flux above 120 °C (250 °F), are frequently used to maintain low moisture during usage, especially when welding crack-sensitive steels.

Electrogas Welding

From a metallurgical viewpoint, the primary feature of the electrogas welding process is the protracted thermal cycle that results from the relatively slow progression rate of the welding arc (see the article "Electroslag and Electrogas Welding" in this Volume). The slow heat-up and cool-down results in a wide, grain-coarsened HAZ and large columnar grains in the weld metal. Low toughness can be a problem in some applications. Control of welding conditions to limit heat input will improve HAZ properties. Low-alloy electrodes are often used when low-temperature weld-metal toughness is required. Table 10 gives typical applications of steels based on grade. Electrogas welding of quenched and tempered carbon steels can result in serious degradation of strength and toughness properties in the HAZ. A postweld heat treatment may be necessary to restore the properties. Some codes (for example, AWS D1.1, Ref 3) prohibit the use of EGW on quenched and tempered steels.

Source: Ref 25

On the positive side, the formation of hard, crack-sensitive microstructures is less likely to occur because of the slow cooling rates, and the elevated time at temperature allows more time for hydrogen to escape (electrogas welding is a low-hydrogen process). Preheating is not normally required.

Baseplate dilution can vary with welding parameters. High voltage and low current will increase sidewall penetration. Up to about 35% dilution is possible. Because this will have a major effect on weld metal properties, it is very important to run procedure qualification tests.

Electrodes for electrogas welding are classified in accordance with AWS A5.26 (Ref 26). The process utilizes either solid electrodes (Table 11) or composite electrodes (Table 12). The composite electrodes can be flux-cored or metal-cored and require either shielding gas or self shielding. Typical properties of carbon steel grades in the as-welded condition are given in Table 13. Carbon dioxide or Ar-CO_2 mixtures are used for the shielded flux-cored and solid-wire electrodes. The solid electrodes used are similar to those used for GMAW. The flux-cored electrodes used for electrogas welding are not the same as those used for FCAW. They have a lower level of slag formers. Flux-cored electrodes offer an advantage over solid electrodes in that they have a higher deposition rate (approximately 20%). This will result not only in faster joint completion rates, but also in lower heat inputs.

(A) AMERICAN IRON AND STEEL INSTITUTE (AISI) DESIGNATION.

Electroslag Welding (Ref 27, 28)

Electroslag welding (ESW) is similar in many respects, to electrogas welding (see the article "Electroslag and Electrogas Welding" in this Volume). Both are used to complete large, vertical welds in a single pass. High heat inputs and protracted thermal cycles are characteristic of these processes. Weld-metal hydrogen levels are low, and preheat is usually not required. The residual stresses and angular distortion are generally low. Weld-metal soundness is excellent provided the welding can be completed without stopping. The slow heating and cooling cycles, however, result in a wide, coarse-grained heat-affected zone and coarse, columnar weld metal. Low toughness and strength can be a problem in certain applications. Some codes, such as AWS D1.1, have restrictions on the use of these processes.

Electroslag welding is not an arc welding process. An arc is used only to initiate melting of a flux in order to form a molten slag. The molten slag, which is conductive, then extinguishes the arc and the heat necessary to complete the weld is generated by electrical resistance to the current passing through the slag. The molten slag also acts to shield the weld metal from the atmosphere. The fluxes used for electroslag welding are unique to the process. Most SAW fluxes will not work in ESW applications. Unlike electrogas welding, electroslag welding may use multiple electrodes. This allows thicker materials (up to 900 mm, or 36 in.) to be welded. Dilution from the baseplates can be quite high (up to 50%), so procedure qualifications are essential.

Process Variations. There are two variations of the process in general use. The conventional method uses a wire electrode (either solid or cored) and a nonconsumable guide to direct the electrode into the molten bath. The welding head moves up the plate as the weld progresses, and sliding copper shoes hold the molten puddle in position.

The consumable guide method employs a consumable guide tube that extends down the length of the joint. The welding head remains stationary at the top of the joint, and a wire electrode (either solid or cored) is fed down the center of the guide tube into the molten puddle. The steadily rising weld puddle consumes both the electrode and the guide tube. Some guide tubes are coated with flux. This provides electrical insulation and supplements the slag, some of which plates out onto the weld surface. Copper dams are used to hold the molten pool in place.

Metallurgically, there is little difference between the variations except that the consumable guide tubes (which comprise 5 to 10% of the weld metal in a 50 mm, or 2 in., plate weld) may not be available in the same range of chemistries as the wire electrodes.

Electrode chemistries and required properties for ESW are given in Ref 29. Typical mechanical properties of electroslag welds in carbon and alloy steels and in structural steels are given in Tables 14 and 15, respectively.

Stud Arc Welding

Stud arc welding is commonly used to attach carbon steel studs to carbon steel plate (see the article "Stud Arc Welding" in this Volume). A primary characteristic of this process is the rapid heating and cooling cycle. Both the HAZ and the weld-metal area are relatively small. The rapid cooling rate can be a problem with medium-carbon and high-carbon steels because the likelihood of martensite formation is high. Preheat is essential for welding medium-carbon and high-carbon steels but is not required for low-carbon steels. Procedure tests should be run on high-carbon steels. Stud arc welding is a low-hydrogen process if the plate surface and studs are free of hydrogen-containing materials.

Studs for attachment to carbon steels are chosen based on their strength. Low-carbon steel studs are made from cold-drawn bar stock in grades 1006 to 1020 (killed or semi-killed). A minimum tensile strength of 380 to 415 MPa (55 to 60 ksi) is required. A stronger heat-treated steel stud (830 MPa, or 120 ksi, tensile strength) is also available. Most carbon steel studs require a flux (affixed to the end of the stud) for deoxidation. Aluminum is commonly used for this purpose.

Welding of Low-Alloy Steels

F.J. Winsor, Welding Consultant

Introduction

THE DETERMINATION of appropriate procedures and practices for low-alloy steels (those containing up to 10% Cr) involves a systematic evaluation of factors such as:

- DESIGN REQUIREMENTS
- AVAILABILITY AND PRACTICABILITY OF USING A PARTICULAR ARC WELDING PROCESS
- PRODUCTIVITY REQUIREMENTS
- CHARACTERISTICS OF FILLER METALS AND OTHER CONSUMABLES
- PROPERTIES OF WELD DEPOSITS
- PREHEATING AND POSTWELD HEAT-TREATMENT REQUIREMENTS DETERMINED BY THE METALLURGICAL CHARACTERISTICS OF THE LOW-ALLOY STEEL

When compared with other steels, the arc welding of low-alloy steels can require greater emphasis on some of these factors, because of unique mechanical property or service requirements, as well as metallurgical characteristics, such as hardenability and hydrogen embrittlement.

This article discusses factors involved in selecting welding processes and consumables and establishing procedures and practices for the arc welding of low-alloy steels. Because of their different design or service requirements and their often different welding characteristics, the low-alloy steels discussed in this article are categorized as:

- HIGH-STRENGTH LOW-ALLOY (HSLA) STRUCTURAL STEELS
- HIGH-STRENGTH LOW-ALLOY QUENCHED AND TEMPERED (HSLA Q&T) STRUCTURAL STEELS
- LOW-ALLOY STEELS FOR PRESSURE VESSELS AND PIPING
- MEDIUM-CARBON HEAT-TREATABLE (QUENCHED AND TEMPERED) LOW-ALLOY (HTLA) STEELS
- ULTRAHIGH-STRENGTH LOW-ALLOY STEELS
- LOW-ALLOY TOOL AND DIE STEELS

Welding Processes. All of the common arc welding processes can be used with low-alloy steels. Shielded metal arc, gas-tungsten arc, gas-metal arc, flux-cored arc, and submerged arc welding processes are used for most applications.

Electroslag and electrogas processes can be used to weld some of the low-alloy structural and pressure vessel steels, although restrictions may be imposed by some codes.

Welding of Low-Alloy Steels

F.J. Winsor, Welding Consultant

Welding Consumables

General information is provided below in terms of filler metals and fluxes and shielding gases.

Filler Metals and Fluxes

The selection of consumables for the arc welding of low-alloy steels is greatly facilitated by reference to American National Standards Institute/American Welding Society (ANSI/AWS) Filler Metal Specifications (Ref 1). These specifications define the requirements for classifying welding consumables in accordance with established parameters for chemical composition, mechanical properties, and usability. The ANSI/AWS specifications are often incorporated into the materials requirements of fabrication codes.

Shielding Gases

Gas-Tungsten Arc Welding (GTAW) and Plasma Arc Welding (PAW). The shielding gas most commonly used in the GTAW and PAW of low-alloy steels is 100% welding grade (99.995%) argon. Although argon is commonly used when gas backing is specified, nitrogen can also be used satisfactorily as a backing gas for many applications.

Gas-Metal Arc Welding (GMAW), Flux-Cored Arc Welding (FCAW), and Electrogas Welding (EGW). The selection of shielding gases used in these processes often depends on filler metal characteristics. Information should be obtained from the filler metal manufacturer or supplier regarding the proper shielding gas or mixture to be used. Use of a shielding gas other than that which is recommended can result in inferior welding performance or unsatisfactory weld metal chemical composition and/or properties.

Argon-oxygen and argon-carbon dioxide mixtures are commonly used for the GMAW and FCAW of low-alloy steels. Either argon-helium-carbon dioxide mixtures or 100% carbon dioxide are used for low-heat-input welding that utilizes small-diameter electrodes and a short-circuiting mode of metal transfer. Carbon dioxide shielding can also be used with larger-diameter electrodes, when its characteristic high spatter level can be tolerated and its resulting weld metal mechanical properties are acceptable.

The type of shielding gas has a significant effect on the mechanical properties of welds in low-alloy steels. A change in shielding from 100% CO_2 to a mixture of 75% Ar and 25% CO_2 generally results in a 10% increase in tensile strength of the weld metal in the as-deposited condition. This is due to greater retention of strengthening elements, such as manganese, silicon, and chromium, in the weld metal when the oxidizing effect of the arc atmosphere is lowered by the decrease in percentage of carbon dioxide. Depending on the original carbon content of the electrode, a carbon dioxide shielding atmosphere can result in either an increase or decrease in the carbon content of undiluted weld metal. If the carbon content of the electrode is less than 0.05%, then the weld metal tends to pick up carbon from the CO_2 shielding gas. If the carbon content of the electrode is greater than 0.10%, then the weld metal tends to lose carbon.

High-Strength Low-Alloy (HSLA) Structural Steels

The HSLA structural steels typically contain less than 0.2% C and less than 2% alloy. They are different from other alloy steels in the sense that they are designed to meet specific mechanical property requirements, rather than a specified chemical composition. The steels have minimum yield strengths that range from 275 to 550 MPa (40 to 80 ksi) and tensile strengths that range from 415 to 655 MPa (60 to 95 ksi). ASTM specifications for typical HSLA as-rolled pearlitic structural steels include A 242, A 440, A 441, A 572, A 588, A 606, A 607, A 618, A 633, A 656, A 690, A 710, and A 715. Other HSLA steels are covered by Society of Automotive Engineers (SAE) Recommended Practice J410c. Some HSLA structural steels contain copper, phosphorus, nickel, chromium, and silicon in various combinations and amounts that provide a level of corrosion resistance that is up to four times better than that of carbon steel. The chemical compositions of typical ASTM HSLA structural steels are given in Table 1.

(A) SINGLE VALUES ARE MAXIMUM UNLESS OTHERWISE NOTED.

(B) THESE GRADES MAY CONTAIN NIOBIUM, VANADIUM, OR NITROGEN.

Filler Metal Selection

The predominant factor in most applications of HSLA steels is tensile strength; the alloy content is incidental. Consequently, filler metal is selected, most frequently, on the basis of providing a weld metal with minimum yield and tensile strength values that are at least equal to those of the base metal. However, HSLA steels are also often used because of their resistance to atmospheric corrosion. Such applications require that the alloy content and corrosion resistance of the weld deposit be considered.

Shielded Metal Arc Welding (SMAW). Some types of carbon steel electrodes (classified in ANSI/AWS specification A5.1) used in this process will deposit weld metal that has mechanical properties that are adequate to match those of some of the HSLA structural steels. Low-alloy steel covered electrodes are classified in ANSI/AWS specification A5.5. Table 2 shows the welding consumables for HSLA structural steels, based on ANSI/AWS D1.1 (Ref 3). This specification requires the use of low-hydrogen filler metals for welding HSLA structural steels in order to satisfy the conditions established for the prequalification of welding procedures.

(A) CONSULT THE APPROPRIATE ANSI/AWS FILLER METAL SPECIFICATION FOR INFORMATION ON THE SIGNIFICANCE OF "X" USED IN THE FILLER METAL DESIGNATIONS. OTHER CLASSIFICATIONS OF FILLER METAL (FOR EXAMPLE, A5.5; E80XX-XX, E7018-W, OR E8018-W COVERED ELECTRODES), AND CORRESPONDING ELECTRODES FOR SAW, GMAW, AND FCAW PROCESSES MAY BE REQUIRED TO ACHIEVE NOTCH TOUGHNESS REQUIREMENTS OR TO MATCH ATMOSPHERIC CORROSION AND WEATHERING CHARACTERISTICS.

(B) FOR BRIDGES, THE WELD METAL SHALL HAVE A MINIMUM CHARPY V-NOTCH IMPACT STRENGTH OF 27 J (20 FT · LBF) AT -20 °C (0 °F).

The low-temperature impact properties, as well as the tensile strength of the weld deposit, can be an important factor when selecting filler metals for the welding of HSLA steels. Various electrodes in ANSI/AWS specifications A5.1 and A5.5 have minimum Charpy impact test requirements at temperatures ranging from -20 to -100 °C (0 to -150 °F). In addition to relying on either the requirements of electrode specifications or typical test results furnished by electrode producers, it is often necessary to run procedure qualification tests to determine the impact properties of the weld metal and heat-affected zones (HAZs), because of code requirements or other considerations.

As indicated in footnote [(a)] of Table 2, low-alloy steel weld metal compositions are available to match the resistance to atmospheric weathering afforded by some HSLA structural steels. Because of the risk of hydrogen cracking when welding HSLA structural steels, most steel producers recommend the use of low-hydrogen electrodes. However, the use of electrodes that are not low in hydrogen may be acceptable in some applications, if the parts are relatively thin and the joints are not restrained or if a higher preheating temperature can be used.

Gas-Metal Arc Welding (GMAW) and Gas-Tungsten Arc Welding (GTAW). Suggested filler metals for the GMAW of low-alloy structural steels are given in Table 2. Similar filler metals can also be employed for GTAW, although this process is not often used for structural welding. The chemical compositions of the low-alloy steel filler metals included in ANSI/AWS specification A5.28 are generally comparable to the weld metal compositions provided by low-alloy steel SMAW electrodes. Some of the filler metals identified in this specification have minimum impact property requirements. This information is useful when selecting filler metals for application where low-temperature notch ductility is important.

Flux-Cored Arc Welding (FCAW). Flux-cored electrodes used for welding HSLA structural steels are classified in ANSI/AWS specifications A5.20 and A5.29. Weld metal compositions are generally comparable to those available from SMAW electrodes. Several classifications of flux-cored electrodes also have specified impact test requirements. Some types of flux-cored electrodes (self-shielding) require no external gas shielding. E80T1-W electrodes provide weld metal that has weathering characteristics similar to those of some low-alloy structural steels. Suggested electrodes for the FCAW of low-alloy structural steels are given in Table 2.

Submerged Arc Welding (SAW). Electrodes and fluxes used for the SAW of HSLA structural steels are classified in ANSI/AWS specifications A5.17 and A5.23. Inasmuch as numerous different electrode/flux combinations can be suitable for a specific application, it is not possible to suggest in this article anything other than broad categories, as shown in Table 2. When selecting electrodes and fluxes, it is often necessary to refer to producer literature for information on available electrode/flux combinations, performance characteristics of fluxes, and typical properties of weld deposits, as well as the electrode/flux specifications. In addition, procedure development tests may be necessary in order to determine the results obtained under representative fabricating conditions.

For the welding of HSLA steels exposed to outdoor environments in the unpainted condition, SAW compositions that match the weathering characteristics, as well as the mechanical properties of several HSLA steels, are available. Producers can offer recommendations on consumables for such applications.

Electroslag Welding (ESW) and Electrogas Welding (EGW). Solid and metal-cored electrodes used in the ESW of HSLA structural steels are classified in ANSI/AWS specification A5.25. Weld metal compositions are similar to those of many of the electrodes available for GMAW and SAW. Chromium-molybdenum, nickel, or nickel-chromium-copper

low-alloy steel weld metals are recommended for exposed, bare, and unpainted applications of ASTM A 588 steel. Classifications EWT2, EWT4, and EWS-EW are useful for other weather-resistant applications.

Flux-cored and solid electrodes classified in ANSI/AWS specification A5.26 for the EGW of HSLA structural steels are similar in composition to many of the flux-cored electrodes classified in ANSI/AWS specification A5.29 and the solid electrodes classified in ANSI/AWS specification A5.28 for GMAW.

The higher-energy input associated with ESW and EGW can result in weld metal and HAZ properties that are significantly different from those obtained with other arc welding processes. To select appropriate consumables, a consultation with producers and welding procedure development tests are recommended.

Welding Procedures and Practices

Preheating. The successful welding of HSLA structural steels requires consideration of a preheat. Generally, the need for preheating increases with increasing carbon and alloy content and with increasing steel thickness. The recommended minimum preheat and interpass temperatures for several HSLA structural steels are given in Table 3.

TABLE 3 MINIMUM PREHEAT AND INTERPASS TEMPERATURES TO WELD HSLA STRUCTURAL STEELS USING LOW-HYDROGEN WELDING PROCESSES

Source: Ref 3

Information on recommended preheat temperatures for other HSLA structural steels can be obtained from steel producers. If the preheat temperature is not sufficiently high, weld cracking can occur, particularly with highly restrained joints. When different preheat temperatures are specified for the joining of different thicknesses or types of HSLA steels, the higher preheat temperature should be used.

Postweld heat treatment is seldom required for welds in HSLA structural steels. However, it may be necessary to consider postweld heat treatment if:

- THE WELDMENT IS EXPOSED TO AN ENVIRONMENT THAT CAN CAUSE STRESS-CORROSION CRACKING
- CONTROL OF DIMENSIONS DURING MACHINING IS IMPORTANT
- IMPROVED DUCTILITY IS REQUIRED

When postweld heat treatment is required, the vanadium content of the weld metal should be no greater than 0.05%. The recommended postweld heat-treatment range for many HSLA structural steels is from 595 to 675 °C (1100 to 1250 °F). For proprietary steels, the postweld heat-treatment recommendations of the producer should be followed.

High-Strength Low-Alloy Quenched and Tempered (HSLA Q&T) Structural Steels

HSLA Q&T structural steels typically contain less than 0.25% C and less than 5% alloy. These steels combine high yield and tensile strengths with good ductility, notch toughness, atmospheric corrosion resistance, and weldability. They are strengthened primarily by quenching and tempering to produce microstructures that contain martensite, bainite, and, in some compositions, ferrite. Some types are produced with a precipitation-hardening treatment that follows hot rolling or quenching. Yield strength values range from approximately 345 to 895 MPa (50 to 130 ksi), and tensile strength values range from 485 to 1035 MPa (70 to 150 ksi), depending on chemical composition, thickness, and heat treatment.

Many of the steels are included in ASTM specifications such as A 514, A 517, and A 543. However, a few steels, such as HY-80, HY-100, and HY-130, are covered by military specifications. The HSLA Q&T steels are furnished primarily as plate, although some are produced as either forgings or castings. The chemical compositions of typical steels are given in Table 4. Heat treatments used by the producers of these steels and the resulting microstructures are shown in Table 5.

Welding Processes

Any of the common arc welding processes can be used to join the quenched and tempered low-alloy structural steels that have minimum yield strengths of ≤1035 MPa (≤150 ksi). However, the GMAW and GTAW processes are preferred for welding steels with minimum yield strengths of [ges]700 MPa ([ges]100 ksi), such as HY-130, because they afford a higher level of notch toughness in the weld metal.

Filler Metals

Welding filler metals and electrode/flux combinations are available for welding most of the HSLA Q&T structural steels. Many of these consumables are classified in ANSI/AWS filler metal specifications for low-alloy steels. The selection of consumables is usually based on factors such as tensile strength, composition, and notch toughness of the weld metal. For some steels, more than one type or classification of welding consumable may satisfy the fabrication requirements.

The selection of welding consumables for a specific application should be based on a thorough evaluation of the design requirements and knowledge of the available weld metal properties, such as tensile strength, ductility, and impact strength. In general, the deposited weld metal should have properties that either match or exceed those of the base metal. However, for welds that are subject to relatively low stresses, the use of a weld metal that has a lower strength than that of the base metal may be acceptable. Typical examples are fillet welds stressed in longitudinal shear, welds carrying low secondary stresses, and welds that join a lower-strength steel to a HSLA Q&T steel. In cases where the design permits, lower-strength weld metal can be advantageous, allowing highly restrained welds to resist the tendency for toe cracking (that is, cracking at the toe of a fillet weld) or lamellar tearing in the steel, especially with corner and T-joints.

Weld Metal Hydrogen

The weld metal hydrogen content must be maintained at very low levels when welding HSLA Q&T steels, in order to avoid hydrogen-induced cracking. The maximum acceptable moisture, or hydrogen content, of covered electrodes, bare filler metal, and fluxes decreases as the strength of the weld metal increases. Welding consumables must be produced, packaged, stored, and used in a manner that limits the weld metal hydrogen content to a low level.

Weld Design

In order to employ HSLA Q&T structural steels advantageously, it is necessary to use appropriate joint designs, careful workmanship, and adequate inspection. Weld joints should be designed and located to avoid abrupt changes in cross section or other stress raisers in regions of high stress. Joints should permit good accessibility for welding and inspection. Groove welds are preferred over fillet welds for many applications, because of inherent stress concentrations associated with fillet welds and because groove welds are more amenable to volumetric methods of examination, such as radiographic or ultrasonic testing. The weld metal should blend smoothly into the base metal, with no abrupt ridges or valleys, and excessive reinforcement should be avoided.

Preheat and Interpass Temperature Control

The successful welding of HSLA Q&T structural steels often requires preheating in order to prevent cracking. However, caution must be exercised, because the preheat temperature affects the cooling rate during welding, thereby possibly affecting the microstructures and properties of the weld metal and HAZs. A preheat or interpass temperature that is too

high can decrease the rate of cooling of the weld metal and HAZs sufficiently to result in the transformation of austenite to either ferrite (containing regions of high-carbon martensite) or coarse bainite. Both structures lack high strength and good toughness. Next to the reaustenitized portion of the HAZ, a region of previously tempered base metal may be overtempered, causing a loss in strength.

Suggested preheat and interpass temperature ranges for some HSLA Q&T steels are given in Table 6. Information on preheating can be obtained from producers of HSLA Q&T steels. Exceeding the recommended maximum temperature should be avoided. If a preheat temperature of 40 °C (100 °F) or less is used, precautions must be taken to ensure that the surfaces to be welded are dry.

TABLE 6 TYPICAL PREHEAT AND INTERPASS TEMPERATURE RANGES TO WELD QUENCHED AND TEMPERED HSLA STRUCTURAL STEELS

BASE METAL ASTM SPECIFICATION OR COMMON DESIGNATION	**THICKNESS**		PREHEAT AND INTERPASS TEMPERATURE RANGE	
	MM	**IN.**	**°C**	°F

	>12.5-28.7	$>\frac{1}{2}\text{-}1.13$	50-150	**125-300**
	>28.9	>1.14	95-150	**200-300**
HY-130	≤16	≤0.63	25-65	**75-150**
	16.3-22.4	0.64-0.88	50-95	**125-200**
	22.6-35.1	0.89-1.38	95-135	**200-275**
	>35.1	**>1.38**	**105-150**	**225-300**

Heat Input

In addition to preheat and interpass temperature, the heat (energy) input during welding and the base metal thickness are factors that affect the cooling rate, and thereby affect the microstructures and mechanical properties of the weld metal and HAZs. As is the case with too high a preheat and interpass temperature, excessive heat input can decrease the rate of cooling sufficiently to produce unfavorable microstructures and properties. Welding heat input is of greater concern in steels with a minimum yield strength of 700 MPa (100 ksi) than it is in lower-strength HSLA Q&T steels.

The welding heat input can be calculated as follows:

$$H = \frac{E.I.60}{S.1000} \qquad \textbf{(EQ 1)}$$

where H is heat input (arc energy), in units of kJ/in.; E is arc voltage, in V; I is welding current, in A; and S is arc travel speed, in units of in./min.

Table 7 shows the maximum permissible welding heat input for butt joints in ASTM A 514/A 517, grade F steel, depending on the preheat temperature and section thickness. Exceeding the maximum specified heat input can result in undesirable microstructures and unacceptable mechanical properties. Because of the different metallurgical characteristics that are possible, other types of steel may require different heat input limitations.

Source: Ref 2

(A) FOR INTERMEDIATE PREHEAT TEMPERATURES AND THICKNESSES, INTERPOLATE TO OBTAIN HEAT INPUT LIMIT. THIS LIMIT CAN BE INCREASED 25% FOR FILLET WELDS.

(B) NO HEAT INPUT LIMIT FOR MOST ARC WELDING PROCESSES. HIGH HEAT INPUT PROCESSES SHOULD NOT BE USED.

Heat input limitations apply to each weld pass and are not considered cumulatively. They also limit the size of weld beads. Large weld beads typically have poor notch toughness. Therefore, a good welding practice for Q&T steels is to deposit many small stringer beads. This technique produces a weld metal that has good notch toughness as a result of the grain refining and tempering effect of successive weld passes.

These heat input limitations are applicable only for single-arc welding processes. Multiple-arc processes, with the arcs in tandem, generally do not allow sufficient time for the metal deposited by the first arc to cool before the second arc passes over it, supplying additional heat. This can significantly influence the transformation of austenite in the weld metal and HAZs and adversely affect the weld properties. Multiple-arc processes should not be used to weld HSLA Q&T steels prior to conducting welding procedure development tests to prove their suitability.

The cooling rates of welds made using the SMAW, GMAW, FCAW, and GTAW processes are usually sufficiently rapid, under normal conditions, so that the mechanical properties of the HAZ approach those of the unaffected quenched and tempered base metal. The use of high heat input welding processes, such as ESW, EGW, or multiple-wire SAW, generally should be avoided when welding HSLA Q&T steels. Such processes may require complete heat treatment (quenching and tempering) of the weldment in order to obtain acceptable mechanical properties.

Postweld Heat Treatment

Postweld heat treatment is seldom required for welds in HSLA Q&T structural steels, except where heavy sections are involved. The mechanical properties of either the base metal or the weld metal can be adversely affected by postweld heat treatment. When weldments of some HSLA Q&T structural steels are heated to above 510 °C (950 °F), intergranular cracking can occur in the coarse-grained region of the weld HAZ. Cracking occurs by stress rupture, usually early in the heat-treatment cycle.

In situations where postweld heat treatment is necessary, some practices may be used singly or in combination to minimize cracking during postweld heat treatment. These practices involve:

- SELECTING A WELD LOCATION, WELD JOINT DESIGN, AND ASSEMBLY SEQUENCE THAT WILL MINIMIZE RESIDUAL STRESSES AND STRESS CONCENTRATIONS
- USING A TYPE OF WELD METAL THAT HAS SIGNIFICANTLY LOWER STRENGTH THAN THAT OF THE HAZ AT THE POSTWELD HEAT-TREATMENT TEMPERATURE
- PEENING EACH WELD LAYER, EXCEPT THE ROOT AND FINAL LAYERS
- HEATING TO THE POSTWELD HEAT-TREATMENT TEMPERATURE RANGE AS RAPIDLY AS POSSIBLE

In the postweld heat treatment of quenched and tempered steels, the mill tempering temperature used by the steel producer should not be exceeded. To avoid unnecessary risks, the steel producer should be consulted prior to reaching a decision regarding postweld heat treatment of a HSLA Q&T structural steel.

Of the available HSLA Q&T structural steels, only ASTM A 514 and A 517 are customarily given postweld heat treatments when the section thickness exceeds a specified amount.

Welding of Low-Alloy Steels

F.J. Winsor, Welding Consultant

Low-Alloy Steels for Pressure Vessels and Piping

A variety of low-alloy steels containing from 0.10 to 0.30% C and up to 10% total alloy are used for welded pressure vessels and piping. Alloy additions include manganese, silicon, molybdenum, chromium, nickel, vanadium, copper, and niobium. Table 8 gives the nominal chemical composition and minimum specified tensile strength values of representative low-alloy steels used in pressure vessels and piping. These steels are usually furnished in the as-rolled, as-forged, or annealed condition. Some steels, such as those shown in Table 9, also may be obtained in the normalized, normalized and tempered, or quenched and tempered condition to provide enhanced mechanical properties.

(A) CLASS 1.

(B) CLASS 2.

(C) CLASS 3

The choice of low-alloy steel to be used for a pressure vessel or piping system is usually made on the basis of one or more desired properties in service, such as tensile strength, resistance to hydrogen attack, resistance to creep and oxidation at elevated temperatures, or low-temperature notch ductility. Weldability is an important consideration, as well.

Heat-resisting low-alloy steels used for pressure vessels and pipe generally contain up to 0.25% C, plus alloy additions such as chromium, molybdenum, vanadium, and silicon. When compared with plain carbon steels, the heat-resisting steels offer greater tensile and creep-rupture strengths at elevated temperatures and greater resistance to oxidation and hydrogen attack. Steels with from 1 to 9% Ni provide greater resistance to notch embrittlement than do carbon steels or many other low-alloy steels and are widely used in low-temperature service.

Welding Processes and Practices

All of the common arc welding processes can be used to join low-alloy steels used for pressure vessels and piping. SMAW, GTAW, GMAW, FCAW, and SAW are used for most applications. Successful welding requires consideration of preheating and control of weld metal hydrogen content. The use of low-hydrogen consumables and practices is essential in welding most low-alloy steels that contain more than minor amounts of alloying elements. When notch toughness requirements are important, control of heat input must be considered.

ESW and EGW can be used for many low-alloy steels. However, careful evaluation is required when good notch toughness in the weld metal and HAZ is important. A postweld grain refinement heat treatment may be required by some codes and specifications. Preheating is not normally necessary with these high heat input processes.

Filler Metal Selection

In order to provide weld metals that match or exceed the service performance characteristics of low-alloy steel base metals used in pressure vessels and piping, it is frequently necessary to base the filler metal selection on considerations of chemical composition and mechanical properties. In most cases, the content of critical elements in the weld metal must either match or exceed that of the base metal.

Shielded Metal Arc Welding. Electrodes for the SMAW of low-alloy steels used for pressure vessels and piping are classified in ANSI/AWS specification A5.5. In addition, 5%Cr-0.5%Mo and 9%Cr-1%Mo electrodes are classified in ANSI/AWS specification A5.4. Nearly all welding of low-alloy steels is done using low-hydrogen electrodes. However, electrodes that are not low in hydrogen can be used satisfactorily in a few applications where base metals are relatively thin and/or where higher preheat temperatures are feasible. Examples include the welding of C-Mo steel pipe and tubing and the welding of the root pass of groove welds in low Cr-Mo pipe and tubing. All-position electrodes that are not low in hydrogen may have better usability than low-hydrogen types for out-of-position welding, especially where frequent changes in welding position are necessary, as in the welding of pipe in the fixed horizontal position.

At present, SMAW electrodes that will deposit weld metal that has a nominal content of 9% Ni, to match that of ASTM A 353 or A 333, grade 8, base metal, for example, are not commercially available. To weld this material, it is common industry practice to use either an austenitic stainless steel electrode classified in ANSI/AWS specification A5.4 or a nickel-chromium-iron or nickel-chromium-molybdenum alloy electrode classified in ANSI/AWS specification A5.11. The selection of dissimilar alloy covered electrodes or other consumables for the welding of 9% Ni steels must be done carefully, based on the design tensile strength and low-temperature impact requirements.

For cyclic temperature service, consideration should be given to the possible adverse effect of the greater coefficient of linear thermal expansion of austenitic stainless steel, compared to that of nickel-base alloy weld metals.

Gas-Tungsten Arc Welding and Gas-Metal Arc Welding. Bare filler metals for the gas-shielded arc welding of low-alloy steels used for pressure vessels and piping are classified in ANSI/AWS specifications A5.28 and A5.9 (classifications ER502 and ER505). The chemical compositions of low-alloy steel bare filler metals are generally comparable to the deposits produced by covered electrodes for SMAW. As with covered electrodes, there is no standard matching composition of bare welding filler metal for joining 9% Ni steel. To weld this material, it is common practice to use a stainless steel filler metal classified in ANSI/AWS specification A5.9 or a nickel-chromium or nickel-chromium-iron alloy filler metal classified in ANSI/AWS specification A5.14, selected to provide the required tensile strength and impact properties in the weld metal.

ANSI/AWS specification A5.9 classifies matching ER502 and ER505 filler metals for the welding of 5Cr-0.5Mo and 9Cr-lMo base metals, respectively. Filler metal of 9Cr-1Mo is also used to weld 7Cr-0.5Mo base metal.

Flux-Cored Arc Welding. Low-alloy steel electrodes for the FCAW of low-alloy steels used in pressure vessels and piping are classified in ANSI/AWS specification A5.29. Also, ANSI/AWS specification A5.22 classifies E502T-X and E505T-X flux-cored electrodes for welding 5Cr-0.5Mo, 7Cr-0.5Mo, and 9Cr-1Mo base metals.

Submerged Arc Welding. Electrodes and fluxes used for the SAW of low-alloy steels for pressure vessels and piping are classified in ANSI/AWS specification A5.23. Low-alloy steels are most often welded using a neutral flux and an alloy steel electrode. Occasionally, a carbon steel electrode can be used with a particular alloy flux designed to yield weld metal of the desired alloy composition.

When selecting electrodes and fluxes for submerged arc welding, it is often necessary or desirable to consult producers of electrodes and fluxes for information on the characteristics of their fluxes, recommendations on electrode/flux combinations, and data on typical properties of weld deposits, in addition to referring to ANSI/AWS specification A5.23. Such information can often be of great assistance in narrowing the search for suitable SAW consumables. Most pressure vessel and piping applications require procedure qualification testing to demonstrate that a particular electrode/flux combination will deposit weld metal that has the required chemical composition and mechanical properties.

To avoid hydrogen-induced cracking, care should be taken to maintain the flux and electrode in a dry condition. Producers should be consulted for recommendations concerning the storage and reconditioning of submerged arc welding flux.

Electroslag and Electrogas Welding. Low-alloy steel electrodes for ESW are classified in ANSI/AWS specification A5.25, whereas low-alloy steel electrodes for EGW are classified in ANSI/AWS A5.26. Only a few of the low-alloy steel compositions in these specifications satisfy requirements for matching chemical compositions of low-alloy steels used for pressure vessels. However, in some situations, nonmatching compositions may be acceptable. Fortunately, electrodes classified in various other filler metal specifications are useful for electroslag and electrogas welding. Thus, solid and metal-cored electrodes classified in ANSI/AWS A5.23 (for SAW) and in ANSI/AWS A5.28 (for GMAW) may also be useful for ESW and EGW. Appropriate testing is required to ensure that the required weld metal chemical composition and mechanical properties are obtained.

Welding Procedures and Practices

Preheating. The successful welding of low-alloy steels used for pressure vessels and piping requires the consideration of preheating. The suggested minimum preheat and interpass temperatures for several low-alloy steels are given in Table 10. The appropriate sections of the ASME Boiler and Pressure Vessel Code (Ref 4) or the American Society of Mechanical Engineers (ASME) B31.1 Power Piping Code and B31.3 Chemical Plant and Petroleum Piping Code should be consulted for preheat recommendations or requirements regarding boilers, pressure vessels, and code piping.

(B) VALUES VARY WITH SIZE.

Postweld heat treatment is often essential for welds in low-alloy steels used for pressure vessels and piping. Various sections of the ASME Boiler and Pressure Vessel Code (Ref 4), the ASME Piping Codes, and military specifications specify requirements for postheat treatment of welds in low-alloy steels. Frequently, purchasers of equipment refer to proprietary specifications that contain postweld heat-treatment requirements. For some materials with certain categories and thicknesses of joints, the codes or other fabrication specifications may allow exemptions from postweld heat-treatment requirements. Because of the differences in various codes and specifications, it is not feasible to provide a universally adequate and reliable summary here of all postweld heat-treatment requirements and practices for low-alloy steel pressure vessel and pipe welding.

Table 11 presents a general view of some of the different postweld heat-treatment temperatures involved in welding low-alloy steels for pressure vessels and piping. The applicable section of the ASME Boiler and Pressure Vessel Code (Ref 4), the ASME Piping Codes, military specifications, or purchaser specifications should be consulted for specific detailed postweld heat-treatment requirements. When dealing with applications that may not fall within the scope of a code or specification, it is a good policy to consult various codes for information to use in determining postweld heat-treatment practices.

Welding of Low-Alloy Steels

F.J. Winsor, Welding Consultant

Heat-Treatable Low-Alloy (HTLA) Steels

The term heat-treatable low-alloy steels applies to medium-carbon HSLA Q&T steels, which typically contain up to 5% of total alloy content and from 0.25 to 0.50% C. The carbon content of these steels is significantly higher than the 0.10 to 0.25% C range that is found in quenched and tempered structural low-alloy steels or low-alloy steels used for pressure vessels and piping.

Medium-carbon low-alloy steels are strengthened by quenching to produce a martensitic structure, followed by tempering to obtain the desired levels of hardness, strength, and ductility. The combination of high carbon content, which promotes high maximum hardness levels, and high hardenability, which is produced by the carbon and alloy content, results in a greater susceptibility to weld cracking.

The high hardness of many of these steels in their final hardened and tempered condition often precludes their being welded in that condition, because of the strong tendency for cold cracking (that is, cracking that develops after solidification is complete). Except for weld repairs, these steels are normally welded in the annealed or over-tempered condition, and then the complete weldment is heat treated to obtain the desired level of hardness or strength. The compositions of several typical HTLA steels are given in Table 12.

Welding Processes and Practices

Any of the common arc welding processes, such as SMAW, SAW, GMAW, GTAW, and FCAW, can be used to join the HTLA steels. It is important to use low-hydrogen welding consumables and processes in order to minimize cold cracking.

Because of its versatility, simple equipment requirements, and availability of electrode choices, the SMAW process is very often used in the fabrication or repair welding of HTLA steels. GTAW is capable of producing welds with the lowest hydrogen content, and this process is often preferred for critical applications. Both GTAW and GMAW processes provide good control of weld metal composition and cleanliness. For some applications, automatic and semiautomatic GTAW, GMAW, FCAW, and SAW processes offer the advantages of greater productivity and higher weld quality, compared with manual welding.

To avoid porosity and to minimize cracking problems, all materials involved in the welding operation must be clean and free of moisture, oil, grease, dirt, paint, or other contaminants. This includes the base metal, weld filler metal, submerged arc fluxes, gloves, fixtures, and handling devices.

The successful welding of HTLA steels requires not only the selection of the proper welding process and filler metal, but the consideration of several other factors:

- PREHEAT AND INTERPASS TEMPERATURE REQUIREMENTS
- ACHIEVEMENT OF A LOW HYDROGEN CONTENT IN THE WELD METAL, ESPECIALLY WHEN THE PREHEAT TEMPERATURE IS LESS THAN 205 °C (400 °F)
- NEED TO MAINTAIN PREHEAT AFTER WELDING IS COMPLETED UNTIL THE COMMENCEMENT OF POSTWELD HEAT TREATMENT

Filler Metals

Shielded Metal Arc Welding. Low-hydrogen electrodes are nearly always recommended for the welding of HTLA steels to minimize weld metal and HAZ cracking. Electrodes that deposit weld metal that has a response to heat treatment matching that of the base metal are available from some electrode manufacturers for use in welding a few HTLA steels

that are quenched and tempered after welding. The chemical composition of the weld metal deposited by these electrodes sometimes, but not always, matches that of the base metal for which they are intended. The main objective is to achieve a weld deposit that responds to a quench and temper heat treatment in a manner similar to that of the base metal. Sometimes this objective can be achieved with weld metal that has a lower carbon and higher alloy content than the base metal. This is advantageous in reducing weld-cracking tendencies. Medium-carbon HTLA steel welding electrodes are not classified in ANSI/AWS specification A5.5 or other standard filler metal specifications. Rather, they are proprietary types designed for welding steels such as American Iron and Steel Institute-Society of Automotive Engineers (AISI-SAE) types 4130, 4140, and 8630. Electrode manufacturers should be consulted for information on the availability of HTLA steel electrodes and applications.

Some applications of HTLA steels do not require that the hardness and strength of the weld match those of the base metal. The location of weld joints and the orientation of applied stresses can be such that weld properties need not match base metal properties after a quench and temper heat treatment. In some repair situations, it may be possible to use the steel in the annealed or over-tempered condition. In this case, after welding the material in that condition, the weldment is placed in service after a stress-relieving or tempering treatment. For such applications, a variety of low-hydrogen carbon steel, low-alloy steel, stainless steel, and nickel alloy covered electrodes may be useful.

Some types of electrodes that deposit non-heat-treatable weld metal can be used to a limited extent for the welding of HTLA steels in the hardened condition, as in repair welding, where it may not be feasible to anneal or over-temper the steel prior to welding nor to stress relieve the weld upon completion. Weld metal from austenitic stainless steel electrodes, such as ANSI/AWS A5.4 E309 (25Cr-12Ni), E310 (25Cr-20Ni), and E312 (29Cr-9Ni), and from nickel alloy electrodes, such as ANSI/AWS A5.11 ENiCrFe-2 and ENiCrFe-3, can tolerate a rather large amount of dilution from the medium-carbon low-alloy steel base metal without cracking. Additionally, these weld deposits have lower strength and greater ductility than the quenched and tempered base metal. Consequently, high shrinkage stresses during welding can result in plastic deformation of the weld deposit, rather than in cracking of the base metal.

Table 13 shows classifications of carbon steel and low-alloy steel covered electrodes commonly used for the welding of HTLA steels in applications that do not require a properties match between the weld metal and the base metal in the quenched and tempered condition. In some instances, the weld metal compositions include one or more of the principal alloying elements in the associated base metal. Also, a weld metal that has a higher strength in the as-welded condition is associated with steels that have higher alloy and carbon contents, which are often heat treated to higher hardness and strength levels. However, it should be noted that all of the weld deposits listed have a low carbon content. Therefore, even though the alloy content of the weld deposit may match that of the base metal, it is unlikely that the carbon content of the weld, even with considerable dilution from the base metal, will be high enough to result in weld metal hardness and strength values that match those of the base metal after a post-weld quench and temper heat treatment. It may be necessary to use one of the higher-strength weld metals in order to satisfy a higher design strength requirement for the weld in the as-welded or stress-relieved condition. If this is not necessary, then the use of a lower-strength weld metal is recommended to decrease the susceptibility to cracking.

(A) WELD METAL PROPERTIES DO NOT MATCH BASE METAL PROPERTIES IN THE QUENCHED AND TEMPERED CONDITION.

Gas-Tungsten Arc Welding and Gas-Metal Arc Welding. There are no standard filler metal specifications that classify medium-carbon, heat-treatable bare electrodes and rods for gas-shielded arc welding processes. Bare filler metal of a composition similar to the base metal can be used for the GTAW and GMAW processes. It is desirable to have the lowest possible phosphorus and sulfur contents, and, in some instances, it may be permissible to use weld metal that has a lower carbon content than the base metal, with the objectives of reducing weld metal hot cracking tendencies and improving weld metal ductility. Many of the standard AISI-SAE steel compositions are available in wire form that is suitable for gas-shielded arc welding. The results of transverse tensile tests of GMAW and GTAW joints in some representative low-alloy steels after quenching and tempering are shown in Table 14.

The surface condition of the filler metal can have a critical effect on arc welding operations. Welding filler metal producers or specialty wire suppliers who are familiar with welding requirements usually are the best sources of bare welding filler metals.

In cases where service requirements do not dictate the need for weld deposits that are heat treatable by quenching and tempering after welding, the carbon steel filler metals classified in ANSI/AWS specification A5.18 or the low-alloy steel filler metals classified in ANSI/AWS A5.28 can be used. Also, nonheat-treatable austenitic stainless steel or nickel alloy filler metals may be acceptable choices for some applications.

Flux-Cored Arc Welding. There are no standard specifications for FCAW electrodes that provide weld deposits that respond similarly to heat treatment as do medium-carbon low-alloy steel-base metals. However, FCAW electrodes of special composition can often be obtained more readily than solid filler metals of similar composition. For example, to achieve weld strength requirements equivalent to a quenched and tempered AISI 4130 steel (0.30C-0.95Cr-0.20Mo) weldment, a FCAW electrode was specially formulated to produce a weld deposit with a composition of 0.15% C, 1.50 to 1.70% Mn, 0.50 to 0.60% Si, 0.60 to 0.80% Cr, and 0.60 to 0.90% Mo. Producers of flux-cored electrodes should be consulted regarding the availability of special electrodes.

Where service requirements do not dictate the need for weld deposits that are heat treatable by quenching and tempering after welding, ANSI/AWS A5.20 carbon steel flux-cored electrodes or ANSI/AWS A5.29 low-alloy steel flux-cored electrodes can be used. A T5 slag system is preferred to T1, because weld deposits often have a higher toughness and lower hardness. Carbon steel deposits can fail, because of low strength, if the fillet size is small or high restraint exists. When selecting FCAW electrodes, it may be helpful to refer to commonly used SMAW electrodes (shown in Table 13). Also, either the non-heat-treatable austenitic stainless steel flux-cored electrodes listed in ANSI/AWS specification A5.22 or proprietary nickel alloy flux-cored electrodes may be suitable choices for some applications.

Submerged Arc Welding. Some low-alloy steel weldments that require a quench and temper heat treatment after welding can be welded by the SAW process. Submerged arc weld metal usually has lower toughness than welds made by GTAW, particularly after heat treatment to a high strength level. Neutral or basic fluxes generally produce welds with better notch toughness. Manufacturers of electrodes and fluxes, as well as steel producers, should be consulted to determine the availability of consumables, recommended welding parameters and heat treatment, and information on mechanical properties for specific applications of SAW. If such information is not available, then welding procedure development tests will be needed.

Preheating

In low-alloy steels, the carbon and alloy contents determine the transformation characteristics (microstructure) of the steel upon cooling from a high temperature. The higher the carbon content, the higher the maximum hardness of as-quenched martensite. If the weld metal and HAZs are allowed to cool rapidly to room temperature during welding of low-alloy steels that have high carbon and high alloy content, then hard, crack-sensitive martensite is likely to form. The risk of cracking is greatly increased by the presence of hydrogen. By slowing the cooling rate, preheating may lower the risk of cracking through the reduction of stresses imposed on the weld metal and HAZs during the transformation to martensite or to martensite and bainite. In some steels, preheating may promote the formation of softer bainite instead of hard martensite. Preheating also promotes the evolution of dissolved hydrogen. Steels with an identical alloy content, but different carbon contents, usually require an increase in preheat temperature with increasing carbon content.

The minimum preheat and interpass temperature required to prevent cracking during the welding of HTLA steels depends on the:

- CARBON AND ALLOY CONTENT OF THE BASE METAL AND WELD METAL
- CONDITION OF HEAT TREATMENT PRIOR TO WELDING
- BASE METAL THICKNESS
- AMOUNT OF RESTRAINT
- AMOUNT OF AVAILABLE HYDROGEN

Figure 1, an isothermal transformation diagram for AISI 4340 steel, shows a M_s temperature (the temperature at which martensite starts to form from austenite upon cooling) of approximately 290 °C (550 °F). At 315 °C (600 °F), the diagram

shows about 30 min of elapsed time, and, at 370 °C (700 °F) about 3 h time, required for isothermal transformation of austenite (A) to bainite (ferrite and carbides, F + C). When welding this steel by using a preheat and interpass temperature ranging from 315 to 345 °C (600 to 650 °F), and maintaining this temperature for a minimum of 3 h after completion of welding, followed by slow cooling, a bainitic microstructure can be obtained in the HAZ and in weld metal of matching composition. It is essential to maintain the preheat after welding for a sufficient time to allow for variations that could result in a longer transformation time. Maintaining preheat after welding also promotes the evolution of hydrogen and reduces the risk of hydrogen-induced cracking.

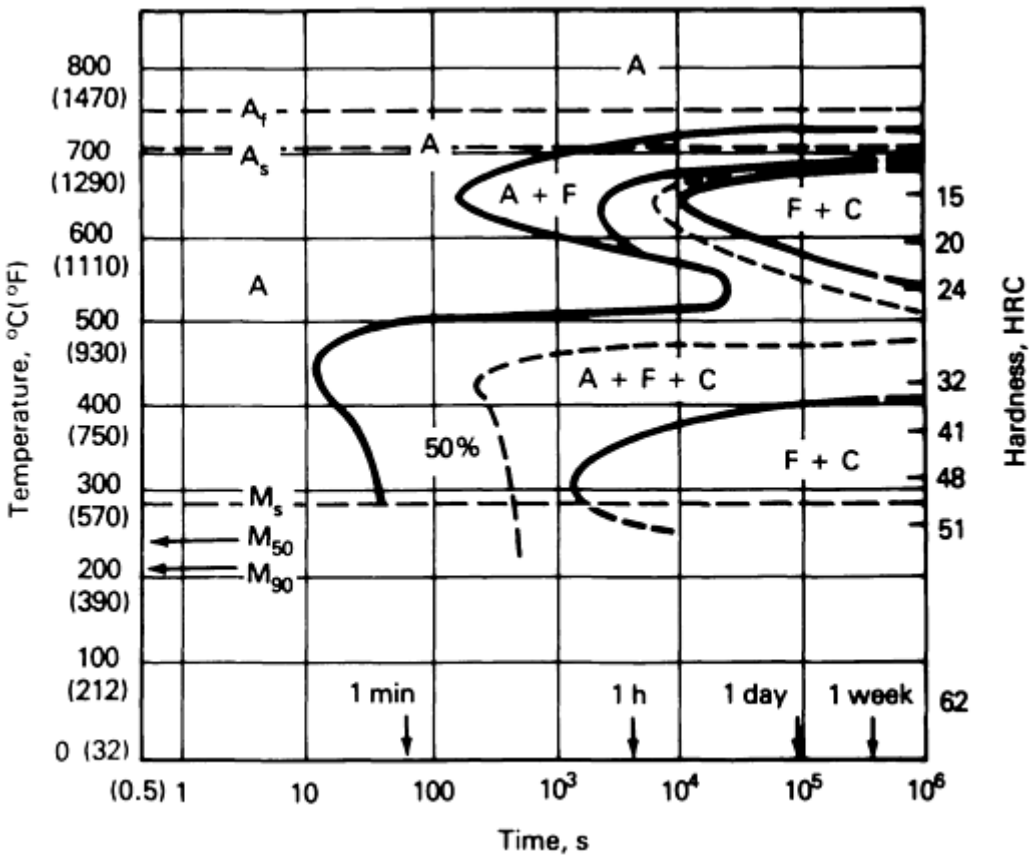

FIG. 1 ISOTHERMAL TRANSFORMATION DIAGRAM FOR AISI 4340 STEEL. SOURCE: REF 5

Unfortunately, preheat and interpass temperatures above about 290 °C (550 °F) promote the formation of a thin oxide layer on the joint surfaces and can also contribute to welder discomfort. These factors can have an adverse effect on weld quality and should be considered when planning the welding operation.

The isothermal transformation diagram in Fig. 2 for AISI 8620 steel, which has a lower carbon and lower total alloy content than AISI 4340, indicates a considerably higher M_s temperature of 405 °C (760 °F). M_s temperatures for HTLA steels with relatively low carbon and alloy contents are usually so high that it is often not feasible to employ a preheat and interpass temperature that is above the M_s temperature for the particular steel. However, with a lower carbon and lower alloy content, these steels have lower hardenability. This means that, with moderate rates of cooling from the welding temperature, there is a possibility for obtaining at least partial transformation to ferrite and carbides, rather than complete transformation to martensite. When martensite does form, its hardness will be lower, because of the lower carbon content. In addition, for steels that have a high martensite formation temperature range, the use of a preheat and interpass temperature below this range can permit partial tempering of the martensite. Because of these factors, lower preheat and interpass temperatures can be used satisfactorily when welding lower carbon and lower alloy content steels.

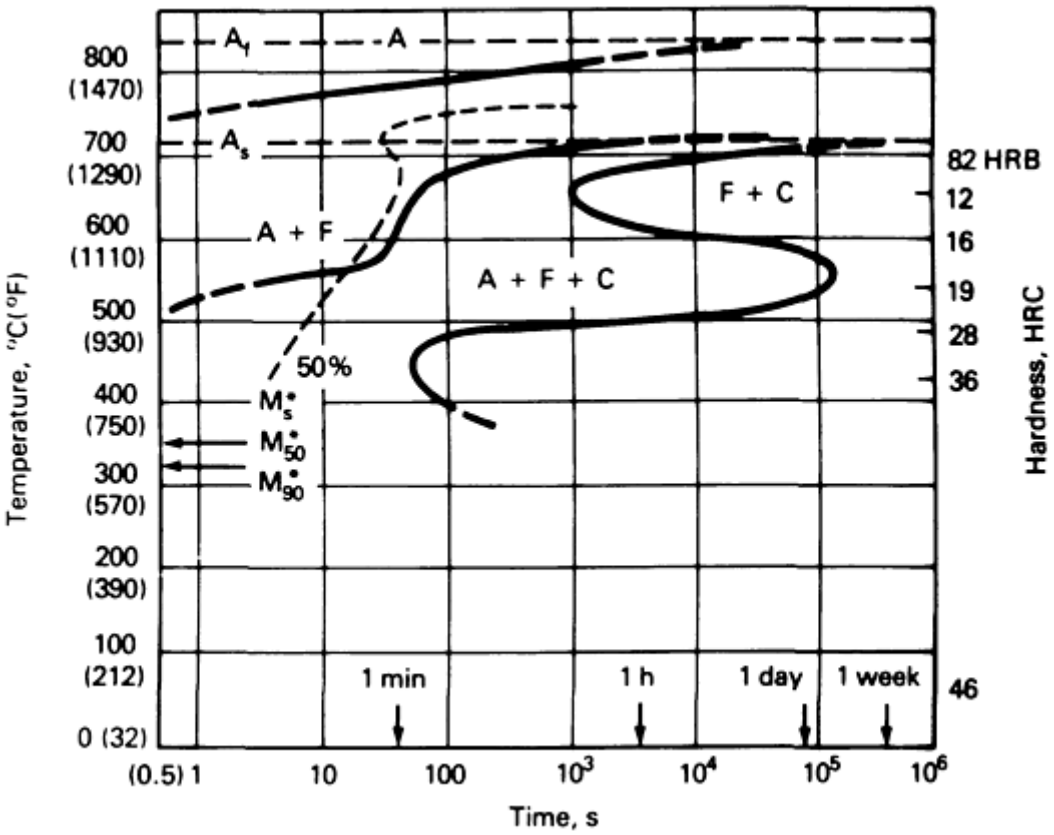

FIG. 2 ISOTHERMAL TRANSFORMATION DIAGRAM FOR AISI 8620 STEEL. * INDICATES ESTIMATED TEMPERATURE. SOURCE: REF 5

For a given initial base metal temperature (preheat) and level of energy input during welding, increasing the section thickness will increase the cooling rate. Therefore, when welding steels of intermediate hardenability, the likelihood of martensite formation also increases with increasing thickness, and it may be necessary to increase the preheat temperature as the section thickness is increased.

Suggested preheat and interpass temperatures for several HTLA steels are given in Table 15. Other than the inherent metallurgical characteristics of the steel, some factors that may permit the use of lower preheat and interpass temperatures than might otherwise be the case are:

- WELDING THE STEEL IN THE FULLY ANNEALED OR OVER-TEMPERED CONDITION
- LOCATING THE WELD IN AREAS OF LEAST SECTION THICKNESS OR WHERE RESTRAINT CONDITIONS MAY BE LEAST SEVERE
- SELECTING PROCESSES AND FILLER METALS THAT OFFER THE LOWEST AMOUNT OF AVAILABLE HYDROGEN
- USING FILLER METALS THAT HAVE THE LOWEST CARBON AND ALLOY CONTENT CONSISTENT WITH OBTAINING THE REQUIRED WELD METAL MECHANICAL PROPERTIES

Note: Data are for low-hydrogen welding processes and low-hydrogen filler metals.

Heat Input

Low-to-moderate levels of heat input are usually preferred for the welding of HTLA steels. High heat input levels tend to promote wide HAZs with enlarged grain size and reduced notch ductility. High heat input also increases the risk of hot cracking (solidification cracking) in the weld metal and the HAZs.

Postweld Heat Treatment

The type of heat treatment required after welding the HTLA steels (that is, postweld stress relieving or tempering or a quench and temper heat treatment of the completed weldment) depends on the metallurgical characteristics of the steel and the mechanical property requirements. Postweld heat treatment details often depend on the preheat and interpass temperature used in welding.

For the higher carbon and higher alloy content steels, welding with low-to-moderate heat input and using preheat and interpass temperatures that are below the M_s temperature of the particular steel will result in the partial or complete transformation to martensite of some or all of the austenite in the weld metal and HAZs. The amount of martensite that forms depends on the preheat temperature and its relation to the martensite transformation temperature range (essentially between M_s and M_{90}, as shown in Fig. 2). If the martensite transformation is incomplete at the preheat temperature, subsequent cooling from that temperature will result in additional martensite formation. Rapid cooling to room temperature can result in weld or HAZ cracking in higher-carbon HTLA steels. If partial or complete transformation to martensite has occurred, then heating the part to a higher temperature for a sufficient time will temper the martensite.

Steels of lower alloy and carbon content have higher temperature ranges of martensite formation (compare AISI 8620 in Fig. 2 to AISI 4340 in Fig. 1), and they are less susceptible to weld cracking than higher carbon and higher alloy content steels. Preheat and interpass temperatures for steels with lower carbon and lower alloy content usually are within or below the martensite-forming temperature ranges, and weldments are given a tempering heat treatment after welding, unless a quench and temper heat treatment is required.

In order to avoid weld metal or HAZ cracking in the higher carbon and higher alloy content steels, it is necessary, upon completion of welding, to proceed immediately with postweld heat treatment without interrupting the preheating. Even with less crack-sensitive steels, it is preferable to start the postweld heat treatment as soon as possible after welding. If a stress relief or tempering heat treatment is specified immediately after welding (usually 595 to 675 °C, or 1100 to 1250

°F), and if the preheat temperature used in welding is within the martensite-formation temperature range for the steel, then the weldment should first be allowed to cool slowly and uniformly to just below the M_{90} temperature, where transformation to martensite will be essentially complete.

Next, the weldment should be immediately heated to the stress-relieving temperature where the martensite will be softened by tempering. After holding at temperature for a sufficient time (usually ~1 h/in. of joint thickness), the weldment can be cooled to room temperature without danger of cracking. It may not always be practical to start the postweld heat treatment immediately after completion of welding. When cooling to room temperature is necessary after welding, it should be done slowly and uniformly to avoid cracking.

Welding of Low-Alloy Steels

F.J. Winsor, Welding Consultant

Ultrahigh-Strength Low-Alloy Steels

The ultrahigh-strength alloy steels used for structural applications have a minimum yield strength of 1240 MPa (180 ksi) and minimum tensile strength of 1380 MPa (200 ksi), combined with good fracture toughness. General types of ultrahigh-strength steels include the nickel-chromium-molybdenum-vanadium steels, nickel-cobalt steels, and the 5% chromium-molybdenum-vanadium steels. The latter are also known as hot-work die steels and are included among the steels discussed in the section "Tool and Die Steels" in this article.

Welded joints in the nickel-cobalt steels generally do not require postweld heat treatment, except for stress relieving in certain applications. Steels in the Ni-Cr-Mo-V series are represented by Aerospace Material Specifications (AMS) 6434, 300M, and D-6a. Some medium-carbon low-alloy steels, such as AISI 4140 and 4340, discussed in the section "Heat-Treatable Low-Alloy (HTLA) Steels," also may be included among the ultrahigh-strength steels. Compositions of several typical ultrahigh-strength steels are given in Table 16.

Welding Processes and Filler Metals

For many important applications of ultrahigh-strength alloy steels, the mechanical properties of the weld metal and the HAZs must be equal to those of the base metal. The required weld metal strength and toughness can only be achieved with very low levels of impurities such as oxygen, hydrogen, nitrogen, carbon, sulfur, and phosphorus.

The preferred process for achieving maximum strength and toughness in both weld metal and HAZs is gas-tungsten arc welding. Plasma arc welding (PAW) can also be used. Dry and pure argon, helium, or mixtures of both can be used for shielding. Shielding gases should be essentially free from oxygen, nitrogen, and hydrogen.

Premium-quality filler metals are produced from selected raw materials by vacuum induction melting (VIM) and vacuum arc remelting (VAR). Filler metals of matching chemical composition are generally recommended for the welding of nickel-cobalt steels. For the 5Cr-Mo-V steels and the medium-carbon low-alloy steels, the filler metal can either have the same composition as the base metal or, for some applications, lower alloy and lower carbon content filler metal can be used, with some sacrifice in strength.

Welding Procedures and Practices

Joint Design, Workmanship, and Inspection. To utilize the properties of ultrahigh-strength steels and to achieve good serviceability of weldments, it is necessary to provide appropriate joint designs, good workmanship, and adequate inspection. In order to minimize cracking tendencies, welded joints in these steels should not be located in areas of abrupt changes in cross section or high stress concentration. Joints should be located to provide good accessibility for welding and inspection. Groove welds are preferable to fillet welds for many applications, because of the inherent stress concentrations usually associated with fillet welds and because groove welds are more amenable to volumetric methods of examination, such as radiographic or ultrasonic methods. Weld metal should blend smoothly with the adjacent base metal, and excessive weld reinforcement should be avoided.

Nickel-cobalt alloy steels are often welded in the quenched and tempered condition. Preferably, the 5% chromium-molybdenum-vanadium steels and the medium-carbon low-alloy steels are welded in the annealed condition. Successful welding of ultrahigh-strength alloy steels requires careful control of welding conditions. Low nitrogen, oxygen, and hydrogen contents in the weld metal are essential. The filler metal, base metal, weld joint area, and deposited weld metal all must be exceptionally clean. An important monitor of weld metal cleanliness is total oxygen content. The oxygen level must be very low to achieve maximum weld metal properties.

In HY-180 weldments, for example, an oxygen content of less than 50 ppm is necessary. Only GTAW and PAW processes are capable of achieving the required low oxygen levels in the weld metal. The oxygen content of weld metals deposited by GMAW is seldom less than 150 ppm, and it is far higher for slag shielded welding processes.

Welding heat input must be controlled to a low and consistent level to produce grain refinement in previously deposited weld beads and to minimize degradation of the properties of the HAZ. GTAW or PAW with cold wire feed is generally recommended for these steels in preference to GMAW or to GTAW or PAW with hot wire feed. For some applications, high-energy welding processes can be used successfully, if the weld metal oxygen content is kept low and some degradation of mechanical properties can be tolerated.

Preheating

Suggested preheat and interpass temperatures for welding ultrahigh-strength steels are given in Table 17. Preheating generally is not required for welding the nickel-cobalt alloy steels, but it is essential in welding the medium-carbon low-alloy steels and the 5Cr-Mo-V alloy steels in order to prevent cracking in the weld metal and HAZs.

TABLE 17 RECOMMENDED PREHEAT AND INTERPASS TEMPERATURES TO WELD SELECTED ULTRAHIGH-STRENGTH STEELS

STEEL DESIGNATION	PREHEAT AND INTERPASS TEMPERATURE RANGE FOR INDICATED SECTION THICKNESS

(A) PREHEATING NOT REQUIRED

Preferred preheat and interpass temperatures for the 5Cr-Mo-V steels (H11 mod and H13) are at least 30 to 55 °C (50 to 100 °F) above the M_s temperature for the steel. The M_s temperature is about 290 °C (550 °F) for H11 mod and about 345 °C (650 °F) for H13 steel. Maintaining the preheat and interpass temperature above the M_s temperature will prevent martensite formation in the weld metal and HAZs during welding. However, high preheat and interpass temperatures can cause welding problems, because of oxidation of the joint faces. The oxide can lead to occasional weld metal porosity or lack of fusion. Although the use of a lower preheat and interpass temperature will overcome this problem, it will allow some of the austenite in the weld zone to transform to martensite. A preheat temperature of about 230 °C (450 °F) can be used without excessive oxidation. For thin sections welded by the GTAW process, a preheat and interpass temperature of 150 °C (300 °F) can be suitable.

If the completed weldment is cooled from the preheat temperature to room temperature, then the remaining austenite will transform to martensite. The volumetric expansion accompanying the martensite transformation will produce high local stresses and can result in cracking of the weld metal or HAZs, especially if the cooling is rapid or nonuniform. In order to avoid this, heat treatment immediately after welding is recommended.

Postweld Heat Treatment

The nickel-cobalt high-strength steels generally do not require postweld heat treatment. Weldments of HP9-4-20 and HP9-4-30 steels can be stress relieved at 540 °C (1000 °F) for 24 h. This postweld heat treatment has no adverse effect on the strength or toughness of either weld metal or base metal. Aging of weldments in HY-180 and AF 1410 steels for a short time at 480 to 510 °C (900 to 950 °F) appears to improve tensile properties and toughness. However, these properties decrease with longer aging times.

The problem of weld metal or HAZ cracking that is due to martensite formation when welding the 5Cr-Mo-V steels and the medium-carbon low-alloy steels can be avoided by postweld heat treatment immediately after welding, rather than allowing the weldment to cool to room temperature. One approach is to raise the temperature after welding to about 55 °C (100 °F) above the M_s temperature and hold it for a sufficient time (indicated by the isothermal transformation diagram) to allow the austenite to transform to a reasonably ductile bainitic structure. The weldment can then be cooled to room temperature without much risk of cracking. A subsequent tempering treatment is required to produce a desirable microstructure in the weld metal and HAZs.

An alternative approach to postweld heat treatment is to allow the weldment to cool slowly and uniformly from the preheat temperature to approximately 95 °C (200 °F), which allows the retained austenite to transform to martensite. The weldment should then be heated to the recommended tempering temperature for the steel to relieve residual welding stresses and to temper the martensite.

Tool and Die Steels

Welding applications for tool and die steels are generally divided into five work operations:

- ASSEMBLY OF COMPONENTS INTO A SINGLE TOOL OR DIE
- FABRICATION OF A COMPOSITE TOOL BY DEPOSITING AN OVERLAY OF TOOL STEEL WELD METAL ON SPECIFIC AREAS OF A CARBON STEEL OR LOW-ALLOY STEEL BASE METAL
- REBUILDING OF WORN SURFACES AND EDGES
- ALTERATION OF A TOOL OR DIE TO MEET A DIFFERENT APPLICATION REQUIREMENT
- REPAIR OF CRACKED, BROKEN, OR OTHERWISE DAMAGED TOOLS, DIES, OR OTHER COMPONENTS

The assembly of components by welding permits the use of less-expensive steels for parts of the assembly that do not require the special properties of tool steel, such as hardness or wear resistance. This practice also permits the use of a tougher steel to provide support for tool steel components or weld overlays. Applications covered by the second and third bullets listed above include most of the welding that is done on tools or dies by hard surfacing, often using special hard-facing alloys, rather than tool steel weld metals. The use of arc welding has significant application for the repair of crocked or broken tools and dies, restoration of worn areas to original dimensions, and alteration of tools and dies to produce modified parts.

Because the manufacturing of complicated tools and dies involves a high material cost, and because premature failures incur the cost of downtime, welding procedures and operations should be carefully planned and controlled to ensure that the required properties are achieved in the completed weldment.

Welding of Low-Alloy Steels

F.J. Winsor, Welding Consultant

Description of Steels

Tool steels are categorized by AISI and the SAE into seven major groups (listed in Table 18) according to the normal hardening medium or the general applications of the alloys. Tool and die steels are produced in small tonnage quantities by processes that yield clean, homogeneous material with close control of chemical composition.

TABLE 18 COMPOSITION OF TOOL AND DIE STEEL GROUPS

GROUP	**STEEL TYPE**	**LETTER SYMBOL**	PRINCIPAL ALLOYING ELEMENTS
WATER-HARDENING	PLAIN CARBON,	W	**. . .**
	HIGH-CARBON, LOW-ALLOY	W	**. . .**
SHOCK-RESISTING	MEDIUM-CARBON, LOW-ALLOY	S	**CR, MN, MO, SI, W**
COLD-WORK	HIGH-CARBON, LOW-ALLOY	S	**CR, MN, MO, SI, W**
	HIGH-CARBON, MEDIUM-	A	**CR, MN, MO, NI, V, W**

	HIGH-CARBON, HIGH-CHROMIUM	D	**CO, CR, MO, V**
HOT-WORK	CHROMIUM	H	**CO, CR, MO, V, W**
	TUNGSTEN	H	**CR, V, W**
	MOLYBDENUM	H	**CR, MO, V, W**
HIGH-SPEED	TUNGSTEN	T	**CO, CR, MO, V, W**
	MOLYBDENUM	M	**CO, CR, MO, V, W**
MOLD STEELS	LOW-TO-MEDIUM CARBON, LOW-ALLOY	P	**CR, MO, NI**
SPECIAL PURPOSE	**MEDIUM-TO-HIGH CARBON, LOW-ALLOY**	**L**	**CR, MO, NI, V**

Welding Processes

All of the common arc welding processes can be used to fabricate or repair tools and dies. Process selection primarily depends on the size and complexity of the work, the requirements for preheat and interpass temperature control and postweld heat treatment, and the availability of filler metal.

The SMAW process is most widely used for these reasons: it often affords more flexibility with regard to accessibility to the joint area and position of welding, it requires relatively simple and portable equipment, and it offers a variety of weld metal compositions based on readily available covered electrodes.

The SMAW, GTAW, GMAW, FCAW, and PAW processes are widely used to repair damaged or worn areas or to fabricate composite tools. Both GTAW and PAW are particularly well suited for use on small areas, thin sections, or sharp edges where greater control of the process is advantageous. To deposit large volumes of weld metal, as in building up large die blocks, filling large cavities, or repairing deep cracks, SMAW that utilizes special large electrodes of up to 19 mm ($\frac{3}{4}$ in.) in diameter can be used, as well as SAW, GMAW, FCAW, and hot-wire PAW. Filler metals for semiautomatic and automatic processes can either be solid wires or composite metal-cored or flux-cored tubular products. SAW process modifications can include the use of alloy-enriched fluxes and the direct addition of metal powders into the weld pool.

Welding of Low-Alloy Steels

Filler Metals

Factors that must be considered when selecting a filler metal for a specific application include:

- COMPOSITION OF THE BASE METAL
- HEAT-TREATED CONDITION OF THE BASE METAL (ANNEALED OR HARDENED AND TEMPERED)
- SERVICE REQUIREMENTS OF THE WELD DEPOSIT
- POSTWELD HEAT TREATMENT

For many tool steel welds, it is essential that the weld metal and the base metal respond similarly to heat treatment, so that the weld metal hardness will be equal to that of the base metal after a quench and temper heat treatment. Although this often means that the weld metal chemical composition must match that of the base metal, that is not always the case. It is sometimes possible to develop the same final hardness or strength in the weld using a weld deposit that has a lower carbon and higher alloy content than the base metal. Where possible, lowering the carbon content of the weld metal generally minimizes the risk of weld cracking and improves the toughness of the weld deposit.

For some applications, either when fabricating a tool or die from components or when repairing a damaged tool or die, the region of welding may not involve the working surface of the tool or die. In those cases, matching the composition or heat-treatment response of the weld metal to that of the base metal may not be essential. A weld deposit composition that offers greater resistance to weld cracking and improved ductility and toughness often is a better choice.

When selecting filler metals for the welding of tools or dies in the hardened condition, the location of the required weld with respect to the working area of the part should be considered. If the location of the weld deposit is in a functional area of the tool, such as a cutting edge or a wear surface, then it is necessary to select a weld metal that will have the desired hardness or strength in the as-welded condition or, possibly, in the stress-relieved or tempered condition, without a hardening heat treatment. If the weld deposit is located away from the working area of the tool or die, then selection of the filler metal can often be based on achieving maximum crack resistance, ductility, and toughness in the weld deposit.

Filler metals for welding tool steels can be divided into three main categories. The first includes those that produce weld deposits that correspond in hardenability or composition to those of some of the basic tool steel types: water-, oil-, and air-hardening; hot-work; and high-speed. Table 19 shows proprietary compositions of typical tool steel weld metals available from covered electrodes and bare solid and cored filler metals. Such weld deposits will be hard in the as-welded condition. These types of filler metal are not included in standard filler metal specifications.

TABLE 19 COMPOSITION OF SELECTED PROPRIETARY HEAT-TREATABLE WELD DEPOSITS USED TO WELD NUMEROUS TYPES OF TOOL STEEL

AISI STEEL TYPE	**FILLER-METAL TYPE**	NOMINAL WELD DEPOSIT COMPOSITION, WT%[(A)]							
		C	**Mn**	**Si**	**Cr**	**Ni**	**V**	**W**	Mo

(A) COMPOSITIONS OF SIMILAR TYPES OF WELD METAL FROM DIFFERENT PRODUCERS CAN VARY.

The second category of filler metals includes carbon and low-alloy steels that have moderate hardness and toughness properties at room temperature in the as-welded or stress-relieved condition. Although some deposit compositions can respond to a quench and temper heat treatment, most of the filler metals in this category are intended for applications where the properties of the weld deposit are not required to match those of the tool steel in the hardened condition. These filler metals are included in ANSI/AWS specifications for carbon steel and low-alloy steel filler metals.

The third category of filler metals includes austenitic stainless steels and the nickel-chromium-iron, nickel-copper, and copper-nickel alloys. These nonhardenable filler metals are often used for the repair welding of tools in the hardened condition, where high weld metal ductility is advantageous in resisting weld metal and base metal cracking. They can also be useful in providing ductile deposits for building up worn tools. Some types of nonhardenable deposit can be overlaid with a hardfacing deposit to provide a hard, wear-resistant surface. Nonhardenable filler metals are included in ANSI/AWS filler metal specifications for stainless steels, nickel alloys, and copper alloys.

F.J. Winsor, Welding Consultant

Welding Procedures and Practices

It is preferable to conduct the welding of tool and die steels with the part in the annealed condition whenever feasible. Tool steels welded in the hardened and tempered condition are more susceptible to cracking. However, many items are successfully repaired in the hardened and tempered condition. When this can be done safely, it avoids the need for annealing before the repair, hardening and tempering afterwards, and the possible costly correction of dimensional changes caused by such heat treatment. If a tool or die has previously been hardened but not yet tempered, then it cannot be safely welded. Annealing is necessary prior to welding.

Preheating. In order to avoid cracking, tools and dies should never be welded without preheating, regardless of composition or heat-treatment condition (annealed or hardened). The preheat and interpass temperature depends on the composition and thickness of the steel and, sometimes, on the heat-treatment condition. Typical preheat and interpass temperatures for welding different types of tool steel are given in Table 20.

TABLE 20 TYPICAL PREHEAT AND INTERPASS TEMPERATURES TO WELD SELECTED TOOL STEELS

AISI STEEL TYPE	PREHEAT AND INTERPASS TEMPERATURE RANGE			
	ANNEALED BASE METAL		HARDENED BASE METAL	
	°C	**°F**	**°C**	°F
W1; W2	120-230	250-450	120-230	**250-450**
S1; S5; S7	150-260	300-500	150-260	**300-500**
O1; O6	150-205	300-400	150-205	**300-400**
A2; A4	150-260	300-500	150-205	**300-400**
D2	370-480	700-900	370-480	**700-900**
H11; H12; H13	480-650	900-1200	370-540	**700-1000**
M1; M2; M10; T1; T2; T4	**510-595**	**950-1100**	**510-565**	**950-1050**

Source: Ref 2

Preheat and interpass temperatures for welding should not be confused with temperatures used for preheating a tool prior to austenitizing during a hardening treatment. The preheat and interpass temperature for welding a hardened tool steel should not exceed the recommended tempering temperature for the steel. Use of a higher preheat temperature will over-temper and soften the tool. If the tempering temperature is unknown, the preheat and interpass temperature should be at the low end of the range recommended for the particular steel.

To weld annealed tool steels in massive sections, the preheat and interpass temperatures should be near the upper end of the recommended range. For thin sections, the lower portion of the range is satisfactory.

Postweld Heat Treatment. *Heat Treating,* Volume 4 of the *ASM Handbook,* contains information on the heat treatment of tool steel materials. The producers of tool and die steels also can be consulted regarding heat-treatment procedures for their products.

Depending on the type of tool steel and weld metal, the weld metal and HAZ can be very hard and brittle in the as-welded condition and susceptible to cracking if the tools are allowed to cool completely to room temperature after welding and before postweld heat treatment.

With tool steels in the annealed condition prior to welding, it is usually necessary to harden and temper the part after welding in order to provide desired performance characteristics. It is often preferable to heat the part to the hardening

temperature as soon as welding is completed, without allowing the part to cool. With some steels, it can be necessary to heat to the hardening temperature in stages in order to avoid cracking. With less-crack-sensitive tool steels, it may not be necessary to proceed with the hardening and tempering heat treatments immediately after completion of welding. In those cases, after welding is completed, the part can be allowed to cool slowly and uniformly to room temperature.

For steels welded in the hardened and tempered condition, reference to isothermal transformation diagrams (Ref 5) can assist in developing postweld heat-treatment practices. For example, with some steels it may be possible to use a preheat and interpass temperature that, if maintained for a reasonable length of time after welding, allows isothermal transformation of austenite to a bainitic microstructure rather than to martensite. Postweld heat treatment involving isothermal transformation of AISI 4340 steel is discussed in the section on welding structural HTLA steels, with reference to Fig. 1, the isothermal transformation diagram for AISI 4340 steel. If the preferred welding preheat and interpass temperature (see Table 20) does not coincide with the desired isothermal transformation temperature, then the temperature of the part should be raised or lowered, as necessary, after welding is completed.

An alternative postweld heat-treatment practice for some tool steels welded in the hardened and tempered condition is to allow the part to cool slowly and uniformly after welding to a temperature from 30 to 55 °C (50 to 100 °F) lower than the M_{90} temperature shown in Fig. 1, permitting transformation to martensite. Then the part should be immediately heated to the recommended tempering temperature.

Repair Practices for Tools and Dies

Base Metal. The type of tool steel to be repaired and its heat-treatment condition are best determined from the original specifications for the tool or die. If this information is not available, then a chemical analysis must be made to determine the carbon and alloy content of the steel. The heat-treatment condition (either hardened and tempered or annealed) can be determined by a hardness test.

Surface Preparation for Welding. Surfaces of tool and die materials must be clean and dry before welding. Prior to repair welding, all cracks and the tool marks produced in removing damaged areas should be removed. Metal removal can be accomplished by machining, grinding, or thermal cutting, depending on the hardness. Preheating is essential before thermal cutting and gouging, and is often desirable before grinding on hardened tools, as well.

Preparation of Repair Area. For the partial repair of cutting edges or working surfaces, the damaged areas should be machined or ground to a uniform depth that will permit a deposit thickness with the required hardness and wear characteristics. Dilution of the weld metal by fusion with the base metal must be considered, particularly when repairing a composite tool that has a carbon steel or a lower alloy steel base supporting the working surface. A groove depth of about 3.2 mm ($\frac{1}{8}$ in.) is commonly used. When it is necessary to repair the entire cutting or working edge, the edge should be chamfered at 45° for a sufficient depth.

Cracks are generally ground in order to remove the damaged base metal and produce a suitable groove for repair welding. Thermal gouging is also used where extensive excavation is required.

Whether the repair requires a full- or partial-penetration weld depends on many factors, such as the location of the repair area, the stresses that will be imposed on the area in service, the type of weld metal required, and the condition of heat

treatment. If the repair requires a hardenable alloy steel weld deposit, or if it is necessary to harden and temper the part after welding, then a partial-penetration weld is generally unsatisfactory, because cracks are likely to propagate from the unwelded root of the repair area.

Welding Processes. The SMAW process is very versatile for the repair welding of small areas. Some types of SMAW electrodes that are available in very large sizes are also used to repair deep cracks or to rebuild large surface areas in massive parts. Some large repairs can be accomplished more economically with semiautomatic or automatic welding processes, such as GMAW, FCAW, SAW, and hot-wire PAW.

Manual GTAW is generally used to repair small areas or edges of parts. Automatic GTAW, using hot or cold wire feed, and hot-wire PAW processes can be used for larger areas.

Repair Practices. If a repair is in a working area of a tool in the annealed condition and is shallow in depth, then a heat-treatable type of deposit that will respond to heat treatment in a manner similar to that of the base metal will be required. If the area has sufficient depth, it can be partially built up with a nonhardenable filler metal and then completed with a tool steel filler metal. The built-up layer should have sufficient strength to support the tool steel deposit under working conditions of the tool. The tool steel deposit should be thick enough to compensate for dilution with the built-up deposit, and it should have adequate wear properties after the quench and temper heat treatment.

A weld deposit used to repair the working surface of a tool in the hardened and tempered condition should have adequate properties after tempering. Alternatively, a hardfacing deposit that does not require heat treatment can be used.

In some cases, the required repairs of either hardened or annealed tools can be in noncritical areas, and a nonhardenable type of filler metal can be used.

When repair welding a cutting edge, the weld metal should be allowed to flow or roll over the edge so that the repaired area can be machined or ground to produce a finished edge without notches or depressions.

Peening is often required to reduce distortion and prevent the cracking of weld deposits. In order to be effective, peening must be done properly; generally, when the deposit is red. Insufficient peening will not relieve stresses, whereas excessive peening can cause cracking.

Welding of Stainless Steels

D.J. Kotecki, The Lincoln Electric Company

Introduction

STAINLESS STEELS can be defined as alloys that contain at least 10.5% Cr, no more than 1.5% C, and more iron than any other single element. There are five major families of stainless steels, based on microstructure and properties:

- MARTENSITIC STAINLESS STEELS
- FERRITIC STAINLESS STEELS
- AUSTENITIC STAINLESS STEELS
- PRECIPITATION-HARDENING (PH) STAINLESS STEELS
- DUPLEX FERRITIC-AUSTENITIC STAINLESS STEELS

Each family requires different weldability considerations, because of the varied phase transformation behavior upon cooling from solidification to room temperature or below.

Often, the optimal filler metal is not the one that most closely matches the base-metal composition. The most successful procedures for one family are often markedly different from those that are appropriate for another family.

This article addresses consumable selection and procedure development for the welding of stainless steels. Additional information about the selection and weldability of these alloys is available in the Section "Selection of Stainless Steels" in this Volume.

Stainless steel base metals and, therefore, the welding filler metals used with them, are almost invariably chosen on the basis of adequate corrosion resistance for the intended application. This usually means that the welding filler metal must at least match (and sometimes overmatch) the contents of the base metal in terms of specific alloying elements, such as chromium, nickel, and molybdenum.

After considering corrosion resistance, the avoidance of cracking becomes the unifying theme in filler-metal selection and procedure development for the welding of stainless steels. Cracking can occur at temperatures that are just below the bulk solidus temperature of the alloy(s) being welded. This hot cracking, as it is called, can appear as large weld-metal cracks, usually along the weld centerline. However, it can also appear as small, short cracks (microfissures) in the weld metal or in the heat-affected zone (HAZ) at the fusion line and, usually, perpendicular to it. Hot cracking in stainless steel welds is of most concern in austenitic weld metals, although it can occur in all types of stainless steel weldments.

Cracking can also occur at rather low temperatures of, typically, 150 °C (300 °F) or below, because of the interaction of high weld stresses, high-strength metal, and diffusible hydrogen. This cold cracking commonly occurs in martensitic weld metals, as well as HAZs, including those of PH stainless steels. Cold cracking can also occur in ferritic stainless steel weldments that have become embrittled by grain coarsening and/or second-phase particles.

In many instances of cold cracking, where the resulting weld has acceptable properties, the substitution of a mostly austenitic filler metal (with appropriate corrosion resistance) for a martensitic or ferritic filler metal serves as a remedy. When hot cracking occurs in an austenitic weld metal, a common remedy is to use a mostly austenitic filler metal that includes a small amount of ferrite. However, another approach toward avoiding hot cracking may be necessary in situations that require low magnetic permeability, high toughness at cryogenic temperatures, resistance to media that selectively attack ferrite (such as urea), or postweld heat treatments (PWHT) that embrittle ferrite, because their requirements may severely limit the amount of ferrite that is acceptable.

Welding engineers who are responsible for filler-metal selection and procedure development for stainless steel welds will often estimate the microstructure of the weld metal, taking the dilution effects into consideration. This task is best accomplished with a constitution diagram for the stainless steel weld metals. Several diagrams that have been developed over the years are described below.

Welding of Stainless Steels

D.J. Kotecki, The Lincoln Electric Company

Constitution Diagrams

In 1949, Anton Schaeffler (Ref 1) published what has become known as the Schaeffler diagram (Fig. 1). This diagram proposed a relationship among alloy elements that promote the formation of ferrite (chromium-equivalent elements) and elements that promote the formation of austenite and the suppression of ferrite (nickel-equivalent elements). To use this diagram, both the chromium and nickel equivalents are first calculated from the composition of a given weld bead. Next, these equivalents are plotted as coordinates on the Schaeffler diagram. This allows an estimated weld-metal microstructure to be determined from the boundaries given in the diagram. Experience has shown that the Schaeffler diagram is reasonably accurate for conventional "300 series" stainless steel weld deposits from covered electrodes. However, it is of limited use when less-conventional compositions are used and when a high level of nitrogen is present.

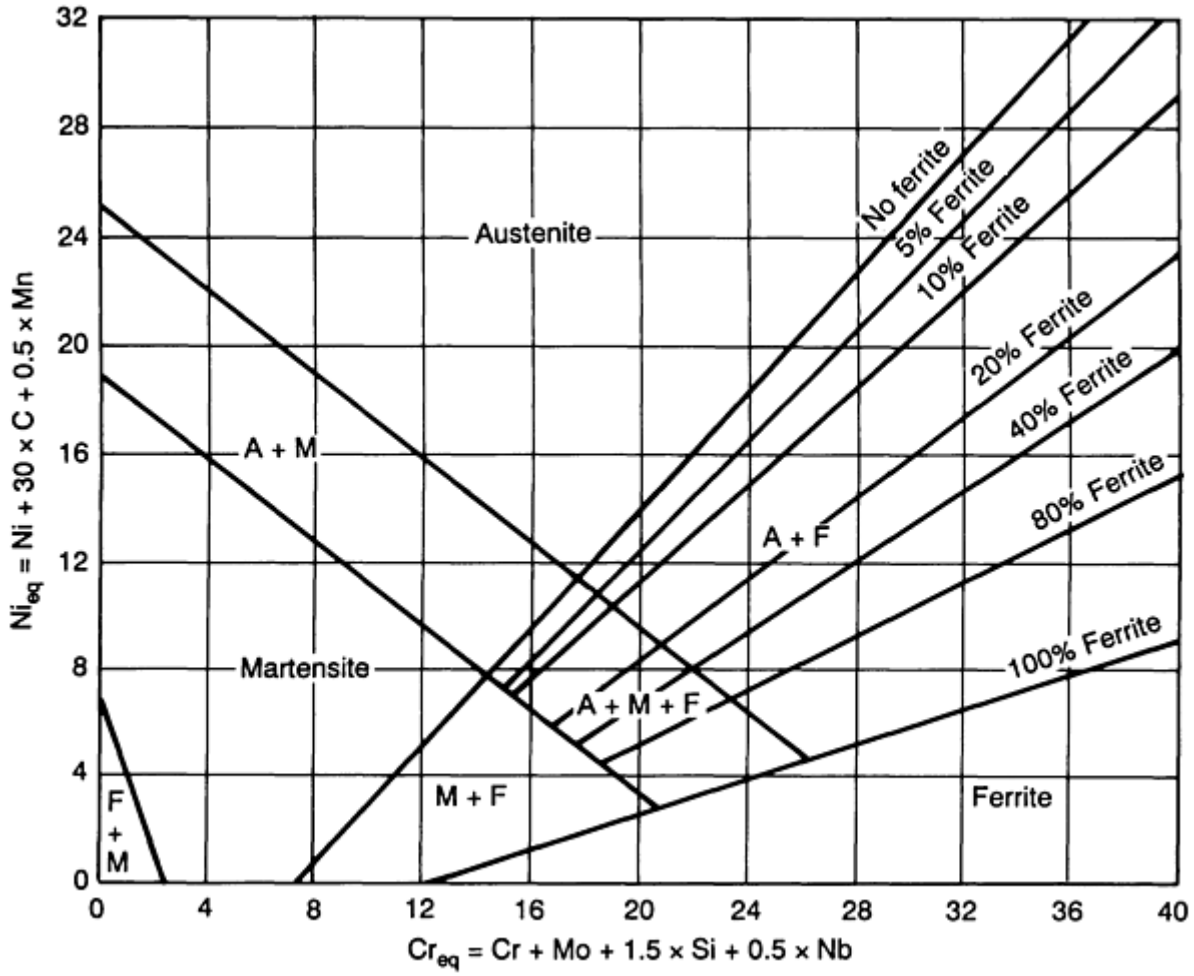

FIG. 1 SCHAEFFLER CONSTITUTION DIAGRAM FOR STAINLESS STEEL WELD METAL

W.T. DeLong recognized the effect of nitrogen in promoting austenite at the expense of ferrite, and he developed a new diagram (Ref 2) that covered a more-restricted composition range and included the effect of nitrogen (Fig. 2). Specifically, a nickel equivalent of 30 × %N was added. To use this diagram, the nickel and chromium equivalents are calculated from the weld-metal analysis. If a nitrogen analysis of the weld metal is not available, then a value of 0.06% should be assumed for the gas-tungsten arc welding (GTAW) process and covered electrodes and a value of 0.08% assumed for gas-metal arc welded metals. If the chemistry is accurate, then the diagram predicts the Welding Research Council (WRC) Ferrite Number within ±3 in approximately 90% of the tests for the alloy 308, 309, 316, and 317 families.

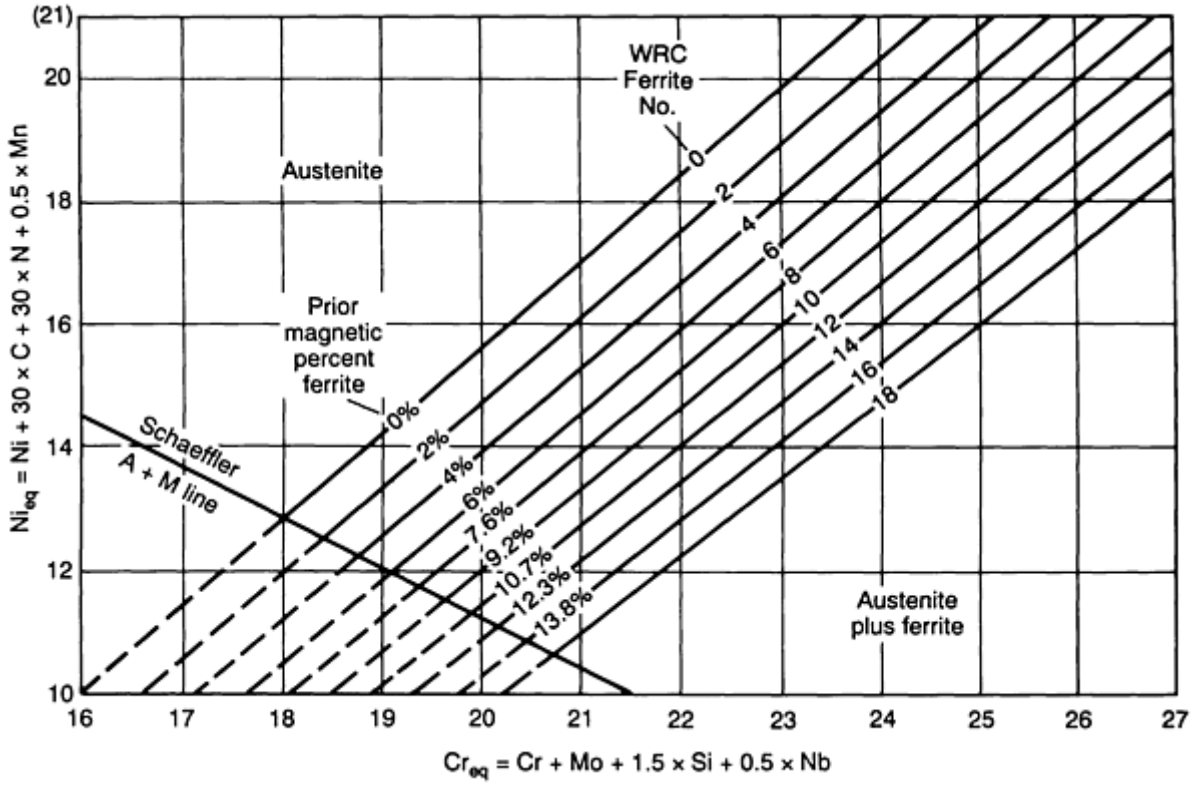

FIG. 2 DELONG CONSTITUTION DIAGRAM FOR STAINLESS STEEL WELD METAL. THE SCHAEFFLER AUSTENITE-MARTENSITE BOUNDARY IS INCLUDED FOR REFERENCE.

In the DeLong diagram, the Ferrite Numbers for alloy 308, 308L, and 347 covered electrodes are similar to those in the Schaeffler diagram, but the alloy 309, 316, and 317 families have Ferrite Numbers that are about two to four times higher. Generally, the DeLong diagram correlates better with GTAW and gas-metal arc welding (GMAW) weld metals than does the Schaeffler diagram, because it allows for nitrogen pickup.

In 1974, at about the time the DeLong diagram was being published, the measurement of ferrite in nominally austenitic stainless steel weld metals was standardized by the ANSI/AWS A4.2 specification in terms of magnetically determined Ferrite Numbers (FN), rather than the metallographically determined "percent ferrite" used by the Schaeffler diagram. The DeLong diagram became part of the "Boiler and Pressure Vessel Code" of the American Society of Mechanical Engineers (ASME).

The DeLong diagram was subsequently discovered to seriously underestimate the ferrite content of weld metals with high manganese contents and overestimate the FN of highly alloyed weld metals, such as alloy 309. Consequently, the Welding Research Council both funded and collected data for the development of a new, more-accurate diagram using computer mapping techniques (Ref 3, 4). A joint effort was conducted by the Colorado School of Mines and the U.S. National Institute of Standards and Technology (NIST). The product of this effort, known as the WRC-1988 diagram (Fig. 3), covers a broader range of compositions than does the DeLong diagram and removes the two errors noted above.

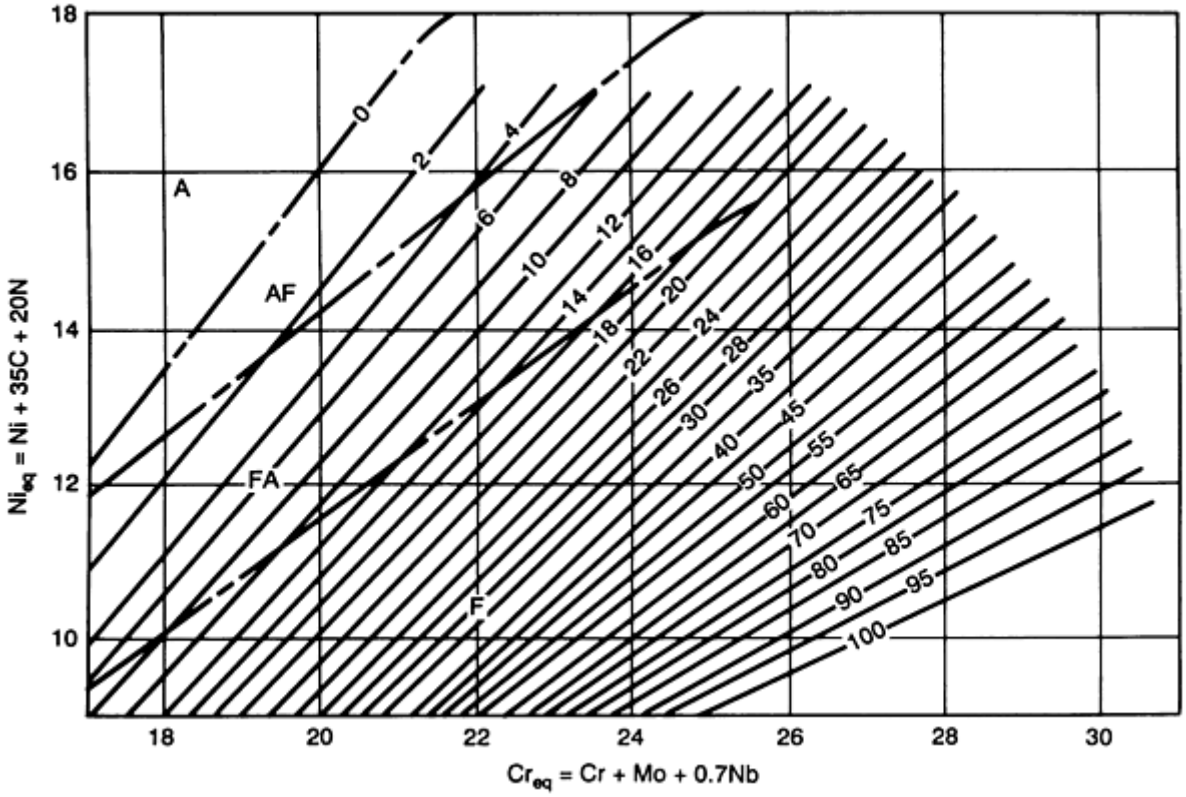

FIG. 3 WRC-1988 DIAGRAM, INCLUDING SOLIDIFICATION-MODE BOUNDARIES

A modification of the WRC-1988 diagram, which allowed the nickel equivalent to include a coefficient for copper, was first proposed by F.B. Lake in 1990 (Ref 5). This modification and an extension of the chromium-equivalent and nickel-equivalent axes were incorporated into the most recent constitution diagram, the WRC-1992 diagram (Ref 6) shown in Fig. 4. Its extended axes permit graphical estimation of the ferrite content of weld metal that comprises very different base metal(s) and filler metal, as could be done less precisely with the Schaeffler diagram.

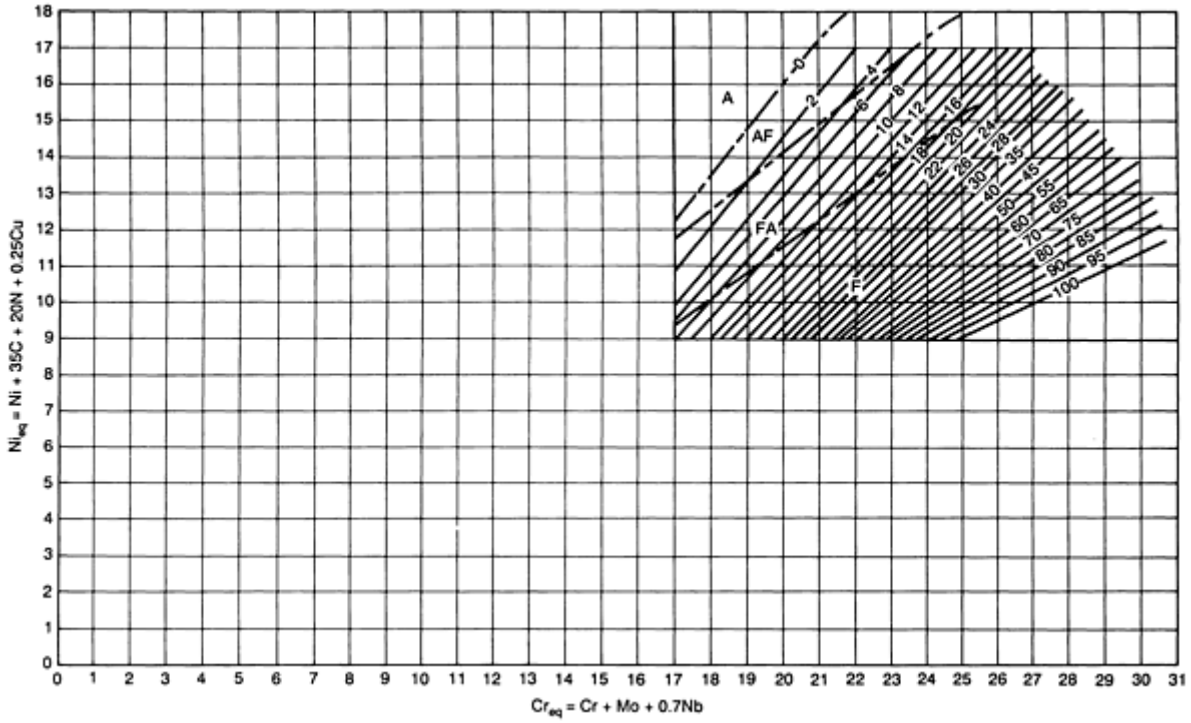

FIG. 4 WRC-1992 DIAGRAM WITH EXPANDED SCALE FOR DILUTION CALCULATIONS. ALTHOUGH EXTENDED AXES ALLOW A WIDE RANGE OF COMPOSITIONS TO BE LOCATED, THE FN PREDICTION IS ONLY ACCURATE FOR WELD COMPOSITIONS THAT FALL WITHIN THE BOUNDS OF THE ISO-FN LINES (0 TO 100 FN). LIMITS OF WRC DIAGRAM WERE DETERMINED BY EXTENT OF DATA BASE, AND EXTENSION OF THE LINES COULD RESULT IN ERRONEOUS PREDICTIONS. SOURCE: REF 6

Although the WRC-1992 diagram is more accurate in predicting ferrite content for many weld metals, the Schaeffler diagram still retains some utility because it can offer reasonably accurate predictions in terms of martensite in lean stainless steel compositions. This is because the WRC-1992 diagram does not include manganese. Manganese has been found (Ref 7) to have no effect on the high-temperature transformation of ferrite to austenite during cooling. Therefore, it does not figure in the nickel equivalent of the WRC-1992 diagram. However, it does have a significant effect on the low-temperature transformation of austenite to martensite during further cooling. It tends to stabilize austenite at low temperatures (Ref 8). Without a manganese effect, it is not possible to put a boundary for the martensite phase in the WRC-1992 diagram.

If the weld deposit is austenitic, then a Ferrite Number around 4 or 5, minimum, typically suffices to prevent hot cracking (Ref 9). In addition, a deposit that is primarily austenitic will not cold crack. These two considerations often influence filler-metal selection and procedure development. In the following sections of this article, the WRC-1992 diagram and, occasionally, the Schaeffler diagram, are used to illustrate the rationale behind many filler-metal choices.

It is appropriate to keep in mind that the ferrite that survives at room temperature after solidification is only a fraction of what existed during solidification. In terms of the utility of constitution diagrams like the WRC-1992 diagram, it is currently thought (Ref 10) that finding ferrite at room temperature is only an indirect indication of the solidification mode. According to this theory, if the weld metal solidifies as ferrite first, with austenite appearing only in the latter stages of solidification, if at all, then the weld metal will be crack resistant. However, if the weld metal solidifies as austenite first, with ferrite only appearing in the latter stages of solidification, if at all, then the weld metal is at risk for cracking.

The dividing line between compositions that solidify as austenite first and compositions that solidify as ferrite first is approximated by the dashed line between the fields labeled "AF" (primary austenite solidification) and "FA" (primary ferrite solidification) in Fig. 3 and 4. This line is not parallel to the isoferrite lines. Rather, it is at a small angle to them, which means that more ferrite is needed at room temperature to represent evidence of primary ferrite solidification in higher-alloyed stainless steel weld metals than in lower-alloyed stainless steel weld metals.

Welding of Stainless Steels

D.J. Kotecki, The Lincoln Electric Company

Martensitic Stainless Steels

Basic Metallurgy. At high temperatures, the equilibrium microstructure of martensitic stainless steels is either entirely or almost entirely austenite. At room temperature, the equilibrium microstructure of these steels is a mixture of ferrite and carbides. The reformation of austenite upon heating occurs very rapidly, but the transformation back to ferrite upon cooling is extremely slow. As a result, these steels have a very high tendency to transform to martensite upon cooling from temperatures at which austenite is the stable phase. In fact, it is very difficult to avoid martensite in these steels. They are air hardening, which means that even upon slow cooling in heavy sections, they form martensite.

The binary iron-chromium phase diagram shown in Fig. 5 indicates that above a level of approximately 12% Cr, binary alloys will not form austenite at any temperature, so they cannot be hardened by heating and cooling. However, the addition of carbon to iron-chromium alloys increases the range of chromium contents over which austenite can be formed at elevated temperatures (Fig. 6). It should be noted that nitrogen, nickel, copper, and, possibly, manganese, also expand this range. Even with 17% Cr, a fully austenitic microstructure can be achieved with about 0.4% C at 1250 °C (2280 °F). It can then be fully hardened. When the corrosion-resisting properties of iron-chromium alloys were first discovered early in the 20th century, it was extremely difficult to remove carbon from melts of iron-chromium alloys. Thus, the first stainless steels, which were discovered more or less simultaneously in Germany and England, were martensitic.

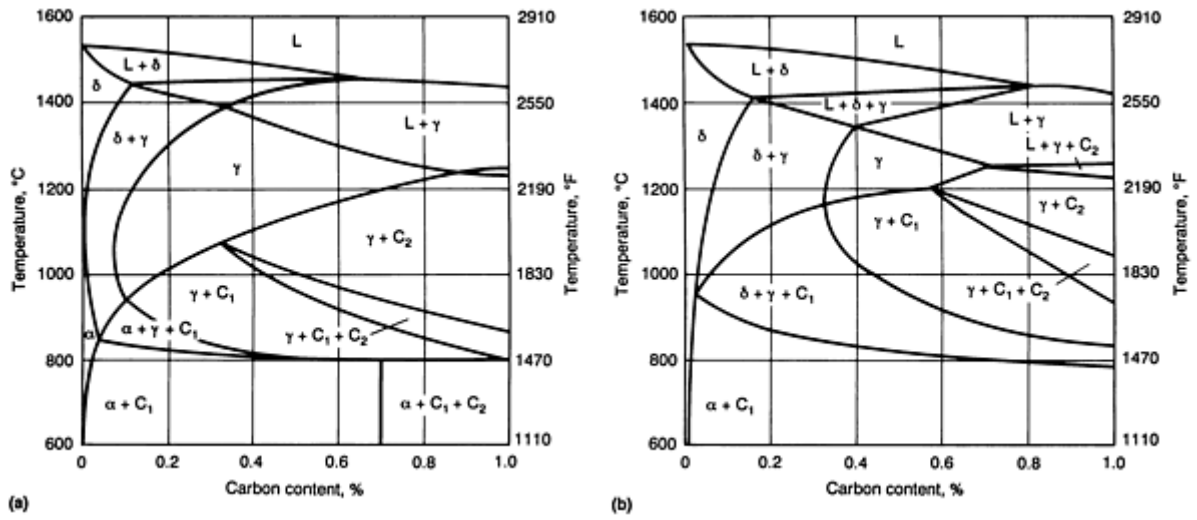

FIG. 6 CONCENTRATION PROFILE IN TERNARY IRON-CHROMIUM-CARBON CONSTITUTION DIAGRAM. (A) 13% CR. (B) 17% CR. SOURCE: REF 12

Carbon content almost entirely determines the hardness of martensite. If virtually 100% martensite can be achieved in a steel, then Fig. 7 shows several relationships that have been found experimentally between carbon and hardness. In particular, it shows that as little as 0.10% C in martensite will result in a hardness value of approximately 35 HRC. The hardness of martensite increases to over 60 HRC at approximately 0.5% C, and it does not change significantly at higher levels of carbon, at least on a macroscale.

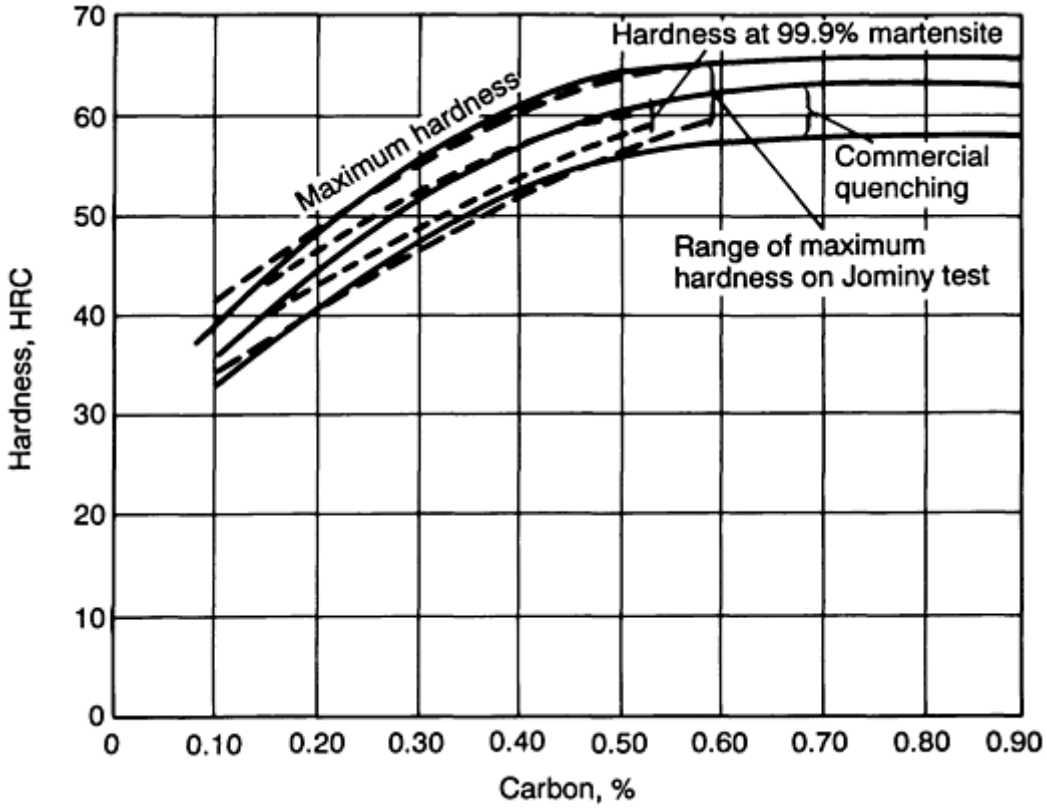

FIG. 7 HARDNESS VALUES OF FULLY HARDENED STEELS WITH A RANGE OF CARBON CONTENTS. SOURCE: REF 13

Figure 7 presents the situation if essentially all martensite is obtained. In carbon and low-alloy steels, rapid cooling is usually necessary to avoid the formation of ferrite. However, as more alloy is added, the avoidance of ferrite becomes easier. At a 12% Cr level, nearly any cooling rate will result in virtually 100% martensite. The prototype of all martensitic stainless steels is type 410 (approximately 12% Cr and 0.10% C). The isothermal transformation diagram for type 410 stainless steel (Fig. 8) indicates that, after cooling from high temperatures and being held at approximately 700 °C (1290 °F), it will take approximately 2 min before any ferrite forms, and several hours will be required before the transformation to ferrite with carbides is complete. Cooling to a holding temperature of 400 °C (750 °F) will require more than 1 week before any ferrite forms.

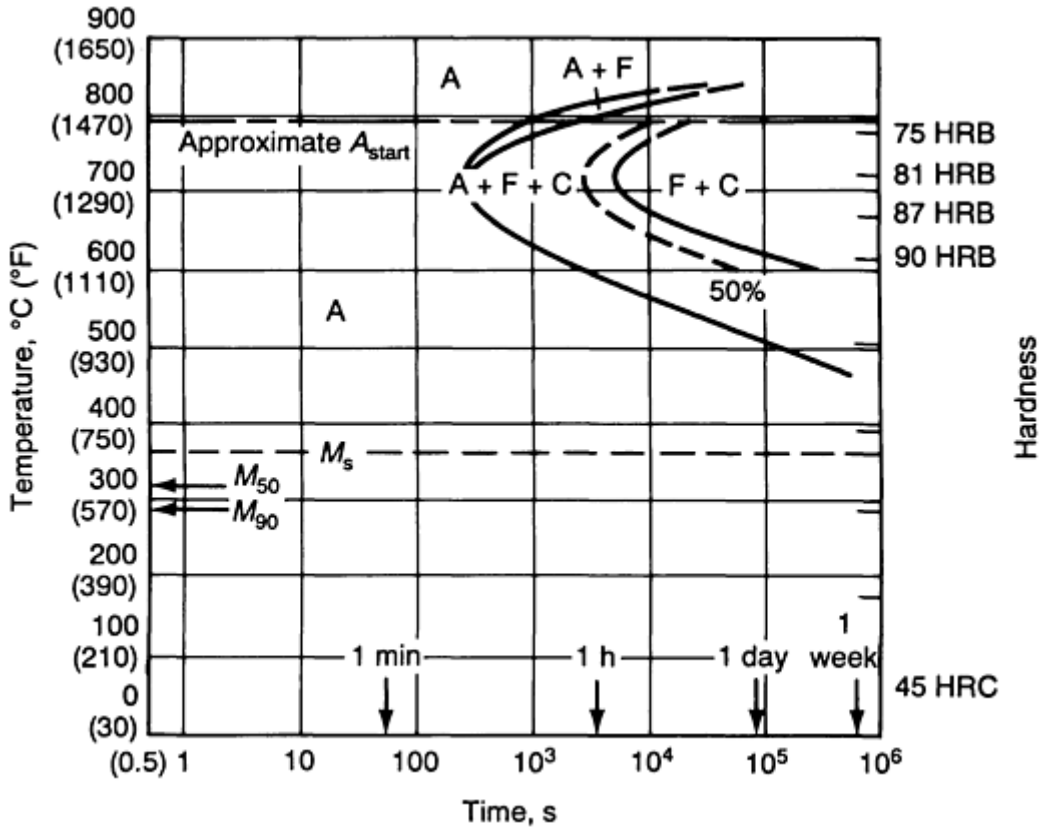

FIG. 8 ISOTHERMAL TRANSFORMATION DIAGRAM FOR TYPE 410 STAINLESS STEEL (12CR-0.1C) AUSTENITIZED AT 980 °C (1800 °F), WITH GRAIN SIZE OF 6 TO 7. A, AUSTENITE; F, FERRITE; C, CARBIDE; M, MARTENSITE; B, BAINITE; P, PEARLITE. SOURCE: REF 14

Figure 8 further shows that martensite begins to form at about 350 °C (660 °F) on cooling type 410 stainless steel and is finished when cooling reaches about 250 °C (480 °F). Alloying at levels that are either above or in addition to 12% Cr serves to further delay ferrite formation and further reduces the martensite-start (M_s) temperature. In the extreme case, some austenite will exist indefinitely, even at room temperature, and refrigeration or complex heat treatments (such as double tempering) may be necessary to induce complete martensite transformation in highly alloyed martensitic stainless steels. Therefore, in any fusion welding process, it must be assumed that regardless of the condition of heat treatment of the base metal, the HAZ and any nearly matching filler metal for martensitic stainless steels in the as-welded condition will be freshly formed martensite. The martensite will be hard and, unless it is very low carbon martensite, it will also be quite brittle and crack-sensitive. Therefore, a standard rule to follow when welding martensitic stainless steels is to weld hot, that is, a high preheat, high interpass temperature, and high heat input are, in most cases, beneficial to accomplishing the weld without incurring cracking.

Martensitic Stainless Steel Base Metals. A number of martensitic stainless steel base metals are identified in Table 1(a). Welding filler metals that have approximately matching compositions, as classified by the American Welding Society (AWS), are also listed in Table 1(b), but only for selected base metals.

NS, not specified; NCW, not considered weldable.

(A) METAL-CORED ELECTRODES, INDICATED BY A "C" IN PLACE OF THE "R" IN THE CLASSIFICATION, ARE ALSO INCLUDED.

Of these base metals, the lower carbon content alloys, especially type 410 and CA-6NM (410NiMo), are often used for turbines in hydroelectric and similar types of facilities. They provide resistance to mild corrosion, cavitation, and moderate abrasion, and they possess relatively high strength. CA-6NM is also used in fittings, valves, and pumps for sour (H_2S-containing) oil and gas service. In this application, the alloy usually must be heat treated to a hardness value that does not exceed 22 HRC. This usually requires a double temper treatment consisting of 2 h at 675 °C (1250 °F) (intercritical temperature range), an air cool to room temperature, and then 4 h at 615 °C (1140 °F) (below lower critical temperature).

Type 420 and similar alloys are used in cutlery, valve parts, gears, shafts, and rollers. One extensive application is a weld overlay on rolls for steel mill continuous casters. This type of alloy is quite brittle in the freshly hardened condition and usually must be tempered to obtain useful toughness properties.

The higher carbon content martensitic stainless steels, such as types 440A, 440B, and 440C, can be hardened to values near 60 HRC. Then, they can be tempered at temperatures up to 480 °C (900 °F) to toughen without experiencing much loss of hardness. In this condition, they serve well as cutting edges and as bearings.

Martensitic stainless steels generally develop full hardness upon air cooling from about 1000 °C (1830 °F). They can be softened by tempering at temperatures ranging from approximately 500 to 750 °C (930 to 1380 °F), unless they contain significant amounts of nickel, in which case the maximum temperature for tempering is reduced. After tempering at 650 to 750 °C (1200 to 1380 °F), their hardness values generally drop to about 30 HRC or lower. This can be useful if it is necessary to soften a martensitic stainless steel before welding to allow enough ductility in the bulk of the material to accommodate shrinkage stresses associated with welding. However, such high-temperature tempering produces rather coarse chromium carbides, which damage the corrosion resistance of the metal. Then, it may be necessary after welding to austenitize, air cool to room temperature, and temper at a low temperature (less than 450 °C, or 840 °F) to restore corrosion resistance.

Engineering for Use in the As-Welded Condition. Except for very small weldments or very low carbon base metals, martensitic stainless steels are not usually used in the as-welded condition. This is due to the very brittle weld area that normally results. This area includes the weld metal itself, if it has a matching or near-matching composition to that of the base metal, and the heat-affected zone. However, repair situations can necessitate that the engineer work with these circumstances.

If a weldment of martensitic stainless steel must be used in the as-welded condition, then it is usually best to avoid both autogenous welds (no filler metal) and welds with matching filler metals. Small parts that are welded by laser-beam welding (LBW), electron-beam welding (EBW), or GTAW processes are an exception, because residual stresses can be very low and the welding processes generate almost no diffusible hydrogen.

If at all possible, an austenitic filler metal, such as type 309 or 309L stainless, or a duplex ferritic-austenitic stainless filler metal, such as type 312 stainless, should be chosen, depending on the base metal. The filler-metal choice should provide for a small amount of ferrite in the weld metal, in order to avoid hot cracking. This can be anticipated by using the extended WRC-1992 diagram (Fig. 4). If the weld metal is austenite with a little ferrite, then the weld metal itself will have appreciable ductility, and only the HAZ will be at risk for cold cracking. This possibility can be minimized by using high preheat temperatures (200 °C, or 390 °F, minimum for type 410 base metal and 350 °C, or 660 °F, minimum for types 440A, 440B, and 440C base metals) and slow cooling after welding.

Example 1: Type 410 base metal (0.10C-12.5Cr-0.04N), Cr_{eq} = 12.5 and Ni_{eq} = 4.3; to be welded with E309-16 manual electrode (0.05C-23.5Cr-13.0Ni-0.06N all-weld metal composition), Cr_{eq} = 23.5 and Ni_{eq} = 15.95.

If the type 410 base metal is plotted in Fig. 9 (point A), along with the all-weld metal composition of the E309-16 electrode (point B), then all possible mixtures of these two metals must lie along the line connecting these two points. If the root pass is diluted with 30% base metal (a typical result to expect), then the actual root pass composition will lie along the tie line, 30% of the distance from point B to point A. This composition is shown as point C in Fig. 9. It would correspond to slightly over 8 FN, which is quite safe in terms of the likelihood of hot cracking. Furthermore, because the tie line is nearly parallel to the isoferrite lines in the diagram, major changes in dilution would have practically no effect on weld-metal ferrite content. Additional weld passes on top of the root pass would have compositions that are also along the tie line, but closer to the E309-16 all-weld metal composition. Therefore, E309-16 would be a very good filler metal

choice if a nonhardenable weld deposit is acceptable. By similar reasoning, type 309 (or 309L) would be an excellent choice for gas-metal arc weld wire, flux-cored wire, or submerged arc wire.

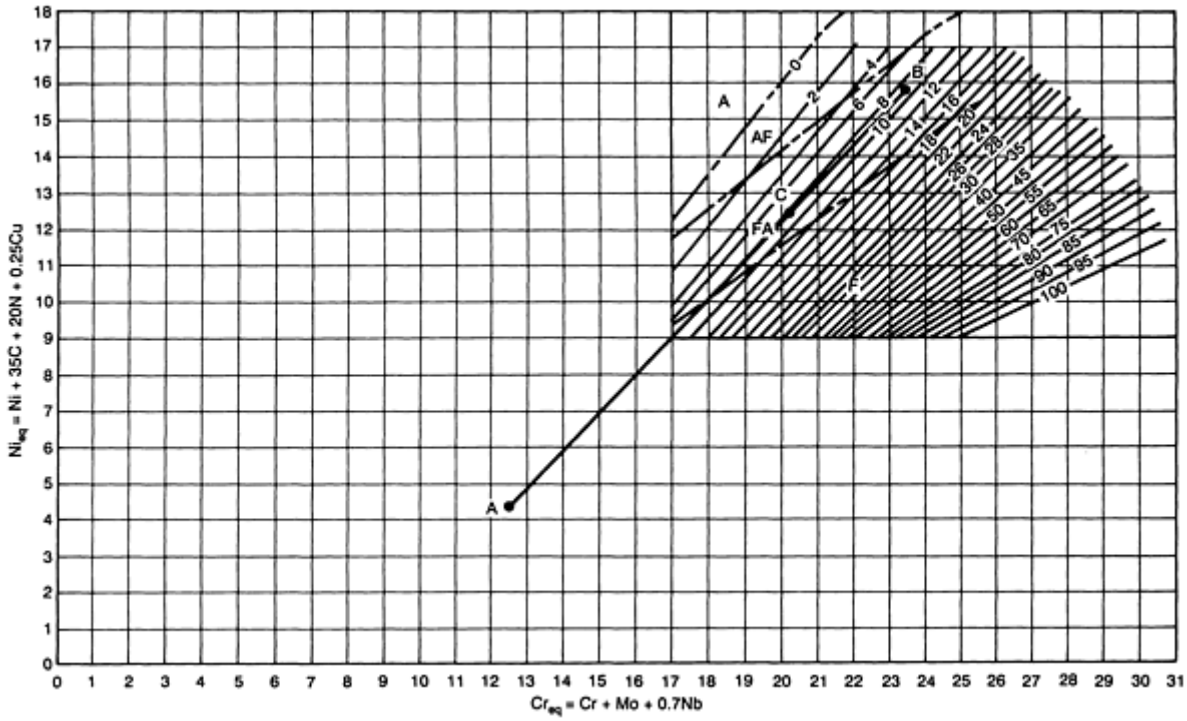

FIG. 9 WRC-1992 DIAGRAM WITH EXPANDED SCALE FOR DILUTION CALCULATIONS, IN WHICH FERRITE IS CALCULATED FOR TYPE 410 STAINLESS STEEL WELDED WITH E309-16 (REFER TO EXAMPLE 1)

Example 2: Type 440A base metal (0.7C-17.0Cr-0.04N), Cr_{eq} = 17.0 and Ni_{eq} = 25.3; to be welded with E309-16 manual electrode (0.05C-23.5Cr-13.0Ni-0.06 N all-weld metal composition), Cr_{eq} = 23.5 and Ni_{eq} = 15.95.

Because the type 440A base metal cannot be plotted on the WRC-1992 diagram, it is necessary to calculate the weld Cr_{eq} and Ni_{eq}. Assuming a 30% dilution, the weld Cr_{eq} = 0.7 (E309-16 Cr_{eq}) + 0.3(440A Cr_{eq}) = 0.7(23.5) + 0.3(17.0) = 21.55; and the weld Ni_{eq} = 0.7(E309-16 Ni_{eq}) + 0.3(440A Ni_{eq}) = 0.7(15.95) + 0.3(25.3) = 18.8. Because the weld-metal composition would clearly lie above and to the left of the 0 FN line in Fig. 4, there would be no ferrite in such a weld deposit. Therefore, E309-16 would not be a good choice for welding type 440A base metal.

Example 3: Type 440A base metal (0.7C-17.0Cr-0.04N), Cr_{eq} = 17.0 and Ni_{eq} = 25.3; to be welded with E312-16 manual electrode (0.10C-29.0Cr-8.8Ni-0.06N), Cr_{eq} = 29.0 and Ni_{eq} = 13.3.

Because the type 440A base metal cannot be plotted on the WRC-1992 diagram, it is necessary to calculate the weld Cr_{eq} and Ni_{eq}. Assuming a 30% dilution, the weld Cr_{eq} = 0.7(E312-16 Cr_{eq}) + 0.3(440A Cr_{eq}) = 0.7(29.0) + 0.3(17) = 25.4; and the weld Ni_{eq} = 0.7(E312-16 Ni_{eq}) + 0.3(440A Ni_{eq}) = 0.7(13.3) + 0.3(25.3) = 16.9. Plotting the weld Cr_{eq} and Ni_{eq} on the WRC-1992 diagram shows this composition corresponds to about 12 FN. Therefore, E312-16 would be a good choice for welding type 440A base metal, if a nonhardenable weld is acceptable.

However, unlike the situation in Example 1, the tie line from the E312-16 electrode all-weld metal composition on the WRC-1992 diagram to the type 440A base-metal composition is nearly perpendicular to the isoferrite lines. This means that large changes in dilution would have a strong effect on weld-metal ferrite content. In particular, it can be calculated that an increase in dilution to just over 35% would put the weld composition into the primary austenite solidification mode and, therefore, at risk of hot cracking. Because higher dilution is normal in submerged arc welding (SAW) and spray-transfer GMAW processes, the avoidance of these processes would be suggested by this example. However, the GMAW process using short-circuiting transfer with type 312 filler wire should be acceptable.

Although the welding filler metals of Examples 1 and 3 seem appropriate choices for avoiding hot cracking in joints in the martensitic stainless steels used in these examples, the weld metals would considerably undermatch the strengths of the base metals, unless the base metals were annealed. The base metals could easily have tensile strength values that exceed 1000 MPa (145 ksi), depending on their condition of heat treatment before welding, whereas the weld metals are likely to have tensile strengths on the order of 550 to 600 MPa (80 to 90 ksi). Furthermore, the austenitic weld metals cannot be hardened by heat treatment. If higher-strength weld metal is essential, then a martensitic filler metal is necessary, which almost always requires a PWHT to obtain reasonable ductility in the weld metal.

Engineering for Use after Postweld Heat Treatment. Because of the major weld-metal strength (hardness) undermatch that often occurs when martensitic stainless steel base metals are welded with austenitic filler metals, these base metals are usually welded with martensitic stainless steel filler metals, and the weldment is subsequently heat treated to improve the properties of the weld area. Heat treatment after welding usually takes one of two forms. The weldment could be either tempered by heat treatment below the austenitic-start temperature or heated above the austenitic-finish temperature to austenitize the entire mass, and then cooled back to nearly room temperature to fully harden it, and then heated again, but to a temperature below the austenitic-start temperature in order to temper the metal to desired properties. Tempering heat treatments at temperatures between the austenitic-start and austenitic-finish temperatures are generally avoided, because they result in a mixture of heavily tempered martensite and fresh untempered martensite, although it is possible to follow such a temper (after cooling to near-room temperature) with a second temper just below the austenitic-start temperature. Such a "double temper" has been successfully used to obtain low hardness and high toughness properties in weldments of CA-6NM (410NiMo).

Tempering at temperatures up to approximately 450 °C (840 °F) has little effect on the hardness of martensitic stainless steels, compared with the hardness of the same steel in the untempered condition. Tempering above 450 °C (840 °F) causes the hardness to fall rapidly with increasing tempering temperatures (Fig. 10), but at the same time, ductility increases. The tempering temperature upper limit is the austenite-start temperature, which is about 800 °C (1470 °F) for the nickel-free alloys, such as types 410, 420, and 440 (Fig. 6 and 8). The addition of nickel to a martensitic alloy reduces the austenite-start temperature appreciably. For CA-6NM, it is about 640 °C (1180 °F).

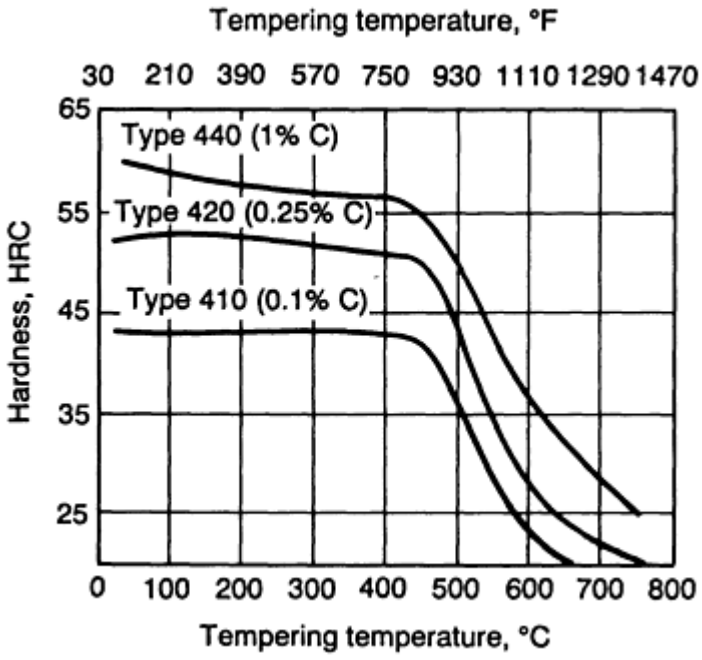

FIG. 10 TEMPERING RESPONSE OF MARTENSITIC STAINLESS STEELS. SOURCE: REF 15

Tempering at temperatures above 450 °C (840 °F), but below the austenitic-start temperature, also can be useful *before* welding, because the base metal is softened and made more ductile, which better accommodates the shrinkage strains that accompany cooling of the weld metal. This helps to avoid weldment cracking during cooling.

With all but the lowest carbon content martensitic stainless steel base metals, high preheat and high interpass temperatures are usually necessary to avoid cracking when the weld metal is also martensitic stainless steel. The alloy CA-6NM only requires approximately 140 °C (280 °F), minimum, whereas types 410 and 420 require approximately 200 °C (390 °F), and type 440 requires approximately 260 °C (500 °F), minimum. However, for a sizable weldment, a safer procedure is to perform all welding at temperatures above the martensite-start temperature of the weld metal, so that no martensite forms in the weld until welding is completed. Preheat and interpass temperatures ranging from 300 to 500 °C (570 to 930 °F) are successfully used. In either case, the weldment must be very slowly cooled to below 100 °C (212 °F) to complete martensite transformation of the weld metal and HAZ without cracking, once welding is finished.

Only after martensite transformation is completed (when the weldment is below 100 °C, or 212 °F) should tempering of the weldment be undertaken. If untransformed austenite is still present, tempering followed by cooling will result in fresh martensite formation when the weldment reaches room temperature, and unexpected hardness (possibly accompanied by cracking) is likely to be encountered.

The availability of matching filler metals is a problem for some martensitic stainless steels. For covered electrodes, only E410-XX and E410NiMo-XX types are commercially significant, as indicated by the ANSI/AWS A5.4 classification. The same compositions are also the only entries in the flux-cored electrode standard, ANSI/AWS A5.22. These compositions, as well as the ER420 classification, are given as solid wires in the ANSI/AWS A5.9 standard. Therefore, Table 1(b), which designates matching filler metals along with selected base metals, has many voids in the filler-metal listings. A few filler-metal producers can produce special orders, such as tubular metal-cored electrodes, in compositions to match the other base metals. Otherwise, the fabricator may be forced to choose a filler metal that does not match the base metal.

One special case deserves mention. Literally thousands of tons of filler metal in the form of tubular wires have been deposited by submerged arc overlay of type 420 and modified-composition weld metals on low-alloy steel rolls for continuous casters. In service, these rolls typically crack from thermal shock. After a period ranging from 6 months to 1 year, their surfaces are sufficiently damaged so that they must be removed from service. If cracking is not too deep, then the cracks can be machined off and the roll rewelded as before.

A very successful welding procedure has been to maintain preheat and interpass temperatures of at least 350 °C (660 °F) from the start to the finish of welding. Because this temperature is above the martensite-start temperature of the weld metal, the weld metal remains as austenite during welding, which may last 1 day or longer. As many as three welding heads, each using 400 to 900 A, can be used on a roll that is about 2 m (6.5 ft) long, which helps to keep the roll hot. The welded roll is covered with insulating material and left to slow cool to nearly room temperature. Then, it is tempered, typically at temperatures of 450 °C (840 °F) or higher, to soften the overlay enough to make it machinable. Molybdenum, vanadium, and, sometimes, niobium, can be added to the basic type 420 composition to modify the tempering response (as well as service performance). Figure 11 illustrates the change in tempering response that results from the alloy modifications.

Ferritic Stainless Steels

Basic Metallurgy. There are essentially three generations of ferritic stainless steels. The first--in which carbon is not very low, so that chromium needs to be high--dates from the early decades of the 20th century, when the decarburization of iron-chromium alloys was quite inefficient. The prototype alloy is type 430 stainless, typically 0.08C-17Cr. Figure 6(b) indicates that this alloy would be fully ferritic at temperatures above approximately 1250 °C (2280 °F). At lower temperatures, ferrite and austenite would co-exist to about 1030 °C (1890 °F). Further cooling would cause carbides to appear as well. Then, at about 920 °C (1690 °F), the austenite would disappear and only ferrite and some carbides would remain at room temperature, under equilibrium conditions. Type 446 stainless (typically, 0.1C-25Cr) is also of this first generation, and it behaves similarly.

It is something of a misnomer to call these first-generation ferritic stainless steels "ferritic" because some austenite appears at certain high temperatures. This austenite has a beneficial effect in that it retards grain growth, which has an important embrittling effect when it occurs. However, because it also tends to transform to martensite under welding conditions, first-generation ferritic stainless steels generally have hard spots after welding (see Fig. 12). In addition, normal weld cooling will cause some supersaturation of the ferrite with carbon, because of declining carbon solubility in the ferrite with falling temperatures below 950 °C (1740 °F). A PWHT at about 760 °C (1400 °F) simultaneously tempers the martensite where austenite existed at higher temperatures, and causes the excess carbon in the ferrite to precipitate as carbides. Both of these effects act to significantly improve the ductility and toughness of type 430 after welding. Type 446 is not ductile at room temperature, even before welding.

The second generation of ferritic stainless steels have lower-carbon and low-nitrogen contents, to which a stabilizer is added to tie up whatever carbon and/or nitrogen is present. The prototype of this second generation is type 409, typically 0.04C-11Cr-0.5Ti. The titanium ties up both carbon and nitrogen, leaving all of the chromium free. Surplus titanium is also a ferritizer. Therefore, the alloy is ferritic at all temperatures. Type 405 is a similar alloy, but it is stabilized with aluminum, which ties up nitrogen, but not carbon. Aluminum is also a powerful ferritizer. The various carbides and/or nitrides produced by the addition of stabilizers help to resist embrittling grain growth in second-generation ferritic stainless steels during welding.

The third generation of ferritic stainless steels arose circa 1970, with the advent of more-efficient decarburization techniques in steelmaking. Carbon and nitrogen levels are typically 0.02% or less, and stabilizers, such as titanium and/or niobium, are often added to tie up any free interstitials. The prototype alloy is type 444 (18Cr-2Mo). There are also a number of proprietary alloys that are not yet covered by an ASTM designation.

The third-generation ferritic stainless steel alloys are austenite-free at all temperatures. However, they can be embrittled by the formation of intermetallic phases at elevated temperatures. They are sensitive to "475 °C (885 °F) embrittlement," because of precipitation of the chromium-rich α' phase, and to embrittlement by σ, χ, and other phases at higher temperatures. Figure 5 indicates that the αphase is approximately FeCr, whereas α' is a chromium-rich ferrite that precipitates from the iron-rich ferrite. The χ phase is a complex iron-chromium-molybdenum intermetallic, which can only appear in molybdenum-bearing steels. Except in the case of α' embrittlement, which disappears rapidly upon exposure to temperatures above approximately 575 °C (1070 °F), temperatures that are high enough to dissolve all of these phases are also high enough to cause severe grain growth in the ferrite. Because this grain growth also has an embrittling effect, heat treatment alone is not usually desirable. In general, hot working to reduce grain size is necessary to restore full ductility and toughness once the alloy is embrittled by σ, χ, or other high-temperature intermetallic compounds.

Ferritic stainless steels of the third generation can be severely embrittled by interstitial contamination during welding, because of improper or contaminated gas shielding. Although nitrogen contamination is most common, carbon, hydrogen,

and oxygen also have detrimental effects on ductility and toughness. Cleanliness, inert backing gas, and high-purity gas shielding conducted with precautions to avoid disturbances are essential if the best weldment properties are to be obtained.

Ferritic Stainless Steel Base Metals. Tables 2(a) and 2(b) list selected ferritic stainless steel base metals, their minimum mechanical property requirements, and some corresponding welding filler metals. Ferritic stainless steels cannot offer the range of mechanical properties (depending on heat treatment) that martensitic stainless steels offer. Whereas the martensitic stainless steels offer only moderate corrosion resistance, that of the ferritic stainless steels can range from moderate, for types 430 or 409, to outstanding, for the third-generation "super ferritics" such as type 444 and UNS Nos. S44627, S44635, S44660, S44700, and S44800. Types 405 and 409 have resistance to atmospheric corrosion. Type 430 also resists mild oxidizing acids and organic acids, and is therefore used in food-handling equipment, sinks, and such. The super ferritics offer exceptional resistance to localized corrosion induced by exposure to aqueous chlorides. Localized corrosion, such as pitting, crevice corrosion, and stress-corrosion cracking, are problems that plague many austenitic stainless steels. Therefore, the super ferritics are often used in heat exchangers and piping systems for chloride-bearing aqueous solutions and seawater.

(A) METAL-CORED ELECTRODES, INDICATED BY A "C" IN PLACE OF THE "R" IN THE CLASSIFICATION, ARE ALSO INCLUDED.

Because of 475 °C (885 °F) embrittlement and σ-phase formation, long-term service temperatures for most ferritic stainless steels are usually limited to 250 °C (480 °F), maximum. However, 475 °C (885 °F) embrittlement does not seem to be a serious problem in the low-chromium types 409 and 405, which have been extensively used in automobile exhaust systems (where temperatures can exceed 575 °C, or 1070 °F, at times, which can dissolve α'). Another exception to the maximum service temperature limit is type 446, which offers outstanding resistance to scaling in air at high temperatures, because of its high chromium content. It is used in compressive loading, as the supports in heat-treat furnaces and the like, where brittleness at room temperature is not an important issue. Because ferritic stainless steels lose toughness and ductility at low temperatures, their use below ambient temperatures is very limited.

The ferritic stainless steels generally require rapid cooling from hot-working temperatures to avoid grain growth and embrittlement from the α phase. As a result, most ferritic stainless steel is used in relatively thin gages, especially in alloys that are high in chromium. The super ferritics are limited to thin plate, sheet, and tube forms. To avoid embrittlement in welding, the general rule is to "weld cold," which means to weld with either no or low preheating; a low interpass temperature; and a low level of welding heat input, commensurate with adequate fusion, to avoid cold laps and other defects.

Engineering for Use in the As-Welded Condition. In contrast to martensitic stainless steels, weldments in ferritic stainless steels (at least in the stabilized grades or super ferritics, that is, second- and third-generation alloys), are usually used in the as-welded condition. If the "weld cold" rule is followed, then embrittlement that is due to grain coarsening in the HAZ can be avoided. However, it is not as easy to avoid coarse grains in the fusion zone if the weld metal is fully ferritic. As a result, a considerable amount (but not all) of the filler metal used to join ferritic stainless steels is austenitic, usually with considerable ferrite.

If an austenitic filler metal is contemplated, then consideration should be given to differences in corrosion resistance (especially localized corrosion resistance) across the joint, as well as to differences in properties, such as the coefficient of thermal expansion (CTE) between austenitic filler metal and ferritic base metal. Nickel-base alloy filler metals are another possible alternative, especially for the third-generation ferritic stainless steels, which have the highest corrosion resistance requirements. High molybdenum content nickel-base alloy filler metals of the ANSI/AWS A5.11 specification, covered-electrode classifications ENiCrMo-3, ENiCrMo-4, and ENiCrMo-10, as well as the ANSI/AWS A5.14 specification, solid-wire classifications ERNiCrMo-3, ERNiCrMo-4, and ERNiCrMo-10, have been successfully used for the most corrosion resistant ferritic stainless steels.

Undoubtedly, the greatest quantity of ferritic stainless steel welded at the present time is type 409, which is used for automobile exhaust system components. The welds are virtually all single-pass fillet or lap welds. The most common filler metal is a matching composition supplied as a 1.1 mm (0.045 in.) diameter metal-cored wire (ANSI/AWS A5.9-92 classification EC409 or EC409Cb), which is used for gas-metal arc welding with argon-oxygen gas mixtures, such as the popular 98Ar-2O_2 mixture. This filler metal is often used in robotic welding, at high travel speeds, in the vertical-down position on rotating pieces that are 18 gage or less in thickness. Welding is done in a short-circuiting transfer mode, or nearly so.

Example 4:

An alternative procedure for welding type 409 base metal in automotive exhaust applications is to use 0.9 mm (0.035 in.) diameter solid austenitic stainless wire, in the short-circuiting transfer mode, with an argon-oxygen gas mixture. Because of the thin gage of the base metal, dilution that is on the order of 40% can be anticipated. Because the filler metal ER308LSi would exceed the corrosion resistance of the type 409 base metal, it could be considered. If the type 409 composition were 0.04C-0.5Mn-0.4Si-11.0Cr-0.5Ti (WRC-1988 Cr_{eq} = 11.0 and Ni_{eq} = 1.4; FN, off the diagram), and if the ER308LSi composition were 0.02C-1.5Mn-0.8Si-19.7Cr-10.2Ni-0.2Mo-0.04N (WRC-1988 Cr_{eq} = 19.9 and Ni_{eq} = 11.7; FN = 9.7), then the 40% dilution weld metal would have Cr_{eq} = 16.34, Ni_{eq} = 7.58, and FN would be off the diagram. Recalculating the chromium and nickel equivalents according to Schaeffler (Fig. 1), the weld metal would be deeply into the A + M + F field, that is, on the order of 50% martensite could be expected in the weld metal. This could be a problem for cracking or forming after welding. Therefore, ER308LSi may not be a good choice for welding type 409 base metal.

Example 5:

Assume that ER309LSi is substituted for the ER308LSi of Example 4. If the ER309LSi composition were 0.02C-1.5Mn-0.8Si-23.5Cr-13.5Ni-0.2Mo-0.04N (WRC-1988 Cr_{eq} = 23.7 and Ni_{eq} = 15.0; FN = 12.8), then the 40% dilution weld metal would have Cr_{eq} = 18.6, Ni_{eq} = 9.56, and FN = 12.6. Recalculating the chromium and nickel equivalents according to Schaeffler (Fig. 1) puts the weld metal just at the upper edge of the A + M + F field, that is, a trace of martensite, at most, would be present in the weld metal. Furthermore, because the calculated weld-metal FN is almost exactly the same as the calculated wire FN, the tie line from the wire composition to the base-metal composition must be nearly parallel to the isoferrite lines in the WRC-1988 diagram. This means that the weld-metal FN will be immune to changes in dilution, although excess dilution should be avoided because it would lead to more martensite. Thus, the ER309LSi filler metal would be a good choice for welding type 409 base metal.

The third generation of ferritic stainless steels, the super ferritics, are often supplied in the form of thin-walled tubing and are used in heat exchangers that handle chloride solutions. Tube-to-tube or tube-to-tubesheet weld joints are often made by orbital GTAW machines at relatively high speeds, without filler metal. The tube-to-tube weld is, of course, fully ferritic, and the high-speed "weld cold" procedure avoids excessive grain growth in materials such as type 444 ferritic stainless steel (18Cr-2Mo). However, the tubesheet in such a heat exchanger is often not type 444, but type 316L.

Example 6:

Type 444 tube welded to type 316L tube sheet by the GTAW process, without filler metal, makes an interesting material combination. If the Type 444 is 0.01C-0.5Mn-0.2Si-18.0Cr-2.0Mo-0.01N-0.4Nb (WRC-1988 Cr_{eq} = 20.28 and Ni_{eq} = 0.55; FN, out of range), and if the type 316L is 0.02C-1.5Mn-0.4Si-17.0Cr-2.2Mo-0.03N (WRC-1988 Cr_{eq} = 19.2, Ni_{eq} = 12.8, and FN = 3.4), and if each base metal is assumed to contribute equally to the weld metal, then the weld metal will have Cr_{eq} = 19.7, Ni_{eq} = 6.7, and FN will be out of range. Recalculating chromium and nickel equivalents for the Schaeffler diagram indicates approximately 40% ferrite, with the remainder being primarily austenite, with some martensite. This would not be the best situation, in terms of weld-metal ductility, but many such combinations have been welded this way and have provided satisfactory service.

Engineering for Use in the Postweld Heat-Treated Condition. In general, only the first-generation ferritic stainless steels are postweld heat treated, especially type 430. If it were welded with matching filler metal (or no filler metal), then both the weld metal and the HAZ would contain fresh martensite in the as-welded condition. In addition, some carbon would have gone into solution in the ferrite at elevated temperatures, and the rapid cooling after welding would result in ferrite in both the weld metal and the HAZ being supersaturated with carbon. Thus, the joint would be quite brittle, compared with the unwelded condition. Ductility could be significantly improved by a PWHT at 760 °C (1400 °F) for 1 h, followed by rapid cooling to avoid the 475 °C (885 °F) embrittlement phenomenon.

Example 7:

Type 430 could also be welded with type 308 or 308L filler metals, which are readily available and would exceed the corrosion resistance of the type 430 base metal in most environments. Then, only the HAZ would suffer embrittlement that is due to welding. For a type 430 composition of 0.06C-0.5Mn-0.2Si-17Cr-0.02N (WRC-88 Cr_{eq} = 17.0 and Ni_{eq} = 2.5; FN, off the diagram), and an E308L-16 electrode with all-weld metal composition of 0.03C-1.0Mn-0.4Si-19Cr-10Ni-0.08Mo-0.06N (WRC-1988 Cr_{eq} = 19.08 and Ni_{eq} = 12.25; calculated FN = 4.4), with 30% dilution, the first weld pass would have Cr_{eq} = 18.46, Ni_{eq} = 9.33, and the calculated FN = 12.9. Further, the weldment could be postweld heat treated for 1 h at 760 °C (1400 °F) to improve the HAZ ductility without harming the weld metal, and a very satisfactory joint would result.

Welding of Stainless Steels

D.J. Kotecki, The Lincoln Electric Company

Austenitic Stainless Steels

Basic Metallurgy. Nominally austenitic stainless steels cover a very broad spectrum of compositions. Many, but by no means all, solidify at least partly as ferrite, which transforms under equilibrium cooling, or hot working, to austenite at high temperatures (above 1000 °C, or 1830 °F) by a diffusion-controlled reaction. The austenite is stable, or at least metastable, to room temperature and below. Some of the leaner austenitic alloys can be induced to transform to martensite, at least in part, by cold work and/or by refrigeration to cryogenic temperatures.

In order to understand the weldability of nominally austenitic stainless steels, it is necessary to first understand their solidification and high-temperature transformation behavior. Austenitic stainless steel compositions are based on a balance between alloy elements that promote ferrite formation and those that promote austenite formation. The prototype ferritizing element is chromium, but molybdenum, niobium, titanium, aluminum, tungsten, and vanadium also promote ferrite. The prototype austenitizing element is nickel, but carbon, nitrogen, and copper all promote transformation of ferrite to austenite at high temperatures. In addition, while manganese does not seem to promote transformation of ferrite to austenite at high temperatures, it clearly does tend to stabilize austenite with respect to transformation to martensite at low temperatures. Further, manganese promotes the solubility of nitrogen in steel (as does chromium), making possible a low-nickel family of austenitic stainless steels that are high in manganese and nitrogen.

The solidification and high-temperature transformation behavior of austenitic stainless steels can be understood by examining sections of the ternary iron-chromium-nickel phase diagram. Figure 13 presents three levels of iron: 70 wt%, 60 wt%, and 55 wt%. Each diagram has a eutectic triangle (labeled "γ+δ+L"), which indicates compositions in which austenite, ferrite, and liquid metal can all coexist.

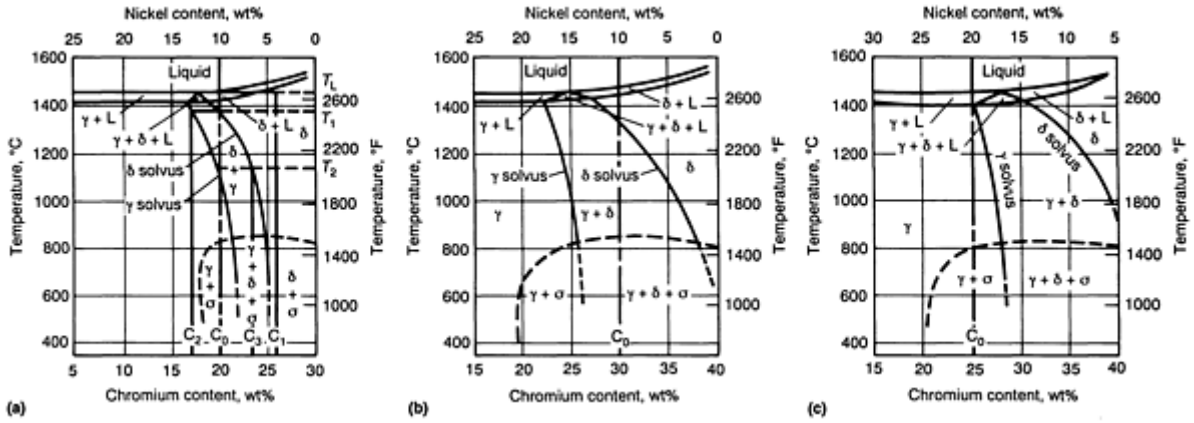

FIG. 13 IRON-CHROMIUM-NICKEL PSEUDO-BINARY DIAGRAM. (A) 70 WT% FE. (B) 60 WT% FE. (C) 55 WT% FE. SOURCE: REF 10

On the left (nickel-rich) side of each diagram are compositions that solidify entirely as austenite and remain austenite to room temperature, for example, an alloy of 10Cr-20Ni in the 70% iron diagram. Close to, and within the left side of, the eutectic triangle are compositions (for example, 17Cr-13Ni) that solidify as austenite in the early stages of solidification, but in which some ferrite will appear in the last stages of solidification. This is called "primary austenite solidification." Further cooling can cause that ferrite to transform to austenite under equilibrium conditions, but under the relatively rapid cooling conditions of welding, some of this ferrite may survive to room temperature.

Close to, and within the right side of, the eutectic triangle are compositions (for example, 19Cr-11Ni) that solidify as ferrite in the early stages of solidification, but in which some austenite will appear in the last stages of solidification. This is called "primary ferrite solidification." Further cooling can cause that ferrite to transform to austenite under equilibrium conditions, but under the relatively rapid cooling conditions of welding, some of this ferrite may, and usually does, survive to room temperature.

Further to the right in Fig. 13 are compositions that solidify entirely as ferrite, but, upon further cooling under equilibrium conditions, transform either partly or entirely to austenite. An alloy of 20Cr-10Ni would be entirely ferrite when solidification was completed, but would begin to transform to austenite at a temperature (T_1 in Fig. 13) slightly below the end of solidification, and would be completely transformed to austenite at a still lower temperature (T_2 in Fig. 13). However, an alloy of 23Cr-7Ni would only partially transform to austenite, that is, some ferrite would be stable at room temperature. Under the relatively rapid cooling conditions of welding, not as much ferrite transforms to austenite, as Fig. 13 indicates, because the diffusion of atoms must occur. As a result, the 20Cr-10Ni alloy weld metal would still contain some ferrite at room temperature, and the 23Cr-7Ni alloy would contain more ferrite than Fig. 13 indicates.

Finally, there are compositions (still further to the right of the eutectic triangle in Fig. 13) that will not form any austenite at any temperature. These are ferritic stainless steels.

Considerable research has shown that alloys that solidify as primary ferrite are the most resistant to hot cracking. Alloys that solidify entirely as austenite are the most susceptible to hot cracking. Alloys that solidify as primary austenite are more susceptible than all alloys in this system, except those that solidify entirely as austenite. Alloys that solidify entirely as ferrite are more resistant to hot cracking than any other alloys, except those that solidify as primary ferrite. Therefore, from a welding viewpoint, the preferred order of solidification is primary ferrite, fully ferritic, primary austenite, and, last, fully austenitic. In the WRC-1988 diagram (Fig. 3), the dashed lines divide the range of chromium equivalents and nickel equivalents into those that solidify fully austenitic (Region A), those that solidify as primary austenite (Region AF), those that solidify as primary ferrite (Region FA), and those that solidify fully ferritic (Region F).

Figures 3 and 13, when considered together, indicate that the ferrite that remains in a nominally austenitic weld metal when it reaches room temperature is only a fraction of that which existed during solidification. Most of the initial ferrite is transformed to austenite. Thus, the more-fundamental piece of information about a given weld metal is its solidification mode. However, this is difficult and time-consuming to assess, whereas the Ferrite Number, measured at room temperature after the fact, is easy to measure using any number of instruments calibrated to the ANSI/AWS A4.2 specification, and the interlaboratory reproducibility of measurement is very high. The conventional wisdom accumulated over numerous years indicates that a 4 FN minimum ill ensure freedom from hot cracking problems in most nominally austenitic stainless steel weld metals. An examination of Fig. 3 indicates that 4 FN is comfortably within the FA region for lower-alloyed weld metals and barely within the FA region for highly alloyed weld metals.

Several caveats need to be remembered when applying the "4 FN minimum" convention. First, it is based on measurement *along the top centerline of an as-welded weld bead.* This means that applying such a rule, either after PWHT or at all points across a multipass overlay, is inappropriate because heat treatment or reheating by a subsequent weld pass reduces ferrite toward its equilibrium value (which may be zero).

Second, this convention derives from experience with normal impurity levels (primarily sulfur and phosphorus). Extraordinarily high impurities, as in free-machining stainless steels, often renders the metal susceptible to hot cracking at any ferrite level. On the other hand, extraordinarily low impurity levels can make low or zero ferrite weld metals fairly crack resistant.

Third, one cannot determine, from a ferrite measurement on unwelded base metal, what its hot cracking susceptibility in autogenous (no filler metal) welding is likely to be. Because hot working erases ferrite, hot-rolled plate is likely to indicate zero ferrite. On the other hand, cold working causes lean alloys, such as types 201, 301, 302, and 304, to transform to martensite, which is ferromagnetic and gives a false ferrite reading with instruments based on magnetic principles. Ferrite can be either estimated from the composition of a base metal (including nitrogen), using the WRC-1988 diagram, or measured by first making a gas-tungsten arc melt of the base metal without using filler metal, and then using a calibrated instrument along the weld centerline.

Fourth, a certificate of test from a filler metal manufacturer that indicates a FN greater than 4 only indicates that the filler metal was properly designed. It cannot take into account the ability of a careless welder to change the Ferrite Number by permitting nitrogen from the air to enter the welding arc. Practices such as long arc length in shielded metal arc welding (SMAW) or self-shielded flux-cored arc welding (FCAW); the disturbance of shielding gas by drafts in gas-shielded welding; or the loss of flux cover, as evidenced by arc "flashing" in the SAW process, can produce enough nitrogen pickup to reduce the ferrite of an otherwise satisfactory weld deposit to an unacceptably low level, which makes hot cracking possible.

Fifth, very lean alloy weld metals, such as ER16-8-2, can solidify as crack-resistant primary ferrite, even when the weld metal measures nearly zero FN.

Sixth, the minimum 4 FN convention is really only applicable to weld metals that solidify under cooling rates normal for conventional SMAW, GMAW, GTAW, and single-electrode SAW. The slow cooling rates of strip cladding can produce lower than normal FN measurements when the weld metal solidifies as primary ferrite. Furthermore, the very rapid cooling rates associated with EBW or LBW can produce marked departures from the expected solidification mode and ferrite content (see Ref 18). Nevertheless, the minimum 4 FN convention has been a very successful guideline in normal welded fabrication of nominally austenitic stainless steels.

Arc welding heats the base metal adjacent to the weld deposit, which can produce undesirable metallurgical reactions. In austenitic stainless steels, a principal concern is grain-boundary carbide precipitation. Whatever carbides were initially present before welding can be dissolved at temperatures above approximately 1000 °C (1830 °F). Then, subsequent slow

cooling through the temperature range from approximately 950 °C (1740 °F) down to approximately 500 °C (900 °F) can cause chromium carbides to precipitate again, usually on austenite grain boundaries. This precipitation can leave the metal adjacent to the grain boundaries depleted in chromium and, therefore, susceptible to intergranular corrosion. The steel is said to be "sensitized." Improper heat treatment can do this to an entire base metal.

Figure 14 gives the times and temperatures that produce sensitization. In particular, it indicates that carbides, although they form quickly, must be quite extensive in order to make the metal susceptible to intergranular corrosion. Generally, a selection of low-carbon (less than 0.03%) base metal is nearly immune to sensitization that is due to welding. Another alternative is to choose a base metal to which a strong carbide-forming element (titanium or niobium) is added, which ties up the available carbon and leaves the chromium free to provide corrosion resistance.

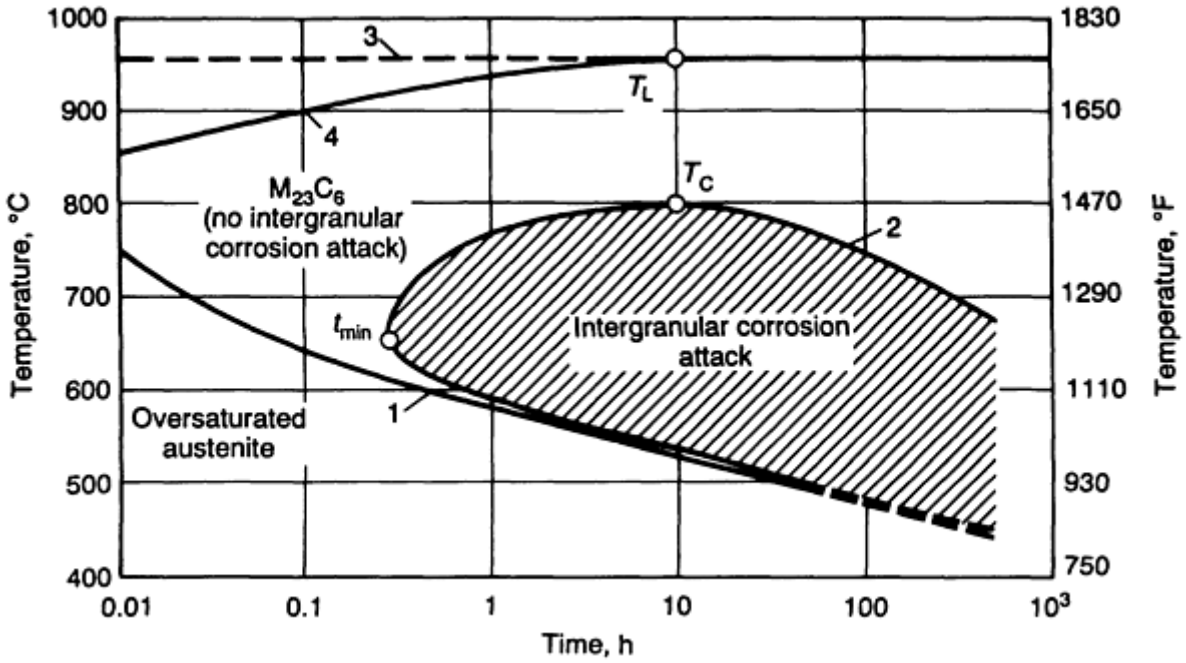

FIG. 14 PRECIPITATION OF CARBIDE $M_{23}C_6$ AND AREA OF INTERGRANULAR CORROSION ATTACK OF STAINLESS STEEL GRADE AISI 304 (0.042C-0.59SI-1.23MN-17.46CR-10.58NI-0.046N). SOURCE: REF 19

The σ phase precipitates slowly in austenite, but more rapidly in ferrite. In nominally austenitic weld metal with some ferrite, cooling rates are still high enough that σ is seldom encountered in the as-welded condition. However, a PWHT at 700 to 900 °C (1290 to 1650 °F) for even 1 h will convert some ferrite to the σ phase, as indicated by Fig. 15. High levels of chromium, molybdenum, silicon, titanium, and/or niobium can greatly accelerate σ formation. The segregation of these elements during solidification can promote σ formation. Because of sensitization and the σ phase, it is best to avoid the heat treatment of nominally austenitic weld metals at temperatures between 500 and 900 °C (930 and 1650 °F).

Austenitic Stainless Steel Base Metals. Tables 3(a) and 3(b) list numerous nominally austenitic stainless steel base metals and their minimum mechanical property requirements, as well as corresponding welding filler metals. The yield strengths of these materials are rather modest, and are comparable to those of mild steels. Austenitic stainless steels cannot be hardened by heat treatment, but they do work harden rapidly. Therefore, high strength is possible in cold-worked forms, especially in drawn wire, in which a tensile strength of 1200 MPa (175 ksi) or higher is achievable. The heat of welding will soften the HAZ of heavily cold-worked austenitic stainless steel.

NS, not specified; NCW, not considered weldable.

(A) ELECTRODES WITH HIGHER SILICON (0.65-1.00%), INDICATED BY "SI" ADDED AT THE END OF THE CLASSIFICATION WERE INCLUDED. METAL-CORED ELECTRODES, INDICATED BY A "C" IN PLACE OF THE "R" IN THE CLASSIFICATION, ARE ALSO INCLUDED.

Even the leanest austenitic stainless steels (such as types 302 and 304, which can be considered the base alloys of the austenitic stainless steels) offer general corrosion resistance in the atmosphere, in many aqueous media, in the presence of foods, and in oxidizing acids such as nitric acid. Types 321 and 347 are essentially type 304 with additions of either titanium or niobium, respectively, which stabilize carbides against sensitization.

The addition of molybdenum in type 316L provides pitting resistance in phosphoric and acetic acids and dilute chloride solutions, as well as corrosion resistance in sulfurous acid (H_2SO_3). An even higher molybdenum content, as in type 317L (3%), and even richer alloys further enhance pitting resistance.

Nitrogen is added to enhance strength at room temperature and, especially, at cryogenic temperatures (as in type 304LN, for example). Nitrogen is also added to reduce the rate of chromium carbide precipitation and, therefore, the susceptibility to sensitization. Nitrogen is also added to molybdenum-containing alloys to increase resistance to chloride-induced pitting and crevice corrosion.

Higher amounts of chromium and/or nickel are used to enhance high-temperature oxidation resistance (as in types 309, 310, and 330, for example). Copper and nickel can be added to enhance resistance to reducing acids, such as sulfuric acid (type 320). Nickel and molybdenum, when present in sufficient amounts, promote resistance to chloride-induced stress-corrosion cracking. As indicated by this discussion and Tables 3(a) and 3(b), there is an enormous number of austenitic stainless steel types.

Engineering for Use in the As-Welded Condition. Most weldments in nominally austenitic stainless steel base metals are put into service in the as-welded condition. In contrast to the situations with martensitic and ferritic stainless steel base metals, many of the nominally austenitic stainless steel base metals have matching, or near-matching, welding filler metals (see Tables 3(a) and 3(b)). In many cases, a nearly matching filler metal is a good choice.

Filler-metal selection and welding procedure development for austenitic stainless steel base metals primarily depend on whether or not ferrite is possible and acceptable in the weld metal. In general, if ferrite is both possible and acceptable, then the suitable choices of filler metals and procedures are broad. If the weld metal solidifies as primary ferrite, then the range of acceptable welding procedures can be as broad as it would be for ordinary mild steel. However, if ferrite in the weld metal is neither possible nor acceptable, then the filler metal and procedure choices are much more restricted, because of hot-cracking considerations.

Most filler-metal compositions are available in a variety of forms. When the presence of ferrite is possible, some filler-metal manufacturers will tailor it to meet specific needs, at least in filler metals that are composites (for SMAW, FCAW, and metal-cored wires for GMAW or SAW processes). For example, in type 308 or 308L filler metals, which are typically selected for joining base-metal types 302, 304, 304L, 305, CF-8, or CF-3, the filler metal can be designed for zero ferrite, more than 20 FN, or any FN value between these extremes, and still be within the composition limits for the classification in the relevant AWS filler-metal specification.

In solid wires of type 308 or 308L, which are used for GMAW, GTAW, or SAW processes, the potential ferrite content of all-weld metal is often designed by the steel producer to provide maximum yield from the heat of steel. Stainless steel producers have generally found that the yield from a heat of steel, which will be reduced to "green rod" for supply to a filler-metal producer, is maximized when the ferrite content ranges from 3 to 8 FN, based on the WRC-1988 diagram. Weld rod demand is usually for a minimum of 8 FN. Poor yields make the production of metal with more than 10 FN uneconomical and, thus, limit its availability. A lack of demand limits production and, thus, the availability of green rod with less than 8 FN. Therefore, most solid-wire compositions are designed to achieve approximately 8 to 10 FN. Solid wires with compositions that are much beyond this range (as in austenitic grades that generally contain some ferrite) usually require special order, heat quantities (of 18 Mg, or 40,000 lb), long lead times, and they command premium prices.

With composite filler metals, the manufacturer can adjust both composition and ferrite content via alloying in either the electrode coating of SMAW electrodes or the core of flux-cored and metal-cored wires. Tailoring composition and ferrite for special applications is much more easily accomplished than it is for solid wires. For most off-the-shelf composite filler metals, the filler-metal manufacturer has a target all-weld metal FN in mind when designing the filler metal. For a given alloy type, such as 308L, the target FN is likely to depend on the economics of filler-metal design, the appropriate Ferrite Number for the specific type of filler metal to avoid hot cracking, and market requirements.

For example, the ANSI/AWS A5.4 classification system recognizes three all-position coating types. In general, E308L-15 electrodes provide better hot-cracking resistance at low or no levels of ferrite than do E308L-16 electrodes, which, in turn, provide better hot-cracking resistance than do E308L-17 electrodes when little or no ferrite is present in the deposit. This difference in cracking resistance without ferrite primarily stems from bead shape. The E308L-15 electrodes tend to produce a convex bead shape. Convexity provides something of a riser, as in a casting, which tends to resist hot cracking. The E308L-16 electrodes tend to produce a nearly flat profile, which provides little or no riser. The E308L-17 electrodes tend to produce a concave profile (as well as a high silicon deposit), which makes this the least crack resistant coating type when there is little or no ferrite in the deposit. Further, the sensitivity to nitrogen pickup with a long arc (and the consequent loss of ferrite) is least with E308L-15 and greatest with E308L-17 electrodes.

As a result, filler-metal manufacturers generally aim their off-the-shelf E308L-15 electrodes toward a lower FN than they do their E308L-16 electrodes, which, in turn, are aimed toward lower FN values than are their E308L-17 electrodes. Of course, the same tendencies apply to other alloy compositions with the same coating types, which can be generalized as EXXX-15, EXXX-16, or EXXX-17, where "XXX" stands for 308, 308L, 309, 309L, 316, 316L, and so on.

Until 1992, the EXXX-17 coating type was not recognized by the ANSI/AWS A5.4 specification as being a distinct type, although the electrodes have been available for many years. Because electrodes that are properly classified as EXXX-17 generally weld satisfactorily on both direct current (dc) and alternating current (ac), they had to be classified as EXXX-16 electrodes until the publication of ANSI/AWS A5.4-92 introduced the EXXX-17 classifications. Using these electrodes and meeting the vertical-up fillet weld size and convexity requirements of the EXXX-16 classifications were difficult to achieve, at best.

Although the EXXX-17 classifications have relaxed vertical-up fillet size and convexity requirements, some electrode manufacturers have been reluctant to change the classification of certain brand names (originally classified as EXXX-16) in order to more correctly reflect the true vertical-up capabilities of the electrodes. The knowledgeable fabricator can detect an electrode that is classified by its manufacturer as EXXX-16, when it properly ought to be classified as EXXX-17, either by attempting to meet the vertical-up fillet requirements of the EXXX-16 classification or by examining the all-weld metal composition that the electrode produces. The EXXX-17 electrodes all produce deposits of low manganese and high silicon. In general, a nominally austenitic electrode with an all-weld metal silicon content that is nearly as high as, or higher than, its manganese content (that is, silicon content approaches the 0.9% maximum of the specification) is in all probability properly classified as an EXXX-17 electrode.

Flux-cored and metal-cored electrodes do not have the clear distinctions that exist among the three main coating types. In general, both off-the-shelf flux-cored and metal-cored electrodes tend to have higher ferrite numbers, more like those of EXXX-17 electrodes, because the higher heat input that normally accompanies the use of these products tends to make the weld metal less crack resistant when little or no ferrite is present.

If a fully austenitic stainless steel as-welded deposit, or one with almost no ferrite, is necessary, and solidification as primary austenite, or fully austenitic solidification, is expected, then the choices of both filler metals and procedures are more restricted. When designing filler metals with low or no ferrite, the producer tries to obtain raw materials with minimal sulfur and phosphorus contents. Generally, high-silicon compositions are avoided, because of their hot-cracking tendencies. Concave beads and high heat input are best avoided in procedure development. As a result, little or no filler metals are even offered commercially as EXXX-17 SMAW electrodes without ferrite. Submerged arc joining with fully austenitic filler metals is usually avoided, because of cracking problems, although submerged arc cladding is more successful. The GMAW process is often restricted to a short-circuiting transfer mode.

A general rule to follow in procedure development for fully austenitic weld metals, in order to avoid or minimize cracking problems, is to "weld ugly." In particular, this means that if cracking is encountered, then welding procedures that produce markedly convex beads can overcome it. For compositions that are very crack sensitive, it may be necessary to make individual weld beads that are so convex that part of the weld bead must be ground away before the next bead is deposited. For the most crack sensitive steels, such as type 320, crack-free welding with matching filler metal may be possible only with either small-diameter (1.6 through 2.4 mm, or 0.06 through 0.10 in.) E320-15 electrodes that are welded on the low side of the recommended current range or small-diameter ($\leq$0.9 mm, or 0.04 in.) GMAW wire in the short-circuiting transfer mode.

Niobium, phosphorus, and sulfur in such alloys generally tend to make hot-cracking problems more severe. As a result, for type 320 stainless steel, both SMAW electrodes (E320LR-15) and GMAW wires (ER320LR) are available with reduced residual elements, as well as low carbon, so that niobium can be minimized without loss of the stabilization of carbides.

Additional welding procedure approaches to eliminating hot cracking with weld metals that solidify either fully austenitic or as primary austenite include those that reduce heat buildup in the steel. Low welding heat input and low preheat and interpass temperatures are all beneficial.

Weld puddle shape has a strong influence on hot-cracking tendencies. Narrow, deep puddles crack more readily than wide, shallow puddles. In particular, it is helpful to adjust welding conditions to obtain a weld pool that is elliptical in surface shape and to avoid tear-drop-shaped weld pools, the sharp tail of which tends to promote hot cracking. Low current and slow travel speed favor an elliptical pool shape. Copper chill blocks also can help to extract heat and speed cooling.

With fully austenitic or primary austenite solidification, it is essential to backfill weld craters to avoid crater cracks, which are a form of localized hot cracking. This means stopping the travel of the arc while continuing to add filler metal, with a down-sloping current, if possible, before breaking the arc, so that the crater becomes convex, rather than concave.

It was noted earlier that the usual choice for a filler metal for austenitic stainless steel is a matching or near-matching composition to that of the base metal. However, one situation generally requires an exception. This situation occurs when a high-molybdenum base metal is chosen for pitting or crevice corrosion resistance in a chloride-containing aqueous solution. Although the high molybdenum content of the weld metal provides resistance to localized corrosion, it invariably has segregation of molybdenum on a microscopic scale. The center of each dendrite is leaner in molybdenum than are the interdendritic spaces. The center of a dendrite then becomes a preferential site for localized corrosion.

It has been found that this preferential localized corrosion in the weld metal can be overcome by using a filler metal that is higher in molybdenum than is the base metal. Thus, a 3% Mo base metal (such as type 317L) requires a filler metal of at least 4% Mo. A 4% Mo base metal (such as type 904L) requires a filler metal of at least 6% Mo. A 6% Mo base metal requires a filler metal of at least 8% Mo. However, stainless steel weld metal that contains more than 5% Mo often has poor mechanical properties. Therefore, a nickel-base alloy of at least 8% Mo is usually chosen for filler metal when joining stainless steels with contents of 4% Mo and higher. The most common filler metals selected are the ENiCrMo-3 or ENiCrMo-10 covered-electrode classifications in ANSI/AWS A5.11 and the ERNiCrMo-3 or ERNiCrMo-10 bare-wire classifications in the ANSI/AWS A5.14 specification.

Engineering for Use in the Postweld Heat-Treated Condition. Austenitic stainless steel weldments are usually put into service in the as-welded condition, except in the situations described below. When non-low-carbon grades are welded and sensitization that is due to chromium carbide precipitation cannot be tolerated, then annealing at 1050 to 1150 °C (1920 to 2100 °F), followed by a water quench, can be used to dissolve all carbides (and any intermetallic compounds, such as σ phase) and to maintain a solid solution. This annealing heat treatment also causes much of the ferrite that is present to transform to austenite.

Autogenous welds in high-molybdenum stainless steel, such as longitudinal seams in pipe, represent another exception. Annealing is used to cause the diffusion of molybdenum to erase the microsegregation of the as-welded condition, thus allowing the weld to match the pitting and crevice corrosion resistance of the base metal. Because these welds generally contain no ferrite in the as-welded condition, no ferrite is lost.

A third exception is the joints between austenitic stainless steel and carbon or low-alloy steel or the weld overlay of carbon or low-alloy steel with austenitic stainless steel filler metal. Type 309 filler metal often has been used for such a joint or overlay, so that the weld metal (especially in a multipass weld where type 309 is used throughout) contains an appreciable amount of ferrite. The HAZ of the carbon or low-alloy steel may require a PWHT at various temperatures from 600 to 700 °C (1110 to 1290 °F), depending on the specific alloy. These temperatures produce both carbide precipitation in the austenitic base metal and weld metal and transformation of ferrite to σ phase in the weld metal.

In the weld metal, carbide precipitation works against σ-phase formation because the carbides tend to precipitate where chromium is highest: at the ferrite-austenite interface. Because carbide precipitation reduces the chromium in the adjacent ferrite, some of it becomes unstable and transforms to austenite. This reduces the amount of ferrite available for σ formation. In a joint, but not in an overlay, corrosion resistance of the weld metal is seldom of concern because of the proximity of carbon or low-alloy steel. At the same ferrite content in the as-welded condition, less ferrite will be available for σ formation in type 309 than in type 309L weld metal. Therefore, the higher-carbon filler metal is often preferred for such applications.

At the same time, carbon from the mild steel or low-alloy steel immediately adjacent to the fusion line migrates to the higher-chromium weld metal, producing a layer of carbides along the fusion line in the weld metal and a carbon-depleted layer in the HAZ of the base metal. This carbon-depleted layer is weak at elevated temperatures. If the weldment is in service at suitable temperatures, then creep failure can occur there. There is also a serious mismatch in the CTE between austenitic stainless steel filler metal and carbon steel or low-alloy steel base metal. Therefore, thermal cycling produces strain accumulations along the interface and can lead to premature failure in creep, as has occurred in joints of chromium-molybdenum low-alloy steels to stainless steels. As a result, such dissimilar joints intended for elevated-temperature service are often welded with nickel-base alloy filler metals.

Although PWHT can be used for stress relief in austenitic stainless steel weldments, the yield strength of austenitic stainless steels falls much more slowly with rising temperature than does the yield strength of carbon or low-alloy steel. In addition, carbide precipitation and σ-phase embrittlement occur in the temperature range (600 to 700 °C, or 1110 to 1290 °F) where carbon steels and low-alloy steels are normally stress relieved. Significant improvement in relieving residual stresses without damaging corrosion resistance is only accomplished with a full anneal at temperatures ranging from 1050 to 1150 °C (1920 to 2100 °F), followed by rapid cooling to avoid carbide precipitation in unstabilized grades.

In stabilized grades, heat treatment at these temperatures causes niobium or titanium carbides to precipitate in part, which accomplishes much of the stabilization. However, rapid cooling is still necessary to obtain full corrosion resistance. In either case, the rapid cooling often reintroduces residual stresses, which means that this approach has to be used carefully. At the annealing temperatures, significant surface oxidation occurs in air. This oxide is tenacious on stainless steels and must be removed by pickling, followed by a water rinse, and then passivation, in order to restore full corrosion resistance.

Welding of Stainless Steels

D.J. Kotecki, The Lincoln Electric Company

Precipitation-Hardening Stainless Steels

Basic Metallurgy. PH stainless steels can be divided into three groups, based on microstructure and precipitation behavior. Martensitic PH stainless steels are solutionized at a high temperature and transform to low-carbon martensite during cooling to room temperature. Then, they are further hardened by aging at an intermediate temperature to precipitate a second phase, which can be an intermetallic compound or a single component, such as copper. Both martensite and the precipitates harden the steel.

Semiaustenitic PH stainless steels can be cooled from their solutionizing temperature to room temperature without martensite formation, remaining rather soft austenite as they cool. Then, they are aged at an intermediate temperature, which causes carbides or an intermetallic compound to precipitate. This precipitation removes alloying elements and, possibly, carbon, from the solid solution, which destabilizes the austenite, allowing it to transform to martensite upon cooling from the aging temperature. Again, both martensite and the precipitates harden the steel.

Austenitic PH stainless steels contain enough alloys to be stable austenite upon cooling from their solutionizing temperature to room temperature. They are still stable austenite upon cooling from their aging temperature after

intermetallic compounds are precipitated. In the case of austenitic PH stainless steels, only the precipitate hardens the alloy. As a result, the austenitic PH stainless steels cannot achieve tensile strengths as high as can be achieved with the martensitic or semiaustenitic grades.

