Controlled atmospheres are not intended to perform the primary cleaning operation for the removal of oxides, coatings, grease, oil, dirt, or other foreign materials from the parts to be brazed. All parts for brazing must be subjected to appropriate prebraze cleaning operations as dictated by the particular metals. Controlled atmospheres commonly are employed in furnace brazing; however, they may also be used with brazing processes that utilize induction, resistance, infrared, laser, and electron-beam heat sources. In applications where a controlled atmosphere is used, postbraze cleaning is generally not necessary. In special cases, flux may be used with a controlled atmosphere (1) to prevent the formation of oxides of titanium and aluminum when brazing in a gaseous atmosphere, (2) to extend the useful life of the flux, and (3) to minimize postbraze cleaning. Fluxes should not be used in a vacuum environment. Some types of equipment, such as metallic muffle furnaces and vacuum systems, may be damaged or contaminated by the use of flux.

The use of controlled atmospheres inhibits the formation of oxides and scale over the whole part and permits finish machining to be done before brazing in many applications. In some applications, such as the manufacture of electronic tubes, eliminating flux is tremendously important.

Pure dry hydrogen is used as a protective atmosphere because it dissociates the oxides of many elements. Hydrogen with a dew point of -51 °C (-60 °F) dissociates the oxides of most elements found in heat-resistant alloys, with the notable exception of aluminum and titanium, which are found in most of the high-strength heat-resistant base metals.

Inert gases, such as helium and argon, do not form compounds with metals. In equipment designed for brazing at ambient pressure, inert gases reduce the evaporation rate of volatile elements, in contrast to brazing in a vacuum. Inert gases permit the use of weaker retorts than required for vacuum brazing. Elements such as zinc and cadmium, however, vaporize in pure dry inert atmospheres.

Vacuum. An increasing amount of brazing of heat-resistant alloys, particularly precipitation-hardenable alloys that contain titanium and aluminum, is done in a vacuum. Vacuum brazing in the range of 13 mPa (10^{-4} torr) has proved adequate for brazing most of the nickel-base superalloys. By removal of gases to a suitably low pressure, including gases that are evolved during heating to brazing temperature, very clean surfaces are obtainable. A vacuum is particularly useful in the manufacture of parts for the aerospace, electronic tube, and nuclear fields, and where metals that react chemically with a hydrogen atmosphere are used or where entrapped fluxes or gases are intolerable. The maximum tolerable pressure for successful brazing depends on a number of factors that are primarily determined by the composition of the base metals, the brazing filler metal, and the gas that remains in the evacuated chamber.

Vacuum brazing is economical for fluxless brazing of many similar and dissimilar basemetal combinations. Vacuums are especially suited for brazing very large, continuous areas where (1) solid or liquid fluxes cannot be removed adequately from the interfaces after brazing, and (2) gaseous atmospheres are not completely efficient because of their inability to purge occluded gases evolved from close-fitting brazing interfaces. It is interesting to note that a vacuum system evacuated to 1.3 mPa (10^{-5} torr) contains only 0.00000132% residual gases based on a starting pressure of 100 kPa (760 torr).

Vacuum brazing has the following advantages and disadvantages compared with brazing that is carried out under other high-purity brazing atmospheres:

- VACUUM REMOVES ESSENTIALLY ALL GASES FROM THE BRAZING AREA, THEREBY ELIMINATING THE NECESSITY FOR PURIFYING THE SUPPLIED ATMOSPHERE. COMMERCIAL VACUUM BRAZING GENERALLY IS DONE AT PRESSURE VARYING FROM

0.0013 TO 13 PA (10^{-5} TO 10^{-1} TORR), DEPENDING ON THE MATERIALS BRAZED, THE FILLER METALS BEING USED, THE AREA OF THE BRAZING INTERFACES, AND THE DEGREE TO WHICH GASES ARE EXPELLED BY THE BASE METALS DURING THE BRAZING CYCLE.

- CERTAIN OXIDES THAT FORM ON BASE METALS (PARTICULARY ON COPPER-BASE METALS) DISSOCIATE IN VACUUM AT BRAZING TEMPERATURES.
- DIFFICULTIES SOMETIMES EXPERIENCED WITH CONTAMINATION OF BRAZING INTERFACES, DUE TO EXPULSION OF GASES FROM THE PARTS TO BE BRAZED, ARE NEGLIGIBLE IN VACUUM BRAZING.
- LOW PRESSURE EXISTING AROUND THE BASE AND FILLER METALS AT ELEVATED TEMPERATURES REMOVES VOLATILE IMPURITIES AND GASES FROM THE METALS. FREQUENTLY, THE PROPERTIES OF BASE METALS ARE IMPROVED. THIS CHARACTERISTIC IS ALSO A DISADVANTAGE WHEN ELEMENTS IN THE FILLER METAL OR BASE METALS VOLATILIZE AT BRAZING TEMPERATURES, THUS CHANGING THE MELTING POINT OF THE FILLER METAL OR PROPERTIES OF THE BASE METAL. THIS TENDENCY MAY, HOWEVER, BE CORRECTED BY EMPLOYING PARTIAL-PRESSURE VACUUM BRAZING TECHNIQUES.

Nickel-Base Alloys

In the selection of a brazing process for a nickel-base alloy, the characteristics of the alloy must be carefully considered. The nickel-base alloy family includes alloys that differ significantly in physical metallurgy (such as the mechanism of strengthening) and in process history (cast versus wrought). These characteristics can have a profound effect on their brazeability.

Precipitation-hardening alloys present several difficulties not normally encountered with solid-solution alloys. Precipitation-hardening alloys often contain appreciable (greater than 1%) quantities of aluminum and titanium for improved strength and corrosion resistance. The oxides of these elements are almost impossible to reduce in a controlled (vacuum or hydrogen) atmosphere. Therefore, nickel plating or the use of a flux is necessary to obtain a surface that allows wetting by the filler metal.

Because these alloys are hardened at temperatures of 540 to 815 °C (1000 to 1500 °F), brazing at or above these temperatures may alter the alloy properties. This frequently occurs when using silver-copper filler metals, which occasionally are used on heat-resistant alloys.

Liquid metal embrittlement is another difficulty encountered in brazing of precipitation-hardening alloys. Many nickel-, iron-, and cobalt-base alloys crack when stressed parts are exposed to molten metals. This is usually confined to the silver-copper filler metals. If precipitation-hardening alloys are brazed in the hardened condition, residual stresses am often high enough to initiate cracking.

Cleanliness, as in all metallurgical joining operations, is important when brazing nickel and nickel-base alloys. Cleanliness of base metal, filler metal, flux (when used for torch or induction brazing), and purity of atmosphere should be as high as practical to achieve the required joint integrity. Elements that cause surface contamination or interfere with braze wetting or flow should be avoided in prebraze processing. All forms of surface contamination such as oils, chemical residues, scale, or other oxide products should be removed by using suitable cleaning procedures. The use of nickel-base filler metals can offer some cost effectiveness in this regard because certain nickel-base brazing filler metals containing boron and/or silicon are known to be self-fluxing and thus more forgiving to slight imperfections in cleanliness.