Some of the PH stainless steels (some martensitic and semiaustenitic grades) can solidify as primary ferrite and have very good resistance to hot cracking. Because martensite is also ferromagnetic, a magnetic Ferrite Number loses meaning in terms of ensuring freedom from hot cracking. In the highly alloyed austenitic PH stainless steels, no ferrite is possible, and it is difficult to weld these without hot cracking.

Precipitation-Hardening Base Metals. Table 4(a) lists several PH stainless steels. Most of their applications are in the aerospace and other high-technology industries. Only one composition, the martensitic type 630 (17-4PH), is made as a welding filler metal in sufficient volume to warrant AWS classification of a matching filler metal, as can be seen in Table 4(b).

(A) METAL-CORED ELECTRODES, INDICATED BY A "C" IN PLACE OF THE "R" IN THE CLASSIFICATION, ARE ALSO INCLUDED.

Type 630 base metal (17Cr-4Ni-3Cu) is also the prototype martensitic PH stainless steel. In the solution-annealed (martensitic) condition, its yield strength is already above 750 MPa (110 ksi). The PH phase is copper, which, after aging at 480 °C (900 °F), is so fine that it can only be detected with a high-powered electron microscope. A yield strength of more than 1200 MPa (170 ksi) is obtained after this aging treatment. Higher aging temperatures coarsen the precipitate and reduce the strength.

Type 632 base metal (15Cr-7Ni-2Mo-1Al) is an example of a semiaustenitic PH stainless steel. In the solution-annealed (austenitic) condition, its yield strength is only on the order of 380 MPa (55 ksi), which is not very different from that of an ordinary austenitic stainless steel. Heat treatment at 955 °C (1750 °F) precipitates carbides and destabilizes the austenite, which transforms to martensite upon subsequent cooling. Then, aging at 510 °C (950 °F) precipitates nickel-aluminum intermetallic compounds. The aged martensite can exhibit a strength of approximately 1500 MPa (220 ksi). Again, aging at a higher temperature coarsens the precipitates and softens the steel.

Type 660 (A286) is the prototype austenitic PH stainless steel. Its high alloy content (15Cr-25Ni-1Mo-2Ti) provides higher corrosion resistance than that of the martensitic or semiaustenitic types. Furthermore, it contains no magnetic phases, which makes it suitable for use in high magnetic fields, such as those associated with superconducting magnets used for fusion energy research. Aging at about 730 °C (1350 °F) causes nickel-titanium intermetallic compound particles to precipitate, hardening the alloy. Its fully hardened yield strength (approximately 590 MPa, or 86 ksi), however, is considerably lower than that available from the martensitic or semiaustenitic grades.

Engineering for Use in the As-Welded Condition. Because PH stainless steels achieve their high strength by heat treatment, it is not reasonable to expect the weld metal to match the properties of the base metal in the as-welded condition. Therefore, the design of a weldment to be used in the as-welded condition generally must assume that the weld metal will under-match the strength of the base metal. If that is acceptable, then austenitic filler metals, such as types 308 and 309, can be suitable filler metals for the martensitic and semiaustenitic PH stainless steels. As with many of the other filler-metal selections in this article, consideration should be given to obtaining some ferrite in the weld metal to avoid hot cracking.

Example 8: Type 630 base metal (0.04C-16.5Cr-4Ni-4Cu-0.3Nb-0.02N, WRC-1992 Cr_{eq} = 16.71 and Ni_{eq} = 6.80; FN, off the diagram) to be welded with E308-16 electrode (0.05C-19.8Cr-9.6Ni-0.06N, WRC-1992 Cr_{eq} = 19.8 and Ni_{eq} = 12.55; FN = 6.2).

Assuming 30% dilution, the first weld bead would have Cr_{eq} = 18.87, Ni_{eq} = 10.83, and the calculated FN = 8.6. This is comfortably safe to ensure freedom from cracking during welding, and the weld composition is sufficiently rich in alloy that the weld metal will be stable as regards transformation of austenite to martensite. Thus, E308-16 is a good filler-metal selection, if its low strength, when compared with that of type 630 base metal, is acceptable. Clearly, type 309 filler metal would do as well.

Type A286 PH stainless steel, which is fully austenitic, presents a different situation if it is to be used in the as-welded condition. If nonmagnetic weld metal is essential, then type 310 filler metal is often the choice. Type 310 probably has the best cracking resistance of all of the fully austenitic filler metals. However, the first bead on A286 would be most at risk for hot cracking, because of the elements picked up from the A286 in the weld metal. Because a joint always presents a greater risk of hot cracking than does an overlay, a possible strategy to adopt is to first butter the A286 with type 310 weld metal. Then, welding type 310 to itself is less risky. In any event, the "weld ugly" practice of low heat input, convex beads, and so on, is always appropriate for crack-sensitive fully austenitic welds.

On the other hand, if a partially magnetic weld joint is acceptable and the weldment will not experience elevated temperatures where embrittlement could occur, then type 312 filler metal (at least for the weld deposits directly on A286) will provide the weld metal with ferrite and minimal hot-cracking risk. Once the A286 is covered with type 312 filler metal, the joint could be finished with a filler metal having a much lower ferrite content, such as type 308 or 309. However, type 309 will not provide ferrite when deposited directly on A286 with normal weld dilution.

Engineering for Use in the Postweld Heat Treated Condition. Normally, PWHT is done on a weldment of PH stainless steel because a weld-metal strength that is comparable to that of the base metal is desired. This, in turn, generally means that the weld metal must also be a PH stainless steel. Many PH stainless steel weldments are light-gage materials that readily lend themselves to autogeneous GTAW or LBW processes. Then, the weld metal matches the base metal and responds similarly to heat treatment.

Except for type 630, matching filler metals for the PH stainless steels are not very easy to locate and do not have AWS classifications. Some are covered by Aerospace Material Specifications (AMS) as bare wires only, which match base-metal compositions. These wires, used for GTAW or GMAW processes, are most likely to be available from suppliers to the aerospace industry. Alternatively, the shearing of base metal into narrow strips can provide filler metal for the GTAW process.

It is a common practice to use type 630 as a filler metal with several of the martensitic and semiaustenitic PH stainless steel base metals. The best weldment properties can then be obtained by a full-solution heat treatment, rapid cooling to room temperature, reheating to age harden at about 480 °C (900 °F), and cooling to room temperature. Because type 630 filler metal will transform to martensite upon cooling from solidification, it is also possible to obtain nearly full-strength weld metal, when using this filler metal, by simply cooling to room temperature and then aging at 480 °C (900 °F) to harden the weld metal. This presupposes that the weld metal does not pick up enough alloying elements by dilution to stabilize austenite and therefore does transform to martensite. When the weldment is simply aged after welding, without first using a solution heat treatment, some portion of the HAZ will have been overaged by the heat of welding and will become the weak link in the weldment. Then, 100% joint efficiency cannot be expected. A procedure qualification test becomes necessary to determine if the weldment strength will be adequate.

Welding of Stainless Steels

D.J. Kotecki, The Lincoln Electric Company

Duplex Ferritic-Austenitic Stainless Steels

Basic Metallurgy. Duplex ferritic-austenitic stainless steels solidify as essentially 100% ferrite. At high temperatures (on the order of 1300 °C, or 2370 °F), austenite nucleates and grows, first, at ferrite grain boundaries and, later, along preferred crystallographic directions within the ferrite grains. Diffusion of alloying elements must occur as the transformation of ferrite to austenite proceeds, with austenite-stabilizing elements (carbon, nickel, nitrogen, and copper) concentrating in the austenite, and ferrite-stabilizing elements (chromium, molybdenum, and tungsten) concentrating in the ferrite. The extent of the transformation depends not only on the balance between austenite-stabilizing elements and ferrite-stabilizing elements in the alloy, but on the time available for diffusion and on the actual diffusion of specific elements. It is possible to quench a duplex stainless steel from near the solidification temperature and to obtain nearly 100% ferrite at room temperature. Slow cooling, annealing, and hot working promote transformation of ferrite to austenite by promoting diffusion.

In a duplex ferritic-austenitic stainless steel, the optimum phase balance is usually approximately equal amounts of ferrite and austenite. Base-metal compositions are usually adjusted to obtain this phase balance as the equilibrium structure at approximately 1040 °C (1900 °F) after hot working and/or annealing. Of the alloying elements that affect the phase balance, carbon is generally undesirable for reasons of corrosion resistance. All of the other elements are slow to diffuse substitutional alloy elements, except for nitrogen. The other alloy elements contribute to determining the equilibrium phase balance, but nitrogen is most important in determining the relative ease of achieving a near-equilibrium phase balance. In developing the earliest duplex stainless steels (such as types 329 and CD-4MCu), nitrogen was not a deliberate alloying element. Therefore, under normal weld cooling conditions, the weld HAZs and matching weld metals reached room temperature with very little austenite, and had poor mechanical properties and corrosion resistance. To obtain useful properties, the welds required an annealing heat treatment, followed by quenching to avoid embrittlement of the ferrite by σ and other phases.

Overalloying of the weld filler metal with nickel causes the transformation to begin at a higher temperature, where diffusion is more rapid. Using this approach, a better phase balance can be obtained in the as-welded condition in the weld metal. However, this approach does nothing for the HAZ. Alloying with nitrogen, in the newer duplex stainless steels, usually solves the HAZ problem. With normal welding heat input and about 0.15% Ni, a reasonable phase balance is achieved in the HAZ. In addition, the nitrogen, when it diffuses to the austenite, imparts improved pitting resistance. On the other hand, if the cooling rate is too rapid and nitrogen is trapped in ferrite, then chromium nitride precipitates, damaging corrosion resistance. Therefore, low welding heat inputs should be avoided with duplex stainless steels.

The ferrite in the duplex stainless steels behaves much like a fully ferritic stainless steel in terms of formation of intermetallic compounds during heat treatment. The α, χ, and other phases can form in the temperature range from 500 to

1000 °C (930 to 1830 °F) in the base metals. High-nickel weld metals can extend the σ range to 1050 °C (1920 °F) or even higher (Ref 21). An α' embrittlement (475 °C, or 885 °F, embrittlement) can occur at temperatures as low as 250 °C (480 °F) to as high as 550 °C (1020 °F), depending on composition and time at temperature. An α' embrittlement occurs extremely slowly below approximately 350 °C (660 °F). Therefore, the American Society of Mechanical Engineers (ASME) code allows the use of UNS No. S31803 alloy at service temperatures up to 315 °C (600 °F). But, generally, the PWHT of duplex stainless steels needs to be done at temperatures above 1040 °C (1900 °F), or not at all.

It has been shown that duplex stainless steel weldments can suffer from hydrogen-induced cracking at very high hydrogen levels (Ref 22), and that lower levels damage ductility (Ref 23). This presents a special problem in duplex stainless steel weld metals, because austenite that occurs along original ferrite grain boundaries acts as a barrier to hydrogen escape. Therefore, the damage to ductility, caused by hydrogen, can remain indefinitely, in contrast to the easy escape of hydrogen from ferritic weld metals. Fortunately, α' embrittlement at 250 °C (480 °F) requires over 1000 h at temperature, whereas hydrogen escape from a 12 mm (0.5 in.) thick weldment can be achieved in about 100 h at this temperature (Ref 22). A postweld soak at this temperature can restore ductility to a hydrogen-damaged weldment.

Duplex Ferritic-Austenitic Base Metals. Tables 5(a) and 5(b) list selected duplex ferritic-austenitic stainless steel base metals and their compositions and mechanical property requirements, along with a limited number of "matching" filler metals. It is noteworthy that the yield strength of these steels is on the order of twice that of ordinary austenitic stainless steels, such as type 304 or 316L. The duplex stainless steels provide resistance to stress-corrosion cracking (SCC) in aqueous chloride-containing media. The level of resistance is generally superior to that of ordinary austenitic stainless steels, but may not be as good as that of the third-generation ferritic stainless steels described above. The newer duplex stainless steels, alloyed with nitrogen and molybdenum, also provide pitting resistance in aqueous chloride-containing media.

(A) METAL-CORED ELECTRODES, INDICATED BY A "C" IN PLACE OF THE "R" IN THE CLASSIFICATION, ARE ALSO INCLUDED.

It is common to estimate pitting resistance of these alloys according to a pitting resistance equivalent (PRE_N). Various expressions have been used to calculate pitting resistance. The most common is (Ref 24):

$$PRE_N = \%CR + 3.3(\%MO) + 16(\%N)$$

When the PRE_N exceeds 40, the duplex stainless steel is said to be a "super duplex." A critical pitting temperature (CPT) of approximately 80 °C (180 °F) in a 6% ferric chloride solution is typically observed with super duplex stainless grades. New alloy developments in this area have led to several proprietary grades that are not yet addressed in ASTM standards.

Of the duplex stainless steels, the most common is probably type 2205. It is used in pressure vessels, piping, valves, fittings, and pumps for offshore oil collection and processing; chemicals handling; desalinization; and paper mills. Its CPT is on the order of 30 °C (85 °F). More-severe environments may require the use of a duplex stainless steel with 25% Cr, of which alloy 255 is the most common. It generally offers a CPT of 35 °C (95 °F) or higher. For the most severe environments that promote SCC, pitting, and crevice corrosion, the super duplex stainless steels are finding increasing application.

Because of their high yield strengths, duplex stainless steels are more difficult to cold form than are the austenitic stainless steels. Further, because of the various high-temperature embrittlements that can occur in these alloys, forging and other hot-working processes require more care than do the same processes with austenitic stainless steels.

Engineering for Use in the As-Welded Condition. As noted above, a weld metal with a matching composition to that of duplex stainless steels often has inferior ductility and toughness, because of a high ferrite content. This problem is less critical with inert gas-shielded weld metals (GTAW or GMAW process), when compared with flux-shielded weld metals (SMAW, SAW, or FCAW processes), but it is still significant. The safest procedure for the as-welded condition is to use a filler metal that matches the base metal in all respects, except that is has a higher nickel content. It is usually better to avoid autogenous welds, especially with the very rapid cooling rates that are typical of EBW or LBW processes. With the GTAW process, especially for the root pass, it is important to design the welding procedure to limit dilution of the weld metal by the base metal. This often means using a wider than normal root opening and more filler metal in the root than one would use for an austenitic stainless steel joint.

The AWS specifications only classify two filler-metal compositions for the duplex stainless steels. The 2209 filler metal composition, used as a covered electrode for the SMAW process or as a bare wire for SAW, GTAW, GMAW, plasma arc welding (PAW), and other welding processes, is a match for type 2205 base metal, except that it has a higher nickel content, which is necessary for proper ferrite control, ductility, and toughness. It can also be used for any lower-alloyed duplex stainless. The 2553 filler metal composition, used as a covered electrode or as a bare wire, is a match for alloy 255 base metal. In general, it can also be used for all lower-alloyed base metals. This leaves only the super duplex alloys, such as 2507, without an acceptable matching or overmatching filler metal in the AWS specifications. The supplier of such base metals should be contacted for welding filler-metal recommendations.

For submerged arc welding of the duplex stainless steels, high-basicity fluxes generally provide the best results, especially if weld-metal toughness is a concern. The toughness of duplex stainless steel weld metal is strongly sensitive to oxygen content, and basic fluxes provide the lowest weld-metal oxygen content with a given wire. Because fluxes for submerged arc welding of stainless steels are not classified by the AWS, the manufacturer is the best source of information regarding flux selection.

Welding procedure development for use in the as-welded condition, in addition to filler-metal selection, involves hydrogen considerations, preheat, interpass temperature, and welding heat input. In the past, argon-hydrogen gas mixtures have been utilized to some extent in the GTAW process to achieve better wetting and bead shape. However, instances of significant hydrogen embrittlement of GTAW weldments made with argon-hydrogen gas mixtures have occurred, and this practice is best avoided for weldments used in the as-welded condition.

Covered electrodes for use in the SMAW process should be treated as low-hydrogen electrodes for low-alloy steels, that is, they should be kept in sealed containers provided by their manufacturer until they are ready for use. Alternatively, they should be held in heated ovens, typically at 125 to 175 °C (260 to 350 °F), and exposure to a humid atmosphere should be limited to a few hours, at most.

In contrast to the situation with low-alloy steels, preheat and interpass temperature control are not practiced with duplex stainless steel weldments for the purpose of hydrogen cracking protection, but for HAZ microstructure control. A minimum preheat of 100 °C (212 °F) and a maximum interpass temperature of 200 °C (390 °F) can be recommended for most duplex stainless steel weldments. This modest preheat/interpass temperature helps to slow the cooling rate to promote more-extensive austenite formation in the HAZ, without posing potential problems with α' embrittlement.

A limitation on welding heat input also serves to promote austenite formation in the HAZ, as well as in the weld metal. Heat input below approximately 1.2 kJ/mm (30 kJ/in.) tends to result in undesirably high ferrite content in the HAZ and, sometimes, in the weld metal. Further, heat input levels above approximately 4 kJ/mm (100 kJ/in.) tend to produce excessive grain growth in the HAZ and, sometimes, in the weld metal, which reduces toughness and may also promote chromium nitride precipitation (Ref 25).

Engineering for Use in the Postweld Heat Treated Condition. Longitudinal seams in pipe lengths, welds in forgings, and repair welds in castings are often annealed after welding. This involves heating to 1040 °C (1900 °F) or higher, followed by rapid cooling, usually a water quench, to avoid σ phase. Annealing permits the use of either an exactly matched filler metal or no filler metal at all, because proper annealing adjusts the phase balance to near equilibrium. Slow heating to annealing temperature permits σand other phases to precipitate during heating, because the precipitation of σ phase occurs in only a few minutes at 800 °C (1470 °F). The production of pipe lengths often includes very rapid induction heating of the pipe, so that the σ phase is completely avoided during heating, and only a brief hold near 1040 °C (1900 °F) is necessary to accomplish phase balance control.

Furnace annealing can produce slow heating. Therefore, σ phase can be expected to form during heating. It is necessary to hold at the annealing temperature for longer times (perhaps an hour or more) to ensure that all σ is dissolved. However, properly mn continuous furnaces can provide high heating rates, especially for light-wall tubes and other thin sections. If the precipitation of σ phase during heating can be avoided, long anneals are not necessary. The extremely low creep strength of duplex stainless steels at their annealing temperatures can result in severe distortion during annealing. Rapid cooling to avoid σ phase also can contribute to distortion that is due to annealing.

High-nickel filler metals can present a special problem when the weldment is to be annealed. A higher nickel content raises the minimum temperature needed to dissolve the σ phase; temperatures as high as 1100 °C (2010 °F) may be needed at levels of 9 to 10% nickel (Ref 21), especially when the molybdenum content exceeds about 3%.

A very significant loss in weld metal yield strength occurs during the annealing of duplex stainless steel weld metals (Ref 21). In the as-welded condition, the yield strength of duplex stainless weld metal, whether matching nickel (approximately 5 to 6% Ni in the weld, as in the base metal) or high nickel (approximately 8 to 10% Ni in the weld), far exceeds base-metal minimum requirements. But after annealing, especially a furnace anneal, the yield strength of the weld metal usually falls to near (or even below) base-metal minimum requirements. It is thought that the strength loss is due to loss of coherence at the austenite-ferrite interfaces. Wrought base metal does not seem to be as badly affected, partly because hot working markedly textures it, that is, it aligns ferrite and austenite in stringers parallel to the rolling direction. Higher nitrogen contents (over 0.2%) in the weld metal may be necessary to maintain weld metal-yield strength after annealing (Ref 21).

Annealing in air causes a tenacious oxide to form on the surface of the duplex stainless steels. This must be removed to obtain optimal corrosion resistance of the weldment. Pickling with nitric plus hydrofluoric acid solutions, rinsing with clear water, and passivation with a nitric acid solution usually produces the optimum corrosion resistance with duplex stainless steels. The steel supplier can provide optimal solution concentrations for each alloy.

Welding Process and Parameter Selection for Stainless Steels

Stainless steels of all types are weldable by virtually all welding processes. In part, process selection is often dictated by available equipment. Perhaps the simplest and most universal welding process is manual SMAW with coated electrodes. It has been applied to material as thin as 1.2 mm (0.05 in.), and there is no upper limit on thickness. Other very commonly used processes for stainless steels are GTAW, GMAW, SAW, FCAW, and several forms of resistance welding. The PAW, LBW, and EBW processes are also used.

Detailed discussion of all of the possible processes and parameters is beyond the scope of this article. However, the common arc welding processes are briefly discussed below, especially with regard to procedure and technique errors that can lead to loss of ferrite control with the common austenitic stainless steel weld metals that are designed to contain a small amount of ferrite (that is, solidify as primary ferrite) for protection from hot cracking.

Shielded-Metal Arc Welding. The ANSI/AWS A5.4-92 specification provides for five different electrode coating types. If the alloy to be deposited were type 308, then the five coating types would be typified by the following five electrode classifications: E308-15, E308-16, E308-17, E308-25, and E308-26. Of these, the E308-25 and E308-26 are typically very heavily coated electrodes, often made with mild-steel or lower-alloyed core wire, with all or most of the alloying elements in the coating. For these two coating types (-25 and -26), the various commercial products are not sufficiently alike to permit a statement to be made about typical current ranges for the various sizes. The -25 coating type is recommended only for direct current, electrode positive (DCEP). The -26 coating type is recommended for alternating current, as well as DCEP. Both the -25 and -26 coating types are generally limited to welding in the flat and horizontal positions. The remaining three coating types are very well standardized in existing commercial products, although the -17 type has been classified separately from the -16 type only since the 1992 edition of the ANSI/AWS A5.4 specification.

The -15 coating type is recommended for welding on DCEP only. Its slag system, which generally consists of lime and fluorspar, permits the easiest out-of-position welding of all of the stainless steel electrode coating types, especially for fixed-position pipe welding. It tends to produce a convex weld surface profile, which provides the best cracking resistance when primary ferrite solidification is not achieved. It usually requires more welder skill to make attractive-appearing welds, but it also has the greatest resistance to porosity when the electrode is exposed to moisture or when the careless welder draws a long arc. Its arc is relatively harsh, and surface ripple is coarse. In general, it produces more spatter than the other coating types.

The -16 coating type is recommended for welding both DCEP and alternating current. Its slag system, which is very high in titanium dioxide, permits fairly easy out-of-position welding, but it is generally necessary to weave slightly for vertical-up welding, which is not necessary for the -15 coating type. It tends to produce a nearly flat surface profile. The characteristics of the -16 coating that are not quite as good as those of the -15 coating type, but are more than adequate for most purposes, are its weld metal cracking resistance when no ferrite is formed; the resistance of the coating to porosity, which is due to either moisture pickup or the drawing of a long arc; and its out-of-position weldability. Its weld surface appearance, spatter level, and slag removal are generally more attractive than those of the -15 coating type.

The -17 coating type is a modification of the -16 coating type, produced by substituting silica and silicates for some of the titanium dioxide, which welds both DCEP and alternating current. The use of this coating type and a comparison to the -16 coating type were described earlier in the section on engineering for use of austenitic stainless steels in the as-welded condition.

Table 6 lists typical welding current ranges for the three more-standardized electrode coating types. Welding voltage is determined by the arc length that the welder holds. Some -16 coated electrodes, and most -17 electrodes, can be used by dragging the coating on the base-metal surface, which maintains a short arc length. This length is generally desirable, because a longer arc length permits more air to enter the arc and the weld metal. Nitrogen from the air can be picked up by the weld metal and become an alloying element. This means that the careless welder who draws a long arc with an electrode designed to produce primary ferrite solidification can add enough nitrogen to change the solidification mode to primary austenite (refer to Fig. 3, which shows that nitrogen promotes austenite and suppresses ferrite). This can result in hot cracks in a weld metal, caused by electrodes designed to produce sufficient ferrite to avoid hot cracking. The -15 coating type is the least sensitive to this error, whereas the -17 coating type is generally the most sensitive.

TABLE 6 TYPICAL CURRENT RANGES FOR STAINLESS STEEL SMAW ELECTRODES

ELECTRODE DIAM		CURRENT (DCEP), A		
MM	**IN.**	**FOR E3XX-15**	**FOR E3XX-16(A)**	FOR E3XX-17(A)

6.4	1/4	**150-225**	**200-300**	**. . .**

(A) CURRENT RANGES ARE TYPICALLY 10% HIGHER WHEN ALTERNATING CURRENT IS USED FOR E3XX-16 OR E3XX-17 ELECTRODES.

Figure 16 provides the suggested procedures for the SMAW of butt joints in stainless steel sheet and plate in the flat position. Figure 17 provides the suggested procedures for butt welds in the vertical and overhead positions. Figure 18 addresses fillet welds in the flat or horizontal positions. Figure 19 considers lap joints, and Fig. 20 considers comer joints. The information in these figures is meant only as a starting point in procedure development. Although originally developed for austenitic stainless steels, the procedures are also reasonable starting points for other stainless steels within the guidelines given elsewhere in this article.

Submerged Arc Welding. The ANSI/AWS A5.9-92 specification classifies both solid and composite (metal-cored tubular or stranded) wires that can be used for several welding processes, including submerged arc welding. Wires are classified only on the basis of their composition and whether they are solid or composite. For the ferrite-containing austenitic grades, the chromium content of a wire of a given alloy type is generally shifted to a higher level for the wires, compared with SMAW electrodes. For example, the chromium content for E308-XX electrodes ranges from 18.0 to 21.0%, but for ER308 wire, it is 19.5 to 22.0%. There is a good reason for this. The composition requirements for SMAW electrodes are for the all-weld metal deposit, that is, the finished weld, whereas the requirements for the wires are for the wire composition, the tool that is used to produce the finished weld. Some loss of chromium is to be expected in transferring the metal across the arc in SAW, as well as in gas-shielded processes. In the SAW process, chromium recovery depends strongly on the specific flux chosen and on the choice of welding parameters.

The AWS filler-metal specifications do not classify fluxes for the submerged arc welding of stainless steels. However, practical experience indicates that there are essentially three groupings of SAW fluxes with respect to chromium recovery. In submerged arc welding of carbon steels and low-alloy steels, it is common to describe fluxes as "neutral" or "active," depending on whether manganese and silicon content of the deposited weld metal vary appreciably with changes in arc voltage or flux-to-wire ratio. However, a flux that is neutral with respect to manganese and silicon recovery may be very aggressive in removing chromium from the weld metal. Therefore, "neutral" and "active" descriptions from the ANSI/AWS A5.17 (mild-steel submerged arc) or ANSI/AWS A5.23 (low-alloy submerged arc) specifications have no meaning with regard to stainless steel.

A somewhat quantitative grouping of fluxes for stainless steels relates all-weld metal chromium content to wire chromium content. A number of fluxes that are high in manganese silicate and the other oxides that are less stable than chromium oxide tend to deplete the chromium of the deposit on the order of 2%, or even more, in absolute terms. With such a flux, a wire of 21% Cr is likely to produce a deposit of only 19% Cr, which fits well with the higher chromium content of the wires of ANSI/AWS A5.9, when compared with the electrodes of ANSI/AWS A5.4. With such fluxes, a higher arc voltage, or any other change that tends to increase the ratio of flux melted to wire melted, will tend to reduce the chromium recovery further. These fluxes are sometimes referred to as "acid" fluxes.

A second group of fluxes for stainless steels are those composed primarily of oxides of calcium, magnesium, titanium, and aluminum, along with calcium fluoride. These compounds are more stable than chromium oxide. Fluxes of this group tend to produce only a small loss of chromium, typically on the order of 0.5 to 1.0%, in absolute terms, when compared with the wire compositions. With such fluxes, a higher voltage, or any other change that tends to increase the ratio of flux melted to wire melted, produces only a small increase in chromium loss. These fluxes are sometimes referred to as "basic" fluxes.

A third group of fluxes for stainless steels are those that include, in the individual flux particles, particles of chromium metal or alloy. The amount of this chromium is usually only slightly more than that needed to make up for the chromium that is lost to oxidation during welding. Therefore, a small chromium increase, typically on the order of 0.5 to 1%, is observed in the weld metal, when compared with the wire. This chromium gain may increase with increase in arc voltage, or with any other welding parameter change that increases the ratio of flux melted to wire melted. These fluxes are sometimes referred to as "chromium-compensating" fluxes.

Loss of chromium not only means loss of some corrosion resistance, but also loss of ferrite in nominally austenitic stainless steel weld metals that are intended to contain some ferrite. The use of an acid flux is likely to produce about 5 FN less than the Ferrite Number calculated from the wire composition using Fig. 3. The use of a basic flux is likely to produce almost the same Ferrite Number as that calculated from the wire composition using Fig. 3. The use of a chromium-compensating flux is likely to produce as much as 5 FN, or more, greater than the FN value calculated from the wire composition using Fig. 3.

A further consideration in flux selection is carbon recovery with martensitic stainless steels. The acid fluxes tend to remove considerable carbon from high-carbon stainless steels, so that the ability to achieve a given hardness level is affected. The basic fluxes tend to recover nearly all of the wire carbon. The chromium-compensating fluxes can do either, depending on the specific oxide balance in a given flux. The use of either an acid flux or a chromium-compensating flux with a martensitic stainless steel wire like ER410 may produce ferrite stringers in what ought to be a fully martensitic deposit. As a result, the mechanical properties may be inferior.

Submerged arc welding permits much broader ranges of current for a given electrode size than does the SMAW process. Current is largely determined by wire feed speed, although increased electrode extension ("stickout") will decrease current at a given wire feed speed. Figure 21 presents typical wire feed speed ranges for a variety of solid electrode sizes

and the corresponding welding currents with austenitic filler metals. Other current ranges result when either composite or martensitic wires are used, because the electrical resistance of these wires differs from that of the austenitic wires. Nevertheless, Fig. 21 can provide a starting point. In general, as the wire feed speed is increased, a corresponding voltage increase is appropriate for the best bead shape. Typically, 26 to 28 V produce the best results at the bottom end of the wire feed speed range, and 32 to 36 V produce the best results at the top end of the wire feed speed range.

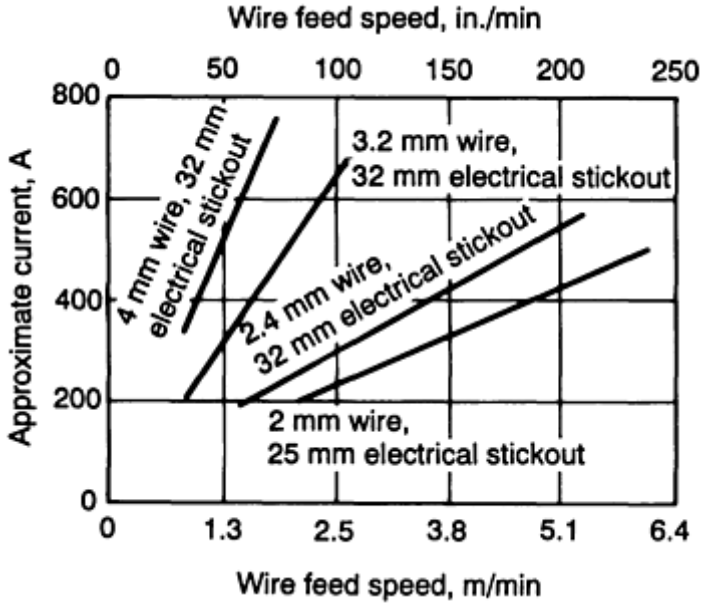

FIG. 21 CURRENT (DCEP) VERSUS WIRE FEED SPEED FOR SUBMERGED ARC WELDING WITH E3XX STAINLESS STEEL ELECTRODES. SOURCE: REF 27

Because there is no classification system for submerged arc fluxes for stainless steels, and because the broad range of chromium recovery that is possible depends on the specific flux chosen, either the advice or literature of the flux manufacturer should be obtained before using an unfamiliar flux.

Figures 22 and 23 provide joint preparations that have proven useful in submerged arc butt welding of stainless steel plate. Figure 24 provides copper backing information for one-side butt welding using the SAW process. Circumferential welding on tubular components is usually done by off-setting the welding head from top-dead-center, so that solidification occurs in the flat position, slightly uphill or slightly downhill. This affects the weld profile, as shown in Fig. 25.

Gas-Tungsten Arc Welding. The GTAW process is widely used for welding stainless steels, especially for full-penetration welds in thin-gage materials and root passes in thicker materials. For almost all gas-tungsten arc welding of stainless steels, thoriated tungsten electrodes (ANSI/AWS A5.12 classification EWTh-2) are preferred, and welding utilizes argon gas shielding with direct current, electrode negative (DCEN) polarity. For heavy sections, sometimes helium or argon-helium mixes can be used to achieve greater heat input or higher welding speeds.

Additions of hydrogen (on the order of 5%) to argon gas shielding have also been used, primarily for austenitic stainless steels, to provide higher heat input and a cleaner weld surface. Hydrogen additions are a possible source of embrittlement for all other types of stainless steels. Both manual and automatic procedures are suitable. In automatic welding, a voltage-controlled head can be used to maintain a constant arc length, and either cold-wire or hot-wire filler-metal additions are used.

Many welds in tubing and light-gage material are made without filler-metal additions, using square butt joints, lap joints, edge joints, corner joints, and the like. Then, the weld metal has nearly the same composition as the base metal. When welding austenitic stainless steels such as type 304 or 316, ferrite is usually desirable in the weld metal, but attempts to measure ferrite in the base metal before welding will generally detect no ferrite. This is not a cause for alarm, because the hot-working operations that were conducted to reduce the original stainless steel ingot to the final form generally cause all ferrite in the base metal to be transformed to austenite. Steelmakers generally prefer to adjust the composition of a stainless steel ingot to contain a small amount (typically 3 to 8 FN) of ferrite as cast, because this improves resistance to the ingot breaking up during the first reductions. Thus, their interest is similar to that of the welding engineer. Although no ferrite may be present after hot working, remelting during welding will return the original as-cast ferrite, which means that ferrite is usually found in the weld metal of autogenous joints in types 304, 316, and similar stainless steel alloys.

The potential for ferrite in an autogenous joint can be assessed from the base-metal certified material test report (CMTR) using the WRC-1988 diagram. To be truly useful for this purpose, the CMTR should include nitrogen. If the CMTR indicates that no ferrite is likely in the autogenous weld, then the addition of a filler metal that will provide ferrite ought to be considered, at least for base metals that normally can be expected to provide some ferrite in near-matching weld-metal compositions.

Filler metals for the GTAW process are classified according to the ANSI/AWS A5.9 specification, and many are listed in Tables 1(a), 1(b), 2(a), 2(b), 3(a), 3(b), 4(a), 4(b), 5(a), and 5(b). Similar compositions in the form of consumable inserts, classified to the ANSI/AWS A5.30 specification, are also available for full-penetration root-pass welding. The consumable inserts provide a little surplus filler metal in order to attain an underside profile that is slightly convex. Consumable inserts can also be purchased with a variety of special shapes that assist in joint alignment, especially for welding pipe.

Pipe and tube welds are often made with a backing gas inside in order to prevent oxidation of the root surface. Although argon backing gas is the safest choice, it is more expensive than nitrogen, which has also been used. Small amounts of nitrogen from backing gas can be picked up in the weld metal, and cases are known where such nitrogen pickup was responsible for loss of ferrite and consequent hot cracking. Nevertheless, many successful welds have been made with nitrogen backing gas.

In the gas-tungsten arc welding of fully austenitic stainless steels, it is often advisable to add filler metal even when it does not appear to be needed. The proper addition of filler metal can be used to obtain a convex bead shape, which has better resistance to hot cracking than does the flat or slightly concave weld shape that often results when no filler metal is added. This can be of critical importance when welding fully austenitic stainless steels without cracking.

The successful gas-tungsten arc welding of nominally austenitic stainless steels (the weld metals of which are designed to contain a little ferrite) can depend on the integrity of the gas shield. Drafts, low gas-flow rates, or excessively high gas-flow rates can cause air (which is about 80% nitrogen) to enter the arc. Nitrogen is then picked up by the weld metal, and a weld, which ought to contain ferrite, can be rendered ferrite-free and sensitive to hot cracking. Proper gas-flow rates, typically 0.3 to 0.8 m^3/h (10 to 30 ft^3/h), and barriers that prevent moving air from reaching the arc area can be used to prevent nitrogen pickup. Special attention to the integrity of both shielding gas and backing gas can be especially important in the successful welding of third-generation ferritic stainless steels, which can be embrittled by traces of nitrogen that are picked up during welding.

Gas-tungsten arc welding can be done with a broad range of welding currents for most applications, with travel speed adjusted to make the proper size of weld for the current chosen. Each individual tungsten electrode size has a corresponding proper current range. These current ranges are not particular to stainless steels. Figure 26 provides some welding procedure information for beginning procedure development in the gas-tungsten arc welding of stainless steels.

Special attention should be given to the role of sulfur and other surface-active elements in controlling penetration in full-penetration GTAW welds. It has been amply demonstrated that sulfur levels on the order of 0.005% and lower tend to produce penetration profiles with very low depth-to-width ratios, because of surface tension gradient effects. On the other hand, sulfur levels of 0.010% and higher seem to ensure a high depth-to-width ratio, which is desirable for full-penetration butt welds (Ref 28).

When searching for a small amount of filler metal for a GTAW application, especially in repair situations, it is not uncommon for the welder and/or engineer to be tempted to remove the coating from a covered electrode of nominally matching composition to a given base metal, and to use the core wire for GTAW filler metal. This can be a very risky approach, because the coating of many covered stainless steel electrodes provides alloy elements. The core wire may not be close to the weld-metal composition. For example, it is not uncommon to produce type 347 weld metal from a covered electrode whose core wire is type 308, and has all of the niobium in the coating. It is also not uncommon to produce type 317L covered electrodes using type 316L core wire. Some stainless steel electrodes are made from mild-steel core wire, and have all of the alloy in the coating. Therefore, before attempting a gas-tungsten arc weld with the core wire from a covered electrode, those concerned should contact the electrode manufacturer to determine what core wire was used to make the electrode.

Gas-Metal Arc Welding. The GMAW process is extensively used for joining both thin and thick stainless steel base metals. Filler metals are classified to the ANSI/AWS A5.9 specification, as are filler metals for submerged arc or gas-tungsten arc welding. For many applications with nominally austenitic filler metals that are intended to contain a little ferrite, high-silicon versions of the basic classifications are preferred for better wetting and bead shape. These high-silicon versions contain from 0.65 to 1.00% Si, versus 0.30 to 0.65% for the normal grades.

With thin materials, the short-circuiting transfer mode is primarily used, with 0.9 mm (0.035 in.) and 1.1 mm (0.045 in.) diameters being the most common. The preferred shielding gas is often a mixture of 90% He, 7.5% Ar, and 2.5% CO_2. Helium-rich gases provide higher voltage in short-circuiting transfer welding, resulting in better wetting and fewer problems with lack-of-fusion defects than occur with argon-rich gases. However, argon-rich gas may be preferred for welding on very thin materials. Typical welding conditions for short-circuiting transfer welding are given in Table 7 and Fig. 27. Short-circuiting transfer is usable both in the flat position and out of position.

With thicker materials, the spray-transfer mode is most often used. In addition to the same two common diameters used in short-circuiting transfer, a 1.6 mm ($\frac{1}{16}$ in.) diameter is often used. The most common shielding gases are argon-rich mixtures, such as argon with from 1% to 5% O, argon with a few percent of carbon dioxide, or argon with both oxygen and carbon dioxide added. Typical welding conditions for spray transfer are given in Table 8 and Fig. 28. Spray-transfer welding is limited to the flat and horizontal positions.

With special pulsing power sources, a spray-like transfer can be produced at a much lower average welding current, more like that of the short-circuiting transfer mode. Pulsed gas-metal arc welding can permit out-of-position welding. So-called "synergic" power sources are claimed to automatically adjust pulse frequency to produce the transfer of a single drop with each pulse, despite variations in electrical stickout or wire feed speed. The pulsed GMAW process is an area of rapid technological development at the present time.

All gas-metal arc welding conducted with nominally austenitic filler metals that are intended to produce a little ferrite is sensitive to the integrity of the gas shielding, as is the GTAW process. Drafts and gas turbulence can permit air to enter the gas stream, resulting in nitrogen pickup and loss of ferrite. As with gas-tungsten arc welding, proper gas-flow rates (0.8 to 1.1 m^3/h, or 30 to 40 ft^3/h) and the use of barriers to exclude drafts from the arc area are essential to shielding gas integrity.

Flux-Cored Arc Welding. The ANSI/AWS A5.22 specification provides for three different classifications of a given alloy type, based on recommended shielding. Using type 308L as an example, an electrode can be classified as E308LT-1 (carbon dioxide shielding), E308LT-2 (Ar-2O shielding), or E308LT-3 (no gas shielding).

In practice, E308LT-1 (and other alloy wires designed for carbon dioxide gas shielding) are usually used in small diameters, that is, 1.6 mm ($\frac{1}{16}$ in.) and 1.1 mm (0.045 in.). Even 0.9 mm (0.035 in.) diameters are becoming available. Despite the use of carbon dioxide shielding gas, low-carbon-deposit compositions can be produced. Many of these wires, especially in 1.1 mm (0.045 in.) and smaller diameters, are welded in the vertical-up and overhead positions, as well as in the downhand position. Although the wires are classified with carbon dioxide gas shielding, in many cases they weld better in the vertical-up and overhead positions with Ar-25CO_2 shielding. The small-diameter wires are generally made from austenitic stainless steel strip (often type 304L), which work hardens very much during reduction to its final diameter. Thus, these wires are mechanically rather hard and tolerate high feed-roll pressures. Equipment for feeding such wires can be the same as for GMAW solid wires.

It is doubtful that there are any flux-cored stainless steel wires that are correctly classified with Ar-2O. The reason for this statement is that the scope of the ANSI/AWS A5.22 specification requires that a wire classified as flux cored must contain a minimum of 5% nonmetallics, by weight of the electrode. This much slag is not compatible with very high argon gas shielding. Certain metal-cored electrodes seem to be improperly classified as EXXXT-2, but they have almost no nonmetallic ingredients and are more properly classified as composite electrodes, according to the ANSI/AWS A5.9 specification.

In practice, E308LT-3 electrodes (and other stainless steel alloy compositions designed for welding without gas shielding) are commonly available in somewhat larger sizes than are the carbon dioxide classifications. The most popular size is still 2.4 mm ($\frac{3}{32}$ in.), although 2.0 mm ($\frac{5}{64}$ in.) and 1.6 mm ($\frac{1}{16}$ in.) sizes are also popular. These wires are generally usable only in the downhand and horizontal positions. In contrast to the carbon dioxide shielded wires, these wires generally produce rather shallow penetration. This feature can require somewhat higher welder skill levels to make sound x-ray quality welds, because of the dangers of slag entrapment. Higher travel speed is usually necessary when this defect is encountered. On the other hand, this shallow penetration is a major advantage for cladding operations, and these electrodes have been extensively used to achieve fully alloyed low-carbon overlays in a minimum number of layers.

The 2.4 mm (0.10 in.) electrodes, typified by E308LT-3, are generally made from thin, mild-steel strip, with all alloying elements in the core. This makes for a mechanically soft wire that often requires special U-grooved gear drive rolls for the wire feeder. Such drive rolls can grip the wire positively all around its circumference and do not tend to flatten the wire, which results in the best feeding characteristics. Special drive-roll conversion kits are offered for feeding these and other very soft wires. Some 2.0 mm (0.08 in.) diameter wires are also very soft, and similar drive rolls may be necessary.

The flux-cored wires designed for use without gas shielding are virtually immune to any effects of drafts on weld-metal ferrite content. They generally produce a fairly heavy fume plume, which means that fume extracting welding guns or other local exhaust systems can be desirable. Because of their immunity to drafts, these wires lend themselves very well to local exhaust.

On the other hand, the wires designed for use without shielding gas are sensitive to nitrogen pickup that is due to excessive arc length, as are SMAW coated electrodes. A proper balance between wire feed speed (current) and voltage will ensure proper ferrite control with such electrodes (Ref 29).

The wires designed for use with carbon dioxide (or Ar-25CO_2) are sensitive to loss of shielding gas, caused by drafts or inappropriate gas-flow rates, although less so than solid wires in the GMAW process. Protection from drafts is necessary for ferrite control, and local exhaust must be used with care so as not to disturb the gas shield. Otherwise, nitrogen can be picked up by the weld and ferrite can be lost. These wires also appear to have a greater tendency to pick up moisture from humid air if they are carelessly stored for long periods of time. Moisture pickup is often evidenced by "worm track" porosity (surface porosity elongated parallel to the solidification direction). This can often be eliminated by increasing the electrical stickout to preheat the wire, but care must be used to avoid loss of gas shielding.

A simple technique is to recess the contact tip approximately 5 to 10 mm (0.2 to 0.4 in.) behind the end of the shielding gas cup, and to then weld with normal distance between the gas cup and the workpiece. In extreme cases of moisture pickup, the wire may require a bake at 260 to 315 °C (500 to 600 °F) to remove the moisture. In humid weather, it is best to return gas-shielded flux-cored stainless steel wires to their packaging, or to store them in a tight plastic bag or in a low-temperature oven (100 °C, or 212 °F), if the wire is not to be used overnight.

Welding of Cast Irons*

Roger A. Bushey, The ESAB Group, Inc.

Introduction

THE FIRST STEP in selecting the type of welding process and consumable to use for welding cast iron is to determine what type or grade of casting needs to be welded. This discussion is not intended to cover all types of cast irons available on the market today (Table 1), but will discuss the major types of cast irons (that is, gray, ductile, malleable, white, and compacted graphite).

TABLE 1 CLASSIFICATION OF CAST IRON BY COMMERCIAL DESIGNATION, MICROSTRUCTURE, AND FRACTURE

COMMERCIAL DESIGNATION	CARBON-RICH PHASE	MATRIX[A]	FRACTURE	FINAL STRUCTURE AFTER
GRAY IRON	LAMELLAR GRAPHITE	P	GRAY	SOLIDIFICATION
DUCTILE IRON	SPHEROIDAL GRAPHITE	F, P, A	SILVER-GRAY	SOLIDIFICATION OR HEAT TREATMENT
COMPACTED GRAPHITE IRON	COMPACTED VERMICULAR GRAPHITE	F, P	GRAY	SOLIDIFICATION
WHITE IRON	FE_3C	P, M	WHITE	SOLIDIFICATION AND HEAT TREATMENT[B]
MOTTLED IRON	LAMELLAR GR + FE_3C	P	MOTTLED	SOLIDIFICATION
MALLEABLE IRON	TEMPER GRAPHITE	F, P	SILVER-GRAY	HEAT TREATMENT
AUSTEMPERED DUCTILE IRON	SPHEROIDAL GRAPHITE	AT	SILVER-GRAY	HEAT TREATMENT

(A) F, FERRITE; P, PEARLITE; A, AUSTENITE; M, MARTENSITE; AT, AUSTEMPERED (BAINITE).

(B) WHITE IRONS ARE NOT USUALLY HEAT TREATED, EXCEPT FOR STRESS RELIEF AND TO CONTINUE AUSTENITE TRANSFORMATION.

Cast iron can be described as an alloy of predominantly iron, carbon, and silicon. Commercially produced irons contain manganese and may be alloyed with nickel, chromium, copper, molybdenum, tin, antimony, vanadium, and various other elements either by themselves or in combinations.

Cast iron is produced by adding excess amounts of carbon to an austenite structure. During solidification, a portion of this carbon separates from the melt as either iron carbide or graphite. The form that the excess carbon takes is determined by the rate of cooling. If the cooling is rapid, the carbon will solidify as iron carbide. If the cooling is slow, the carbon will solidify as graphite. The type of carbon present and its shape will determine the type and, in particular, the properties of the cast iron. These properties are of prime importance when considering the welding procedure to be used. A flowchart illustrating the structure of the common types of commercial cast irons, as well as the processing required to obtain them, is shown in Fig. 1.

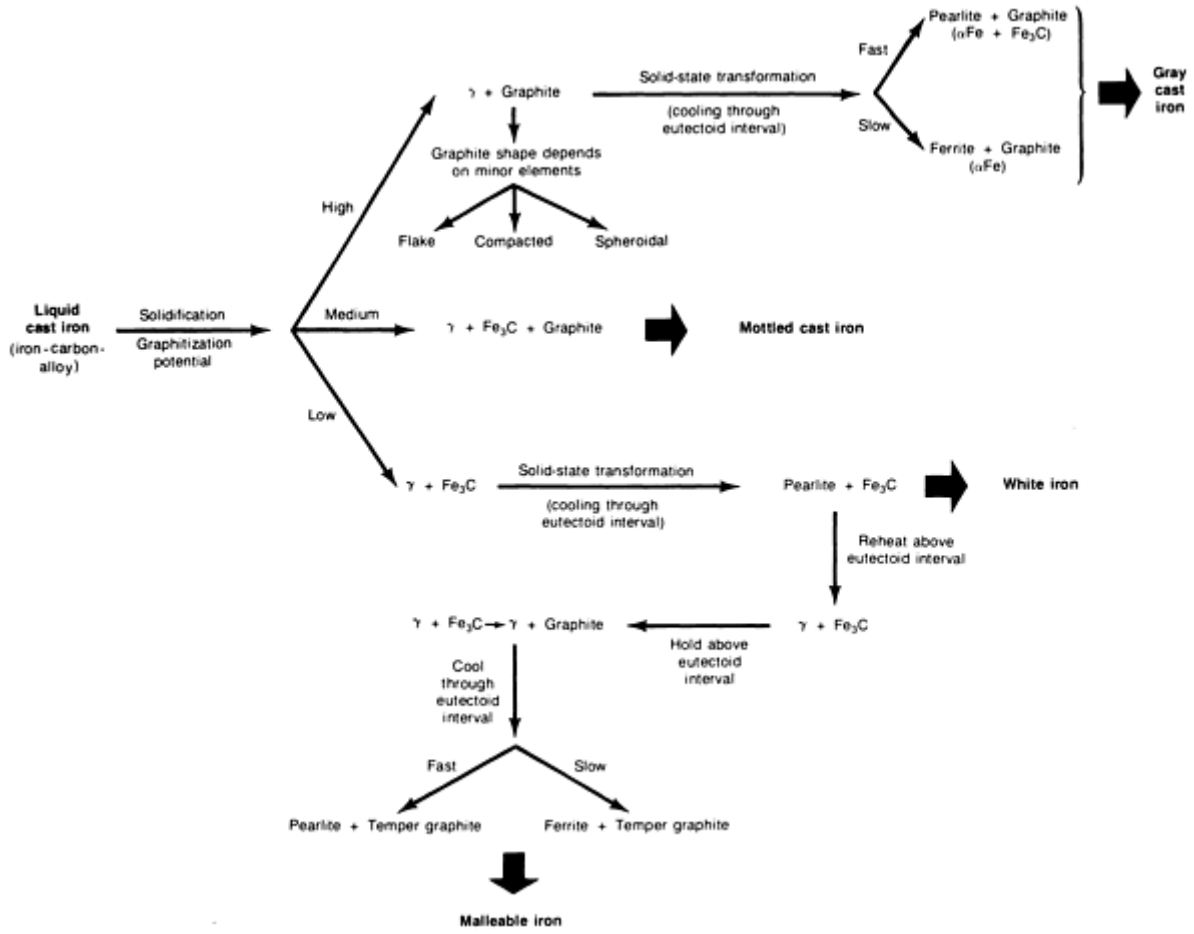

FIG. 1 FLOWCHART SHOWING BASIC MICROSTRUCTURES AND PROCESSING STEPS REQUIRED TO OBTAIN COMMON COMMERCIAL CAST IRONS

Welding of Cast Irons*

Roger A. Bushey, The ESAB Group, Inc.

Classification

Historically, the first classification of cast iron was based on its fracture. Two types of iron were initially recognized:

- *WHITE IRON:* EXHIBITS A WHITE, CRYSTALLINE FRACTURE SURFACE BECAUSE FRACTURE OCCURS ALONG THE IRON CARBIDE PLATES; IT IS THE RESULT OF METASTABLE SOLIDIFICATION (FE_3C EUTECTIC)
- *GRAY IRON:* EXHIBITS A GRAY FRACTURE SURFACE BECAUSE FRACTURE OCCURS ALONG THE GRAPHITE PLATES (FLAKES); IT IS THE RESULT OF STABLE SOLIDIFICATION (GR EUTECTIC)

With the advent of metallography, and as the body of knowledge pertinent to cast iron increased, other classifications based on microstructural features became possible:

- *GRAPHITE SHAPE:* LAMELLAR (FLAKE) GRAPHITE, SPHEROIDAL (NODULAR) GRAPHITE, COMPACTED (VERMICULAR) GRAPHITE, AND TEMPER GRAPHITE; TEMPER GRAPHITE RESULTS FROM A SOLID-STATE REACTION (MALLEABILIZATION)
- *MATRIX:* FERRITIC, PEARLITIC, AUSTENITIC, MARTENSITIC, BAINITIC (AUSTEMPERED)

This classification is seldom used by the floor foundryman. The most widely used terminology can be made in two categories:

- *COMMON CAST IRONS:* FOR GENERAL-PURPOSE APPLICATIONS, THEY ARE UNALLOYED OR LOW-ALLOY
- *SPECIAL CAST IRONS:* FOR SPECIAL APPLICATIONS, GENERALLY HIGH-ALLOY

The correspondence between commercial and microstructural classification, as well as the final processing stage in obtaining common cast irons, is given in Table 1. Special cast irons differ from the common cast irons mainly in the higher content of alloying elements (>3%). Higher alloy content promotes microstructures with special properties for elevated-temperature applications, corrosion resistance, and wear resistance.

Gray Cast Iron

Gray cast iron is the most common form of cast iron. The excess carbon solidifies as flakes of graphite. This type of cast iron has moderate strength, excellent damping and machinability, but poor ductility. It contains 2 to 4% C, 1 to 3% Si, and up to 1% Mn, and has a tensile strength of up to 275 MPa (40 ksi).

The properties and the microstructure of gray iron can be altered with additions of alloying elements. The tensile strength of these alloyed gray cast irons can be as high as 550 MPa (80 ksi). Because of these many variables and different alloying systems, special welding procedures may be required. Because of the alloys added, some gray iron can be considered unweldable.

White Cast Iron

If cooling is rapid, then the excess carbon remains in the metastable form of iron carbide. This material is referred to as white cast iron. Because it contains a large amount of this intermetallic compound, white cast iron is very brittle, greatly reducing its ductility and weldability. The formation of iron carbide does improve hardness and abrasion resistance in these cast irons.

If large amounts of this iron carbide (also referred to as cementite) are present, the material is prone to cracking and is considered unweldable. White cast iron contains 2.5 to 3.8% C, 0.2 to 2.8% Si, and as much as 5.5% Ni, 30% Cr, 6.5% Mo, and 30% Mn, if designed for wear resistance. Tensile strengths can range from 160 to 620 MPa (23 to 90 ksi).

Malleable Cast Iron

White iron, if given the proper heat treatment, can transform into a ductile form of cast iron known as malleable iron. The iron carbides present are dissociated during a high-temperature anneal above 870 °C (1600 °F) for more than 60 h. During this process, irregularly shaped graphite nodules are precipitated and grow in the solid iron matrix. If the atmosphere in the furnace is of an oxidizing nature, some of the carbon will be oxidized, producing a white-heart malleable iron that is considered weldable. If the atmosphere is of a reducing nature, the entire amount of carbon is retained, and the material is a blackheart malleable iron, considered unweldable.

Malleable cast iron contains 2 to 2.8% C and 1 to 1.7% Si. Tensile strengths can range from 310 to 620 MPa (45 to 90 ksi) and elongations from 2 to 20%.

Ductile Cast Iron

Adding nodularizers, such as manganese or rare earths, makes the carbon solidify as small spheroids instead of flakes. Graphite in spheroidal form causes minimal interruption in the continuity of the metallic matrix. This is the most favorable form in which the graphite can be dispersed in order to achieve the desired mechanical properties. Ductile cast irons possess the highest strength and ductility of the cast irons. They combine the principal advantages of gray iron (machinability) with the advantages of steel (high strength, toughness, ductility, hot workability, and hardenability).

Ductile iron (also known as spheroidal graphite or nodular iron) typically contains 3 to 4% C, 1.8 to 2.8% Si, and a maximum of 0.7% Mn. Manganese levels are sometimes restricted if impact properties are important. Higher manganese content in the heat-affected zone during welding can reduce the impact resistance of the weld. Ductile iron has tensile strengths of 415 to 830 MPa (60 to 120 ksi). Alloying additions are sometimes made to ductile irons to improve heat and corrosion resistance. These alloyed grades can contain 2 to 3% C, 1 to 6% Si, 0.7 to 2.4% Mn, 18 to 36% Ni, and up to 5.5% Cr.

The matrix of ductile irons can be varied by heat treatment, alloying, or casting practices. The common as-cast product is 65-45-12. This designation means it has a tensile strength of 65 ksi (450 MPa), a yield strength of 45 ksi (310 MPa), and a tensile elongation of 12%. If this matrix, which has a 10 to 20% pearlite structure, is annealed, the structure becomes ferritic, producing a 60-40-18 iron material. Many different types of higher-strength grades can be produced. In general, as the strength of the iron increases, so do the problems that can be experienced during welding.

Compacted Graphite

Compacted graphite, or vermicular graphite, irons have structures and properties that are in between those of gray irons and ductile irons. The graphite forms interconnected flakes as in a graphite iron, but the flakes are thicker. Compacted graphite iron has better machinability and damping characteristics than ductile iron, but has improved ductility.

Welding of Cast Irons*

Roger A. Bushey, The ESAB Group, Inc.

Weldability

Many microstructural and mechanical properties can be obtained in a cast iron. Therefore, there is a wide range to their weldability. White cast iron is generally considered unweldable, while a ductile iron is generally easier to weld than gray iron.

During welding, a full spectrum of thermal gradients is experienced across the weldment and into the heat-affected zone of the cast iron. This results in many different microstructures and properties. The various microstructures can be classified into different zones and regions, as shown in Fig. 2. The nature and relative size of these zones will be determined by the heat generated during welding, the composition of the iron casting being welded, and the welding consumable used. Each zone will be discussed separately to provide a better understanding of the zones themselves and how welding procedures can affect their characteristics.

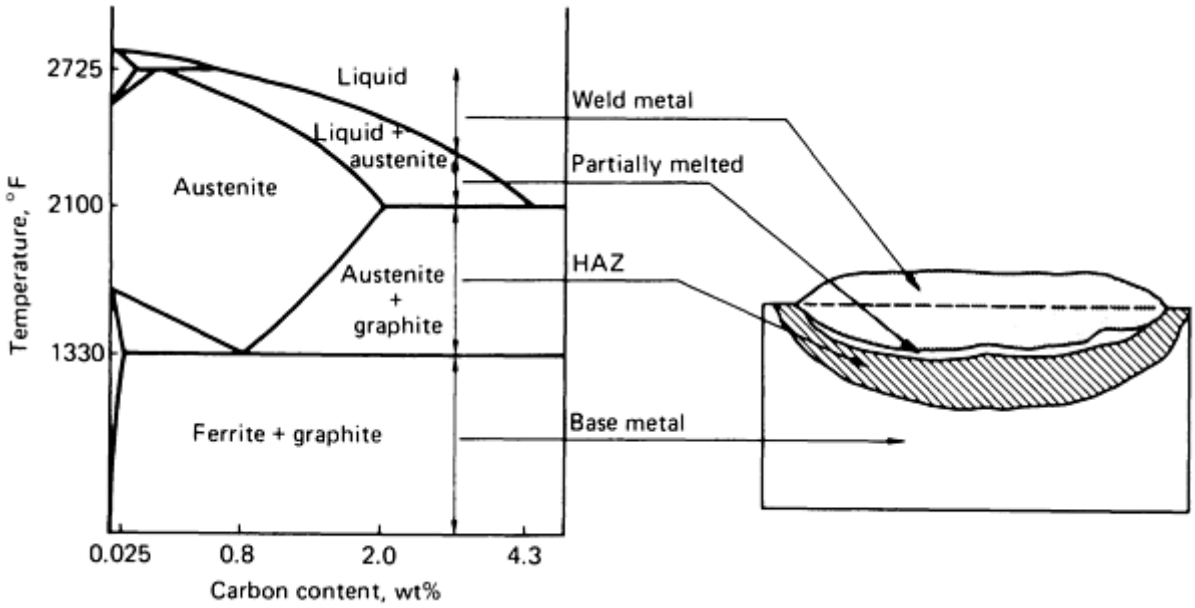

FIG. 2 SCHEMATIC REPRESENTATION OF THE TEMPERATURE ZONES IN A TYPICAL CAST IRON WELDING

Heat-Affected Zone (HAZ). The welding process by its nature is characterized by rapid cooling when compared to a casting procedure. Therefore, the properties of the weld--as well as the sections of the casting exposed to these high temperatures, known as the heat-affected zone--can be different from the rest of the casting.

During welding, the carbon can diffuse into the austenite. When cooling occurs, this austenite transforms to martensite. This martensitic structure is very brittle and susceptible to cracking. The amount of martensite formed depends on the chemistry or type of cast iron and on the thermal history. The brittle martensitic structure can be modified by tempering using preheat and interpass temperature control, by multiple-pass welding (stringer beads), or by a postweld heat treatment.

The partially melted region is an area next to the HAZ where the heat of the weld has been high enough to cause partial melting of the base metal, near the fusion line. This is the most critical zone in the weld, because upon cooling, this area freezes as white iron (that is, when held at high temperature long enough for carbon to dissolve) due to the high cooling rates. The region is very complex and may contain many different types of microstructures. If the amount of graphite dissolved during welding is high enough and forms a continuous molten matrix, it is likely that the carbide network will also be continuous, leading to problems. Because the partially melted region contains a great proportion of hard products, it is the hardest zone of the weld.

The high hardness and resulting low toughness make this region responsible for many of the mechanical problems experienced in the welding of cast iron. The most effective way to reduce the severity of cracking problems is to reduce the peak temperatures and the duration at the high temperatures. This can be controlled by heat input, preheat, interpass temperature, and proper filler metal selection.

The use of a low melting point filler metal will help reduce the peak temperature experienced in the partially remelted region. However, if a weldment is sufficiently small and a high heat input was used, the temperature of the base metal may be raised enough to cause severe fusion line problems even if no preheat was used. If, on the other hand, a high preheat temperature was used to prevent the formation of martensite in the HAZ and reduce the stresses, fusion line cracking may occur even with a low heat input. Some amount of trial-and-error procedure testing may be necessary. A welding procedure that can handle the partially melted region and the HAZ will likely produce a successful weld.

Fusion Zone. The properties and microstructure of the fusion zone are dictated by the welding consumable used. This area is made up of the melted filler metal consumable and some dilution from the iron casting. Because of the turbulence of the weld pool, the weld deposit has a relatively uniform composition. All efforts should be made to minimize the dilution.

Identification of Iron Casting. It is important to determine the type of casting to be welded in order to ensure the best weldment possible. If the type of casting is not known, it will be necessary to try and obtain this information. Records kept on the material purchased may indicate the type or manufacturer of the iron casting. Examination of a small piece under the microscope will indicate its structure. Some of the newer types of cast irons available today are difficult to distinguish from one another; much experience is usually needed. A detailed chemical analysis and hardness level of the cast iron will also help in classifying the material. If all else fails, the casting should be assumed to be a gray cast iron, and caution should be exercised when proceeding.

Weldability of a Casting. One attempt to classify the weldability of a casting is given in Ref 1. The document describes techniques to determine a no-crack temperature based on a carbon equivalent (CE) number. In order to obtain an accurate CE number, the following new CE formula was devised:

$$CE = C + 0.31\ SI + 0.33\ P + 0.45\ S - 0.028$$
$$Mn + Mo + Cr - 0.02\ Ni - 0.01\ Cu$$

The no-crack temperature can then be found for the specific casting under test by using Fig. 3. The procedure was used to show a correlation between the CE of a casting and a no-crack temperature. These data should be used only as a guide to establish a preheat temperature for a casting. Many factors other than preheat affect the ability to produce a sound weld. These include filler metal selection, peening, heat input, local contaminants, trapped sand, and absorbed lubricants in the casting.

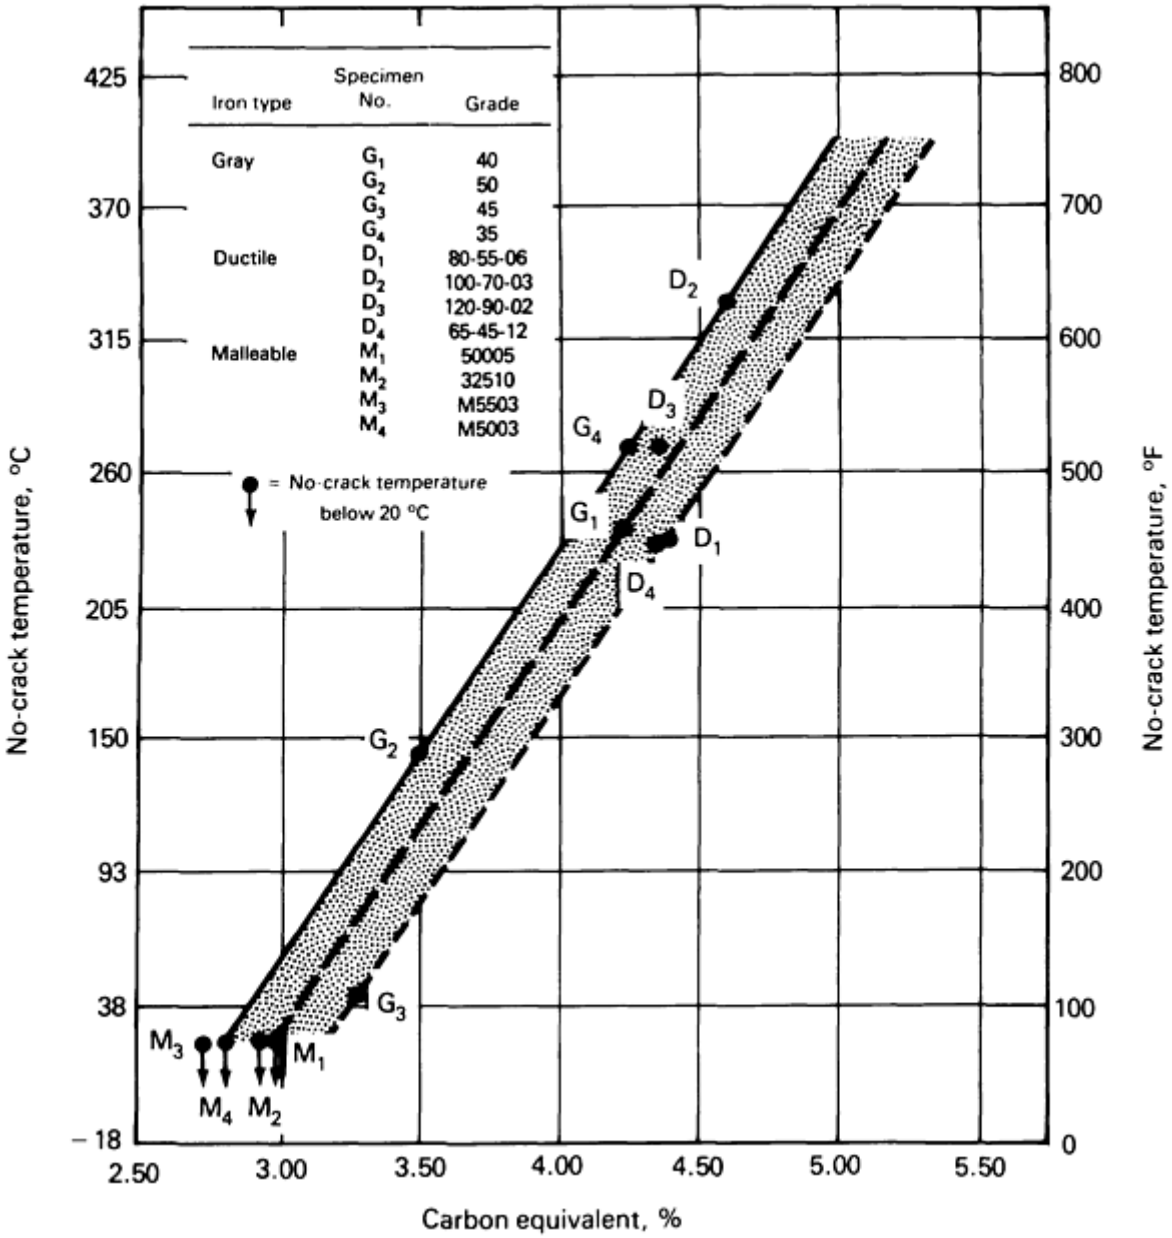

FIG. 3 EFFECT OF CARBON EQUIVALENT ON NO-CRACK TEMPERATURE FOR SELECTED GRADES OF IRON CASTINGS. SOURCE: REF 1

Preheat. One of the most important considerations in welding cast irons is the use of preheat. It:

- PREVENTS CRACKING CAUSED BY TEMPERATURE GRADIENTS AND THERMAL STRESSES
- REDUCES RESIDUAL STRESSES IN THE CASTING
- REDUCES DISTORTION
- REDUCES HARDNESS OF THE HAZ
- REDUCES TEMPERATURE GRADIENTS WHEN WELDING DISSIMILAR BASE METALS
- REDUCES HYDROCARBON CONTAMINANTS IN CASTINGS THAT HAVE BEEN IN SERVICE (CONTAMINANTS ARE BURNED OFF)

How much preheat to give a cast iron is debatable, but the following are some general guidelines:

- THE HIGHER THE CE, THE HIGHER THE PREHEAT TEMPERATURE
- IF THE TYPE OF CASTING IS KNOWN BUT THE SPECIFIC CHEMISTRY IS NOT, THEN THE PREHEAT SHOULD BE BASED ON THE MICROSTRUCTURE AND THE STRENGTH OF THE CASTING
- LOW-STRENGTH CAST IRONS USUALLY REQUIRE LOWER PREHEAT TEMPERATURE THAN HIGH-STRENGTH CAST IRONS
- A CASTING WITH A COMPLEX SHAPE WILL USUALLY REQUIRE A HIGHER PREHEAT TEMPERATURE TO CONTROL DISTORTION OR RESIDUAL STRESSES
- WHEN WELDING THIN METAL TO A THICK BASE METAL, IT IS RECOMMENDED TO PREHEAT THE THICK MEMBER TO DECREASE ITS HEAT SINK CAPACITY AND TO REDUCE THERMAL STRESSES
- MALLEABLE OR DUCTILE CAST IRONS USUALLY REQUIRE LOWER PREHEAT TEMPERATURES THAN GRAY OR WHITE CAST IRON

Preheat is applied to control the microstructure of the weld area. The influence of preheat on the microstructure in a typical cast iron is indicated below:

PREHEAT TEMPERATURE		RESULTING MICROSTRUCTURE
°C	**°F**	
22	72	**MARTENSITE**
100	212	**PEARLITE TRANSFORMATIONS OCCUR.**
200	392	**A GREATER PORTION OF MARTENSITE AND CARBIDES ARE REPLACED BY PEARLITE.**
300	572	**ALMOST ALL MARTENSITE IS REPLACED BY PEARLITE.**
400	**752**	**ALL MARTENSITE IS TRANSFORMED.**

Source: Ref 1

Preheating to temperatures above 315 °C (600 °F) slows the cooling rate to the point that formation of martensite is minimized, reducing the tendency of the cast iron to crack. Slow cooling also helps minimize residual stresses.

Preheating needs to be done properly. Preheat should be applied so that the weld joint is in compression, not tension (Fig. 4). If the proper method is used while the weld metal is contracting during cooling, the base metal will also contract.

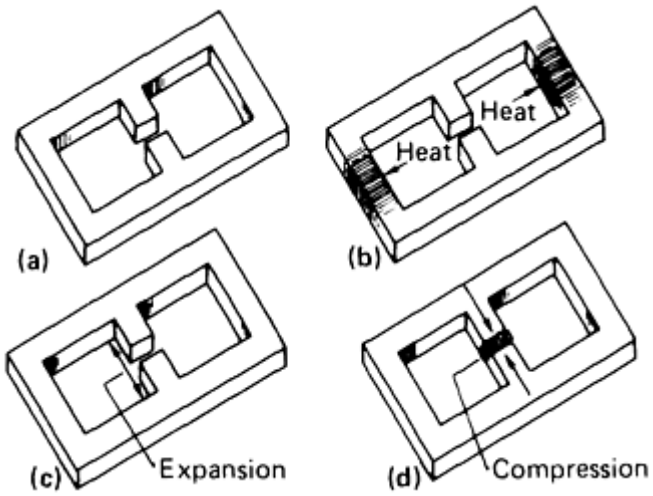

FIG. 4 PROPER METHOD OF PREHEATING CAST IRON CASTINGS TO PREPARE SAMPLES FOR WELDING. (A) CASTING AT ROOM TEMPERATURE. (B) HEAT APPLIED TO PERIMETER OF CASTING. (C) VERTICAL MEMBERS OF CASTING IN TENSION. (D) VERTICAL MEMBERS IN COMPRESSION READY TO BE WELDED

The need to weld complex shapes may necessitate preheating the entire structure. This helps eliminate stresses due to thermal gradients. The area to be welded should be brought to an even higher temperature if necessary. After welding, the entire structure should then be slow cooled to reduce stresses.

Preweld Testing. Cast irons, because they are porous, can collect many contaminants during service. Preheating the casting before welding can help bum out some of these contaminants (for example, grease, oils, or certain chemicals). Another technique uses the electrode selected for the repair. In the area to be repaired, a small stringer bead of 50 to 75 mm (2 to 3 in.) is deposited. The bead is then removed by grinding until the weld bead is back to the original surface of the casting. If a dense porosity-free weld exists, then the possibility is good that the casting contains limited amounts of contaminants. If, however, porosity does exist, then the contaminants must be removed prior to welding. Castings that have excessive amounts of contaminants will exhibit porosity throughout the entire weld. However, if the level of contaminants is lower, then the weld bead will appear to be sound. The only way to determine lack of fusion or porosity due to contaminants is to grind to the base of the weld metal. This procedure can be done without preheat, provided the area tested will not require subsequent machining.

Base-Metal Preparation. The only way to deposit a sound weld on a cast iron is to begin with a sound, clean base metal. When a known crack or defect is to be repaired, it should be completely removed before welding can begin. This also applies when repairing other defects, such as casting tears, porosity, shrinkage defects, and inclusions. The entire defect should be removed before attempting the repair.

Contaminants such as casting skin, coatings, sand, rust, paint, oil, grease, moisture, dirt, and other foreign materials should be removed prior to welding. Castings exposed to high temperatures may have surfaces that are heavily oxidized or carburized, and these surfaces should be removed before attempting a repair.

Baking the casting at temperatures from 370 to 480 °C (700 to 900 °F) will remove most of the organic materials, such as oil and grease. Castings that are impregnated with silt or sand cause additional problems. One method is to apply a weld, then grind, and examine the weld. If the weld metal is not free of porosity, the procedure should be repeated until a sound weld is obtained.

Many of the methods used for removing defects in the castings may make the crack or defect worse unless special procedures are used. One technique is to pin the defect before starting any procedure. This is done by locating the ends of the defect, either visually or with magnetic particle or liquid penetrant testing, followed by drilling holes at this location. The crack or defect will terminate in the hole and not propagate through the casting.

An alternative method involves welding a ductile weld bead perpendicular to the direction of the crack or defect. A nickel or nickel-iron electrode can be used. The defect can then be excavated or removed.

There are several methods of cutting and gouging the iron castings before repair. The air carbon arc process is the most commonly used. Either direct or alternating current can be used with cast irons. The arc length should be kept to a minimum, but the carbon electrode should not be allowed to touch the casting. This will prevent the formation of a high melting point slag on the surface of the casting, which will interfere with cutting. To prevent the formation of large HAZs in the castings, the heat input used for this procedure should be kept to a minimum. The HAZ should be removed by grinding or other mechanical means before welding.

An alternative method is the use of shielded metal arc cutting electrodes. These can be used provided they do not require supplemental compressed air or a special torch. The electrodes have special exothermic flux coatings that concentrate the heat into a very small crater at the tip of the electrode. When the electrode tip is placed in contact with the iron casting, the high concentration of heat from the arc causes the metal to melt.

Once the contaminants and defects are removed, the casting must be prepared for welding. This will require the casting to be machined or ground to achieve a proper joint configuration. The design of the weld groove is important in the casting in order to achieve a sound weld and to provide useful performance. Factors such as base metal thickness, type of base metal, filler metal, service application, and accessibility will determine the design of the groove.

Welds in thin cast irons can be made with single V or U grooves. Standard steel weld groove designs can be used for superficial repairs. However, if a nickel-base filler metal is required, the groove angles need to be increased to allow for the manipulation of the sluggish weld pool. Figure 5 illustrates some of the suggested joint preparations.

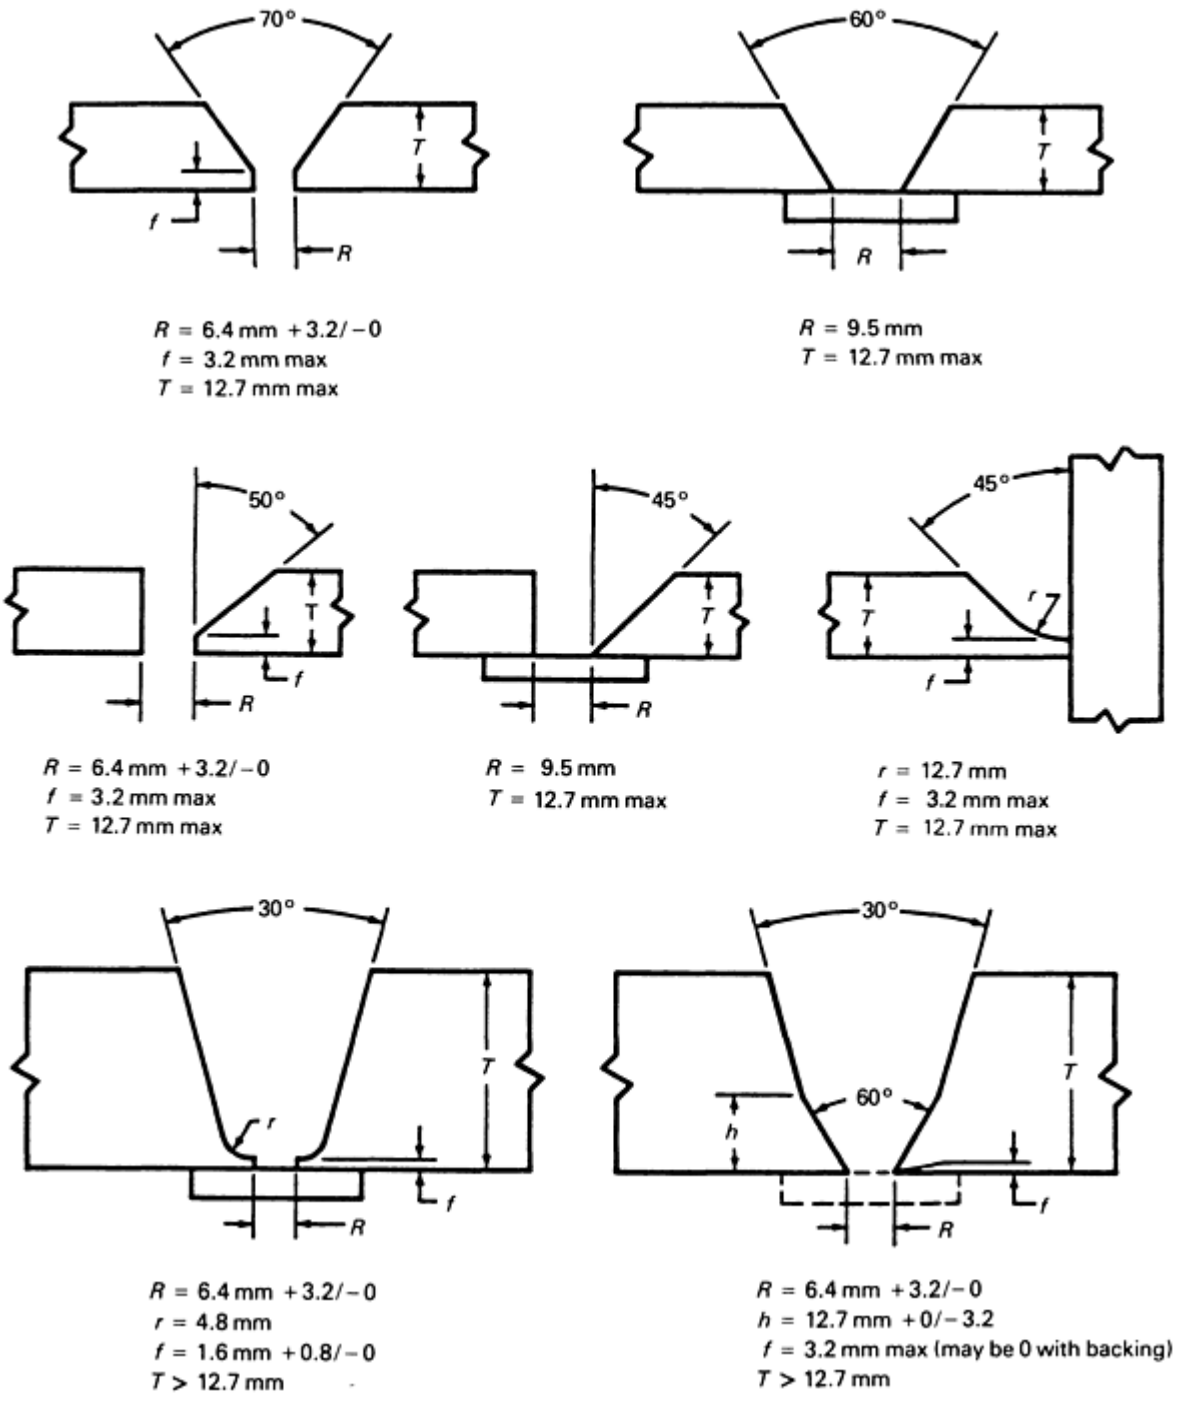

FIG. 5 RECOMMENDED JOINT PREPARATION FOR WELDS USING SINGLE U OR V GROOVES. SOURCE: REF 1

For castings thicker than 13 mm ($\frac{1}{2}$ in.), the groove must be designed so that the stresses caused by welding can be distributed uniformly in the casting. Double-welded joints are used in such applications when possible. For thicknesses up to 19 mm ($\frac{3}{4}$ in.), a double-V groove or a double-bevel groove is recommended. For thicknesses over 19 mm ($\frac{3}{4}$ in.), a double-U groove or double-J groove is recommended. When only one side of the section is accessible, a modified U groove can be used. This type of joint allows access to the joint root and decreases the width of the weld face, helping to decrease the mass of the weld metal and shrinkage stresses. These joints are illustrated in Fig. 6. When welding thick material, the groove faces are sometimes buttered to help minimize stresses.

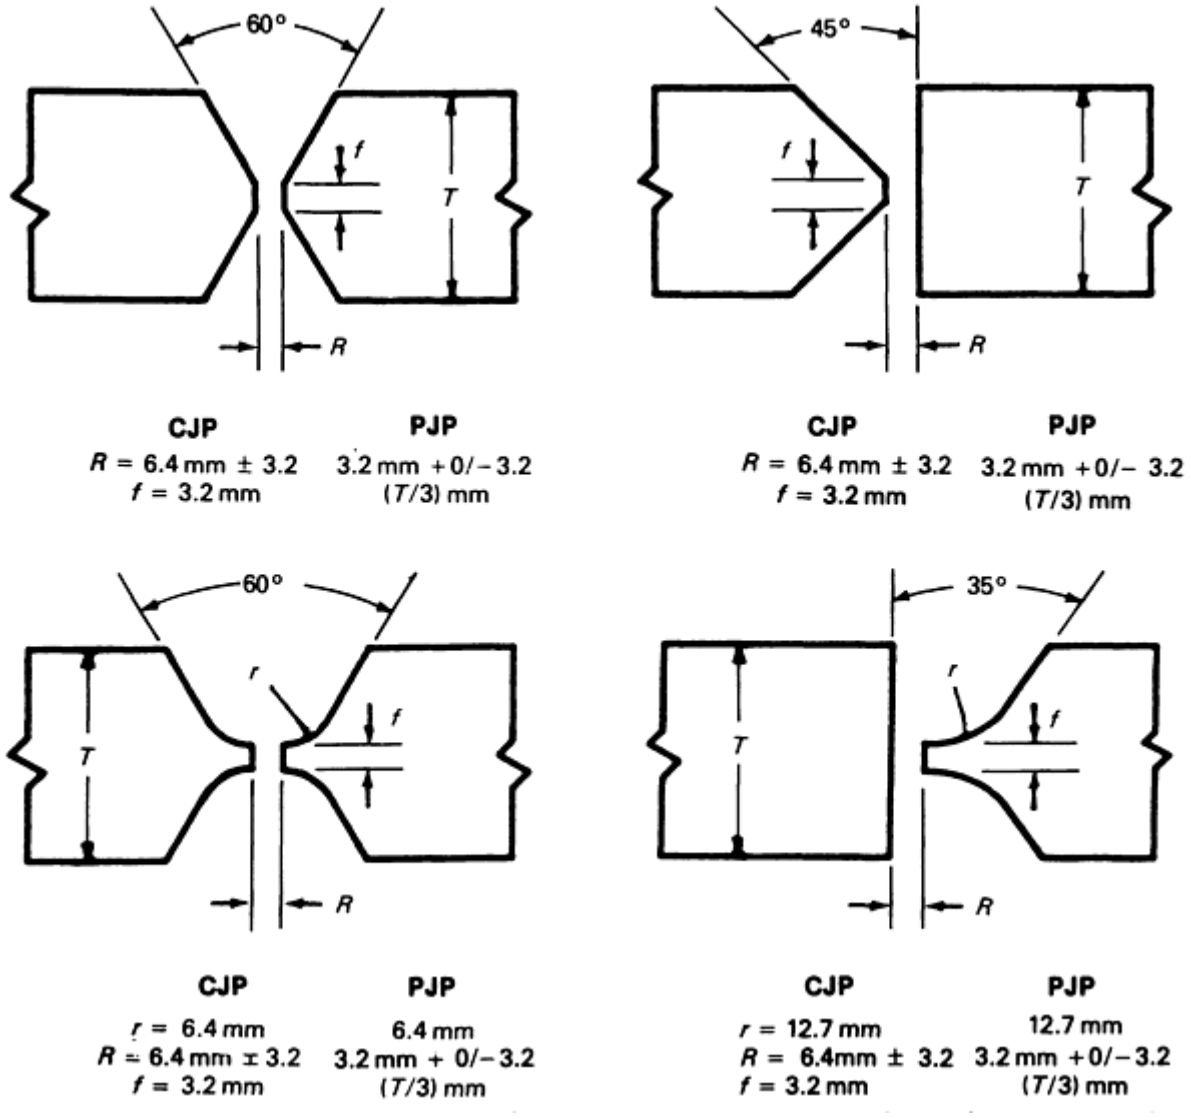

FIG. 6 RECOMMENDED DIMENSIONS FOR COMPLETE JOINT PENETRATION (CJP) AND PARTIAL JOINT PENETRATION (PJP) GROOVES. SOURCE: REF 1

The joint penetrations for braze welding a cast iron are essentially the same as those for arc welding, except the edges are rounded (Fig. 7). This facilitates access, flow, and finishing.

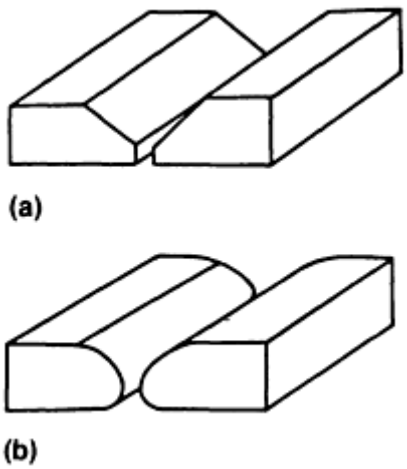

FIG. 7 RECOMMENDED GROOVE CONFIGURATIONS FOR JOINING CAST IRONS. (A) ARC WELDING. (B) BRAZE WELDING. SOURCE: REF 1

The degree of joint preparation required depends on several factors, such as the relative strength of the weld metal, the strength of the base plate, the stresses the casting will see in service, and the thickness of the casting being welded. If there is a question, then a complete joint penetration is preferred. The savings in time and filler metal should be weighed carefully against the conditions in the service environment.

Thick castings of gray iron are sometimes joined with welds having less than complete joint penetration. When nickel-base welding consumables are used, the welds are stronger than the gray cast iron, making partial-penetration welds acceptable. For castings over 13 mm ($\frac{1}{2}$ in.) thick, welding only two-thirds of the thickness should be adequate, and a double-U groove is recommended.

When welding other castings having higher strength levels, such as ductile iron, a complete joint penetration is recommended. Welds to be exposed to fatigue loading, or welds used for pipe applications, should always be complete joint penetration welds.

Special Techniques. The strength of a weld or its fitness for service can be improved by using various special techniques:

- GROOVE FACE GROOVING
- STUDDING
- JOINT DESIGN MODIFICATIONS
- PEENING

Groove Face Grooving. The face of the weld is grooved as shown in Fig. 8. The grooves are then filled with a weld, after which the joint is filled. As a result, the weld interface is irregular so that the path of a crack, if initiated, would not be straight.

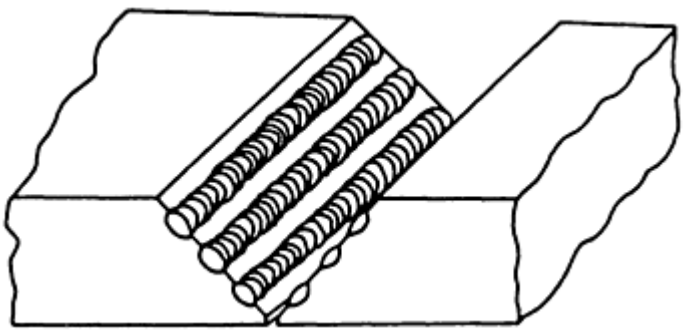

FIG. 8 GROOVE FACE GROOVING FOR WELDING OF CAST IRONS. SOURCE: REF 1

Studding is a mechanical means used to increase the strength and quality of a joint. The studs are either threaded or driven into the joint and must be made of a material compatible with the filler metal used (Fig. 9).

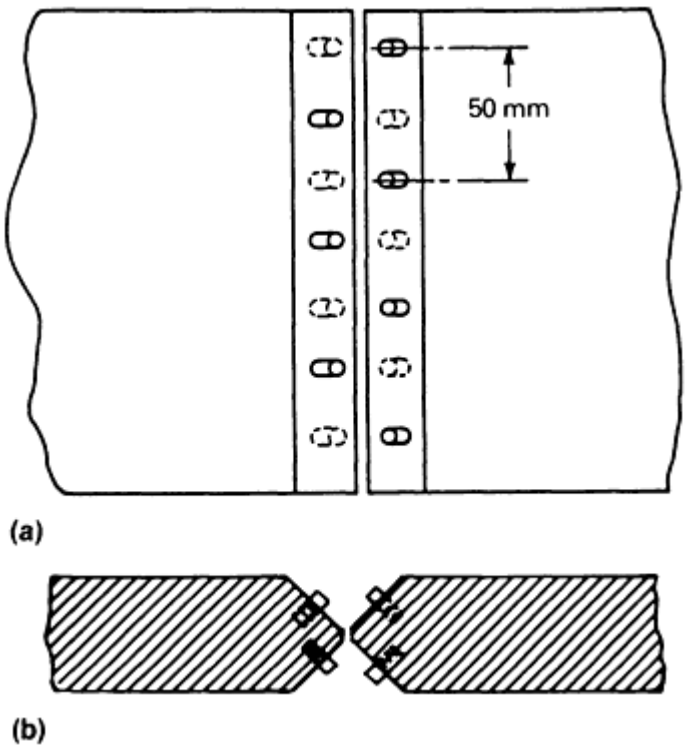

FIG. 9 APPLICATION OF STAGGERED STUD PATTERN TO PROVIDE INCREASED STRENGTH AT WELD INTERFACE. (A) TOP VIEW. (B) FRONT VIEW. SOURCE: REF 1

Joint design modifications in iron castings can improve the service of the welds. Figure 10 shows some samples of these improvements. Figure 10(a) shows a partial joint penetration weld (left) compared with a complete penetration weld (right). Figure 10(b) shows how to improve the casting design to help eliminate problems with changes in metal thickness, so that the weld is not in a highly stressed region. Figure 10(c) shows the addition of a fillet weld to help eliminate the flexing between the two members, again helping to reduce stress concentrations at the weld joint.

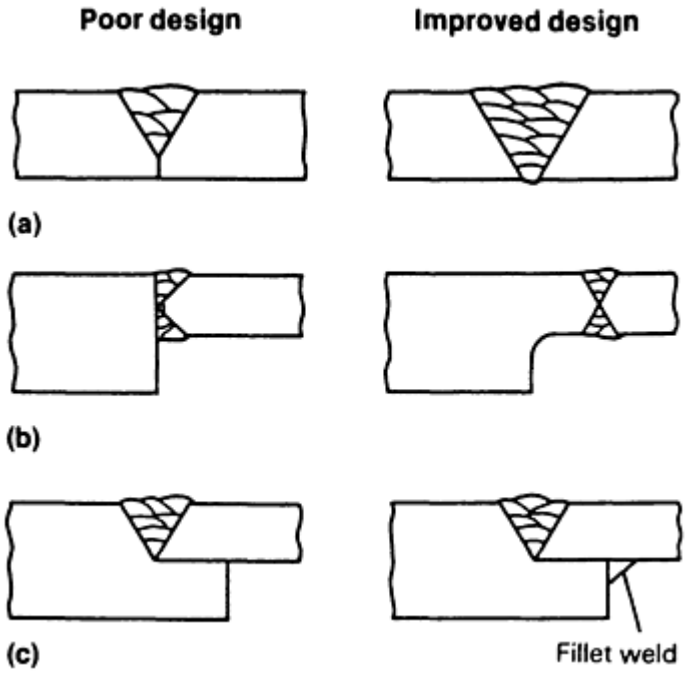

FIG. 10 MODIFICATION OF JOINTS TO PRODUCE OPTIMUM WELD. (A) PARTIAL JOINT PENETRATION WELD (LEFT) CHANGED TO COMPLETE JOINT PENETRATION WELD (RIGHT). (B) PART MODIFIED TO ALLEVIATE PROBLEMS CAUSED BY CHANGES IN METAL THICKNESS. (C) ADDITION OF SECONDARY FILLET WELD TO REDUCE STRESS CONCENTRATIONS OF PRIMARY WELD. SOURCE: REF 1

Peening can help distribute the stresses associated with a weld. A 13 to 19 mm ($\frac{1}{2}$ to $\frac{3}{4}$ in.) rounded ballpeen hammer is used to make repeated, moderate strikes perpendicular to the weld surface. The weld metal should be maintained at or near red hot and not allowed to cool below 540 °C (1000 °F). If a reciprocating air hammer is used, it should be operated at 620 kPa (90 psi) on welds up to 75 mm (3 in.) in length. The tool used should be no wider than the weld bead and should have a tip radius equivalent to one-half the tip width. Travel speed would be 750 to 1000 mm/min (30 to 40 in./min).

Postwelding Treatment

The final stress level of a welded casting is affected by the rate at which the casting is cooled after welding. The casting should be allowed to cool slowly to minimize the residual stresses caused by welding. This can be accomplished by:

- BURYING THE ENTIRE CASTING IN SAND OR VERMICULITE
- POSTHEATING THE CASTING WITH A TORCH
- TRANSFERRING THE CASTING TO A FURNACE
- COVERING THE CASTING WITH AN INSULATING BLANKET

A postweld heat treatment may be necessary to:

- IMPROVE THE DUCTILITY OF THE HAZ
- IMPROVE THE MACHINABILITY OF THE WELD AND HAZ
- TRANSFORM THE MARTENSITIC MICROSTRUCTURE FORMED DURING WELDING TO A LESS BRITTLE PHASE
- RELIEVE RESIDUAL STRESSES IN THE CASTING

The need for postweld heat treatment will depend on the condition of the casting, possible distortion during subsequent machining, the desired finish of the machined surfaces, and prior heat treatment. Thermal stress cracking due to temperature variations in the casting can be avoided by keeping postweld heating and cooling rates below 55 °C/h (100 °F/h) for complex parts; slower rates may be necessary under some circumstances. Table 2 gives the recommended holding temperatures and cooling rates for the postweld heat treatment of gray and ductile cast irons.

Welding Processes and Consumables

Oxyfuel welding (OFW) is any welding process that uses oxygen and a fuel gas as a heating medium. It involves melting the base plate and filler metal with a welding torch flame. The fuel gas and oxygen are mixed in the proper

proportions in a mixing chamber. Molten metal from the groove faces and filler metal intermix and, upon cooling, form a continuous deposit.

The major advantage of the OFW process is the control the welder has over the rate of heat input, the temperature of the weld zone, and the oxidizing and reducing potential of the welding torch flame. The weld bead size and shape, as well as the viscosity of the weld pool, can be controlled because the filler metal is added independently of the welding flame. The OFW process is ideal for welding thin sections, tubes, and small-diameter pipe.

Acetylene is the preferred fuel gas. Other fuel gases (for example, methylacetylene propadiene, propylene, propane, natural gas, and several proprietary gases) are excessively oxidizing and do not develop sufficient heat to properly weld cast irons.

Oxyfuel welding is widely used to repair minor defects in gray cast iron and is used less frequently for ductile iron castings. The slow heating rate of OFW causes a large HAZ to develop but prevents the formation of the brittle martensitic structure.

The consumables for the oxyfuel welding of gray iron are normally cast with higher levels of carbon and silicon than the castings; this compensates for losses experienced during welding. The weld metal has a graphitic structure, making it machinable, and is a good color match. The chemical compositions for three gray iron welding rods are given in Table 3. The RCI filler material is used to join Class 20 through 35 gray irons, and RCI-A is used for gray castings with higher levels of nickel and molybdenum of Class 35 through 45.

(B) COPPER-BASE FILLER METALS FREQUENTLY USED IN THE BRAZE WELDING OF CAST IRONS ARE NO LONGER INCLUDED IN THIS SPECIFICATION. FOR INFORMATION PERTAINING TO THESE MATERIALS SEE ANSI/AWS A7.6.

(C) NICKEL PLUS INCIDENTAL COBALT.

These consumables, along with some proprietary filler metals, have been designed to furnish weld metal having adequate strength and a minimum level of iron carbide. This is achieved by alloying with elements that promote solid solution strengthening in combination with a graphitizing agent. Nickel, manganese, molybdenum, and silicon are the most common. The addition of phosphorus promotes fluidity of the molten iron. If the phosphorus level is high, then a hard, brittle, iron/iron phosphide eutectic can be formed.

The RCI-B filler material given in Table 3, along with additional proprietary filler metals, is designed for welding ductile iron castings. A ductile iron welding rod contains additions of nodularizing elements such as magnesium or cerium. These types of filler metals are capable of producing weld metal with a nodular graphite structure, provided the magnesium or cerium is high enough to compensate for losses incurred during welding. Cerium-containing rods may be the preferred

nodularizing element to minimize porosity. Rods containing magnesium can develop a scum during welding unless enough flux is used. This scum is hard to remove and can cause contaminated and low-strength welds.

The filler metals listed in Table 3 have been used for welding malleable cast iron. However, the OFW process can create a wide HAZ of brittle white iron, lowering the ductility of the base metal and making it more prone to cracking. Some foundries repair the rough castings while still having a white iron microstructure before the malleabilizing heat treatment.

Fluxes are used to protect the molten metal from oxidation, to increase the fluidity of the slag formed, and to help dissolve oxides and other impurities. Fluxes used for OFW when utilizing acetylene fuel gas contain sodium borate, or boric acid, soda ash, and some iron oxide powder. Some fluxes are designed specifically for welding ductile iron by lowering the melting point; otherwise, the fluxes are used for both gray and ductile iron.

The weld preparation for OFW must be wider than that for the arc-welding processes to allow for manipulation of the welding rod and torch. Groove angles of 90 to 120° are common.

A preheating temperature of 540 to 650 °C (1000 to 1200 °F) is recommended for the oxyfuel welding of cast irons. This allows for a quick repair and provides slow cooling. If possible, the entire casting should be preheated to minimize local thermal stresses. Gray iron is especially susceptible to cracking due to thermal stresses introduced by localized preheating. If done carefully with a torch, localized preheating can be used successfully on small castings.

After the proper preheating temperature is reached, the repair should be done immediately before the base metal adjacent to the weld area is allowed to cool. The casting should not be allowed to cool below 315 to 425 °C (600 to 800 °F). If the casting cools below this temperature during welding, or if welding is interrupted, the casting should be reheated before welding is resumed. The casting should not be exposed to extreme temperatures during welding to help reduce thermal stresses. During OFW, the area being repaired should not exceed 675 °C (1250 °F). Excessive preheating and welding time may introduce additional stresses, may distort the casting, and may reduce tensile strength.

The temperature of the casting must be monitored during welding. The recommended practice is to preheat the entire casting in a furnace, maintain an interpass temperature during welding, and cool slowly in a furnace. If a permanent furnace is not available, a temporary furnace can be made from sheet metal and fire brick on top of several gas burners.

Several techniques are unique to OFW when welding cast irons:

- THE SIZE OF THE WELDING TORCH SHOULD BE SIMILAR TO THOSE USED FOR MILD STEEL.
- A NEUTRAL FLAME OR SLIGHTLY REDUCING FLAME IS RECOMMENDED. AN OXIDIZING FLAME IS NOT RECOMMENDED, BECAUSE IT CAN CAUSE LOSS OF SILICON, LEADING TO THE FORMATION OF WHITE CAST IRON AND POROSITY.
- AFTER THE CASTING IS AT THE PROPER PREHEAT TEMPERATURE, THE FLUX IS SPRINKLED ONTO THE GROOVE FACES TO BE WELDED. THE CONE OF THE FLAME SHOULD BE KEPT APPROXIMATELY 3.2 TO 6.4 MM ($\frac{1}{8}$ TO $\frac{1}{4}$ IN.) FROM THE BASE METAL. CONTACTING THE CONE TO THE BASE METAL SHOULD BE AVOIDED, BECAUSE IT COULD CAUSE OXIDATION OF SILICON AND CARBON, RESULTING IN HARD SPOTS.
- WHEN THE BOTTOM OF THE GROOVE HAS MELTED, THE TORCH FLAME IS MOVED FROM SIDE TO SIDE TO MELT BOTH GROOVE FACES. AT THIS POINT, THE WELDING ROD IS ADDED SLOWLY TO FORM THE WELD POOL. FURTHER ADDITION OF THE ROD SHOULD BE DONE BY MELTING THE ROD IN THE WELD POOL, NOT IN THE FLAME.
- FURTHER ADDITION OF FLUX SHOULD BE DONE BY HEATING THE TIP OF THE WELDING ROD IN THE OUTER PORTION OF THE WELDING FLAME AND DIPPING THE ROD INTO THE FLUX. WHITE SPOTS AND GAS BUBBLES IN THE WELD POOL INDICATE THAT IMPURITIES ARE PRESENT AND THAT ADDITIONAL FLUX IS NEEDED.
- USING A STIRRING ACTION WITH THE WELDING ROD HELPS THE IMPURITIES FLOAT TO THE SURFACE IN THE SLAG AND HELPS MAINTAIN A GOOD FUSION WITH THE GROOVE FACES. EXCESSIVE STIRRING SHOULD BE AVOIDED IN ORDER TO MINIMIZE

OXIDATION.

One recommended practice for depositing the filler metal is called block sequence (Fig. 11). This procedure requires depositing welds approximately 25 mm (1 in.) long in different sections of the joint. The ends of each length should be staggered. Care must be taken to obtain complete fusion between each section and both groove faces. Excess molten metal that might have run ahead of the block must be remelted before welding over it. Another method, called the cascade method, involves depositing thin layers in succession, where each layer is longer than the previous one (Fig. 11). The repaired casting can then be given a postweld heat treatment. Large castings with complex shapes or castings that require excessive machining should be given a postweld stress relief immediately after welding. This requires holding the casting at 540 to 650 °C (1000 to 1200 °F) for 1 h per inch of thickness, followed by slow cooling.

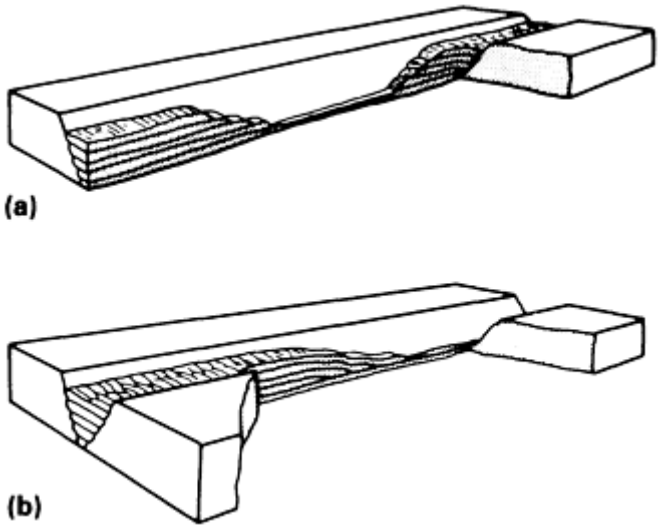

FIG. 11 METHODS APPLIED TO THE OFW PROCESS TO DEPOSIT FILLER METAL WITH MINIMUM WELD STRESS. (A) BLOCK SEQUENCE. (B) CASCADE SEQUENCE

Flame spraying (FLSP) of gray iron is mainly used to repair worn areas, defects, and broken corners on gray iron glass molds. The FLSP process is preferred because deposits as thin as 0.10 to 0.13 mm (0.004 to 0.005 in.) can be applied uniformly to a complex contour of a casting. Finishing time is minimal, and the deposits can be hand filed or machined back to the original contours of the casting. Flame spraying allows a high-strength bond with varying hardness values.

The FLSP process uses a special acetylene torch designed to store and inject powder particles into the gas stream ahead of the flame. These particles then become semimolten as they pass through the flame before striking the casting.

The powders used for FLSP are manufactured by an atomization process and then blended to become an aggregate of various-sized particles. The correct mesh size distribution is necessary in order to obtain an efficient flow of powder through the torch and to maintain reasonable efficiency in thermal spraying deposition.

Various powders have been developed to conform to the Aerospace Material Specification 4779 standard. The standard has the following specifications:

ELEMENT	CONTENT, WT%
CARBON	**0.6 MAX**
SILICON	**4.0-5.0**
IRON	**1.5 MAX**

BORON	**1.0-2.2**
NICKEL	**BAL**

Altering the percentage of each element causes variations in performance and hardness. The hardness range can vary from 165 to 392 HV (85 HRB to 40 HRC).

The area of the casting to be sprayed must be cleaned beforehand. All oxides must be removed. Sand blasting is not recommended, because small particles of silica can become embedded in the casting and cause bonding problems.

The preheat temperature for FLSP is 260 to 315 °C (500 to 600 °F). The preheated area is then sprayed completely with a layer 0.10 to 0.18 mm (0.004 to 0.007 in.) thick. With the torch flame only, the area is then heated to 1010 to 1150 °C (1850 to 2100 °F), starting at one edge until complete fusion is obtained. After the initial deposit has been fused, additional layers can be deposited using the same technique.

Braze welding is a welding process in which the filler metal has a melting point above 450 °C (840 °F) but below the melting point of the casting. Unlike brazing, the filler metal in braze welding is not distributed in the joint by capillary action.

Braze welding was originally developed to repair cracks or broken cast iron parts. Because the process does not require the casting to be melted, the temperature is lower, reducing the formation of brittle cementite, and thus reducing the tendency toward cracking.

The molten filler metal must wet the hot base casting in order for a proper metallic bond to be created between the filler metal and the unmelted casting. This heat is generated with an oxyfuel gas torch.

Flux must be used to properly clean and protect both the base metal and weld metal. The filler metal is fed into the heated groove face in one or more passes until the groove is completely filled. The joint design is similar to joints used for oxyfuel gas welding. Typical groove and joint designs are shown in Fig. 5, 6, 7, 8, 9, and 10.

Advantages. There are some distinct advantages of braze welding over fusion welding:

- BECAUSE LESS HEAT IS REQUIRED, THERE IS LESS DISTORTION AND SUSCEPTIBILITY TO CRACKING.
- THE DEPOSITED WELD METAL IS RELATIVELY SOFT AND DUCTILE, RESULTING IN DEPOSITS THAT HAVE EXCELLENT MACHINABILITY AND LOW RESIDUAL STRESSES.
- JOINTS CAN BE PRODUCED WITH ADEQUATE STRENGTH FOR MANY APPLICATIONS.
- EQUIPMENT REQUIRED IS VERY SIMPLE AND RELATIVELY EASY TO USE.
- CAST IRONS, WHICH ARE VERY SENSITIVE TO TEMPERATURE GRADIENTS OR THERMAL SHOCK, CAN BE BRAZE WELDED WITHOUT EXCESSIVE PREHEATING.

Limitations of braze welding include:

- THE JOINT STRENGTH IS CONTROLLED BY THE WELD METAL OR WELD INTERFACE.
- THE SERVICE TEMPERATURES WILL BE LOWER THAN THOSE IN FUSION WELDS DUE TO THE LOWER MELTING TEMPERATURES OF THE FILLER METAL. IF A COPPER ALLOY IS USED, IT IS LIMITED TO 260 °C (500 °F) OR LOWER.
- BRAZE-WELDED JOINTS WILL NOT MATCH THE COLOR OF THE CASTING.
- DEFECTS ARE HARDER TO LOCATE IN THE BRAZE-WELDED JOINTS, MAKING THEM MORE DIFFICULT TO INSPECT THAN FUSION-WELDED JOINTS.

Equipment and Techniques. The equipment used for braze welding consists of a welding torch and associated components. Braze welding can be used to join castings to other castings or castings to other metals (for example, steel or stainless steel), provided the proper filler metal is used.

A preferred technique of braze welding is to butter one or both faces of the groove prior to welding. The buttered layer can be the same alloy as the filler metal or a different filler metal that will act as a buffer between the two metals to be joined.

The filler metal used for this process is predominantly a 60Cu-40Zn brass alloy. Tin, iron, manganese, silicon, and nickel are added to improve flow characteristics, lower the melting temperature, decrease the volatilization of zinc, react with oxygen, and increase strength and hardness. Table 4 gives the chemical composition and properties of several filler metal rods. Even though the minimum tensile strengths of these alloys range from 275 to 485 MPa (40 to 70 ksi), they may decrease if the service temperature is above 260 °C (500 °F).

(A) MINIMUM AT ROOM TEMPERATURE.

Fluxes for braze welding are basic fluxes of alkali fluoride and borax mixtures. They are designed to clean the base metal casting and weld metal, and are active over the full melting range of the filler metal. Braze-welding fluxes contain some iron oxide or manganese dioxide, which combines with the free carbon on the cast iron surface to promote wetting. Fluxes are applied by dipping the heated filler metal into the flux or by brushing onto the joint. They are also precoated on filler metal or applied through the oxyfuel gas flame.

The cleanliness of the castings to be braze welded is very important, because contaminants will inhibit the wetting of the filler metal. This wetting is necessary to accomplish the metallic bond between the filler metal and the casting. Both the groove faces and the surfaces adjacent to the joint must be cleaned of all contaminants and foreign materials. This includes graphite smears caused by machining. Graphite smears will adversely affect the wetting of the filler metal. Smears can be removed by quickly heating the cast iron to a dull red color with a slightly oxidizing flame and then wire brushing after cooling. Malleable iron, because of its lower carbon content and rough graphite nodules, can be cleaned by abrasive blasting.

The joints used for braze welding are similar to those used for oxyfuel welding. For thicknesses over 2.4 mm ($\frac{3}{32}$ in.), single and double-V grooves are prepared, with groove angles between 90 and 120°. This allows a large weld-interface area between the base metal and the weld metal. Square grooves can be used for thicknesses of 2.4 mm ($\frac{3}{32}$ in.) or less. In large casting repairs, studs may be inserted into the groove surfaces to increase the strength of the repair (Fig. 9).

The malleable cast iron grades are the easiest to braze weld. Ductile iron is more difficult to braze weld because of its higher total carbon content. The graphite flakes in gray cast iron make it the most difficult to braze weld; special groove preparation will be necessary. The groove surfaces need to be cleaned with caustic or decarburized with an oxidizing oxyfuel flame.

Preheating can be done locally, or the entire part can be heated, depending on the complexity of the part. The part should be preheated to 425 to 480 °C (800 to 900 °F) and slow cooled after welding.

Braze welding uses an oxyfuel gas torch with a slightly oxidizing flame. This is obtained by increasing the oxygen/fuel ratio until the feather disappears and the cone becomes slightly necked. Once the smeared graphite is removed from the groove surfaces, this type of flame is no longer required.

The technique for braze welding is as follows:

- THE BRAZE-WELDING FLUX IS APPLIED TO THE GROOVE FACES AND FILLER METAL TO BE USED.
- THE BASE METAL CASTING IS HEATED UNTIL THE FILLER METAL MELTS, WETS THE CASTING, AND FLOWS ONTO THE GROOVE FACES.
- THE GROOVE IS THEN FILLED WITH ONE OR MORE PASSES. THE CONE OF THE GAS FLAME SHOULD NOT BE DIRECTED ON THE COPPER-ZINC FILLER METAL OR ON IRON-BASE METALS.

Welding of Cast Irons*

Roger A. Bushey, The ESAB Group, Inc.

Arc-Welding Processes

The arc-welding processes used for welding cast irons are shielded metal arc welding, gas-metal arc welding, flux-cored arc welding, gas-tungsten arc welding, and submerged arc welding.

More than 90% of all industrial welding is done by arc welding. Arc welding has a lower heat input than oxyfuel gas welding because it has a faster welding speed and higher deposition rate. Arc welding may achieve temperatures in excess of 5000 °C (9000 °F) in the arc. Such intense heat allows necessary fusion while heating only a small portion of the weldment. This causes high cooling rates and results in large thermal expansion and contraction stresses. The high cooling rate may also cause more HAZ problems than normally encountered with oxyfuel gas welding. Arc-welding processes are capable of producing welds of high quality when the proper procedure and consumables are used.

Shielded Metal Arc Welding

Shielded metal arc welding (SMAW) is the most widely used process. It uses the heat of the arc to melt the base metal and the tip of the consumable-covered electrode. Protection of the weld pool is achieved by decomposition of the electrode covering.

The electrode and the part to be welded constitute a circuit that also includes the power source, welding leads, and electrode holder. Once an arc is established between the electrode and the base metal, globules of molten metal rapidly form on the tip of the electrode. The molten metal is then transferred through the arc stream into the weld pool. Filler metal is then deposited as this covered electrode is consumed.

The current used can be either an alternating current (ac) or direct current (dc). Any power source capable of supplying the proper range, type and polarity of current, and open circuit voltage may be used.

The advantages of this welding process include a wide range of consumables, good availability, low-cost power sources, and all-position capabilities.

The consumables used for welding cast irons are quite varied. Economic considerations and weld requirements will determine the appropriate electrode for each application.

Cast iron electrodes are covered with a flux to improve arc stability, to reduce porosity, and to add alloying elements. These electrodes produce a composition, mechanical properties, microstructure, and matching color similar to cast iron.

Steel electrodes are made with carbon-steel-core wire and are classified as ESt (Table 5). This classification comes from ANSI/AWS A5.15-90 specification. These steel electrodes are specifically designed for the welding of cast iron, and are different from ordinary mild steel electrodes. The welds deposited by these electrodes are not readily machinable, and it is almost impossible to prevent the formation of hard weld metal with low ductility.

(A) MINIMUM

This electrode is normally used to repair small pits, cracks, and other defects when the casting does not require machining. Because the shrinkage of steel is greater than that of cast iron, high tensile stresses develop upon cooling, possibly causing cracking. Groove preparation, as shown in Fig. 5, 6, 7, 8, and studs, as shown in Fig. 9, are recommended for any sizable casting.

Preheating the casting is recommended only when absolutely necessary in order to prevent excessive stresses. Steel electrodes are used at low current to limit the amount of dilution from the casting. The recommended polarity and current for this electrode is dc reverse (electrode positive). The weld beads deposited by these electrodes should be short and widely separated, followed by a light peening after each deposit. After welding, the slag should be completely removed, especially prior to painting.

The hardness level of the weld deposit of a steel electrode depends on dilution of the casting. Small single beads with high dilution have hardnesses as high as 500 HB. Heavier beads with less dilution and multiple passes will have lower hardness levels.

Low-hydrogen electrodes, such as E7016 and E7018, are sometimes used to weld cast irons. They are generally used for cosmetic repair in nonstructural applications where machining is not necessary and cracking is not a major concern. These electrodes are classified in ANSI/AWS A5.1, are readily available at low cost, and are easy to use. The color match of their weld deposit to the casting is good. Because of the dilution of the casting, the weld metal deposit of these electrodes will contain carbon levels of 0.8 to 1.5%. As a result, the deposit will have a high level of hardness and, with rapid cooling, can produce crack-sensitive martensitic microstructures. This can be minimized by using preheat, slow cooling, and postweld annealing.

Stainless steel electrodes are generally not used for welding cast irons. This is due to the formation of chromium carbides during the welding operation, resulting in a crack-prone brittle microstructure. Cracking in the HAZ is likely to occur as a result of differences in tensile strength and coefficient of expansion between the stainless steel weld deposit and the casting.

Nickel-base electrodes are widely used to weld cast irons. Nickel, unlike iron, does not form carbides and has a low solubility for carbon. As the weld metal solidifies and cools, carbon is rejected from solution as graphite. This increases the volume of the weld metal, reducing shrinkage stresses and reducing the likelihood of cracking.

Nickel-base electrodes can be classified into four categories:

- PREDOMINANTLY NICKEL
- 50NI-50FE
- NICKEL-IRON-MANGANESE
- NICKEL COPPER

Predominantly Nickel Electrodes. The electrodes classified as ENi-CI and ENi-CI-A (see Table 5 for composition) produce a weld deposit having a high nickel content; therefore, it is soft and machinable. The "A" designation is used for electrodes to which aluminum has been added to levels from 1 to 3%. These electrodes are used for surfacing applications and where the diluted weld deposit must be machined.

50Ni-50Fe Electrodes. The electrodes classified as ENiFe-CI and ENiFe-CI-A (see Table 5 for composition) have approximately the same level of nickel and iron. These electrodes are different from the high-nickel electrodes in that the:

- WELDS ARE STRONGER AND MORE DUCTILE.
- STRENGTH OF THE ELECTRODES MAKES THEM SUITABLE FOR WELDING DUCTILE AND HIGH-STRENGTH GRAY IRONS.
- ELECTRODES CAN BE USED FOR DISSIMILAR JOINTS, SUCH AS CAST IRON TO CARBON STEEL AND NICKEL-BASE ALLOYS. IF THE DISSIMILAR JOINT USES CAST IRON WELDED TO A CHROMIUM-CONTAINING STEEL SUCH AS STAINLESS STEEL, THEN A BUTTERING LAYER SUCH AS ENI-1 ELECTRODE (ANSI/AWS 5.11) SHOULD BE USED ON THE CAST IRON. THIS WILL HELP PREVENT THE FORMATION OF CHROMIUM CARBIDES IN THE WELD DEPOSIT.
- ELECTRODES CAN BE USED TO WELD GRAY IRONS HAVING HIGH LEVELS OF PHOSPHORUS BECAUSE THE IRON IN THE WELD METAL CAN TOLERATE PHOSPHORUS BETTER THAN NICKEL.

At a chemical composition of 30% Ni and 70% Fe, the nickel-iron alloy has its lowest coefficient of expansion. The weld deposit from ENiFe-CI and ENiFe-CI-A electrodes has approximately this 30Ni-70Fe composition because of base metal dilution. Therefore, these electrodes can be used for thicker sections of casting than the high-nickel electrodes.

Because of the formation of nickel-iron compositions, the weld hardness levels are higher than those made with high-nickel electrodes. Therefore, the use of ENi-CI-A is preferred when machinability is important. In multipass welds, each pass is tempered by each subsequent pass, reducing the hardness and resulting in improved machinability. Typical hardness levels are given in Table 6.

Nickel-Iron-Manganese Electrodes. When manganese is added to the nickel-iron alloy, it improves strength, ductility, and resistance to cracking. The composition of this electrode is given in Table 5 as ENiFeMn-CI. The strength of this alloy is sufficient for joining nodular irons up to the 80-55-06 grades. It is also used where increased wear resistance is needed on surfacing or buildup applications.

Nickel-copper electrodes are also used for welding cast irons, but because of their sensitivity to iron dilution, they will have limited usage. They are to be used with low-penetration procedures because the dilution with iron may cause weld cracking.

Copper-base electrodes are mainly used for surfacing iron castings on bearing surfaces to improve corrosion and wear resistance, or for joining cast irons to dissimilar metals. As described in the section "Base-Metal Preparation" in this article, base metal cleanliness when welding cast iron is very important, especially prior to using copper-base electrodes.

Copper-base electrodes are classified in ANSI/AWS A5.6-84, and the composition and mechanical property requirements are given in Table 7. The coverings developed for these copper-base electrodes perform satisfactorily on cast iron.

Phosphor-Bronze Electrodes. The electrodes classified as ECuSn-A and ECuSn-C are referred to as phosphor-bronze because of the residual phosphorus used for deoxidizing the molten metal during their manufacture. These electrodes, because of their chemical makeup, flow sluggishly and require preheat and interpass temperatures of at least 205 °C (400 °F) on thick base metal. Eliminating moisture from the surface of the metals requires that the electrodes be baked at 120 to 150 °C (250 to 300 °F) prior to use.

The ECuSn-C electrodes have a higher tin content than the ECuSn-A electrodes, resulting in a weld deposit with a higher hardness, tensile strength, and yield strength. Hardness levels for the ECuSn-C electrode deposit range from 85 to 100 HB; for the ECuSn-A electrode deposit, from 70 to 85 HB.

Aluminum-bronze electrodes are also used for welding cast irons. The ECuAl-2 electrode is classified in ANSI/AWS A5.6, and the composition and mechanical property requirements are given in Table 7. This electrode has a weld deposit that has a higher tensile strength than the tin-bronze electrodes (minimum of 415 MPa, or 60 ksi) and a hardness of 130 to 150 HB. Aluminum-bronze electrodes also require close attention to the cleanliness of the base plate prior to welding.

The ECuMnNiAl electrode is also listed in Table 7. This electrode is used for the repair of cast irons where a higher tensile strength is needed than that provided by the ECuAl-A2, ECuSn-A, or ECuSn-C electrode deposit. The ECuMnNiAl electrodes vary the level of aluminum and have higher levels of iron, manganese, and nickel than the ECuAl-A2 electrode. This results in higher minimum tensile strengths of 515 MPa (75 ksi) and hardness levels of 160 to 200 HB.

Gas-Metal Arc Welding

Gas-metal arc welding (GMAW) produces coalescence of metals by heating them with an arc between a continuously fed filler metal electrode and the cast iron to be welded. Shielding is obtained from an externally supplied gas.

This process can produce high deposition rates, high heat input, and deep-penetration welds by varying the arc voltage, gas shielding, and wire-feed speeds of the electrode. These electrodes will function in all positions if used at the proper settings.

The transfer of the molten metal from the electrode to the cast iron being welded can occur in three different modes:

- SPRAY
- GLOBULAR
- SHORT CIRCUITING

The mode of transfer is determined by the heat input and the type of shielding gas used.

Spray transfer takes place at the highest heat input of the three modes and is used in the flat position. An inert gas is required, such as argon or helium or a mixture of the two gases. Spray transfer gives the highest deposition rates and the greatest penetration of the three modes of transfer. It is also the most likely to cause cracking due to the high heat input, resulting in the largest HAZ. Additional information is available in the article "Transfer of Heat and Mass to the Base Metal in Gas-Metal Arc Welding" in this Volume.

The globular transfer mode gives a slightly lower heat input, with the metal transferring as large droplets. This lower heat input makes globular transfer less likely to cause cracking and results in welds having lower penetration than with the spray transfer mode. Globular transfer can be used in all positions, but may require a very experienced welder for the vertical and overhead positions.

The short-circuiting transfer mode is the lowest-heat-input and lowest-penetration mode. This is achieved by having the welding electrode actually contact the weld pool many times per second. As a result, short circuiting produces the smallest HAZ and the lowest crack sensitivity of the three transfer modes. Shielding gases for this process include argon, helium, carbon dioxide, or mixtures of these gases. Short circuiting should be used only on thin sections or with high preheat in order to avoid incomplete-fusion and incomplete-penetration defects.

Choosing the Right Transfer Mode. Selection of transfer mode is dictated by the size and complexity of the casting to be welded, the deposition required, and the weld position to be used. Generally, the low-heat-input processes are preferred because they minimize the melting of the cast iron and stresses introduced by arc welding.

Consumable Electrodes. The consumables of this welding process closely parallel those of SMAW. Steel, nickel-base, nickel-iron, nickel-iron-manganese, and copper-base electrodes are used.

Steel Electrodes. A typical application that uses steel electrodes is the repair of casting defects in noncritical areas of the casting that will not be machined. The color match that steel electrodes provide is excellent. Because the weld will be hard due to the increase in carbon level from dilution of the casting in the weld deposit, steel electrodes should not be used where machining is required. Areas to be welded should be preheated, and parameters should be chosen to minimize penetration--for example, short-circuiting transfer and the use of small-diameter electrodes with a carbon dioxide or C-25 ($75Ar/25CO_2$) shielding gas. The typical welding electrodes used that fall into this category are ER70S-3 and ER70S-6. These electrodes are designed with significant quantities of deoxidizers such as manganese and silicon.

Nickel-base electrodes containing 95% or higher levels of nickel are used to weld cast iron. These electrodes are used when there is highly diluted weld metal and the deposit must be machined. The most common is electrode containing 99% or greater nickel, with no additional deoxidizers. Another electrode that falls into this category is the ERNi-1 electrode classified in ANSI/AWS A5.14. This electrode contains approximately 4% Ti as a deoxidizer, which leads to the formation of titanium carbides, increasing the hardness of the deposit. Table 8 gives recommended shielding gas and welding parameters.

(A) POLARITY, DCEP.
(B) SPRAY TRANSFER.

Nickel-iron electrodes are also used for the GMAW process. They will deposit a harder weld metal and, therefore, are more sensitive to cracking than the high-nickel electrodes.

Nickel-Iron-Manganese Electrodes. As stated in the section "Shielded Metal Arc Welding" of this article, the addition of manganese increases the crack resistance and strength of the weld deposit. As a result, this consumable is suitable for welding the higher-strength grades of ductile iron, such as 65-45-12 and 80-55-06. The typical hardness level of the weld deposit is 80 to 95 HRB. The composition of this electrode is 12% Mn, 44% Ni, and the remainder iron.

Copper-Base Electrodes. Electrodes containing predominantly copper can be used to join or surface cast iron. The electrodes are classified as ERCuSn-A, ERCuAl-A2, and ERMnNiAl in ANSI/AWS A5.7. Table 9 gives the chemical composition and minimum mechanical properties of these electrodes.

Flux-Cored Arc Welding

Flux-cored arc welding (FCAW) produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the workpiece. The equipment used for GMAW can also be used for FCAW. Shielding may be provided by the decomposition of the flux fill (self-shielding) or as an external shielding gas (gas-shielded).

Core Composition. The electrode core contains slag formers, arc stabilizers, deoxidizers, and metal alloys. Depending on the makeup and the shielding gas, the electrode may achieve a deep- or shallow-penetration weld.

Electrode Types. The different types of FCAW electrodes include steel, iron-nickel, and nickel-iron-manganese.

Steel electrodes are classified in ANSI/AWS A5.20. They are classified based on type of slag system and gas-shielding requirements. The gas-shielded types EXXT-1 and EXXT-2 are futile-or acid-base, and EXXT-5 is basic. The EXXT-5 electrodes are preferred for welding cast iron, because they have lower penetration, resulting in less dilution and therefore greater crack resistance.

The EXXT-4, EXXT-7, and EXXT-8 electrodes are steel electrodes that are classified as self-shielding or require no external shielding gas. These electrodes can be used to weld cast iron.

The weld deposit of these steel flux-cored electrodes will become hardenable steel with the pickup of carbon from the cast iron. This will make these deposits hard to machine and susceptible to cracking.

Iron-Nickel Electrodes. Flux-cored electrodes having a 70/30 iron-nickel ratio are used to repair heavy cast iron vessels. These heavy castings include the pouring ladles and molds in foundries and steel plants. The high hardness of the weld metal is not detrimental, because all it is required to do in service is to fill in voids and maintain the proper contours.

Nickel-iron-manganese electrodes are flux-cored electrodes with the nickel-iron-manganese matrix described previously. The typical composition is 1% C, 5% Mn, 40% Fe, and the balance nickel. The addition of manganese improves the strength, ductility, and machinability of the weld deposit. These electrodes are used for upgrading or repairing castings, fabrication, surfacing, and welding dissimilar metals. Typical welding conditions for the nickel-iron-manganese electrodes are given in Table 10.

Gas-Tungsten Arc Welding

Gas-tungsten arc welding (GTAW) produces the coalescence of metals by heating them with an arc between a tungsten electrode (nonconsumable) and the workpiece. Shielding is obtained from an inert gas such as argon or gas mixtures. This process can make autogenous welds or welds using a filler metal. The filler metals would be the same as those used for GMAW; however, the ENi-1 electrode containing titanium is not recommended.

The GTAW process is used for the welding of cast iron utilizing nickel or nickel-base filler metal with an argon shielding gas. The procedure for GTAW welding should minimize dilution of the weld by the base metal.

Again, it is of utmost importance to make sure that the groove surface to be welded is free of contaminants. The joint design must be wide enough to facilitate manipulation of the torch and retention of the external shielding gas.

Submerged Arc Welding

Submerged arc welding (SAW) produces the coalescence of metals by heating them with an arc or multiple arcs between a bare metal electrode(s) and the workpiece. The arc, as well as the molten metal, is protected by a granular flux. This welding process is capable of producing welds only in the flat position.

The electrode used for SAW can be either solid or flux-cored. The SAW process is designed and used for high-deposition welding. The equipment used is similar to that for GMAW. The flux can be added manually or by some automatic feeding system.

The only filler metals used for SAW are nickel-base materials. Further alloy additions can be made by variations in the flux, by using powdered metals, or by adding welding wire. The nickel-iron-manganese electrode can be used for groove, fillet, or surfacing applications. This alloy is more resistant to cracking and therefore is more widely used than other nickel-base electrodes.

The selection of the flux is also very important for ensuring a quality weld. The flux must be matched to the filler metal to be used, alloy requirements, strength requirements, and multiple-pass requirements. Welding conditions for SAW are given in Table 11.

TABLE 11 RECOMMENDED PARAMETERS FOR SAW OF CAST IRONS WITH NICKEL-BASE ELECTRODES

Surfacing and Overlaying

Surfacing processes are used to restore surfaces or to improve the surface properties of iron castings damaged by corrosion, spalling, or wear. Any process used for the fabrication, maintenance, or repair of iron castings can be used successfully for surfacing.

Materials for surfacing can be any material normally used for the brazing or welding of iron castings. Ceramic powders and hardfacing alloys not normally associated with cast iron are gaining wide acceptance.

Oxyfuel gas welding was first used for buildup. The total heat input to the base metal is high, producing a large HAZ; however, the cooling rate is quite slow, reducing the residual stresses and the formation of hard martensitic microstructures. This process allows good control of the metal size, shape, and thickness, thus requiring less expensive equipment. However, it is a low-deposition process.

The arc-welding processes are the most commonly used for surfacing cast irons. Process selection depends on the application, grade or type of cast iron, degree of dilution allowable, thickness of the deposit desired, and the intended service.

Thermal spraying processes are employed for surfacing to improve wear or corrosion properties, to salvage mismachined parts, and to improve the service life of a cast iron.

Flame spraying uses the heat from a fuel gas and oxygen to melt surfacing material in the form of cord, powder, rod, or wire. Compressed air is used to propel the melted particles onto the cast iron to be surfaced. The fuel gas usually used for this process is acetylene. Flame spraying can produce bond strengths of 17 to 41 MPa (2.5 to 6.0 ksi), depending on the surfacing material used. Bond strengths of 70 MPa (10 ksi) can be obtained by using special techniques, such as high-energy compressed gas with detonation gun systems. Powders containing boron and silicon can be fused after spraying, producing a homogeneous metallurgical structure with the substrate.

Arc spraying uses the heat produced between two electrically conductive wires. Compressed air is then used to atomize and propel the molten surfacing metal particles to the surface of cast iron. Arc spraying has the highest deposition rate of all the surfacing processes. Bond strengths of 35 to 70 MPa (5 to 10 ksi) are possible, but strength depends on the surfacing metal used.

Plasma spraying involves the use of a water-cooled gun containing a tungsten cathode surrounded by a copper anode nozzle. The arc generated in the gun produces a plasma, which is forced through a small orifice in the copper nozzle by an ionized shielding gas. An additional envelope of inert or mixed carrier gas is added to the stream as it passes out of the gun. The metal or ceramic powders used for surfacing cast iron are pressure fed into the gas stream, melted, then propelled to the cast iron. A clean surface is of utmost importance for achieving a good bond between the thermal spray deposit and the cast iron substrate being surfaced.

Additional processes, such as laser and electron beam, can be used to melt surfacing material to produce layers of deposited metal on cast iron. The surfacing material can take many forms, such as powder, rod, wire, or strip, as long as they can be fed into the beam. Laser remelting is used on thermal spray deposits when a denser deposit with a metallic bond is required.

Surfacing Materials. Filler metals used for surfacing and overlaying are the same as those used in the other welding processes described. Copper alloys are used for corrosion resistance or to build up surfaces for wear. Alloys designed for corrosion resistance are covered under ANSI/AWS A5.6 and A5.7. Classifications, such as CuSn-A, CuSn-C, CuAl-A2, and Cu-NiAl, are used for this purpose.

Hardfacing alloys, as covered in ANSI/AWS A5.13, are used for surfacing cast irons. Copper alloys, such as the CuZn grades B, C, and D, are used for bearing surfaces. A buttering layer of CuAl-2 is recommended before trying to apply a surface of the CuZn grades. If several layers are required, then a stress relieving of 315 °C (600 °F) is recommended after each layer is added.

Stainless steels, not typically used for joining or repairing iron castings, are used for surfacing to increase corrosion and oxidation resistance. Carbon absorption into the stainless steel is a problem. It can cause the formation of chromium carbide and can lower the crack resistance by reducing the level of ferrite. This can be eliminated by first surfacing with a low-carbon nickel electrode before adding the stainless steel surface. The stainless steel deposit may increase in nickel level as a result of the buttering, thus lowering the volume of ferrite, but the formation of chromium carbides is eliminated. The amount of dilution can be minimized by overlapping the beads.

A deposit with a convex shape is recommended. This will help eliminate the tendency of the weld to separate from the casting due to differences in the coefficient of expansion between stainless steel and cast iron.

High-nickel alloys are used for surfacing to correct machining errors, to provide surface machinability in castings containing high phosphorus, and to improve resistance to caustic attack. Classifications such as ENi-CI and ENi-CI-A, which are discussed in the "Shielded Metal Arc Welding" of this article, are used. In addition, alloys covered in ANSI/AWS A5.11 and A5.14 are also used.

The corrosion resistance of a nickel overlay can be greatly reduced if it becomes diluted with iron and carbon from the cast iron. This dilution can be minimized by overlapping beads up to one-half the bead width. Stringer beads are the

preferred method except for the SAW process. Widely oscillated beads with straight polarity (electrode negative) are used for SAW surfacing applications. Again, a buffer layer of nickel should be added to reduce the effects caused by differences in the coefficient of expansion between the surfacing material and the iron casting.

Cast iron alloys are used for buildup when comparable microstructure is required in the application. These electrodes are available in gray, ductile, and malleable iron compositions. The use of preheat, the proper interpass temperature, and a postweld heat treatment may be necessary to ensure a crack-free deposit.

Hardfacing alloys are specified in ANSI/AWS A5.13 and A5.21. They are used for over-laying when wear is the main concern. These alloys may increase the low-stress abrasion resistance, hot hardness, and corrosion resistance of the casting. For more demanding service conditions, nickel- or cobalt-base alloys may be used.

Special precautions must be taken when using hardfacing alloys containing high levels of chromium carbides, which are designed to stress crack in service. Several layers of an iron-nickel alloy, such as ENiFe-CI or ENiFe-CI-A are used to obtain a buffer zone between the hardfacing alloy and the iron casting. Preheating and techniques for minimizing dilution are required when welding these high-chromium alloys.

Ceramic materials or other refractory materials can be overlayed on cast iron when thermal distortion of the casting is important. Other materials, such as alumina and chromium oxide, are used in high-temperature wear and corrosion-resistance applications. Tungsten carbide is applied when surface temperatures up to 540 °C (1000 °F) will be encountered in service or when abrasion resistance is the main concern.

Minimizing dilution of the base iron casting into the weld deposit can be kept to a minimum by:

- MAXIMIZING THE AMOUNT OF METAL DEPOSITED PER UNIT LENGTH. THE BEADS BEING DEPOSITED SHOULD BE OVERLAPPED AS MUCH AS POSSIBLE
- MINIMIZING THE AMOUNT OF HEAT INPUT IN ORDER TO REDUCE THE AMOUNT OF BASE METAL MELTING. THE USE OF STRAIGHT-POLARITY DC CURRENT WILL HELP DECREASE THE PENETRATION
- USING MULTIPLE LAYERS INSTEAD OF ONLY ONE LAYER

Caution must be exercised when considering the reduction in penetration or melting of the cast iron substrate. The deposited weld metal must melt part of the casting to adhere properly. A rule of thumb is that a minimum of 5 to 10% dilution is needed for complete fusion.

Welding of Aluminum Alloys

Paul B. Dickerson, Aluminum Company of America (retired)

Introduction

ALUMINUM AND ITS ALLOYS can be joined by as many or more methods than any other metal. The primary methods used are the gas-shielded arc welding processes, which are described in detail in this article. Other methods are briefly reviewed.

Aluminum has several chemical and physical properties that need to be understood when using the various joining processes. The specific properties that affect welding are its oxide characteristics; the solubility of hydrogen in molten aluminum; its thermal, electrical, and nonmagnetic characteristics; its lack of color change when heated; and its wide range of mechanical properties and melting temperatures that result from alloying with other metals. Various property values are provided in Tables 1, 2, 3, and 4.

Welding of Aluminum Alloys

Paul B. Dickerson, Aluminum Company of America (retired)

Properties of Aluminum

Oxide. Aluminum has a strong chemical affinity for oxygen and it will oxidize immediately upon exposure to air. Thermal treatments and moist storage conditions will increase oxide thickness, as will electrochemical "anodizing" treatments applied for ornamental, architectural, and wear-resistance applications. The natural oxide is thin enough to be removed by either inert-gas welding arcs or fluxes. However, the thicker oxide should be reduced by chemical or mechanical means prior to welding.

Aluminum oxide melts at about 2050 °C (3720 °F), which is much higher than the melting point of the base alloy. If the oxide is not removed or displaced, the result is incomplete fusion. The fluxes used with some joining processes in order to remove the oxide contain chlorides and fluorides that must be removed after the joining operation to avoid a possible corrosion problem in service. This has led to a wide acceptance of the inert-gas arc welding processes, which remove the oxide without use of a flux.

Aluminum oxide is an electrical insulator. If it is thick enough, as in anodic coatings, then it can prevent arc initiation. In this case, oxide reduction is required not only in the weld joint, but also at the location of the ground lead connection. A thick oxide on a gas-metal arc welding (GMAW) electrode (from a thermal treatment or storage in a humid atmosphere) can produce erratic electrical commutation in the contact tube of the gun, with poor welding results.

Hydrogen Solubility. Hydrogen dissolves very rapidly in molten aluminum. However, hydrogen has almost no solubility in solid aluminum and it has been determined to be the primary cause of porosity in aluminum welds. High temperatures of the weld pool allow a large amount of hydrogen to be absorbed, and as the pool solidifies, the solubility of hydrogen is greatly reduced. Hydrogen that exceeds the effective solubility limit forms gas porosity, if it does not escape from the solidifying weld.

Any source of hydrogen--such as lubricant on the base metal or filler, moisture on the surface or in the form of a hydrated oxide on the base or filler metals, moisture leaks or condensation inside the nozzle of a water-cooled torch, or moisture in the shielding gas--must be eliminated in order to produce sound welds. The aluminum-magnesium (5*xxx* series) alloys are most sensitive to forming a hydrated oxide, and spooled bare electrode must be stored in a dry, heated area. The moisture cannot be removed from the hydrated oxide by heating, as is done with flux-coated electrodes.

Electrical Conductivity. When arc welding, the ground connection can be attached anywhere on the part. This is preferred to the attachment of the ground cable to a steel work table, because the insulating oxide on the aluminum and rust on the steel can both cause a poor transfer of the electric current. Arcing at contact points can occur and can mar the aluminum surface. Aluminum alloys possess high electrical conductivity and pure aluminum has 62% that of pure copper, as shown in Tables 1, 2, 3, and 4.

High electrical conductivity permits the use of long contact tubes in GMAW guns, because resistance heating of the electrode does not occur, as is experienced with ferrous electrodes. Long contact tubes are desirable to provide multiple contact points for good current commutation. Arcing in short contact tubes is common with aluminum, because of its natural insulating oxide, when only a couple of contacts are available. This is especially true when the arc is being initiated using a constant-voltage power supply and a fast electrode "run-in" speed, which cause a high-current surge.

The nonmagnetic property of aluminum minimizes problems of "arc blow" and makes it a suitable material for clamps and fixtures when arc welding other materials. Vacuum attachments, rather than magnetic devices, are required for lifting or attaching portable welding tracks and the like.

Thermal Characteristics. The thermal conductivity of aluminum is about 6 times that of steel. Although the melting temperature of aluminum alloys is substantially below that of ferrous alloys, higher heat inputs are required to weld aluminum because of its high specific heat. Even so, if a slow welding pace is employed, then the heat can be conducted

ahead of the arc, requiring continuous adjustments of welding parameters. Most uniform welding conditions dictate high heat inputs with moderate welding speeds.

High thermal conductivity makes aluminum very sensitive to fluctuations in heat input by the welding process. Specifically, a steady heat input is required with the faster welding processes, such as GMAW, to avoid variations in penetration and fusion. For instance, both of these discontinuities can result from the fluctuations in current that occur in the root pass of a groove or fillet weld when manipulating a GMAW gun powered by a constant-voltage machine. For assemblies subjected to radiographic examination, the use of a constant-current (drooping volt-ampere characteristic) power supply with the GMAW process is preferred in order to produce the soundest welds in aluminum.

The thermal expansion of aluminum is about twice that of steel, and aluminum welds shrink about 6% by volume during solidification. Thin material must be fixtured or "tack welded" closely to keep the edges of the joint in alignment. Shrinkage must be balanced by the welding sequence to control distortion. Weld termination craters must be given more attention and avoided in order to prevent shrinkage voids and crater cracking.

Aluminum does not change color as it is heated. Therefore, the welder must be in a position to see the melting under the arc in order to control the degree of melting as the weld progresses.

Forms of Aluminum. Most forms of aluminum can be welded. All the wrought forms (sheet, plate, extrusions, forgings, rod, bar, and impact extrusions), as well as sand and permanent mold castings, can be welded. Welding on conventional die castings produces excessive porosity in both the weld and the base metal adjacent to the weld because of internal gas. Vacuum die castings, however, have been welded with excellent results. Powder metallurgy (P/M) parts also may suffer from porosity during welding because of internal gas.

The alloy composition is a much more significant factor than the form in determining the weldability of an aluminum alloy. Compositions of the major wrought base alloys and their relative weldability ratings are given in Tables 1 and 2. Similar data are listed in Tables 3 and 4 for the common casting alloys.

Welding of Aluminum Alloys

Paul B. Dickerson, Aluminum Company of America (retired)

Filler Alloy Selection Criteria

When choosing the optimum filler alloy, the end use of the weldment and its desired performance must be prime considerations. Many alloys and alloy combinations can be joined using any one of several filler alloys, but only one filler may be optimal for a specific application. Table 5 lists the chemical composition and melting range of standard aluminum filler alloys.

(B) WROUGHT ALLOY WITH COMPOSITION IDENTICAL TO CAST ALLOY A356.0.

(C) WROUGHT ALLOY WITH COMPOSITION IDENTICAL TO CAST ALLOY A357.0

The primary factors commonly considered when selecting a welding filler alloy are:

- EASE OF WELDING OR FREEDOM FROM CRACKING
- TENSILE OR SHEAR STRENGTH OF THE WELD
- WELD DUCTILITY
- SERVICE TEMPERATURE
- CORROSION RESISTANCE
- COLOR MATCH BETWEEN THE WELD AND BASE ALLOY AFTER ANODIZING

Each of these factors is addressed below.

Sensitivity to Weld Cracking. Ease of welding is the first consideration for most welding applications. In general, the non-heat-treatable aluminum alloys can be welded with a filler alloy of the same basic composition as the base alloy. In some cases, as shown in Table 5, a small amount of grain refiner, such as titanium, is added to the filler alloy to minimize cracking during welding. For example, filler alloys 5554 and 5556 are identical to base alloys 5454 and 5456, respectively, except that titanium is added to the filler alloy.

The heat-treatable aluminum alloys are some-what more complex, metallurgically, and are more sensitive to "hot short" cracking, which results from heat-affected zone (HAZ) liquidation during the welding operation. Generally, a dissimilar alloy filler having higher levels of solute (for example, copper or silicon) is used in this case. At high solute levels, there is sufficient eutectic liquid available for the back-filling (healing) of tears that formed during solidification. Typically, alloys used as filler for welding heat-treatable aluminum alloys have a lower melting temperature than the base alloy. By allowing the low-melting-point constituents of the base alloy adjacent to the weld to solidify before the weld metal, stresses are minimized on the base metal during its hot short condition, and tendencies for intergranular cracking are greatly reduced. One heat-treatable base alloy that exhibits low sensitivity to hot short cracking is 2219, which can be welded with a similar filler alloy, 2319.

A simple inverted "T" fillet weld test (Ref 1, 2) can be used to determine the compatibility of a filler alloy with a base alloy. It is a measure of weldability in terms of resistance to weld metal hot cracking. This test requires that a continuous fillet weld be made joining 13 to 25 mm ($\frac{1}{2}$ to 1 in.) plate by the gas-tungsten arc welding (GTAW) process. The total length of cracking that results from a given combination of base and filler alloys provides a quantitative comparison with other alloy combinations. When no cracking is observed in the continuous fillet weld, a more sensitive discontinuous weld test can be used. In this case, a weld nugget is deposited and allowed to solidify before depositing an overlapping weld nugget. Typical weld cracking results obtained from the fillet weld test and similar tests (Ref 3, 4, 5, 6) are shown in Fig. 1 and 2. These tests, as well as field experience, have indicated that:

- THE HIGH-PURITY L*XXX* SERIES ALLOYS AND 3003 ARE EASY TO WELD WITH BASE ALLOY FILLER, 1100 ALLOY, OR AN ALUMINUM-SILICON ALLOY FILLER, SUCH AS 4043.
- ALLOY 2219 EXHIBITS THE BEST WELDABILITY OF THE 2*XXX* SERIES BASE ALLOYS AND IS EASILY WELDED WITH 2319, 4043, AND 4145 FILLERS.
- ALUMINUM-SILICON-COPPER FILLER ALLOY 4145 PROVIDES THE LEAST

SUSCEPTIBILITY TO WELD CRACKING WITH 2*XXX* SERIES WROUGHT COPPER BEARING ALLOYS, AS WELL AS ALUMINUM-COPPER AND ALUMINUM-SILICON-COPPER ALUMINUM ALLOY CASTINGS.

- THE CRACKING SENSITIVITY OF ALUMINUM-MAGNESIUM ALLOY WELDS DECREASES AS THE MAGNESIUM CONTENT OF THE WELD INCREASES ABOVE 2%. THE HIGH-MAGNESIUM CONTENT ALUMINUM FILLER ALLOYS 5356, 5183, AND 5556 CAN BE USED TO WELD THE ALUMINUM-MAGNESIUM WROUGHT AND CAST ALUMINUM ALLOYS WITH RELATIVE EASE, USING THE GAS-SHIELDED ARC WELDING PROCESSES.
- THE 6*XXX* SERIES BASE ALLOYS ARE MOST EASILY WELDED WITH THE ALUMINUM-SILICON TYPE FILLER ALLOYS, SUCH AS 4043 AND 4047. HOWEVER, THE ALUMINUM-MAGNESIUM TYPE FILLER ALLOYS CAN ALSO BE EMPLOYED SATISFACTORILY WITH THE LOW-COPPER BEARING 6*XXX* ALLOYS WHEN HIGHER ASWELDED SHEAR STRENGTH AND WELD METAL DUCTILITY ARE REQUIRED. THE 6*XXX* ALLOYS SHOULD NOT BE WELDED WITH BASE ALLOY FILLER OR WITHOUT A FILLER ADDITION, BECAUSE IT CAN RESULT IN CRACKING. WHEN 4043 FILLER ALLOY IS USED, THE WELD METAL SHOULD POSSESS A MINIMUM OF 50% 4043; WITH 5356 FILLER ALLOY, THE WELD METAL SHOULD CONSIST OF 70% 5356, MINIMUM (REF 7). JOINTS IN 6*XXX* SERIES ALLOYS ARE OFTEN BEVELED OR SPACED TO PERMIT THE EXCESS FILLER ALLOY DILUTION.
- THE 7*XXX* SERIES (ALUMINUM-ZINC-MAGNESIUM) ALLOYS EXHIBIT A WIDE RANGE OF CRACK SENSITIVITY DURING WELDING. ALLOYS 7005 AND 7039, WITH A LOW (<0.1%) COPPER CONTENT, HAVE A NARROW MELTING RANGE AND CAN BE READILY JOINED WITH THE HIGH-MAGNESIUM CONTENT FILLER ALLOYS 5356, 5183, AND 5556. THE 7*XXX* SERIES ALLOYS THAT POSSESS A SUBSTANTIAL AMOUNT OF COPPER, SUCH AS 7075 AND 7178, HAVE A VERY WIDE MELTING RANGE WITH A LOW SOLIDUS TEMPERATURE AND ARE EXTREMELY SENSITIVE TO WELD CRACKING WHEN ARC WELDED.
- THE RECENTLY INTRODUCED ALUMINUM-LITHIUM ALLOYS ARE WELDABLE WHEN CORRECT FILLER ALLOYS ARE SELECTED. ALLOYS 2090 AND 2095 CAN BE EASILY WELDED WITH 2319 ALLOY.

Groove weld strength is another major consideration when selecting a proper filler alloy. The heat of welding softens the aluminum alloys adjacent to the weld if they are in any temper other than annealed. In most groove welds, the HAZ of the base alloy will control the as-welded strength of the joint.

For non-heat-treatable aluminum alloys, the zone adjacent to the weld will be completely annealed, as illustrated in Fig. 3. A few seconds at a temperature above 343 °C (650 °F) will completely remove any effect of work hardening for 25 to 38 mm (1 to 1 $\frac{1}{2}$ in.) in any direction from the weld in these alloys. The welding procedure and choice of fusion welding process have little effect on the transverse ultimate tensile strength of groove welds; they simply affect the width of the HAZ. The mechanical properties of groove welds in common non-heat-treatable alloys are listed in Table 6.

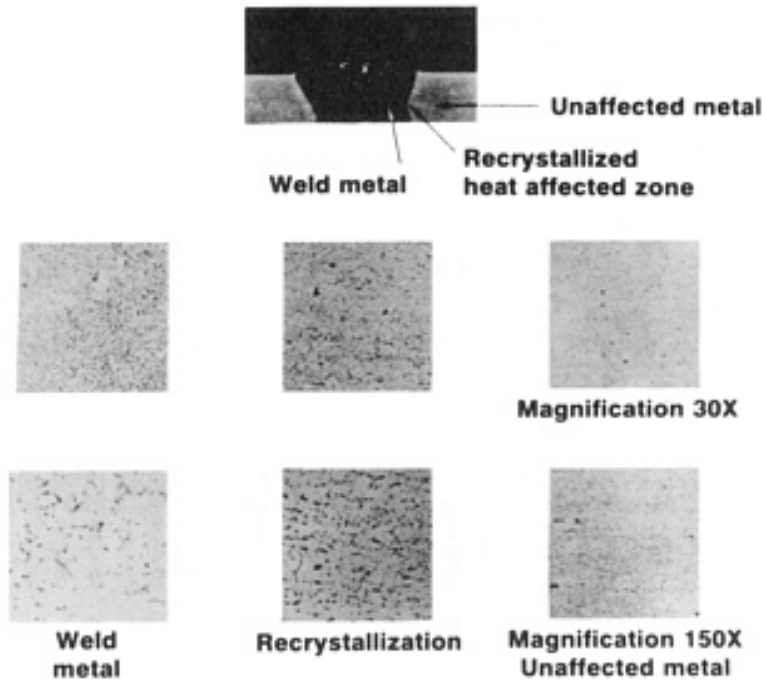

FIG. 3 PHOTOMICROGRAPHS SHOWING HAZ MICROSTRUCTURES OF A SINGLE-PASS GAS-METAL ARC WELD ON 6.35 MM (0.25 IN.) THICK 5083-H116 ALLOY. KELLER'S REAGENT USED AS ETCHANT

The heat-treatable alloys require 2 to 3 h at their annealing temperature, combined with slow cooling, for a complete anneal. This does not occur during welding, and the HAZ will consist of several stages of dissolution and varying degrees of precipitation, based on the thermal conditions, as shown in Fig. 4. The degree of softening in the HAZ is quite sensitive to the peak temperature reached at a specific location, as well as the time at temperature.

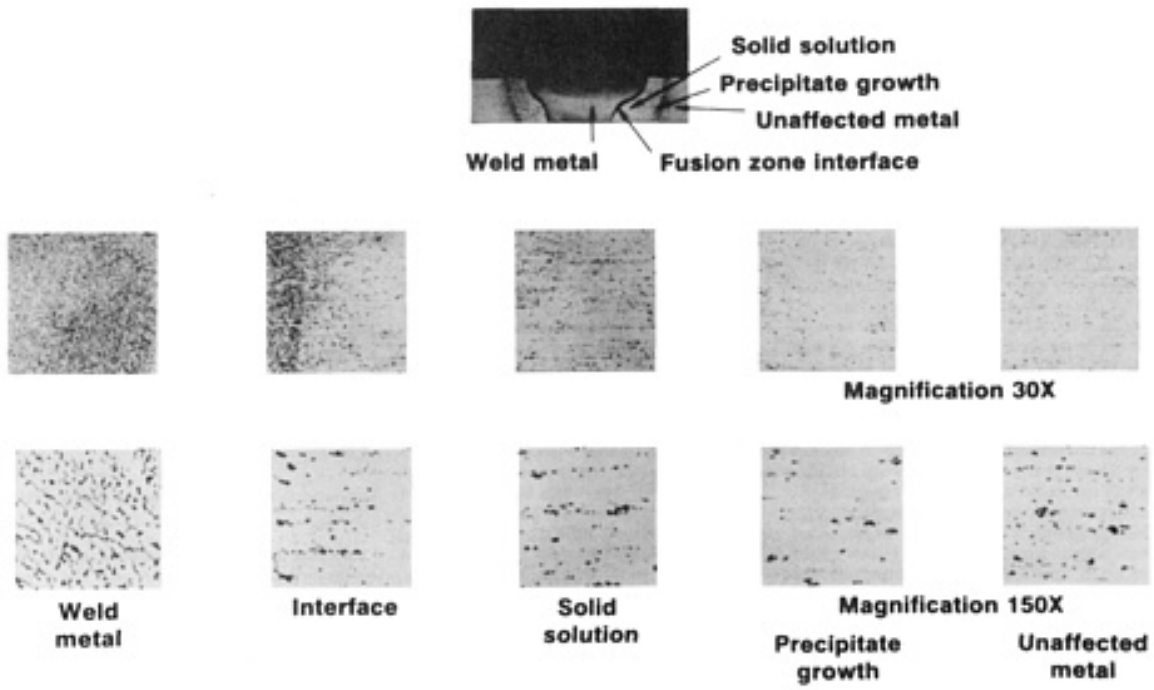

FIG. 4 PHOTOMICROGRAPHS SHOWING HAZ MICROSTRUCTURES OF A SINGLE-PASS GAS-METAL ARC WELD ON 6.35 MM (0.25 IN.) THICK 6061-T6 ALLOY. KELLER'S REAGENT USED AS ETCHANT

Factors such as preheat temperature, interpass cooling, heat input of the joining process and welding technique, use of "chill" bars, and rate of cooling all have an effect on the degree of softening that results from welding the heat-treatable aluminum alloys. Preheat, lack of interpass cooling, and slow, weaving weld passes all increase peak temperatures and extend high temperatures farther from the weld, as well as increase the time at these high temperatures so as to reduce the mechanical properties in the HAZ. These factors alone, as well as the use of too small a specimen to provide an adequate "heat sink," can create sufficient overheating that the minimum values required for procedure qualification may not be met. The weldable 7*xxx* series alloys 7005 and 7039 are least sensitive to these variables and will naturally age (dissolved precipitate will reprecipitate) at room temperature for 2 to 4 weeks following the welding operation to provide high strength without a postweld thermal operation. Typical mechanical properties for groove welds in the heat-treatable aluminum alloys are listed in Table 7.

(B) POSTWELD ARTIFICIALLY AGED ONLY.

(C) FOR THICKNESSES GREATER THAN 19 MM ($\frac{3}{4}$ IN.), 4643 FILLER IS REQUIRED.

(D) POSTWELD AGED AT ROOM TEMPERATURE FOR 30 DAYS

When heat-treatable alloy weldments are given a postweld solution heat treatment and artificial aging, the filler selection is limited. The heat-treatable filler alloy 2319 will provide the highest strength for 2014 and 2219 base alloys. Heat-treatable alloy castings are often repaired or welded with a filler of the same composition as the base alloy and can be postweld heat treated to the desired strength. In most cases, the filler is either not a heat-treatable alloy or is one that is only mildly responsive to strengthening thermal treatments. In these cases, dilution of the base alloy into the weld metal is necessary to obtain a weld metal alloy that can be postweld heat treated.

Filler alloy 4043 (5% Si, balance Al) is a non-heat-treatable alloy. When it is used to weld 6061 alloy, some magnesium from the 6061 must be alloyed with it to provide an aluminum-silicon-magnesium mixture in the weld metal. This new weld metal mixture will respond to a postweld solution heat treatment and produce a groove weld with a tensile strength equal to that of the original 6061-T6. When thick sections, that is, 19 mm ($\frac{3}{4}$ in.) and thicker, are welded, the bevel is normally so wide that the dilution effect may not reach the center of the weld. Filler alloy 4643, which contains some magnesium itself, has been used to provide the highest strength in these cases, as shown for a 76 mm (3 in.) groove weld in Table 8. This filler is also useful for fillet welds in thinner metal.

Complete re-solution heat treatment is not always practical, because the rapid quench from a high temperature can cause distortion of a welded assembly. An alternate method for increasing the welded strength of heat-treatable alloys is to weld them in the solution heat-treated temper (T4) and age them after welding is complete. To accomplish this effectively, a welding procedure that keeps the heat input relatively low and short in duration should be employed (Ref 8, 9, 10). Tables 7 and 8 compare mechanical properties for postweld solution heat treating and aging versus artificial aging only for 2219 and 6061 alloys. An example of this is highway light poles tapered in a very workable 6*xxx*-T4 alloy, welded to the base, and artificially aged to the T6 temper.

Filler alloys 5183, 5356, 5556, and 5654, which contain over 3% Mg, are not normally recommended for use when parts are to be postweld aged. These high-magnesium content aluminum alloys can be sensitized to stress-corrosion cracking (SCC) when subjected to a relatively long-time precipitation heat treatment (artificial aging) under conditions of high residual stress (Ref 11, 12).

Fillet weld strength represents a significant consideration when selecting a welding filler alloy. Minimum shear strength values for several common filler alloys are listed in Table 9 (Ref 13). Filler alloy 5556 produces the highest fillet weld strength in the as-welded condition. This is nearly twice the shear strength of 4043 fillet welds.

(A) AS-WELDED.

(B) ARTIFICIALLY AGED AFTER WELDING.

(C) SOLUTION HEAT-TREATED AND AGED AFTER WELDING

Because several filler alloys can be used to weld many base alloys, the higher-strength weld metal can provide an economic advantage in some applications. For instance, 6061 is commonly welded with 4043 filler, although 5556 filler can also be used. For a symmetrical design requiring a force per unit length of 875 N/mm (5000 lbf/in.) of fillet weld length, an 11 mm ($\frac{7}{16}$ in.) fillet would be required for the 4043 filler versus a 6.4 mm ($\frac{1}{4}$ in.) fillet for 5556 filler. The 6.4 mm ($\frac{1}{4}$ in.) fillet can be made in a single weld pass, but three passes normally would be required for the 11 mm ($\frac{7}{16}$ in.) fillet size. Not only can the 5556 weld be made in one-third of the time, but distortion from the volume of weld metal shrinkage is also minimized by the smaller weld.

The ductility of aluminum welds is excellent for the non-heat-treatable alloys when like filler alloys are used. Using free-bend elongation values as the measure of weld metal ductility, the highest ductility is observed with the pure aluminum alloys. Excellent ductility is also experienced in 5*xxx* series alloys welded with 5*xxx* series fillers. Tables 6 and 7 list the free-bend elongation of butt joints in commonly welded base alloys.

Welds in the heat-treatable alloys do not exhibit as high ductility as the non-heat-treatable alloys. In addition, postweld heat treatments generally reduce ductility, compared to the as-welded condition. About a 50% higher ductility level is

obtained when a 5*xxx* series filler is used with 6061 and 6063 base alloys, rather than an aluminum-silicon filler alloy, such as 4043.

Low weld ductility results when welding the aluminum-copper alloys with 4043 or 4145 filler alloys. However, moderate ductility can be obtained when the aluminum-copper alloys are welded with 2319 filler. In addition, 2319 produces the highest weld metal ductility with the aluminum-copper alloys after postweld heat treatments.

Welds in Al-Zn-Mg-Cu alloys, such as 7075 and 7178, possess very low ductility (1% or less). This, in addition to their high sensitivity to cracking when arc welded, generally discourages their use for arc welded applications. The low copper content 7*xxx* series alloys, 7005 and 7039, exhibit good weld ductility with 5183, 5356, and 5556 fillers.

Low ductility is experienced at the weld fusion zone when joining a high silicon content alloy (such as 356.0 casting) to a high magnesium content base alloy (such as 5083). No favorable filler selection is available. If an aluminum-magnesium filler compatible with 5083 is used, then a low-ductility interface of Mg_2Si occurs on the 356.0 side of the weld. Use of an aluminum-silicon filler compatible with the 356.0 casting moves the low-ductility interface to the 5083 side of the weld. A desirable solution is to weld either the 5083 to an aluminum-magnesium casting or the 356.0 (7 Si) casting to a wrought alloy, such as 6061, which is also welded with an aluminum-silicon filler alloy.

Temperature Versus Performance. Aluminum alloys lose a substantial portion of their strength as temperatures exceed 200 °C (390 °F). The aluminum-copper 2*xxx* series alloys exhibit the best elevated-temperature properties, as indicated in Table 10. The 5*xxx* series base and filler alloys with nominal magnesium contents that exceed 3% are not recommended for use at sustained temperatures above 66 °C (150 °F) because they can be sensitized to SCC (Ref 11). Base alloy 5454 and its companion filler alloy 5554 were developed specifically to provide the highest strength among the 5*xxx* alloys for sustained elevated-temperature service. Filler alloy selections suitable for welding common wrought and cast alloys for sustained elevated-temperature service are listed in Table 11.

With decreasing temperature, aluminum alloys and their weldments gain strength (Table 10). Rather than becoming brittle, the aluminum alloys either maintain or increase in ductility as the temperature decreases below 0 °C. Typical properties for 5083 plate welded with 5183 alloy filler are shown in Fig. 5. The high magnesium content 5*xxx* series alloys have very good cryogenic properties and, because of their excellent weldability, have been used widely for the storage and transport of liquid oxygen and liquid natural gas. Additional information is available in the Section "Selection of Nonferrous Low-Temperature Materials" and the article "Welding for Cryogenic Service" in this Volume.

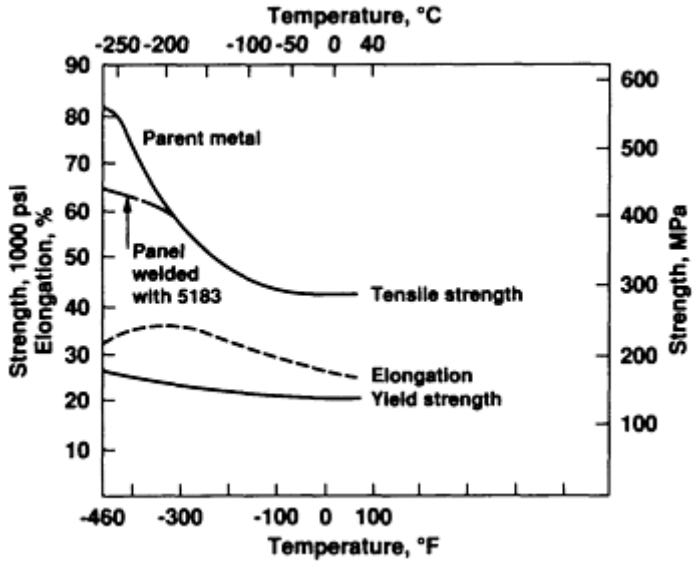

FIG. 5 TYPICAL ROOM-TEMPERATURE AND LOW-TEMPERATURE TENSILE PROPERTIES OF 5083-O BASE ALLOY PLATE WELDED WITH 5183 ALLOY FILLER

Corrosion resistance of the non-heat-treatable alloys is not altered significantly by the heat of welding. The aluminum-magnesium-silicon heat-treatable alloys, such as 6061 and 6063, also have high corrosion resistance in the welded condition. The 2*xxx* and 7*xxx* series heat-treatable alloys, which contain substantial amounts of copper and zinc, respectively, can have their resistance to corrosion altered by the heat of welding. For example, in the aluminum-copper alloys, the HAZ becomes cathodic, whereas in the aluminum-zinc alloys, it becomes anodic to the remainder of the weldment in the presence of water or other electrolytes (Ref 12). The solution potentials across the weld zone for a 5*xxx*, 2*xxx*, and 7*xxx* series weldment are shown in Fig. 6.

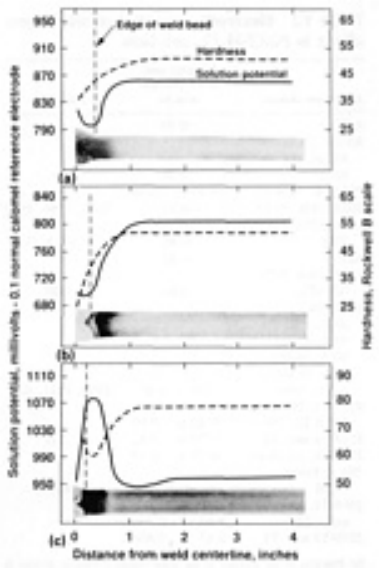

FIG. 6 PLOT OF SOLUTION POTENTIAL AND HARDNESS VERSUS DISTANCE FROM WELD CENTERLINE TO SHOW EFFECT OF THE HEAT OF WELDING ON METALLURGICAL CHANGES IN SELECTED ALUMINUM ALLOYS. (C) 7039-T651 BASE ALLOY WELDED WITH 5183 ALLOY FILLER. GTAW-DCEN, TWO PASSES

Different aluminum alloy compositions produce slightly different electrode potentials in the presence of various solutions. Selective corrosion can result in immersed service, where the base alloy and weld metal possess significant differences in potential. Table 12 lists the solution potentials for common aluminum alloys in a salt solution.

(A) POTENTIAL OF ALL TEMPERS IS THE SAME UNLESS A SPECIFIC TEMPER IS DESIGNATED.

(B) MEASURED IN AN AQUEOUS SOLUTION OF 53 G NACL + 3 G H_2O_2 PER LITER AT 25 °C (77 °F).

(C) POTENTIAL VARIES WITH QUENCHING RATE DURING FABRICATION.

The alloy with the more negative potential in the weldment will attempt to protect the other part. Thus, if the weld metal is anodic to the base metal (as is a 5356 weld in 6061-T6), the small weld can be attacked preferentially to protect the larger surface area of the base metal. The greater the area to be protected and the greater the difference in electrode potential, the more rapidly will corrosive action occur.

Optimum corrosion resistance is obtained when the solution potential of the filler is the same as that of the base alloy, as shown in Table 12 for 4043 filler alloy and 6061-T6. If this is not practical, then a preferred arrangement is to have the larger base alloy surface area be anodic to the weld metal, such as 7005-T6 welded with 5356 filler.

For the welds shown in Fig. 6, the HAZ in the 5*xxx* alloy is mildly cathodic, whereas the 2*xxx* alloy exhibits a greater cathodic differential. The 7*xxx* series HAZ is anodic to the unaffected material and would be of greatest concern. Fabrications in the 7*xxx* alloys are usually painted to avoid galvanic corrosion. However, as an additional safety precaution in some cases, the weld area is metallized with another aluminum alloy to prevent galvanic corrosion if a void occurs in the paint coating. Most unprotected aluminum-base and filler alloy combinations are very satisfactory for general atmospheric conditions.

In some cases, an alloy constituent can be formed by alloying components of the base and filler alloys to produce an anodic zone at the transition of the weld and base metal. If a 5*xxx* alloy is welded with an aluminum-silicon filler, or vice versa, then a magnesium silicide constituent can be formed. For certain immersed conditions, such as a mild acid condition, the magnesium silicide can be highly anodic to all other parts of the weldment (Ref 14, 15). A very selective knifelike corrosive attack can result from this immersed service.

Some chemical exposures or special circumstances can require special controls within the elements of an alloy. In the case of hydrogen peroxide exposure, the manganese and copper impurities have been controlled to low limits in 5652 and 5254 base alloys, as well as 5654 filler alloy. In some cases, a high-purity aluminum alloy is chosen for special exposure. A filler alloy of equal or higher purity to that of the base alloy is generally acceptable in these cases, and filler alloy 1188 would meet most of these requirements.

Weld and Base Metal Color Match. A good color match between the weld metal and the base metal is often desired for ornamental or architectural applications that are given either chemical or electrochemical finishes. The final color of the alloy depends on the chemical composition of the alloy. Ideally, a filler alloy should possess the same composition as the base alloy for an optimum color match. This can be accomplished for most of the non-heat-treatable alloys, but it is not practical with the majority of the heat-treatable aluminum alloys because of weld cracking sensitivity. Thus, dissimilar alloys with the same color response to the final surface treatment are used with these alloys. The two alloying elements of primary interest are silicon and chromium. Silicon in an alloy will create a gray-to-black color, depending on the percentage of silicon (Fig. 7). Thus, welds made with aluminum-silicon filler alloys would exhibit a sharp color contrast with all but the aluminum-silicon base alloys or those clad with an aluminum-silicon alloy. Chromium causes an alloy to take on a yellow or gold shading when anodically treated. Of lesser concern is manganese, which causes a faint gray color.

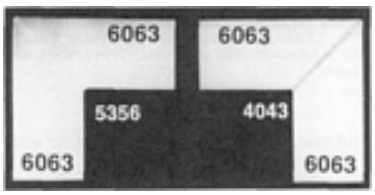

FIG. 7 CLEAR ANODIC COATING ON 6063 WELDS MADE WITH ALUMINUM-MAGNESIUM (5356) AND ALUMINUM-SILICON (4043) FILLERS

The filler alloys that are recommended to obtain a good color match with various base alloys are listed in Table 13. Base alloys 6061 and 6063, which are most commonly welded with 4043 alloy filler, are of the most concern. Because a black weld results when a 4043 weld is anodized, filler alloy 5356 is preferred for the best color match (Fig. 7).

Filler Alloy Choices. The final determination of the optimal filler alloy for joining an aluminum alloy or combination of alloys should be made after a thorough analysis of the final performance desired from the weldment. Usually, a filler alloy can be selected to meet the service conditions with little or no compromise in the ease-of-welding characteristic. The criteria discussed for an alloy type can be applied to the cast aluminum alloys, as well as to the wrought aluminum alloys.

Table 14 provides a comprehensive matrix for selecting a filler alloy for the GTAW and GMAW processes, based on the various requirements or service conditions presented previously. Commonly welded wrought and cast aluminum alloys are included to assist in selecting a filler for welding an alloy to itself or to another aluminum alloy. The corrosion data are based on performance in fresh or salt water and do not necessarily apply to other exposure conditions. In addition, all ratings are based on as-welded performance and may not apply when the weldment is subjected to postweld thermal treatments.

Note: Combinations having no ratings are not recommended.

Source: Aluminum Company of America

(A) A, B, C, AND D REPRESENT RELATIVE RATINGS (WHERE A IS BEST AND D IS WORST) OF THE PERFORMANCE OF THE TWO COMPONENT BASE ALLOYS COMBINED WITH EACH GROUP OF SELECTED FILLER ALLOYS. W, EASE OF WELDING (RELATIVE FREEDOM FROM WELD CRACKING); S, STRENGTH OF WELDED JOINT IN AS-WELDED CONDITION (RATING APPLIES SPECIFICALLY TO FILLET WELDS, BUT ALL RODS AND ELECTRODES RATED WILL DEVELOP PRESENTLY SPECIFIED MINIMUM STRENGTHS FOR BUTT WELDS); D, DUCTILITY (RATING BASED ON FREE BEND ELONGATION OF THE WELD); C, CORROSION RESISTANCE IN CONTINUOUS OR ALTERNATE IMMERSION OF FRESH OR SALT WATER; T, PERFORMANCE IN SERVICE AT SUSTAINED TEMPERATURES >65 °C (>150 °F); M, COLOR MATCH AFTER ANODIZING.

(B) NO FILLER SUITABLE.

Quality control requirements for bare aluminum filler rod and electrode are stated in Ref 16. To maintain the quality level to which they are produced, the filler wire must be protected during shipment, storage, handling, and use. The spooled filler wire, which is most critical, is normally packaged in a sealed plastic bag and carton. The best storage place is a dry, heated area. If stored in an unheated area, then the packaged product should be brought to the production area and allowed to reach that ambient temperature before the carton is opened. If the temperature of the wire is more than 9 °C (16 °F) below the room temperature when the package is opened, moisture in the atmosphere can condense on the wire, creating a hydrated oxide. The 5*xxx* (aluminum-magnesium) series filler alloys are most sensitive to this situation and can be ruined after just a few seconds of exposure, because the hydrated oxide can cause excessive porosity in the weld. For the same reason, the spooled product should be removed from the welding apparatus at the completion of work and stored in a cabinet where the relative humidity is kept below 35%. A small resistance heating unit in an electrical socket on the inside of a sealed cabinet will accomplish this. If the product is not removed from the equipment, a small resistance heater inside the spool enclosure can also be effective.

Welding of Aluminum Alloys

Paul B. Dickerson, Aluminum Company of America (retired)

Preparation for Welding

Joint Designs. Typical joint geometries for ac-GTAW and GMAW processes used with aluminum are shown in Fig. 8. Because good penetration control can be obtained with GTAW, welds can be made from a single side without backing. When mechanizing the GTAW process and when using the GMAW process by manual or mechanical means, the use of a temporary grooved backing is very helpful in controlling the uniformity of penetration for single-sided welds. When welding from both sides, a temporary support of the initial weld pass can be given by an angle or rod when a thin land is employed, or the land can be thickened to provide support. In either case, back gouging to sound weld metal is required before application of the initial root pass.