Attempting to braze over the refractory oxides of titanium and aluminum that may be present on precipitation-hardenable nickel-base alloys must be avoided. Procedures to prevent or inhibit the formation of these oxides before and/or during brazing include special treatments of the surfaces to be joined or brazing in a highly controlled atmosphere. Surface treatments include electrolytic nickel plating and reducing the oxides to metallic form. As stated earlier in this section, a typical practice is to nickel plate the joint surface of any alloy that contains aluminum and/or titanium. For vacuum brazing of alloys containing aluminum and titanium in trace amounts, use of 0.0025 to 0.0075 mm (0.0001 to 0.0003 in.) thick plate is considered optimal. Alloys with up to 4% AI and/or titanium require 0.010 to 0.015 mm (0.0004 to 0.0006 in.) thick plate, and alloys with aluminum and/or titanium contents greater than 4% require 0.020 to 0.030 mm (0.0008 to

0.0012 in.) thick plate. When brazing in a pure dry hydrogen atmosphere, thicker plating (0.025 to 0.038 mm, or 0.001 to 0.0015 in.) is desirable for alloys with high (>4%) aluminum and/or titanium contents.

Atmospheres. Dry, oxygen-free atmospheres that are frequently used include inert gases, reducing gases, and vacuum. The brazing atmosphere, whether gaseous or vacuum, should be free from harmful constituents such as sulfur, oxygen, and water vapor. When brazing in a gaseous atmosphere, monitoring of the water vapor content of the atmosphere (that is, the dew point) is the common practice. A dew point of -50 °C (-60 °F) results in average brazeability; average; -60 °C (-80 °F) or below produces a better quality braze.

Stresses. During brazing, residual or applied tensile stress should be eliminated or minimized as much as possible. Also, inherent stresses present in the precipitation-hardening alloys may lead to stress-corrosion cracking. Therefore, stress relieving or annealing prior to brazing is also recommended for all furnace, induction, or torch brazing operations. Brazing filler metals that melt below the annealing temperature are likely to cause stress-corrosion cracking of the base metal.

Thermal Cycles. Consideration must be given to the effect of the brazing thermal cycle on the base metal. Filler metals that are suitable for brazing nickel-base alloys may require relatively high temperatures. This is particularly true for the filler-metal alloy systems most frequently used in brazing of nickel-base alloys--the nickel-chromium-silicon or nickel-chromium-boron systems.

Solid-solution-strengthened nickel-base alloys such as Inconel 600 may not be adversely affected by brazing temperatures of 1010 to 1230 °C (1850 to 2250 °F). Precipitation-strengthened alloys such as Inconel 718 may, however, display adverse property effects when exposed to brazing cycles with maximum temperatures that are higher than their normal solution heat treatment temperatures. Inconel 718, for example, is solution heat treated at 955 °C (1750 °F) for optimum stress-rupture life and ductility. Braze temperatures of 1010 °C (1850 °F) or above result in grain growth and a corresponding decrease in stress-rupture properties, which cannot be recovered by subsequent heat treatment.

Consideration of base-metal property requirements for service enables selection of an appropriate braze alloy. Lower melting temperature (below 1040 °C, or 1900 °F) braze filler metals are available within the nickel-base alloy family and within other brazing filler-metal systems (see Table 1).

Inconel 718 is often used in the fabrication of air diffusers for aerospace turbine engines. One manufacturer found that vacuum brazing of diffuser components at 10^{-4} torr in a cold-walled vacuum furnace provided the best results. Prior to brazing, all joint surfaces were nickel plated to 0.005 to 0.015 mm (0.0002 to 0.0006 in.) thicknesses. Plating was done in accordance with specification AMS 2424 or equivalent. Prior to assembly, application of BNi-2 braze filler metal tape (approximately 0.11 mm, or 0.0045 in., thick) was preplaced between all joint surfaces. After assembly, an additional braze slurry of BNi-2 filler metal was applied to all joints to ensure joint soundness.

Brazing of ODS Alloys

Oxide dispersion-strengthened alloys are P/-M alloys that contain stable oxides evenly distributed throughout the matrix. The oxide does not go into solution in the alloy even at the liquidus temperature of the matrix. However, the oxide is usually rejected from the matrix upon melting of the matrix, which occurs during fusion welding, and cannot be redistributed in the matrix on solidification; therefore, these alloys are usually joined by brazing. There are two commercial classes of ODS alloys: the dispersion-strengthened nickel, and mechanically alloyed Inconel MA 754, Inconel MA 6000, and Incoloy MA 956.

Inconel MA 754, dispersion-strengthened nickel alloys, and dispersion-strengthened nickel-chromium alloys are the easiest to braze of the family of ODS alloys. Vacuum, hydrogen, or inert atmospheres can be used for brazing. Prebraze cleaning consists of grinding or machining the faying surfaces and washing with a solvent that evaporates without leaving a residue. Generally, brazing temperatures should not exceed 1315 °C (2400 °F) unless demanded by a specific application that has been well examined and tested. The brazing filler metals for use with these ODS alloys usually are not classified by AWS. In most cases, the brazing filler metals used with these alloys have brazing temperatures in excess of 1230 °C (2250 °F). These include proprietary alloys that are based on nickel, cobalt, gold, or palladium.

Brazements made of ODS alloys to be used at elevated temperature must be tested at elevated temperature to prove fitness-for-purpose. In the case of stress-rupture testing, AWS specification C3.2 may be used as a guide because it gives

the actual joint configuration. The configuration shown in Fig. 4 is preferred by some as a test model, although any test configuration without stress raisers is adequate. The elevated-temperature brazement properties for Inconel alloy MA 754 should meet the following requirements:

SHEAR STRESS		**TEMPERATURE**		SERVICE LIFE, H
MPA	**KSI**	**°C**	**°F**	
26	3.8	980	1800	>**1000**
9.0	**1.3**	**1095**	**2000**	>**1000**

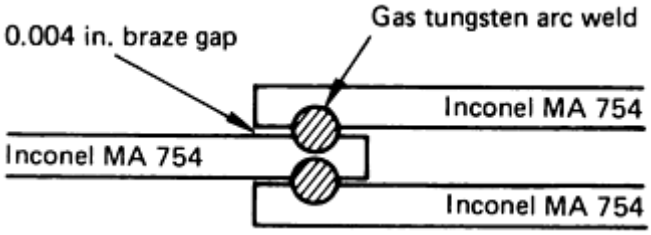

FIG. 4 BRAZING SPECIMEN ASSEMBLY USED TO EVALUATE STRESS-RUPTURE PROPERTIES OF BRAZED INCONEL MA 754

Inconel MA 6000 is a nickel-base ODS alloy that is also γ' strengthened. The amount of alloying elements in the base metal matrix plus the γ' precipitations cause an interesting problem in the brazing of this alloy. Inconel MA 6000 has a solidus temperature of 1300 °C (2372 °F); therefore, the brazing temperature should be no higher than 1250 °C (2282 °F). Additionally, because 1230 °C (2250 °F) is the γ' solution treatment temperature, it becomes important to carefully select the brazing filler metal and to heat treat the assembly after brazing. The AWS-specified BNi and BCo filler metals, as well as specially formulated filler metals, have been used for this alloy.

Inconel MA 6000 is used for its high-temperature strength and corrosion resistance; unfortunately, the passive oxide scale that provides good corrosion resistance also prevents wetting and flow of brazing filler metal. Therefore, correct cleaning procedures are very important. Surfaces to be brazed should be mechanically cleaned with a water-cooled, low-speed belt or wheel of approximately 320-grit and stored in a solvent, such as methanol, until immediately before the beginning of the brazing cycle.

Cobalt-Base Alloys

The brazing of cobalt-base alloys is readily accomplished with the same techniques used for nickel-base alloys. Because most of the popular cobalt-base alloys do not contain substantial amounts of aluminum or titanium, brazing atmosphere requirements are less stringent. Table 2 gives typical compositions of several cobalt-base alloys. These materials can be brazed in either a hydrogen atmosphere or a vacuum. Filler metals are usually nickel- or cobalt-base alloys or gold-palladium compositions. Silver- or copper-base brazing filler metals may not have sufficient strength and oxidation resistance in many high-temperature applications. Although cobalt-base alloys do not contain appreciable amounts of aluminum or titanium, an electroplate or flash of nickel is often used to promote better wetting of the brazing filler metal.

Nickel-base brazing alloys such as AWS BNi-3 have been used successfully on Haynes 25 for honeycomb structures. After brazing, a diffusion cycle was reportedly used to raise the braze joint remelt temperature to 1260 to 1315 °C (2300 to 2400 °F). Table 3 presents the effects of a high-temperature braze (1225 °C, or 2240 °F, for 15 rain) on the mechanical properties of Haynes 25. One cobalt-base brazing filler metal (AWS BCo-1, see Table 1) appears to offer a good combination of strength, oxidation resistance, and remelt temperature for use on Haynes 25 foil.

(A) RT, ROOM TEMPERATURE

Cobalt-base alloys, much like nickel-base alloys, can be subject to liquid metal embrittlement or stress-corrosion cracking when brazed under residual or dynamic stresses. This frequently is observed when using silver- or silver-copper-base (BAg) filler metals. Liquid metal embrittlement of cobalt-base alloys by copper-base (BCu) filler metals occurs with or without the application of stress; therefore, BCu filler metals should be avoided when brazing cobaltbase alloys.

Brazing of Heat-Resistant Alloys, Low-Alloy Steels, and Tool Steels

Revised by Darrell Manente, Vac-Aero International Inc.

Brazing of Low-Alloy Steels and Tool Steels

Low-alloy steels constitute a category of ferrous materials that exhibit mechanical properties superior to plain carbon steels as the result of additions of such alloying elements as manganese, nickel, chromium, and molybdenum. Total alloy content can range from 2.07% up to levels just below that of stainless steels, which contain a minimum of 10% Cr. For many low-alloy steels, the primary function of the alloying elements is to increase hardenability in order to optimize mechanical properties and toughness after heat treatment. In some cases, however, alloy additions are used to reduce environmental degradation under certain specific service conditions. For compositions of specific low-alloy steels, see the article "Classification and Designation of Carbon and Low-Alloy Steels" in Volume 1 of the *ASM Handbook.*

Tool steels are any steels used to make tools for cutting, forming, or otherwise shaping a material into a part or component adapted to a definite use. Tool steels could be classified as low-alloy steels, but they are generally considered to be a separate group. Table 4 lists selected tool steels and their typical uses.

TABLE 4 PRINCIPAL TYPES OF TOOL STEELS

AISI/SAE DESIGNATION	**DESCRIPTION**	TYPICAL USES
W1, W2	WATER-HARDENING GRADES	**COLD-HEADING DIES, WOODWORKING TOOLS**

(A) MOST WEAR-RESISTANT GRADE

Brazing Filler Metals

The AWS BAg, BCu, and BNi brazing filler metals can be used effectively to braze low-alloy steels or tool steels. The specific type of brazing filler metal used depends on the application, the available brazing equipment, and the strength requirements of the braze joint. Many BAg brazing filler metals are used for torch or induction brazing. BCu and BNi brazing filler metals are used for furnace brazing. High-solidus-point brazing filler metals can be chosen so that a component can be brazed and then heat treated. For example, a plate assembly made from 4340 material can be brazed with copper filler metal at 1120 °C (2050 °F) for 10 min. The plates are then kept at a temperature of 845 °C (1550 °F) for 1 h in order to austenitize the base metal and subsequently quenched in oil. The plates are tempered at 510 °C (950 °F) for 2 h in order to produce a hardness of about 40 HRC. The copper braze filler is not affected by the heat treatment due to its relatively high melting point.

Precleaning

The surface condition of the material will determine the cleaning method that is chosen. For example, a newly machined component would normally require only a vapor degreasing operation or a solvent wipe in order to remove machining lubricants. A component with a light oxide layer on the surface might be grit blasted with Al_2O_3 and then vapor degreased. This component could also be cleaned with emery paper or a stainless steel wire brush and wiped with a solvent.

A component with a heavy oxide layer on the surface would require a combination of mechanical and chemical cleaning in order to ensure that the oxide layer was removed. Another option available for removing oxides is to furnace clean

components in an atmosphere of vacuum or hydrogen. While this method will reduce oxides of iron and nickel, other oxides may not be reduced (Fig. 4).

Fixturing

Fixturing methods for heat-resistant alloys are also suitable for low-alloy steels and tool steels. However, greater use can be made of metal fixturing because many of these brazements are made at lower temperatures.

Atmospheres and Fluxes

Low-alloy steels and tool steels can be brazed in air, vacuum, hydrogen, nitrogen or endothermic or exothermic atmospheres. Components can also be torch or induction brazed in air using fluxes containing fluorides, borates, or chlorides.

Components brazed with AWS BNi brazing filler metals are usually brazed in a vacuum. Vacuum nitrogen, or hydrogen atmospheres are generally used for brazing components with BCu or BAg brazing filler metals. Care must be taken to ensure that the chosen atmosphere does not cause carburization or decarburization of the component.

Brazing of Copper, Copper Alloys, and Precious Metals

Roy E. Beal, Amalgamated Technologies, Inc. Rodger E. Cook, The Wilkinson Company

---

Introduction

COPPER, COPPER ALLOYS, AND PRECIOUS METALS are probably the most easily brazed metals available. A wide range of brazing filler metals is used to join the many different coppers, copper alloys, and precious metals that are manufactured. The selection of the brazing process and the filler metal depends on the alloy or material composition, the shape and dimension of the parts to be joined, and the intended application. Gold, silver, and the platinum group metals are well known for their resistance to oxidation at high temperatures. Not only does this characteristic make the precious metals desirable in industrial and medical applications, it helps enhance the brazeability of components made from them.

Brazing of Copper, Copper Alloys, and Precious Metals

Roy E. Beal, Amalgamated Technologies, Inc. Rodger E. Cook, The Wilkinson Company

---

Copper and Copper Alloys

Because the brazeability of most copper alloys is very good, the material considerations are generally not as difficult as those of some other metals. However, the specific metallurgy of the individual copper or copper alloy is an important factor and should be considered when selecting a manufacturing method. Most brazing operations will result in recrystallization of the copper alloy being joined. Fine grain sizes can be eliminated and the cold-working step removed, which may or may not be desirable. Often, electrical conductivity is an important factor in a copper alloy brazed joint when overall resistance across the joint must be controlled. Therefore, the finished metallurgical structures, grain sizes, and mechanical properties of the specific copper alloy must be considered when brazing is utilized.

The metallurgical structures of brazed joints are largely those of the brazing filler metal, enriched with copper from the parent material. Because some surface melting of the copper alloys being joined occurs, the interfaces usually show primary dendrites of a copper-rich phase growing from the copper alloy and braze metal interface. The brazing filler metal becomes more copper-rich, producing additional dendritic growth with increased brazing temperature and time.

The widely used oxygen-containing coppers must be carefully handled when heated. Brazing temperatures are normally above 480 °C (900 °F), which allows the dispersed copper oxides in the material to react with a hydrogen atmosphere, creating a high-pressure steam within the solid metal. Tough-pitch coppers cannot be satisfactorily brazed by furnace

techniques that utilize hydrogen as the atmosphere, either in the form of exothermic or endothermic gases or in the form of dissociated ammonia. Because the torch brazing of tough-pitch coppers also can cause problems with embrittlement, it generally should be avoided.

Copper metals that have been deoxidized by phosphorus or other elements and oxygen-free coppers can be readily brazed in hydrogen-containing atmospheres with no embrittlement. Brazing can also be accomplished without flux, if a copper-phosphorus brazing filler metal is used. When other copper materials, such as those containing lead, tellurium, silver, and other elements, are brazed, a copper-phosphorus filler metal can be used without flux, although flux is sometimes recommended.