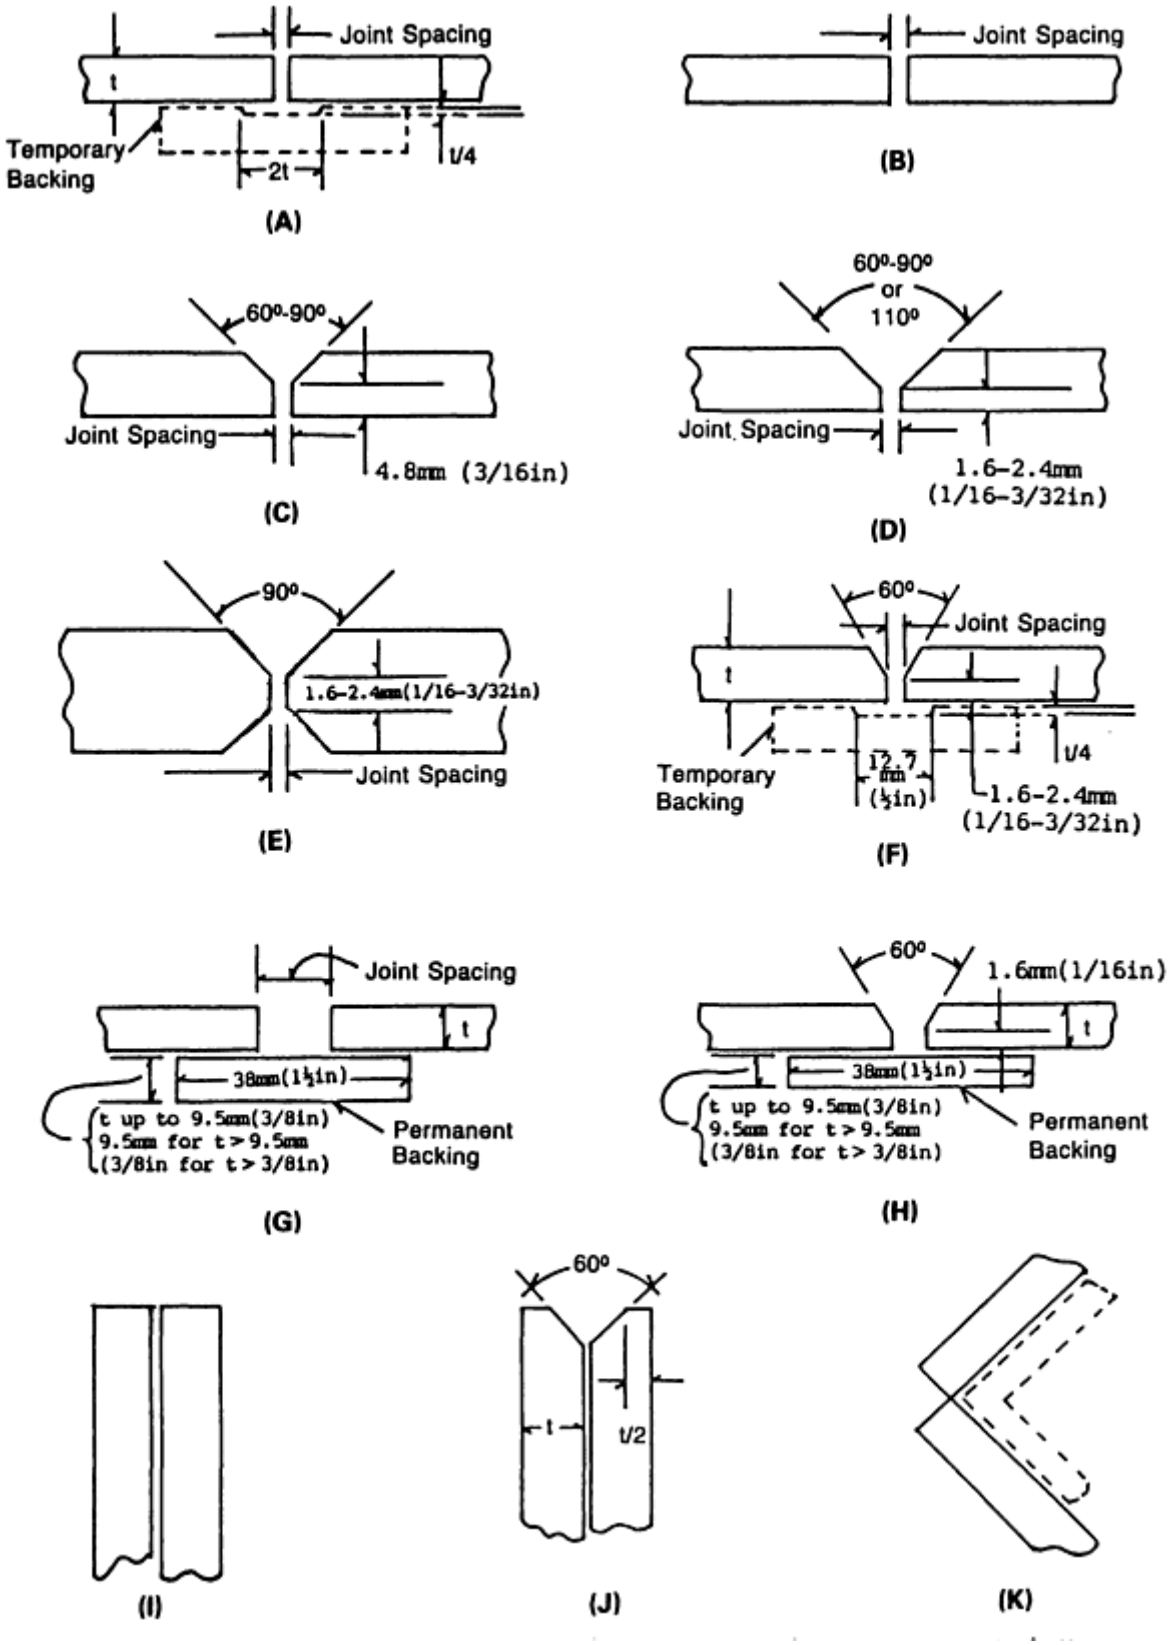

FIG. 8 TYPICAL JOINT GEOMETRIES USED FOR AC-GTAW AND GMAW OF ALUMINUM COMPONENTS. LETTERS CORRESPOND TO EDGE PREPARATIONS IN TABLES 15, 17, AND 18. SOURCE: AMERICAN WELDING SOCIETY

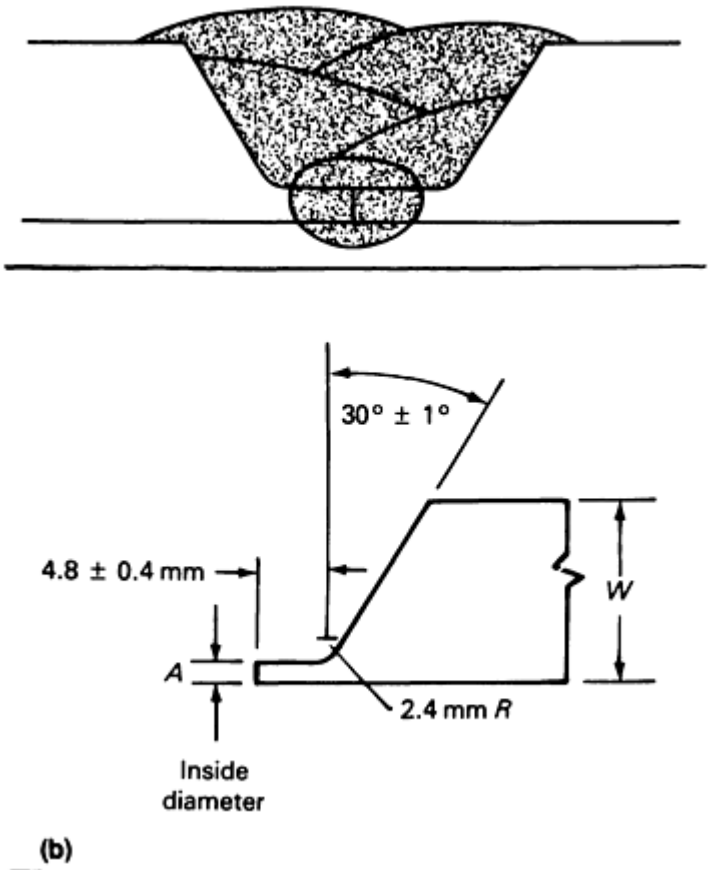
A 60° included "V" bevel is standard for GMAW. For GTAW, the bevel varies from 60° to 90°, and for overhead groove welds, a 110° minimum "V" bevel is required for root pass control. The large angles are needed to allow the gas nozzle access to the joint to provide adequate inert-gas shielding of the root passes. For proper nozzle access with 25 mm (1 in.)

and thicker material, single "U" and double "U" bevels are required. A special joint design used for aluminum pipe and other single-sided access joints, which permits uniform and complete penetration welds without backing, is shown in Fig. 9 (Ref 17).



PIPE SIZE		*A*		W_{MAX}

When welding from a single side, the oxide on the opposite side is not removed by the action of the arc and inert-gas shield. Therefore, it must be physically stretched (Fig. 10) out of the way to permit complete root fusion for full-penetration welds. To accomplish this, the depth of the penetration reinforcement needs to be greater than the levels normally allowed by specifications governing other metals. Practical values for the root reinforcement (*R*) are (Ref 18):

THICKNESS, *T*		ROOT REINFORCEMENT, *R*	
mm	**in.**	**mm**	in.
$T \le 1.6$	$T \le \frac{1}{16}$	$1.5T$	**$1.5T$**
$1.6 < T \le 6.4$	$\frac{1}{16} < T \le \frac{1}{4}$	2.4	$\frac{3}{32}$
$6.4 < T \le 12.7$	$\frac{1}{4} < T \le \frac{1}{2}$	3.2	$\frac{1}{8}$
$12.7 < T \le 25.4$	$\frac{1}{2} < T \le 1$	4.0	$\frac{5}{32}$
$T > 25.4$	**$T > 1$**	**4.8**	$\frac{3}{16}$

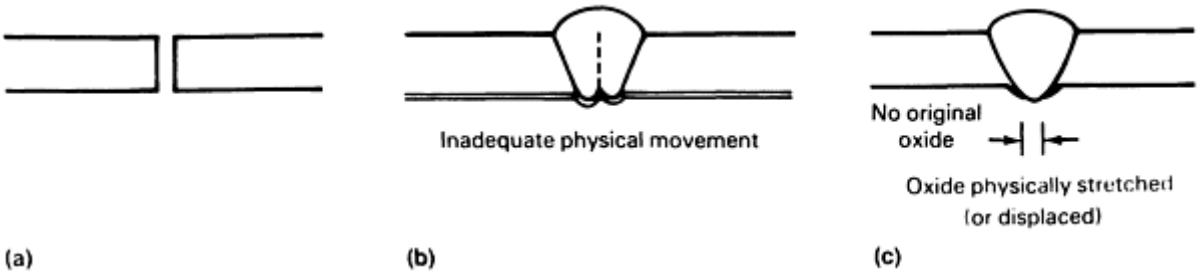

FIG. 10 EFFECT OF PHYSICAL STRETCHING ON ROOT FUSION. (A) ORIGINAL OXIDE SURFACES. (B) INCOMPLETE (POOR) ROOT FUSION. (C) COMPLETE (PROPER) ROOT FUSION

When an integral aluminum backing is used, the base metal edge spacing must be adequate to permit the arc cleaning action to remove the oxide from the backing surface and thus allow proper fusion. An opening of about 1*t* (one times the thickness) is required for thicknesses up to 9.5 mm ($\frac{3}{8}$ in.). For thicker material, the edge spacing should be sufficient to allow two root passes--one along each edge. Integral backings should either be flush with the base metal or possess a shallow groove and should be tack welded to the base metal. Any projections up into the joint to control edge spacing can result in poor fusion along each side of the projection because the oxide cannot be displaced.

Back gouging is normally done mechanically with pneumatic chisels, portable milling cutters, and routers. The gouge should possess a 3.2 mm ($\frac{1}{8}$ in.) minimum radius at its base. Sharp diamond-shaped chisels and sharp saw cuts do not permit proper fusion at their root when welded. Plasma arc cutting can be used to make square and beveled cuts that are free from surface contaminants. The plasma arc welding (PAW) process can also be used for back gouging. Argon-hydrogen gas mixtures are preferred for the best surface smoothness. Surface cracks can occur when arc cutting or gouging the heat-treatable aluminum alloys. These cracks can extend about 2.3 mm (0.090 in.) into the metal and must be mechanically removed before welding over that surface.

Surface Preparation. All surface lubricants on the base metal must be removed following metal working, sawing, and machining operations in order to avoid porosity. Vapor degreasers and any chlorinated solvent must be isolated from the welding area, because the arc radiation can alter these cleaning solutions chemically, resulting in toxic gases. Petroleum-base solvents can be used satisfactorily in the welding area.

Water stains, heat-treating oxides, chemical conversion coatings, and anodic finishes must be removed by chemical etching or mechanical means. Stainless steel brushes are preferred to avoid rust contamination of the joint. If a power brush is used, then a light pressure should be applied to remove the thick oxide. A high force can embed the oxide or contaminant into the surface and increase, rather than eliminate, weld discontinuities.

Surface moisture can be removed by a slight preheat of the joint prior to welding. A brief exposure at a maximum temperature of 120 °C (250 °F) should be controlled with the 5*xxx* series and heat-treatable aluminum alloys to avoid lowering corrosion resistance and reducing mechanical properties, respectively.

Optimal welding occurs when the metal is clean and dry, and possesses a minimum oxide thickness. In multiple-pass welds, it is common to wire brush the previously deposited surface in order to minimize the oxide or surface "smut" and thereby facilitate the subsequent weld pass.

Welding Processes

The GTAW process has been used to weld thicknesses from 0.25 to 150 mm (0.010 to 6 in.) and can be used in all weld positions. Because it is relatively slow, it is highly maneuverable for welding tubing, piping, and variable shapes. It permits excellent penetration control and can produce welds of excellent soundness. Weld termination craters can be filled easily as the current is tapered down by a foot pedal or electronic control.

The ac-GTAW process provides an arc cleaning action to remove the surface oxide during the positive electrode half of the cycle and a penetrating arc when the electrode is operated at negative polarity. It is used primarily to weld thicknesses up to 6.3 mm ($\frac{1}{4}$ in.) and can be used for manual, mechanized, or automated applications. Typical manual welding procedures are listed in Tables 15, 16, and 17.

(A) JOINT DESIGNS AS SHOWN IN FIG. 8.

(B) HIGHER CURRENTS AND WELDING SPEEDS CAN BE EMPLOYED IF A TEMPORARY BACKING IS USED FOR COMER JOINTS.

(C) USE LOW SIDE OF CURRENT RANGE FOR HORIZONTAL AND VERTICAL JOINTS.

Optimal control of penetration in groove welds is obtained with a balanced ac wave, which permits a wide tolerance in the welding current or heat input between insufficient and excessive penetration. The fairly wide melting pattern does not penetrate readily into narrow grooves or corners and tends to bridge the root of fillet welds. When a wave balance control is available on the power supply, an increase in the percentage of the negative polarity can be beneficial, as long as adequate arc cleaning action is maintained.

The ac-GTAW process is particularly useful for welding aluminum pipe. An integral backing is suitable for structural and electrical bus applications; however, for fluid flow of water, gas, oil, and chemicals, crevice corrosion can result at the backing interface within the pipe. The joint configuration shown in Fig. 9 has been used for all-position GTAW of aluminum pipe and is considered standard for this purpose (Ref 17).

Argon shielding gas is normally used. However, for increased penetration capabilities and use on thick base metal, a mixture of argon with 25 to 50% helium can be used. Welding operations must be protected from wind gusts, which can disturb the inert-gas shielding, when welding near open doors and windows or when welding outdoors.

The alternating current arc (whether sinusoidal or square wave) requires a superimposed high-frequency power to maintain the ionized gas circuit when the current changes polarity. This avoids rectification, which reduces the arc cleaning action and arc stability.

Pure or zirconia-tungsten electrodes, which form a ball on the end during welding, should be used with ac-GTAW. Fine spitting of thoria-tungsten electrodes will occur when used with alternating current and should be limited to direct current (dc) operations.

The dc-GTAW Process. Negative electrode polarity direct current can be used to weld aluminum by manual and mechanized means. Helium gas shielding or a mixture of helium with 5 to 10% argon is used with a thoria-tungsten electrode. Because no arc cleaning occurs, the oxide must be minimized on the surface prior to welding. This is normally accomplished by chemical etching, followed by a mechanical "scraping" of the joint surfaces immediately prior to welding. Internal oxide stringers and associated poor fusion can occur if this cleaning is not done thoroughly. The deep, narrow penetration allows welding of square groove joints in thicknesses up to 12.7 mm ($\frac{1}{2}$ in.) and permits welding of heat-treatable alloys with a lower heat input than does ac-GTAW. This can result in higher as-welded mechanical properties with the heat-treatable alloys. The process is most widely used by the aerospace industry for this purpose.

Manual dc-GTAW using negative electrode polarity has been applied primarily to the repair of thick castings or weldments in thick plate. Agitation of the weld pool with the filler rod is sometimes required to break up the surface oxide for proper weld fusion. An excellent fabrication technique utilizing this process has been tack welding of fillet joints in 4.8 mm ($\frac{3}{16}$ in.) and thicker non-heat-treatable alloys, such as 5083 and 5456. A very small fillet reinforcement possessing deep penetration can be made, and there is little or no interference when the continuous weld is produced.

Variable Polarity PAW. This inert-gas process provides good arc cleaning action and sufficient penetration capabilities, such that a "keyhole" is created. It is best used in the vertical weld position so that when the keyhole is generated, the weld metal backfills the joint. The process is only used in mechanized or automated environments, and the equipment is very expensive. The weld is less sensitive to oxide conditions than those produced by either ac- or dc-GTAW, and high-quality welds can be made. Inert-gas backing is desirable for some of the aluminum alloys, such as the aluminum-copper-lithium type. Square groove joints up to 16 mm ($\frac{5}{8}$ in.) can be welded in a single pass.

GMAW is the major high-speed production process for arc welding aluminum. The equipment is portable, and the process can be easily used in all weld positions. It uses positive electrode dc power, which gives it a continuous cleaning action and concentrates the arc to produce rapid melting. Widely varying thicknesses can be welded without the need to preheat. Spooled aluminum wire is automatically fed through the welding gun, melted at the arc, and then sprayed across the arc. Because the electrode and filler are the same, the process is a one-handed operation that is easily mechanized or adapted for robotic operations. Manual travel speeds normally range from 7.6 to 15.2 mm/s (18 to 36 in./min). However, mechanized welds have been made at speeds that exceed 42 mm/s (100 in./min). Initially, GMAW was limited to 3.2 mm

($\frac{1}{8}$ in.) and thicker material. However, the availability of pull-type wire feed apparatus and pulsed-dc power supplies has extended its use with smaller electrodes and lower average currents to weld thicknesses of less than 1 mm (0.040 in.).

GMAW is best used in lap, fillet, or groove welds with integral or temporary backing. Typical welding procedures are listed in Tables 18 and 19. It is not recommended for corner or edge joints, unless the metal is thick enough to provide a substantial ledge or trough upon which to deposit the filler. Heat input needs to be constant for uniform penetration. A constant voltage power supply can be used for straight stringer passes. However, when the arc is oscillated transversely or in line with the joint, wide current excursions produce variable penetration and fusion. Weld starts with short contact tubes and fast electrode feed rates, as used in equipment designed for welding ferrous metals, and a constant voltage power supply often results in poorly fused starts, arcing in the contact tube, and excessive "burn backs" when used with aluminum.

(B) NUMBER OF WELD PASSES GIVEN IS FOR ONE SIDE ONLY.

(C) FOR 5*XXX* SERIES ELECTRODES, USE A WELDING CURRENT IN THE HIGH SIDE OF THE RANGE GIVEN AND AN ARC VOLTAGE IN THE LOWER PORTION OF THE RANGE; FOR 1*XXX*, 2*XXX*, AND 4*XXX* SERIES ELECTRODES, USE THE LOWER CURRENTS AND THE HIGHER VOLTAGES IN THEIR RANGES.

(D) METAL THICKNESSES OF [GES]19.0 MM ([GES] $\frac{3}{4}$ IN.) FOR FILLET WELDS CAN EMPLOY A DOUBLE-VEE BEVEL OF [GES]50° INCLUDED VEE WITH 2.4-3.2 MM ($\frac{3}{32}$ - $\frac{1}{8}$ IN.) LAND THICKNESS IN THE ABUTTING MEMBER.

The optimal equipment for the GMAW of aluminum to meet radiographic standards and to overcome excessive downtime in maintaining the equipment consists of:

- A CONSTANT-ENERGY (CONSTANT-CURRENT, OR "DROOPER") TYPE POWER SUPPLY
- A WIRE FEEDER POSSESSING A "TOUCH-START" OR SLOW RUN-IN FEATURE AND RADIUSED TOP AND BOTTOM DIVE ROLLS
- A WELDING GUN POSSESSING A CONTACT TUBE OF 100 MM (4 IN.) OR MORE IN LENGTH
- NONMETALLIC GUIDES AND LINERS FOR THE ELECTRODE CIRCUITRY

For 1.2 mm ($\frac{3}{64}$ in.) and smaller diameter electrodes, as well as for robotic installations, the wire feeding apparatus should be a pull or push-pull type.

Argon gas shielding is most often used. However, when welding with 5*xxx* series electrode alloys and in facilities that possess highly loaded power circuits, a mixture of argon with 50 to 75% helium will provide improved weld quality.

Other arc welding processes include shielded metal arc welding (SMAW), as well as electroslag and electrogas welding (ESW, EGW). SMAW with flux-coated rods has been replaced to a very substantial degree by the GMAW process. SMAW can be effective on 9.5 mm ($\frac{3}{8}$ in.) and thicker aluminum where high heat inputs are used. However, it produces porous and erratic welds on thinner metal. Excessive spatter limits its use overhead, and the flux requires removal after welding. Because a flux is used, the alloys that can be welded are limited (refer to Tables 1, 2, 3, 4).

The ESW and EGW processes have been used experimentally, but the processes are not in commercial use with aluminum. GMAW can be used for the few applications appropriate for the ESW and EGW processes.

The oxyfuel gas welding (OFW) process uses a flux and either an oxyacetylene or oxyhydrogen gas flame. When the oxyacetylene flame is used, a slightly reduced flame is required, which causes a carbonaceous deposit that obscures the weld and slows the travel speed. The best visibility, control, and weld speed are obtained when an oxyhydrogen flame is used with aluminum alloys. The flux (composed of chlorides and fluorides) must be removed after welding to avoid corrosion in service. For this reason, GTAW has generally replaced OFW of aluminum alloys. The use of a flux limits the alloys for which it is suitable (Tables 1, 2, 3, 4) and produces the greatest heat input. This results in the lowest mechanical properties and highest sensitivity to weld cracking with heat-treatable aluminum alloys. The advantage of the OFW process is the low equipment investment.

Electron-beam welding (EBW) in a vacuum chamber produces a very deep, narrow penetration at high welding speeds. The low overall heat input produces the highest as-welded strengths in the heat-treatable alloys. The high thermal gradient from the weld into the base metal creates very limited metallurgical modifications and is least likely to cause intergranular cracking in butt joints when no filler is added. Fixturing to provide transverse compressive loading on the joint can be very helpful in avoiding intergranular cracking in the fusion zones or HAZs. Alloys are more prone to have porosity when welded in a vacuum.

For lap joints and butt joints with an integral backing, a shim of filler alloy is commonly placed at the interface of the heat-treatable aluminum alloys to prevent transverse cracking at the interface. For the 6*xxx* series and for 2014, 2024, and 7075 alloys, a filler alloy shim is often desirable between the abutting edges of square groove welds. This adds two additional oxide layers to the joint and can result in weld inclusions.

Laser-beam welding (LBW) is now considered to be a viable fusion joining process for aluminum with the advent of commercially available, stable, high-power laser systems. Because of aluminum's high reflectivity, effective coupling of the laser beam and aluminum requires a relatively high power density. High power densities are obtained by minimizing the focused spot size of the beam through optical considerations and higher power levels.

When sufficient power densities are obtained (that is, on the order of 10^6 W/cm^2, or 6×10^6 W/in.^{2}), successful laser-beam welds on aluminum can be produced, with minimal distortion, and at high processing speeds. Inert gas shielding is commonly used. Filler metal is required when welding heat-treatable aluminum alloys.

Joining Aluminum to Other Metals

Very brittle intermetallic compounds are formed when metals such as steel, copper, magnesium, or titanium are fusion welded to aluminum. Bimetallic transition materials in sheet, plate, and tubular forms are commercially available in combinations of aluminum to such other metals as steel, stainless steel, and copper. These are made by rolling, explosion welding, fiction welding, flash welding, or hot pressure welding and provide the easiest method for fusion welding aluminum to other metals. Conventional GTAW and GMAW methods, as well as resistance spot welding, are used to join the aluminum side of the transition piece to the intended component. The dissimilar metal is joined to the opposite side of the bimetallic transition.

A wide range of dissimilar metals can be joined directly to aluminum by such means as ultrasonic welding, pressure welding, friction welding, explosion welding, and soldering. Hot dip or electroplated coatings on the dissimilar metal facilitate diffusion bonding and the brazing of aluminum to these metals.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Introduction

NICKEL ALLOYS can be joined reliably by all types of welding processes or methods, with the exception of forge welding and oxyacetylene welding. Because the majority of consumables are used with arc welding processes, it is those processes that are discussed in this article. The wrought nickel alloys listed in Table 1 can be welded under conditions similar to those used to weld austenitic stainless steels. Cast nickel alloys, particularly those with a high silicon content, present difficulties in welding. The arc welding of heat-resistant and corrosion-resistant nickel alloys is described in the Sections "Selection of Nonferrous Corrosion-Resistant Materials" and "Selection of Nonferrous High-Temperature Materials" in this Volume.

The most widely employed processes for welding the non-age-hardenable (solid solution-strengthened) wrought nickel alloys are gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), and shielded metal arc welding (SMAW). Submerged arc welding (SAW) and electroslag welding (ESW) have limited applicability, as does plasma arc welding (PAW). Although the GTAW process is preferred for welding the precipitation-hardenable alloys, both the GMAW and SMAW processes are also used.

Heat Treatment of Nickel Alloys

Preweld Heating and Heat Treating. Preweld heating of wrought alloys is not required, unless the base metal is below 16 °C (60 °F), in which case a path that is 255 to 305 mm (10 to 12 in.) wide on both sides of the joint should be warmed to 16 to 21 °C (60 to 70 °F) to avoid the condensation of moisture that can cause porosity in the weld metal.

Nickel alloys are usually welded in the solution-treated condition. Precipitation-hardenable (PH) alloys should be annealed before welding if they have undergone any operations that introduce high residual stresses (see the section "Welding of Precipitation-Hardenable Alloys" in this article).

Postweld Treatment. No postweld treatment, either thermal or chemical, is required to maintain or restore corrosion resistance, although in some cases a full solution anneal will improve corrosion resistance. Heat treatment may be necessary to meet specification requirements, such as stress relief of a fabricated structure to avoid age hardening or stress-corrosion cracking (SCC) of the weldment in hydrofluoric acid vapor or caustic soda. If welding induces moderate-to-high residual stresses, then the PH alloys would require a stress-relief anneal after welding and before aging (see the section "Welding of Precipitation-Hardenable Alloys" in this article).

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Cleaning of Workpieces

Nickel and nickel alloys are susceptible to embrittlement by lead, sulfur, phosphorus, and other low-melting-point elements. These materials can exist in grease, oil, paint, marking crayons or inks, forming lubricants, cutting fluids, shop dirt, and processing chemicals. Work-pieces must be completely free of foreign material before they are heated or welded. Both sides of the workpiece should be cleaned in the area that will be heated by the welding operations. When no subsequent heating is involved, the cleaned area may be restricted to 50 mm (2 in.) on each side of the joint.

Shop dirt, oil, and grease can be removed by either vapor degreasing or swabbing with acetone or another nontoxic solvent. Paint and other materials that are not soluble in degreasing solvents may require the use of methylene chloride, alkaline cleaners, or special proprietary compounds. If alkaline cleaners that contain sodium carbonate are used, then the cleaners themselves must be removed prior to welding. Spraying or scrubbing with hot water is recommended. Marking ink can usually be removed with alcohol. Processing material that has become embedded in the work metal can be removed by grinding, abrasive blasting, and swabbing with a 10 vol% HCl solution, followed by a thorough water wash. Further information on the cleaning of nickel and nickel alloys is given in the article "Nickel Alloy Plating" in *Surface Engineering*, in Volume 5, *ASM Handbook*.

Oxides must also be removed from the area involved in the welding operation, primarily because of the difference between the oxide and base metal melting points. Oxides are normally removed by grinding, machining, abrasive blasting, or pickling.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Joint Design

Various joint designs are used in the arc welding of nickel alloys (Fig. 1). Although the same design can be used for GTAW and SMAW processes, the GMAW and SAW processes require special considerations. A joint design developed for other metals is not necessarily suitable for nickel alloys and should not be used unless it proves to be satisfactory, based on either experience or tests.

(A) TO OBTAIN LINEAR FEET OF WELD PER POUND OF CONSUMABLE ELECTRODE, TAKE THE RECIPROCAL OF POUNDS PER LINEAR FOOT. IF THE UNDERSIDE OF THE FIRST BEAD IS CHIPPED OUT AND WELDED, ADD 0.31 KG/M (0.21 LB/FT) OF METAL DEPOSITED (EQUIVALENT TO 0.43 KG/M, OR 0.29 LB/FT, OF CONSUMABLE ELECTRODE).

(B) FOR GMAW (EXCEPT WITH THE SHORT-CIRCUITING ARC), ROOT RADIUS SHOULD BE ONE-HALF THE VALUE SHOWN AND BEVEL ANGLE SHOULD BE TWICE AS GREAT.

FIG. 1 TYPICAL JOINT CONFIGURATIONS AND DIMENSIONS FOR GTAW, GMAW, AND SMAW APPLICATIONS. DIMENSIONS IN SCHEMATIC GIVEN IN INCHES

Beveled Joints. Beveling is usually not required for metal that is 2.4 mm (0.093 in.) or less in thickness, although thinner sections of certain alloys are sometimes beveled. Metal thicker than 2.4 mm (0.093 in.) should be beveled to form a V-, U-, or J-shaped groove and should be welded using either a backing material or a gas, unless welding from both sides. Otherwise, erratic penetration can result, leading to crevices and voids that are potential areas for joint weakness and accelerated corrosion in the underside of the joint. To attain the best underbead contour on joints that cannot be welded from both sides, the GTAW process should be used for the root pass.

For metal that is more than 9.5 mm ($\frac{3}{8}$ in.) thick, a double U- or V-shaped groove design is preferred. The added cost of preparation is justified, because less welding time and material are required and less residual stress is developed than with a single-groove design.

Beveling is best accomplished by machine, usually a plate planer or other machine tool. Plasma arc and electric arc cutting can be used for joint penetration, but all oxidized metal must be removed from the joint area by grinding or chipping for a depth of 0.8 to 1.6 mm ($\frac{1}{32}$ to $\frac{1}{16}$ in.).

Corner and lap joints can be welded when service stresses will not be excessive. However, they should be avoided if service temperatures are high or if service conditions involve thermal or mechanical cycling. When comer joints are used, a full-penetration weld must be made, usually with a fillet weld on the root side. Lap joints should be welded on both sides.

Design Considerations. Molten nickel alloy weld metal does not flow as easily as steel weld metal. This characteristic cannot be compensated for by using extra heat input or pooling, because serious loss of residual deoxidizers may result. For joints in metal up to 16 mm ($\frac{5}{8}$ in.) thick, ample accessibility is provided by V-groove butt joints beveled to a 60° groove angle. For thicker metal, U-groove butt joints are machined to a 15° bevel angle and a 4.8 to 7.9 mm ($\frac{3}{16}$ to $\frac{5}{16}$ in.) radius. Single bevels used to form T joints should have an angle of 45°. The bottom radius of a J-shaped groove for T joints should be at least 9.5 mm ($\frac{3}{8}$ in.), and the bevel angle described above should be used for J- and U-shaped grooves. For full-penetration welds, the bevel and groove angles should be about 30% more than those used for carbon steels.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Welding Fixtures

Proper fixturing and clamping hold the workpieces firmly in place, minimize buckling, maintain alignment, and, when needed, provide compressive stress in the weld metal. A backing bar, or any portion of a fixture that might contact the workpiece, should be made of copper. This metal has such a high thermal conductivity that inadvertent welding against the copper will reduce the chance that the bar will fuse to the weldment. In addition, the grooves in copper bars are often used to contour, without sticking, the side underneath the weld.

Backing bars, when used, should incorporate a groove of suitable contour to permit penetration of weld metal and avoid the possibility of trapping gas or flux at the bottom of the weld. Grooves in backing bars used in the GMAW process usually have a shallow semielliptical shape that is 0.38 to 0.89 mm (0.015 to 0.035 in.) deep and 4.8 to 6.4 mm ($\frac{3}{16}$ to $\frac{1}{4}$ in.) wide. Square corner grooves are used with the GMAW and GTAW processes to accommodate the backing gas. A machined passageway is connected to the gas supply, and holes that are 1.6 mm ($\frac{1}{16}$ in.) in diameter are drilled 75 mm (3 in.) apart from the bottom of the groove to the passageway, permitting the backing gas to flow along the weld. The gas flows out of the groove at the ends of the bar. Figure 2 shows groove designs for backing bars.

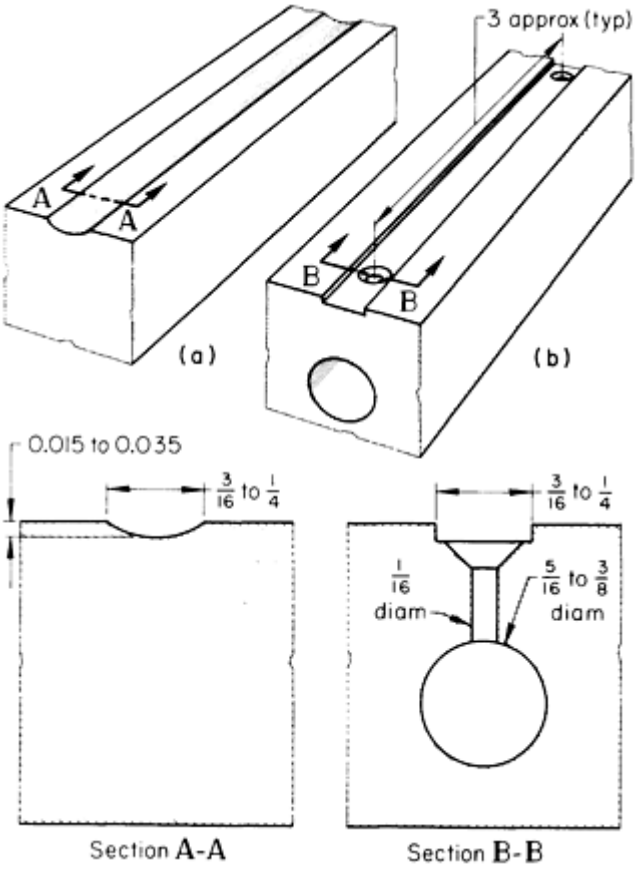

FIG. 2 GROOVE CONFIGURATIONS FOR BACKING BARS. (A) STANDARD GROOVE FOR USE WITHOUT A BACKING GAS. (B) SQUARE-CORNER GROOVE EMPLOYED WITH BACKING GAS (GROOVE DEPTH DEPENDS ON GAS FLOW REQUIRED AND LENGTH OF BAR). DIMENSIONS GIVEN IN INCHES

The clamping and restraint requirements for nickel alloys are about the same as for low-carbon steel. The hold-down bars should be located close enough to the line of the weld to maintain alignment and provide the proper degree of heat transfer. Generally, hold-down pressure should be just enough to maintain alignment, but high restraint can be advantageous when welding square groove joints in thin metals using the GMAW process without a filler metal. When the pieces to be welded are positioned with a zero root opening and hold-down bars are brought very close to the line of welding, and when a high hold-down pressure is used, the heat of welding creates an expansive force that results in compression in the line of the weld. This compression will have an upsetting effect on the hot weld metal and can cause the weld to develop a slight top and bottom crown, or weld reinforcement, without the use of filler metal.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Welding of Precipitation-Hardenable Alloys

The PH alloys require special welding procedures because of their susceptibility to cracking. Cracks can occur in the base-metal heat-affected zone (HAZ) upon aging or in service at temperatures above the aging temperature, as a result of residual welding stress and stress induced by precipitation. Before welding these alloys, a full-solution anneal is usually performed. After welding, the appropriate aging heat treatment is performed. To further improve alloy properties, a full anneal after welding, followed by a postweld heat treatment, can be incorporated in the welding procedure.

Preweld and Postweld Treatments. Any part that has been subjected to severe bending, drawing, or other forming operations should be annealed before welding. If possible, heating should be done in a controlled-atmosphere furnace to limit oxidation and minimize subsequent surface cleaning.

The aluminum and titanium hardened alloys must be stress relieved (solution treated) after welding and before precipitation hardening. To avoid prolonged exposure of the welded structure to temperatures within the precipitation-hardening range, rapid heating in a furnace preheated to the appropriate temperature is recommended. When the workpiece is large, compared with the furnace area, it may be necessary to preheat the furnace to a temperature that is 110 to 280 °C (200 to 500 °F) above the solution-treatment temperature and then to reset the furnace controls when the workpiece has reached the solution-treatment temperature. The stresses created by repair or alteration welding must be relieved in a similar fashion by rapid heating to the solution-treating temperature prior to re-aging. If satisfactory stress relief of the weldment is not feasible, particularly if the structure is complicated, then preweld overaging treatments may be helpful. Preheating, however, is not a satisfactory substitute for postweld heat treatment. Although PH alloys can be welded in the aged condition, if temperatures encountered in service are in the PH range, then the weldment must be solution treated and reaged.

General Welding Procedures. Precipitation-hardenable alloys are usually welded by the GTAW process, but SMAW and GMAW processes are also applicable. Heat input during the welding operations should be held to a moderately low level in order to obtain the highest possible joint efficiency and minimize the extent of the HAZ. For multiple-bead or multiple-layer welds, many narrow stringer beads should be used, rather than a few large, heavy beads.

Any oxides that form during welding should be removed by abrasive blasting or grinding. If such films are not removed as they accumulate on multiple-pass welds, then they can become thick enough to inhibit weld fusion and produce unacceptable laminar-type oxide stringers along the weld axis.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Welding of Cast Nickel Alloys

Cast nickel alloys can be joined by the GTAW, GMAW, and SMAW processes. For optimum results, castings should be solution annealed before welding to relieve some of the casting stresses and provide some homogenization of the cast structure.

Light peening of solidified metal after the first pass will relieve stresses and, thus, reduce cracking at the junction of the weld metal and the cast metal. The peening of subsequent passes is of little, if any, benefit. Stress relieving after welding is also desirable.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Gas-Tungsten Arc Welding

Nickel alloys, both cast and wrought and either solid-solution-strengthened or precipitation-hardenable, can be welded by the GTAW process. The addition of filler metal is usually recommended. Direct current electrode negative (DCEN) is recommended for both manual and machine welding. Parameters for manual GTAW of alloy 400 are given in Table 2.

TABLE 2 PARAMETERS FOR MANUAL GTAW OF 1.6 MM (0.062 IN.) THICK ALLOY 400

JOINT TYPE	**BEVELED BUTT, 1.6 MM ($\frac{1}{16}$ IN.) ROOT OPENING**
ELECTRODE	**2.4 MM ($\frac{3}{32}$ IN.) DIAM EWTH-2, TAPERED TO 0.4 MM ($\frac{1}{64}$ IN.) DIAM**
FILLER METAL	**1.6 MM ($\frac{1}{16}$ IN.) DIAM ERNICU-7**
NUMBER OF PASSES	**3**
WELDING CURRENT, A	**70-90 (DCEN)**
VOLTAGE, V	**10-12**
SHIELDING GAS:	
AT TORCH, M^3/H (FT^3/H)	**0.6 (20)**
BACKING GAS, M^3/H (FT^3/H)	**0.08-0.14 (3-5)**
PREHEAT AND POSTHEAT TREATMENT	**NONE**
INTERPASS TEMPERATURE, °C (°F)	**175 (350) MAXIMUM**

The welding torch should be set or held at an angle of 90° to the work. A slight deviation is permissible to provide a better view of the work, but an acute angle can lead to aspiration of the surrounding air and contamination of the shielding gas. The largest gas nozzle size applicable to the job should be used, and a minimum practical distance between the nozzle and the work should be maintained. A gas lens should be used to improve shielding gas flow and coverage (see the article "Gas-Tungsten Arc Welding" in this Volume).

Shielding Gas. Either argon or helium, or a mixture of the two, is used as a shielding gas for welding nickel and nickel alloys. Additions of oxygen, carbon dioxide, or nitrogen to argon gas will usually cause porosity or erosion of the electrode. Argon with small quantities of hydrogen (typically 5%) can be used and may help avoid porosity in pure nickel, as well as aid in reducing oxide formation during welding. The advantages and disadvantages of using helium, rather than argon, when welding thin metal without the addition of filler metal, are:

- *IMPROVED SOUNDNESS:* POROSITY-FREE WELDS ARE MORE EASILY OBTAINED IN ALLOY 400, AND THE POROSITY OF WELDS IN NICKEL 200 IS LESS.
- *INCREASED WELDING SPEED:* WITH DCEN, WELDING SPEED CAN BE INCREASED AS MUCH AS 40% OVER THAT ACHIEVED WITH ARGON AT THE SAME CURRENT SETTING, BECAUSE WELDING SPEED IS A FUNCTION OF HEAT INPUT, AND HEAT INPUT IS CONSIDERABLY GREATER WITH HELIUM.
- *DECREASED ARC STABILITY:* AT LOWER CURRENT LEVELS (<120 A), ARC STABILITY IS LOWERED AS HELIUM CONTENT IS INCREASED. MIXTURES OF ARGON AND HELIUM HELP STABILIZE THE ARC WHILE MAINTAINING THE BENEFITS OF THE HELIUM SHIELDING GAS.

Because the purity and dryness of the welding gas are important, welding-grade shielding gas should be used. Furthermore, the welding area should be screened to avoid drafts, because disruption of the shielding atmosphere and drawing in of air can cause porosity in the weld metal.

Electrodes. Pure-tungsten electrodes or tungsten alloyed with thoria or zirconia can be used. The alloyed electrodes are more economical, because of their lower vaporization loss. Overheating that is due to the use of excessive amperage must be avoided at all times.

The best arc stability and penetration control are achieved by tapering the electrode tip. The taper angle should be approximately 30°, with a flat land of about 0.38 mm (0.015 in.) diameter on the tip end. Larger taper angles are used to produce a narrower bead and deeper penetration. After its selection, the taper angle should be maintained, because changes in the angle can affect penetration and bead width.

Electrode extension (stick out) should be short, and the amount should be based on joint design. For example, a maximum extension of 4.8 mm ($\frac{3}{16}$ in.) can be used for butt welds in thin metal, but a 9.5 to 13 mm ($\frac{3}{8}$ to $\frac{1}{2}$ in.) extension is required for some fillet welds or for reaching the bottom of the groove welds.

The electrode should be inclined slightly in the forehand position. Filler metal, when used, should be added carefully at the leading edge of the weld pool to avoid contact with and contamination of the electrode. If contamination occurs, then the electrode should be cleaned and reshaped.

Filler Metals. Compositions of the filler metals used with the GTAW process are, in general, similar to those of the base metals with which they are used. Because of high welding temperatures, filler metals are alloyed to resist porosity and hot cracking of the weld metal. Filler-metal additions and dilution ratios should be adjusted to ensure that the weld metal contains about 75% filler metal.

Table 3 lists the compositions of filler metals used for the gas-tungsten arc welding of nickel and nickel alloys. Filler metals of the ERNi-1 classification are used for welding the high-nickel-content alloys (for example, Nickel 200 and 201), whereas those of the ERNiCu-7 classification are used for welding nickel-copper alloys (for example, alloys 400 and 404).

(A) SINGLE VALUES ARE MAXIMUM (EXCEPT WHERE OTHERWISE SPECIFIED).

Joint Design. All joint designs shown in Fig. 1 can be used when welding nickel alloys by the GTAW process. If no filler metal is used, then the sections to be joined must be held tightly together to promote satisfactory fusion.

Welding Techniques. When a filler metal is used, the wire diameter should be related to the work-metal thickness. For example, a 1.6 mm ($\frac{1}{16}$ in.) diameter wire is generally used to weld 1.6 mm ($\frac{1}{16}$ in.) thick sheet. During welding, the hot end of the wire must remain under the shielding gas to avoid oxidation. A short arc length should be maintained to ensure that deoxidizing elements transfer to the weld pool.

To ensure a sound weld, the arc should be maintained at the shortest possible length. When no filler metal is added, the arc length should be 1.3 mm (0.05 in.), maximum, and preferably 0.5 to 0.8 mm (0.02 to 0.03 in.). When filler metal is used, the arc should be kept as short as possible, consistent with filler-metal diameter, to avoid loss of gas coverage. This loss can result in oxidation and reduced penetration. A short arc also reduces weld spatter with filler wire.

The speed of welding affects penetration, weld width, and weld soundness, especially when no filler metal is added. For a given thickness of metal, there is a range of welding speeds that results in minimum porosity. Speeds outside this range, either faster or slower, can result in increased porosity. When welding thinner-gage material, the required heat input is considerably lower. This contributes to increased porosity, which is due to the increased solidification rate of the molten weld pool.

Complete-penetration welds require the use of grooved backing bars that permit local gas shielding (Fig. 2b), or the purging of the inside of the workpiece. The surface condition affects the porosity level in thin sheet material to a much larger degree, because the surface layer makes up a larger percentage of the overall thickness of material.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Gas-Metal Arc Welding

The solid-solution nickel-base alloys can be joined by the GMAW process. In addition, the use of special procedures allows PH alloys (for example, alloy K-500) to be gas-metal arc welded.

Spray, globular, and short-circuiting metal transfer methods are suitable. Varying the power input produces the different types of metal transfer. The pulsed arc process is also used. In these methods, the filler metal is a current-carrying consumable and is typically 0.89, 1.14, or 1.57 mm (0.035, 0.045, or 0.062 in.) in diameter. Table 4 lists typical conditions for the welding of nickel-base alloys using spray-type metal transfer (Table 4(a)), short-circuiting metal transfer (Table 4(b)), and pulsed-arc transfer (Table 4(c)) with various nickel-base filler metals.

Welding current is most often provided by constant-voltage power supplies, although all standard direct current (dc) power supplies are satisfactory. Direct current electrode positive (DCEP) is used because it is virtually impossible to transfer metal in a controlled manner when using DCEN. The amperage should be well within the maximum rating of the equipment, but it should be sufficient to obtain the desired melting rate.

The shielding gas used in the gas-metal arc welding of nickel alloys by spray or globular transfer can be argon, which yields good results. The addition of 15 to 20% He is beneficial when welding nickel alloys with short-circuiting arc or pulsed-arc transfer methods. As the helium content increases from 0 to 20%, the weld beads become progressively wider and flatter, and penetration decreases. The addition of oxygen or carbon dioxide to argon stabilizes the arc, but results in heavily oxidized and irregular bead surfaces. With standard constant-voltage GMAW power sources, helium alone has been used as a shielding gas, but it creates an unsteady arc with excessive weld spatter and is a difficult atmosphere in which to initiate an arc. With pulsed GMAW power sources in which the waveform can be controlled, helium can be very effective for overlaying, resulting in low base metal dilution.

Gas flow rates vary from 0.71 to 2.8 m^3/h (25 to 100 ft^3/h), depending on joint design and position. A flow rate of 1.4 m^3/h (50 ft^3/h) is used most frequently. The choice of gas used with short-circuiting metal transfer is influenced by the type of equipment available. Argon, without additions, is suitable for use with equipment that has both inductance and slope control. Argon gas produces convex beads, which may cause cold lapping (lack of fusion), but it also provides a pronounced pinch effect that can be controlled by inductance. The addition of helium is helpful when induction and slope cannot be varied. Helium imparts a wetting action, and the arc is hotter. These factors greatly decrease the possibility of cold lapping. As the percentage of helium increases, the gas flow rate must be increased to ensure adequate protection.

The size of the gas nozzle is important when using a short-circuiting arc. When a 1:1 mixture of argon and helium is used at a flow rate of 1.1 m^3/h (40 ft^3/h) through a 9.5 mm ($\frac{3}{8}$ in.) diameter nozzle, at a wire feed rate of 6.4 m/min (250 in./min), and a wire diameter of 1.1 mm (0.045 in.) the current can be increased to 160 to 180 A without adversely affecting weld quality. An argon-helium mixture is recommended as the shielding gas with the pulsed-arc GMAW process. The gas flow rate should range from 0.42 to 1.3 m^3/h (15 to 45 ft^3/h). An excessive flow rate can interfere with the arc.

Filler metals used in the GMAW process are listed in Table 3. The appropriate wire diameter depends on the method used and the thickness of the base metal. With globular or spray transfer, 0.89, 1.14, and 1.57 mm (0.035, 0.045, and 0.062 in.) diameter wire is used. The short-circuiting and pulsed-arc processes generally require wire that is 1.14 mm (0.045 in.) or less in diameter.

Joint designs recommended for the GMAW process are shown in Fig. 1. For U-shaped groove designs that use globular or spray transfer methods, the root radius should be decreased by about 50%, and the bevel angle should be doubled. With these transfer methods, the use of high amperage on small-diameter wire produces a high level of arc force. As a result, the arc cannot be deflected from a straight line, as is possible when the welding process utilizes covered electrodes. Because the arc must contact all areas to be fused, the joint design must provide an intersection with the arc force line. When a short-circuiting arc is used, the U-shaped groove designs are the same as those employed with the other arc welding processes.

Welding Techniques. Positioning the electrode holder vertically along the centerline of the joint yields the best results. Some inclination is permissible to allow a better view of the work, but excessive displacement can cause the surrounding atmosphere to be drawn into the shielding gas, causing porous or heavily oxidized welds. Arc length is also important. Too short an arc causes spatter, and too long an arc results in loss of control and reduced penetration.

Because arc length is directly proportional to voltage, particular care must be paid to the voltage setting to ensure properly controlled arc length. In addition, once a procedure has been qualified, consistent torch-to-work positioning should be maintained to prevent possible changes in transfer mode caused by loss (or gain) of energy available at the arc. The alteration in energy at the arc is caused by I^2R energy changes corresponding to wire extension changes.

Cold lapping (lack of fusion) can occur with the short-circuiting, globular, and pulsed-arc processes if manipulation is faulty. The torch should be advanced at a rate that will keep the arc in contact with the base metal, just ahead of the weld pool. The manipulation and angle used with the pulsed-arc torch are similar to those used in the SMAW process. To avoid undercutting, a slight pause should be made at the limit of the weave. Excessive welding speeds and improper torch positioning can cause oxides on the surface of underlying passes to become entrapped between weld passes. Slower

welding speeds and good torch positioning allow the arc to reduce certain oxides and/or allow time to float the oxides to the surface of the molten weld puddle.

Plasma Arc Welding

Using the keyholing mode, the PAW process can produce acceptable welds in nickel alloys that are up to about 7.6 mm (0.3 in.) thick. Argon-hydrogen mixtures are used as orifice and shielding gases. Levels from 5 to 8% H_2 are optimum. The amount of current needed for keyholing decreases as hydrogen content increases (up to about 7% H_2). Above this level, torch starting becomes more difficult. If helium or hydrogen is used, then the arc starting ability is subsequently reduced.

Typical travel speed and current parameters for keyhole welding are:

TRAVEL SPEED		CURRENT, A	
MM/MIN	**IN./MIN**	**NICKEL 200**	ALLOY 400
205	8	185	**155**
255	L0	200	**175**
305	12	220	**195**
355	**14**	**235**	**215**

Typical conditions for welding 5.97 mm (0.235 in.) thick Nickel 200 using 95% Ar-5% H_2 gas are: current, 245 A; voltage, 31.5 V; feed rate, 355 mm/min (14 in./min); and gas flow, 0.28 m^3/h (10 ft^3/h) (orifice) and 1.3 m^3/h (45 ft^3/h) (shielding) (Ref 1, 2).

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Shielded Metal Arc Welding

The SMAW process can be used for welding nickel and nickel alloys. Although the minimum metal thickness is usually about 1.3 mm (0.050 in.), thinner metal can be welded when appropriate fixtures are provided. The types of joints used, as well as bead and groove dimensions, are given in Fig. 2.

Electrodes. The composition of electrodes used in the SMAW process are given in Table 5. Electrode composition is selected to be similar to that of the base metal with which the electrode is to be used. Electrodes of the ENi-1 classification are used to weld wrought and cast forms of nickel and nickel alloys to themselves and to steel. ENiCu electrodes can be used to weld nickel-copper alloys to themselves, to surface steel with a nickel-copper alloy, to weld the

clad side of a nickel-copper-clad steel, and to weld nickel-copper alloys to steel. ECuNi electrodes can be used to weld nickel-copper, copper-nickel, and nickel wrought alloys when overlaying steel. A buttering layer of ENi-1 is usually placed onto the steel surface before a copper-nickel surface layer is made.

(A) SINGLE VALUES ARE MAXIMUM (EXCEPT WHERE OTHERWISE SPECIFIED).

ENiCrMo-3 electrodes typically are used to join a wide range of pitting and crevice corrosion-resistant alloys. The lowest alloyed materials employed with these electrodes are the molybdenum-modified type 317 stainless steels. ENiCrMo-3 electrodes are used for richer alloy compositions of the nickel-chromium-iron-molybdenum families, up to and including alloy 625. Intermediate alloys welded with ENiCrMo-3 include alloy 825, alloy 20, alloy G, and alloy G-3. This type of electrode is widely used because its high nickel content allows good dissimilar weldability, whereas the high molybdenum content matches or exceeds the pitting resistance of the base alloys being welded. Because of the strength of the ENiCrMo-3 electrode, welding to many high-strength low-alloy (HSLA) grade steels can be performed without sacrificing strength.

Other electrodes in this alloy group, such as ENiCrMo-4 and ENiCrMo-10, are used to join alloys to themselves or to steel. They are also used to join alloys in the ENi-Cr-Mo group to each other. Usually, the base metal is welded with a higher alloyed welding electrode to counteract the microsegregation that occurs in the weld deposit. For example, in a pitting environment, such as the SO_2 environments found in flue gas desulfurization (FGD) applications, the choice would be a nickel-chromium-molybdenum alloy group with a higher molybdenum-containing welding electrode family.

Nickel-chromium-iron electrodes, such as ENiCrFe-2 and ENiCrFe-3, are designed to weld the same family of alloys, as well as dissimilar metal joints involving carbon steel, stainless steel, nickel, and nickel-base alloys. Other welding electrodes with the ENi-Cr-Fe electrode grouping are special-application chemistry electrodes, such as ENi-Cr-Fe-7, which are used to weld alloy 690 to itself, to alloy 600, and to butt weld alloy 690 to steel or to overlay certain grades of steel in nuclear boiler and pressure water reactor applications.

Nickel-chromium-cobalt-molybdenum electrodes, such as ENi-Cr-Co-Mo-1, are readily used to join nickel-chromium-iron alloys, especially when service temperatures will exceed 790 °C (1450 °F) and could reach up to 1150 °C (2100 °F) in oxidizing atmospheres.

Nickel-molybdenum electrodes, such as ENMo-1, are designed to weld nickel-molybdenum alloys to themselves and to other nickel-, cobalt-, and iron-base metals. They are normally used in the flat position only.

Covered electrodes should be kept in sealed, moisture-proof containers in a dry storage area prior to their use. All opened containers of unused electrodes should be stored in a cabinet equipped with a dessicant or heated to 6 to 8 °C (10 to 15 °F) above ambient temperature prior to use. If the electrodes are exposed to excessive moisture, then they can be reclaimed by rebaking at 260 °C (500 °F) for 2 h or at 315 °C (600 °F) for 1 h. The electrode diameter should be chosen on the basis of quality requirements and position of welding, rather than on speed of production.

Welding Current. The SMAW process utilizes DCEP. Each electrode size has an optimum amperage range in which good arcing characteristics prevail and outside of which the arc becomes unstable or the electrode overheats. Suggested electrode diameters and current settings for various metal thicknesses are shown in Table 6. Variables such as type of backing, tightness of clamping, and joint design influence the required amount of current density. Actual welding currents should be developed by making sample welds in metal of the same composition and thickness as the metal to be welded.

(A) WHERE A RANGE IS SHOWN, THE SMALLER DIAMETER ELECTRODES ARE USED FOR THE FIRST PASSES AT THE BOTTOM OF THE GROOVE, AND THE JOINTS ARE COMPLETED WITH THE LARGER DIAMETER ELECTRODES.

(B) CURRENT SHOULD BE IN THE RANGE RECOMMENDED BY THE ELECTRODE MANUFACTURER.

(C) USE MINIMUM AMPERAGE AT WHICH ARC CONTROL CAN BE MAINTAINED.

Welding Position. Flat-position welding should be used whenever possible, because it is faster, more economical, and produces a weld of good quality. The recommended electrode position for flat-position welding is an inclination of about 20° from the vertical, ahead of the weld pool. This position facilitates control of the molten flux and prevents slag entrapment. A short arc must be maintained to prevent atmospheric contamination of the arc and weld and to prevent porosity.

For vertical welding, the arc should be slightly shorter than for flat-position welding, and the amperage should be 10 to 20% lower than the values in Table 6. The electrode should be approximately a 90° angle to the joint. For overhead welding, the arc should be slightly shorter than for flat-position welding, and the welding current should be reduced by 5 to 15 A from the values shown in Table 6.

Welding Techniques. Because molten nickel alloy weld metal is not as free flowing as iron-base alloys, it must be deposited where it is needed. Therefore, a slight weave is required. The amount of weave will depend on joint design, welding position, and type of electrode. Although a straight stringer bead made without weaving can be used for single-pass work, and is satisfactory at the bottom of a deep groove on thicker sections, a weave is generally desirable.

When a weave is used, it should be no wider than approximately three times the electrode diameter. Some deviation from this role may be necessary during vertical welding. A slight weave, if it is not excessive, can help prevent possible centerline solidification cracking problems.

Weld spatter should be avoided. Spatter indicates that the arc is too long, that excessive amperage is being used, or that the current is straight polarity (DCEN). Other causes of spatter are wet electrodes or base metal and slag that run under the arc during welding.

Arc blow may occur when one or both of the metals being welded is magnetic. The arc is deflected from its normal path by a magnetic force in the base metal. One method of overcoming arc blow is to change the location of the ground connection on the workpiece or to change the direction of the electrical path to the arc. A dissimilar joint (for example, steel welded to a nickel-base alloy) can cause considerable arc blow toward the steel side of the joint.

When the arc is to be broken, it should be shortened slightly, and the rate of travel should be increased to reduce the size of the weld pool. This practice reduces the probability of crater cracking, ensures that the crater does not develop a rolled leading edge, and prepares the way for restriking the arc. Another technique to prevent crater cracking is called crater filling, in which the weld pool is held stationary for a short period of time before the arc is broken. This technique is usually incorporated at the end of a weld.

The manner in which the arc is restruck has a significant effect on the soundness of the weld. A reverse (or T) restrike is recommended. The arc should be struck at the leading edge of the crater and carried back to the extreme rear of the crater at a normal welding speed. The direction is then reversed, weaving is commenced, and the weld is continued. Advantages of this procedure are:

- THE WELDER HAS AN OPPORTUNITY TO ESTABLISH THE CORRECT ARC LENGTH BEFORE ACTUAL WELDING COMMENCES.
- SOME PREHEAT IS APPLIED TO THE COLD CRATER.
- THE FIRST DROPS OF RAPIDLY COOLED WELD METAL ARE DEPOSITED WHERE THEY WILL BE REMELTED, THUS RESTRICTING THE POROSITY TO A MINIMUM.

Another technique is to make the restrike where the weld metal can be readily removed (for example, 13 to 25 mm, or $\frac{1}{2}$ to 1 in., behind the crater on top of the previous pass). Later, the restrike area can be ground to be level with the rest of the bead. This technique is used when the weld must meet rigid radiographic standards and calls for less welder skill than the reverse-restrike method.

Welding procedures should be qualified before production begins. In one plant where this was not done, qualifying tests of the welding procedure were conducted before further welds were made when cracks appeared in the weld metal of a joint in a 13 mm ($\frac{1}{2}$ in.) thick Nickel 200 cylinder.

The original procedure for this weld specified a V-shaped groove butt joint with a 60° included angle, a 3.2 mm ($\frac{1}{8}$ in.) root face, and zero root opening (Fig. 3a). An ENi-1 electrode that was 355 mm (14 in.) long by 48 mm ($\frac{3}{16}$ in.) wide was used with a welding current of 235 A. On the first pass, a weld bead that was 165 mm ($6\frac{1}{2}$ in.) long was deposited with each electrode. On the second pass, a weld bead that was 75 mm (3 in.) long was deposited with each electrode. A cross section of the completed weld is shown in Fig. 3(b). An investigation showed that cracks in the weld metal were caused by the high welding current and low travel speed, which had resulted in the weld pool being held in a superheated condition for an excessively long time.

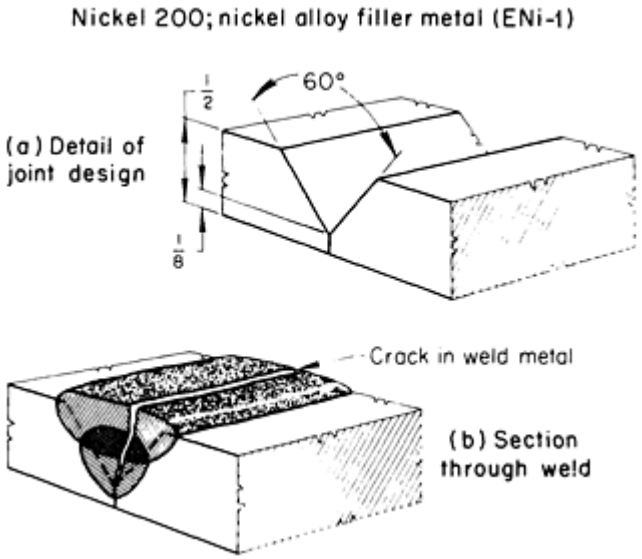

FIG. 3 JOINT CONFIGURATIONS FOR WELDING 13 MM ($\frac{1}{2}$ IN.) NICKEL 200 AND SUBSEQUENT CRACK IN WELD METAL CAUSED BY EXCESSIVE HEAT INPUT. DIMENSIONS GIVEN IN INCHES

Therefore, a qualified procedure was established, specifying a welding current of 210 A and an increased travel speed, which resulted in a 305 mm (12 in.) long weld for each electrode on the first pass and 230 mm (9 in.) long welds per electrode on the second pass. Electrode type and length, and all other welding conditions, were unchanged. An included angle of 80° and a 1.6 to 2.4 mm ($\frac{1}{16}$ to $\frac{3}{32}$ in.) root face would have produced a better welded joint, but the workpieces had been machined and roll formed before the problem arose.

Cleaning the Weld Bead. In multiple-pass welding, all flux and slag must be removed before each succeeding bead is deposited. All slag should be completely removed from completed welds, especially if service involves high temperatures. The slag is easily removed with either hand tools or a hand or power wire brush.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Submerged Arc Welding

Submerged arc welding can be used to join solid-solution nickel alloys. Alloy 400, Nickel 200, and several Ni-Cr-Fe alloys are most frequently welded by this process. Joints in metal up to 75 mm (3 in.) thick have met American Society of

Mechanical Engineers (ASME) codes and other specification requirements. The SAW process cannot be used to weld the PH nickel alloys.

Joint Design. Some joint designs used in the submerged arc welding of nickel-alloy plate are shown in Fig. 4. Single compound-angle grooves, single U-grooves, and double U-grooves are used for metal that is 19 mm ($\frac{3}{4}$ in.) or more thick. The double U-groove is usually preferred, because it results in a lower level of residual stress and can be completed in less time, with less filler metal. A single V-groove is used for stock up to 13 mm (1 in.) thick.

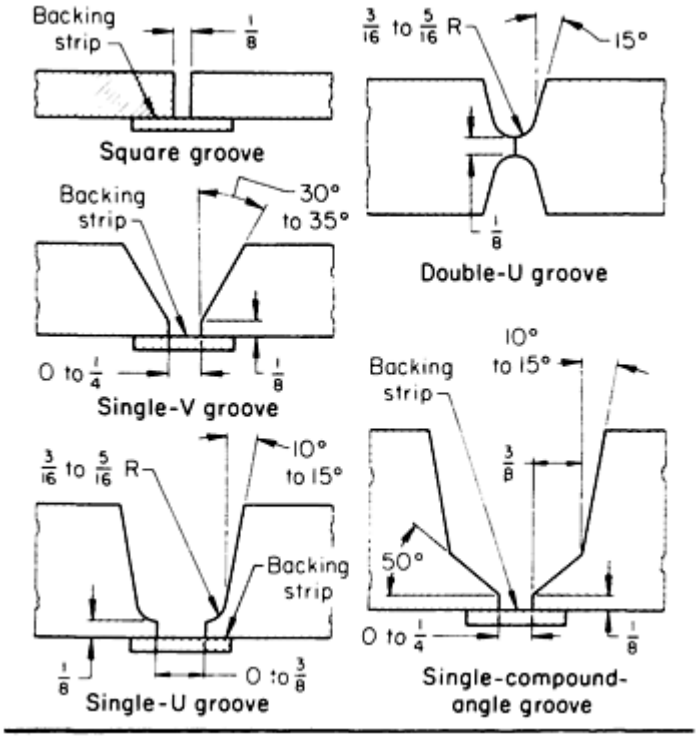

FIG. 4 TYPICAL DIMENSIONS FOR SAW OF NICKEL ALLOYS. BACKING STRIPS ARE OPTIONAL WITH ZERO ROOT OPENINGS. DIMENSIONS GIVEN IN INCHES

Electrodes. The compositions of the electrode wires used in the SAW process are the same as those of the filler metals or electrode wires used in GTAW and GMAW processes (Table 3). Submerged arc welding is possible with the following electrodes: ERNi-1, ER-CuNi, ERNiCu-7, ERNiCr-3, ERNiCrFe-5, and ERNiCrMo-3.

Wire that ranges from 1.14 to 2.36 mm (0.045 to 0.093 in.) in diameter can be used for all nickel alloys. The 1.6 mm ($\frac{1}{16}$ in.) diameter wire is generally preferred. Small-diameter wires are used to weld metal that is up to 13 mm ($\frac{1}{2}$ in.) thick, and 2.4 mm ($\frac{3}{32}$ in.) diameter wires are used for heavier sections. The approximate amounts of filler metal needed for a single compound angle, a single U-groove, and a single V-groove are given in Table 7.

Fluxes. The fluxes used in the submerged arc welding of carbon and stainless steels are not satisfactory when welding nickel alloys. Special proprietary fluxes are available and must be used. Loss of alloy elements (especially chromium), poor weld contour, flux entrapment, weld cracking, and inclusions can result when the wrong flux is used.

Only enough flux cover to prevent arc flashing should be used because excessive flux can cause a deformed bead surface. Slag entrapment can be prevented by appropriate joint design and by correct placement of beads. Slag is easily removed from welds in the bottom of grooves. Fused flux is self-lifting from exposed welds and should be discarded. Unfused flux can be recovered by means of a vacuum system, and it can be reused, if clean. Screening to adjust particle size is not required.

Fluxes should be stored in dry storage areas. Opened containers should be resealed to prevent moisture pickup. However, flux that has absorbed moisture can be reclaimed by drying at 315 °C (600 °F) for 1 h. Hoppers used for fluxes appropriate for the welding of steel and other metals should be thoroughly cleaned before being filled with flux appropriate for the welding of nickel alloys.

Welding Current. Direct current electrode negative (typically used for groove plus cladding applications) or direct current electrode positive (typically used for cladding applications) can be used. Reverse polarity (DCEP) is preferred for butt welding, because it produces a flatter bead with deeper penetration at a rather low arc voltage (30 to 33 V). Straight polarity (DCEN) results in a slightly higher rate (typically 30% higher) of deposition at increased voltage (over 35 V) and requires oscillation. The flux covering, however, must be appreciably deeper. Consequently, flux consumption and the risk of slag entrapment increase. Alternating current and the two wire series technique for multiple arc welding are not suitable for use with the available fluxes.

Bead Deposition. The bead location in a multiple-pass layer should provide an open, or reasonably wide, root area for the next bead. Slightly convex beads are preferred to concave beads. Bead contour is controlled by voltage, travel speed, and the position of the electrode.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Minimizing Weld Defects

The defects and metallurgical difficulties encountered in the arc welding of nickel alloys include:

- POROSITY
- SUSCEPTIBILITY TO HIGH-TEMPERATURE EMBRITTLEMENT BY SULFUR AND OTHER CONTAMINANTS
- CRACKING IN THE WELD BEAD, CAUSED BY HIGH HEAT INPUT AND EXCESSIVE WELDING SPEEDS
- STRESS-CORROSION CRACKING IN SERVICE

Porosity. Oxygen, carbon dioxide, nitrogen, or hydrogen can cause porosity in welds. In the SMAW and SAW processes, porosity can be minimized by using electrodes that contain deoxidizing or nitride-forming elements, such as aluminum and titanium. These elements have a strong affinity for oxygen and nitrogen and form stable compounds with them. Presence of deoxidizers in either type of electrode serves to reduce porosity. In addition, porosity is much less likely to occur in chromium-bearing nickel alloys than in non-chromium-bearing alloys.

In the GMAW and GTAW processes, porosity can be avoided by preventing the access of air to the molten weld metal. Gas backing on the underside of the weld is sometimes used.

In the GTAW process, the use of argon with up to 10% H_2 as a shielding gas helps to prevent porosity. Bubbles of hydrogen that form in the weld pool gather the diffusing nitrogen. Too much hydrogen (>15%) in the shielding gas can result in hydrogen porosity.

Cracking. Hot shortness of welds can result from contamination by sulfur, lead, phosphorus, cadmium, zinc, tin, silver, boron, bismuth, or any other low-melting-point elements, which form intergranular films and cause severe liquid-metal embrittlement at elevated temperatures. Many of these elements are found in soldering and brazing filler metals. Hot cracking of the weld metal usually results from such contamination. Cracking in the heat-affected zone is often caused by intergranular penetration of contaminants from the base-metal surface. Sulfur, which is present in most cutting oils used for machining, is a common cause of cracking in nickel alloys. The removal of foreign material from the surfaces of the work metal is imperative (see the section "Cleaning of Workpieces" in this article). Weld metal cracking also can be caused by heat input that is too high, as a result of high welding current and low welding speed (Fig. 3). Welding speeds have a large effect on the solidification pattern of the weld. High welding speeds create a tear-drop molten weld pool, which leads to uncompetitive grain solidification at the center of the weld. At the weld centerline, residual elements will collect and cause centerline hot cracking or lower transverse tensile properties.

In addition, cracking may result from undue restraint. When conditions of high restraint are present, as in circumferential welds that are self restraining, all bead surfaces should be slightly convex. Although convex beads are virtually immune to centerline splitting, concave beads are particularly susceptible to centerline cracking. In addition, excessive width-to-depth or depth-to-width ratios can result in cracking that may be internal (that is, subsurface cracking).

Stress-Corrosion Cracking. Nickel and nickel alloys do not experience any metallurgical changes, either in the weld metal or in the HAZ, that affect normal corrosion resistance. When the alloys are intended to contact substances such as concentrated caustic soda, fluorosilicates, and some mercury salts, however, the welds may need to be stress relieved to avoid stress-corrosion cracking. Nickel alloys have good resistance to dilute alkali and chloride solutions. Because resistance to stress-corrosion cracking increases with nickel content, the stress relieving of welds in the high-nickel-content alloys is not usually needed.

Effect of Slag on Weld Metal. Because fabricated nickel alloys are ordinarily used in high-temperature service and in aqueous corrosive environments, all slag should be removed from finished weldments. If slag is not removed in the latter type of application, then crevices and accelerated corrosion can result. Slag inclusions between weld beads reduce the strength of the weld. If the service temperature approximates the melting point of the slag, then severe corrosion can occur when slag is present on the weld surfaces, particularly in oxygen-containing atmospheres. Fluorides in the slag can react with moisture or elements in the environment to create highly corrosive compounds.

Slag also acts as an accumulator of sulfur, particularly in reducing atmospheres, which can lead to service failure in atmospheres that would be considered adequately low in sulfur. In one instance, although only 0.01% S was present in the atmosphere, the sulfur content of the slag on the weld surface rose from 0.02% to 2 or 3% after a one-month exposure. Sulfur pickup also depresses the melting temperature of the weld slag and, consequently, the maximum safe operating temperature of the weldment.

Welding of Nickel Alloys

Revised by E.B. Hinshaw, Inco Alloys International, Inc.

Joining of Dissimilar Metals

Nickel and nickel alloys have been successfully joined to other nickel alloys and carbon and low-alloy steels, stainless steel, and a number of copper alloys. Filler metal, or consumable electrode, must be selected to ensure a compatible metallurgical relationship between the two base metals. Several factors are involved:

- DIFFERENCES IN THERMAL EXPANSION OF THE BASE METALS
- POSSIBILITY OF PERMANENT CHANGES IN VOLUME AFTER EXTENDED SERVICE AT ELEVATED TEMPERATURE
- EFFECT OF WELD-METAL DILUTION AT THE INTERFACES WITH THE BASE METAL

All of these factors influence the choice of filler metal and welding process.

An example of a good metallurgical combination is the welding of nickel to alloy 400. Because these metals are completely compatible, they can be welded to each other by any welding process, using any compatible filler metal.

Dilution of Weld Metal. The composition of the weld metal can be expected to differ from that of the filler metal, or consumable electrode, and the base metals being joined, because some elements are lost through the arc when they are transferred from the filler-metal electrode to the weld metal during welding. Filler metal and base metal mixing results in the formation of a unique alloy. The composition of the weld metal is fairly uniform for a given bead, except in a narrow band at the edge of the weld, just adjacent to the fusion line in the near heat-affected zone of the weld. This area is sometimes referred to as the "unmixed zone." Although this region can never entirely be eliminated, its size can be minimized by lowering the overall heat input during welding. The amount of dilution varies from bead to bead. The welding process, current density, deposition rate, welding speed, weld-metal thickness, and welding technique have a significant influence on the amount of base-metal dilution that occurs in the weld deposit. Another region that forms in the near heat-affected zone of the weld is the "partially melted zone." This region can lower the overall corrosion resistance of the weldment, but can be controlled by lowering or limiting the heat input during welding.

The dilution of a nickel-base alloy by a dissimilar metal can be tolerated only to a limited degree. When a stainless steel filler metal is used to weld alloy 400 to an austenitic stainless steel, any significant amount of copper pickup from the alloy 400 causes the weld metal to become hot short and to crack. Thus, stainless steel filler metal should not be used when the welding process can cause a considerable amount of dilution. Neither nickel-copper nor copper-nickel types of filler metal can be used in this instance, because chromium from the stainless steel dilutes the weld metal and causes cracking. Although nickel or a nickel-chromium-iron or nickel-chromium-molybdenum filler metal is best, they should only be used after the welding procedure has been qualified by tests.

Filler Metals/Welding Electrodes. Selection of the correct filler metal helps produce a weld that meets the service requirements for strength, corrosion resistance, and soundness and tolerates dilution without causing cracking susceptibility in the weld metal. Crack sensitivity of the weld metal is proportional to the amount of dilution, especially when there is a considerable difference in the composition of a base metal and a filler metal.

Some combinations of base metal and filler metal produce undesirable weld-metal compositions:

- A FERRITIC WELD-METAL DEPOSIT DILUTED BY NICKEL, CHROMIUM, OR COPPER
- AN 18-8 STAINLESS STEEL WELD-METAL DEPOSIT DILUTED BY MORE THAN 3% CU
- AN 18-8 TYPE OF WELD-METAL DEPOSIT SUFFICIENTLY DILUTED BY NICKEL OR CHROMIUM TO RESULT IN THE FULLY AUSTENITIC CRACK-SENSITIVE WELD-METAL COMPOSITION (FOR EXAMPLE, 35% NI AND 15% CR)
- ANY NICKEL-COPPER OR COPPER-NICKEL ALLOY WELD-METAL DEPOSIT DILUTED BY MORE THAN 6 TO 8% CR

Manipulation of the welding arc so that it impinges primarily on the base metal nearest in composition to the filler metal helps reduce dilution. For most combinations of dissimilar metals, filler-metal suppliers should be consulted before a filler metal is selected. The addition of ample filler metal to the root pass helps lower the amount of base-metal dilution and also prevents the probability of producing a concave weld deposit profile, instead of the preferred convex shape.

The coefficients of thermal expansion (CTEs) of the base metals must be considered when selecting filler metals for joining dissimilar metal combinations. CTE differences are a major factor in situations where there is temperature cycling (for example, welding of 300 series stainless steel to carbon or low-alloy steel at temperatures above 425 °C, or 800 °F). A large difference in CTE values can induce stresses of sufficient magnitude to produce cracking in the weld metal. Some of the nickel-base electrodes (ENiCr, ENiCrFe, ERNiCr, and ERNiCrFe) and matching filler metals can be used to weld a wide range of base-metal combinations. These electrodes and filler metals can tolerate considerable dilution without loss of strength or ductility. Filler-metal ERNiMo-6 can be used to join nickel-base alloys, cobalt-base alloys, and stainless steels to themselves and to other metals and alloys. The low chromium content of this filler metal, however, should be carefully considered when welding oxidation-resistant materials.

Although GTAW and GMAW processes can be employed, the SMAW process is the most widely used to join nickel and nickel alloys to dissimilar metals. The welding current should be maintained near the middle of the recommended range for the electrode in order to control dilution. Dilution usually can be kept below 25% by manipulating the electrode to

dissipate the arc force on already-deposited weld metal. When depositing the first bead, the arc should be directed toward the member from which dilution of the weld metal will be least detrimental. Welding procedures that reduce the amount of penetration, which can cause dilution of the weld metal by the base metal, will increase the probability of securing a good weld. Table 8 gives recommended welding consumables for joining selected nickel-base alloys.

Example 1: Elimination of Weld Cracking and Distortion.

The welding of an alloy 400 skirt box to a low-carbon steel (ASTM A 285) cover for a fluorine generator resulted in cracking of the weld metal and warping of the cover (Fig. 5). Cracks resulting from excessive dilution were eliminated by modifying the way in which the beads were deposited. Weld crater cracks were prevented by taking care when ending the weld bead and breaking the arc. The alloy 400 skirt boxes replaced low-carbon steel skirt boxes that had corroded.

(B) HELIUM MASS SPECTROMETER WITH INTERNAL VACUUM OF 3.3 PA (0.025 MM HG)

FIG. 5 FLUORINE-GENERATOR COVER MADE BY SMAW OF SIMILAR (ALLOY 400 TO ALLOY 400) AND DISSIMILAR (ALLOY 400 TO LOW-CARBON STEEL) MATERIALS. (ASTM A 285). BOTH WELDS USED NICKEL ALLOY FILLER METAL. A CORNER JOINT AND DOUBLE FILLET WELD WAS UTILIZED TO JOIN THE SIMILAR ALLOYS. A T-JOINT AND DOUBLE FILLET WELD WAS UTILIZED TO JOIN THE DISSIMILAR MATERIALS. PARAMETERS COMMON TO BOTH SETUPS: POWER SUPPLY, 400 A (DC); STRESS RELIEF, 1 H AT 620 ± 14 °C (1150 ± 25 °F)

The original procedure for removing corroded skirt boxes, making new boxes, and welding the new boxes to the cover plate was:

1. REMOVE CORRODED LOW-CARBON STEEL SKIRT BOXES BY AIR-CARBON ARC CUTTING.
2. CLEAN SURFACES OF LOW-CARBON STEEL COVER BY SURFACE GRINDING.
3. CLEAN ALL JOINT AREAS ON THE ALLOY 400 PLATES WITH TRICHLOROETHYLENE AND REMOVE MILL SCALE WITH A SURFACE GRINDER.
4. ASSEMBLE THE ALLOY 400 SKIRT BOX AND WELD THE FOUR COMERS IN ONE PASS EACH WITH A 4.0 MM ($\frac{5}{32}$ IN.) DIAMETER ENICU-4 ELECTRODE, USING A WELDING CURRENT OF 130 A.
5. WELD THE ALLOY 400 SKIRT BOX TO THE LOW-CARBON STEEL COVER WITH INTERMITTENT WELDS, USING THE SEQUENCE OF WELD BEAD DEPOSITION SHOWN IN FIG. 5(B). (THE BOX AND COVER WERE FIRST TACK WELDED AT THE STARTING PLACE FOR EACH OF THE 255 MM, OR 10 IN., LONG WELDS.) DEPOSIT FIVE BEADS AS SHOWN IN FIG. 5(C), WITH A 4.0 MM ($\frac{5}{32}$ IN.) DIAMETER ENICU-1 ELECTRODE, USING A WELDING CURRENT OF 154 A.
6. STRESS RELIEVE AT 620 ± 14 °C (1150 ± 25 °F) FOR 1 H IN A REDUCING ATMOSPHERE. (THE ASSEMBLY WAS PLACED IN THE FURNACE WHEN THE FURNACE TEMPERATURE WAS LESS THAN 315 °C (600 °F), AND, AFTER HEATING, WAS ALLOWED TO COOL TO 315 °C, OR 600 °F, BEFORE IT WAS REMOVED.)
7. TEST THE WELDS WITH A HELIUM MASS SPECTROMETER UNDER AN INTERNAL VACUUM OF 3.3 PA (0.025 MM HG). (WELDS THAT FAILED THE TEST WERE REWELDED.)

During deposition of the first bead, considerable arc blow toward the alloy 400 skirt box was encountered. The ground connection was repositioned several times, but no improvement was obtained. When the welds were tested with a helium mass spectrometer, leakage caused by cracks in the weld beads was detected. An investigation revealed that some cracks had resulted from excessive dilution of the weld metal by iron (analysis showed 30% Fe in bead 1 in Fig. 5b), a result of the high welding heat, and that cracks in the weld craters had been caused by ending beads too abruptly. In addition to the cracking, there was excessive distortion of the cover, where the cover edges were warped upward toward the skirt boxes for 3.2 mm ($\frac{1}{8}$ in.) maximum, along the sides and about 6.4 mm ($\frac{1}{4}$ in.) across the ends. The distortion was not reduced during stress relieving (step 6).

Experimentation resulted in the adoption of a new welding procedure (step 5) that minimized distortion and eliminated weld-metal cracking. The remaining steps in the original procedure were retained, unchanged. In the new procedure, when welding the box to the cover plate, both parts were securely clamped to a welding surface plate. The sequence of weld-bead deposition was the same as for the original method (Fig. 5b), but only firm weld beads were deposited (Fig.

5d). Bead 1 was placed mostly on the alloy 400, which resulted in considerably less dilution by iron (7%, compared with 30%). The bead was ended very slowly to avoid the danger of subsequent crater cracking. The welds were made with an electrode that was slightly larger than the original (4.8 mm, or $\frac{3}{16}$ in., diameter instead of 4.0 mm, or $\frac{5}{32}$ in., diameter), using from 145 to 150 A welding current, instead of 154 A. These modifications reduced the current density and, thus, the heat input.

When the clamps were released, no significant distortion of the cover plate was observed. All joints passed the helium leak-detection test.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Introduction

COPPER AND COPPER ALLOYS offer a unique combination of material properties that makes them advantageous for many manufacturing environments. They are widely used because of their excellent electrical and thermal conductivities, outstanding resistance to corrosion, ease of fabrication, and good strength and fatigue resistance. Other useful characteristics include spark resistance, metal-to-metal wear resistance, low-permeability properties, and distinctive color.

Copper and copper alloys find their greatest use for electrical conductors and in the manufacture of electrical components. In its pure form, copper has a face-centered cubic crystal structure and a density of 8.968 g/cm^3 (0.32 lb/in.^{3}), which is about three times the density of aluminum. The electrical conductivity of copper is only slightly lower than that of silver, but it exceeds the electrical and thermal conductivity of aluminum by one-and-a-half times. The electrical conductivity reference standard of engineering materials is copper with a rating of 100% IACS (International Annealed Copper Standard). All other materials are compared on a conductivity basis to the IACS standard. Special processing of copper can produce some forms which reach 102% IACS.

Their excellent resistance to fresh water, salt water, and alkaline solutions makes copper alloys ideally suited for fabrication of tubing, valve fittings, heat exchangers, and chemical equipment. Copper reacts with sulfur and ammonia compounds. Ammonium hydroxide solutions will rapidly attack copper and its alloys, causing severe corrosion.

Many copper alloys are used for bearings and wear surfaces. Their excellent metal-to-metal wear resistance and lack of galling makes them excellent bearing surfaces. The good malleability and formability of copper and its alloys, as well as its aesthetically pleasing color, make it a prime candidate for architectural applications such as ornamentation and roofing.

In manufacturing, copper is often joined by welding. The arc welding processes are of prime concern. Arc welding can be performed using shielded metal arc welding (SMAW), gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), plasma arc welding (PAW), and submerged arc welding (SAW). These joining processes will be discussed with reference to specific copper alloy groups. The effects of various alloying agents are also discussed relative to welding metallurgy and process considerations. Examples of standard joint geometry, process parameters, and specific applications are described.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Alloy Metallurgy and Weldability

Many common metals are alloyed with copper to produce the various copper alloys. The most common alloying elements are aluminum, nickel, silicon, tin, and zinc. Other elements and metals are alloyed in small quantities to improve certain material characteristics, such as corrosion resistance or machinability. Copper and its alloys are divided into nine major groups. These major groups are:

- *COPPERS,* WHICH CONTAIN A MINIMUM OF 99.3% CU
- *HIGH-COPPER ALLOYS,* WHICH CONTAIN UP TO 5% ALLOYING ELEMENTS
- *COPPER-ZINC ALLOYS (BRASSES),* WHICH CONTAIN UP TO 40% ZN
- *COPPER-TIN ALLOYS (PHOSPHOR BRONZES),* WHICH CONTAIN UP TO 10% SN AND 0.2% P
- *COPPER-ALUMINUM ALLOYS (ALUMINUM BRONZES),* WHICH CONTAIN UP TO 10% AL
- *COPPER-SILICON ALLOYS (SILICON BRONZES),* WHICH CONTAIN UP TO 3% SI
- *COPPER-NICKEL ALLOYS,* WHICH CONTAIN UP TO 30% NI
- *COPPER-ZINC-NICKEL ALLOYS (NICKEL SILVERS),* WHICH CONTAIN UP TO 27% ZN AND 18% NI
- *SPECIAL ALLOYS,* WHICH CONTAIN ALLOYING ELEMENTS TO ENHANCE A SPECIFIC PROPERTY OR CHARACTERISTIC, FOR EXAMPLE, MACHINABILITY

Many copper alloys have common names, such as oxygen-free copper (99.95% Cu min), beryllium copper (0.2 to 2.0% Be), Muntz metal (Cu-40Zn), Naval brass (Cu-39.25Zn-0.75Sn), and commercial bronze (Cu-10Zn).

A more standardized system of identification is the Unified Numbering System (UNS). In this system, wrought alloys of copper are designated by numbers 1*xxxx* to 7*xxxx*, and cast alloys are designated 8*xxxx* to 9*xxxx*; thus, the same alloy can be produced as a wrought and cast product.

Table 1 lists various copper alloys that are frequently arc welded, their UNS numbers, and their physical properties. Many of the physical properties of copper alloys are important to the welding processes, including melting temperature, coefficient of thermal expansion, and electrical and thermal conductivity. As shown in Table 1, certain alloying elements greatly decrease the electrical and thermal conductivities of copper and copper alloys. This will in turn significantly affect the weldability of the alloys. The copper and copper alloys listed in Table 1 are rated for their relative weldability using SMAW, GTAW, and GMAW.

TABLE 1 NOMINAL COMPOSITIONS, MELTING POINTS, RELATIVE THERMAL CONDUCTIVITIES, AND WELDABILITIES OF WROUGHT COPPERS AND COPPER ALLOYS THAT ARE COMMONLY ARC

Several alloying elements have pronounced effects on the weldability of copper and copper alloys. Small amounts of volatile, toxic alloying elements are often present in copper and its alloys. As a result, the requirement of an effective ventilation system to protect the welder and/or the welding machine operator is more critical than when welding ferrous metals.

Zinc reduces the weldability of all brasses in relative proportion to the percent of zinc in the alloy. Zinc has a low boiling temperature, which results in the production of toxic vapors when welding copper-zinc alloys. Effective forced ventilation is mandatory, and source-capture systems are necessary to contend with the fumes.

Tin increases the hot-crack susceptibility during welding when present in amounts from 1 to 10%. These alloys are typically the phosphor bronzes and tin brasses. Tin, when compared with zinc, is far less volatile and toxic. During welding, tin may preferentially oxidize relative to copper. The results will be an oxide entrapment, which may reduce the strength of the weldment.

Beryllium, aluminum, and nickel form tenacious oxides that must be removed prior to welding. The formation of these oxides during the welding process must be prevented by shielding gas or by fluxing, in conjunction with the use of the appropriate welding current. The oxides of nickel interfere with arc welding less than those of beryllium or aluminum. Consequently, the nickel silvers and copper-nickel alloys are less sensitive to the type of welding current used during manufacture. Beryllium-containing alloys also produce toxic fumes during welding.

Silicon has a beneficial effect on the weldability of copper-silicon alloys because of its deoxidizing and fluxing actions. The combination of this effect and the low thermal conductivity makes silicon bronzes the most weldable of the copper alloys for any arc process.

Phosphorus is beneficial to certain copper and copper alloys as a strengthener and deoxidizer. When added to brass, phosphorus inhibits dezincification corrosion. In the amounts normally present in most copper alloys, phosphorus does not adversely affect or hinder welding.

Chromium, like beryllium and aluminum, can form a refractory oxide on the surface of the molten weld pool. Arc welding should be done in an inert protective atmosphere to prevent formation of chromium oxides.

Cadmium has no serious effect on the weldability of copper. However, the low boiling temperature of cadmium does result in evaporation of this alloy at welding temperatures, thereby creating a potential health hazard. Cadmium will also form an oxide in the molten weld metal, but the oxide can be easily reduced by fluxing agents.

Oxygen can cause porosity and reduce the strength of welds made in certain copper alloys that do not contain sufficient quantities of phosphorus or other deoxidizers. Oxygen may be found as a free gas or as cuprous oxide. Most commonly welded copper alloys contain deoxidizing elements--usually phosphorus, silicon, aluminum, iron, or manganese. These elements will readily combine with oxygen and eliminate the potential for porosity. The same deoxidizers are also included in the filler metals. The soundness and strength of arc welds made in commercial coppers depend upon the cuprous oxide content. As the oxide content decreases, weld soundness increases. Deoxidized coppers provide the best results because they are free from cuprous oxides and contain residual amounts of phosphorus.

Iron and manganese do not significantly affect the weldability of the alloys that contain them. Iron is typically present in some special brasses, aluminum bronzes, and copper-nickel alloys in amounts of 1.4 to 3.5%. Manganese is commonly used in these same alloys, but at lower concentrations than iron.

Free-Machining Additives. Lead, selenium, tellurium, and sulfur are added to copper alloys to improve machinability. Bismuth is beginning to be used for this purpose as well when lead-free alloys are desired. These minor alloying agents, while improving machinability, adversely affect the weldability of copper alloys by rendering the alloys hot-crack susceptible. The adverse effect on weldability begins to be evident at about 0.05% of the additive and is more severe with larger concentrations. Lead is the most harmful of the alloying agents with respect to hot-crack susceptibility. However, alloys that contain 0.5 to 4% Pb are not ordinarily welded and are not included in Table 1.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Factors Affecting Weldability

Besides the alloying elements that comprise a specific copper alloy, several other factors affect weldability. These factors are the thermal conductivity of the alloy being welded, the shielding gas, the type of current used during welding, the joint design, the welding position, and the surface condition and cleanliness. The effects of the shielding gas, type of current, and joint design used during welding are discussed under the sections for each individual process and alloy, described later in this article.

Effect of Thermal Conductivity. The behavior of copper and copper alloys during welding is strongly influenced by the thermal conductivity of the alloy. Table 1 shows the relative thermal conductivities based on the conductivity of alloy C10200 (oxygen-free copper). As shown in Table 1, the thermal conductivity varies greatly from this baseline value, which is 339 kJ/m^2 in meters per hour at 20 °C (226 Btu/ft^2 in feet per hour at 68 °F). The range is from 100, for alloys C10200 and C11000, to lows of 8 to 12 for nickel silvers and copper-nickel alloys and 9 for alloy C65500. In comparison, carbon steel has a thermal conductivity of 13 on this scale.

When welding commercial coppers and lightly alloyed copper materials with high thermal conductivities, the type of current and shielding gas must be selected to provide maximum heat input to the joint. This high heat input counteracts the rapid head dissipation away from the localized weld zone. Depending on section thickness, preheating may be required for copper alloys with lower thermal conductivities. The interpass temperature should be the same as for preheating. Copper alloys are not postweld head treated as frequently as steels, but some alloys may require controlled cooling rates to minimize residual stresses and hot shortness.

Welding Position. Due to the highly fluid nature of copper and its alloys, the flat position is used whenever possible for welding. The horizontal position is used in some fillet welding of corner joints and T-joints.

Vertical and overhead positions and the horizontal position are less frequently used in welding butt joints. These positions are ordinarily restricted to GTAW, GMAW, and PAW of the less conductive aluminum bronzes, silicon bronzes, and copper-nickel alloys. Small-diameter electrodes and filler-metal wires are used in conjunction with low welding currents for out-of-position welding. Current pulsation is used with GTAW, GMAW, and PAW, to control weld pool fluidity.

When using SMAW, out-of-position welding is usually limited to the joining of aluminum bronzes and copper-nickel alloys, but it can also be done on some phosphor bronzes and silicon bronzes.

Precipitation-Hardenable Alloys. The most important precipitation-hardening reactions are obtained with beryllium, chromium, boron, nickel, silicon, and zirconium. Care must be taken when welding precipitation-hardenable copper alloys to avoid oxidation and incomplete fusion. Whenever possible, the components should be welded in the annealed condition, and then the weldment should be given a precipitation-hardening heat treatment.

Hot Cracking. Copper alloys, such as copper-tin and copper-nickel, are susceptible to hot cracking at solidification temperatures. This characteristic is exhibited in all copper alloys with a wide liquidus-to-solidus temperature range. Severe shrinkage stresses produce interdendritic separation during metal solidification. Hot cracking can be minimized by reducing restraint during welding, preheating to slow the cooling rate and reduce the magnitude of welding stresses, and reducing the size of the root opening and increasing the size of the root pass.

Porosity. Certain elements (for example, zinc, cadmium, and phosphorus) have low boiling points. Vaporization of these elements during welding may result in porosity. When welding copper alloys containing these elements, porosity can be minimized by fast weld speeds and a filler metal low in these elements.

Surface Condition. Grease and oxide on work surfaces should be removed before welding. Wire brushing or bright dipping can be used. Millscale on the surfaces of aluminum bronzes and silicon bronzes is removed for a distance from the weld region of at least 13 mm (0.5 in.), usually by mechanical means. Grease, paint, crayon marks, shop dirt, and similar contaminants on copper-nickel alloys may cause embrittlement and should be removed before welding. Millscale on copper-nickel alloys must be removed by grinding or pickling; wire brushing is not effective.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Arc Welding Processes

Copper and most copper alloys can be joined by arc welding. The commercial alloys that are readily arc welded are listed in Table 1. Welding processes that use gas shielding are generally preferred, although SMAW can be used for many noncritical applications.

Argon, helium, or mixtures of the two are used as shielding gases for GTAW, PAW, and GMAW. Generally, argon is used when manually welding material that is less than 3 mm (0.13 in.) thick, has low thermal conductivity, or both. Helium or a mixture of 75% helium and 25% argon is recommended for machine welding of thin sections and for manual welding of thicker sections of alloys that have high thermal conductivity. Small amounts of nitrogen can be added to the argon shielding gas to increase the effective heat input.

Shielded metal arc welding can be used to weld a wide range of thicknesses of copper alloys. Covered electrodes for SMAW of copper alloys are available in standard sizes ranging from 2.4 to 4.8 mm ($\frac{3}{32}$ to $\frac{3}{16}$ in.). Other sizes are available in certain electrode classifications, and the reader is referred to ANSI/AWS A5.6 "Specification for Covered Copper and Copper Alloy Arc Welding Electrodes."

Higher thermal conductivity and thermal expansion of copper and copper alloys result in greater weld distortion than in comparable steel welds. The use of preheat, fixtures, proper welding sequence, and tack welds can minimize distortion or warping.

Gas-Tungsten Arc Welding

Gas-tungsten arc welding is well suited for copper and copper alloys because of its intense arc, which produces an extremely high temperature at the joint and a narrow heat-affected zone (HAZ). In welding copper and the more thermally conductive copper alloys, the intensity of the arc is important in completing fusion with minimum heating of the surrounding, highly conductive base metal. A narrow HAZ is particularly desirable in the welding of copper alloys that have been precipitation-hardened.

The most frequent use of GTAW for copper and copper alloys is on sections up to 3 mm (0.13 in.) thick that have been prepared with a square edge. Often no filler metal is used in joining these thicknesses. Filler metal is usually required in GTAW of sections thicker than 3 mm (0.13 in.). Gas-tungsten arc welding of sections thicker than 13 mm (0.5 in.) is performed only if GMAW equipment is not available or if special conditions exist. These conditions would include hot shortness of the base metal or adjacent heat-sensitive features that make it necessary to limit the heat input to the base material. Under certain conditions, pulsed GMAW would be the preferred process.

Type of Current. Direct current electrode negative (DCEN) is used for GTAW of most copper and copper alloys. This permits the use of an electrode that has a minimum diameter for a given welding current and that provides maximum penetration of the base material. Alternating current stabilized by high frequency is used on beryllium coppers and aluminum bronzes to prevent the buildup of tenacious oxide film on the base metals.

Electrodes. Many of the standard tungsten or alloyed tungsten electrodes can be used in GTAW of copper and copper alloys. The selection factors normally considered for tungsten electrodes apply in general to the copper and copper alloys. Except as noted for the specific classes of copper alloys, thoriated tungsten (usually EWTh-2) is preferred for its better performance, longer life, and greater resistance to contamination.

Gas-Metal Arc Welding

Gas-metal arc welding is used to join all of the coppers and copper alloys listed previously in Table 1. Gas-tungsten arc welding is preferred for thicknesses less than 3 mm (0.13 in.), while GMAW is preferred for section thicknesses above 3 mm (0.13 in.) and for the joining of aluminum bronzes, silicon bronzes, and copper-nickel alloys.

The major application of GMAW of copper alloys is in the joining of material thicknesses between 3 and 13 mm (0.13 and 0.5 in.) thick, and the process is almost invariably selected for arc welding sections of copper alloys thicker than 13 mm (0.5 in.). The high deposition rate for GMAW is a major advantage in this application when compared to GTAW or SMAW. The greater heat input to the weld, compared with that for GTAW, is a disadvantage in some applications due to the formation of a wider HAZ.

Direct current electrode positive (DCEP) is used exclusively for GMAW of copper alloys. Typically, argon is used as a shielding gas. Helium or mixtures of argon and helium are often used when hotter arc voltages are needed with standard operating current levels. A square-groove joint is not ordinarily used for welding thicknesses greater than 3 mm (0.13 in.), except for coppers. Single-V-grooves are used for thicknesses of 3 to 13 mm (0.13 to 0.5 in.). When section thicknesses exceed 13 mm (0.5 in.), double-V-grooves or double-U-grooves are used as joint preparations.

Welding Position. Most GMAW of copper alloys is done in the flat position with spray transfer; fillet welds acceptable for many applications can be produced in a horizontal position. Gas-metal arc welding is preferred to GTAW or SMAW when weld positions other than flat are required. Out-of-position welding is usually restricted to the less-fluid copper alloys, such as aluminum bronzes, silicon bronzes, and copper-nickel alloys. Small-diameter filler metals and low welding currents are preferred for such applications, and a globular or short-circuiting transfer is ordinarily used. The development of pulsed spray transfer has been quite advantageous for welding of coppers and copper alloys. Small- to medium-diameter wires can be readily used out-of-position for vertical and overhead welding of most alloys.

Shielded Metal Arc Welding

When compared with SMAW of low-carbon steels, SMAW of copper and copper alloys uses larger root openings, wider groove angles, more tack welds, higher preheat and interpass temperatures, and higher welding currents. Welding of coppers and copper alloys using SMAW is almost always restricted to flat-position welding. Out-of-position welding using this process is usually limited to the joining of phosphor bronzes and copper-nickel alloys.

Plasma Arc Welding

The welding of coppers and copper alloys using PAW is comparable to GTAW of these alloys. Argon, helium, or mixtures of the two are used for the welding of all alloys. Hydrogen gas should never be used when welding coppers. Plasma arc welding has two distinct advantages over GTAW: (1) the tungsten is concealed and entirely shielded, which greatly reduces contamination of the electrode, particularly for alloys with low-boiling-temperature constituents such as brasses, bronzes, phosphor bronzes, and aluminum bronzes; and (2) the constricted arc plume gives rise to higher arc energies while minimizing the growth of the HAZ. As with GTAW, current pulsation and current ramping may also be used. Plasma arc welding equipment has been miniaturized for intricate work, known as microplasma welding.

Plasma arc welding of coppers and copper alloys may be performed either autogenously or with filler metal. Filler metal selection is identical to that outlined for GTAW. Automation and mechanization of this process is readily performed and is preferable to GTAW where contamination can restrict production efficiencies. Welding positions for PAW are identical to those for GTAW. However, the plasma keyhole mode has been evaluated for thicker sections in a vertical-up position. Generally, all information presented for GTAW is applicable to PAW.

Submerged Arc Welding

The welding of thick gage material, such as seamed pipe formed from heavy plate, can be achieved by continuous metal-arc operation under a granular flux. Effective deoxidation and slag-metal reactions to form the required weld-metal composition are critical, and the SAW process is still under development for copper-base materials. A variation on this process can be used for weld cladding or hardfacing. Promising results have been seen with the copper-nickel alloys for section thicknesses greater than 13 mm (0.5 in.). V-groove and U-groove joint designs similar to those used in GMAW are satisfactory.

Commercially available fluxes should be used for the copper-nickel alloys. Welding conditions, which are greatly dependent upon the flux used, are provided by the flux manufacturer. Special attention should be given to the weld bead sequence when multi-pass welds are deposited, to ensure complete fusion while maintaining proper bead contour. X-ray quality results can be obtained when the technique is correctly performed.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Filler Metals

Both covered electrodes and bare electrode wire and rods are available for welding copper and copper alloys. Tables 2, 3, and 4 list the various American Welding Society (AWS) classifications for the filler metals for GTAW, GMAW, and SMAW, respectively.

TABLE 2 FILLER METALS FOR GTAW OF COPPER AND COPPER ALLOYS

FILLER METAL	**AWS CLASSIFICATION**	PRINCIPLE CONSTITUENTS[B]
COPPER	ERCU	**98.0 MIN CU + AG, 1.0 SN, 0.5 MU, 0.50 SI, 0.15 P**

Copper Filler Metals. The electrodes and rods used to weld the coppers, primarily deoxidized and electrolytic tough pitch (ETP) coppers, are designated as ERCu and have a minimum copper content of 98%. These filler metals, which can be used with GMAW, GTAW, and PAW processes, have electrical conductivity ratings of 25 to 40% IACS.

The covered electrodes used for SMAW are designated as ECu. These are normally used with DCEP. Compared to carbon steel electrodes of the same diameter, the required welding current for ECu electrodes is typically 30 to 40% greater.

Copper-Zinc Filler Metals. Copper-zinc (brass) weld rods are available in three classifications: RBCuZn-A (Naval Brass), RCuZn-B (Low-Fuming Brass), and RCuZn-C (Low-Fuming Brass). These particular welding rods are used for braze welding of copper, bronze, and nickel alloys. Their electrical conductivity is about 25% IACS; thermal-conductivity values are about 30% of those of copper.

Copper-zinc filler metals cannot be used as electrodes for the arc welding processes. The high zinc content tends to become volatile during arc welding and boils from the molten weld pool. This boiling of the low-melting-temperature constituents results in a porous weld.

Copper-Tin Filler Metals. The copper-tin (phosphor bronze) welding electrodes and rods are designated as ECuSn-A, ERCuSn-A, and ECuSn-C. The ECuSn-A and ECuSn-C electrodes contain approximately 5 and 8% Sn, respectively. Phosphorus is used as a deoxidizer for both electrodes. These electrodes are suitable for welding bronze, brass, and copper if the presence of tin in the weld metal is not objectionable. These filler metals are also commonly used for repair welding of castings. Greater weld-metal strength and hardness are obtained with the ECuSn-C electrodes than with the ECuSn-A electrodes.

The ERCuSn-A rods can be used with GTAW and PAW for joining phosphor bronzes. Preheat temperatures of about 200 °C (400 °F) are required when welding with these electrodes, particularly for heavy sections.

Copper-Silicon Filler Metals. Copper-silicon (silicon bronze) electrodes are used in barewire form for GMAW, GTAW, PAW, and sometimes for oxyfuel welding. The designation for these electrodes is ERCuSi-A. Chemical compositions contain between 2.8 and 4.0% Si with approximately 1.5% Mn, 1.0% Sn, and 1.0% Zn. These filler metals are frequently used to weld silicon bronzes and brasses. They are also used for braze welding of galvanized steel. The electrical conductivity is about 6.5% IACS, and the thermal conductivity is approximately 8.4% of that of copper. The covered electrodes in this filler metal classification are designated as ECuSi and are used primarily for welding copper-zinc alloys with the DCEP setting. The covered electrode can also be used for welding of silicon bronze, copper, and galvanized steel. Weld-metal mechanical properties are slightly higher than those of silicon bronze base metal.

Copper-Aluminum Filler Metals. There are a number of copper-aluminum (aluminum) bronze filler metals for both hardfacing and joining applications. The first of these is designated as ERCuAI-A and is an iron-free aluminum bronze. It is used as a surfacing alloy for wear-resistant surfaces with relatively light loads and for resistance to corrosive media, such as salt water and some commonly used acids. This alloy is not recommended for joining applications. Another hardfacing filler metal is ECuAl-B, which is a covered electrode containing 7.5 to 10% AI. These electrodes are used for surfacing applications and repair welding of aluminum bronze castings with similar compositions.

The covered electrodes for SMAW are designated as ECuAl-A2 and contain from 6.5 to 9% A1. The bare-wire electrodes for GTAW, GMAW, and PAW contain from 8.5 to 11% Al and are designated as ERCuAl-A2. This electrode has a higher strength than the covered electrode. Both filler metals can be used for joining aluminum bronzes, silicon bronzes, copper-nickel alloys, copper-zinc alloys, manganese bronzes, and many combinations of dissimilar metals.

ERCuAl-A3 electrodes and rods are used for repair welding of aluminum bronze castings using GMAW and GTAW. The high aluminum content produces welds with less tendency to crack in highly stressed cross sections.

Repair of both wrought and cast aluminum bronze materials containing nickel can be performed with copper-nickel-aluminum electrodes and bare wire. The designations for these metals are ECuNiA1 and ERCuNiA1. These electrodes offer good corrosion resistance as well as good cavitation resistance in both salt water and brackish water.

Joining of manganese-nickel-aluminum bronzes is performed with covered electrodes, designated as ECuMnNiAl, and bare filler metals, designated as ERCuMnNiAl. Like the copper-nickel-aluminum electrodes, these electrodes have good resistance to cavitation, erosion, and corrosion.

Copper-Nickel Filler Metals. Covered electrodes for this classification are designated as ECuNi, and bare electrode wire and rods are designated as ERCuNi. The nominal compositions are 70% Cu and 30% Ni. Titanium is used as a deoxidizer in these filler metals, which are used for the joining of copper-nickel alloys.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Coppers

As indicated in Table 1, coppers include oxygen-free, ETP, and deoxidized grades that contain [ges]99% Cu (UNS Numbers C10100 to C 15760). The coppers are welded using GTAW, GMAW, and SMAW. Additional information on the properties and applications of coppers can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

When using GTAW to join commercial coppers, weld quality will differ depending on the cuprous oxide content of the copper. The nominal welding conditions, however, for a given thickness and joint design are approximately the same. Table 5 lists several representative welding conditions for GTAW of commercial coppers.

Note: The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications.

(A) COPPER, CARBON, GRAPHITE, OR CERAMIC TAPE BACKING STIPS OR RINGS MAY BE USED (SEE TEXT).

(B) MIXTURES OF ARGON AND HELIUM ARE ALSO USED (SEE TEXT).

(C) DEPTH OF BACK V IS 9.5 MM (3/8 IN.) OF STOCK THICKNESS.

(D) USE OF FILLER METAL IS OPTIONAL FOR THICKNESSES OF 6.4 MM ($\frac{1}{4}$ IN.) OR LESS.

Effect of Cuprous Oxide. Cuprous oxide may be present within the base metal or introduced through oxidation of the molten weld pool during the arc welding process. Migration of cuprous oxides to the grain boundaries lowers the strength and ductility of the weld and adversely affects fatigue properties.

The best results in the arc welding of copper are obtained on the deoxidized coppers because these alloys are free of cuprous oxides and they contain residual phosphorus. This phosphorus combines with oxygen, which is absorbed during the heating or welding, and prevents the formation of cuprous oxide. The strength, ductility, and porosity of welds made in alloy C10200 (oxygen-free copper) are intermediate between the same properties for welds made in deoxidized coppers (alloys C12000 and C12200) and those made in alloy C11000 (ETP copper), which contains 0.02 to 0.5% oxygen.

While cuprous oxide does have an adverse effect on the mechanical properties of coppers, weld properties of arc welded coppers containing cuprous oxide are superior to those obtained from oxyacetylene welding of oxygen-bearing coppers. Welds made by oxyfuel welding are subject to gassing and embrittlement.

Shielding Gases. Argon is the preferred shielding gas when welding copper sections up to 1.6 mm (0.06 in.) thick. As sections grow thicker, slower travel speeds and higher preheat temperatures are required when using argon shielding gas. For sections in excess of 1.6 mm (0.06 in.), helium is the preferred gas. The risk of oxide entrapment in the weld pool is greatly reduced when using helium. Also, compared to argon, helium provides deeper penetration or higher travel speed for the same welding current.

Mixtures of argon and helium shielding gases result in intermediate welding characteristics. For welding positions other than the flat position, a mixture of 65 to 75% He with argon provides a good balance between the penetrating effect of helium and the ease of control for argon. Gas flow rate usually ranges from 7.1 to 19 L/min (15 to 40 ft^3/h), with higher values being used for high currents in the welding of thick sections.

Type of Current. As indicated in Table 5, DCEN is preferred for GTAW of commercial coppers.

Electrodes. In GTAW of coppers, best results for electrode life and maintenance are obtained using a thoriated tungsten electrode containing 2% thoria (EWTh-2). Proper electrode preparation for the welding of copper is usually a pointed electrode with an included angle of 60°. The tip of the point is truncated with a diameter approximately one-third the diameter of the electrode.

Welding Without Filler Metal. Square-groove butt joints on copper up to 3 mm (0.13 in.) thick can be gas-tungsten arc welded without the use of filler metal. However, filler metal is sometimes required as thicknesses approach this value. Copper sections greater than 3 mm (0.13 in.) may be gas-tungsten arc welded without the use of filler metal by making two passes, one from each side.

Filler Metals. As shown in Table 5, copper sections greater than 3 mm (0.13 in.) that are joined by GTAW typically require the use of filler metals. As discussed above, the adverse effect of the formation of cuprous oxide requires that the filler metal contain a residual deoxidizer. The deleterious effect of oxygen is even more severe within the filler metal than within the base metal, because the filler metal has greater exposure to welding heat.

In most cases, copper filler metal is selected that contains a maximum of 0.15% P and 0.50% Si as deoxidizers. This filler metal is known as ERCu, as shown in Table 2. Alloys such as C12000 and C12200 (deoxidized coppers) do not contain enough residual phosphorus to ensure sound welds and are not used as filler metal. The ERCu filler metal has other advantages, such as relatively high electrical conductivity (30 to 40% IACS) and good color match to the copper base metal. Any of the other filler metals listed in Table 2 can be used in GTAW of commercial coppers. Most of the alloys contain adequate amounts of deoxidizing elements such as phosphorus, silicon, iron, aluminum, or titanium. These filler metals offer the advantage of greater joint strengths, but they have lower electrical conductivity and poor color match.

Welding Technique. Either the forehand or backhand welding technique can be used when GTAW is used for coppers. Forehand welding is preferred for all welding positions. It produces a smaller and more uniform bead size than is possible with backhand welding; however, a greater number of passes may be required to fill the joint.

The weld joint should be filled using one or more stringer beads or narrow weave beads. Wide oscillation of the arc while welding should be avoided, lest the edges of the bead be intermittently exposed to the atmosphere and consequently to oxidation. The first bead should penetrate the root of the joint and be relatively thick, to provide time for deoxidation of the weld metal and to avoid cracking of the bead.

Joint Designs. Welding of butt joints with thicker cross sections requires the use of filler metal and a root opening, due to the high thermal conductivity of copper. Clearance is needed to prevent the base metal from conducting the heat away too rapidly and solidifying the filler metal, thus choking the joint before it is filled.

Because of the high fluidity of copper, backing rings or strips are ordinarily used in GTAW of butt joints. The backing rings are typically made of copper, carbon, graphite, or ceramic tape. Backing is needed both for tightly fitted butt joints used in thin metal and for loosely fitted butt joints in thick metal, to prevent the loss of the fluid weld pool. Backing may also be used when needed for this purpose with other joint geometries.

Preheating. For GTAW of sections greater than 3 mm (0.13 in.), preheating of the base material is typically required to maintain the base metal at welding temperature. Without preheating, the high thermal conductivity of coppers results in excessive loss of heat away from the weld zone. The small arc that is typically used in GTAW cannot maintain sufficient welding heat in thick sections of copper, even under the most favorable conditions. Preheat temperatures are also shown in Table 5.

Deoxidized Copper. When copper weldments require the strength of the base metal, deoxidized coppers are usually used. Even with the localized heat input of GTAW, special fixturing and other welding conditions may be needed to minimize distortion, as shown in the following example.

Example 1: Redesign of Joint and Fixture to Minimize Distortion in GTAW of Alloy C12000.

A wafer of nuclear fuel was encapsulated in a can and cover assembly constructed of alloy C12000 using automatic GTAW. The completed weldment is shown in Fig. 1(a). As shown in detail A in Fig. 1, the can has a machined recess for the wafer and a 0.13 mm (0.005 in.) thick bottom. The can-to-cover joint had raised lips, which eliminated the need for filler metal.

FIG. 1 CONDITIONS FOR GTAW OF A NUCLEAR FUEL CONTAINER. DISTORTION IN WELDING WAS MINIMIZED BY INCREASING THE MASS OF THE FIXTURE TO INCREASE HEAT WITHDRAWAL AND BY CHAMFERING JOINT EDGES TO PERMIT REDUCTION OF WELDING CURRENT.

The weld had to provide a hermetic seal without distortion of the assembly, including the thin can bottom that was only 4.8 mm (0.19 in.) from the welded area. A mass spectrometer was used to conduct leak testing of the weldment.

The welds were made in a controlled atmosphere chamber with the can mounted in a rotating copper chill-block clamping fixture underneath a stationary electrode. Welding conditions are given in the table accompanying Fig. 1.

Originally the fixture and joint shown in Fig. 1 and detail A were used. However, at currents high enough for fusion, the welds were porous, the joint leaked, and the can warped unacceptably.

The porosity that caused leaking resulted from the machining operation of the can. The lubricant was wiped under the surface of the metal by the cutting tool, and subsequent cleaning operations failed to remove it. Machining without a lubricant eliminated the difficulty. To minimize distortion, the joint and fixture were improved as follows. The square lips of the joint were chamfered (40°) to a sharp edge, as shown in detail B in Fig. 1. This was done to reduce the heat input required to make the weld. With the chamfered lips, the welding current could be lowered because a smaller mass of metal was being melted at any instant. The mass of the fixture was increased, as shown in Fig. 1(b), to increase heat withdrawal. The redesigned fixture also provided complete support for the thin can bottom against pressure during leak testing.

Before welding, the assembly was retained in the fixture, which was held by a small chuck with all of the 0.13 mm (0.005 in.) thick can bottom resting on the thick copper backing, as shown in detail B of Fig. 1. The fixture assembly was welded in a chamber that was first vacuum-purged and then filled with 100% Ar under slightly positive pressure.

The torch was rigidly mounted on a sliding base with locating stops with which the electrode tip was positioned over the seam and clamped into position. In the argon atmosphere it was not necessary to provide a shielding gas to the electrode tip or to use an electrode cup. The electrode was ground to a sharp point to reduce current flow and arc wander.

During welding, the chuck holding the fixture was rotated by a variable-speed drive. Arc stability was maintained by a superimposed high-frequency current that was continuous. Current upslope was not controlled. Two revolutions at 3.5 rev/min were used, because slight variations in pressure between the cover and the can caused variations in the thickness of the weld bead after the first revolution. The second revolution smoothed out these irregularities and ensured adequate penetration of the base metal along the circumference of the joint. After the second revolution, the current was tapered to 0 A in 5 s.

Distortion was minimized because of the low welding current, the high heat-sink efficiency, and rigid support by the fixture. Control of heat input was also helpful in preventing excessive internal gas expansion after the joint was closed.

After welding, the chamber was evacuated to 1.3×10^{-4} Pa (10^{-6} torr). The interior of the can remained at approximately 0.1 MPa (15 psi). Under the pressure differential, the can, still in the fixture, was inspected for leaks by use of a mass spectrometer. The fixture supported the can bottom against internal pressure.

Oxygen-Free and ETP Coppers. Compared to GMAW or other processes with nonlocalized heat input, GTAW is preferred for the joining of either oxygen-free copper (alloy C10200) or ETP copper (alloy C11000) for thicknesses up to approximately 13 mm (0.5 in.).

Because of the absence of a deoxidizer, gas-tungsten arc welds in alloy C 10200 have slightly lower strength and ductility and are slightly more porous. Gas-tungsten arc welds in alloy C11000 have somewhat lower tensile strength than those in deoxidized coppers, and they are also more porous (see the section "Effect of Cuprous Oxide" in this article). However, the properties of gas-tungsten arc welds in ETP copper are acceptable in many applications involving welded electrical conductors, particularly when tensile strength is relatively unimportant, as in the induction-coil weldment described in the following example.

Example 2: Automatic GTAW of Joints between Alloy C11000 Bar and Tubing.

A solid bar approximately 9 m (30 ft) long of alloy C11000 was gas-tungsten arc welded automatically to a comparable length of tubing of the same alloy. The weldment was used in making water-cooled induction coils for low frequency (60 to 180 Hz) induction heating that required more cross-sectional area for electrical conduction than was provided by the tubular section alone. Figure 2 shows a weldment with a cross section of typical size. The 9 m (30 ft) length was standard for inductor stock. The weldment was bent into coils with an inside diameter of 100 mm (4 in.). The bar stock was located to the inside of the coil. The requirement of the joint was to maintain good electrical conductivity.

FIG. 2 CONDITIONS FOR AUTOMATIC GTAW OF ALLOY C11000 TUBING AND BAR INDUCTOR COILS. THE POSITIONS OF THE ASSEMBLY, GUIDE ROLLS, AND TORCH DURING WELDING ARE SHOWN.

Originally, the bar and tubing were torch brazed along the entire length using a silver alloy filler metal. Not only was the filler metal expensive, but brazing was slow, requiring two operators to handle the lengths of tubing and bar. A faster and less costly method was developed by mechanizing a GTAW procedure in which no filler metal was used, thus increasing the production rate.

Welding conditions for the application are given in the table accompanying Fig. 2. The fixture, designed to accommodate the sizes of inductor bar and tubing regularly used, consisted of six guide rolls, as shown in Fig. 2. These guide rolls properly aligned the assembly during welding. A chain and variable-speed drive was used to pull the assembly through the rolls during welding. Positioning of the torch over the joint was achieved by using an adjustable mount.

The first 25 mm (1 in.) of the leading edge of the joint was brazed prior to welding, to prepare the assembly for feeding through the guide rolls. The position of the assembly, guide rolls, and electrode holder during welding is shown in Fig. 2. The relative travel speed of the assembly as pulled through the rolls was 5.5 mm/s (13 in./min). A single pass was used without coolant for each side of the weldment and the ends were trimmed after welding.

The high thermal conductivity of alloy C11000 caused rapid dissipation of the heat energy. However, this difficulty was overcome without preheating by the use of helium as the shielding gas. Helium provided a hotter arc than could be obtained with argon. Thus, it was possible to produce the relatively deep, narrow beads at the stated travel speed. Oxygen from the oxide in alloy C11000 caused some porosity, but this was minimized by the fast freezing promoted by the high travel speed. The required joint properties were obtained in spite of the potential for porosity.

Gas-Metal Arc Welding

As has been previously discussed, oxygen has a detrimental effect when copper is welded. The resulting porosity and reduced weld strength described for GTAW of copper are more pronounced in GMAW. This is due to the greater heat input associated with the process. Gas-metal arc welds of deoxidized coppers compare favorably in density and strength with the welds made using GTAW. However, the greater heat input and lesser localization of heat obtained with GMAW result in greater porosity and lower strength in the HAZ of the welds. This is especially true in coppers that contain insufficient amounts of deoxidizer, particularly ETP copper. Consequently, GMAW has less applicability than GTAW to the welding of ETP copper, oxygen-free copper, or low-phosphorus-deoxidized copper up to approximately 13 mm (0.5 in.) thick.

Nominal Conditions. Table 6 gives the nominal conditions for gas-metal arc butt welding of copper and copper alloys. In welding joints for which the root opening is between 2.5 and 3 mm (0.10 and 0.13 in.), mixtures of helium and argon are used as shielding gas instead of pure argon. This results in lower requirements for preheat, deeper penetration into the weld joint, and higher rates of filler metal deposition.

Note: The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications.

(A) THICKNESSES UP TO 38.1 MM (1 1/2 IN.) ARE SOMETIMES WELDED BY USE OF SLIGHTLY HIGHER CURRENT AND LOWER TRAVEL SPEED THAN SHOWN FOR A THICKNESS OF 12.7 MM (1/2 IN.).

(B) COPPER BACKING.

(C) GROOVED COPPER BACKING.

(D) OR 75AR-25HE.

(E) SPECIAL WELDING SEQUENCE IS USED (SEE TEXT).

(F) SEE TABLE 1 FOR COMPOSITIONS.

(G) THE FINAL PASS IS MADE ON THE ROOT SIDE AFTER BACK CHIPPING. WIRE BRUSH AFTER EACH PASS.

(H) SEVERAL PASSES ARE MADE ON THE FACE SIDE, THEN SEVERAL ON THE BACK SIDE, UNTIL THE WELD IS COMPLETED. BACK CHIP THE ROOT PASS BEFORE MAKING THE FIRST PASS ON THE BACK SIDE. WIRE BRUSH AFTER EACH PASS.

(I) SIMILAR TO THE DOUBLE V-GROOVE WELD, BUT WITH A GROOVE RADIUS OF 9.5 MM ($\frac{3}{8}$ IN.).

(J) THE FINAL PASS IS MADE ON THE ROOT SIDE AFTER BACK CHIPPING.

(K) SHOULD NOT BE OVERHEATED; AS LITTLE PREHEAT AS POSSIBLE SHOULD BE USED.

(L) WELDING CONDITIONS BASED ON ALLOYS C51000, C52100, AND C52400; CURRENT IS INCREASED OR SPEED IS DECREASED FOR ALLOY C50500.

(M) HOT PEENING BETWEEN PASSES IS RECOMMENDED FOR MAXIMUM STRENGTH.

(N) SLIGHT PREHEAT MAY BE NEEDED ON HEAVY SECTIONS; INTERPASS TEMPERATURE SHOULD NOT EXCEED 315 °C (600 °F).

(O) WITH ALUMINUM BRONZE BACKING.

(P) NO PREHEAT IS USED ON ANY THICKNESS; INTERPASS TEMPERATURE SHOULD NOT EXCEED 95 °C (200 °F).

(Q) WITH SILICON BRONZE BACKING

Filler Metals (Electrode Wires). The recommended ERCu electrode contains phosphorus, tin, silicon, and manganese as deoxidizers to minimize porosity. The electrode produces sound, trouble-free welds that also provide good color match to the copper base metal and have good electrical conductivity. The ERCu electrode was used as a basis for the conditions listed in Table 6.

Copper electrodes of higher purity than ERCu are seldom used in GMAW of copper, because these usually result in welds that are porous, due to the absence of deoxidizers. Most of the electrodes listed in Table 3 can be used. Any of the electrodes other than ERCu will produce dense, strong welds, but they will result in poor color match and unacceptable electrical conductivities. Filler metals should be deposited as stringer beads or narrow weave beads using the spray-transfer mode; weaving of the electrodes may result in oxidation at the edges of the weld.

Welding Technique. The forehand welding technique should be used in the flat position. For vertical-position welding, an upward progression should be utilized. Gas-metal arc welding of copper is not recommended for the overhead position due to poor bead contour. The preferred process for overhead-position welding is GTAW.

Joint Design. A square-groove joint is used for the single-pass welding of coppers up to 3 mm (0.13 in.) thick. A backing bar is used for zero root openings, and a grooved copper backing bar is used for root openings of 1.6 mm (0.06 in.) maximum. The square-groove joint can also be used for one-pass-per-side welding of coppers up to 6 mm (0.25 in.) thick.

Single-V-groove joints are used when welding coppers of sections above 6 mm (0.25 in.). The filler metal is deposited on one side using three or more passes, and the root pass is back gouged to sound metal before the last pass is applied to the back of the joint. In some applications, the root pass is applied using GTAW and subsequent passes are completed via GMAW for rapid buildup.

If heavy sections (thicker than 13 mm, or 0.5 in.) are to be welded, these should be prepared with a double-V- or a double-U-groove joint. Welding is performed by applying alternating passes to opposite sides of the joint, if readily accessible, to minimize distortion. In a small, closed vessel, limited access may prevent the use of this technique, and in addition, heat buildup often prevents welding on both sides.

Preheating. Because of the high thermal conductivity of copper, sections thicker than 6 mm (0.25 in.) are usually preheated. As shown in Table 6, single-V-groove joints in 6 mm (0.25 in.) thick copper, welded using 1.6 mm ($\frac{1}{16}$ in.) diameter filler metal, are also preheated.

Deoxidized Coppers. Heavy-wall copper pressure vessels (up to about 40 mm, or 1.5 in., wall thickness), which are usually made from phosphorus-deoxidized copper, are frequently gas-metal arc welded. Residual phosphorus helps obtain maximum weld strength while minimizing porosity. In order to meet the high heat demand in welding these heavy-walled vessels, welding currents and preheat temperatures may be higher than those shown in Table 6.

Similar operating conditions are employed in welding crucibles for arc melting of refractory metals in controlled atmospheres. These crucibles are typically heavy-wall deoxidized copper cylinders with wall thicknesses up to 32 mm (1.25 in.), diameters of 0.3 to 1.2 m (1 to 4 ft), and lengths of 1 to 7.5 m (3 to 25 ft). Formed and welded copper plate is used, because seamless tubes of this size are not available. Longitudinal seams are welded, and flanges are welded to each end of the cylinders by GMAW. Such cylinders are preheated to 650 °C (1200 °F) before welding. Welding is done automatically, to avoid exposing operators to such heavy sections at elevated temperatures.

Oxygen-Free and ETP Coppers. The GMAW process is also used for welding oxygen-free copper in the production of the crucibles previously described. These crucibles are also used for arc melting of refractory metals. However, the weld properties are inferior to those produced with deoxidized copper. Because oxygen-free copper contains no residual deoxidizer, heating and welding cycles must be kept as short as possible, and gas shielding must be completely effective to avoid excessive porosity. Although the strength and soundness of welds in oxygen-bearing coppers, such as ETP copper, are substantially less than in oxygen-free copper, the reduced properties are seldom important for welds in electrical conductors. Busbars made of ETP copper are frequently joined using the GMAW process. The use of filler metals such as ERCu or another of the standard filler metals listed in Table 3 significantly lowers the electrical conductivity of the joint. In order to minimize this adverse effect, large root faces are used to increase the contact area at the joint line. For improved electrical conductivity, a filler metal with chemical composition approximately 0.75% Sn, 0.25% Si, and 0.20% Mn is sometimes used for welding ETP copper busbars.

Shielded Metal Arc Welding

Problems with porosity and low weld strength, due to oxygen content of the base metal and oxygen absorption during welding, are more severe in joining coppers by SMAW than by the gas-shielded processes. The resulting lower mechanical properties greatly limit the usefulness of weldments produced using SMAW. Additionally, electrical conductivity suffers greatly.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of High-Strength Beryllium Coppers

The wrought high-strength beryllium coppers include alloys C17000 and C17200, which contain nominally 1.7 and 1.9% Be, respectively, and up to 0.25% Co. A free-machining grade version of C17200 is available that is modified with a small lead addition, but this grade is not recommended for welding. The high-strength beryllium coppers are joined by GTAW and GMAW. Additional information on the properties and application of these materials can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Copper alloys C17000 and C17200, high-strength beryllium coppers, are readily welded using GTAW. These alloys are more easily welded than the high-conductivity beryllium coppers, which exhibit higher melting temperature and less fluidity. Gas-tungsten arc welding can be used for section thicknesses in excess of 13 mm (0.5 in.) when the use of the preferred GMAW process is not practical.

Nominal Conditions. Table 7 lists the suggested starting points for nominal conditions for GTAW of high-strength beryllium coppers. The shielding gas is usually a mixture of argon and helium to obtain a hot arc, smooth and spatter-free welds, and maximum electrode life.

TABLE 7 NOMINAL CONDITIONS FOR GTAW OF BERYLLIUM COPPERS

For butt joints having zero root opening; welding with a zirconiated tungsten electrode, filler metal of the same composition as the base metal, argon-helium gas at 12 L/min (25 ft^3/h)

Note: The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications.

(A) HIGH-FREQUENCY-STABILIZED ALTERNATING CURRENT IS PREFERRED; DCEN, WITH A THORIATED TUNGSTEN ELECTRODE, IS SUITABLE UNDER SOME CONDITIONS (SEE TEXT).

(B) FOR COMPOSITION, SEE TABLE 1.

(C) MAXIMUM ROOT FACE IS 1.6 MM (1/16 IN.).

(D) GAS-TUNGSTEN ARC WELDING IS USED ON THESE THICKNESSES ONLY WHEN GMAW CANNOT BE USED.

Electrodes. The preferred electrode when using alternating current is zirconiated tungsten (EWZr); noncritical applications can use the more economical pure tungsten (EWP). For DCEN, the thoriated electrodes (such as EWTh-2) are preferred.

Filler Metals. The addition of filler metals is almost always required to provide proper fill for the joint or to provide joint reinforcement in a V-groove weld. This is due to the high concern for strength when welding these alloys. Rods or strips of the same composition as the base metal are generally used as filler metals; the standard filler metals of other copper alloys are weaker and offer no advantages.

Joint Design. As Table 7 indicates, the typical joint designs for GTAW of high-strength beryllium copper are square-groove or 90° single-V-groove butt joints with a 1.5 mm (0.06 in.) maximum root face and zero root opening. The 90° single-V-groove butt welds can be used for thicknesses in excess of 13 mm (0.5 in.).

Preheating and Postweld Heat Treatment. As shown in Table 7, preheat temperatures of 150 to 200 °C (300 to 400 °F) are recommended for GTAW of section thicknesses greater than 3 mm (0.13 in.). Maximum weld strength is obtained by solution annealing and aging after welding. Aging treatments are 3 h at 315 °C (600 °F) for alloy C17000 and 3 h at 345 °C (650 °F) for alloy C17200. This postweld treatment does not consistently provide the full strength of solution-annealed and aged base metal, even for welds made under optimum conditions. Higher strength can be obtained by cold working the annealed metal to a higher temper and modifying the aging treatment.

For some applications, the intermediate weld metal strength obtained by aging after welding, without a solution anneal, is adequate. Omission of solution annealing avoids the expense and distortion associated with this high-temperature operation. Following are three applications of GTAW of high-strength beryllium coppers. Welding conditions for GTAW for three applications are shown in Table 8.

Example 3: Gas-Tungsten Arc Welding of High-Strength Beryllium Coppers in an Alloy C17000 Pressure Vessel.

The pressure vessel was used to scavenge propane from a freon bubble chamber. Use of GTAW was dictated because the vessel could not be solution-annealed after welding because of danger of warpage. The service conditions for this vessel included pressure of 41 MPa (6 ksi) and rapid thermal cycling. This application is shown in Table 8.

Example 4: Gas-Tungsten Arc Welding of High-Strength Beryllium Copper in a Cylindrical Generator Liner.

A cylindrical generator liner was constructed using alloy C17000 and alloy C17200. It was back-extruded from a cast billet. Longitudinal rings about 6 by 6 mm (0.25 by 0.25 in.) were machined on the outer surface. Nine reinforcing rings were rolled from extruded alloy C17000, equally spaced along the longitudinal rings, and welded to them. The reinforcing rings measured 40 mm (1.5 in.) wide and 32 mm (1.25 in.) high. The liner, used in a magneto-hydrodynamic electrical power generator, contained plasma at 1650 to 1925 °C (3000 to 3500 °F). This application is shown in Table 8.

Example 5: Gas-Tungsten Arc Welding of High-Strength Beryllium Copper in a Cover-to-Housing Weldment.

For ocean-cable use, a cast beryllium copper cover made from alloy C17000 was welded to a housing of the same alloy. The cast cover was welded to an extruded housing to produce a joint that was watertight at 83 MPa (12 ksi). This application is shown in Table 8.

Gas-Metal Arc Welding

Alloys C17000 and C17200 are more easily welded using the GMAW process than is high-conductivity alloy C17500. These alloys have lower melting temperatures, greater fluidity, and 50% lower thermal conductivities. The GMAW process is generally preferred for the welding of precipitation-hardened, high-strength beryllium coppers in thicknesses of 6 mm (0.25 in.) and greater. This process is also preferred for thicknesses from 6 mm (0.25 in.) down to 2.5 mm (0.1 in.) if heat treatment is to be done after welding.

Nominal Conditions. Table 6 gives the nominal welding conditions for GMAW of high-strength beryllium coppers. The shielding gas used for GMAW is typically a mixture of argon and helium. Direct current electrode positive is used to prevent the buildup of oxides during welding. The filler metal is ordinarily of the same composition as the base metal, for joints requiring maximum strength. However, electrode wires ERCuSi-A and ERCuA1-A2 can be used when joint strength is less critical. Preheating, postweld heat treating, and joint designs are generally the same as discussed in the section on GTAW of high-strength beryllium coppers.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of High-Conductivity Beryllium Copper

The traditional wrought high-conductivity alloys (C17500 and C17510) contain 0.2 to 0.7% Be and nominal 2.5% Co (or 2% Ni). The leanest and most recently developed high-conductivity alloy is C17410, which contains somewhat less than 0.4% Be and 0.6% Co. This section will describe the GTAW and GMAW of alloy C17500, the most frequently welded high-conductivity beryllium copper alloy. Additional information on the properties and applications of these materials can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Gas-tungsten arc welding of precipitation-hardened copper alloy C17500 (high-conductivity beryllium copper) is performed for thicknesses up to 6 mm (0.25 in.). This process produces a narrow HAZ, which is desirable. Ordinarily, the maximum thickness that can be gas-tungsten arc welded without substantial decrease in strength is about 13 mm (0.5 in.). However, thicker sections have been gas-tungsten arc welded. For weldments that require postweld heat treatments, GTAW is generally used only for thicknesses up to 2.5 mm (0.1 in.), with GMAW being used for thicker sections.

High-conductivity beryllium copper is more difficult to weld than the high-strength beryllium coppers because of its higher thermal conductivity, which is about twice that of the high-strength beryllium coppers. A difficulty common to the beryllium coppers is the formation of surface oxides, both beryllium oxide and cuprous oxide. The beryllium oxide is a tenacious oxide that inhibits wetting and fusion during welding. Cleanliness of the joint faces and surrounding surfaces before and during welding is necessary to ensure weld soundness.

Nominal Conditions. Table 7 gives the nominal starting conditions for GTAW of high-conductivity beryllium copper alloy C17500. Shielding gas, type of current, and electrode type are the same as for C17000 and C17200 high-strength alloys.

Type of Current. Variation in arc length or welding speed during GTAW can result in the formation of tenacious films on beryllium coppers. For this reason, high-frequency stabilized alternating current is preferred in automatic welding and must be used in manual welding. The alternating current continually breaks up the oxide coating, and high-frequency adds to the cleaning action during welding. Direct current electrode negative can be employed in the automatic welding of beryllium coppers. The advantage is found with the high heat input to the work and the deep penetration of this polarity. Close control of the arc length and welding speed must be maintained to minimize oxide formation.

High-conductivity beryllium coppers are more susceptible to porosity and cracking than welds made in high-strength beryllium copper. This is particularly true in multi-pass welding. However, successfully welded joints exhibit improved mechanical properties in HAZ compared with similar joints in high-strength beryllium coppers.

Filler Metals. Material with the same composition as the base alloy (C17500) is generally used, since high electrical conductivity is desired in the welds. If maximum electrical conductivity through the weld joint is not a requirement, silicon bronze filler metal is satisfactory. Aluminum bronze filler metals can be used but are less satisfactory than silicon bronze.

Joint Design. As Table 7 indicates, the usual joint designs for GTAW of high-conductivity beryllium copper are square-groove or 90° single-V-groove butt joints with a 1.6 mm (0.06 in.) root face and zero root opening. All joints should be backed with grooved copper or graphite backing strips or rings.

Preheating. Preheating is not ordinarily needed for welding alloy C17500 up to about 3 mm (0.13 in.) thick. However, thicker stock that may require multipass welds is usually preheated to approximately 425 °C (800 °F).

Gas-Metal Arc Welding

Gas-metal arc welding is preferred to GTAW for joining alloy C17500 with section thicknesses greater than 2.5 mm (0.1 in.) when the weldment is to be heat treated to obtain maximum weld strength. It is also the process of choice for joining thicknesses in excess of 6 mm (0.25 in.) if the welding is done on precipitation-hardened material. Gas-metal arc welding can be used for thicknesses up to 19 mm (0.75 in.).

As pointed out in the discussion of GTAW of alloy C17500, the three important factors in arc welding this alloy are: (1) high thermal and electrical conductivities; (2) oxide-forming characteristics; and (3) responsiveness to heat treatment. Although compromise is necessary between weld strength and conductivity, high thermal conductivities are typically the prime objectives in welding assemblies using this alloy.

Nominal Conditions. Table 6 lists the typical conditions for GMAW of high-conductivity beryllium coppers. Typically, DCEP is used. Argon is a suitable shielding gas; however, greater heat input, which is usually required when welding this alloy, can be obtained through the use of an argon-helium gas mix.

Filler Metals. As with GTAW for high-conductivity beryllium coppers, GMAW utilizes a filler metal of similar composition to the base metal. If reduced conductivity is an acceptable result of the weld metal, wires made of high-strength beryllium copper alloys C17000 and C17200 can be used for greater welding ease. Because of the precipitation-

hardening characteristics of beryllium coppers, the joint strength is always somewhat lower than that of the base material and depends on the initial condition of the base metal, the welding conditions, and the filler-metal selection.

Other electrodes, such as ERCuSi-A or ERCuAl-A2, can be used for GMAW of alloy C17500. Because of their lack of beryllium content, however, these alloys do not develop the high strength attained when beryllium copper filler metal is used.

Preheating and Postweld Aging. Section thicknesses of alloy C17500 greater than 3 mm (0.13 in.) are usually preheated at 315 to 480 °C (600 to 900 °F), depending on section thickness. When a beryllium copper filler metal is used, strength can be increased by aging after welding. The aging heat treatment for alloy C17500 is 480 °C (900 °F) for 3 h.

Properties of Weldments. Based on its high thermal conductivity and moderate to high strength, alloy C17500 is used for welded water-cooled assemblies such as tuyeres for blast furnaces, attrition mills for grinding beryllium chips to powder, and molds for the continuous casting of steel. While some strength is lost in the weld metal and the adjoining HAZ when alloy C17500 is welded, the magnitude of this decrease is affected by the condition and thicknesses of the base metal, and by joint design, welding process, and parameters.

Welding of Cadmium and Chromium Coppers

Typically, the welding procedures for GTAW of coppers are a satisfactory basis for determining initial welding parameters for cadmium and chromium coppers. These alloys have lower thermal and electrical conductivities than copper, and they can be welded with lower preheats and heat inputs than those required for copper. Section thickness limitations are the same as for GTAW of coppers. In addition to GTAW, GMAW can be used for the joining of cadmium and chromium coppers. The nominal conditions previously stated for GMAW welding of coppers are satisfactory for the welding of cadmium and chromium coppers.

The filler metal types, welding currents, polarities, and shielding gas mixtures for either GTAW or GMAW of coppers are suitable for the joining of cadmium and chromium coppers. These alloys should be welded using the standard joint geometries listed for GTAW and GMAW of coppers.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Copper-Zinc Alloys

Brasses are basically copper-zinc alloys and are the most widely used group of copper alloys. As shown in Table 1, brasses can be categorized as low-zinc brasses (5 to 20% Zn), high-zinc brasses (30 to 40% Zn), tin brasses, and special brasses. Copper-zinc alloys are joined by GTAW, GMAW, and SMAW. Additional information on the properties and applications of copper-zinc (brass) alloys can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Table 1 lists the copper-zinc (brass) alloys and shows their relative weldability. The low-zinc brasses are shown to have good weldability using GTAW. High-zinc brasses, tin brasses, special brasses, and nickel silvers have only fair weldability. This is because of the high zinc content or the moderate zinc content in combination with other elements, such as oxide-forming aluminum or nickel.

Gas-tungsten arc welding is sometimes used for the welding of copper-zinc alloys with 20% Zn or less. Alloys containing up to 1% Pb can also be welded with this process. Gas-tungsten arc welding is used because of its ability to weld rapidly with a highly localized heat input. It should be noted that most leaded copper alloys are generally not recommended for arc welding.

Section thicknesses of copper-zinc alloys ordinarily welded using GTAW are limited to about 9.5 mm (0.4 in.). However, thick sections of cast alloys such as manganese bronze are sometimes repair welded in localized areas. Preheating is not normally required for the welding of these alloys.

Shielding Gas. Selection of the proper shielding gas for GTAW of copper-zinc alloys is influenced by the heat required to fuse the metals together. This requirement is directly related to the thermal conductivity of the base metal. Normally argon is used for GTAW of the less conductive materials. Helium or helium mixes are the preferred shielding gases for alloys having higher thermal conductivities. However, the use of helium and helium-rich gas mixes can reduce the fumes produced when welding the less conductive alloys, such as high-zinc brasses, tin brasses, special brasses, and nickel silvers.

Filler Metals. Filler metals used in GTAW of copper-zinc alloys should not contain zinc. The addition of filler metal is recommended when welding sections greater than 1.6 mm (0.06 in.) thick. The arc is concentrated on the filler metal, thus reducing the zinc loss and fuming of the base material. For the welding of low-zinc brass, ERCuSn-A is recommended; ERCuSi-A and ERCuAl-2 are recommended for high-zinc alloys.

The silicon found in ERCuSi-A helps to decrease the zinc fumes. For this reason and to provide reinforcement, ERCuSi-A is sometimes used, with alternating current, on copper-zinc alloys 1.3 mm (0.05 in.) or less. Thinner sections of high-zinc alloys are sometimes gas-tungsten arc welded using ERCuAl-A2. The addition of this filler metal produces sound welds but does not decrease zinc vaporization.

Thin brass sheets less than 1.6 mm (0.06 in.) thick can be welded without the addition of filler metal. Zinc fuming can be limited through the use of high electrode travel speed, which generates short weld pool arc times. Tube sheet joints can be made with brass members, using the same kind of joint preparation, if high electrode speed is maintained.

Gas-Metal Arc Welding

Unleaded brasses can be welded using GMAW. These brasses include both the low-zinc alloys (red brasses) and the high-zinc alloys (including yellow brasses, tin brasses, and special brasses). Copper-zinc alloys are not used as filler metals for GMAW due to the violent fuming and loss of zinc that accompanies arc welding of these zinc-bearing alloys.

Low-Zinc Brasses. Table 6 lists nominal conditions for butt welding of low-zinc brasses, using GMAW. These alloys include up to 20% Zn. Direct current electrode positive is always used.

Silicon bronze (ERCuSi-A) wire provides easy welding, since it has good fluidity at low welding currents. A 60° single-V-groove is used with this filler metal. When ERCuSn-A electrode wire is used, its sluggish flow characteristics make a 70° V-groove advisable for heavier sections, as shown in Table 6. ERCuSn-A is primarily used for a better color match on low-zinc copper alloys. The wider groove provided with the 70° V-groove joint allows more room for manipulation of the molten weld pool. Except for color, weld metal properties are comparable when using either of these two types of electrodes. A preheat in the range of 95 to 315 °C (200 to 600 °F) is sometimes required for low-zinc brasses due to their relatively high thermal conductivities.

High-Zinc Copper Alloys. Nonleaded copper alloys that have zinc contents from 20 to 40% or more can be gas-metal arc welded. However, the weldability is less than with nonleaded low-zinc brasses. The evolution of zinc fumes is more severe, and the welds experience greater porosity and lower strength than with low-zinc brasses. Both wrought and cast alloys can be joined by GMAW. Massive sections, such as for manganese bronze ship propellers, are regularly repair welded using this process.

The nominal conditions for gas-metal arc butt welding of high-zinc copper alloys (yellow brasses, tin brasses, special brasses, and nickel silvers) are given in Table 6. Welding parameters and variables are generally the same when using either ERCuAl-A2 or ERCuSn-A filler metals. The difference between the two filler metals is a higher weld-metal strength with ERCuAl-A2 and better color match with ERCuSn-A. Preheating is seldom necessary since these alloys have

relatively low thermal conductivities. However, preheating does help to limit zinc fuming in some applications, because it permits the use of lower welding amperages.

Shielded Metal Arc Welding

Brasses can be welded using SMAW. A variety of covered electrodes can be used, including phosphor bronze, silicon bronze, or aluminum bronze (ECuSi, ECuSn-A, ECuSn-C, ECuAl-A2, ECuAl-B). Relatively large welding grooves are required for good joint penetration and to avoid the entrapment of slag. Welding is typically done using a backing strip of copper or brass.

Phosphor bronze electrodes, such as ECu-Sn-A and ECuSn-C, have been used for SMAW of low-zinc brasses. Preheating of the base metal from 200 to 260 °C (400 to 500 °F) is required. Application of filler metal should be in narrow, shallow stringer beads.

The high-zinc copper alloys can be welded with aluminum bronze (ECuAl-A2) electrodes. Preheat and interpass temperatures are 260 to 370 °C (500 to 700 °F). The arc is held directly on the molten weld pool rather than toward the base metal, and it is advanced slowly to minimize zinc volatilization and fuming.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Phosphor Bronzes

The phosphor bronzes (C50100-C52400) contain additions of tin (up to 10%) and phosphorus (0.2%), which produce good resistance to flowing seawater and to most nonoxidizing acids (except hydrochloric acid). Phosphor bronzes are joined by GTAW, GMAW, and SMAW. Additional information on the properties and applications of phosphor bronzes can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Sheet and other wrought forms of phosphor bronze can be gas-tungsten arc welded up to approximately 13 mm (0.5 in.). The process can also be used to join or repair phosphor bronze castings. Copper-tin alloys solidify with large, weak, dendritic grain structures that are susceptible to cracking. Hot peening each layer of multi-pass welds reduces cracking and stresses and therefore the likelihood of weld metal cracking.

Nominal Conditions. The use of GTAW for joining nonleaded phosphor bronzes is described in Table 9. Square-groove butt joints are employed, and the current used is DCEN or a stabilized alternating current arc.

TABLE 9 NOMINAL CONDITIONS FOR GTAW OF SQUARE-GROOVE BUTT JOINTS IN PHOSPHOR BRONZES

WORKPIECE THICKNESS		ROOT OPENING		ELECTRODE (EWTH-2) DIAMETER		WELDING ROD DIAMETER[(A)]		SHIELDING GAS	GAS FLOW RATE		CURRENT (DCEN), A	TRAVEL SPEED		PREHEAT TEMPERATURE		NUMBER OF PASSES

3.2	1/8	1.6	1/16	3.2	1/8	3.2	1/8	ARGON	15	30	100-220	1.27	50	NONE USED		1

Notes: (1) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications. (2) Higher welding current or lower welding travel speed is used in welding alloy C50500.

(A) ERCUSN-A, OR ROD OF COMPOSITION CLOSE TO THAT OF THE BASE METAL

The nominal conditions shown in Table 9 are based primarily on the three phosphor bronzes given in Table 1, which have low thermal conductivities. These include alloys C51000, C52100, and C52400. When welding alloy C50500, higher welding currents or slower welding travel speeds are required. This alloy, commonly known as phosphor bronze-1.25% E, contains approximately 98.7% Cu and has 3 to 4 times the thermal conductivity of the other alloys in this grouping.

Shielding Gas. The use of argon as a shielding gas is most common, since argon restricts the size of the HAZ. This minimizes the area where mechanical properties are decreased. When necessary for thicker sections, helium shielding gas can be used, along with an argon backup gas shield.

Filler metal may be added to the weld joint using either ERCuSn-A or wire of approximately the same composition as the base metal. When matching the composition of the base metal is not essential, ERCuSi-A filler metal can be used instead, producing stronger welds. When welding section thicknesses less than 3 mm (0.13 in.), phosphor bronze strip can be butt welded using autogenous GTAW.

Preheating is not normally required for GTAW of thin sections of phosphor bronzes. Thick sections usually require preheating to 175 or 200 °C (350 or 400 °F) and are slowly cooled after welding. Due to the hot-short nature of phosphor bronze, weld layers should be thin, and interpass temperature should not exceed 200 °C (400 °F). Hot peening is often used to refine grain size and minimize distortion.

Gas-Metal Arc Welding

Table 6 gives the nominal conditions for GMAW of butt joints using phosphor bronze. Lead-bearing or other free-machining types are not welded. Table 10 gives GMAW conditions that can be used as starting points for establishing welding conditions for joining phosphor bronzes. As with GTAW, the welding conditions are based on three poorly conductive phosphor bronze alloys (C51000, C52100, and C52400). When welding the more conductive alloy C50500, higher welding currents or slower welding speeds are needed. For joining thicknesses of 9.5 to 13 mm (0.4 to 0.5 in.), 90° single-V grooves are used rather than the narrow grooves used for most other poorly conductive alloys.

TABLE 10 SUGGESTED CONDITIONS FOR GMAW OF PHOSPHOR BRONZES

(A) ERCUSN-A PHOSPHOR BRONZE ELECTRODES AND ARGON SHIELDING GAS

Filler Metals. For joining phosphor bronzes, ERCuSn-A electrode wire is generally used. The filler metal wire that contains about 0.5% Si is sometimes used to minimize porosity in the weld.

Preheating. As with other copper alloys, preheating of the phosphor bronzes helps in obtaining complete fusion. Also, porosity is minimized because the freezing rate of the weld pool is decreased, and more gas is permitted to evolve before solidification. However, preheating increases the susceptibility of the weld to the formation of large columnar grains and the risk of hot cracking. This susceptibility requires that welding be performed with a stringer bead technique and that

each weld layer be peened. A small weld pool and rapid electrode travel speed are required. Interpass temperatures while welding should not exceed the preheat temperatures because of the hot shortness of the phosphor bronze alloys.

Shielded Metal Arc Welding

Shielded metal arc welding is done on a limited basis for phosphor bronzes. The covered electrodes typically used are ECuSn-A and ECu-Sn-C. These electrodes may be used interchangeably and are designed for use with DCEP.

Preheating is required in the range of 150 to 200 °C (300 to 400 °F), since the phosphor bronzes are very sluggish. However, because of the hot shortness of these alloys, the interpass temperature must not exceed the preheat temperature. This is extremely important in thicker sections. Stringer beads with rapid travel speed are normally used. In groove welding, the first two passes are made with a weaving technique. The width of the weave should not exceed two electrode diameters. The remaining passes are made without appreciable traverse weaving and with the use of narrow stringer beads. The development of the coarse, dendritic structure with low strength and ductility is minimized by the control of preheat and interpass temperatures. Hot peening is often used after welding to reduce grain size. For the maximum ductility, the welded assembly should be postweld heat treated to 480 °C (900 °F) and cooled rapidly. Groove joints should be wide, with an included angle of 80 to 90° to achieve proper washing and tie-in at the walls of the groove.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Aluminum Bronzes

As shown in Table 1, aluminum bronzes (C60600-C64400) are complex alloys based on the Cu-Al-Ni-Fe-Si-Sn system. They are welded using GTAW, GMAW, or SMAW. Some aluminum bronzes are also used as hardfacing alloys (see the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume). Additional information on the properties and applications of aluminum bronzes can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Gas-tungsten arc welding is readily used for joining aluminum bronzes up to 9.5 mm (0.4 in.). Aluminum bronze castings are also repair welded by GTAW. Conditions differ somewhat from those of most other copper alloys. Porosity is minimized in the weld metal by the presence of iron, manganese, or nickel in the filler metal or base metal.

Nominal Conditions. Table 11 lists the nominal conditions for welding of aluminum bronze alloys. Conditions must be selected to avoid difficulties that result from the tenacious refractory aluminum oxide films that form almost instantaneously during any heating process such as welding unless oxygen is completely excluded from the metal. Heat input requirements are not high, since aluminum bronzes have a thermal conductivity near that of carbon steel.

TABLE 11 NOMINAL CONDITIONS FOR GTAW OF ALUMINUM BRONZES

Note: The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications.

(A) PREHEATING IS NOT ORDINARILY USED IN WELDING THE THICKNESSES SHOWN.

(B) ZIRCONIATED OR UNALLOYED ELECTRODES ARE RECOMMENDED WITH HIGH-FREQUENCY-STABILIZED ALTERNATING CURRENT.

(C) PREFERRED WELDING ROD IS ERCUAL-A2; OTHERWISE ERCUAL-A3 OR ROD OF THE SAME COMPOSITION AS THE BASE METAL.

(D) DIRECT CURRENT ELECTRODE NEGATIVE CAN ALSO BE USED IN MAKING SINGLE-PASS WELDS (SEE TEXT).

(E) USE OF WELDING ROD IS OPTIONAL FOR THICKNESSES UP TO 1.6 MM ($\frac{1}{16}$ IN.).

(F) ZERO ROOT OPENING FOR T-JOINTS; 9.5 MM ($\frac{3}{8}$ IN.) MAX FOR CORNER JOINTS

Shielding Gas. Argon is typically used with alternating current as a shielding gas for the welding of aluminum bronzes. For better penetration or faster travel speed, direct current can be used with argon, helium, or a mixture of these two gases. While the shielding gas protects the weld pool and adjacent base metal, the use of a special flux augments the shielding effect of the gas. The flux is applied to the edge of the weld joints to increase fluidity and help protect the base metal from oxide formation. Aluminum oxide forms even at room temperature, and the flux prevents air from reaching the prepared edges until the protective argon shielding gas can become effective in the localized area.

Type of Current. As stated above, alternating current is used for GTAW of aluminum bronzes. The alternating current is stabilized by continuous high frequency and is preferred to DCEN, since it prevents oxide formation on the surface of the weld pool. High-frequency-stabilized alternating current is particularly desirable when multi-pass welding of these alloys is performed. Direct current electrode negative can be used in a single-pass welding, particularly for automatic welding. Surfaces must be well cleaned and protected, and the arc must be closely controlled.

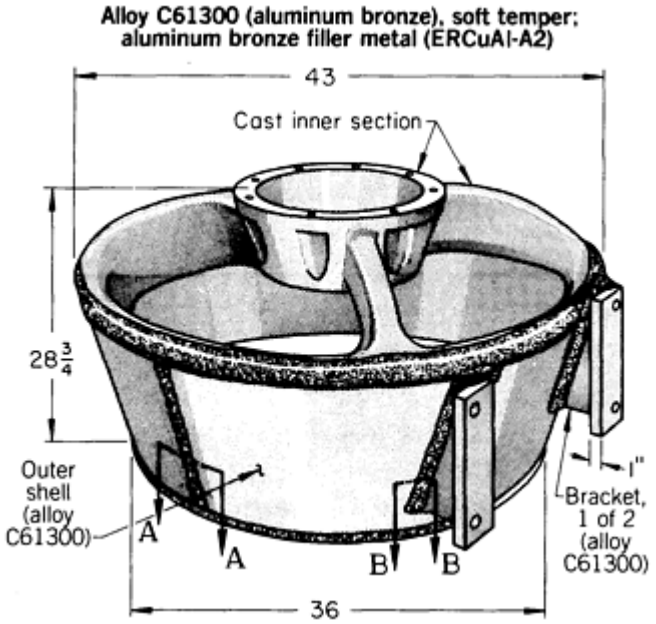
Electrodes. Gas-tungsten arc welding of aluminum bronzes typically uses zirconiated tungsten (EWZr) or unalloyed tungsten (EWP) electrodes. Thoriated tungsten electrodes are used with direct current; however, these electrodes cause the arc to wander when they are used with alternating current. The thoriated tungsten gives a longer tip life and is easier to start. Electrode preparation for use with direct current is a tapered cone-shaped tip. For alternating current, the end of the electrode is typically balled via an arc melting process.

Filler Metals. ERCuAl-A2 is ordinarily used for joining aluminum bronzes. ERCuAl-A3 or other aluminum bronze wire of matching chemical composition can be used when the composition and color of the weld metal must closely match that of the base metal.

Preheating of aluminum bronzes for GTAW of sections thinner than approximately 6 mm (0.25 in.) is not necessary. Aluminum bronzes have a low thermal conductivity but may require preheating for section thicknesses greater then 6 mm (0.25 in.). When preheating is required, the preheat and interpass temperature should not exceed 150 °C (300 °F) for alloys with less than 10% Al. In the following example, preheating was used for joining of a 9.5 mm (0.4 in.) thick aluminum bronze.

Example 6: Use of GTAW versus GMAW to Avoid Melt-Through of Neighboring Sections.

The propeller housing for the Kort nozzle shown in Fig. 3 was originally made as a one-piece sand casting from aluminum bronze alloy 9B (ASTM B148), which contains 10% Al and 1% Fe. Difficulties were experienced in the coring necessary to produce the thin outer shell. This led to the production of this outer shell as a separate piece that was welded to the casting to make a two-piece structure.



Circumferential welds joining outer shell to cast inner section were made by gas metal arc welding

FIG. 3 CONDITIONS FOR GTAW OF A PROPELLER HOUSING. THE WELDMENT REPLACED A SINGLE-PIECE CASTING, THEREBY REDUCING COST AND IMPROVING SERVICEABILITY.

The inner section was cast in propeller bronze as one intricate piece that included a central hub and shaft-mounting flange connected to the main body of the nozzle by four arms. The outer shell was cut from 9.5 mm (0.4 in.) thick alloy C61300 (aluminum bronze) with soft temper and was wrapped around the cast intersection after being cold formed into a truncated cone. Before cold forming, all edges of the shell were machined to a 35° bevel to provide a groove for subsequent welding.

The assembly was tack welded together, and then circumferential seams at the top and bottom were gas-metal arc welded. Next, to avoid melt-through of the cast intersection (and resultant poor effect on the propeller stream), GTAW was used for the longitudinal seam in the shell and for joining two brackets to the shell. The brackets were used for mounting the shell to the hull of the vessel. Figure 3 illustrates the weldment as constructed.

Not only was the cost of production reduced by eliminating the complex and expensive coring in the casting, but the weight of the welded housing was less than that of the completed cast housing. Furthermore, the cast housing had been made of an alloy that, although easy to cast, did not resist erosion, corrosion, or cavitation as well as did the alloys used in the welded assembly.

Gas-Metal Arc Welding

Gas-metal arc welding with aluminum bronze electrode wire is the preferred technique for welding aluminum bronzes. Because of the comparatively high surface tension of the molten weld pool and the relatively low thermal conductivity of the base metal, welding can be performed in all positions. Welding in the vertical and overhead positions is usually performed with either the globular or short-circuiting mode of metal transfer, using filler metal up to 1.6 mm ($\frac{1}{16}$ in.) in diameter.

Nominal Conditions. The nominal conditions for gas-metal arc butt welding of aluminum bronze are given in Table 6. Backing strips or rings of aluminum bronze are used when welding material up to 3 mm (0.13 in.) thick. These conditions make it necessary to use helium or argon-helium mixes for shielding gas instead of the argon shown in Table 6. These hotter shielding gases provide adequate heat input.

Filler Metals. ERCuAl-A2 ordinarily is used in the GMAW of aluminum bronze. The 1.5% Fe present in this wire reduces the hot-short cracking susceptibility of the weld metal. The use of ERCuAl-A3 also produces welds that are free from hot shortness. Joints made with ERCuAl-A3 are also stronger and harder, but lower in ductility.

Joint Design. The joining of aluminum bronzes thicker than 13 mm (0.5 in.) requires wider root openings and groove angles than those indicated in Table 6. This is necessary to avoid incomplete fusion and to improve the penetration resulting from the use of a thicker section, which increases the weld heat-sink characteristics.

Preheating. For most thin sections of aluminum bronzes, preheating is not required prior to welding. If preheat is used, the preheat and interpass temperatures should not exceed 150 °C (300 °F) for alloys that contain less than 10% Al. When aluminum content exceeds 10%, preheat temperatures should be elevated to 260 °C (500 °F). Again, interpass temperatures should not exceed preheat temperatures, due to the hot shortness of these alloys.

Shielded Metal Arc Welding

Aluminum bronzes are readily welded using SMAW for both the wrought and cast forms. The fluxing action of the electrode coating removes the aluminum oxides that form on the surface of the alloys.

Except for thin sections, a 70 to 90° V-groove joint is used. Typically, a backing strip of the same composition as the base metal is also utilized. Deposition technique and bead thickness are not critical, because the weld metal has excellent hot strength and ductility.

Electrodes. Aluminum bronze electrodes ECuAl-A2 and ECuAl-B are used for SMAW of aluminum bronze alloys C61300 and C61400. Preheating of thick sections of these alloys may be needed and is usually in the range of 200 °C (400 °F) with a controlled interpass temperature not exceeding 200 °C (400 °F). Depending upon section thickness and overall mass, preheat and interpass temperatures may vary from 65 to 425 °C (150 to 800 °F). Weldments made of aluminum bronze alloys containing 7% Al need not be heat treated after welding. Aluminum bronzes having an aluminum content greater than 7% are usually welded with electrodes that contain more aluminum than do ECuAl-A2 and ECuAl-B. These higher-aluminum bronze electrodes, ECuAl-C, ECuAl-D, and ECuAl-E, are best known as surfacing electrodes and have nominal aluminum contents of 12.5, 13.5, and 14.5%, respectively. These electrodes are described in AWS A5.13 and have strength corresponding to the aluminum content. In welding high-aluminum bronzes, thick sections may require preheating up to 620 °C (1150 °F), and fan cooling may be necessary to avoid cracking. These alloys may also require annealing at 620 °C (1150 °F), followed by fan cooling for stress relief.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Silicon Bronzes

Silicon bronzes (C64700-C66100), which are based on the Cu-Si-Sn system, are the most weldable of the copper alloys. Silicon bronzes can be welded by most arc welding processes, the most commonly utilized being GTAW, GMAW, and SMAW. Additional information on the properties and applications of silicon bronzes can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Silicon bronze alloys that do not contain lead can be gas-tungsten arc welded in thin and moderately thick sections. These alloys are typically the most weldable of all copper alloys. Inherent characteristics of these bronzes that contribute to their weldability include low thermal conductivity, good deoxidation of the weld metal by silicon, and protection offered by the resulting slag. Silicon bronzes have a relatively narrow hot-short range just below the solidus, and they must be rapidly cooled through this range to avoid weld cracking.

Nominal Conditions. Table 12 lists the nominal welding conditions for GTAW of silicon bronzes. The data for manual welding include welding conditions for various positions. Because of their low fluidity, silicon bronzes are the only group of copper alloys where GTAW is applied extensively in the vertical and overhead positions. Direct current electrode negative with argon or helium shielding can be used for section thicknesses less than 1.6 mm (0.06 in.). Zirconiated (EWZr) or pure tungsten (EWP) electrodes are recommended.

Note: The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications.

(A) THICKNESSES GREATER THAN ABOUT 12.7 MM (1/2 IN.) ARE GAS-TUNGSTEN ARC WELDED ONLY WHEN IT IS NOT PRACTICAL TO USE GMAW.

(B) WIRE FEED RATE OF 2.9-3.2 M/MIN (115-125 IN./MIN).

(C) ROOT FACE IS 1.6 MM ($\frac{1}{16}$ IN.) FOR THICKNESSES OF 12.6 MM ($\frac{1}{2}$ IN.) OR LESS, AND 3.2 MM ($\frac{1}{8}$ IN.) FOR THICKNESSES GREATER THAN 12.7 MM ($\frac{1}{2}$ IN.)

(D) MAXIMUM ROOT OPENING IS EQUAL TO BASE METAL THICKNESS, *T*.

Filler Metals. The conventional silicon bronze filler metal, ERCuSi-A, which is similar in composition to alloy C65500 (high-silicon bronze A), can be used to weld any of the silicon bronzes. Alloy C65500 is the most commonly used of all the silicon bronzes. Thin sections of this alloy are readily welded using GTAW without the addition of filler metal.

Joint Design. On metal thicknesses greater than 6 mm (0.25 in.) a V-groove with a 60° included angle is used. Butt joints in thin sections can be welded without special preparation.

Preheating. Silicon bronzes have the lowest thermal conductivity of all copper alloys. The thermal conductivity of these alloys is less than that of carbon steels. Further, these alloys exhibit hot shortness. Based on this, preheating can be harmful to the welding of these alloys, and interpass temperature on multi-pass welds should not exceed 95 °C (200 °F).

Gas-Metal Arc Welding

The nonleaded silicon bronzes are readily welded using GMAW. Nominal conditions for GMAW of silicon bronzes in various thicknesses and joint designs are given in Table 6. This process is used for section thicknesses greater than 6 mm (0.25 in.). Rapid travel speeds (minimum of 3.5 mm/s, or 8 in./min) should be used to avoid excessive heat buildup. As shown in Table 6, the welding current used for these alloys is slightly lower than that used for other copper alloys. Because of the low thermal conductivity of silicon bronzes (Table 1), the resulting low heat input to the weld is adequate for complete fusion and good penetration. Argon shielding gas is preferred. A thin layer of oxide forms on the weld metal after each pass and must be removed by wire brushing prior to the next weld pass.

All silicon bronze alloys can be gas-metal arc welded using ERCuSi-A filler metal. The chemical composition of this wire is similar to that of alloy C65500 (high-silicon bronze A), which is the most frequently used silicon bronze. These wires may include up to 1.5% Sn instead of, or in addition to, the 1.5% Mn specified as a maximum for alloy C65500.

Joint Preparation. Metal thicknesses of 6 to 19 mm (0.25 to 0.75 in.) should utilize a single 60° V-groove. For silicon bronze alloys of section thicknesses greater than 19 mm (0.75 in.), U-grooves or 60° double-V-groove joints can be used.

Preheating. As with GTAW of silicon bronze alloys, preheating is not required and should not be used with GMAW of silicon bronze. Interpass temperatures must be held below 95 °C (200 °F) to prevent weld cracking. Stress relieving of silicon bronze weldment is recommended to prevent stress-corrosion cracking failures.

Shielded Metal Arc Welding

Shielded metal arc welding of silicon bronze alloys is usually done using ECuAl-A2 aluminum bronze electrodes. Welding temperatures are easily attained, due to the low thermal conductivity of silicon bronzes. As with other arc welding processes, preheat and interpass temperatures should not exceed 95 °C (200 °F) to prevent hot-short cracking.

Groove dimensions are similar to those used for steel joints. Metal thicknesses up to 4 mm (0.16 in.) can be welded with square grooves. Thicker sections can be welded with a single-V-or double-V-groove of 60° included angle.

Weld properties in silicon bronzes joined using SMAW are usually substantially lower than those of welds made by the gas-shielded processes. Based on this, these welds may not meet code or design requirements for strength. Peening of welds reduces residual stress and minimizes weld distortion.

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Copper-Nickel Alloys

Copper-nickel alloys (C70000-C79900) are the most corrosion-resistant copper-base alloys. Alloy C71500 (Cu-30Ni) has the best general resistance to aqueous corrosion, but alloy C70600 (Cu-10Ni) is often selected because it offers good resistance at lower cost. Copper-nickel alloys are readily welded by GTAW, GMAW, and SMAW. Additional information on the properties and applications of copper-nickel alloys can be found in Volume 2 of the *ASM Handbook.*

Gas-Tungsten Arc Welding

Gas-tungsten arc welding is the preferred process for joining copper-nickel alloys with section thicknesses up to 1.6 mm (0.06 in.). This process may also be used for thicker sections. Automatic welding produces satisfactory results in thin sections of tube sheets. Manual welding is normally used for sheet and plate thicknesses up to 6 mm (0.25 in.).

Nominal Conditions. Conditions by which copper-nickel alloys can be manually and automatically welded using GTAW are given in Table 13. These include butt joints with square- and single-V-groove preparation.

TABLE 13 NOMINAL CONDITIONS FOR GAS-TUNGSTEN ARC BUTT WELDING OF COPPER-NICKEL ALLOYS

WORKPIECE THICKNESS		BUTT-JOINT GROOVE	ELECTRODE DIAMETER(A)		ERCUNI WELDING ROD DIAMETER(B)		FLOW RATE OF ARGON		CURRENT (DCEN), A	TRAVEL SPEED		NUMBER OF PASSES

9.5	3/8	70-80° SINGLE-V	4.8	3/16	4.0	5/32	15	30	270-290(C)	0.15	6	4

Notes: (1) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking. They are subject to adjustments necessary to meet the special requirements of individual applications. (2) Root opening is zero. Preheating is not needed.

(A) PREFERRED ELECTRODE MATERIAL IS EWTH-2.

(B) FILLER METAL (ERCUNI) MUST BE USED ON ALL WELDED JOINTS (SEE TEXT).

(C) CURRENT SHOULD BE INCREASED IN EQUAL INCREMENTS WITH EACH PASS, UP TO A MAXIMUM OF ABOUT 375 A, WITH LARGER WELDING RODS.

Preferred conditions include the use of argon shielding gas, DCEN, and thoriated tungsten electrodes. However, these variables are not critical for copper-nickel, since these alloys have low heat conductivities. Helium may be substituted for argon as a shielding gas, but argon provides better arc control and stability. Alternating current can be employed for automatic welding if there is adequate control of arc length.

During GTAW of alloy C70600, slightly higher welding currents or slower travel speeds should be used, due to the higher thermal conductivity of this alloy. Preheating is not necessary, and backing strips or rings can be used. Backing strips or rings should be made of copper or copper-nickel alloy, not carbon, graphite, or steel.

Filler Metals. ERCuNi is used as a filler metal in GTAW of copper-nickel alloys. This filler metal contains 0.20 to 0.50% Ti to minimize porosity and the possibility of oxygen embrittlement in either the weld metal or the HAZ. Because the standard copper-nickel alloys do not contain titanium or a comparable deoxidizer, filler metal should be used even in welding thin sheets of copper-nickel. This will avoid the formation of porosity. However, special compositions of alloys C70600 and C71500 are available that do contain titanium. Thin sheets of these special alloys can be welded without the use of a filler metal. In multi-pass welding of copper-nickel alloys, the filler metal diameter and welding current may be increased with successive passes to provide efficient deposition. Autogenous welds can sometimes be made on sheet thicknesses up to 1.6 mm (0.06 in.), but porosity may be a problem due to the absence of deoxidizers in the base metal.

Gas-Metal Arc Welding

Gas-metal arc welding is the preferred welding process for non-leaded copper-nickel alloys thicker than approximately 1.6 mm (0.06 in.). Table 14 lists welding conditions for GMAW of copper-nickel alloy plate. The preferred welding position is the flat position. Argon is the preferred shielding gas; however, argon-helium mixes give better penetration on thick sections. Direct current electrode positive is recommended.

TABLE 14 SUGGESTED CONDITIONS FOR GMAW OF COPPER-NICKEL ALLOY PLATE

WORKPIECE THICKNESS		ELECTRODE FEED[A]		ARC VOLTAGE, V	WELDING CURRENT (DCEP), A[A]
mm	in.	m/min	in./min		
6.4	$\frac{1}{4}$	4.5-5.6	180-220	25-26	130-140

(A) ERCUNI ELECTRODE, 1.6 MM ($\frac{1}{16}$ IN.), ARGON SHIELDING GAS

Nominal conditions for gas-metal arc butt welding of non-leaded copper-nickel alloys for various joint designs and thicknesses are given in Table 6. These alloys can be satisfactorily welded using either spray or short-circuiting transfer. Spray transfer is normally used for sections greater than 6 mm (0.25 in.). Pulsed spray transfer or short-circuiting transfer can be used to weld thin sections. These transfer methods provide better control of the molten weld pool when welding in the vertical and overhead positions. Selection of processing conditions is not critical in GMAW of these poorly heat-conductive alloys. Alloy C70600 is usually welded at a slightly higher current or slower travel speed than alloy C71500.

Filler Metals. ERCuNi electrode wire is the common choice for GMAW of copper-nickel alloys. This wire resembles alloy C71500 in composition, since it has a 70 to 30 copper-to-nickel ratio. ERCuNi contains 0.15 to 1.00% Ti, which serves as a deoxidizer to minimize porosity and prevent oxygen embrittlement. Titanium also improves the fluidity of the weld pool.

Joint Design. For GMAW of butt joints in non-leaded copper nickels 3 mm (0.13 in.) thick, the joint design usually includes a square-groove weld and grooved copper backing. This is indicated in Table 6. For thicknesses between 3 and 13 mm (0.13 and 0.5 in.), single-V-grooves of 60 to 80° and grooved copper backing are typically used. For section

thicknesses greater than 13 mm (0.5 in.), double-V-groove or double-U-groove joints are used. As with GTAW of copper-nickel alloys, backing material should be made of copper or copper-nickel rather than carbon, graphite, or steel.

Preheating and Postheating. The copper-nickel alloys have thermal conductivity equal to or lower than that of low-carbon steel. Therefore, no preheating or postheating is needed. However, interpass temperatures should be maintained below 65 °C (150 °F).

Shielded Metal Arc Welding

Both wrought and cast forms of copper-nickel alloys can be welded using SMAW. The weldability of these alloys is similar to that of low-carbon steels, because the thermal conductivity of these alloys is quite similar to that of steel. Copper-nickel electrode ECuNi is used in welding the copper-nickel alloys C70600 and C71500 with DCEP.

The weld deposits ordinarily have a high center crown, and the slag is viscous when molten and quite adherent when cold. Therefore, special care is needed to ensure complete slag removal before complete solidification of the weld metal, to prevent slag entrapment when cleaning between passes. Welding in both the vertical and overhead positions using SMAW provides good results in these alloys, although best results are obtained in the flat position. This process is preferred in some applications where access to the joint is limited, as in the butt welding of copper-nickel pipe.

Welding of Copper Alloys

Revised by M. Ned Rogers, Batesville Casket Company

Welding of Dissimilar Metals

Copper and many copper alloys can be welded to other (dissimilar) copper alloys, to carbon and alloy steels, to stainless steels, and to nickel and nickel alloys using GTAW and GMAW. Tables 15 and 16 provide guidelines for joining copper and copper alloys to dissimilar metals.

TABLE 15 ELECTRODES AND PREHEAT AND INTERPASS TEMPERATURES USED IN GTAW OF COPPER AND COPPER ALLOYS TO DISSIMILAR METALS

STAINLESS STEELS	ERCUAL-A2 OR ERCU OR ERCUNI-3 (540 °C, OR 1000 °F)	ERCUSN-A (200 °C, OR 400 °F)	ERCUAL-A2 (65 °C MAX, OR 150 °F MAX)	ERCUAL-A2 (65 °C MAX, OR 150 °F MAX)	ERCUAL-A2 OR ERCUNI-3 (65 °C MAX, OR 150 °F MAX)

Notes: (1) Filler metal selections shown are based on weldability except where mechanical properties are usually more important. (2) Preheating usually is used only when at least one member is thicker than 3.2 mm ($\frac{1}{8}$ in.) or is highly conductive (see text). Preheat and interpass temperatures are subject to adjustment based on size and shape of weldment.

(A) THESE COMBINATIONS ARE SELDOM WELDED; AS A STARTING POINT IN DEVELOPING WELDING PROCEDURES, USE OF ERCUAL-A2 FILLER METALS IS RECOMMENDED, EXCEPT FOR COMBINATIONS INCLUDING PHOSPHOR BRONZE.

Notes: (1) Electrode selections in table are based on weldability, except where mechanical properties are usually more important. (2) Preheating usually is used only when at least one member is thicker than 3.2 mm ($\frac{1}{8}$ in.) or is highly conductive (see text). Preheat and interpass temperature are subject to adjustment based on size and shape of weldment.

(A) THESE COMBINATIONS ARE SELDOM WELDED; AS A STARTING POINT IN DEVELOPING WELDING PROCEDURES, USE OF ERCUAL-A2 ELECTRODES IS RECOMMENDED, EXCEPT FOR COMBINATIONS INCLUDING PHOSPHOR BRONZE.

Gas-Tungsten Arc Welding

Copper and many copper alloys can be gas-tungsten arc welded to other materials with good results. The use of a filler metal is typically required. Copper and its alloys have been readily gas-tungsten arc welded to steels, stainless steels, nickel, and nickel alloys. Gas-tungsten arc welding for the joining of these dissimilar metals is usually restricted to thin sections less than 3 mm (0.13 in.) thick. Preliminary surface welding, also known as buttering, is ordinarily not required for thin sections. For section thicknesses exceeding 3 mm (0.13 in.), the preferred joining process is GMAW or SMAW. Usually, when GTAW is used to join copper alloys to dissimilar metals, the arc is directed at the more conductive metal being welded. Table 15 shows combinations of dissimilar metals that are joined by GTAW with the aid of copper alloy or nickel alloy filler metals. The recommended filler metals, preheat temperature, and interpass temperature for each combination are given.

Except when one or both members of the joint being welded have high thermal conductivity, preheating is not required for GTAW of copper and dissimilar metals. This is restricted to section thicknesses of 3 mm (0.13 in.) or less.

Gas-Metal Arc Welding

The GMAW process can be used for joining nearly all combinations of the weldable copper alloys. Two major considerations when developing the GMAW procedures are: (1) the composition of the welding wire to be used as an

electrode; and (2) the preheat temperatures required. As with the other arc welding processes, the arc is typically directed at the more conductive material to concentrate the heat energy on this base metal.

The electrodes as well as preheat and interpass temperatures for GMAW of copper and copper alloys to dissimilar metals are given in Table 16. This table includes all alloys listed in Table 15 for GTAW, plus the high-zinc brasses, tin brasses, and special brasses. As is shown in Table 16, ERCu-A1-A2 comes close to being the universal electrode for GMAW of dissimilar copper alloys. However, this filler metal is incompatible with phosphor bronzes. Silicon bronze (ERCuSi-A) and phosphor bronze (ERCuSn-A) electrodes are useful for many combinations of copper alloys that do not contain nickel. Copper electrodes (ERCu) are suitable for final welding passes (cap or cover passes) of coppers to any of the commonly welded copper alloys. Underlying or preliminary weld deposits are typically made with alloy electrodes. For joining copper to copper-nickel alloys, ERCuNi (copper-nickel) electrodes are generally used.

Generally, for welding dissimilar copper alloys, the electrode selected should be suitable for welding one of the materials within the combination to itself. The primary exception to this general rule is in the welding of silicon bronzes to copper-nickel alloys. The only electrode that can be used successfully for the joining of this combination is ERCuAl-A2.

As has been stated in the sections of this article dealing with specific alloy groups, alloys which have susceptibility to hot cracking, oxide formation, or other deterrents to weld strength characteristics should be noted when welding a dissimilar-metal combination. Typically, the restrictions for preheat, interpass temperature, and surface cleansing that apply to the individual alloy also apply to that alloy when joining it to other copper alloys or other metal groups. Of particular importance is preheat and interpass temperature for alloys that exhibit hot shortness.

For GMAW of copper or copper alloys to ferrous or nickel alloys, the primary consideration is dilution. Strength is not a factor because it is quite easy to generate weld metal whose strength is equal to that of the two base materials. The difficulty is in retaining the ductility demanded by the in-service requirements of the weldment. The most serious effect of excessive dilution is the formation of shrinkage cracks. These can start in the weld metal itself and propagate into the base metal.