The brazing characteristics of most copper filler metals and alloys are improved when a flux is used. In this case, phosphorus-deoxidized and oxygen-free coppers can be joined with a brazing filler metal from the silver series, which may contain zinc, cadmium, or nickel.

High-copper-content or copper alloys that contain metals that are more refractory, such as chromium or zirconium, will form oxide films that slow or prevent the flow of the brazing filler metal. Under these conditions, cleaning operations are often needed to remove the surface oxides prior to brazing. The brazing operation is then carried out in either a protective atmosphere or one that has essentially reducing conditions. Fluxes can be used to assist in the surface oxide removal or to prevent their reformation during the brazing process.

Some of the high-copper-content materials, such as chromium copper, are effectively hardened by the presence of the chromium element. In these cases, it is important to heat treat the material. This can sometimes be carried out in conjunction with the brazing operation when an appropriate brazing filler metal is selected.

Brass represents the largest group of copper alloys. Brass compositions usually contain from 5 to 40% zinc. The higher zinc contents require the use of fluxes in most brazing applications, especially when the zinc level is above 15%. Other elements are added to generate special properties, such as when lead is added to improve machining. This addition makes brazing very difficult. At a lead level of 8%, brazing is essentially impossible. Tin is added to produce a range of materials, including admiralty and naval brass. Modifications may contain other elements, such as manganese and nickel. Brasses with some aluminum content are more difficult to join than the other brasses mentioned and require specially made fluxes.

The next-largest group is bronze alloys, the most important of which are phosphor-bronze, silicon-bronze, and aluminum-bronze. Although phosphor-bronze alloys can be joined by most methods, this material has a weakness for hot cracking in cold-worked conditions. Therefore, parts should be stress relieved at temperatures from 290 to 345 °C (550 to 650 °F) before brazing. Similar problems, such as hot shortness, can be encountered with silicon-bronze alloys. Aluminum-bronze or silicon-bronze alloys that contain aluminum require special attention, because of the tenacity of the surface oxides. Generally, a special American Welding Society (AWS) type 4 flux is used in conjunction with low-melting-point, high-silver-percentage filler metals.

Copper-nickel alloys are widely used for corrosion protection and for durability in marine environments. Filler metals that contain phosphorus are not acceptable because of brittle nickel-phosphide formation. Most copper alloys can be joined to other coppers and copper alloys. Compatibility is important and can require compromise to suit the individual characteristics of the two metals involved. For example, when copper alloys that contain aluminum need to be joined to any other copper material, the AWS type FB4-A flux is required for good results.

Thus, the first step in the successful brazing of copper and copper alloys is to understand the metallurgy of the alloy involved and the effect of alloy additions on the properties of the surface to be brazed. The finished joints between the same or dissimilar metals must have a sufficiently matched composition in order to avoid joint brittleness, adverse diffusion, and large nonuniform phases. Ductility values also must be satisfactory.

Filler Metals

More filler metals are available for copper and copper alloys than for any other metal system. They vary widely in composition and cost. Standard alloys are listed by AWS reference code in Table 1. Many of the alloys contain high percentages of silver and copper, because these elements form a eutectic at a 77% silver level. Because of the high cost of silver, alloys containing phosphorus, zinc, cadmium, and other elemental additions were developed.

(B) SPECIAL FILLER METAL USED IN BRAZING NICKEL SILVER KNIFE HANDLES.

(C) CONDUCTIVITY OF FILLER METAL AFTER VOLATILIZATION OF LITHIUM IN BRAZING

The most widely used silver alloy is BAg-1, which has a solidus temperature of 607 °C (1125 °F) and a liquidus temperature of 618 °C (1145 °F). It is generally recognized as being the lowest-melting-point silver brazing alloy.

Other widely used filler metals are the RB-CuZn, BCuP, and BAu series. The copper-zinc (RBCuZn) filler metals have relatively high liquidus temperatures and are anodic to copper, leading to lower corrosion resistance. Zinc-containing filler metals sometimes lose this element or form voids if overheating is allowed to occur.

The copper-phosphorus (BCuP) filler metals are self-fluxing when used to braze copper. Fluxes may be necessary when joining other copper alloys. The high-phosphorus filler metals are not resistant to sulfur-containing atmospheres. Copper-phosphorus and copper-silver-phosphorus brazing filler metals are recommended only for copper and copper alloys without nickel, because brittle phosphide can form when nickel is present.

Silver alloy (BAg) filler metals can join all brazeable coppers and copper alloys, as well as many dissimilar combinations. The lower-melting-point alloys are good for joining brass. There is a trend toward avoiding filler metals that contain cadmium, because of its toxicity. Cadmium-bearing filler metals must not be used for food equipment. Lithium-containing filler metals that are joined in protective atmospheres are self-fluxing.

Gold (BAu) alloys are high-cost filler metals that are used in specialized applications, such as vacuum and electronic products. Although these filler metals can join copper alloys, they are generally not used because of their cost. The main application is in situations where low vapor pressure is important.

Brazing Fluxes

Four primary categories of fluxes are used to braze coppers and copper alloys. There are no standard compositions and fluxes are classified by type only.

Type FB3-A is the general-purpose, low-temperature flux used with all coppers and copper alloys, except those with high levels of aluminum.

Types FB3-C and FB3-D have higher active temperature ranges, respectively, up to 1205 °C (2200 °F). These fluxes can be used with any filler metal that is appropriate from Table 1. Other fluxes are classified by liquid, powder, and slurry forms, according to application.

Type FB4-A flux is specifically designed for aluminum-containing copper alloys and has a wide range of activity from 595 to 879 °C (1100 to 1600 °F).

The AWS brazing flux classifications for coppers and copper alloys are given in Table 2. Major ingredients, filler metal type for which the flux is suitable, activity temperature range, application process, and recommended base metals are also given in Table 2.

TABLE 2 BRAZING FLUXES

CLASSIFICATION	FORM	FILLER METAL TYPE	TYPICAL INGREDIENTS	APPLICATION	ACTIVITY TEMPERATURE RANGE		RECOMMENDED BASE METALS

MAY ALSO HAVE APPLICATION WHEN MINOR AMOUNTS OF TITANIUM OR OTHER METALS ARE PRESENT,WHICH FORM REFRACTORY OXIDES**

Note: The selection of a flux designation for a specific type of work may be based on the filler metal type and the description above, but the information here is generally not adequate for flux selection.

The highest-temperature fluxes are types FB3-I, FB3-J, and FB3-K, which work at temperatures from 760 to 1205 °C (1400 to 2200 °F). These are generally used with the RBCuZn filler metals, with long and active conditions at temperature, although they can be used with all other brazing filler metals for copper alloys.

Joint Clearance and Design

Joint clearances are primarily related to the brazing filler metals being used and their capillary attraction. If the gap is too small, then the brazing filler metal will not flow into the joint. Typical joint clearances are identified in Table 1.

Clearance can also influence the mechanical strength of the brazed joints. Allowances should be made in joint design for relative expansion of the parts at the brazing temperature, especially where dissimilar metals are involved. Penetration of the brazing filler metal through a joint to the opposite side of placement can be an effective measure of brazing filler metal flow, and a preferable joint design allows this observation to be made. Generally, braze joints should be designed for an effective joint area of 80%, in order to allow for voids.

In the case of a lap joint, the joint length should be, at a minimum, three times the thickness of the thinnest component being joined.