Two methods are frequently used to control dilution in GMAW of combinations involving copper alloys. The first is to braze one side of the joint, thus promoting a minimum amount of dilution on that side, and weld the other side of the joint. The second technique is to overlay one or both joint surfaces with a buffer material. This technique, known as buttering, is typically used on thicker sections. Filler-metal selection again should be based upon the composition of the base alloy and the requirements for weld-metal strength and ductility. Additional information on buttering can be found in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume.

Welding of Copper Alloys

Safe Welding Practices

Many of the elements used in producing copper alloys, as well as copper itself, have low or very low permissible exposure limits, as set by the American Conference of Governmental Industrial Hygienists. These would include such elements as arsenic, beryllium, cadmium, chromium, lead, manganese, and nickel. When welding, brazing, or soldering copper or copper alloys, adequate ventilation is required to ensure that contaminant levels do not exceed the human exposure limits. Precautions may include local exhaust ventilation, general area exhaust ventilation, operator respiratory protection, or a combination of these. The reader is referred to ANSI/AWS Z49.1, "Safety in Welding and Cutting," for detailed information.

Copper alloys that contain appreciable amounts of beryllium, cadmium, or chromium may present health hazards to the welder and others. Exposure to welding fumes containing these elements can produce adverse health defects. The user should consult the Occupational Safety and Health Administration guidelines for the specific element.

Fumes and dust of copper and zinc can cause irritation of the upper respiratory tract, nausea, metal-fume fever, skin irritation, dermatitis, and eye problems. It should be noted that cadmium and beryllium fumes are toxic when inhaled.

Fluxes used during welding, brazing, and soldering of certain copper alloys may contain fluorides and chlorides. Again, these fumes can be irritating to the eyes, nose, throat, and skin. Additionally, some fluorine compounds are toxic.

Proper personal hygiene must be emphasized, particularly before eating. Food and beverages should not be stored or consumed in and/or around the work area. Contaminated clothing should be changed. For more detailed information on safety considerations, see the article "Safe Practices" in this Volume.

Introduction

MOST MAGNESIUM ALLOYS can be joined by gas-tungsten arc welding (GTAW) and gas-metal arc welding (GMAW). Relative weldability ratings, joint design and surface preparation, and the use of filler metals and shielding gases suitable to arc welding are discussed in this article. For more information on arc welding, see the Section "Fusion Welding Processes" in this Volume.

Weldability

Table 1 lists some magnesium alloys that are weldable, along with their respective weldability ratings based on a scale of A (excellent) to D (limited). This rating is based largely on freedom from susceptibility to cracking, and to some extent on joint efficiency. Under optimum welding conditions, including favorable joint design, joint efficiencies of 60 to 100% can be obtained for virtually all of the magnesium alloys. Alloys rated A in Table 1 are likely to have high joint efficiency ratings.

In the magnesium-aluminum-zinc alloys (AZ31B, AZ61A, AZ63A, AZ80A, AZ81A, AZ91C, and AZ92A), aluminum content up to about 10% (Table 2) aids weldability by helping to refine the grain structure, while zinc content of more than 1% increases hot shortness, which may cause weld cracking. Alloys with high zinc content (ZH62A, ZK51A, ZK60A, and ZK61A) are highly susceptible to cracking and have poorer weldability. Thorium-containing alloys (HK31A, HM21A, and HM31A) have excellent arc weldability and are rated B + or A in Table 1.

(A) RARE EARTH ELEMENTS ARE IN THE FORM OF DIDYMIUM.

(B) DIDYMIUM, NOT LESS THAN 70% NEODYMIUM ANY REMAINDER SUBSTANTIALLY PRAESODYMIUM.

(C) THORIUM AND DIDYMIUM TOTAL 1.5 TO 2.4.

(D) ZIRCONIUM SOLUBLE 0.40 MIN, BUT DETERMINATION NOT REQUIRED FOR ROUTINE ACCEPTANCE.

Welds in magnesium alloys are characterized by a fine grain size averaging less than 0.25 mm (0.01 in.). Magnesium alloys containing more than 1.5% Al are susceptible to stress corrosion, and residual welding stresses must be relieved.

Welding of Magnesium Alloys

Filler Metals

Compositions of the four most commonly used electrode wires for GMAW and filler metals (when used) for GTAW are given in Table 3. The choice of electrode wire or filler metal is governed by the composition of the base metal (Table 4).

(A) WELDING NOT RECOMMENDED.

(B) WELDING DATA NOT AVAILABLE

Electrode wires or filler metals having compositions conforming to ER AZ61A or ER AZ92A (Mg-Al-Zn) are considered satisfactory for welding alloys AZ10A, AZ31B, AZ31C, AZCOML, AZ61A, AZ80A, ZE10A, and ZK21A to themselves or to each other. ER AZ61A is usually preferred for welding aluminum-containing wrought products because of its tendency to resist crack sensitivity. The ER AZ92A filler metal shows less crack sensitivity for welding the cast magnesium-aluminum-zinc and magnesium-aluminum alloys. The same electrode wires or filler metals are used for joining any one of the above alloys to high-temperature alloys HK31A, HM21A, and HM31A. However, when the high-temperature alloys are joined to each other, ER EZ33A is recommended. Joints of wrought or cast alloys welded with ER EZ33A filler metal exhibit good mechanical properties at high temperatures.

The choice of electrode wire or filler metal for welding wrought alloys to cast alloys should be based on the recommendations outlined above, except that ER AZ101A may be used instead of ER AZ61A or ER AZ92A.

When aluminum-containing cast alloys are joined to aluminum-containing cast alloys, ER AZ101A or ER AZ92A electrode wire or filler metal is usually recommended. However, for joining HK31A and HZ32A to themselves or to each other, ER EZ33A is preferred; for joining HK31A and HZ32A to any of the other cast alloys, ER AZ101A is used. Filler rod of the same composition as the base metal should be used for most welds.

Shielding Gases

Only the inert gases are used for shielding in arc welding of magnesium alloys. Argon is the most widely used. Helium and various mixtures of argon and helium have also proved satisfactory, but because of the higher cost per unit volume of helium, and because two to three times more helium than argon is required for the same degree of shielding, the use of pure helium has gradually decreased. Pure helium is also undesirable because it raises the current required for spray arc transfer and increases weld spatter. The factors determining shielding-gas selection for magnesium alloys are similar to those for aluminum.

Joint Design

Typical joint designs for gas shielded arc welding of various thicknesses of magnesium alloy sheet and plate are presented in Table 5. The metal thickness ranges vary for GTAW in accordance with the type of current used (alternating current; direct current electrode negative, DCEN; and direct current electrode positive, DCEP) and vary for GMAW in accordance with the mode of metal transfer.

TABLE 5 TYPICAL JOINT DESIGNS USED FOR GAS SHIELDED ARC WELDING OF SELECTED THICKNESSES OF MAGNESIUM ALLOY SHEET AND PLATE

(A) SUGGESTED MINIMUM AND MAXIMUM THICKNESS LIMITS.

(B) USING 300 A AC OR DCEN, OR 125 A DCEP.

(C) USING 400 A DCEP.

(D) SINGLE-PASS FULL-PENETRATION WELD. SUITABLE FOR THIN MATERIAL.

(E) FULL-PENETRATION WELD. SUITABLE FOR THICK MATERIAL. ON MATERIAL THICKER THAN SUGGESTED MAXIMUM, USE DOUBLE-V-GROOVE BUTT JOINT TO MINIMIZE DISTORTION.

(F) NOT RECOMMENDED BECAUSE SPRAY ARC WELDING IS MORE PRACTICAL OR ECONOMICAL, OR BOTH.

(G) FULL-PENETRATION WELD. USED ON THICK MATERIAL. MINIMIZES DISTORTION BY EQUALIZING SHRINKAGE STRESS ON BOTH SIDES OF JOINT.

(H) NO MAXIMUM. THICKEST MATERIAL IN COMMERCIAL USE COULD BE WELDED IN THIS TYPE OF JOINT.

(I) SINGLE-PASS FULL-PENETRATION ESPECIALLY IF A SQUARE CORNER IS REQUIRED.

(J) SINGLE-PASS OR MULTIPLE-PASS FULL-PENETRATION WELD. USED ON THICK MATERIAL TO MINIMIZE WELDING. PRODUCES SQUARE JOINT CORNERS.

(K) SINGLE WELD T-JOINT. THICKNESS LIMITS ARE BASED ON 40% JOINT PENETRATION.

(L) DOUBLE WELD T-JOINT. SUGGESTED THICKNESS LIMITS BASED ON 100% JOINT PENETRATION.

(M) DOUBLE WELD T-JOINT. USED ON THICK MATERIAL REQUIRING 100% JOINT PENETRATION.

(N) SINGLE OR DOUBLE WELD JOINT. STRENGTH DEPENDS ON SIZE OF FILLET. MAXIMUM STRENGTH IN TENSION ON DOUBLE WELD JOINTS IS OBTAINED WHEN LAP EQUALS FIVE TIMES THE THICKNESS OF THE THINNER MEMBER.

Edges are prepared by milling, sawing, shearing, arc cutting, chipping, planing, routing, sanding, or filing. Sheet up to about 2.03 mm (0.080 in.) thick is generally single sheared; double shearing is preferred for sheet thicker than 2.03 mm (0.080 in.). Double-bevel edges are preferred over single-bevel edges because less distortion occurs during welding.

Fit-Up. Components of weldments should fit closely at abutting edges, preferably with no root opening, although a root opening up to 1.6 mm ($\frac{1}{16}$ in.) is usually permissible. If tack welds are used, the first tack should be a short distance from the end of a seam. The best practice in tack welding is to use 3.2 mm ($\frac{1}{8}$ in.) tacks spaced 25 to 50 mm (1 to 2 in.) on centers for sheet up to 1.65 mm (0.065 in.) thick, and 6.4 mm ($\frac{1}{4}$ in.) tacks spaced 100 to 125 mm (4 to 5 in.) on centers for sheet or plate from 1.65 to 6.4 mm (0.065 to $\frac{1}{4}$ in.) thick.

Welding fixtures must be rigid enough to resist movement of the workpieces during welding. Hold-down bars must exert enough pressure to keep the edges from overlapping or rising away from the backing bar or plate. A backing bar or strip normally is used when welding sheet metal components to help control joint penetration, root surface contour, and heat removal. The gas is usually supplied through holes in the backing strip. When a backing strip cannot be used because of space limitations, a chemical flux is sometimes painted on the root side of the joint to smooth the root surface and control joint penetration. Backing plates are made of mild steel, stainless steel, magnesium, aluminum, or copper and are cut with a small groove that is positioned directly under the seam. They prevent excessive metal drop-through and minimize distortion. Depth of the grooves in backing plates depends on base-metal thickness, the welding process used, and the absence or presence of a root opening in the joint. Typical groove depths are given in Table 6. When a temporary backing bar or strip is used, the root side of the joint should be shielded with inert gas to prevent oxidation of the root surface.

TABLE 6 TYPICAL DEPTH OF GROOVES IN BACKING BARS OR PLATES USED IN ARC WELDING OF MAGNESIUM ALLOYS

BASE-METAL THICKNESS		DEPTH OF GROOVE					
		GTAW		GMAW			
				NO ROOT OPENING(A)		ROOT OPENING

9.53	0.375	1.52	0.060	2.03	0.080	1.52	0.060

(A) WITH NO ROOT OPENING, GROOVES IN BACKING BARS OR PLATES ARE DEEPER TO PERMIT BETTER BALANCE BETWEEN TOP AND BOTTOM WELD REINFORCEMENT. USE OF A ROOT OPENING PERMITS BALANCING REINFORCEMENT WITH A SHALLOWER GROOVE DEPTH.

Surface Preparation

Magnesium alloys are usually supplied with either an oil coating, an acid pickled surface, or a chromate coated surface. Surfaces and edges must be cleaned just before welding to remove oxides and dirt picked up during forming, assembly,

and fixturing. Electrode wire or filler metal must be mechanically or chemically cleaned. A partly used spool of electrode wire or filler metal should be properly stored to protect it from dirt.

Mechanical cleaning with aluminum or stainless steel wool, aluminum oxide abrasive cloth, or power wire brushes with stainless steel bristles is preferred for most production jobs. In shops where chemical finishing equipment is available, a cleaning bath of 190 mL/L (24 oz/gal) chromic acid, 40 mL/L ($5\frac{1}{3}$ oz/gal) ferric nitrate, 0.5 mL/L ($\frac{1}{16}$ oz/gal) potassium fluoride, and water to make 3.8 L (1 gal) can be used. Parts are dipped in this bath, which is maintained at 20 to 30 °C (70 to 90 °F), for about 3 min, then are rinsed thoroughly in hot water and dried in air. Ceramic or stainless steel tanks are preferred; tanks lined with lead, synthetic rubber, or a vinyl-based material are also acceptable.

Welding of Magnesium Alloys

Preheating

The need for preheating castings is determined largely by section thickness and amount of restraint. Thick sections, particularly if the magnitude of joint restraint is small, seldom need preheating. Thin sections and highly restrained joints often require preheating to prevent weld cracking, particularly in the high-zinc alloys. Maximum preheat temperatures for all of the common cast magnesium alloys are given in Table 7. In practice, if preheating is used, the temperature is usually less than the maximum shown in Table 7.

TABLE 7 PREHEAT TEMPERATURES AND POSTWELD HEAT TREATMENTS FOR MAGNESIUM ALLOY CASTINGS

ALLOY	TEMPER OF ALLOY[A]		MAXIMUM PREHEAT TEMPERATURE[B]		POSTWELD HEAT TREATMENT[C]

(A) T4, SOLUTION HEAT TREATED; T6, SOLUTION HEAT TREATED AND ARTIFICIALLY AGED; T5, ARTIFICIALLY AGED; F, AS CAST. "AFTER TREATMENT" MEANS AFTER POSTWELD HEAT TREATMENT.

(B) HEAVY AND UNRESTRAINED SECTIONS USUALLY NEED NO PREHEAT; THIN AND RESTRAINED SECTIONS MAY NEED PREHEATING, UP TO MAXIMUM TEMPERATURES SHOWN, TO AVOID WELD CRACKING. A SULFUR DIOXIDE OR CARBON DIOXIDE ATMOSPHERE IS RECOMMENDED WHEN TEMPERATURE EXCEEDS 370 °C (700 °F).

(C) TEMPERATURES SHOWN ARE MAXIMUM ALLOWABLE. FURNACE CONTROLS SHOULD BE SET SO TEMPERATURE DOES NOT EXCEED INDICATED MAXIMUM. A SULFUR DIOXIDE OR CARBON DIOXIDE ATMOSPHERE IS RECOMMENDED WHEN TEMPERATURE EXCEEDS 370 °C (700 °F).

(D) FOR $1\frac{1}{2}$ H MAX.

(E) 16 H AT 170 °C (335 °F) MAY BE USED INSTEAD OF 4 H AT 215 °C (420 °F).

(F) QUENCH IN WATER AT 60 TO 105 °C (140 TO 220 °F) BEFORE SECOND HEAT TREATMENT.

(G) THIS PHASE OF HEAT TREATMENT IS OPTIONAL AND SERVES TO INDUCE GREATER STRESS RELIEF. SOME LOSS IN HIGH-TEMPERATURE CREEP STRENGTH MAY OCCUR IN EZ33A DUE TO THE 345 °C (650 °F) STRESS RELIEF.

(H) AIR COOL AFTER QUENCHING.

(I) AIR COOL AFTER SECOND HEAT TREATMENT

Welding of Magnesium Alloys

Gas-Metal Arc Welding

Power supplies used for welding magnesium alloys furnish DCEP. Constant-voltage machines must be used for short circuiting welding and are generally preferred for spray arc welding. Constant-current (drooping volt-ampere output)

machines can be used for spray arc welding and are sometimes advantageous for welding that is performed at a current level near the minimum for spray transfer because weld spatter is less. Special constant-voltage machines that are designed to pulse the current output must be used in pulsed arc welding. For detailed information on power supplies and modes of metal transfer, see the article "Power Sources" and "Transfer of Heat and Mass to the Base Metal in Gas-Metal Arc Welding" in this Volume.

Electrode holders, wire feeders, and related equipment used for GMAW of magnesium alloys are generally the same as those used for welding other metals.

Metal Transfer. Three modes of metal transfer are suitable for welding magnesium alloys: short circuiting, pulsed arc, and spray transfer. Pulsed arc transfer can be achieved only with a power supply designed to produce a pulsing secondary current. Without the pulsing feature, the type of transfer that would be obtained in the specific operating range of current, wire feed, and wire size for this process would be globular, which is not suitable for welding magnesium alloys.

Each of the three modes of transfer is best suited to a specific (sometimes overlapping) range of base-metal thickness and welding current, as shown in Table 8. Curves that show the relationship among current, electrode wire size, and wire-feed rate for each mode are presented in Fig. 1.

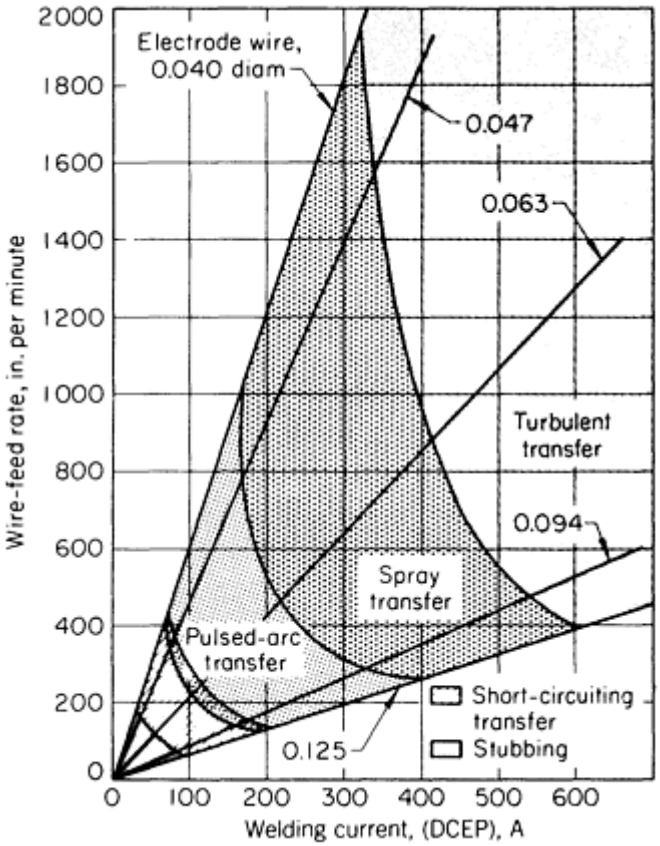

FIG. 1 PLOT OF WIRE-FEED RATE VERSUS WELDING CURRENT AS A FUNCTION OF ELECTRODE WIRE DIAMETER AND MODE OF METAL TRANSFER

Welding positions are restricted to flat, horizontal, and vertical-up by the high deposition rate and fluidity of the weld metal.

Typical operating conditions for gas metal arc butt welding of magnesium alloys in the thickness range from 0.64 to 25 mm (0.025 to 1 in.) are presented in Table 8. These operating conditions are intended as a guide and should be altered to the extent required by experience with specific applications.

Gas-Tungsten Arc Welding

Gas-tungsten arc welding is used more extensively than GMAW for joining magnesium alloys. It is well suited for welding thin sections. Control of heat input and the molten weld pool is better with GTAW than GMAW. Alternating current machines with a high-frequency current superimposed on the normal welding current for arc stabilization and direct current machines with continuous amperage control are used. For thin sheets, both alternating current and DCEP are used. On material over 4.8 mm ($\frac{3}{16}$ in.) thick, alternating current is preferred because it provides deeper penetration. Direct current electrode negative is seldom used on magnesium alloys because the arc lacks cathodic cleaning action. Alternating current machines should be equipped with a primary contactor, actuated by a switch on the torch or by a foot switch, for starting and stopping the arc. Otherwise, the arcing that occurs while the electrode approaches or draws away from the workpiece may result in burned spots on the work. Pure tungsten, zirconiated, and thoriated electrodes, from 0.25 to 6.35 mm (0.010 to 0.250 in.) in diameter, are used for GTAW of magnesium alloys. Additional information on power supplies, electrodes, and related items for GTAW is given in the article "Gas-Tungsten Arc Welding" in this Volume.

Manual Welding. Data on current settings, electrode diameter, shielding-gas flow, filler-metal diameter, and filler-metal consumption for manual GTAW of butt joints in magnesium alloys 1.0 to 12.7 mm (0.040 to 0.500 in.) thick are given in Table 9. For best results, the electrode should be held close to the work to produce an arc about 0.8 mm ($\frac{1}{32}$ in.) long. The preferred angles of torch, joint, and filler metal are given in Fig. 2. Welding should be done at a uniform speed in a straight line. A weaving or rotary motion should be used only for fillet welds or large corner joints. Forehand welding is preferred; a minimal number of stops produces the best results. If stops are required, the weld should be restarted on weld metal about 13 mm ($\frac{1}{2}$ in.) from the end of the previous weld.

TABLE 9 TYPICAL PARAMETERS FOR MANUAL GTAW OF BUTT JOINTS WITH MAGNESIUM ALLOYS

BASE-METAL THICKNESS		JOINT DESIGN(A)	NO. OF PASSES	ELECTRODE DIAMETER		AC CURRENT(B), A	ARGON FLOW RATE		FILLER METAL

(A) A, SQUARE GROOVE BUTT JOINT, ZERO ROOT OPENING; B, 60° BEVEL, SINGLE-V-GROOVE BUTT JOINT 1.6 MM ($\frac{1}{16}$ IN.) ROOT FACE, ZERO ROOT OPENING; C, 60° BEVEL, DOUBLE-V-GROOVE BUTT JOINT 4 MM ($\frac{3}{32}$ IN.) ROOT FACE, ZERO ROOT OPENING.

(B) THORIUM-CONTAINING ALLOYS WILL REQUIRE ABOUT 20% HIGHER CURRENT. WITH HELIUM SHIELDING, REQUIRED WELDING CURRENT WILL BE REDUCED BY ABOUT 20 TO 30 A.

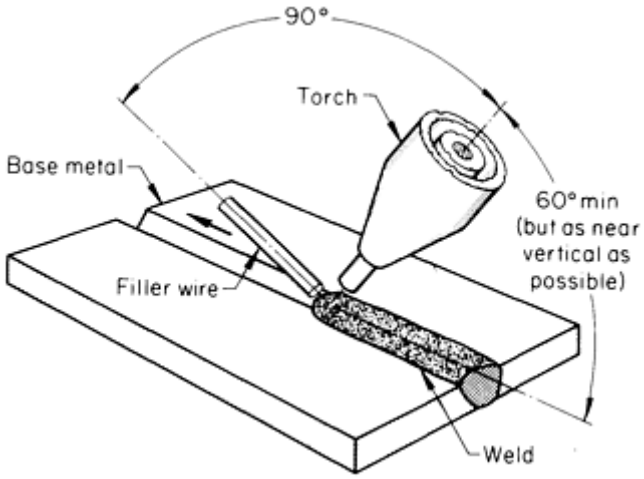

FIG. 2 RECOMMENDED GTAW SETUP FOR JOINING TWO MAGNESIUM ALLOY PLATES

To minimize the risk of weld cracking, either of the methods shown in Fig. 3 should be used: method A, in which starting and runoff plates (or tabs) are used to start and end the weld; or method B, in which the weld is made in two increments by passes that begin in the middle and progress toward opposite ends. Also, the base metal (and fixture, if used) should be preheated to at least 95 to 150 °C (200 to 300 °F). If the thickness of the two compositions to be welded differs by 6.4 mm ($\frac{1}{4}$ in.) or more, the thicker section should be preheated to approximately 150 °C (300 °F).

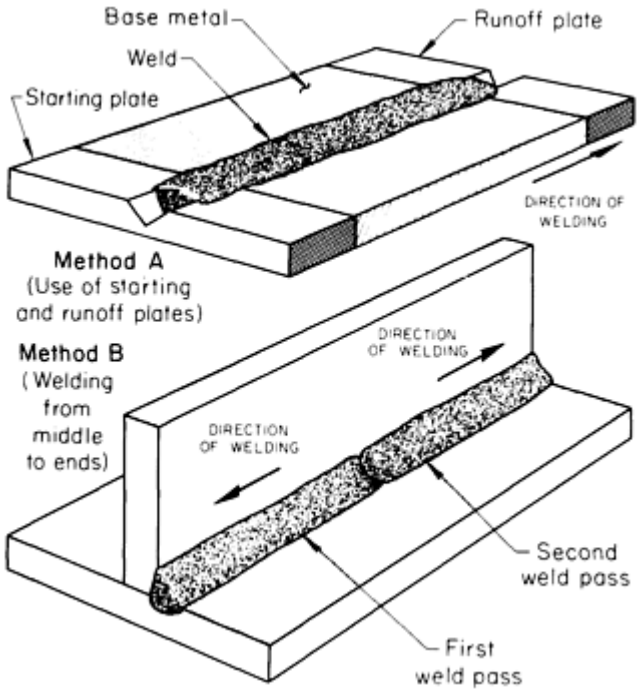

FIG. 3 TECHNIQUES TO PREVENT CRACKING OF WELD WHEN JOINING MAGNESIUM ALLOY PLATES

Short-Run Production. In short production runs for which the cost of elaborate fixtures cannot be justified, tooling costs can be minimized by fabricating the components so that they can be tack welded into position.

Example 1: Tack Welding for Short-Run Production.

To minimize tooling costs on short production runs of electronic deck assemblies, which were essentially two rectangular boxes 50 by 50 by 100 mm (2 by 2 by 4 in.), as shown in Fig. 4, tack welds were used instead of fixturing to position some of the component pieces. Formed sheet sections of 1.3 mm (0.050 in.) thick AZ31B-H24 were tack welded into position by GTAW, using 1.6 mm ($\frac{1}{16}$ in.) diam ER AZ61A filler wire. The tack welds were 3.2 mm ($\frac{1}{8}$ in.) long and were spaced on 50 mm (2 in.) centers (starting at each comer). A tool plate and toggle clamps held the pieces for tack welding. Tack welds were not used to hold angle pieces.

FIG. 4 MANUAL GTAW OF ELECTRONIC DECK ASSEMBLY

Welding of the assembled and tack welded components was completed by manual GTAW with 1.6 mm ($\frac{1}{16}$ in.) diam ER AZ61A filler wire. The comer joints were welded with continuous beads about 50 mm (2 in.) long, and the flanged bottom of the top part of the assembly was joined to the sides with 25 mm (1 in.) long fillet welds. Extruded angle sections were fillet welded to the ends of the boxes with welds about 25 mm (1 in.) long (Fig. 4, detail A).

The assembly was repositioned manually so that all welds could be made in either the flat or the horizontal position. A standard alternating current power supply with a high-frequency arc stabilizer was used. Helium was selected as the shielding gas because a hotter and more stable arc was produced than would have been possible with argon shielding gas. Preheating was not used, but after welding, the assemblies were stress relieved at 175 °C (350 °F) for $3\frac{1}{2}$ h to prevent stress-corrosion cracking. Welds were inspected visually.

Example 2: Manually Welded T-Joint.

The welding of a single 3.2 mm ($\frac{1}{8}$ in.) fillet in a 205 mm (8 in.) long T-joint between sheets of alloy AZ31B, 1.6 and 3.2 mm ($\frac{1}{16}$ and $\frac{1}{8}$ in.) thick (see Table 10), was used as a quick shop test for welder qualification. The welder adjusted the machine settings, gas flow, and welding speed to produce a sound weld with proper contour and adequate penetration, using manual GTAW. After welding, the joint was broken by striking a blow against the unwelded side of the vertical stem to open and expose the root of the weld. The fracture was then examined for depth of penetration, porosity, lack of fusion, and other defects. Welding conditions and a view of the joint are given in Table 10.

(A) A 300 A AC/DC POWER SUPPLY WITH CONTINUOUS HIGH FREQUENCY WAS USED FOR ALL THREE APPLICATIONS, WITH A LIGHT-DUTY WATER-COOLED WELDING TORCH. ALL WORKPIECES WERE PREWELD CLEANED BY CHROMIC-SULFURIC PICKLING. NO PREHEAT WAS USED.

(B) INCLUDES FIXTURING, WELDING, AND UNLOADING

Example 3: Manually Welded Single-V-Groove Butt and Corner Joints.

Structural frames were fabricated by welding the mitered ends of 25 by 25 by 4.8 mm (1 by 1 by $\frac{3}{16}$ in.) angles extruded from alloy AZ31B. One of the four right angle corners of one of these structural frames is shown in Table 10. Manual GTAW was used because production quantity was less than 50 pieces per month.

The procedure consisted of mitering, edge beveling, cleaning, assembling on a fixture, and welding. Horizontal joint edges were beveled 45° with a 1.0 mm (0.040 in.) deep root face; vertical joint edges were beveled to form a similar root face for a 90° corner joint. After acid pickling and rinsing, the angles were assembled on a clamping fixture with flat backing bars for the horizontal joints and corner backing bars for the vertical joints. The backing bars for both the horizontal and vertical joints were provided with backing grooves that were 3.2 mm ($\frac{1}{8}$ in.) wide by 0.51 mm (0.020 in.) deep. The outside corner joint was single-pass welded, vertical-up; the grooved butt joint was single-pass welded in the flat position. No preheat was used, but the frames were postweld stress relieved at 175 °C (350 °F) for 1 $\frac{1}{2}$ h. Welding conditions are given in Table 10.

Example 4: Square-Groove-Welded Butt Joints.

Gas-metal arc welding was to be used on the square-groove-welded butt joints (with 1.0 mm, or 0.040 in., root opening) in 3.2 mm ($\frac{1}{8}$ in.) thick AZ31B-H24 sheet, but contact tube arcing occurred and contamination of the filler metal resulted. Rather than delay production while the arcing problem was being eliminated, manual GTAW was used instead. Good mechanical properties were obtained in single-pass welds, using argon shielding on the torch side and a grooved copper backing bar, but no gas backing, on the underside. Joint alignment was maintained with bolted hold-down bars. Welding conditions are given in Table 10.

Automatic welding of magnesium alloys by GTAW is similar to manual welding, except that higher currents and welding speeds are used. Table 11 can be used as a guide to determine settings for automatic welding. Alternating current is best, although DCEP can be used. A balanced-wave alternating current machine, or a conventional alternating current machine equipped with a battery bias for wave balancing, should be used.

(A) MAXIMUM SPEED LIMITATION BECAUSE OF UNDERCUTTING OR ARC INSTABILITY.

(B) DIAMETER OF FILLER METAL, 2.39 MM (0.094 IN.)

Constant alignment of electrode and filler metal is important in automatic welding. Filler metal is fed into the arc at a low angle to the work so that the filler rod touches the weld surface just ahead of the electrode. The arc length shown in Table 11 should be preset and maintained. Travel speeds up to 2410 mm/min (95 in./min) can be used on thin sheet, but 610 to 915 mm/min (24 to 36 in./min) is more common. Automatic welding is not necessarily restricted to high-production applications; sometimes the high degree of control that can be attained with automatic welding is required regardless of quantity.

Example 5: Automatic Welding of Extrusions.

Airtight doors for an aerospace application were made by welding panels of alloy AZ31B-H24 sheet to frames extruded from AZ31B. The frames, which acted as stiffeners, also contained a groove for an air seal. Cross sections of similar offset butt joints in two designs of door assemblies are shown as joints A and B in Fig. 5. The offset lip of the extruded frames provided a single-bevel groove butt joint and supplied backing for the weld; the lap joint on the underside was not welded. Although production quantities were low, automatic GTAW was used because weld quality was good and the equipment was available. Automatic travel was obtained by mounting the welding equipment on the motorized carriage of a cutting machine. Differences in welding conditions for the two joints resulted from operator choice or judgment. Both procedures produced satisfactory welds, but the difference in welding speeds would have been significant had production quantities been large.

Repair Welding of Castings

A significant portion of the total amount of welding that is done on magnesium alloy castings is for repair. Repair welding is usually limited to the repair of defects in clean metal, including broken sections, sand or blowholes, cracks, and cold shuts. Repair welding is not recommended in areas containing flux or oxide inclusions or excessive porosity. Castings that have been organically impregnated for pressure tightness or that may contain oil in pores should not be welded. Many magnesium castings are aircraft parts that are heat treated to meet strength requirements. These castings must be heat treated again after welding. The type, size, and location of defects in castings vary so much that each job presents its own welding problems; procedures cannot be standardized. However, to complete most repairs:

- CASTINGS MUST BE STRIPPED OF PAINT AND DEGREASED BEFORE WELDING; CONVERSION COATINGS SHOULD BE REMOVED FROM DEFECTIVE AREAS WITH STEEL WOOL OR WITH A POWER WIRE BRUSH HAVING STAINLESS STEEL BRISTLES; A ROTARY DEBURRING TOOL IS RECOMMENDED FOR REMOVING DEFECTS AND PREPARING THE WORKPIECE FOR WELDING.
- CASTINGS SHOULD BE CLAMPED IN PLACE, AND THE SURFACE ADJOINING THE FRACTURE SHOULD BE BEVELED FOR THE WELD (TABLE 5).
- PREHEATING, IF NECESSARY, SHOULD BE DONE AT THE TEMPERATURES RECOMMENDED IN TABLE 7. EITHER LOCAL HEATING WITH A TORCH OR FURNACE HEATING CAN BE USED. THE USE OF A PROTECTIVE ATMOSPHERE DURING FURNACE HEATING WILL REDUCE THE POSSIBILITY OF OXIDATION AT TEMPERATURES ABOVE 370 °C (700 °F).
- WELDING SHOULD BE DONE IMMEDIATELY AFTER PREHEATING. REHEATING MAY BE NECESSARY IF THE TEMPERATURE OF THE CASTING DROPS SIGNIFICANTLY BELOW THE PREHEAT TEMPERATURE.
- MEDIUM-SIZE WELD BEADS SHOULD BE USED.
- WELDING SHOULD PROGRESS FROM THE CENTER OF THE BREAK TO THE OUTSIDE EDGES. THE ARC SHOULD NOT BE ALLOWED TO DWELL TOO LONG IN ANY ONE AREA BECAUSE WELD CRACKING MAY RESULT.
- HIGH WELDING CURRENT, WHICH MAY CAUSE WELD CRACKING OR INCIPIENT MELTING IN THE HEAT-AFFECTED ZONE (HAZ), SHOULD BE AVOIDED; LOW WELDING CURRENTS, WHICH MAY CAUSE COLD LAPS, OXIDE CONTAMINATION, OR POROSITY, SHOULD ALSO BE AVOIDED.
- A FOOT CONTROL SHOULD BE USED TO FADE IN AND OUT THE ARC GRADUALLY TO MINIMIZE THERMAL SHOCK FROM ARC STOPS. THERMAL SHOCK MAY CAUSE CRACKING.

The examples that follow describe procedures that were used in successful repair welding of specific castings.

Example 6: Repair of an Aircraft Wheel Rim Casting.

After machining, aircraft wheel film castings of AZ91C-T4 were occasionally found to have small sand holes (Fig. 6). Defects, of a size that could be removed by cutting a groove about 3.2 mm ($\frac{1}{8}$ in.) deep and 13 mm ($\frac{1}{2}$ in.) wide, were repaired by welding. The defective area was cleaned by cutting a smoothly blended groove (see Fig. 6, Before welding), using a burring tool. After complete removal of defective material was verified by liquid-penetrant inspection, the groove and surrounding area were wire brushed to prepare for GTAW. The relatively thick section of the casting in the repair area and the wide groove for the deposit ensured that the weld would be under low restraint; therefore, preheating was not necessary. Ordinarily, a standard filler metal, such as ER AZ92A or ER AZ101A, would prove satisfactory for welding the AZ91C base metal; in this application, a filler metal of the same composition as the base metal was specified. The weld was made by striking the arc at the bottom of the groove and proceeding in a circular direction along the groove wall to fill the groove, as shown in the "After welding" view in Fig. 6.

FIG. 6 REPAIR WELDING OF AZ91C ALLOY AIRCRAFT WHEEL RIM CASTING

After welding, the weld reinforcement was ground to 0.8 mm ($\frac{1}{32}$ in.) above the base-metal surface, and surface weld quality was verified by liquid-penetrant inspection. After passing inspection, the casting was heat treated to the T6 condition. The casting was accepted after radio-graphic inspection indicated satisfactory internal weld quality.

Example 7: Repair Welding of a Jet Engine Casting.

During an aircraft jet engine overhaul, fluorescent-penetrant inspection revealed a 64 mm ($2\frac{1}{2}$ in.) long crack near a rib in the cast AZ92A-T6 compressor housing shown in Fig. 7. The thickness of the section containing the crack ranged from

4.8 to 7.9 mm ($\frac{3}{16}$ to $\frac{5}{16}$ in.). Repair welding was permissible. The part was vapor degreased to remove surface grease and dirt and soaked in a commercial alkaline paint remover. The crack was then marked with a felt-tip marker, and the part was stress relieved at 205 °C (400 °F) for 2 h. The crack was removed by slotting the flange through to the periphery. Each side of the slot was beveled to approximately 30° from vertical to form a 60° double-V-groove. The area to be welded was cleaned with a power wire brush with stainless steel bristles. Welding was done by manual GTAW, without preheating.

FIG. 7 REPAIR WELDING OF A CAST AZ92A ALLOY COMPRESSOR HOUSING

The welding technique maintained a low-amperage arc (less than 70 A) directed onto the base metal while filler metal was deposited on the sides of the groove, working from the innermost point outward. After a molten weld pool formed, the arc was weaved slightly while depositing a bead on the sides of the groove. During welding, heat input was adjusted by a foot-operated current-control rheostat to maintain a uniform weld pool. After welding was completed on one side of the slot, the casting was turned over. Excess drop-through and areas of incomplete penetration were removed by grinding. The underside was then welded by the same technique used for the first side. After welding, the casting was stress relieved at 205 °C (400 °F) for 2 h and inspected by the fluorescent-penetrant method.

Sand casting repairs can be made with manual GTAW. Figure 8 shows three repairs for the correction of surface flaws that occur in machining, defects resulting from the casting process, and deficiencies in design. Welding was done with high-frequency stabilized alternating current. The castings were preheated and maintained at temperature during welding to avoid cracking. To avoid distortion, the postweld heat treatments were used as a compromise between stress relieving and an aging treatment. However, when repair-welded areas were large enough so that the heat of welding caused a significant reduction in mechanical properties, welding was followed by a full heat treatment. Radiographic inspection was used in establishing the welding procedure, and all repair welds were subjected to fluorescent-penetrant inspection. Fillet welds were left as welded; other types of welds were finished to conform to the contour of the casting or to the desired shape.

FIG. 8 MANUAL GTAW REPAIR OF SAND CASTINGS

Example 8: Repair Welding of a Machining Scratch.

The views at the top in Fig. 8 show a portion of an alloy AZ92A-T6 sand casting with a machining scratch 6.4 mm ($\frac{1}{4}$ in.) long and 0.76 mm (0.030 in.) deep. This scratch was repaired by gas tungsten arc surface welding. Machining flaws up to 9.5 mm ($\frac{3}{8}$ in.) square in castings of various shapes and sizes have been corrected by this method.

Example 9: Repair Welding of Wall Thinning.

The middle views in Fig. 8 show a flanged cylindrical alloy EZ33A sand casting that was one of about 200 such castings in which core shift caused the 6.4 mm ($\frac{1}{4}$ in.) wall to thin to 3.2 mm ($\frac{1}{8}$ in.), beginning about 25 mm (1 in.) away from one of the flanges. To repair these thin areas without distortion of the cylinder, a 75 by 100 mm (3 by 4 in.) piece of 6.4 mm ($\frac{1}{4}$ in.) alloy HK31A plate was formed to fit the outside wall of the cylinder, drilled in the center with a 13 mm ($\frac{1}{2}$ in.) diam hole, and clamped in place over the thin area. The patch was tack welded at the four corners and then gas tungsten arc welded along the periphery with intermittent 6.4 mm ($\frac{1}{4}$ in.) fillet welds 25 mm (1 in.) long. During welding, the inside of the cylinder was flushed with helium to prevent oxidation of heated portions. After the patch had been fillet welded to the cylinder, the center hole was plug welded, using successive small beads to ensure fusion to the wall of the casting and to minimize the possibility of cracking, which can occur when large beads are deposited. The part was then finish machined using plates to hold the flanges.

Example 10: Application of an All-Weld-Metal Boss.

Because a design change was made after the first run of flanged cylindrical alloy EZ33A castings had been produced, a boss had to be added to one of the flanges on each casting, as shown in the views at the bottom in Fig. 8. Using a buildup welding procedure of successive small beads, a cylindrical boss 25 mm (1 in.) in diameter by 6.4 mm ($\frac{1}{4}$ in.) high was produced on the flange by manual GTAW. In later production, the pattern was changed, and the boss was cast integrally with the flange.

Defects in Repair Welds. Oxide inclusions are caused by (1) welding on unsound base metal, (2) inadequate cleaning of base metal or filler metal, (3) maintaining too long an arc, (4) insufficient flow of shielding gas, (5) leaky gas connections, and (6) defective shielding-gas hoses that allow the drawing in of air.

Tungsten inclusions are caused by maintaining too long an arc, using too high a current, and touching the weld pool, base metal, or filler metal with the electrode.

Porosity is usually caused by welding on unsound base metal, poor preweld cleaning of base metal or filler metal, and contamination of the shielding gas.

Microshrinkage, a defect consisting of interdendritic voids detectable on magnification, is caused by too rapid current decay at the end of a weld, which results in too rapid freezing of the weld pool. As a result, the weld pool is unable to serve as a riser to feed the solidifying weld metal below.

Base-metal cracks are usually caused by excessive heat input or by carrying the arc too far over onto the base-metal surface during repair welding.

In repair welds of magnesium alloys that contain rare earth elements or thorium, a light-colored area at the HAZ of the weld is often visible on a radiograph taken with the x-ray beam parallel and the x-ray film perpendicular to the weld edge. This is caused by eutectic-enriched material with high atomic numbers absorbing substantially more radiation. Eutectic enrichment is caused by the melting of eutectic material at a lower temperature and heat expansion of the parent grains, squeezing this material into a layer at the edge of the weld. Below this layer is a darker area on the radiograph where eutectic material has vacated. Above the eutectic-rich layer appears another eutectic-depleted zone due to the first solidification of higher melting constituents. The effect can be minimized by avoiding preheat and by rapid welding.

Heat Treatment After Welding

Heat treated castings are often heat treated again after welding. The heat treatments shown in Table 7 depend on the temper before welding and the temper required after welding. Only the minimum heat-treating time ($\frac{1}{2}$ h) for complete solution is used for welded AZ81A, AZ91C, AZ92A, and QE22A castings to avoid abnormal grain growth in the deposited weld metal. As noted in Table 7, some solution treatments require an SO_2 or CO_2 atmosphere.

If complete solution treatment is not required, magnesium alloys containing more than 1.5% Al should always be stress relieved to prevent stress-corrosion cracking in service. Postweld stress-relieving temperatures and times are given in Table 12.

Introduction

COMMERCIALLY PURE TITANIUM and most titanium alloys can be welded by procedures and equipment used in welding austenitic stainless steel and aluminum. Because of the high reactivity of titanium and titanium alloys at temperatures above 550 °C (1020 °F), additional precautions must be applied to shield the weldment from contact with air. Also, titanium base metal and filler metal must be clean to avoid contamination during welding.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Weldability

Unalloyed titanium and all alpha titanium alloys are weldable. Although the alpha-beta alloy Ti-6Al-4V and other weakly beta-stabilized alloys are also weldable, strongly beta-stabilized alpha-beta alloys are embrittled by welding. Most beta alloys can be welded, but because aged welds in beta alloys can be quite brittle, heat treatment to strengthen the weld by age hardening should be used with caution.

Unalloyed titanium is generally available in several grades, ranging in purity from 98.5 to 99.5% Ti. These grades are strengthened by variations in oxygen, nitrogen, carbon, and iron. Strengthening by cold working is possible but is seldom used. All grades are usually welded in the annealed condition. Welding of cold-worked alloys anneals the heat-affected zone (HAZ) and negates the strength produced by cold working.

Alpha alloys Ti-5Al-2.5Sn, Ti-6Al-2Sn-4Zr-2Mo, Ti-5Al-5Sn-2Zr-2Mo, Ti-6Al-2Nb-1Ta-1Mo, and Ti-8Al-1Mo-1V are always welded in the annealed condition.

Alpha-beta alloys of Ti-6Al-4V can be welded in the annealed condition or in the solution-treated and partially aged condition, with aging completed during postweld stress relieving. In contrast to unalloyed titanium and the alpha alloys, which can be strengthened only by cold work, the alpha-beta and beta alloys can be strengthened by heat treatment.

The low weld ductility of most alpha-beta alloys is caused by phase transformation in the weld zone or in the HAZ. Alpha-beta alloys can be welded autogeneously or with various filler metals. It is common to weld some of the lower-alloyed materials with matching filler metals. Filler metal of an equivalent grade or one grade lower is used to ensure good weld strength and ductility. Filler metal of matching composition is used to weld the Ti-6Al-4V alloy. This extra-low-interstitial (ELI) grade improves ductility and toughness. The use of filler metals that improve ductility may not prevent embrittlement of the HAZ in susceptible alloys. In addition, low-alloy welds can be embrittled by hydride precipitation. However, with proper joint preparation, filler-metal storage, and shielding, hydride precipitation can be avoided.

Sheet thicknesses 2.54 mm (0.100 in.) and thinner can be welded without filler metal additions by the fused-root welding technique. Filler metal may be added to repair unfused and sunken weld-metal areas. The lack of a joint line on the root face of the weld indicates 100% penetration.

Metastable beta alloys Ti-3Al-13V-11Cr, Ti-11.5Mo-6Zr-4.5Sn, Ti-8Mo-8V-2Fe-3Al, Ti-15V-3Cr-3Al-3Sn, and Ti-3Al-8V-6Cr-4Zr-4Mo are weldable in the annealed or solution heat treated condition. In the as-welded condition, welds are low in strength but ductile. Beta alloy weldments are sometimes used in the as-welded condition. Welds in the Ti-3Al-13V-11Cr alloy embrittle more severely when age hardened. To obtain full strength, the metastable beta alloys are welded in the annealed condition; the weld is cold worked by peening or planishing, and the weldment is then solution treated and aged. This procedure also obtains adequate ductility in the weld.

For additional information on the weldability of titanium alloys, see the Section "Selection and Weldability of Nonferrous Low-Temperature Materials" in this Volume.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Process Selection

The following fusion-welding processes are used for joining titanium and titanium alloys:

- GAS-TUNGSTEN ARC WELDING (GTAW)
- GAS-METAL ARC WELDING (GMAW)
- PLASMA ARC WELDING (PAW)
- ELECTRON-BEAM WELDING (EBW)
- LASER-BEAM WELDING (LBW)
- FRICTION WELDING (FRW)
- RESISTANCE WELDING (RW)

Fluxes cannot be used with these processes because they combine with titanium to cause brittleness and may reduce corrosion resistance. The welding processes that use fluxes are electroslag welding, submerged arc welding, and flux-

cored arc welding. These processes have been used on a limited basis. However, they are not considered to be economical because they require high-cost, fluoride-base fluxes.

Gas-tungsten arc welding is the most widely used process for joining titanium and titanium alloys except for parts with thick sections. Square-groove butt joints can be welded without filler metal in base metals up to 2.5 mm (0.10 in.) thick. For thicker base metals, the joint should be grooved, and filler metal is required. The heated weld metal in the weld zone must be shielded from the atmosphere to prevent contamination with oxygen, nitrogen, and carbon, which will degrade the weldment ductility.

Welding may be done manually or automatically. Local shielding can be accomplished by the use of backup shields (Fig. 1) and torch-trailing shields (Fig. 2). For complex weld geometries, rigid or collapsible plastic bags purged and filled with inert gas (usually argon) may be used. For welds with high chemical purity requirements, the use of vacuum weld chambers is recommended.

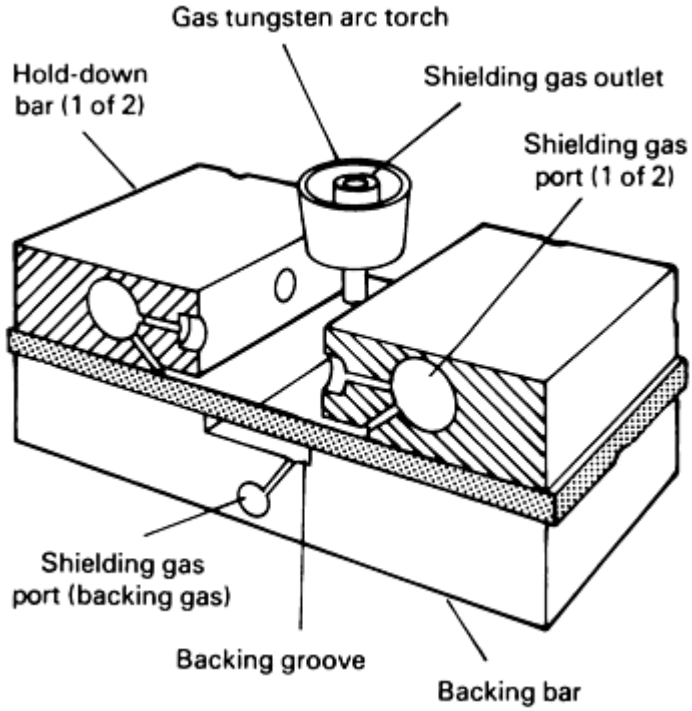

FIG. 1 SETUP FOR INERT GAS SHIELDING FOR GTAW OF TITANIUM ALLOYS OUTSIDE A WELDING CHAMBER. GAS SHIELDING IS FROM THE TORCH AND THROUGH PARTS IN HOLD-DOWN BARS, BACKING BARS, AND FROM TRAILING AND BACKUP SHIELDS.

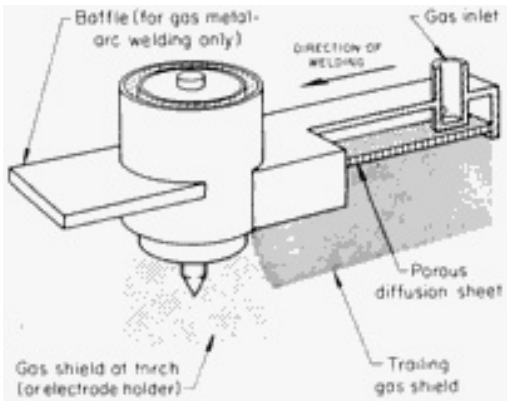

FIG. 2 ARRANGEMENT FOR SHIELDED AUTOMATIC WELDING OF TITANIUM ALLOYS IN AIR. THE BAFFLE SHOWN ON THE LEADING SIDE OF THE TORCH (OR ELECTRODE HOLDER) IS SELDOM USED FOR GTAW, BUT

IS USED FOR GMAW.

Gas-metal arc welding is used to join titanium and titanium alloys more than 3.18 mm (0.125 in.) thick. It is applied using pulsed current or the spray mode and is less costly than GTAW, especially when the base metal thickness is greater than 13 mm (0.50 in.).

Plasma arc welding is also applicable to joining titanium and titanium alloys. It is faster than GTAW and can be used on thicker sections, such as one-pass welding of plate up to 13 mm (0.50 in.) thick, using square-butt and keyhole techniques.

Electron-beam welding is used in the aircraft and aerospace industries for producing high-quality welds in titanium and titanium alloy plates ranging from 6.4 mm (0.25 in.) to more than 76 mm (3 in.) thick. Because the welding is performed in a high-vacuum atmosphere, low contamination of the weldment is achieved.

Laser-beam welding is increasingly being used to join titanium and titanium alloys. Square-butt weld joint configurations can be used, and the welding process does not require the use of vacuum chambers; gas shielding is still required. This process is more limited than electron-beam welding regarding base metal thickness, which cannot usually exceed 13 mm (0.50 in.).

Friction welding is useful in joining tube, pipe, or rods, where joint cleanliness can be achieved without shielding.

Resistance welding is used to join titanium and titanium alloy sheet by either spot welds or continuous seam welds. The process is also used for welding titanium sheet to dissimilar metals, that is, cladding titanium to carbon or stainless steel plate.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Filler Metals

For welding titanium thicker than about 2.5 mm (0.10 in.) by the GTAW process, a filler metal must be used. For PAW, a filler metal may be used for welding metal less than 13 mm (0.5 in.) thick.

Composition. Thirteen titanium and titanium alloy filler-metal (or electrode) classifications are given in AWS A5.16. Five of these are essentially unalloyed titanium, and the remainder are titanium alloy filler metals. Maximums are set on carbon, oxygen, hydrogen, and nitrogen contents. Compositions for titanium and titanium alloy filler metals are given in Table 1.

Notes: Titanium constitutes the remainder of the composition. Single values are maximum. Analysis of the interstitial elements carbon, oxygen, hydrogen, and nitrogen shall be conducted on samples of filler metal taken after the filler metal has been reduced to its final diameter and all processing operations have been completed. Analysis of the other elements may be conducted on these same samples or it may have been conducted on samples taken from the ingot or the rod stock from which the filler metal is made. In case of dispute, samples from the finished filler metal shall be the referee method. Residual elements, total, shall not exceed 0.02%, with no single such element exceeding 0.05%. Residual elements need not be reported unless a report is specifically required by the purchaser. Residual elements are those elements (other than titanium) that are not listed in Table 1 for the particular classification, but which are inherent in the raw material or the manufacturing practice. Residual elements can be present only in trace amounts and they cannot be elements that have been intentionally added to the product.

Source: ANSI/AWS A5.16-90, American Welding Society, 1990

Filler-metal composition is usually matched to the grade of titanium being welded. For improved joint ductility in welding the higher strength grades of unalloyed titanium, filler metal of yield strength lower than that of the base metal is occasionally used. Because of the dilution that occurs during welding, the weld deposit acquires the required strength. Unalloyed filler metal is sometimes used to weld Ti-5Al-2.5Sn and Ti-6Al-4V for improved joint ductility. The use of unalloyed filler metals lowers the beta content of the weldment, thereby reducing the extent of the transformation that occurs and improving ductility. Engineering approval, however, is recommended when using pure filler metal to ensure that the weld meets strength requirements. Another option is filler metal containing lower interstitial content (oxygen, hydrogen, nitrogen, and carbon) or alloying contents that are lower than the base metal being used. The use of filler metals that improve ductility does not preclude embrittlement of the HAZ in susceptible alloys. In addition, low-alloy welds may enhance the possibility of hydrogen embrittlement.

Preparation. The filler metal, as well as the base metal, should be clean at the time of welding. As shown in Fig. 3, wires used for filler metals have a large surface-to-volume ratio. Therefore, if the wire surface is slightly contaminated, the weld may be severely contaminated. Some procedures require that the filler wire be cleaned immediately before use. The use of an acetone-soaked, lint-free cloth serves to assess surface contamination caused by the die lubricant used in the wire drawing operation, in addition to cleaning the filler wire. Pickling in nitric-hydrofluoric acid solution is also used for cleaning.

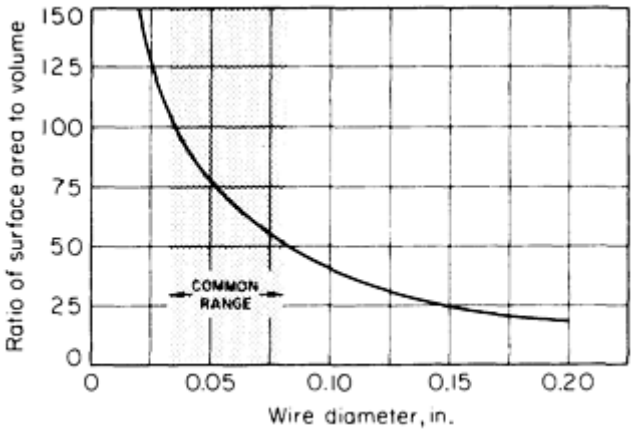

FIG. 3 RATIO OF FILLER-METAL (ELECTRODE) WIRE SURFACE AREA TO VOLUME FOR VARIOUS WIRE DIAMETERS. "COMMON RANGE" INDICATES RANGE OF WIRE DIAMETERS MOST OFTEN USED FOR WELDING TITANIUM.

Shielding Gases

In welding titanium and titanium alloys, only argon and helium, and occasionally a mixture of these two gases, are used for shielding. Because it is more readily available and less costly, argon is more widely used. Argon shielding gas was used in the examples given in this article.

Because of its high purity (99.985% min.) and low moisture content, a liquid argon supply is often preferred. The argon gas should have a dew point of -60 °C (-75 °F) or lower. The hose used for the shielding gas should be clean, nonporous, and flexible, and may be made of Tygon or vinyl plastic. Because rubber hose absorbs air, it should not be used. Excessive gas flow rates that cause turbulence should be avoided, and flowmeters are usually employed for all gas shields. Pressure gages may be used for trailing and backup shields.

Characteristics. The type of shielding gas used affects the characteristics of the arc. At a given welding current, the arc voltage is much greater with helium than with argon. Because the heat energy liberated in helium is about twice that in argon, higher welding speeds can be obtained, weld penetration is deeper, and thicker sections can be welded more rapidly using helium shielding. However, when using pure helium for welding, arc stability and weld-metal control are sacrificed.

Argon is used when welding thin and thick sections where the arc length can be altered without appreciably changing the heat input. Argon-helium mixtures are also used, particularly 75% argon, which improves arc stability, and 25% helium, which increases penetration. The 75Ar-25He mixture is also frequently utilized as the shielding gas at the torch in automatic operations. Furthermore, helium is used in shielding out-of-position welds.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Joint Preparation

If welding is done outside a controlled-atmosphere welding chamber, joints must be carefully designed so that both the top and the underside of the weld can be shielded (Fig. 1). Dimensions of typical joints are given in Table 2. For welding titanium alloys, joint fit-up should be better than for welding other metals, because of the possibility of entrapping air in the joint. The joint should be clamped to prevent separation during welding.

TABLE 2 DIMENSIONS OF TYPICAL JOINTS FOR WELDING TITANIUM AND TITANIUM ALLOYS

BASE-METAL THICKNESS		ROOT OPENING[A]	GROOVE ANGLE, DEGREES	WELD-BEAD WIDTH[A]

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Cleaning

To obtain a good weld, the joint and the surfaces of the workpiece at least 51 mm (2 in.) beyond the width of the gas trailing shield on each side of the weld groove must be meticulously cleaned. The cleaning procedure depends on whether the oxide layer in the joint area is light or heavy.

Degreasing. Grease and oil accumulated during forming and machining must be removed before welding to avoid weld contamination. Scale-free metal requires only degreasing. Degreasing precedes descaling for metal with an oxide scale. Methods of degreasing include steam cleaning, alkaline cleaning, vapor degreasing, and solvent cleaning.

For vapor degreasing, toluene rather than a chlorinated solvent should be used, because residues from chlorinated solvents (and also from silicated solvents) may contribute to cracking of titanium weldments. Solvent cleaning is frequently used, especially for large components that cannot conveniently be placed in a vapor degreaser or washer for alkaline cleaning. Solvents applied include methyl ethyl ketone, toluene, acetone, and other chlorine-free solvents. Because methyl alcohol has reportedly caused stress corrosion, it is prohibited for use on aerospace hardware.

In solvent cleaning, the joint areas are hand-wiped with the solvent just before welding. All wiping should be done with clean, lint-free cloths or a cellulose sponge. Plastic or lint-free gloves should be worn; rubber gloves are likely to leave traces of plasticizer that can cause porosity in the weld metal. Handprints are also a source of contamination.

After a lightly oxidized joint area has been degreased, it should be pickled for a short time. A typical mixture is 4 wt% hydrofluoric acid and 40 wt% nitric acid. Because hydrogen is detrimental to the properties of titanium, causing embrittlement and sometimes contributing to weld porosity, pickling should be performed cautiously. Industrial practice usually is to maintain the acid bath at a high oxidation potential of 30 wt% or more nitric acid, which simultaneously holds the ratio of nitric acid to hydrofluoric acid at 10 to 1 strictly as a factor of safety. If the nitric acid content falls below 30 wt% and the ratio of nitric acid to hydrofluoric acid falls below 10 to 1, excessive hydrogen pickup is possible.

Oxide Removal. Lightly oxidized joint areas may also be cleaned by brushing with a stainless steel wire brush or by draw filing. When weld corrosion resistance is important, however, these cleaning methods should be followed immediately by acid pickling. Steel wool or abrasives should never be used, because of the danger of contamination.

If grinding is required, the use of silicon carbide burrs is preferred, because wheels produce residues of rubber or resin on the surface that contaminate the weld. To prevent burning, excessive heat should be avoided while grinding, and low rotating speeds should be used.

If titanium has been exposed to temperatures above 540 °C (1000 °F), a more complex removal treatment, such as chemical, salt bath, mechanical, or combinations of these treatments is required. The salt baths are basically sodium hydroxide to which oxidizing agents or hydrogen has been added to form sodium hydride.

One procedure for removing heavy scale involves subjecting the parts to liquid abrasive blasting or salt-bath descaling after degreasing. These treatments are usually followed by pickling in nitric-hydrofluoric acid for the removal of light scale. When salt-bath descaling is used, oxide removal can be hastened by removing the workpieces from the bath, scrubbing them with brushes, and then re-immersing them. To prevent hydrogen pickup during salt-bath descaling, cycle time must be short (preferably no more than 2 min) and bath temperature must be carefully controlled.

Selection of cleaning method depends largely on the size and shape of the parts and on the cleaning methods available in a particular plant.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Equipment for Gas-Tungsten Arc Welding

Power Supplies. Inverters are the preferred power supply for welding titanium, because the current can be controlled more closely than with motor-generator sets; slight variations in welding current may cause variations in penetration. Transformer-rectifiers may also be used. Direct current electrode negative (DCEN) is always used for GTAW of titanium because deeper weld penetration and a narrower bead can be obtained than with direct current electrode positive (DCEP). Also, in manual welding, DCEN is easier to control.

The power supply should include accessories for arc initiation because of the danger of tungsten contamination of the weld if the arc is struck by torch starting. If welding is to be done in air, controls for extinguishing the arc without pulling the torch away from the workpiece are needed, so that shielding-gas flow continues and the hot weld metal is not contaminated by air.

Electrodes. The conventional thoriated tungsten types of electrodes (EWTh-1 or EWTh-2) are used for GTAW of titanium. Electrode size is governed by the smallest diameter able to carry the welding current. To improve arc initiation and control the spread of the arc, the electrode should be ground to a point. The electrode may extend one and a half times the size of the diameter beyond the end of the nozzle.

Shielding. To ensure a diffuse, nonturbulent flow of shielding gas, nozzles of torches for welding titanium are larger than those used for welding other metals. With a 0.8 mm ($\frac{1}{32}$ in.) diam electrode, a 14 mm ($\frac{9}{16}$ in.) ID nozzle is ordinarily used, and with a 1.6 mm ($\frac{1}{16}$ in.) diam electrode, a 19 mm ($\frac{3}{4}$ in.) ID nozzle is used.

Because titanium has low thermal conductivity, the area ahead of the arc does not exceed 540 °C (1000 °F); therefore, leading shields are seldom required when welding is done by the GTAW process. For welding operations where a trailing shield (Fig. 2) is not adaptable, the nozzle of the torch is fitted with a concentric outer shroud through which a supplementary supply of shielding gas is fed. In Fig. 4, which shows this type of torch, a shielding gas is diffused through copper shavings contained in the outer shroud that cool the gas substantially, helping to protect the metal near the weld.

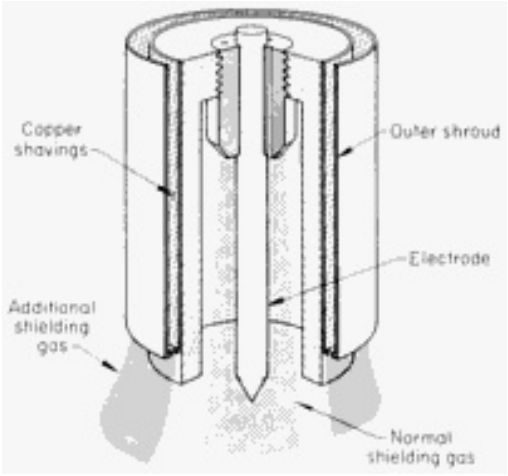

FIG. 4 SECTIONAL VIEW OF A TORCH NOZZLE EQUIPPED WITH AN OUTER SHROUD. COPPER SHAVINGS IN THE OUTER SHROUD PROVIDE ADDITIONAL GAS SHIELDING FOR MANUAL INERT GAS WELDING.

Shielding of the underside of a weld is provided by slotted backing bars, usually copper, through which a diffuse flow of argon or helium is maintained (Fig. 1). Gas channels in the clamping fixtures also provide diffuse flow of inert gas to the weld area. These fixtures are placed close to the weld to avoid the danger of air contamination.

Fixtures. Copper fixtures are usually employed for GTAW. Although other metals are sometimes used, they should be nonmagnetic; arc blow tends to occur with magnetic metal fixtures. Metal fixtures are sometimes water cooled, but this method introduces the possibility of moisture from the air condensing on the fixtures.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Stress Relieving

Most titanium weldments are stress relieved after welding to prevent weld cracking and susceptibility to stress-corrosion cracking in service. Stress relief also improves fatigue strength. An assembly subjected to a substantial amount of welding and severe fixturing restraint may require intermediate stress relieving of the partially welded structure, which should be done in an inert atmosphere. Otherwise, the unwelded joints may have to be recleaned before being welded.

With unalloyed titanium and alpha titanium alloys, time and temperature should be controlled to prevent grain growth. Stress relieving times and temperatures for several weldable titanium alloys are given in Table 3. For alloys not mentioned in this table, tests should be conducted to ensure that stress relieving does not reduce fracture toughness, creep strength, or other important properties.

TABLE 3 STRESS-RELIEVING TIMES AND TEMPERATURES FOR SELECTED TITANIUM ALLOYS

TI-13V-11CR-3AL	480	900	0.5
	540	1000	6

(A) DATA ALSO APPLY TO EXTRA-LOW-INTERSTITIAL (ELI) MODIFICATIONS.

Stress relieving of Ti-13V-11Cr-3Al weldments causes aging and subsequent embrittlement of the weld and HAZ and, therefore, is not recommended. Re-solution heat treatment (re-annealing) may be used to relieve stresses if the welded assembly is amenable to such treatment. All titanium surfaces should be free of dirt, fingerprints, grease, and residues before stress relieving. Contaminated surface metal must be removed from the entire weldment by machining or descaling and pickling to remove 0.025 to 0.050 mm (0.001 to 0.002 in.) per surface.

Welding of Titanium Alloys

Revised by R. Terrence Webster, Consultant

Repair Welding

Repair welds should follow the established specification requirements for the original welds and be made prior to final heat treatment. Manual or automatic GTAW is generally used for repairing butt and fillet welds. Repairs can also feature a combination of welding processes such as GTAW and the initial welding process (GMAW, PAW, or hot wire welding).

Repair welds must always be carefully executed, and all traces of liquid-penetrant inspection material must be removed. Generally, inspection is performed on both faces of the repair weld and several inches beyond the repaired area.

Welding of Zirconium Alloys

R. Terrence Webster, Consultant

Introduction

ZIRCONIUM is a corrosion-resistant structural metal that has many physical and mechanical properties similar to titanium and austenitic stainless steels. Zirconium alloys are weldable; procedures and equipment are similar to those used for welding titanium and austenitic stainless steels. Zirconium has a low coefficient of thermal expansion, which contributes to low distortion during welding.

Because of the reactivity of zirconium with oxygen, nitrogen, and hydrogen, the metal must be shielded during welding with high-purity inert gas or a good vacuum. Furthermore, zirconium should be free of oil, grease, and dirt to avoid the dissolving of carbon- and oxygen-containing materials, which can embrittle the metal or create porosity and may reduce the corrosion-resistant properties of the metal.

Zirconium and its alloys are available in two general categories: commercial grade and reactor grade. Commercial-grade zirconium designates zirconium that contains hafnium as an impurity. Reactor-grade zirconium designates zirconium from which most of the hafnium has been removed to make it suitable for nuclear reactor applications. Because pure zirconium has relatively low mechanical properties, various alloying elements are added to enhance its mechanical properties.

Zirconium and its alloys are available in plate, sheet, bar, rod, and tubing form in a variety of material specifications. The four most common grades of commercial zirconium alloys, as specified in ASTM B 550, are given in Table 1. For reactor grades, the hafnium content is reduced to a minimum and other impurities are closely controlled. Chemical compositions of the most common grades of nuclear-grade Zircaloys, as specified in ASTM B 351, are given in Table 2.

Zirconium can only be welded to itself or to other reactive metal alloys, such as titanium, niobium, or tantalum. When welded to nonreactive metals, intermetallics that embrittle the weld metal are formed.

Welding of Zirconium Alloys

R. Terrence Webster, Consultant

Process Selection

Zirconium alloys are highly reactive to oxygen and nitrogen in air at high temperatures. Consequently, the selected welding processes and procedures must be capable of shielding the weldment and heat-affected zones (HAZ) from contamination. The use of fluxes is generally avoided, because reactivity with the chemicals in the fluxes causes brittleness and may reduce the corrosion resistance of zirconium weldments.

The following welding processes can be used for welding any of the zirconium alloys:

- GAS-TUNGSTEN ARC WELDING (GTAW)
- GAS-METAL ARC WELDING (GMAW)
- PLASMA ARC WELDING (PAW)
- ELECTRON-BEAM WELDING (EBW)
- LASER-BEAM WELDING (LBW)
- FRICTION WELDING (FRW)
- RESISTANCE WELDING (RW)
- RESISTANCE SPOT WELDING (RSW)
- RESISTANCE SEAM WELDING (RSEW)

The selection of a welding process depends on several factors: weld joint, tensile and corrosion-resistant property requirements, cost, and design configuration.

Gas-tungsten arc welding is the most widely used process for joining zirconium alloys. It employs techniques similar to those used for welding stainless steel, that is, the direct current power supply is connected for straight polarity (electrode negative, DCEN). Two desirable features are a contactor for making and breaking the arc and high-frequency arc starting. Recommended electrodes are thoriated tungsten, Type EWTh2.

Plasma arc welding is also commonly used, especially for autogenous welding of butt joint thicknesses from 3.18 to 1.52 mm (0.125 to 0.600 in.).

Gas-metal arc welding is occasionally used for joint thicknesses from 3.18 mm (0.125 in.) or more, because of its more-rapid weld time and the consequent savings in shielding gas and production time. Weld quality is more difficult to maintain, because of weld spatter and arc instability, which result in weld contamination and weld defects.

Electron-beam welding is rarely used, because of high equipment operating cost as well as weld chamber size limitations.

Laser-beam welding has had very limited use in joining zirconium and has been applied primarily in nuclear reactors.

Friction welding is used to join zirconium tubes to zirconium rods, as well as to dissimilar metal alloys (for example, zirconium to stainless steel) for heat-exchanger applications.

Resistance welding is especially useful for the seam or spot welding of thin sheets, because no shielding is required.

Shielding Gases

High-purity argon (99.996% Ar; -65 °C, or -85 °F, dew point), helium, or a mixture of the two gases are used to weld zirconium alloys. Argon has the advantage over helium in terms of lower cost, and it provides good stability and weld metal control. Helium is used to obtain deeper penetration into the joint, and mixtures of argon and helium are frequently used in automatic operations. Helium is the gas most often used to fabricate nuclear reactor equipment.

Filler-Metal Selection

Three zirconium and zirconium-alloy electrodes are identified in American .Welding Society (AWS) specification A5.24-90 (Table 3). The filler-metal composition is selected to match the base-metal composition. Type ERZr2 is used to weld commercially pure zirconium (grade R60702); type ERZr3 to weld Zr-1.5Sn alloy (grade R60704); and type ERZr4 to weld Zr-2.5Nb alloy (grades R60705 and R60706). For critical nuclear applications, the impurities are more closely controlled and the hafnium level is minimized. The nuclear-grade zirconium alloys (Table 1) are welded with filler wire of the same grade chemical composition.

Process Procedures

Joints and welding wire should be cleaned before welding. Most welding wire is adequately acid cleaned prior to spooling or packaging. When cut lengths of wire are found to be dirty, it is good practice to wipe each piece with a clean cloth and solvent prior to use. If it is necessary to clean spooled wire, then a wipe with solvents will usually be satisfactory. If wire is acid cleaned, then the acid bath should be fresh and should not contain iron or any other contaminant that will remain on the wire surface.

Heavy grease and machining oil on the work-piece can be removed using degreasing solvents or reagent methanol, acetone, methyl ethyl ketone (MEK), or the equivalent. If acetone is used, then an alcohol rinse should follow.

Heavy mill scale (usually gray in color) should be removed by grinding. The blue surface oxide that develops when the metal is heated above 315 to 425 °C (600 to 800 °F) can be removed either by wire brushing (with a clean austenitic stainless steel wire brush not used for other metals) or by grinding or acid pickling, which are more effective than wire brushing. A common treatment is to soak from 2 to 5 min in room-temperature solution of 35% HNO_3 and 5% HF in water, followed by a thorough clean-water rinse and air drying.

A joint cleaned by degreasing can still be covered by a very light oil film that is approximately the equivalent thickness of the residue left by fingerprints. This can be effectively removed by abrasive or detergent cleaning, using common household cleansers or detergents, followed by air drying. Air drying can be accelerated by rinsing with methanol, acetone, or other solvents.

Joints cleaned by abrasive, detergent, or acid pickling should be kept entirely clean of dirt, including fingerprints. Generally, it is good practice to clean and to weld a joint within the same work shift. When this is not possible, the joint should be covered with paper or bagged with plastic sheet or another material to minimize the accumulation of dust and dirt.

ASTM specification B 614 ("Descaling and Cleaning Zirconium and Zirconium Alloy Surfaces") should be consulted for cleaning details.

Preheating is not normally required for zirconium welding. The commercial alloys have enough ductility to prevent weld cracking (of uncontaminated welds). Preheating is an aid to moisture removal and is good practice where the shop temperature is low or the humidity is high (it is better to control temperature and humidity in the welding area). Heat can be applied by any conventional means. However, if torch heating is used, then the torch should be moved continuously to avoid local heating of the metal.

Interpass cleaning is not required if the weld deposit is bright and shiny. Light temper colors (straw to light blue) should be removed by brushing with a clean austenitic stainless steel brush.

To prevent weld contamination from the oxygen and nitrogen in air, the weld must be shielded during welding and cooling to below 480 °C (896 °F).

The commercial grades of zirconium will most often be welded in air, and the weldments will require gas shielding on the torch side and the back side of the weld. For sheet, plate, and pipe welds, this requires a gas trailing shield on the torch side and a back-up gas shield for the back side. The shielding gases must envelope the weldment during welding and cooling.

Complex assemblies that are difficult to shield in air can be welded in a chamber. The chamber can be capable of either being evacuated and back filled with argon or helium or it can be supply purged with shielding gas before and during the welding operation. Taping a plastic bag over the part to be welded and sealing the bag at the point where the welding cables enter the bag will simulate an enclosed chamber when helium is introduced into the bag system as a shielding gas.

Heat Treatment. Preweld heat treatment is not required. Postweld stress relief for commercial grades R60702 and R60704 can be used when high residual stresses occur. Grade R60705 must be stress relieved within 14 days after welding to prevent delayed hydride cracking (DHC). Commercial-grade zirconium alloys can be heat treated in air or in an inert atmosphere. Nuclear-grade zirconium alloys are usually heat treated in an inert atmosphere.

Introduction

SURFACING, as applied to welding technology, refers to the deposition of a filler metal on a base metal (substrate) to impart some desired property to the surface that is not intrinsic to the underlying base metal. There are several types of surfacing: hardfacing, buildup, weld cladding, and buttering.

Hardfacing is a form of surfacing that is applied for the purpose of reducing wear, abrasion, impact, erosion, galling, or cavitation. As will be described in the first section of this article, hardfacing alloys may be deposited by oxyfuel welding, various arc welding methods, laser welding, and thermal spray processes.

The term buildup refers to the addition of weld metal to a base metal surface for the restoration of the component to the required dimensions. Buildup alloys are generally not designed to resist wear, but to return the worn part back to, or near, its original dimensions or to provide adequate support for subsequent layers of true hardfacing materials.

A weld clad is a relatively thick layer of filler metal applied to a carbon or low-alloy steel base metal for the purpose of providing a corrosion-resistant surface. Weld cladding is normally carried out by arc welding, the subject of the second section of this article. It should be pointed out, however, that cladding can also be accomplished by solid-state welding processes (roll cladding or explosion cladding) and vacuum brazing. These non-fusion techniques are described elsewhere in this Volume.

Buttering also involves the addition of one or more layers of weld metal to the face of the joint or surface to be welded. It differs from buildup in that the primary purpose of buttering is to satisfy some metallurgical consideration. It is used primarily for the joining of dissimilar metal base metals, as is described in the final section of this article.

Many of the principles associated with successful welding of dissimilar metals are also addressed in the sections on "Hardfacing" and "Weld Cladding" in this article, because these processes also involve a combination of materials with significantly different chemical, mechanical, and physical properties. Such combinations pose a number of challenges for the welding engineer, as evidenced by the discussions of dilution control found throughout this article.

Hardfacing, Weld Cladding, and Dissimilar Metal Joining

J.R. Davis, Davis & Associates

Hardfacing

Hardfacing is the application of a hard, wear-resistant material to the surface of a component by welding, thermal spraying, or allied welding processes to reduce wear or loss of material by abrasion, impact, erosion, galling, and cavitation (Ref 1). The stipulation that the surface be modified by welding, thermal spraying, or allied welding processes excludes the use of heat treatment or surface modification processes such as flame hardening, nitriding, or ion implantation as a hardfacing process. The stipulation that the surface be applied for the main purpose of reducing wear excludes the application of materials primarily used for prevention or control of corrosion or high-temperature scaling. Weld overlays to control corrosion are described in the section on "Weld Cladding" in this article. Corrosion and/or high-temperature scaling may, however, have a major effect on the wear rate and, hence, may become a significant factor in the selection of proper materials for hardfacing.

Hardfacing applications for wear control vary widely, ranging from very severe abrasive wear service, such as rock crushing and pulverizing, to applications to minimize metal-to-metal wear, such as control valves where a few thousandths of an inch of wear is intolerable. Hardfacing is used for controlling abrasive wear, such as that encountered by mill hammers, digging tools, extrusion screws, cutting shears, parts of earthmoving equipment, ball mills, and crusher

parts. It is also used to control the wear of unlubricated or poorly lubricated metal-to-metal sliding contacts such as control valves, undercarriage parts of tractors and shovels, and high-performance bearings.

Hardfacing is also used to control combinations of wear and corrosion, as encountered by mud seals, plows, knives in the food processing industry, valves and pumps handling corrosive liquids, or slurries. In most instances, parts are made of either plain carbon steel or stainless steel, materials that do not provide desirable wear on their own. Hardfacing alloys are applied to critical wear areas of original equipment or during reclamation of worn parts.

Hardfacing Materials

Hardfacing materials include a wide variety of alloys, carbides, and combinations of these materials. Conventional hardfacing materials, also referred to as weld overlays, are normally classified as steels or low-alloy ferrous materials, high-chromium white irons or high-alloy ferrous materials, carbides, nickel-base alloys, or cobalt-base alloys. A few copper-base alloys are sometimes used for hardfacing applications, but for the most part, hardfacing alloys are either iron-, nickel-, or cobalt-base. Out of a total hardfacing market of about 18×10^6 kg (40×10^6 lb) per year, it has been estimated that iron-base hardfacing alloys account for about 90% by weight, but only about 75% by dollar volume (Ref 2).

Microstructurally, hardfacing alloys generally consist of hard phase precipitates such as borides, carbides, or intermetallics bound in a softer iron-, nickel, or cobalt-base alloy matrix. Carbides am the predominant hard phases in iron- and cobalt-base hardfacing alloys. Carbon contents of iron- and cobalt-base hardfacing alloys generally range up to 4 wt%. Borides, as well as carbides, are the predominant hard phases in nickel-base hardfacing alloys. Combined carbon plus boron contents generally range up to 5 wt%. The specific carbide and/or boride phases that form are determined by matrix alloying additions.

The matrix alloys in most cobalt-, nickel-and high-alloy iron-base hardfacing alloys generally contain up to 35% Cr, up to 30% Mo, and up to 13% W, with smaller amounts of silicon and manganese.

Thermal spray materials, which encompass an extremely wide range of metals and alloys, carbides, ceramics, and polymers, are described in the section on "Thermal Spraying" in this article.

Hardfacing Alloy Categories (Ref 2)

Hardfacing (weld overlay) materials can be grouped into five general categories:

- BUILDUP ALLOYS
- METAL-TO-METAL WEAR ALLOYS
- METAL-TO-EARTH ABRASION ALLOYS
- TUNGSTEN CARBIDES (FOR EXTREME EARTH SLIDING AND CUTTING WEAR)
- NONFERROUS ALLOYS

The buildup alloys include low-alloy pearlitic steels and highly alloyed austenitic manganese steels. For the most part, these alloys are not designed to resist wear but to return a worn part back to, or near, its original dimensions and to provide adequate support for subsequent layers of true hardfacing materials. However, austenitic manganese steels are used as wear-resistant materials under mild wear conditions. Typical examples of applications where buildup alloys are used for wearing surfaces include tractor rails, railroad rail ends, steel mill table rolls, and large slow-speed gear teeth.

The metal-to-metal wear alloys are martensitic air-hardening steels that, with care, can be applied (without cracking) to wearing areas of machinery parts (hence, these materials are commonly referred to as machinery hardfacing alloys). Typical applications of this alloy family include undercarriage components of tractors and power shovels, steel mill work rolls, and crane wheels.

The metal-to-earth abrasion alloys are high-chromium white irons in which chromium carbides are formed during alloy solidification. The metal-to-earth alloys possess resistance to sliding and crushing (that is, low- and high-stress abrasion) on a moderate scale. Typical applications for these material types include shovel teeth, rock crusher parts, plowshares, and auger flights.

Tungsten carbides are actually composite materials, and their use involves the transfer of discrete tungsten carbide particles (which in the welding consumable forms are encased in a steel tube) across the welding arc and into the molten weld pool, where they are subsequently "frozen" into the overlay structure by the matrix formed from the melting of the steel tube. The tungsten carbides are intended for use under extreme sliding and cutting conditions. Typical applications for these tungsten carbides include cutting teeth and edge-holding surfaces of rock drill bits, and quarrying, digging, and earthmoving equipment.

The nonferrous hardfacing alloys are used in environments that are too aggressive for the ferrous hardfacing alloys or where high resistance to a specific type of wear (other than abrasion) is required. For the purpose of this article, they are classified as follows:

- COBALT-BASE, INCLUDING CARBIDE-CONTAINING ALLOYS AND LAVES PHASE ALLOYS
- NICKEL-BASE, INCLUDING BORIDE-CONTAINING ALLOYS, CARBIDE-CONTAINING ALLOYS, AND LAVES PHASE ALLOYS
- COPPER-BASE ALLOYS

Also included in this section is a discussion of several cobalt-substitute materials, some iron-base or nickel-base, which share with the cobalt-base alloys resistance to a variety of wear conditions and corrosive media.

Whereas the ferrous hardfacing alloys and tungsten carbide composites find extensive use in agriculture, mining, construction, and the steel industry, the nonferrous alloys are typically used in the chemical processing, power, automotive, and oil industries, all of which require resistance to a hostile environment in addition to resistance to wear. The cobalt-base alloys are especially resistant to deformation and chemical attack at high temperatures (500 °C < $T \leq 900$ °C, or 930 °F < $T \leq 1650$ °F) and are used to protect dies and guide rolls in the steel industry. Other common applications of the nonferrous hardfacing alloys include valve seating surfaces (both control valves and diesel exhaust valves), pump parts, extrusion screw flights, rock bit bearings, marine bearings, and glass molding hardware.

Iron-Base Alloys (Ref 1)

As described above, iron-base hardfacing alloys are more widely used than cobalt- and/or nickel-base hardfacing alloys and constitute the largest volume use of hardfacing alloys. Iron-base hardfacing alloys offer low cost and a broad range of desirable properties. Most equipment that undergoes severe wear, such as crushing and grinding equipment and earthmoving equipment, is usually very large and rugged. Parts subjected to wear usually require downtime for repair. For this reason, there is a general temptation to hardface them with the lowest cost and most readily available materials. As a result, literally hundreds of iron-base hardfacing alloys are in use today.

Due to the great number of alloys involved, iron-base hardfacing alloys are best classified by their suitability for different types of wear and their general microstructures rather than by chemical composition. Most iron-base hardfacing alloys can be divided into the following classes:

- PEARLITIC STEELS
- AUSTENITIC STEELS
- MARTENSITIC STEELS
- HIGH-ALLOY IRONS

Pearlitic steels are essentially low-alloy steels with minor adjustments in composition to achieve weldability. These alloys contain low carbon (<0.2% C) and low amounts of other alloying elements (for example, up to 2% Cr), resulting in a pearlitic structure. Pearlitic steels are useful as buildup overlays, primarily to rebuild carbon steel or low-alloy steel machinery parts back to size. Examples include shafts, rollers, and other parts in heavy machinery subjected to rolling, sliding, or impact loading. Typically, this group of alloys has high impact resistance and low hardness (in the range 25 to 37 HRC), as well as excellent weldability. Table 1 lists the composition and properties of a typical low-alloy pearlitic steel (EFe1) used for buildup applications.

TABLE 1 COMPOSITIONS, HARDNESS, AND ABRASION DATA FOR A PEARLITIC LOW-ALLOY STEEL (EFE1) AND AUSTENITIC MANGANESE STEELS (EFEMN-C AND EFEMN-CR) USED FOR BUILDUP OVERLAYS AND AIR-HARDENING OF MARTENSITIC STEELS USED FOR METAL-TO-METAL WEAR APPLICATIONS

Austenitic steels are usually stabilized by manganese additions. Austenitic iron-base hardfacing alloys essentially are modeled after Hadfield steels. Most commercially available alloys in this category can be broadly subdivided into low-chromium and high-chromium alloys.

Low-chromium alloys usually contain up to 4% Cr and 12 to 15% Mn and some nickel or molybdenum (Table 1). Low-chromium austenitic steels generally are used to build up manganese steel machinery parts subjected to high impact (impact crusher or shovel lips).

High-chromium austenitic steels, which may normally contain 12 to 17% Cr in addition to about 15% Mn, are used for the buildup and joining of austenitic manganese steels as well as carbon and low-alloy steels. In addition, the as-deposited hardness of high-chromium steels is higher (~24 HRC) than that of low-chromium steels (~18 HRC).

The high strength of the austenitic manganese steels is the result of a synergism between manganese and carbon (Ref 3). In suppressing the formation of phases other than austenite, manganese not only increases carbon solubility at lower temperatures but also encourages carbon supersaturation of the structure. Both high inherent strength and a high work-hardening rate result from this.

Because the austenitic manganese steels are metastable, problems of carbide embrittlement tend to arise when the alloys are cooled slowly or reheated. Manganese steel components are therefore kept as cool as possible during the buildup (repair) process. Often, the bulk of the part is submerged in water during the welding process. Compositions and properties of austenitic manganese steel hardfacing alloys used for buildup applications are given in Table 1.

Martensitic steels are designed to form martensite on normal air cooling of the weld deposit. As a result, these steels are often termed "self-hardening" or "air-hardening," and they resemble tool steels with hardnesses in the range of 45 to 60 HRC. The carbon content of the martensitic steels ranges up to 0.7%. Other elements such as molybdenum, tungsten, nickel, and chromium (up to 12%), are added to increase hardenability and strength and to promote martensite formation. Manganese and silicon usually are added to aid weldability.

The major hardfacing applications for martensitic steels include unlubricated metal-to-metal rolling or sliding parts such as undercarriage parts of tractors. The impact resistance of martensitic steels is inferior to that of pearlitic or austenitic alloys, but there is a compensating increase in hardness and resistance to abrasive wear.

In hostile environments, a higher chromium content is beneficial. AWS ER420 and modified versions containing nickel, molybdenum, and niobium (or vanadium) are therefore the natural choice when high temperatures and mildly corrosive environments are encountered. For applications using steel mill hot-work rolls (which demand considerable hot hardness, resistance to oxidation, and resistance to thermal fatigue) both ER420 and EFe3 have been found suitable. Other applications for the metal-to-metal martensitic wear alloys in Table 1 include crane wheels (EFe2), pincer guide shoes (EFe3), and blast furnace bells (ER420).

The high-chromium irons encompass a wide range of compositions in which chromium may vary between approximately 6 and 35 wt%, and carbon may vary from about 2 to 6 wt%. Other possible alloying additions include molybdenum, manganese, and silicon.

The most important microstructural feature in the high-chromium irons, at least from a wear standpoint, is an M_7C_3 carbide, which forms in abundance during solidification and contains chromium, iron, and (if present) molybdenum. The matrix around these carbide particles can be austenitic, pearlitic, or martensitic (Ref 4). In general, the austenitic alloys rely on manganese for austenite stability.

Carbon content is a good indicator of abrasion resistance for this class of materials. To illustrate this fact, low- and high-stress data are plotted for selected alloys in Fig. 1. This information was generated by the use of six different alloys (open arc/flux-cored wires) and nine different sets of welding parameters (Ref 5). The carbon contents referred to in the figures are those of the second layer of the two-layer overlays tested. The use of a shaded zone, rather than a line, indicates that there was considerable scatter in the data (particularly at the lower carbon contents, in the case of high-stress abrasion). The test methods and parameters were identical to those described in the footnotes to Table 1 in this article.

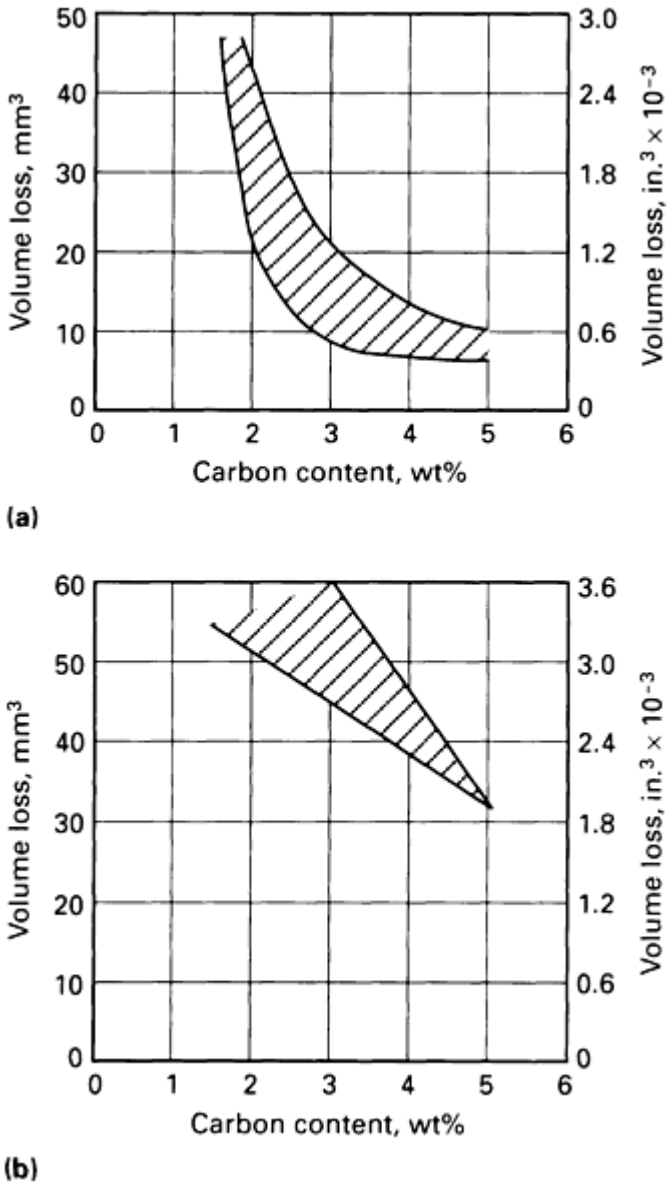

FIG. 1 PLOT OF VOLUME LOSS VERSUS CARBON CONTENT FOR HIGH-CHROMIUM WHITE IRON METAL-TO-EARTH ABRASION HARDFACING ALLOYS. (A) LOW-STRESS CONDITION. (B) HIGH-STRESS CONDITION. SOURCE: REF 5

At high carbon and chromium levels, the formation of a hypereutectic microstructure, containing large, spinelike carbide particles (with a hexagonal cross section), is favored. At lower carbon and chromium contents, the microstructure is hypoeutectic. The microstructures of three high-chromium irons (as deposited by the open arc welding process) are shown in Fig. 2. The nominal compositions of the same three alloys are presented in Table 2. As can be seen, ERFeCr-A3 (at a chromium content of 11 wt% and a carbon content of 2.6 wt%) exhibits a hypoeutectic (primary austenite) microstructure. The other two alloys, ERFeCr-A4(Mod) (29Cr-3.5C) and ERFeCr-A2 (28Cr-4.3C), possess a hypereutectic (primary carbide) structure. In Fig. 2, the large, spinelike carbides are shown in cross section.

TABLE 2 COMPOSITIONS OF HIGH-CHROMIUM WHITE IRONS USED FOR METAL-TO-EARTH ABRASION APPLICATIONS

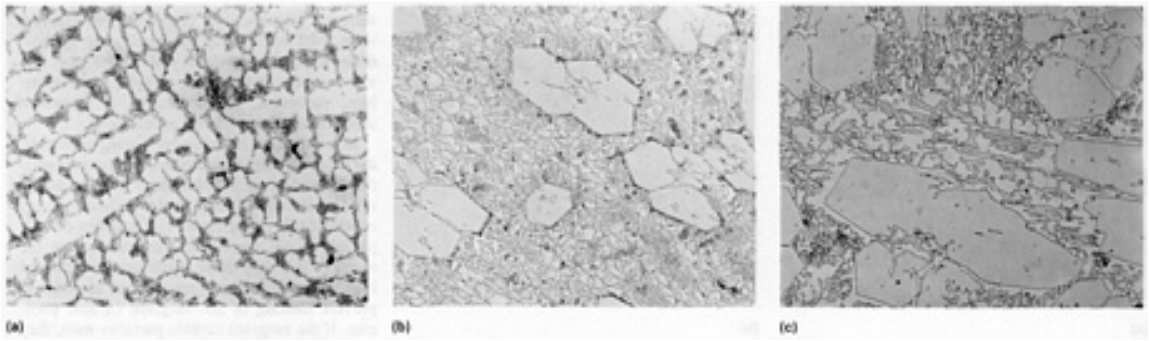

FIG. 2 MICROSTRUCTURES OF HIGH-CHROMIUM WHITE IRON METAL-TO-EARTH ABRASION ALLOYS HARDFACED WITH TWO-LAYER FLUX-COLORED OPEN ARC DEPOSIT. (A) ERFECR-A3. (B) ERFECR-A4(MOD). (C) ERFECR-A2. 300×. SOURCE: REF 2

In addition to M_7C_3, deposits of ERFeCr-A2 contain small quantities of M_6C, and deposits of ERFeCr-A4(Mod) contain small quantities of both M_6C and M_3C. With regard to the matrix, both ERFeCr-A3 and ERFeCr-A4(Mod) exhibit a face-centered cubic (fcc) austenitic structure as deposited. ERFeCr-A2 is largely austenitic but may also contain small quantities of ferrite or martensite. The presence of martensite in the matrix structure of a high-chromium iron is believed to be beneficial to its high-stress abrasion resistance, because of the additional support martensite provides to surface carbides.

For a given hardfacing consumable, deposit (overlay) microstructure is strongly influenced by the welding process and parameters used. Factors of concern, in this regard, include:

- OVERLAY/SUBSTRATE INTERMIXING
- CHANGES IN COMPOSITION DUE TO LOSSES IN THE ARC
- DEPOSIT COOLING RATE

With regard to industrial applications of the high-chromium metal-to-earth abrasion alloys, the low-carbon (2 to 3% C) hypoeutectic materials are usually selected for situations involving moderate abrasion and impact, whereas the higher-carbon (4 to 6% C) hypereutectic alloys are used in applications involving severe abrasion and little or no impact. Specific uses include crusher cones and pump casings (ERFeCr-A3), bulldozer blades and crusher hammers [ERFeCr-A4(Mod)], and coal pulverizer liners and gravel pumps (ERFeCr-A2).

Carbides (Ref 1, 2)

The amount of carbides used for hardfacing applications is small compared to iron-base hardfacing alloys, but carbides are extremely important for severe abrasion and cutting applications. Historically, tungsten-base carbides were used exclusively for hardfacing applications. Recently, however, carbides of other elements, such as titanium, molybdenum, tantalum, vanadium, and chromium, have proved useful in many hardfacing applications.

In contrast to the other hardfacing materials, the tungsten carbide composites do not rely upon the formation of suitable hard phases during weld pool solidification. Instead, these overlay materials rely on the transfer of tungsten carbide particles from the welding consumable to the overlay. It is important, therefore, to limit the heat input of the welding process in order to prevent melting of the tungsten carbide particles. If the tungsten carbide particles melt, they mix with iron to form much softer iron-tungsten carbides, thus reducing abrasion resistance. For this reason, oxyacetylene deposits usually exhibit higher abrasion resistance than arc-welded tungsten carbide overlays. An advantage of the tungsten carbide composites is that the size of the hard particles in the overlay can be controlled. This is important because abrasion resistance is dependent upon the size relationship between microstructural features (such as carbides) and the

abrading particles. It is believed that if the abrading particles are large in comparison to the microstructural particles, then, after a running-in period (during which the softer matrix material at the surface is worn down), the abrading particles ride over the hard microstructural outcrops. On the other hand, if the abrading particles are small in comparison to the microstructural particles, it is believed that the opportunity exists for wear of the matrix around the microstructural particles. Eventually, these may drop out, having played only a small role in resisting abrasion.

Several tungsten carbide composites are available in a variety of tubular product forms. Popular compositions are 40, 50, 55, and 60 wt% tungsten carbide, with a carbon steel tube making up the balance. For each composition, several carbide size ranges are available. As an example, for the 60% tungsten carbide oxyacetylene welding consumable, four mesh size ranges are available:

AWS DESIGNATION	MESH SIZE RANGE
RWC-12/20	12-20
RWC-20/30	20-30
RWC-30/40	30-40
RWC-40/120	40-120

The same composition is also available in flux-coated form for shielded metal arc welding and as a continuous wire (with an internal flux) for open arc welding.

Tungsten carbide composites generally possess very high resistance to abrasion and very low impact strength. Performance in a given situation is dependent upon:

- CARBIDE VOLUME FRACTION
- SIZE RELATIONSHIP BETWEEN THE CARBIDES AND THE ABRASIVE MEDIUM
- WELDING TECHNIQUE APPLIED

Important factors are the distribution of carbides in the overlay (because the particles tend to sink, turbulence in the molten weld pool is an advantage), and the amount of carbide dissolution and reprecipitation in the steel matrix during welding. Impact strength generally decreases with increasing carbide volume fraction.

Table 3 relates tungsten carbide composites and the previously mentioned alloys on the basis of low-stress and high-stress abrasion data (generated under identical test conditions). These values should be compared with the values in Table 1 and Fig. 1. Micrographs of the test deposits are shown in Fig. 3. Noteworthy features include:

- THE DIFFERENCE IN SIZE OF THE TUNGSTEN CARBIDE PARTICLES IN THE TWO MATERIALS
- THE EXTENT TO WHICH SECONDARY CARBIDES HAVE PRECIPITATED WITHIN THE MATRIX

The tungsten carbide composites have been used to solve a wide variety of industrial sliding and drilling abrasion problems. Some of the common applications are plowshares, ditchdigger teeth, ripper teeth, and oil well drilling tools. For extremely hostile environments, some nonferrous tungsten carbide products (cobalt- and nickel-base products in the form of bare cast rods) are available. Also, several alternative composite materials, utilizing other carbides (for example, vanadium, titanium, or niobium), are available that have the advantage of creating a more homogeneous deposit because of their lower densities.

Cobalt-Base Alloys (Ref 1, 2)

The two types of commercially available cobalt-base hardfacing alloys are carbide-containing alloys and alloys containing Laves phase. Compositions and properties of cobalt-base hardfacing alloys are given in Tables 4 and 5, respectively.

Carbide-containing cobalt-base alloys have been widely used since the early 1900s, when a cobalt-base alloy with the nominal composition of Co-28Cr-4W-1.1C was first developed. The chief difference between the various carbide-containing cobalt-base alloys is in carbon content (hence, carbide volume fraction, room-temperature hardness, and level of abrasion resistance). Chromium-rich M_7C_3 is the predominant carbide in these alloys, although tungsten-rich M_6C is evident in those alloys having a high tungsten content, and chromium-rich $M_{23}C_6$ is common in the low-carbon alloys. Figure 4 relates the carbon content and the resistance to low-stress abrasion for the carbide-containing cobalt-base alloys (ERCoCr-A, -B, -C, and -E). The low-stress abrasion data in this figure were generated using the ASTM G 65 dry sand/rubber wheel test.

Laves Phase Alloys. Laves phase is a type of topologically closed-packed intermetallic compound. Historically, metallurgists have avoided the presence of Laves phase in most alloys because of its detrimental effect on mechanical properties. However, in the early 1960s, the usefulness of Laves phase in resisting metal-to-metal wear was discovered; subsequently, alloys containing Laves phase have become commercially available. As listed in Table 4, there are two different Laves phase-containing cobalt-base alloys commercially available for hardfacing applications: Co-29Mo-9Cr-2.5Si (T-400) and Co-29Mo-18Cr-3.5Si (T-800). Both of these alloys contain at least 50 vol% of Laves phase, bound in a cobalt-base matrix alloyed with chromium and molybdenum.

Because the Laves intermetallic phase is so abundant in these alloys, its presence governs all the material properties. Accordingly, the effects of the matrix composition in these alloys are less pronounced than is the case for the carbide-containing cobalt-base alloys. for example. The Laves phase is specifically responsible for outstanding abrasion resistance, but it severely limits the material ductility and the impact strength. In fact, it is difficult to attain crack-free overlays on all but the smallest components given adequate preheat. For this reason, these alloys have been more successful as thermal spray materials. Figure 4 compares the abrasion resistance of various nonferrous hardfacing alloys, including T-400 and T-800 Laves phase cobalt-base alloys. The microstructure of a two-layer plasma transferred arc (PTA) deposit of alloy T-800 is shown in Fig. 6.

Nickel-Base Alloys (Ref 1, 2)

Most commercially available nickel-base hardfacing alloys can be divided into three groups: boride-containing alloys, carbide-containing alloys, and Laves phase-containing alloys. The compositions of some typical nickel-base hardfacing alloys are listed in Table 6. Selected properties of these alloys are listed in Table 7.

The boride-containing nickel-base alloys were first commercially produced as spray-and-fuse powders. The alloys are currently available from most manufacturers of hardfacing products under various tradenames and in a variety of forms, such as bare cast rod, tube wires, and powders for plasma weld and manual torch. This group of alloys is primarily composed of nickel, chromium, boron, silicon, and carbon. Usually, the boron content ranges from 1.5 to 3.5%, depending on chromium content, which can be as high as 16%. The higher chromium alloys generally contain a large amount of boron, which forms very hard chromium borides with hardnesses of approximately 1800 DPH (kg/mm^2).

Of all the hardfacing alloys, the boride-containing nickel-base alloys are microstructurally the most complex. The complexity of this type of alloy structure is evident in Fig. 7, which shows a two-layer PTA deposit of ERNiCr-C (see Table 6 for composition). The alloy compositions represent a progression in terms of iron, chromium, boron, and carbon contents. Iron content is largely incidental, allowing the use of ferrocompounds during manufacture. Together with nickel, the other three elements determine the level and type of hard phase within the structure upon solidification, boron being the primary hard-phase forming element (for which nickel and chromium. compete) and carbon being the secondary hard-phase former. The actual phases that form in boride-containing nickel-base alloys are listed in Table 8 on the basis of chromium content.

TABLE 8 PHASES FORMED IN BORIDE-CONTAINING NICKEL-BASE HARDFACING ALLOYS

CHROMIUM CONTENT	SECONDARY PHASES		DOMINANT HARD PHASE
	COMPOUND FORMED	REQUIRED CONDITIONS	
LOW (~5 WT%)	NI_3SI	>3 WT% SI	NI_3B
MEDIUM (~15 WT%)	NI_3SI	>2.5 WT% SI	NI_3B AND CHROMIUM BORIDE (USUALLY CRB, ALTHOUGH CR_2B AND CR_3B_2 MAY ALSO BE PRESENT)
HIGH (~25	NI_3SI	>3 WT% SI	CRB AND CR_5B_3

WT%)

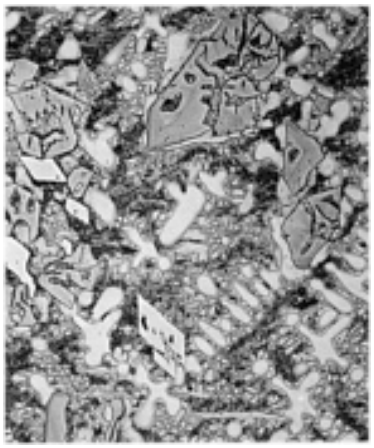

FIG. 7 MICROSTRUCTURE OF ERNICR-C (TWO-LAYER PLASMA TRANSFERRED ARC DEPOSIT) BORIDE-CONTAINING NICKEL-BASE HARDFACING ALLOY. 425×. SOURCE: REF 2

The chief purpose of silicon in the material is to provide, in conjunction with boron, self-fluxing characteristics. However, as an important matrix element and as a potential promoter of intermetallic precipitates, it also has a powerful influence on the wear properties of the alloys.

Boron content influences the level of silicon required for silicide (Ni_3Si) formation. The higher the boron content, the lower is the silicon content required to form silicides.

Because of the boride and carbide dispersions within their microstructures, the boride-containing nickel-base alloys exhibit excellent resistance to abrasion (ERNiCr-C, ERNiCr-B, and Alloy 40 in Fig. 4). Low-stress abrasion resistance generally increases with boron and carbon contents, hence the hard-phase volume fraction for these materials. Although their performance is not as good under self-mated sliding conditions as that of cobalt-base materials, the boride-containing nickel-base alloys possess moderate resistance to galling. Of the nonferrous materials, the boride-containing nickel-base alloys are the least resistant to corrosion. This is attributed to the lack of chromium in the matrix that follows boride and carbide formation.

Originally, the boride-containing nickel-base alloys were developed from brazing alloy compositions specifically for use with the spray-and-fuse process (for which their self-fluxing properties are ideal). During the fusing cycle of this process, it is believed that oxides within the sprayed coating combine with some of the silicon and boron to form a borosilicate slag (which floats to the surface of the deposit). The only other commercially significant spray-and-fuse alloys are some silicon-containing and boron-containing derivatives of the carbide-containing cobalt-base materials. Microstructurally, and in a property sense, these alloys bear little resemblance to their traditional counterparts because the presence of boron markedly changes the matrix chromium content and the types of hard phase that form during solidification. Additional information on the spray-and-fuse process can be found later in this article in the section on "Thermal Spraying."

Carbide-Containing Alloys. The use of carbide-containing nickel-base alloys has been somewhat limited to date. However, these alloys are gaining popularity as alternatives to cobalt-base hardfacing alloys. This is particularly applicable in the nuclear power industry, where it has been found that high-cobalt hardfacing alloys are sources of the highly radioactive ^{60}Co isotope that deposits in pipes, fittings, and valve bodies (Ref 6). Wear and corrosion of hardfacing alloys lead to the release of ^{59}Co into the primary coolant. The ^{59}Co deposits on the reactor core, where it is transmuted to the radioactive ^{60}Co isotope, which is then released back to the coolant. The most popular and widely used cobalt-free alloys are in the Ni-Cr-Mo-C and Ni-Cr-Fe-C systems. Table 6 lists several compositions of these alloys.

Generally, carbide-containing nickel-base alloys have poor oxyacetylene weldability, which has made then unsuitable for hardfacing applications in the past. Carbide-containing nickel-base alloys of the Ni-Cr-Mo-Co-Fe-W-C system are more

readily weldable by oxyacetylene methods and are gaining popularity as low-cost alternatives to cobalt-base alloys. These alloys, depending on precise composition, contain M_7C_3- or M_6C-type carbides similar to cobalt-base alloys.

Laves Phase Alloys. Only one Laves phase-containing nickel-base alloy is commercially available: Ni-33Mo-16Cr-3.5Si (T-700 in Table 6). This alloy, like most nickel-base alloys, is difficult to weld using the oxyacetylene process, but it can be readily welded using gas-tungsten arc welding or the PTA process. It can also be applied using the plasma or high-velocity oxyfuel thermal spray techniques. Although it has excellent metal-to-metal wear resistance and moderate abrasive wear resistance, it possesses poor impact resistance.

High-Silicon Stainless Steels (Ref 2)

Recently, several new high-silicon stainless steels have been introduced that may also be considered as alternate materials to cobalt-base alloys. These exhibit identical anti-galling characteristics and possess equal resistance to cavitation erosion. Some of these have been developed for general use and others for specific applications (for example, hydroelectric turbines and nuclear valves). Some are based on type 200 (manganese- and nitrogen-containing) austenitic stainless steel; others are based on type 300 stainless steel. One of these latter compositions is as follows (Ref 7):

ELEMENT	COMPOSITION, WT%
CARBON	0.12
CHROMIUM	21.0
NICKEL	8.0
SILICON	5.0
MANGANESE	6.5
IRON	BAL

These high-silicon hardfacing alloys differ from the traditional carbide-containing cobalt-base alloys in terms of their corrosion resistance (they are better in some aqueous media and worse in others), their mechanical properties (particularly at high temperatures), and their thermal stability.

Copper-Base Alloys (Ref 2)

Copper-base hardfacing alloys fall in the aluminum bronze category. Examples include ECu-AlB (Cu-9Al-4Fe-1Si) and ECuAl-D (Cu-13.5Al-4Fe). Silicon and other types of bronze are also available in welding consumable form for hardfacing. Aluminum, silicon, and iron are added to the bronzes to strengthen the solid solution, and, in excess of their solubility limits (about 8%, in the case of aluminum), to provide precipitation hardening.

Wear tests have shown that the aluminum bronzes possess anti-galling characteristics (self-coupled) comparable to those of ER-CoCr-E; low-stress abrasion resistance of the aluminum bronzes, however, was very low. Components typically protected using the aluminum bronzes include gears, cams, bearings, and cold drawing/forming dies. These alloys are not recommended for elevated-temperature use because their mechanical properties considerably decrease at temperatures >200 °C (>390 °F).

Hardfacing Alloy Selection (Ref 1)

Hardfacing alloy selection is guided primarily by wear and cost considerations. However, other manufacturing and environmental factors must also be considered, such as base metal; deposition process; and impact, corrosion, oxidation, and thermal requirements. The factors affecting hardfacing process selection are discussed in the next section of this article. Usually, the hardfacing process dictates the hardfacing or filler-metal product form.

Hardfacing alloys usually are available as bare rod, flux-coated rod, long-length solid wires, long-length tube wires (with and without flux), or powders. The most popular processes, and the forms most commonly associated with each process, are (Ref 2):

HARDFACING PROCESS	CONSUMABLE FORM
OXYFUEL/OXYACETYLENE (OFW/OAW)	BARE CAST OR TUBULAR ROD
SHIELDED METAL ARC (SMAW)	COATED SOLID OR TUBULAR ROD (STICK ELECTRODE)
GAS-TUNGSTEN ARC (GTAW)	BARE CAST OR TUBULAR ROD
GAS-METAL ARC (GMAW)	TUBULAR OR SOLID WIRE
FLUX-CORED OPEN ARC	TUBULAR WIRE (FLUX CORED)
SUBMERGED ARC (SAW)	TUBULAR OR SOLID WIRE
PLASMA TRANSFERRED ARC (PTA)	POWDER
LASER BEAM	POWDER

In general, the impact resistance of hardfacing alloys decreases as the carbide content increases. As a result, in a situation where a combination of impact and abrasion resistance is desired, a compromise between the two must be made. In applications where impact resistance is extremely important, austenitic manganese steels are used to build up worn parts.

Frequently, wear is accompanied by aqueous corrosion from acids or alkalis, such as those encountered in the chemical processing or petroleum industries or in flue gas scrubbers. Few of the iron-base hardfacing alloys possess the necessary corrosion resistance in such aqueous media. As a result, nickel- or cobalt-base hardfacing alloys generally are recommended when corrosion resistance combined with wear resistance is required. For example, a knife used to cut tomatoes in a food processing plant can last many times longer than a tool steel knife if the edge is made of a cobalt-base alloy.

Oxidation and hot corrosion resistance of iron-base alloys is also generally poor. Typically, boride-containing nickel-base alloys do not contain sufficient chromium in the matrix to resist oxidation. Hence, Laves phase-containing or carbide-containing nickel- or cobalt-base alloys typically are recommended for applications in which wear resistance combined with oxidation or hot corrosion resistance is required.

The ability of an alloy to retain strength at elevated temperatures is important for wear applications such as hot forging dies or valves for service at 870 °C (1600 °F), as well as service in coal gasification/liquefaction applications. Iron-base alloys with martensitic structures lose hardness at elevated temperatures. Generally, the high-temperature strength retention of a hardfacing alloy increases with its tungsten or molybdenum content. In applications requiring elevated-temperature strength and wear resistance, cobalt-base alloys or Laves phase alloys are recommended.

Wear-resistant materials typically are classified by type and alloy content, which largely determines their properties. These materials have structures consisting of hard phases (carbides, borides, or Laves phases) in a matrix hardened to a level that depends on the desired alloy properties.

Table 9 provides an extensive list of hardfacing materials along with their specific advantages and applications. Such recommendations are also available from producers of hardfacing alloys. The following steps should be taken in selecting a hardfacing alloy:

- ANALYSIS OF THE SERVICE CONDITIONS TO DETERMINE THE TYPE OF WEAR AND ENVIRONMENTAL RESISTANCE REQUIRED
- SELECTION OF SEVERAL HARDFACING ALLOY CANDIDATES
- ANALYSIS OF THE COMPATIBILITY OF THE HARDFACING ALLOYS WITH THE BASE METAL, TAKING INTO CONSIDERATION THERMAL STRESSES AND POSSIBLE CRACKING
- FIELD TESTING OF HARDFACED PARTS
- SELECTION OF AN OPTIMUM HARDFACING ALLOY, CONSIDERING COST AND WEAR LIFE
- SELECTION OF THE HARDFACING PROCESS FOR PRODUCTION OF WEAR COMPONENTS, CONSIDERING DEPOSITION RATES, THE AMOUNT OF DILUTION, DEPOSITION,

EFFICIENCY, AND OVERALL COST, INCLUDING THE COST OF CONSUMABLES AND PROCESSING

TABLE 9 SELECTION GUIDE FOR HARDFACING ALLOYS

TYPES OF MATERIALS	ADVANTAGES	APPLICATIONS
LOW HARDNESS		
PEARLITIC STEELS	LOW COST, CRACK-RESISTANT	A BUILDUP MATERIAL TO RESTORE DIMENSION OR AS A LOW-COST BASE FOR SURFACING APPLICATIONS
MILD STEELS	AN EXCELLENT BASE FOR HARDFACING	
LOW-ALLOY STEELS	SOME TOUGHNESS FOR BUILDUP OF WORN AREAS	
AUSTENITIC STEELS	EXCELLENT FOR HEAVY IMPACT, TOUGH	FOR METAL-TO-METAL WEAR UNDER HEAVY IMPACT CONDITIONS
LOW-CARBON NI-CR STAINLESS	GOOD CORROSION RESISTANCE	CORROSION-RESISTANT SURFACING OF LARGE TANKS, NUCLEAR VESSELS
HIGH-CARBON NI-CR STAINLESS	OXIDATION AND HOT WEAR RESISTANT	FURNACE PARTS, RED HEAT FRICTIONAL WEAR
14% MN, CR-NI	HIGH YIELD STRENGTH AUSTENITIC	BUILDUP, CRACK REPAIR, JOINING MANGANESE ALLOYS OR MANGANESE TO MILD STEEL
14% MN, 1% MO	FAIR ABRASION AND CORROSION RESISTANCE, WORK HARDENS	RAILWAY TRACK BUILDUP
14% MN, 3% NI	WORK HARDENS	BUILDUP AND JOINING OF MANGANESE PARTS
SEMIAUSTENITIC STEELS	LOW-COST CRACK-RESISTANT MATERIALS	HARDFACING APPLICATIONS
COPPER ALLOYS	RESISTANCE TO SEIZING UNDER FRICTIONAL WEAR CONDITIONS	FOR BUILDUP OF BEARING SURFACES
MEDIUM HARDNESS		
NICKEL-BASE ALLOYS	GOOD CORROSION RESISTANCE AND EXCELLENT HOT HARDNESS	FOR APPLICATIONS WHERE HOT HARDNESS IS IMPORTANT
NICKEL-CHROMIUM	RESISTANCE TO OXIDATION	FOR CORROSIVE WEAR CONDITIONS
NICKEL-CHROMIUM-MOLYBDENUM	RESISTANCE TO EXHAUST GAS CORROSION	FOR HARDFACING TRUCK, BUS, AND AIRCRAFT ENGINE VALVES
NICKEL-CHROMIUM-MOLYBDENUM-TUNGSTEN	CORROSION-RESISTANT PROPERTIES	FOR SURFACING APPLICATIONS
NICKEL-CHROMIUM-BORON	CORROSION-RESISTANT AS WELL AS ABRASIVE-	PUMPING SERVICE APPLICATIONS, ESPECIALLY IN THE OIL FIELDS

	RESISTANT PROPERTIES	
MARTENSITIC ALLOY IRONS	EXCELLENT ABRASION RESISTANCE	FOR OVERCOMING ABRASIVE WEAR WHERE LIGHT OR NO IMPACT IS INVOLVED
CHROMIUM-MOLYBDENUM	ABRASION RESISTANCE WHILE WITHSTANDING LIGHT IMPACT	FOR THE BUILDUP OF MACHINE PARTS SUBJECT TO REPETITIVE METAL-TO-METAL WEAR WITH OR WITHOUT LIGHT IMPACT
CHROMIUM-TUNGSTEN	HIGH COMPRESSIVE STRENGTHS	
AUSTENITIC ALLOY IRONS	BETTER CRACK-RESISTANT PROPERTIES THAN THE MARTENSITIC ALLOY IRONS	WHERE EROSIVE WEAR WITH OR WITHOUT LIGHT IMPACT IS PRESENT
CHROMIUM-MOLYBDENUM	GOOD CRACK-RESISTANT QUALITIES	PUMP AND TURBINE BUILDUP
NICKEL-CHROMIUM	CRACK-RESISTANT, LIGHT IMPACT	FOR EROSIVE WEAR WITH LIGHT IMPACT
MARTENSITIC STEELS	ABRASION RESISTANCE WITH MEDIUM IMPACT	FOR A VARIETY OF ABRASIVE WEAR CONDITIONS WHERE THERE MAY ALSO BE INVOLVEMENT WITH MEDIUM IMPACT
LOW CARBON (UP TO 0.30% C)	LEAST EXPENSIVE, TOUGH	
MEDIUM CARBON (0.30-0.65% C)	GOOD RESISTANCE TO MEDIUM IMPACT	
HIGH CARBON (0.65-1.7% C)	FAIR ABRASION RESISTANCE	
HIGH HARDNESS		
HIGH-CHROMIUM IRONS	EXCELLENT EROSION-RESISTANT PROPERTIES	FOR GENERAL USE WHERE HOT GASES OR MATERIALS ARE INVOLVED
AUSTENITIC	GOOD ABRASION-RESISTANT QUALITIES	FOR FARM AND EARTH-MOVING EQUIPMENT WORKING IN SANDY SOILS
MARTENSITIC	ABILITY TO BE REHARDENED AFTER ANNEALING	AS A HARDFACING IN STEEL MILLS AND REFINERIES WHERE HOT EROSION (595 °C, OR 1100 °F) IS A WEAR PROBLEM
TUNGSTEN-MOLYBDENUM ALLOYS	HIGH RED HARDNESS	FOR HARDFACING OF COKE OVEN PARTS AS WELL AS OTHER HOT (425 TO 650 °C, OR 800 TO 1200 °F) STEEL MILL APPLICATIONS
CHROMIUM-TUNGSTEN-COBALT ALLOYS	HIGH RED HARDNESS, HIGH HOT STRENGTH AND CREEP-RESISTANT QUALITIES	FOR MOST HARDFACING APPLICATIONS, BUT BEST SUITED TO THOSE APPLICATIONS WHERE HOT WEAR AND ABRASION (ABOVE 650 °C, OR 1200 °F) ARE INVOLVED (JET ENGINE TURBINE BLADES, GAS ENGINE EXHAUST VALVE)
LOW CARBON (UP TO 1.0% C)	GOOD OXIDATION RESISTANCE, TOUGH	
MEDIUM	RESISTANT TO ABRASION AND	

CARBON (1.4% C)	OXIDATION	
HIGH CARBON (2.5% C)	GOOD ABRASION RESISTANCE, BRITTLE	
TUNGSTEN CARBIDES	THE ULTIMATE IN ABRASION-RESISTANT QUALITIES	A VARIETY OF MATERIALS USED FOR HARDFACING TO MEET AN EXTREMELY WIDE RANGE OF SEVERE ABRASIVE CONDITIONS, ESPECIALLY OIL WELL DRILL BITS, TOOL JOINTS, ROCK DRILL BITS
FINE-GRAIN TUBULAR RODS	A RELATIVELY SMOOTH, EXTREMELY WEAR-RESISTANT SURFACE, GAS WELD	
COARSE GRANULAR TUBE ROD	DEVELOPS A ROUGH CUTTING SURFACE AS THE DEPOSITED BINDER WEARS AWAY	
GRANULES OR INSERTS	DEVELOPS AN EXTREMELY ROUGH ABRASIVE CUTTING SURFACE AS GRANULES OR INSERTS BECOME MORE EXPOSED. HIGHLY ABRASIVE, BUT BRITTLE UNDER IMPACT CONDITIONS

Hardfacing Process Selection (Ref 1)

Hardfacing process selection may be as important as hardfacing alloy selection, depending on the engineering application. Service performance requirements not only dictate hardfacing alloy selection, but also have a strong influence on hardfacing process selection. Other technical factors involved in hardfacing process selection include (but are not limited to) hardfacing property and quality requirements, physical characteristics of the workpiece, metallurgical properties of the base metal, form and composition of the hardfacing alloy, and welder skill. Ultimately, economic considerations predominate, and cost is the determining factor in the final process selection.

The term "hardfacing" is sometimes used to describe true welding processes, in which both the filler material and a small amount of the base metal are molten and are bonded metallurgically. Such processes, which include oxyfuel, arc, and laser welding methods, are preferred for applications that require dense and relatively thick coatings with excellent bonding between the hardfacing material and the base metal. Thermal spray processes are used for applications that require a thin, hard coating applied with minimum work distortion and where a purely mechanical bond between the hardfacing material and the base metal is acceptable.

Property and Quality Requirements. Welded hardfacing deposits are, in effect, mini-castings characterized by variable composition (segregation) and solidification kinetics that influence deposit microstructure. It is not surprising, therefore, that the properties and quality of welded hardfacing deposits should depend on welding process and technique, as well as on alloy selection.

Composition variations also derive from base-metal dilution during welding, although carbon pickup in oxyfuel gas welding (OFW) processes and solute volatilization during arc welding processes are additional factors. Dilution is the inter-alloying of the hardfacing alloy and the base metal and is usually expressed as the percentage of base metal in the hardfacing deposit. A dilution of 10% means that the deposit contains 10% base metal and 90% hardfacing alloy (see the section on "Weld Cladding" in this article for more detailed information). The wear resistance and other desirable properties of the hardfacing alloy are generally thought to degrade as dilution increases. The maximum amount of allowable dilution depends on specific service requirements. Welding process and technique should, however, be selected so as to control dilution to less than 20% for the hardest layer. More dilution is acceptable for buildup layers.

Dilution is nil in thermal spraying processes and tends to be acceptably low in conventional OFW processes. Dilution is generally more of a problem in arc weld hardfacing processes, ranging from approximately 5% in plasma arc welding

(PAW) hardfacing processes to as much as 50% in submerged arc welding (SAW). Laser hardfacing dilution is also low, ranging generally from 1 to 10%. High-dilution welding processes can be tolerated in applications requiring relatively thick hardfacings that can be applied in multiple layers. The effects of dilution on the microstructure of a high-chromium, white iron hardfacing alloy deposited in multiple layers on low-carbon steel substrate using shielded metal arc welding (SMAW) are illustrated in Fig. 8. The first layer (Fig. 8a) microstructure in this particular case was hypoeutectic with interdendritic eutectic and exhibited a hardness of 55 HRC. The second layer (Fig. 8b) consisted of a fine hypereutectic microstructure with a large percentage of eutectic and exhibited a hardness of 57 HRC. The third (Fig. 8c) and fifth (Fig. 8d) layers were microstructurally equivalent, consisting of primary M_7C_3 carbides in eutectic matrices. The hardness in the third and subsequent layers ranged from 60 to 61 HRC.

(C) THIRD LAYER SHOWING A COARSE HYPEREUTECTIC STRUCTURE OF PRIMARY M_7C_3 CARBIDES IN A EUTECTIC MATRIX, 61 HRC. (D) FIFTH LAYER SHOWING A STRUCTURE SIMILAR TO BOTH THE THIRD AND FOURTH PASSES, 60 HRC. SOURCE: REF 1

The microstructures and mechanical properties of hardfacing deposits, like castings, vary depending on solidification kinetics as well as on dilution. Solidification generally is rapid in thermal spray processes, with nearly amorphous structures being achieved with some thermal spray processes. Solidification kinetics tend to be somewhat slower in conventional weld hardfacing processes. As a rule, hardfacing deposits produced by OFW processes tend to solidify more slowly than hardfacing deposits produced by arc welding processes. These differences in solidification rate produce widely different microstructures and widely different properties regardless of dilution. The effects of welding process on the microstructure of a cobalt-base (ERCoCr-A) hardfacing alloy deposited on a low-carbon steel substrate are illustrated in Fig. 9.

Physical Characteristics of the Workpiece. The size, shape, and weight of the workpiece have a strong influence on hardfacing process selection. Large, heavy workpieces that are difficult to transport are most conveniently hardfaced using manual or semiautomatic hardfacing processes in which the hardfacing equipment can be moved to the workpiece. Gas shielded metal arc and open arc welding processes, for which portable equipment is readily available, are well suited to field applications involving inaccessible surfaces on large, difficult-to-transport workpieces. Thermal spraying processes and equipment also are available for *in situ* field hardfacing applications.

Hardfacing process selection is more involved in applications where the workpiece is sufficiently small so that it can be readily transported to the welding equipment. Thermal spraying processes and OFW, SAW, gas-tungsten arc welding (GTAW), PAW, and gas-tungsten arc welding (GMAW) are all well suited to in-plant hardfacing of small workpieces. Preference is usually given to thermal spraying and/or OFW or GTAW for small workpieces requiring thin, accurately placed hardfacing deposits. Large quantities of small workpieces can usually be hardfaced most economically using dedicated, specially designed, fully automatic hardfacing equipment and processes.

Metallurgical Characteristics of the Base Metal. As described below, base-metal surface preparation is important in thermal spray hardfacing processes. However, base-metal composition, melting temperature range, and thermal expansion and contraction characteristics have a significant effect on welding process selection.

Steels are generally suitable base metals for hardfacing. Low-alloy and medium-carbon steels with carbon contents up to 0.4% can be easily hardfaced by all welding processes with generally excellent results. Higher-carbon steels are similarly readily amenable to hardfacing, but preheating is necessary to minimize deleterious martensitic reactions in the heat-affected zone (HAZ). Austenitic stainless steels, with the exception of the free-machining grades, and most nickel-base alloys can also be easily hardfaced by all welding processes with excellent results. Martensitic stainless steels, tool steels, die steels, and cast irons are also amenable to hardfacing, but greater attention to preheat, interpass temperature, and postweld heat treatment is required. Age-hardenable base metals present special hardfacing problems and generally require solution and/or overaging heat treatments prior to hardfacing, as well as careful attention to preheat, interpass temperature, and postheat.

Hardfacing welding processes require that the base metal melting temperature range be higher than or at least equal to that of the hardfacing alloy. Thermal spraying processes, on the other hand, do not require a base metal melting temperature advantage.

Base metal thermal expansion and contraction characteristics affect solidification strain. Workpieces frequently have to be uniformly heated to relatively high temperatures during welding to enable the deposition of crack-free hardfacing alloys. Welding process selection is important in that it directly affects heat input and preheat requirements.

Thermal expansion and contraction differences between the hardfacing alloy and base metal are important in applications involving thermal cyclic service conditions. Large differences can result in shear failures in thermal spray deposits or thermal fatigue failures in welded deposits. Buffer layers are often deposited between the base metal and hardfacing alloy to counteract large differences in thermal expansion and contraction characteristics. Frequently, dilution, which is generally regarded to be detrimental, can be used to good advantage to form *in situ* buffer layers and to minimize the risk of thermal fatigue failure. Hardfacing process selection is an important consideration in this regard.

Hardfacing Product Forms. Hardfacing process selection is often limited by product form. Hardfacing alloys normally are available as bare cast rod, covered electrodes, wire, and powders. However, not all alloys are available in all product forms.

Virtually all hardfacing alloys can be produced in powder form, and most hardfacing alloys can be produced in rod form. Rods generally are available in bare cast form or in tubular form. Bare cast rod diameters are limited to a large extent by alloy characteristics and casting processes to a range of 3.2 to 8.0 mm ($\frac{1}{8}$ to $\frac{5}{16}$ in.). Bare cast rod lengths usually range from 250 to 700 mm (10 to 28 in.), but some hardfacing alloys can be cast in extra long, continuous lengths with diameters as small as 3.2 mm ($\frac{1}{8}$ in.). Tubular rods consist of highly alloyed powder cores encased in low-alloy sheaths. Tubular rods can be produced in discrete lengths or in spooled continuous coils. Discrete-length tube rods generally are available in the same diameter range as bare cast rod. Long-length tube rods, or tube wire as they are properly named, normally are available in diameters ranging from 4.0 to 1.6 mm ($\frac{5}{32}$ to $\frac{1}{16}$ in.). Some of the tougher, more ductile hardfacing alloys can be produced as solid drawn wire. Some of the more brittle hardfacing alloys can be produced, at a premium cost, as solid wire using extrusion techniques.

Welder Skill. It is essential to consider hardfacing quality requirements in relation to welder/operator skill, as well as in relation to the hardfacing process. As a rule, hardfacing by manual welding processes such as OFW or GTAW requires high welder proficiency, whereas hardfacing by automatic welding processes, such as SAW, requires a minimum of operator skill, assuming machine control settings have previously been established. Thermal spraying and related powder welding processes generally require intermediate welder/operator skills.

Manual GTAW can be used to obtain high-quality deposits on relatively small areas, such as the interlock regions of turbine blades. In this type of application, thin layers can be deposited with dilution as low as 10%, but relatively high welder skill and close control of the welding operation are necessary. In contrast, earthmoving and mining equipment can be hardfaced adequately in the field by relatively unskilled welders. Selection of process is usually based on maximum deposition rate: high dilution rates seldom significantly affect the suitability of the coating for service.

Cost is ultimately the determining factor in hardfacing process selection. Hardfacing costs basically consist of labor, materials, and in some instances, new equipment cost. Transportation cost also must be considered.

Labor costs depend primarily on the level of welder skill required and process deposition rates, but surface preparation and finishing costs also must be considered. Deposition rates are normally lowest with manual hardfacing processes. Considerably higher deposition rates are possible with automatic arc welding hardfacing processes. Deposition rates as high as 27 kg/h (60 lb/h) are possible with multiwire or powder and wire submerged arc hardfacing processes, but dilution is also high. An ideal welding process for hardfacing would be one with the ability to limit dilution while achieving a high deposition rate. Typical dilution percentages; deposition rates; and minimum deposit thicknesses for different welding processes and various forms, compositions, and modes of application of hardfacing alloys are given in Table 10.

TABLE 10 CHARACTERISTICS OF WELDING PROCESSES USED IN HARDFACING

WELDING PROCESS	MODE OF APPLICATION	FORM OF HARDFACING ALLOY	WELD-METAL DILUTION, %	DEPOSITION		MINIMUM THICKNESS[A]		DEPOSIT EFFICIENCY, %
				kg/h	lb/h	mm	in.	
OAW	MANUAL	BARE CAST ROD, TUBULAR ROD	1-10	0.5-2	1-4	0.8	MATH OMITTED	100

(D) VARIES WIDELY DEPENDING ON POWDER FEED RATE AND LASER INPUT POWER

Hardfacing material costs depend on the prevailing price of raw materials and product form. Raw material cost is predominant in tungsten-, cobalt-, and nickel-base hardfacing alloys, whereas product form is the predominant cost in iron-base hardfacing alloys. As a rule, tubular rod and wire are the least expensive hardfacing product forms. In contrast, solid wire is the most expensive hardfacing product form. Cast rod and powder are generally intermediate in cost. Powder, depending on specific powder size requirements, tends to be less expensive than cast rod. However, deposit efficiency, measured as the percentage of hardfacing consumable retained on the workpiece surface, is generally slightly lower for hardfacing processes that utilize powder consumables than for hardfacing processes that utilize rod consumables. Thermal spraying processes are particularly poor in this regard, with typical deposit efficiencies as low as 70%.

Equipment costs vary from simple arc welding equipment to fully automated laser beam hardfacing systems. The more advanced automatic hardfacing equipment often costs 100 to 1000 times as much as simple arc welding equipment, depending on the level of instrumentation and computer control.

It is relatively easy to estimate or predetermine the cost of hardfacing. It is more difficult to estimate the value of hardfacing. For maintenance applications, it has been suggested that hardfacing is preferred over total replacement when the cost advantage (*CA*) is positive. The cost advantage can be calculated by:

$$CA = \frac{CN}{PN} - \frac{CR}{PR} \qquad \textbf{(EQ 1)}$$

where *CN* is the cost of a new component; *CR* is the cost of hardfacing plus downtime costs; *PN* is the work output during the service life of a new component; and *PR* is the work output during the service life of a hardfaced component. Most of the data needed for the above calculation usually can be obtained; *PR* is perhaps the most difficult value to assess, but reasonable estimates can be made based on relative laboratory wear test results. If the workpiece is hardfaced with an alloy of essentially the same chemical composition as the wom material, it is reasonable to assume that *PR* = *PN.* On the

other hand, if the hardfacing material is more wear-resistant than the worn material, then *PR* > *PN*. Therefore, from Eq 1, *CA* is likely to be positive, which is the primary objective of hardfacing.

Hardfacing by Oxyfuel Gas Welding

Oxyfuel gas welding (OFW) is a process in which the heat from a gas flame is used to melt hardfacing materials onto workpiece surfaces. During hardfacing, the workpiece is only superficially melted. The gas flame is created by the combustion of a hydrocarbon gas and oxygen. Acetylene is the most widely used fuel for OFW. In fact, OFW is commonly referred to as oxyacetylene welding (OAW), even though other fuel gases, such as methylacetylene propadiene (MAPP), occasionally are used in certain OFW processes.

Hardfacing by OFW is a versatile process, readily adaptable to all hardfacing product forms, including powder. As described below, OFW hardfacing processes that use fillers in powder form are commonly referred to as manual powder torch welding or powder welding. Oxyfuel gas welding equipment is simple, and capital equipment costs are low. Furthermore, OFW equipment is mobile and can be used for fusion welding and cutting operations, as well as for hardfacing. More importantly, OFW processes generally produce hardfacing deposits with optimum microstructures for wear-resistant applications.

Hardfacing by OFW, however, is not without limitations. Hardfacing by manual OAW requires a high degree of welder skill to obtain smooth, high-quality deposits, as the welding rod and the torch flame have to be separately manipulated. The speed of welding and low deposition rates often preclude the use of OAW for hardfacing applications on large components that require large quantities of hardfacing alloy, unless automation of the operation is warranted by configuration of the surface and a large number of identical parts.

Oxyacetylene welding is best suited to hardfacing applications in which the surface area to be hardfaced is minimal. Thus, for hardfacing steam valves, automotive and diesel engine valves, cutter blades for wood and plastic, chain saw bars, and plowshares and other agricultural implements, it is often the most satisfactory process as it can be easily employed in field applications.

Most steel workpieces can be hardfaced by OFW processes. High-manganese and high-sulfur steels are exceptions. High-speed steel workpieces are difficult to hardface and should be fully annealed before hardfacing. Cast iron workpieces also can be hardfaced by OFW processes, but cast iron substrates generally require the use of fluxes and special welding precautions.

Dilution is generally low (1 to 10%) in OFW hardfacing deposits, as only the surface of the workpiece in the immediate area being hardfaced is brought to the melting temperature. The hardfacing rod is melted and spread over the surface of the workpiece. The melted rod does not mix or alloy with the base metal, but only with the melted surface. Superficial workpiece melting of steel workpieces produces a wet appearance, called "sweating."

Operating Procedures. Workpiece surfaces must be thoroughly cleaned before hardfacing. If impurities are present on surfaces of the workpiece, or if an excessive amount of oxide is produced in heating (usually, a neutral or reducing flame is used), it may be necessary to dislodge the solid contaminants by prodding or rubbing with a hardfacing rod tip. Oxide trapped beneath the hardfacing overlay can react with carbon in the hardfacing alloy to produce a gas and thus cause porosity. Hardfacing alloys usually contain a deoxidizer that controls a moderate amount of oxidation.

It is often necessary to preheat workpieces prior to hardfacing, regardless of the welding process, to prevent cracks in the hardfacing deposit. Preheating not only reduces tensile strain associated with thermal contraction differences between the hardfacing alloy and the workpiece, but in the case of OFW, also permits the use of a softer flame and results in less dilution. Small low-carbon steel workpieces can be preheated locally with a torch, but large workpieces are best preheated with gas burners in a brick muffle furnace, allowing sufficient soak time to ensure even heating.

With practice, one-layer hardfacing deposits up to 1.6 mm ($\frac{1}{16}$ in.) thick can be deposited, particularly if the workpiece is inclined so that the deposition is slightly uphill. Alternatively, thick deposits can be applied in several layers. Hardfacing deposits by OFW can be remelted as necessary to improve deposit quality or surface appearance.

Common Flaws. Hardfacing deposits applied by OFW generally are characterized by low dilution and high deposit quality. Discontinuities are possible, however, depending on the skill of the welder and the quality of the filler material.

Porosity is probably the most common flaw observed in hardfacing deposits applied by OFW. Porosity in hardfacing deposits, like porosity in castings, can result from inadequate feeding or gas evolution during solidification. Porosity resulting from inadequate feeding is sometimes referred to as microshrinkage. Microshrinkage is most common at the termination of the hardfacing deposit and usually results from the inability of the hardfacing deposit to accommodate solidification shrinkage after the flame is withdrawn. This type of flaw can be minimized or prevented by withdrawing the flame very slowly and allowing solidification to progressively occur from the bond line to the surface.

Porosity can also occur by gas evolution during solidification if the total gas content in the molten deposit is greater than the solid solubility limit. Gas-induced porosity generally derives from slag or non-metallic inclusions trapped in or on the surface of the base metal. However, the initial gas content of the filler materials and possible gas pickup during OFW are also contributing factors.

Manual Powder Torch Welding (Ref 9)

Also termed "powder welding," manual powder torch welding is a modified OFW process in which powder application and fusion occur in a single operation using a special oxyacetylene torch. Powder is fed from a small hopper mounted on a gas welding torch into the fuel gas supply and conveyed through the flame to the workpiece surface. By following general oxyacetylene surfacing practice, smooth, thin, dense deposits are obtained. Deposit thickness is controlled by powder flow rate and movement of the torch. A dilution of 1 to 5% in the deposit occurs from this process.

Deposits ranging from 0.75 to 3 mm (0.030 to 0.125 in.) in thickness can be applied at a rate of 1.3 mm (0.050 in.) per pass. Sweating of the base metal during surfacing generates a fusion-type bond with the hardfacing alloy. Ease of application and material recovery are enhanced because of close control of the powder flow into the welding flame.

Oxyacetylene torch flame adjustment is essential to produce good powder deposition. The amount of excess acetylene required for hardfacing varies depending on alloy composition. The amount of excess acetylene is conveniently measured in terms of the flame geometry as the ratio between the length of the oxyacetylene feather and the length of the inner cone. The length of the inner cone, indicated by the value *X*, is the distance from the torch tip to the extreme end of the inner cone.

The length of the oxyacetylene feather is measured from the torch tip to the extreme end of the intermediate zone, generally expressed in multiples of the length of the inner cone. A neutral flame is thus classified as 1×. Cobalt-base powders are usually applied using 2× to 3× flame. The oxyacetylene feather is two to three times the length of the inner cone.

Tungsten carbide-containing composite powders should be applied using a 1.5× flame. Nickel-base powders are welded with a neutral or slightly oxidizing flame. Because flame characteristics change somewhat when powder is being sprayed, the powder feed handle should be depressed and final flame adjustment made while the powder is being sprayed. Alloys commonly welded with this process contain boron and silicon, which combine with any oxide skin to form an easily removed slag and to provide a clean weld pool.

The manual torch process is well suited for small repairs or for hardfacing of small areas requiring a wide range of hardnesses (about 20 to 60 HRC). Typical applications of manual torch welding include glass dies and molds, brick molding equipment, components for the cement industry, cast iron parts for foundries, feed screws, hammer mill hammers, and pump parts.

Hardfacing by Arc Welding (Ref 1)

In hardfacing by arc welding, the heat from an electric arc is used to melt the hardfacing material onto the workpiece surface. The electric arc is developed by impressing a voltage between an electrode and the workpiece. The voltage required to sustain the arc varies with the distance between the electrode and workpiece and with the arc welding process. The filler material is provided by the electrode used to form the arc or can be externally introduced into the arc. Arc welding processes in which the filler derives directly from the electrode are sometimes referred to as consumable electrode processes. Arc welding processes in which the filler is externally introduced into the arc are sometimes referred to as nonconsumable electrode processes. As a rule, nonconsumable electrode processes are accomplished at lower power requirements than are consumable electrode processes, resulting in less dilution and lower deposition rates. Consumable and nonconsumable electrode hardfacing processes both require that the filler materials be protected from oxidation as they are melted and joined to the workpiece surfaces.

Filler materials in consumable electrode hardfacing processes are sometimes protected by fluxes as in SMAW, SAW, and flux-cored open arc welding, or by inert gases, as in GMAW. The selection of a particular consumable or nonconsumable electrode hardfacing process depends on consideration of the factors discussed in the section on "Hardfacing Process Selection" in this article.

Shielded Metal Arc Welding. The electrodes used in the SMAW consumable electrode hardfacing process generally consist of discrete lengths of filler material rod covered with specially formulated coatings. The filler material rod generally ranges in diameter from 3.2 to 8.0 mm ($\frac{1}{8}$ to $\frac{5}{16}$ in.) and may be cast or of tubular construction. The electrode coating protects the filler material during welding by chemical reaction as the electrode melts. The coating can be fortified to increase alloy content during melting, as well as to simply provide molten metal protection. Coating ingredients also determine or affect the shape of the weld, amount of penetration, cooling rate of the weld, stabilization of the arc, and refinement of the hardfacing deposit.

The selection of the proper power supply for SMAW consumable electrode hardfacing is not a serious problem. Motor-generators, direct current rectifiers, and alternating current transformers can be used. Direct current electrode positive (DCEP) normally is recommended for hardfacing. Direct current electrode negative (DCEN) can be used to increase deposition rates slightly, but there is a tendency for the weld beads to be high and narrow. Although direct current is recommended, alternating current has been used in many applications with reasonably good success. Arc stability and burnoff characteristics are not quite as good by this method.

Speed of travel, position of the electrode in relation to the weld pool, arc voltage, and amperage are modified to minimize penetration and the consequent dilution of the deposit. Typical welding currents for small 3.2 mm ($\frac{1}{8}$ in.) diam hardfacing electrodes range from 60 to 130 A, depending on the alloy. Welding currents for larger 6.4 mm ($\frac{1}{4}$ in.) diam hardfacing electrodes range from 150 to 330 A.

Depending on the surface area to be hardfaced, the bead-deposit pattern may be of the stringer or weave type, with or without staggering of beads, as dictated by service requirements. Selection of the bead pattern and sequence also depends on the accessibility of the surface to be hardfaced and the distortion limits of the workpiece.

Deposition rates vary considerably with welding conditions. Normally from 1.4 to 1.8 kg (3 to 4 lb) of metal per hour of arc time can be applied. The recovery of alloy in the deposit generally ranges from 65 to 75% of the electrode weight, excluding stub loss. The average stub loss is approximately 75 mm (3 in.), which corresponds to about 20% of a 350 mm (14 in.) long electrode.

There are many advantages to the SMAW consumable electrode process. The intense heat of the arc permits the hardfacing of large parts without preheat. Small areas of parts machined or fabricated to close tolerances can be hardfaced without distorting the entire part. Difficult-to-reach areas are best accessed with coated electrodes. The overall process is relatively fast, as preheat and high interpass temperatures do not have to be maintained. Another attractive feature of this process is the portability of the equipment. Gasoline engine-driven generators can be readily taken into the field.

There are also some disadvantages to the SMAW consumable electrode process that must be considered. Penetration tends to be high, and dilution rates of 20% or more are not uncommon. This results in lower hardness and less resistance to abrasion. Two or three layers of weld metal normally are required to obtain maximum wear properties. Coated electrodes also leave a slag covering on the surface of the weld deposit which must be removed prior to each succeeding pass. Because coated electrodes usually are deposited with no more than a small amount of preheat, cracking or cross checking may occur, especially with the higher alloy electrodes that produce hard overlays.

The hardfacing material is at its maximum temperature, and hence its maximum thermal expansion, as it is being deposited. The workpiece, by contrast, may be near ambient temperature during the welding process and may be considerably less expanded than the hardfacing material. Severe strains develop in the hardfacing deposit as it cools after welding. These strains are accommodated by plastic deformation, in the case of a ductile hardfacing material or by cracking and cross checking, in the case of more brittle hardfacing materials. Cracking or cross checking does not affect the wear resistance of the overlay in many applications.

Submerged arc welding is a consumable electrode hardfacing process in which the area between the electrode and workpiece is shielded by a blanket of granular, fusible flux material. Electrodes in the SAW hardfacing process consist of continuous lengths, or coils, of filler materials--generally in tubular wire form.

The fluxes used for hardfacing by SAW are mineral compositions specially formulated to protect the molten filler metal without appreciable gas evolution. Submerged arc fluxes are generally finely divided, free-flowing granules in the solid state, which are placed by gravity along the surface to be hardfaced in advance of the electrode. The flux becomes molten and highly conductive under the arc, creating localized conditions conducive to high deposition rates.

Hardfacing filler materials can be deposited over a wide range of welding currents, voltages, and travel speeds, each of which can be controlled independently. Generally, however, the current, voltage, and workpiece travel speed are adjusted for hardfacing applications to produce a bead approximately 15 mm ($\frac{5}{8}$ in.) wide with a slightly convex surface and sides tapering into the base metal. Welding current usually ranges from 300 to 500 A for most SAW hardfacing applications. However, it is not uncommon to increase current to as much as 900 A to increase deposition rate.

A number of features make SAW particularly attractive for hardfacing. Because it is an automatic process, SAW requires little skill on the part of the operator for efficient operation. High deposition rates are possible, usually ranging as high as 4.5 to 9.0 kg/h (10 to 20 lb/h), depending on the job. The process is capable of making porosity-free deposits that are smooth and even on the surface and that either can be used aswelded or require only a minimum of grinding to clean up. The filler metal is protected from the atmosphere by flux, which also completely surrounds the arc, requiring no shielding for the operator.

The major disadvantages of hardfacing by SAW are that: (1) it is generally limited to hardfacing simple cylindrical or flat workpieces; and (2) it is not particularly adaptable to the surfacing of small parts. Hardfacing in other than the flat position requires special flux retainers. Preheating the workpiece in excess of 315 °C (600 °F) usually makes slag removal extremely difficult unless the slag is designed for easy hot slag removal. Occasionally, small portable units are used, but normally SAW units are fairly large and are mounted on stationary tracks, thus limiting their use for field operations. It is imperative that the flux be kept dry prior to use; therefore, storage can be a problem. Dilution is relatively high. It is not uncommon to find interalloying with the base metal, reaching or exceeding levels of 30%. Consequently, two or three layers of weld metal may be required for maximum wear resistance. Dilution can be reduced by long stickout techniques and by heavy overlap of individual weld beads.

Flux-cored open arc welding is a semiautomatic or automatic process in which the arc between the electrode and workpiece is shielded by a self-generated or self-contained gas or flux. Flux-cored open arc electrodes are continuous lengths, or coils, of filler material in tubular wire form. Open arc tubular filler materials are generally of low-carbon steel sheath construction with alloying elements, deoxidants, arc stabilizers, and a shielding gas source and/or flux contained in the core as powder or granules. High-alloy filler materials are generally shielded by a self-generated CO_2 gas deriving from the reaction between carbonaceous materials contained in the core and the atmosphere, or by vaporization of fluorides in the corn. Arc shielding is often supplemented in low-alloy filler materials with flux and/or aluminum or magnesium additions, which serve as deoxidizers.

Low equipment cost is one of the primary advantages of the flux-cored open arc hardfacing process. Neither flux-handling nor gas-regulating equipment is required. Thus the flux-cored open arc hardfacing process is a simple semiautomatic welding process requiring only a torch and a device to feed the continuous electrode wire. Conventional power, supplied with drooping voltage-amperage characteristics, is well adapted to flux-cored open arc hardfacing equipment. Motor-generator units are frequently used for field applications because of their portability. In-plant operations normally make use of direct current rectifiers. Although flux-cored open arc hardfacing is a semiautomatic process, it is not necessary to have a constant-potential power supply for its operation.

Flux-cored open arc equipment generally is designed for small-diameter welding wires, usually 1.2 mm ($\frac{3}{64}$ in.), 1.6 mm ($\frac{1}{16}$ in.), or 2.8 mm ($\frac{7}{64}$ in.). Most ferrous metals can be hardfaced with ease. Cast iron and chilled iron should be handled cautiously. Open arc is a high-energy process capable of much higher deposition rates than SMAW. The 2.8 mm ($\frac{7}{64}$ in.) diam rod can be deposited with welding currents as high as 500 A. The flux-cored open arc hardfacing process is closely related to the submerged arc process, except that it does not require a flux burden over the bead; consequently,

them is little or no slag to be removed from the overlay. Most hardfacing alloys can be deposited by the flux-cored open arc process without preheat, and there is good recovery of elements across the arc. Hardfacing by fluxcored open arc welding is an easy process to use, and only a short time is required to train an operator for the average application.

Arc stability and melting rates are excellent. The best hardfacing characteristics are obtained from DCEP. However, good results can be obtained with an alternating current supply at 26 to 30 V. Hardfacing deposits are comparable in soundness to deposits made with covered electrodes, at deposition rates three to five times faster than with covered electrodes.

Hardfacing by flux-cored open arc welding is not without disadvantages. Because the arc is not shielded with inert gas or a blanket of granular flux, considerable spatter and some porosity can be expected with this process. In addition, because of high welding currents, it is not particularly well adapted to the hardfacing of small parts. The recovery of weld metal from the tube wire to the deposit normally averages near 80 to 85% or higher. The amount of cross cracking and distortion is comparable to that of other arc welding processes.

Gas-metal arc welding is a consumable electrode hardfacing process in which the filler material and workpiece surfaces are protected by a flowing shielding gas--carbon dioxide, argon, or helium, either singly or in combination with a small amount of oxygen. The GMAW process is suitable for semiautomatic hardfacing, and the versatility of the process lends itself to the hardfacing of complex shapes. Hardfacing using GMAW can be fully mechanized. The hardfacing deposit is visible at all times in GMAW, thereby enabling high-quality deposits. Hardfacing by GMAW utilizes small-diameter (generally 1.6 mm, or $\frac{1}{16}$ in., or less) hardfacing filler wires or electrodes. Gas-metal arc hardfacing wires can be deposited in either spray arc or short arc modes. The spray arc mode produces a continuous stream of droplets about the same diameter as the hardfacing wire, which are projected by electromagnetic force from the tip of the wire. Deposition rates are high, as is dilution. In the short arc mode, lower voltages are used, and transfer of the molten hardfacing wire is more globular, usually resulting in more spatter.

Hardfacing by GMAW, unlike SMAW, requires a constant-potential power source with voltage, slope, and wire-feed rate controls. Best results for 1.6 mm ($\frac{1}{16}$ in.) diam cobalt-base hardfacing wires in the spray arc mode are generally obtained at 18 to 26 V, with wire-feed rates ranging from 45 to 65 mm/s (110 to 150 in./min.). Best results in the short arc mode are generally obtained at 16 to 18 V, with wire-feed rates ranging between 35 to 40 mm/s (80 to 100 in./min.). The use of auxiliary shielding gases adds to the cost of hardfacing by GMAW. However, the higher cost is generally offset by the higher deposit quality associated with GMAW.

Gas tungsten arc welding is a nonconsumable electrode arc process in which the heated area of the workpiece, molten hardfacing alloy, and the nonconsumable electrode are shielded from the atmosphere by a flow of shielding gas fed through the torch. Thoriated tungsten is the preferred nonconsumable electrode material. Conventional power supplies with drooping voltage-amperage characteristics are normally used for hardfacing. Motor-driven generators can be used, as can alternating current transformers with continuous high-frequency current. Direct current electrode negative is always used to minimize tungsten contamination in the hardfacing deposit. Argon generally is used as the shielding gas, but helium is also suitable.

Hardfacing by manual GTAW is a useful alternative to hardfacing by OAW techniques, particularly when large components or reactive base metals are involved. Gas-tungsten arc welding is preferred for hardfacing on reactive base metals such as titanium-stabilized stainless steels or aluminum-bearing nickel-base alloys. Gas-tungsten arc welding also is preferred over OAW for hardfacing applications in which carbon pickup is unacceptable or in applications involving filler materials that tend to boil under the influence of an oxyacetylene flame. The localized, intense heat of GTAW generally results in more base metal dilution than OAW. Base metal dilution can be minimized by torch oscillation, by using no more amperage than is necessary, and/or by concentrating the arc on the hardfacing deposit rather than on the workpiece. Hardfacing deposition rates generally are comparable in manual GTAW and OAW, despite the difference in base metal dilution.

Hardfacing by GTAW can be accomplished automatically by simply attaching the torch to an oscillating mechanism and using a mechanized device to feed the hardfacing filler material into the arc region. This, of course, requires long-length filler rod or continuous wire. High-quality, reproducible hardfacing deposits can be produced by automatic GTAW by controlling filler-metal feed rates, torch oscillation, and travel speed. Current-delay controls can be used to control the final stages of solidification in the hardfacing deposit to minimize shrinkage and crater cracking.

The arc action in GTAW is generally smoother, quieter, and freer of weld spatter than in other consumable electrode arc welding processes. The use of a separate filler rod or wire enables greater operator control of deposit shape. Gas-tungsten arc welding is more adaptable to hardfacing small intricate parts and generally produces higher-quality deposits than other hardfacing processes.

Plasma Arc Welding. Hardfacing by PAW is similar to hardfacing by GTAW in that both processes employ a gas-shielded arc between a nonconsumable tungsten electrode and the workpiece as the primary heat source for hardfacing. The processes differ in that the PAW process maximizes the use of plasma as a secondary heat source. The plasma is formed by ionizing the gas flowing in a nozzle surrounding the electrode. The electrode generally is recessed into the nozzle. The plasma gas generally emerges from a constricting orifice arrangement. The PAW process can use bare rod or wire as a hardfacing consumable, but more often powder is used as the consumable. When powder is used, the process is often referred to as the plasma transferred arc (PTA) process.

Plasma transferred arc surfacing, as shown schematically in Fig. 10, is a welding process in which the powder is introduced into a combined arc/plasma stream to form a molten pool on the workpiece. The resulting deposit is homogeneous and dense, with excellent metallurgical bonding with the base metal (workpiece). This process uses a constricted arc. The alloy is carried from a powder feeder to the plasma torch in a stream of argon gas, which forms the plasma and is directed away from the torch into the arc effluent, where it is melted and fusion-bonded to the base metal. A direct current power source connecting the tungsten electrode and the workpiece provides energy for the transferred arc.

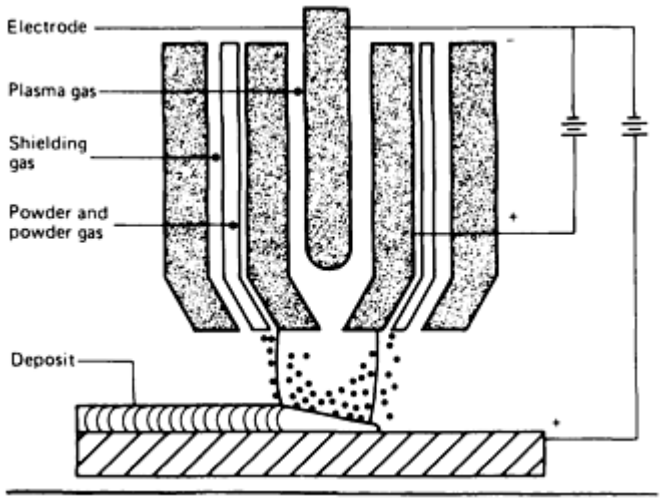

FIG. 10 SCHEMATIC OF THE PLASMA TRANSFERRED ARC HARDFACING PROCESS. SOURCE: REF 1

A second direct current power source connecting the tungsten electrode and the arc-constricting orifice supports a nontransferred arc. This nontransferred arc supplements the heat of the transferred arc and serves as a pilot arc to initiate the transferred arc. Argon is passed through a gas diffuser to provide a blanket of shielding gas in and around the arc zone.

Hardfacing with the PTA process has many advantages. Deposits ranging from 0.64 to 3.2 mm (0.025 to 0.125 in.) thick can be produced rapidly in a single pass. A dilution of 5 to 20% in the deposit is typical. Powder recoveries as high as 95%, with deposition rates up to 4.5 kg/h (10 lb/h), are possible, depending on the size and shape of the part being hardfaced. Still higher deposition rates ranging up to 18 kg/h (40 lb/h) are possible using the plasma arc hot wire process, which, as its name implies, uses wire hardfacing consumables and two independently controlled systems operating in one weld pool to melt and fuse a hardfacing alloy to a substrate. This process, however, is considered a weld cladding operation and is described later in this article.

Hardfacing by the PTA process has some disadvantages. The equipment is relatively expensive and is limited to straight-line or cylindrical parts, except when special tooling is provided. Usually, several parts are needed for setup, which makes the process somewhat unattractive to the low-volume job shop. The torch is mounted on a carriage and track that require permanent installation. There are two circuits employed in this process; therefore, either a special power supply or two separate conventional power units are required. Argon consumption is somewhat higher than with GTAW. Argon has to

be supplied to the center of the torch to protect the electrode. Shielding gas is necessary to protect the weld metal, and argon is also used as a carrier for the powder. Large parts being faced with hard alloys normally require preheat. This is a serious potential problem with the PAW process, if excessive preheats and prolonged hardfacing times cause overheating of the torch.

Laser Hardfacing (Ref 10)

Laser hardfacing, also commonly referred to as laser cladding, differs little in principle from traditional forms of hardfacing; the primary difference is the use of a high-energy laser beam heat source rather than an arc or gas flame. Laser beams offer potential in applying thin overlays or when access to the surface to be hardfaced can be achieved more readily by a laser beam than with an electrode or torch.

Cobalt-, nickel-, and tungsten carbide-base hardfacing alloys are the usual cladding materials used for laser hardfacing. As with conventional hardfacing methods, the materials are used in applications involving metal-to-metal contact, impact, erosion, and abrasion wear resistance. Other laser hardfacing materials include titanium carbide, Fe-Cr-Ni-B alloys, aluminum bronzes, and ceramics. Substrates have included carbon and low-alloy steels, stainless steels, nickel-base alloys (including superalloys), aluminum, cast irons, and tool steels (Ref 11).

Hardfacing material selection depends on its metallurgical compatibility with the substrate material. Alloys that form brittle intermetallic phases with the substrate are undesirable. For example, cobalt forms harmful intermetallics with titanium, and cobalt-base hardfacing alloys would be unsuitable on titanium alloy substrates.

Processing. The hardfacing alloy is melted by a laser beam and allowed to spread freely and freeze over the substrate. The beam also melts a very thin layer of the substrate, which combines with the liquid weld metal to the least extent necessary and solidifies to form a strong metallurgical bond. A good fusion bond can be achieved with a dilution zone that is only 10 to 20 μm thick.

The hardfacing alloy can be in several forms, examples of which are a prealloyed powder that is applied to the sample surface with or without a binder, a self-fluxing powder that is flame-sprayed, a hardfacing alloy that is plasma-sprayed, or a chip that is preplaced. Laser consolidation of these coatings results in densification and smoothening, eliminates channels to the substrate, improves the bonding between coating and substrate, and reduces porosity, all of which contribute to the strength and integrity of the hardfacing layer. Processing parameters for laser cladding are a power density that ranges from 10 to 1000 MW/m^2 and an interaction time from 0.1 to 1 s. The shielding gas could be any of the inert gases or a combination of gases, such as He/Ar and H_2/Ar.

To date the most successful application of laser hardfacing involves a proprietary process that utilizes a specially designed powder-feed apparatus. Using such equipment, the powder and an assist gas are fed to the weld area through a ceramic nozzle; a shielding gas of helium and argon surrounds the powder-gas mixture as it leaves the nozzle (Fig. 11). The powder delivery nozzle is positioned in such a manner as to flood the entire melt pool with powder. The feeding angle is generally from 35 to 45° to the horizontal, and the feed tube, which typically has a 3 mm (0.12 in.) diam, is positioned 10 to 12 mm (0.4 to 0.5 in.) from the substrate. Typically, the powder flow rate is from 0.005 to 0.1 cm^3/s (0.0003 to 0.006 $in.^3/s$), particle velocity is from 1 to 2 m/s (3.3 to 6.6 ft/s), and carrier gas velocity is from 3 to 7 m/s (10 to 23 ft/s). Desirable dilutions are from 3 to 8%. Overlay thickness can be varied from 0.15 to 4 mm (0.005 to 0.15 in.). Uniform feeding of the powder ensures uniform surfacing layers. Unlike plasma-sprayed coatings, porosity and unmelted powder particles are almost never observed within a laser hardfacing layer.

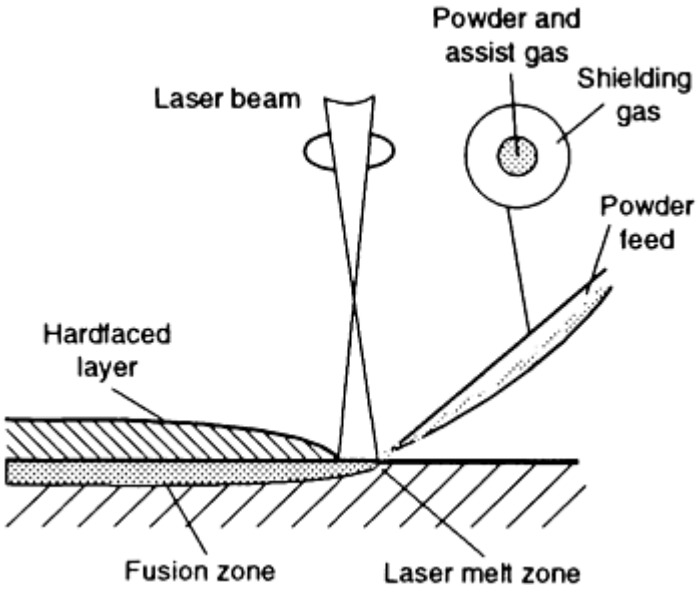

FIG. 11 SCHEMATIC OF THE LASER HARDFACING PROCESS USING DYNAMIC POWDER FEED. COURTESY OF QUANTUM LASER CORPORATION

Laser hardfacing deposits are commonly achieved by relatively large doughnut-shape beams, or by somewhat focused beams that are oscillated. These ensure a desirable deposit profile. Hardfacing material can also be added in rod, wire, or sheet form, but special procedures are needed because of reflectivity problems.

Thermal stresses in the weld metal can cause harmful cracking, but this can be eliminated by an appropriate preheating practice. Low power densities, large beam diameters, and slow sample translation rates tend to produce crack-free deposits.

Laser Hardfacing Applications. Because one of the primary goals of laser hardfacing is to improve the tribological properties of components, several applications have been found for the technique. Some of them are in the exploratory stage, others are in the pilot-plant stage, and a few have reached the production stage.

Ayers and Gnanamuthu (Ref 12) give several examples of laser hardfacing for improved wear resistance, such as Tribaloy T-800 on powder-coated ASTM A 387 steel, Haynes Stellite alloy No. 1 cast rods placed on AISI 4815 steel, and a mixture of WC and iron powder applied without binder on AISI 1018 steel.

In addition to stainless steel on mild steel, Steen (Ref 13) has reported successful laser hardfacing of nickel, bronze, Fe-B, and Stellite SF6 on mild steel; chromium on titanium; stainless on aluminum; mild steel on stainless; and Stellite on brass. Other examples of laser hardfacing are AISI 1016 steel clad with a mixture of chromium, manganese, and carbon powders (Ref 14) and gray cast iron hardfaced with a powder-fed mixture of molybdenum, chromium-carbide (Cr_3C_2), chromium, nickel, and silicon (Ref 15).

Bruck (Ref 16) demonstrated laser hardfacing within a confined space by coating the inside surface of small-bore pipes (inside diameter of 50 to 100 mm, or 2 to 4 in., and length of 0.3 to 1.2 m, or 1 to 4 ft). An oscillating mirror placed in the pipe formed a 12.5 mm (0.5 in.) wide melt pass, into which the hardfacing alloy powder was fed. The pipe was rotated and translated to cover the entire inner surface. Previously, chromium plating was used, but the laser technique appreciably improved galling resistance. Using suitable cooling techniques, the pipe temperature was maintained below 500 °C (930 °F) to avoid deterioration of the core properties, as well as distortion.

La Rocca (Ref 17) describes laser hardfacing of exhaust valves with a cobalt-base alloy at an Italian automotive manufacturer. The cobalt-base powder was fed into the laser melt pool. The laser hardfacing material was superior to GTAW material in terms of thickness uniformity, uniform microstructure and elemental distributions, and adhesion. When compared to GTAW, excess-metal removal was reduced by 10 to 15%. One British automotive manufacturer used production-stage laser hardfacing of a nickel-alloy turbine blade shroud interlock by powder feeding either a Tribaloy

alloy or a Nimonic alloy (Ref 18). Previously, a manual arc melting technique was used. Laser hardfacing reduced hardfacing time from 14 min to 75 s, improved productivity and quality, reduced cost by 85%, and reduced powder consumption by 50%. Table 11 lists components that are laser hardfaced for commercial applications.

Hardfacing, Weld Cladding, and Dissimilar Metal Joining

J.R. Davis, Davis & Associates

Thermal Spraying

Thermal spraying comprises a group of processes in which divided molten metallic or nonmetallic material is sprayed onto a prepared substrate to form a coating. The sprayed material is originally in the form of wire, rod, or powder. As the coating materials are fed through the spray unit, they are heated to a molten or plastic state and propelled by a stream of compressed gas onto the substrate. As the particles strike the surface, they flatten and form thin platelets that conform and

adhere to the irregularities of the prepared surface and to each other. They cool and accumulate, particle by particle, into a lamellar, castlike structure. In general, the substrate temperature can be kept below approximately 200 °C (400 °F), eliminating metallurgical change of the substrate material. The spray gun generates the necessary heat for melting through combustion of gases, an electric arc, or a plasma. Figure 12 illustrates a general thermal spraying process.

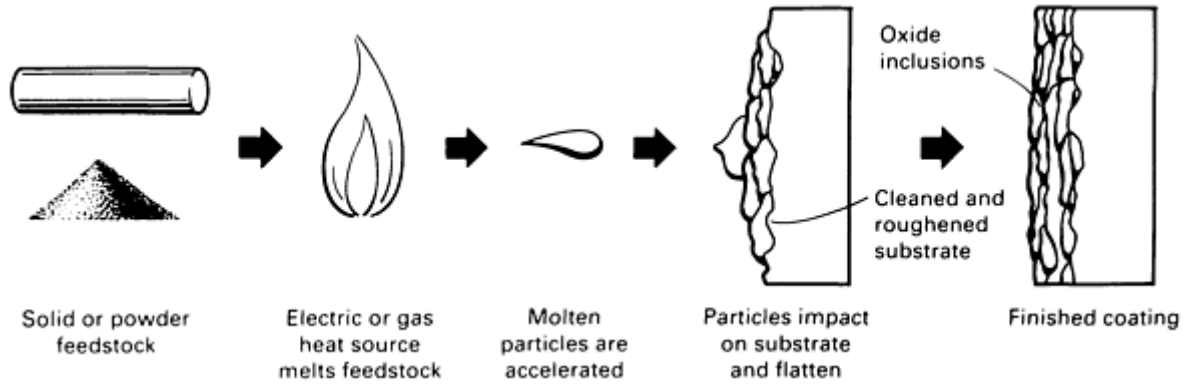

FIG. 12 SCHEMATIC OF THE GENERAL THERMAL SPRAY PROCESS. SOURCE: REF 20

The deposited structures of thermal spray coatings differ from those of the same material in the wrought form because of the incremental nature of the coating buildup and because the coating composition is often affected by reaction with the process gases and the surrounding atmosphere while the materials are in the molten state. For example, where air or oxygen is used as the process gas, oxides of the material applied may be formed and become part of the coating. The as-applied structures of all thermal spray coatings are similar in their lamellar nature; the variations in structure depend on the particular thermal spray process used, the processing parameters and techniques employed, and the material applied. Figure 13 illustrates the microstructure that results from the thermal spray process. As shown in this figure, the molten particles spread out and deform (splatter) as they impact the substrate, at first locking onto irregularities on the roughened surface, then interlocking with each other.

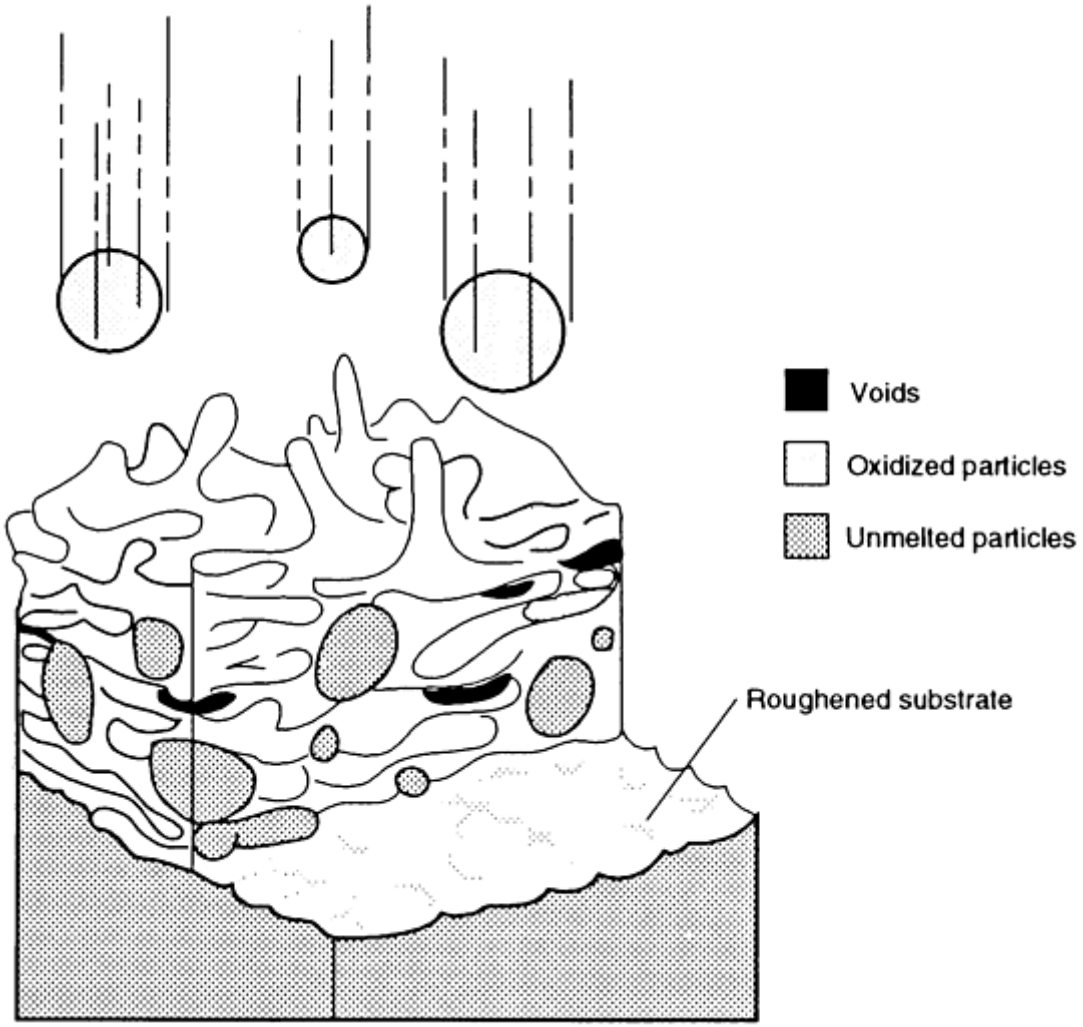

FIG. 13 SCHEMATIC SHOWING THE BUILDUP OF A THERMAL SPRAY COATING. MOLTEN PARTICLES SPREAD OUT AND DEFORM (SPLATTER) AS THEY STRIKE THE TARGET, AT FIRST LOCKING ONTO IRREGULARITIES ON THE SUBSTRATE, THEN INTERLOCKING WITH EACH OTHER. VOIDS CAN OCCUR IF THE GROWING DEPOSIT TRAPS AIR. PARTICLES OVERHEATED IN THE FLAME BECOME OXIDIZED. UNMELTED PARTICLES MAY SIMPLY BE EMBEDDED IN THE ACCUMULATING DEPOSIT. COURTESY OF THE MATERIALS ENGINEERING INSTITUTE, ASM INTERNATIONAL

The bond between the sprayed coating and the substrate is generally mechanical. Proper surface preparation of the substrate before spraying is often the most critical influence on the bond strength of the coating. Surface preparation techniques will be discussed later in this section.

Thermal spraying is a very versatile technique in that it can be used both in-shop or on-site. The thermal spray process permits rapid application of high-performance material in thicknesses from a few mils to more than 25 mm (1 in.) thick on parts of a variety of sizes and geometries. A list of applications would include coatings for:

- WEAR RESISTANCE
- OXIDATION RESISTANCE
- CORROSION RESISTANCE
- DIMENSIONAL RESTORATION
- THERMAL BARRIERS
- ELECTRICAL CONDUCTIVITY OR RESISTIVITY
- BIOMEDICAL DEVICES

Thermal Spray Processes (Ref 19, 20)

Currently, five different commercially available thermal spray methods are in use:

- OXYFUEL WIRE (OFW) SPRAY
- ELECTRIC ARC WIRE (EAW) SPRAY
- OXYFUEL POWDER (OFP) SPRAY
- PLASMA ARC (PA) POWDER SPRAY
- HIGH-VELOCITY OXYFUEL (HVOF) POWDER SPRAY

Of these, the plasma arc process is most commonly used. Market studies indicate that by the year 2000, plasma spraying will capture about 48% of the market, the HVOF process 25%, the electric-arc method 15%, and the combustion methods (OFW and OFP) a combined 12% (Ref 21). Table 12 compares important process characteristics associated with these techniques. Selection of the appropriate thermal spray method is typically determined by:

- DESIRED COATING MATERIAL
- COATING PERFORMANCE REQUIREMENTS
- ECONOMICS
- PART SIZE AND PORTABILITY

TABLE 12 COMPARISON OF THERMAL SPRAY PROCESSES

PROCESS	GAS FLOW		FLAME OR EXIT PLASMA TEMPERATURE		PARTICLE IMPACT VELOCITY		RELATIVE ADHESIVE STRENGTH[(A)]	COHESIVE STRENGTH	OXIDE CONTENT, %	RELATIVE PROCESS COST[(A)]	MAXIMUM SPRAY RATE		POWER		ENERGY REQUIRED TO MELT	
	M^3/H	FT^3/H	°C	°F	M/S	FT/S					KG/H	LB/H	KW	HP	KW/KG	KW/LB
FLAME POWDER: POWDER FEEDSTOCK, ASPIRATED INTO THE OXYGEN/FUEL-GAS FLAME, IS MELTED AND CARRIED BY THE FLAME ONTO THE WORKPIECE. PARTICLE VELOCITY IS RELATIVELY LOW, AND BOND STRENGTH OF DEPOSITS IS LOW. POROSITY IS HIGH AND COHESIVE STRENGTH IS LOW. SPRAY RATES ARE USUALLY IN THE 0.5 TO 9 KG/H (1 TO 20 LB/H) RANGE. SURFACE TEMPERATURES CAN RUN QUITE HIGH.	11	400	2200	4000	30	100	3	LOW	6	3	7	15	25-75	34-100	11-22	5-10
FLAME WIRE: IN FLAME WIRE SPRAYING, THE ONLY FUNCTION OF THE FLAME IS TO MELT THE MATERIAL. A STREAM OF AIR THEN DISINTEGRATES THE MOLTEN MATERIAL AND PROPELS IT ONTO THE WORKPIECE. SPRAY RATES FOR MATERIALS SUCH	71	2500	2800	5000	180	600	4	MEDIUM	4	3	9	20	50-100	70-135	11-22	5-10

AS STAINLESS STEEL ARE IN THE RANGE OF 0.5 TO 9 KG/H (1 TO 20 LB/H). SUBSTRATE TEMPERATURES ARE FROM 95 TO 205 °C (200 TO 400 °F) BECAUSE OF THE EXCESS ENERGY INPUT REQUIRED FOR FLAME MELTING.																
WIRE ARC: TWO CONSUMABLE WIRE ELECTRODES ARE FED INTO THE GUN, WHERE THEY MEET AND FORM AN ARC IN AN ATOMIZING AIR STREAM. THE AIR FLOWING ACROSS THE ARC/WIRE ZONE STRIPS OFF THE MOLTEN METAL, FORMING A HIGH-VELOCITY SPRAY STREAM. THE PROCESS IS ENERGY EFFICIENT; ALL INPUT ENERGY IS USED TO MELT THE METAL. SPRAY RATE IS ABOUT 2.3 KG/H/KW (5 LB/H/KW). SUBSTRATE TEMPERATURE CAN BE LOW BECAUSE ENERGY INPUT PER POUND OF METAL IS ONLY ABOUT ONE-EIGHTH THAT OF OTHER SPRAY METHODS.	71	2500	5500	10,000	240	800	6	HIGH	0.5-3	1	16	35	4-6	5-8	0.2-0.4	0.1-0.2

PLASMA SPRAYING PROVIDES FREE-PLASMA TEMPERATURES IN THE POWDER HEATING REGION OF 5500 °C (10,000 °F) WITH ARGON PLASMA, AND 4400 °C (8000 °F) WITH NITROGEN PLASMA--ABOVE THE MELTING POINT OF ANY KNOWN MATERIAL. TO GENERATE THE PLASMA, AN INERT GAS IS SUPERHEATED BY PASSING IT THROUGH A *DC* ARC. POWDER FEEDSTOCK IS INTRODUCED AND IS CARRIED TO THE WORKPIECE BY THE PLASMA STREAM. PROVISIONS FOR COOLING OR REGULATION OF THE SPRAY RATE MAY BE REQUIRED TO MAINTAIN SUBSTRATE TEMPERATURES IN THE 95 TO 205 °C (200 TO 400 °F) RANGE. TYPICAL SPRAY RATE IS 0.1 KG/H/KW (0.2 LB/H/KW).																
DETONATION GUN: SUSPENDED POWDER IS FED INTO A 1 M (3 FT) LONG TUBE ALONG WITH OXYGEN AND FUEL GAS. A	11	400	3900	7000	910	3000	8	VERY HIGH	0.1	10	1	2	100-270	135-360	220	100

SPARK IGNITES THE MIXTURE AND PRODUCES A CONTROLLED EXPLOSION. THE HIGH TEMPERATURES AND PRESSURES (1 MPA, OR 150 PSI) THAT ARE GENERATED BLAST THE PARTICLES OUT OF THE END OF THE TUBE TOWARD THE SUBSTRATE.																
HIGH-VELOCITY OXYFUEL: IN HVOF SPRAYING, A FUEL GAS AND OXYGEN ARE USED TO CREATE A COMBUSTION FLAME AT 2500 TO 3100 °C (4500 TO 5600 °F). THE COMBUSTION TAKES PLACE AT VERY HIGH CHAMBER PRESSURE, EXITING THROUGH A SMALL-DIAMETER BARREL TO PRODUCE A SUPERSONIC GAS STREAM AND VERY HIGH PARTICLE VELOCITIES. THE PROCESS RESULTS IN EXTREMELY DENSE, WELL-BONDED COATINGS, MAKING IT ATTRACTIVE FOR MANY CORROSION-RESISTANT APPLICATIONS.	28-57	1000-2000	3100	5600	610-1060	2000-3500	8	VERY HIGH	0.2	5	14	30	100-270	135-360	22-200	10-90

EITHER POWDER OR WIRE FEEDSTOCK CAN BE SPRAYED, AT TYPICAL RATES OF 2.3 TO 14 KG/H (5 TO 30 LB/H).																
HIGH-ENERGY PLASMA: THE HIGH-ENERGY PLASMA PROCESS PROVIDES SIGNIFICANTLY HIGHER GAS ENTHALPIES AND TEMPERATURES, ESPECIALLY IN THE POWDER HEATING REGION, DUE TO A MORE STABLE, LONGER ARC AND HIGHER POWER DENSITY IN THE ANODE NOZZLE. THE ADDED POWER (TWO TO THREE TIMES THAT OF CONVENTIONAL PLASMA) AND GAS FLOW (TWICE AS HIGH) PROVIDE A LARGER, HIGHER TEMPERATURE POWDER INJECTION REGION AND REDUCED AIR ENTRAINMENT. ALL THIS LEADS TO IMPROVED POWDER MELTING, FEWER UNMELTS, AND HIGH PARTICLE IMPACT VELOCITY.	17-28	600-1000	8300	15,000	240-1220	800-4000	8	VERY HIGH	0.1	4	23	50	100-250	135-335	9-13	4-6
VACUUM PLASMA: VACUUM PLASMA USES A CONVENTIONAL PLASMA TORCH IN A CHAMBER AT	8.4	300	8300	15,000	240-610	800-2000	9	VERY HIGH	(B)	10	10	24	50-100	70-135	11-22	5-10

PRESSURES IN THE RANGE OF 10 TO 50 KPA (0.1 TO 0.5 ATM). AT LOW PRESSURES THE PLASMA IS LARGER IN DIAMETER, IS LONGER, AND HAS A HIGHER VELOCITY. THE ABSENCE OF OXYGEN AND THE ABILITY TO OPERATE WITH HIGHER SUBSTRATE TEMPERATURES PRODUCE DENSER, MORE ADHERENT COATINGS HAVING MUCH LOWER OXIDE CONTENTS.

(B) PPM LEVELS.

The oxyfuel wire spray process (also called wire flame spraying or the combustion wire process) is the oldest of the thermal spray coating methods and among the lowest in capital investment. The process utilizes an oxygen-fuel gas flame as a heating source and coating material in wire form. Any material in the form of wire and capable of being melted below 2480 °C (4500 °F) can be flame-sprayed. Solid-rod feed stock has also been used. During operation, the wire is drawn into the flame by drive rolls that are powered by an adjustable air turbine or electric motor. The tip of the wire is melted as it enters the flame, atomized into particles by a surrounding jet of compressed air, and propelled to the workpiece. Figure 14 shows a schematic of the OFW spray process.

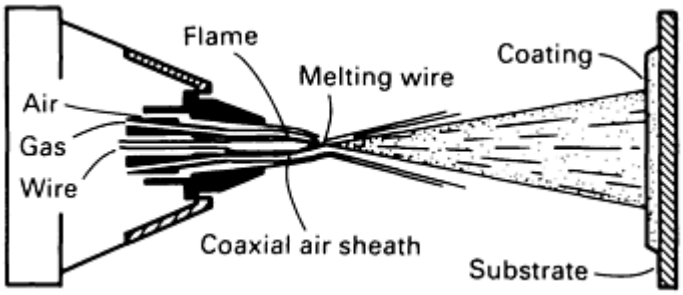

FIG. 14 SCHEMATIC OF THE OXYFUEL WIRE SPRAY PROCESS. SOURCE: REF 20

Spray rates for this process range from 0.5 to 10 kg/h (1 to 20 lb/h) and are dictated by the melting point of the material and the choice of fuel gas. Common fuel gases are acetylene, MAPP gas, propane, propylene, and natural gas, each combined with oxygen. The wire spray gun is most commonly used as a hand-held device for on-site application, although an electric-motor-driven gun is recommended for fixed-mounted use in high-volume, repetitive production work.

The OFW process is widely used for corrosion protection of large outdoor structures, such as bridges and storage tanks, and for restoration of dimension to worn machinery components. It is a good choice for all-purpose spraying. Coatings can be applied rapidly and at low cost, and a wide variety of metal coating materials are available. Typical spray materials include austenitic and martensitic stainless steels, nickel aluminide, nickel-chromium alloys, bronze, Monel, babbitt, aluminum, zinc, and molybdenum. In general, oxyfuel wire flame-sprayed coatings exhibit lower bond strengths, higher porosity, a narrower working temperature range, and higher heat transmittal to the substrate than plasma or electric arc-sprayed coatings.

Electric arc wire spraying also applies coatings of selected metals in wire form. Push-pull motors feed two electrically charged wires through the arc gun to contact tips at the gun head. An arc is created that melts the wires at temperatures above 5500 °C (10,000 °F). Compressed air atomizes the molten metal and projects it onto a prepared surface. Figure 15 shows a schematic of the EAW spray process.

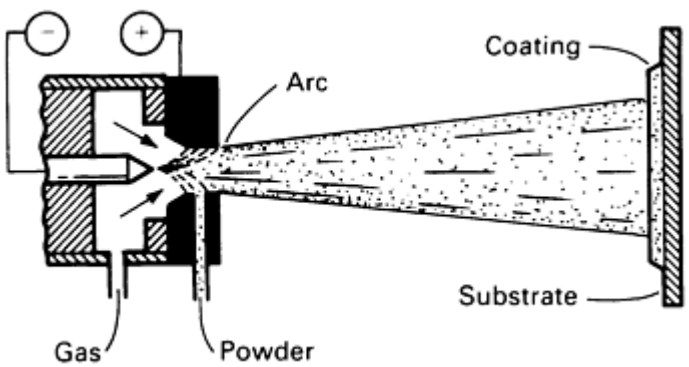

FIG. 15 SCHEMATIC OF THE ELECTRIC ARC WIRE SPRAY PROCESS. SOURCE: REF 20

The EAW process is excellent for applications that require heavy coating buildup or have large surfaces to be sprayed. The arc system can produce a spray pattern ranging from 50 to 300 mm (2 to 12 in.) and can spray at high speeds. It has built-in flexibility, allowing coating characteristics, such as hardness or surface texture, to be tailored to specific applications.

The EAW method is characterized by strong coating adhesion because of the high particle temperatures produced. Because the process uses only electricity and compressed air, it allows equipment to be moved relatively easily from one installation to another, and it eliminates the need to stock oxygen and fuel gas supplies. Materials applied by the EAW method are similar to those used in the OFW process.

The oxyfuel powder spray method, which also uses combustion gases as the heat source, extends the range of available coatings and subsequent applications to include ceramics, cermets, carbides, and fusible hardfacing coatings. Using either gravity flow or pressurized feed, powder is fed into the gun and carried to the gun nozzle, where it is melted and projected by the gas stream onto a prepared surface (Fig. 16). For general-purpose spraying, the gravity-flow system is used. When exacting coating consistency and/or high spray rates are desired, the pressurized feed system is used. Oxyfuel powder guns are the lowest-cost thermal spray equipment, are easiest to set up, and make it easy to change coating materials. The OFP method finds widest use in short-run machinery maintenance work and in the production spraying of abradable clearance-control seals for gas turbine engines. The OFP spray equipment is lighter and more compact than other forms of thermal spray equipment, but because of the lower particle velocities obtained, the coatings generally have lower bond strength, higher porosity, and a lower overall cohesive (interparticle) strength than the coatings produced by other thermal spray processes.

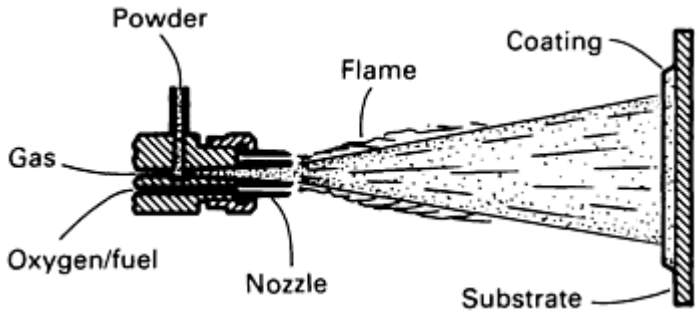

FIG. 16 SCHEMATIC OF THE OXYFUEL POWDER SPRAY PROCESS. SOURCE: REF 20

Flame spray and fuse is a modification of the OFP spray method. The materials used for coating are self-fluxing, fusible materials which require postspray heat treatment. In general, these are the boride-containing nickel-base alloys described earlier in this article. In practice, parts are prepared and coated as in other thermal spray processes and then fused. Fusing is accomplished using one of several techniques, such as flame or torch; induction; or in vacuum, inert, or hydrogen furnaces. These alloys generally fuse between 1010 to 1175 °C (1850 to 2150 °F), depending upon composition.

Spray-and-fuse coatings are used in applications where excessive wear is a problem. Coating hardnesses can be as high as 65 HRC. The use of spray-and-fuse coatings is limited to substrate materials that can tolerate the 1010 to 1175 °C (1850 to 2150 °F) fusing temperatures. Fusing temperatures may alter the heat-treated properties of some alloys. However, the coating will usually withstand additional heat treatment of the substrate.

Plasma arc spraying is one of the most sophisticated and versatile thermal spray methods. The PA spray process uses coating materials in the form of powders, which are heated with a plasma heat source (Fig. 17). Temperatures that can be obtained with commercial plasma equipment have been calculated to be greater than 11,000 °C (20,000 °F) and are far above the melting or even the vaporization point of any known material. Decomposition of materials during spraying is minimized because of the high gas velocities produced by the plasma, resulting in extremely short residence time in the thermal environment. The plasma process also provides a controlled atmosphere for melting and transport of the coating material, thus minimizing oxidation, and the high gas velocities produce coatings of high density.

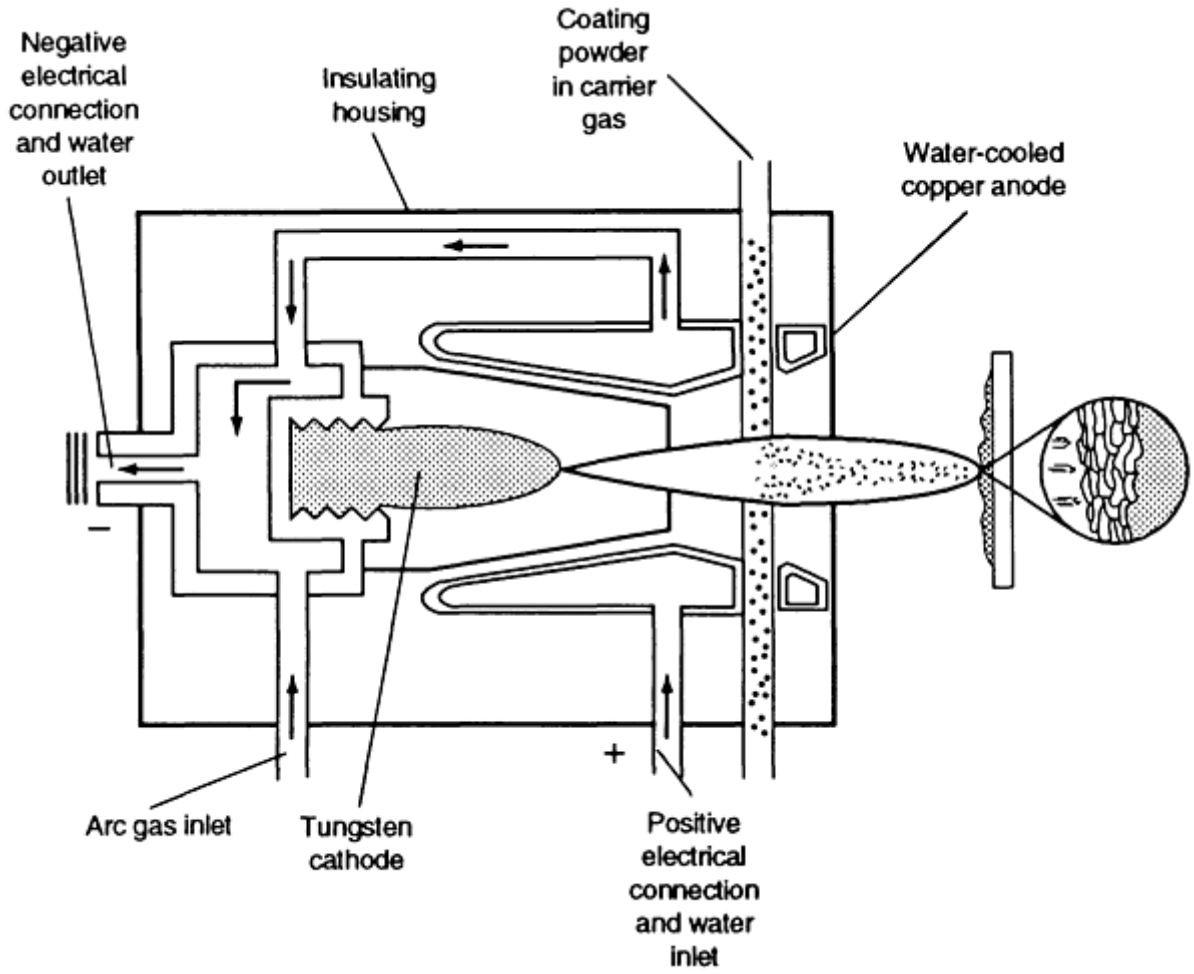

FIG. 17 SCHEMATIC OF THE PLASMA ARC SPRAY PROCESS. COURTESY OF D. BAXTER, *ADVANCED MATERIALS & PROCESSES*

The plasma gun operates on the principle of raising the energy state of a gas by passing it through an electric arc. The release of energy in returning the gas to its ground state results in exceedingly high temperatures. A gas such as nitrogen or argon enters a direct-current arc between a tungsten cathode and a copper anode that make up the nozzle (Fig. 17). Both components are cooled by a constant flow of water through internal passages. Here the plasma gas first dissociates (in the case of nitrogen, into two atoms), followed by ionization that releases free electrons. The electrons recombine outside the electric arc, and energy is released as heat and light. In addition, frequent collisions transfer energy from the electrons to the positive ions, accelerating them until the plasma reaches a state of equilibrium. The result is a thermal plasma in which the energy of the electrons has been turned into enthalpy, or heat content. At this point, powdered coating material suspended in a gas is injected into the plasma and is subsequently melted and propelled at high velocity to the workpiece. In practice, a small amount of a secondary gas, such as hydrogen or helium, is mixed with the primary plasma gas to increase operating voltage and thermal energy.

The high temperatures and high gas velocities produced by the plasma process result in coatings that are superior in mechanical and metallurgical properties to low-velocity OFW or OFP coatings. The plasma process is particularly efficient for spraying high-quality coatings of ceramic materials, such as zirconium oxide for turbine engine combustors and chromium oxide for printing rolls. The plasma process is also readily field-portable and is thus used for large on-site applications such as power utility plant boiler tubes.

Current plasma spray technology permits fully automatic start/stop operation and closed-loop computer control for power level, plasma gas flow, and powder feed rate. System problems can be diagnosed via computer modem to the equipment manufacturer, and system performance can be documented and stored on a digital recorder or data logger.

With any thermal spray powder method, the degree to which a given flame effectively melts and accelerates the powder depends on the type of coating material and the size and shape of the particles. Each particular coating material and gun combination has an optimum particle size. Particles much smaller than ideal will overheat and vaporize; much larger particles will not melt and may fall from the flame or rebound from the target. For the highest coating density, powders are sized between about 44 μm (325 mesh) and 10 μm (Ref 1, 9). The lower limit ensures free flow. Coarser powder may be sized up to 100 μm, with typical distribution falling between 88 μm (170 mesh) and 44 μm (325 mesh). Powder shape ranges from spherical to acicular; spherical is best because of reduced surface area and consistent flow.

Any material that melts without subliming and is available as a properly sized powder has potential as a plasma spray process coating. Plasma spray coatings may be elemental (aluminum, molybdenum, nickel, or chromium), alloyed (nickel-, iron-, or cobalt-base), ceramics and cermets (Al_2O_3, Cr_2O_3, or Cr_3C_2), composites (nickel-aluminum, cobalt-bonded tungsten carbide, or clad Al_2O_3), or mechanical blends.

In one process variation, the plasma gun and workpiece are enclosed in a vacuum chamber, and the entire operation is carried out in an inert atmosphere at low pressure (7 kPa, or 50 torr). Advantages of this low-pressure plasma technique include improved bonding and density of the deposit, improved control over coating thickness (even with an irregular work surface), and higher deposit efficiency. However, facility cost is higher, and workpiece size is limited by the vacuum chamber size. This modification is suitable for coating turbine airfoils, blade tips, and shroud segments with complex coatings such as NiCrAlY and other MCrAlY-type alloys. Very fine powder (-325 mesh) generally is used for low-pressure plasma spraying to achieve maximum density. If high-purity coatings are also desired, then the powder must be manufactured under inert cover and atomized in an inert gas to preserve purity.

The high-velocity oxyfuel powder spray process represents the state of the art for thermal spray coatings. The HVOF process uses extremely high kinetic energy and controlled thermal energy output to produce very-low-porosity coatings that exhibit high bond strength, fine as-sprayed surface finish, and low residual stresses. Both pulsed-combustion and continuous-combustion HVOF methods are used.

Pulsed-Combustion HVOF. The detonation gun (or D-gun) process was the first HVOF method introduced and was initially developed for the deposition of hard, wear-resistant materials such as oxides and carbides (Ref 1, 9). The extremely high particle velocities achieved in the detonation gun result in coatings with higher density, greater internal strength, and superior bond strength than can be achieved with conventional plasma spraying or oxyfuel powder spraying. Detonation gun coatings have been successfully applied to critical areas of precision components made from virtually all commercial alloys. The typical coating thickness is less than 0.75 mm (0.030 in.), but many applications require only 0.075 mm (0.003 in.) or less of finished coating.

This process, which is depicted schematically in Fig. 18, uses a controlled series of explosions of a mixture of oxygen and acetylene to blast the powder onto the surface of the workpiece. The detonation gun consists of a water-cooled barrel several feet long, with an inside diameter of about 25 mm (1 in.), and associated gas- and powder-metering equipment. In operation, a mixture of oxygen and acetylene is fed into the barrel along with a charge of powder. The gas is then ignited, and the detonation wave accelerates the powder to about 760 m/s (2500 ft/s), while heating it close to, or above, its melting point. Temperatures up to 3900 °C (7000 °F) are reached inside the gun. The distance that the powder is entrained in the high-velocity gas is much longer than in a plasma or flame spray device, which accounts for the high particle velocity. After the powder has exited the barrel, a pulse of nitrogen purges the barrel. The gun discharges four to eight times per second.

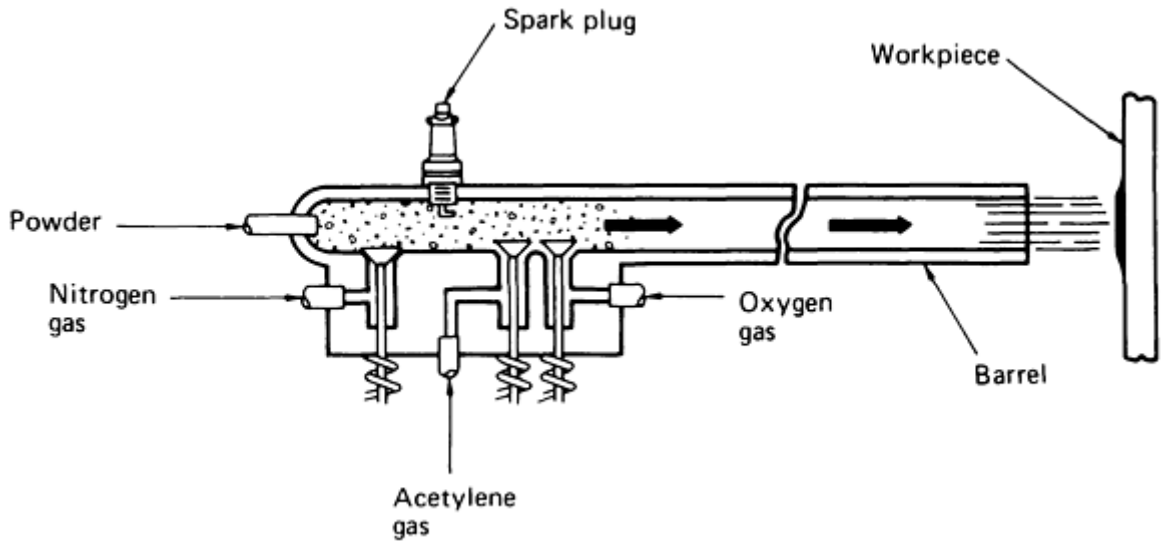

FIG. 18 SCHEMATIC OF THE DETONATION GUN (D-GUN) HVOF PROCESS. SOURCE: REF 1

Suitable materials for detonation gun coatings include pure metals, alloys, oxides, carbides, composites, and mechanical blends of two or more components. Historically, the detonation gun has proven particularly advantageous in applying hard wear-resistant carbide and oxide coatings. Detonation gun coatings have been successfully applied to critical areas of precision parts made from virtually all commercial alloys. The substrate surface is seldom heated above 150 °C (300 °F) during the coating process. As a result, a part can be fabricated and fully heat treated prior to coating. In addition, very high melting point materials (such as WC-Co) can be deposited on relatively low melting point substrates (such as aluminum). Usually, there is little or no distortion, and the substrate microstructure and strength are not changed by the coating process.

Continuous-combustion HVOF processes, which also feature internal, confined combustion, operate with an oxyfuel mixture consisting of oxygen and either propylene, propane, hydrogen, and even liquid fuels such as kerosene. High-velocity oxyfuel guns have combustor sections (air- or water-cooled), which combust the fuel/oxygen mixtures under pressure and accelerates the combusted gas streams down a confined cooled tube. Powders, with carrier gases, are fed into the nozzle where the particles are entrained with the confined, high-pressure combusting gases.

The high-velocity gases produce uniquely characteristic multiple shock diamond patterns, which are visible in the flame (Fig. 19). Combustion temperatures approach 2750 °C (5000 °F) and form a circular flame configuration. Powder is injected into the flame axially to provide uniform heating, and powder particles are accelerated by the high velocity gases, which typically approach speeds ranging from 1370 m/s (4500 ft/s) to as high as 2160 m/s (7100 ft/s). Particle velocities range from 760 m/s (2500 ft/s) to more than 900 m/s (3000 ft/s).

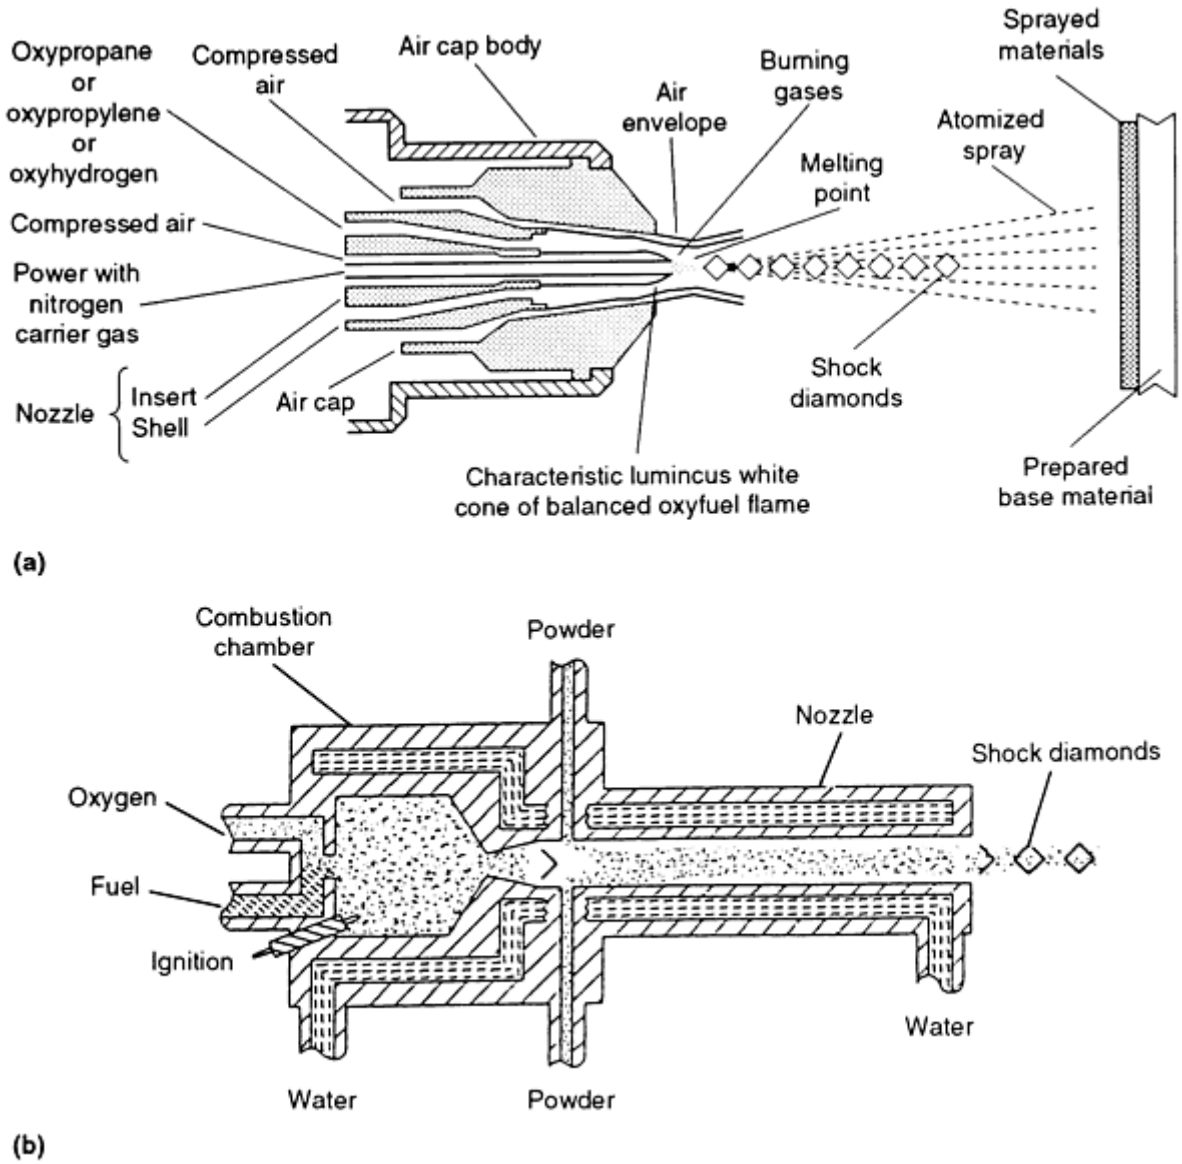

FIG. 19 SCHEMATICS OF (A) AIR-COOLED AND (B) WATER-COOLED CONTINUOUS COMBUSTION HVOF THERMAL SPRAY PROCESSES. (A) COURTESY OF METCO PERKIN ELMER. (B) SOURCE: REF 22

Continuous-combustion HVOF spray coating processes are separated into four major designs: (1) internal combustion, with the hot gases directed into a chamber where they mix with and heat a mixture of carrier gas and powder particles; (2) simultaneous injection of powder into a combustion chamber, where the mixture continuously bums and heats the particles; (3) confined combustion into which a stream of powder with carrier gas is injected; and (4) high-pressure liquid fuel systems with radial injection of powders downstream of the combustor exit. Figure 19 illustrates two of these variations. Common to all HVOF methods is that the gases are being burned under higher-than-atmospheric pressures, with the combustion gases, carrier gas, and an entrained distribution of powders being accelerated in the tube. The length of the nozzle, the design of heating chambers, the geometry/location of powder feed, and the cooling, either by water or air, are the major features which differ.

The low residual coating stress produced in the continuous-combustion HVOF process allows significantly greater thickness capability than the plasma method, while providing lower porosity, lower oxide content, and higher coating adhesion. Coatings produced by the continuous-combustion HVOF process also have much better machinability compared with other methods, and coating porosity has closely approached wrought materials, as verified by gas permeability testing. Continuous-combustion HVOF systems are available with closed-loop computer control and robotics capability. Figures 20 and 21 compare the bond strengths and hardness of coatings deposited with various thermal spray processes. The correlation between hardness and particle velocity is shown in Fig. 22.

Surface Preparation (Ref 20)

Thermal spray coatings rely primarily on mechanical bonding to the substrate surface. Because bonding relies on this mechanical interlocking of spray particles with the substrate surface, preparation of the surface is critical to a successful coating. Preparation of the substrate before spraying is virtually the same for all thermal spray processes. More detailed information on surface preparation can be found in Ref 23.

Chemical Cleaning. Chemical cleaning is used on parts that are contaminated or impregnated with material that cannot be removed by other methods. Surfaces can be chemically cleaned by vapor degreasing, steam, hot detergent washing, or application of an industrial cleaning solvent. Degreasing is usually the most economical and a fast way to remove lubricants and oils.

Grit blasting is the most frequently used surface preparation procedure. The roughening cleans the surface of contamination that may inhibit bonding and creates an irregular profile of minute surface irregularities. This enhances the adhesion of the coating. Before application of the thermal spray coating, the cleaned substrate should be blasted to a white-metal condition (according to Steel Structures Painting Council specification SSPC-SP5-82) with a minimum surface profile of 6 μm (250 μm) R_a (arithmetic average surface roughness). Sharp angular grit (18 to 24 mesh average) should be used. Typical-grit blasting materials include chilled iron grit, alumina (Al_2O_3), silica sand, crushed flint, crashed garnet, silicon carbide, and crushed slag.

Rough threading is often used in conjunction with grit blasting for cylindrical surfaces. It consists essentially of machining a thread form on the area to be sprayed. This type of preparation provides excellent adhesion of the coating to the substrate.

Bond coats are often used when an extremely high bond strength is desired or when mechanical deformation of the substrate is not possible or practical. This involves spraying materials that are exothermic and self-bonding. Nickel-aluminum alloys (Ni-5 to 20Al) and molybdenum are the most commonly used bond materials. A thin coating (normally about 50 to 125 μm, or 2 to 5 mils) of bond material is generally applied before the thermally sprayed overcoat. Care should be taken to ensure that the bond material is compatible with the overcoat and that a galvanic cell will not be created, which may be detrimental to the performance of the coating system.

Preheating of the substrate is often beneficial. Preheating to 65 to 95 °C (150 to 200 °F) will eliminate surface condensation and will reduce shrink differentials between the coating and the substrate. It is generally employed only with the flame spray processes, which use their flame as the heat source for warming the substrate.

Finishing Treatment

Thermal spray coatings usually exhibit two common features in the as-deposited condition, a sandpaper-like surface finish and a structure with inherent porosity. A typical surface roughness of an as-sprayed coating ranges from 5.0 to 13 μm (200 to 500 μin.) R_a. The porosity usually ranges from 2 to 17 vol%, depending on the process by which the coating is deposited and the material sprayed. In many cases, thermal spray coatings are applied to machine elements where the coated component must conform to close dimensional tolerances or have a high surface finish. In many applications, coatings are exposed to corrosive solutions or hydraulic fluids, which can infiltrate the pores, resulting in fluid leakage or corrosion of the base material. These conditions can contribute to the premature failure of the coating. Many applications require the coating to be sealed before finishing by machining or grinding, to protect the thermal spray coating.

Sealing is the process by which the pores of a coating are filled to eliminate the possibility of infiltration by fluids or corrosive media that can contribute to premature failure. Sealing materials, which may be applied by brushing, spraying, or dipping, include petroleum-based waxes and organic materials such as phenolics, epoxy resins, polyesters, polyurethanes, and polyimides.

Coating Finishing Method. Thermal spray coatings are finished to dimension either by single-point machining or by grinding. Hard surfacing materials such as ceramics and carbides are restricted to grind finishing, typically with diamond wheels. Thermal spray coatings are sufficiently different from the same material in wrought form that different grinding wheel and finishing tool recommendations are almost always required. Therefore, tools and wheels should not be chosen based on experience with the parent material in wrought or cast form.

Most thermal spray coatings exhibit some degree of porosity. However, the HVOF method produces coatings closest in machining and grinding behavior to wrought materials. In general, thermal spray coatings can be machined to 1 to 2 μm (40 to 80 μin.) R_a and ground to 0.25 to 0.5 μm (10 to 20 μin.) R_a. Many plasma spray ceramic coatings can be lapped down to 0.025 to 0.05 μm (1 to 2 μin.) R_a.

Thermal Spray Materials and Applications

The most outstanding feature of thermal spray coatings is probably their diverse applicability. There are two primary reasons for this. First, materials selection is almost unlimited. In fact, more than 200 coating materials with different characteristics of toughness, coefficient of friction, hardness, and other properties are available. These materials can be grouped as follows:

- PURE METALS
- METAL ALLOYS
- CERMETS
- CERAMICS
- CARBIDES
- POLYMERS
- SPECIAL COMPOSITE MATERIALS SUCH AS NICKEL-ALUMINUM AND NICKEL-GRAPHITE COMPOSITE POWDERS

Second, the thermal spray process, properly controlled, imparts very little heat to the substrate (100 to 260 °C, or 200 to 500 °F), avoiding metallurgical change, distortion, and oxidation. This allows thermal spray coatings to be applied to practically any substrate (metals, plastics, composites, etc.). Also, such coatings can often be applied to the finish machined part, a practice unthinkable with welding, heat treating, or other high-temperature processes.

Thermal spray coatings provide the design engineer with many options. They offer material properties not available in wrought metals. Coatings can be applied to selected areas rather than treating the entire part. Manufacturing costs can be reduced by eliminating unnecessary processing steps. Extraordinary performance characteristics can be designed into a part to extend its useful life, creating a new, marketable product in the process.

Thermal spray coatings provide the solution to many mechanical, electrical, and corrosion resistance problems involving metal parts and assemblies. However, there are certain applications where such coatings should not be used. Before a thermal spray coating is specified, its suitability can usually be determined according to these criteria (Ref 24):

- NO STRENGTH IS IMPARTED TO THE BASE MATERIAL BY A SPRAYED DEPOSIT. THE COMPONENT TO BE SPRAYED MUST, IN ITS PREPARED FORM, BE ABLE TO WITHSTAND ANY MECHANICAL LOADING THAT WILL BE EXPERIENCED IN SERVICE. (IN A FEW APPLICATIONS, SOME STRENGTH CAN BE ADDED BY A THERMAL SPRAY COATING; HOWEVER, SUCH USES ARE UNUSUAL AND SHOULD BE CAREFULLY TESTED.)
- IF THE AREA ON A PART TO BE SPRAYED OR ANY SECTION OF THE TOTAL AREA WILL BE SUBJECTED TO SHEAR LOADING IN SERVICE, THE PART IS NOT A SUITABLE CANDIDATE FOR THERMAL SPRAYING. GEAR TEETH, SPLINES, AND THREADS ARE EXAMPLES.
- POINT LOADING WITH LINE CONTACT ON A SPRAYED METAL DEPOSIT WILL EVENTUALLY SPREAD THE DEPOSIT, CAUSING DETACHMENT. IF THE DEPOSIT IS ON A MOVING COMPONENT WITH SUCH LOADING, IT WILL FAIL RAPIDLY. FOR EXAMPLE, NEEDLE AND ROLLER BEARING SEATS, WHERE THE BEARING ELEMENTS ARE IN DIRECT CONTACT WITH THE SPRAYED DEPOSIT, MAY NOT BE GOOD THERMAL SPRAY CANDIDATES.
- IF THE BASE METAL OF A COMPONENT TO BE TREATED HAS BEEN NITRIDED, NON-HVOF THERMAL SPRAYING IS NOT RECOMMENDED UNLESS THE NITRIDING IS FIRST REMOVED. OTHER FORMS OF SUBSTRATE HARDENING REQUIRE SPECIAL TREATMENT, SUCH AS INTENSIVE GRIT BLASTING. THERMAL SPRAYING OF NITRIDED TURBINE ENGINE COMPONENTS USING HVOF METHODS IS DESCRIBED IN REF 25.

To date, the most common application area for thermal spraying has been advanced aircraft gas turbine components such as compressor blades, compressor stator vanes, beating housings, and labyrinth seals. Common coating materials include cobalt-base (Laves phase) alloys T-400 and T-800, tungsten carbide-cobalt materials, and chromium carbide-nickel chromium cermets (Cr_3C_2-20 to 30% NiCr). Other key application areas are listed below.

Wear coatings are used to resist abrasion, erosion, cavitation, and fretting, and to reduce friction. These coatings consist of a wide range of metals and their alloys, ceramics, cermets, carbides, and even low-friction plastics. Typical coating hardness ranges from 20 to 70 HRC. Metal matrices are hardened by rapid solidification, by dispersions introduced from the spray process, by the addition of separate hard phases (for example, carbides of chromium, tungsten, titanium and/or tantalum), or by oxide inclusions. Table 13 lists friction and wear applications for various thermal spray materials.

TABLE 13 THERMAL SPRAY COATINGS USED FOR HARDFACING APPLICATIONS

TYPE OF WEAR	COATING MATERIAL	COATING PROCESS[(A)]	APPLICATIONS
ADHESIVE WEAR	SOFT BEARING COATINGS:		
	ALUMINUM BRONZE	OFW, EAW, OFP, PA, HVOF	BABBITT BEARINGS, HYDRAULIC PRESS SLEEVES, THRUST BEARING SHOES, PISTON GUIDES, COMPRESSOR CROSSHEAD SLIPPERS
	TOBIN BRONZE	OFW, EAW	
	BABBITT	OFW, EAW, OFP	
	TIN	OFW, EAW, OFP	
	HARD BEARING COATINGS:		
	MO/NI-CR-B-SI BLEND	PA	BUMPER CRANKSHAFTS FOR PUNCH PRESS, SUGAR CANE GRINDING ROLL JOURNALS, ANTIGALLING SLEEVES, RUDDER BEARINGS, IMPELLER SHAFTS, PINION GEAR JOURNALS, PISTON RINGS (INTERNAL COMBUSTION); FUEL PUMP ROTORS
	MOLYBDENUM	OFW, EAW, PA	
	HIGH-CARBON STEEL	OFW, EAW	
	ALUMINA/TITANIA	OFP, PA	
	TUNGSTEN CARBIDE	OFP, PA, HVOF

Corrosion Resistance. Zinc and aluminum and their alloys are the metals most widely used for thermal spray anticorrosion coatings. They are extensively used for the corrosion protection of iron and steel in a wide range of environments and have been shown to provide very long-term protection (over 20 years) in both marine and industrial locations. Properties and applications of zinc and aluminum thermal spray coatings are described in the article "Thermal Spraying Coatings" in this Volume.

Other coating materials for corrosion-resistant applications include austenitic stainless steels, aluminum bronze, nickel-base alloys, and MCrAlY materials. Selection of a specific alloy depends on the particular environment. When using these alloys, it must be understood that these coatings will not galvanically protect the underlying steel. This can be a particular problem due to the porosity of thermal spray coatings. Great care must be taken to ensure that these coatings are properly sealed in order to prevent penetration of the corrosive medium to the underlying steel and subsequent corrosion at the coating/substrate interface.

Oxidation Protection. Thermal spray coatings are extensively used by industry to protect steel components and structures from heat oxidation at surface temperatures to 1095 °C (2000 °F). By ensuring long-term protection, thermal spray coatings show real economic advantages during the service lives of such items. Coatings are particularly effective in protecting low-alloy and carbon steels. Table 14 lists thermal spray coatings for use in high-temperature applications.

Source: Ref 20

Aluminum has been widely used to protect such steels in a number of applications involving high surface temperatures up to 550 °C (1020 °F). Nickel-chromium alloys and some of the MCrAlY alloys have also provided protection in severe environments (up to 1000 °C, or 1830 °F).

Thermal insulation provides low-thermal-conductivity zirconium and/or aluminum oxides that are deposited as coatings to reduce heat conduction to base metals. These insulating oxide coatings can also reduce heat loss, reduce thermal transient effects, and reduce the high-temperature oxidation/corrosion effects by lowering temperatures of the coated base metals. Thermal spray processes usually introduce a controlled level of porosity, which further enhances the coating insulation and increases its thermal shock resistance.

Thermal barrier coatings consist of a low-conductivity (thermal) ceramic deposited over an MCrAlY bond coat. The ceramic of choice is partially-stabilized zirconia (7 to 8 wt% Y_2O_3-ZrO_2) deposited at a thickness of 0.25 mm (0.010 to 0.040 in.) with 10 to 15% porosity. A bond coat of NiCrAlY or CoCrAlY is used at a thickness of 0.125 mm (0.005 in.). Both coatings are used on components used in gas turbine engines and adiabatic engines to improve efficiency and reduce metal temperatures or cooling requirements.

Electrically conductive coatings include silver, copper, aluminum, zinc, and bronze alloys. Typical conductivities of these sprayed metals are reported to be 40 to 90% of wrought materials, depending on the spray coating method. In addition, superconducting plasma-sprayed Y-Ba-Cu-O, Cu/Nb_3Sn, and Nb_3Sn materials that have zero resistance at low to intermediate temperatures of 100 K (-280 °F) have been deposited by thermal spraying. Conductive coatings designed to shield electronic components against radio frequency or electromagnetic interference such as aluminum, zinc, and tin coatings, are also sprayed.

Dimensional Restorative Coatings. Thermal spray is used as a coating to repair or resurface (up to 3 mm, or 0.12 in. thick) worn and/or corroded parts, as well as to repair new part errors (for example, undersize parts), to repair nicks or other blemishes, or to renew surfaces that are corroded or worn in use.

Medically Compatible Coatings. Interactive bonding coatings on implants use thermal spray coatings to provide biocompatible titanium (commercially pure Ti or Ti-6Al-4V alloy) and/or ceramic (calcium phosphates) surfaces on both dental and orthopedic devices, to improve wear surface and/or tissue adhesion. Coating porosity and high surface roughness can be produced in thermal spray coatings to improve further tissue adherence.

Hardfacing, Weld Cladding, and Dissimilar Metal Joining

J.R. Davis, Davis & Associates

Weld Cladding

The term weld cladding usually denotes the application of a relatively thick layer ([ges]3 mm, or $\frac{1}{8}$ in.) of weld metal for the purpose of providing a corrosion-resistant surface. Hardfacing, as described earlier in this article, produces a thinner surface coating than a weld cladding and is normally applied for dimensional restoration or wear resistance. Typical base metal components that are weld-cladded include the internal surfaces of carbon and low-alloy steel pressure vessels, paper digesters, urea reactors, tubesheets, nuclear reactor containment vessels, and hydrocrackers. The cladding material is usually an austenitic stainless steel or a nickel-base alloy, although certain copper-base alloys are also sometimes used. Some specialized cladding is also carried out using silver filler metal. Weld cladding is usually performed using the submerged arc welding process (SAW). However, flux-cored (either self-shielded or gas-shielded), plasma arc, and electroslag welding methods can also produce weld claddings. Filler metals are available as covered electrodes, coiled electrode wire, and strip electrodes. Table 15 lists some of the filler metals for stainless steel weld claddings.

Application Considerations (Ref 26)

The technique of weld cladding is an excellent method to impart properties to the surface of a substrate that are not available from that base metal, or to conserve expensive or difficult-to-obtain materials by using only a relatively thin surface layer on a less expensive or abundant base material. This technique has several inherent limitations or possible problems that must be considered when planning for weld cladding. The thickness of the required surface must be less than the maximum thickness of the overlay that can be obtained with the particular process and filler metal selected.

Welding position also must be considered when selecting an overlay material and process. Certain processes are limited in their available welding positions; for example, SAW can be used only in the flat position. In addition, when using a high-deposition-rate process that exhibits a large liquid pool, welding vertically or overhead may be difficult or impossible. Some alloys exhibit eutectic solidification, which leads to large molten pools that solidify instantly rather than with a "mushy" (liquid plus solid) transition. Such materials are also difficult to weld except in the flat position.

Composition Control of Stainless Steel Weld Overlays (Ref 26)

The economics of stainless steel weld cladding are dependent on achieving the specific chemistry at the highest practical deposition rate in a minimum number of layers. The fabricator selects the filler wire and welding process, whereas the purchaser specifies the surface chemistry and thickness, along with the base metal. The most outstanding difference between welding a joint and depositing an overlay is in the area of dilution. The percentage of dilution equals the amount of base metal melted (x) divided by the sum of base metal melted and filler metal added ($x + y$), the quotient of which is multiplied by 100.

$$\%dilution = \frac{x}{x+y} x100 \qquad \textbf{(EQ 2)}$$

For stainless steel cladding, a fabricator must understand how the dilution of the filler metal with the base metal affects the composition and metallurgical balance, such as the proper ferrite level to minimize hot cracking, absence of martensite at the interface for bond integrity, and carbon at a low level to ensure corrosion resistance. The prediction of the microstructures and properties (such as hot cracking and corrosion resistance) for the austenitic stainless steels has been the topic of many studies (Ref 27). During the last two decades, four microstructure prediction diagrams have found the widest application. These include the Schaeffler diagram, the DeLong diagram, and the Welding Research Council (WRC) diagrams (WRC-1988 and WRC-1992). Each of these is described below.

The Schaeffler diagram (Fig. 23), published in 1949, has been extensively used for estimating the ferrite content of stainless steel weld metals (Ref 28). The diagram contains phase fields and iso-ferrite lines that permit prediction of the weld structure from the composition. It is still widely used for predicting the ferrite content of dissimilar weld deposits. This involves calculating a "chromium equivalent" (Cr_{eq}) and a "nickel equivalent" (Ni_{eq}) for each base metal and for the proposed filler metal, plotting each equivalent on the Schaeffler diagram, and drawing tie lines between the plotted points, proportioned according to expected dilution, to obtain an estimate of the weld metal ferrite content.

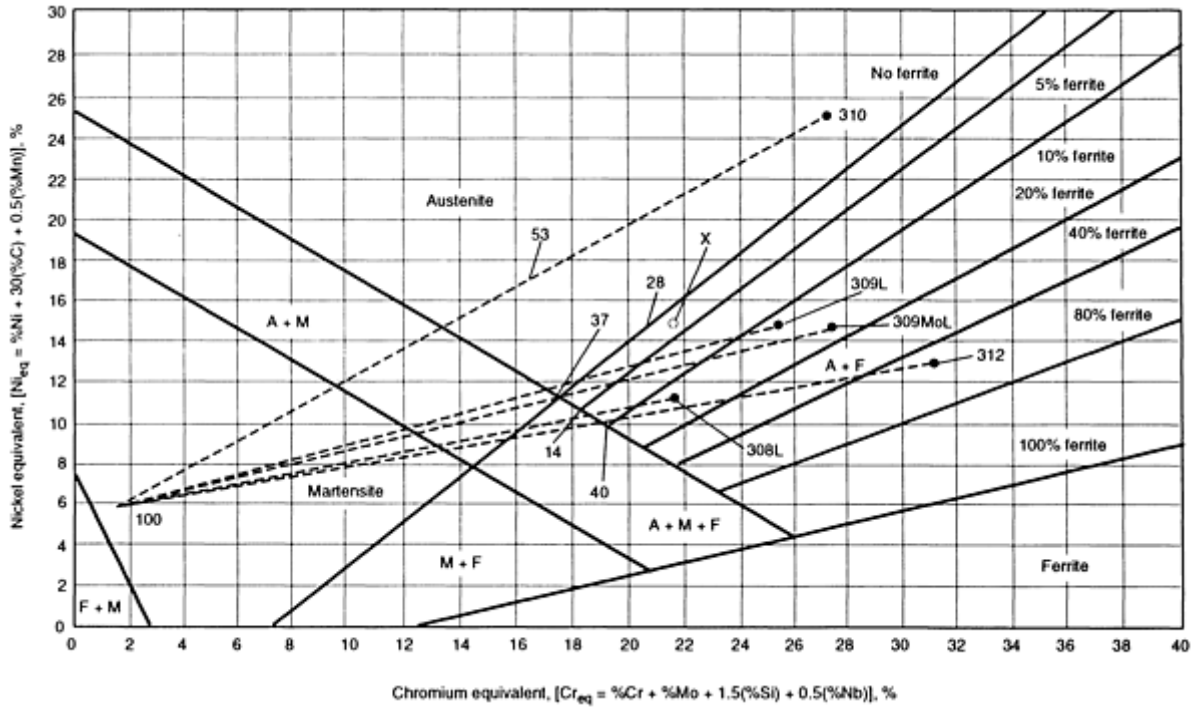

FIG. 23 SCHAEFFLER DIAGRAM FOR STAINLESS STEEL WELD METAL. A, AUSTENITE; F, FERRITE; M, MARTENSITE. POINT 100 IS ASTM A 387A STEEL. EXAMPLE: POINT X ON THE DIAGRAM INDICATES THE EQUIVALENT COMPOSITION OF TYPE 318 (316 CB) WELD DEPOSIT CONTAINING 0.07% C, 1.55% MN, 0.57% SI, 19.02% CR, 11.87% NI, 2.16% MO, AND 0.80% NB. EACH OF THESE PERCENTAGES WAS MULTIPLIED BY THE "POTENCY FACTOR" INDICATED FOR THE ELEMENT IN QUESTION ALONG THE AXES OF THE DIAGRAM TO DETERMINE THE CHROMIUM AND THE NICKEL EQUIVALENT. WHEN THESE WERE PLOTTED AS POINT X, THE CONSTITUTION OF THE WELD WAS INDICATED AS AUSTENITE PLUS FROM 0 TO 5% FERRITE; MAGNETIC ANALYSIS OF THE ACTUAL SAMPLE REVEALED AN AVERAGE FERRITE CONTENT OF 2%. FOR AUSTENITE-PLUS-FERRITE (A+F) STRUCTURES, THE DIAGRAM PREDICTS THE PERCENTAGE OF FERRITE WITHIN 4% FOR THE FOLLOWING STAINLESS STEELS: 308, 309, 309 CB, 310, 312, 316, 317, 318 (316 CB), AND 347. SOURCE: REF 26

As an example of the use of the Schaeffler diagram, suppose a type 304L clad surface is specified (shown as a triangle in Fig. 23). A desirable composition is approximately 20% Cr equivalent and 11% Ni equivalent. If an ASTM A 387A plate (point 100 on the diagram) is specified, all combinations of weld deposit lie on a line connecting point 100 with a proposed filler metal. As an example, note the line connecting point 100 with type 310 stainless steel. The diagram shows that weld-deposit compositions with up to 53% dilution (53% of the length of the line connecting the base metal and the filler metal) will be fully austenitic. Although sufficient alloy might be present, at least for a first layer, the absence of ferrite may make the deposit sensitive to fissuring. The same procedure can be used to estimate the usefulness of other filler metals.

Good metallurgical practice dictates that the first layer contain no martensite, shown as M in the diagram. This limits the dilution. If a process can be found that has less than 14% dilution, then a type 308L could be deposited with absence of martensite. On the other hand, if a first layer is made using type 312 stainless, any dilution factor less than 40% prevents the formation of martensite. Choosing a filler metal for the first layer that falls in the A + F region with 3 to 15% ferrite and no martensite meets the metallurgical requirements of a sound deposit. Proper composition and thickness may be achieved in a single layer, but more often a second layer is required.

Special consideration must be given to carbon levels for the austenitic stainless steels. Figure 24 predicts the carbon in the deposit once the base metal carbon and cladding process dilution factors have been established. To illustrate its use, suppose a base metal plate with 0.20% C and a welding process that results in 30% dilution are established. The diagram indicates that the deposit chemistry will contain approximately 0.07% C. If the specification requires 0.04% C maximum, a second layer would be required to achieve the necessary carbon level. Using the same diagram with the first layer

composition of 0.07% C, and assuming the same dilution factor, the diagram predicts that a second layer will contain approximately 0.03% C. This would meet the specification of 0.04% C maximum.

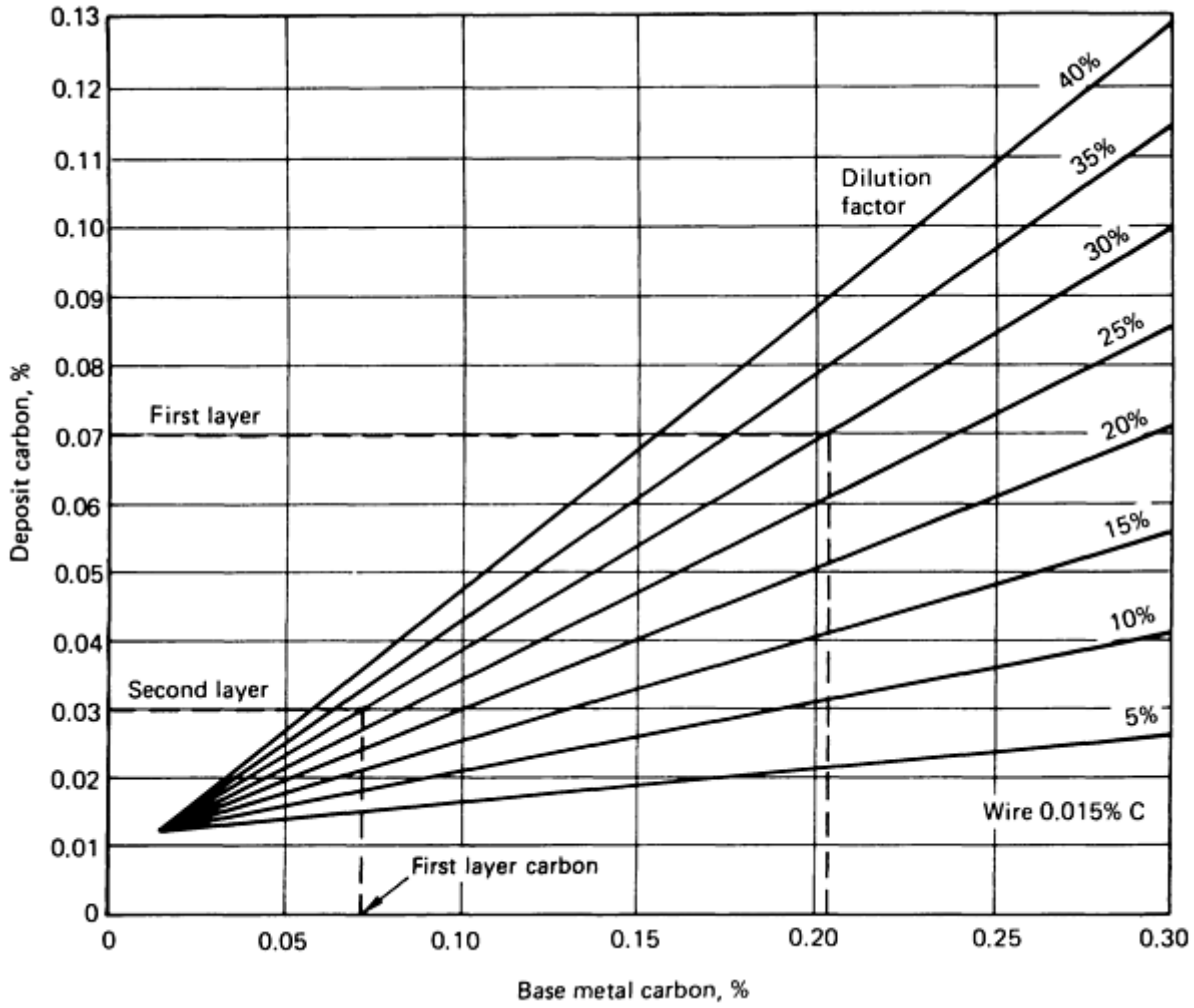

FIG. 24 PERCENTAGE OF CARBON IN THE DEPOSIT AFTER BASE METAL CARBON AND CLADDING DILUTION FACTORS HAVE BEEN ESTABLISHED. SOURCE: REF 26

Several problems have been identified when using the Schaeffler diagram for predicting the physical and mechanical properties of a weld. The Schaeffler diagram does not consider the effect of nitrogen in promoting austenite at the expense of ferrite, and it is incorrect in its treatment of manganese. Manganese does not promote the high-temperature formation of austenite at the expense of ferrite, as predicted by the diagram, although manganese does stabilize austenite in its low-temperature transformation to martensite. Also, the Schaeffler diagram makes its predictions in terms of percent ferrite. This has been found to be imprecise, and the magnetically based Ferrite Number (FN) unit was developed for the specification and determination of ferrite content. The basis for the FN scale is described in the American Welding Society standard AWS 4.2, "Standard Procedures for Calibrating Magnetic Instruments to Measure the Delta Ferrite Content of Austenitic and Duplex Austenitic Ferritic Steel."

The DeLong Diagram. A second widely used prediction diagram, the DeLong diagram (Fig. 25) was published in 1974 and incorporated some improvements (Ref 29). It has an FN scale and includes a coefficient for nitrogen in the Ni_{eq}, though the range of compositions is more limited than for the Schaeffler diagram.

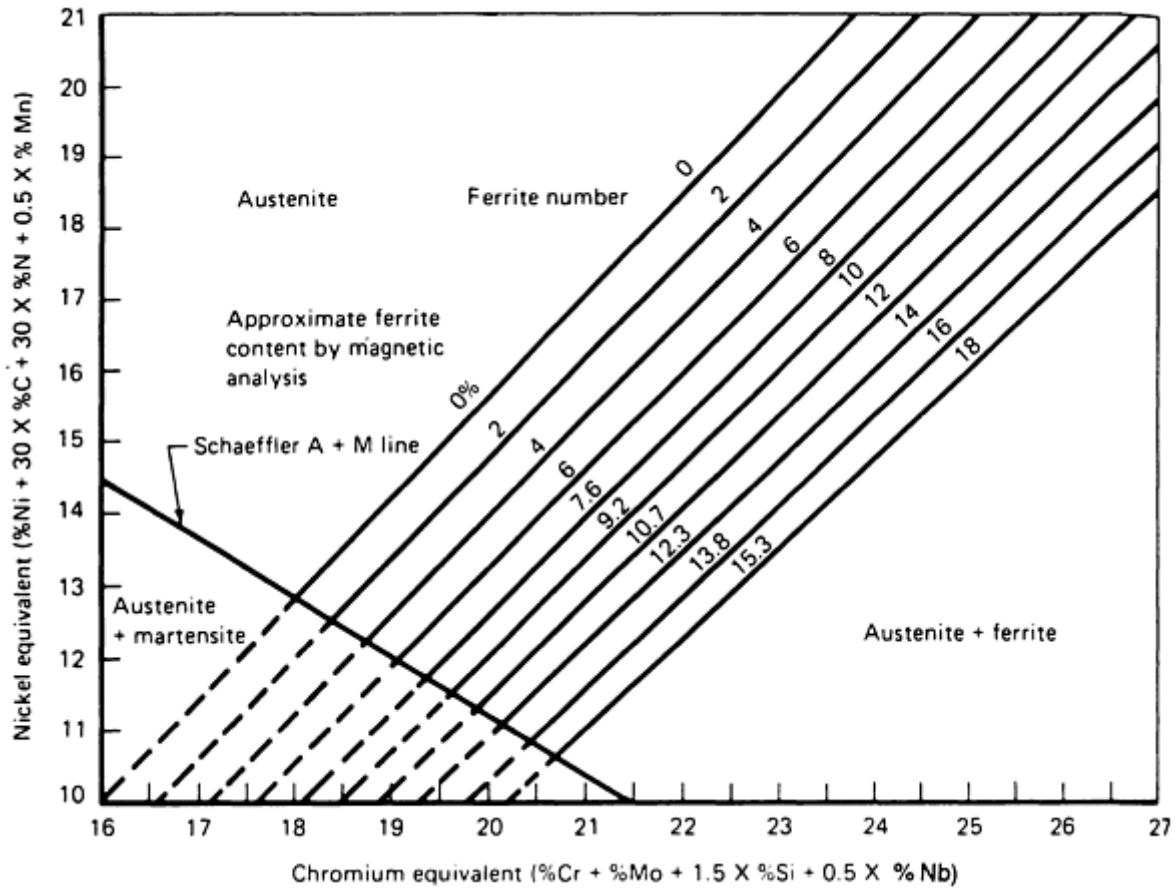

FIG. 25 THE DELONG CONSTITUTION DIAGRAM, REVISED JANUARY 1973 TO CONVERT IT TO THE WELDING RESEARCH COUNCIL'S FERRITE NUMBER (FN) SYSTEM FOR WELD METALS

The difference in the applicability of the Schaeffler and DeLong diagrams is substantial (Ref 30). The DeLong diagram is a finely tuned subset of the Schaeffler range, designed specifically for the 300-series stainless steel welds containing small amounts of ferrite. Its widely accepted use with these alloys is documented by its inclusion in the AWS filler metal specifications A5.4 and A5.9 and in the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code. Prediction of FN for compositions that fall outside the range of the DeLong diagram (for example, duplex stainless steels) is the most quantitative use of the Schaeffler diagram; however, its extension to fully ferritic compositions and the inclusion of martensitic regions provides much qualitative information about the general effect of alloying elements and characteristic mechanical properties of alloy families.

In effect, the DeLong diagram traded improved prediction accuracy for a more limited composition range, but a range that included all the common austenitic stainless steel weld metals. However, it has been found to incorrectly handle manganese (as does the Schaeffler diagram) and to overestimate the FN of more highly alloyed compositions, such as type 309 (Ref 30). It also has had limited application to dissimilar metal joints.

The WRC-1988 diagram (Fig. 26) overcomes many of the problems associated with the Schaeffler and DeLong diagrams (Ref 30). It was developed with data measured by the most recent definition of the FN scale. It removed the erroneous manganese coefficient from the Ni_{eq}, and it eliminated the systematic overestimation of FN for highly alloyed weld metals. While it covers a much broader range of compositions than does the DeLong diagram, it has a narrower composition range than the Schaeffler diagram, because it extends only over the composition range of the commercial alloys with which it was developed.

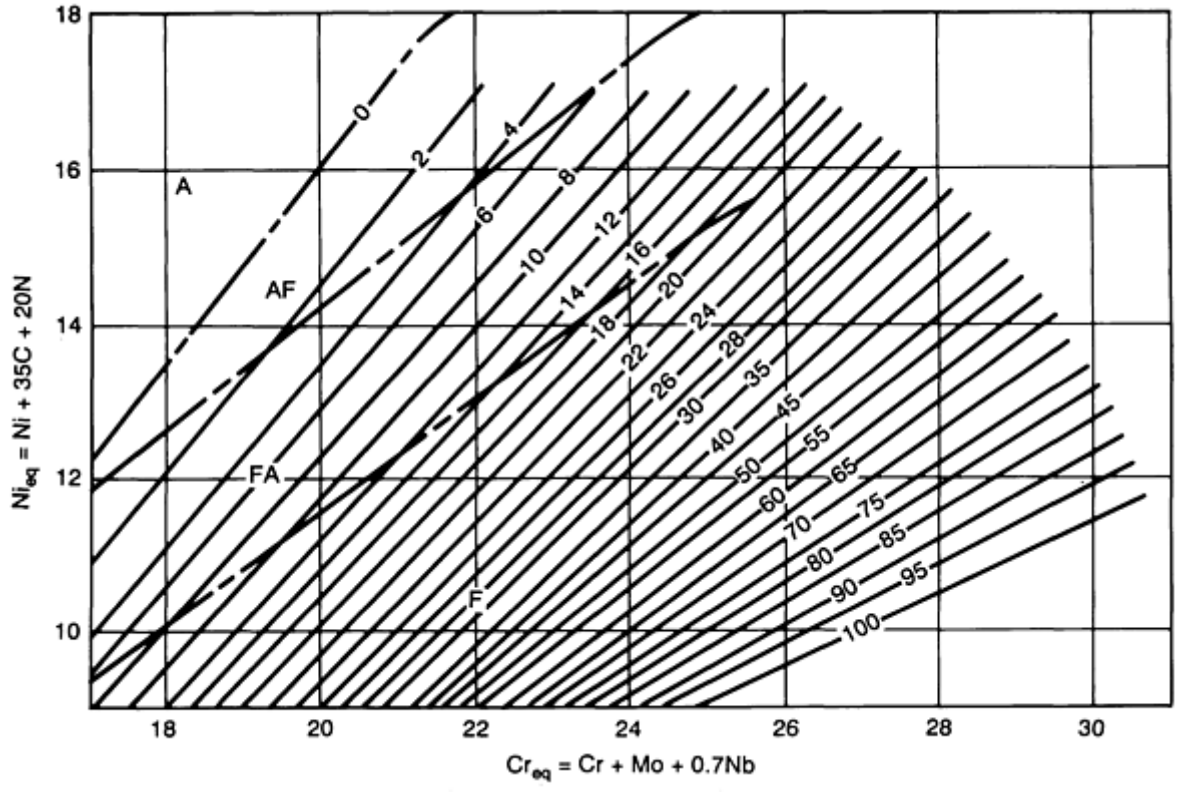

FIG. 26 THE WRC-1988 DIAGRAM, INCLUDING SOLIDIFICATION-MODE BOUNDARIES. SOURCE: REF 30

In the interval since the WRC-1988 diagram first appeared, it has been subjected to considerable evaluation and review. Independent data from more than 200 weld metals have confirmed the improved prediction accuracy of the WRC-1988 over that of its predecessors (Ref 31). The WRC-1988 diagram predicts the ferrite content of the conventional 300-series stainless steels with a higher degree of accuracy than the DeLong diagram, is more accurate than the Schaeffler diagram for predicting the ferrite content of duplex stainless steels, and is suitable for new alloys containing extended compositional ranges. It also includes primary solidification-mode data to reveal relationships to the FN response. Recent studies have emphasized that the solidification mode is more accurate than the FN for predicting the resistance to hot cracking (Ref 30). These studies indicate that the initial solidification structure (primary austenite or ferrite) directly determines the sensitivity to cracking by controlling the solubility of elements that promote cracking at these temperatures.

The WRC-1992 Diagram. In recent years, duplex ferritic-austenitic stainless steels have been used more frequently. Some of these steels and their welds contain significant amounts of copper (often about 2 wt%). While these compositions might be plotted on the WRC-1988 diagram, greater accuracy can be obtained with the modified WRC-1992 diagram (Ref 32). Whereas the Schaeffler diagram offers predictions for Cr_{eq} from 0 to 40 and Ni_{eq} from 0 to 32, the WRC-1992 diagram is more limited, considering Cr_{eq} from 17 to 31 and Ni_{eq} from 9 to 18 (Fig. 27). As indicated in the following example, the WRC-1992 diagram is useful for predicting the FN for dissimilar metal joints.

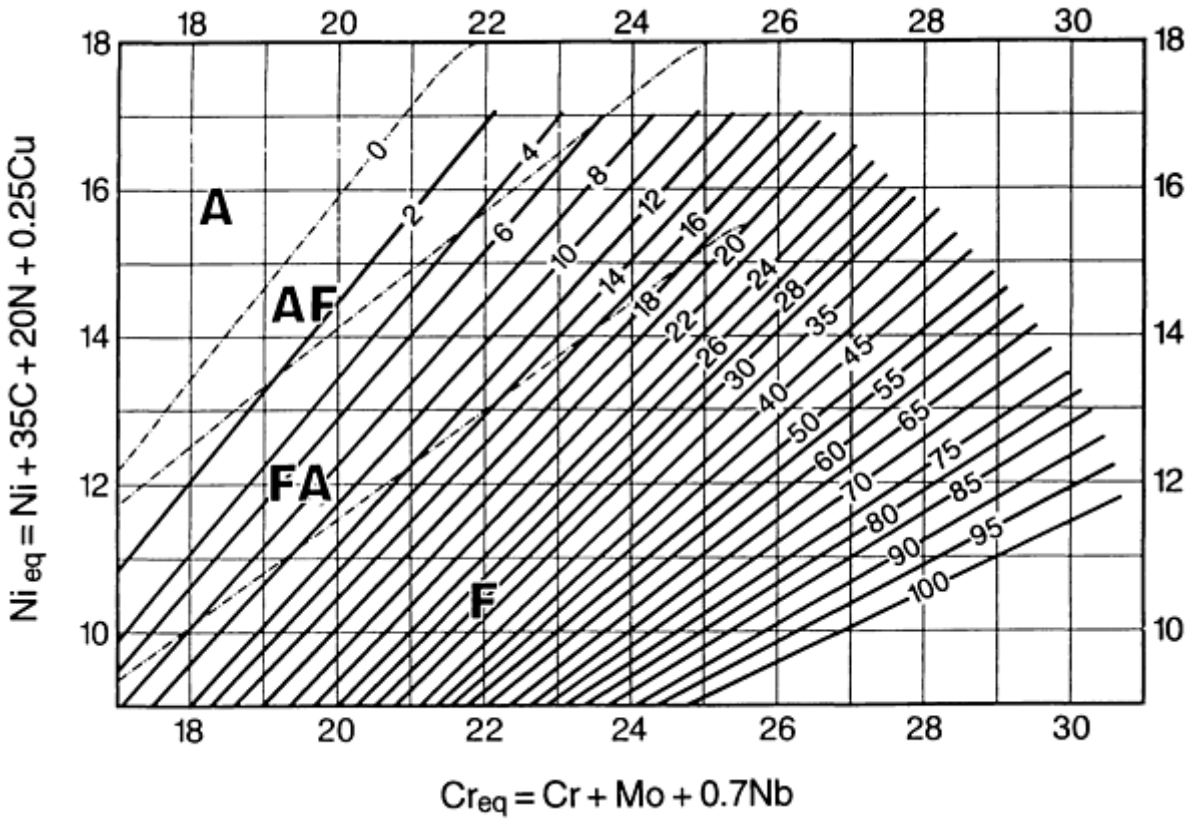

FIG. 27 THE WRC-1992 DIAGRAM. SOURCE: REF 32

Example 1: Weld Cladding of AISl 1050 Steel with AWS A5.4 Class E312-16 Electrode

(Ref 32). Table 16 lists typical plate composition and all-weld-metal composition produced with this electrode. The Cr_{eq} and Ni_{eq} for the AISI 1050 steel (0.0 and 17.50, respectively) do not permit an FN calculation for this material. The Cr_{eq} and Ni_{eq} for the E312-16 electrode all-weld-metal composition (29.0 and 11.9, respectively) result in a predicted 88.2 FN for this material. If the Cr_{eq} and Ni_{eq} for each composition is plotted in Fig. 28 and a line drawn between the point corresponding to the AISI 1050 composition (Point A in Fig. 28) and the point corresponding to the E312-16 composition (Point B in Fig. 28), then all possible mixtures of these two materials must lie along this line.

TABLE 16 BASE METAL AND WELD METAL COMPOSITIONS PRODUCED WHEN AISI 1050 CARBON STEEL WAS WELD CLAD USING E312-16 STAINLESS STEEL FILLER METAL

See Example 1 in text.

MATERIAL	AISI 1050	E312-16 ALL-WELD-METAL	30% DILUTION CLADDING
C, %	0.50	0.060	0.192
MN, %	0.30	1.20	0.93
SI, %	0.02	0.60	0.43
CR, %	. . .	29.00	20.30
NI, %	. . .	8.60	6.02
N, %	0.004	0.06	0.043
CR_{EQ}	0.00	29.00	20.30
NI_{EQ}	17.58	11.90	13.60
WRC-1988 FN	. . .	88.2	4.6

Source: Ref 32

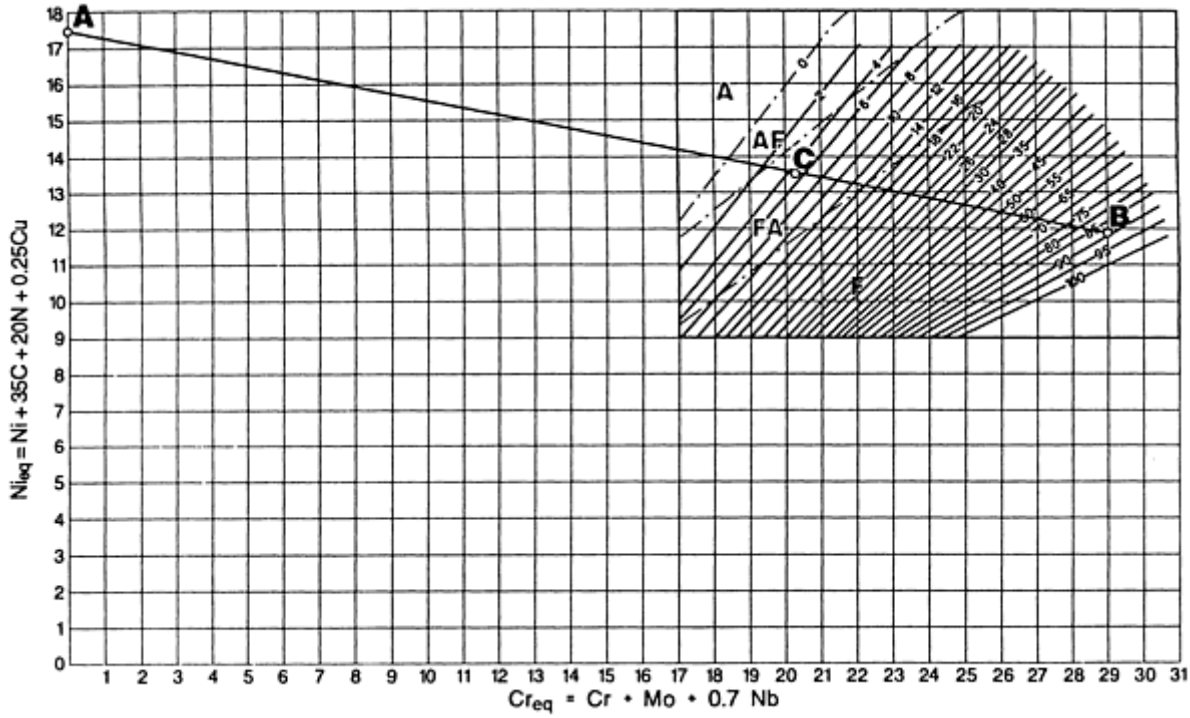

FIG. 28 DILUTION CALCULATION IN EXAMPLE 1 USING THE WRC-1992 DIAGRAM. SOURCE: REF 32

The lever rule is then used to estimate the position of the weld metal. In SMAW, typical dilution is 30%. A weld pass of E312-16 with 30% dilution from AISI 1050 steel would lie at a Point C, located 30% of the distance from Point B to Point A in Fig. 28. Mathematically, this can be calculated as:

$$CR_{EQ}(C) = 0.7\ CR_{EQ}(B) + 0.3\ CR_{EQ}(A)$$
$$= 0.7(29.00) + 0.3(0.00) = 20.30 \quad \textbf{(EQ 3)}$$

$$NI_{EQ}(C) = 0.7\ NI_{EQ}(B) + 0.3\ NI_{EQ}(A)$$
$$= 0.7(11.90) + 0.3(17.58) = 13.60 \quad \textbf{(EQ 4)}$$

The Cr_{eq} and Ni_{eq} of Point C correspond to 4.6 FN, which indicates that the weld pass will have sufficient FN to avoid fissuring (Ref 30). Any additional passes overlapping part of this first pass will also lie along the line between Point B and Point A, but they will be closer to Point B than is Point C, so all subsequent passes will contain even more ferrite than the first pass and the weld cladding should be crack-free.

Control of dilution plays an important part in the economics of the weld cladding process. Although each process has an expected dilution factor, experimenting with the welding parameters can minimize dilution. A value between 10 and 15% is generally considered optimum. Less than 10% raises the question of bond integrity, and greater than 15% increases the cost of the filler metal. Unfortunately, most welding processes have considerably greater dilution.

Because of the importance of dilution in weld cladding as well as hardfacing applications, each welding parameter must be carefully evaluated and recorded. Many of the parameters that affect dilution in weld cladding applications are not so closely controlled when arc welding a joint. These parameters include:

- *AMPERAGE:* INCREASED AMPERAGE (CURRENT DENSITY) INCREASES DILUTION. THE ARC BECOMES HOTTER, IT PENETRATES MORE DEEPLY, AND MORE BASE METAL MELTING OCCURS.
- *POLARITY:* DIRECT CURRENT ELECTRODE NEGATIVE (DCEN) GIVES LESS PENETRATION AND RESULTING LOWER DILUTION THAN DIRECT CURRENT ELECTRODE POSITIVE

(DCEP). ALTERNATING CURRENT RESULTS IN A DILUTION THAT LIES BETWEEN DCEN AND DCEP.

- *ELECTRODE SIZE:* THE SMALLER THE ELECTRODE, THE LOWER THE AMPERAGE, WHICH RESULTS IN LESS DILUTION.
- *ELECTRODE EXTENSION:* A LONG ELECTRODE EXTENSION FOR CONSUMABLE ELECTRODE PROCESSES DECREASES DILUTION. A SHORT ELECTRODE EXTENSION INCREASES DILUTION.
- *TRAVEL SPEED:* A DECREASE IN TRAVEL SPEED DECREASES THE AMOUNT OF BASE METAL MELTED AND INCREASES PROPORTIONALLY THE AMOUNT OF FILLER METAL MELTED, THUS DECREASING DILUTION.
- *OSCILLATION:* GREATER WIDTH OF ELECTRODE OSCILLATION REDUCES DILUTION. THE FREQUENCY OF OSCILLATION ALSO AFFECTS DILUTION--THE HIGHER THE FREQUENCY OF OSCILLATION, THE LOWER THE DILUTION.
- *WELDING POSITION:* DEPENDING ON THE WELDING POSITION OR WORK INCLINATION, GRAVITY CAUSES THE WELD POOL TO RUN AHEAD OF, REMAIN UNDER, OR RUN BEHIND THE ARC. IF THE WELD POOL STAYS AHEAD OF OR UNDER THE ARC, LESS BASE METAL PENETRATION AND RESULTING DILUTION WILL OCCUR. IF THE POOL IS TOO FAR AHEAD OF THE ARC, THERE WILL BE INSUFFICIENT MELTING OF THE SURFACE OF THE BASE METAL, AND COALESCENCE WILL NOT OCCUR.
- *ARC SHIELDING:* THE SHIELDING MEDIUM, GAS OR FLUX, ALSO AFFECTS DILUTION. THE FOLLOWING LIST RANKS VARIOUS SHIELDING MEDIUMS IN ORDER OF DECREASING DILUTION: GRANULAR FLUX WITHOUT ALLOY ADDITION (HIGHEST), HELIUM, CARBON DIOXIDE, ARGON, SELF-SHIELDED FCAW, AND GRANULAR FLUX WITH ALLOY ADDITION (LOWEST).
- *ADDITIONAL FILLER METAL:* EXTRA METAL (NOT INCLUDING THE ELECTRODE), ADDED TO THE WELD POOL AS POWDER, WIRE, STRIP, OR WITH FLUX, REDUCES DILUTION BY INCREASING THE TOTAL AMOUNT OF FILLER METAL AND REDUCING THE AMOUNT OF BASE METAL THAT IS MELTED.

Procedures for Stainless Steel Weld Cladding (Ref 26)

Submerged arc welding is by far the most commonly used process for weld cladding. The process is adaptable for use with single wires as the electrode filler metal, multiple wires, or strip. Alternating current is often used, but direct current, with either reverse or straight polarity, has been found preferable in numerous instances. Oscillation of the filler metal is frequently found desirable. Typical welding parameters for stainless steel weld cladding by SAW are given in Table 17.

TABLE 17 TYPICAL WELDING PARAMETERS FOR STAINLESS STEEL WELD CLADDING BY SAW

(A) VARIATIONS IN CURRENT, VOLTAGE, AND TRAVEL SPEED AFFECT PERCENTAGE OF DILUTION.

(B) CONSTANT POTENTIAL

The single-wire process is largely used for overlaying limited areas or where it is necessary to limit the heat input. Wires from 1.6 to 4.8 mm (or $\frac{1}{16}$ to $\frac{3}{16}$ in.) diam are practical. The small-size wires are generally employed with oscillation to keep dilution low, to provide a wide (up to about 25 mm, or 1 in.) weld bead, and to give uniformly good tie-ins with the adjacent beads. Either alternating or direct current may be employed for single-wire overlays.

Productivity (deposition rate) is greatly increased by the use of multiple wires (Table 17). Two-wire series arc (each wire connected to the poles of an alternating current power source) is a frequently used method for producing type 347 stainless steel weld cladding of petrochemical pressure vessels. The wire size is usually either 3.2 or 4.0 mm ($\frac{1}{8}$ or $\frac{5}{32}$ in.) in diameter. Alternating current is essential to achieve uniform fusion of both wires. The height of the welding head over the base metal greatly influences the penetration and hence the dilution. If the base metal has a non-uniform surface, or if the head cannot be accurately controlled above the base metal, the process may not be acceptable because of variations in dilution, or even lack of penetration in spots.

"Shingling" is a technique used to minimize dilution in single- or two-wire weld claddings. By providing an overlap of as much as 70% of a bead width, it is possible to reduce the dilution from 30 or 35% to 15 or 20%. In some applications, this allows the cladding to be deposited in a single layer at considerable cost savings as compared with two-layer overlays.

To further improve productivity, fabricators have increased the number of wires deposited by a single welding head. Up to six wires have been used with oscillation to deposit beads 150 mm (6 in.) or more in width. Usually, the wire sizes are 1.6 to 4.0 mm ($\frac{1}{16}$ to $\frac{5}{32}$ in.) in diameter. Direct current electrode negative has been found best for relatively low dilution (around 15%). Sometimes the wire that overlaps the previously deposited bead is connected to the positive tap of the power source (DCEP), which gives somewhat greater penetration and ensures good tie-in with the previous bead.

For weld cladding the inside surfaces of large pressure vessels, as shown in Fig. 29(a)and 29(b), wide beads produced by oscillated multiple-wire systems or strip electrodes have become the means to improve productivity and minimize dilution while offering a uniformly smooth surface. Welding parameters for stainless steel strip weld overlays are illustrated in Fig. 30, 31, 32. In Fig. 30, the effect of increased current on dilution, penetration, and bead thickness of a 60 mm (2.4 in.) strip is shown. Figure 31 illustrates the effect of travel speed on dilution, penetration, and bead dimensions using a 60 mm (2.4 in.) strip. Productivity of different strip sizes (deposition rate versus arc current) is shown in Fig. 32.

The fluxes for submerged arc overlays should have low bulk density, especially for wide weld beads produced with multiple wire or strip electrodes. Standard fused fluxes, therefore, are usually unsuitable. Agglomerated fluxes, which have much lower bulk density, are commonly used for this purpose. Low-bulk-density fused fluxes have been successfully produced by a manufacturing process known as foaming. Such foamed fluxes have even lower bulk density than agglomerated fluxes.

Agglomerated fluxes (or bonded fluxes) have a distinct advantage over fused fluxes in that it is possible to introduce alloying elements by means of the flux. When this is done, they are known as reinforced, or alloyed, fluxes. For stainless steel weld claddings, chromium is commonly added to the fluxes to overcome the oxidation of chromium, which is characteristic of SAW of stainless alloys, and to compensate for the dilution with the non-chromium or low-chromium base metal. Other alloying elements often added to reinforced fluxes are manganese, nickel, molybdenum, and niobium. With reinforced fluxes, it is possible to produce various modified stainless weld overlays using a single filler metal as an electrode, for example, a type 347 overlay with a 308 or 309 filler metal using a niobium-alloyed flux. Table 18 lists variations in chemical compositions of series-arc weld deposits using an agglomerated flux and type 308 or 309 wire.

Another method for providing the desired stainless steel cladding composition is to introduce a layer of powdered metal under the submerged arc flux. This procedure is sometimes known as bulk welding. It is suitable for use either with single-wire or strip electrodes. The powdered metal not only provides the alloying elements needed in the overlay, but it also greatly reduces the dilution. A schematic of the process is shown in Fig. 33.

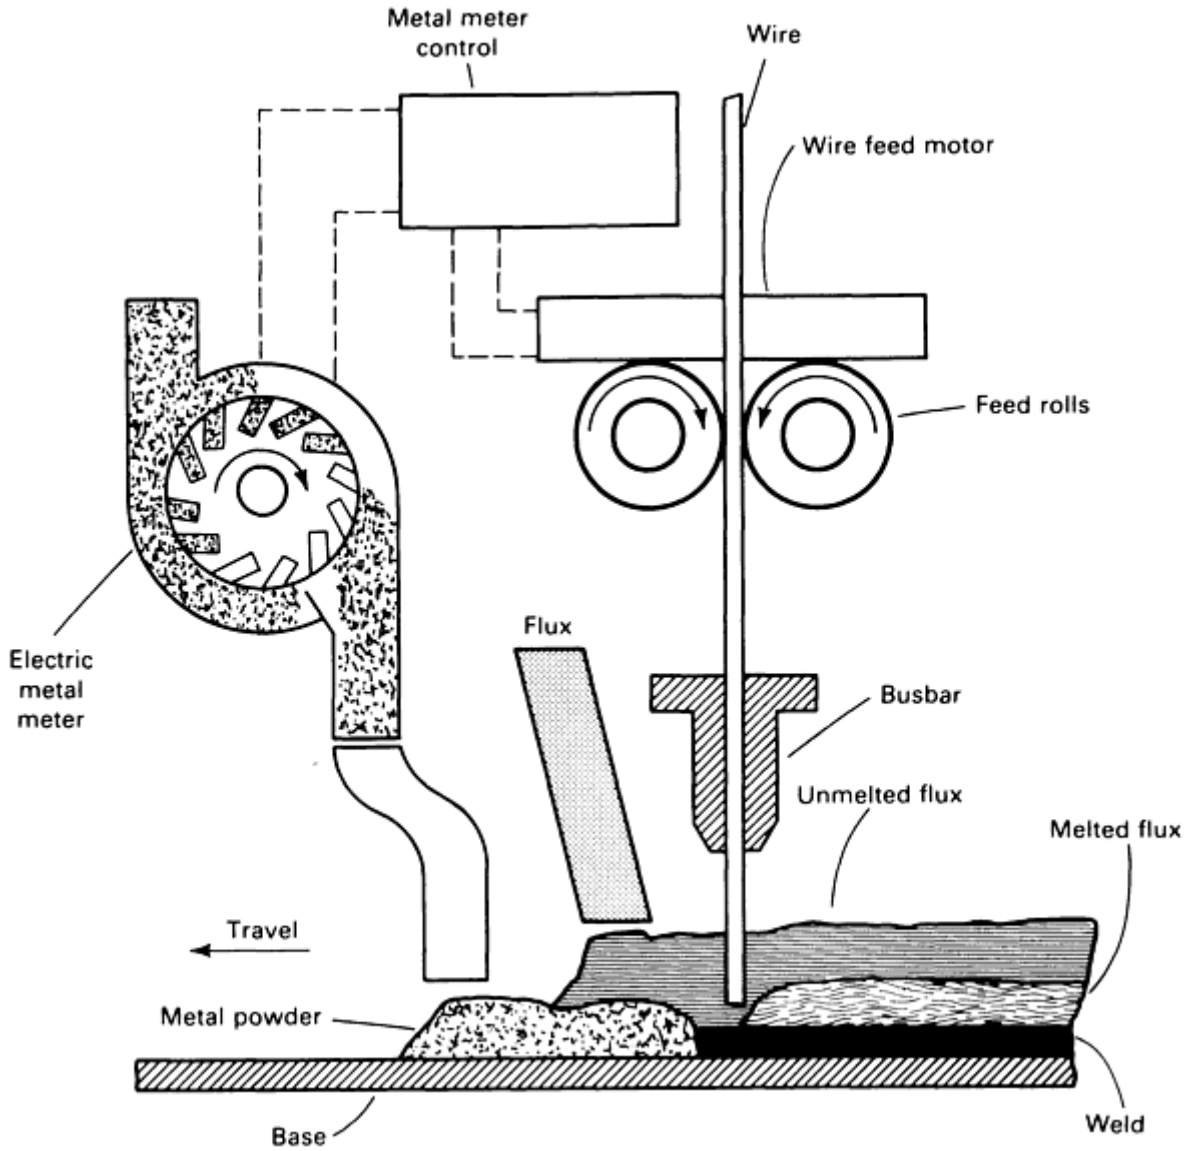

FIG. 33 SCHEMATIC OF THE BULKWELDING PROCESS USING METAL POWDER JOINT FILL. SOURCE: REF 9

Either method of adding alloying elements by using powdered alloys, either as an ingredient of the flux or separately underneath the flux, is subject to variability of the deposit composition. When reinforced fluxes are employed, the recovery of the alloying ingredient is dependent on the arc voltage, with a measurable difference in recovery by a change of as little as 1 or 2 V. This is not the case when the powdered alloys are separately fed below the flux, but in this case variability results if the height of the powder layer varies. Thus, it is unwise to rely on these methods of alloy adjustment of the weld overlay composition for more than three percentage points.

Still another method of providing the desired composition for the cladding is to use tubular wire for the filler metal. Whereas the solid wire producer is limited in the compositions that can be produced and still provide hot workability and cold drawing capability, the producer of tubular wire is virtually unlimited as to the compositions that can be produced. For example, the strip can be chromium or chromium-nickel steel, to which the core ingredients are added to give a weld deposit of austenitic stainless steel, rich enough in the essential alloys to compensate for both oxidation and dilution losses. Another distinct advantage of tubular wires is for relatively small production applications of compositions that are not available as "shelf items" in solid-wire form. Small quantities of tubular wires can also be prepared for experiments to determine the optimum composition for a particular application. The effective cross section of tubular wire for current-carrying ability is substantially less than solid wire of the same diameter. Welding parameters that have been established for solid wires will have to be adjusted to take this and other differences into account.

Self-Shielded Flux-Cored Wire. Tubular wires are produced that contain not only the alloying ingredients, but also the fluxing and gas-shielding ingredients. This permits the deposition of weld claddings without the need of an external flux, as is needed with SAW, or an external gas, as is needed with gas-shielded solid wire welding. Weld claddings are produced by manually directed welding guns for limited areas using a single tubular filler wire.

High productivity procedures have been developed using multiple wires in a manner similar to six-wire SAW. These wires have inherently low penetration characteristics, making them highly suitable for cladding. Deposition rates of 35 to 45 kg/h (80 to 100 lb/h) are often achieved. In addition, improved wire feed roll mechanisms have lessened the problems of kinking and crushing of these thin-wall electrodes during the wire-feeding process, thereby increasing the productivity of multiple-wire applications. Some fabricators who use self-shielded flux-cored wires prefer to limit the automatic cladding process to two or three wires, particularly because the gain in productivity with increasing numbers of wires diminishes. A three-wire welding head for overlay applications is shown in Fig. 34.

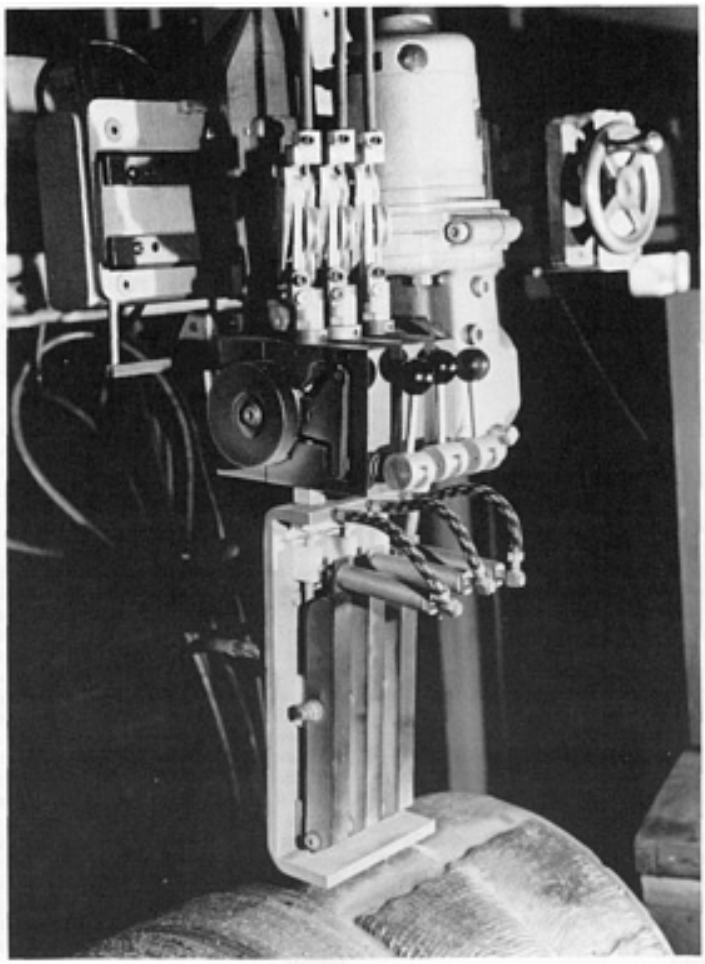

FIG. 34 THREE-WIRE WELDING HEAD FOR WELD CLADDING APPLICATIONS. COURTESY OF STOODY COMPANY

Metallurgically, flux-cored wires offer potentially higher alloyed claddings, permitting a considerable cost saving to produce the desired composition in a single layer. Also, dilution is minimized with this process. Furthermore, carbon content can be kept to much lower levels than is possible with solid wires, partly due to the ability to have very low-carbon ingredients in the flux-cored wire and partly due to the low dilution. Typical welding parameters for stainless steel weld cladding using self-shielded flux-cored wires are given in Table 19.

(A) 100% DUTY CYCLE

The plasma arc hot wire process is used for depositing stainless steel claddings on pressure vessels subjected to corrosive, high-temperature, and high-pressure hydrogen environments. The setup for this process is illustrated in Fig. 35. Using this method, two filler-metal wires are fed at a constant speed through individual hot wire nozzles to intersect in the weld pool beneath the plasma arc. The filler metals are electrically connected in series and energized by an alternating current constant-potential power supply. Resistance heating occurs in each electrode between the wire contact tip and the weld pool. Input power is selected for a given filler-metal feed rate so that maximum resistance heating is induced into both electrodes without resulting in an open arc between them. While a single hot wire increases the deposition rate considerably over the cold wire or powder methods, a dual hot wire process permits deposition rates as high as 18 to 32 kg/h (40 to 70 lb/h), thus making the hot wire process commercially competitive with other weld cladding processes. A continuously made stainless steel weld overlay made by the hot wire process is shown in Fig. 36.

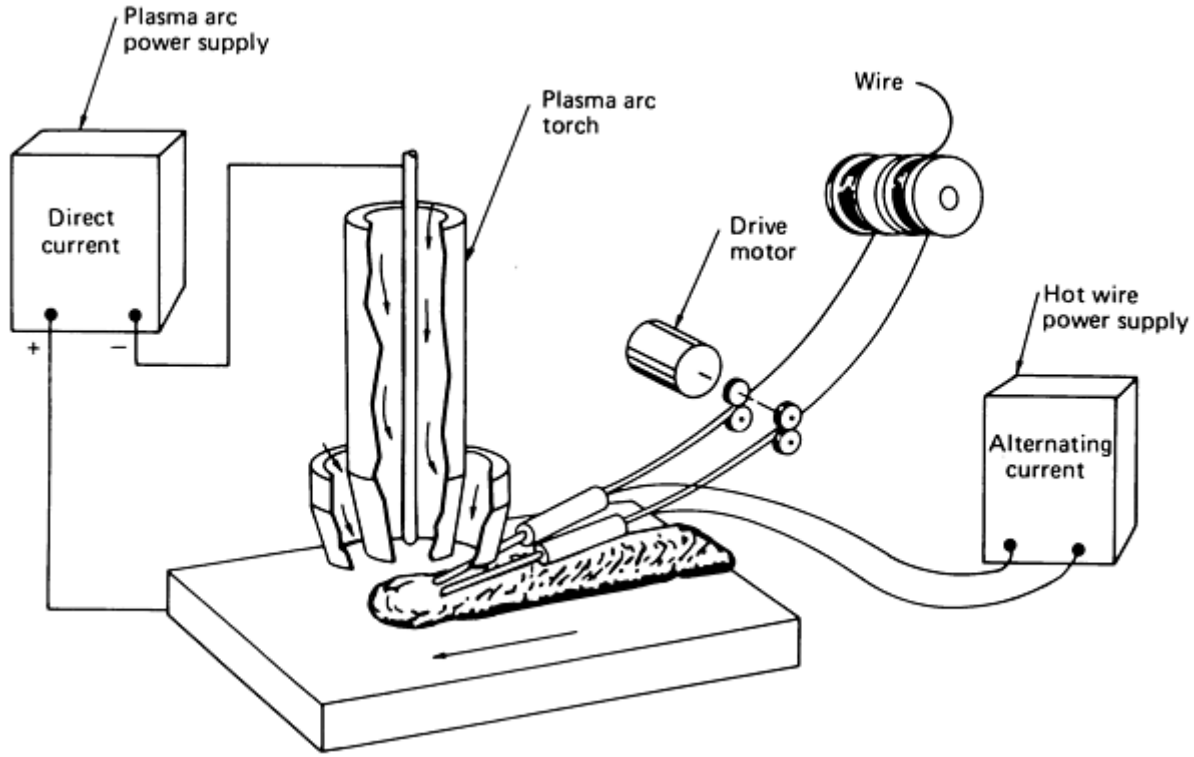

FIG. 35 SCHEMATIC OF THE PLASMA ARC HOT WIRE WELD CLADDING PROCESS. SOURCE: REF 1

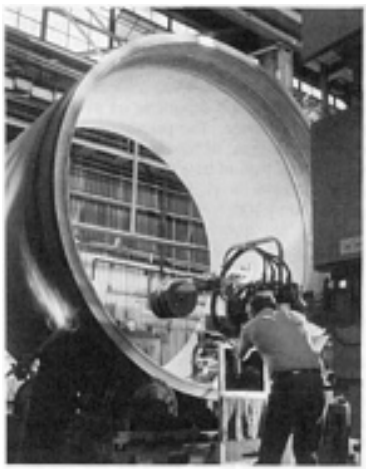

FIG. 36 PLASMA ARC HOT WIRE PROCESS FOR WELD CLADDING THE INTERNAL SURFACE OF A PRESSURE VESSEL SHELL. COURTESY OF NOOTER CORPORATION

Advantages of the hot wire process include:

- ACCURATE CONTROL OF DILUTION AND THUS COMPOSITION OF THE OVERLAY
- LITTLE OR NO CHANGES DUE TO OXIDATION OF THE ELEMENTS IN THE PROCESS
- PARAMETERS THAT CAN BE INDEPENDENTLY AND ACCURATELY CONTROLLED
- SINGLE-LAYER OVERLAYS THAT CAN BE PRODUCED IN THICKNESSES RANGING FROM 4.0 TO 8.0 MM ($\frac{5}{32}$ TO $\frac{5}{32}$ IN.)
- APPLICABILITY TO MANY CORROSION-RESISTANT ALLOYS, SUCH AS MONEL, INCONEL, AND HASTELLOY ALLOYS

Typical welding parameters for stainless steel weld cladding by the plasma arc process are given in Table 20.

TABLE 20 TYPICAL WELDING PARAMETERS FOR STAINLESS STEEL WELD CLADDING BY THE PLASMA ARC PROCESS

Electroslag Overlays. The electroslag welding process has been adapted to produce stainless steel weld claddings. This process offers the ability to use wider strip (up to 300 mm, or 12 in.) than the submerged arc process and more uniform penetration into, and lower dilution with, the base metal. Its principal disadvantages are operator exposure to the radiant heat from the molten slag and a sharper compositional change at the fusion line, which may give unsatisfactory service in certain high-temperature pressure vessels (for example, disbonding in hydrocracker or hydrosulfurizer service).

For large heavy-wall pressure vessels, the electroslag overlay process typically uses strip 4.0 mm (0.16 in.) thick by 150 mm (6 in.) wide. The effect of electroslag welding parameters on dilution using a 150 mm (6 in.) strip is shown in Fig. 37. As in SAW, energy is created by ohmic resistance as the electric current flows from the strip to the work through the molten slag; no arc exists. Unlike SAW, however, the slag bath is relatively thin. To provide the required electrical resistance, viscosity, and other properties, the fluxes must be significantly higher in fluorides than for SAW (Ref 26). A typical fused flux composition comprises 49% CaF_2, 21% CaO, 21% SiO_2, and 9% Al_2O_3.

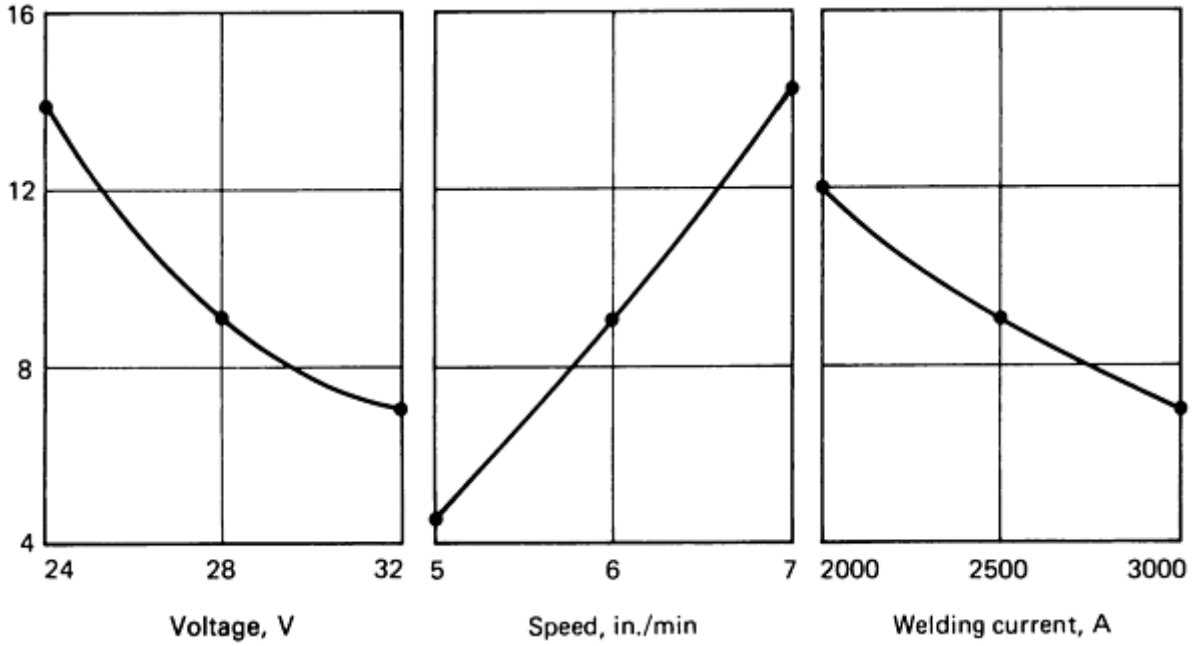

FIG. 37 EFFECT OF WELDING PARAMETERS ON DILUTION USING 150 MM (6 IN.) STRIP IN ELECTROSLAG WELD CLADDING PROCESS. SOURCE: REF 26

Because of disbonding of weld claddings deposited on pressure vessels in a hydrogen environment, electroslag weld claddings are not used for single-layer overlays; but where two-layer overlayers are specified, the electroslag process is used for the second layer. Higher productivity and a smoother surface are thus obtained, the first layer having been deposited by the SAW.

Extremely low carbon levels are possible because of low dilution with the base metal and a removal of carbon through oxidation in the process. Using a 0.18% C base metal and a 0.01% C strip, one investigator produced weld-metal carbon levels of 0.02% in the first layer and 0.01% in the second (Ref 26). The electroslag weld cladding process also can be applied for weld overlays of nickel-chromium (Inconel) alloys in the same manner as for stainless steel.

Weld Overlays Other Than Stainless Steel (Ref 26)

Many of the procedures described for stainless steel weld cladding are applicable to other alloys. Generally, nickel-base alloys can be produced successfully using essentially the same procedures as for stainless steels. Some of the common alloy filler metals used are given in Table 21. Figure 38 shows the use of both Inconel and stainless steel strip overlays used to clad a large pressure vessel shell.

Metals and alloys that do not tolerate significant amounts of iron cannot be used in weld overlays on steels. Titanium, zirconium, magnesium, and aluminum are examples of incompatible metals for cladding steel. Pure copper is also unsatisfactory, but some copper alloys, such as aluminum-bronze and silicon-bronze, can be applied to steels. The incompatible metals are usually bonded by explosion cladding or roll bonding techniques, which are described elsewhere in this Volume.

Dissimilar Metal Joining

Because various portions of a process system operate at different service conditions, different structural alloys are used in the design, and hence, dissimilar-metal welded joints may be required. Many factors must be considered when welding dissimilar metals, and the development and qualification of adequate procedures for the various metals and sizes of interest for a specific application must be undertaken.

Most combinations of dissimilar metals can be joined by solid-state welding (diffusion welding, explosion welding, friction welding, or ultrasonic welding), brazing, or soldering where alloying between the metals is normally insignificant. In these cases, only the differences in the physical and mechanical properties of the base metals and their influence on the serviceability of the joint should be considered. When dissimilar metals are joined by fusion welding processes, alloying between the base metals and a filler metal, when used, becomes a major consideration. The resulting weld metal can behave much differently from one or both base metals during subsequent processing or in service.

In this section, the principal factors that are responsible for failure (cracking) of dissimilar metal arc welds are described. These include:

- GENERAL ALLOYING PROBLEMS (BRITTLE PHASE FORMATION AND LIMITED MUTUAL SOLUBILITY) OF THE TWO METALS
- WIDELY DIFFERING MELTING POINTS
- DIFFERENCES IN COEFFICIENTS OF THERMAL EXPANSION
- DIFFERENCES IN THERMAL CONDUCTIVITY

In addition, service considerations that can result in dissimilar-metal weld failure by carbon migration or by corrosion/oxidation are addressed. Lastly, a brief review of specific dissimilar metal combinations and filler metal selection guidelines are presented. Additional information on welding dissimilar metals can be found throughout this Volume and in Ref 33 and 34.

Factors Influencing Joint Integrity (Ref 33)

Weld Metal. In the fusion welding of dissimilar-metal joints, the most important consideration is the weld metal composition and its properties. Its composition depends upon the compositions of the base metals; the filler metal, if used; and the relative dilutions of these. The weld metal composition is usually not uniform, particularly with multipass welds, and a composition gradient is likely to exist in the weld metal adjacent to each base metal.

These solidification characteristics of the weld metal are also influenced by the relative dilutions and the composition gradients near each base metal. These characteristics are important with respect to hot cracking of the weld metal during solidification.

The basic concepts of alloying, the metallurgical characteristics of the resultant alloy, and its mechanical and physical properties must be considered when designing a dissimilar-metal joint. For the fusion welding processes it is important to investigate the phase diagram of the two metals involved. If there is mutual solubility of the two metals, the joint can usually be made successfully. If there is little or no solubility between the two metals to be joined, the weld joint will not be successful. The intermetallic compounds that are formed between the dissimilar metals must be investigated to determine their crack sensitivity, ductility, susceptibility to corrosion, and so on. The microstructure of this intermetallic compound is extremely important. In some cases, it is necessary to use a third metal that is soluble with each metal in order to produce a successful joint.

Dilution. In dissimilar-metal welding, the filler metal must alloy readily with the base metals to produce a weld metal that has a continuous, ductile matrix phase. Specifically, the filler metal must be able to accept dilution (alloying) by the base metals without producing a crack-sensitive microstructure (dilution was defined and described earlier in this article in the sections on "Hardfacing" and "Weld Cladding"). The weld metal microstructure must also be stable under the expected service conditions. A successful weld between dissimilar metals is one that is as strong as the weaker of the two metals being joined, that is, possessing sufficient tensile strength and ductility so that the joint will not fail.

In multipass welding, the composition of each weld bead should be relatively uniform. However, definite compositional differences are likely in succeeding weld beads, especially between a root bead, the beads adjacent to the base metals, and the remaining fill beads. The average composition of the whole weld metal can be calculated when: (1) the ratio of the volumes of base metals melted to the entire weld metal volume can be determined; and (2) the compositions of the base and filler metals are known. The dilution can be based on area measurements on a transverse cross section through a test weld. Figure 39 illustrates how to determine the dilution by two base metals, A and B, when welding with filler metal F.

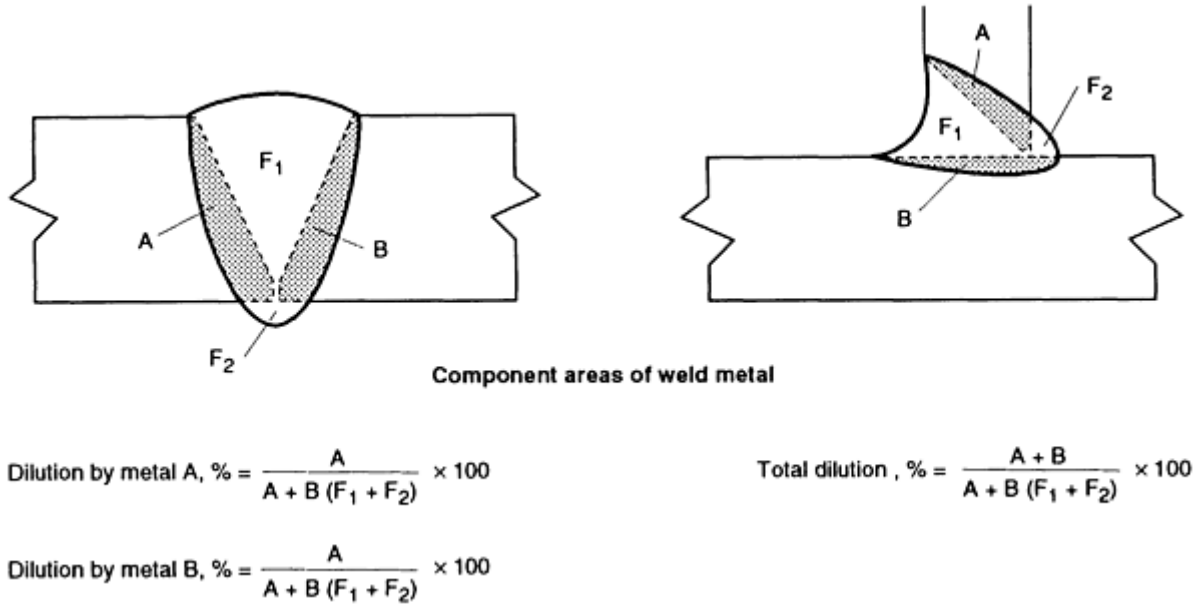

FIG. 39 DILUTION IN A DISSIMILAR-METAL WELDED JOINT. SOURCE: REF 33

The average percentage of a specific alloying element in the diluted weld metal can be calculated using the following equation developed by the American Welding Society (Ref 33):

$$X_W = (D_A)(X_A) + (D_B)(X_B) + (1 - D_T)(X_F) \quad \textbf{(EQ 5)}$$

where X_w is the average percentage of element X in the weld metal; X_A is the percentage of element X in base metal A; X_B is the percentage of element X in base metal B; X_F is the percentage of element X in the filler metal F; D_A is the percent dilution by base metal A, expressed as a decimal; D_B is the percent dilution by base metal B, expressed as a decimal; and D_T is the percent total dilution by base metals A and B, expressed as a decimal.

To illustrate the calculation of weld metal composition, assume that type 316 stainless steel is welded to a 2.25Cr-1Mo (UNS K21590) low-alloy ferritic pressure vessel steel with a nickel-chromium alloy filler metal ERNiCr3. The nominal chemical compositions of the three alloys are:

ALLOY	COMPOSITION, WT%			
	CR	**NI**	**MO**	FE
2.25CR-1MO	2.5	. . .	1.0	**95.5**
TYPE 316	17.0	12.0	2.5	**63.0**
ERNICR-3	**20.0**	**72.0**	**. . .**	**3.0**

Assuming that the total dilution is 35%, 15% by the Cr-Mo alloy steel and 20% from the type 316 stainless steel, the average percentages of Cr, Ni, and Mo in the weld metal are calculated as follows:

$$CR, \% = 0.15(2.5) + 0.20(17) + 0.65(20) = 16.8 \quad \textbf{(EQ 6)}$$

$$NI, \% = 0.20(12) + 0.65(72) = 49.2 \quad \textbf{(EQ 7)}$$

$$MO, \% = 0.15(1) + 0.20(2.5) = 0.65 \quad \textbf{(EQ 8)}$$

Melting Temperatures. The difference in melting temperatures of the two metals that are to be joined must also be considered. This is of primary interest when a fusion welding process utilizing considerable heat is involved, since one metal may be molten long before the other when subjected to the same heat source. Significant difference between the melting temperatures of the two base metals or between those of the weld metal and a base metal can result in rupture of the metal having the lower melting temperature. Solidification and contraction of the metal with the higher melting temperature will induce stresses in the other metal while it is in a weak, partially solidified condition. This problem may be solved by depositing one or more layers of a filler metal of intermediate melting temperature on the face of the base metal with the higher melting temperature. This procedure is known as buttering. The weld is then made between the buttered face and the other base metal. The buttering layer should serve to reduce the melting temperature differential. Buttering may also be used to provide a transition between materials with substantially different coefficients of thermal expansion but which must endure cycling temperatures in service. Similarly, buttering may be used to provide a barrier layer that will slow the migration of undesirable elements from the base metal to the weld metal during postweld heat treatment or in service at elevated temperatures.

Thermal Conductivity. Most metals and alloys are relatively good conductors of heat, but some are much better than others. Rapid conduction of heat from the molten weld pool by an adjacent base metal may affect the energy input required to locally melt the base metal. When two dissimilar metals of significantly different thermal conductivities are welded together (for example, plain carbon steels and copper-base alloys), the welding procedure must provide for this difference. Often the welding heat source must be directed at the metal having the higher thermal conductivity to obtain the proper heat balance.

When welding dissimilar metals, heat loss to the base metals can be balanced somewhat by selectively preheating the metal having the higher thermal conductivity. Dilution is more uniform with balanced heating.

Preheating the base metal of higher thermal conductivity also reduces the cooling rate of the weld metal and the HAZ. The net effect of preheating is to reduce the heat needed to melt that base metal.

The coefficient of thermal expansion of the two dissimilar base metals is another important factor. Large differences in thermal expansion coefficients of adjacent metals during cooling will induce tensile stress in one metal and compressive stress in the other. The metal subject to tensile stress may hot crack during welding, or it may cold crack in service unless the stresses are relieved thermally or mechanically. This factor is particularly important in joints that will operate at elevated temperatures in a cyclic temperature mode. A common example of this is austenitic stainless steel/ferritic steel pipe butt joints used in energy conversion plants.

Ideally, the thermal expansion coefficient of the weld metal should be intermediate between those of the base metals, especially if the difference between those of the two base metals is large. If the difference is small, the weld metal may have an expansion coefficient equivalent to that of one of the base metals.

Welding Considerations (Ref 33)

Welding Process. The three most popular arc welding processes utilized for joining dissimilar metals are SMAW, GMAW, and GTAW. Selecting the welding process to make a given dissimilar-metal joint is almost as important as selecting the proper filler metal. As described in the articles in this Volume that cover the various fusion welding processes, the depth of fusion into the base metals and the resulting dilution may vary with different welding processes and techniques.

It is not uncommon with SMAW for the filler metal to be diluted up to 30% with base metal. The amount of dilution can be modified somewhat by adjusting the welding technique. For example, the electrode can be manipulated so that the arc impinges primarily on the previously deposited weld metal. The dilution rate can be kept below 25% with this technique. If dilution from one base metal is less detrimental than from the other, the arc should be directed toward that metal. This

technique is also applicable to GTAW. Other means to control dilution are described in the section on "Weld Cladding" in this article.

Dilution rates with GMAW can range from 10 to 50%, depending upon the type of metal transfer and the welding gun manipulation. Spray transfer gives the greatest dilution; short-circuiting transfer, the least dilution. Penetration with SAW can be greater, depending on polarity, and can result in more dilution.

Regardless of the process, dilution is also affected by other factors, including joint design and fit-up. It is always best to have a minimum uniform dilution along the joint. Variations in dilution may produce inconsistent joint properties.

Selection of a suitable filler metal is an important factor in producing a dissimilar-metal joint that will perform well in service. One objective of dissimilar-metal welding is to minimize undesirable metallurgical interactions between the metals. The filler metal should be compatible with both base metals and be capable of being deposited with a minimum of dilution.

Two important criteria that should govern the selection of a proper filler metal for welding two dissimilar metals are as follows:

- THE CANDIDATE FILLER METAL MUST PROVIDE THE JOINT DESIGN REQUIREMENTS, SUCH AS MECHANICAL PROPERTIES OR CORROSION RESISTANCE.
- THE CANDIDATE FILLER METAL MUST FULFILL THE WELDABILITY CRITERIA WITH RESPECT TO DILUTION, MELTING TEMPERATURE, AND OTHER PHYSICAL PROPERTY REQUIREMENTS OF THE WELDMENT.

The Schaeffler diagram is commonly used to predict weld metal microstructure and subsequent filler metal selection when joining a stainless steel to a carbon or low-alloy steel. Figure 40 illustrates the procedure with an example of a single-pass weld joining mild steel to type 304 stainless steel with ER309 stainless steel filler metal. First a connecting line is drawn between the two points representing the base metal compositions, based on their chromium and nickel equivalents. Point X, representing the relative dilutions contributed by each base metal is then located on this line. If the relative dilutions are equal, point X is at the midpoint of the line. A second line is drawn between point X and the point representing the ER309 filler metal composition. The composition of the weld pass lies somewhere on this line, the exact location depending upon the total dilution. With 30% dilution, the composition would be at point Y and would be considered acceptable. If a succeeding pass joins the first pass to mild steel, the dilution with the mild steel should be kept to a minimum, to avoid martensite formation in the weld metal.

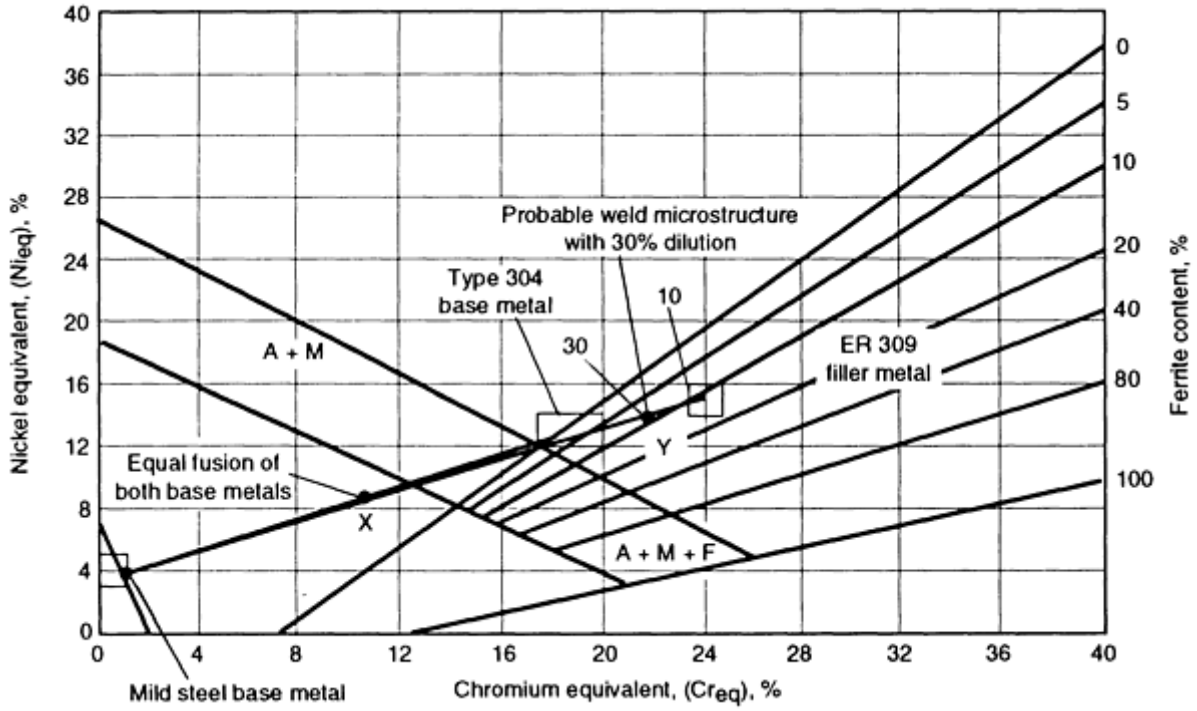

FIG. 40 PREDICTION OF WELD METAL COMPOSITION FROM THE SCHAEFFLER DIAGRAM. A, AUSTENITE; F, FERRITE, M, MARTENSITE. SEE TEXT FOR DETAILS. SOURCE: REF 33

For improved accuracy in predicting the microstructure of dissimilar-metal welds, the WRC-1988 or WRC-1992 diagrams should be used. The following example demonstrates the use of the WRC-1992 diagram for predicting the microstructure of a structural steel/stainless steel weld.

Example 2: Joining Type 304 Stainless Steel to ASTM A 36 Structural Steel with E309L-16 Electrode

(Ref 32). Table 22 lists typical plate compositions and all-weld-metal composition from the electrode. The Cr_{eq} and Ni_{eq} for the A 36 steel (0.00 and 7.08, respectively) do not permit an FN calculation for this material. The Cr_{eq} and Ni_{eq} for the type 304 stainless steel (18.83 and 12.45, respectively) result in a calculated 3.2 FN for this material. The Cr_{eq} and Ni_{eq} for these two base metals are shown in Fig. 41 and Point D (A 36) and Point E (type 304). Any mixture of these two base metals will lie along the line connecting Point D to E. If each base metal contributes equally to the weld metal, then the overall base metal contribution is given by the midpoint of the line between Point D and Point E, indicated in Fig. 41 as Point F. If one base metal contributed more than the other to the joint (for example, due to unequal plate thickness of a complex joint design), the Point F would slide along this line proportionately toward the greater contributor. In any case, the average base metal contribution to the weld pool would be along this line.

TABLE 22 BASE METAL AND WELD METAL COMPOSITIONS PRODUCED WHEN ASTM A 36 STRUCTURAL STEEL AND TYPE 304 STAINLESS STEEL WERE JOINED BY SMAW USING E309L-16 FILLER METAL

See Example 2 in text.

MATERIAL	**AISI 304**	**ASTM A 36**	**E309L-16 ALL-WELD-METAL**	70% E309L-16, 15% AISI 304, 15% A 36

Source: Ref 32

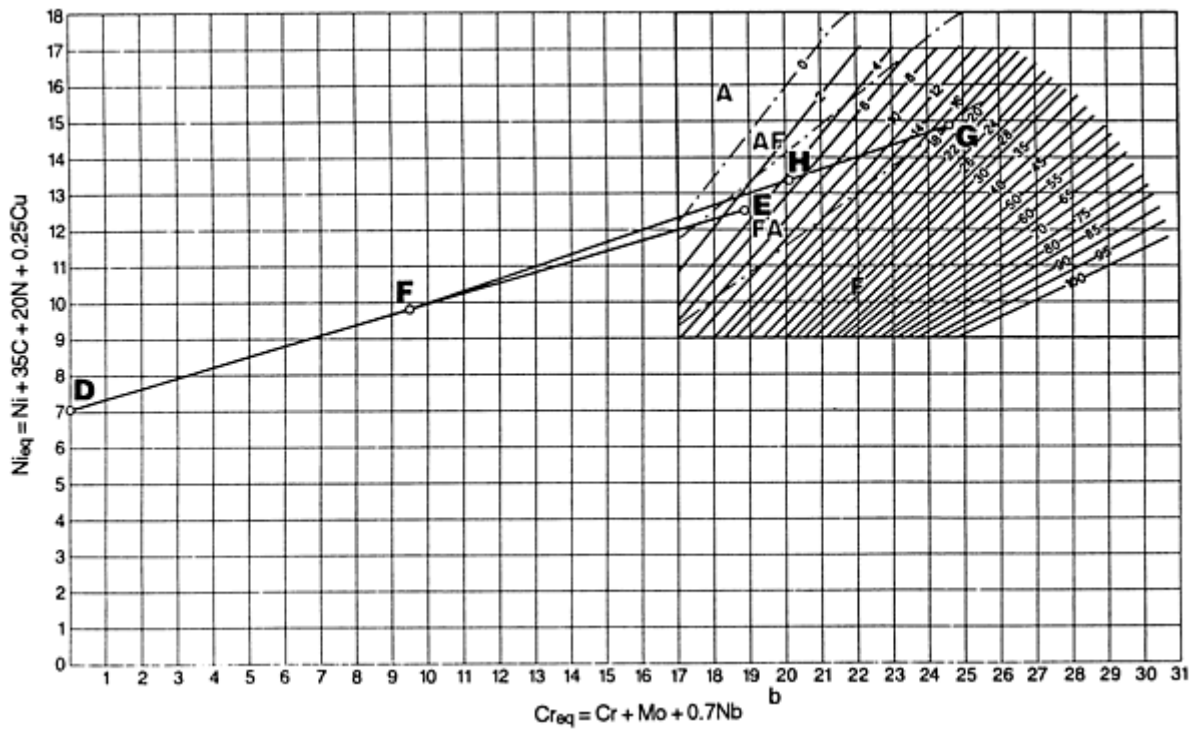

FIG. 41 DILUTION CALCULATION IN EXAMPLE 2 USING THE WRC-1992 DIAGRAM. SOURCE: REF 32

The all-weld-metal Cr_{eq} and Ni_{eq} (24.60 and 14.95, respectively) for the E309L-16 electrode is shown as Point G in Fig. 41, and a 17.4 FN would be predicted for that electrode. The root pass weld metal, consisting of the E309L-16 electrode and equal parts of the two base metals, must lie along the line from Point G to Point F in Fig. 41. Assuming the normal 30% base metal dilution with the shielded metal arc process, the root pass weld would lie 30% of the distance along the line from Point G to Point F. This is shown as Point H in Fig. 41. The calculations to reach Point H are as follows:

$$CR_{EQ}(F) = 0.5\ CR_{EQ}(D) + 0.5\ CR_{EQ}(E)$$
$$= 0.5(0.00) + 0.5(18.83) = 9.47 \quad \textbf{(EQ 9)}$$

$$NI_{EQ}(F) = 0.5\ NI_{EQ}(D) + 0.5\ NI_{EQ}(E)$$
$$= 0.5(7.08) + 0.5(12.45) = 9.77 \quad \textbf{(EQ 10)}$$

$$CR_{EQ}(H) = 0.7\ CR_{EQ}(G) + 0.3\ CR_{EQ}(F)$$
$$= 0.7(24.60) + 0.3(9.47) = 20.04 \quad \textbf{(EQ 11)}$$

$$NI_{EQ}(H) = 0.7\ NI_{EQ}(G) + 0.3\ NI_{EQ}(F)$$
$$= 0.7(14.95) + 0.3(9.77) = 13.39 \quad \textbf{(EQ 12)}$$

Point H corresponds to 4.3 FN, which would be expected to result in a crack-free root pass in this joint. Higher dilution, or excess dilution from the A 36 side of the joint, could reduce the ferrite content and increase the likelihood of cracking.

Buttering. If dilution of austenitic stainless steel filler metal is a problem, it may be controlled by first buttering the joint face of the carbon or low-alloy steel with one or two layers of type 309 or 310 stainless steel filler metal, as shown in Fig. 42(a) and 42(b). After machining and inspecting the buttered layer (Fig. 42c), the joint between the stainless steel component and the buttered steel part can be made using conventional welding procedures and the appropriate filler metal for welding the stainless steel base metal (Fig. 42d and 42e). A low-alloy steel component can be heat-treated after the buttering operation, then joined to the stainless steel part. This avoids a postweld heat treatment that might sensitize the austenitic stainless steel to intergranular corrosion. Additional information on buttering can be found in the article "Dissimilar Welds with Stainless Steels" in this Volume.

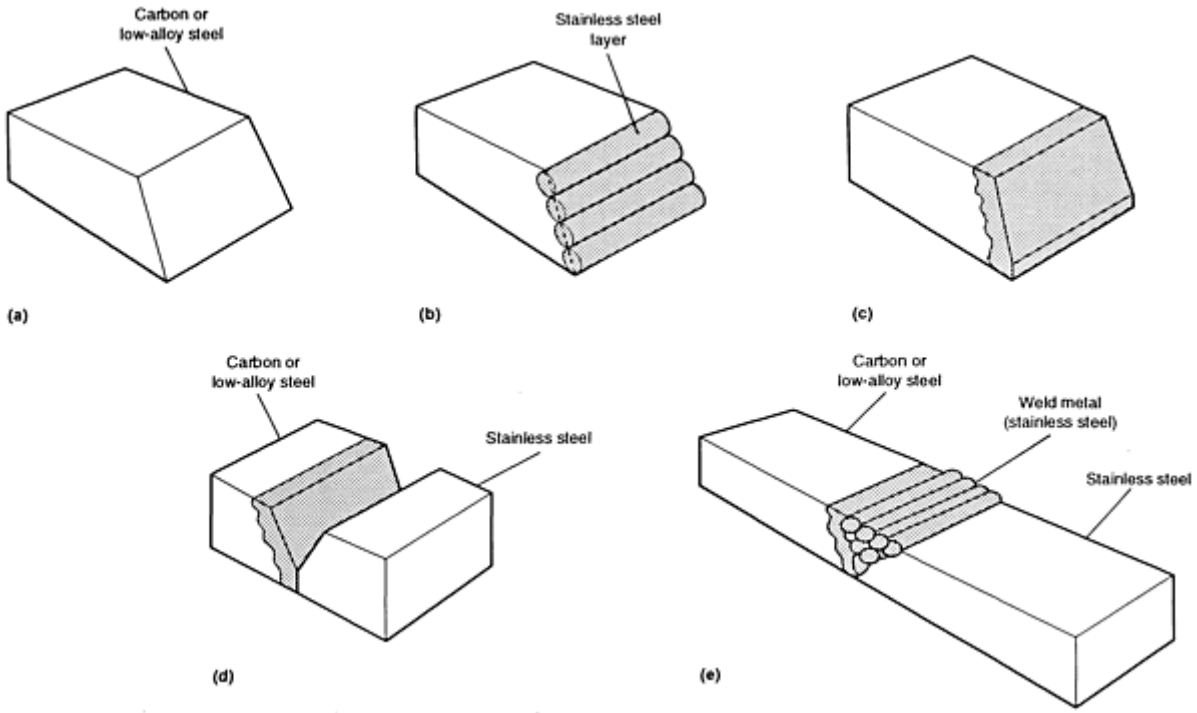

FIG. 42 BUTTERING TECHNIQUE USED TO ASSIST WELDING STAINLESS STEEL TO CARBON OR LOW-ALLOY STEEL. (A) EDGE PREPARED FOR BUTTERING. (B) FACE BUTTERED WITH FILLER METAL. (C) BUTTERED FACE PREPARED FOR WELDING. (D) JOINT ALIGNED FOR WELDING. (E) JOINT WELDED WITH STAINLESS STEEL FILLER METAL. SOURCE: REF 33

Joint Design. When designing butt joints between dissimilar metals, consideration must be given to the melting characteristics of each base metal and the filler metal, as well as to dilution effect. Large grooves decrease dilution, permit better control of viscous weld metal, and provide room for better manipulation of the arc for good fusion.

The joint design should provide for appropriate dilution in the first few passes placed in the joint when welding from one side. Improper dilution could result in a layer of weld metal possessing mechanical properties that are inappropriate for the intended service, particularly when the joint will be exposed to cyclic stresses. When welding from both sides, back gouging of the first weld can provide better control of dilution in the first few passes of the second weld.

Dissimilar-metal joints are often made with groove geometries similar to those used in conventional similar-metal welds and are left in the as-welded condition. However, removing the excess penetration of the weld root eliminates possible defects that may be present in the root of the joint, and it eliminates notches and crevices associated with backing rings. Removing the weld root also improves the capabilities of nondestructive tests (radiography, liquid penetrant, and ultrasonic). Provision can also be made for removing the exterior reinforcement to eliminate stress concentrations associated with undercutting and with the change in section thickness across the as-welded joint. Again, inspection capabilities are improved.

Preheat and Postweld Heat Treatments. Selection of an appropriate preheat or postweld heat treatment (PWHT) for a welded joint can present a problem with some dissimilar metal combinations. The appropriate heat treatment for one component of the weldment may be deleterious to the other component for the intended service conditions. For example,

if an age-hardenable nickel-chromium alloy is welded to a nonstabilized austenitic stainless steel, exposure of the weldment to the aging treatment for the nickel-chromium alloy would sensitize the stainless steel and decrease its resistance to intergranular corrosion (weld decay).

One solution is to use a stabilized austenitic stainless steel if that is acceptable. Another solution might be to butter the face of the age-hardenable, nickel-chromium alloy component with a similar alloy that is not age-hardenable. This component is then heat-treated to obtain the desired properties. Finally, the buttered surface is welded to the stainless steel component.

Service Considerations (Ref 33)

Property Considerations. A dissimilar metal joint normally contains weld metal having a composition different from that of one or both base metals. The properties of the weld metal depend on the filler metal composition, the welding procedures, and the relative dilution with each base metal. There also two different HAZs, one in each base metal adjacent to the weld metal. The mechanical and physical properties of the weld metal as well as those of the two HAZs, must be considered for the intended service.

Special considerations are generally given to dissimilar-metal joints intended for elevated-temperature service. A favorable situation exists when the joint will operate at constant temperatures. During elevated-temperature service, internal stresses can decrease by relaxation and reach an equilibrium. However, it is best to reduce the effect of large differences in coefficients of thermal expansion when large temperature fluctuations cannot be avoided in service. The problem can be avoided by selecting base metals with similar thermal expansion characteristics.

Figure 43 gives the mean linear thermal expansion coefficients as a function of temperature for several alloys commonly associated with transition butt joints for steam plant applications. The thermal expansion coefficient of 2.25Cr-1Mo steel is about 25% less than that of types 304 and 316 austenitic stainless steel. In certain applications, transition joints between austenitic stainless steel and low-alloy steel may experience numerous temperature changes during operation. For a given change in temperature, the stress imposed at the weld joint is proportional to the difference in their coefficients of thermal expansion. Stress analyses of welded joints between these two types of steel indicate that the stresses introduced by thermal change are nearly an order of magnitude greater than those produced by the operating pressures and any thermal gradients across the joint.

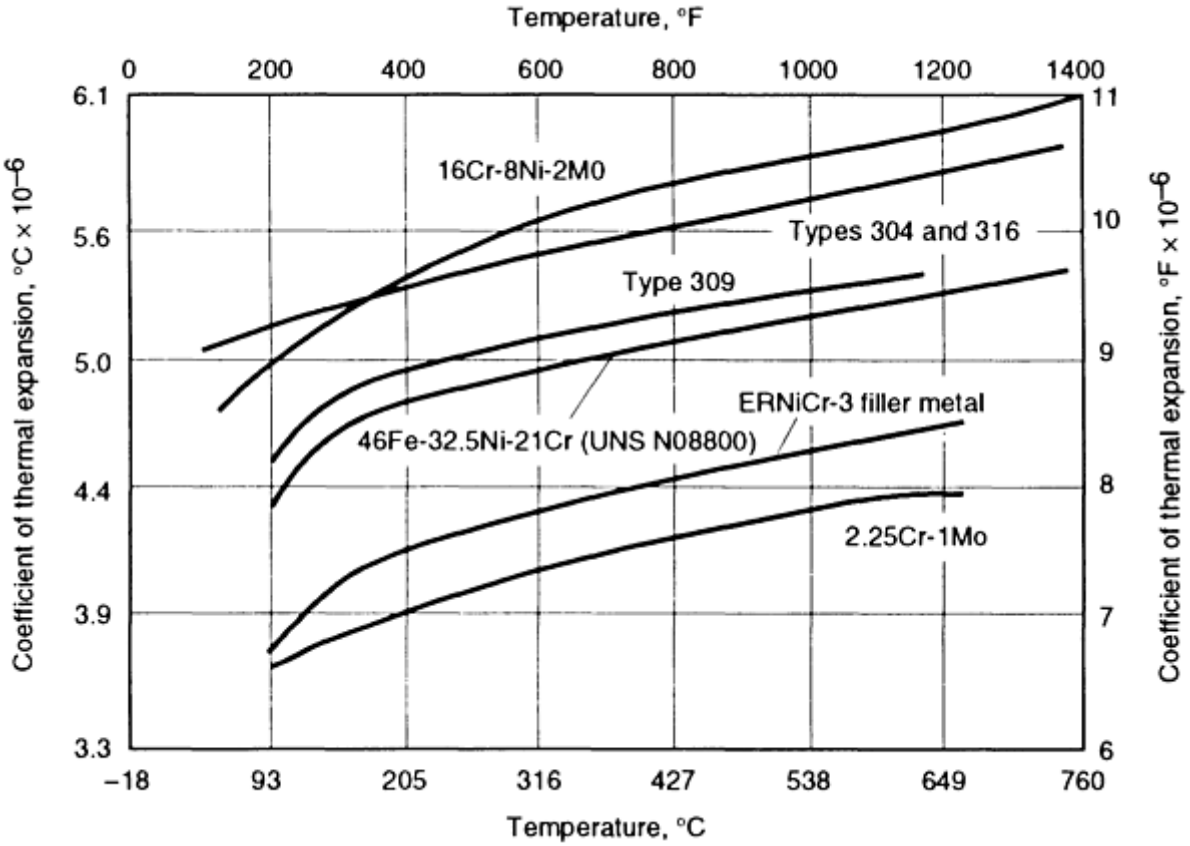

FIG. 43 MEAN COEFFICIENTS OF THERMAL EXPANSION AS A FUNCTION OF TEMPERATURE FOR TRANSITION BUTT-JOINT MATERIALS. SOURCE: REF 33

Experience with dissimilar-metal transition joints has shown a significant number of failures in less than the expected service life. The majority of the transition joint failures in austenitic steel/ferritic steel joints occur in the ferritic steel HAZ, adjacent to the weld interface. These failures are generally attributed to one or more of the following causes:

- HIGH STRESSES AND THE RESULTING CREEP AT THE INTERFACE AS A RESULT OF THE DIFFERENCES BETWEEN THE COEFFICIENTS OF THERMAL EXPANSION OF THE WELD AND BASE METALS
- CARBON MIGRATION FROM THE FERRITIC STEEL INTO THE STAINLESS STEEL, WHICH WEAKENS THE HAZ IN THE FERRITIC STEEL
- PREFERENTIAL OXIDATION AT THE INTERFACE, ACCELERATED BY THE PRESENCE OF STRESS

Carbon Migration. There is the likelihood of significant chemical composition gradients in the weld metal, particularly in the regions adjacent to the base metals. In addition, operation at elevated temperatures can cause interdiffusion between the weld metal and the base metal that, in turn, results in microstructure changes. A dissimilar-metal weld made between a low-alloy steel and an austenitic stainless steel, with an austenitic stainless steel filler metal, illustrates this problem. Chromium in steel has a greater affinity for carbon than does iron. When a carbon or low-alloy steel is welded with a steel filler metal containing a significant amount of chromium, carbon will diffuse from the base metal into the weld metal at temperatures above about 425 °C (800 °F). The diffusion rate is a function of temperature and exposure time, and it increases rather rapidly at 595 °C (1100 °F) and above. Carbon migration can take place during PWHT heat treatment or service at elevated temperatures.

Austenitic steel has a greater solubility for carbon than does ferritic steel. Therefore, carbon depletion in a carbon or low-alloy steel is greater when an austenitic stainless steel filler metal is used in preference to a ferritic steel filler metal. On the other hand, carbon migration is not as serious a problem when a nickel-chromium-iron filler metal is used.

If carbon migration is extensive, it will be indicated by a lightly etching, low-carbon band in the carbon steel HAZ and a dark, high-carbon zone in the stainless steel weld metal, as seen in a transverse metallographic section. The extent of carbon migration during PWHT or elevated-temperature service should be determined during welding procedure qualification. It is known to influence long-time stress-rupture strength during elevated-temperature service.

During cyclic temperature service, the HAZ will be subjected to varying shear stresses because of the differences in coefficients of thermal expansion of the base and weld metals. These stresses may produce fatigue failure in the decarburizing band next to the weld interface.

Corrosion and Oxidation Resistance. The weld metal and both base metals have specific corrosion behaviors that must be considered by the designer in the initial selection of materials. For example, with dissimilar metal weldments, the formation of galvanic cells can cause corrosion of the most anodic metal or phase in the joint. Also, the weld metal is usually composed of several microstructural phases, and very localized cells between phases can result in galvanic corrosion at the microstructural level. To minimize galvanic corrosion, the composition of the weld metal can be adjusted to provide cathodic protection to the base metal that is most susceptible to galvanic attack. However, other design requirements should not be seriously compromised to do this. Instead, some other form of protection should be used.

A galvanic cell associated with a high-strength steel may promote hydrogen embrittlement in the HAZ of that steel if it is the cathode of the cell. Hydrogen embrittlement must be considered if the service temperature of the weldment will be in the range of -40 to 95 °C (-40 to 200 °F), and the weld will be in a highly stressed area of the assembly. Residual stresses developed in the weld zone are often sufficient to promote hydrogen embrittlement and stress-corrosion cracking.

Chemical compositional differences in a dissimilar-metal weld can also cause high-temperature corrosion problems. Compositional variations at the interfaces between the different metals can result in selective oxidation when operating at high temperatures in air and formation of notches at these locations. Such notches are potential stress-raisers in the joint and can cause oxidation failure along the weld interface under cyclic thermal conditions.

Specific Dissimilar Metal Combinations (Ref 33)

The emphasis in the following section will be on joining carbon and low-alloy steels to various dissimilar materials (both ferrous and nonferrous) by arc welding. See other articles in this Section of the Handbook for additional information (for example, "Welding of Nickel Alloys" and "Welding of Copper Alloys").

Stainless Steels to Carbon or Low-Alloy Steels. Austenitic, ferritic, or martensitic stainless steels can be readily fusion welded to carbon or low-alloy steels using a filler metal that can tolerate dilution by both base metals without formation of flaws in the joint. An austenitic stainless steel or nickel alloy filler metal is commonly used. The choice depends on the application and the service conditions.

Generally, carbon or low-alloy steels are joined to 300-type stainless steels using austenitic filler metals, such as types E/ER 308, 309, 316, and 347. Such filler metals are used for service applications below 425 °C (800 °F). For higher temperatures or when high-temperature cyclic service is a concern, high-nickel filler metals such as ERNiCr-3 and ENiCrFe-3 are used. The coefficients of thermal expansion of high-nickel alloys approximate those of ferritic steels, and during cyclic-temperature service, the major differential expansion stresses are located primarily at the tough stainless steel/weld metal interface. Another advantage of a nickel-base weld metal is that it markedly reduces carbon migration from the ferritic steels to the weld metal. Extensive carbon migration into stainless steel weld metal weakens the HAZ of the carbon or low-alloy steel.

The problem of cracking between ferritic steels, such as the 2.25Cr-1Mo steel described earlier, and austenitic stainless steels is a recurring problem in such operations as the petrochemical industry and electric utility generating plants. Cracking has been repeatedly observed in HAZs of the ferritic portions of dissimilar-metal welds, particularly those that have been subjected to a large number of thermal cycles and extended time at elevated temperatures around 565 °C (1050 °F). Such cracking must be minimized, since repair maintenance and non-productive downtime are costly. High-nickel filler metals have proven useful in such applications.

Buttering is also used to improve the weldability between ferritic and austenitic stainless steel joints. A thick overlay (13 mm, or $\frac{1}{2}$ in., or greater) of a highly austenitic weld metal, such as type 309 stainless steel, can be deposited on carbon or low-alloy steel components so that stainless steel/stainless steel welds can be made subsequently in the field. This technique has limited reliability for high-temperature cyclic service and has not been used extensively for material combinations other than ferritic steels, stainless steels, and some high-nickel alloys.

A filler metal for joining a 4*xx*-series stainless steel to a carbon or low-alloy steel can be selected using the following general rules:

- FOR WELDING ONE HARDENABLE CHROMIUM STEEL TO ANOTHER WITH A HIGHER CHROMIUM CONTENT, FILLER METAL CONTAINING CHROMIUM EQUAL TO THAT OF EITHER STEEL MAY BE USED. FURTHERMORE, ANY FILLER METAL WHOSE CHROMIUM CONTENT LIES BETWEEN THESE LIMITS IS EQUALLY SATISFACTORY, PROVIDED THE WELDMENT IS PROPERLY HEAT-TREATED.
- A GENERAL RULE FOR WELDING ANY CHROMIUM STEEL TO ANY LOW-ALLOY STEEL IS TO USE A FILLER METAL THAT HAS THE SAME COMPOSITION AS THE LOW-ALLOY STEEL, PROVIDED THAT IT MEETS THE SERVICE REQUIREMENTS OF THE APPLICATION. WITH ANY LOW-ALLOY STEEL FILLER METAL, THE CHROMIUM THAT IS PICKED UP BY DILUTION WITH THE CHROMIUM STEEL BASE METAL MUST BE CONSIDERED.
- FOR WELDING ANY CHROMIUM STEEL TO A CARBON STEEL, CARBON STEEL FILLER METAL CAN BE USED. A CHROMIUM STEEL FILLER METAL CAN ALTERNATIVELY BE USED, BUT IT IS PREFERABLE TO USE A LESS HARDENABLE FILLER METAL.

When the properties of the HAZ in the chromium stainless steel are important, both the stainless steel and other steel can be buttered with type 309 or 310 austenitic stainless steel weld metal. An appropriate preheat or PWHT can be used to obtain desired properties in the buttered components. The stainless steel surfaces can then be welded together without preheat using a suitable austenitic stainless steel filler metal, such as type 308.

Nickel-Base Alloys to Steels. Nickel alloys can easily be welded to steels using a suitable filler metal and proper control of dilution. Nickel-base filler metals are generally used because of their good ductility and tolerance of dilution by iron. Suggested nickel-base filler metals for welding nickel alloys to steel or stainless steel are listed in Table 23.

Source: Ref 33

Sulfur and phosphorus in nickel and nickel alloys cause hot cracking. The melting techniques used to produce nickel and its alloys are designed to keep the content of these elements to low levels. By contrast, the sulfur and phosphorus contents in some steels are typically higher. Consequently, dilution should be carefully controlled when joining a steel to a nickel alloy with a nickel alloy filler metal, to avoid hot cracking in the weld metal.

Most nickel-base weld metals can accept a substantial amount of iron dilution, but the dilution limit generally varies with the welding process. Weld metal deposited with nickel- or nickel-chromium-covered electrodes can tolerate up to approximately 40% iron dilution. With bare nickel or nickel-chromium filler metals, however, dilution should be kept to about 25%.

Acceptable limits of iron dilution for nickel-copper weld metal vary, depending on the weld process. With SMAW, iron dilution of up to about 30% can be tolerated. Submerged arc weld metal should not be diluted by more than 25%.

With the gas-shielding processes, nickel-copper weld metal is less tolerant of iron dilution, especially if the weld is to be thermally stress-relieved. The maximum limits for iron dilution in a welded joint are 10% when it will be used as-welded and 5% when it will be stress-relieved. A buttering layer of nickel or nickel-copper weld metal should be applied to the steel face in order to avoid exceeding these limits.

Nickel-copper weld metal has a maximum dilution tolerance for chromium of about 8%. Consequently, nickel-copper filler metal should not be used to join nickel-copper alloys to stainless steels (see Table 23).

Cobalt-Base Alloys to Steels. Metallurgically, cobalt-base alloys behave similarly to the high-temperature nickel-chromium alloys with respect to welding. When joining a cobalt alloy to a stainless steel, a filler metal with a composition similar to that of the cobalt alloy is recommended. A nickel alloy filler metal may also be suitable for some applications. In any case, the filler metal selection, welding process, and welding procedure for the application should be established by suitable tests.

Copper-Base Alloys to Steels. As described in the article "Welding of Copper Alloys" in this Volume, copper and many copper-base alloys can be joined to carbon, low-alloy, and stainless steels by GTAW, GMAW, and SMAW. Iron dilution can be minimized by the use of appropriate welding procedures or by placement of a buttering layer of nickel on the steel. Tables 24 and 25 show combinations of dissimilar metals by GTAW and GMAW with the aid of copper-base or nickel-base filler metals.

(A) ELECTRODE SELECTIONS IN TABLE ARE BASED ON WELDABILITY, EXCEPT WHERE MECHANICAL PROPERTIES ARE USUALLY MORE IMPORTANT. PREHEATING USUALLY IS USED ONLY WHEN AT LEAST ONE MEMBER IS THICKER THAN 3.2 MM ($\frac{1}{8}$ IN.) OR IS HIGHLY CONDUCTIVE (SEE TEXT). PREHEAT AND INTERPASS TEMPERATURES ARE SUBJECT TO ADJUSTMENT BASED ON SIZE AND SHAPE OF WELDMENT.

Aluminum-Base Alloys to Steels. With respect to fusion welding, iron and aluminum are not compatible metals. Their melting temperatures differ greatly: 660 °C (1220 °F) for aluminum versus 1538 °C (2800 °F) for iron. Both metals have almost no solubility for the other in the solid state, especially iron in aluminum, and several brittle intermetallic phases can form ($FeAl_2$, Fe_2Al_5, or $FeAl_3$). Consequently, fusion welds joining iron and aluminum are brittle. In addition, high welding stresses would be expected because of the significant differences in the thermal expansion coefficients, thermal conductivities, and specific heats of iron and aluminum. Aluminum can be joined to carbon or stainless steel by brazing, solid-state welding or by high-energy processes such as electron-beam welding.

Introduction

RESISTANCE WELDING (RW) encompasses a group of processes in which the heat for welding is generated by the resistance to the flow of electrical current through the parts being joined. These processes are most commonly used to weld two overlapping sheets or plates that may have different thicknesses. A pair of electrodes clamp the workpieces under pressure to provide good electrical contact and to contain the molten metal in the joint. The electrodes conduct electrical current to the joint; resistance to the flow of current heats the faying surfaces, forming a weld (Ref 1).

The required heat generated through the electrical resistance of the two bodies to be joined is given by

$$H = I^2RT \qquad \textbf{(EQ 1)}$$

where H is the heat generated in joules; I is the current in amperes; R is the resistance in ohms; and t is the time of current flow, in seconds. The actual temperature rise at the joint depends on the interrelationship of the three component variables. These variables are affected by:

- COOLING EFFECT OF THE ELECTRODE
- EFFECT OF FOLLOW UP ON RESISTANCE
- EFFECT OF SHUNTING

Pressure is applied even before the current is activated to ensure a good bond. Accurate control and timing of the electric current and application of pressure is an essential feature of resistance welding.

The strength of the bond also depends on the cleanliness of the mating surfaces, although the process is more tolerant of the presence of oxide layers and contaminants than other welding processes. Resistance welding processes require specialized machinery, but they have the major advantages of not requiring filler metals, shielding gases, or flux.

The three major resistance welding processes are resistance spot welding (RSW), resistance seam welding (RSEW), and projection welding (PW). Flash welding (FW) is also classified as a resistance welding process, but it is unique in that the heat for welding is created at the faying surfaces of the joint not only by resistance to the flow of electric current, but also by arcs across the interface. Upset welding (UW) differs from flash welding in that no arc is generated by the process. Capacitor discharge stud welding incorporates a stud which serves as a weld member and is a process similar to flash welding. High-frequency resistance welding (HFRW) concentrates current of the surface of the part to heat the base metal and cause the coalescence of metal.

This article addresses procedure development and considerations for using these processes to join specific types of materials. Additional information about these processes can be found in the Section "Fusion Welding Processes" in this Volume.

Resistance Spot Welding

Resistance spot welding is the most common form of resistance welding. It is a process in which laying surfaces are joined in one or more overlapping spots by the heat generated by resistance to the flow of electric current through workpieces that are held together under force by electrodes. The contacting surfaces in the region of current concentration are heated by a short-time pulse of low-voltage, high-amperage current to form a fused nugget of weld metal. When the flow of current ceases, the electrode force is maintained while the weld metal rapidly cools and solidifies. The electrodes are retracted after each weld, which usually is completed in a fraction of a second.

The size and shape of the individually formed welds are limited primarily by the size and contour of the electrode faces. The weld nugget forms at the faying surfaces (Fig. 1), but does not extend completely to the outer surfaces. In a cross section, the nugget in a properly formed spot weld is obround or oval in shape; in plan view, it has the same shape as the electrode face (which usually is round) and approximately the same size. The spots should be at a sufficient distance from the edge of the workpiece (edge distance) so that there is enough base metal to withstand the electrode force and to ensure that the local distortion during welding does not allow expulsion of metal from the weld. Additional information is available in the article "Resistance Spot Welding" in this Volume.

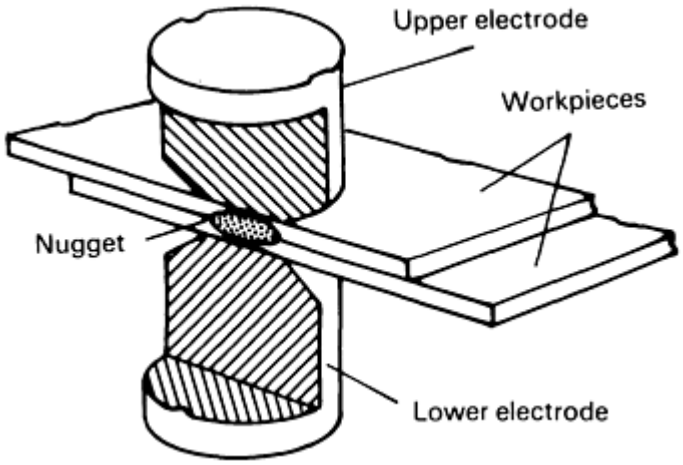

FIG. 1 CUTAWAY VIEW SHOWING LOCATION AND SHAPE OF WELD NUGGET RELATIVE TO THE INNER AND OUTER SURFACES OF WORKPIECES IN A RESISTANCE SPOT WELDING SETUP

RSW Applications

Weldability and the thickness of the metals joined are key factors in determining whether two materials can be resistance spot welded.

Material Selection (Ref 2). Practically all combinations of ductile metals and alloys can be spot welded (Table 1). Some, like copper to aluminum, and aluminum to magnesium, form alloys having little strength. Others, such as zinc and some of the high-chromium alloys, experience grain growth even during a very short welding period. Although welding times are relatively short, the material is adversely affected by the heat conducted through the sheet to the point that the physical properties such as the strength and corrosion resistance of the material surface are typically reduced in value. The short welding period is also necessary in stainless steel to prevent carbide precipitation when the carbon content is high enough to permit it. High-carbon steels weld readily, but the weld will be in the full-hardened state and will require subsequent heat treatment. This can be accomplished automatically by a control that applies preheating, postheating, or both as part of the welding cycle. To ensure that the control can apply the compensating quench or temper cycle, the electrodes must open immediately after the cycle is complete. Excessive hold time will quench the joint, negating the benefits associated with this control function.

Source: Ref 3

Zinc-alloy die castings can be welded with little loss of strength, but the ductility is reduced. Free-turning Bessemer screw-machine steel frequently refuses to weld, or results in brittle welds, and hence its use for welded parts should be avoided. Usually, however, when clean, properly prepared metal parts are spot welded, the strength of the welds is perfectly satisfactory. Table 1 lists combinations that have been successfully welded. Many other combinations may also be satisfactorily welded. Copper and silver are difficult to weld, but they may be welded by the use of low-conductivity electrodes (for example, refractory alloys such as Elkonite and Trodaloy). Copper alloys are more commonly resistance brazed. In many applications, the weldability of copper is increased if it has a tinned surface.

Thickness Parameters (Ref 4). Parts of widely different thicknesses may be spot welded. For example, 0.4 mm ($\frac{1}{64}$ in.) material can be welded to a 150 mm (6 in.) thick piece and would require only slightly more power input and pressure than to weld two pieces of 0.4 mm ($\frac{1}{64}$ in.) material, as it is not necessary to heat the 150 mm (6 in.) piece through, and the push-up is obtained on the thinner piece. The thickness of the thinner component is referred to as the governing metal thickness because it dictates the heat input. However, the thermal mass of the larger component may make RSW applications impractical because the thick section may not reach fusion temperature before the thin piece is melted. The limit to welding pieces of equal thickness with an uninterrupted flow of current seems to be approximately 3.2 mm ($\frac{1}{8}$ in.). Greater thicknesses may be welded by a technique known as pulsation welding. In the pulsation welding method, the current is turned off during the weld at intervals that allow the electrodes to cool the electrode/workpiece surface. This ensures that the heat will be generated as desired, primarily at the faying surface.

Sheet Steel Limitations. Spot welded lap joints are widely used in joining sheet steel up to about 3.2 mm ($\frac{1}{8}$ in.) thick (Table 2) and are used occasionally in joining steel 6.4 mm ($\frac{1}{4}$ in.) or more in thickness, *t*. Thicknesses of 25 mm (1 in.) or more have been joined by spot welding, but this requires special equipment and would not ordinarily be economical. Many assemblies of two or more sheet metal stampings that do not require gastight or liquid-tight joints can be more economically joined by high-speed RSW than by mechanical methods.

TABLE 2 MINIMUM DIMENSIONS FOR SINGLE-IMPULSE SPOT WELDS IN LOW-CARBON STEEL

Source: Ref 5

For aluminum and magnesium welds, minimum spot spacing, *S*, should equal 8*t*. A spot spacing value of 16*t* would be even better if the strength requirements of the joint permit such spacing (Ref 5).

Joint Design Recommendations. Like other welds, resistance spot welds are subject to shrinkage on cooling. To minimize distortion, welds should be positioned to balance shrinkage forces (Fig. 2).

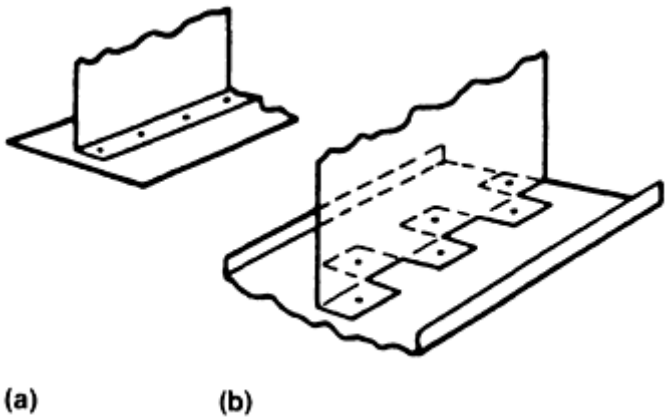

FIG. 2 PLACEMENT OF WELDS TO JOIN TWO SHEETS OF METAL IN A T-JOINT. (A) CONFIGURATION NOT RECOMMENDED DUE TO UNBALANCED SHRINKAGE FORCES. (B) PREFERRED SETUP THAT RESULTS IN BALANCED FORCES AND MINIMUM DISTORTION

Distortion can also result from electrode skidding. This is related to stress introduced at the time of electrode impact and machine deflection under high electrode force. The components must be designed to provide methods of accommodating variations (for example, by incorporating slip joints and minimizing material stackups).

Even when welding of multiple spot thicknesses is feasible, it can be more troublesome than simple welds of two sheet thicknesses. Scalloped edges permit alternate welding of spots in two thicknesses only (Fig. 3). However, scalloped edges are rarely used and the current trend is toward triple-metal-thickness welding as a method of reducing capital cost.

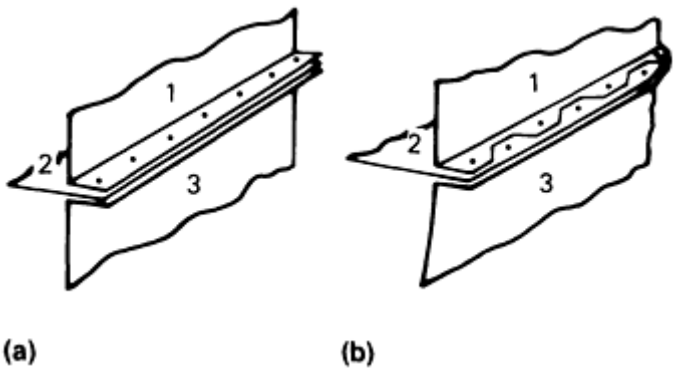

FIG. 3 PLACEMENT OF WELDS TO JOIN THREE SHEETS OF METAL IN A T-JOINT. (A) CONFIGURATION THAT CAN BE USED TO JOIN THREE STOCK THICKNESSES. (B) RECOMMENDED CONFIGURATION INCORPORATING

SCALLOPED EDGES TO PERMIT ALTERNATE WELDING OF SPOTS IN TWO THICKNESSES ONLY

Spot-welded assemblies should be designed so that joint areas are readily accessible to the electrode and simple, inexpensive electrodes can be used. When special electrode shapes are required, every effort should be made to avoid extremes of shape and to provide as accessible a joint as possible. Deep, narrow joint areas should be avoided. Figure 4 provides guidelines for accessibility of joints.

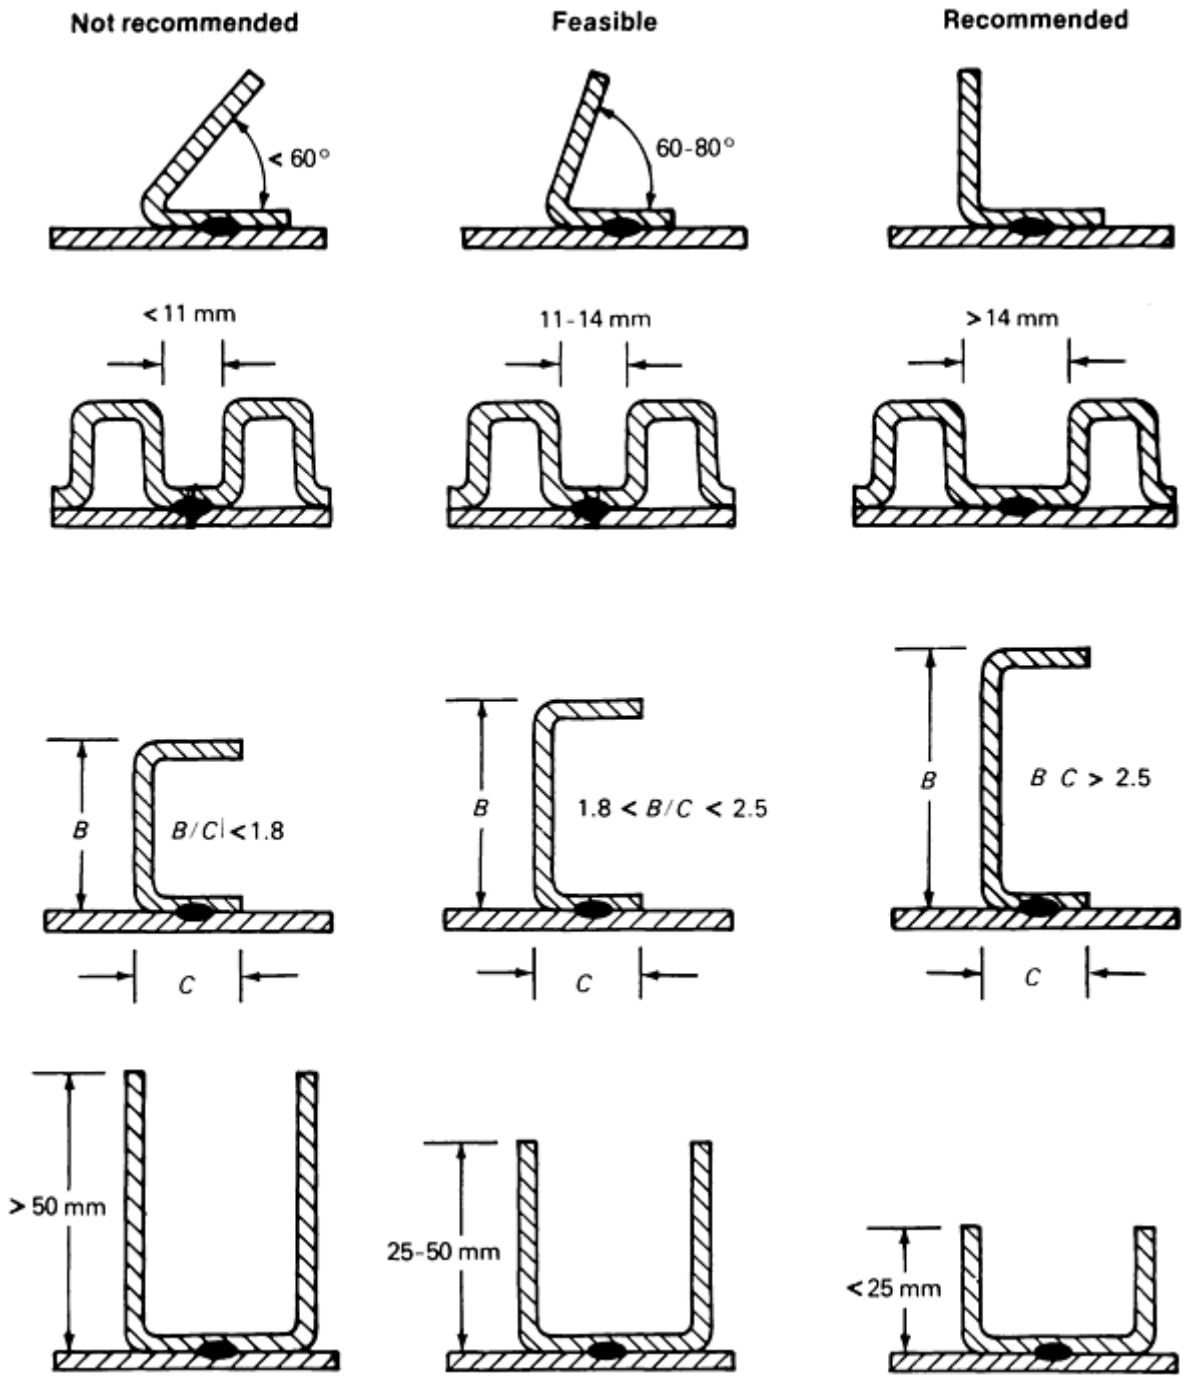

FIG. 4 GRADUAL IMPROVEMENTS IN JOINT DESIGN THAT PROVIDE OPTIMUM ACCESS TO SELECTED JOINT CONFIGURATIONS USING STANDARD ELECTRODES

Weld Strength in RSW Joints. The strength of a single spot weld in shear depends on the cross-sectional area of the nugget in the plane of the faying surfaces.

Lap joints may fail either by shear through the nugget, or by tearing of the base metal adjacent to the weld nugget. Low weld strengths are typically associated with weld nugget shear failure, and high strengths are typically associated with base metal tearing. A minimum nugget diameter that is unique to the type of base material, surface condition, and metal gage used, is required in order to obtain failure by base metal tearing.

Increasing the nugget diameter above this minimum value can produce an increase in the weld strength. Figure 5 shows the slight increase in strength values obtained for low-carbon steel as a result of increases in nugget size.

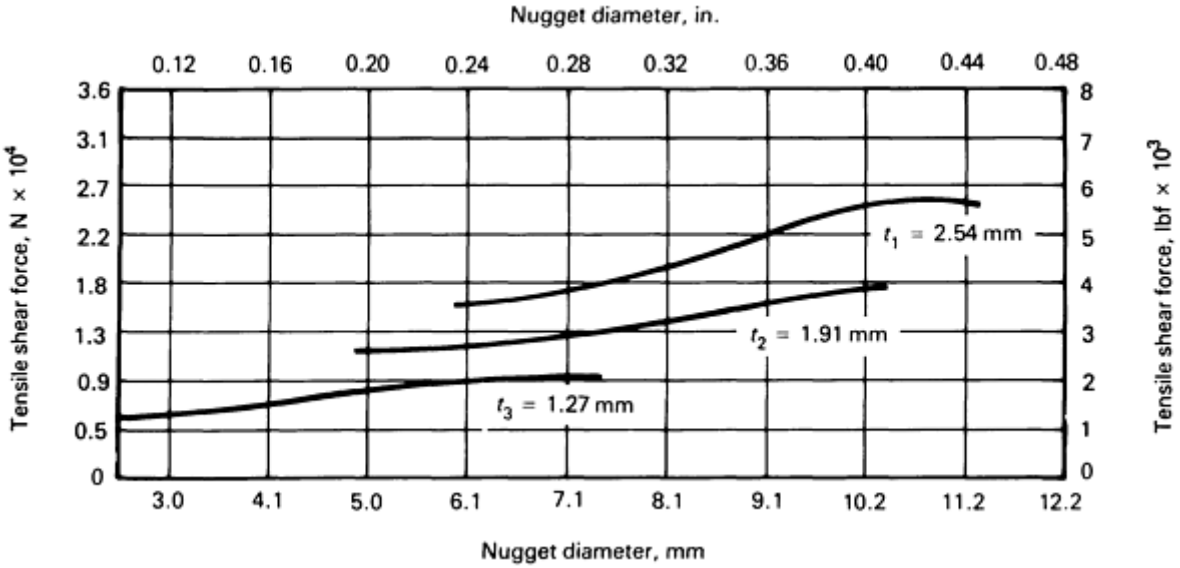

FIG. 5 PLOT OF TENSILE SHEAR STRENGTH VERSUS WELD NUGGET DIAMETER AS A FUNCTION OF SHEET THICKNESS, *T*, FOR 1008 LOW-CARBON STEEL

The strength of multiple spot-welded joints depends on material thickness, spot weld spacing, and weld pattern. The spacing between adjacent spot welds may alter the joint weld strength due to current shunting through previous welds. As the spacing between adjacent spot welds decreases, the joint shear strength may decrease.

Table 3 summarizes the relationship between resistance spot welding variables and joint strength for uncoated low-carbon steel.

(A) SHAPE DEFINITIONS: E, TRUNCATED CONE; A, POINTED; B, 75 MM (3 IN.) RADIUS.

(B) APPLIES TO TRUNCATED CONE ELECTRODES ONLY AND IS MEASURED FROM THE PLANE OF THE ELECTRODE FACE.

(C) FOR INTERMEDIATE THICKNESSES, FORCE AND WELD TIME MAY BE INTERPOLATED.

(D) MINIMUM WELD SPACING IS MEASURED FROM CENTERLINE TO CENTERLINE.

Power Requirements. Nearly all RSW of low-carbon steel is direct-energy welding, in which single- or three-phase 60-cycle alternating current, drawn ordinarily from 220 or 440 V implant power lines and stepped down to about 2 to 20 V, is fed directly to the electrodes as each weld is made.

Direct and Series Welding

Spot welds are classified as either direct or series welds.

Direct Single-Spot Welding. Single-spot welds are usually made by direct welding. Figure 6 shows schematically three arrangements used for making this type of weld; these arrangements may be modified to meet special requirements. In all of the arrangements shown, one transformer secondary circuit makes one spot weld.

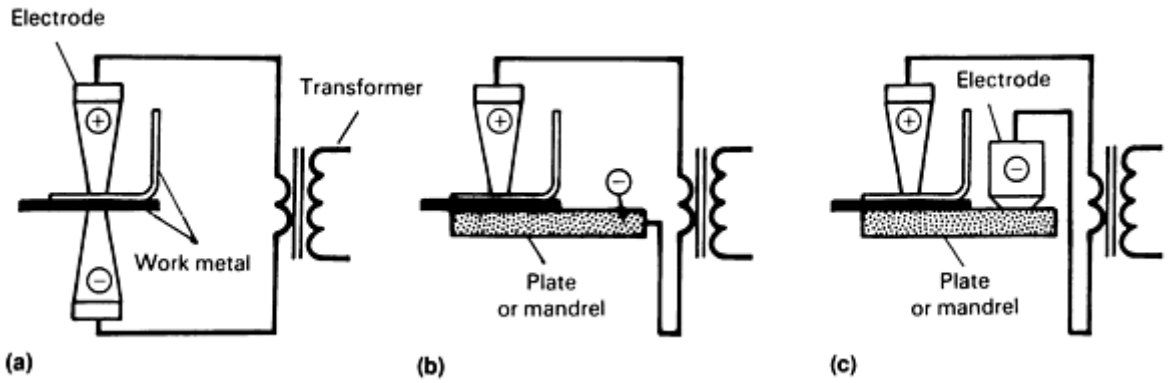

FIG. 6 RELATION OF WORK METAL TO ELECTRODES WHEN MAKING SINGLE-SPOT WELDS BY DIRECT WELDING

The simplest and most common arrangement in which two workpieces are sandwiched between opposing upper and lower electrodes, is shown in Fig. 6(a). In Fig. 6(b), a conductive plate or mandrel having a large contacting surface is used as the lower electrode; this reduces marking on the lower workpiece and conducts heat away from the weld more rapidly and may be necessary because of the shape of the workpiece. In the arrangement in Fig. 6(c), a conductive plate or mandrel beneath the lower workpiece is used for the same purposes but in conjunction with a second upper electrode.

Direct Multiple-Spot Welding. Two arrangements of the secondary circuit for making two or more spot welds simultaneously by direct welding are shown in Fig. 7(a) and 7(b). In direct multiple-spot welding (as well as in series multiple-spot welding, described below), tip contour and surface condition must be the same for each electrode. Also, the force exerted by all the electrodes on the workpieces must be equal, regardless of inequalities in work-metal thickness. The force can be equalized by using a spring-loaded electrode holder or a hydraulic equalizing system. The use of a conductive plate or mandrel, as in Fig. 7(b), minimizes weld marks on the lower workpiece.

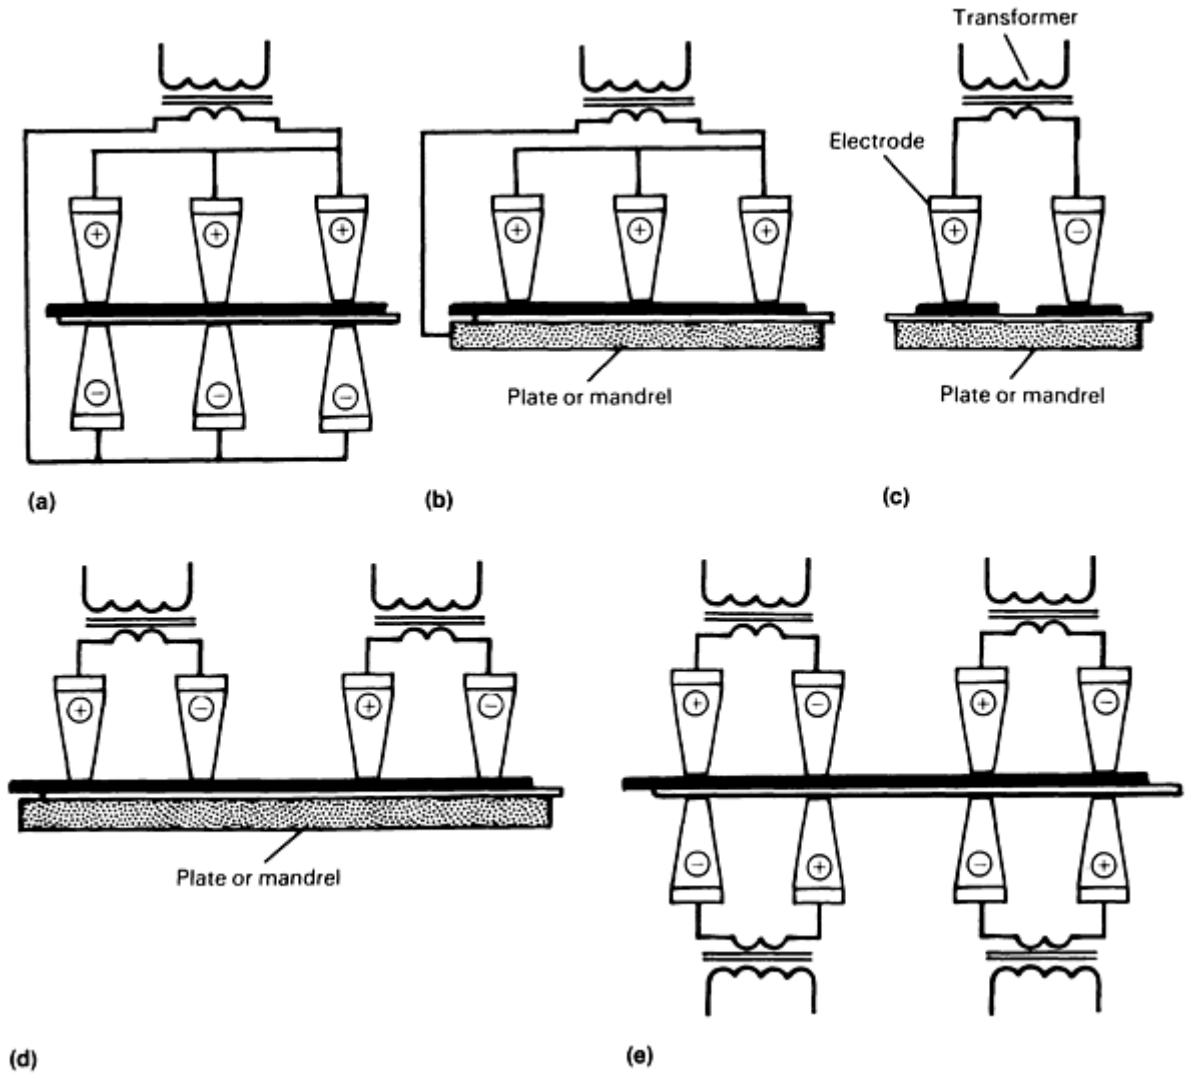

FIG. 7 RELATION OF WORK METAL TO ELECTRODES WHEN MAKING MULTIPLE-SPOT WELDS. (A) AND (B) DIRECT WELDING. (C), (D), AND (E) SERIES WELDING

Series Multiple-Spot Welding. Three arrangements for making a number of spot welds simultaneously by series welding are shown in Fig. 7(c), 7(d), and 7(e). In Fig. 7(d), each of the two transformer secondary circuits makes two spot welds. A portion of the current bypasses the weld nuggets through the upper workpiece.