Brazing Processes

The selection of the brazing process is as important as the selection of the brazing filler metal. In fact, one often depends on the other. When a specific process is required, the range of allowable filler metals may be restricted. The number of parts to be made and the production rates desired also influence brazing process selection. Another consideration is the materials to be joined, because brazing may affect their mechanical properties. All parts for brazing must be cleaned prior to the brazing operation.

Brazing can be carried out with a flux or in an atmosphere. Several different atmospheres are appropriate for copper and copper-alloy brazing. AWS atmosphere types, as well as approximate compositions, filler metals, and braze metal combinations, are described in Table 3. Note that some base metals require a low dew point, in addition to the protective atmospheres.

TABLE 3 ATMOSPHERES FOR BRAZING COPPER AND COPPER ALLOYS

(A) FLUX REQUIRED IN ADDITION TO ATMOSPHERE WHEN ALLOYS CONTAINING VOLATILE COMPONENTS ARE USED.

(B) COPPER SHOULD BE FULLY DEOXIDIZED OR OXYGEN-FREE.

(C) HEATING TIME SHOULD BE MINIMIZED TO AVOID OBJECTIONABLE DECARBURIZATION.

(D) FLUX MUST BE USED IN ADDITION TO THE ATMOSPHERE IF APPRECIABLE QUANTITIES OF ALUMINUM, TITANIUM, SILICON. OR BERYLLIUM ARE PRESENT.

Furnace brazing has, as its primary advantage, the ability to handle mass production. However, a small furnace can be used for a wide variety of parts, materials, and filler metals. Furnaces can operate on either a batch or continuous basis. Furnaces can be mesh belt conveyor, batch, or pusher (where parts are loaded on trays) systems. The objective is to achieve minimum-cost operation for the particular application. Another advantage is that a number of joints can be brazed simultaneously in a furnace.

Copper and copper alloys are often furnace brazed on a conveyor or mesh belt system. This allows the use of protective atmospheres that can be either exothermic or endothermic. The conveyor furnace also allows for controlled heating and cooling rates. Separate belts are sometimes used for each zone to control these rates. The metallurgy of the alloys to be joined must be considered.

Brazing furnaces can be expensive, especially for mass-production operations with protective atmospheres, as well as preheating and cooling zones. Although electrical furnaces cost more to run, gas furnaces usually require muffles or linings that must be periodically replaced, which raises the overall expense and narrows the cost differential.

The brazing furnace must be designed to handle the desired temperature and mass load. Furnace linings are used when fluxes are necessary, even in electrically heated units, because flux can corrode the heating elements. Parts that can be self-fluxed and joined in a protective atmosphere avoid this potential flux problem.

Copper and copper alloys must not be exposed to gases containing sulfur. Leaks into the lining from gas firing can be a problem. Brasses are not generally furnace brazed.

The operation of a brazing furnace depends on the filler metal, the melting temperature, and the characteristics of the copper alloys to be joined. It is usually desirable to braze at approximately 28 °C (50 °F) higher than the liquidus of the filler metal. Most brazing filler metals can be used, except those that have large amounts of zinc and are subject to volatilization.

A dry hydrogen atmosphere can be used for some brazing filler-metal and base-metal combinations. However, as noted earlier, the hydrogen atmosphere must be completely avoided when oxygen-containing copper metal is used, because it would embrittle the copper.

An example of a furnace braze application without a protective atmosphere is the contact arm assembly shown in Fig. 1, which was joined with BCuP-5 filler metal.

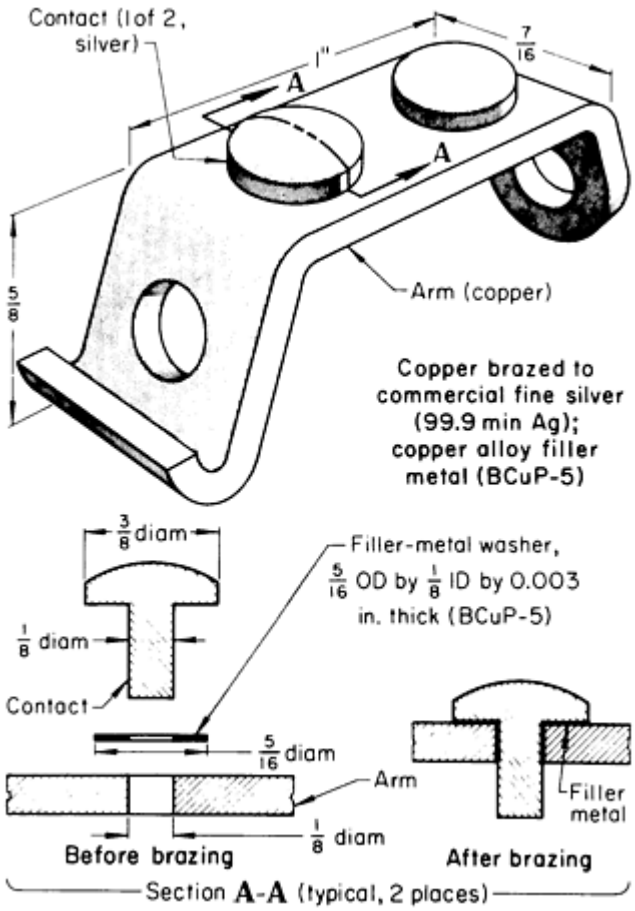

FIG. 1 FURNACE BRAZED CONTACT ARM ASSEMBLY, BRAZED WITHOUT PROTECTIVE ATMOSPHERE, 42 °C (75 °F) BELOW THE LIQUIDUS OF THE FILLER METAL

Components to be furnace brazed are preassembled with the filler metal preplaced for brazing. Preferably, the parts should be self-jigging. External jigs and fixtures can be used when absolutely necessary, but add extra capital and operating expense, because the parts have to be assembled in the jigs and the jigs themselves have a finite life. Fully enclosed parts must be vented to permit the escape of trapped air. Failure to do so can be dangerous.

Torch brazing of copper and copper alloys is used on many components and in numerous industrial applications. Examples are radiators, condensers, refrigerators, construction piping, motors, electrical equipment, and others. Equipment costs are low. The braze operator must be skilled in adjusting the heating flame and directing energy to the part to be joined. Torches can be extremely small, for electronic applications, or very large, for heavy fabrications and castings. Production capacity varies from one part to mass-production lots.

Tough-pitch coppers require reducing atmospheres because of hydrogen embrittlement. Brass can lose zinc by volatilization and must not be overheated or held too long at brazing temperature. Alloys with refractory elements require flux and reducing flames. Some copper alloys, such as phosphor bronze, crack if heated too rapidly.

Filler metals for torch brazing were described in Table 1. The filler material can be in wire, powder, or paste form. The application can be manual or automatic.

Examples of torch brazing applications are return bends in heat exchangers, which are usually automatically torch brazed; fin assemblies, which are usually manually torch brazed; instrumentation tubes; oil coolers; and large electrical parts.

A common example is a return bend joint 0made with alloy C12000, which is a phosphorus-deoxidized copper. A 9.5 mm ($\frac{3}{8}$ in.) diameter tube with a 0.5 mm (0.02 in.) wall thickness is typical. Tube ends of the heat exchanger are expanded to

allow insertion of the return bend. A clearance of 0.10 to 0.23 mm (0.004 to 0.009 in.) is used to provide a pressure-tight joint. Each leg of the rerum bend is fitted with a 0.75 mm (0.03 in.) diameter BCuP-5 filler wire. The joint is self-fluxing and multiple joints are passed through a series of torch flames to quickly make the joint in approximately 5 s.

Another example is an eight-station turntable for the automatic torch brazing of instrument assemblies (Fig. 2). These components are usually small and are joined at multiple stations by indexing the table. This system uses unskilled operators and can achieve high production rates. The brazing filler metal can be in flux-paste form or a wire feeding unit can be used in conjunction with separate fluxing.

FIG. 2 BULB AND TUBE ASSEMBLY, BRAZED BY MECHANICALLY HELD TORCHES ON AN EIGHT-STATION TURNTABLE

Induction brazing is less efficient with copper alloys than with other metals. However, this process is widely used because of its high-production capability, especially in situations where flames cannot be tolerated and atmosphere protection is an alternative to fluxing. Induction brazing usually minimizes the possible warping of parts. However, the initial costs of the induction heating equipment is high. The low efficiency of the process also demands relatively high power requirements.

Inductor design is similar to that needed for other metals. The objective is controlled heat input and distribution. Single- or multiple-turn inductors are utilized, sometimes in conjunction with concentrators, to focus heat in desirable locations.

Brazing filler metals for induction heating are usually the silver-containing alloys and the copper-phosphorus and copper-phosphorus-silver alloys.

An advantage of induction brazing is exemplified by the chromium-copper (C18200) post shown in Fig. 3. The heating step in the brazing process is a critical factor in obtaining optimum mechanical properties, because precipitation hardening can occur with improper heating. The brazing of a tungsten-silver contact required the use of a nickel-containing silver alloy, BAg3, to join with chromium-copper. Induction brazing is the best option for retaining material properties.

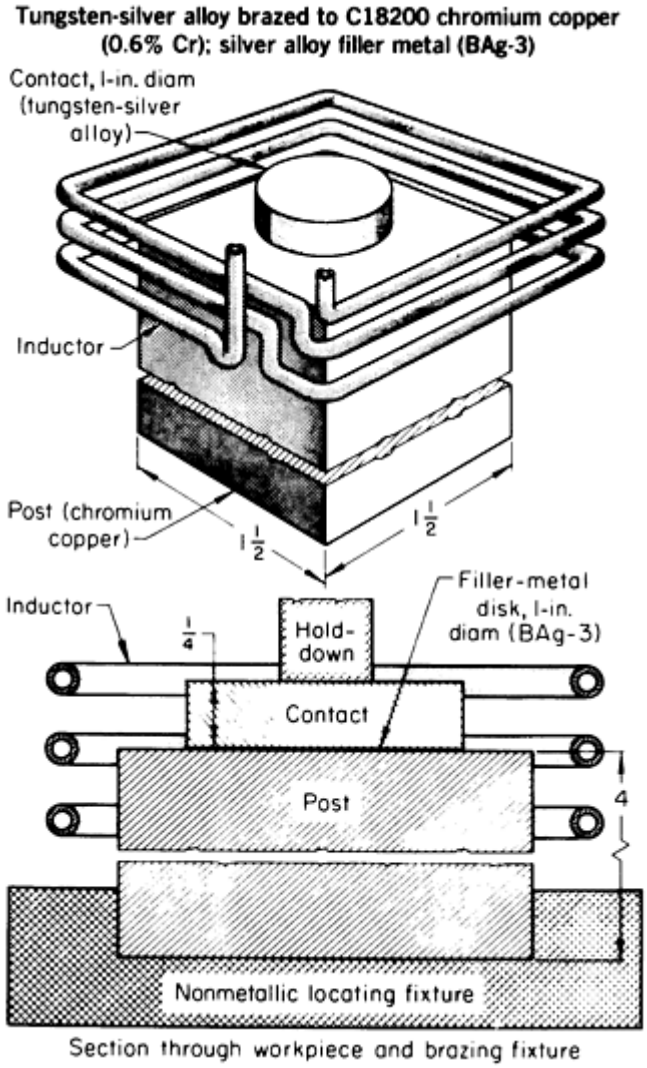

FIG. 3 TUNGSTEN-SILVER ALLOY CONTACT IN POSITION FOR INDUCTION BRAZING TO C18200 CHROMIUM-COPPER (0.6% CR) POST; BAG-3 SILVER ALLOY FILLER METAL

Another example is the use of multiple-station inductors in the brazing of armatures for motors. A preformed BCuP-5 filler metal is placed at the desired joint area and the inductor is allowed to bring the assembly to temperature quickly without flux.

Resistance brazing is used for small parts, such as terminals, fasteners, and attachments. The filler metal, which is usually preplaced, is often BCuP-5, because it can be used without flux. However, most brazing filler metals that contain silver have been used. Heat generation occurs by resistance through the assembly, using a standard resistance welding machine. A second heating method is to use graphite blocks as the contact, which spreads the heat over a larger area. This method is widely used in the electronics industry and for joining high-conductivity coppers and alloys. Brazing times are very short at 10 to 20 Hz with very high current inputs. A small quantity of hydrogen can be used for oxidation protection, except when joining tough-pitch coppers.

Portable resistance welding machines are used in the manufacture of electrical equipment, transformers, bus bars, and other components. Large areas can be joined by making a series of spot brazes.

Salt-bath dip brazing of copper and copper alloys is a less-popular brazing process. The procedure uses a molten neutral salt at the brazing temperature. The brazing filler metal is preplaced and the molten salt is used to activate joining. The procedure is useful for unusually shaped parts or those with multiple joints, such as heat exchangers. Applications include waveguides, which allow simultaneous brazing of all joints in a single immersion. A cast bronze alloy (C22000), for example, can be joined to a thin-walled tube to close tolerances without warpage. Self-jigging of parts is preferable during the assembly process, before the parts are mounted into the external jig used in the dip braze. External jigs must allow for expansion of the parts during brazing. A disadvantage of this process is the need to remove all residual salts after brazing.

Brazing of Copper, Copper Alloys, and Precious Metals

---

Precious Metals

Throughout history, precious metals have been used as adornments and jewelry. Even today, the use of gold in jewelry is the major source of demand for fabricated gold. Brazing is routinely employed in the manufacture of jewelry to produce joints that match in color and surface condition to the base materials. Biocompatibility and relative ease of workability have also historically placed precious metals in the fields of dentistry and medicine.

Like copper, precious metals exhibit good thermal and electrical conductivity, in addition to superior corrosion resistance--required traits for materials used for high-reliability electrical contacts.

Material Composition

Jewelry golds are usually yellow or white in color. The term "karat" refers to the fineness or percentage of gold in the alloy, with 24 karat (k) being pure gold. Diluting gold to 18 k would then mean that the resulting alloy is 75% Au (18 parts gold, plus six parts of other metals). Yellow golds are generally alloys containing gold, copper, silver, and zinc. White golds are lightened by the substitution of nickel for some of the copper in the alloy.

Dental materials may contain any of the precious metals in almost any combination. It is not unusual to find a dental casting material that is composed of gold, silver, platinum, palladium, iridium, and/or other precious or nonprecious metals to achieve special performance characteristics (for example, matched coefficient of thermal expansion with dental porcelain).

Precious-metal-base electrical and electronic materials are found in wide variety. Many of the original precious metal contact materials were derived from existing dental and jewelry alloys. Silver graphite, silver nickel, and silver metal oxides (for example, Ag-CdO) are common switch and relay materials fabricated by powder metallurgy or the oxidation of a wrought alloy. In many cases, these silver contact materials are provided with a silver backing to facilitate brazing. Parts that are not silver backed must be treated to provide a suitable surface for brazing. Silver graphite contacts can be air fired to remove surface carbon. Silver metal oxide parts can be chemically treated to remove surface nonmetallics. Additional surface treatment, plating, or coining can then be employed. Another very common silver contact alloy is coin silver (90Ag-10Cu).

Sterling silver (92.SAg-7.5Cu) is well-known for its application in jewelry, flatware, and decorative household serving utensils.