Push-Pull Welding. Figure 7(e) is commonly referred to as push-pull welding. The advantage to this process is that the secondary loop area is quite small. This is common for components such as floor pans where a normal welding unit would have a throat several feet deep.

Procedure Development and Practice Considerations for Resistance Welding

Resistance Seam Welding

Resistance seam welding is a process in which heat caused by resistance to the flow of electric current in the work metal is combined with pressure to produce a welded seam. This seam, consisting of a series of overlapping spot welds, is normally gastight or liquid-tight. Two rotating, circular electrodes (electrode wheels), or one circular and one bar-type electrode, are used for transmitting the current to the work metal. When two electrode wheels are used, one or both wheels are driven either by means of a gear-driven shaft or by a knurl or friction drive that contacts the peripheral surface of the electrode wheel.

The series of spot welds is made without retracting the electrode wheels or releasing the electrode force between spots, although the electrode wheels may advance either continuously or intermittently.

Additional information is available in the article "Resistance Seam Welding" in this Volume.

Seam Welding Machines

A seam welding machine is similar in construction to a spot welding machine, except that one or two electrode wheels are substituted for the spot welding electrodes. Generally, seam. Welding is done in a press-type resistance welding machine.

There are four basic types of RSEW machines:

- *CIRCULAR:* AXIS OF ROTATION OF THE ELECTRODE WHEELS IS AT RIGHT ANGLES TO THE FRONT OF THE MACHINE (FIG. 8A).
- *LONGITUDINAL:* AXIS OF ROTATION OF THE ELECTRODE WHEELS IS PARALLEL TO THE FRONT OF THE MACHINE (FIG. 8B), AND THROAT DEPTH IS TYPICALLY 305 TO 915 MM (12 TO 36 IN.).
- *UNIVERSAL:* A SWIVEL-TYPE HEAD AND INTER-CHANGEABLE LOWER ARMS ALLOW THE AXIS OF ROTATION OF THE ELECTRODE WHEELS TO BE SET EITHER AT RIGHT ANGLES OR PARALLEL TO THE FRONT OF THE MACHINE.
- *PORTABLE:* WORK IS CLAMPED IN A FIXTURE, AND A PORTABLE WELDING HEAD IS MOVED OVER THE SEAM. THIS TYPE OF MACHINE IS USED FOR WORKPIECES THAT ARE TOO BULKY TO BE HANDLED BY REGULAR MACHINES

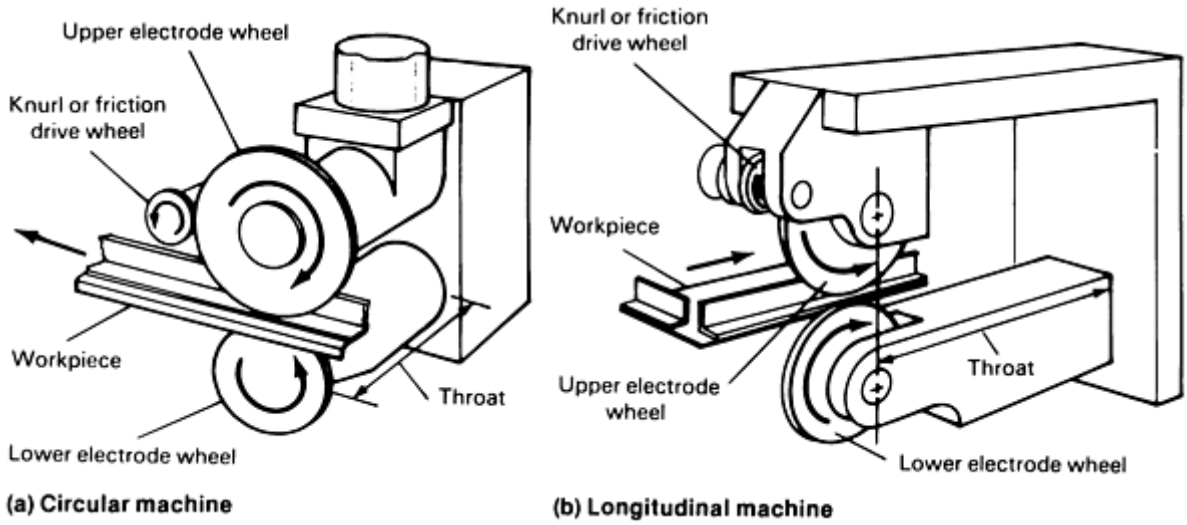

FIG. 8 RELATION OF ELECTRODE WHEELS TO OTHER COMPONENTS IN CIRCULAR AND LONGITUDINAL RSEW MACHINES

Electrodes

Electrode wheels made of Resistance Welder Manufacturers Association (RWMA) class 1 material were once used for seam welding of aluminum and magnesium alloys, galvanized steel, and tin-plated steel. However, class 1 material is now uncommon because of the restrictions on cadmium exposure. Typically, class 2, 3, or 20 materials are used (similar to spot welding electrodes).

Electrode wheels range in diameter from 50 to 610 mm (2 to 24 in.). Table 4 shows the diameters and body widths of commonly used electrodes, in relation to the size of the welding machine. Narrower wheels are used in machines with knurl or friction drive; wider wheels, in gear drive and idler machines.

TABLE 4 COMMON SIZES OF ELECTRODE WHEELS USED FOR RESISTANCE SEAM WELDING APPLICATIONS

MACHINE SIZE	**WHEEL DIAMETER**		WHEEL WIDTH[A]	
	mm	**in.**	**mm**	in.
SMALL	18	7	9.5	$\frac{3}{8}$
MEDIUM	20	8	9.5-13	$\frac{3}{8}$ - $\frac{1}{2}$
LARGE	**25-30**	**10-12**	**9.5-19**	$\frac{3}{8}$ - $\frac{3}{4}$

(A) DATA ARE FOR BODY WIDTH.

A small-diameter electrode wheel (Fig. 9a), or a large-diameter wheel mounted on a canted axis (Fig. 9b), can be used to avoid interference with a sidewall when a narrow flange is being welded on an inside radius or on a re-entrant curve. Beads, fibs, and other extensions on the surfaces to be seam welded can be passed over by cutting notches in the electrode wheels (Fig. 10).

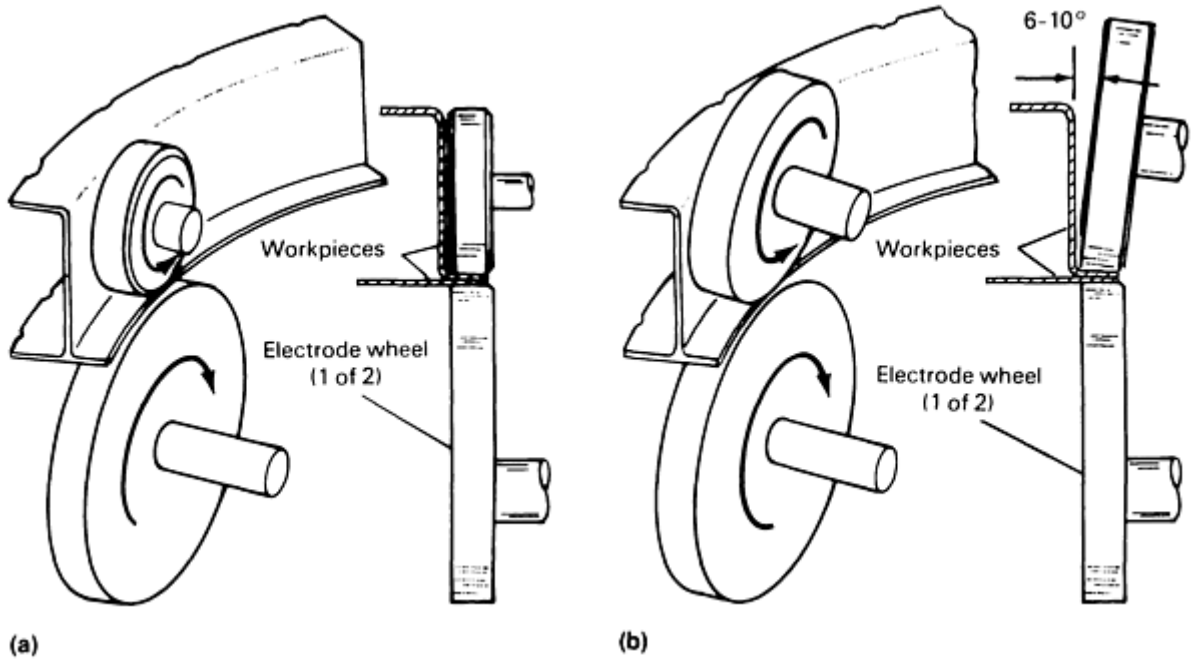

FIG. 9 UPPER ELECTRODE WHEELS DESIGNED TO AVOID INTERFERENCE WITH A SIDEWALL. (A) SMALL-DIAMETER WHEEL. (B) CANTED LARGE-DIAMETER WHEEL

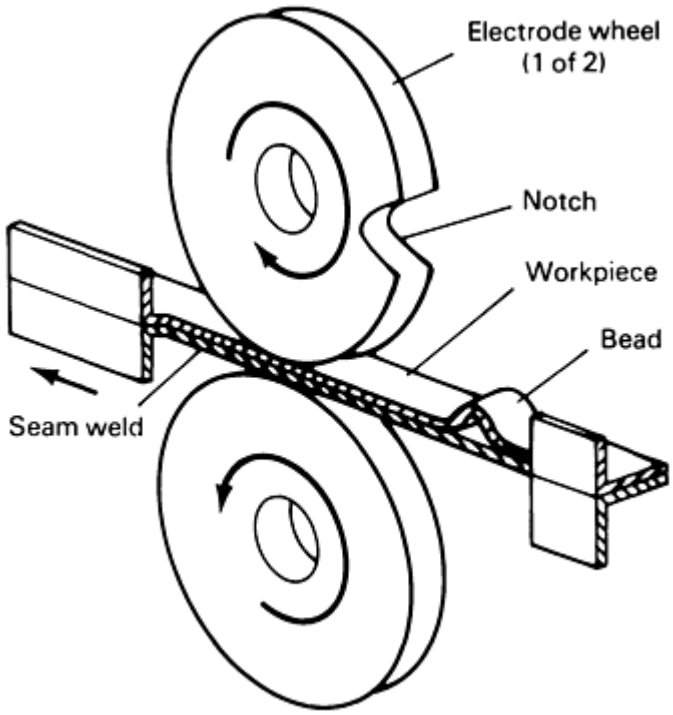

FIG. 10 NOTCH ELECTRODE WHEEL USED TO SEAM WELD A WORKPIECE HAVING AN OBSTRUCTION IN THE PATH OF THE WHEEL

Process Variations

Seam welding operations vary primarily in terms of travel speed and duration of the welding current. In continuous-motion welding, the electrodes (or workpieces) are driven at a constant speed, and welding current is either interrupted or

flows continuously. In either case, a continuous, leaktight seam is generated. This method is generally used for metals less than about 4.8 mm ($\frac{3}{16}$ in.) thick.

In intermittent-motion welding, rotation of the electrode wheels is automatically stopped to produce a spot weld; the electrodes are then rotated to move the workpiece the required distance for the next weld. This method is often used for aluminum and steel alloys less than 4.8 mm ($\frac{3}{16}$ in.) thick and selected metals greater than 4.8 mm ($\frac{3}{16}$ in.) thick.

Lap Seam Welding. In this process (also known as stitch or roll welding), the on and off cycling of the current while the electrodes continuously rotate actually determines the weld spacing (Fig. 11a). The minimum joint overlap is the same as for spot welding. There is generally no forging (that is, mash-down) with lap seam welding.

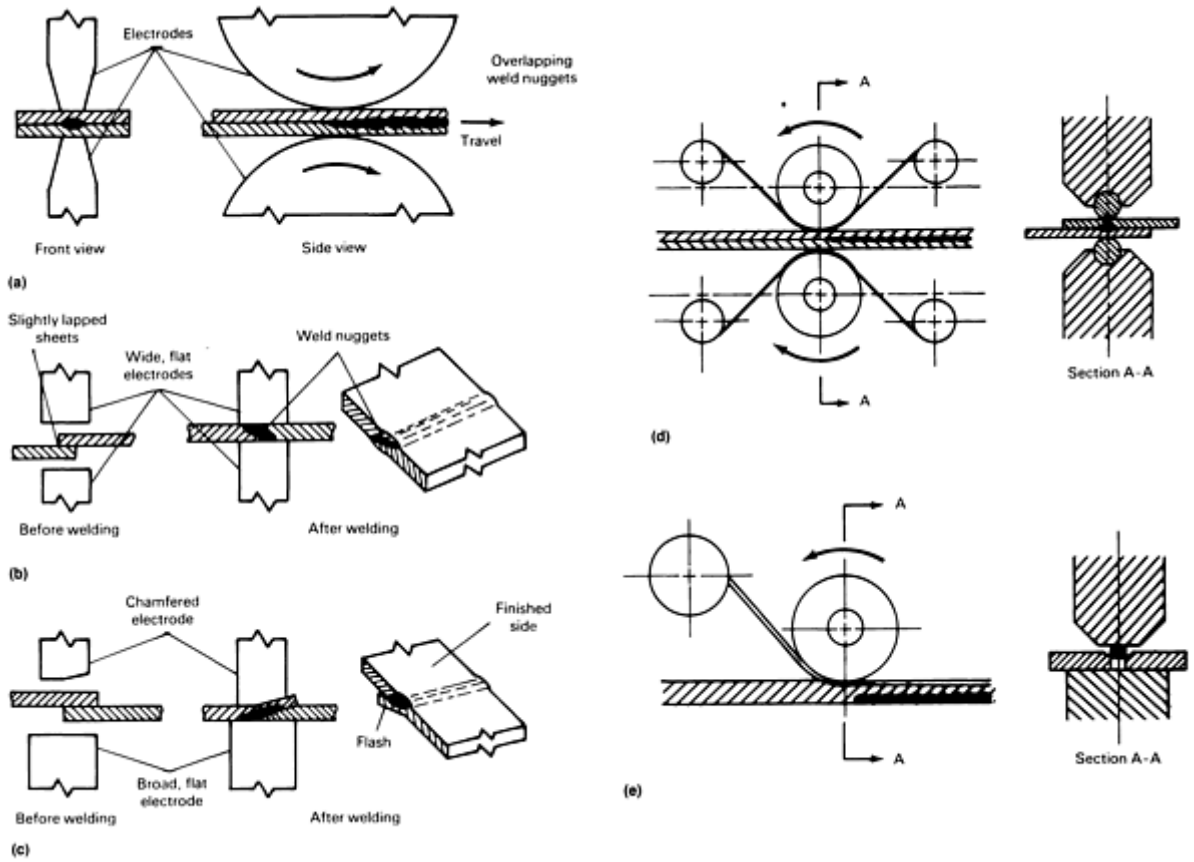

FIG. 11 PROCESS VARIATIONS OF SEAM WELDING. (A) LAP SEAM WELDING. (B) MASH SEAM WELDING. (C) METAL FINISH SEAM WELDING. (D) ELECTRODE WIRE SEAM WELDING. (E) FOIL BUTT SEAM WELDING

Mash seam welding generally has less overlap than lap seam welding and produces more mash-down (electrode force) with its continuous current (Fig. 11b). Joint thicknesses after welding usually vary from 120 to 150% of the sheet thickness. Continuous seams produced by this method have smooth appearance, but rigid workholding fixtures are required to minimize distortion.

Metal Finish Seam Welding. This process uses a chamfered electrode wheel, and one side of the joint is mashed down while the other side of the joint has a smooth, flat finish (Fig. 11c). Overlap is greater than for mash seam welding, and higher current amperages and electrode forces are also required.

Electrode wire seam welding is an internationally patented process that requires an intermediate wire electrode between each wheel electrode and the workpiece (Fig. 11d). The electrode wire seam welding process is used almost

exclusively for seam welding of tin mill products to fabricate cans. The copper wire travels around the wheel electrodes at the welding speed. The circular or flat cross-section of copper wire electrode provides a continuously renewed surface, but it is not consumed in the welding operation. The tin build-up which would occur on a copper wheel electrode is thus avoided. The process requires specially designed welding systems. The seam welds may be made with two wheel electrodes, or one wheel electrode and a mandrel electrode.

Foil Butt Seam Welding. This process requires metal foil to be placed on one or both sides of a butt joint prior to seam welding (Fig. 11e). The foil distributes current to the edges of the sheet, provides additional electrical resistance, helps to contain the molten metal, and also serves as a filler.

Applications

Resistance seam welding can be applied to a variety of workpiece shapes. Girth welds can be made in round, square, or rectangular parts by using electrode wheels of suitable diameter. Longitudinal welds can also be made.

Advantages of RSEW, as compared with resistance spot and projection welding, are:

- GASTIGHT OR LIQUID-TIGHT JOINTS CAN BE PRODUCED
- OVERLAP CAN BE LESS THAN FOR RESISTANCE SPOT WELDS OR PROJECTION WELDS, AND SEAM WIDTH CAN BE LESS THAN THE DIAMETER OF SPOT OR PROJECTION WELDS (TABLE 5)
- ROLLED SECTIONS ARE FREQUENTLY WELDED IN-LINE, THEREBY ELIMINATING SUBSEQUENT OPERATIONS

(B) FOR RWMA CLASS 2 ELECTRODE MATERIAL (MINIMUM CONDUCTIVITY, 75% IACS; MAXIMUM HARDNESS, 75 HRB). WHEEL WIDTH IS OVERALL WIDTH OF A FIAT-FACE WHEEL OR OF A WHEEL WITH A 75 MM (3 IN.) RADIUS FACE; FACE WIDTH IS THAT OF THE CONTACTING SURFACE OF FLAT-FACE WHEELS.

(C) FOR LARGER ASSEMBLIES, MINIMUM CONTACTING OVERLAP INDICATED SHOULD BE INCREASED 30%.

Limitations of RSEW, apart from those it shares with spot and projection welding, are:

- THE WELD ORDINARILY MUST PROCEED IN A STRAIGHT OR UNIFORMLY CURVED LINE
- OBSTRUCTIONS ALONG WITH THE PATH OF THE ELECTRODE WHEEL MUST BE AVOIDED OR BE COMPENSATED FOR IN THE DESIGN OF THE WHEEL
- SHARP CORNER RADII OR ABRUPT CHANGES IN CONTOUR ALONG THE PATH OF THE ELECTRODE WHEEL MUST BE AVOIDED (TABLE 6)
- FATIGUE LIFE OF RESISTANCE SEAM WELDS IS USUALLY SHORTER THAN THAT OF WELDS MADE BY OTHER SEAM WELDING METHODS

The shorter fatigue life is due to two factors. First, the most common method of cooling the electrode is flood cooling, which quenches the weld. Second, RSEW electrodes move continuously, preventing the application of postweld heat treatment to temper the weld.

TABLE 6 RECOMMENDED MINIMUM RADII OF CURVATURE FOR SEAM WELDED ALUMINUM AND STEEL COMPONENTS

(A) 0.8 MM $\leq T \leq$ 1.3 MM (0.031 IN. $\leq T \leq$ 0.051 IN.).

(B) $T \leq$ 1.6 MM ($T \leq$ 0.063 IN.).

(C) $T \leq$ 2.0 MM ($T \leq$ 0.079 IN.).

(D) $T \leq$ 3.0 MM ($T \leq$ 0.12 IN.).

Metals Welded. Low-carbon, high-carbon, low-alloy, high-strength low-alloy (HSLA), stainless, and many coated steels can be resistance seam welded satisfactorily. Alloys with carbon levels above about 0.15% may tend to form areas of hard martensite upon cooling.

Procedure Development and Practice Considerations for Resistance Welding

Projection Welding

Resistance projection welding (RPW) is a welding process in which current flow and heating are localized at a point or points predetermined by the design or shape of one or both of two parts to be welded (Fig. 12). The process is closely related to resistance spot welding (RSW), in which current flow and heating are localized by one or both electrode contact faces, which determine the location, size, and shape of the weld produced.

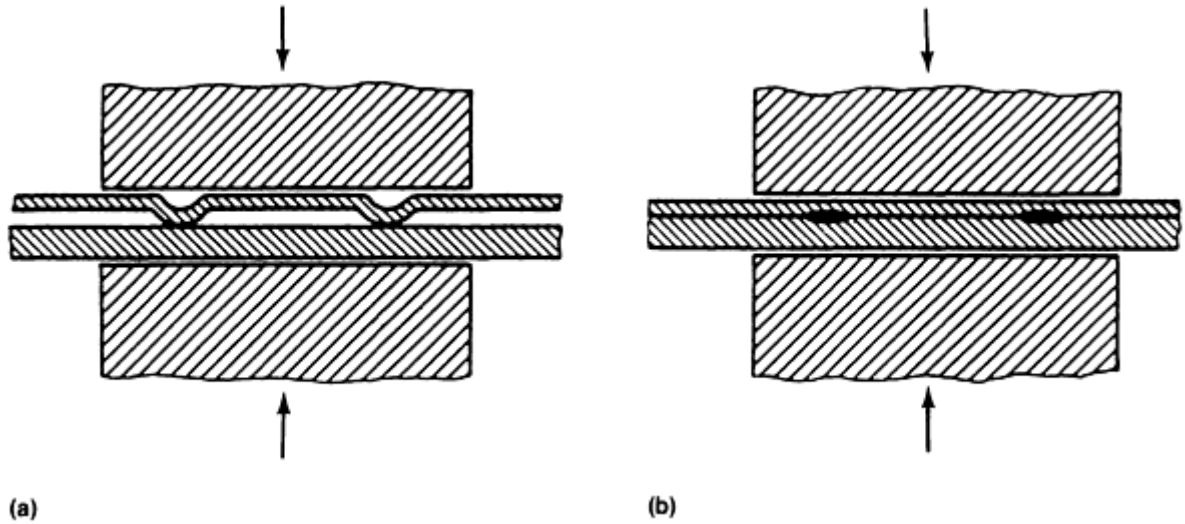

FIG. 12 RELATION OF WELD NUGGETS TO EMBOSSED REGIONS OF METAL SHEETS USED IN PROJECTION WELDING. (A) ELECTRICAL CIRCUIT LOOP IS COMPLETED WHEN CURRENT TRAVELS THROUGH EMBOSSED PROJECTION CONTACT POINTS. (B) ADDITION OF PRESSURE AFTER WELDING CURRENT IS TURNED OFF CAUSES PLASTIC DEFORMATION WHICH FLATTENS THE PROJECTIONS.

Projections may be of any practical shape that can properly concentrate the welding current (Fig. 13). In cross-wire projection welding, the curved surfaces of two intersecting wires perform the function of a projection. The shapes of parts may also take the place of conventional projections in projection welding of special types of joints.

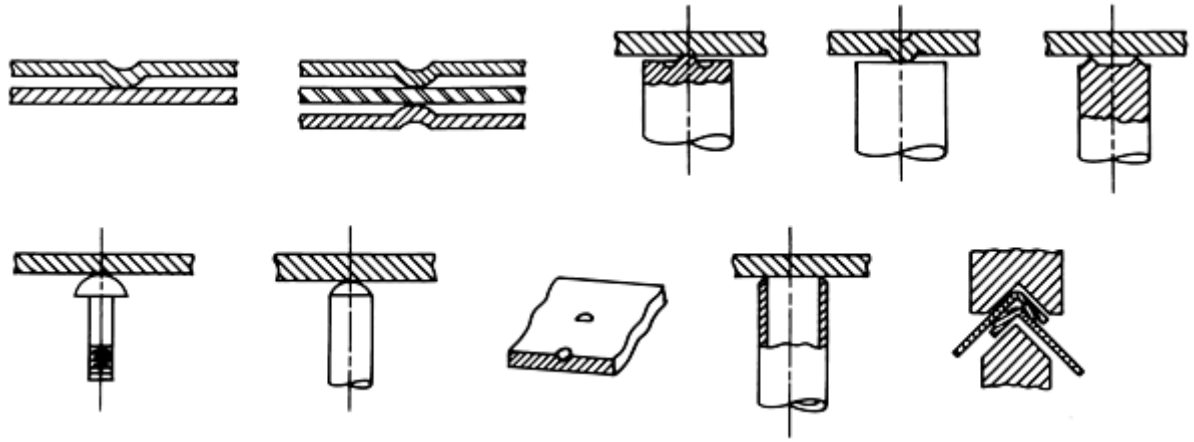

FIG. 13 SCHEMATICS SHOWING SELECTED SETUPS WHICH CAN BE USED IN PROJECTION WELDING OPERATIONS

Additional information is available in the article "Projection Welding" in this Volume.

Formation of the Weld. The formation of a projection weld nugget, which depends on the design of the projection, the selection of welding conditions, and the adequacy of the resistance welding equipment, is shown in Fig. 14. In this application, 2.33 mm (0.092 in.) thick low-carbon steel is projection welded using embossed spherical projections and a weld time of 20 cycles ($\frac{1}{3}$ s).

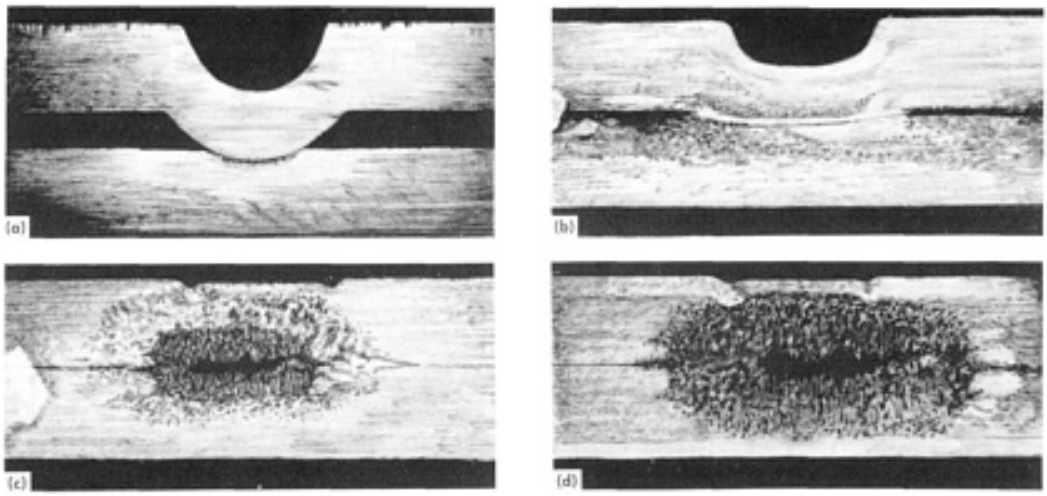

FIG. 14 FORMATION OF A WELD NUGGET DURING PROJECTION WELDING OF AN EMBOSSED SPHERICAL PROJECTION. SEE TEXT FOR EXPLANATION.

In the first stage of fabrication (Fig. 14a), the workpieces are brought together under pressure without application of welding current, and the projection may be slightly compressed and indented into the surface of the mating workpiece. Figures 14(b), 14(c), and 14(d) show the stages of formation of a typical weld at 20, 60 to 70, and 100% of the weld time (or heat time).

At about 20% of weld time (Fig. 14b), collapse of the projection is nearly complete, and a pressure weld is formed. A nugget of fused weld metal does not begin to form until about 50% of the weld time has elapsed. At about 60 to 70% of weld time (Fig. 14c), fusion has progressed a sufficient distance from the interface to produce a well-defined weld nugget that has about half its final thickness (penetration) and diameter. Sheet separation adjacent to the weld nugget has been

reduced to zero, and the softened metal above the nugget has been flattened against the face of the upper electrode (compare with Fig. 14b). Nugget diameter, penetration, and shear strength continue to increase as weld time progresses. Figure 14(d) shows the fully developed weld nugget.

Applicability

Projection welding is used where there is a high thickness ratio (for example, nuts welded to sheet), and where the appearance of the sheets must be controlled (for example, appliance surfaces). The principal application of projection welding is the joining of stamped low-carbon, low-alloy, and high-strength low-alloy (HSLA) steel parts. During stamping (punching, drawing, or forming), one of the parts must have a projection which has been formed during the stamping operation to enable projection welding. Projection welding is also used for joining screw-machine parts to stamped parts; the projection is machined or cold formed on the end of the screw-machine part.

Projection welding is most successful in workpieces 0.56 to 3.18 mm (0.022 to 0.125 in.) thick. Stock 0.25 mm (0.010 in.) thick has been projection welded; projection design is critical, however, and machines with low-inertia heads and fast follow-up are needed. Sections less than 0.25 mm (0.010 in.) thick are more adaptable to spot welding.

Advantages. The principal advantages of projection welding are:

- THE NUMBER OF WELDS THAT CAN BE MADE SIMULTANEOUSLY WITH ONE OPERATION OF THE WELDING MACHINE IS LIMITED ONLY BY THE ABILITY OF THE CONTROLS TO REGULATE CURRENT AND FORCE.
- BECAUSE OF GREATER CURRENT CONCENTRATION AT THE WELD, AND THUS LESS CHANCE OF SHUNTING, NARROWER FLANGES CAN BE WELDED, AND WELDS CAN BE SPACED CLOSER TOGETHER BY PROJECTION WELDING THAN BY SPOT WELDING.
- ELECTRODES USED IN PROJECTION WELDING HAVE FACES LARGER THAN THE PROJECTIONS AND LARGER THAN THE FACES OF ELECTRODES USED FOR MAKING SPOT WELDS OF COMPARABLE NUGGET DIAMETER. CONSEQUENTLY, BECAUSE OF LOWER CURRENT DENSITY, ELECTRODES REQUIRE LESS MAINTENANCE THAN DO SPOT WELDING ELECTRODES.
- PROJECTION WELDS CAN BE MADE IN METAL THAT IS TOO THICK TO BE JOINED BY RSW.
- FLEXIBILITY IN SELECTION OF PROJECTION SIZE AND LOCATION ALLOWS WELDING OF WORKPIECES IN THICKNESS RATIOS OF 6 (OR MORE) TO 1. WORK-PIECES IN THICKNESS RATIOS GREATER THAN ABOUT 3 TO 1 SOMETIMES ARE DIFFICULT TO SPOT WELD.
- THE PROCESS CAN BE USED TO MAKE LEAKPROOF JOINTS (FOR EXAMPLE, RING PROJECTIONS).

Limitations of projection welding include:

- FORMING OF ONE OR MORE PROJECTIONS ON ONE OF THE WORKPIECES MAY REQUIRE EXTRA OPERATIONS UNLESS THE PARTS ARE PRESS FORMED TO DESIGN SHAPE.
- WHEN SEVERAL WELDS ARE MADE AT ONCE WITH THE SAME ELECTRODE, ALIGNMENT OF THE WORK AND DIMENSIONS (PARTICULARLY HEIGHT) OF THE PROJECTIONS MUST BE HELD TO CLOSE TOLERANCES TO OBTAIN CONSISTENT WELD QUALITY.
- WHEN MAKING SIMULTANEOUS PROJECTION WELDS, THE PROJECTION LAYOUT WILL BE DICTATED BY THE SHUNT CURRENT PATHS, WHICH MAY NOT COINCIDE WITH THE DESIRED LOCATION.
- BECAUSE TWO PARTS ARE MOVING RELATIVE TO EACH OTHER DURING THE WELDING PROCESS, PROPER GAGING IS DIFFICULT.

Cross-Wire Welding

Resistance welding of crossed wires is a type of projection welding process. In practice, it usually consists of welding a number of parallel wires at right angles to one or more other wires or rods. There are many specific ways to perform the welding operation, depending upon production requirements, but the final finished product is essentially the same regardless of the method used.

Typical crossed-wire products include items such as stove and refrigerator racks, grills of all kinds, lamp shade frames, poultry equipment, wire baskets, fencing, grating and concrete rein-forcing mesh.

Welding Machines

Press-type machines, with either single-phase or three-phase transformers, usually are used for projection welding. The welding head in these machines is guided by bearings or ways and moves in a straight line. Platens with T-slots or tapped holes are used for mounting the welding dies or electrodes. Rocker-arm machines generally are not used for projection welding because the electrode moves in an arc that can cause slippage between the components as the projection collapses.

At the start of the welding stroke (Fig. 15a), equal air pressure is applied to the top of the piston and to the diaphragm. By the time the piston has completed its travel, the diaphragm has been compressed by the retraction of the internal shaft. Retraction of the internal shaft simultaneously compresses the diaphragm and closes the welding-current switch; the control lever for the switch rides in the shaft collar.

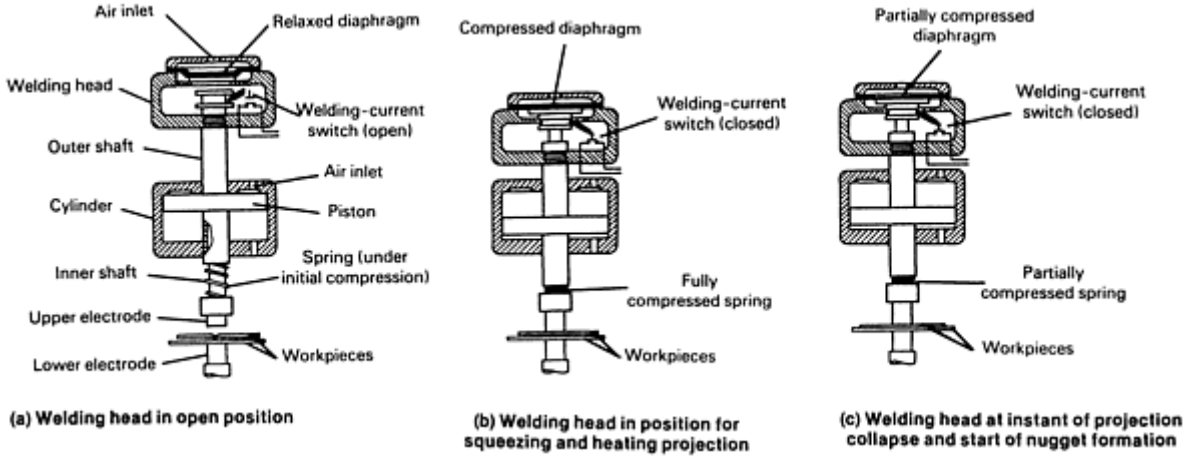

FIG. 15 SCHEMATIC SHOWING MOTION OF INTERNAL COMPONENTS IN A LOW-INERTIA WELDING HEAD USED FOR PROJECTION WELDING OPERATIONS

When the welding current is initiated (Fig. 15b), the only remaining mass to be moved is the internal shaft and its attached electrode. Air pressure acting on the diaphragm and the force of the compressed spring between the inner and outer shafts easily overcome the low inertia of the system and move the upper electrode downward as the projection collapses. Thus, the workpieces are kept in close contact under partial electrode force until the welding head follows and forges the weld region with the full electrode force (Fig. 15c). This setup, however, is no longer used because diaphragm cylinders are now classified as obsolete technology.

Process Variables

The major variables that affect projection welding are welding current, electrode force, and weld time.

Specifications for projection welding of stainless steels relative to low-carbon steel from 0.36 to 3.18 mm (0.014 to 0.125 in.) thick are given in Table 7. These data are intended to serve as starting points and should be adjusted to suit the specific application and the equipment used.

(A) SETDOWN, % = (DECREASE IN JOINT HEIGHT ÷ DIAMETER OF SMALLER WIRE) × 100.

(B) FOR 15.30, AND 50% SETDOWN.

Welding current required for projection welding, although slightly less per weld than that needed for spot welding, must be high enough to cause fusion before the projection is completely flattened. The recommended current is the highest current that, when used with the current electrode pressure, does not cause excessive expulsion of metal.

Electrode force used in projection welding depends on the work metal, the size and design of the projection, the number of projections in the joint, and the welding machine. Excessive force causes the projections to collapse before the weld area has reached the proper temperature, resulting in the formation of ring welds, in which fusion occurs around the periphery of the projection but is incomplete at the center. For best weld appearance, the electrode force should be such that the projection is flattened completely after the metal has reached welding temperature.

Weld time for a given type and thickness of work metal depends on welding current and rigidity of the projection. Weld time is less important than electrode force in projection welding of low-carbon, low-alloy, and HSLA steel, provided that the time is sufficient to produce a nugget of adequate size at the chosen welding current. A short weld time creates higher production efficiency and less discoloration and distortion of the workpiece. After the proper electrode force and welding current are determined, the weld time is adjusted to make the desired weld.

Electrodes

An electrode designed for RSW can be used for projection welding if the electrode face is large enough to cover the projection being welded, or the pattern of projections being welded simultaneously. To minimize marking and indentation of workpieces, the recommended electrode-face diameter for making a single projection weld usually is two or more times the diameter of the projection. In multiple-projection welding, the electrode face should be large enough to extend beyond the boundaries of the pattern of projections by approximately the diameter of one projection. RWMA class 2 electrode materials generally are preferred as general-purpose materials because they provide the best compromise among electrical and conductivity, strength, hardness, and temperature resistance. Typically, class 10, 11, or 12 materials are used on the bottom side of the weld to resist damage from the high localized force.

Flash Welding

Flash welding (FW) commonly is used to join sections of metals and alloys in production quantities. It is a resistance/forge welding process in which the items to be welded are securely clamped to electric current-carrying dies, heated by the electric current, and upset (Fig. 16). Clamping ensures good electrical contact between the current-carrying dies and the workpiece and prevents the parts from slipping during the upsetting action. Flash welding equipment must be durable to withstand high clamping force and upset pressures without deflecting. If deflection occurs, misalignment of workpieces may occur during welding. Flash welding is rapid and economical, and when properly executed, welds of uniform high quality are produced. A typical flash welding machine comprises a horizontal press-transformer combination with conducting work-clamping dies mounted on the press platens.

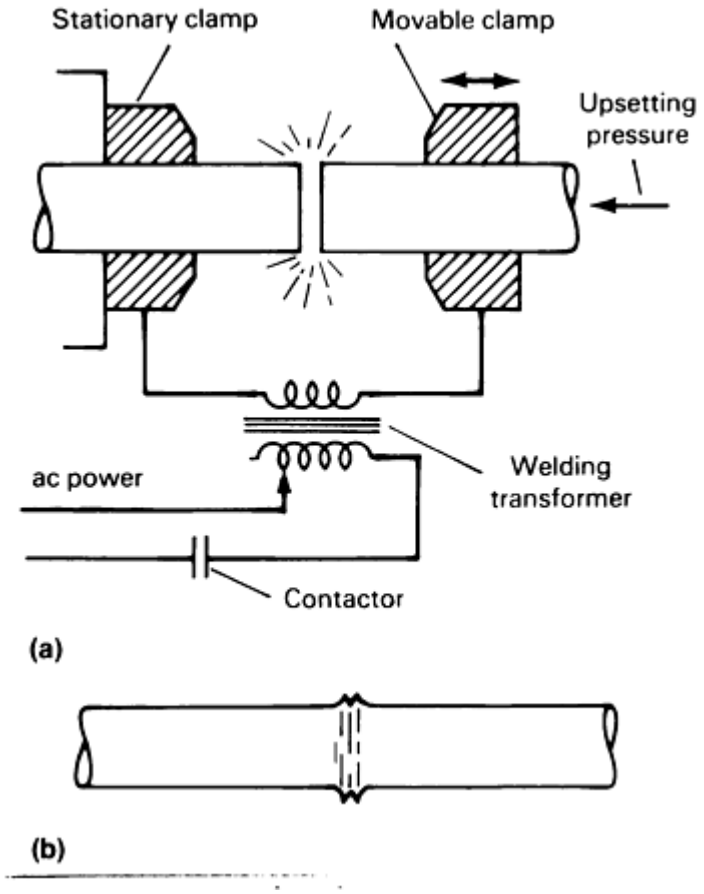

FIG. 16 WELD PRODUCED WHEN USING THE FLASH WELDING PROCESS. (A) WORKPIECES SECURELY CLAMPED IN CURRENT-CARRYING DIES BEFORE UPSETTING OPERATION IS INITIATED. (B) FINISHED WELD PRODUCED AFTER UPSETTING OPERATION

Additional information is available in the article "Flash Welding" in this Volume.

Applications

Flash welding can be used for joining many ferrous and nonferrous alloys and combinations of dissimilar metals. In addition to low-carbon steels, metals that are flash welded on a production basis include low-alloy steels, tool steels, stainless steels, aluminum alloys, magnesium alloys, nickel alloys, and copper alloys. Table 9 gives typical upsetting pressures for numerous classes of alloys.

Welding Parameters

Fundamentally, flash welding involves heating the ends of the pieces to be welded and subsequently forging them together. During the heating phase, a thermal distribution pattern is established along the axial length of the pieces being joined, which is characterized by a steep temperature gradient.

The major difference between the temperature pattern developed in flash welding and that developed in resistance welding is that flash welding produces a much steeper thermal gradient. This steep thermal gradient, combined with the resulting characteristic upset pattern, enables flash welding to accommodate a much greater variety of materials and shapes than can be welded by resistance welding.

Once the proper temperature-distribution pattern has been established, the abutting surfaces are rapidly forced together. The parts must be securely held together during the forging process to prevent slipping. Three distinct peaks are characteristic of flash welds (Fig. 17). The two peaks on either side of the weld line represent the material displaced by the upsetting action; the center peak is the molten metal extruded out of the weld, including oxides or contaminants formed during heating.

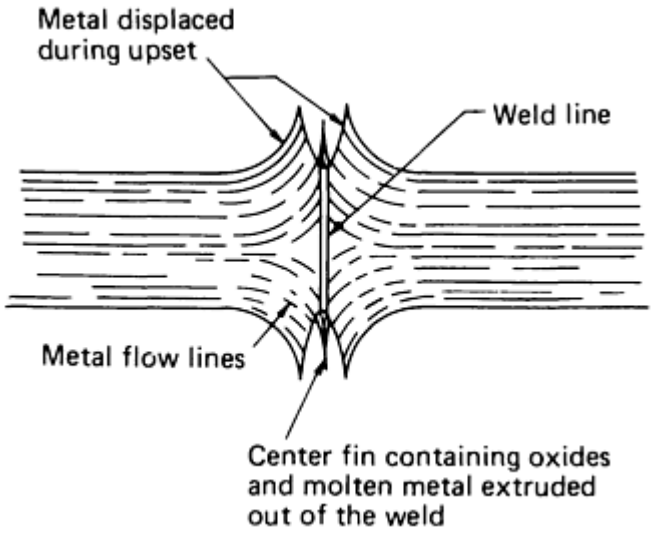

FIG. 17 SCHEMATIC SHOWING CROSS-SECTIONAL VIEW OF TYPICAL PEAKS AND FLOW LINES GENERATED IN A FLASH WELD

Heat (Energy) Sources

One of the major considerations for flash welding is the electrical power service. Flashing is a term used to describe the major heating process during flash welding. When the ends of the workpiece are brought together under light pressure, an electrical short circuit is established through the material. Because the abutting surfaces are not perfectly matched, the short-circuit current flows across the joint only at a few small contact areas. The large amount of current flowing through a relatively small area causes very rapid heating to the melting point. Heating is so rapid and intense that molten metal is expelled explosively from the joint area. Following this expulsion, a brief period of arcing occurs. Arcing is not sustained due to the low voltages employed. Studies have shown that stable flashing can be maintained with as low as $2\frac{1}{2}$ to 3 V, but typically the flashing voltage for alternating-current machines is from 5 to 10 V.

Following the expulsion of molten metal and subsequent arcing, small craters are formed on the ends of the abutting surfaces. The pieces are steadily advanced toward one another, and other short circuits are formed and additional molten metal is expelled. This process continues as random melting, arcing, and expulsion occur over the entire cross-sectional surface. During flashing, many active areas are in various stages of this sequence (Fig. 18). Flashing surfaces act as heat sources, and the steep thermal profile is established primarily from these heat sources. Temperatures of the flashes are at or above the melting point of the material and are progressively lower as distance progresses from the flashing surface toward the clamp.

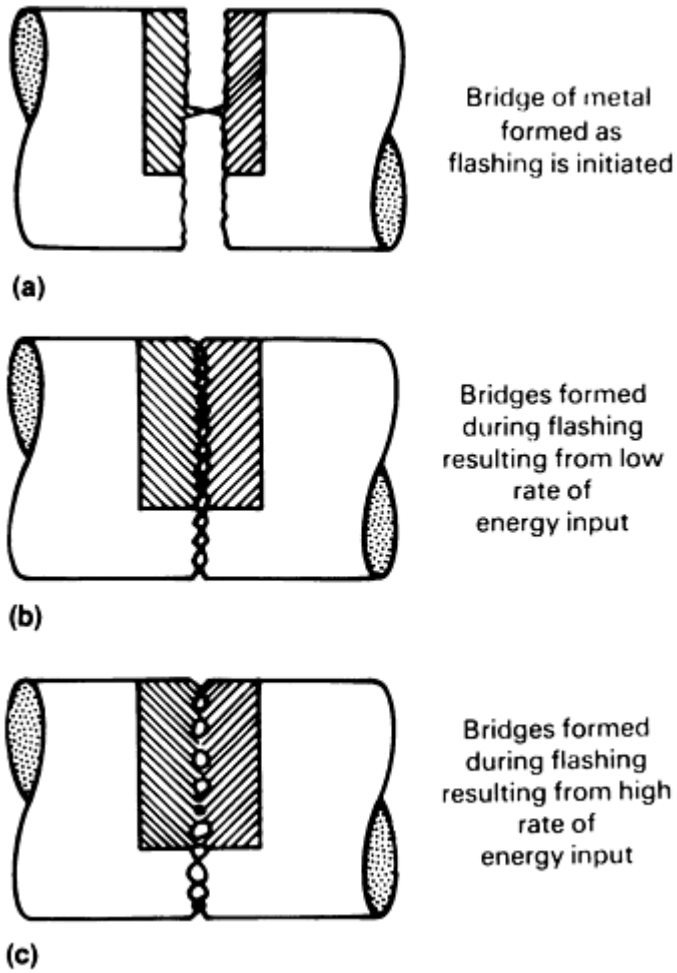

FIG. 18 GROWTH OF CONTACT POINTS PRODUCED BY ENERGY INPUT DURING FLASH WELDING

Force

Parts to be welded must be clamped or fixtured securely to provide good electrical contact with current-carrying dies and to transmit the upset forces. Also, a reliable source of force for the upsetting action is required. Systems for generating these forces vary greatly and are determined by the cross sections to be welded. The simplest welding machines derive their power for clamping and upsetting from the operator (that is, the parts are clamped to the dies via screw, lever, cam, or toggle force-multiplying linkages). Upset forces are generated in a similar manner. In larger machines, these forces are generated by pneumatic systems, oil hydraulic systems, combination air/oil hydraulic systems, or motor-driven cam systems.

Machines

Machines used for flash welding generally consist of a mainframe; a low-impedance welding transformer; a stationary platen; a movable platen on which clamping dies, electrodes, and other tools needed to position and hold the work-pieces are mounted; flashing and upsetting mechanisms; and the necessary electrical, air, or hydraulic controls (Fig. 19).

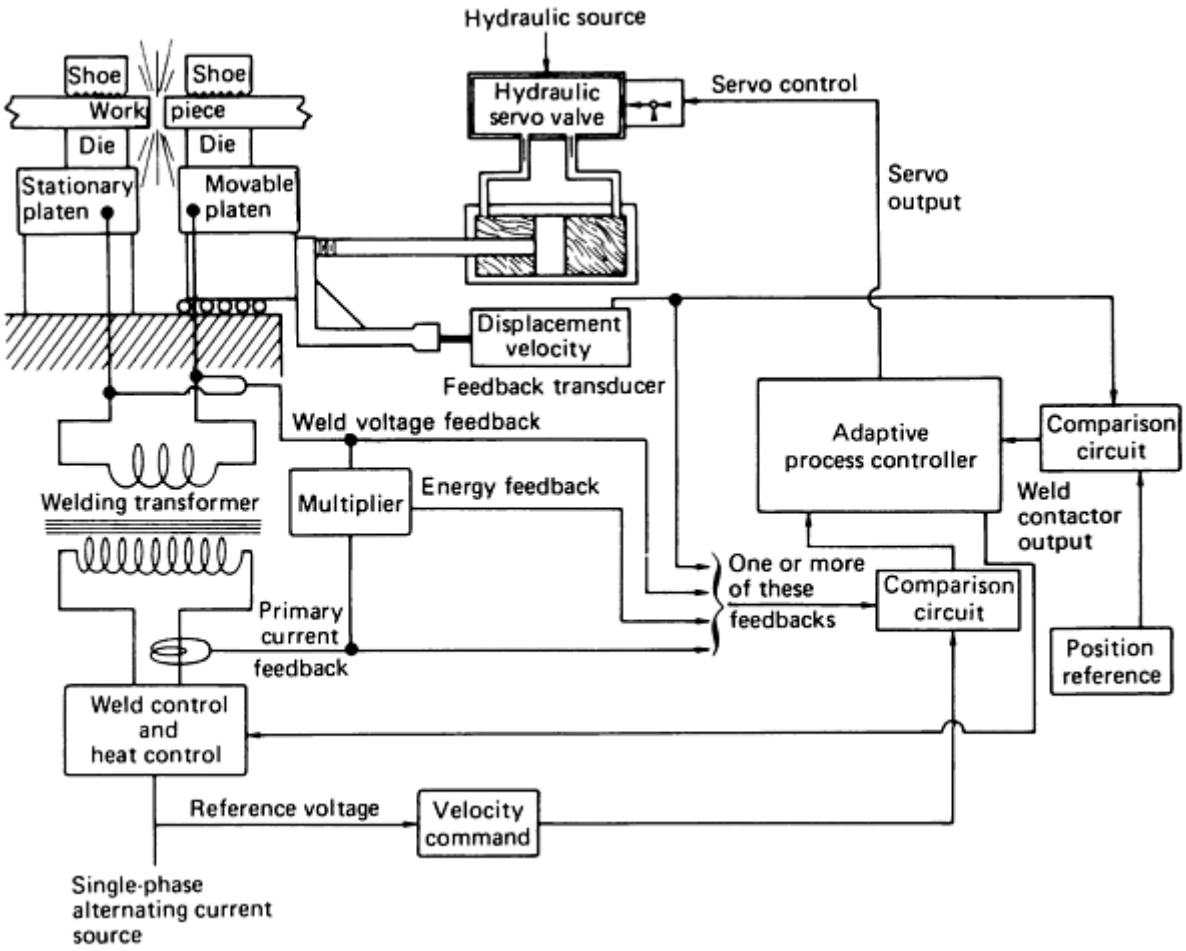

FIG. 19 FLOW DIAGRAM SHOWING ADAPTIVE CONTROLS USED TO CONTROL AND MONITOR FLASH WELDING PROCESS

Flash welding machines may be manual, semiautomatic, or fully automatic. With manual operation, the operator controls the speed of the platen from the time flashing is initiated until the upset is completed. In semiautomatic operation, the operator manually initiates flashing and then actuates an automatic cycle that completes the weld. In fully automatic operation, after the operator initiates the welding sequence, a fully automatic cycle can be used through the use of position-indicating devices and timers. Values for the various welding parameters are preselected by the operator. Automatic feedback control is used in some applications. These fully adaptive circuits vary from current to voltage feedback circuits, and data are obtained to control the welding sequences. Figure 19 shows various adaptive controls used by different flash welding unit manufacturers.

Transformers are used to supply electrical energy for the welding operation. The transformer tap switch frequently is a rotary, eight-step, knife-type, fully enclosed locking switch, which provides convenient adjustment of the welding voltage to suit work requirements. Voltages from 4 to 16 V are common.

Clamping Dies and Fixtures

Workpieces must be accurately clamped to maintain alignment, to allow the secondary current to pass into the workpieces, and to apply the upsetting force properly. Generally, the parts of the clamping mechanism that actually grip the workpiece are the electrodes, often called clamping dies. The surface of the material in contact with the dies must be cleaned of scale, rust, paint, or contaminants to ensure proper current flow.

The materials commonly used for clamping dies are RWMA class 3 and hardened tool steels such as H11, L6, and O1. Bronze and other copper-base electrode materials can be used in some applications. The die half (upper or lower) that

conducts the current usually is made of a copper-base material. The other half is made of the same copper-base material or of hardened steel.

Cooling of Electrodes. The need for water cooling of flash welding electrodes depends on the size of the electrode, die, or fixture, the magnitude of the flashing current, and the production rate. When the mass of the electrodes is large compared with that of the workpiece, the heat sink generally is large enough to dissipate the heat generated by the resistance to current flow and the heat absorbed from the workpiece. With high flashing currents and high production rates, electrodes generally must be cooled.

Shape and Size of Clamping Dies. Generally, the shape of the clamping-die surface is such that the die encompasses almost the entire workpiece surface. The required area of clamping-die contact depends on the current needed for heating the workpiece and the pressure needed for holding it. Semicircular dies are used where the line contact provided by V-shape dies gives insufficient surface for the current to flow without burning the workpiece, or for holding the workpiece without marking it.

Table 10 gives the minimum lengths of clamping dies for welding rounds, tubing, and other sections of various diameters or minimum dimensions; these data are for welding steels of low or medium forging strength.

Preweld Processing

Parts that are flash welded come in a variety of forms, including forgings; rolled or extruded bar; sheet, strip, or plate, ring preforms; and castings. Each of the above parts or assemblies requires preweld preparation.

Cleaning. As a minimum precaution, the ends of the workpiece that are clamped on the current-conducting die must be free from dirt, scale, surface oxidation, and grease. In addition, the ends of the workpiece that extend into the weld zone must be free from any contamination that could react with the base metal at the high temperatures developed during welding. Cleaning is needed because of the high current densities developed in the workpiece at the current-conducting dies. If insufficient electrical contact is made, weld quality is poor and localized hot spots can develop between the current-conducting dies and the workpiece. These localized hot spots are called "die burns." Many of the alloys welded have tightly adherent, highly resistive oxides that must be removed prior to welding.

In addition, poor fit-up, loose scale, and grease may cause the parts to slip during upsetting. Common cleaning techniques include (1) abrading the surfaces by grinding, grit blasting, or wire brushing; (2) pickling or chemical descaling; and (3) vapor degreasing.

End Preparation. Die burns, upset slippage, and inferior welds may be caused by poor fit-up between the current-conducting dies and the workpiece. In some cases, the ends of the workpiece must be machined or ground to fit the dies, particularly in welding of rough forgings or castings. Also, a chamfer may be required on the ends of the workpiece to initiate flashing action.

Alignment of Workpiece. After the workpieces are clamped in the welding unit, the alignment of the workpieces with respect to each other along the axis of upset must be maintained. After the flashing process and during upsetting, any misalignment may cause the parts to overlap one another or cause a skewed weld. If this occurs, insufficient metal will be extruded out of the weld zone during upsetting and a poor-quality weld will be formed (Fig. 20).

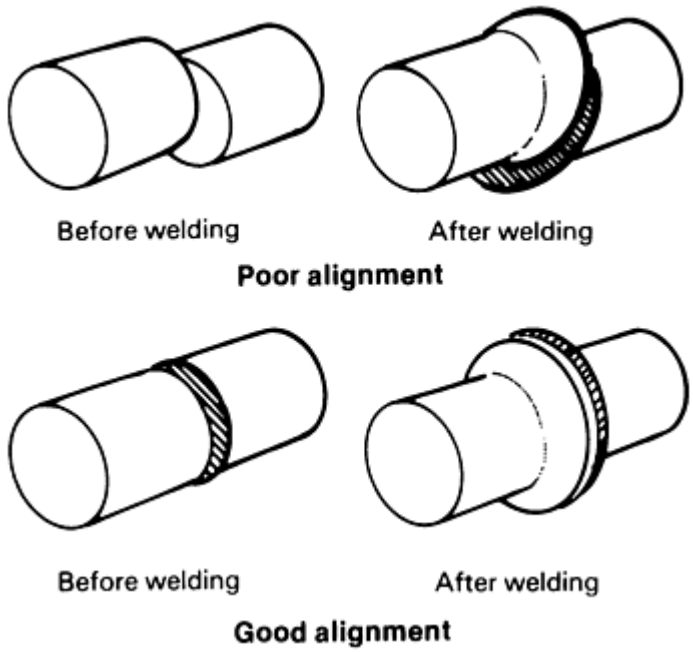

FIG. 20 EFFECT OF WORKPIECE ALIGNMENT ON JOINT QUALITY AND WELD UPSET

Dimensional Tolerances. Some combinations of joint length and stock thickness are difficult or even impossible to weld. Table 11 gives relationships between joint length (sheet width) and sheet thickness that have proven successful in a large number of production jobs. Relationships of tube diameter to wall thickness that have been successfully welded are listed in Table 12.

Burnoff. After the parts are clamped in the welding machine and the welding power is activated, the abutting surfaces are brought together for a brief period of violent flashing. This phase of the welding sequence is called "burnoff." It serves the function of squaring off the abutting surfaces and compensates for inconsistencies in end preparation.

Preheating is a resistive heating phase of the welding process in which the heat is generated by the electrical resistance of the workpieces. It is accomplished by bringing the workpieces together under light pressure, creating a short circuit. The pressure must be great enough to prevent flashing, but not so great that workpieces are prematurely welded.

In practice, preheating is performed in a cyclic manner, workpieces are brought together briefly, then separated for a brief period to allow the heat generated to diffuse into them. This sequence is repeated several times. Fully automatic machines perform this function, thus eliminating operator variables.

Flashing. The primary purpose of flashing is to generate enough heat to produce a plastic zone that permits adequate upsetting. The rate of energy input must be in proper proportion to the travel of the platen or movable die, so that constant flashing is maintained until the appropriate amount of metal is flashed off and the required plastic zone is obtained.

Upsetting (Forging). Bonding takes place during the upsetting action, and some metal must be extruded from the weld zone to remove slag and other inclusions not expelled during flashing. The extruded metal must extend beyond the cross-sectional boundaries of the workpiece to ensure that maximum amounts of slag and inclusions are removed when the weld upset is removed during subsequent trimming. When the weld upset is removed, no evidence of the weld should remain. Porosity near the outer surface on an etched section of the weld, or a crevice around the workpiece after the weld upset has been removed, indicates incomplete bonding because of either insufficient upsetting force or insufficient plasticity during upsetting.

A large upset produced by an excessive upsetting force can be detrimental to weld quality, can waste metal, and indicates that most of the plastic metal has been extruded, requiring bonding to take place in metal where plasticity may not have been sufficient to ensure a good weld.

Procedure Development and Practice Considerations for Resistance Welding

Upset Welding (Ref 11)

Upset welding (UW) is a resistance welding process that produces coalescence over the entire area of faying surfaces or progressively along a butt joint by the heat obtained from the resistance to the flow of welding current through the area where those surfaces are in contact. Pressure is applied before heating is started and is maintained throughout the heating period (Fig. 21). The equipment used for upset welding is very similar to that used for flash welding. It can be used only if the parts to be welded are equal in cross-sectional area. Upset welding differs from flash welding in that the parts are clamped in the welding machine and force is applied to bring the parts tightly together. High-amperage current is then passed through the joint, which heats the abutting surfaces. When they have been heated to a suitable forging temperature, an upsetting force is applied and the current is stopped. The high temperature of the work at the abutting surfaces, plus the high pressure, causes coalescence to take place. After cooling, the force is released and the weld is completed. There is no arc or flash in upset welding. The area at the joint is usually enlarged over its original dimension.

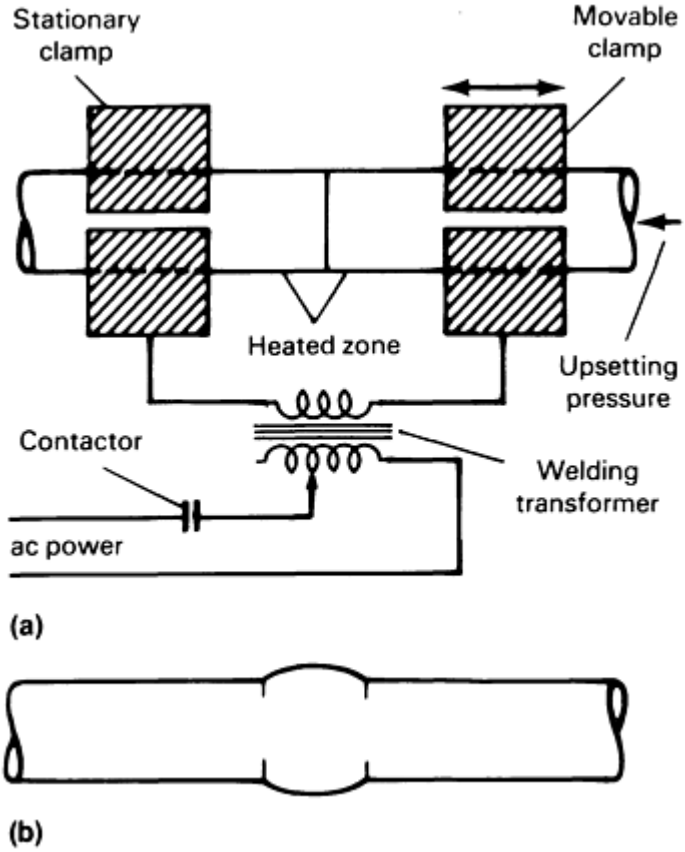

FIG. 21 WELD OBTAINED WHEN USING THE UPSET WELDING PROCESS. (A) WORKPIECES SECURELY CLAMPED IN CURRENT-CARRYING DIES WHILE PRESSURE AND CURRENT ARE APPLIED. (B) FINISHED WELD PRODUCED AFTER WELDING OPERATION IS COMPLETED

This process is used for welding small wires, tubing, piping, rings, and strips where the cross-sectional areas of both pieces are identical. If intimate contact is not obtained because of improper joint preparation, the weld will be defective.

Additional information is available in the article "Upset Welding" in this Volume.

Procedure Development and Practice Considerations for Resistance Welding

High-Frequency Resistance Welding

High-frequency resistance welding (HFRW) is a resistance welding process that produces coalescence of metals by the heat generated from the resistance of the workpieces to a high-frequency current (10 to 500 kHz) and the rapid application of an upsetting force once heating is completed. The current is applied to the base metal by using electrodes that are held against the surface of the workpiece. The principal applications of HFRW are for making such structural shapes as pipe and tubing from continuous strips of metal. Two process variations of HFRW are continuous seam welding (Fig. 22a, b, c, d, e, and f) and finite-length butt welding (Fig. 22g), which is a variation of induction upset welding (UW-I).

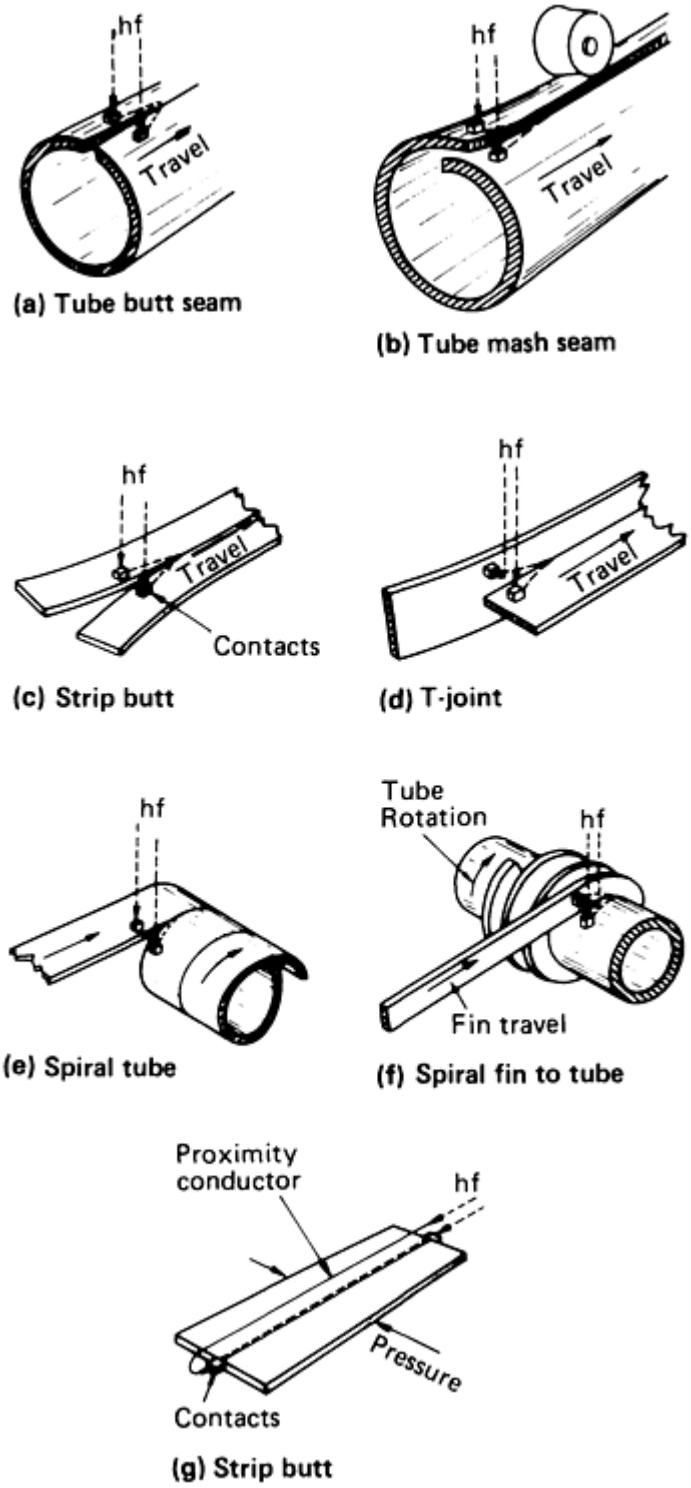

FIG. 22 TYPICAL HIGH-FREQUENCY WELDING APPLICATIONS USED TO JOIN PLATES AND TO FORM TUBES

Detailed information is available in the article "High-Frequency Welding" in this Volume.

Continuous seam welding can be described by its most common application, high-frequency upset welding (UW-HF) of a tube (Fig. 23). A pair of electrodes is placed on either side of an open V formed by the converging edges of the strip being made into tubing. The angle of this V typically varies from 4 to 7°. The edges of the strip converge between the weld pinch rolls, where a certain degree of forging upset is accomplished.

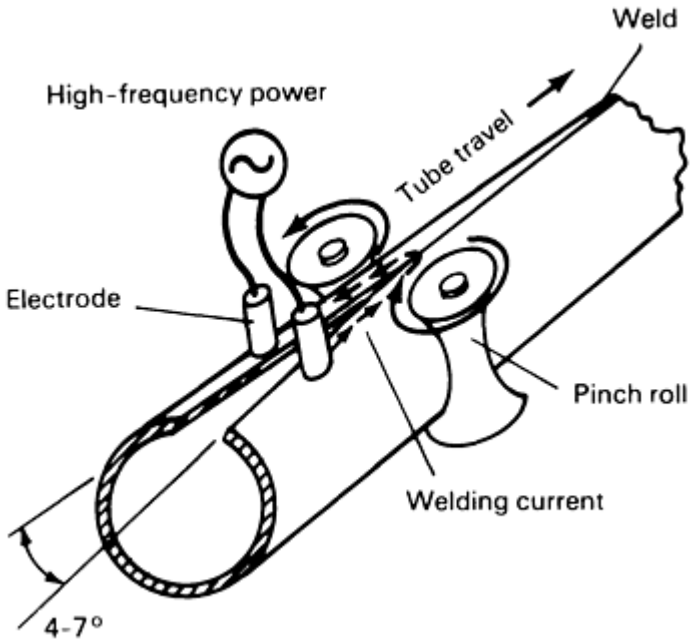

FIG. 23 HIGH-FREQUENCY LONGITUDINAL BUTT SEAM WELDING OF A TUBE

As the material moves through the rolls from the contacts to the point of welding, high-frequency current introduced at the electrodes flows on the opposing faying surfaces of the strip, down one side of the V to the point of welding, and back to the other electrode. Because this process is performed at frequencies of about 400 kHz, the depth of heating is quite shallow and heating occurs rapidly. Power is adjusted to bring the edges to a welding temperature at the time they join, and contaminants on the surfaces, as well as most of the molten material, are squeezed out of the seam toward the inside and outside of the tube when the weld is completed. This upset material can be trimmed off flush to the surfaces of the tube if desired.

The other applications of continuous high-frequency resistance seam welding (Fig. 23) vary from tube welding only in the shape of the workpiece. Contacts introduce current at the open part of a V that is being closed by rolls at the point at which the material has been heated to a high enough temperature to weld.

Finite-Length Welding. The process shown in Fig. 22(g), in which a butt joint of finite length is welded between two parts, is used for applications in coil end joining as well as in the manufacture of strip and sheet blanks for subsequent press forming. In this process, heating is accomplished along a seam that has already been closed under light pressure. The path of the heating current is controlled by the use of a proximity conductor positioned over the seam. The high-frequency heating causes the edges to be brought to welding temperature, after which pressure is increased to weld the joint. The appropriate frequency is selected to achieve heating through the material thickness. For example, 10 kHz can be used up to 6.4 mm (0.25 in.) thickness. Joints made this way can be produced very quickly, typically in 1 s. Compared to flash welding, the amount of upset is small, no shower of sparks and debris is emitted from the weld, and very little metal is consumed in making the joint.

Welding Parameters. Table 13 gives typical HFRW weld speeds as a function of wall thickness for tube and pipe products.

Capacitor Discharge Stud Welding

The capacitor discharge process uses direct current produced by the rapid discharge of a capacitor bank to create an electric arc and the heat needed for melting both stud and workpiece. The weld time is very short, ranging from 1 to 6 ms. Because the weld time is so short, no ferrule or fluxing is required. The equipment consists of a stud gun, capacitor discharge power/control unit, and suitable weld cable. Figure 24 illustrates a portable capacitor discharge stud welding system.

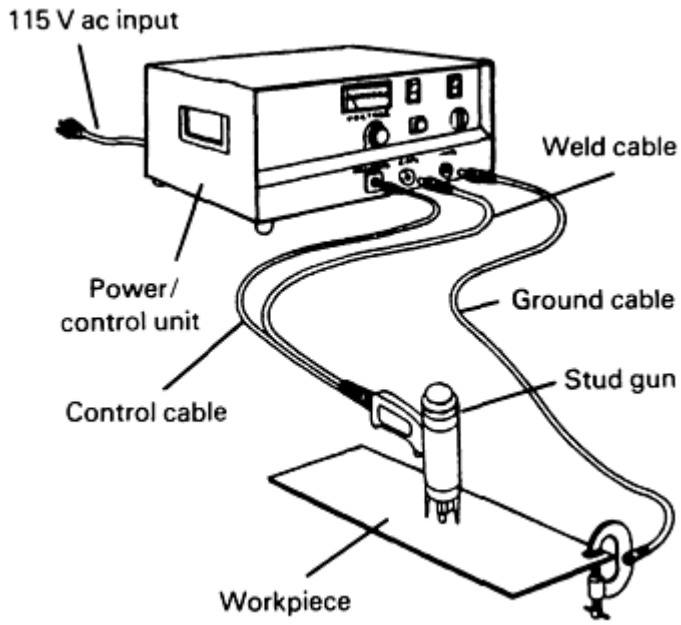

FIG. 24 KEY COMPONENTS OF A PORTABLE CAPACITOR DISCHARGE STUD WELDING SYSTEM

The three different methods of capacitor discharge stud welding include: initial contact, initial gap (Fig. 25), and drawn arc. The difference among these three methods is in the manner of arc initiation. The initial contact and initial gap methods utilize a small, specially engineered projection or tip to obtain arc initiation, whereas the drawn arc method initiates the arc by drawing the stud away from the workpiece.

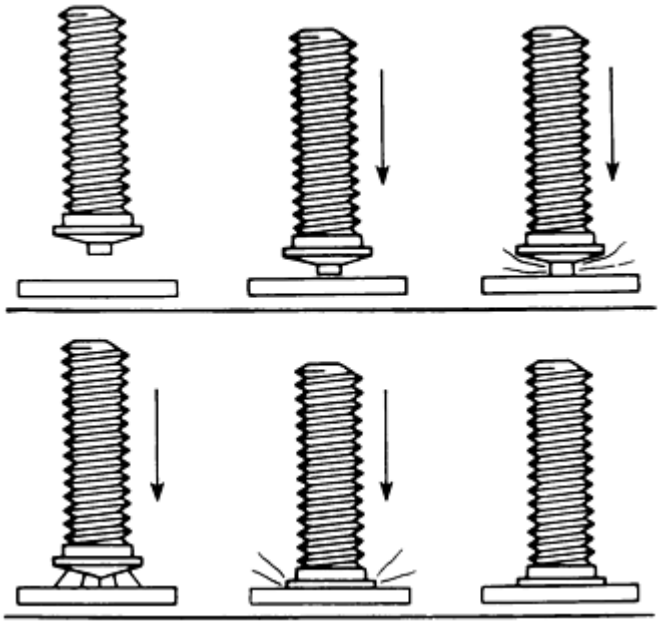

FIG. 25 SEQUENCE OF OPERATIONS REQUIRED TO WELD A STUD TO A WORKPIECE USING THE INITIAL GAP METHOD OF CAPACITOR DISCHARGE STUD WELDING

Studs. Low-carbon steel, stainless steel, aluminum, and brass are the materials used most often for studs welded commercially with the capacitor discharge method. The preferred weld base of a capacitor discharge welding stud is round, and the shank may be of almost any shape--threaded, unthreaded, round, square, rectangular, tapered, or grooved. The maximum weld-base diameter being welded commercially with the capacitor discharge welding process is 13 mm ($\frac{1}{2}$ in.).

Weld Current/Weld Time Relationships. The weld current process ranges from approximately 600 to 25,000 A, depending on stud size and weld method. The weld current range with the drawn arc method is approximately 600 to 3000 A, whereas with the initial contact or gap method the range is approximately 2500 to 25,000 A. Weld time with the drawn arc method is generally in the range of 4 to 6 ms, whereas with the initial contact and gap method it is generally in the range of 1 to 3 ms.

Metals Welded. The capacitor discharge stud welding process is an arc welding process, but differs from other arc welding processes in that the weld is made in a few milliseconds. For this reason, acceptable metallurgical results can be obtained without shielding the arc or using a flux. The welding of aluminum using the drawn arc method of capacitor discharge stud welding does require a shielding gas, however. Because of the speed at which the weld takes place, very little metal is melted. Weld penetration is slight, and very little stud metal intermixes with the plate metal. Therefore, studs may be welded to very thin metals without melt-through, and many dissimilar metals can be welded with acceptable results. Various stud and plate material combinations can be welded (Table 14).

Procedure Development and Practice Considerations for Resistance Welding

Resistance Welding of Stainless Steels

Stainless steels are readily resistance welded by spot, seam, projection, flash, upset, high-frequency, and capacitor discharge. Generally, the weld time and welding current are less than those used for welding carbon steel, but the electrode force is usually greater. Austenitic stainless steels of the 300 series are resistance welded more often than any other metal except lowcarbon steel. Ideally, stainless steel to be resistance welded should contain a maximum of 0.08% C (as in types 304, 316, and 347), although steels of higher carbon content (such as types 301, 302, 309, and 310) can be successfully resistance welded.

The martensitic and ferritic types of stainless steel can be welded satisfactorily. The martensitic types are less frequently resistance welded, because joints made in them are hard and brittle in the as-welded condition.

Equipment

Resistance welding of stainless steel requires less transformer capacity than for equivalent thicknesses of other metal, under the same conditions. The welding machines use a singlephase alternating-current power supply, a three-phase rectifier, or a frequency-converter power supply. A weld made with a three-phase power supply usually requires slightly higher current and a longer weld time than a weld made with a single-phase supply.

Factors Affecting Resistance Welding of Stainless Steels

The characteristics of stainless steel that affect resistance welding include electrical resistivity, thermal conductivity, melting temperature, strength at elevated temperatures, coefficient of thermal expansion, and contact resistance.

Electrical Resistivity. Stainless steels have much higher electrical resistance than carbon steels. As a result, more heat is generated in a stainless steel with the same current. Therefore, resistance welding of a stainless steel requires lower currents or shorter weld times than welding of a carbon steel.

Thermal Conductivity. Stainless steel has a lower thermal conductivity than carbon steel and, therefore, heat is conducted away from the weld zone more slowly. This, in conjunction with the electrical resistivity, means that less heat has to be applied to reach the melting temperature.

Melting temperatures of stainless steels have an effect on the amount of heat required to produce fusion for welding. The austenitic stainless steels melt in various ranges between 1370 and 1455 °C (2500 and 2650 °F), and the martensitic and ferritic alloys melt in ranges between 1400 and 1530 °C (2550 and 2790 °F). Plain low-carbon steels melt at temperatures between 1480 and 1540 °C (2700 and 2800 °F).

Coefficient of Thermal Expansion. Austenitic and nitrogen-strengthened austenitic stainless steel expands and contracts with changing temperature almost 50% more than does plain carbon steel. These dimensional changes and the slower heat diffusion in austenitic grades result in greater thermal stress, which leads to warping. The ferritic, martensitic, and precipitation-hardening grades of stainless steel have coefficients of thermal expansion from 6 to 11% lower than that of plain carbon steel.

High strength at room and elevated temperatures of nitrogen-strengthened stainless steels and, to a lesser extent, of straight-chromium grades makes it necessary to use greater electrode force than is required for carbon steel to bring the work-metal surfaces together for the required intimate contact at points of welding.

Contact resistance of stainless steel is higher than that of carbon steel and, therefore, greater electrode pressure is needed to make good resistance welds. In addition, the welding process is more stable because the base material is not as susceptible to surface contamination.

Welding Characteristics of Stainless Steels

Austenitic Stainless Steels. All of the austenitic stainless steels in the solution-annealed condition contain carbon in solution. When the steel is heated to the temperature range of 425 to 815 °C (800 to 1500 °F), as in the weld heat-affected zone (HAZ), carbon combines with chromium, resulting in chromium carbide precipitation at the grain boundaries. Precipitation of chromium carbide (sensitization) makes the material susceptible to intergranular corrosion. Sensitization to intergranular corrosion is influenced in austenitic stainless steel by (1) the carbon content, (2) the solubility of the carbon, (3) the presence of one or more stabilizing elements, (4) the proximity of the actual metal temperature to 1200 °F, and (5) the time period during which the metal is held in that temperature range. The first three factors are controllable only through selection of composition; the latter two are controllable by adjustment of welding conditions such as heat input, size of spot, production rate, and provisions for cooling.

Martensitic stainless steels most often welded are types 403,410,414, and 431. These steels can be resistance welded in the annealed, hardened or hardened-and-tempered condition. Regardless of prior condition, welding produces a hardened martensitic zone adjacent to the weld. The hardness of this zone depends mainly on carbon content, although it can be controlled to a degree by welding procedure. As the hardness of the metal in the HAZ increases, its susceptibility to cracking increases and its toughness decreases. Steels having a maximum carbon content of 0.15%, such as types 403 and 410, often produce satisfactory welds without postweld heat treatment. Steels with higher carbon content, such as types 420 and 440A, generally require postweld heat treatment.

Ferritic grades of stainless steel most often welded are types 405,430,442, and 446. Resistance welds in these steels exhibit reduced ductility at room temperature because of grain growth in the HAZ. Ferritic stainless steels can also become embrittled if heated to approximately 475 °C (885 °F). This phenomenon, known as "885 °F embrittlement," may be encountered in the HAZ of a ferritic stainless steel weld. If properties in the as-welded condition are unsuitable, annealing must follow welding. Postweld annealing, in addition to improving ductility, helps restore normal corrosion resistance.

Precipitation-hardening grades of stainless steel can be resistance welded in the annealed or aged (hardened) condition. If they are welded in the aged condition, the strength of the weld area is significantly reduced because the heat of welding anneals the material subjected to it. Generally, most of the strength may be restored by simply re-aging the weldment. When maximum strength is required in the weld area, it is best to resistance weld these grades in the annealed condition and then age the weldment.

Procedure Development and Practice Considerations for Resistance Welding

Resistance Welding of Aluminum Alloys

Aluminum alloys, both of the non-heat-treatable and heat-treatable types, either wrought or cast, can be resistance welded. Some of these alloys are welded more readily than others. Gas shielding may be required to maximize joint quality. Characteristics of aluminum alloys include comparatively high thermal and electrical conductivity, a relatively narrow plastic range (about 95 to 205 °C, or 200 to 400 °F, temperature differential between softening and melting), considerable shrinkage during cooling, a troublesome surface oxide, and an affinity for copper electrode materials.

Base-Metal Characteristics

Although aluminum alloys can be resistance spot and seam welded, some alloys or combinations of alloys have higher as-welded properties than others. Table 15 gives melting ranges, electrical and thermal conductivities, and resistance weldability of some wrought alloys and casting alloys.

TABLE 15 MELTING RANGES, ELECTRICAL AND THERMAL CONDUCTIVITIES, AND RESISTANCE WELDABILITY OF COMMON ALUMINUM ALLOYS

(B) BASED ON COPPER ALLOY 102 AS 100%. WHICH HAS A THERMAL CONDUCTIVITY OF 391 W/M · K (226 BTU/FT · H · °F) AT 20 °C (68 °F). LOW CARBON STEEL HAS A THERMAL CONDUCTIVITY OF ABOUT 13% ON THIS RELATIVE SCALE.

(C) RW, READILY WELDABLE; ST, WELDABLE IN MOST APPLICATIONS BUT MAY REQUIRE SPECIAL TECHNIQUES FOR SPECIFIC APPLICATIONS; LW. LIMITED WELDABILITY AND USUALLY REQUIRES SPECIAL TECHNIQUES; NR. WELDING NOT RECOMMENDED

Alclad Alloys. Resistance welding is also done on Alclad products made by roll cladding some of the alloys listed in Table 15 with a thin layer of aluminum or aluminum alloy. Because this layer is anodic to the core alloy, it provides electrochemical protection for exposed areas of the core. Alclad alloys 2219, 3003, 3004, 6061, and 7075 have a cladding of alloy 7072, which contains 1% Zn; Alclad alloy 2014 has a cladding of alloy 6003 or sometimes alloy 6053, both of which contain about 1.2% Mg; and Alclad alloy 2024 has a cladding of alloy 1230, which contains a minimum of 99.3% Al.

Effects on Weldability. The hardness of an alloy is one variable influencing weldability. Any alloy in the annealed condition (O temper) is more difficult to weld than the same alloy in a harder temper. In general, alloys in the softer tempers are much more susceptible to excessive indentation and sheet separation and to low or inconsistent weld strength. Greater deformation under the welding force causes an increase in the contact area and variations in the distribution of current and pressure. Therefore, welding of aluminum alloys in the annealed condition or in the softer tempers is not recommended without special electromechanical or electronic controls.

High-strength alloys such as 2024 and 7075 are easy to resistance weld, but may require applications of a forge pressure, because they are more susceptible to cracking and porosity than the lower-strength alloys.

Resistance Welding Machines

Aluminum alloys can be resistance welded with single-phase direct-energy, three-phase direct-energy, and stored-energy machines. Best results are obtained by using a machine that has these features:

- ABILITY TO HANDLE HIGH WELDING CURRENTS FOR SHORT WELD TIMES
- SYNCHRONOUS ELECTRONIC CONTROLS FOR WELD TIME AND WELDING CURRENT
- LOW-INERTIA WELDING HEAD FOR RAPID FOLLOW-UP OF ELECTRODE FORCE
- SLOPE CONTROL (FOR SINGLE-PHASE WELDING MACHINES)
- MULTIPLE-ELECTRODE-FORCE SYSTEM TO PERMIT PROPER FORGING OF THE WELD NUGGET AND REDRESSING OF ELECTRODES

Electrodes and Electrode Holders

Selection of electrode material and face shape, maintenance of the face, and cooling of the electrode are important in producing consistent spot and seam welds in aluminum alloys.

Copper Alloy Electrodes. Resistance Welder Manufacturers Association (RWMA) classes 1, 2, and 3 are used for welding aluminum alloys. These electrode materials have high electrical and thermal conductivities, which combined with adequate cooling help keep the temperature of the electrode below the temperature at which aluminum will alloy with copper and cause electrode pickup.

Design of spot welding electrodes suitable for spot welding of aluminum includes both straight and offset electrodes. Construction details of each are shown in Fig. 26. Straight electrodes should be used whenever possible, because deflection and skidding may occur with offset electrodes under similar welding conditions. If offset electrodes are used, the amount of offset should be the minimum permitted by the shape of the assembly being welded.

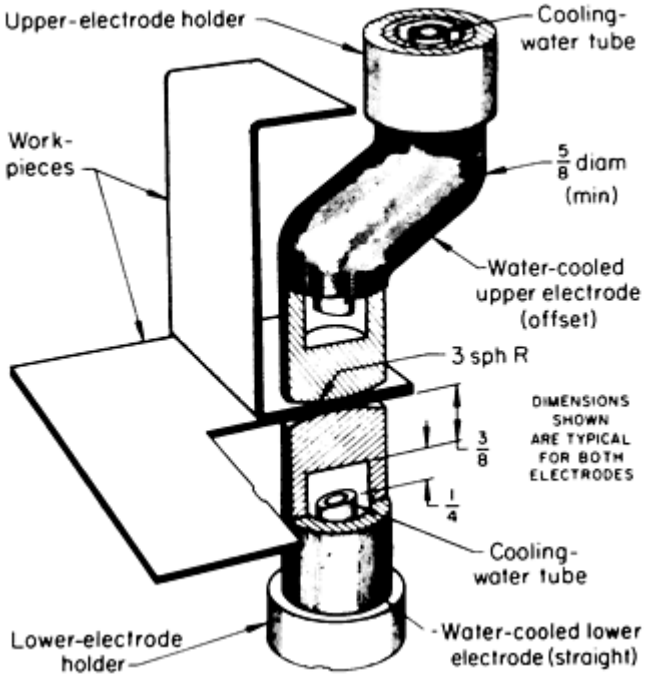

FIG. 26 CUTAWAY VIEW SHOWING INTERNAL COMPONENTS OF STRAIGHT AND OFFSET RADIUS-FACE ELECTRODES USED IN RESISTANCE SPOT WELDING OF ALUMINUM ALLOYS

Only electrodes that have the cooling-water hole within 9.5 mm ($\frac{3}{8}$ in.) of the face surface should be used.

Preweld Surface Preparation

Although welds for some purposes can be made satisfactorily without any preweld surface preparation, welds that are free of cracks, porosity and sheet separation, and that have the most uniform strength and symmetry, are obtained only with correct procedures for cleaning and reduction or removal of oxide film. In addition, adequate surface preparation reduces electrode contamination.

Procedure Development and Practice Considerations for Resistance Welding

Resistance Welding of Copper and Copper Alloys

Resistance spot welding is widely used for joining copper and copper alloys. Principal applications include welding sections up to about 1.52 mm (0.060 in.) thick, particularly those alloys with low electrical conductivities. Many copper alloys with low conductivities can be seam welded easily. Coppers with a low weldability factor are difficult to seam weld. Projection welding is not recommended for copper or for most brasses. Bronzes can be projection welded with satisfactory results in many applications.

Welding Characteristics

The resistance weldability of any copper alloy is inversely proportional to its electrical and thermal conductivities. Generally, alloys with lower conductivities are easier to weld. Compared with steel, most copper alloys require shorter weld time, lower electrode force, higher current, and different electrode materials that are compatible with the alloy being welded.

Welding Equipment

Single-phase and three-phase direct-energy and electrostatic stored-energy (capacitor-discharge) welding machines are used for resistance welding of copper and copper alloys. The addition of slope control to single-phase direct-energy welding machines is not necessary for spot welding most copper alloys. In welding high-zinc brasses, the use of upslope can result in an increase of as much as 20% in weld strength. Downslope is not recommended for welding of any of the copper alloys.

Welding Machine Controls. Copper alloys are particularly sensitive to variations in welding conditions, and therefore all direct-energy machines used for welding these alloys should be equipped with synchronous electronic controls, especially in applications requiring short weld times. These devices are capable of controlling weld time and welding current for repeated operations with extreme accuracy.

Electrodes

The current used for resistance welding of copper alloys is much higher than that used for welding low-carbon steel, and therefore, the electrode must have high electrical conductivity to minimize heat buildup.

Electrode Materials. The Resistance Welder Manufacturers Association (RWMA) class 1 electrode materials (typically tungsten or molybdenum alloys), containing copper and cadmium, are sometimes used for welding copper and high-conductivity brass and bronze. Class 2 materials, containing copper and chromium, are used on low-conductivity brass and bronze and the copper-nickel alloys. Class 3 materials are used in electrodes for seam welding.

Electrodes must be sufficiently water cooled to minimize sticking to the work metal and to prolong their life. Face contours must be carefully prepared and the electrodes must be properly aligned for welding.

Selection of Process

Weldability of the work metal often determines which process should be used for a given application. Some of the coppers and copper alloys can be spot welded, but not seam welded because of high conductivity, and not projection welded because of low compressive strength of the projections at elevated temperature.

Coppers

Coppers and copper alloys having electrical conductivity higher than about 30% IACS are the least well suited for resistance spot, projection, or seam welding, mainly because of severe electrode pickup.

Thin copper stock can be welded using electrodes faced with RWMA class 13 (tungsten) or class 14 (molybdenum), but surface appearance is poor and frequent electrode maintenance is required. A tinned coating on wire or sheet is helpful in welding copper.

Beryllium Copper

Beryllium copper alloys can be resistance welded most successfully in thin gages. Spot welding produces satisfactory welds; seam welding is less successful. Projection welding is satisfactory, provided that the projections can be formed with the work metal in the annealed condition and without cracking the work metal around the projection. Close control of welding conditions is required for consistent weld size and joint strength.

Oxide films produced by heat treating must be removed to ensure low and consistent contact resistance. Work metals that have not been heated after rolling frequently need only degreasing before welding.

Low electrical conductivity (22% IACS for alloys C17000 and C17200) contributes to the weldability of beryllium copper alloys. However, they are more difficult to resistance weld than low-carbon steel. Alloy C17500 has an electrical conductivity of 45% IACS and is more difficult to resistance weld than higher-strength, lower-conductivity beryllium copper.

Low- and High-Zinc Brasses

The low-zinc brasses are difficult to weld, although easier than copper, and are subject to electrode pickup. Welds made in these brasses may lack strength, principally because of comparatively high electrical conductivity (32 to 56% IACS).

The high-zinc brasses have an electrical conductivity of 27 to 28% IACS and can be both spot and projection welded over a wide range of conditions. Electrode pickup can be a problem unless weld time, welding current, and electrode force are properly selected.

Excessive electrode pickup and blowthrough of the weld may occur when long weld times, high energy input, and low electrode forces are used. Yellow brasses (alloys C26800 and C27000) are less susceptible to electrode pickup than cartridge brass except when long weld times and high energy input are used. Electrode force should be sufficient to prevent arcing or expulsion of molten metal, to which these alloys are subject because of their 30 to 40% Zn content, which boils at about 905 °C (1665 °F). As shown in Table 16, the recommended electrode force, when using electrodes having a face diameter of 4.8 mm ($\frac{3}{16}$ in.), is approximately 1.8 kN (400 lbf).

Copper Nickels

The copper-nickel alloys have electrical conductivities of 4.5 to 11% IACS, are readily spot and seam welded with relatively low welding current, and generally do not alloy with the electrode material and cause electrode pickup.

Bronzes

The phosphor bronzes, except alloy C50500, which is not recommended for resistance spot and seam welding because of its high electrical conductivity (48% IACS), have relatively low electrical conductivity (11 to 20% IACS) and am readily spot and seam welded using low welding currents. Electrode pickup can be reduced by use of a type F (radius) electrode face and frequent redressing to keep the face clean and smooth. Hot shortness can be minimized by supporting the workpieces to prevent strain during welding and by using a greater minimum overlap than recommended by the data in Table 17.

(A) MINIMUM EDGE DISTANCE IS EQUAL TO ONE HALF THE CONTACTING OVERLAP.

Nickel Silvers

Nickel silvers, which have about the same conductivities (6 to 10.9% IACS) as copper nickels, are spot welded as readily as copper nickels but are more difficult to seam weld. Surface contaminants such as lead and bismuth (which form low-melting eutectics with copper and nickel) or sulfur (which may be introduced in forming) must be removed before resistance welding.

Procedure Development and Practice Considerations for Electron-Beam Welding

Introduction

ELECTRON-BEAM WELDING (EBW) can produce deep, narrow, and almost parallel-sided welds with low total heat input and relatively narrow heat-affected zones in a wide variety of common and exotic metals. In many applications, a single pass is sufficient to weld the components. When initially applied to industrial applications in the 1950s, EBW had to be performed totally in a vacuum environment. In this form, EBW was primarily used because of its ability to reliably produce very high quality welds in materials normally considered extremely difficult to join (for example, refractory metals, oxidizable metals, stainless steels, and superalloys). This made it ideally suited for use in aerospace, nuclear, and other similar (high-technology) manufacturing industries.

During the 1960s, the capability of employing the EBW process for medium-vacuum and nonvacuum welding tasks was developed. This increased production capacity helped make EBW more attractive to other industries desiring to take advantage of the numerous joining benefits it provided. However, the use of EBW required that all applications have a demonstrated capacity for fairly high-volume production.

Today, EBW is used to join not only difficult-to-weld materials but also common materials such as steel ($\leq$150 mm, or 6 in., thick), aluminum ($\leq$305 mm, or 12 in., thick), and copper ($\leq$100 mm, or 4 in., thick) (Ref 1). These and other metals (in thicknesses ranging from foil to plate dimensions) can be electron-beam welded. In addition, EBW can be used to join numerous combinations of dissimilar metals. See the Section "Fusion Welding Processes" in this Handbook for a description of EBW systems and equipment.

Procedure Development and Practice Considerations for Electron-Beam Welding

Weld Geometry

Part Configuration. Whether a component is welded in a vacuum or at atmospheric pressure (nonvacuum), part configuration and the corresponding joint designs used are critical parameters in the successful application of EBW. A circular weld in the axial direction, for example, that joins a disk-shaped member (gear or cup) to a shaft (Fig. 1) may

experience severe constraint. Such joints are practical in easily welded metals--those that are soft, have low yield points, and exhibit low shrinkage--but not in difficult-to-weld steels that have high strength, hardenability, or machinability due to high sulfur content.

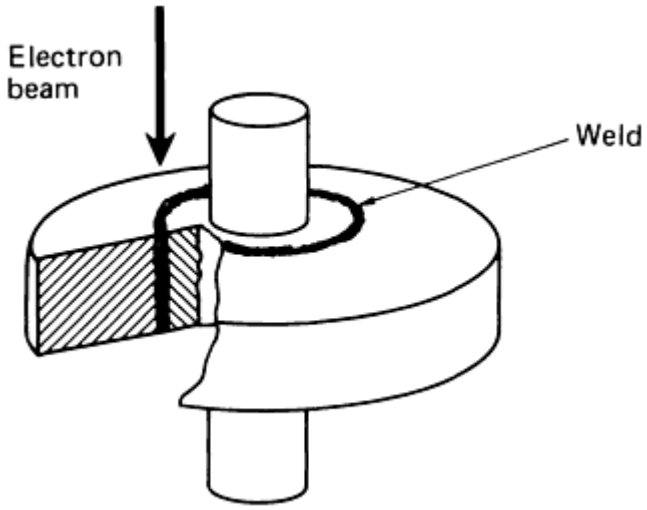

FIG. 1 CUTAWAY VIEW SHOWING LOCATION AND PENETRATION OF A CIRCULAR ELECTRON-BEAM WELD JOINING A DISK-SHAPED COMPONENT TO A SHAFT

The difficulties encountered in welding shapes such as those shown in Fig. 1 are aggravated if the weld zone is broadened by defocusing the electron beam. This is a frequent problem if exact beam position cannot be controlled, either because of beam instability, magnetism of the parts, or excessive tolerances in fixturing on high throughput machines. The need for beam broadening can be eliminated by the use of closed-loop beam position control systems.

Shrinkage stress is minimal in radial welds, as shown in Fig. 2. The volume of molten metal is less constrained by the axial direction if the gear hub is allowed to move by using push fit and no restraints. The weld must also have root clearances--the weld zone must not extend into the shaft. Stresses are lower if the melt zone has parallel side boundaries. Triangular weld zones that are caused by broadened beams, uneven beam power distribution, or incomplete penetration have more complex stresses which may result in cracking.

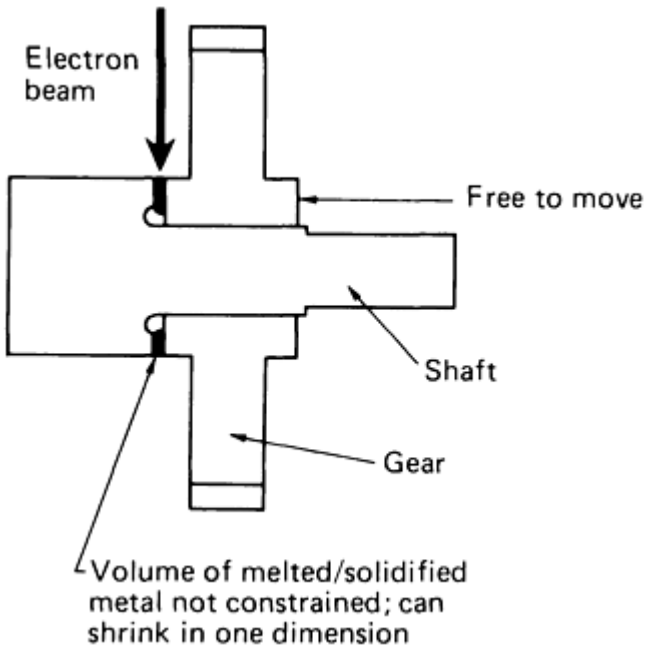

FIG. 2 SHRINKAGE STRESS IN A RADIAL WELD

The same principles of joint design discussed above for joints between shafts and disklike members apply equally to T-joints and comer joints between plates. Figure 3 shows recommended and nonrecommended weld configurations. Although true for all welding methods, it is essential in EBW (which is usually performed in a single pass) that constraints on the volume of the melt must be avoided by self-aligning interlocking steps in the joint. In multilayer arc welds, the individual weld bead is less constrained in volume and shrinks from its surface downward. Functionally, it is not useful to make the cross section of the joint any less thick than the plates that are being joined. If two welds are made in succession, the second weld may be constrained by the first (Fig. 3), which may lead to solidification cracking. It is thus advisable to direct the beam at the joint parallel to the faying surfaces and to cause melting over the whole contact area.

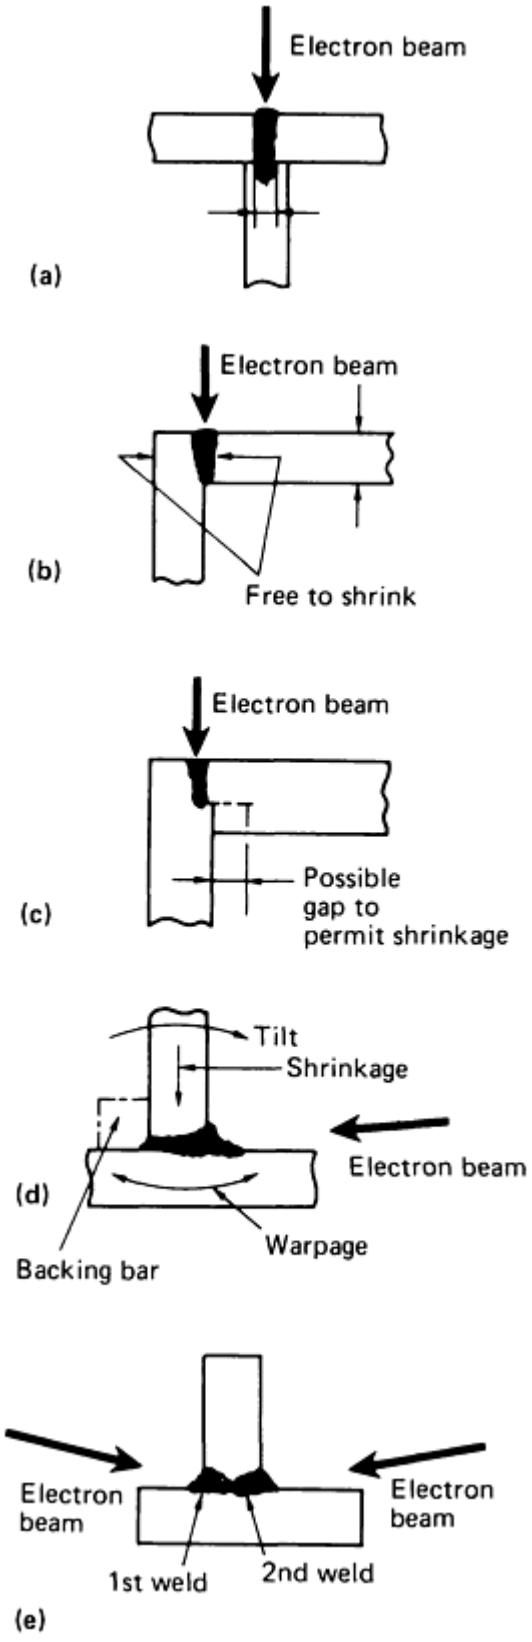

FIG. 3 OPTIMUM VERSUS LEAST DESIRABLE WELD CONFIGURATIONS. (A) NOT RECOMMENDED--MAXIMUM CONFINEMENT OF MOLTEN METAL, MINIMUM JOINING CROSS SECTION (ARROWS); WASTES BEAM ENERGY FOR MELTING, NONFUNCTIONAL METAL. (B) MOST FAVORABLE--VOLUME OF MELT NOT CONFINED; MAXIMUM JOINING CROSS SECTION (ARROWS). (C) NOT RECOMMENDED--MAXIMUM CONFINEMENT OF MELT (UNLESS GAP IS PROVIDED); JOINING CROSS SECTION LESS THAN PLATE CROSS SECTION. (D) MOST FAVORABLE--MINIMUM CONSTRAINT AND CONFINEMENT OF MELT; MINIMUM INTERNAL STRESSES; WARPAGE CAN BE OFFSET BY BENDING PRIOR TO WELDING; TILT CAN BE OFFSET BY LOCATION OF T-ARM AT LESS THAN 90°

TO BASE PRIOR TO WELDING. FILLET OBTAINED BY PLACING WIRE IN RIGHT CORNER AND MELTING IT WITH THE BEAM. (E) NOT RECOMMENDED--TWO SUCCESSIVE WELDS; SECOND WELD IS FULLY CONSTRAINED BY THE FIRST WELD AND SHOWS STRONG TENDENCY TO CRACK.

Surface Geometry. Usually, EBW does not use or need filler wire. Therefore, neither V-grooves nor corners can be filled; in fact, they are detrimental. Surface tension pulls some of the molten metal up the V-shaped surfaces so that it is no longer available to fill the space created by the keyhole that is generated by the moving beam. Voids remain in the actual joint plane (Fig. 4).

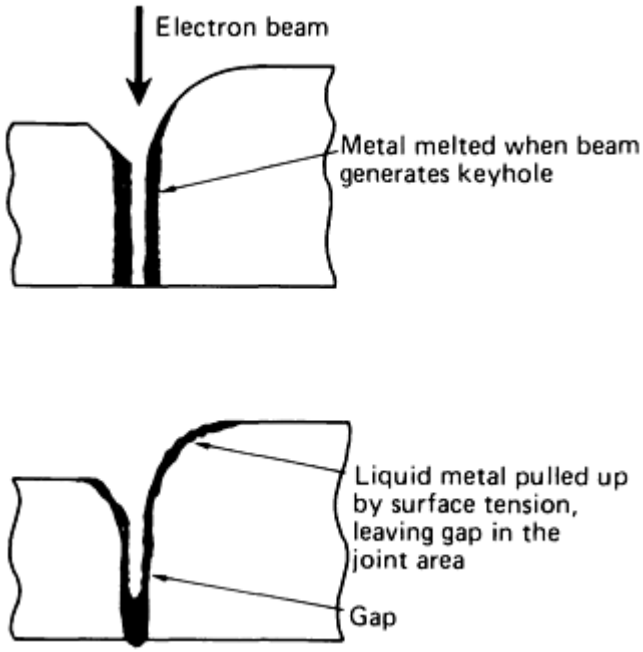

FIG. 4 GAP IN JOINT PLANE CREATED BY SURFACE TENSION

A step in the surfaces at the joint line is also undesirable. Any small lateral shift of the beam from the low to the high side, and vice versa, changes the penetration to some extent. In the extreme case, this shift may be equal to the height of the step, as shown in Fig. 5. On circular welds, with joint configurations similar to Fig. 5(a), a noncircular weld profile may develop with irregularities that can lead to uneven applied stresses. By contrast, a mere shift in the melt zone, as shown in Fig. 5(b), does not affect weld quality, as long as the entire joint line is covered.

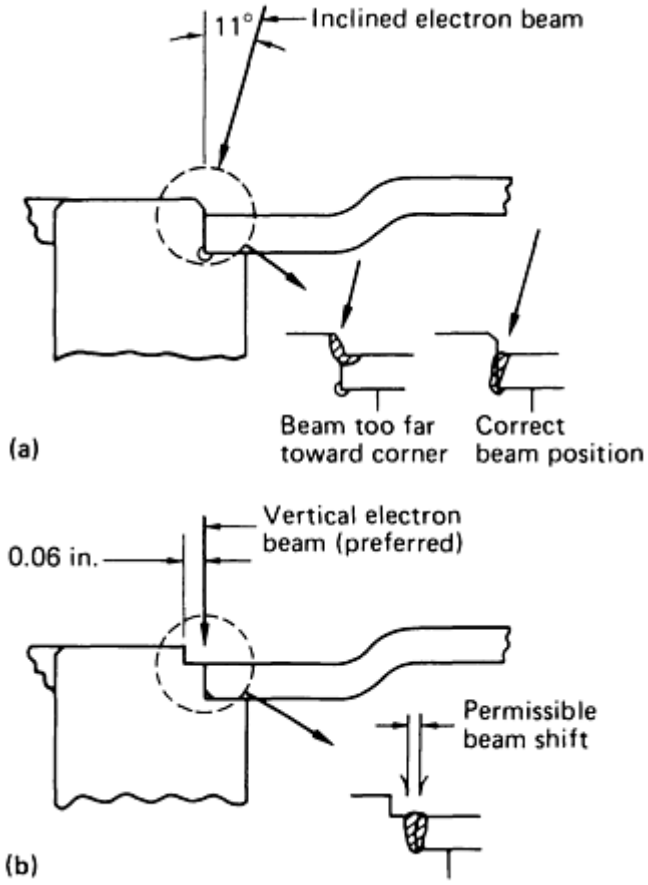

FIG. 5 EFFECT OF BEAM AND MELT ZONE POSITION ON WELD PENETRATION. (A) INCLINED ELECTRON BEAM. (B) VERTICAL ELECTRON BEAM

Configurations for Wide Welds Bridging a Gap. The high speed and autogenous nature of an electron-beam weld can be advantageous when a wide weld (6.5 to 13 mm, or $\frac{1}{4}$ to $\frac{1}{2}$ in.) is needed without great depth-to-width ratio. The atmospheric electron beam has been used extensively to make such welds in mass-production automotive parts such as catalytic converter cases and die-cast aluminum intake manifolds.

The easiest weld to make with an electron beam is an edge-weld in the vertical position of the beam (weld horizontal and flat), as illustrated by the edge-flange weld in Fig. 6. In vacuum, the beam must be defocused; in air, the standoff must be short enough to prevent substantial beam scattering. The standoff is not critical because energy flow is not influenced by standoff as it is in electric arc welding.

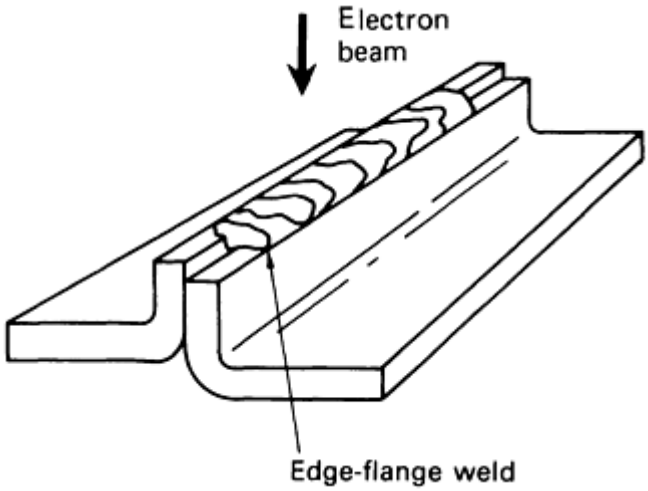

FIG. 6 EDGE-FLANGE WELD TYPICALLY USED TO JOIN THIN PANELS

For edge welds, changes in energy input per unit length and changes in power density affect only the amount of molten metal. Offset and gaps up to the thickness of the sheet to be joined often can be tolerated (Ref 2). In making an edge-flange weld (Fig. 6), the same advantages exist, provided the flange is high enough. For joining thinner sheet that is tightly clamped, edge welds also can be made with the electron beam in the horizontal position.

The nonvacuum EBW (EBW-NV) process can tolerate and fill large gaps if sufficient sacrificial metal is available to be melted by the beam (Fig. 7). If not, surface tension may pull whatever metal is melted to either side of the weld joint.

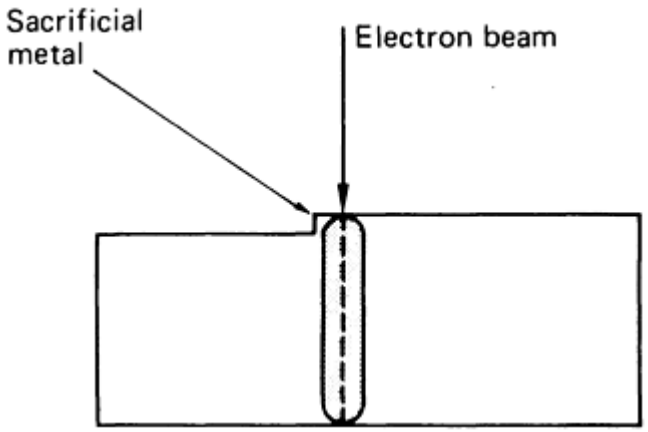

FIG. 7 USE OF SACRIFICIAL METAL TO FILL A LARGE GAP IN A SQUARE-GROOVE WELD

Melt-Zone Configuration. Welds with parallel sides of the melt zone (Fig. 8a) show minimum warpage and only transverse shrinkage when they are unconstrained. Triangular melt zones (Fig. 8b) cause warpage. If there are constraints, the hindered warpage and shrinkage cause internal stresses. A parallel-sided melt zone is preferred in either case; to obtain this configuration, joint design must allow for a full-penetration weld.

Procedure Development and Practice Considerations for Electron-Beam Welding

Joint Design

Figures 9, 10, 11, 12, and 13 show the commonly used joint and weld types for EBW. Different joint preparations, joint designs, and welding positions are used to meet special requirements. For preferred joint configurations and shrinkage stresses encountered in various joint designs, see the section on weld geometry for electron-beam welding in this article.

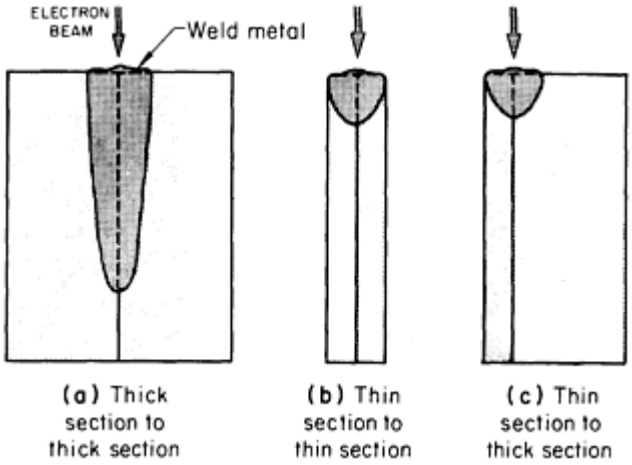

FIG. 13 TYPICAL WELDS GENERATED BY EBW OF EDGE JOINTS HAVING COMPONENTS OF EQUAL AND UNEQUAL SECTION THICKNESSES

Welds in Butt Joints

Butt joints are the most common of the five basic joint types used in EBW. The basic square-groove weld, which is shown in Fig. 9(a), 9(b), and 9(c), needs only the simplest and least expensive joint preparation. It is suitable for either partial- or full-penetration welds. Good fit-up and external fixtures are needed. The flush joint (Fig. 9b) is preferred to the stepped joint (Fig. 9c) for joining unequal thicknesses, chiefly because control of conditions for making sound full-penetration welds is less critical than for the stepped joint. A wider beam is used in welding the stepped joint, and the beam angle must he carefully controlled to avoid scarfing the upper edge of the thicker member (angle too small) or missing the bottom of the joint (angle too large), especially if the thinner member is more than about 9.5 mm ($\frac{3}{8}$ in.) thick.

In Fig. 9(d), the joint is rabbeted to make it self-aligning, but the offset is small to avoid leaving an unwelded seam near the root of the weld (compare Fig. 9e). In Fig. 9(d) to (g), the joints are self-aligning and may be self-fixturing in circular, circumferential, and certain other joint arrangements. In Fig. 9(e) and 9(f), the joints are both self-aligning and self-backing; each, however, leaves an unwelded seam near the root of the weld.

In Fig. 9(g) and 9(h), two ways are shown of providing integral and filler metal. The lip of the joint in Fig. 9(g) provides more filler metal than the shoulder of the joint in Fig. 9(h), but because it conceals the joint, a scribed line or other means for beam placement and for scanning must be provided before the welding operation can proceed.

The slant-groove weld (also called angular or scarf) shown in Fig. 9(j) is used in butt joints to facilitate fixturing. It is also used where limitations on the beam location prevent fusion for the entire groove depth if the basic square-groove weld (Fig. 9a) were used. Greater weld depth, as measured parallel to the beam axis, is needed for full penetration of a given metal thickness than with the square-groove weld. This type of weld and variations of it are used both in butt joints and in corner joints.

A slant-butt joint can also be welded with beam alignment set at 90° to the surface of the work. This beam angle permits the production of defect-free welds where fit-up is poor or where the joint opening is larger than can be tolerated when the beam is aligned with the groove. In a related type of weld, the joint has a square-groove preparation, and the beam is at an angle to the groove. The main reason for using this type of weld is difficulty of access with other types of welds.

Welds in Corner Joints

Eight types of electron-beam welds frequently made in corner joints are shown in Fig. 10. Corner joints are second only to butt joints in frequency of use for EBW.

Important differences between butt and corner joints are notch sensitivity and suitability for nondestructive testing. To compare alignment, self-fixturing, and the occurrence of portions of unwelded seam, see Fig. 9 and 10.

The two simplest and most economical welds in corner joints are the melt-through (Fig. 10a) and basic square-groove (Fig. 10b) welds. Neither is self-aligning or self-fixturing; manipulation of the work for weld (b) in Fig. 10 can be simplified by using a horizontal electron beam and corresponding work orientation (rotated 90° from the orientation shown). The melt-through weld (Fig. 10a), unless made with a fusion zone wide enough to eliminate the unwelded seam completely, is weaker than the square-groove weld and is notch sensitive.

The corner-flange weld (Fig. 10h), usually made only on thin stock, requires precision forming of the 90° bend. Welds in corner joints are subject to high stress concentrations.

Welds in T-Joints

Three types of electron-beam welds made in T-joints are shown in Fig. 11. The melt-through or blind weld (Fig. 11a), like melt-through welds in butt or corner joints, leaves an unwelded seam with resulting low strength, notch sensitivity, and corrosion susceptibility. Figure 11(b) is the preferred joint design. The double-square-groove weld (Fig. 11c) is used primarily on sections 25 mm (1 in.) or more thick. For welds similar to Fig. 11(b) and 11(c), filler metal can be added.

Welds in Lap Joints

Three types of electron-beam welds made in edge joints are shown in Fig. 13. Thick sections can be joined by deep, narrow square-groove welds (Fig. 13a). Shallow welds made with a low-power, partially defocused beam are used to join thin sections to each other or to thick sections, as shown in Fig. 13(b) and 13(c). Shallow edge welds can be made at high speed. Welds of this type are particularly useful on hermetically sealed assemblies, which may be designed for planned salvage by removal of the weld region and subsequent rewelding.

Butt Joints Versus Corner and T-Joints

The concentration of bending stresses at the weld in corner and T-joints is sometimes avoided by designing the work for a butt joint on a straight section near the corner or T (flange neck or welding neck construction). This principle of design is applicable also to butt joints between members having different thicknesses, and it can be applied to straight line, circular, and circumferential joints.

In welding such a joint in magnetic metals, if the beam path is too close to the corner, T, or shoulder, the beam may be deflected away from the metal that it passes near on its way to the joint, causing it to enter the work at an angle and possibly to miss the lower portion of the joint. To avoid this, the beam clearance should be 0.8 mm (0.030 in.) or more, depending on the height of the magnetic projection (Fig. 14).

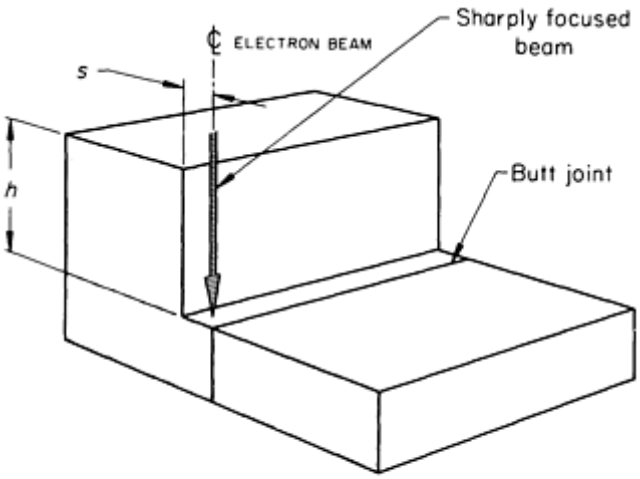

FIG. 14 JOINT LOCATION AND BEAM CLEARANCE FOR AN EBW BUTT JOINT NEAR A PROJECTING CORNER, T, OR SHOULDER CONSISTING OF MAGNETIC WORK METAL

Procedure Development and Practice Considerations for Electron-Beam Welding

Special Joints and Welds

Many variations of the basic joint and weld types described in the preceding section and illustrated in Fig. 9, 10, 11, 12, and 13 are used to meet the needs of individual applications. Some of these special joints and welds are discussed below.

Plug and puddle welds are usually made by manually (or automatically) manipulating the work under a fixed beam at low power. Filler metal used for plug welds is often preplaced at the weld site. Puddle welding is used mainly to fuse shallow defects together locally.

Multiple-Pass Welds. Most electron-beam welds produce the desired penetration in a single pass. Tack welds and cosmetic or smoothing passes are not considered penetration passes. Welds several inches deep can be made in most metals in a single pass. Weld depth obtainable in a single pass can be nearly doubled by welding from both the face and the back of the work.

In a variation on straight-through two-pass welding from opposite sides, separate welds that meet or almost meet can be made at an angle of 90° to each other in a rabbeted square-groove joint.

Tangent-tube welds are longitudinal welds joining two parallel tangent tubes (or cylinders). The tubes may differ in size; the beam is perpendicular, or nearly perpendicular, to the common axial plane of the two tubes. Added filler metal may be used for reinforcement. Thinner wall tubes can be joined more easily by EBW than by arc welding methods.

Three-Piece Welds. Welds can be made that join three or more pieces in which there is penetration in a single pass into all of the pieces. Many of the difficulties encountered in welding very thin metal or foil are eliminated by sandwiching it between two thicker sections.

Multiple-tier welds are welds made simultaneously in in-line, separated joints (usually butt joints) in a single pass of the electron beam. A more detailed discussion is given in the section of this article on multiple-tier welding .

Welds using integral filler metal may be of the types shown in Fig. 9(g) and 9(h), in which an overhanging lip or a shoulder provides filler metal to a butt joint, or both members may be made thicker at the joint than elsewhere.

EBW in High Vacuum

Most EBW is done in a vacuum environment where the maximum ambient pressure is less than 0.13 Pa (1×10^{-3} torr). Maintenance of this degree of vacuum is important because of the effect that ambient pressure has on both the beam and the weld produced, as discussed below.

Applications. High-precision applications that require welding to be done in a high-purity environment to avoid contamination by oxygen or nitrogen are ideally suited for high-vacuum EBW (EBW-HV). These applications include the nuclear, aircraft, missile, and electronics industries. Typical products include nuclear fuel elements, pressure vessels for rocket propulsion systems, special alloy jet engine components, and hermetically sealed vacuum devices. Welding of reactive metals such as zirconium and titanium in high vacuum is preferred over medium- or nonvacuum EBW because of the affinity of reactive metals to oxygen and nitrogen.

Effect of Pressure on Beam. Under ambient high-vacuum conditions, the frequency of collisions between beam electrons and residual gas molecules is extremely low, and any dispersion (i.e., beam-broadening effect) that would result from such scattering collisions is minimal. However, because the frequency of scattering collisions increases with the density of gas molecules present, this effect becomes greater as the surrounding environment pressure is increased. Only at ambient pressure values below 0.13 Pa (1×10^{-3} torr) is the effect of scattering insignificant enough that the beam can be held in sharp focus over distances of several feet (depending on the particular characteristics of the electron gun and electron optics being employed) to achieve maximum effectiveness in producing relatively deep, narrow welds.

Beam scattering from collisions with residual gas molecules begins to occur at ambient pressures above 0.13 Pa (1×10^{-3} torr) and initially results in decreased penetration and increased weld width. This scattering effect reduces the maximum working distance that can be employed for producing a similar electron-beam weld as obtained under high-vacuum conditions at ambient pressures greater than 0.13 Pa (1×10^{-3} torr).

In EBW-NV, where the ambient pressure is 10 MPa (760 torr) and above, the scattering dispersion of the beam increases so that penetration and working distance capacity are appreciably reduced below values obtainable in either high- or medium-vacuum processes. However, the penetration and working distance capabilities of EBW-NV are appreciably greater than those of conventional arc welding processes. Electron-beam dispersion characteristics and their effect on weld penetration at various ambient pressures are shown in Fig. 15.

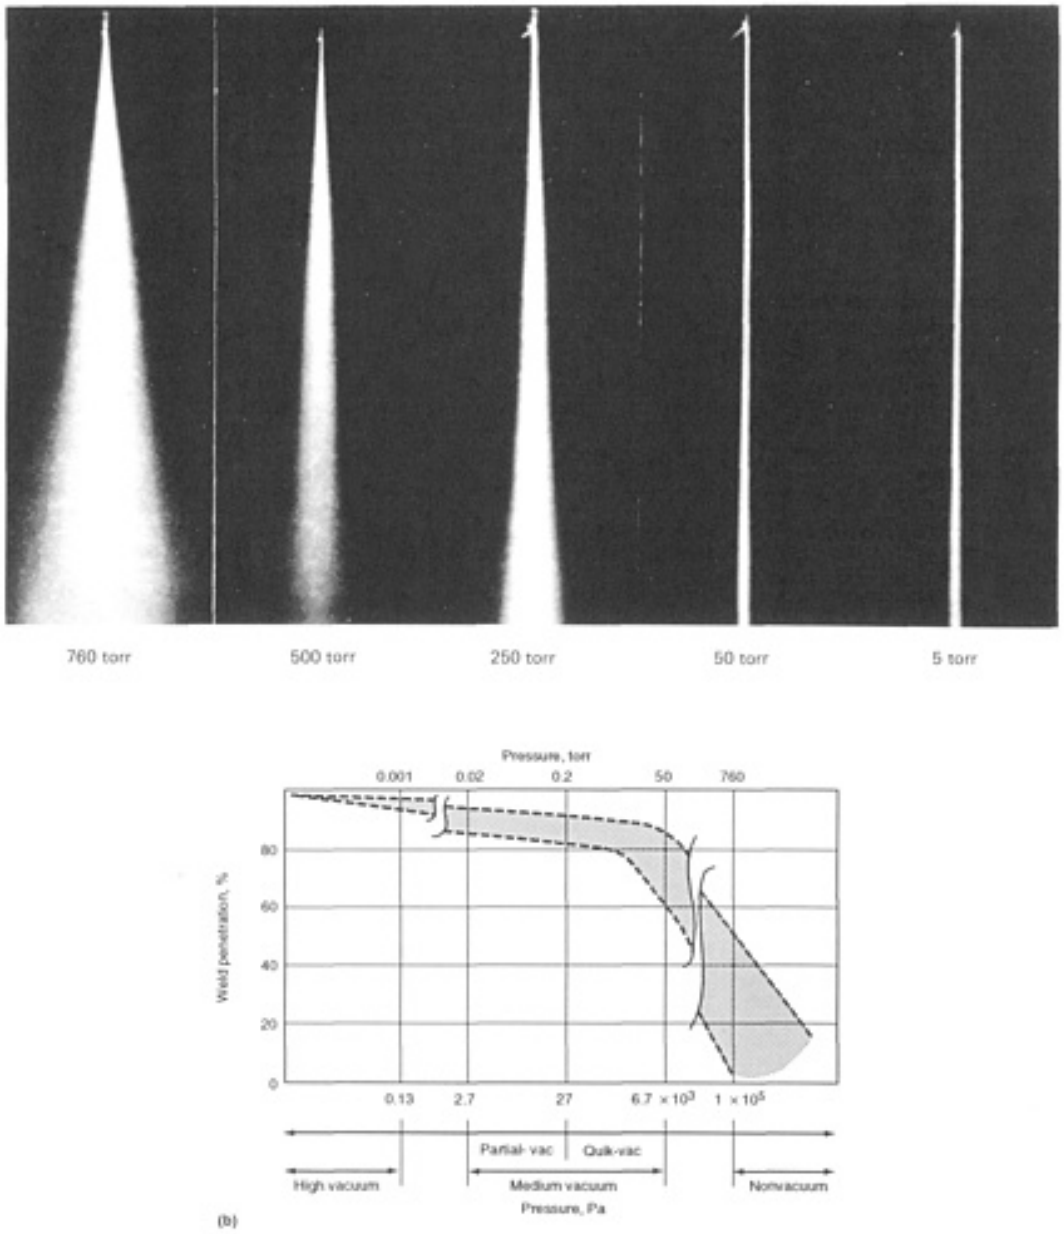

FIG. 15 EFFECT OF PRESSURE ON BEAM INTENSITY AND RESULTING WELD QUALITY. (A) DISPERSION PATTERNS OF ELECTRON BEAM AT SELECTED PRESSURES. (B) WELD PENETRATION AS A FUNCTION OF AMBIENT PRESSURE LEVEL. ADDITIONAL PARAMETERS SUCH AS BEAM VOLTAGE, BEAM TRAVEL DISTANCE, AND TYPE OF AMBIENT GAS USED CAN PRODUCE A WIDE RANGE OF VALUES, THUS ACCOUNTING FOR THE SPREAD IN THE PENETRATION DATA.

Effect of Pressure on Weld and Heat-Affected Zone. The maintenance of a high vacuum in the work chamber protects the weld metal and the HAZ from oxidation and contamination by harmful gases, serving the same function as inert shielding gases do in arc welding, while also degassing the weld. The contamination level as a function of pressure is discussed in the section EBW in Medium Vacuum in this article.

The nearly complete absence of gaseous impurities eliminates the serious contamination difficulties that usually are encountered when attempting to arc weld relative metals such as titanium and zirconium.

Width of Weld and Heat-Affected Zone. Electron-beam welds made in a high vacuum are narrower and have a narrower HAZ than comparable welds made in medium vacuum or at atmospheric pressure, and they are much narrower than the narrowest welds made in production welding by GTAW. The narrow width of the heat-affected zone in

hardenable steels and other hardenable alloys permits welding of these metals after heat treatment, in many instances without loss of strength.

Limitations. A major limitation in the use of high vacuum in the work chamber is the effect on unit production time, because of the need to pump the chamber down before each load is welded. Pumpdown time is typically about 3 min for a 0.85 m^3 (30 ft^3) chamber and 10 min for an 8.5 m^3 (300 ft^3) chamber. The above pumpdown times are realistic only for a very clean and well-maintained system. In production, pumpdown may be nearly double the above times.

The effect of this limitation on unit production time is reduced by welding a number of assemblies in each load and by keeping chamber size as small as possible. Small chambers specially designed for use with small workpieces have typical pumpdown times of I min (3.69×10^6 mm^3, or 225 $in.^3$, chamber) and 15 s or less (1.0×10^6 mm^3, or 60 $in.^3$, chamber).

A second major limitation in the use of high vacuum is that work size is limited by chamber dimensions. This limitation is sometimes circumvented by the use of a chamber having special openings and seals that permit oversize work to extend outside the chamber, or by the use of a portable clamp-on chamber.

Welding Conditions. Welding in high vacuum is done with low-voltage, as well as high-voltage, equipment. Beam voltage ranges from 15 to 185 kV; beam current, 2 to 1000 mA; and welding speed, 100 to 5000 mm/min (4 to 200 in./min) for most applications. However, higher welding speeds are used for special thin section applications. The energy input to the work needed to produce a weld of the required depth of penetration and width is the basis for selecting the welding conditions.

Depth of penetration is increased by increasing the voltage or current for greater beam power, or by decreasing the welding speed. Table 1 lists approximate energy inputs per inch of weld length for making narrow single-pass electron-beam welds 6.4 to 75 mm (0.25 to 3 in.) deep in the weldable alloys of copper, iron, nickel, aluminum, and magnesium. These values are intended to serve as guidelines for establishing conditions for welding work for which no previous experience is available. Energy-input requirements for specific applications depend on the alloy composition and special operating conditions such as the use of beam oscillation or a defocused beam.

TABLE 1 ENERGY INPUT AT THE WELD FOR SINGLE-PASS EBW IN HIGH VACUUM FOR VARIOUS DEPTHS OF PENETRATION

DEPTH OF PENETRATION		ENERGY INPUT PER WELD LENGTH FOR INDICATED METAL[(A)]									
		Cu		**Fe**		**Ni**		**Al**		Mg	
mm	**in.**	**kj/mm**	**kj/in.**	**kj/mm**	**kj/in.**	**kj/mm**	**kj/in.**	**kj/m**	**kj/in.**	**kj/mm**	kj/in.
6.35	0.25	0.3	0.7	0.2	5	0.2	4	0.1	2	0.04	**1**
12.7	0.50	0.6	0.15	0.4	10	0.3	8	0.2	5	0.1	**3**
19.1	0.75	1.0	0.25	0.7	18	0.6	15	0.3	8	0.2	**5**
25.4	1.00	1.5	0.37	1.1	27	0.9	22	0.5	13	0.3	**8**

(A) VALUES ARE APPROXIMATE AND APPLY TO THE COMMONLY WELDED ALLOYS OF THE METALS. THEY ARE INTENDED TO SERVE AS STARTING POINTS FOR ESTABLISHING CONDITIONS FOR MAKING NARROW WELDS. ENERGY INPUT MAY VARY SUBSTANTIALLY FROM THESE VALUES IN SPECIFIC APPLICATIONS, DEPENDING ON THE COMPOSITION OF THE ALLOY AND SPECIAL OPERATING CONDITIONS. ENERGY INPUT AT WELD = [(BEAM VOLTAGE) (BEAM CURRENT) 0.6]/WELDING SPEED, WHERE ENERGY INPUT IS IN KJ/IN.; BEAM VOLTAGE IS IN KV; BEAM CURRENT IS IN MA; AND WELDING SPEED IS IN IN./MIN.

EBW in Medium Vacuum

Electron-beam welding in a medium vacuum (EBW-MV) usually is performed at a welding (work) chamber pressure of about 10 Pa (7.5×10^{-2} torr), or at a work chamber pressure ranging from 0.4 to 40 Pa (3×10^{-3} to 3×10^{-1} torr)--the total partial-vacuum region. The gun chamber, where the beam is generated, is held at 1.3 to 13 mPa (10^{-5} to 10^{-4} torr), as in high-vacuum welding. A diffusion pump is required to provide this gun chamber vacuum, but only a mechanical-type pump is required to evacuate the work chamber to the final partial vacuum welding pressure desired.

Comparison with High-Vacuum EBW. The chief advantage of welding in medium vacuum, compared with welding in high vacuum, is the short pumpdown time for the welding chamber, which ordinarily does not exceed 40 s for a general-purpose chamber (of about 0.11 m^3, or 4 ft^3) and which is less than 5 s for the specially designed chambers used in welding small parts. Accordingly, EBW-MV permits mass production of parts, using a chamber of minimum volume.

Production rates for welding in medium vacuum depend on part design and other factors; maximum production rate is typically about 60 pieces per hour for general-purpose, manually operated equipment; upwards of 600 pieces per hour for specially tooled semiautomatic machines; and 1500 pieces per hour for fully automatic single-purpose machines. General-purpose chambers and tooling are used for short runs.

Welds on reactive metals and other welds for which the effects of contamination by gases are especially critical are preferably made in high vacuum. The contamination level of air (total concentration of gases present) is proportional to pressure, as follows:

PRESSURE		GASES, PPM
PA	**TORR**	
0.0013	10^{-5}	**0.01**
0.13	10^{-3}	**1.3**
13	10^{-1}	**132**
50	**4×10^{-1}**	**500**

Lower contamination levels are obtainable than those actually observed for arc welding with inert-gas shielding.

Penetration and Weld Shape. Penetration at a given power level is ordinarily 5 to 10% less than for EBW-HV, and welds are wider and slightly more tapered. These changes are caused by the scattering of the electrons in the beam by collision with gas molecules, which makes the beam broader.

The effect of welding chamber pressure on penetration and weld shape is shown in Fig. 16 for welds made on type 304 stainless steel, using a beam length of 405 mm (16 in.) without changing focus. Maximum penetration shown in Fig. 16 is approximately 13 mm ($\frac{1}{2}$ in.). Welding conditions were 150 kV, 30 mA, and 1525 mm/min (60 in./min). Penetration drops off rapidly at pressures of 13 Pa (10^{-1} torr) or more at this beam length and at somewhat lower pressures when the beam path is longer.

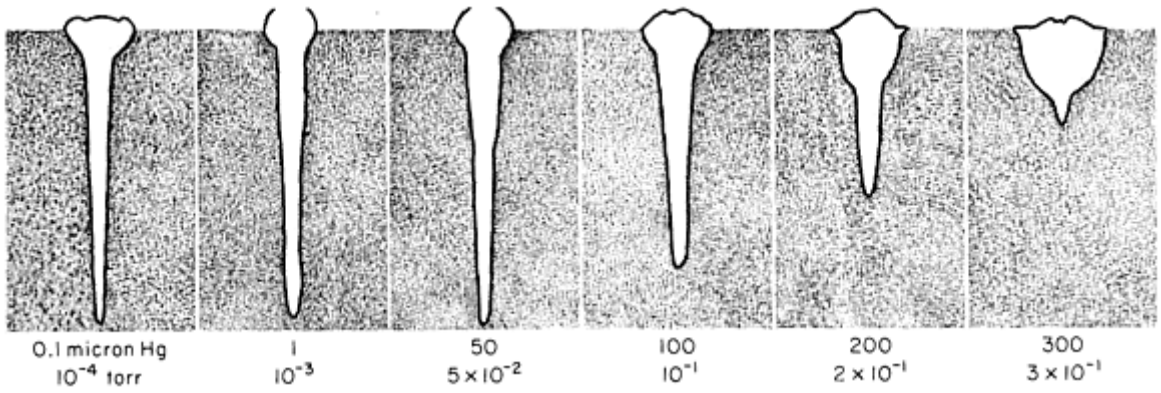

FIG. 16 EFFECT OF WELDING-CHAMBER PRESSURE ON PENETRATION AND WELD SHAPE FOR TYPE 304 AUSTENITIC STAINLESS STEEL

Comparison With Nonvacuum EBW Welding. Disadvantages of medium-vacuum welding, compared with welding at atmospheric pressure, include limitations on work size imposed by the need to enclose the work in a vacuum chamber and the time needed for chamber pumpdown.

Beam deflection and oscillation, which cannot be used in welding at atmospheric pressure, can be used in EBW-MV.

Applications. Most parts that can be welded in high vacuum can also be welded in medium vacuum. Depth of penetration is less than in high-vacuum welding, and depth-to-width ratio is less than about 10 to 1. Reactive metals are less readily welded in medium vacuum than in high vacuum. Medium-vacuum welding can be acceptable, however, for refractory metal welding when absorption of small amounts of oxygen can be tolerated. Medium-vacuum welding has been used for welding mass-produced automobile parts, such as gears and shafts, that are welded to close tolerances and that are not subsequently finished.

Procedure Development and Practice Considerations for Electron-Beam Welding

Nonvacuum (Workpiece Out-of-Vacuum) Welding

In EBW-NV (workpiece out-of-vacuum), which is also referred to as atmospheric EBW, the work to be welded is not enclosed in a vacuum chamber. Instead, it is welded at atmospheric pressure. A radiation-tight enclosure or chamber, similar to that used in high- or medium-vacuum EBW, surrounds the weld area. A vacuum, however, is not provided in this welding enclosure.

A nonvacuum electron beam is generated at high vacuum in the same manner as in high- and medium-vacuum welding. It is focused down through a series of individually pumped stages, each connected to the other by concentrically aligned orifices, decreasing in diameter in the direction of increasing pressure; this differential pumping scheme provides the high vacuum (gun region) to atmospheric (workpiece region) pressure gradient necessary to allow the beam to pass down through the column and exit out into the ambient atmosphere.

Figure 17 depicts a typical EBW-NV gun/column assembly. This unit can be mounted in either a vertical or a horizontal position and is capable of motion during welding. The gun/column assembly depicted in Fig. 17 is capable of beam power levels greater than 35 kW and beam transmission efficiencies in excess of 90%.

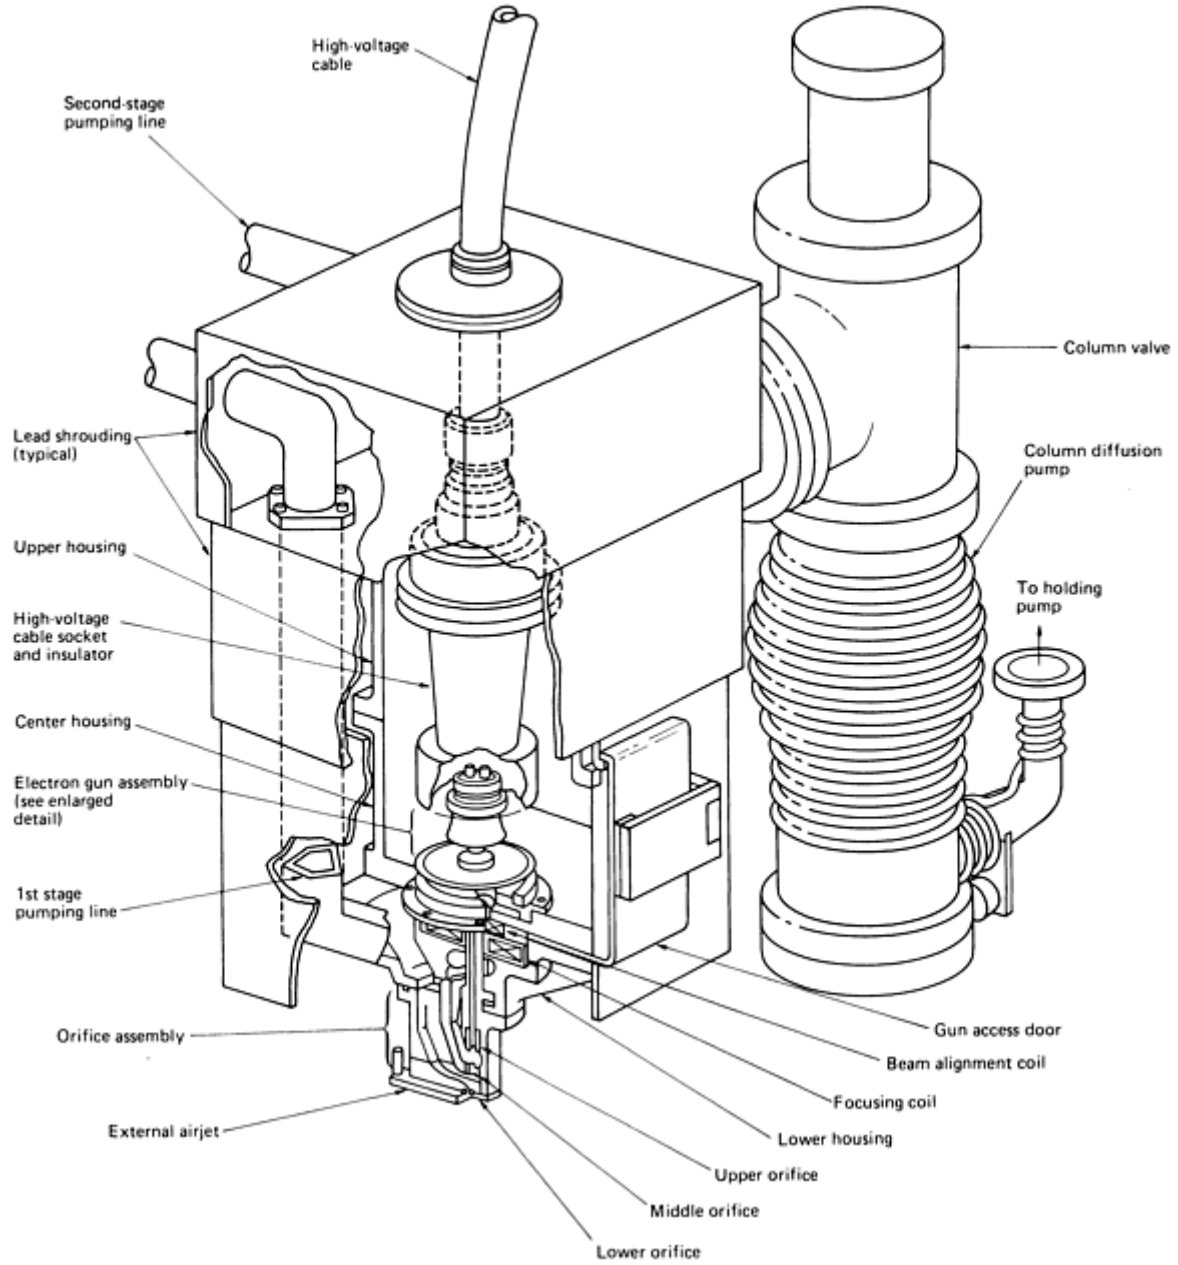

FIG. 17 SCHEMATIC WITH CUTAWAY VIEW SHOWING PRIMARY COMPONENTS OF A TYPICAL EBW-NV GUN/COLUMN APPARATUS. COURTESY OF LEYBOLD-HERAEUS VACUUM SYSTEMS INC.

Production rates are generally much higher for EBW-NV than for EBW-HV and EBW-MV, because no work chamber vacuum pumpdown time is required for each chamber load. This results in a lower per part production cost. Because pumpdown time for high- and medium-vacuum welding varies with chamber cleanliness and ambient humidity, elimination of work chamber pumpdown time in EBW-NV produces appreciable time savings. This saving, however, is gained at the expense of a reduction in penetration and working distance capability, thus imposing limits on the thickness and shape of the workpiece. Additionally, most (but not all) out-of-vacuum welds cannot be made as narrow and parallel sided as welds made in a vacuum.

When welding in ambient atmospheric air alone, the practical working distance of the nonvacuum process is normally limited to the range of from 9.5 to 22 mm ($\frac{3}{8}$ to $\frac{7}{8}$ in.); however, when welding in the presence of a lighter ambient gas, such as helium, this practical working distance range is extended to 25 to 50 mm (1 to 2 in.). For this reason, most commercial nonvacuum EBW units are equipped to provide a "helium blowdown," which is an effluent of helium that

extends out from the nonvacuum column and along the beam travel path. The effect of this helium effluent is that it reduces the degree of beam scattering incurred using only air, thus allowing the working distance capability of the nonvacuum unit to be approximately doubled.

Most metals that can be arc welded or electron-beam welded in a vacuum also can be welded in nonvacuum. As stated previously, inert-gas shielding of the weld zone can be provided when the molten weld metal (or HAZ) cannot be exposed to air. On readily welded metals, weld properties approach those of welds made in a vacuum; on difficult-to-weld metals, weld properties are usually lower than those of welds made in a vacuum.

Ordinarily, filler metal is not used in EBW-NV. The addition of a suitable filler metal may be helpful, however, in joining metallurgically incompatible metals or in avoiding weld cracking caused by hot shortness. Selection of the filler-metal composition in such applications is critical.

Operating conditions for nonvacuum welding differ substantially from those for welding in high or medium vacuum. Because beam dispersion increases in proportion to pressure and distance traveled, at pressures above the high-vacuum level, the nonvacuum beam becomes dispersed at travel distances greater than several inches in air at atmospheric pressure.

To provide an electron beam of sufficient energy to minimize the scattering effect of collisions with residual gas molecules within the electron-beam transfer column (i.e., the differentially pumped gun/column assembly), the applied gun voltage is held at a constant high value (from 150 to 200 kV). This also helps extend the work distance of the beam after it has exited the column and entered the ambient atmosphere. The practical working distance (standoff distance) for nonvacuum welding, as measured from the bottom of the final exit orifice to the top of the workpiece, ranges from 13 to 50 mm ($\frac{1}{2}$ to 2 in.), although some nonvacuum welding is performed at both shorter and longer standoff distances.

With voltage held constant, beam current, working distance, and welding speed are selected to provide the required penetration and weld shape for a sound weld. Because it is usually desirable to keep working distance as short as possible and welding speed high, beam current is the primary control variable in nonvacuum welding.

The small size of the exit orifice on the electron gun makes it necessary to focus the beam at or very close to the exit orifice. Accordingly, it is not possible to vary weld characteristics to a significant degree by changing focus. Similarly, beam deflection and oscillation are not possible. The absence of these adjustment capabilities in nonvacuum welding is not a handicap, because beam width is ordinarily great enough so that it does not promote undercutting or porosity at the root of the electron-beam weld.

A cosmetic pass is seldom needed on electron-beam welds made at atmospheric pressure, because a smooth surface is produced on welds in most metals. The smoothness of the crown also improves the ease of nondestructive inspection of the as-welded surface; wire brushing is often adequate preparation for radiographic or liquid-penetrant inspection.

The limitation on workpiece shape imposed by the need for a short working distance can be overcome to some degree by the use of electron gun nozzles specially designed to extend into restricted spaces. Filler metal is not ordinarily used except where necessary for weld reinforcement to produce the desired weld properties or to avoid cracking.

A stream of dry filtered air, or an inert shielding gas such as argon or helium, is passed across the weld region in the space between the work and the electron gun, or may be supplied through a special insert nozzle assembly that is part of the exit orifice and is designed to minimize entrance of welding vapors and other contaminants into the gun. Auxiliary inert-gas shielding is supplied where needed for complete protection of the molten weld metal and the HAZ from gaseous contaminants. Welds are sometimes made on carbon and alloy steel and other readily weldable metals without using shielding gas. However, shielding gas is often used; helium is the preferred gas. Weld shape can be changed by varying the flow of helium.

Penetration. Nonvacuum electron-beam welds are seldom deeper than 9.5 mm ($\frac{3}{8}$ in.). Welds having penetration much greater than 25 mm (1 in.) are easily produced, but ordinarily this requires a reduction in welding speed, with a corresponding increase in production cost. Figure 18 provides a comparison of penetration, as a function of weld speed, in steel and aluminum, employing a fixed power level and work distance and using a helium shield to improve power density.

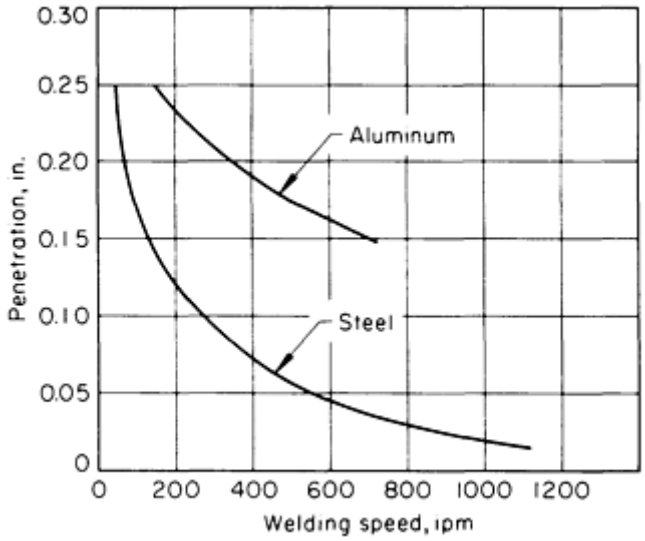

FIG. 18 PLOT OF PENETRATION VERSUS WELDING SPEED AS A FUNCTION OF MATERIAL AT A BEAM POWER OF 9 KW

Studies made of nonvacuum welding of steel pipe showed that, at speeds of 2.5 to 25 m/min (100 to 1000 in./min), full-penetration welds could be made in metal twice as thick if helium shielding gas was used instead of air. Table 2 gives the results of this comparison in terms of welding speed for joining steel pipe 1.3 to 3.8 mm (0.050 to 0.150 in.) thick in air or in helium. Welding speeds were 2.16 to 2.24 times greater in helium as in air. Beam power used was 12 kW.

TABLE 2 SPEEDS FOR NONVACUUM FULL-PENETRATION WELDING OF CARBON AND LOW-ALLOY STEEL PIPE AT A BEAM POWER OF 12 KW

WALL THICKNESS		WELDING SPEEDS				RELATIVE WELDING SPEED IN HELIUM(A)
		IN AIR		IN HELIUM

(A) BASED ON WELDING SPEED IN AIR BEING EQUIVALENT TO 1.00

Weld Shape and Heat Input. Nonvacuum electron-beam welds are generally wider and more tapered than high-vacuum welds (medium-vacuum welds differ only slightly in shape from high-vacuum welds).

Weld shrinkage across nonvacuum electron-beam welds is generally less than half that of gas-tungsten arc welds on the same work metal and thickness and is typically about twice that for high-vacuum electron-beam welds.

Tooling generally is designed specifically for welding a particular assembly in mass production. Providing fixtures and equipment that permit welding at high speeds and efficient work handling is the key to obtaining high production rates and low cost.

The work-handling equipment is at atmospheric pressure instead of in a vacuum; hence, general-purpose welding positioners and related fixtures usually are satisfactory. Hold-down clamping devices can be simpler than those often needed for arc welding similar parts, because angular distortion or dihedral warpage is generally low. Locating and alignment mechanisms are simpler than for welding in a vacuum, because of their accessibility and because beams are

wider and lower accuracy is required in tracking the joint. Maintenance of work-handling equipment is greatly simplified by its out-of-chamber location.

Applications. Nonvacuum electron-beam welding is used in the production of transmission-train components, steering column jackets, die-cast aluminum intake manifolds, and catalytic converters. In addition, several appliance (and other consumer-related) items also are produced using the EBW-NV process. Figure 19 shows a catalytic converter that was nonvacuum electron-beam welded with the beam in a horizontal position.

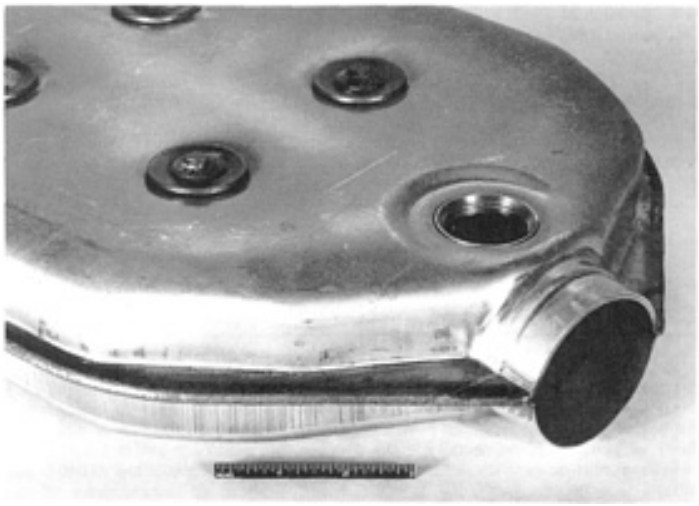

FIG. 19 CATALYTIC CONVERTER ASSEMBLY CONSISTING OF SEAMS JOINED BY EBW-NV PROCESS

Controlling Heat Effects

The extent of heat-affected base metal in EBW is controlled mainly by regulating the welding speed, width, and shape of the weld. In general, the width of the HAZ is proportional to the average width of the weld, which also strongly influences shrinkage and distortion.

Damage to heat-sensitive attachments, inserts, or encapsulated materials close to the weld joint is controlled mainly by regulating the width and shape of the weld bead. Damage to nearby finished functional surfaces on the workpieces or to nearby drilled or tapped holes or other crucial features of the workpieces can often be avoided in EBW because of the narrowness of the welds.

Joint designs that provide constricted sections near the weld to retard heat transfer from the weld, or that provide an integral heat sink, and the use of external heat sinks or chill bars are also helpful in controlling heat effects in EBW.

Narrow, closely controlled electron-beam welds, with low heat input, can be made in close proximity to heat-sensitive attachments, inserts, or encapsulated materials without damaging them, often when no other welding process can meet this requirement.

Procedure Development and Practice Considerations for Electron-Beam Welding

Welding of Thin Metal

Electron-beam welding can be advantageous for joints in which at least one member is made of thin metal (<2.4 mm, or $\frac{3}{32}$ in., and as thin as 0.025 mm, or 0.001 in.). Applications include instrument parts, instrument enclosures, pressure or hermetic seals, diaphragms, encapsulations, electrical connectors, and electronic devices, of various metals.

The joint area must be heated to melting temperatures in joining thin sections, just as in joining thick sections, but the rate of heat transfer away from the joint is much lower because of the reduced cross section. Hence, local heat buildup is greater, which increases weld width and decreases depth-to-width ratio. In addition, minimum beam spot size has a much greater effect on depth-to-width ratio in joining thin metal than in joining thick metal. The minimum usable beam spot size obtainable generally ranges from about 0.13 to 0.51 mm (0.005 to 0.020 in.) in diameter. Because of these conditions, depth-to-width ratio for full-penetration welds joining two sections thinner than about 2.4 mm ($\frac{3}{32}$ in.) usually does not exceed about 5 to 1 and may be less than 1 to 1.

When voltage, current, welding speed, and other variables have been optimized for a specific joint, use of a heat sink may still be necessary to avoid overheating thin material, depending on the base-metal properties (melting point, specific heat, and thermal conductivity) and metal thickness. Best results usually are obtained by the use of copper chill blocks machined to fit the workpiece closely at the joint area. Fixtures made of other metals may be effective as chill blocks if the contact area is sufficiently large and close to the heat source.

Joining Thin Sections to Thick Sections. In joining thin sections to thick sections by EBW, the joint is usually designed so that the thick member serves as a heat sink for the thin member, and the point of beam impingement is slightly removed from the thin metal. When these precautions are taken, welding behavior and heat dissipation are generally the same as in welding thick sections under similar conditions. Depth of penetration in the thicker section is usually made only slightly greater than the thickness of the thin section.

Even with the aid of the heat-sink capacity of a thicker member, heat input by arc welding often cannot be localized sufficiently and controlled closely enough to avoid damage to metal foil thickness. In some applications, using EBW instead of gas-metal arc welding can eliminate excessive foil melting.

Partial-Penetration Welds. The precise control of heat input obtainable in EBW permits partial-penetration welds having uniform depth to be made in metals as thin or thinner than 0.25 mm (0.010 in.).

Work-metal thickness must be uniform, and workpiece fixture arrangement and dimensions must be selected to provide a constant rate of heat loss adjacent to the path of the weld along its entire length, with special provisions made for weld starting and stopping. Beam power, focus, and workpiece travel speed must be closely regulated to minimize variation in penetration.

For the closest control of penetration, both beam power and focus can be regulated by sensitive, fast-response closed-loop servomechanisms or feedback controllers, and workpiece travel speed can be held within extremely narrow limits by precision, mechanical worktable traverse, or rotary-motion systems. To compensate automatically for the effect of any variation in voltage on focus, the servomechanism regulating the beam focus can be coupled to the voltage supply by solid-state devices that have a response time of less than 17 μs.

Partial-penetration welds in thin metal are not subject to root voids, root porosity, or cold shuts, which are flaws frequently encountered in partial-penetration welds in thick metal, because such welds in thin metal have relatively low depth-to-width ratios and a wide-angle V-shape with a gently radiused bottom.

Data on the relation of depth to width for high-vacuum partial-penetration welds in thin sections are given in Table 3. The ratio of depth to width is lower for the welds in the thinner sections. Penetration was from 50 to 85% of the work-metal thickness, and all welds were made with chill bars in intimate contact with the underside of the work at the weld location.

TABLE 3 RELATION OF DEPTH TO WIDTH (*D*/*W*) FOR PARTIAL-PENETRATION ELECTRON-BEAM WELDS OF THIN SECTIONS IN A HIGH VACUUM

WORK METAL[A]	THICKNESS,		WELD DIMENSIONS[A]				*D*/*W* FOR WELD
			DEPTH, *D*		WIDTH, *W*[B]		
	mm	in.	mm	in.	mm	in.

	0.51	0.020	0.43	0.017	0.38	0.015	**1.1**
STAINLESS STEELS							
17-4 PH	0.13	0.005	0.10	0.004	0.36	0.014	**0.3**
TYPE 301	**0.25**	**0.010**	**0.15**	**0.006**	**0.28**	**0.011**	**0.5**

(A) CHILL TOOLING WAS IN INTIMATE CONTACT WITH THE UNDERSIDE OF THE WORK AT THE WELD LOCATION.

(B) WIDTH OF THE WELD AT THE CROWN, WHICH WAS THE GREATEST WIDTH FOR THE GENTLY RADIUSED WIDE-ANGLE V-SHAPED WELDS

Depth of penetration generally varies 10 to 15% from a mean value for a work thickness of about 0.51 mm (0.020 in.), and the percentage variation is greater for welds in thinner metal. Accordingly, partial-penetration welds are not ordinarily made in metal about 0.25 mm (0.010 in.). Beam oscillation is sometimes used to smooth out variations in penetration, but such oscillation must be controlled closely in order to be effective.

Procedure Development and Practice Considerations for Electron-Beam Welding

EBW of Thick Metal

For joining thick sections, electron-beam welding in a vacuum has three principal advantages over other welding processes:

- MUCH DEEPER PENETRATION CAN BE OBTAINED IN A SINGLE PASS. EXTREMELY NARROW, ONLY SLIGHTLY TAPERED WELDS AND A SMALL HAZ CAN BE PRODUCED.
- FOR JOINTS ON MOST WELDABLE METALS, NO FILLER METAL IS NEEDED. WHERE A FILLER METAL IS REQUIRED, THE QUANTITY IS USUALLY VERY SMALL.
- JOINTS HAVE CLOSELY FITTED PARALLEL GROOVE FACES REQUIRING NO EDGE PREPARATION, INSTEAD OF V-GROOVES OR U-GROOVES.

The disadvantages of EBW for joining thick metal include: high equipment cost, size limitations imposed by the dimensions of the vacuum chamber in which the work must be placed, and the time needed for evacuating the chamber.

Deep welds made in a vacuum are usually narrow; weld width for penetration deeper than 6.4 mm ($\frac{1}{4}$ in.) is typically about $\frac{1}{5}$ to $\frac{1}{20}$ of the section thickness, except for a somewhat greater width at the crown of the weld. Welds may be either full or partial penetration.

Effects of Pressure. Penetration capability is greatest for EBW in high vacuum. The effect that welding pressure has on penetration of steel is shown in Table 4. A constant weld speed of 890 mm/min (35 in./min) and beam power of 7.5 kW from 150 kV/50 mA for high and medium vacuum, and 175 kV/43 mA for nonvacuum were used to obtain the data in Table 4.

TABLE 4 TYPICAL PRESSURE AND BEAM TRAVEL DISTANCE SPECIFICATIONS REQUIRED TO OBTAIN MAXIMUM WELD PENETRATION OF STEEL

TYPE OF SYSTEM	**AMBIENT WORKPIECE PRESSURE**		**BEAM TRAVEL DISTANCE**		MAXIMUM PENETRATION	
	pa	**torr**	**mm**	**in.**	**mm**	in.
HIGH VACUUM	0.013	1×10^{-4}	455	18	25	**1**
MEDIUM VACUUM	130	1	205	8	16	$\frac{5}{8}$

NONVACUUM	**1.0×10^5**	**760**	**13**	$\frac{1}{2}$	**4.0**	$\frac{5}{32}$

Full-Penetration Welds. In welding carbon steel, single-pass, full-penetration, vacuum (high/medium) electron-beam welds are made commercially in thicknesses up to approximately 100 mm (4 in.); production EBW-HV has been done on aluminum alloy plates 150 mm (6 in.) thick, and 230 mm (9 in.) thick aluminum alloy sections have been welded experimentally under near-optimum conditions.

Two-Pass Full-Penetration Welding. Penetration can be nearly doubled by making two passes, one on each side of the work, but cold shuts, voids, and porosity are encountered at the root of the second weld unless conditions are adjusted for the pass made on the second, or back, side. A broader second-side weld with a larger radius at the root helps to reduce the incidence and severity of these flaws, but they often remain a problem.

Partial-Penetration Welding. Welds that do not penetrate completely through the work metal are satisfactory in many applications in welding thick metal; joint design and product requirements often rule out full penetration.

Problems and Flaws. In making vacuum electron-beam welds 3.2 to 13 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) deep in weldable metals, weld quality is ordinarily equal to or better than that of arc welds in the same metal. Special precautions are needed to avoid certain types of discontinuities in welds about 13 mm ($\frac{1}{2}$ in.) deep or deeper. Fusion-zone porosity, gas pockets, and cold shuts are more serious problems than in arc welding, particularly in deep welds.

Reducing the welding speed usually helps to reduce porosity and gas entrapment. Extreme care in cleaning the work metal may be necessary where the problem is severe. When flaws are found near the root of the weld, they can be avoided or minimized by any adjustment of welding conditions that broadens the weld and increases the radius of the weld at the root. Sometimes the joint can be designed so that any root flaws are in a noncritical region, or in integral or separate backup metal that will be machined away after welding.

As in arc welding, cold shuts (incomplete fusion) are sometimes encountered at the root of a deep partial-penetration weld or of a full-penetration weld that has a poorly fitted backing strip. These discontinuities are troublesome because they are difficult to detect. Normally they cannot be detected by radiographic methods. Ultrasonic testing can detect the larger cold shuts. Many cannot be observed on roughly polished macrosections of electron-beams welds, but require a metallographic polish and examination at a magnification of at least 100 diameters for detection. Cold shuts can usually be avoided or minimized by reducing the welding speed or by otherwise changing conditions so as to broaden the weld and increase the radius of the weld at the root.

Poor fit-up or excessive joint gap can cause excessive shrinkage, underfill, undercut, voids, and cold shuts. Joint gap should not exceed 0.25 mm (0.010 in.) for narrow welds deeper than about 13 mm ($\frac{1}{2}$ in.) in most metals, although sound welds have been obtained using joint gaps of 0.76 mm (0.030 in.), by use of a procedure that increased weld width.

Welding with the beam at a slight angle to the joint is helpful in avoiding flaws related to poor fit-up, but may increase weld width excessively and require an unduly low welding speed for deep welds.

Excessive mismatch can cause discontinuities of the same general types as poor fit-up; mismatch limits depend on joint design and dimensions, and on operating conditions. Weld quality in joining thick sections is ordinarily unaffected by changes in surface roughness of the joint faces between about 1.60 to 2.50 μm (63 and 1000 μin.).

A problem that is unpredictable and inconsistent in making electron-beam welds deeper than about 13 mm ($\frac{1}{2}$ in.) is arc-outs, or sudden failures of electron emission during welding. However, problems of arc-out have decreased with the newer machines and experience accumulated in operation.

Work-metal composition and quality also influence arc-outs, which are more frequent when welding materials with low vaporization points, or when welding materials susceptible to outgassing in a vacuum or those that contain nonmetallic inclusions.

Use of Filler Metal

Fusion of closely fitted groove faces generally provides sufficient weld metal, or extra metal is provided where necessary by including extra stock thickness or integral shoulders or lips in the joint preparation. Where product requirements or other circumstances prevent the use of a joint preparation and welding conditions that will provide sufficient weld metal, filler metal is added.

Prevention of Cracking. Filler-metal (shim stock) additions can prevent cracking in electron-beam welds in a crack-susceptible metal or combination of dissimilar metals. It may be needed even when joint design, fit-up, and operating conditions are selected to achieve minimum joint restraint and residual stress. In other applications, the use of preplaced filler metal can provide weld metal that is less brittle than would be obtained by welding a base metal (or metals) alone.

Among the base metals for which added filler metal is often required are heat-treatable aluminum alloys 6061, 6063, and 6066, free-machining steels, and other free-machining alloys.

Many combinations of dissimilar metals that are susceptible to cracking when welded directly, usually because of the formation of brittle intermetallic phases, can be electron-beam welded with the aid of filler metal that has a composition compatible with both metals of the combination.

Preventing Porosity. The EBW of rimmed steel without filler metal ordinarily results in severe porosity in the weld, even when welding speed is slow and other conditions are selected to increase the time during which gas can escape from the molten weld metal. Inserting a filler metal that contains a deoxidizer such as aluminum, manganese, or silicon helps to minimize porosity.

Copper alloys C11000 (tough pitch copper) and other types of copper that do not contain residual deoxidizers also produce porous welds when joined without filler metal, but sound welds can be made with the aid of nickel filler metal or a deoxidizing filler metal.

Preplacement of Filler Metal. The technique most frequently used for the addition of filler metal in EBW, especially for deep welds, is preplacement. A shim of filler metal, usually of foil thickness, can be inserted between the groove faces when the joint is assembled for welding, or a wire or other suitable shape can be preplaced over the joint, being held in position by tack welding, if necessary.

Filler-Wire Feeding. Electrically operated filler-wire feeding systems that are modifications of wire-feed equipment used in GTAW, or specially designed electron-beam wire feeders, are sometimes used in the vacuum chamber. Usually, filler-wire feeding does not help in joining incompatible metals unless they are very thin.

The design of the wire-feeding nozzle and the technique with which it is used are important in guiding the wire so that it intercepts the weld pool. Any filler metal inserted into the beam path absorbs energy and affects penetration.

The wire-feeding nozzle is normally held as close to the weld pool as is possible without damage to the nozzle, and the wire is directed into the forward edge of the pool. The tip of the nozzle should be made of a heat-resistant material and should be coated so as to prevent molten weld metal from adhering to it if inadvertent contact is made. The nozzle is usually pointed in the direction of workpiece travel.

Wire-Feeding Equipment. Several design features are desirable in a wire feeder for EBW. These include means of making positioning adjustments from outside the vacuum chamber during welding, such as changing the proximity of the nozzle to the weld pool, changing the angle of incidence between the workpiece and nozzle, and controlling the movement of the wire relative to the beam to ensure accurate interception.

A simple, variable-resistance, controlled motor drive is ordinarily satisfactory, as a 10% variation in wire speed causes no adverse effect other than a slight variation in weld width. It is desirable to be able to control the timing so that wire feed can be started and stopped independently of the beam and table. Being able to adjust the timing of the wire feeder eliminates sticking of the wire to the workpiece at the end of the weld. Vibrating the nozzle at subsonic rates promotes flow of molten metal into the weld joint and results in less wire sticking at the end of the weld.

Welding Technique When Feeding Filler Wire. The wire-feed rate is usually set at approximately the same rate as the welding speed. Beam power must be sufficient to melt the wire as fast as it is fed. The wire diameter is selected so as to provide 1.25 times the volume of filler metal needed to fill the joint cavity. Where needed, backing strips or rings are used to prevent loss of molten weld metal.

The filler metal can be deposited during the weld pass, using a low welding speed to allow time for the molten metal to fill the joint gap, but for deep welds it is preferably deposited in a separate pass. If cracking is a problem, another method used on thin metal is to deposit filler metal on the joint, and then make the welding pass to distribute the filler metal more effectively. Additional information on the wire-feed process and related equipment can be found in the section Electron Beam Welding as a Repair Method of this article.

Tack Welding

In fixturing work for EBW, clamping often is supplemented or replaced by tack welding, which is usually done with the electron beam. Fixturing time and cost are often substantially reduced by the effective use of tack welds.

In some applications, selection of the tack welding procedure is critical to avoid unacceptable variation in the shape and dimensions of the final weld bead and to avoid root porosity or cold shuts. Reduced power and other special operating conditions are often used.

Techniques. Perhaps the most common technique is to make one or more suitably spaced tack welds at full or reduced beam power before making the welding pass. For circular or circumferential welds, one or more tack welds are usually made. Melt-through (spike) tack welds can be used on straight-line lap joints.

A shallow seal pass at reduced beam power can also be made along the full length of the joint to keep the workpieces aligned, to be followed by the full-power penetration pass. For some applications, it is convenient to leave occasional unwelded gaps as an aid for tracking the joint during the penetration pass.

EBW of Poorly Accessible Joints

One of the advantages of EBW is the capability of reaching into areas lying deep within narrow openings. This is accomplished by virtue of the electron beam having a small diameter, long working distance, and frequently, the capability of being projected at an angle. Many joints that are inaccessible for welding by other processes can be electron-beam welded. This capability is used both in fabrication and in repair work. It is especially useful in salvaging intricate castings.

Workpiece Requirements. For limited-access welding, the workpiece must satisfy three general requirements: (1) the weld area must be on a line-of-sight path from the beam source; (2) there must be sufficient sidewall clearance to avoid beam-fringe interference; and (3) the beam path must be free of magnetic fields.

Beam characteristics that determine applicability of EBW to poorly accessible joints are beam diameter and the working distance or effective beam length available between the exit end of the beam transfer column and the work. These characteristics in turn depend on the beam power used, which is selected to produce the desired penetration, and on beam focal length, which is influenced by the design of the gun, the chamber, and the focusing coil.

Sidewall Clearance. Parts intended for fabrication by EBW can often be designed with sufficient sidewall clearance for the beam power required. Where insufficient sidewall clearance exists in repair welding, lowering the beam power or slightly changing the angle of incidence of the beam often avoids interference. In repair welding, tests should be made on simulated joints, using the same type of work metal and the required beam power, rather than risking damage to difficult-to-replace parts.

Where close sidewall clearances are involved, it is especially important to avoid magnetic fields, which can cause damage to the part by deflecting the beam. A test run on low power is commonly used to detect beam deflection; however,

allowance must be made for the increase in deflection at full welding power. Magnetically soft materials with induced magnetism can usually be demagnetized with magnetic-particle inspection equipment or with coils.

Minimum beam clearance for making welds close to magnetic metal that projects above the work surface at the joint is given in Fig. 14.

Multiple-Tier Welding

The deep-penetration properties of the electron beam make it possible to weld two or more tiers of joints simultaneously. The joints can be separated by an air space as great as several inches, provided that the space can be evacuated and the joints aligned in the path of the beam. This type of weld cannot be made by any other welding process.

In multiple-tier welding, the electron beam must pierce at least the upper tiers in such a way that the molten metal flows in behind the advancing beam, as in keyholing. The molten weld metal is held in place by the combined forces of capillarity, surface tension, and viscosity. Welding conditions must be carefully selected and controlled.

Difficulties. ln-line welds are progressively different in shape and size, because of the scattering and reduction in beam density and other effects on the beam that take place when it penetrates each layer of metal in turn.

Internal weld spatter may cause difficulty if it interferes with service performance and there is no access for cleaning. Other difficulties such as undercut, underfill, and excessive root bead may be correctable. Hidden welds, which are difficult or impossible to inspect, require some acceptable indirect method of controlling joint reliability.

Applications. Multiple-tier welding has been applied to a variety of joints. Two-tier joints separated by as much as 75 mm (3 in.) have been welded in a single pass in joining honeycomb panels to end frames or structural shapes where only one side was accessible.

Welding With Extreme Accuracy

The development of feedback servomechanisms for controlling variations in beam power and beam spot size, as well as in work travel and speed, permits EBW within tolerances of a few thousandths of an inch in high-vacuum machines.

With the use of closed-loop feedback control systems, variations in beam voltage and current can be held to approximately 1% for a 10% variation in the supply line, which is well within the tolerances that can be maintained by the remainder of the system.

Although the diameter of the beam spot cannot be measured directly with special techniques, it can be estimated by measuring the width of the weld or by calibrating the controls for the focusing and beam-power settings. Depending on machine characteristics, beam spots effective for most welding purposes can be set up in the range of 0.25 to 0.76 mm (0.010 to 0.030 in.) in diameter without difficulty. Assuming a very small beam variation, an application requiring a beam spot of only 0.25 mm (0.010 in.) diam would require a means of holding the joint-to-beam coincidence with a runout of less than ±0.13 mm (±0.005 in.).

For welding with a 0.25 mm (0.010 in.) diam beam, a pileup of manufacturing tolerances could easily cause the beam to miss the joint. Therefore, for most production purposes, small beam spots are not economically feasible.

Various types of travel mechanisms of rigid construction are available with runout tolerances of approximately 80 μm/m (0.001 in./ft) or with total deviations of 0.08 to 0.12 mm (0.003 to 0.005 in.) for a complex traverse pattern. However, joint runout depends also on the manufacturing tolerances of the part and on accuracy of fit-up and fixturing. In some applications, 20 to 25 possible sources of error, such as magnetic deflection of the beam, and human and systematic errors in beam alignment, can be found.

Use of Scanning

Scanning is a method of checking the runout between the beam spot and the joint to be welded. Its purpose is to indicate the final adjustments needed to align the beam with respect to the joint and to expose possible unsuspected discrepancies in beam behavior or workpiece travel that would interfere with welding. Details of the procedure vary with joint design and the type of equipment available; in one widely used method, a low-power beam is used for visual scanning of the joint during a simultaneous welding pass.

Accuracy of Beam Alignment. Beam alignment is generally a matter of workpiece alignment, as even guns of the adjustable type are usually fixed during welding. Where the gun does traverse the joint, the principles of alignment are the same. Most joints are designed for simple path shapes--straight lines and circles--that can be adequately traced with precision-made carriages, cross-feeds, turntables, eccentric tables, and spindles.

Scanning Procedure. The workpiece is fixtured, and the joint is aligned for travel direction and is moved to its approximate location under the gun. The chamber is closed and pumped down to a vacuum sufficient for safe operation of the gun. A low-power beam is turned on and focused sharply on the workpiece surface. The specific power settings will vary with the working distance selected and the power ratings of the machine; however, they should be sufficient only to create a detectable spot without overheating the workpiece.

The joint line is then adjusted to its precise location with respect to the beam spot, the workpiece is traversed through a complete cycle, and the runout is equalized. Maximum allowable tolerance on runout is determined from a consideration of joint design and weld width, which is mainly a function of the spot size and travel speed.

Considerable latitude in required accuracy of alignment can be gained where beam oscillation can be used. Usually, if the runout approaches one-half the effective welding beam spot width (spot size plus oscillation amplitude), the cause must be determined and corrected. If the runout is within tolerances, production parts ordinarily need only periodic scanning as a quality-control measure.

Problems in Scanning. Some of the causes of excessive runout and other difficulties encountered during scanning are as follows:

- POOR JOINT DESIGN, INACCURATE JOINT PREPARATION
- IMPROPER FIT-UP, INADEQUATE FIXTURING
- LACK OF PRECISION IN WORKPIECE TRAVERSING MECHANISM
- OBSTRUCTIONS IN THE BEAM PATH
- INDISTINCT OR UNDETECTABLE JOINT LINE
- BEAM DEFLECTION BY ELECTRIC OR MAGNETIC FIELDS

The corrections required for mechanical discrepancies are self-evident; the effects of electric and magnetic fields may be less obvious.

The negatively charged electrons that comprise the electron beam constitute a negative space charge. When the electrons strike an insulated metal part, negative charges are built up, causing mutual repulsion between the part and the beam. By grounding the part, excess electrons are conducted away. To avoid unintentional deflection of the beam by nearby magnetic fields, workpieces, fixtures, and tooling components made of magnetic materials should be demagnetized before welding.

Scanning techniques vary in detail, depending on the type of equipment used and also on joint design. It is not always necessary to position the beam spot precisely on the joint line. When welding dissimilar metals, dissimilar thicknesses of the same metal, or certain self-locating joints, it is often necessary to position the beam a short distance from the visible joint line. A corner edge or a scribed line can often serve as a reference, or measurement can be made with an optical grid.

Some special-purpose EBW machines are not intended for scanning. Nearly all general-purpose machines, however, make some provision for this operation. On machines with a fixed gun located in an upper section of the vacuum chamber, a built-in internal optical viewing system is generally provided for scanning. Machines having movable guns can be equipped with external telescopes and internal mirror systems.

Optical Scanning. Optical systems usually consist of horizontally mounted monocular or binocular telescopes with internal illumination and reflecting mirrors that provide a line of sight coaxial with the beam path. Magnifying power may be 10 to 40 times, depending partly on working distance. High-precision alignment can be obtained.

There are two common methods of using this equipment. One method makes use of a low-power beam that is sighted telescopically on the workpiece surface. Using a calibrated grid, measurements to 0.025 mm (0.001 in.) can be made. In the other method, the beam is centered on a crosshair reticle embodied in the optical system. The beam is then turned off and the workpiece joint is moved into coincidence with the crosshair, under internal illumination. The advantage of the latter method is that, after the beam is turned off, the chamber need no longer remain under vacuum, and further alignment work can be done in the open, if necessary.

Before scanning, the mirror surfaces of the internal optical system should be cleaned, because vapor deposition takes place during welding. The frequency of cleaning may vary from a few to many hours of operation, depending on the amount of vapor created and the proximity of the weld. Mirror surfaces are usually protected with glass shields that can be removed for cleaning or replacement.

Scanning Without Optics. Scanning can also be done without visual aids where great precision is not required. On machines that are not equipped with viewing optics, scanning is done by direct observation through sight-glass ports. From one to four such ports may be located in the chamber wall, usually spaced 90° apart, to permit checking beam alignment from several angles. The beam spot is generated the same as for optical scanning.

Electronic Scanning. Checking the location of an electron beam with respect to the joint can be done with an electronic device that displays the relationship on an oscilloscope. The equipment makes use of a low-power electron beam that is made to oscillate at 60 Hz transversely across the joint. The amplitude of the oscillation is sufficient to display the workpiece surface for a short distance on either side of the joint, as well as the joint line itself. In addition, each oscillation pulse is interrupted momentarily to permit the beam to assume its normal welding position, causing a relatively large spot to appear on the display. When the spot coincides with the joint line of the display, the beam is accurately aligned for welding.

Figure 20(a) shows the display condition for a beam centered exactly on the joint. The V represents the joint line, with the beam spot centered accurately; the two horizontal arms (of equal length with a centered beam) at the top of the V represent the adjacent workpiece surface. The broken lines above the work (at left in Fig. 20a) show the plane of oscillation; the wavy line along the joint in the same view shows the approximate amplitude of oscillation.

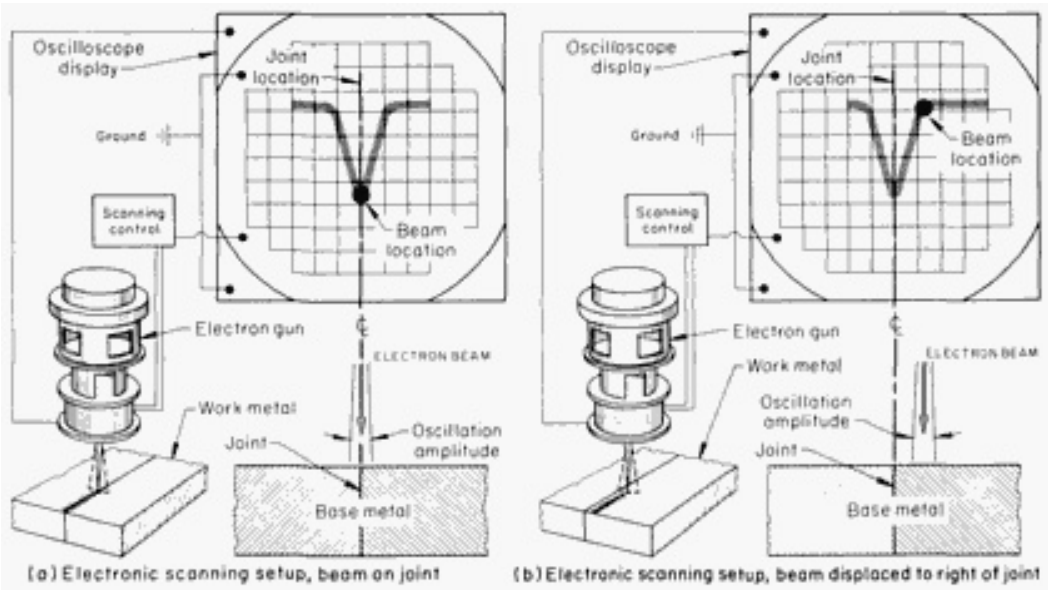

FIG. 20 ELECTRONIC SCANNING APPARATUS WITH CRT DISPLAY TO SHOW ALIGNMENT OF ELECTRON BEAM RELATIVE TO WELD BEFORE WELDING OPERATION IS CARRIED OUT. (A) ELECTRON BEAM CENTERED ALONG LENGTH OF JOINT. (B) ELECTRON BEAM DISPLACED FROM CENTERLINE OF JOINT

If the beam location were displaced to the right of the joint, the display would look like Fig. 20(b); an opposite-handed display would indicate displacement to the left. By the relative depth of the V, the display also indicates the amount of joint separation from apparent zero to approximately 0.15 mm (0.006 in.). A joint mismatch of a few thousandths of an inch is indicated by the relative height of the horizontal arms. In setting up for electronic scanning (under vacuum), the work is provisionally aligned as for optical scanning, making sure that the joint line is parallel to the direction of travel.

Joint Tracking

Joints that have a path that deviates from a straight line or circle usually require an automatic tracking device for EBW of production quantities. For small production lots, manual tracking, using a coordinate drive having separate controls, sometimes can be used. Whether the method is controlled manually or automatically, the motion required to generate the curve is usually imparted to the workpiece, although limited motion can be imparted to some guns.

Manual Joint Tracking. In manual tracking, the welding operator must closely observe the joint at the point where the weld is being made to anticipate any change in direction. The conditions best suited to this type of operation are: (1) a joint path consisting of a smooth curve, (2) slow travel speed, and (3) a low-power beam with oscillation, to form a weld as wide as possible. The welding operator is capable of regulating two motions of the workpiece (or gun) by manually adjusting the remote controls of the travel mechanism.

For a low heat input, to permit the use of the low welding speeds needed when manual tracking is used, beam pulsation can be combined with beam oscillation.

Automatic Joint Tracking. Mechanical, electromechanical, numerical control, and computerized systems are sometimes used for welding joints that deviate from straight lines or circles. The use of computerized numerical control (CNC) has become highly prevalent in EBW equipment. The capability of a CNC for allowing the weld seam path of a part to be quickly "digitized" and "edited" makes it an ideal tool for programming and tracking the actual weld seam path.

Electromechanical joint tracking systems make use of a stylus, or probe, that rides in the joint. Lateral movements of the stylus (which precedes the beam), resulting from a change in joint position, are converted to electrical signals by a transducer. The electrical signals drive a positioning servomotor that maintains preset alignment of the joint-to-gun focus. These electrical signals define a right error, a left error, and the correct gun position. Precision is usually better, response-delay time is shorter, and other problems associated with mechanical tracking with templates are avoided.

Tape-Controlled Joint Tracking. Workpiece (or gun) motion can be programmed for the complete welding cycle by conventional numerical-control equipment. The actual position of the workpiece with respect to the programmed tape input can be controlled to approximately ±0.025 mm (±0.001 in.). As with other tracking systems in which the generated motion is independent of the joint path, the two paths must coincide. There must be a high degree of assurance that the prior processing of the workpiece, its fixturing, and beam alignment have been done with repeatable accuracy. The tape input information must be sufficiently fine to generate the curve within the desired accuracy.

Beam Oscillations

Through the use of a two-axis deflection coil, either a static (fixed) or an oscillatory (periodic) motion can be imparted to the beam spot through a separate deflection control module. Generally, this control consists of a set of amplifiers for driving the *x-y* axes and a function generator for programming the beam spot motion desired. Beam spot motions employed comprise a variety of shapes and may consist of straight, fixed, or periodic deflection, or a combination of both. Square wave, circular, hyperbolic, or parabolic beam spot motions can easily be programmed, employing angular beam deflections of up to 15° and frequencies greater than 5000 Hz. This beam oscillation capability allows wider welds, slower cooling rates, and more uniform weld shapes to be produced, without necessarily using beam defocusing. Also, beam oscillation capability reduces the need for accurate beam-to-seam alignment and makes precise joint tracking less critical. In addition, programmed beam oscillation can be used to control microshuts and porosity in partial-penetration welds, thus reducing undercut and underfill for better bead control and for maximizing penetration capability.

Use of a Pulsed Beam

Beam operation can be changed from continuous to intermittent on machines equipped with pulsing controls. Although available repetition rates (frequencies) and pulse lengths depend on the control unit, frequencies in the range of 0.1 to 3000 Hz with pulses up to about 60 to 70 ms in duration are representative. Beam pulsation reduces the rate of heat input, but is independent of other beam conditions. Therefore, pulsation can be combined with oscillation and deflection, as well as travel speed, to influence weld behavior.

At very low frequencies, such as 1 Hz, with a 5 to 10 ms pulse length, each pulse produces a separate weld, even at low travel speed. By increasing travel speed and adjusting pulse frequency and pulse length, tack welds, spot welds, or intermittent welds can be made at normal production rates. Increasing pulse frequency to approximately 35 to 100 Hz while maintaining short pulse lengths makes it possible to overlap the successive welds to form a continuous weld at speeds suitable for manual tracking.

Pulsed beams generally result in lower peak temperatures, especially in the area adjacent to the weld, as compared to continuous welding, although total heat input may be greater because of the slower welding speed used. At higher pulse frequencies, pulsation has been used to control the solidification pattern of the weld and the microstructure of the HAZ. Pulsation also has been used in rewelding to fuse cold shuts, fill gas pockets, and smooth irregular root areas.

Procedure Development and Practice Considerations for Electron-Beam Welding

Electron Beam Welding as a Repair Method

Restoration of worn or damaged components traditionally has been an important application for welding technology. Some repairs are approached by welding a new detail in the area requiring restoration. However, it is frequently more suitable and cost effective to use a weld buildup process to restore the dimensions and structural integrity of the affected area. Welding processes such as manual or automatic GTAW or GMAW traditionally have been utilized for this type of repair; these processes facilitate the addition of filler wire to accomplish a weld buildup. While these processes enable efficient and relatively fast buildup of filler metal, they have a potential drawback of relatively high heat input, which may cause distortion when section thicknesses are small.

The EBW process has been employed extensively for original equipment manufacture mainly because of its ability to minimize or eliminate distortion through high weld speed, small HAZ, and small bead size. In the past, application of EBW for repair has been relatively limited, confined primarily to butt welding of repair insert details, penetration of parent metal (e.g., to eliminate a crack), or melting of preplaced filler wire. The matching of automatic wire-feed equipment to EBW equipment, however, has led to the development of a system that incorporates the inherent advantages of EBW systems and offers the additional capability of achieving a precise, multiple-pass weld buildup with minimum heat input. The addition of this capability has greatly increased the utilization of EBW as a repair mechanism.

Electron-Beam Wire-Feed Process and Equipment for Repairs

Electron-beam welding units used for weld buildup repairs are high-voltage, high-vacuum machines (150 kV, 13 mPa, or 10^{-4} torr). The availability of a highly controlled welding atmosphere is a distinct advantage for the electron-beam process, particularly when welding reactive materials such as titanium. High-voltage, high-vacuum EBW machines are equipped with signal generators that oscillate and deflect the beam in the *x-y* directions. They are also capable of making circles and other geometric figures. Beam deflection frequency can be varied, and the beam can be focused above or below the point of impingement. Beam pulsing and modulation of the pulse are also possible. All these tools can be used in weld buildup repairs. Current electron-beam vacuum chambers can accommodate parts up to 1525 mm (60 in.) in diameter. On the floor of the chamber is an *x-y* table; fixed to this table is a variable-speed rotary table. The component to be repaired, typically a cylindrical ring or case, is fixtured to this rotary table. An automatic filler-wire feeder delivers wire to the beam impingement point, enabling a continuous multiple-pass weld buildup when the component is rotated under the beam. Typically, a fused spot is less than 0.51 mm (0.020 in.) in diameter, allowing for an extremely small HAZ.

The wire-feed equipment is an adaptation of standard GTAW wire-feed equipment, and the technique is similar to that employed in cold wire circumferential automatic GTAW. The precision wire feeder delivers wire through a nozzle, which can be positioned in the *x*, *y*, and *z* directions and which is easily visible in the coaxial optical system of the electron-beam welding machine. Wire entry angle, nozzle position, wire speed, weld speed, accelerating voltage, focal position,

deflection, and amperage are critical factors in EBW buildup. Both inside and outside surfaces can be restored, depending on the position of the wire feeder within the chamber.

A relatively small filler-wire diameter (≤0.89 mm, or 0.035 in.) typically is employed to attain a precise low-heat input and a weld buildup typically 1.0 to 1.3 mm (0.040 to 0.050 in.) wide and 2.54 to 7.62 mm (0.100 to 0.300 in.) high, although much larger buildups could possibly be attained by multiple applications of the process. Electron-beam weld buildup lends itself readily to automation, thereby opening the process to use by less skilled operators. On some machines, all parameters are preset. The operator merely lines the machine up on the surface to be welded and pushes the start button. The wire feeder automatically activates and adjusts itself to produce a smooth, precise buildup.

Application of Electron-Beam Wire-Feed Process for Repairs

The electron-beam wire-feed process has been applied primarily for restoration of worn or damaged gas turbine aircraft engine components, which are typically cylindrical in shape with diameters ranging from 100 to 1525 mm (4 to 60 in.), lengths from 25 to 915 mm (1 to 36 in.), and section sizes from 1.3 to 12.7 mm (0.050 to 0.500 in.). Repair of gas turbine engine components has become increasingly attractive to commercial and military operators because of the cost and lead time involved in the procurement of spare parts. Repairs are typically conducted at 50 to 70% of the cost of a new component, with three to six times improvement in replacement time.

One of the key gas turbine engine component repairs is the restoration of the rotating labyrinth-type air seals used to maximize engine pressure gradients. As seals wear or are damaged, engine efficiency drops and fuel consumption rises. Hence, restoring minimal seal clearances has become increasingly attractive. Seal design is typically of the straight knife edge or tapered knife edge type (Fig. 21). Materials vary from iron-base alloys (AMS 6508 and A-286) to high-nickel alloys (Incoloy 901 and Waspaloy) to titanium alloys (Ti-6Al-4V, Ti-8Al-1Mo-1V, and Ti-6Al-2Sn-4Zr-2Mo).

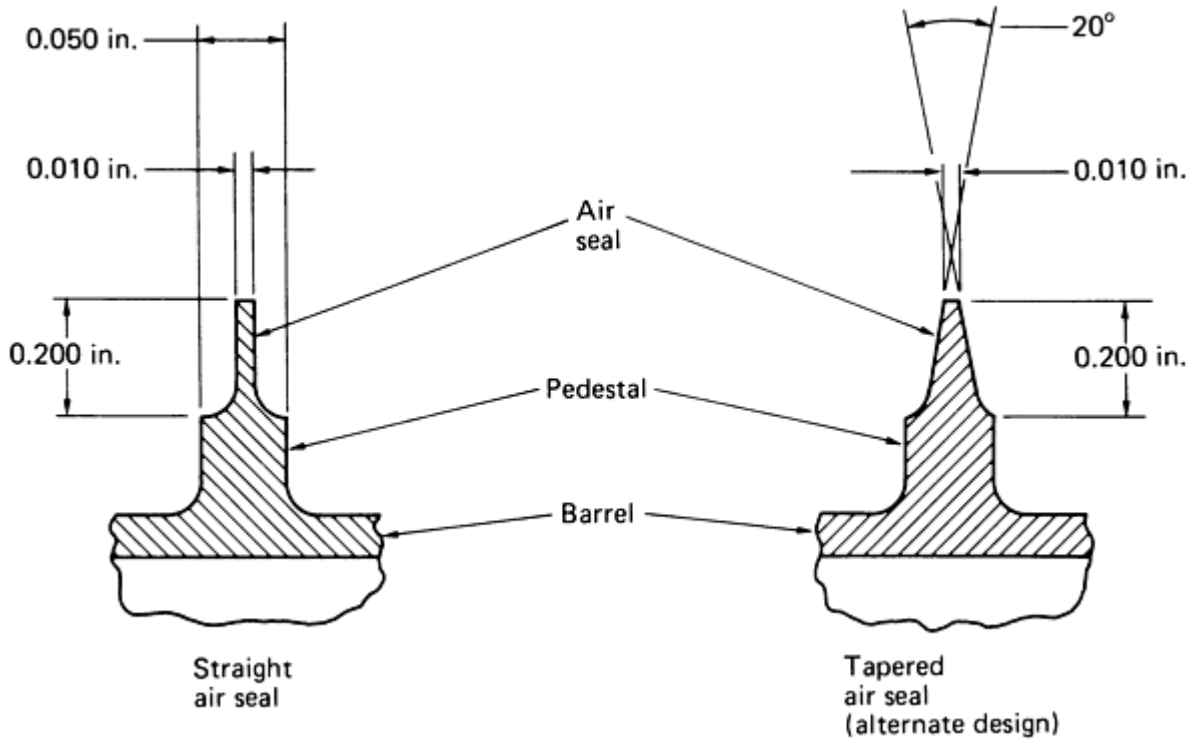

FIG. 21 SCHEMATIC COMPARING CROSS SECTIONS OF STRAIGHT AND TAPERED AIR SEALS

Currently, virtually all air seal restoration is done by welding. Gas-tungsten arc welding, gas-metal arc welding, and electron-beam welding have all been successfully applied depending on requirements of engine manufacturers, component design, material, and experience and equipment of repair stations. Prior to the establishment of the electron-beam wire-feed process, utilization of the standard electron-beam weld process for this type of repair was limited to

competitive weld buildup processes (GTAW and GMAW) and was primarily applied where distortion and HAZ size were a primary concern.

Initial application of the standard electron-beam process involved welding a machining ring onto a premachined pedestal on which the worn air seal was removed, as shown in Fig. 22. The knife edge configuration was then machined into the welded ring. Later, a split ring concept was introduced. In this procedure, an edge-rolled ring was assembled into a shallow groove premachined into the pedestal top (Fig. 22). Circumferential spike welds from each side welded the ring in place and the ends of the split ring were radiused to blend the discontinuity in the ring. The wall thickness of the as-rolled ring was the finished thickness of the knife edge, typically about 0.25 mm (0.010 in.), and the outside diameter was finish machined after welding. Disadvantages of this weld buildup system include ring detail cost and the amount of post-repair machining required.

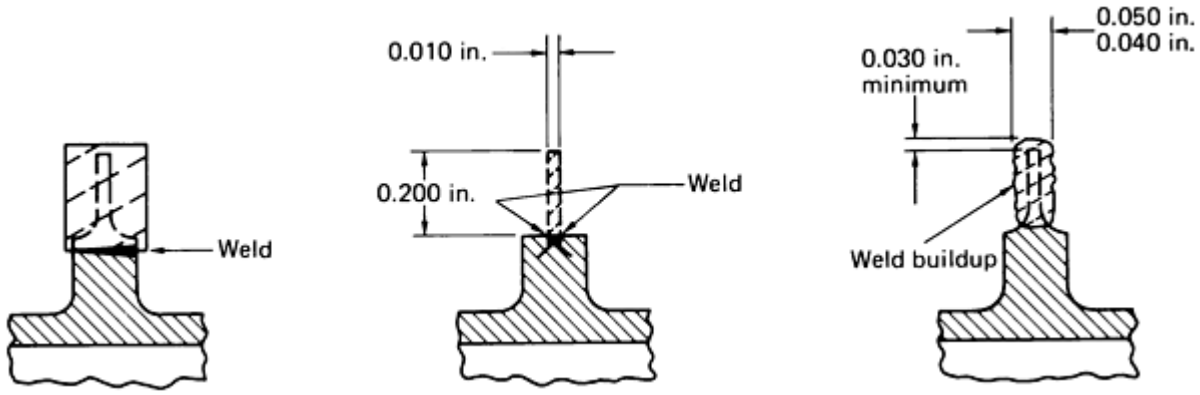

FIG. 22 SEQUENCE OF OPERATIONS REQUIRED FOR EBW REPAIR OF AN AIR SEAL. SEE TEXT FOR DETAILS.

The application of the precision wire-feed electron-beam process (Fig. 22) to gas turbine seal repairs provides both the material application efficiency and cost advantages of weld buildup systems and the inherent low heat input and controlled atmosphere advantages of the EBW process. A typical automatic wire-feed electron-beam air seal repair, applied to a compressor rotor spacer for a gas turbine engine, is shown in Fig. 23. This part is made from a titanium (Ti-6Al-4V) forging. The outside diameter of the knife edges wear in service, and the knife edges must be restored to maintain the proper tip clearance. The knife edge material is machined close to the diameter of the pedestal; a weld buildup is made using Ti-6Al-4V titanium filler wire, and a new knife edge is machined. The multiple-pass technique typically deposits 0.25 to 0.38 mm (0.010 to 0.015 in.) of radial buildup per pass. Penetration of the HAZ below the pedestal top typically does not exceed 0.38 mm (0.015 in.). Because the entire weld buildup operation is performed in a vacuum, there is no weld metal or HAZ oxidation. Cost is minimized by the high speed of the EBW process, which substantially exceeds that of the standard GTAW buildup process.

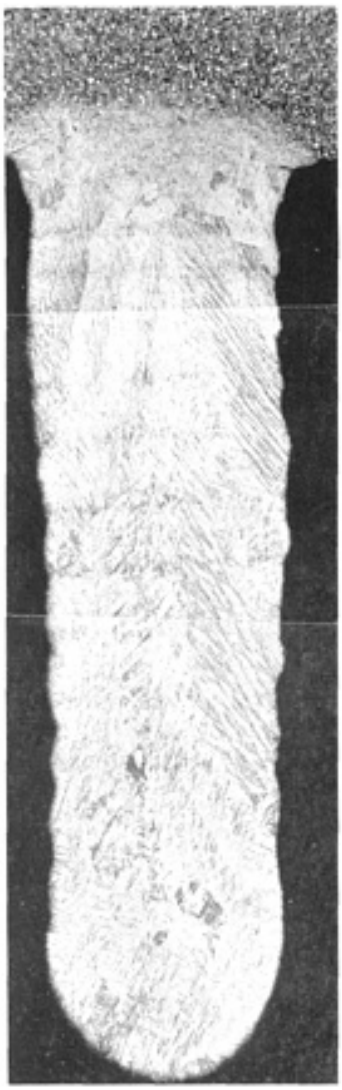

FIG. 23 PHOTOMICROGRAPH OF A TYPICAL AUTOMATIC WIRE-FEED ELECTRON-BEAM REPAIR OF AN AIR SEAL. 15×

Air seal repairs also are routinely performed on steel and nickel alloy parts. Experience with nickel-base superalloys containing relatively high percentages of gamma prime that form hardening elements has shown these alloys to be crack sensitive during welding or postweld heat treatment. Crack-free precision wire-feed EBW buildup repairs, however, are achieved when appropriate process parameters are utilized.

In applying the process to steel alloys, parameters should be optimized to avoid a pronounced swirl pattern at the buildup interface which may be encountered due to uneven mixing of the weld buildup and substrate. Potential swirling is associated with certain steel alloys and may be a potential source of porosity or cracking.

Quality assurance testing is an integral part of all gas turbine engine repairs. The high degree of control inherent in the precision wire-feed electron-beam repair process facilitates in-process control and quality assurance. Because of the high degree of control the electron-beam process offers, process variables can be kept to a minimum. This built-up consistency tends to ensure a long-term high level of quality assurance.

Weld parameters are developed by the analysis of microsections of sample welds and by nondestructive testing. Once an acceptable process has been established for a component, a weld schedule is initiated and weld parameters are maintained. Any changes in equipment or process must be qualified by the analysis of new microsections. Quality of finished air seals is ensured by one or more of the following tests, depending on customer requirements:

- VISUAL
- LIQUID PENETRANT
- FLUORESCENT MAGNETIC PARTICLE
- X-RAY
- ETCH INSPECTION

Future Applications for Repair

Although the most common application of the precision wire-feed electron-beam buildup process has been in the repair of gas turbine engine air seals, the process is not limited to this type of application. Various other wear restoration applications have been developed, including spline and groove buildups. Although the process is most efficiently utilized as a continuous multiple-pass process on cylindrical components, planar buildup can be achieved by utilizing sequential weld pass patterns or oscillation. The process is also potentially applicable for new part manufacture to enable a component to be machined from a smaller, less costly forging with selective electron-beam buildup to provide material for specific structural features (for example, outside diameter bosses on cylindrical cases).

Procedure Development and Practice Considerations for Electron-Beam Welding

Joining of Dissimilar Metals

The joining of dissimilar metals is an important application of EBW. The weldability of two dissimilar metals or alloys depends primarily on their physical properties, such as melting points, thermal conductivities, and coefficients of thermal expansion. Weldability generally can be determined by examination of the phase diagram of the alloys to be welded. If intermetallic compounds are formed by the metals to be welded, the weld metal will be brittle. However, many combinations that are difficult to weld or unweldable by other processes can be welded by the electron-beam process.

Procedure Development and Practice Considerations for Electron-Beam Welding

EBW of Low-Carbon Steel

Low-carbon steels are readily electron-beam welded. Grain size in both the weld and the heat-affected zone (HAZ) is significantly smaller than in arc welds, because of the lower heat input and extremely rapid heating and cooling. Rimmed steel causes excessive gassing. A technique used to weld rimmed steel is to sandwich an aluminum alloy shim about 0.25 mm (0.010 in.) thick in the joint to provide deoxidizing action during welding. Welding at a low travel speed or otherwise adjusting welding conditions to produce a more tapered weld and thus to allow more time for the escape of gases from the molten weld metal also helps to reduce porosity. Semikilled steel is easier to weld than rimmed steel, but some oxygen may remain to cause porosity. Fully killed steel is readily weldable.

Procedure Development and Practice Considerations for Electron-Beam Welding

EBW of Hardenable Steel

The variation in weldability by EBW among hardenable steel follows the same pattern as for arc welding of these steels. Properties of electron-beam welds in a given hardenable steel differ from those of arc welds mainly because of the narrowness of the fusion and HAZ and the extremely rapid heat-melt-cool cycles.

Hardness traverses across the midpoint of electron-beam (high-vacuum) and gas tungsten arc welds in 1.57 mm (0.062 in.) thick heat treated 4340 steel are plotted in Fig. 24. For both welds, maximum hardness was produced uniformly in the weld metal, and hardness dropped off abruptly at the edge of the weld metal.

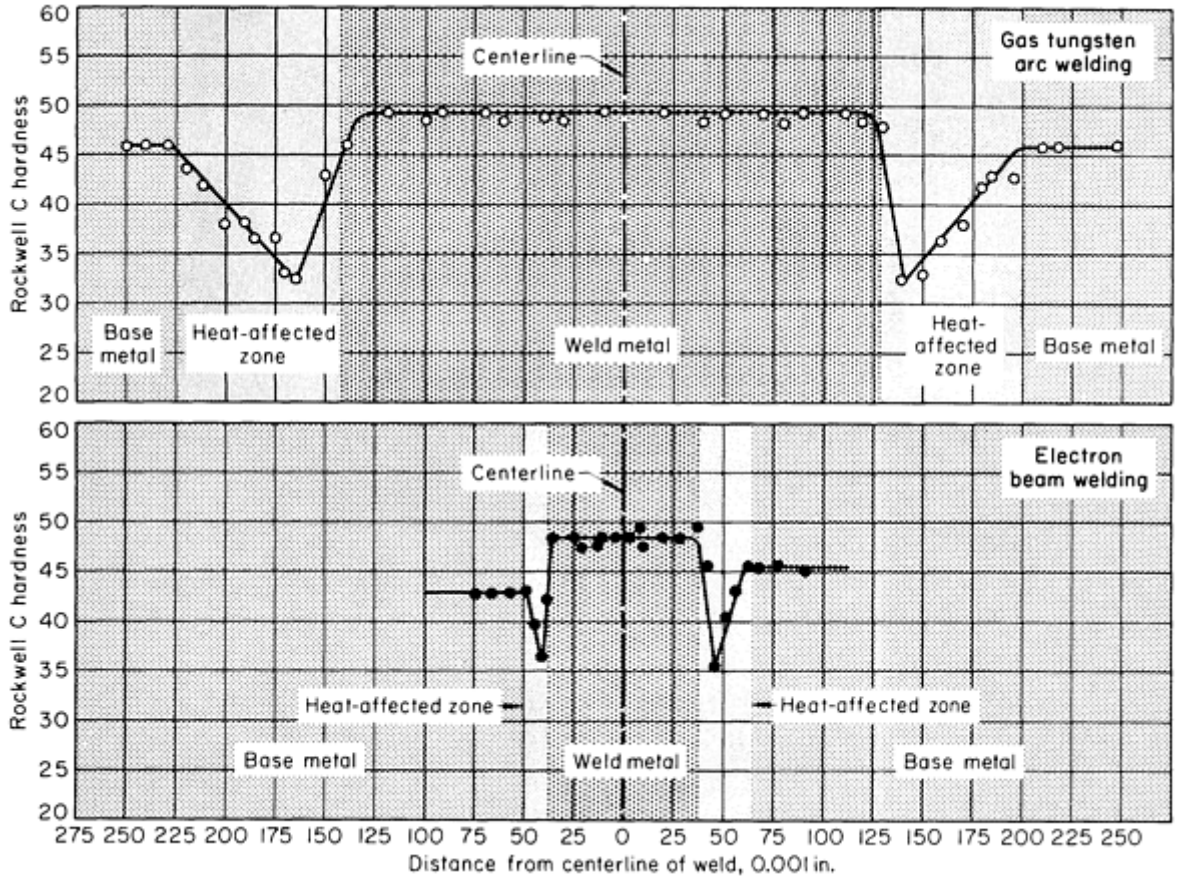

FIG. 24 HARDNESS PROFILE OF HIGH-VACUUM EBW AND GTAW BUTT JOINTS USED TO JOIN 1.57 MM (0.062 IN.) THICK MEDIUM-CARBON ULTRAHIGH-STRENGTH STEEL

Similar hardness traverses for electron-beam welds in 9.65 mm (0.380 in.) thick heat-treated 1024 (modified) are shown in Fig. 25. The hardness profile across this weld was similar to that for the electron-beam welds in 1.57 mm (0.062 in.) thick 4340 steel. Tempering after welding eliminated or minimized the hardness differential in the HAZ (Fig. 25).

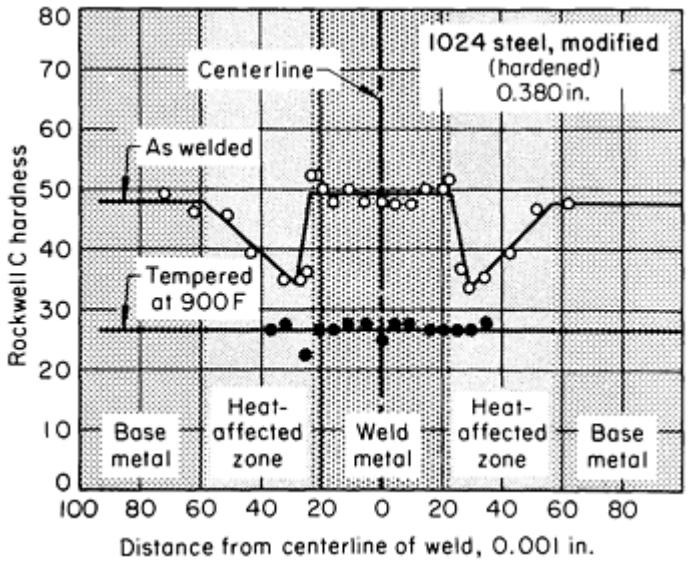

FIG. 25 HARDNESS-PROFILE OF HIGH-VACUUM EBW BUTT JOINT USED TO JOIN 9.65 MM (0.380 IN.) THICK

Prevention of Cracking. Cracking can be a problem in EBW of hardenable steel, just as in arc welding, if the weld is made in a highly restrained joint, especially in welding parts that have been hardened. Deep circular welds in heavy sections are particularly troublesome. Partial-penetration welds are more likely to crack under restraint than full-penetration welds. It is desirable to place the joint in a location that will allow the part to shrink freely as it cools after welding. Welding through carburized or nitrided cases is not recommended.

Cracking of electron-beam welds in hardenable steels can also be minimized by reducing the welding speed to allow more buildup of heat in the base metal, and by preheating, postheating, and allowing the work to cool in the chamber after welding.

Medium-carbon steels except for the free-machining types, are readily electron-beam welded (for hardness traverses, see Fig. 25). Weldability decreases with increasing carbon content.

Low-alloy steels containing less than 0.30% C are usually electron-beam welded without preheating or postheating. When preheating is used--to prevent cracking in highly restrained joints, for example--a temperature of 260 to 315 °C (500 to 600 °F) is usually adequate. If the part has been hardened and tempered prior to welding, the postweld tempering must be done at a temperature slightly below that at which the base metal was originally tempered.

Two of the most frequently electron-beam-welded alloy steels of this type are 8620 and 9310. Components made of these steels often are case hardened, then assembled by EBW, without distortion or heat damage to the case. Before welding, the case should be removed from the immediate vicinity of the joint to prevent microcracks from forming in it.

High-strength alloy steels containing more than 0.30% C are electron-beam welded either in the annealed or the normalized condition or in the quenched and tempered condition, although weldability is better for the annealed or normalized condition. The hardness profile for electron-beam welds in hardened high-strength alloy steel sections no thicker than about 65 mm ($\frac{1}{4}$ in.) is ordinarily like that shown for 1.57 mm (0.062 in.) thick heat-treated 4340 steel in Fig. 24, and joint strength can approach that of the base metal, without preheating or postweld treatment other than stress relief.

When a shielding gas is substituted for air in nonvacuum welding, assuming the same operating conditions, penetration is greater when a gas is used that has a lower molecular weight (or nominal density) than that of air. Penetration is less when a gas that has a higher molecular weight than that of air is used. In tests on welding 4340 steel, using a fixed beam power of 6.4 kW, working distances of 6.4, 13, and 25 mm ($\frac{1}{4}$, $\frac{1}{2}$, and 1 in.), and welding speeds of about 380 to 2030 mm/min (15 to 80 in./min), penetration was increased when helium was substituted for air and was decreased when argon was substituted for air, as shown in Fig. 26. The relative capacities of helium, air, and argon to scatter the electrons of the beam by collisions of electrons with gas molecules are controlled by their molecular weights and relative densities. On the average, when helium was used as a shielding gas, penetration depth was about twice that obtained when welding was done in air, and when argon was used, penetration depth was about half that when welding was done in air. Thus, with helium shielding, penetration averaged about four times that with argon, especially at higher welding speeds. The speed at which a given thickness of 4340 steel could be welded with full penetration, using helium, was two to four times that with air. Using argon, speed was 25 to 50% that with air.

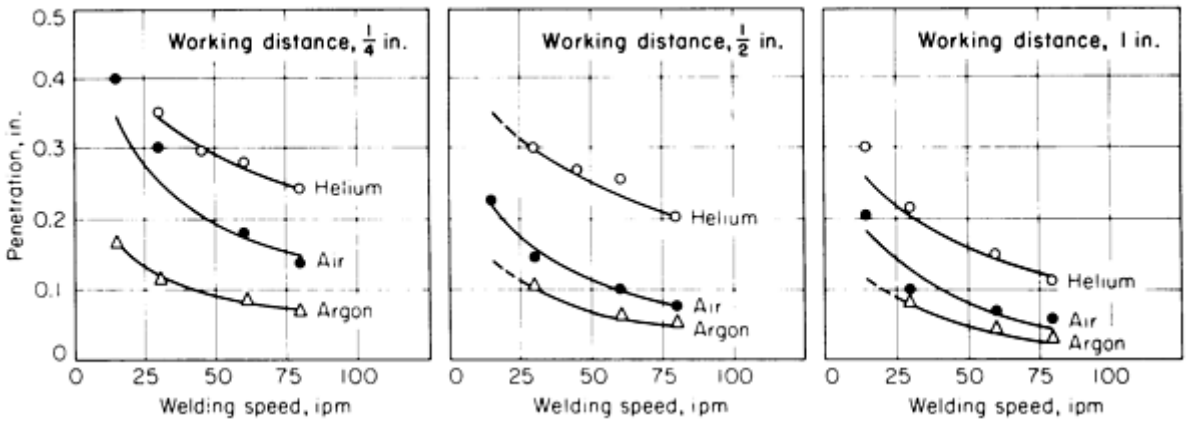

FIG. 26 PLOT OF PENETRATION VERSUS WELDING SPEED AS A FUNCTION OF SHIELDING GASES AND WORKING DISTANCES FOR NONVACUUM EBW OF 4340 MEDIUM-CARBON ULTRAHIGH-STRENGTH STEEL. BEAM POWER WAS 6.4 KW.

In EBW of thicker sections of high-strength alloy steels, preheating or postheating, or both, is usually needed to prevent cracking. In studies on full-penetration, single-pass welding of 15 mm (0.6 in.) thick annealed D-6ac steel, which is used frequently for missile castings, cracking was observed when preheating was not used and was eliminated by preheating at 540 to 565 °C (1000 to 1050 °F). Welding was started with the joint at a temperature of 370 °C (700 °F), and the joint temperature remained above 345 °C (650 °F) for 8 to 10 min after completion of the weld. Hardness profiles for the joints welded with and without preheat are shown in Fig. 27. Sound welds were also obtained in 55.9 mm (2.2 in.) thick annealed D-6ac steel, after preheating to 425 to 455 °C (800 to 850 °F); welding was started when joint temperature was no lower than 260 °C (500 °F).

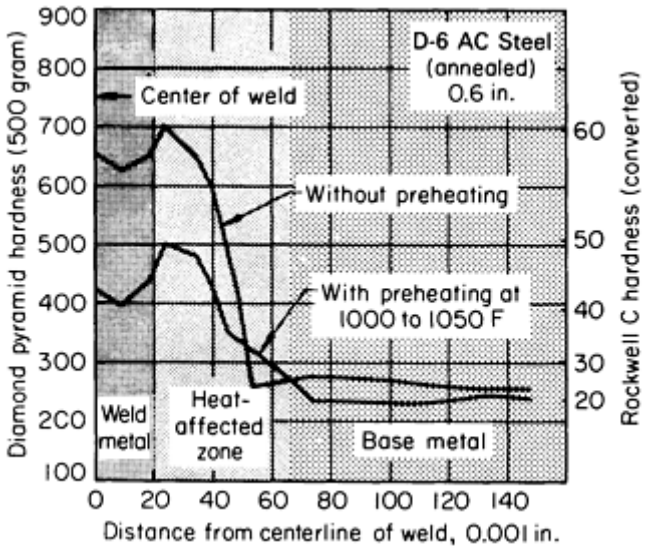

FIG. 27 EFFECT OF PREHEATING ON THE HARDNESS OF 15 MM (0.6 IN.) THICK D-6AC LOW-ALLOY ULTRAHIGH-STRENGTH STEEL

High-Carbon Steels. Because of the low total heat input and the rapid thermal cycling that are characteristic of EBW, weld cracking of steels containing more than 0.50% C is less likely than in arc welding. Even bearing steels such as 52100, which are seldom arc welded, have been electron-beam welded on a high-production basis. The 52100 steel is welded in the spheroidize-annealed condition in applications where joint performance is not critical to the function of the part and where service stresses in the joint are low. Preheating and postheating are not necessary.

EBW of Tool Steels

The chief advantage of EBW over other welding processes in joining tool steels is its ability to produce joints at high speed without annealing or other heat-treating operations. Hardness profiles similar to those shown for low-alloy steels in Fig. 24 and 25 were also obtained for H11 tool steel. For full-penetration butt welds on hardened (50 HRC) sections 5.72 ram (0.225 in.) thick, the hardness of the weld metal and the immediately adjacent base metal was 56 to 57 HRC, and hardness dropped to a minimum of 43 to 46 HRC in the HAZ, as measured after double tempering at 550 °C (1025 °F). The overtempered portion of the HAZ was only 0.13 mm (0.005 in.) wide.

Small dies of D2 tool steel have been electron-beam welded in production. A larger operation is the production of bimetal band saws. Specially designed high-vacuum machines, which are referred to as "air-to-air" machines, are used to produce band-saw blades by welding 1.6 mm ($\frac{1}{16}$ in.) wide M2 high-speed-steel cutting-edge strips to 6150 steel bands. The composite blade is about 0.8 mm ($\frac{1}{32}$ in.) thick and is welded at speeds above 7.6 m/min (300 in./min) in a special vacuum chamber. In "air-to-air" bimetallic strip welding, the backing band and edging strip are continuously fed through slots in a series of differentially pumped chambers and welded in a high vacuum without any interruption of this continuous product flow.

EBW of Hardened and Work-Strengthened Metals

The full properties of hardened and work-strengthened base metals can be retained on functional surfaces very close to the narrow electron-beam weld zone. In addition to confining the decrease in base-metal properties to a very narrow zone, EBW of hardened or work-strengthened metals also produces joint quality superior to that produced by arc welding. Some high-strength steels, however, cannot be electron-beam welded in the hardened condition without cracking or without an unacceptable decrease in strength and hardness. These steels, such as 52100 beating steel, are normally annealed before welding and given a postweld heat treatment for controlled strength and hardness. In Example 1, EBW was chosen over gas-tungsten arc welding (GTAW) because of the narrow fusion zone and HAZ obtained by the electron-beam process.

Example 1: Selection of Electron-Beam Welding to Minimize Tempering in the Heat-Affected Zone.

Fabrication of armor for military aircraft involved the welding of corner joints in 7.9 mm ($\frac{5}{16}$ in.) thick armor plate. The armor plate was made by roll-bonding H 11 tool steel to an alloy steel (AMS 6545) containing 9% Ni, 4% Co, and 0.30% C. Welding was done with the plate in the hardened condition; the H11 steel was hardened to 60 HRC and the alloy steel to 50 HRC. The plate was not difficult to weld. Either GTAW or EBW could be used to obtain sound welds using the joint designs shown in Fig. 28.

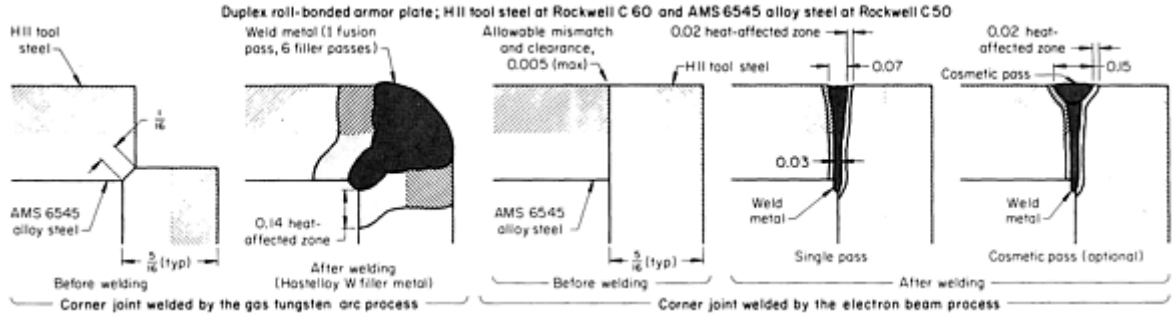

FIG. 28 SCHEMATIC OF CROSS SECTIONS THROUGH CORNER JOINTS AND WELDS TO SHOW VARIATION IN THE SIZE OF WELDS AND HAZ THAT ARE OBTAINED WITH EBW AND GTAW

The weld and HAZ of the electron-beam process are compared with those of GTAW in Fig. 28. Joint designs differed; if the joint for GTAW had been made the same as the joint for EBW, a V-groove would have been required, and about the same amount of weld metal would have been needed. Gas-tungsten arc welding was done in one fusion pass and six filler-metal passes, using 1.57 mm (0.062 in.) diam Hastelloy W wire.

Electron-beam welding was done in a single pass. Because of the occasional undercutting, a second (cosmetic) pass was sometimes used. Even when the second pass was used, the weld and the HAZ were much narrower than were those created by arc welding, and they were unaffected below the crown of the weld. Because the general effect of the welding heat was to decrease the hardness and strength of the base metal, EBW, which produced less heat, was selected.

There were no unusual problems associated with the EBW procedure. Plates were machined square and then were degreased. Just before welding, surface films were removed from all surfaces to be welded by brushing with a stainless steel wire brush followed by wiping with alcohol. The plates were then fixtured into an assembly roughly resembling a bathtub having sides about 250 mm (10 in.) high and a floor area of about 510 by 1015 mm (20 by 40 in.). A maximum tolerance of 0.13 mm (0.005 in.) was allowed on fit-up for joint mismatch and clearance. Starting and runoff tabs, made of the same duplex plate, were attached to joint ends to contain variations in beam initiation and termination. The fixture was a simple arrangement of toggle clamps and stainless steel blocks that could be set up for flat-position welding on a track-guided carriage in the vacuum chamber.

After beam alignment and vacuum pump-down, each joint was welded in a single pass without tack welding and without beam oscillation. Because undercutting occurred where fit-up approached the maximum tolerance, a second (cosmetic) pass occasionally was used. The effect of the cosmetic pass on the weld cross section is shown in Fig. 28; the machine settings for the defocused beam used to make the cosmetic pass are in the table with Fig. 28.

Procedure Development and Practice Considerations for Electron-Beam Welding

EBW of Stainless Steels

The properties and the welding metallurgy of stainless steels are discussed in the Section "Selection of Stainless Steel" in this Volume.

Austenitic Stainless Steels

The high cooling rates typical of EBW help to inhibit carbide precipitation, because of the short time during which the steel is in the sensitizing-temperature range. Filler metal is used in welding joints that cannot be fitted together closely.

Effect of Air and Helium Atmospheres on Selected Parameters. Figure 29 shows the effect of welding speed on penetration of nonvacuum welds made in austenitic stainless steel and the effect of ambient gas and power on the penetration versus speed curve. Curves identified as helium penetration-versus-speed curves were performed using a helium effluent-style lower orifice design, that is, using a lower (exit) orifice that is capable of blowing helium into the atmosphere with enough directed flow to provide a helium gas column in which the beam can travel.

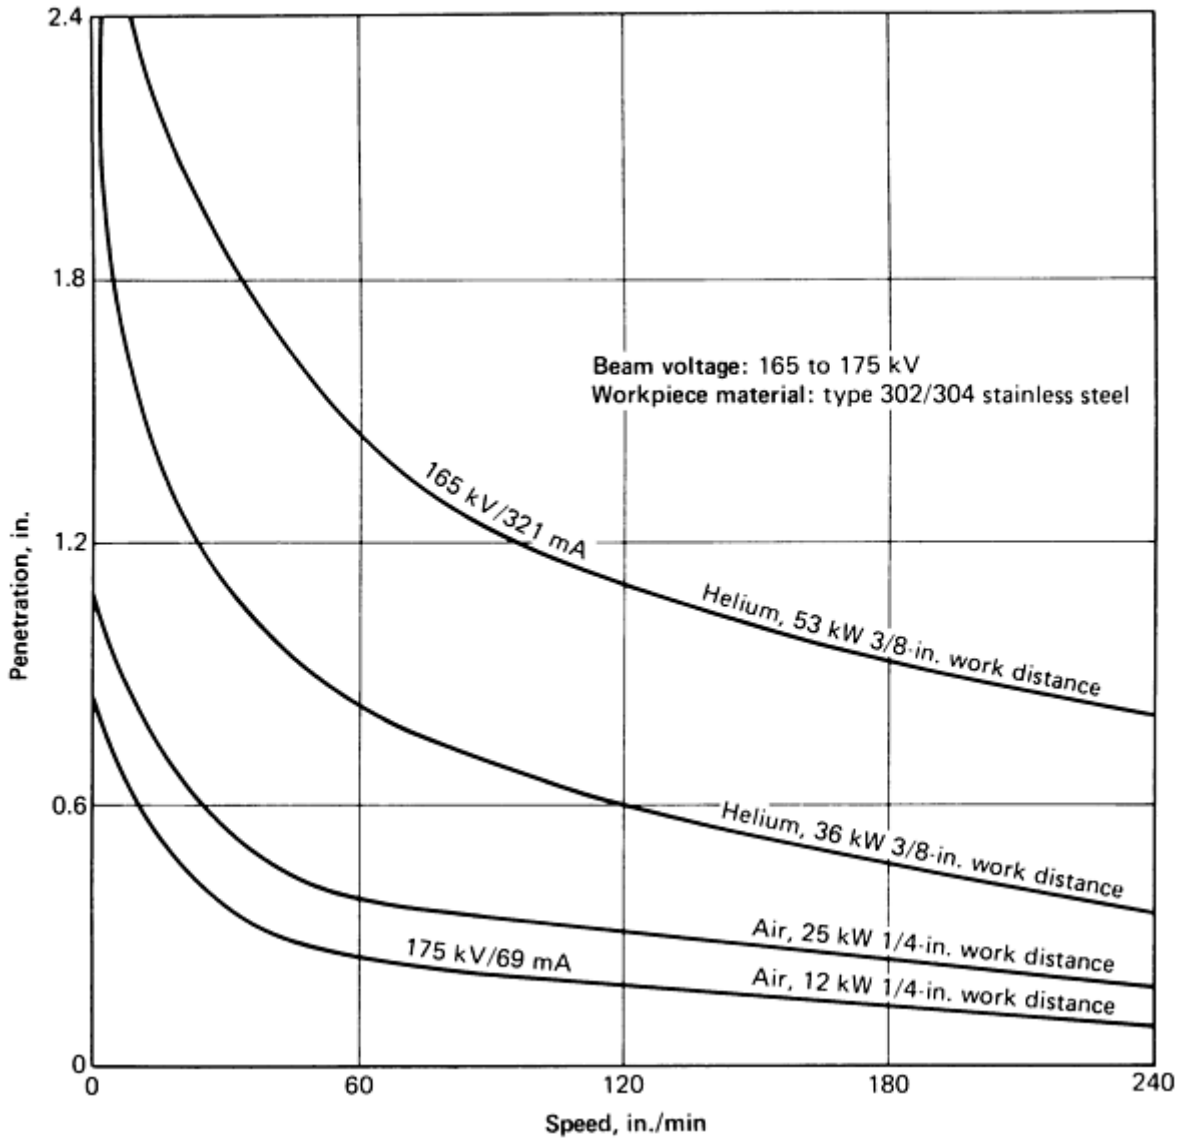

FIG. 29 PLOT OF PENETRATION VERSUS WELDING SPEED AS A FUNCTION OF SELECTED BEAM VOLTAGES, ATMOSPHERES, POWER LEVELS, AND WORK DISTANCES TO WELD TYPE 302 TO TYPE 304 AUSTENITIC STAINLESS STEELS

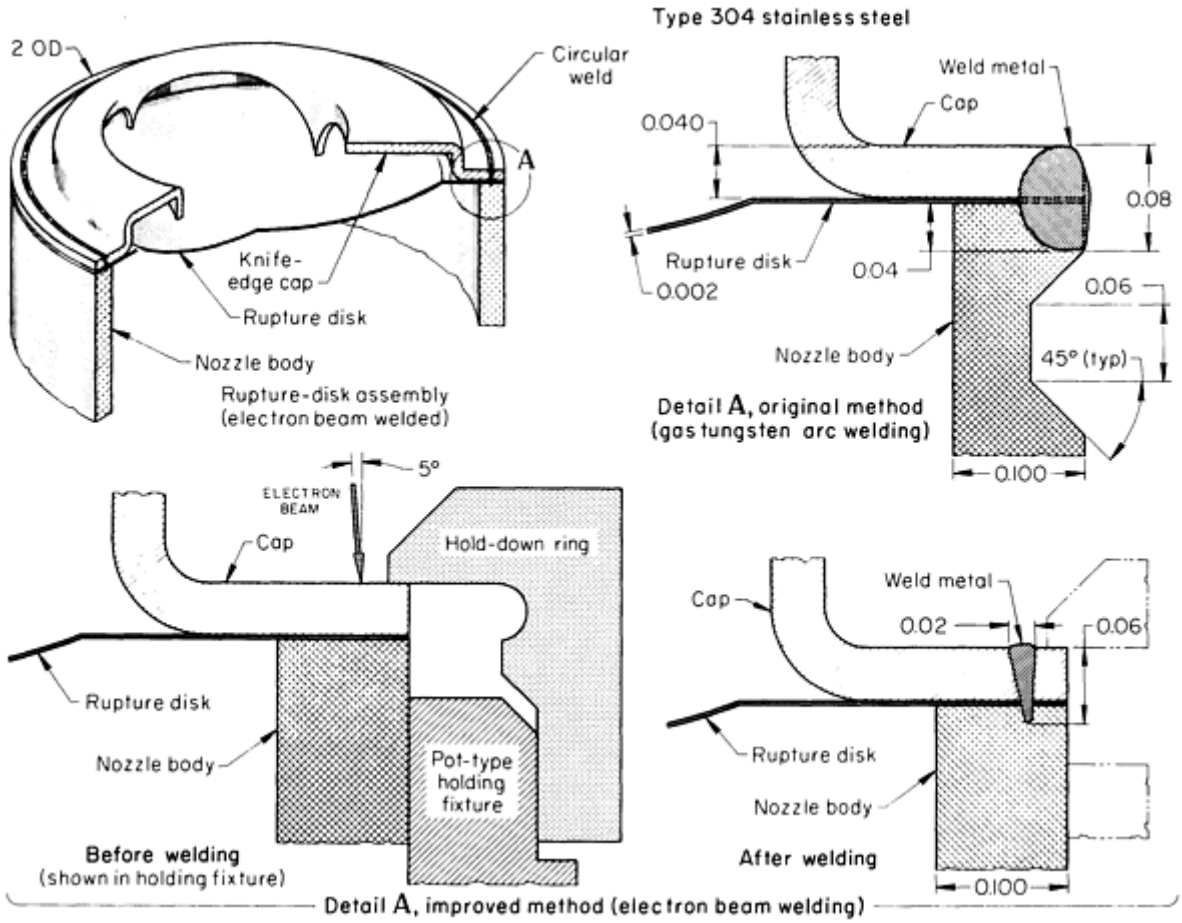
Example 2: Melt-Through Welding of 0.05 mm (0.002 in.) Thick Foil.

A rupture-disk assembly (Fig. 30) designed for gas-pressure relief consisted of three components: (1) a 50 mm (2 in.) diam nozzle of 2.5 mm (0.100 in.) thick type 304 stainless steel attached to an outer pressure vessel (not shown); (2) a 0.05 mm (0.002 in.) thick cupped rupture disk of type 304 stainless steel; and (3) a 1.02 mm (0.040 in.) thick cap, also of stainless steel, containing an off-center flued-in hole with downward-pointing knife edges.



JOINT TYPE	**CIRCULAR, THREE-PIECE COMER**
WELD TYPE	**MELT-THROUGH (SPIKE)**
MACHINE CAPACITY	**50 KV AT 250 MA**
GUN TYPE	**DIODE; FIXED DURING WELDING**
VACUUM CHAMBER	**STEEL: 1370 × 1220 × 1220 MM (54 × 48 × 48 IN.) WITH FULL-WIDTH END DOORS**
FIXTURES	**56-PIECE HOLDING TOOL WITH INDIVIDUAL ROTATION; TABLE WITH *X-Y* MOTION**
WELDING POWER	**26 KV AT 16 MA**
WELDING VACUUM	**0.65 MPA (5×10^{-6} TORR)**
PUMPDOWN TIME	**10 MIN**
WORKING DISTANCE	**38 MM (1.5 IN.)**
BEAM FOCAL POINT	**SHARP AT WORK SURFACE**
BEAM SPOT SIZE	**∼0.51 MM**

	(~0.020 IN.) DIAM
WELDING SPEED	**2540 MM/MIN (100 IN./MIN)**
NUMBER OF PASSES	**ONE, PLUS 30° DOWNSLOPE**
SETUP TIME	**48 MIN**
PRODUCTION RATE	**44 $\frac{1}{2}$ PIECES/H**

FIG. 30 COMPARISON OF EBW AND GTAW WELDS APPLIED TO A TYPE 304 STAINLESS STEEL RUPTURE DISK ASSEMBLY

The three components were joined by a single weld that was required to have a leak rate of less than 10^{-8} cm^3/s (6×10^{-10} $in.^3/s$) when tested with a helium mass spectrometer. When pressure in the nozzle exceeded the design limit, the cupped rupture disk reversed its shape from concave to convex, puncturing itself against the knife-edge of the cap. Leaktightness, rather than high tensile strength, was the welding objective. The material was selected for long, maintenance-free service, rather than for resistance to a corrosive environment.

Originally, the components were joined in one pass by GTAW, using the design shown in detail A, original method, Fig. 30. A circular groove was cut in the nozzle wall to help localize the weld bead, which was made without filler metal. Light pressure was applied at both ends of the assembly to hold the parts in alignment for welding.

This procedure resulted in numerous rejects because of leaks. Often, difficulty was encountered in getting the disks to lie absolutely flat on the joint surface. The 0.05 mm (0.002 in.) thick rupture disks, having been blanked and formed in the work-hardened condition, were tough, springy, and sometimes burred. As a result, they occasionally were burned back, instead of being fused into the weld bead, causing leaks. It was usually impossible to salvage this type of defect by rewelding.

To eliminate these difficulties, the operation was converted to EBW, even though initial equipment and tooling costs were high. The EBW machine used for this application had a relatively large vacuum chamber with full-width doors to facilitate loading and unloading of large, multiple-part fixtures. The holding fixture used had 56 receptacles to position and individually rotate 56 assemblies under a stationary gun. The fixture was mounted on a horizontal table equipped with *x-y* motion control to permit optical alignment of the beam for welding each part in turn.

Each assembly was fitted into a cylindrical receptacle or pot that was equipped with a hold-down ring that forced the periphery of the disks and caps into close alignment, as shown in detail A, improved method, Fig. 30. A melt-through or spike weld was made, rather than an edge-flange weld at the periphery.

With this setup, the blanking and forming operations on the disks could be allowed the more realistic tolerance of ±0.05 mm (±0.002 in.) on flatness. The electron beam was angled slightly and was positioned close to the hold-down ring so that, in the event of a leak, the joint could be rewelded by running a second weld just inside the first weld.

The weld-localizing groove needed for the original GTAW was eliminated, and the electron-beam melt-through weld was made at a heat input of 0.0098 kJ/mm (0.25 kJ/in.) of weld length, which was much lower than for arc welding. The hold-down ring provided a slight chill effect, but enabled the nozzle body to function effectively as a heat sink.

Welding results from the electron-beam procedure were good. Joint defects of all types dropped to 3%, and most of the rejects could be salvaged by rewelding. A production rate of $44\frac{1}{2}$ assemblies per hour was a significant improvement over the original arc method.

Martensitic Stainless Steels

Although these steels can be electron-beam welded in almost any heat-treated condition, welding will produce a hardened, martensitic HAZ. Hardness and susceptibility to cracking increase with increasing carbon content and cooling rate.

Precipitation-Hardenable Stainless Steels

Precipitation-hardenable stainless steels can, in general, be electron-beam welded to produce good mechanical properties in the joint. The semiaustenitic types, such as 17-7 PH and PH 14-8 Mo, can be welded as readily as the 18-8 types of austenitic stainless steel. The weld metal becomes austenitic during welding and remains austenitic during cooling. In the more martensitic types, such as 17-4 PH and 15-5 PH, the low-carbon content precludes formation of hard martensite.

Some of the precipitation-hardenable stainless steels have poor weldability because of their high phosphorus content. Steels 17-10 P and HNM are not usually electron-beam welded.

EBW of Heat-Resistant Alloys

Because of the marked differences in composition and weldability among heat-resistant alloys (nickel-base, iron-base, and cobalt-base), generalizations concerning EBW of these alloys are not useful.

Solid-Solution Nickel-Base Alloys. Hastelloy N, Hastelloy X, and Inconel 625 are readily electron-beam welded. Hastelloy B and Inconel 600 can be welded to type 304 stainless steel and to themselves.

Precipitation-hardenable nickel-base alloys that are rated good in weldability by the electron-beam process include Inconel 700, alloy 718, Inconel X-750, and René 41. Alloy 718 can be welded in either the annealed or the aged condition. Inconel X-750 should be welded in the annealed condition, and René 41 should be welded in the solution-treated condition. Alloys of this group that have fair weldability include casting alloys 713C and GMR-235 and wrought Udimet 700 and Waspaloy.

Iron-Nickel-Chromium Base Alloys. This group of alloys is also known as the iron-base heat-resistant alloys. The most readily welded alloy of this group, using EBW, is 19-9 DL, which has excellent weldability and which produces the best results when preheating is used. Alloy N-155 has good weldability, and alloys 16-25-6 and A-286 are rated fair. Alloy A-286 is usually welded in the solution-treated condition; hot cracking may result if welded in the aged condition.

Cobalt-Base Alloys. HS-21 has good weldability in unrestrained joints (and is generally poor in restrained joints). Cast alloy H-31 (X-40) has fair-to-good weldability, and alloy S-816 has fair weldability.

EBW of Refractory Metals

Electron-beam welding is the preferred technique for welding of refractory metals and their alloys. These materials, with melting temperatures in excess of 2200 °C (4000 °F), can be processed more efficiently with the intense heat source of the electron beam, which allows for localized fusion without excessive heating of the adjacent base metal. Weld-zone properties in refractory metals and alloys are particularly sensitive to contamination by interstitial elements such as carbon, hydrogen, nitrogen, and oxygen, which increase the already high ductile-to-brittle transition temperature of the weld zone and increase the notch sensitivity beyond the limits required for practical processing of these materials.

The possibility of atmospheric contamination during welding is essentially eliminated by EBW in a high-vacuum environment. Interstitial impurities already present in the base metal, however, have a significant effect on the weldability of the metal and alloy system. The Group V metals (e.g., niobium and tantalum) are softer, less subject to strain hardening, and less prone to the brittle behavior usually associated with the Group VI metals (molybdenum and tungsten). The very low room-temperature ductility of the Group VI metals gives rise to cracking problems due to cyclic thermal stresses during welding. Preheating above 300 °C (575 °F) reduces the susceptibility to this problem.

Excessive grain growth in the weld HAZ and fusion zones can produce cracking during the welding process or during subsequent application of the weldment. Grain coarsening can be controlled to some extent by specifying a fine-grained starting material and minimizing the total heat input during welding. The morphology of the fusion zone is also important. High welding speeds (>610 mm/min, or 24 in./min) selected to minimize heat input can promote pronounced directionality of grain growth in the weld pool, leading to a plane of weakness at the weld centerline. High-frequency (>1

kHz) beam oscillation can be applied to restore an elliptical weld-pool geometry at high travel speeds and eliminate the pronounced delineation of the weld centerline.

As with any low-ductility weldment, the degree of restraint imposed on the joint during the welding operation should be minimized. Most refractory metals and alloys can be welded in thin (<1.0 mm, or 0.04 in.) sheet. The weldability decreases with increasing section thickness in accordance with the increase in restraint. Weld joints should be designed to reduce the restraint by effective use of flange butt and standing edge designs, and by the incorporation of relief grooves to accommodate elastic/plastic strain in the material adjacent to the weld zone.

In contrast to many other alloy systems, the weldability of refractory metals tends to improve with the addition of alloying elements. Specific alloying elements can improve the low-temperature ductility of refractory metals and thus directly affect the weldability and weld mechanical properties. The overall weldability of tungsten is improved by the addition of substitutional alloying elements such as rhenium and molybdenum. As indicated previously, interstitials also raise the transition temperature; this effect can be reduced by alloying with elements that form stable carbides, oxides, and nitrides. For example, titanium and zirconium in molybdenum "scavenge" the interstitial impurities to improve low-temperature ductility and provide a dispersion-strengthening effect. Examples of successful electron-beam welds made in refractory metals and alloys are given in Table 5.

TABLE 5 TYPICAL APPLICATIONS AND CONDITIONS FOR EBW OF REFRACTORY METALS AND ALLOYS

APPLICATION	**BEAM SETUP**					COMMENTS
	KV	**MA**	**mm/min**	**in./min**	**FOCUS**

Tungsten is the most difficult refractory metal to weld because of its high melting point (3410 °C, or 6170 °F), sensitivity to thermal shock, and room-temperature brittleness of welds and the HAZ. High-purity tungsten sheet can be electron-beam welded if the weld area is preheated and if external restraint is minimal. Successful welds have been made in sections as thick as 4.1 mm (0.16 in.); however, the resulting as-welded material is brittle and highly notch sensitive. Tungsten metal, manufactured by a chemical vapor deposition process, has also been proven to be weldable in sections <0.5 mm (<0.02 in.).

Molybdenum can be readily welded by EBW if chemical purity, grain size, and texture of the base metal are carefully monitored. Partly because of its lower melting point (2610 °C, or 4730 °F), molybdenum has better thermal shock resistance than tungsten; thus, narrower welds and higher welding speeds can be used. Preheating may or may not be necessary, depending on the starting material and the degree of restraint on the weld joint. When preheating is used, the workpiece should be heated to 205 °C (400 °F) or higher, followed by a postweld stress relief at 870 to 980 °C (1600 to 1800 °F).

Figure 31 shows an electron-beam weld zone in high-purity molybdenum. Penetration is approximately 3.05 mm (0.12 in.) to the root of a step-butt weld joint. This weld was made without preheat but with a high-frequency oscillation to

maintain an elliptical weld pool and influence the direction of grain growth in the solidifying metal. The growth direction at the center of the fusion zone is parallel to the welding direction, and the section is therefore an end view of the columnar grains. This type of solidification structure should not be confused with the grain refinement phenomena sometimes claimed to result from stirring of the weld pool. Because solidification in high-purity metals is essentially a columnar-planar growth, refinement most probably cannot be achieved by stirring the weld pool.

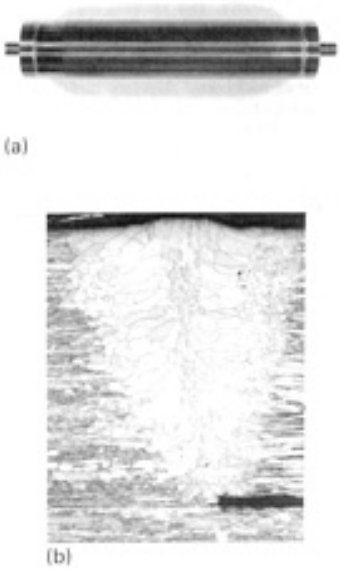

FIG. 31 ELECTRON-BEAM WELD ZONE IN HIGH-PURITY MOLYBDENUM. (A) MOLYBDENUM HEAT PIPE TEST ASSEMBLY SHOWING END CAPS JOINED BY EBW. (B) PHOTOMICROGRAPH SHOWING MORPHOLOGY OF WELD FUSION ZONE. 25×

Titanium and zirconium are the common alloying elements added to molybdenum to scavenge interstitial impurities and improve low-temperature ductility. The transition temperatures of welds in these alloys, however, are still above room temperature. Significant increases in the low-temperature ductility of these alloys can be obtained by solution and aging heat treatments. The greatest improvements in ductility are obtained by solution and aging heat treatments. The greatest improvements in ductility are obtained by the addition of rhenium; a 50 wt% addition of rhenium lowers the transition temperature of recrystallized molybdenum from approximately 52 to 205 °C (125 to 400 °F).

Niobium, which melts at 2468 °C (4474 °F), is easier to weld than molybdenum or tungsten. Gas-tungsten arc welding is often used, but EBW provides better protection, narrower welds, and lower heat input. Preheating is not necessary, but postweld vacuum stress relief is used to restore ductility and toughness, especially in the niobium alloys.

Unalloyed niobium is easily electron-beam welded, but has relatively low strength. More alloys have been developed, mainly for higher strength, than for the other refractory metals. Alloying usually reduces weldability, but most weld joints in alloys retain about 75% efficiency, and good structural properties can be obtained for service temperatures in the range of about 1095 to 1650 °C (2000 to 3000 °F), depending on the alloy. Chill tooling is often used, but copper, nickel, and stainless steel should be avoided to prevent contamination of the weld metal.

Tantalum is the most easily weldable of the four refractory metals. Because of its high melting point (2996 °C, or 5425 °F) and good thermal conductivity, thicknesses of 1.52 mm (0.060 in.) or more must be rapidly heated to high temperatures for welding. Copper chills are used to avoid distortion and weld sagging and to shorten the time the assembly has to remain in the vacuum chamber, thus limiting grain growth.

Weldability of tantalum alloys containing other refractory elements is somewhat lower than that of unalloyed titanium; however, successful welds have been made in alloys Ta-10W, T-111 (Ta-8.0W-2.5Hf-0.003C), and T-222 (Ta-9.64W-2.4Hf-0.01C). Because of high vapor pressure, alloys containing vanadium are better welded by the gas-tungsten arc process.

EBW of Aluminum Alloys

Single-pass, full-penetration welds with depth-to-width ratios of more than 20 to 1 have been made in 150 mm (6 in.) thick aluminum alloy plates. The low heat input, narrow HAZ, and short heat cycle result in minimum decrease in mechanical properties, especially in assemblies of some of the heat-treatable alloys.

Non-Heat-Treatable Alloys. The mechanical properties of electron-beam welds in the non-heat-treatable alloys (1*xxx*, 3*xxx*, and 5*xxx* series) are virtually the same as those obtained by GTAW. If the alloy is in a strain-hardened condition, the weld properties closely approach the annealed properties of the base metal.

Heat-treatable alloys of the 2*xxx*, 6*xxx*, and 7*xxx* series are crack sensitive to varying degrees when welded. Some may also be prone to porosity. The condition of the zone immediately adjacent to the weld is critical in determining weldability.

The effect on penetration of varying working distance (within practical operating limits and with other variables held constant) is shown in Fig. 32 for 6.4 mm ($\frac{1}{4}$ in.) thick aluminum alloy 2219. When maximum working distance was used, penetration was only about 80%, and maximum weld width was about one-third greater than with minimum working distance.

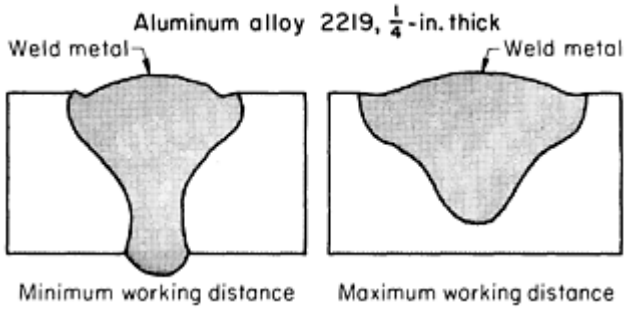

FIG. 32 VARIATION IN PENETRATION OF 6.5 MM ($\frac{1}{4}$ IN.) THICK 2219 ALUMINUM ALLOY AS A FUNCTION OF WORKING DISTANCE WHEN USING NONVACUUM EBW

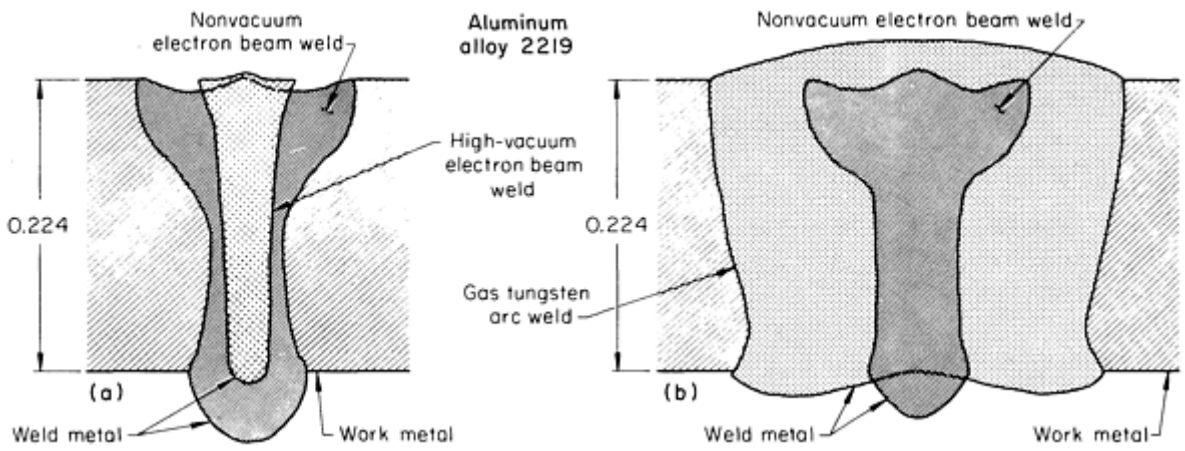
Typical shapes of full-penetration welds made in 5.69 mm (0.224 in.) thick aluminum alloy 2219 by nonvacuum EBW (EBW-NV) and high-vacuum EBW (EWB-HV) and by GTAW are shown in Fig. 33.



WELDING CONDITIONS	EBW-NV VERSUS EBW-HV		EBW-NV VERSUS GTAW	
	HIGH-VACUUM EBW	**NONVACUUM EBW**	**GTAW**	NONVACUUM EBW
VOLTAGE, KV	150	140	13V	**140**
CURRENT, MA	20	30	270A	**20**
WELDING SPEED, MM/MIN (IN./MIN)	2540 (100)	2540 (100)	510 (20)	**510 (50)**
WELDING ENERGY, KJ/MM (KJ/IN.)	**0.071 (1.8)**	**0.098 (2.5)**	**0.41 (10.5)**	**0.13 (3.36)**

FIG. 33 COMPARISON OF FULL-PENETRATION WELDS OBTAINED BY SELECTED WELDING PROCESSES TO JOIN 2219 ALUMINUM ALLOY. (A) EBW-NV VERSUS EBW-HV. (B) EBW-NV VERSUS GTAW

Comparing the nonvacuum and high-vacuum electron-beam welds in Fig. 33(a), heat input for the nonvacuum weld was about 40% greater, producing a midpoint weld width about 33% greater and a maximum crown width 160% greater than those of the high-vacuum weld. Comparing the nonvacuum electron-beam weld to the gas-tungsten arc weld in Fig. 33(b), heat input for the typical nonvacuum weld was 32% of that for the arc weld, producing a midpoint weld width about 25% and a maximum weld width about 56% of the corresponding widths for the arc weld. Compared to the arc weld, the widest weld produced by EBW-NV under workable operating conditions was about 42% as wide at midpoint and about 70% as wide at the crown.

Studies on welding 6.4 mm ($\frac{1}{4}$ in.) thick aluminum alloy 2219 showed average shrinkage of 0.08 to 0.13 mm (0.003 to 0.005 in.) for high-vacuum welds and shrinkage of 0.36 mm (0.014 in.) for high-heat-input nonvacuum welds, compared with a normal shrinkage of 0.76 mm (0.030 in.) for gas-tungsten arc welds.

The 6*xxx* series alloys are only slightly affected by the heat cycles of EBW. Alloys 2219, 7039, and 7005 appear to be the least affected alloys of their respective series. The techniques used to prevent cracking in EBW of the heat-treatable aluminum alloys are:

- SPECIAL CARE IN PREWELD CLEANING TO AVOID POROSITY AND OXIDE INCLUSIONS IN THE WELD METAL
- PRESTRESSING JOINTS IN COMPRESSION BY USING INTERFERENCE FITS WHEN POSSIBLE
- USE OF A DUCTILE FILLER METAL, USUALLY IN THE FORM OF A THIN STRIP PREPLACED IN THE JOINT, WHICH WILL YIELD UNDER SHRINKAGE STRESS AND FILL JOINT OPENINGS
- SELECTION OF BEAM POWER, BEAM SPOT SIZE, AND WELDING SPEED TO CREATE AS NARROW WELDS AS PRACTICAL DURING SHORT WELDING HEAT CYCLES, THUS AVOIDING EXCESSIVE GRAIN-BOUNDARY MELTING
- USE OF POSTWELD HEAT TREATMENT TO RESTORE THE STRENGTH AND DUCTILITY OF THE WELD AND HAZ
- DESIGNING OR LOCATING JOINTS TO BE FREE OF EXTERNALLY IMPOSED RESTRAINTS, REINFORCING JOINT AREAS, AND, WHEN POSSIBLE, WELDING IN THE SOLUTION-TREATED CONDITION, WITH POSTWELD AGING

Some aluminum alloy welded joints (for example, 38.1 ram, or 1.5 in., thick, welded 7075-T651 plate) exhibit lower mechanical properties than unwelded plate due to overaging in the HAZ. Postweld solution and aging heat treatments improve joint properties. At high travel speeds, porosity can develop in the weld from vaporization of certain elements,

such as zinc, in the alloy. Aluminum alloy 7075, which contains 5.6% Zn, is an example of this. Travel speed should be reduced in EBW of high-zinc aluminum alloys so that the vapor has time to escape to the surface before the weld metal solidifies. Zinc-free alloys (the 6*xxx* series alloys, for example) can be welded at higher speeds without the threat of porosity.

EBW of Copper and Copper Alloys

The EBW of copper and its alloys is influenced by the same factors that affect the arc welding of these metals (see the article "Welding of Copper Alloys" in this Volume). The high thermal conductivity of copper causes less difficulty in electron-beam welding than in arc welding.

Molten metal may be expelled from the weld joint during EBW of nondeoxidized coppers (especially alloy C11000, tough pitch copper), causing spatter and uneven weld surfaces. This can usually be remedied by the use of a cosmetic pass. The vacuum environment eliminates possible hydrogen embrittlement; nevertheless, root voids and porosity still can occur.

The presence of low-melting elements ordinarily makes the welding of free-machining copper alloys impractical, and the volatility of zinc prevents the welding of the brasses and other zinc-containing copper alloys. The remaining zinc-free copper alloys can generally be electron-beam welded without any unusual problems.

EBW of Magnesium Alloys

Electron-beam welding is used to a limited extent, chiefly for repair, on commercial wrought and cast magnesium alloys that contain less than 1% Zn. The relative suitability of alloys for EBW is generally the same as for arc welding, as discussed in the article "Welding of Magnesium Alloys" in this Volume.

Techniques. Special techniques and close control of operating variables are needed to prevent voids and porosity at the root of the weld, because of the high vapor pressure of magnesium, which has the lowest boiling point (1107 °C, or 2025 °F) of any commonly welded metal. This difficulty is aggravated by the presence of zinc, which has an even lower boiling point (906 °C, or 1663 °F). It is usually impractical to electron-beam weld magnesium alloys that contain more than 1% Zn.

Circular oscillation of the beam or the use of a slightly defocused beam is helpful in obtaining sound welds. The most satisfactory technique is to use integral or tightly fitted backing of the same alloy and to ensure that welding conditions are held to values that trial welds have shown will either minimize porosity and voids or localize them in an area where they can be tolerated or removed by machining.

EBW of Titanium Alloys

All of the commercial alloys of titanium that can be joined by arc welding can also be joined by EBW. Their relative weldability and response to heat cycling in EBW are generally the same as in arc welding, which is discussed in the article "Welding of Titanium Alloys" in this Volume.

Applicability. The vacuum environment of EBW prevents exposure to the atmospheric contaminants that cause embrittlement of titanium alloys, whereas arc welding processes must use elaborate and costly shielding methods to accomplish this. Cost studies show that direct labor costs for EBW of titanium sections more than 25 mm (1 in.) thick are less than for arc welding, provided a suitably large vacuum chamber is available.

Techniques. Filler metal is not ordinarily used, and the work is not preheated. Tack welding, contrary to experience in GTAW, presents no difficulties in EBW. For optimum results, welding is done in a high vacuum, but medium-vacuum welding is satisfactory for many applications.

Alloy Ti-6Al-4V, the alloy most frequently used in assemblies to be welded, can be electron-beam welded in either the annealed or the solution-treated-and-aged condition. For weldments that will be used at elevated temperatures, a preferred process sequence is anneal, weld, solution treat, and age. For other service conditions, a process sequence of solution treat, age, and weld gives almost the same strength properties and only slightly lower fracture toughness.

Procedure Development and Practice Considerations for Electron-Beam Welding

EBW of Beryllium

Beryllium is well suited for EBW. Narrow fusion zone and low heat input help control cracking. Also, the vacuum atmosphere controls toxic beryllium fumes and prevents oxidation. Weldability primarily is affected by the chemical composition of the metal. Beryllium oxide is the major contaminant in powder source material. Lower beryllium oxide content has been found to improve ductility, as well as weldability (Ref 3). Generally, the beryllium oxide content is limited to 1.5 wt% maximum. Lower aluminum content also is reported to improve weldability by decreasing crack susceptibility. The aluminum tends to produce a hot short condition. This hot short condition is reduced if the aluminum is tied up in a compound, such as $AlFeBe_4$, rather than existing as free aluminum in the grain boundaries (Ref 4).

Autogenous Welds. Cracking can be minimized in autogenous welds (no filler metal added) by reducing joint restraint during cooling. This is accomplished by appropriate fixturing, proper joint design, thin members, and good part fit-up. Most welding must be accomplished at sharp focus to minimize the size of the fusion zone. For deep welds, preheat has been found to improve weldability. For example, welds 1.3 mm (0.050 in.) thick have been made without preheat in low-oxide powder source beryllium (Ref 5). The same metal can be welded up to 2.5 mm (0.1 in.) thick with a preheat of approximately 345 °C (650 °F). In addition to cracking, high oxide levels can cause porosity and excessive cratering in the weld. Typical parameters for autogenous welds are given in Table 6.

TABLE 6 EFFECT OF PREHEAT ON THE WELDABILITY OF BERYLLIUM AND CONDITIONS FOR FULL-PENETRATION WELDS

THICKNESS		VOLTAGE, KV	CURRENT, MA	TRAVEL SPEED		PREHEAT TEMPERATURE TO PREVENT CRACKING	
MM	IN.			MM/MIN	IN./MIN	°C	°F
2.54	0.100	110	7.5	510	20	500	**500**
1.90	0.075	100	7.0	510	20	500	**500**
1.40	**0.055**	**90**	**5.0**	**510**	**20**	**120**	**250**

Braze Welds. The greatest success in EBW of beryllium is obtained by using a ductile filler metal in the weld; generally, aluminum is used. Optimum properties are obtained when the fusion-zone microstructure consists of beryllium dendrites surrounded by a ductile aluminum matrix. A fusion zone with less than 30% Al contains large beryllium dendrites which are susceptible to microcracking (Ref 4). Welds can be made with less than 30% Al in the fusion zone, but caution must be used.

Filler metal may be added by several methods. One method is to preplace aluminum shim stock in the joint. Care must be taken to ensure the shim stays in the joint during the weld. This may be accomplished by tack welding the joint prior to the penetration pass. By using a 0.51 mm (0.020 in.) thick by 2.54 mm (0.100 in.) deep 1100 aluminum shim, welds to 3.05 mm (0.120 in.) penetration have been made without preheat. A typical weld is shown in Fig. 34.

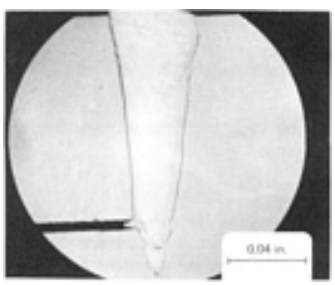


FIG. 34 ELECTRON-BEAM BRAZE WELD IN BERYLLIUM. COURTESY OF ROCKWELL INTERNATIONAL ENERGY SYSTEMS GROUP

An alternative method to brazing welds is to use an electron-beam cold wire-feed process similar to that used for stainless steel (Ref 6). In this process, a narrow, deep groove in the beryllium is filled with aluminum wire fed into the weld pool. A typical joint uses 718 aluminum wire, 0.76 mm (0.030 in.) in diameter, fed into a modified J-groove. The weld joint has a 0.64 mm (0.025 in.) root radius with a 10° 20' included angle. Welds to 2.54 mm (0.100 in.) have been successfully made this way (Fig. 35).

Procedure Development and Practice Considerations for Laser-Beam Welding

J. Mazumder, University of Illinois at Urbana-Champaign

Introduction

LASER-BEAM WELDING (LBW) is a joining process that produces coalescence of material with the heat obtained from the application of a concentrated coherent light beam impinging upon the surface to be welded. The principles of laser beams and the LBW process are discussed in the article "Laser-Beam Welding" in this Volume. In the present article, the steps that must be considered when selecting the LBW process will be described. Included will be a review of the individual process variables that influence procedure development of the process. In addition, joint design and special practices related to LBW will be discussed.

Procedure Development and Practice Considerations for Laser-Beam Welding

J. Mazumder, University of Illinois at Urbana-Champaign

Process Selection

Laser-beam welding is characterized by its low distortion and low specific energy input. It is an accurate inertialess method capable of high welding speeds for most materials, including many difficult-to-join materials. The process is often selected for high-volume, high-speed applications for joining materials/components that pose problems during arc welding, such as titanium alloys used for pacemakers. Often the selection criteria depends on economics, which is related to joining rate, welding speed, distortion, and postwelding treatment needs, among many other considerations. Another important consideration is whether the higher speeds can offset the higher initial capital costs within a reasonable time period. Low specific energy input is responsible for applications such as pace-makers because it reduces the possibility of thermal damage of the sophisticated electronics contained in such devices. Some manufacturers of cigarette lighters are now using LBW as an alternative to resistance welding because of the lower porosity in laser welds.

Economics combined with the smaller HAZ and higher overall weld toughness associated with LBW makes it a popular joining method for high-volume automotive applications. For example, multiple pieces of different compositions are joined by LBW to form blanks for automobile body components such as side-frame panels. These blanks need considerable weld toughness to withstand the stresses induced during subsequent press forming operations. Weld geometry is another consideration for the selection of the process. Since a smaller volume of material is melted due to the low specific energy input, weld defects such as undercuts are also minimized. This is especially important for applications involving dissimilar workpiece thicknesses, which have a higher probability of undercuts.

Another example where the narrow HAZ combined with high welding speed makes LBW a preferred method is the welding of planetary gears used in automobile powertrains. Planetary gear teeth are so closely spaced that it is difficult to access the weld joint without melting the neighboring gear teeth using conventional (arc) welding. This is one of the oldest LBW applications and it is routinely carried out worldwide.

Metallurgical considerations are sometimes responsible for the selection of the LBW process. The characteristic low specific energy input for this process results in a higher cooling rate. Higher cooling rates are often needed to suppress precipitation of harmful intermetallic compounds (which may promote brittle fracture) during the solidification of the weld pool. This is an important criteria for welding of many superalloys. For titanium alloys, high cooling rate limits the grain growth and oxidation during solidification, making it possible to weld titanium alloys outside a vacuum chamber with modest inert gas shielding. High cooling rates also help to avoid sensitization during welding of stainless steels. On the other hand, high cooling rates may cause problems in many ferrous alloys by promoting martensitic transformation and higher residual stresses; however, this is often balanced by the smaller size of the HAZ.

In many applications where resistance spot welding has been traditionally used, laser welding can offer many advantages, including single-side access and reductions in weight and costs by removing the tab* needed in resistance welding. Up to 60 kg (130 lb) of steel can be saved from an automobile by replacing resistance spot welding with laser welding and taking advantage of the design flexibility (Ref 1).

Another key factor in the successful implementation of laser welding is the selection of the right laser for a given application. Characteristics and parameters of commercial lasers available for welding are listed in Table 2 of the article

"Laser-Beam Welding" in this Volume. Carbon dioxide (CO_2) lasers with up to 25 kW power capacities and pulsed Nd:YAG lasers with up to 500 W peak power have been the workhorse for the industry until recently. The majority of the CO_2 laser applications involve lasers up to 5 kW. Recently, continuous Nd:YAG lasers with power capacities up to 2.5 kW have been made available.

In addition to welding speed and depth of penetration, which are the most important LBW attributes, the flexibility and precision of beam delivery are also important criteria for selecting LBW. Multiaxis workstations and robotics are already available in the market for CO_2 laser applications. However, one of the major advantages of the Nd:YAG laser is its capability to deliver the energy through a fiber. Unfortunately, no fibers are yet available for CO_2 lasers with a 10.6 μm wavelength. Most of the high-speed and deep-penetration welding are carried out with CO_2 lasers with power in excess of 1 kW. Continuous Nd:YAG lasers can outperform CO_2 lasers with the same power capacity, but they are limited by the maximum power of 2.5 kW. For reflective materials such as aluminum, Nd:YAG has better coupling, especially for conduction-mode welding, due to their shorter wavelength (1.06 μm). For deep-penetration welding, the coupling advantage is not significant.

Procedure Development and Practice Considerations for Laser-Beam Welding

J. Mazumder, University of Illinois at Urbana-Champaign

Procedure Development

The key factor for procedure development is the selection of optimum independent and dependent process variables. The independent process variables for laser welding include incident laser-beam power, incident laser-beam diameter, traverse speed, absorptivity, shielding gas, depth of focus and focal position, and weld design and gap size. The important dependent variables are depth of penetration, microstructure and mechanical properties of laser-welded joints, and weld pool geometry. Detailed discussions of most of these variables are provided in Ref 2. They are discussed below in view of their role in procedure development.

Power density is defined as the incident power per unit area. In any welding process it is the power density that determines the depth of penetration and joining rate for the process, not the total power of the source. Therefore, beam diameter and spatial distribution of the laser-beam energy play an extremely important role because they determine the area of incidence. Two other variables affecting the ultimate power density driving the welding process are absorptivity and plasma-beam interaction, such as refraction. Position of focus with respect to the substrate and depth of focus of the beam also affects the power density and penetration depth.

Spatial distribution of the energy is generally constant for a given laser whereas absorptivity is a function of the substrate, its surface condition, and the laser-beam wavelength. Therefore, the most common practice for process development with a given laser and material is the selection of focusing optics for optimum power density and working distance by controlling the beam diameter. Thus, a working knowledge of the focusing optics is important for an engineer developing the laser welding process. Important formulae related to the laser as a welding tool will be summarized in following subsections dealing with process variables.

Interaction time is defined as the time a particular point on the substrate spends under the laser beam. In simple terms, it is the ratio of the beam diameter to the traverse speed. Strictly on the basis of heat transfer, one should account for the total time of heating and cooling at the point above the ambient temperature. This is, however, a much more difficult quantity to keep track of compared to the ratio of the traverse speed and beam diameter. Again, it is the interaction time which controls the weld pool profile, not the traverse speed alone. Laser welding procedure development involves the selection of optimum power density and interaction time after the selection of the laser.

Laser-Beam Power. As mentioned in the article "Laser-Beam Welding" in this Volume, laser-beam power is one of the primary variables in determining the penetration depth in laser welding. For process development, the first caution one should take is to calibrate the laser output power with the power delivered at the substrate. There is often a measurable loss due to the reflective and transmissive optics used to deliver the beam from the laser to the workpiece. For systems with fiber delivery, input coupling is often responsible for part of this loss. Fibers also scramble the spatial distribution resulting in poor focusing properties. Almost all commercial lasers are equipped with some kind of power-measuring device based either on a flowing-water calorimeter where the full beam is dumped, or a solid-state detector where a fraction of the laser energy is continuously deposited. Additional calorimetric devices should be maintained to measure power at the workpiece for periodic calibration of output power with the power delivered at the weld pool. For lasers with power in excess of a few hundred watts, water-cooled calorimeters are the most popular. For on-line monitoring many multi-kilowatt systems also use precalibrated solid-state detectors, usually behind one of the cavity mirrors which has a small leak around 1% or less. Several vendors offer both types of power meters. An excellent source of laser-beam device vendors is *Laser Focus World* buyer's guide, which is published annually (Ref 3).

In addition to the absolute power measurement, the beam mode (that is, the spatial distribution of energy) and beam diameter should be monitored since they also strongly affect the power density.

Laser-beam diameter is one of the most important variables since it determines the power density for a given total power (see the article "Laser-Beam Welding" for a more detailed discussion). The spatial distribution of energy in the beam affects the focusing characteristics of the beam. For a Gaussian beam, the diameter is defined as the $1/e^2$ of the central value (Fig. 1) and it contains almost 86% of the total power. The diffraction limited focal spot size, d_{min}, for such a Gaussian beam is given by the following relationship:

$$d_{mim} = \frac{1.27\, f\, l}{D} \qquad \textbf{(EQ 1)}$$

where D is unfocused beam diameter, f is the focal length of the focusing optics, and λ is the wavelength of the laser beam. This is an ideal situation and often the focused beam diameter will be larger due to aberrations and other imperfections in the focusing optics.

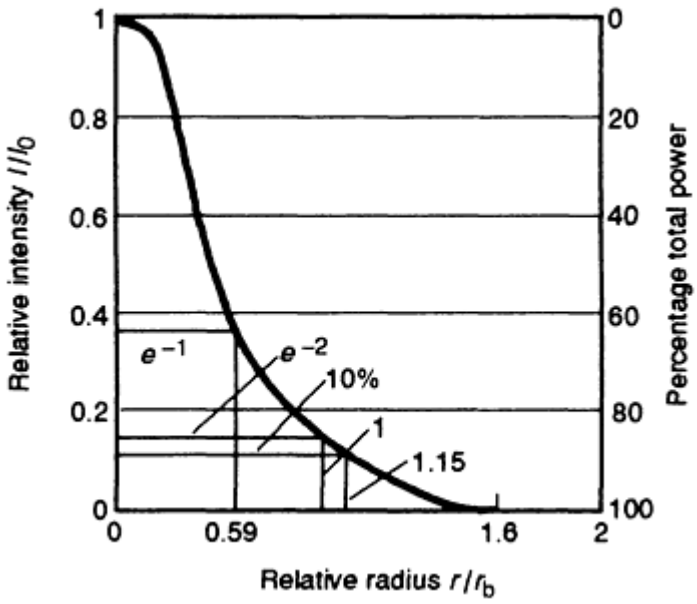

FIG. 1 VARIATION OF RELATIVE INTENSITY AND PERCENTAGE OF TOTAL POWER WITH RADIUS FOR A GAUSSIAN BEAM. SOURCE: REF 4

Diffraction limited spot size for various types of laser beam can be estimated using the relationships given in Eq 2, 3, 4. For a rectangular beam with a plane wave front:

$$d_{mim} = \frac{2 f l}{D} \qquad \textbf{(EQ 2)}$$

For a circular beam with a plane wave front:

$$d_{mim} = \frac{2.44 f l}{D} \qquad \textbf{(EQ 3)}$$

For a multimode beam (or a transverse electromagnetic mode (TEM_{mnq}) as described in the following subsection on laser-beam spatial distribution) with a plane wave front:

$$d_{mim} = \frac{2.44 f l}{D}(2m + n + 1) \qquad \textbf{(EQ 4)}$$

For example, if a 25 mm (1 in.) $TEM_{01}CO_2$ laser beam is focused by a 100 mm (4 in.) focal-length lens, the diffraction limited spot diameter is:

$$d_{mim} = \frac{2.44x100x10.6x10^{-3}}{25}(2.0 + 1 + 1) = 0.21mm$$

However, as indicated earlier, these are estimates for the theoretically possible minimum spot size. One of the more popular means for evaluation of beam quality is the recently developed "M^2 concept" (Ref 5), which is defined as:

$$M = \frac{\text{divergence of actual beam}}{\text{divergence of ideal gaussian Beam}} = \frac{q\,Actual}{q\,gaussian}$$

The correlated beam diameter based on the M^2 concept is:

$$d_{mim} = \frac{4M^2 f l}{p D} \qquad \textbf{(EQ 5)}$$

In this case, M has to be measured at two known locations in the beam propagation path. This reinforces to the point that a proper measurement technique for beam diameter is imperative for estimating the actual beam diameter and the power density.

There are several commercial systems now available for beam diameter measurement. Sasnet, *et al.* (Ref 5) describe one system which is specifically designed for beam evaluation based on the M^2 concept. This instrument is capable of measuring the beam width within 0.5 μm accuracy in two mutually perpendicular transverse directions. Knife edges are used to scan the beam and a set of lenses are traversed in the direction of the beam propagation to change the positions of the beam width. The measurement procedure and data acquisition and display are computer controlled.

Another commercial system is based on a hollow rotating needle which samples the beam. This is based on the research carried out by Loosen, *et al.* (Ref 6) and Lim and Steen (Ref 7) which resulted in the development of a laser-beam analysis system based on a rotating needle which reflects part of the beam to a set of detectors.

Although beam quality related to the ideal Gaussian beam is a good starting point, there is evidence that for high-power laser processing, this characterization may not be sufficient (Ref 8). Spatial coherence and temporal and local fluctuations are generally ignored, but they do affect the processing behavior. Many European research groups are working on characterizing the beam in terms of the mode coherence coefficient (MCC) which is based on a set of suitable modes and averaged intensity distribution and which takes into account the partial coherence properties of the beam.

Another complication of high-power laser welding is interaction with the plasma column. Rockstroh, *et al.* (Ref 9) found that free electrons in the plasma column cause absorption and refractions. For welding of aluminum with a CO_2 laser, as much as 30% of the energy is lost in the plasma and the refracted beam diameter is 8% larger. This measurement is based on the electron density measurement using emission spectroscopic technique. This observation is subsequently supported by similar measurements made by Lober, *et al.* (Ref 10, 11). Complete characterization of beam diameter will require both measurement at the focal spot before processing and monitoring of the beam refraction during the process using spectroscopic techniques.

Laser-Beam Spatial Distribution. Every laser resonator cavity, defined by the mirrors of the laser, has certain stable configurations of the electromagnetic field called "modes." A well-defined mode has a definite spatial distribution for the laser beam. As evident from Eq 4, the mode affects the focused beam diameter and leads to higher spot size for a given $f\lambda$ focusing optics. The general convention for indexing a mode is TEM_{mn} (transverse electromagnetic mode with *m* number of radial zero fields and *n* number of angular zero fields). TEM_{00} is the ideal Gaussian beam and will provide the smallest focused spot and highest power density. Most of the fast axial-flow lasers offer a TEM_{00} or TEM_{01} beam. Most of the transverse-flow lasers offer TEM_{01} (donut-shaped spatial distribution).

Intensity distribution for different modes can be calculated using the Hermite polynomial for rectangular coordinates and the LaGuerre polynomial for polar coordinates using the expressions for a TEM_{mn} mode beam given in Eq 6, 7, 8. For a rectangular coordinate:

$$\sqrt{\mathrm{I}_{mn}(x,y)} = \{H_m(\sqrt{2.x/R_b})H_n(\sqrt{2.y/R_b}).\exp[-(x^2+y^2)/R_b^2]^2\} \qquad \textbf{(EQ 6)}$$

For a polar coordinate:

$$\mathrm{I}_{mn}(r,q) = [L_m^n(2r^2/R_p^2)]^2(\sqrt{2.r/R_o})^{2n}.\exp[-2r^2/R_b^2]\cos^2 nq \qquad \textbf{(EQ 7)}$$

For a Gaussian beam with TEM_{00} mode:

$$1(\lambda) = \mathrm{EXP}(-2R^2/R_b^2) \qquad \textbf{(EQ 8)}$$

In Eq 6, 7, and 8, *x* is a variable, *r* is the radial position, 0 is the angular position of the beam, R_b is the beam radius at the $1/e^2$ point, H_m is the Hermite polynomial of order *m*, and L_m^n is the generalized LaGuerre polynomial.

A schematic of intensity distributions for different beam modes is shown in Fig. 2. For process development, the lowest-order mode available is the best choice for achieving the highest power density from a given power.

FIG. 2 BEAM CROSS SECTIONS FOR FOUR DIFFERENT TEM MODES. SOURCE: REF 12

The position of focus with respect to the substrate surface influences the weld pool profile and penetration during laser welding. The optimum position for the focal point of the laser beam with respect to the substrate was investigated by Wilgoss, *et al.* (Ref 13). Figure 3 shows the transverse profiles generated by moving the focus point in 2.5 mm (0.1 in.) steps perpendicular to the plane of the workpiece. The reported plate thickness for this study was 6 mm (0.25 in.). When the focal point was positioned deep inside the workpiece, a V-shaped weld resulted necessitating more precise alignment than that for a parallel-sided weld of the same cross section. When the beam was focused well above the level of the workpiece surface, a large "nail head" with a consequent loss of penetration was observed.

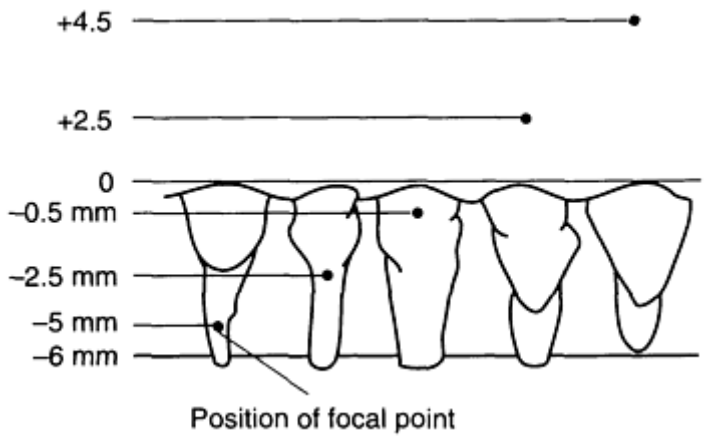

FIG. 3 TRANSVERSE PROFILES AS A FUNCTION OF FOCUS POSITION FOR A LASER-BEAM WELDED TYPE 310 STAINLESS STEEL. NEGATIVE AND POSITIVE NUMBERS INDICATE POSITION OF FOCAL POINT BELOW AND ABOVE, RESPECTIVELY, SURFACE OF PLATE. BEAM POWER, 5 KW. TRAVERSE WELDING SPEED, 16 MM/S (38 IN./MIN). SOURCE: REF 13

Wilgoss, *et al.* (Ref 13), concluded that the optimum focus is approximately 1 mm (0.04 in.) below the level of the workpiece surface. This produced welds with little or no "nail head" and nearly parallel sides.

Engel (Ref 14) reported that for several metals the optimum position of the focus is 1.25 mm to 2.5 mm (0.05 to 0.1 in.) below the surface. Research work by Alexander (Ref 15) using a 10 kW laser and 1.9 mm ($\frac{3}{4}$ in.) thick AISI 1020 steel revealed that the optimum position of focus was 2 mm (0.08 in.) below the surface. When the beam was focused 4 mm (0.16 in.) below the surface, the depth of penetration was almost the same as that for the 2 mm (0.08 in.) focus depth. The general consensus is that the optimum position for the focal point is below the surface, but the exact distance is dependent on the thickness of the workpiece and the laser power used.

Depth of focus is extremely important for welding thin-section materials because for a shallow depth of focus, the substrate comes in and out of the focal position due to thermal distortion. Depth of focus is defined as the distance over which the focus beam has the same approximate intensity. According to the Laser Institute of America, depth of focus is defined as the range over which the focused spot radius is increased by 5%. Based on this definition the depth of focus (Z) is given by:

$$Z = \pm \frac{0.32p\,R_b^{\,2}}{l} \approx \pm \frac{R_b^{\,2}}{l} = \frac{2.33(F\,l)^2}{l} = 1.488F^2\,l \qquad \textbf{(EQ 9)}$$

where F equals $f\lambda$ of the optics.

One can see from the above expression that as the *F* number of the focusing optics increases, depth of focus also increases. However, this is also accompanied by an increased beam diameter and decreased power density. As a result, these variables must be optimized for each particular application.

A common practice in determining the focal position and depth of focus is to carry out a trial bead-on-plate weld on an inclined plate and use the position where the plasma seems to be the visually strongest. This is a quick, but not necessarily the most accurate approach, for establishing the focal position.

Absorptivity. The importance of absorptivity and its role in laser welding is discussed in the aforementioned article "Laser-Beam Welding." For deep-penetration welding with power densities exceeding 10^6 W/cm^2, keyhole formation leads to high absorption by trapping the beam inside the hole by total internal reflection. However, the absorption during the initial transient period is dependent on wavelength and surface conditions. There are several techniques to enhance the initial absorption (Ref 16). They include nonmetallic absorbing coatings, preheating, surface roughening, periodic surface structure or induced grating structure**, and the application of an electric field of the correct sign.

Traverse Speed. The role of traverse speed during laser welding is also discussed in the article "Laser-Beam Welding." Generally, welding speed increases with increasing laser power as shown in Fig. 4. For a given thickness and power, a range of speed can be used to make successful welds. However, the fusion zone size will increase with the decreased speed within that range. For process development, the nugget size or fusion zone size is often prescribed by the design engineer for strength considerations. The laser welding engineer needs to select an optimum combination of speed and power to deliver the required nugget size.

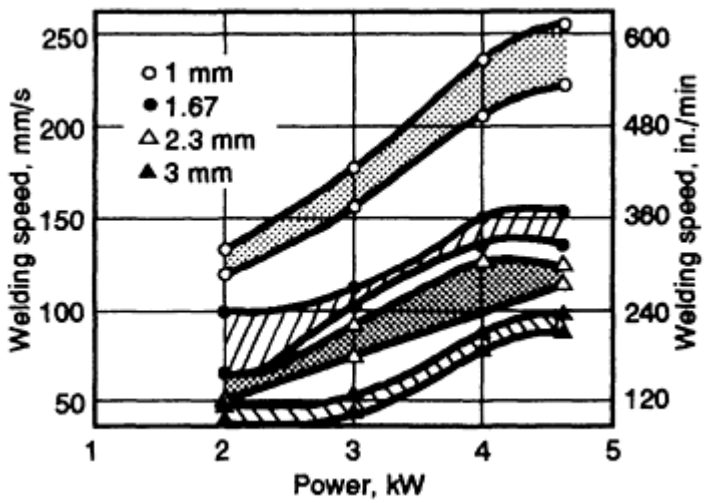

FIG. 4 WELDING SPEED VERSUS LASER POWER FOR A 5 KW CO_2 LASER. THE BASE METAL IS TI-6AL-4V. SOURCE: REF 17

Shielding Gas. The plasma produced during laser welding absorbs and scatters the laser beam. It is necessary, therefore, to remove or suppress plasma. The higher the power, the more clearly the phenomenon can be observed. An example of the way in which the depth of penetration decreases with the amount of beam absorption caused by plasma is shown in Fig. 5. Plasmas of this type can be removed by supplying a shielding gas such as helium. Shielding gas is also required to protect the weld surfaces from oxidation. Both the composition and flow rate of the shielding gas influence the depth of penetration (Ref 19, 20).

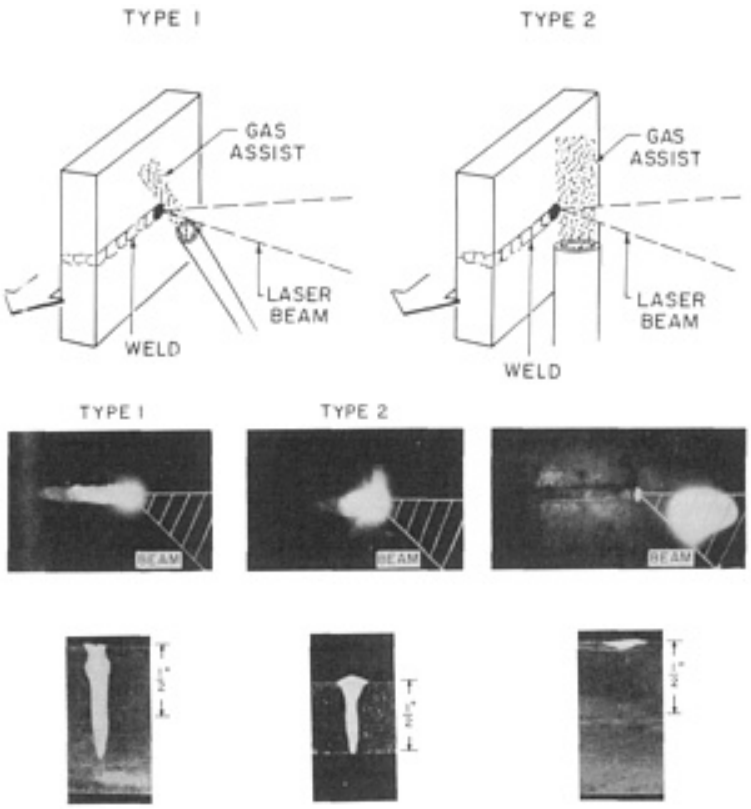

FIG. 5 EFFECT OF GAS ASSIST ON THE CROSS SECTION OF THE WELD. SOURCE: REF 18

Seaman (Ref 19) studied the role of shielding gas in high-power continuous-wave CO_2 laser welding. Weld cross sections made with various shielding gases and gas mixtures show a 60% difference in penetration. However, gases that permit the greatest penetration do not necessarily blanket (displace air from above the weld rapidly) the weld effectively at characteristically high laser welding speeds. This means that compromises are necessary to permit sound, deep-penetration laser welds (Ref 19).

The effect of the composition of the shielding gas on depth of penetration was studied by Seaman (Ref 19) and Rein, *et al.* (Ref 20). Generally, helium is used as the shielding gas for high-power laser welding. As shown in Fig. 6, helium seems to improve beam transmission whereas argon can cause severe beam blockage (Ref 19). This is probably due to the lower ionization potential of argon (15 eV) compared to that of helium (25 eV). The effects of air and CO_2 on beam transmission lie between the extremes represented by argon and helium (Fig. 7). Rein, *et al.* (Ref 20) have shown that the addition of small quantities of hydrogen, sulfur hexafluoride, and CO_2 to the helium enhances penetration at welding speeds below 40 mm/s (95 in./min).

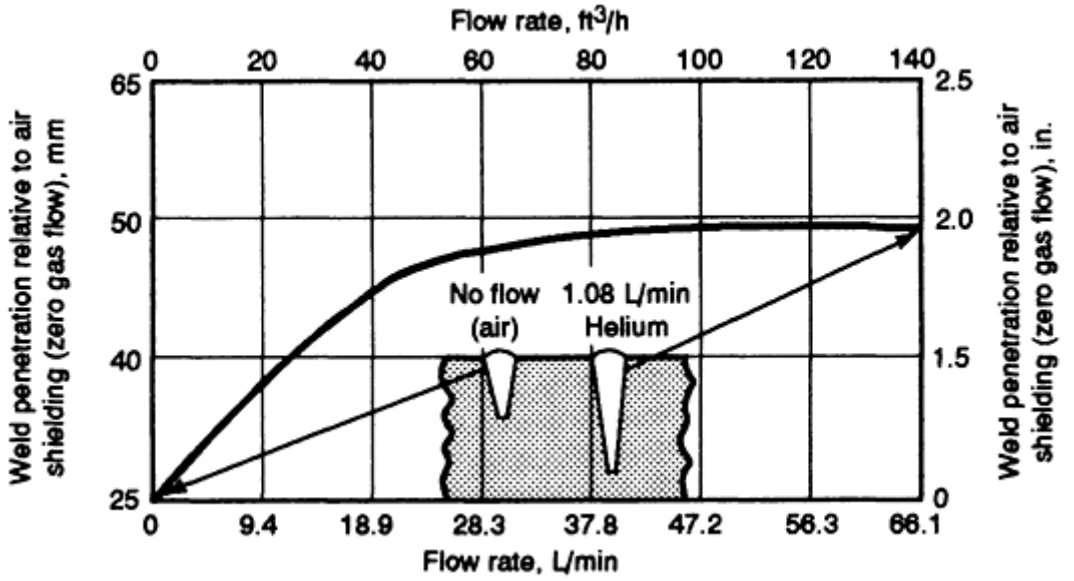

FIG. 6 EFFECT OF SHIELDING GAS ON DEPTH OF PENETRATION DURING LBW OF AN AUSTENITIC STAINLESS STEEL. LASER POWER, 15 KW. TRAVEL SPEED, 25 MM/S (60 IN./MIN). SOURCE: REF 19

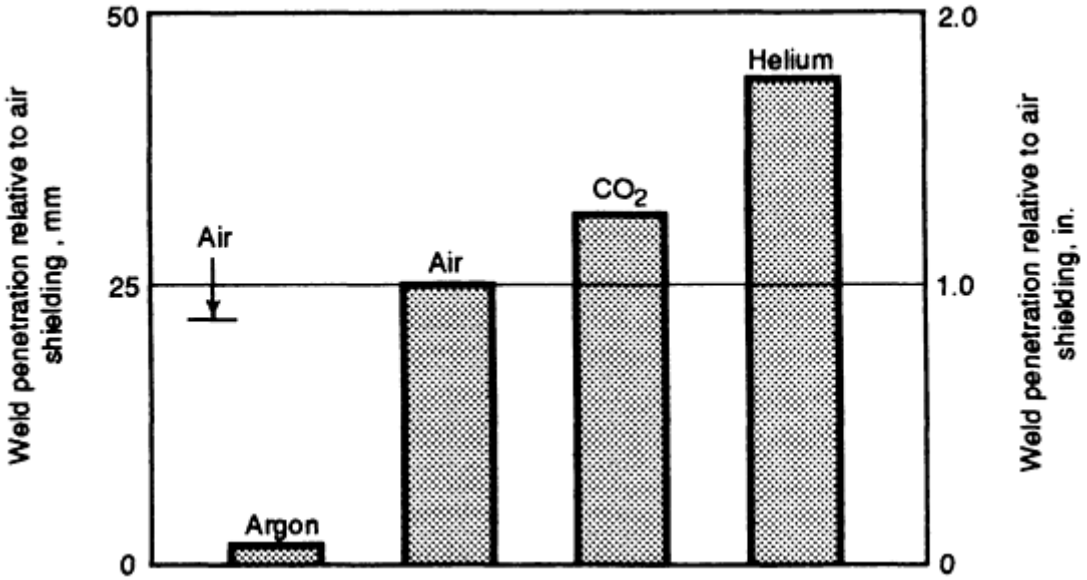

FIG. 7 COMPARISON OF LASER WELD PENETRATION ACHIEVED WITH DIFFERENT SHIELDING GASES. SOURCE: REF 9

The ionization potential of the shielding gas is not the only consideration for laser welding, especially at higher speeds. This is because gases with higher ionization potentials have lower atomic numbers and lower masses. These lighter gases are less effective in displacing air from the laser/material interaction area in the short time available in high-speed welding. Heavier gases are better able to displace air in a short time. Therefore, a mixture of heavier and lighter gases will result in optimum penetration. Figure 8 shows that as speed increases, the improvement resulting from the addition of a small amount of argon to helium (10% Ar and 90% He) becomes more noticeable.

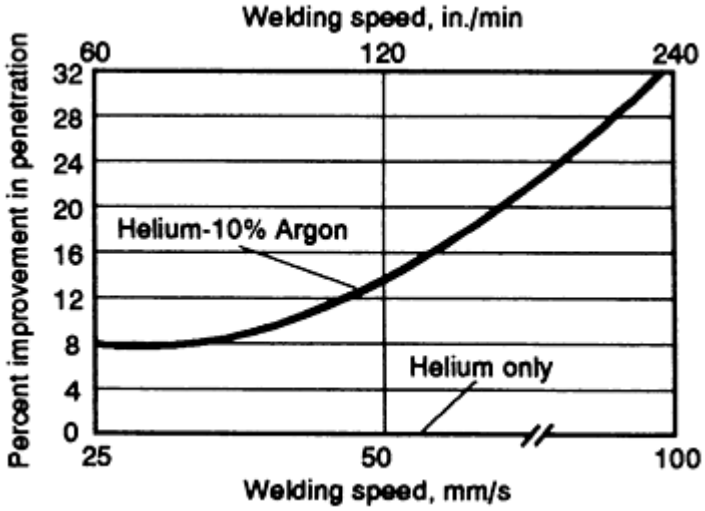

FIG. 8 IMPROVEMENTS IN WELD PENETRATION RESULTING FROM THE BLANKETING EFFECT OF A 10% ARGON ADDITION TO A HELIUM SHIELDING GAS. SOURCE: REF 19

For mass-scale production, the cost of shielding gas is also an important consideration. Recently, Chrysler Corporation replaced helium with CO_2 for plasma suppression during laser welding (Ref 21). The shielding gas is delivered from the side at an angle to suppress the plasma and remove metal vapor from the interaction point. For 14 kW laser power, a welding speed of 20 m/min (65 ft/min), and a shielding gas flow rate of 40 L/min (85 ft^3/h), CO_2 shielding resulted in a wider weld nugget size but mechanical properties were acceptable. The cost for helium gas is estimated to be $403,000 (3 shifts/day, 7 days a week) for a year compared to $80,600 for CO_2 gas; therefore, for process development, there is room for optimization of gas selection. However, one should remember that the use of CO_2 gas for a CO_2 laser may cause problems for the concentric gas shield due to preferential absorption.

Proper implementation of a shielding gas for plasma suppression can also be applied for joining difficult-to-weld materials with volatile alloying elements such as aluminum alloy 5083. Blake and Mazumder (Ref 22) demonstrated that with a properly designed helium suppression jet, magnesium losses and porosity formation could be minimized during laser welding of 5083 aluminum alloy. The resulting weld had a tensile strength equal to its parent material. This demonstrates that for process development, shielding gas can also be used to control the chemistry and weld defects.

Procedure Development and Practice Considerations for Laser-Beam Welding

J. Mazumder, University of Illinois at Urbana-Champaign

Joint Preparation, Fit-up, and Weld Design

Most weld joint geometries used in conventional fusion welding processes (for example, autogenous automatic gas-tungsten arc welding or electron-beam welding) are suitable for LBW. However, it must be remembered that the laser beam is focused to a spot of a few hundred micrometers in diameter and thus fit-up tolerances and alignment requirements are also of that order of magnitude.

Different types of joint design reported for laser-beam welding were reviewed by Shewell (Ref 23). Some of the important joint geometries are illustrated in Fig. 9 and 10.

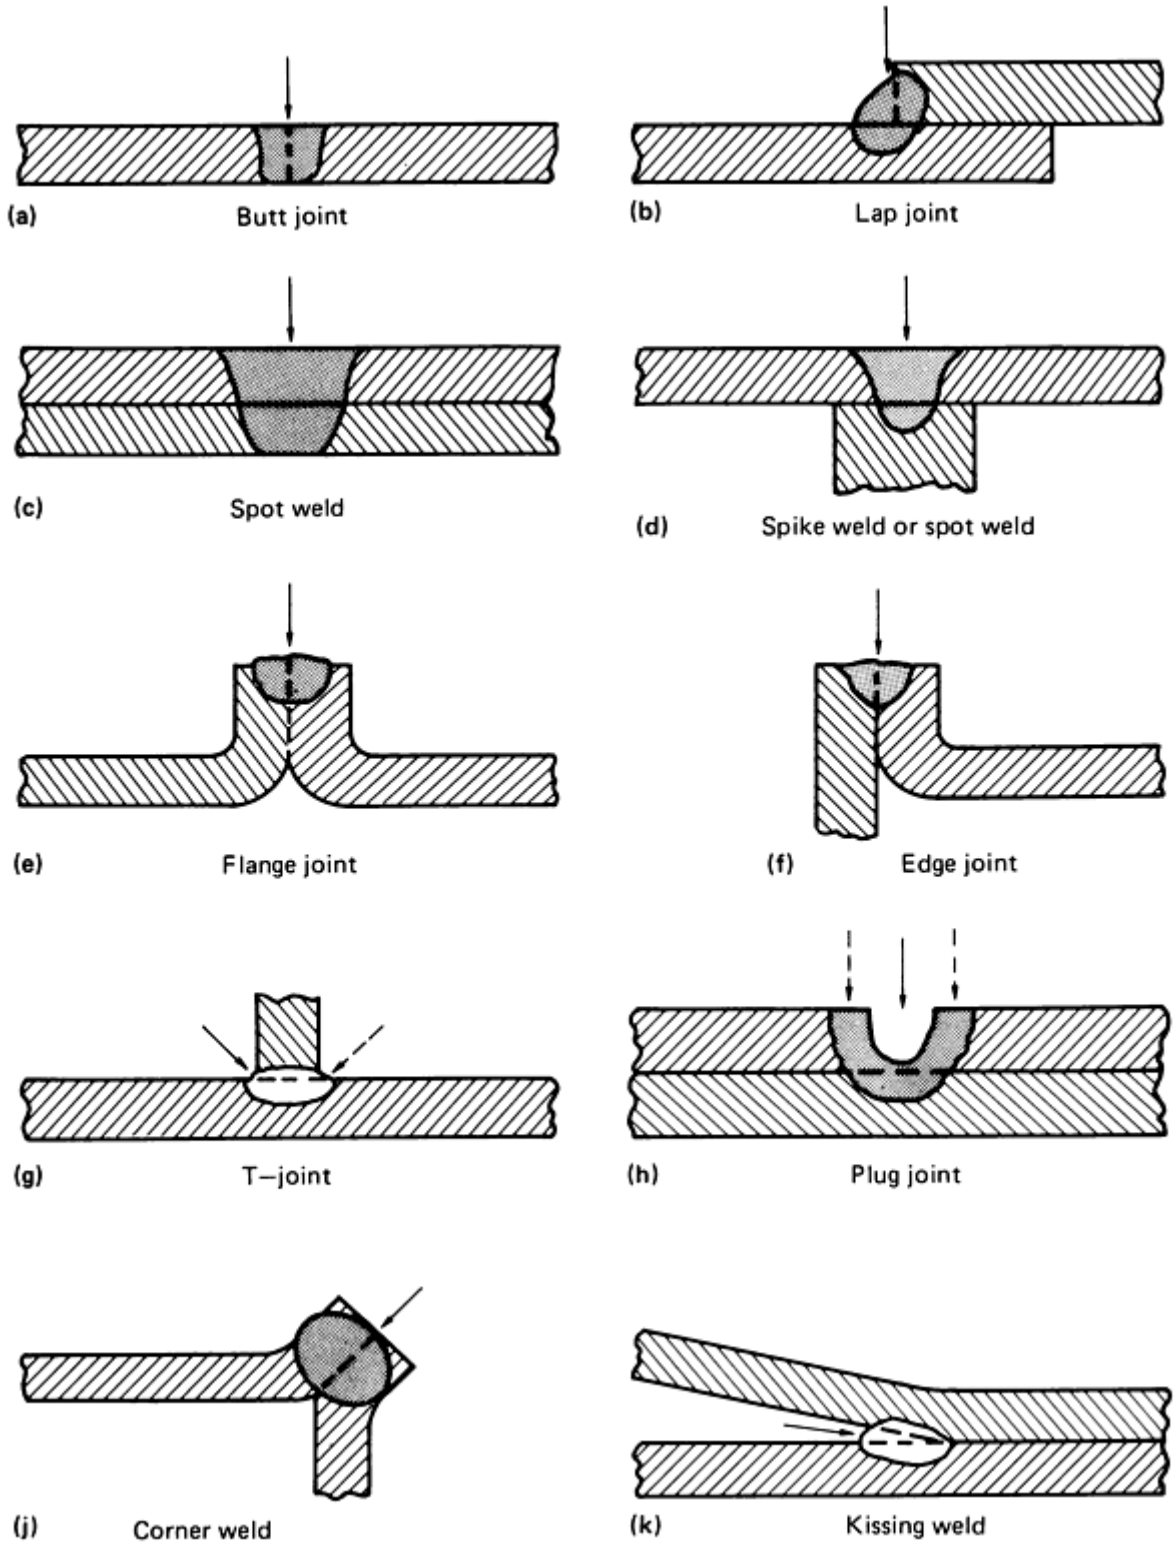

FIG. 9 JOINT DESIGNS FOR LASER-BEAM WELDS ON SHEET METAL. ARROWS SHOW DIRECTION OF LASER BEAM. SOURCE: REF 23

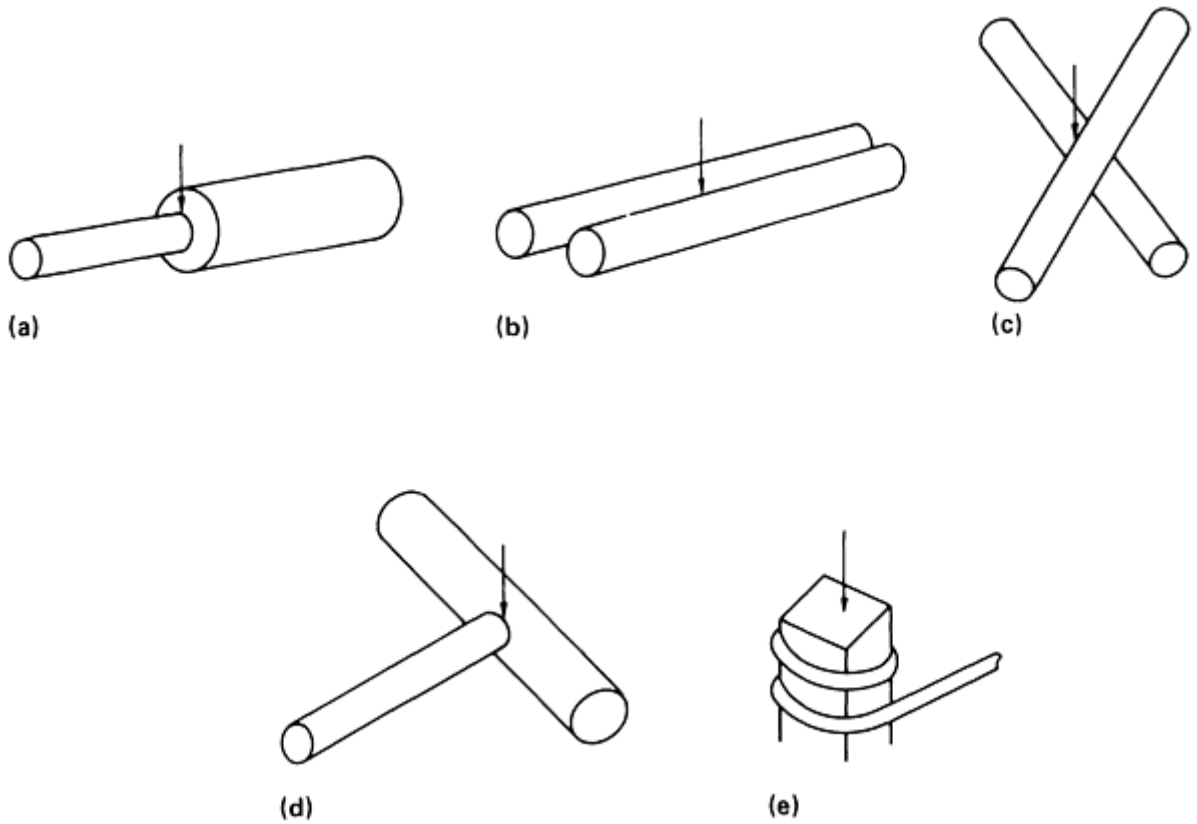

FIG. 10 JOINT DESIGNS FOR LASER-BEAM WELDS ON WIRE. ARROWS SHOW DIRECTION OF LASER BEAM. (A) BUTT WELD. (B) ROUND-TO-ROUND LAP WELD. (C) CROSS-JOINT WELD. (D) SPOT WELD FOR T-JOINT. (E) TERMINAL OR LUG WELD

Butt Joint--Full-Penetration Type. Material to be laser welded does not need beveled edges. Sheared edges are acceptable if square and straight (Ref 24, 25). The fit-up tolerance should be within 15% of the workpiece thickness. Misalignment and out-of-flatness should be less than 25% of material thickness, as shown in Fig. 11(a), to keep the laser beam from wandering. The transverse alignment should be kept within half of the focused beam diameter (Ref 17, 26). Clamping is recommended and buckling is not troublesome except when welding material thinner than 0.25 mm (0.01 in.) (Ref 24).

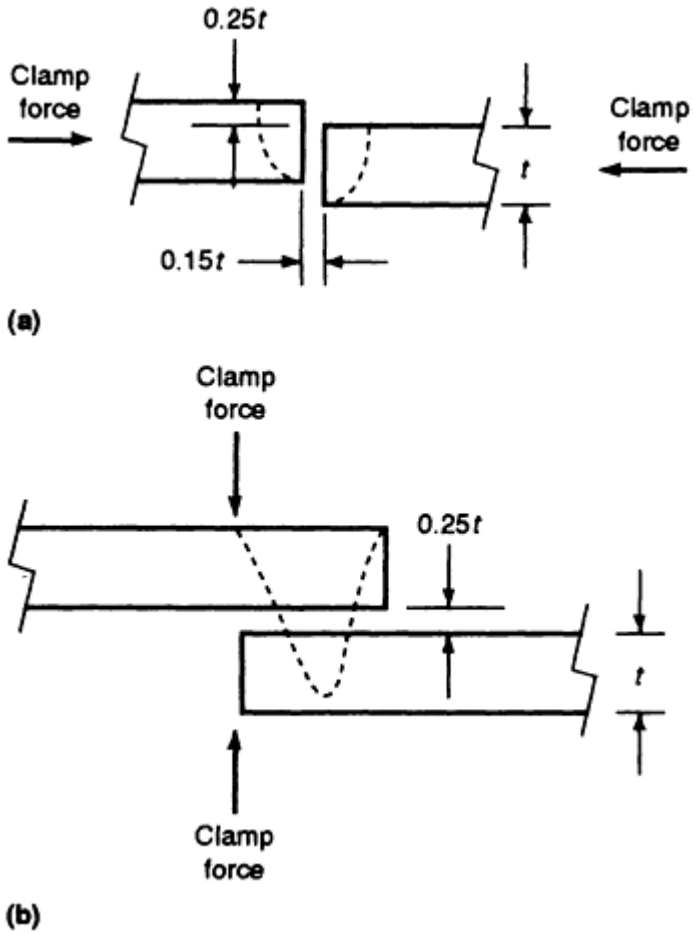

FIG. 11 CLAMPING AND TOLERANCES FOR A BUTT JOINT (A) AND A LAP JOINT (B). DIMENSIONS ARE IN UNITS OF PERCENT OF MATERIAL THICKNESS *T.* SOURCE: REF 25

Lap Joints. Air gaps severely limit penetration and welding speeds (Ref 24). Compressive clamping, as shown in Fig. 11(b), should be used to maintain a separation of less than 25% of the material thickness (Ref 25). For welding of dissimilar thicknesses, the thinner material should be placed on top to be welded to the thicker one (Ref 25).

Pulsed laser spot lap joints demand tighter tolerances than joints produced with continuous power laser welding. The maximum gap for ferrous and nickel alloys is 15% of the material thickness, and the gap must be less for higher conductivity materials (Ref 23). Baranov, *et al.* (Ref 27) studied the influence of gap size on the formation and strength of spot lap joints in laser welding. They reported for laser spot lap joints of 0.4 mm (0.016 in.) thick steel and 0.33 mm (0.013 in.) thick nickel, a gap of up to 0.1 mm (0.004 in.) has little influence on joint strength as there is almost no change in the diameter of the fusion zone. On the other hand, the shape of the weld pool changes with the gap size. It has also been observed that the presence of air in the gap may lead to the formation of porosity and nonfusion (Ref 27). Micropores sometimes form in the fusion zone and the number of pores and their size increase with increasing gap size.

Flange joints, as with butt joints, require straight, square edges, good fit-up, clamping, and precise transverse alignment. Flange joints are suitable for welding high-shrinkage metals such as aluminum (Ref 24).

Kissing Welds. This type of joint is called a kissing weld because the weld pool forms where two pieces just "kiss." This offers a small angle between the two parts that traps most of the energy of the laser beam. Very little (if any) pressure is required during welding, but the facing surfaces must fit well (Ref 23). A gap between the sheets will allow radiation to escape. This joint successfully joins thin foils in situations where spot welding would produce melt through.

Polarization Effect on Kissing Weld. One of the unique advantages of a kissing weld is the ability to take advantage of the polarization behavior of the laser light. If the laser light is polarized perpendicular to the wall of the metal, the beam is

preferentially reflected and it delivers all the energy at the joint. This increases the joint efficiency considerably. This idea was originally proposed by Sepold in 1987 (Ref 28). Subsequently, this concept is used for laser welding of pipes.

Wire Joints. The joint configurations for wires shown in Fig. 10 were developed by the electronics industry. For wire-to-wire joints, the two wires must share the incident laser energy. In a cross joint, for example, the laser beam should be directed at the intersection of the wires so that both wires are exposed directly to the beam.

Use of Consumables and Special Welding Practices

Laser welding is ideal for autogenous welding. The main consumable for laser welding is the shielding gas which was discussed earlier. For thick-section welding, a filler wire can be used to make multipass welds. Sometimes filler metals (or injected powders) are used during laser welding to control the weld bead geometry. The most common use of filler metals, however, is to prevent undercutting. The use of filler materials to control the weld chemistry is also common. For example, insertion of aluminum foil during butt welding of semikilled steel results in a porosity-free sound weld. Vaporization losses during laser welding of some alloys can be compensated for by the addition of filler materials or powder of desired composition. Energy consumption during LBW is lower with powder injection than with wire-fed filler metals. The wire surface reflects considerable amounts of energy and reduces the energy efficiency of the process.

As with arc welding processes, metallurgical considerations such as preweld and postweld heat treatments are also applicable to laser welding. The primary differences between LBW and other welding processes are the narrower HAZ associated with laser welds as well as the high cooling rates that result in higher localized residual stresses. These high cooling rates can be used beneficially for materials with brittle intermetallic phases. High cooling rate leads to extension of solid solubility and avoids brittle precipitates for many alloys.

Procedure Development and Practice Considerations for Diffusion Welding

S.B. Dunkerton, The Welding Institute

Introduction

THE JOINING OF MATERIALS IN THE SOLID STATE can be an attractive alternative to fusion-welding processes. In fact, metals that are conventionally difficult to weld and combinations of dissimilar materials can only be welded using a solid-state process. The wide range of techniques that are available for solid-phase joining have various modes of heat and pressure application.

Diffusion welding represents one extreme within this range, in that it involves minimal pressurization, but relatively high temperatures and long periods of time. In its simplest form, the process involves holding premachined and cleaned parts in intimate contact, and then heating them in a protective atmosphere. As its name implies, diffusion has a major role in the joining of mating parts, although other mechanisms, such as microyielding and oxide dissolution, are also critical steps in successful welding.

The process of diffusion welding has been utilized for many years, although it did not attain industrial acceptance until the 1970s or 1980s, and then, only for specialized applications. A comprehensive, although somewhat dated, review of systems that have been successfully joined using diffusion welding is provided in Ref 1.

The specific advantages of the process include its ability to join most metals and some nonmetals in like or dissimilar combinations, the minimal amount of deformation that results, and the fact that the weld area is mostly independent of welding time. These advantages are offset by the need to machine paris to fairly tight tolerances on component fit-up, as well as on surface finish. However, the requirements that are generally specified can readily be achieved using standard machine shop practices.

Procedure Development and Practice Considerations for Diffusion Welding

S.B. Dunkerton, The Welding Institute

Process Variants

Solid-Phase Process. The more-conventional form of diffusion welding utilizes uniaxial loading, which can be applied by dead weight, mechanical, pneumatic, or hydraulic means. The applied load is such that macrodeformation of the parent material(s) does not have to be reached. Because deformation also depends on welding temperature, temperatures that range from 50 to 75% of the melting point are usually employed. Heat can be applied by radiant, induction, and either direct or indirect resistance heating. Most welding operations are performed in vacuum or inert gas atmospheres, although welding in air has been reported (Ref 2). When welding noble metals, the requirements for a clean atmosphere are less stringent, but protection can prevent parent-metal oxidation while maintaining a clean weld interface.

An examination of the proposed sequence of stages in diffusion welding (Ref 3, 4) emphasizes the importance of the original surface finish. In forming a bond, it is necessary for the two metal surfaces to come into atomic contact (Fig. 1). Hence, microasperities and surface contaminants must be removed from the bonding faces. The applied load first causes the plastic deformation of surface asperities, thereby reducing interfacial voids. Bond development then continues by diffusion-controlled mechanisms, including grain-boundary diffusion and power-law creep.

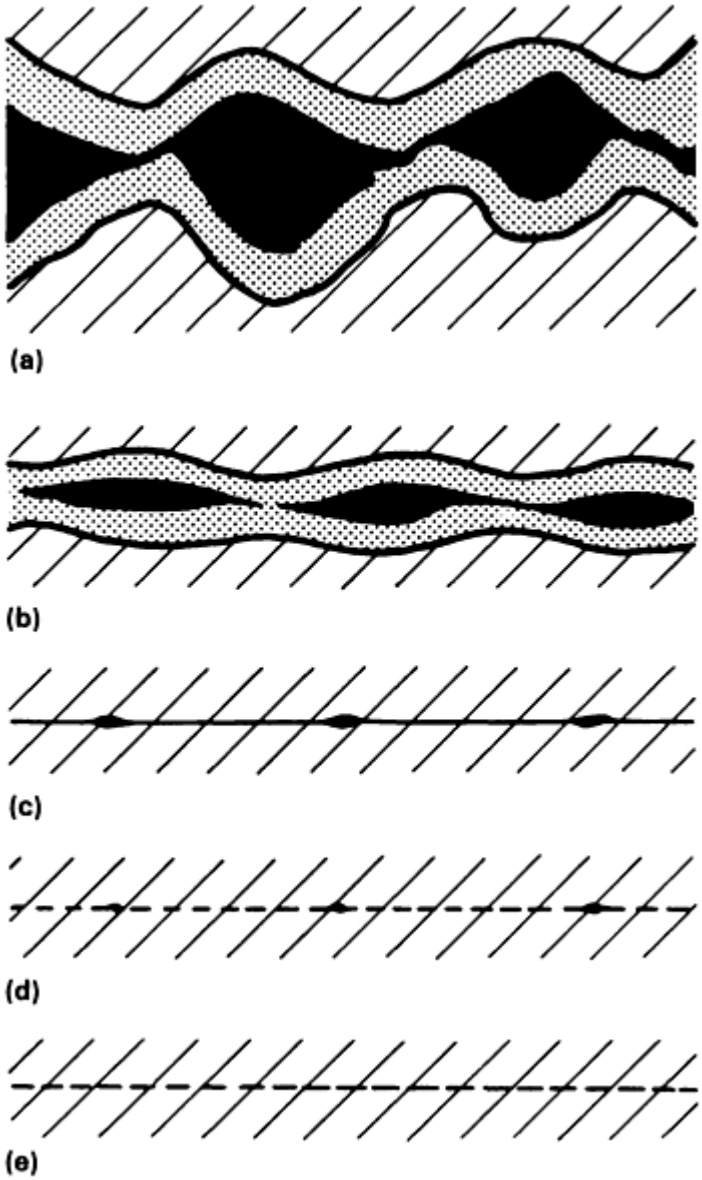

FIG. 1 MECHANISM OF DIFFUSION WELDING. (A) INITIAL "POINT" CONTACT AND OXIDE CONTAMINANT LAYER. (B) AFTER SOME "POINT" YIELDING AND CREEP, A THINNER OXIDE LAYER WITH LARGE VOIDS RESULTS. (C) AFTER FINAL YIELDING AND CREEP, SOME VOIDS REMAIN WITH VERY THIN OXIDE LAYER. (D) CONTINUED VACANCY DIFFUSION ELIMINATES OXIDE LAYER AND LEAVES FEW SMALL VOIDS. (E) COMPLETION OF BONDING

Premachined parts for uniaxial diffusion welding should have a surface finish of greater than 0.4 μm (16 μin.), roughness average (RA). Swabbing with acetone or petroleum ether, which should occur immediately prior to set-up in the welding machine, can suffice as a degreasing measure. Ultrasonic cleaning also has been used. Many researchers have examined the removal of oxide, prior to welding, by ion bombardment or other means. This can be applicable to certain metals if welding is to be carried out in the same vacuum chamber, or if the parts are in-vacuo coated with an oxide-resistant material. However, the additional cost and time involved in this procedure make it impractical for most industrial applications.

The liquid-phase process is applicable only to dissimilar material combinations or to like materials in situations where a dissimilar metal insert is used. Solid-state diffusional processes lead to the formation of a different phase at the weld interface. The liquid-phase welding temperature is based on the temperature at which this phase (usually, eutectic) melts. This thin layer of liquid spreads along the interface to form a joint at a lower temperature than the melting point of either of the parent metals. A reduction in welding temperature leads to the solidification of the melt. At the point where this phase is diffused into the parent metals, by holding at temperature, the process is known as transient liquid-phase

diffusion welding. The optimal welding time and temperature can be estimated using the applicable phase diagram and solidification kinetics (Ref 5).

The superplastic forming/diffusion welding (SPF/DW) technique has been developed specifically within the aerospace industry. Its industrial importance is such that it is worthy of separate consideration. The process is used commercially for titanium and its alloys, specifically those that exhibit superplastic properties at elevated temperatures within defined strain-rate conditions (Ref 6, 7, 8). This process also has been successfully utilized for advanced aluminum alloys (Ref 9). Because the temperature and pressure conditions coincide with the conditions required for welding, the two processes have been combined into one manufacturing operation.

Hot Isostatic Pressing (HIP). HIP welding is a solid-phase process that involves the application of a high-temperature, high-pressure gas to components. Isostatic pressurization allows the welding of more-complex geometries than the uniaxial welding process can handle.

A hot isostatic press consists of a furnace within a gas pressure vessel. Its size can range from a diameter of 100 mm (4 in.) to a diameter of 1.1 m (44 in.) and a height of 2.2 m (88 in.). Argon gas is typically used, and there is a need to encapsulate the bond interfaces to prevent the gas from entering the site of the bond. This is most often achieved by locating the specimen in an evacuated and sealed steel can, although various other means can be used, as well.

The pressures associated with HIP welding are significantly higher than those used in uniaxial welding. However, because the pressure is isostatic, the level of deformation is extremely low. In addition, less premachining is required. Typical HIP cycles can last from 6 to 16 h, but because many components can be fitted into one furnace, the unit costs on large production runs can be low. Bryant (Ref 10) has developed a graphical procedure to determine the minimum pressure and temperature required for the HIP welding of several metals and alloys.

Procedure Development and Practice Considerations for Diffusion Welding

S.B. Dunkerton, The Welding Institute

Carbon and Low-Alloy Steels

Although diffusion welding is applicable to this class of steels, industrial applications are limited. The process is used in situations where it is essential to avoid or minimize distortion and postweld machining, and for complicated geometries that involve internal features.

These steels are generally welded without the use of filler material (interlayer). The parts themselves are machined to a good surface finish (<0.4 μm, or 16 μin., RA surface roughness, and flat) and assembled in a heating unit such that force can be applied uniaxially or isostatically.

In terms of uniaxial diffusion welding, a wide range of bonding conditions have been shown to give sound joints, that is, temperatures of 900 to 1200 °C (1650 to 2190 °F), pressures of 5 to 14 MPa (0.7 to 2 ksi) and times of 5 to 120 min. Because the parameters are interdependent, as temperature increases, the load and/or time can be reduced and vice versa. Figure 2 depicts a typical cross section of a joint in 0.4% C steel, in which a layer of ferrite indicates the bond line of the sound bond that has formed.

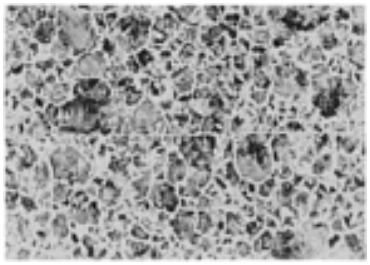

FIG. 2 CROSS SECTION OF DIFFUSION WELD IN 0.4% C STEEL. 50×

Tensile strength develops as temperature/pressure/time increase. Parent-metal tensile strength is readily achieved; failure occurs away from the joint interface, even when welding is not complete. Work has shown that only 80% bonding is necessary to achieve the equivalent parent-metal strength (Ref 11). However, ductility and joint-line toughness require a greater level of bond integrity.

Joints made in 0.4% C steel and a 1Cr-0.25Mo alloy steel have shown low Charpy impact values, when compared with the parent steels (Ref 12, 13). With the 0.4% C steel, it is possible to improve the toughness properties by using a postweld normalizing heat treatment (equivalent to the thermally cycled and normalized parent material). However, although the chromium-molybdenum steel had an improved microstructure after a postweld quench and temper heat treatment, it still had low joint-line toughness. This indicates the greater difficulty in forming a sound joint as alloy content increases.

Therefore, when diffusion welding carbon and low-alloy steels, the final application and service requirements should be considered carefully. The process is useful in low-stress applications, but when impact toughness is required, the fitness of a particular steel for the specific purpose needs to be examined. For higher-carbon-content steels and low-alloy steels, a suitable postweld heat treatment is recommended to return the steel to its original condition. However, it should be noted that some of the high temperatures referred to earlier ([ges]1100 °C, or 2010 °F) can cause significant grain coarsening.

The HIP welding of these steels also can be used when typical conditions involve a temperature of 1100 °C (2010 °F), a pressure of 100 MPa (14.5 ksi), and a bonding time of 4 h. Again, grain coarsening and the property considerations described above need to be reviewed.

High-Strength Steels

Although diffusion welding has not been widely applied to high-strength steels, it is a feasible process, and guidelines similar to those identified for carbon and low-alloy steels will apply. Because diffusion welding relies on microplastic yielding in the early stages of bonding, it is necessary to use parameters at the higher end of the ranges specified previously, that is, temperatures above 1000 °C (1830 °F) and pressures of 7 MPa (1 ksi) and above.

Although good tensile properties can be achieved, the as-bonded toughness will be low. In addition, a postweld heat treatment to restore the parent microstructure is recommended.

Procedure Development and Practice Considerations for Diffusion Welding

S.B. Dunkerton, The Welding Institute

Stainless Steels

Stainless steels can be diffusion welded using conditions similar to those that are used for high-strength steels. These steels are normally covered by a thin adherent oxide (chromium oxide) that must be broken up and/or dissolved during the welding process. This is possible when higher temperatures and/or higher pressures are used. Alternatively, stainless steels can be welded in dry hydrogen, which will reduce the oxide film, or the oxide can be removed prior to welding. The latter measure has been accomplished by anodic cleaning of the steel surfaces, followed immediately by copper plating to protect the surfaces from reoxidation. Again, if a dry hydrogen atmosphere is used, then the copper oxide will be reduced during welding and a sound bond will be attained.

Although few property data are available on the diffusion welding of stainless steels, it is known that tensile strength is readily achieved, whereas toughness is more difficult. If high welding temperatures are employed, then it will generally be necessary to use a postweld heat treatment to restore properties.

Procedure Development and Practice Considerations for Diffusion Welding

S.B. Dunkerton, The Welding Institute

Aluminum-Base Alloys

Diffusion welding of aluminum alloys is difficult, because of the presence of a tenacious surface oxide film. The surface oxide can be disrupted by the use of large deformations and/or high temperatures in, for example, roll bonding. However, for low-deformation diffusion welding, interlayers of similar or dissimilar materials have been used. The specific procedures to be followed for aluminum alloys vary, depending on the alloy system.

For aluminum-magnesium-silicon alloys (specifically, Al-0.6Mg-0.9Si-0.5Mn), diffusion welding without an interlayer has yielded tensile strengths of 145 MPa (21 ksi) for a welding temperature of 550 °C (1020 °F) (Ref 14). However, this

does induce deformation of the components. It has been more attractive to use copper or silver interlayers, which can be applied as a coating or a foil. These interlayers can be used to provide a solid-state weld or a transient liquid-phase (eutectic) weld. Care needs to be taken to achieve the latter, to ensure that the heating rate is not so slow as to allow the interlayer to be diffused away before the eutectic temperature is reached. Solid-state diffusion welds made with either copper or silver have yielded joint strengths of 85 MPa (12 ksi) for bonding temperatures as low as 450 °C (840 °F).

More attention has been directed to the diffusion welding of alloys that are of interest to the aerospace industries, that is, 7010 (Ref 15), 7475 (Ref 16, 17) and 8090 (Ref 18, 19, 20, 21). No clear guidelines exist as to the best practice for welding these alloys, because researchers have investigated many techniques and the results point in sometimes conflicting directions. Welding the alloys without an interlayer is possible, if disruption of the oxide can take place during welding. Some success has been achieved by welding the 7475 alloy with a "rough" surface (that is, brushed in air), by surface grinding the alloy in an argon atmosphere prior to welding, and by grit blasting with fine alumina particles followed by chemical cleaning in hot 30 wt% NaOH solution. Long welding times have been used for this material and high strengths have been reported by welding at 515 °C (960 °F) under a load of 5 MPa (0.7 ksi) for 5 h, followed by a postweld heat treatment to T6 condition. In instances where interlayers have been used for this alloy system, the material that has shown the greatest promise is zinc.

Aluminum-lithium alloys are currently attracting great attention for applications in the aerospace industries. This is because lithium significantly increases the elastic modulus of aluminum, by approximately 6% for each wt% addition of lithium, and simultaneously decreases its density by 3%. For aerospace applications, improvements in specific modulus and strength can lead directly to weight savings. In addition, it has been shown that aluminum-lithium alloys can develop superplastic behavior after appropriate thermomechanical processing, which means that advantage can be taken of the SPF/DW procedures already established in this industry.

Superplastic forming after welding restricts the welding temperature that can be used. Ideally, the temperature should be lower than or equal to the superplastic temperature for the alloy. In addition, the welding time must be restricted to avoid grain growth in the parent sheet, which could affect the superplastic-forming properties.

Aluminum-lithium alloys have been bonded with no interlayer and with interlayers of zinc, copper, zinc-copper, pure aluminum, and aluminum alloys. Surfaces have been prepared by a number of techniques, such as grinding with emery paper, shot peening, chemical etching, and degreasing. All techniques have shown some degree of success, but it is difficult to compare results, because the testing methods to achieve shear strength are varied. Generally, all of these welds require some form of postweld heat treatment to restore properties (for example, solution treatment at 535 °C, or 995 °F, followed by quenching). A section through a diffusion weld containing a pure aluminum interlayer is shown in Fig. 3. The position of the original aluminum foil is discernible by the presence of spheroidal precipitates, similar in size and shape to those precipitated in the grain boundaries of the aluminum alloy.

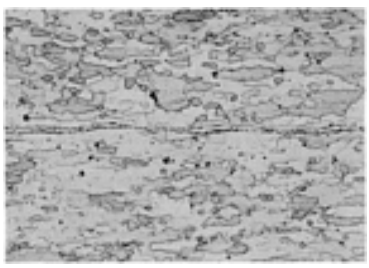

FIG. 3 CROSS SECTION OF DIFFUSION WELD IN ALUMINUM-LITHIUM ALLOY CONTAINING PURE ALUMINUM INTERLAYER. 75×

In order to avoid surface contamination during heating to the welding temperature, greater care needs to be taken with the aluminum-lithium alloys, because of the reactivity of lithium. However, this reactivity is also claimed to make this alloy system somewhat easier to weld than other less-reactive aluminum alloys.

Procedure Development and Practice Considerations for Diffusion Welding

S.B. Dunkerton, The Welding Institute

Reactive and Refractory Metals

The diffusion welding of titanium alloys is well documented, because of its commercial application and importance to the aerospace industry. Many titanium airframe structures are now manufactured using the SPF/DW process, which provides significant benefits through weight and cost savings. Typical examples include hot-air nozzles, landing-gear doors, intricately shaped housings, keel sections, and heat-exchanger ducts. Most of the detailed procedures for welding are commercially sensitive. The factors that are important are (Ref 22):

- METALLURGICAL CONDITION OF THE STARTING MATERIAL
- CHARACTERIZATION OF THE SUPERPLASTICITY OF THE MATERIAL
- SURFACE CLEANLINESS
- TOOLING MATERIAL AND SURFACE CONDITION
- WELDING ATMOSPHERE
- FORMING AND WELDING PARAMETERS
- PART GEOMETRY

The primary alloy that is used is Ti-6Al-4V. It has been established that commercially available sheet material containing an equiaxed, uniform, small grain size (preferably, <10 μm, or 400 μin.) is suitable for superplastic forming. Conventional cutting processes are used for the preparation of sheet material, which is then subjected to an etching treatment prior to placement in the press. Although tooling is typically made of a 22Cr-4Ni-9Mn stainless steel with appropriate surface-parting compounds, ceramic-faced tooling has also been used. During the application of heat at temperatures ranging from 900 to 930 °C (1650 to 1710 °F), argon gas provides a protective atmosphere that is also utilized, under pressure, to

effect forming and diffusion welding. Tool-to-titanium sealing, in order to contain the forming/bonding pressure of 2 to 4 MPa (0.3 to 0.6 ksi), is of paramount importance to leakage prevention.

Multiple-sheet fabrication requires the application of a stop-off material (typically, yttria and a binder) after conventional titanium cleaning. The application of a stop-off material utilizes a silk-screen technique that allows complex patterns to be transferred to the sheet. The multiple-sheet pack is plumbed with stainless steel capillary tubes for internal gas pressurization (between the sheets), as opposed to single-sheet processing, where gas pressure access is achieved directly through tooling parts. The process allows formed titanium shapes that are far more complex than those produced by conventional forming methods. Parts can feature integral end flanges, deep beads, corner beads, and small-bend radii. In addition, compound contour; multiple, variable, hollow sections; and complex sandwich (including circular) structures with varying core configurations can be fabricated.

Zirconium and its alloys also have been joined by diffusion welding, as have the refractory metals of tungsten, tantalum, niobium, and molybdenum (Ref 23).

Other Alloys

Other alloy systems have been diffusion welded, but with few industrial applications. Copper bonds to itself readily, if the surface oxide can be disrupted, and temperatures ranging from 850 to 950 °C (1560 to 1740 °F) have been employed. Alternatively, a liquid-phase procedure that uses silver as an interlayer has been adopted to reduce welding times. The nickel- and cobalt-base alloys are bondable, but some alloy systems exhibit good high-temperature strength that inhibits the microyielding required for diffusion welding. Beryllium alloys also can be bonded at low temperatures (Ref 24).

The noble metals, such as gold, bond readily because of their very thin surface oxide. Gold, in particular, is often used as an interlayer material when welding temperatures are restricted, because bonds can be achieved at temperatures as low as 250 to 350 °C (480 to 660 °F), if the surfaces and atmosphere are clean.

Dissimilar Metal Combinations

Ferrous-to-Ferrous Combinations. Dissimilar steel joints have not bee extensively investigated in diffusion-welding research, primarily because it was initially believed that the process would mostly be used to join material combinations that were difficult to join by other, more-conventional methods. However, this is not strictly true, and in situations where multiple joints can be formed in one welding operation, the process can be economically viable for dissimilar steel joints.

The literature on steel includes the bonding of high-speed steels to carbon steels for prismatic cutting tools (Ref 25) and the joining of pure iron to a range of carbon steels (Ref 26). In this latter work, the bond tensile strength was greater than 430 MPa (62 ksi), which exceeds that of the weaker parent metal. A slight increase in tensile strength occurred with a decrease in welding temperature from 1000 to 900 °C (1830 to 1650 °F).

Nonferrous-to-Nonferrous Combinations. Many combinations have been studied within this category, but the most common one uses aluminum as one of the parent materials (Ref 27, 28, 29).

The diffusion welding of aluminum to copper and titanium results in the formation of intermetallic compounds at the bond interface. With copper, it has been found that the aluminum/copper intermetallic can reach 15 μm (600 μin.) in thickness before a reduction in the joint strength occurs (Ref 30). Also described in this work is the fact that the parent aluminum strength was not achieved, even before the excessive growth of the intermetallic, which suggests that full bonding can be achieved only after the time necessary for extensive intermetallic formation. However, aluminum-to-titanium diffusion bonds can reach a tensile strength that is equal to that of the parent aluminum, and it is claimed that intermetallic thicknesses of up to 10 μm (400 μin.) can be tolerated (Ref 31). Again, an interlayer of silver can be used to promote bonding between the aluminum and titanium, such that the parent aluminum strength can be achieved in shorter welding times.

The aerospace and nuclear industries have driven the development of a wide variety of special alloy and dissimilar-metal combinations. Examples of materials that have been successfully joined include nickel-stainless steel (Ref 32), uranium-stainless steel (Ref 33), beryllium-nickel (Ref 34), beryllium-stainless steel (Ref 34), thorium dioxide dispersion-strengthened-nickel alloys (Ref 35), zirconium-steel (Ref 36), and copper-Monel (Ref 37).

Ferrous-to-Nonferrous Combinations. The joining of aluminum to steel has received a great deal of interest. This subject has been reviewed by Elliot and Wallach (Ref 38), who recognized that the two major problems associated with this metal combination are:

- THE TENACIOUS OXIDE LAYER ON THE ALUMINUM, WHICH, BEING STOICHIOMETRIC AND HIGHLY STABLE, INHIBITS WELD FORMATION
- THE FORMATION OF BRITTLE INTERMETALLICS, SUCH AS THE $FEAL_3$ AND FE_2AL_5 TYPES, AT THE JOINT INTERFACE

These problems are generally overcome by using interlayers, both to promote welding and to prevent the formation of brittle intermetallic compounds. Silver has been successfully used as an interlayer, either as a foil interlayer or applied by electroplating (Ref 39, 40), vapor deposition (Ref 41, 42), or sputter deposition (Ref 43) on one or both surfaces. Both solid- and liquid-phase joints have been produced, the latter of which involves melting of the aluminum-silver eutectic.

Other interlayer materials that have been examined include nickel and a multilayer system of zinc and silver. However, both of these have disadvantages. The nickel also forms brittle intermetallics with iron that inhibit joint strength. In the multilayer system, the zinc was found to erode the silver, thereby removing the diffusion barrier. In addition, aluminum and steel alloys can be diffusion welded without any interlayer by a careful evaluation of the process parameters and with a higher amount of aluminum deformation.

The diffusion welding of refractory metals to steels has been another major research area. Molybdenum has been welded directly to steel, but the formation of brittle intermetallics limits the strength of the joints. Lison and Stelzer (Ref 25) have investigated the interlayers required to give good joint properties for this metal combination, based on metallurgical compatibility and the coefficients of thermal expansion. A complex multilayer system was devised, in which tantalum, vanadium, nickel, and copper were positioned in the following order: Mo-Ta-Ni-Cu-steel. Initially, the Mo-Ta-V combination was bonded at 1500 °C (2730 °F) for 40 min, whereas the remaining bonds were formed at 850 °C (1560 °F) in 20 min. The mechanical properties of such a joint are not given, but metallographic examination revealed full bond formation.

Metal-Ceramic Joining. Recent developments in gas-turbine and ceramic-engine technology have created an interest in the diffusion welding of ceramics to steels, because the low temperatures used for joining minimize the residual stresses created by thermal mismatch. Silicon nitride and zirconium oxide are two examples of oxides that have been successfully welded to steel using the diffusion welding process (Ref 44, 45).

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Introduction

FRICTION WELDING (FRW) is a solid-state welding process that uses the compressive force of the workpieces that are rotating or moving relative to one another, producing heat and plastically displacing material from the faying surfaces, thereby creating a weld. Process variations include inertia, direct-drive, linear, and orbital radial friction welding, as well as friction surfacing. (Additional information is available in the articles "Fundamentals of Friction Welding,", "Friction Welding,", "Radial Friction Welding,", and "Friction Surfacing" in this Volume.) This article provides information about practice considerations for the two most common variations: inertia and direct-drive friction welding.

Inertia welding obtains heat for welding that is supplied by stored rotational kinetic energy. Figure 1 depicts the parameter characteristics of the process. The inertia of the system is changed by either adding or removing flywheels from the rotating spindle that provides rotary motion and/or by changing the spindle speed.

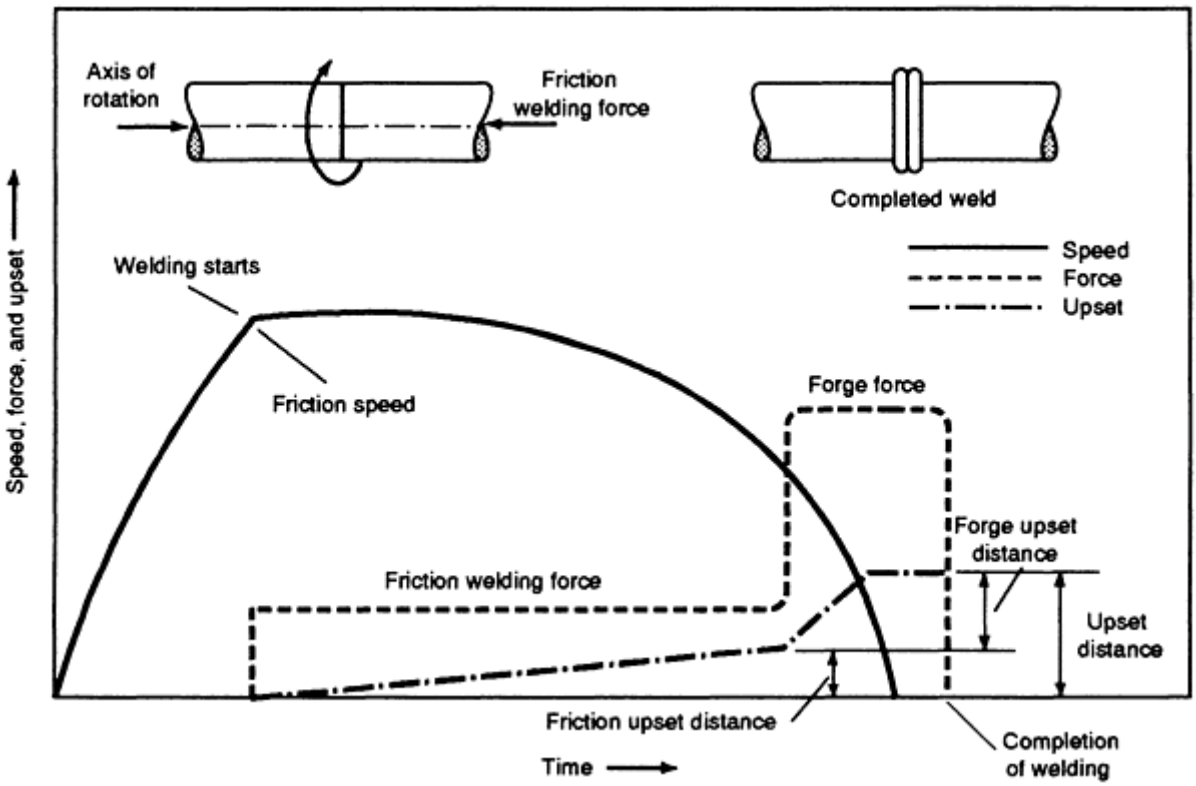

FIG. 1 INERTIA WELDING PARAMETER CHARACTERISTICS. SOURCE: ANSI/AWS C6.1-89

After the inertial mass is set, the parts are loaded in the machine (one in the spindle and one in the fixture/tailstock). The spindle speed and welding forces are set to predetermined levels. The spindle is then accelerated to velocity. After this velocity is attained, the drive system is disengaged, allowing the flywheel (and the part in the spindle) to effectively coast. The stationary part is then brought into contact with the rotating one, under a given applied force, and frictional heating begins. The flywheel is stopped by the transitioning of its kinetic energy into thermal energy (frictional heating) at the welding interface. This energy heats the part and allows forging to occur by displacing material at the interface.

Direct-drive friction welding differs from inertia welding, primarily in how the energy is delivered to the joint. Figure 2 depicts the characteristics of this process. In direct-drive friction welding, like inertia welding, one of the parts is loaded into a rotating spindle while the other is held stationary. However, the spindle is of a given mass and is not changed, as it is in inertia welding. To start the process, the spindle is set into motion at a constant rotational velocity (rev/min). The parts are then brought into contact under a low force (termed first friction force, or preheat force) and allowed to heat for a preset time or distance. In most applications, a higher welding force (termed second friction force, or welding force) is then applied, which increases the rate and amount of material extruded from the joint. The second friction force is controlled through a preset time or distance. After the preset time or distance has been reached for the first two friction stages, the rotating spindle is brought to a stop using some type of braking mechanism. This is typically a caliper brake(s) system and/or an electric-type brake in the spindle drive motor. In most cases, a third increase in the welding force (usually referred to as the upset force) is applied at the start of or after braking, which consolidates the joint. In contrast to inertia welding, where the microstructure at the interface reflects a rotational-type forging, direct-drive friction welding produces an axially forged microstructure in the weld. However, if braking times are increased, allowing the upset force to be applied while the spindle may still be rotating, some rotational-type forging can be obtained.

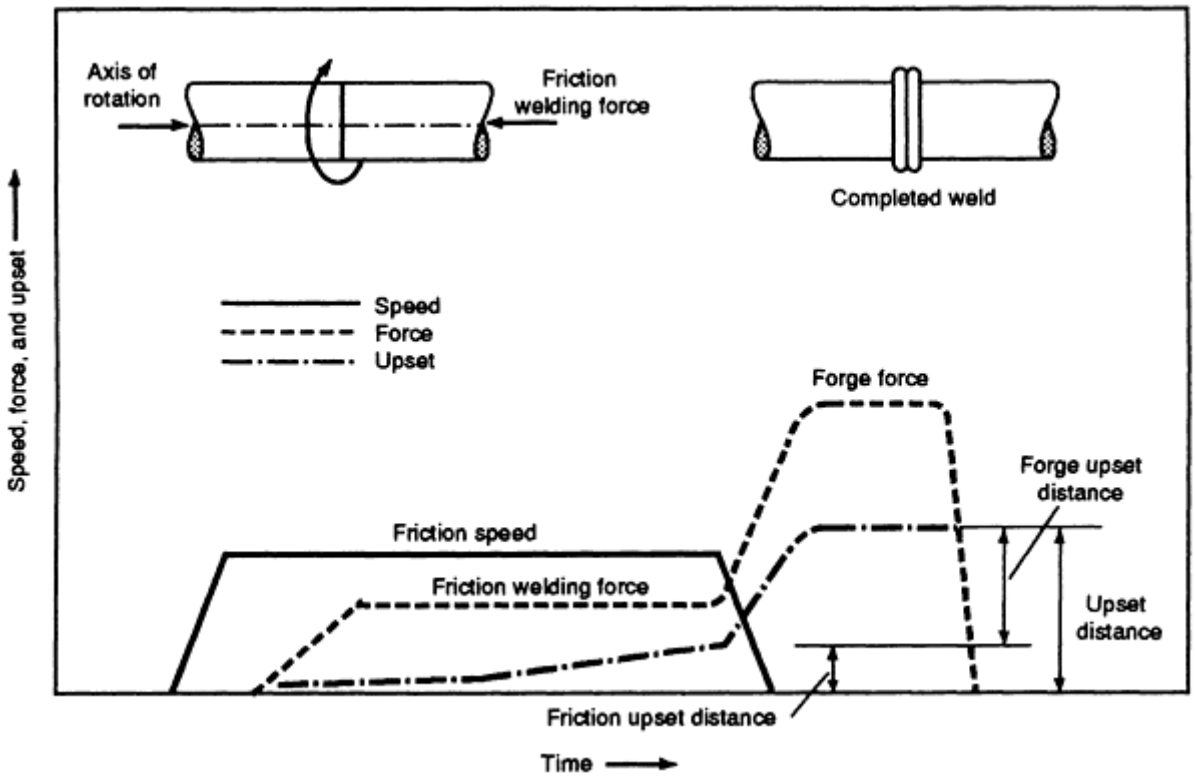

FIG. 2 DIRECT-DRIVE FRICTION WELDING PARAMETER CHARACTERISTICS. SOURCE:ANSI/AWS C6.1-89

One advantage that direct-drive friction welding possesses is reduced torque peaks, compared with those experienced in inertia welding. The initial torque peak is reduced by applying a low initial welding force (first friction), which reduces the rate at which heating occurs. This practice typically is used to reduce the power requirements at the beginning of the welding cycle. In addition, the spindle rotation in this process is either nearly or completely stopped before the final upset of the parts, thus minimizing the final torque peak. This is advantageous when welding thin-walled tubes, the walls of which could tend to tear under high torque peaks. Although torque peaks in inertia welding can be reduced by using lower welding forces, they will still be larger than those of direct-drive friction welding.

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Inertia Welding Parameter Calculations

Differences in part geometry (bar-to-bar, tube-to-tube, bar-to-plate, and so on) affect welding parameter calculations. The calculation procedures described here are based on carbon steel. For a given alloy system, inertia welding spindle speeds are set within a specified range of surface velocities. The actual surface velocity depends on the size of the part to be joined. Surface velocities for welding carbon steels in all geometries typically range from 90 to 610 m/min (300 to 2000 ft/min). The actual spindle speed (rev/min) is calculated by:

$$rev/mim = \frac{c\,S}{p\,OD} \qquad \textbf{(EQ 1)}$$

where χ, the conversion factor, is 12 for the U.S. customary unit and 1000 for the metric SI unit, S is the surface velocity (m/min or ft/min), and OD is the outside diameter of the part (mm or in.).

For solid bars and a fixed welding force, lower surface velocities tend to reduce center heating. Center heating is not a problem with tube-type geometries, which means there is greater flexibility in the surface velocities used. The effect of surface velocity on the heat pattern in a solid bar is shown in Fig. 3.

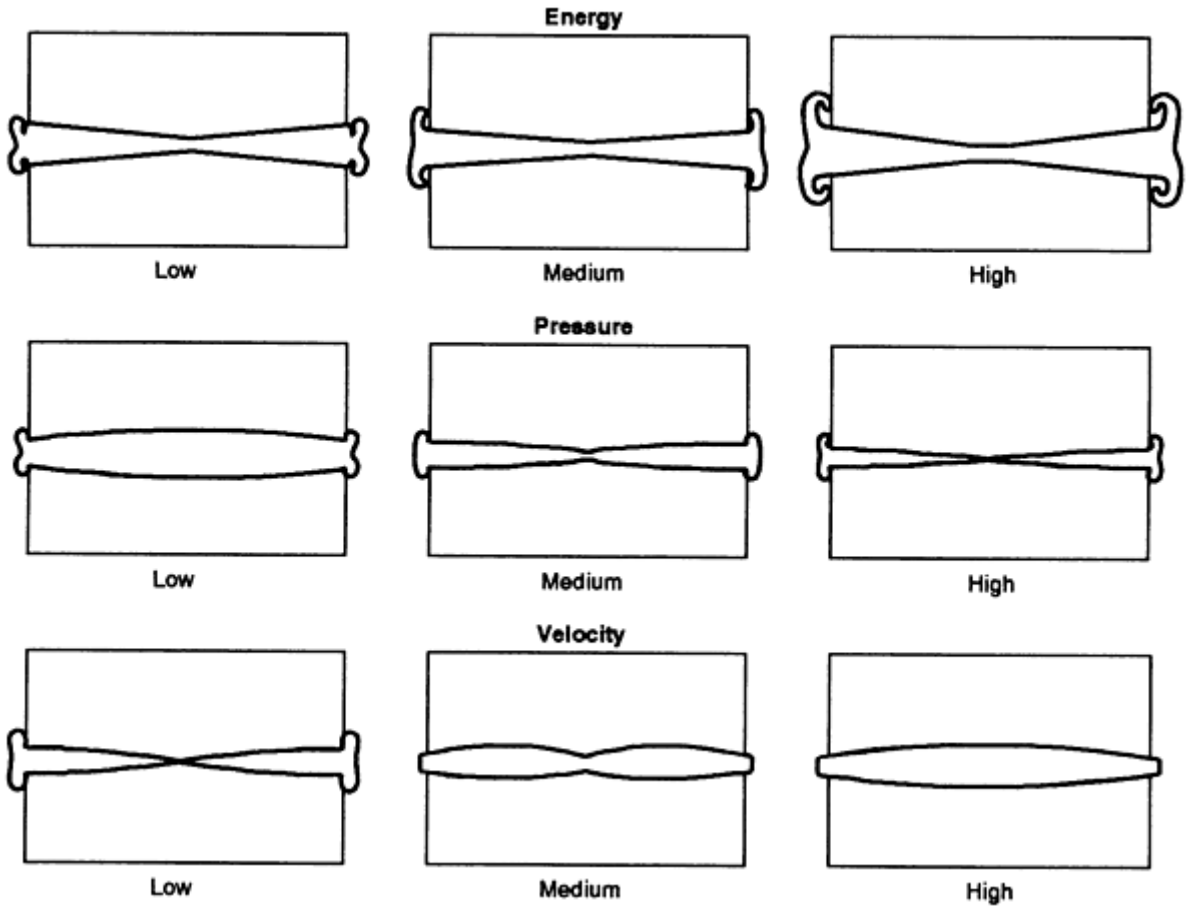

FIG. 3 EFFECT OF WELDING VARIABLES ON THE HEAT PATTERN AT THE INTERFACE AND FLASH FORMATION OF INERTIA WELDS

As mentioned in the introduction of this article, rotating flywheels are the source of energy for joining in the inertia welding process. During the welding-force stage where spindle deceleration occurs (see Fig. 1), the process is characterized by a loss of material from the interface to the flash. Larger inertias prolong the welding cycle. In addition, while maintaining a constant applied energy (combination of spindle speed and mass), rotational forging may be extended using larger flywheels and lower surface velocities.

The calculation of the flywheel energy that is needed to produce a weld depends on the surface velocity, material type, and joint geometry. As shown in Table 1 for a solid bar of low-carbon steel, the moment of inertia (expressed as wK^2 in mass units) is 0.18 kg · m^2 (4.2 lb · ft^2). This is found by using Eq 2 and the approximate flywheel energy (E_T) of 63 N · m/mm^2 (30,000 ft · lbf/$in.^2$) for the inertia welding of low-carbon steels per square inch:

$$wK^2 = \frac{E_T C}{(rev/mim)^2} \qquad \textbf{(EQ 2)}$$

where the value of C is 5873 for the U.S. customary unit and 182.4 for the SI unit, E_T is the total flywheel energy, and the $(rev/min)^2$ value is that for the spindle, which was calculated in Eq 1.

TABLE 1 TYPICAL INERTIA WELDING CONDITIONS FOR LOW-CARBON STEEL

PARAMETER	VALUE
BAR-TO-BAR	
DIAMETER, MM (IN.)	**25.4 (1)**
WELD AREA, MM^2 ($IN.^2$)	**506 (0.78)**
TOTAL MOMENT OF INERTIA, WK^2, $KG \cdot M^2$ ($LB \cdot FT^2$)	**0.18 (4.2)**
SPEED	
ANGULAR VELOCITY, REV/MIN	**5725**
SURFACE VELOCITY, M/MIN (FT/MIN)	**460 (1500)**

SURFACE VELOCITY, M/MIN (FT/MIN)	**460 (1500)**
TOTAL FORCE, KN (LBF)	**91.7 (20,600)**
UPSET DISTANCE, MM (IN.)	**5.1 (0.200)**

In the inertia welding process, there is flexibility in how the welding force can be applied, although a single force followed by an upset force is often used. The typical forces for welding carbon steels range from 96.5 to 207 MPa (14 to 30 ksi). The second-stage force (forging force), which can vary from 1.5 to nearly 4 times the welding force, is usually determined through experimentation. The effect of the welding force on the size of the heat-affected zone (HAZ) is inverse to that of surface velocity, that is, welds made at low welding forces have heat-affected areas resembling those produced with high surface velocities (see Fig. 3).

When designing an initial set of inertia welding parameters, the normal order of selection can be summarized as:

- CHOOSE THE DESIRED SPINDLE SPEED (REV/MIN)
- CALCULATE THE TOTAL MOMENT OF INERTIA (WK^2) THAT IS NEEDED FOR THE REQUIRED ENERGY LEVEL, E_T
- CHOOSE THE NEAREST AVAILABLE TOTAL MOMENT OF INERTIA (WK^2) LEVEL ON THE WELDING MACHINE
- RECALCULATE THE NECESSARY REV/MIN WITH THE TOTAL MOMENT OF INERTIA (WK^2) THAT IS AVAILABLE ON THE MACHINE
- CALCULATE THE NECESSARY WELDING FORCE (AND UPSET FORCE, IF USED)

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Direct-Drive Friction Welding Parameter Calculations

Like those of inertia welding, the parameters for direct-drive friction welding were originally developed on carbon steel. Parameter calculations also involve only welding forces and spindle speeds. The same equation (Eq 1) is used for calculating the spindle rev/min value. Surface velocities for the direct-drive friction welding of carbon steels range from

76 to 182 m/min (250 to 600 ft/min). Tubes require slightly higher surface velocities than do bars. Typical welding pressure values for carbon steels range from 83 to 166 MPa (12 to 24 ksi) for the second friction force and from 166 to 332 MPa (24 to 48 ksi) for the upset force. Although first friction forces vary, they are typically 10 to 20% of the second friction force. Examples of welding parameters for bar-to-bar and tube-to-tube direct-drive welds are shown in Table 2.

TABLE 2 TYPICAL DIRECT-DRIVE FRICTION WELDING CONDITIONS FOR LOW-CARBON STEEL

Carbon Steels

Generally, most metals that can be hot forged can readily be friction welded with either process variant. Carbon steels, which fall into this category, have been the fundamental basis of welding-parameter calculations for both inertia and direct-drive friction welding. Low- and medium-carbon steels are the easiest to weld and generally require no postweld heat treatments. Higher carbon and alloy steels also are easily joined, but the welding-parameter window is narrower than it is for low-carbon steels. This is primarily due to the reduced forgeability characteristics of the higher-carbon steels. Steels that contain significant amounts of free-machining elements, such as lead, also can be friction welded. However, these free-machining elements can cause undesirable directional properties near the bond line and may also act as dry lubricants that reduce frictional heating. Heat-treatable steels also can be friction welded. The rapid quenching of the weld area can present hardenability problems and a subsequent tempering or annealing procedure may be required. Hardenable steels such as these should be welded with longer heating times in order to reduce the cooling rate.

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Stainless Steels

Stainless steels are commonly joined using either friction welding process. Austenitic and ferritic stainless steels are easily joined to each other and to themselves using either process. Because the heat-treatable stainless steels are sensitive

to temperature and pressure, a post-weld thermal treatment may be necessary to achieve the desired weld properties. Precipitation-hardenable stainless steels are often solution heat treated and aged after welding. In some cases, however, heat-treated base material must be stress relieved.

Welding parameters for stainless steels are similar to those used with carbon steels. Surface velocities for both bars and tubes fall within the same range as for carbon steels for both process variants. The flywheel energies, E_T, and welding forces for the inertia welding of stainless steels are typically 30 to 50% higher than those for carbon steels. For direct-drive friction welding, the welding forces are nearly the same as those used for carbon steel. Another factor relevant to the friction welding of stainless steel is the location of the weld when subjected to a corrosive environment. If possible, it should be located outside of the corrosive environment. In some instances, an increased corrosion rate occurs near the weld. This can be a concern, depending on the application.