The platinum-group metals are platinum, palladium, iridium, rhodium, ruthenium, and osmium. With the exception of osmium, pure and alloyed platinum-group metals have a wide range of applications including jewelry, thermocouples, glass melting vessels and tools, labware, medical devices, and catalysts.

Precious metal plated or clad materials can be brazed, but they require process controls sufficient to prevent excessive diffusion or blistering of the plating or cladding.

Filler Metals

The fields of jewelry and dentistry each have selections of brazing filler metals that satisfy the specific demands of their disciplines. An extremely wide variety of gold jewelry filler metals is available. One important consideration in the selection of filler metals for gold jewelry is that the filler metal does not reduce the gold content of the finished brazement. Table 4 gives a partial list of gold filler metals for jewelry applications.

(A) WHITE GOLD.

(B) GREEN GOLD.

Platinum jewelry can be brazed with binary alloys of gold-platinum, platinum-silver, or palladium-silver, or multiple precious metal alloys (some of which contain copper).

Silver jewelry is generally brazed with silver-base filler metals that contain copper and zinc (and in some cases, include additions of tin, nickel, or cadmium). However, the elimination of cadmium is becoming more prevalent due to stringent Occupational Safety and Health Administration (OSHA) regulations.

There are some proprietary variations in the compositions of brazing filler metals for dentistry, although they are usually composed of gold, silver, copper, zinc, and tin. Table 5 gives typical dental gold filler metals with physical properties.

(A) NOT APPRECIABLY AFFECTED BY AGE HARDENING.

Filler metals for industrial applications of precious metals usually come from the American Welding Society (AWS) BAu and BAg groups. Pure gold and gold-base alloys can be brazed with materials from the BAu or BAg metals. Pure silver and silver-base alloys can be brazed with the BAg and, in some cases, the BCuP (see Fig. 1) filler metals. Platinum and palladium are brazeable with pure gold (which melts at 1063 °C, or 1945 °F) as a filler or by using one of the platinum jewelry filler metals.

Fluxes and Atmospheres

Generally, fluxes and atmospheres suitable for copper brazing will be sufficient for applications joining precious metals because precious metals are oxidation resistant. The user can choose a flux or atmosphere that corresponds to the type of filler metal used, or in the case of dissimilar metal brazing to precious metals, a flux or atmosphere that will protect the nonprecious base material.

Joint Clearance and Configuration

The brazing of precious metals may be achieved by following the criteria established for joint clearance and design for copper brazing (see the section "Copper and Copper Alloys" in this article).

Brazing Processes

Precious metals can be joined using furnace brazing, torch brazing, induction brazing, and resistance brazing processes.

Furnace Brazing. In the production of crown and bridge work, a dental laboratory technician may have to join a part that has been partially porcelain coated. The technician may in that case employ the use of a vacuum porcelain firing furnace to perform the brazing operation on the exposed metal surfaces. High-volume industrial applications (for example, electrical contact manufacture) may call for the use of furnace brazing.

Torch Brazing. In the dental laboratory and at the jeweler's bench, the most widely used process for brazing is manual torch brazing. Dental lab technicians frequently torch braze one-of-a-kind configurations that have been fixtured by embedding the parts into high-temperature-resistant plaster. Automated torch brazing has been applied to high-volume jewelry applications, such as chainmaking. Industrial precious metal users employ both manual and automated torch brazing.

Induction Brazing. Precious metal parts brazed to dissimilar metals (for example, the brazing of a contact to a holder), sometimes require the localized heating attainable by induction heating (Fig. 3). The same type of efficiency deficit encountered when induction brazing is used to braze copper is also present when the process is applied to precious metals (see the section "Copper and Copper Alloys" in this article).

Resistance Brazing. Because copper and precious metals are highly conductive, the process of resistance brazing of precious metals is applicable, but also limited by short times and high current outputs.

Brazing of Aluminum Alloys

E.B. Gempler

Introduction

ALUMINUM is a commonly used base material for brazing. It is easily fabricated by most manufacturing methods, such as machining, forming, and stamping. Although most brazing processes are applicable, the use of aluminum requires more attention. It is different from most metals in two ways: it quickly reforms its tenacious oxide coating whenever a reactive form of oxygen is present, such as air or water, and it is always brazed at temperatures close to its melting point. The latter factor compromises strength (in terms of holding shape during brazing) and tends to increase the rapidity in which the brazing alloy reacts with the base metal. The net result is that cycle times are critical and fixturing forces must be controlled.

Brazing of Aluminum Alloys

E.B. Gempler

Base Metals

The non-heat-treatable wrought alloys typically used as base metals are listed in Table 1. Those that are most successfully brazed are the l*xxx* and 3*xxx* series and the low-magnesium members of the 5*xxx* series.

TABLE 1 MELTING RANGES AND BRAZEABILITY OF SOME COMMON ALUMINUM ALLOYS

(B) USED BOTH PLAIN AND AS THE CORE OF BRAZING SHEET.

(C) USED ONLY AS THE CORE OF BRAZING SHEET.

(D) SAND AND PERMANENT MOLD CASTINGS ONLY

The commonly brazed heat-treatable wrought alloys are the 6*xxx* series. Because the 2*xxx* and 7*xxx* series of aluminum alloys have melting points that are too low, they are not normally brazeable. Exceptions are the 7072 alloy, which is used for cladding material only, and 7005 alloy. Alloys with a solidus temperature above 595 °C (1100 °F) are readily brazed using the aluminum-silicon filler metals.

There are several brazeable cast aluminum alloys, which are listed in Table 1 along with their melting range and degree of brazeability. The most readily brazeable are those with the higher solidus temperatures, such as the 710 and 711 alloys.

Filler Metals

Alloys used in flux brazing usually contain between 7 and 12% silicon-balanced aluminum, and tramp metals are controlled to levels below 0.2%.

Alloys employed in fluxless brazing use higher percentages of silicon (>9%) and have varying additions of magnesium to enhance oxide film modification to promote wetting, as well as reduce the partial pressures of oxygen beating gases in the chamber. These alloys are primarily found in clad form. Some are semiproprietary to processes used in the automotive heat-exchanger industry. The vacuum (fluxless) alloys, BAlSi-6 through -11, are identified in Table 2. The alloys BAlSi-3 through -5 also can be used with the fluxless process if modifications related to magnesium are made, either in the base metal or as an addition to the furnace.

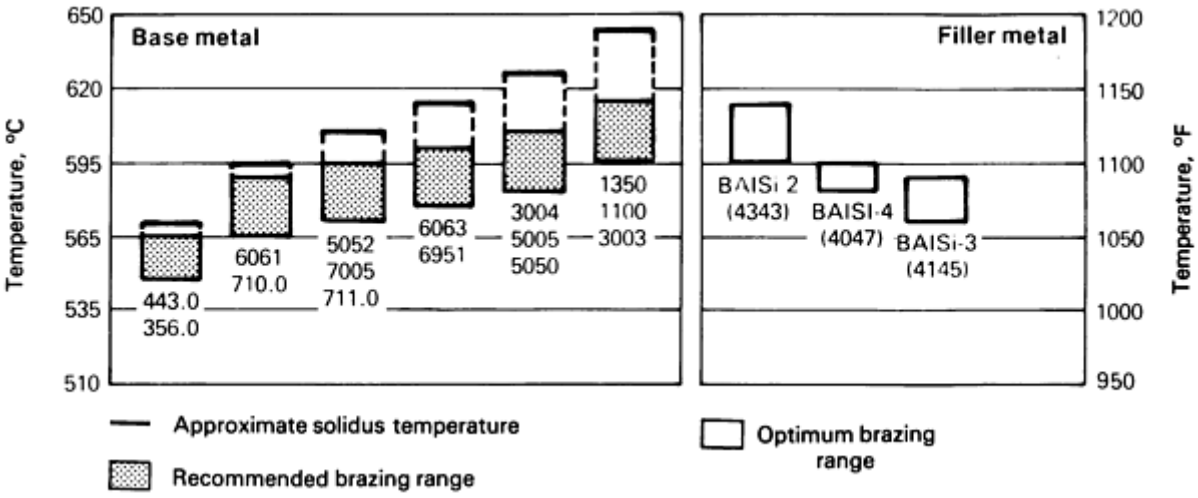

FIG. 1 COMPARISON OF BRAZING TEMPERATURE RANGES OF ALUMINUM ALLOY BASE METALS AND ALUMINUM ALLOY BRAZING FILLER METALS

Non-clad forms of brazing alloys are usually shim or wire stock and are limited to AA4047. Some paste forms are also available from powdered alloy and flux or from powdered alloy and binder for either flux or fluxless processes. These materials are available in the United States from only a few vendors.