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Aluminum-Base Alloys

Aluminum alloys are commonly joined by either of the friction welding processes. In inertia welding, rotational forging will form flow lines with radial patterns, as opposed to the straight flow patterns produced with direct-drive friction welding or flash welding. An advantage of direct-drive friction welding is that thin-walled aluminum tubes are somewhat easier to join. This is because the rotation of the spindle can be stopped prior to forging. Because severe hot working of the materials will occur, the heat-affected regions of friction welds are very narrow and have a fine-grained structure. In addition, the severe hot working leads to dynamic recrystallization at the interface.

Parameters for the inertia welding of aluminum alloys differ somewhat from those used for carbon steel. The differences are due to the higher thermal conductivity of these materials. The surface velocities used for welding aluminum alloys are approximately 30 to 50% higher than those used for carbon steel. Inertia welding pressures are significantly lower than they are for carbon steels, ranging from 20 to 50% of those used for a similar-sized carbon steel part. The flywheel energy is from 20 to 50% of that for carbon steel. For direct-drive friction welding, the surface velocities are 10 to 50% higher than they are for carbon steel, depending on the type of aluminum alloy. Welding and upset pressures are typically 30 to 50% of those used for carbon steel.

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Reactive and Refractory Metals

The reactive metals comprise titanium and zirconium, whereas the refractory metals comprise tungsten, tantalum, niobium, and molybdenum. Of all these metals, the titanium alloys have been studied most extensively, primarily because of their application in the aerospace industry. In the inertia welding process, titanium alloys have flywheel energies that are similar to those of steel. Surface velocities are typically at the higher end of the scale, ranging from values that are equivalent to those used for carbon steel to values that are 40% greater. However, welding forces are very low, typically ranging from 10 to 30% of those used for welding carbon steel. This difference is attributed primarily to the lower thermal conductivity of titanium.

Work has been done using direct-drive friction welding for titanium, although to a lesser degree than inertia welding. The welding parameters for the direct-drive friction welding of titanium are similar to those of steel, with a slight reduction in the welding forces. Most friction-welded joints in titanium can be used in the as-welded condition. However, somewhat better tensile and fatigue properties are obtained if stress relieving or solution annealing and aging procedures are used.

Zirconium has properties that are very similar to those of titanium. Therefore, initial welding parameters should be based on the parameters for titanium.

Both friction welding processes can be used to join molybdenum and tungsten. Current applications include the friction welding of molybdenum and tungsten wires in drawing operations for the lighting industry. Although there is not much friction welding currently being performed on niobium and tantalum, it is expected that these alloys could also be successfully welded. Tantalum has a very high melting temperature and very good low-temperature ductility. This suggests that a forge-welding process could be applicable.

Copper-, Nickel-, and Cobalt-Base Materials

Copper and nickel are commonly friction welded. Copper alloys are typically used in a dissimilar-metal welding application with aluminum. In the inertia welding process, surface velocities are nearly twice those of carbon steel, because of the high thermal conductivity of copper. Flywheel energies and welding forces are approximately 50% of those used for carbon steel.

For direct-drive friction welding, higher surface velocities would be required, given the high thermal conductivity of copper. However, welding forces would be lower, because the strength of copper is lower than that of carbon steel.

Nickel-base alloys also are commonly joined using the inertia welding process. Surface velocities are much lower than those of steel, typically ranging to a level that is no higher than 50% of that for carbon steel. However, because of increased elevated-temperature properties, flywheel energies and welding forces are nearly double those required for carbon steels. After inertia welding, the joint in heat-treatable nickel-base alloys is often subjected to a solution and aging treatment. This is needed to precipitate second-phase particles (that is, γ' and γ'') that have been taken back into solution by the thermal cycle of the weld.

In direct-drive friction welding, the surface velocities are approximately half those used for carbon steel, whereas welding forces are nearly double those used for carbon steel. The welding procedures for cobalt-base alloys are similar to those for nickel-base alloys.

Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding

Tim Stotler, Edison Welding Institute

Dissimilar Metals

In terms of process requirements for the inertia or direct-drive friction welding of dissimilar material combinations, it is typically found that the welding parameters tend to be closer to those used for the higher-strength material in the combination. This results in a significant loss of the lower-strength material during welding and upsetting. As in any other joining process, it must also be remembered that the strength of the bond can be no higher than that of the lower-strength material. The combinations of metals that have been joined using the friction welding processes are shown in Fig. 4. Other combinations may be possible, with additional procedure development.

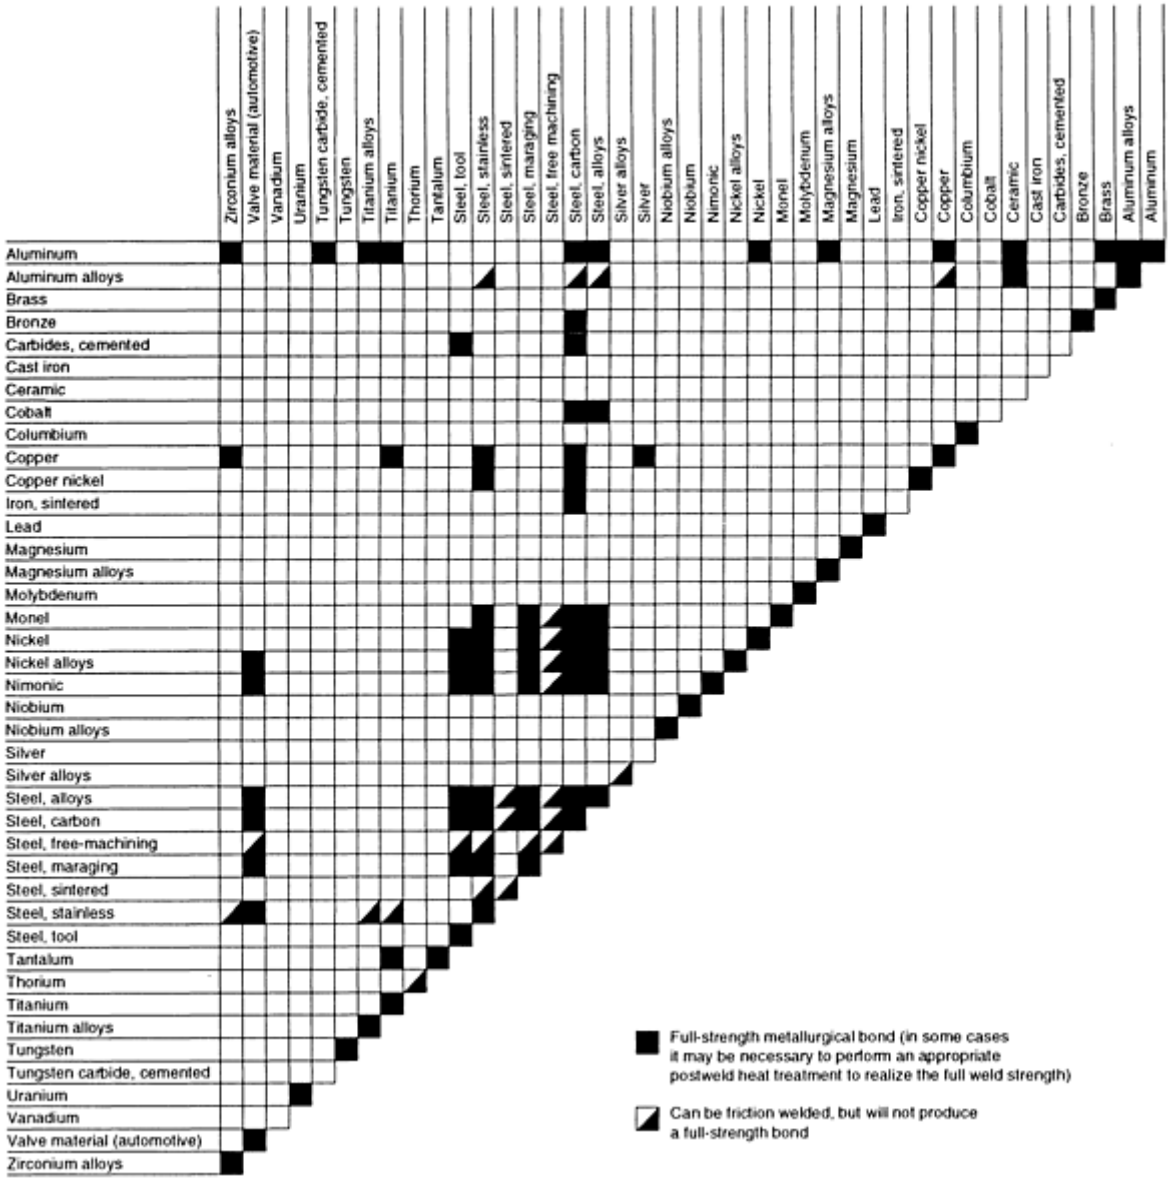

FIG. 4 MATERIAL COMBINATIONS THAT ARE WELDABLE BY FRICTION WELDING PROCESSES. LIST OF ALLOYS WAS COMPILED FROM AVAILABLE FRICTION WELDING LITERATURE. SOURCE: ANSI/AWS C6.1-89

Two of the most common dissimilar joints produced using the friction welding processes are:

- COPPER TO ALUMINUM
- ALUMINUM TO STEEL OR STAINLESS STEEL

In such applications, some surface preparation may be required prior to joining, because of oxidation of the aluminum surface. In most cases where aluminum is used in a joint, a dry machining or chemical etching of the aluminum is preferred. As mentioned previously, a majority of the forging (material loss) will occur in the aluminum, especially for the aluminum-to-steel joint.

The joining of aluminum to ceramics has also been performed, primarily for the electrical industry. Steel has also been attached to ceramics using an aluminum interlayer. This is performed by first welding the steel to the aluminum, followed by welding the bimetal joint to the ceramic. Using an interlayer for applications such as this is common when two

incompatible materials require joining. The interlayer materials must be selected on the basis of their forgeability and compatibility with the two parent materials.

Procedure Development and Practice Considerations for Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics, Inc.

Introduction

ULTRASONIC WELDING (USW) is effectively used to join both similar and dissimilar metals with lap-joint welds. Various metals differ in weldability based on their compositions and properties. The metals that are considered more difficult to weld are those that require either high power or long weld times, or both, and those that incur operational problems, such as tip sticking or short tip life. Most ductile metals can be welded together. Figure 1 identifies some of the monometallic and bimetallic combinations that currently can be ultrasonically welded on a commercial basis.

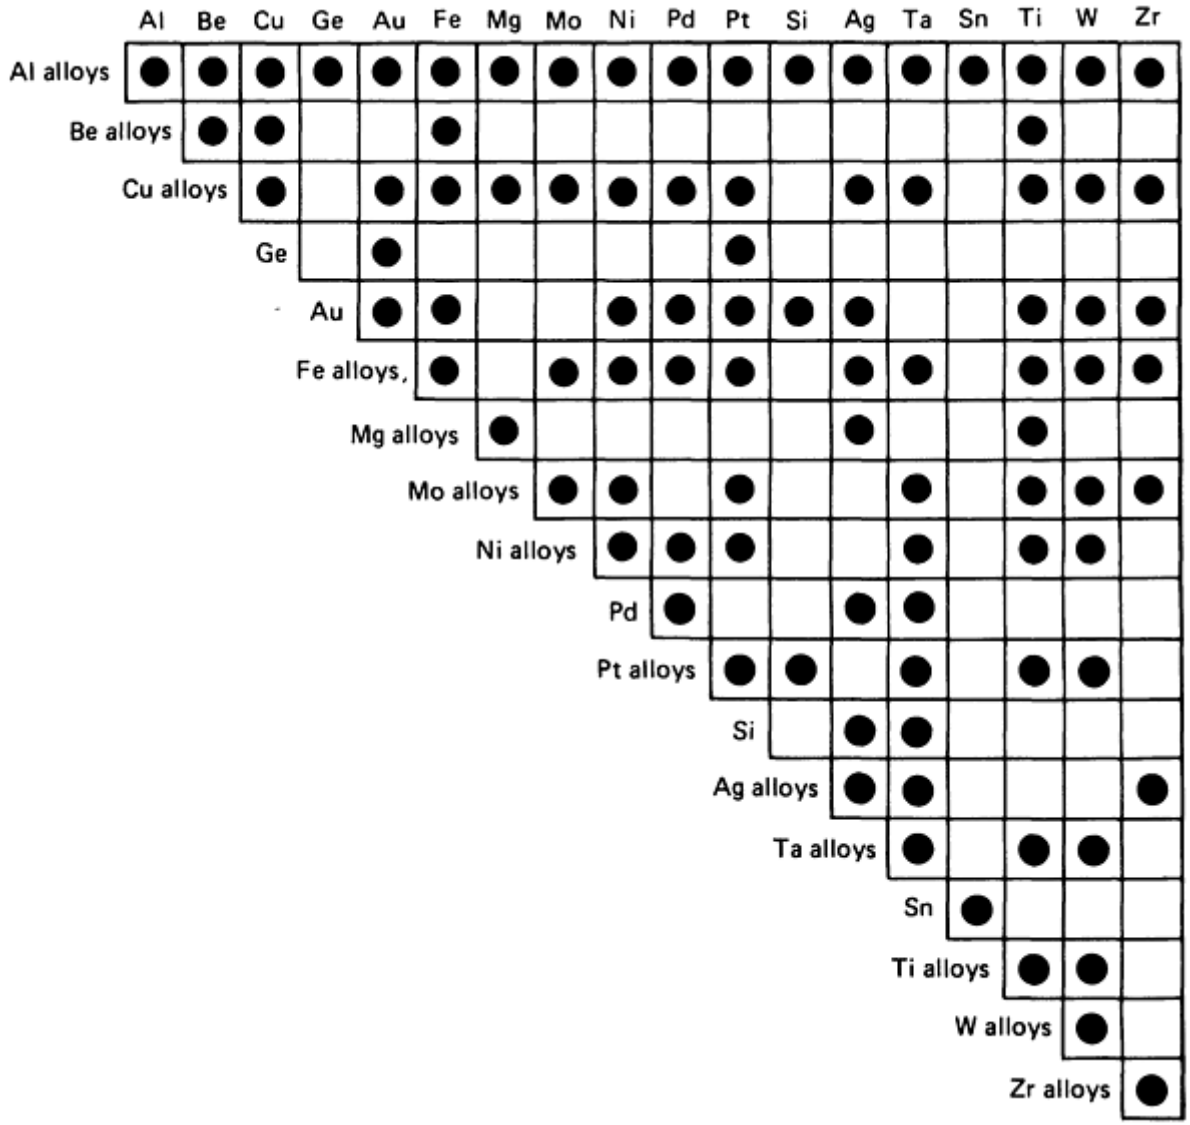

FIG. 1 CHART SHOWING ULTRASONICALLY WELDABLE METAL COMBINATIONS. BLANK AREAS IN THE CHART REPRESENT COMBINATIONS THAT HAVE NOT BEEN SUCCESSFULLY JOINED OR IN WHICH WELDING HAS NOT BEEN ATTEMPTED. SOURCE: AMERICAN WELDING SOCIETY

In ultrasonic welding, the temperature at the weld is not raised to the melting point. Therefore, there is no nugget similar to that formed in resistance welding. Weld strength is equal to the strength of the base metal. However, ultrasonic welding is typically restricted to relatively thin materials (foil or extremely thin gage thicknesses). The process, which can also be used for joining plastics, is finding wider applications in that field than in metals joining.

Ultrasonic welding is used extensively in the electronics, aerospace, and instrument industries. It is also used for producing packages and containers and for sealing applications.

This article describes procedure considerations for the ultrasonic welding of specific material types. For descriptions of USW processes and equipment, see the article "Ultrasonic Welding" in this Volume.

Procedure Development and Practice Considerations for Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics, Inc.

Difficult-to-Weld Alloys

Satisfactory welds can be made in certain ferrous alloys. Frequently, however, low tip life and poor peel strength are encountered.

Carbon and Low-Alloy Steels. A weld between a 0.9% C steel and iron is shown in Fig. 2. Because many other processes are available for joining ferrous metals, ultrasonic welding usually is not chosen. Copper flash or copper plating on steel will sometimes improve the quality of the weld.

FIG. 2 PHOTOMICROGRAPH SHOWING WELD INTERFACE CROSS SECTION OF 0.81 MM (0.032 IN.) THICK HIGH-CARBON (0.9 WT% C) STEEL ULTRASONICALLY WELDED TO 0.81 MM (0.032 IN.) THICK IRON. 1000×

High-Strength Steels. Ultrasonic welding of high-strength steels is not considered to be viable.

Stainless Steels. A weld in 0.35 mm (0.014 in.) thick half-hard AISI 300-series stainless steel is shown in Fig. 3. Although it is possible to produce welds in stainless steels using ultrasonic welding, it is not the process of choice.

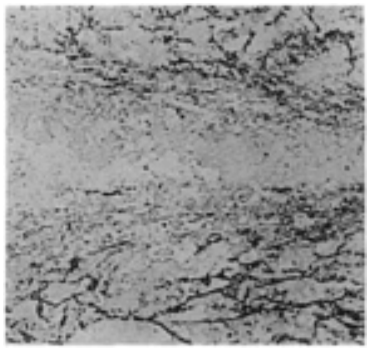

FIG. 3 PHOTOMICROGRAPH SHOWING WELD INTERFACE CROSS SECTION OF TWO 0.36 MM (0.014 IN.) THICK PIECES OF HALF-HARD AISI 300-SERIES STAINLESS STEEL THAT ARE ULTRASONICALLY WELDED TO EACH OTHER. 500×

Procedure Development and Practice Considerations for Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics, Inc.

Weldable Materials

Aluminum Alloys. All combinations of aluminum alloys are ultrasonically weldable. The significant diffusion that is typical of ultrasonic welds in aluminum is shown in Fig. 4. In general, the hardness of work-hardenable aluminum should range from quarter-hard to half-hard. Annealed materials exhibit high deformation when ultrasonically welded.

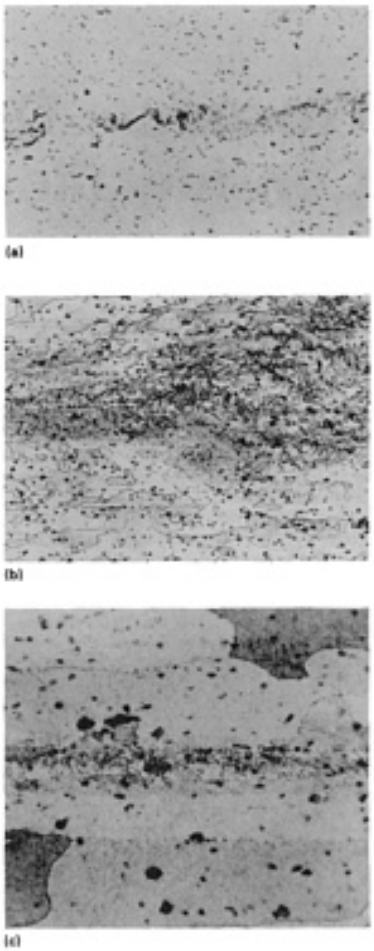

FIG. 4 PHOTOMICROGRAPHS OF WELD INTERFACE CROSS SECTIONS OF SELECTED ULTRASONICALLY WELDED ALUMINUM ALLOYS. (A) TWO PIECES OF 0.30 MM (0.012 IN.) THICK 1100 H14 ALLOY. 500×. (B) TWO PIECES OF 0.81 MM (0.032 IN.) THICK 2024-T3 BARE ALUMINUM ALLOY. 150×. (C) TWO PIECES OF 1.02 MM (0.040 IN.) THICK 2020 ALLOY. 750×

Some aluminum alloys (particularly the 1100 series and 2036 alloy) tend to stick to the welding tip. Tip sticking can sometimes be overcome by using high power and a short welding time. Hardened tool steel tips exhibit the most satisfactory results. Other solutions include using a mechanical stripper where light sticking occurs or placing a thin-gage steel shim between the vibrating tip and the weldment.

Various tip geometries and surface finishes can be used for welding aluminum, including circular radiused, flat cross-hatched, bulls-eye, and serrated types. Tips can be circular, rectangular, line-shaped, and so on, as suits the end use of the workpiece.

The aluminum adjacent to the tip should be less than 2.5 mm (0.1 in.) thick for the highest strength results. The material to which it is welded does not require a thickness limitation. Solid wires with diameters up to 3.18 mm (0.125 in.) or stranded wires with diameters up to 6.4 mm (0.25 in.) also can be welded.

Commercial applications of ultrasonically welded aluminum alloys include:

- SEAM WELDING OF LIGHT-GAGE FOILS
- WELDING OF STRANDED WIRE TO TERMINALS
- JOINING MULTIPLE LAYERS OF ALUMINUM FOIL TO A CAPACITOR TERMINAL
- JOINING ALUMINUM FRAMES TO ALUMINUM GRILLES FOR HEATING DUCTS
- AIRCRAFT PANEL WELDING FOR THE A-10 AIRCRAFT

- ALUMINUM INTERCONNECT WELDING ON PHOTOVOLTAIC PANELS

Reactive and Refractory Base Metals. The photomicrographs in Fig. 5 show ultrasonic welds in molybdenum. This material, as well as other reactive and refractory metal alloys, are difficult, but not impossible, to join using the ultrasonic welding process. In general, weldability appears to depend on the hardness and the ductility of the materials. Softer, more-ductile materials are more likely to weld, whereas hard, brittle materials tend to exhibit stress crocks under ultrasonic activation.

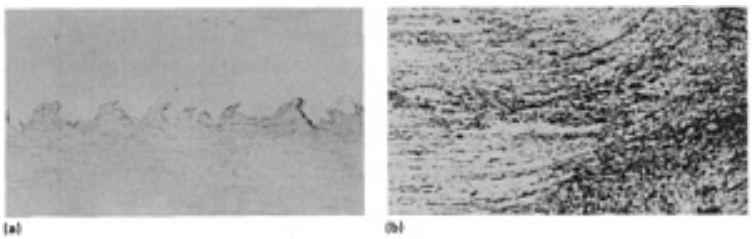

FIG. 5 PHOTOMICROGRAPHS OF WELD INTERFACE CROSS SECTIONS OF SELECTED ULTRASONICALLY WELDED MOLYBDENUM ALLOYS. (A) 0.13 MM (0.005 IN.) THICK NICKEL JOINED TO 0.51 MM (0.02 IN.) THICK MOLYBDENUM. 200×. (B) TWO PIECES OF 0.20 MM (0.008 IN.) THICK ARC CAST MOLYBDENUM WELDED TOGETHER. 140×

The welding of materials in this class is limited to thin sections with thicknesses under 0.4 mm (0.016 in.).

Titanium alloys, which have a very hard oxide layer, should be chemically etched before welding is attempted. Oxide removal should occur not more than 24 h prior to welding, unless the material is sealed and stored in an inert atmosphere.

Copper Alloys. The greatest industrial use of ultrasonic welding is in the joining of copper and brass materials. Copper alloys can be joined together or to other materials, such as aluminum, with great success. Various tip geometries and surface finishes can be used.

Welds in copper sheet that is up to 2 mm (0.08 in.) thick provide excellent joint strength. Stranded wires for wire harness applications represent one common use. Bundles that have a cross-sectional area up to 30 mm^2 (0.05 $in.^2$) are readily weldable.

The high thermal conductivity of copper is not the deterrent to ultrasonic welding that it is with fusion welding. Applications include:

- STRANDED WIRE TO STRANDED WIRE JOINTS FOR AUTOMOTIVE, TRUCK, AND APPLIANCE HARNESSES
- STRANDED WIRES JOINED TO TERMINALS FOR AUTOMOTIVE AND OTHER ELECTRICAL HARNESSES
- JOINING OF STRANDED WIRES TO SOLID WIRES
- SOLID WIRE TO SOLID WIRE JOINTS IN COMMUTATORS FOR AUTOMOTIVE ENGINE STARTER MOTORS
- JOINING OF COPPER STRIP TO COPPER STRIP FOR ELECTRICAL GROUNDING GRIDWORK
- JOINING OF FLAT WIRE TO FLAT WIRE FOR AUTOMOTIVE ENGINE STARTERS AND COILS
- JOINING OF FLAT COPPER SLUG TO ALUMINUM PLATE FOR AUTOMOTIVE ENGINE IGNITION MODULES
- JOINING OF ENAMELED WIRE TO STEEL HOUSING FOR SOLENOID COIL GROUND
- JOINING OF COPPER TUBE CLOSURES FOR HEATING, VENTILATING, AND AIR CONDITIONING (HVAC) INDUSTRY

- JOINING OF BRASS U-SHAPED SECTION TO A BRASS PLATE FOR A BRUSH HOLDER
- JOINING OF COPPER STEEL LAMINATE TO ITSELF FOR A COMMUNICATIONS CABLE SHEATHING

Precious Metals. Most of the precious metals (that is, gold, silver, platinum, and their alloys) are weldable ultrasonically. Materials plated with such metals are also ultrasonically weldable.

Nickel-Base Alloys. Many nickel-base alloys and nickel-plated materials are ultrasonically weldable. Figure 6 is a photomicrograph of nickel ultrasonically welded to gold-plated Kovar.

FIG. 6 PHOTOMICROGRAPH SHOWING WELD INTERFACE CROSS SECTION OF 0.08 MM (0.003 IN.) THICK NICKEL ULTRASONICALLY WELDED TO 0.08 MM (0.003 IN.) THICK GOLD-PLATED KOVAR. 300×

Figure 7 shows a weld in the nickel-base alloy Inconel X. A heat-affected zone (HAZ) is produced in nickel. Significant penetration across the interface is exhibited. Nickel sulfamate plating gives better results than electroless nickel plating when joining nickel-plated materials.

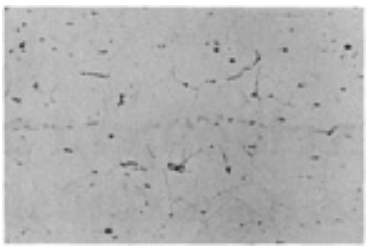

FIG. 7 PHOTOMICROGRAPH SHOWING WELD INTERFACE CROSS SECTION OF TWO 0.30 MM (0.012 IN.) THICK PIECES OF SOLUTION HEAT TREATED AND AGED INCONEL X THAT WERE ULTRASONICALLY WELDED TO EACH OTHER. 150×

Procedure Development and Practice Considerations for Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics, Inc.

Dissimilar Metal (Nonferrous-to-Nonferrous) Combinations

Perhaps one of the most useful characteristics of ultrasonic welding is its ability to weld dissimilar material combinations. Primarily used to join copper and aluminum alloys, this technique promotes the advantages of using aluminum as a backing plate and the solderability of copper for attaching circuitry. [For example, copper slugs are ultrasonically welded to an aluminum backing plate for automotive-engine ignition modules and for antilock braking system (ABS) sensors]. The copper is more suitable for soldering the circuitry and provides a better match to the expansion coefficient of the chip carrier. This is important if the stress of thermal cycling is to be overcome.

When using aluminum for electrical wiring applications, one of the major causes of failure has occurred at the mechanical crimp between the aluminum wire and the connector. Problems have involved corrosion and loosening of the wire at the joint, as a result of thermal stress. In some applications, a copper "pigtail" inserted between the aluminum wire and the connector can eliminate this problem.

Other typical applications include:

- CONSTRUCTION OF A LITHIUM BATTERY, WHICH REQUIRED THE JOINING OF EITHER THIN ALUMINUM, COPPER, OR NICKEL SHEETS TO EXPANDED NICKEL MESH. ALL THREE VARIATIONS PROVIDED ELECTRICALLY AND THERMALLY SOUND JOINTS OF ADEQUATE STRENGTH
- COPPER WIRES WELDED TO COPPER-FLASHED STEEL PLATE TO MAKE A CARBON BRUSH HOLDER FOR A LOCOMOTIVE ELECTRIC TRACTION MOTOR. THE ULTRASONIC WELDED ASSEMBLY REPLACED A COMPLICATED PROCESS THAT REQUIRED RIVETING AND FORMING OF THE "BRIDGE" FOR THE BRUSH
- COPPER WIRES WELDED TO COPPER-PLATED STEEL FOR AN AUTOMOBILE SEAT SWITCH
- COPPER WIRES WELDED TO STAINLESS STEEL AS PART OF A PHOTOVOLTAIC ASSEMBLY
- COPPER WIRES AND STRIPS WELDED TO SILVER-PLATED TERMINALS

Procedure Development and Practice Considerations for Explosion Welding

Vonne D. Linse, Edison Welding Institute

Introduction

EXPLOSION WELDING (EXW), like all other welding or joining processes, has a well-defined set of input parameters or conditions that must fall within certain limits for the desired weld quality to be achieved. Contrary to other joining processes, however, the EXW occurs so rapidly (within a time period of a few microseconds) that there is no time for in-process adaptive control or modification of the welding parameters or conditions. Therefore, a total quality joining approach must be taken to ensure that proper process parameters are applied and controlled to consistently achieve high-quality welds. The quality must be built into the prewelding stages of the preparation of the process materials and setups before welding takes place. It is necessary to be thoroughly familiar with every aspect of the process and the quality level that must be applied in order to ensure the consistent quality of the end-product weld.

This article provides a general overview of the important mechanistic aspects of EXW, the process-material interactions, and the critical aspects or parameters that must be controlled. The procedure for ensuring control is also discussed. This type of approach to setting and controlling process parameters is particularly important when explosion welding dissimilar or metallurgically incompatible metals. Metallurgically incompatible combinations, such as titanium and steel, aluminum and steel, and zirconium and steel, will form brittle intermetallic compounds at the explosion weld interface if excessive energies are used during welding. The intermetallic compounds result in poor-quality welds. Setting and controlling process parameters are also important when welding the newer advanced materials, which have little tolerance for parametric variation (Table 1). Information about the principles underlying this process is available in the article "Fundamentals of Explosion Welding" in this Volume. Information about EXW equipment and applications can be found in the article "Explosion Welding" in this Volume.

Critical Process Parameters

In order to fully understand EXW and its control, it is helpful to know the general characteristics of the process, particularly the rates, pressures, and energies involved. The following are the general process parameters:

TRAVERSE RATE, M/S (FT/S)	**2000-3000 (6600-9800)**
PRESSURE, GPA (10^6 PSI)	**1.5-6.0 (0.22-0.88)**
PRESSURE TIME DURATION, μS	**5-20**
ENERGY DEPOSITION/UNIT AREA, J/CM^2 (BTU/FT^2)	**100-300 (90-260)**
ENERGY DEPOSITION RATE, MJ/S (BTU/H)	**20-90 (70×10^6 - 310×10^6)**

By comparison, standard fusion welding processes will typically have traverse rates of a fraction of a meter/second and energy depositions/unit area in the range of 10,000 to 30,000 J/cm^2 (9000 to 26,000 Btu/ft^2). The low-energy input of EXW and the high rate of deposition at the weld interface allow the weld to be made with an absolute minimum of thermal excursion and no resultant beat-affected zone (HAZ).

Procedure Development and Practice Considerations for Explosion Welding

Vonne D. Linse, Edison Welding Institute

Fundamentals of EXW

The overall mechanisms of EXW are well known and are shown in Fig. 1. In general, the energy from an explosive accelerates one of the two components being welded (prime or clad) across a gap or standoff to collide with the second component (base) and form a solid-state metallurgical weld or bond between the two. The various aspects or mechanisms of the process have been investigated and reported over the years; however, the process is still largely controlled by most commercial users on a more or less empirical basis. Important process-input parameters are selected primarily on the basis of past experience and usually are not calculated from basic principles of theory. The following sections ("Explosives and Explosive Detonation" , "Component Acceleration" , and "Component Collision") cover the latter approach to understanding and controlling EXW on a more fundamental basis. This requires breaking down and treating each mechanistic aspect of the process in a step-by-step sequence.

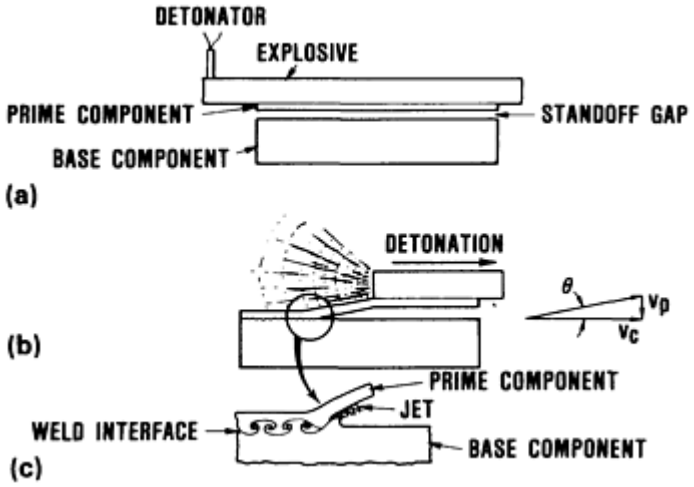

FIG. 1 SCHEMATIC SHOWING MECHANICS OF EXW. (A) ALIGNMENT OF COMPONENTS TO BE JOINED BEFORE DETONATION. (B) MOTION OF COMPONENTS AT DETONATION TO FORM WELD PLUS VECTOR DIAGRAM OF VELOCITY COMPONENTS. (C) CLOSE-UP VIEW OF WAVELIKE WELD INTERFACE CHARACTERISTIC OF EXW PROCESS

Explosives and Explosive Detonation

The explosive is the energy source for the process. It releases its energy in a very specific manner during detonation. It is, therefore, necessary to first understand the manner in which the welding explosive detonates and how its energy is delivered to the prime or cladding component.

In almost all instances, the explosives used for welding can be classified as nonideal. They do not detonate in a manner that can be easily defined by the physics equations-of-state typically used for extremely-high-velocity military or weapons explosives. This results from the fact that these explosives are almost always granular in nature, with the primary ingredient typically being ammonium nitrate (NH_4NO_3). Other ingredients (for example, sensitizers, density control agents, and diluents) are then blended to produce an explosive that yields the desired detonation velocity, pressure, and duration of pressure.

The detonation characteristics of the explosive are controlled by its composition, particle size distribution, pour or packing density, layer thickness, confinement, moisture content, and, in some instances, age. The detonation performance of the explosive should be tailored to match the metals or alloy combination being welded with respect to the density, thickness, and sonic or shock wave velocity of the prime component, as well as the sonic velocity of the base component (if it is different from that of the prime component).

Detonation is a progressive event that starts at the detonator and progresses into the undetonated explosive at a rate known as the detonation velocity. Within the detonation region itself (Fig. 2), the detonation front consists of an initial high-pressure shock wave intense enough to trigger the high-pressure chemical reaction that follows in the reaction zone. In an ideal explosive, the reaction goes almost instantaneously to completion; therefore, the reaction zone is extremely short (usually <1 mm, or 0.04 in.). In a nonideal explosive, however, the reaction zone is much longer (5 to 25 mm, or 0.2 to 1 in.) because the reaction takes longer to complete. While the pressure in the reaction zone of a nonideal explosive is much lower than that in the initial shock wave, it has a much longer duration in which the high-pressure gases in the zone can deliver their impulse to accelerate the prime component. Behind the reaction zone is the third and final region of relatively low-pressure expanding gases, which contribute little, if any, to the impulse delivered to the acceleration of the prime component. Each type of explosive has characteristic detonation velocity, pressure, and duration factors that can be applied to predict the specific velocity, pressure, and duration for a given thickness and density of that explosive. For welding, it is usually desirable for nonideal explosives to detonate in the range of 2000 to 3000 m/s (6600 to 9800 ft/s). If the explosive is manufactured to exacting specifications, it is possible to control the detonation velocity within ±2% of the target terminal velocity. With nonideal explosives, however, such factors as run-up regions near the initiation point and predetonation compression due to the precursor shock wave in the prime component ahead of the EXW collision front can cause nonsteady-state detonation conditions, which in turn can result in nonuniform weld quality.

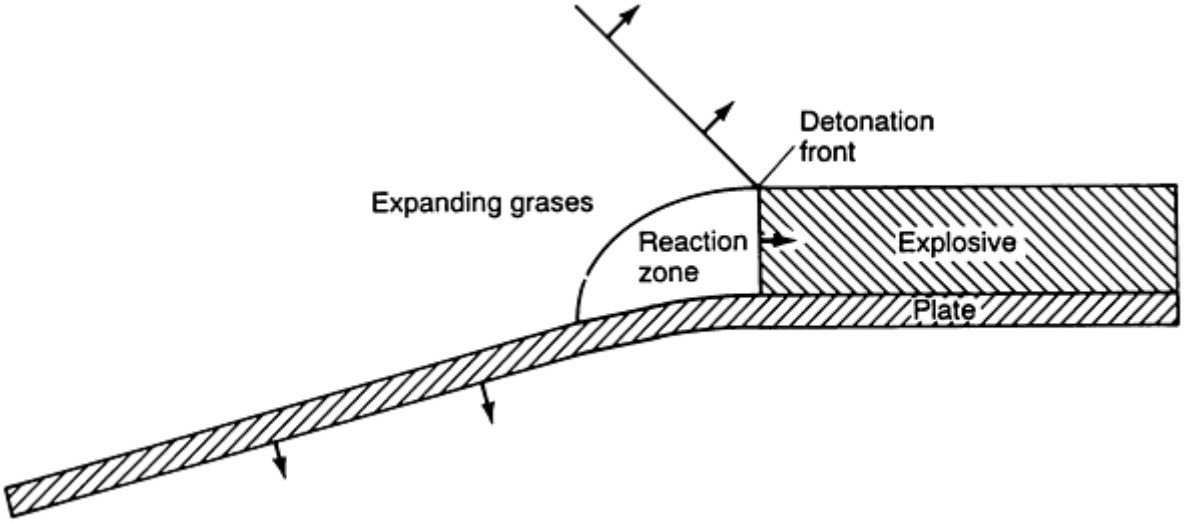

FIG. 2 SCHEMATIC SHOWING DETONATION REGIONS IN A NONIDEAL EXPLOSIVE AND THE ASSOCIATED ACCELERATION OF THE PRIME COMPONENT

Component Acceleration

For welding, the explosive is distributed over the top or exposed surface of the prime component and is detonated such that the detonation front progresses in a grazing or tangential manner over the length of the prime component. In doing so, the explosive delivers a specific level of impulse to the prime component that causes it to be accelerated to a terminal bend angle, θ, and velocity, v_p, as shown in Fig. 1. For explosion welding, the acceleration region before terminal conditions are reached is the important region.

The acceleration of the prime component actually results from the two separate zones of the detonation region in the explosive. First is the contribution of the high-pressure shock front in the explosive. This imparts a high-pressure shock wave into the prime component. The shock wave traverses back and forth, or rattles, between the opposite surfaces of the component, causing it to accelerate quickly in its early stages. The effects of this contribution diminish quickly and cause the component to reach only approximately 80% of the full-potential bend angle (Fig. 3) and velocity. As the effects of the shock component begin to diminish, the expanding high-pressure gas from the trailing reaction zone takes over and continues the acceleration more gradually until the terminal angle and velocity are obtained when the reaction is completed. This contribution (Fig. 3) plus the shock contribution yields the total impulse delivered to the prime component. In an ideal explosive, nearly all of the acceleration comes from the extremely high pressure of the shock wave and very little from the trailing reaction zone; therefore, the primary component reaches terminal conditions much more quickly with an ideal or near-ideal explosive.

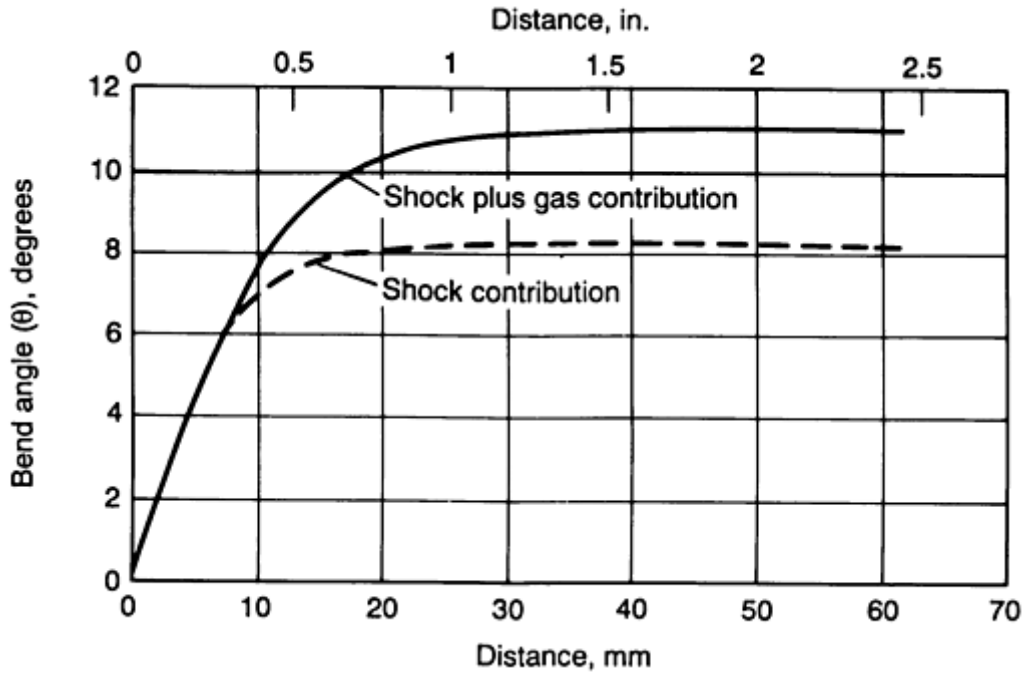

FIG. 3 PLOT OF PRIME PLATE COMPONENT BEND ANGLE VERSUS DISTANCE TO SHOW CONTRIBUTION OF SHOCK WAVE AND GAS PRESSURE TO ACCELERATION

The prime component acceleration depends on the following parameters:

- EXPLOSIVE PRESSURE (SHOCK AND GAS)
- DURATION OF THE EXPLOSIVE PRESSURE PULSE
- SONIC OR SHOCK WAVE VELOCITY OF THE PRIME COMPONENT
- THICKNESS OF THE PRIME COMPONENT
- DENSITY OF THE COMPONENT MATERIAL

With the above variables, the acceleration characteristics of the prime component can be calculated. In addition, techniques exist to directly measure the acceleration of a prime component (Ref 2). Precise knowledge of the acceleration achieved for a specific prime component/explosive combination is extremely important. It allows the exact standoff or separation distance to be set between the prime and base components to obtain the required collision angle and prime component velocity in the next step of EXW (that is, the collision and welding step).

Component Collision

Once the accelerated prime component crosses the standoff gap, it collides with the stationary base component. The exact collision angle and prime component velocity achieved at the time of the collision will, of course, depend on the combination of the acceleration characteristics of the prime component and the standoff distance selected for the system. The standoff distance is usually selected to ensure that the collision occurs while the prime component is still undergoing acceleration, usually in its final stages.

The collision is characterized by:

$$V_p = 2v_c \sin\left(\frac{q}{2}\right) \qquad \textbf{(EQ 1)}$$

where v_p is the velocity of the prime component or the relative velocity of the prime and base components; v_c is the collision point velocity of the welding front, which also equals the detonation velocity, v_d, of the explosive; and θ is the collision angle. If any two of the above variables are known, it is then easy to calculate the third variable. The relative component velocity, v_p, at the time of the collision is very important in that it determines the equation-of-state pressure generated at the collision point. This pressure, which must be sufficient to generate hydrodynamic flow of both materials at the collision point, can be determined from the characteristic pressure versus plate (or particle) velocity for the material or materials being welded. Figure 4 shows a high pressure versus particle velocity plot for a similar material collision (Fig. 5). Initially, the pressure required for dynamic yielding of the two materials being welded is calculated. This pressure is then located on the curve, and a mirror image of the curve is drawn through the selected pressure. The point at which the mirror-image curve intersects the zero pressure line or abscissa is the minimum prime plate velocity necessary to obtain the desired pressure and accompanying dynamic flow and jetting necessary for welding to occur.

Jetting and Weld Formation

When the required minimum collision pressure, a minimum duration of the pressure pulse, and a minimum collision angle are obtained, the surfaces of the two materials being joined locally flow in the immediate region of the collision point. Because of the angular geometry of the collision, these surfaces at the collision point are forced to reverse their flow direction with severe shearing flow and to be ejected out ahead of the advancing collision point in the form of a fine fingerlike mist (that is, a jet) (Fig. 5). Under the extremely high hydrodynamic pressures involved, this jet, which consists of a combination of both parent materials, has an extremely high temperature. When the collision conditions of the weld are within an appropriate range (as discussed in the section "Parametric Limits for Welding" in this article), most of the jet, with its attendant heat, is ejected out of the weld interface with little or no effect on the remaining weld zone. Of greatest importance, however, is that the surface-scarfing action of the jet removes the surface layers containing the oxides and other contaminants that typically inhibit solid-state interaction. This allows the two metals to directly weld or bond under the substantial residual pressure of the collision, which continues to act from some period of time on the two metals at the weld interface. This residual pressure on the interface after the collision also counteracts any reflected stress waves from separating the weld while it is forming.

Procedure Development and Practice Considerations for Explosion Welding

Vonne D. Linse, Edison Welding Institute

Weld Characteristics

Of particular importance is the nature or characteristics of the explosion weld itself. When properly made, it is, in essence, a solid-state bond or weld without any HAZ to degrade its strength, as is typical of all other heat-dependent welding or joining processes.

Weld Interface. Morphologically, two types of explosion weld interfaces can be created. First is the flat or straight-line interface, which occurs only when the collision conditions are at or near the lower limits for jetting and welding. This type of condition is typically avoided in most instances because a slight drop in collision conditions or parameters during welding would stop the welding and leave a nonwelded region.

In most cases, the explosion weld interface will have a wave morphology that is exclusively characteristic of the process. A typical, wavy explosion weld interface between copper and niobium is shown in Fig. 6. This wave formation, which has been the subject of considerable investigation (Ref 3, 4), results from the localized dynamic compression of the two metals in the region immediately adjacent to the collision point and weld interface. The compression causes localized bulk flow of the metals, which become unstable and make the weld interface oscillate above and below the theoretical plane of the interface. The size of the wave pattern is the one postwelding characteristic that can be used to determine the collision conditions used to make the weld and to allow for adjustments in subsequent welds of the same material type and thickness. The wavelengths or frequency of the interfacial wave in an explosion weld is directly related to the thickness of the prime or cladding plate and its angle of collision with the base plate (Ref 5, 6), as shown in Fig. 7. For practical purposes, this relationship is relatively independent of the types or combinations of metals or alloys being welded. It also shows that the wave formation ceases at collision angles of 4° or less.

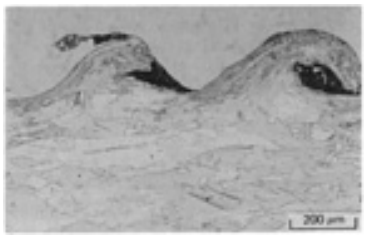

FIG. 6 PHOTOMICROGRAPH SHOWING TYPICAL WAVY WELD INTERFACE OBTAINED WHEN NIOBIUM AND COPPER ARE JOINED BY EXW

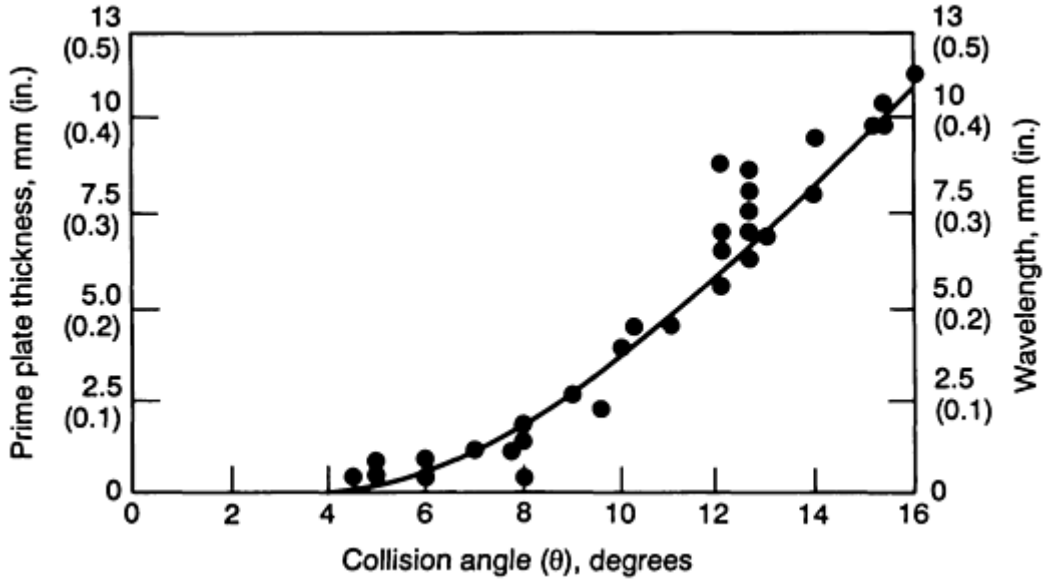

FIG. 7 RELATIONSHIP OF WAVELENGTH TO PLATE THICKNESS AS A FUNCTION OF COLLISION ANGLE

Wave Amplitude. The amplitude of the waves, on the other hand, is more difficult to predict. It depends on several factors, including the relative flow characteristics of the two metals being joined and the collision point velocity of the EXW process.

Control of the wave size, particularly the wavelength, is an important part of controlling several aspects of the explosion weld because:

- WAVE SIZE DETERMINES THE AMOUNT OF LOCALIZED FLOW AND WORK HARDENING IN AND ADJACENT TO THE EXPLOSION WELD INTERFACE.
- EXCESSIVE COLLISION ENERGIES AND WAVE SIZES CAN RESULT IN THE FORMATION OF LARGER MELT POCKETS ON THE FRONT AND BACK SLOPES OF THE WAVES, ALONG WITH RESIDUAL HEAT EFFECTS ON THE REGION IN AND ADJACENT TO THE WELD INTERFACE, WHICH WILL AFFECT THE MECHANICAL PROPERTIES OF THE WELD.
- WAVE SIZE IS AN EXTREMELY CRITICAL FACTOR IN PREVENTING ADIABATIC SHEAR DEFECTS OR CRACKS FROM FORMING ADJACENT TO THE WELD INTERFACE IN SPECIFIC ALLOYS (FOR EXAMPLE, CERTAIN HIGH-STRENGTH NICKEL-BASE AND TITANIUM ALLOYS).

Parametric Limits for Welding. All the above considerations and an understanding of the EXW and its controlling parameters can be assembled to produce a parametric envelope or window of parameters within which a high-quality

explosion weld can be consistently produced. The basic concept of the boundaries defining the envelope has been advanced by several researchers (Ref 7, 8, 9).

A typical parametric envelope is defined by four distinct boundary segments (Fig. 8). The lower boundary (1) is controlled by the collision pressure and dwell time of the pressure pulse. The left boundary (2), although somewhat complicated, is primarily controlled by the sonic velocities of the two materials being welded. The right boundary (3) is controlled by the upper sonic-velocity limit at which a jet will form. It is almost never of concern because EXW is typically conducted at collision velocities significantly below this limit. The upper limit (4 or 4A) is primarily controlled by the kinetic-energy release generated at the collision point. In similar or metallurgically compatible combinations of metals or alloys, increasingly higher amounts of energy in this area of the envelope result in increasingly greater amounts of residual heat effects (for example, large melt pockets, interface voids, and a general degradation of the weld quality and properties). Therefore, this boundary (4) cannot be sharply defined in this instance. In metallurgically incompatible systems, however, this upper boundary (4A) becomes very sharply defined because it corresponds to the energy level at which a brittle intermetallic compound begins to form. Welding at or above this limit produces a weld that is typically brittle and can fail catastrophically in service. Typically, this boundary is relatively close to the lower boundary (1), thus leaving a relatively small amount of latitude in collision parameters permissible to obtain a high-quality weld.

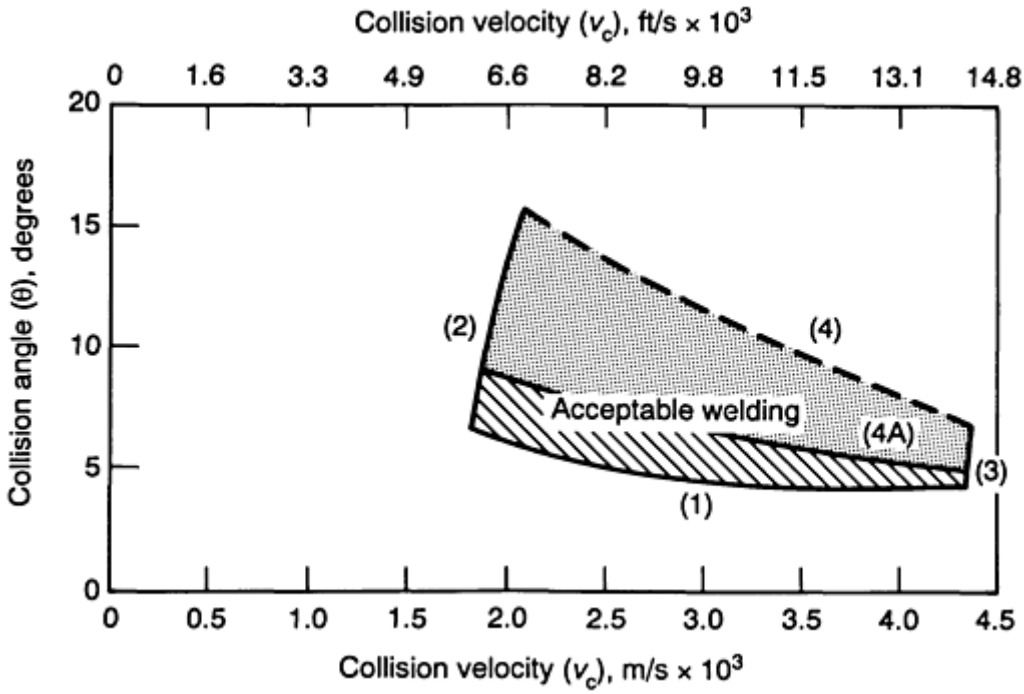

FIG. 8 PLOT OF COLLISION ANGLE VERSUS COLLISION VELOCITY TO OBTAIN TYPICAL EXW PROCESS PARAMETRIC ENVELOPE FOR BOTH SIMILAR AND DISSIMILAR METAL COMBINATIONS. SEE TEXT FOR DETAILS.

Each of the above boundaries can be calculated with relative accuracy for almost all material combinations and thicknesses to be explosion welded. With these limits defined, the collision conditions must then be maintained to fall within the boundaries sufficiently away from the edges to allow for minor variations in the collision conditions during EXW. If this is accomplished, then a reproducible, high-quality explosion weld can always be expected and produced.

Selection Criteria for Brazing and Soldering Consumables

A. Rabinkin, AlliedSignal Amorphous Metals

Introduction

THE ULTIMATE GOAL of brazing and soldering technologies is to join parts into an assembly through metallurgical bonding (Ref 1, 2, 3, 4, 5). This can be achieved by placing a relatively low-melting-temperature alloy, or filler metal, in the clearance, or gap, between the base materials to be joined, and then heating the assembly until the filler metal has melted and spread throughout the gap. The molten metal that fills the gap reacts with the parts being joined and, after solidification, forms an integral whole. The basic brazing/soldering process is depicted in Fig. 1. Assembly heating can be carried out using a variety of means, including electromagnetic induction, Joule heating, ovens, flames, and other forms.

Selection Criteria for Brazing and Soldering Consumables

A. Rabinkin, AlliedSignal Amorphous Metals

Process Stages

There are three major stages in any brazing or soldering process. The first stage occurs during the heating of an assembled workpiece, when the filler metal melts, flows, and completely fills the gap between the parts. Because this gap is usually rather small, ranging from approximately 10 to several hundred μm (0.4 to ~10 mils), the degree to which a molten alloy penetrates into the gap is primarily determined by surface tension effects and, of course, by the chemical-reaction-driven phenomenon that plays an important role in wetting. Because physical properties of the filler metal and base material, such as part dimensions and surface tension forces, have a major role, this first stage can be conditionally called the physical stage.

The second stage, which normally occurs at a given joining temperature, is characterized by an intensive solid-liquid interaction, accompanied by a substantial mass-transfer through the interface with strongly uneven rates. The base material volume that immediately adjoins the liquid filler metal either dissolves or is reacted with the filler metal in this stage. At the same time, a small amount of elements from the liquid phase penetrates into the solid base material. Such mass-transfer unbalance is due to dramatically different diffusion rates in the solid and liquid phases. This redistribution of components in the joint area results in changes to the filler-metal composition, and sometimes, the onset of solidification of the filler metal.

Because all of the processes in this second joining stage have a distinctly metallurgical character, it is called the metallurgical stage. In soldering, these processes proceed to a lesser degree than they do in the brazing process, because of the substantially lower melting temperature of the solder alloys. Here, the dissolution of the base material and mutual diffusion occur to a lesser degree than they do in brazing, but because they can still be significant, protection of the base-material surface is required.

The last stage, which overlaps with the second, is characterized by the formation of the final joint microstructure and progresses during the solidification and cooling of the joint. Here, the crystallization process takes place. Post-solidification cooling causes annealing of the filler metal and partial relief of the thermal stresses induced upon cooling. This stage has very similar features in both brazing and soldering processes.

Cleaning the base-material components being joined and protecting them from oxidation during heating are essential in both brazing and soldering processes. Chemically active substances, called fluxes, are commonly used to provide such cleaning and shielding. The use of nonmetallic agents in fluxes is generally undesirable, because of the increased propensity for their entrapment and the resultant formation of voids in the finished joint. However, the use of certain active elements that can be added to filler-metal alloys to act as a flux can be advantageous. However, this concept usually only works with brazing filler metals. For solders, working temperatures are generally too low for the reduction reactions to take place with adequate speed, although in some cases these reactions do indeed occur.

Selection Criteria for Brazing and Soldering Consumables

A. Rabinkin, AlliedSignal Amorphous Metals

Product Forms and Joint Considerations

Basic forms of both brazing and solder filler metals include solid preforms and powders, which are used mostly in the compound form of paste; plastic-bonded tape (brazing filler metals); and rosin-core wire. Conventional paste forms of joining alloys, which consist of a filler-metal powder, fluxing agent, and a binder/solvent, are applied at externally

accessible locations of the clearance between the base-material components. This practice requires substantial filler-metal flow during joining to achieve constituent filler-metal-phase fusion and binder/solvent extraction. In addition, organic binders in a brazing filler metal decompose when used in the high-vacuum brazing of parts intended for critical, high-temperature service. Such binder decomposition can result in the formation of soot in the joint, which can degrade the performance of expensive vacuum equipment.

A basic requirement for any joint is that its strength and ductility be adequate for the service requirements. Generally, the strength of any materialincreases with decreasing grain size, whereas ductility is affected by the presence of brittle phases, which will be discussed later. Therefore, it is important to limit grain size and the amount of brittle phases, in addition to limiting the porosity in joints. Ideally, the maximum size that the grains in a joint should achieve is equal to half the width or even the complete width of the clearance between the base-material components. Thus, the use of a smaller clearance necessarily limits the maximum grain size, promotes higher cooling rates of the filler-metal alloy, and thereby results in a refined joint microstructure (grain size). A smaller clearance also promotes improved retention of base-material properties, because of curtailed base-material erosion achieved by using a smaller volume of filler metal. The size of the grains and the extent of the brittle intermetallic phases in the parent filler metal directly affect the strength of the brazed joint. This consideration is particularly important under transient heating/cooling conditions, such as torch or belt oven brazing, and during automatic solder die bonding, because of the increase in filler-metal grain size and the growth of brittle phases under both liquid and solid-state diffusion processes. The rapid dissolution of constituent filler-metal alloy phases allows the use of higher joining throughput speeds and/or lower joining temperatures. The choice of a specific filler-metal alloy composition depends on the composition of the base material, conditions being compatible with the base material during the joining operation, and the ability of the entire joint to meet the service requirements of the device. Other considerations include a low filler-metal surface tension and, in the case of brazing alloys, the need to reduce surface oxides on the base material. Specific parameters that determine the soundness of a metallic bond include:

- FILLER-METAL MELTING TEMPERATURE SHOULD BE LOWER THAN THAT OF THE CORRESPONDING BASE MATERIAL.
- TO PROVIDE THE DRIVING FORCE NECESSARY FOR JOINING, FILLER-METAL SURFACE TENSION (IN BOTH SOLID AND LIQUID STATES) SHOULD BE LOWER THAN THAT OF THE BASE MATERIAL.
- TO FORM A GOOD METALLIC BOND, BOTH FILLER METAL AND BASE MATERIAL MUST BE SIMILAR RELATIVE TO STRUCTURE, COMPOSITION, AND PHYSICAL PROPERTIES.
- TO REMOVE THE OXIDE FILM PRESENT ON THE BASE MATERIAL, THE FILLER METAL MUST CONTAIN ELEMENTS THAT PROMOTE THE CHEMICAL REDUCTION/DECOMPOSITION OR THE PHYSICAL REMOVAL OF THE OXIDE LAYER.

Brazing Filler Metals

Brazing filler metal alloy compositions can be grouped into four categories. The first and largest group is eutectic-type alloys that have aluminum, nickel, cobalt, or copper as a base, to which silicon/boron (in the case of aluminum- and nickel-base alloys) and phosphorus (in the case of copper- and nickel-base alloys) are added. The presence of one or more of these elements in the alloys tends to impart lower melting temperatures and surface tensions to the filler metal, as well as compatibility with the base material in terms of structure, composition, and properties. Silicon combined with a small amount of magnesium is what lowers the surface tension and melting temperature of aluminum-base alloys, whereas the magnesium addition serves as a fluxing agent. Boron and silicon are used in high-temperature brazing alloys in which the presence of phosphorus (another potential melting-temperature depressant element) could cause unacceptable joint brittleness. Of the alloy additions that promote the self-fluxing of the filler metal during brazing, boron has the greatest "penetrating power." On the other hand, phosphorus is a beneficial fluxing element for use in copper (low-temperature brazing), whereas silicon, for example, would cause unacceptable copper-joint brittleness. The boron- and phosphorus-containing alloys are brittle because various intermetallic phases precipitate when ingot manufacturing technology is used.

This brittle character has limited the available forms of conventionally produced brazing alloys to just powder forms. Fortunately, it was discovered that the presence of silicon, phosphorus, and boron in many conventional filler-metal alloys that have near-eutectic compositions facilitates the conversion of such alloys into ductile, thin, amorphous alloy foil forms when rapid solidification (RS) technology is used. In many cases, a foil filler metal produced by the RS process is very

well suited for use in brazing applications. The advantageous utilization of microcrystalline/amorphous RS soldering or brazing foil has been growing since the early 1980s (Ref 5).

The second group of brazing filler metals, which are characterized by a phase diagram that includes a peritectic reaction (for copper-tin alloys) or a minimum in the liquidus curve (for gold-nickel alloys), are used primarily in vacuum-brazing applications and, therefore, require no alloying elements to serve as fluxing agents.

The third group of alloys, which is probably the most widely used, is based on the copper-silver binary eutectic system that is modified by substantial additions of zinc and cadmium (both providing fluxing activity) and minor additions of tin and nickel. However, applicability of cadmium-containing alloys is limited, because of more-stringent Environmental Protection Agency restrictions on cadmium usage.

The fourth group of brazing filler-metal alloys consists of eutectic titanium/zirconium-base alloys to which copper and/or nickel are added. These materials may be used extensively in the brazing of titanium-base alloys in the near future.

The first three groups of conventional brazing filler metals have been classified by the American Welding Society into seven well-defined categories (Table 1).

TABLE 1 MAJOR CLASSES OF BRAZING FILLER METALS

NO.	ALLOY FAMILY AND TYPE	AWS DESIGNATION	FORMS	BASE MATERIALS JOINED	MAJOR APPLICATIONS
1	AI-SI, EUTECTIC	BALSI	PREFORMS, WIRE, RODS, FOIL, POWDER, RS FOIL[A]	ALUMINUM AND ALUMINUM ALLOYS, STEEL TO ALUMINUM AND ALUMINUM TO BERYLLIUM	CAR RADIATORS, HEAT EXCHANGERS, HONEYCOMB AIRCRAFT STRUCTURES, STRUCTURAL PARTS
2	CU-X, SOLID SOLUTION CU-ZN PERITECTIC CU-SN, PERITECTIC	BCU RBCUZN NONE	PREFORMS, WIRE, RODS, FOIL, POWDER, RS FOIL	COPPER AND COPPER ALLOYS, COPPER TO MILD STEEL, COPPER TO STAINLESS STEEL	HEAT EXCHANGERS, STRUCTURAL PARTS, AUTOMOTIVE PARTS
3	CU-P, EUTECTIC	BCUP	PREFORMS, WIRE, RODS, FOIL, POWDER, RS FOIL	COPPER TO COPPER, COPPER TO SILVER/OXIDE POWERED METAL COMPOSITES	ELECTRICAL CONTACTS, BUS BARS, HEAT EXCHANGERS
4	CU-AG, EUTECTIC	BAG	PREFORMS, FOIL, POWDER	MOST FERROUS AND NONFERROUS METALS, EXCEPT ALUMINUM AND MAGNESIUM	MOST WIDELY USED UTILITY FILLER METALS
5	TM-SI-B[B], EUTECTIC (NI/FE + CR)-SI-B	BNI	POWDER, TAPE[C], RS FOIL	AISI 300 AND 400 SERIES STEELS AND NICKEL- AND COBALT-BASE SUPERALLOYS; CARBON STEELS; LOW-ALLOY STEELS; AND COPPER	AIRCRAFT TURBINE COMPONENTS, AUTOMOTIVE PARTS, HEAT EXCHANGERS, HONEYCOMB STRUCTURES
	(NI, PD)-SI-B	NONE	POWDER, TAPE, RS FOIL	AISI 300 SERIES STAINLESS STEELS, CEMENTED CARBIDE, SUPERALLOYS	HONEYCOMB STRUCTURES, CEMENTED CARBIDE/POLYCRYSTALLINE DIAMOND TOOLS, ORTHODONTICS, CATALYTIC CONVERTERS
	(CO,CR)-SI-B	BCO	POWDER, TAPE, RS FOIL	COBALT-BASE HEAT-RESISTANT CORROSION-RESISTANT SUPERALLOYS	AIRCRAFT ENGINES, HONEYCOMB MARINE STRUCTURES

6	AU-NI, SOLID SOLUTION	BAU	PREFORMS, WIRE, RODS, FOIL, TAPE	NICKEL-BASE HEAT-RESISTANT ALLOYS, STEELS	HONEYCOMB STRUCTURES, STRUCTURAL TURBINE PARTS
7	CU-(TI,ZR)-NI EUTECTIC AND PERITECTIC	NONE	CLADDED STRIP, RS FOIL	TITANIUM/ZIRCONIUM-BASE ALLOYS	TITANIUM TUBING, AIRCRAFT ENGINES, HONEYCOMB AIRCRAFT STRUCTURES, AIRCRAFT STRUCTURAL PARTS, CHEMICAL REACTORS

Solders

Despite a long history of development and usage, those solders used today are still lead- or tin-base alloy systems to which a small amount of silver, zinc, antimony, bismuth, indium, or a combination thereof, have been added. The filler-metal and base-material reactions of many solders are characterized by the formation of intermetallic phases in the bulk of the joint as well as at the joint interfaces. Intermetallic phases with low plasticity play a dual role: on one hand, they improve soldered joint strength; on the other hand, they lessen the long-term fatigue life expectancy. The latter is of paramount importance for the reliable service of electronic devices, particularly surface-mount circuit boards and silicon dice that are connected by soldering and continuously experience power and thermal cycling. It is well known that materials with large intermetallic crystals have low resistance to fatigue because of high stress concentration in the vicinity of the crystals. The size of the intermetallic crystals formed in joints upon crystallization with transient soldering processes is determined by the initial size of the crystals in the starting solder filler metal and by the dissolution and precipitation processes initiated during the soldering operation. Here again, RS solders that possess a very uniform microcrystalline structure can have an advantage over conventional solders, because their application results in a strong and uniform joint that has a high resistance to fatigue (Ref 5).

Brazing of Cast Irons and Carbon Steels

Ann Severin, Lucas-Milhaupt, Inc.

Introduction

CAST IRONS AND CARBON STEELS are brazeable materials, although the brazeability of cast iron is lower than that of carbon steel. Similar heating methods and brazing procedures are used for both types of materials. However, there are differences between the two that must be considered when making cleaning and filler-metal decisions.

Brazing of Cast Irons and Carbon Steels

Ann Severin, Lucas-Milhaupt, Inc.

Base-Metal Brazeability

Cast irons are lower in brazeability than carbon steels, because of their higher carbon and silicon contents (Table 1), and because of sand inclusions on as-cast surfaces. Carbon, in the form of graphite, inhibits the wettability of a filler metal on a base metal. Silicon promotes graphite formation. Because the different types of cast irons listed in Table 1 have varying carbon and silicon contents, the form of the graphite will vary, giving each type distinct wetting characteristics.

TABLE 1 CHEMICAL COMPOSITION RANGES FOR TYPICAL UNALLOYED CAST IRONS AND PLAIN CARBON STEELS

MATERIAL	COMPOSITION, %				
	C	**SI**	**MN**	**S**	P
GRAY IRON	2.5-4.0	1.00-3.00	0.25-1.00	0.02-0.25	**0.05-1.00**
MALLEABLE IRON	2.00-2.60	1.10-1.60	0.20-1.00	0.04-0.18	**0.18**$^{(A)}$
DUCTILE IRON	3.00-4.00	1.80-2.80	0.10-1.00	0.03$^{(A)}$	**0.10**$^{(A)}$

(A) MAXIMUM.

Malleable iron is considered to be the most brazeable of the three types of cast iron, because it has low carbon and silicon contents, and because it experiences a heat treatment that causes the graphite to form in irregularly shaped nodules. The nodules can be easily removed by mechanical means, such as shot or grit blasting.

Ductile Iron. The free carbon of ductile iron also is in the form of nodules. These nodules, which are spherical in shape, are formed when a minute amount of magnesium is added to the molten iron. The chemical composition of ductile iron is similar to that of gray iron, but with lower limits on the amounts of sulfur and phosphorus. Ductile iron also can be cleaned for brazing by mechanical means.

Gray iron is the least brazeable of the cast irons, because it forms large graphite flakes that inhibit the wetting of the metal surface. This material is brazeable only in conjunction with special cleaning methods, which are described in the cleaning section of this article.

Carbon steels are easily brazed using a wide variety of heating methods and filler metals, but the heat-treatment requirements and the service conditions need to be considered when choosing the heating method and the filler metal.

Dissimilar metals can be joined to carbon steels and cast irons by means of brazing. This method of joining two or more different materials is successful because the low interaction between the base metals generally results in a ductile joint. Coefficients of thermal expansion (CTE) (Table 2) are the major consideration when designing joints that comprise two different materials. The joints should be designed so that the filler metal is in compression, rather than tension, after brazing. The joint also should be designed so that an adequate gap exists at the brazing temperature to allow the flow of filler metal. The ideal gap, when brazing with the BAg series of materials, is approximately 0.050 to 0.127 mm (0.002 to 0.005 in.).

TABLE 2 COEFFICIENTS OF THERMAL EXPANSION FOR SELECTED MATERIALS

Figure 1 shows a cross section of the interface of a joint made by the silver brazing of cast iron to carbon steel. The cast iron had been cleaned by the fused-salt method described in the section "Cleaning and Fixturing Procedures." In Fig. 1, note the clean line at the interface of the steel, versus the irregular shape of the cast iron interface. This is caused by the cleaning process, which removes surface impurities and leaves an irregular, but iron-rich, surface. These surface irregularities greatly increase the joint area, so that after the proper fused-salt cleaning, it is possible to produce a brazed bond that exceeds the strength of the cast iron base metal. It should also be noted that the low interaction between the base metal and the filler metal results in a very ductile joint between two materials that would otherwise be difficult to join by other methods.

Brazing of Cast Irons and Carbon Steels

Ann Severin, Lucas-Milhaupt, Inc.

Filler-Metal Selection

The most common filler metals used for the brazing of carbon steels and cast irons are those in the American Welding Society (AWS) BAg and BCu series. Filler metals from the RBCuZn series also have been used successfully. However, the BAg series is used because they melt and flow at low temperatures, whereas the BCu series are used because they are inexpensive, when compared with the silver-base filler metals. The trade-off is that the use of BCu materials requires more heat to melt the filler metal. The BCu materials are generally brazed in an atmosphere furnace, which necessitates capital investment in a furnace. The BAg materials, on the other hand, may be brazed by using a torch, an induction heater, a furnace, a resistance heater, or a variety of other means (Ref 2).

The BNi series also can be used in special applications that require chemical or oxidation resistance. The RBCuZn filler metals can be used with a torch, induction heater, or furnace. These alloys can be used either in the typical manner, which relies on capillary flow to make the joint, or in the process known as braze welding, which distributes filler metal by deposition, rather than by capillary flow.

Service Conditions. Temperature and environment are the two factors that need to be evaluated when choosing a filler metal for cast irons and carbon steels. The BAg series of filler metals generally has good long-term strength at temperatures up to 205 °C (400 °F) (Ref 3). Some of the higher-temperature filler metals, such as BAg-13 and BAg-13a, can be used for joints that require high strength up to 425 °C (800 °F) (Ref 4).

The BCu filler metals are generally used for service up to 480 °C (900 °F). The addition of nickel and manganese to copper has created filler-metal alloys with improved high-temperature properties. These materials are not covered by AWS specifications.

Service environment factors that need to be considered when choosing a filler metal include the expected exposure to corrosive environments, water, vibration, and loads. An example of a potential problem is the use of a high-zinc-content filler metal in an application involving contact with flowing water. There have been documented cases of the dezincification of filler-metal joints that eventually failed in service because of the loss of strength in the brazed joint (Ref 5).

A detailed and thorough testing program should be completed for the design and brazement of any critical component, in order to ensure that the finished part will withstand the intended service conditions.

The brazed joint design is another factor in filler-metal selection. Most filler metals are available in either wrought forms (wire, strip, or preformed part) or as a paste (powdered metal in a binder suspension with or without flux, depending on use). Some filler metals are available in limited forms, because of manufacturing difficulties. Ideally, the specific form will allow the brazer to utilize easy assembly and inspection methods and to produce a quality brazed joint. The joint must be designed to accommodate the specific filler-metal form.

In a silver-brazed joint, the greatest strength is achieved when the gap between the two mating parts ranges from 0.0381 to 0.0762 mm (0.0015 to 0.003 in.). Then, the strength of the joint can be equal to or greater than that of the base metal. It is difficult to make a joint that has a narrower gap, because the filler metal would not flow properly between the mating surfaces. When gaps are beyond 0.127 mm (0.005 in.), joint strength drops off, and approaches the tensile strength of the filler metal. If the gap gets too large, then capillary action can be inhibited and the filler metal may not fill the joint, which lowers joint strength even further.

Different silver brazing filler metals have varying degrees of fluidity. Generally, the narrower the melting range (solidus-liquidus), the more fluid the alloy. If the gaps are designed to be tight, then a more fluid filler metal, such as BAg-1 or BAg-7, would be appropriate. If the gaps are larger than 0.102 mm (0.004 in.), then BAg-3 would be a better choice.

Carbon steel and cast iron joints brazed with pure copper should be designed to have a 0.0508 mm (0.002 in.) press fit to a 0.0127 mm (0.0005 in.) gap. Any gap beyond this size will not be filled by pure copper, which is very fluid and has no gap-filling ability. A different filler metal would be required.

If possible, the design should allow visual examination of a joint to ensure that a brazed joint has been made. If a ring can be buried in a fitting/tube joint, then a fillet is evidence that the filler metal has melted and flowed up through the joint to make the fillet.

The heat source is also a factor in determining the type and form of filler metal best suited for a particular brazing cycle. Furnace brazing requires preplaced paste, rings, washers, or other shapes of preforms. Manual brazing can use either the forms described above or bulk wire that is hand fed into the joint when the part reaches a temperature that is higher than the liquidus of the filler metal. Vacuum brazing requires filler metals that will not volatilize in a vacuum at the brazing temperature. Therefore, filler metals with high vapor pressure elements, such as zinc and cadmium, should be avoided. However, these elements are desirable when torch brazing, because they aid wetting and depress melting points.

Heat-treatment requirements will also guide filler-metal selection. The chosen filler metal should allow one of three options when it is used to braze a carbon steel or cast iron that requires a heat treatment.

The first option is that brazing and heat treatment occur at the same temperature. This assumes that the brazing time is short enough to prevent base-metal and filler-metal interactions that can cause erosion or liquid-metal embrittlement. If quenching is required, then it should be conducted after solidification at a temperature that is below that of the filler metal.

The second option is for heat treatment followed by a subsequent brazing operation. In this case, brazing is usually done at the lowest temperature and shortest time possible to minimize the effects on the prior heat treatment. The effect of time at temperatures on heat-treated parts is shown in Table 3.

TABLE 3 EFFECT OF BRAZING TEMPERATURE ON HARDNESS OF SELECTED STEELS

BASE METAL	**CONDITION**	**HARDNESS BEFORE BRAZING**	**HARDNESS AFTER BRAZING SHORT TIME AT 635 °C (1175 °F)**	**HARDNESS AFTER BRAZING SHORT TIME AT 705 °C (1300 °F)**	HARDNESS AFTER BRAZING SHORT TIME AT 760 °C (1400 °F)
LOW-CARBON STEEL	ANNEALED	55-70 HRB	55-70 HRB	55-70 HRB	**55-70 HRB**
	COLD ROLLED	60-90 HRB	55-80 HRB	55-75 HRB	**55-70 HRB**
LOW-ALLOY OR LOW-CARBON STEEL (0.40-0.50 C)	ANNEALED	90-100 HRB	90-100 HRB	90-100 HRB	(A)
	HEAT TREATED TO 1030 MPA (150 KSI)	32 HRC	22-32 HRC	18-25 HRC	(A)
CARBON AND LOW-ALLOY TOOL STEEL	HARDENED AND TEMPERED	50-65 HRC	28-32 HRC	20-25 HRC	(B)
HIGH-SPEED STEEL	**HARDENED**	**65 HRC**	**59-63 HRC**	**46-50 HRC**	**. . .**

Source: Ref 6

(A) MAY HARDEN SLIGHTLY.

(B) MAY HARDEN.

The third option is to braze first and then heat treat. In this case, brazing is done at a temperature above the required heat-treatment temperature. This option usually is used with the BCu filler metals. The subsequent heat treatment is conducted at a low enough temperature to avoid affecting the braze. This is especially useful for parts that need to be case hardened or carburized in situations where brazing after heat treatment would soften or distort the parts.

If high hardness is a requirement and the part must be brazed after hardening, then a different material such as a high-speed tool steel should be considered. Hardened high-speed tool steels and other hot-worked steels exhibiting secondary hardening are only slightly softened by the lower-temperature filler metals in the AWS BAg series.

Before a part is brazed, its physical requirements in finished form must be known in order to select the heat treatment and filler metal that will provide the correct properties. The *ASM Handbook,* Volume 1, *Properties and Selection: Irons, Steels, and High-Performance Alloys,* and Volume 4, *Heat Treating,* offer valuable data for the selection of the appropriate heat treatment.

Brazing of Cast Irons and Carbon Steels

Ann Severin, Lucas-Milhaupt, Inc.

Cleaning and Fixturing Procedures

Many processes are used for the brazing of cast irons and carbon steels. All of them involve the same basic considerations, as described below.

Because of the difficulty in wetting cast irons, trials for cleaning the cast irons prior to production should be conducted. Samples should be made that will reflect the cleaning, flux, filler metals, and selected process in order to check the wettability of the base metal. If the samples are not uniformly wetted or if the contact angle is great, then the variables should be changed until uniform wetting and a small contact angle are achieved. Testing is also useful on steel parts, but is not as critical, because they are much easier to braze. It is advisable to run sample parts prior to brazing expensive machined parts, in order to check furnace atmospheres and other processing variables.

Cleaning

The first step required, when making a brazed joint, is to clean all parts, whether they are cast iron or carbon steel. They must be free from grease, dirt, oxides, and other contaminants in order for the filler metal to wet and flow on the surface of the base metal. Therefore, all processing fluids and mill scale must be removed. Generally, solvents or alkaline detergent-type cleaners are used for this purpose. It is important to match the cleaning method to the type of contaminant to be removed (that is, water based for water-based coolants, and solvents or alkaline degreasers for oily residues). Special procedures for specific materials are described below.

Cleaning of Cast Irons. Prior to brazing, cast irons require special cleaning procedures. Ductile and malleable cast iron are usually cleaned by abrasive blasting with steel or nickel shot to remove the graphite, silicon, and sand inclusions on the surface. Other methods for preparing ductile and malleable cast irons include various pickling and other chemical treatments, searing with an oxidizing flame, and heating to temperatures between 870 and 900 °C (1600 and 1650 °F) in a strongly decarburizing atmosphere.

Gray cast irons generally require cleaning in fused salts prior to brazing, because that method has proved to be the most effective. The fused-salt bath generally is maintained at temperatures between 400 and 480 °C (750 and 900 °F). At these temperatures, salt baths exhibit the required high chemical activity that is necessary to remove surface oxides, graphite, and sand from the iron surface. This action is further enhanced by the induction of direct current into the bath. By changing the polarity, the action of the bath can be changed from oxidizing to reducing, and vice versa.

Castings are immersed in the bath, suspended from bus bars or fixtures that are insulated from the tank of molten salt. Generally, the castings are attached to the negative polarity and the tank is made positive, which creates a reducing action in the bath that is capable of removing oxides and sand from the casting surfaces. The polarity is then reversed and the oxidation reaction begins. During this portion of the cycle, the graphite is removed. The current is then reversed again (to a reducing action) to remove the iron oxide that formed in the oxidation reaction. After the castings are rinsed in water and dried, they are ready for brazing. Although it is generally not necessary, ductile and malleable cast irons also can be cleaned by the fused-salt method.

In some applications, the brazing of all types of cast irons has been accomplished without special cleaning by using a black-type flux (AWS FB3-C or AMS 3411) and by silver brazing with a filler metal that contains nickel, such as BAg-3, BAg-4, or BAg-24. Brazing with RBCuZn-type filler metals has also been done without prior precleaning. If joint integrity, repeatability, and consistency are important, then prior precleaning is recommended.

Cleaning of low-carbon steels is generally accomplished by either chemical or mechanical means, the former of which is more popular. Chemical methods include alkaline detergents, solvents, vapor degreasing, and acid pickling. Mechanical methods include dry or wet abrasive blast cleaning, wire brushing, machining, or grinding. The selected cleaning method must provide a chemical match to the contaminant being removed. Some of the newer synthetic lubricants and coolants are easily removed with water-based cleaners, but not by vapor degreasing. Although the part may appear clean, residues of these materials can remain and will inhibit the wetting of the steel.

Chemical Cleaning. Alkaline cleaning, including soak, spray, and barrel cleaning, is widely used for removing oily, semisolid, or solid soils from steel. It is generally satisfactory for removing most cutting and grinding fluids, grinding and polishing abrasives, and some pigmented drawing compounds.

Solvent cleaning is capable of removing oil, grease, loose metal chips, and other contaminants from steel components. Parts are immersed and soaked in a common organic solvent. Spray methods can be employed, as well.

Vapor degreasing utilizes the hot vapors from a boiling chlorinated hydrocarbon solvent to remove surface contaminants such as oils, greases, and waxes. To supplement the vapor, some degreasing units are equipped with facilities for immersing the work in the hot solvent or for spraying with clean solvent. Others are equipped with ultrasonic equipment to remove oils and greases from crevices.

Mechanical Cleaning. Although mechanical methods are less widely used than chemical methods, they are usually preferred for removing heavy scale, and they can be indispensable in removing the more tenacious lubricants, such as a pigmented drawing compound. Mechanical methods are also useful in surface preparation that involves abrading or roughening, which may be required on a very smooth surface to promote wetting and filler-metal flow.

In dry grit blasting, the grits that are used on carbon and low-alloy steels consist of metallic particles of chilled cast iron nickels or of hardened cast steel. Wet blasting employs abrasives of many different types and sizes, suspended in a liquid carrier. Certain ingredients in the liquid carrier, such as rust inhibitors and the minerals in the water, can adversely affect the wetting action in brazing and could necessitate an additional cleaning process to remove all traces of liquid carrier from the work.

Fixturing

Fixturing is necessary to hold parts in alignment during the brazing process. The considerations are the same, whether brazing cast irons or carbon steels. Ideally, the parts would be self-fixturing by virtue of gravity, press fitting (copper filler metal only), tack welding, knurling, staking, expanding, interlocking, or other mechanical means. If tack welding is used, then the area surrounding the tack should be mechanically cleaned to remove any oxides that form during the welding operation. A mechanical method must avoid introducing contaminants, grease, or oils, or else a final cleaning process must be added.

If the part cannot be designed to be self-fixturing, then external fixturing must be designed. A fixture for torch brazing should be lightweight and have as little actual contact as possible with the parts to be brazed, to prevent it from acting as a heat sink.

The fixture material that is used will depend on the temperature and atmosphere of the brazing operation, how many times the fixture is to be used, the base metal, and the brazing process to be used. Fixtures are generally constructed of steel, stainless steel, nickel-base alloy, molybdenum, graphite, or ceramic. Regardless of the process or base metal, the differences in CTE between the base metal and the fixture material must be considered, in order to prevent warpage or damage to the brazed part. CTE differences can also be used advantageously to pull parts into place during the heating process.

Brazing of Cast Irons and Carbon Steels

Ann Severin, Lucas-Milhaupt, Inc.

Filler Metal and Flux/Atmosphere Procedures

Filler metal can be supplied to the joint by hand or by using automatic feeding methods when the base metal reaches the brazing temperature. It also can be preplaced in the joint prior to heating. Hand feeding is the simplest method, however, because it requires no equipment. The choice of wire gage is important, because a wire of large diameter will act as a heat sink, cooling the joint when it touches a part. This requires that the part be heated to a higher temperature, which could cause base-metal degradation. The amount of filler metal that is applied is determined by the operator.

Automatic wire feed machines are used on rotary torch brazing tables. Although this type of machine supplies a measured amount of filler metal to the joint, the wire can act as a heat sink if the wire gage is too large.

Preforms, in the form of wire or foil products, can supply filler metal to the joint in a consistently measured amount. Preforms can be used in any type of brazing operation in which the filler metal can or must be preplaced in the joint prior to heating.

Another common form of filler metal is a paste product, in which a powdered filler metal is mixed with either a binder or a flux/binder system. The choice of paste is determined by the brazing temperature and the atmosphere in which brazing occurs.

The best joint is made by preplacing the filler metal at the base of a joint (Fig. 2) and drawing it up, in order to form a joint. This gives the smallest, most even fillet, and ensures that a joint is formed over the entire shear length of the mating surfaces. However, it is not always practical to create a joint in this manner.

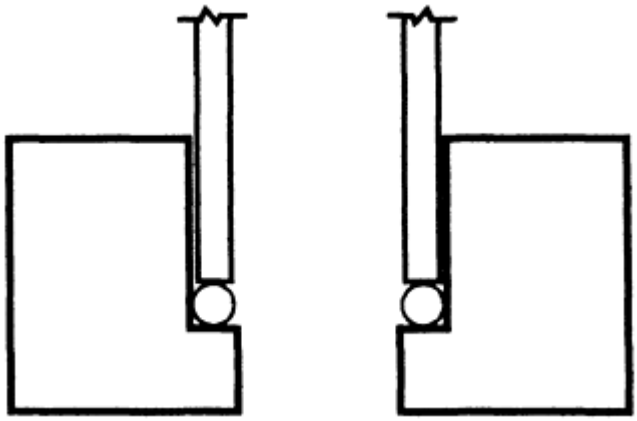

FIG. 2 SCHEMATIC OF A CROSS SECTION OF A PART WITH A BURIED RING OF BRAZING FILLER METAL PRIOR TO BRAZING

Fluxes and/or atmospheres are necessary when making a joint on carbon steels or cast irons. The fluxes used with these materials usually consist of borates and fluorides. Some may have additions of boron to promote wetting, especially on cast irons. Brazing fluxes act to prevent oxidation of both base metal and filler metal and to clean off any residual oxides on the base metal.

Fluxes that conform to AWS FB3A or FB3C can be used when torch brazing with the BAg filler metals. High-temperature torch brazing with RBCuZn filler metals can utilize either a vapor flux that is supplied in the flame or a high-temperature flux that conforms to FB3D. Furnace brazing should utilize a flux that is designed to be active for long periods of time; this type of flux is not covered by AWS designations. The selected flux must be compatible with the combination of base metal and filler metal and with the temperature range in which brazing occurs. Fluxes that are spent by overheating will not allow the filler metal to flow properly.

Brazing atmospheres act in a manner similar to fluxes, by providing a gas atmosphere to protect the part from oxidation and to remove residual oxides. High-temperature brazing using a BCu or a high-temperature copper alloy filler metal can be conducted in hydrogen or dissociated ammonia atmospheres. Low-temperature brazing using BAg filler metals also is possible when hydrogen or dissociated ammonia atmospheres are used. Endothermically generated atmospheres containing from 14 to 16% hydrogen can be used for carbon steels and properly cleaned cast irons. Flux should be used to prevent the vaporization of zinc whenever zinc-containing filler metals are used. Vacuum could be used, if it is available, but it generally is not used, because of the cost.

Brazing of Cast Irons and Carbon Steels

Ann Severin, Lucas-Milhaupt, Inc.

Heating Methods

The heating methods used for the brazing of carbon steel and cast iron are varied. Often, the choice of heating method depends on the process that provides the best results for the lowest cost. When determining the best-suited process and heating method, factors such as part size, planned production and lot sizes, filler-metal and base-metal combinations, and heat-treatment requirements need to be considered.

Torch brazing is commonly used to braze cast irons and carbon steels. This method is particularly suited for cast irons, because the short cycle times preclude the formation of graphite from free carbide or pearlite, which would lower the high-temperature properties of the cast iron. Torch brazing is used for the brazing of single pieces or numerous pieces. Generally, the lower-temperature BAg filler metals are used, although the RBCuZn filler metals can be used, as well. Torch size must be adjusted for the size of part being brazed. Usually, smaller parts or parts that must be brazed in place are the most suitable for torch brazing.

The induction brazing of cast irons and carbon steels is useful on parts that need very fast and localized heating to maintain heat-treatment properties at the maximum level, while ensuring a sound brazed joint. Both cast iron and carbon steel induct heat well, and the only limitations are the size of the part and accessibility to the joint area. Nearly any part shape can be brazed using induction heating, as long as a suitable inductor can be designed to give the desired heating pattern. Induction heating equipment tends to be expensive, but relatively inexpensive fixturing and inductors make it suitable for a wide variety of parts. When making steel parts, induction is useful for simultaneous brazing and hardening operations. When brazing dissimilar metals using an induction method, attention should be given to the differential heating rate of the two metals. The cycle and the coil placement must be such that the two metals are brought to temperature evenly, or else a cold joint can result.

A cold joint occurs when the filler metal melts, but cannot bond to one or both of the base metals because they have not reached the melting temperature of the filler metal. When the molten filler metal hits the colder base metal, it freezes, without making a bond.

Salt-bath brazing is another suitable method for the brazing of cast irons and carbon steels, but it is becoming less common, because of the environmental requirements associated with maintaining a salt bath. Salt-bath brazing is suited to applications where many joints must be made at once, such as the joining of tubing to headers for heat exchangers. This process generally uses the BAg, RBCuZn, or BCu filler metals. The selection of a suitable salt depends on the temperature that is needed for the filler metal to melt and flow. The carburizing of steels can be accomplished by using a carburizing salt. Generally, the higher-temperature copper-zinc filler metals are used in this process. Salt-bath brazing also is suited to applications that would involve daily use of the bath, because of the cost of maintaining and heating the bath.

Furnace brazing of cast irons and carbon steels is generally used when:

- THE PARTS ARE LARGE.
- THERE IS A WIDE VARIETY IN THE GAGES OF THE MATERIALS TO BE BRAZED.
- THERE ARE MANY JOINTS PER PART.
- LARGE PRODUCTION VOLUMES ARE REQUIRED.
- A PROTECTIVE ATMOSPHERE IS REQUIRED.

Furnace brazing is only practical when the filler metal can be preplaced in or at the joint during assembly and held in position during the brazing cycle.

The process can take place in different types of furnaces, such as batch or continuous belt ovens, which can operate in air, hydrogen, nitrogen, argon, or combusted gas atmospheres. Cast irons and carbon steels that are brazed in air need flux,

and postcleaning is required, as well. When brazing without flux, the atmosphere must be able to reduce the oxides that are present and prevent the formation of new ones. The reduction of oxides must take place below the solidus temperature of the filler metal, in order to enable the filler metal to wet the base metal and flow into the braze joint.

When furnace brazing, the parts are cleaned and assembled with the filler metal preplaced at or in the joint. Calculations should be made to determine the amount of filler metal needed, and a preformed ring, slug, or shim should be designed to provide the correct amount of filler metal. A paste form of filler metal also can be used.

Fixtures may be necessary to hold parts in the proper alignment during brazing. They should be lightweight and should not hinder the natural expansion or shrinkage of the base metal during heating and cooling. Restriction may cause base-metal distortion and/or brazed-joint cracking. The furnace brazing of cast irons and carbon steels generally employs BAg, BCu, and RBCuZn filler metals.

Regardless of the selected heating method, fluxes must be removed because they are corrosive and may contaminate systems and/or mask leaks. Fluxes are best removed by hot-water rinses or by using proprietary solutions that remove them, along with surface scale and oxidation products.

Brazing of Stainless Steels

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Introduction

STAINLESS STEEL ALLOYS as a group are not difficult to braze, but those alloys that also contain titanium or aluminum require additional precautions to prevent alloy oxidation during the brazing cycle. Excellent results can be obtained when standard wrought stainless steels are brazed.

The brazeability and weldability of these steels do vary with composition. The quality of brazed joints depends on the selection of the brazing process, process temperature, filler metal, and the type of protective atmosphere or flux that is used. These choices must be compatible with the intended performance of the brazed item.

Brazing of Stainless Steels

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Applicability

Brazing is often used to join stainless steels to a variety of dissimilar metals, such as carbon steels, low-alloy steels, and copper alloys, in combinations that would not otherwise weld satisfactorily. This capability is a principal advantage of the brazing process.

A wide variety of brazing filler-metal compositions are available to achieve compatibility, strength, corrosion resistance, and other desirable properties when joining dissimilar metals. When the appropriate heating techniques are employed, brazing provides a means to obtain strong, corrosion-resistant, leak-tight joints in small or thin-walled components with minimal buckling or warpage. Brazing also can produce joints in delicate assemblies and in very thin-gage metals that would be difficult or impossible to obtain if conventional welding techniques were used. Brazing is also suitable for the mass production of small- and medium-sized assemblies on various types of continuous furnace equipment. Finally, brazing enables the production of joints in inaccessible locations by the preplacement of filler metal and the subsequent heating of the workpiece. Often, such joints cannot be made by other joining processes.

Brazing of Stainless Steels

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Brazeability

As a class, stainless steels are no more difficult to braze than carbon and low-alloy steels. The high quantities of chromium that are present in stainless steels cause the chromium oxide films that are on the surfaces of all stainless steels, as well as the films of titanium oxide that form on the surfaces of titanium-stabilized stainless steels, such as type 321. If these oxides, which are both refractory and strongly adherent, are inadequately removed, they will prevent the molten filler metal from wetting the base metal, and thus will prevent a capillary joint from being formed between the metals being joined.

The formation of chromium oxide is accelerated when stainless steels are heated in air. Although the oxide may have been removed from the surface by chemical cleaning at room temperature, a new oxide layer that seriously interferes with wetting will rapidly form when the steel is heated in air to the brazing temperature. The adverse effect of oxides on wetting can be alleviated by:

- CHEMICALLY CLEANING THE SURFACE OXIDE FROM THE STEEL AT ROOM TEMPERATURE, QUICKLY FOLLOWED BY HEATING TO THE BRAZING TEMPERATURE IN A CHEMICALLY INERT GASEOUS ATMOSPHERE, SUCH AS ARGON
- HEATING THE STEEL DIRECTLY TO THE BRAZING TEMPERATURE IN A STRONGLY REDUCING ATMOSPHERE, SUCH AS HYDROGEN, AFTER A LESS-INTENSE CLEANING, WHICH CHEMICALLY REDUCES THE OXIDE AND THEREBY PROMOTES WETTING ACTION
- COATING THE AREA AT THE JOINT WITH A CHEMICALLY ACTIVE FLUX THAT DISSOLVES THE OXIDE DURING HEATING TO THE BRAZING TEMPERATURE
- HEATING IN A VACUUM (AFTER CLEANING), WHICH REDUCES MANY OXIDES, SUCH AS CHROMIUM OXIDE, AND PREVENTS THE GROSS FORMATION OF OTHER OXIDES
- DEGREASING ALONE, IF THE PROPER FLUX OR CONTROLLED ATMOSPHERE IS USED, PRIOR TO BRAZING STAINLESS STEELS WITH CLEAN SURFACES, THAT IS, WITHOUT BLACK OR GREEN OXIDE COATINGS
- SELECTING LOWER-MELTING-POINT BRAZING FILLER METALS TO REDUCE OXIDATION

POTENTIAL

Inclusions and Surface Contaminants. When brazing stainless steel, base-metal inclusions and surface contaminants are even more deleterious than they are when brazing carbon steel. Base-metal inclusions, such as oxides, sulfides, and nitrides, interfere with the flow of filler metal. Flow is also impeded by surface contaminants, which may include lubricants, such as oil, graphite, molybdenum, disulfide, and lead, which are applied during machining, forming, and grinding. Other contaminants are the aluminum oxide particles that are produced either by grit blasting or by grinding with aluminum oxide wheels or belts.

Some filler-metal powders that are used in paste form with stainless steel contain organic binders. Acrylics and other plastics are often used for this purpose. Although some powders form a soot residue, it usually does not interfere with filler-metal flow.

The brazing characteristics of stainless steel can also be seriously impaired by unsuitable fixturing materials, such as graphite, or by a protective atmosphere that contains nitrogen. Carbon in graphite fixtures unites with hydrogen to form methane (CH_4), which carburizes stainless steel and impairs its corrosion resistance. Dissociated ammonia will result in nitriding of the stainless steel, unless the ammonia is sufficiently dry and completely (100%) dissociated. Both carburizing and nitriding interfere with brazing quality.

Brazing Processes. Stainless steels can be brazed by all conventional brazing processes, including furnace, torch, induction, resistance, and salt-bath dip brazing. Furnace brazing is most widely used, because applications generally require brazing in protective atmospheres, including a vacuum. Most of the applications described in this article utilize furnace brazing.

Brazing of Stainless Steels

Brazing Filler Metal

Most stainless steels can be brazed with any one of several different filler-metal families, including silver, nickel, copper, and gold. In most applications, filler metals are selected on the basis of their mechanical properties, corrosion resistance, service temperature, and compatibility with the base metal. This selection leads to the required brazing temperature, based on service use or manufacturing sequence, and to the required heating method. Table 1 lists the composition requirements of the filler metals that are most commonly used to braze stainless steels. A complete list of brazing filler metals can be found in ANSI/AWS A5.8, which specifies filler metals for the brazing and braze welding processes.

Source: AWS A5.8-81, "Specification for Brazing Filler Metals"

(A) SINGLE VALUES ARE MAXIMUM PERCENTAGES, UNLESS OTHERWISE INDICATED.

(B) MINIMUM.

(C) ALL BNI ALLOYS HAVE A LIMIT OF 0.10 CO AND 0.005 SE.

Silver brazing filler metals, specifically the BAg group, are the most widely used type of filler metal in the brazing of stainless steels. The BAg-3 filler metal, which contains 3% Ni, is probably selected most frequently, although several other filler metals also can be used successfully. Silver brazing filler metals, especially those that contain zinc and chlorine, are primarily used in torch brazing where flux is applied and should not be considered for furnace brazing.

Joints brazed with silver-base filler metals cannot be used for high-temperature service applications. The recommended maximum service temperature is 370 °C (700 °F) (BAg-3). The recommended joint fitting allowances for silver brazing are relatively loose, that is, the diametral clearance is generally from 0.05 to 0.10 mm (0.002 to 0.004 in.).

Of the silver brazing filler metals shown in Table 1, all except BAg-19 and, possibly, BAg-13, are used at brazing temperatures that fall within the effective range of sensitizing temperatures (540 to 870 °C, or 1000 to 1600 °F) for austenitic stainless steels. Chromium carbide precipitation occurs in the sensitizing temperature range, which impairs the corrosion resistance of the base metal. Carbide precipitation, however, depends on time as well as temperature, and exposure to the sensitizing temperature range for only a few minutes is unlikely to result in a significant amount of precipitate. Nevertheless, the lower melting temperatures of the silver brazing filler metals prohibit the resolution treatment of the base metal after brazing. If corrosion resistance in service is sufficiently critical, an extra-low-carbon, titanium-stabilized or niobium-tantalum-stabilized type should be selected instead of a nonstabilized type of austenitic stainless steel.

Ferritic and martensitic stainless steels that contain little or no nickel are susceptible to interface corrosion in plain water or moist atmospheres, when they are brazed with nickel-free silver brazing filler metals, using a liquid or paste flux. Filler metal that contains nickel helps to prevent interface corrosion. However, for complete protection, special silver brazing filler metals that contain nickel and tin (for example, BAg-21) could be used, and brazing should be done in a protective atmosphere without flux.

Most silver brazing filler metals contain appreciable amounts of copper and zinc, either singly or in combination. Overheating or heating for an excessive period of time may result in extensive penetration of grain boundaries by copper and zinc, thereby embrittling the brazed joint.

Cadmium, which is added to some silver brazing filler metals to lower the melting temperature and improve wetting, also penetrates grain boundaries. The effect is accelerated when parts are brazed under tensile stress. Cadmium-containing fumes are extremely toxic, and operators must take every precaution to avoid inhaling them. Many new alloys that have similar brazing and functional characteristics of the cadmium-bearing alloys, but without their environmental and safety concerns, are being introduced to the market. Filler metals that contain cadmium and/or zinc should not be used in a protective atmosphere, including vacuum, because cadmium gases off readily. Because the loss of zinc or cadmium raises the melting point of the filler metal, brazeability is adversely affected.

Virtually all of the silver brazing filler metals are suitable for brazements that are used in fabricating vacuum chambers and pumps, where pressures as low as 1.3×10^{-3} Pa (10^{-5} torr) are encountered. However, for high-vacuum work (pressures of less than 1.3×10^{-4} Pa, or 10^{-6} torr), the filler metal must not contain cadmium or zinc. Vaporization of these metals interferes with the production of the vacuum and can contaminate the vacuum chamber and pumps. Selection of a suitable silver brazing filler metal for service in vacuum at a pressure below 1.3×10^{-3} Pa (10^{-5} torr) is considered in Example 1.

Nickel brazing filler metals are the next most frequently used filler metals for stainless steels. The BNi group of nickel brazing filler metals provides joints that have excellent corrosion resistance and high-temperature strength. These filler metals are typically supplied in the form of powders mixed with a binder. A limited number of filler metals are also available as sintered rods, preforms, and foils. However, these filler metals may alloy with stainless steel, forming intermetallic phases with two undesirable characteristics. First, the phases are considerably less ductile than either the base metal or the filler metal, even at elevated temperatures, and are therefore a potential source of rupture. Second, the alloys formed with stainless steel are higher-melting-point alloys that are likely to freeze at brazing temperatures, thus blocking further flow into the joint during brazing. To achieve flow in deep joints, diametral clearances as large as 0.10 to 0.20 mm (0.004 to 0.008 in.) are necessary. Knurling of male members sometimes helps in the centering of loosely fitting components. With such large clearances, joints that are brazed with nickel brazing filler metals do not develop their greatest strength. The brazed joint is much stronger with a clearance of 0.025 to 0.076 mm (0.001 to 0.003 in.).

Because of the relatively high brazing temperatures required for the nickel brazing filler metals, their use is generally limited to furnace brazing in a controlled atmosphere (including vacuum), although there are occasional exceptions, as will be seen when Fig. 15 is discussed. Torch brazing with BNi brazing filler metals is used to braze small parts and small quantities.

Copper Brazing Filler Metals. The high brazing temperature and the need for a protective atmosphere generally limits the use of copper filler metals to furnace applications. The BCu brazing filler metals (which are practically pure copper) melt at approximately 1080 °C (1980 °F), and flow freely at 1120 °C (2050 °F).

Copper is not recommended for exposure to certain corrosive substances, such as the sulfur in jet fuel and in sulfur-beating atmospheres. Furthermore, copper brazing filler metals exhibit poor oxidation resistance at elevated temperatures and should not be exposed to service temperatures higher than 430 °C (800 °F). When copper brazing filler metal is used, the recommended diametral allowance on joint fit ranges from a 0.10 mm (0.004 in.) clearance to a 0.05 mm (0.002 in.) interference.

Gold brazing filler metals (the BAu group) are sometimes used for the brazing of stainless steel, although their high cost restricts their use to specialized applications, such as the fabrication of aerospace equipment (Example 4). When gold brazing filler metal is used, them is minimal alloying with the stainless steel base metal. As a result, joints exhibit good ductility, strength, and corrosion resistance. When maximum corrosion resistance is needed, BAu-4 should be used.

Cobalt brazing filler metals (the BCo-1 group) are very rarely used for the brazing of stainless steels. However, this type of filler metal is included in Table 1, and it is available for that purpose.

Fluxes

Flux usually is not required for furnace brazing in strongly reducing or inert atmospheres. However, in some furnace brazing applications, flux is necessary. It is always required for torch brazing and is usually required for induction and resistance brazing, unless atmospheric protection is provided.

Any of the American Welding Society (AWS) types of FB3-A through FB3-J fluxes are suitable for all stainless steel brazing applications where flux is needed. The ANSI/AWS 5.31 specification for fluxes used in brazing and braze welding processes provides more details. There are basically three groups of these fluxes, based on their activity range, and they are further classified by their form (powder, paste, slurry, or liquid). The FB3-A, -F, and -G types of flux contain borates and fluorides and have an effective temperature range from 570 to 870 °C (1050 to 1600 °F). These fluxes are suitable for use with silver brazing filler metals.

Type FB3-C flux contains the same ingredients as type FB3-A, except for the addition of boron, and it has a higher effective temperature range from 570 to 930 °C (1050 to 1700 °F). This flux has an extended heating time capability.

The FB3-D, -I, and -J types of flux also contain borates and fluorides, such that its activity ranges from 760 to 1200 °C (1400 to 2200 °F). These fluxes are often selected for use with silver brazing filler metals if the brazing temperature is above 730 °C (1350 °F). They are well suited for use with copper, nickel, and gold brazing filler metals.

Brazing of Stainless Steels

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Torch Brazing

For stainless steel, the fundamentals of torch brazing, as well as the advantages and limitations, are basically the same as for carbon steels. However, because of the metallurgical characteristics of stainless steel and its requirements for corrosion resistance, the best results are obtained when special consideration is given to the type of flame at the torch and to the filler-metal composition.

Flame Adjustment. To aid in reducing the oxide that is already present, and to prevent further oxidation of the workpiece surfaces, a flame that ranges from neutral to slightly reducing should be used when torch brazing stainless steel to itself. A reducing flame is also satisfactory for brazing stainless steel to nickel alloys or carbon steels. Although a slightly oxidizing flame is typically best for brazing oxide-containing (tough pitch) copper, a slightly reducing flame is usually best when brazing stainless steel to copper. Use of a reducing flame to braze copper is not recommended because this type of flame will remove oxygen from the copper and can also cause hydrogen embrittlement.

Filler Metals. The silver brazing filler metals that flow at relatively low temperatures are used almost exclusively for the torch brazing of stainless steels. BAg-3 is most often used, because it flows well in the temperature range from 700 to 760 °C (1300 to 1400 °F) and provides joints that have greater resistance to corrosion than those brazed with filler metals such as BAg-1 or BAg-1a (although these filler metals are also used). The use of brazing filler metals that require temperatures higher than approximately 760 °C (1400 °F) results in excessive oxidation, thus making it difficult to obtain adequate wetting of the brazed joint. In special applications, higher-melting-point filler metals must be used (Example 1).

Flux. Type FB3-A flux is most widely used for the torch brazing of stainless steel because it has a working range from 560 to 870 °C (1050 to 1600 °F) and is well suited for use with the lower-melting-point silver brazing filler metals. However, in some applications, other types of FB3 fluxes are preferred.

Example 1: Torch Brazing of Parts for High-Vacuum Service.

The sleeve and tube assembly shown in Fig. 1 is typical of brazements used in vacuum systems. The tubes and the sleeve are type 304L austenitic stainless steel. The BAg-18 (60Ag-10Sn-30Cu) brazing filler metal, which has proved satisfactory for the brazing of assemblies used in high-vacuum service, was used with type FB3-B flux. This silver brazing filler metal does not contain zinc or cadmium. It should be noted that vacuum grades of the silver brazing filler metals, such as BVAg-18, are available, and that they limit the amount of impurities that can be detrimental to components of the vacuum tube industry. Again, ANSI/AWS A5.8 should be consulted for further details.

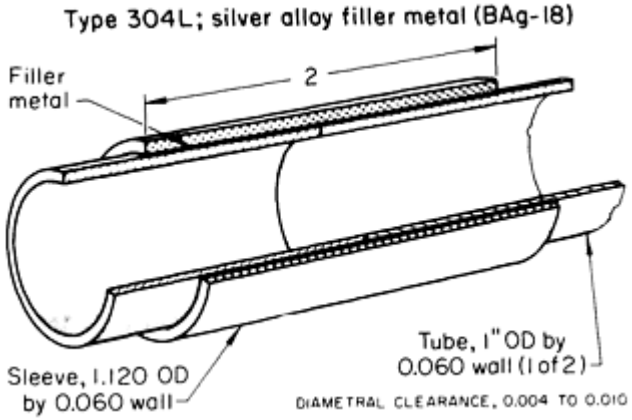

FIG. 1 ASSEMBLY THAT WAS TORCH BRAZED WITH A SILVER BRAZING FILLER METAL FOR USE IN A HIGH VACUUM ATMOSPHERE SYSTEM

Brazing was conducted with a manually manipulated oxyacetylene torch and a strong reducing flame. The assembly shown in Fig. 1 could have been brazed in a furnace or by induction, but production was small and did not justify the investment for such equipment.

Example 2: Torch Brazing of Stainless Steel to Nickel.

The brazed assembly shown in Fig. 2, which consists of a type 304 stainless steel tube and a pure nickel tube, was resistance heated in service. Requirements for this assembly were:

- TRANSMISSION OF ELECTRICITY WITHOUT DEVELOPING HOT SPOTS
- STRAIGHTNESS AND SMOOTHNESS, BECAUSE THE ASSEMBLY HAD TO SLIDE INTO A LARGER ASSEMBLY
- JOINING AT MINIMUM TEMPERATURE, BECAUSE NUMEROUS SMALL INSULATED WIRES WERE IN THE ASSEMBLY AT THE TIME OF JOINING AND WERE SUBJECT TO DAMAGE IF THE JOINING TEMPERATURE WAS TOO HIGH

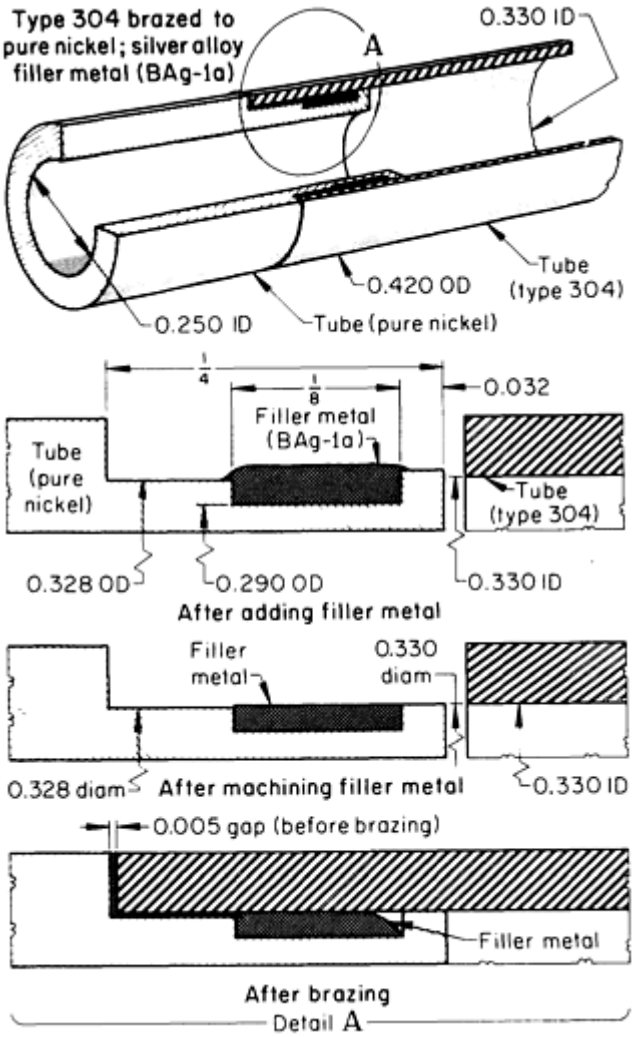

FIG. 2 TORCH-BRAZED ASSEMBLY OF A STAINLESS STEEL TUBE AND A PURE NICKEL TUBE

Torch brazing with silver brazing filler metal proved to be a desirable way to make the joint, because of the relatively low brazing temperature, high electrical conductivity of the joint, minimal distortion, ease of removing excess filler metal, and ease of radiographic inspection.

The joint design (Fig. 2) allowed the preplacement of the brazing filler metal (BAg-1a) in a 3.2 mm ($\frac{1}{8}$ in.) wide groove that was machined into the shoulder of the nickel tube. The filler metal was then melted with a torch, and both filler metal and shoulder were machined to match the inside diameter of the stainless tube (zero-clearance fit).

Several heating methods were tried in an attempt to braze the nickel tube to the stainless steel tube, including induction heating in an inert gas and multiple-torch heating. However, the use of a single oxyacetylene torch operated by a skilled technician proved to be the most successful method. The sequence of operations for single-torch brazing was:

- COMPONENTS WERE CLEANED WITH ACETONE
- FLUX PASTE WAS PLACED ON THE NICKEL TUBE IN THE AREA TO BE BRAZED
- THE TWO TUBES WERE ASSEMBLED IN A FIXTURE WITH A 0.13 MM (0.005 IN.) GAP THAT SHOWED SURFACE (DETAIL A IN FIG. 2)
- THE ASSEMBLY WAS HEATED WITH A TORCH UNTIL THE FILLER METAL FLOWED TO THE OUTSIDE SURFACE (FLOW TEMPERATURE OF 640 °C, OR 1175 °F, FOR BAG-1A)

- EXCESS FLUX THAT FLOWED TO THE SURFACE WAS REMOVED MANUALLY

It was possible to inspect the entire joint by making two radiographs. Only scattered porosity was detected in a routine radiographic inspection of the brazed joints.

Brazing of Stainless Steels

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Furnace Brazing

Almost all furnace brazing of stainless steel is done in a protective atmosphere (including vacuum). One exception is the application described in Example 11, in which air was the furnace atmosphere. In this case, a liquid flux was used and the time at brazing temperature was short, which helped to prevent excessive oxidation.

The protective atmospheres most often used in furnace brazing of stainless steel are dry hydrogen and dissociated ammonia. These atmospheres are effective in reducing oxides, protecting the base metal, and promoting the flow of brazing filler metal. The low-cost exothermic atmospheres that are widely used in furnace brazing of low-carbon steel are not suitable for stainless steel. An inert gas, such as argon, or a vacuum environment, can be used to satisfy special requirements and to provide protection in applications for which hydrogen or hydrogen-bearing gases are unsatisfactory.

Selection of the furnace atmosphere depends on the degree of protection that must be given to the base metal or metals, the flow characteristics of the brazing filler metal, the brazing temperature, and cost. Special requirements that arise from the brazing of dissimilar metals are often a major factor in atmosphere selection. The availability of equipment can also be an important consideration.

Furnace Brazing in Dry Hydrogen. A dry hydrogen atmosphere is preferred for many stainless steel brazing applications. Hydrogen, which is the most strongly reducing protective atmosphere, reduces chromium oxide and promotes excellent wetting by many filler metals without the need for flux. The principal disadvantages of hydrogen are its cost, its difficulty in drying sufficiently, the need for special furnace equipment, and the potential danger involved in improper storage and handling. The following examples describe applications in which a specific type of stainless steel was joined to either the same or another type of stainless steel.

Example 3: Selection of BAg-13 Silver Brazing Filler Metal for Brazing at 930 °C (1700 °F).

The type 347 stainless steel retainer assembly shown in Fig. 3 was furnace brazed in dry hydrogen, using BAg-13 silver brazing filler metal, which was selected in preference to lower-melting-point silver brazing filler metals because the upper limit of its brazing temperature range (860 to 970 °C, or 1575 to 1775 °F) permitted brazing at 930 °C (1700 °F). At furnace temperatures above 980 °C (1800 °F), dry hydrogen is strongly reducing, and the use of a brazing flux is not required for satisfactory wetting action. Thus, by judicious selection of the brazing filler metal and the furnace atmosphere, the extra cost of applying the flux and of removing flux residue after brazing was avoided.

FIG. 3 RETAINER ASSEMBLY FURNACE BRAZED WITH BAG-13 FILLER METAL

The components were vapor degreased, assembled (keeping their outside diameters concentric), and spot welded (to make them self-jigging) at four locations 90° apart (Fig. 3). A ring of brazing filler metal wire in a 1 mm (0.040 in.) diameter was preplaced at the joint, and assemblies were loaded two-across on the mesh belt of a conveyor-type furnace. The heating chamber of the furnace was elevated from the entrance and discharge level to conserve the lighter-than-air hydrogen and to prevent oxygen in the atmosphere from mixing with the hydrogen, which could either raise the dew point or cause an explosion.

Quality standards for brazed assemblies, which were checked by 100% visual inspection, required that the joint exhibit full braze penetration (360° fillets on both sides of the joint) and be pressure-tight.

Example 4: Use of a Gold Brazing Filler Metal for Brazing in an Aerospace Heat Exchanger.

In the fabrication of a high-reliability heat exchanger for manned space flights, 2552 fins of 0.10 mm (0.004 in.) thick type 347 stainless steel were brazed to 0.64 mm (0.025 in.) thick type 347 stainless steel side panels, as shown in Fig. 4. The 5104 fin-to-panel joints had to be strong and corrosion resistant.

FIG. 4 HEAT-EXCHANGER ASSEMBLY IN BRAZING FIXTURE AND DETAIL OF JOINTS BRAZED WITH GOLD BRAZING FILLER METAL

Silver and copper brazing filler metals could not be used, because of their incompatibility with sulfur-bearing rocket fuel. The BNi series of nickel brazing filler metals had the necessary compatibility, but made nonductile joints that were unreliable under tension peel stress. Therefore, gold brazing filler metals were used. The necessary brazing characteristics for the fin-to-panel joints were present in BAu-4 (nominal composition, 82Au-18Ni). The strength and ductility of the resulting brazed joints justified the high cost of this particular brazing filler metal.

The fins and side panels were cleaned by vapor degreasing. The side panels were then pickled, rinsed in clean water, and dried. The brazing filler metal was deposited on the panels in the form of a powder suspended in an organic binder. Multiple lap joints were made between the flat-crown-hairpin ends of the fins and the flat side panels. The assembly was placed in a fixture (Fig. 4), and then the entire assembly and fixture were placed in the retort of a bell-type furnace and sealed. The sealed retort was purged with a volume of hydrogen that was equivalent to five times that of the retort. The retort was then heated to a brazing temperature of 1020 °C (1860 °F) and held for 7 to 10 min. The joint gaps at brazing temperature ranged from 0.000 to 0.254 mm (0.010 in.). After brazing, the retort was purged with argon while being cooled to 150 °C (300 °F) and was not opened until after purging and cooling.

The joints brazed by this procedure were the final brazed joints in the assembly. In a prior brazing operation, tubes had been joined to the fins (Fig. 4) by brazing at 1080 °C (1970 °F) using a higher-melting-point gold brazing filler metal of 70Au-22Ni-8Pd.

The completed assemblies were visually inspected and pressure tested at pressures that far exceeded those of the intended service environment: 1.86 MPa (270 psi) on the outside of the tubes and 11.8 MPa (1710 psi) on the inside. Acceptance pressure test values were 3.7 MPa (540 psi) on the outside and 15.7 MPa (2275 psi) on the inside of the tubes. Selected brazed assemblies were tested to bursting. These assemblies were required to withstand at least three times the service pressures before bursting. The assemblies that were brazed with gold brazing filler metals passed all tests and had three times the bursting strength of the assemblies brazed with undiffused nickel brazing filler metal.

Example 5: Combination Brazing and Solution Heat Treatment of an Assembly of Three Types of Stainless Steel.

Three different stainless steels were selected to make the cover for a hermetically sealed switch. The switching action had to be transmitted through the cover without breaking the seal. This was accomplished by providing a diaphragm through which a shoulder pin was inserted, as shown in Fig. 5. The switch was actuated by depressing the pin, which in turn deflected the diaphragm. The pin (type 303), the diaphragm (PH 15-7 Mo), and the cover (type 305) were assembled as shown in Fig. 3, and then brazed using a silver-base filler metal in a furnace with dry hydrogen.

FIG. 5 THREE-STEEL SWITCH-COVER ASSEMBLY THAT UTILIZED BRAZING TEMPERATURE AS PART OF SOLUTION HEAT TREATMENT

Silver brazing filler metal BAg-19 was chosen because it flowed at a temperature that coincided with the solution heat-treating temperature for the PH 15-7 Mo diaphragm (950 °C, or 1750 °F). A holding fixture was needed to keep the PH 15-7 Mo diaphragm in position during the brazing cycle. To avoid carburizing the diaphragm, the material selected for the fixture was stainless steel, rather than graphite. The furnace was a batch-type tube furnace with a 120 mm (5 in.) diameter high-heat zone that was 460 mm (18 in.) long. The moisture content of the hydrogen atmosphere was carefully controlled, because the lithium-containing filler metal flowed too freely when the atmosphere was too dry, and it did not seal the joints.

After being cleaned, the components were assembled with two preform rings of BAg-19 wire. Tweezers were used to avoid contaminating the cleaned surfaces. Each assembly was held in a stainless steel fixture, which in turn was placed on a stainless steel furnace sled. The sled was pushed into the high-heat zone of the furnace and held at 950 °C (1750 °F) for 10 min, before being pulled into an intermediate cooling zone at 1830 °C (1000 °F) and held for 5 min. Finally, it was pulled to the water-cooled zone, where it cooled to room temperature. The brazing of the two joints and the solution treating of the PH 15-7 Mo diaphragm were accomplished simultaneously at the brazing temperature of 950 °C (1750 °F). To complete the heat-treating process, the assembly was cooled to -70 °C (-100 °F), held for 8 h, and then aged at 510 °C (950 °F) for 1 h.

A 25 mm (1 in.) square piece of PH 15-7 Mo was processed with each batch of cover assemblies and used as a hardness test specimen to verify that the diaphragms had been correctly heat treated. Brazed assemblies were inspected by the brazing operator. The joints were required to be fully sealed and to not have any voids. The pins were required to be perpendicular within 4°. Perpendicularity was measured on a comparator. Randomly selected samples were given a push-out test, in which joints had to withstand a push of 60 N (14 lbf). All assemblies were given 100% visual inspection at high magnification.

Example 6: Simultaneous Brazing of a Heat-Exchanger Assembly.

An air-to-air heat-exchanger assembly, shown in Fig. 6, consisted of 185 thin-walled (0.20 mm or 0.008 in.) tubes and two 1.6 mm ($\frac{1}{16}$ in.) thick headers. All components were made of type 347 stainless steel. The tubes were assembled with the headers by flaring the tube ends to lock them in place and provide metal-to-metal contact for the brazing filler metal. All 370 joints were brazed during a single pass through a continuous conveyor-type electric furnace.

FIG. 6 HEAT-EXCHANGER ASSEMBLY WITH TUBE-TO-HEADER JOINTS BRAZED IN ONE PASS THROUGH A FURNACE

Although a nickel brazing filler metal was preferred for this high-temperature application, because of the resistance to heat and corrosion that it provides, the selection of a specific nickel brazing filler metal presented a problem. Higher-melting-point, boron-containing nickel brazing filler metals, such as BNi-1 and BNi-3, will react with the base metal, partially dissolve, and therefore are likely to erode thin materials. Fortunately, the extent of erosion can be modified by controlling the brazing temperature and time, as well as the amount of filler metal.

Although there are nickel brazing filler metals that contain silicon in place of boron, they generally require much higher brazing temperatures, which can result in grain coarsening in the base metal. Therefore, after numerous tests, BNi-3 filler metal was selected on the basis of its brazing temperature and excellent fluidity. The problem of applying the correct amount of filler metal to avoid erosion was solved by preparing a slurry from an accurately controlled mixture of filler-metal powder, acrylic-resin binder, and xylene thinner.

Before the filler metal was applied, the heat-exchanger assembly was cleaned ultrasonically in acetone and carefully weighed to determine the proportionate weight of filler metal that would be required. Half of the total amount of filler metal was then applied to one end of the assembly by spraying. The assembly was reweighed, and the remaining filler metal was applied to the opposite end. At all stages of processing, the assembly was handled by operators wearing clean, lint-free cotton gloves.

The assembly was placed on a holding fixture made of stainless steel sheet, on which a stop-off compound had been applied to prevent the assembly from brazing to the fixture if the brazing filler metal flowed excessively. Assemblies were placed 300 mm (12 in.) apart on the conveyor, as they traveled through the furnace at 9 m/h (30 ft/h) under the protection of dry hydrogen.

After brazing, each side was subjected to 100% visual inspection to detect the presence of fillets, and the assemblies were pressure tested in accordance with customer requirements. Because of the thin-walled (0.20 mm, or 0.008 in.) tubing, this assembly was brazed more consistently and at a lower cost than could have been achieved by other joining processes.

Example 7: Combined Brazing and Hardening of a Shaft Assembly.

The shaft assembly shown in Fig. 7 consists of three bars or screw machine products (a shaft, a drive pin, and a guide pin) and two stampings (upper and lower mounting plates), all made from type 410 stainless steel and furnace brazed together using four joints. By brazing with copper filler metal at 1120 °C (2050 °F), it was possible to austenitize and harden the assembly to the required minimum hardness value of 40 HRC during the brazing and cooling operations, thereby avoiding separate hardening operations after brazing.

(F) ASSEMBLIES WERE IN HIGH HEAT ZONE FOR ABOUT 10 MIN.

FIG. 7 FOUR-JOINT SHAFT ASSEMBLY THAT WAS SIMULTANEOUSLY FURNACE BRAZED AND HEATED FOR HARDENING

Because the joints were all relatively short, an interference fit of 0.000 to 0.025 mm (0.001 in.) was satisfactory. Typically, a clearance fit between mating parts is required with longer joints in stainless steel. The automatic staking of components was used to make the assembly self-fixturing.

As shown in Fig. 7, a full ring of 0.50 mm (0.020 in.) diameter BCu-1 copper wire was preplaced around the 13 mm ($\frac{1}{2}$ in.) diameter shaft to braze the shaft to the upper and lower mounting plates. A small amount of BCu-2 copper paste was applied at one end of the drive pin to braze it to the two mounting plates. Because of the separation between the two plates on the guide-pin side, a small amount of BCu-2 copper paste was manually applied on each end of the guide pin. The assemblies were placed in brazing trays, with the shaft in a vertical position, and were supported in this position by ceramic spacers.

The brazing trays were then placed on the mesh belt of a continuous-type conveyor furnace containing a dry hydrogen atmosphere. They were transported up an incline to the horizontal preheat and high-heat chambers at a speed of 6 m/h (20 ft/h). Because the assemblies were small, they became heated to the brazing temperature in about 2 min. After 8 min at the brazing temperature, the assemblies were conveyed into water-jacketed cooling chambers, where they cooled rapidly in the hydrogen atmosphere to room temperature. Brazed assemblies that were bright and oxidation-free emerged from the exit end of the furnace.

The brazed assemblies were 100% visually inspected for complete joint coverage. Hardness tests on a sampling basis were used to determine whether the assemblies had responded properly to hardening. Tempering to the desired final hardness followed the simultaneous brazing and hardening operation.

Example 8: Medical Device Brazed, Rather than Welded, in Hydrogen.

Because of the need for strong, corrosion-resistant, and leak-proof joints in a stainless steel blood-cell washer (Fig. 8), the process that was selected was hydrogen furnace brazing with BNi-7 brazing filler metal. The devices are used to expedite and standardize cell-washing procedures in blood banks and hematology laboratories. Therefore, neither voids nor cracks could be tolerated, because the possibility of breeding bacteria in the devices had to be avoided.

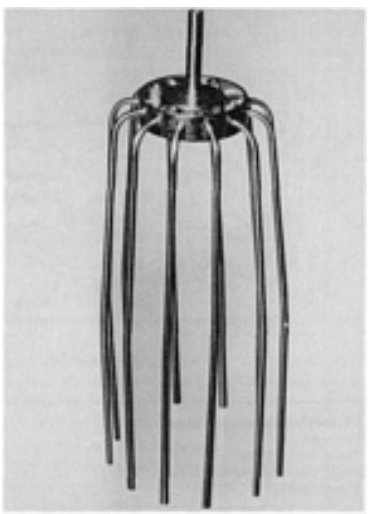

FIG. 8 MANIFOLD AND CANNULAS TUBE ASSEMBLY OF A BLOOD-CELL WASHER THAT WAS HYDROGEN FURNACE BRAZED WITH BNI-7 BRAZING FILLER METAL AT 1040 °C (1900 °F). COURTESY OF WALL

COLMONOY CORPORATION

Brazing, rather than welding, was chosen to join the manifold and the delicate tube parts of the washer, a rake-like component with twelve prong-like cannulas tubes that extend approximately 150 mm (6 in.) from a cylindrical manifold.

The manifold assembly was brazed using BNi-7 nickel brazing filler metal in a hydrogen atmosphere at 1040 °C (1900 °F). After assembling the tubes to the manifold, the brazing filler metal was applied to the joints and the assembly was placed in the furnace. Components were wired to stainless steel fixtures to maintain uniform tube spacing.

The brazing permitted the filler metal to flow completely around the thin-walled tubes, which was not possible with welding, leaving smooth fillets without voids that could trap harmful bacterial particles. Additional advantages of brazing were that it: minimized the amount of assembly distortion, eliminated flux hazards, simplified inspection procedures, and prevented the oxidation.

Furnace Brazing in Dissociated Ammonia

When ammonia is free of moisture and is 100% dissociated, it becomes a suitable atmosphere for the brazing of stainless steel using selected brazing filler metals without requiring a flux. Although dissociated ammonia is strongly reducing, it is less so than pure, dry hydrogen. Consequently, it will promote wetting action by reducing chromium oxide on the surface of stainless steel, but it may not be sufficiently reducing to promote the flow of some brazing filler metals, such as copper oxide powders. Because of its high (75%) hydrogen content, dissociated ammonia forms explosive mixtures with air and must be handled with the same precautions as those required for the handling of hydrogen.

A dissociated-ammonia atmosphere is prepared by heating anhydrous liquid ammonia in the presence of an iron or nickel catalyst. The decomposition of ammonia to form hydrogen and nitrogen begins at 315 °C (600 °F), and the rate of decomposition increases with temperature. Unless the atmosphere used in brazing stainless steel is completely decomposed, that is, 100% dissociated, even minute amounts of raw ammonia (NH_3) in the atmosphere will cause the nitriding of stainless steel, especially steels containing little or no nickel. In addition, because of the solubility of ammonia in water, the atmosphere that comes from the dissociator must be extremely dry (preferably having a dew point of -60 °C, or -80 °F, or lower). To ensure a very low dew point, the atmosphere that comes from the dissociator is commonly processed by being passed through a molecular-sieve dryer. To avoid the oxidation of base metal and brazing filler metal, the atmosphere must be kept pure and dry while it is inside the furnace. In the following examples of production practices, dissociated ammonia was used successfully in the furnace brazing of austenitic and precipitation-hardening (PH) stainless steels.

Example 9: Brazing in Dissociated Ammonia Without Flux.

The pressure gage subassembly shown in Fig. 9 comprises five diaphragms of 17-7 PH stainless steel, a deep-drawn cup and a top fitting of type 304 stainless steel, and a connector of copper alloy 145 (tellurium-bearing copper). Originally, these subassemblies were furnace brazed with a silver brazing filler metal that required a flux. Because applying flux and assembling the fluxed components with gloved hands was time consuming, the decision was made to change to fluxless brazing in an atmosphere of dissociated ammonia. Although this necessitated using a more-expensive brazing filler metal (BAg-19), the higher cost was offset by the greater productivity of each operator. In addition, subassemblies brazed with BAg-19 in dissociated ammonia exhibited fewer leaks and had improved corrosion resistance and a better appearance than those brazed with the original filler metal and a flux.

FIG. 9 PRESSURE-GAGE SUBASSEMBLY THAT COMBINED FURNACE BRAZING WITH SOLUTION HEAT TREATMENT

Prior to brazing, the deep-drawn type 304 cups were fully annealed at 1090 °C (2000 °F). Annealing served to avoid the erosive penetration of brazing filler metal in zones of high residual stress. All components were chemically cleaned and then assembled by hand, along with seven preplaced rings of brazing filler metal. The assemblies were placed on holding fixtures, which were loaded on the belt of a conveyor furnace heated to 980 °C (1800 °F). The cooling chamber of the furnace was cooled to below 15 °C (60 °F) to ensure rapid cooling of the 17-7 PH diaphragms from the solution-treating temperature, thereby combining solution treating with the brazing operation.

After brazing, the assemblies were cooled to -40 °C (-40 °F), dried, and then heated to 510 °C (950 °F) in dry, dissociated ammonia to harden the diaphragms to 44 to 48 HRC. Brazed assemblies were pressure tested in a bellows halogen leak detector by applying Freon at 520 kPa (75 psi) and then adding compressed air to bring the total pressure up to 2.1 MPa (300 psi). Leakage of Freon in the gas-air mixture would have been detected by the halogen leak detector. The requirement was for no leakage at the most sensitive setting of the leak detector.

The rejection rate for leakage, based on the 750,000 bellows that were produced, dropped from 2.8%, with the original silver brazing filler metal, to 1.0%, with the BAg-19 brazing filler metal. Field corrosion returns dropped 96%. By eliminating the stains caused by flux, it was no longer necessary to paint the assemblies.

Brazing of Stainless Steels

Furnace Brazing in Argon

Argon is occasionally used as a furnace atmosphere when brazing stainless steels to other stainless steels or to reactive metals such as titanium (Example 10). Argon has the advantage of being chemically inert in relation to all metals. Therefore, it is a useful protective atmosphere for metals that can combine with or absorb reactive atmospheres such as hydrogen. Because an argon atmosphere has the disadvantage of being unable to reduce oxides, the surface of stainless steel components must be exceptionally clean and oxide-free when brazed in argon.

Example 10: Brazing in an Argon Atmosphere.

A manufacturer of jet engines designed a gear-reduction box of commercially pure titanium. This complicated fabrication was made from assemblies of stampings and machined forgings, most of which were joined by gas-tungsten arc welding (GTAW) in argon-filled welding chambers. However, brazing was more appropriate for the joining of some assemblies.

A typical assembly that was furnace brazed in argon is shown in Fig. 10. This assembly consisted of a machined forging of commercially pure titanium (per Aerospace Material Specification 4921) and a length of seamless type 347 stainless steel tubing that was flared or expanded for a distance of approximately 8 mm ($\frac{5}{16}$ in.) to accept the titanium forging.

(F) 1 MM (0.040 IN.) DIAMETER WIRE

FIG. 10 STAINLESS STEEL AND TITANIUM ASSEMBLY THAT WAS FURNACE BRAZED IN AN ARGON ATMOSPHERE

The outside diameter of the titanium forging was held to 12.70 mm (0.500 in.), +0.000 and -0.025 mm (-0.001 in.). The inside diameter of the stainless steel tube was held to 12.73 mm (0.501 in.), +0.025 mm (+0.001 in.) and -0.000 mm or in. This allowed for a diametral clearance of 0.025 to 0.076 (0.001 to 0.003 in.) between components at room temperature. From 0 to 900 °C (32 to 1650 °F), the mean coefficient of thermal expansion (CTE) of commercially pure titanium is $10.3^{-6}/K$. From 0 to 870 °C (32 to 1600 °F), the mean CTE of type 347 stainless steel is $20 \times 10^{-6}/K$. Calculation of the expansion that would occur when both components were heated to 900 °C (1650 °F) indicated a 0.102 mm (0.004 in.) diametral clearance between the titanium and the stainless steel. Adding the diametral clearance at room temperature (0.025 to 0.076 mm, or 0.001 to 0.003 in.) to the 0.102 mm (0.004 in.) clearance gave a total diametral clearance at brazing temperature of 0.127 to 0.178 mm (0.005 to 0.007 in.), which is within a range that will result in a successful joint.

The selected brazing filler metal was the BAg-19 silver, because it has high fluidity in an argon atmosphere and a brazing temperature that is lower than that of pure silver. Most alloy elements in silver brazing filler metals form brittle intermetallic compounds with titanium, which result in unreliable joints. With the exception of a minute amount of lithium, the only alloying element contained in BAg-19 is 7.5% Cu. By limiting the time at brazing temperature, sound ductile joints were made, and the formation of the titanium copper intermetallic phase was minimized.

Prior to assembly, the titanium forging was degreased and cleaned in a solution that contained 40% nitric acid plus 2% hydrofluoric acid. The stainless steel tubing and the brazing filler metal (preformed rings of 0.102 mm, or 0.004 in., diameter BAg-19 wire) were cleaned by washing in acetone. Operators wore clean, lint-free, white cotton gloves for all subsequent handling of the components during assembly, and kept them on until after brazing was completed.

The titanium forging was inserted into the expanded end of the stainless steel tube until it was completely seated. A brazing filler metal ring was placed around the outside diameter of the titanium tube at the joint intersection. The

assembly was placed upright (forging down) in a titanium sheet-metal-holding fixture and was loaded into an Inconel retort. The retort was designed for displacement purging with an inlet and exit manifold for the argon atmosphere. After loading, the retort cover was seal welded to its base, using the GTAW process.

The retort was purged for 30 min with pure, dry argon at 4.2 m^3/h (150 ft^3/h) and then placed in a gas-fired pit-type furnace. The retort was heated to 315 °C (600 °F), and it was held at that temperature for an additional 30 min, or until the dew point of the exiting argon was -60 °C (-70 °F), as recorded on an electrolytic water analyzer. The furnace temperature was then raised until the assembly temperature reached 900 °C (1650 °F), as indicated by a Chromel-Alumel thermocouple attached to the titanium holding fixture within the retort. As soon as this temperature was reached, the retort was removed from the furnace and fan-cooled to room temperature.

The retort cover was opened by grinding away the seal weld, and the assemblies were removed. The titanium and stainless steel components emerged bright and clean, with evidence of excellent brazing filler metal flow. Radiographic inspection showed over 95% joint coverage. All joints were visually inspected on both sides.

Brazing of Stainless Steels

Furnace Brazing in an Air Atmosphere

The principal advantages of furnace brazing are high production rates and a means for using controlled protective atmospheres at controlled dew points, which often precludes the use of a flux to obtain satisfactory wetting action. In most furnace-brazing applications, both of these advantages are exploited. Occasionally, however, furnace brazing is selected solely on the basis of production rate, and brazing is performed without a protective atmosphere, but with a suitable flux. Under these conditions, the lower-melting-point brazing filler metals are generally selected, as in the following application.

Example 11: Substitution of Furnace Brazing in Air Atmosphere for Torch Brazing.

The gas-valve bobbin assembly shown in Fig. 11 was satisfactorily brazed by both the torch and furnace brazing processes. The choice of process primarily depended on the required production rate. Cost data proved that furnace brazing increased the production rate per hour, reduced the direct labor rate per hour, and reduced the direct labor cost per assembly.

ASSEMBLY PRODUCTION RATE/H	**140**

(A) AIR ATMOSPHERE.

(B) PREFORMED RINGS, PREPLACED AS SHOWN IN ILLUSTRATION, 0.8 MM (0.031 IN.)

FIG. 11 STAINLESS STEEL AND COPPER GAS-VALVE BOBBIN THAT WAS FURNACE BRAZED IN AN AIR ATMOSPHERE

As Fig. 11 shows, the bobbin assembly consisted of four parts: a screw made of type 446 stainless steel, a base made of type 303 stainless steel, a tube made of a copper alloy closely related to nickel-silver (74Cu-22Ni-4Zn), and a plug made of copper alloy 187 (99Cu-1Pb), which held the screw in place and blocked gas passage through the tube.

All components were thoroughly vapor degreased before brazing. They were assembled with two preformed rings of 0.787 mm (0.031 in.) diameter BAg-3 brazing filler metal wire. The diametral clearance on the joints was 0.076 to 0.127 mm (0.003 to 0.005 in.). One preform, with a 9.5 mm ($\frac{3}{8}$ in.) internal diameter, was placed over the neck of the plug. The other, with a 12.7 mm (0.5 in.) internal diameter, was placed over the tube adjacent to the base joint. The joint areas were coated with type FB3-A brazing flux, and the assemblies were brazed in a continuous-belt conveyor furnace. Brazing filler metal BAg-3 was chosen, in preference to BAg-1 or BAg-1a, in order to avoid the risk of interface corrosion.

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Furnace Brazing in a Vacuum Atmosphere

The majority of vacuum brazing is performed in two types of equipment utilizing either hot- or cold-walled furnaces. The hot-walled structure utilizes a retort that is evacuated and placed into a furnace, which provides the heat source. The retort can be single-pumped, providing a vacuum to temperatures up to 980 °C (1800 °F), or double-pumped for temperatures above 980 °C (1800 °F) to prevent the retort from collapsing. Limitations of the hot-walled furnace (retort) include longer cycle times, because the retort is heated externally; a 1200 °C (2200 °F) temperature limit; and slower cooling rates. Some advantages of hot-walled furnaces are lower initial capital expenditures, reduced contamination from the retort, and easy upkeep and maintenance.

The cold-walled vacuum furnace is typically designed with a water-cooled outer jacket that is protected by radiation shielding adjacent to the inner wall. The heating elements are exposed directly to the workload. A braze cycle may have temperatures that exceed 2200 °C (4000 °F), depending on the heating element material and the load-support structure. Heating and cooling rates for cold-walled vacuum furnaces are substantially less than they are for the hot-walled vacuum retort. Higher braze temperatures, in excess of 1260 °C (2300 °F), are obtainable in vacuum furnaces and are frequently employed.

Effect of Filler-Metal Composition. Vacuum brazing of many structural configurations made of austenitic stainless steels offers excellent heat and corrosion resistance for high-temperature service applications. Brazing filler metals, such as gold, gold-palladium, and nickel, offer greater high-temperature strength and oxidation resistance. Problems can occur when brazing the 300 series of stainless steels, because of the carbide precipitation and loss of corrosion resistance that results when brazing in the temperature range from 480 to 815 °C (900 to 1500 °F). Brazing at temperatures in excess of 815 °C (1500 °F), using brazing filler metals with melting points that are higher than this temperature, followed by rapid cooling, will reduce carbide precipitation and improve corrosion properties.

Occasionally, wetting does not occur with a particular lot of stainless steel. Generally, alloying elements such as titanium and aluminum contribute to poor wettability.

Martensitic stainless steels, such as the 400 series, can be brazed successfully in vacuum. The use of a suitable brazing filler metal can result in austenitizing and brazing at the same time, followed by rapid cooling to harden the stainless steel.

Care must be exercised when selecting brazing filler metals for use in vacuum. Silver brazing filler metals, such as BAg-1, BAg-1a, and BAg-3, contain alloying elements of zinc and cadmium, which have very high vapor pressures. These elements vaporize if the furnace pressure is too low or the brazing temperature is excessive, or if a combination of these conditions exists. Copper and silver also vaporize under low-pressure conditions at higher brazing temperatures. Therefore, if brazing alloys containing copper or silver are to be used in vacuum, the furnace chamber must be backfilled with an appropriate atmosphere to 300 to 500 μm (12 to 20 mils) until melting occurs to prevent the loss of these elements. Caution must be exercised with the furnace exit gases because these gases are extremely toxic. Two materials that should never be put in a vacuum furnace under any condition are zinc and cadmium. It is recommended that specific alloys (for example, BAg-8 or BAg-13a) or other alloys free of zinc or cadmium be used when brazing in a vacuum furnace. A partial pressure may still be required for many of the alloys to prevent the vaporization of the silver.

Example 12: Vacuum Brazing to Improve Beverage Can Filling Nozzles.

Because of a continuous problem in obtaining uniform and void-free fillets when using silver brazing filler metals and induction brazing methods, a switch was made to vacuum furnace brazing using a nickel brazing filler metal. The beverage filling nozzle shown in Fig. 12 is an assembly consisting of 16 short tubes brazed to a cast body section that connects to the supply piping. The tubes are pressed into the holes that are drilled at angles through the body, and then brazed to form a tight joint. Both the body and tubes are made from type 304 stainless steel.

FIG. 12 STAINLESS STEEL TYPE 304 BEVERAGE CAN FILLING NOZZLE. TUBES ARE VACUUM BRAZED WITH A NICKEL BRAZING FILLER METAL AT 1120 °C (2050 °F). LEFT, LOCATION WHERE PASTE ALLOY IS PLACED AROUND TUBE. RIGHT, COMPLETED NOZZLE, SHOWING SMOOTH, VOID-FREE FILLETS. COURTESY OF WALL COLMONOY CORPORATION

The nozzles require a smooth surface that will not harbor bacteria. This means that the brazed joints must have uniform, smooth fillets and full-length void-free filler metal penetration. In addition, the entire assembly must be resistant to chemical attack by the beverages being handled, by steam, or by cleaning compounds.

The prior method of brazing using silver-base filler metals was not very successful in obtaining void-free joints or consistent results. In addition, many of the beverages being handled did attack the silver brazing filler metal, causing corrosion and discoloration in the joint area.

The nickel brazing filler metal selected for this application was BNi-9 (81.5Ni-15Cr-3.5B), because of its excellent capillary flow characteristics, low base-metal erosion, and self-fluxing properties. In addition, the alloy would be unaffected by subsequent processing operations, which include passivation and electropolishing.

The stainless parts were degreased and a small bead of the nickel brazing filler metal was placed around each tube. The brazing was done in a vacuum furnace at 1135 °C (2075 °F), where the part was heated and cooled at a controlled rate to ensure thermal stability. Careful control of the brazing cycle is the key element in obtaining the uniform fillets and void-free joints required for the nozzles.

Example 13: Cryogenic Valve Nickel Brazed in Vacuum.

Cryogenic valves that are used to handle liquid nitrogen and liquid hydrogen require construction that provides high strength and impact resistance at extremely low temperatures, as well as light weight and good corrosion resistance (Fig. 13). Valves that are part of the propellant loading systems for ballistic missiles were used at temperatures of -250 °C (-425 °F), and at pressures of nearly 41.4 MPa (6 ksi). The body, flanges, seat, and bonnet were brazed with BNi-2 brazing filler metal in a vacuum furnace.

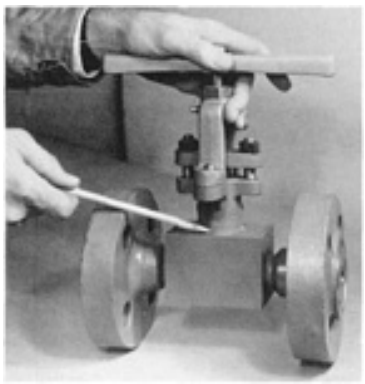

FIG. 13 CRYOGENIC VALVE THAT WAS VACUUM BRAZED WITH BNI-2 BRAZING FILLER METAL. ALL JOINTS ON THE BODY, FLANGES, SEAT, AND BONNETS WERE BRAZED SIMULTANEOUSLY. COURTESY OF WALL

COLMONOY CORPORATION

The valve seat and disc were cast from 17-7 or 17-4 PH steel or from stellite. They were brazed in place at the same time the assembly was brazed. Brazing replaced the welding of the seat, which in this case had trouble in terms of weld deposit cracking. All parts, except the valve seat, were finish-machined before brazing. By eliminating the need for machining after brazing, costs were reduced enough to pay for the brazing operation.

Brazing of Stainless Steels

Induction Brazing

The behavior of stainless steels, in terms of heating via electrical induction, depends on the metallurgical and physical properties of the particular material. This behavior can be considerably different from that of carbon and low-alloy steels, as well as from that of the more widely used nonferrous metals. In addition, the response of the steel to induction heating varies considerably, depending on whether a stainless steel is magnetic or nonmagnetic at room temperature. Differences in specific heat and electrical conductivity markedly affect the response to heating by induction.

Ferritic and martensitic (SAE 400 series) stainless steels are ferromagnetic at all temperatures, up to the Curie temperature. Thus, given the same power input, these steels generally heat faster than austenitic stainless steels, which are nonmagnetic in the annealed condition. Although cold working may induce slight magnetism in the austenitic chromium steels, the 400 series of chromium-nickel steels are strongly magnetic. The rate of heating to the temperature at which the filler metal flows usually affects induction-coil design and coupling. It may also influence the selection of power output frequency and other processing variables.

Stainless steels can be induction brazed in an air atmosphere, using a suitable flux. However, for critical applications, induction brazing is sometimes done in a protective or a vacuum atmosphere (refer to Example 14). In other applications, an inert gas, such as argon, can be used as a protective atmosphere to either minimize or prevent oxidation.

Example 14: Brazing a Tube to an End Blank.

The assembly shown in Fig. 14, which is part of a solenoid, consisted of a type 321 stainless steel brazed to a type 416 end blank. The former material is a nonmagnetic austenitic steel, whereas the latter is martensitic and ferromagnetic. Consequently, although both metals were easily brazed, the achievement of a proper joint clearance between the two components was complicated by the marked differences in the CTEs of the two steels. Thus, calculations were needed to determine the room-temperature clearance required to provide a suitable clearance at the brazing temperature.

ASSEMBLY PRODUCTION RATE/H	**140**

(A) VACUUM TUBE.

FIG. 14 INDUCTION-BRAZED ASSEMBLY

Because the assembly was not intended for high-temperature service, the selection of the low-melting-point silver brazing filler metal (BAg-1) and a relatively low brazing temperature of 650 °C (1200 °F) were utilized to minimize heating and oxidation of the stainless steel components.

For brazing that is conducted at this temperature, calculations based on CTE values showed that the following dimensions and tolerances in the joining area would be satisfactory: for the tube diameter, 12.4 mm (0.494 in.) +0.000, -0.025 mm (-

0.001 in); and for the inside diameter of the end blank, 12.7 mm (0.500 in.) +0.000, -0.025 mm (-0.001 in.). Thus, the diametral clearance at room temperature ranged from 0.127 to 0.178 mm (0.005 to 0.007 in.).

The shape of the assembly and the low melting point and brazing temperatures favored brazing by induction. The end blank was in the hardened and tempered condition prior to brazing, and the short induction heating cycle (10 s) did not reduce the hardness to less than the required minimum.

Prior to brazing, the components were vapor degreased. The end of the tube was dipped in flux and inserted in the end blank. A preformed ring of filler-metal wire was slipped over the tube and positioned at the top of the joint. Then, the end blank was placed on a holding fixture, positioned in a single-turn inductor (Fig. 14), and heated for 10 s. After brazing, the assembly was cooled in air for 10 s before being removed from the holding fixture. The assembly was then washed in hot water to remove the flux residue.

Example 15: Induction Brazing in a Vacuum Atmosphere.

A distinctive advantage of induction brazing, as applied to stainless steel, is its suitability for simple setups that permit brazing in vacuum. Closed, nonmetallic containers with reasonably good strength and dielectric properties can provide an enclosure for the assembly to be brazed and can be evacuated prior to brazing. Because the inductor can be placed outside the container, it can heat the assembly efficiently without being part of the vacuum system.

Stainless steel collar-and-tube assemblies (Fig. 15) were brazed in a simple setup that combined induction heating and the protection afforded by heating in vacuum. The vacuum container consisted of a high-silica, low-expansion glass tube with copper end fittings connected to a vacuum system. The collar-and-tube components, with preformed BNi-7 filler-metal rings pressed into place on the shoulder of each collar, were positioned and held inside the glass tube by means of a simple holding fixture. The tube was sealed and evacuated with a multiple-turn inductor, outside the tube, in position to heat one of the collars. When the vacuum reached 0.133 Pa (10^{-3} torr), heating was started. The collar was heated slowly to 970 °C (1775 °F). After 4 min, the power was shut off. The tube was then repositioned to bring the second collar into the field of the inductor, and the heating sequence was repeated.

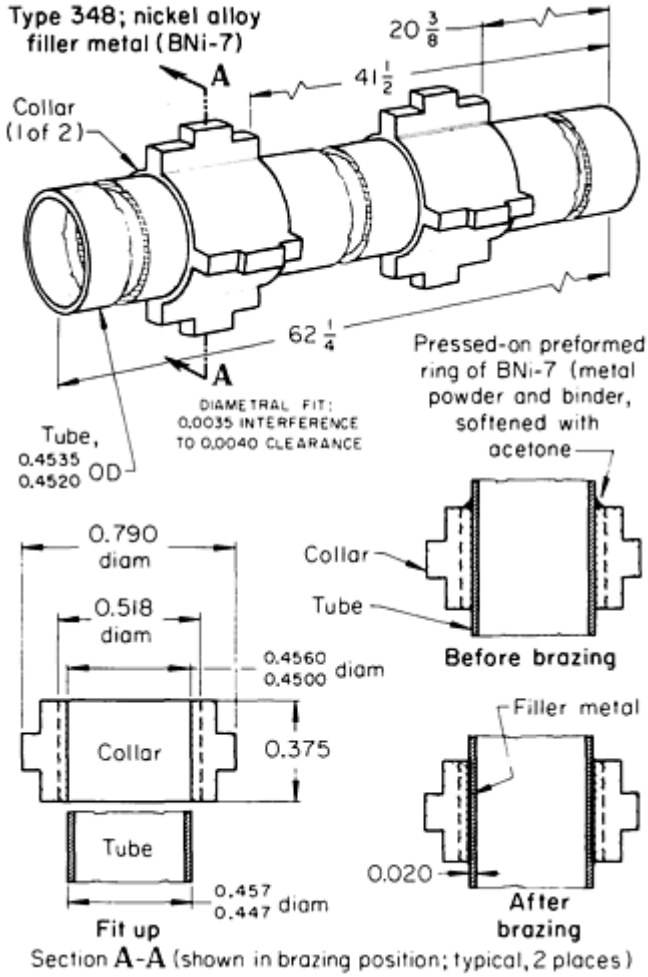

FIG. 15 COLLAR AND TUBE ASSEMBLY THAT WAS INDUCTION BRAZED IN VACUUM

When the second collar had cooled to the point at which no glow was visible in normal light, the tube was backfilled for 5 min with argon. Brazed joints were inspected visually and metallographically. They were found to be sound and acceptable in all respects. The induction heating source was an 8 kVA spark-gap converter with an operating frequency of 175 to 200 kHz. The water-cooled external inductor coil was made of 6.4 mm ($\frac{1}{4}$ in.) diameter copper tubing. The production rate was 22 assemblies per day.

Brazing of Stainless Steels

Revised by Matthew J. Lucas, Jr., General Electric Aircraft Engines

Dip Brazing in a Salt Bath

The brazing of stainless steel by immersing either all or a portion of the assembly in molten salt offers essentially the same advantages and limitations that would apply to the brazing of similar assemblies made of carbon steel.

Example 16: Change From Torch or Induction Brazing to Dip Brazing.

The television wave-guide assembly shown in Fig. 16 consisted of a type 304 stainless steel flange brazed to a tube of copper alloy 230 (red brass, 85Cu-15Zn). Satisfactory end use depended on minimal distortion. When the assembly was

brazed by torch or induction brazing, the rejection rate sometimes reached 70%, because of distortion caused by uneven heating. When dip brazing was adopted, the rejection rate dropped to nearly zero.

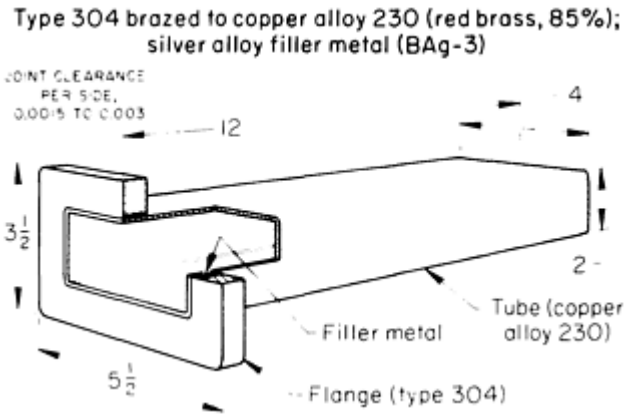

FIG. 16 TELEVISION WAVE-GUIDE ASSEMBLY JOINED BY SALT-BATH DIP BRAZING

Prior to brazing, the stainless steel flange was degreased and pickled, and the brass tube was degreased and bright dipped. Then, the flange was placed on the tube, the tube end was flared outward slightly, a preform of the BAg-3 filler metal was placed over the tube adjacent to the flange, and FB3-A flux (AMS 3410D) flux was applied to the joint. The assembly was suspended flange-down over an electrically heated salt bath to preheat the flange and dry the flux. Next, the assembly was lowered slowly into the molten bath, which was maintained at 730 °C (1350 °F) for a distance of approximately 25 mm (1 in.) above the flange. After being held in the bath for 0.5 min, the assembly was removed and air cooled. The flux residue was removed by rinsing the assembly in 60 °C (140 °F) water. The production rate was 30 assemblies per hour.

Brazing of Stainless Steels

High-Energy-Beam Brazing

High-energy-beam brazing techniques, such as those based on electron or laser beams, have been used to a limited extent. Both electron- and laser-beam brazing are performed in a manner similar to electron- and laser-beam welding, except that the beam is defocused to provide a larger beam and to reduce the power density to prevent the base metal from melting. Generally, the speed at which the beam is swept is increased so that a larger area of the part is heated and more uniform heating of the part occurs.

In electron-beam brazing, the high vacuum used in the work chamber (0.0133 to 0.00133 Pa, or 10^{-4} to 10^{-5} torr) permits the adequate flow of brazing filler metal on properly cleaned joints without the use of a reducing atmosphere or flux. Thus, flux entrapment does not occur, and the work does not require cleaning after brazing. The high-vacuum atmosphere and the absence of flux provide a brazing environment that avoids the problems associated with prepared atmospheres, which are encountered when brazing some stainless steels, as well as the more-reactive metals (such as titanium).

In laser-beam brazing, the paris are normally protected with a shielding gas to prevent the occurrence of oxidation. If necessary, the beam spot diameter can be enlarged substantially, depending on the type of equipment, while providing an adequate amount of heat input for brazing. A work movement technique can be used if an area substantially larger than the beam spot size is to be heated, and the work can be rotated or indexed under the beam for uniform heating. In high-energy brazing, the brazing temperatures are quickly attained, and heat can be localized to minimize grain growth, the softening of cold-worked metal, and, in austenitic stainless steels, the sensitizing of the material by carbide precipitation.

Applications. Electron-beam brazing is a convenient method for brazing small assemblies, such as instrument packages. It combines the versatility and close controllability of electron-beam heating with the advantages of vacuum brazing. Packaged devices can be encapsulated with an internal vacuum without damaging the basic package.

Tube-to-header joints in small heat-transfer equipment made of heat-resistant alloys and refractory metals are sometimes brazed using an electron beam. In one technique, the tube-to-header joint is electron-beam welded on the top side of the header. The heat of the beam causes the brazing filler metal that is preplaced on the reverse side of the header at the joint to melt and flow. Small-diameter, thin-walled stainless steel tubes are readily joined by electron-beam brazing, as in the following example.

Example 17: Use of Defocused Beam for the Electron-Beam Brazing of Small Tubes.

Capillary and other small-diameter tubes used in instrument packages required that leak-tight joints be made without overheating the other portions of the assembly. The avoidance of flux was also necessary, because entrapped flux would be either difficult or impossible to remove. These conditions were satisfied by electron-beam brazing.

Figure 17 shows a typical joint in type 304 tubing with a 2.55 mm (0.100 in.) outside diameter and a 0.254 mm (0.010 in.) thick wall that was brazed by the electron-beam process. The joint design was based on the use of a 19 mm ($\frac{3}{4}$ in.) long socket coupling that was counterbored with a diametral clearance of 0.076 to 0.127 mm (0.003 to 0.005 in.) over the tube diameter and to a depth of 6.4 mm ($\frac{1}{4}$ in.). The average joint clearance (per side) was therefore 0.050 mm (0.002 in.). Tubes and socket couplings were deburred and solvent cleaned. They were then assembled with two wire-ring preforms of BCu-1a brazing filler metal, as shown in Fig. 17. The tubes were held in position with a small clamping fixture, and the assembly was mounted in a fixed position on a table in the vacuum chamber.

FIG. 17 JOINT BETWEEN TWO CAPILLARY TUBES OF AN INSTRUMENT PACKAGE, MADE BY ELECTRON-BEAM BRAZING USING A LOW-POWER DEFOCUSED BEAM IN A HIGH-VACUUM ATMOSPHERE

After pumpdown, the joint was brought to the brazing temperature by moving the table back and forth under the defocused electron beam, which caused the heat of the 4.76 mm ($\frac{3}{16}$ in.) diameter beam spot to be applied primarily to the central portion of the coupling. After being heated by conduction at a relatively low beam power, the brazing filler metal melted and flowed through the joint in approximately 30 s.

About ten assemblies were brazed, at a rate of one per pumpdown, using the machine settings and other brazing conditions specified in Fig. 17. Sensitizing the austenitic stainless steel was not a problem in this application, because the service environment was not significantly corrosive. The relatively short-time brazing cycle minimized grain growth and the dilution of the thin-walled tubing with copper brazing filler metal.

Brazing of Heat-Resistant Alloys, Low-Alloy Steels, and Tool Steels

Revised by Darrell Manente, Vac-Aero International Inc.

Introduction

PROCEDURES for brazing heat-resistant alloys, low-alloy steels, and tool steels share much in common. This article focuses primarily on brazing of heat-resistant alloys; some information about particulars involved in the brazing of low-alloy steels and tool steels is also provided.

Brazing of Heat-Resistant Alloys, Low-Alloy Steels, and Tool Steels

Revised by Darrell Manente, Vac-Aero International Inc.

Brazing of Heat-Resistant Alloys

Heat-resistant alloys are frequently referred to as superalloys, because of their strength, oxidation resistance, and corrosion resistance at elevated service temperatures (650 to 1205 °C, or 1200 to 2200 °F). This article discusses primarily nickel- and cobalt-base alloys. Superalloys can also be subdivided (according to manufacturing technology) into two categories: conventional cast and wrought alloys and powder metallurgy (P/M) products. Powder metallurgy products may be produced in conventional alloy compositions and as oxide-dispersion-strengthened (ODS) alloys. Almost any metal, as well as nonmetallics, can be brazed to these heat-resistant alloys, if it can withstand the heat of brazing. For additional information on these alloys, see Volume 1 of the *ASM Handbook.*

Brazing Filler Metals

The American Welding Society (AWS) has classified several gold-, nickel-, and cobalt-base brazing filler metals which can be used for elevated-temperature service (Table 1). These brazing filler metals are suitable for high-temperature service; however, if the application is for temperatures above 980 °C (1800 °F) or in severe environments, the required brazing filler metal may not be in Table 1. It should be noted that for lower service temperatures, copper (BCu) (below 480 °C, or 900 °F) and silver (BAg) (below 425 and 200 °C, or 800 and 400 °F) brazing filler metals have been used for many successful applications.

(A) IF DETERMINED, COBALT IS 0.1% MAXIMUM UNLESS OTHERWISE SPECIFIED.

Many nickel-palladium-base brazing filler metals exhibiting good wetting and flow are not classified by AWS but are also available. These filler metals have been developed to replace gold-containing (BAu) brazing filler metals, which are more expensive.

Another group of brazing filler metals not classified by AWS are used for repair and overhaul of nickel- and cobalt-base superalloy aerospace and industrial turbine engine components. Many of these brazing filler metals are proprietary compositions of the engine manufacturer for which they were developed. However, a good variety of these filler metals are commercially available. These "diffusion braze" filler metals do not contain silicon. However, they do contain boron, which acts as a melting point suppressant. Both boron and silicon react with metals (such as chromium and molybdenum) to form intermetallic phases. These intermetallic phases are very hard and brittle and can seriously weaken a brazed joint. It is possible to perform annealing heat treatments on diffusion brazed joints that result in the diffusion of the boron out of the brazed joint and into the base metal. The result is a brazed joint in which intermetallic phases are partially dissolved or eliminated completely (Fig. 1). Diffusion heat treatment increases the strength and ductility of the brazed joint.

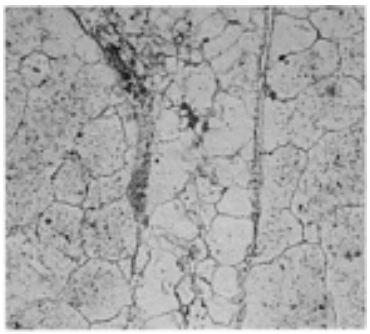

FIG. 1 PHOTOMICROGRAPH OF THE CRACK REPAIR OF A DIFFUSION BRAZED JOINT BY HEAT TREATING OF THE IN-792 BASE METAL. SAMPLE WAS ETCHED WITH KALLING'S REAGENT. 76×

Silicon atoms do not diffuse as easily as boron atoms (because silicon atoms are larger and sit on a regular lattice site, whereas boron atoms sit on interstitial sites, providing much faster diffusion paths). Therefore, similar heat treatments do not tend to dissolve or eliminate silicon intermetallic phases.

These boron-containing filler metals (used on their own or mixed with base metal powder to act as a gap filler) are used to fill cracks and eroded areas on turbine engine components. Some type of cleaning operation (such as hydrogen fluoride cleaning or mechanical cleaning) is employed before the brazing operation in order to remove oxides on the components and thus facilitate brazing filler metal wetting.

A second group of filler metals not classified by AWS are used for wide gaps (1.52 mm, or 0.060 in., and greater) and eroded areas. These filler metals are generally nickel- or cobalt-base superalloys that have additions of a melting point suppressant. These filler metals do not tend to flow away from the area in which they are placed. The microstructure of the joint formed using these filler metals is homogeneous and more closely approximates the base metal microstructure (Fig. 2).

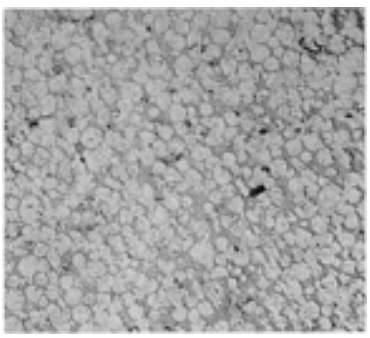

FIG. 2 MICROSTRUCTURE OF A WIDE GAP FILLER METAL BRAZE REPAIR. SAMPLE WAS ETCHED WITH KALLING'S REAGENT. 40×

Generally, heat-resistant alloys are brazed with nickel- or cobalt-base alloys containing boron and/or silicon, which serve as melting-point depressants. In many commercial brazing filler metals, the levels are 2 to 3.5% B and 3 to 10% Si. Phosphorus is another effective melting-point depressant for nickel and is used in filler metals from 0.02 to 10%. It is also used where good flow is important in applications of low stress, where service temperatures do not exceed 760 °C (1400 °F).

In addition to boron, silicon, and phosphorus, chromium is often present to provide oxidation and corrosion resistance. The amount may be as high as 20%, depending on the service conditions. Higher amounts, however, tend to lower brazement strength.

Cobalt-base filler metals are used mainly for brazing cobalt-base components, such as first-stage turbine vanes for jet engines. Most cobalt-base filler metals are proprietary. In addition to containing boron and silicon, these alloys usually contain chromium, nickel, and tungsten to provide corrosion and oxidation resistance and to improve strength.

Product Forms. Available forms of AWS classified and proprietary brazing filler metals include wire, foil, tape, paste, and powder. The form used can be dictated by the application or by the composition of the filler metal. If the filler metal required for a specific application is only available as a dry powder, then brazing aids such as cements and pastes are available to help position the brazing filler metal.

Brazing filler metal powders usually are gas atomized and sold in a range of specified particle sizes, which ensures uniform heating and melting of the brazing filler metal during the brazing cycle. These powders can be mixed with plasticizers or organic cements to facilitate positioning. If the mixture must support its own weight until the brazing cycle begins, an organic binder or cement is required. These binders burn off in atmosphere brazing and little or no residue results. When the brazing filler metal is supplied as a paste, it is simply a premixed powder and binder.

Brazing Tapes and Foils. Brazing filler metals in the form of tapes and amorphous foils appear similar, but the foils are usually made by rapid solidification during melt spinning operations and tend to exhibit homogeneous amorphous structures. Brazing tapes are made of powder that is held together by a binder and formed into a rather fragile sheet. Most amorphous foils have a high metalloid (phosphorus, silicon, boron) content, while tapes can be made from brazing filler metals that have no metalloid content. The metalloids usually are melting-point depressants and frequently form brittle phases. In some cases, where the composition is workable, such as BAu, foils can be made by cold rolling. Foil products can also be produced by rolling an alloy of suitable composition into a foil before adding the metalloids. Tapes and foils are best suited for applications requiring a large area joint, good fit-up, or where brazing flow and wetting may be a problem.

Brazing wires of nonfabricable alloys usually are made by P/M processes from gas atomized powder, which is held together by a binder or by extruding powder into wire and sintering. This form of brazing filler metal is better able to support itself than are pastes and powders of filler metal, but is not used to replace tapes or amorphous foils where precision is needed in preplacing the filler metal, such as joint gaps less than 0.13 mm (0.005 in.).

Surface Cleaning and Preparation

Cleaning of all surfaces that are involved in the formation of the desired brazed joint is necessary to achieve successful and repeatable brazed joints. All obstruction to wetting, flow, and diffusion of the molten brazing filler metal must be removed from both surfaces to be brazed prior to assembly. The presence of contaminants on one or both surfaces to be brazed may result in void formation, restricted or misdirected filler-metal flow, and contaminants included within the solidified brazed area, which reduces the mechanical properties of the resulting brazed joint. Common contaminants are oils, greases, residual liquid penetrant fluids, pigmented markings, residual casting or coring materials, and oxides formed either through previous thermal exposures or by exposures to contaminating environments or engine service.

Chemical cleaning methods are most widely used. As part of any chemical cleaning procedure for preprocessing assemblies for brazing, a degreasing solvent should be used to remove all oils and greases and to ensure wettability of the chemicals used for cleaning. Oils and greases form a very thin film on metals, which prevents wettability by both the

subsequent chemical cleaning and/or the molten filler metals. Oils and grease removers that are widely used include degreasing solutions such as stabilized perchloroethylene or stabilized trichloroethylenes. These may be used as simple manual soaks, sprays, or by suspending the parts in a hot vapor of the aforementioned chemicals, commonly referred to as a vapor degreasing process. In conjunction with these processes, anodic and cathodic electrolytic cleaning can be used.

Other cleaning methods include alkaline-based cleaners and emulsion-type cleaners. Alkaline-based cleaners use mixtures of phosphates, carbonates, silicates, soaps, detergents, and hydroxides. Emulsion-type cleaners contain wetting agents, surface actuators, fatty acids, and hydrocarbons.

A chemical cleaning procedure can be a simple single-step process or may involve multistep operations. If the surfaces of the brazed joint are in the machined condition, vapor degreasing may be sufficient to remove machining oils, handling oils, and liquid penetrant fluids to yield a sound, clean surface for brazing. If, on the other hand, one or both of the surfaces to be brazed is not a machined surface, then additional chemical cleanings should be employed. Once vapor degreasing is accomplished, care must be taken to maintain the surface cleanliness of the brazed components by handling in an environmentally clean atmosphere. Additional methods of chemical cleaning to remove oxides and other adherent metallic contaminants include immersion in phosphate acid cleaners or acid pickling solutions, which are comprised of nitric, hydrochloric, or sulfuric acids or combinations of these.

Care must be taken in time of exposure for both acid cleaning and acid pickling of heat-resistant base metals. Overexposure during chemical cleaning can lead to excessive metal loss, grain-boundary attack, and selective attack on microstructural phases. As the last step in chemical cleaning, an ultrasonic cleaning in alcohol or clean hot water is recommended to ensure removal of all traces of previous cleaning solutions.

If no subsequent mechanical cleaning is used, the components to be brazed should be stored and transported to the braze preparation areas in dry, clean containers, such as plastic bags. The time between cleaning and braze application to the assembled joints should be kept as short as manufacturing processes allow.

Mechanical cleaning usually is confined to those metals with heavy tenacious oxide films or to repair brazing on components exposed to service. (Nickel- or cobalt-base superalloy components that require repair brazing can be processed in hydrogen fluoride atmospheres in order to remove oxide films.) Mechanical methods are standard machining processes--abrasive grinding, grit blasting, filing, or wire brushing (stainless steel bristles must be used). These are used not only to remove surface contaminants, but to slightly roughen or fray the surfaces to be brazed.

Care must be taken that the surfaces are not burnished and that mechanical cleaning materials are not embedded in the metals to be brazed. In grit blasting, choice of the blasting medium is critical. Wet and dry grit blasting commonly are used, but wet mediums are subject to additional cleaning requirements to remove the embedded grit. The mediums used are iron grits, silicon carbide grits, and grits composed of brazing filler metals. Grit sizes as coarse as No. 30 (0.589 mm, or 0.0232 in.) are recommended for cleaning forgings and castings. Finer grits (No. 90 and No. 100, 0.165 and 0.150 mm [0.0065 and 0.0059 in.], respectively) are used for general blasting. All grit mediums should be changed frequently, as extensive reuse of the same medium results in loss of sharp angles or facets. Once these configurations are lost or markedly reduced in the grit medium, burnishing rather than cleaning occurs. Overused medium results in the entrapment of oxides in the metal. If possible, the angle of grit blasting should be less than 90° to the surfaces to be cleaned. This also reduces the chances of embedding the oxides or medium in the surfaces to be brazed.

Care must be taken to remove all blasting medium from the surface after mechanical cleaning, as these mediums will contaminate the braze. Iron grit may impart an iron film which oxidizes as a rust. Aluminum oxides, if not removed, prevent wetting and flow of the brazing filler metal; thus, use of aluminum oxides are not recommended. Silicon carbide is extremely hard and has sharp facets. Consequently, it becomes embedded if an improper blasting angle is used. Blasting with a nickel-base brazing filler metal or similar alloy gives the best results; stainless steel blasting medium is also acceptable.

After mechanical cleaning, air blasting or ultrasonic cleaning should be used to remove all traces of loosened oxides or cleaning medium. Care must be taken to ensure maintenance of the clean surfaces and components; once cleaned, they should be assembled and brazed as soon as possible.

Hydrogen Fluoride Cleaning. The successful repair of superalloy components requires that oxides formed during service, on external surfaces and within cracks, be removed prior to brazing to ensure proper wetting and flow of the braze material. For cobalt-base superalloy parts, heating in a hydrogen-rich atmosphere (hydrogen reduction) is generally

successful in this regard. However, hydrogen reduction is not effective in reducing oxides of aluminum and titanium that are formed on nickel-base superalloy parts in service because these oxides exhibit a high degree of thermodynamic stability. Hydrogen fluoride reduction, on the other hand, has been shown capable of reducing these oxides from the surfaces of nickel-base parts.

Oxides of aluminum and titanium are changed to their respective metallic fluorides by the fluoride ions created in the hydrogen fluoride process. Oxides of chromium are also changed to chromium fluoride by the fluoride ions. In addition, workpiece surfaces are depleted of aluminum and titanium so that oxides of these metals do not tend to reform during subsequent operations, such as braze repair (Fig. 3).

Nickel Flashing. Certain heat-resistant alloys that are used as base metals in brazed assemblies--particularly nickel-base alloys containing high percentages of aluminum and titanium (such as Inconel 718)--may require a surface pretreatment to ensure maintenance of the cleaned surfaces. This surface pretreatment after cleaning is generally an electroplate of nickel, commonly referred to as nickel flashing. Thickness of the plate flashing is kept under 0.015 mm (0.0006 in.) for alloys with less than 4% (Ti + Al) and 0.020 to 0.030 mm (0.0008 to 0.0012 in.) for alloys with greater than 4% (Ti + Al). This promotes wettability in the braze joint without seriously affecting the braze strength and other mechanical properties of the braze. The thickness of nickel plating may have to be increased as the brazing temperature is increased and as the time above 980 °C (1800 °F) is increased. Titanium and aluminum will diffuse to the surface of the nickel plating upon heating.

Fixturing

One prerequisite to successful brazing that is often neglected is proper fixturing. Two types of fixtures are used: "cold" fixtures and "hot" fixtures.

Cold fixtures are used primarily for assembly purposes. In most cases, cold fixtures are made of hot or cold rolled iron, stainless alloys, nonferrous alloys, or nonmetals, such as phenolics and laminates. These fixtures are used for assembly and subsequent tack welding of parts to be brazed. They need not be massive or heavy, but should be sturdy enough to assemble components as required by design.

Hot fixtures (fixtures used in the furnace for brazing) must have good stability at elevated temperatures and the ability to cool rapidly. Metals can be used but generally are not stable enough to maintain tolerances during the brazing cycle. Therefore, ceramic, carbon, or graphite assemblies often are used for hot fixturing. Ceramics, due to their high processing cost, are used for small fixtures and for spacer blocks to maintain gaps during brazing of small components. Graphite has

been found to be the most suitable material for maintaining flatness in a high vacuum or argon atmosphere, and it provides faster cooling because of its high thermal conductivity, which is partially due to its porosity. Graphite should be coated with an Al_2O_3 slurry to prevent carburization of parts during the brazing cycle. It should not be used in a pure dry hydrogen atmosphere as it will cause carburization of the base metals by gaseous transfer. Molybdenum and tungsten may be used, but they are generally avoided because of their cost.

Controlled Atmospheres

Controlled atmospheres (including vacuum) are used to prevent the formation of oxides during brazing and to reduce the oxides present so that the brazing filler metal can wet and flow on clean base metal. Controlled-atmosphere brazing is widely used for the production of high-quality joints. Large tonnages of assemblies of a wide variety of base metals are mass produced by this process.