Brazing of Aluminum Alloys

E.B. Gempler

Brazing Sheet

Brazing sheet is usually made by roll bonding the filler metal to the base metal. It can be single clad (on one side only) or double clad, and is an extremely useful way to apply filler metal.

Brazing sheet is advantageously used in the assembly of high-production items, such as heat exchangers and other complex assemblies, because the filler metal is already in place, thus avoiding an extra step that would slow down the assembly operation. Brazing sheet is an excellent aid in assemblies where many joints need to be brazed simultaneously.

Fluxes

Brazing that is performed in air or other oxygen-containing atmospheres requires the use of a chemical flux. These fluxes, whether used in torch, furnace, or dip brazing, or in braze pastes, usually contain chlorides and/or fluorides, the fumes of which are hazardous to the operator if inhaled. Flux fumes must be exhausted, not only for health reasons, but because they are highly corrosive to most metals.

Fluxes act as deoxidizers and prevent reoxidation by coating the surfaces. They are used to aid the wetting and flow of the filler metal on deoxidized and clean aluminum.

There are four generic types of fluxes in two basic formulas: chloride active and fluoride active. Chloride-active fluxes consist of either a straight chloride flux or a chloride flux modified with zinc. Fluoride-active fluxes consist of either a straight fluoride or a modified fluoride that produces an inert film over the brazed parts after brazing. In both cases, the modification is intended to reduce corrosion in postbrazed products.

In torch brazing, fluxes can be applied dry or mixed with either alcohol or water and painted, or sprayed, or they can be applied by dipping the joining parts. A suitable flux for torch or furnace brazing must:

- BEGIN TO MELT AT A TEMPERATURE LOW ENOUGH TO MINIMIZE OXIDATION OF THE PARTS
- BE ESSENTIALLY MOLTEN AT THE TIME THE FILLER METAL MELTS
- FLOW OVER THE JOINT AND FILLER METAL TO SHIELD THEM FROM OXIDIZING GASES
- PENETRATE OXIDE FILMS
- LOWER THE SURFACE TENSION TO ENCOURAGE WETTING
- REMAIN LIQUID UNTIL THE FILLER METAL HAS MELTED
- BE RELATIVELY EASY TO REMOVE AFTER BRAZING IS COMPLETE

Fluxes for dip brazing are less active than those used for torch or furnace brazing, because parts to be brazed are totally immersed in the molten flux. Therefore, oxygen cannot reach the surface of the parts to reform oxides. In dip brazing, the flux acts as a heat transfer medium, in addition to its fluxing action, to bring the aluminum parts to final temperature for brazing.

Powdered fluxes are mixed with liquids and powders to form pastes. Pastes can be mixed in the brazing operation or they can be bought premixed from several suppliers.

Brazing of Aluminum Alloys

E.B. Gempler

Joint Designs

Assemblies to be brazed can be designed with many types of joints. When joints are designed to permit the application of flux, provisions must be made to ensure the displacement of flux and accompanying gases and to allow the flow of filler metal into the joint.

Lap joints can be used to achieve joint strength that is equal to the strength of the base metal. Lap joints that require a long flow path for the filler metal should be designed for flow in one direction only, to prevent the entrapment of potentially corrosive flux. Scarf and butt joints usually are not as strong as the base metal, but they can be designed to give satisfactory performance. (It should be noted that scarf and butt joints are weaker than lap joints because their mating area is less than that of lap joints.) For fluxless brazing, line contact is desirable and zero clearance is preferred. Certain brazing alloys (for example, the BNi series) can approach the strength of the parent metal if homogenized for a long period of time to provide grain size and microstructure characteristics similar to those of the parent metal.

In flux brazing, joint clearances must be sufficient to prevent premature solidification of the filler metal in small capillary spaces that are caused by the mutual solubility of the base metal and filler metal. These spaces can entrap flux and cause porosity. Clearances that range from 0.05 to 0.10 mm (0.002 to 0.004 in.) can suffice for narrow laps when preplaced filler metal is used. Wider laps may require clearances up to 0.25 mm (0.010 in.). With brazing sheet, line contact is desirable. Clearances should not exceed 0.076 mm (0.003 in.).

Preblaze Cleaning

Non-heat-treatable alloys usually can be cleaned by degreasing. However, this cleaning method is being replaced by solvent cleaning using special water-base products, because of environmental requirements. Chemical deoxidation may be required for components that have been severely worked, such as in spinning, drawing, or extrusion processes.

For heat-treatable alloys, chemical cleaning is necessary to reduce the tenacious oxide films, which tend to be thicker, because of thermal processing methods such as solution heat treatment. Aluminum-silicon alloys often require a special nitric-hydrofluoric acid mix to remove the excess silicon smut that is not removed by alkaline (5% NaOH) or nitric-acid solutions alone. If necessary, stainless steel wire brushes, steel wool, or abrasive cloth can be used to achieve abrasive cleaning.

Thin, high-silicon-content braze foil should only be degreased to prevent the loss of available filler metal that is needed at the braze joint.

Brazing of Aluminum Alloys

E.B. Gempler

Assembly

In flux brazing, self-fixturing is an excellent assembly method. It may be accomplished through the use of tabs, rivets, screws, or tack welds. Self-fixturing is cost-effective, quick, and lends itself to many different types of assemblies. Care must be exercised when choosing fastener or tack weld alloys with solidus temperatures that are higher than the brazing process temperature.

Spring-loaded fixtures can be useful, especially for high-production and complicated assemblies. These fixtures are excellent for stacked assemblies, such as plate-fin heat exchangers. When adjusted properly, spring-loaded fixtures can prevent the crushing of assemblies that often is due to thermal expansion and aluminum softening during heating.

Both coil springs and strap springs are used. Strap springs are less costly to use, but typically do not have the inherent resiliency of coil springs. Coil springs are more expensive than strap springs, but coil springs offer variations in coil

diameter, coil thickness, stiffness, initial pressure, and the number of coils used that cannot be obtained with strap springs. Strap springs vary in width and thickness and are tightly bound around the fixture. When heated, strap springs tend to stretch and do not return to their original setting, thus losing stiffness and producing an effective loss in resiliency.

Weighted fixtures are often used on low-production runs and in cases where variations in shape and size preclude the use of more-expensive fixture types.

It is often necessary to apply stop-offs to parts of the assembly to be brazed in order to prevent filler metal from flowing onto certain areas. Stop-offs can consist of refractory oxides, graphites, or any number of commercial compounds readily available from welding and brazing suppliers. Furnace and dip brazing operations often use stop-offs to prevent fixtures and jigs from being brazed to the work. Stop-offs for fluxless brazing are usually refractory oxides sprayed on the jigs or fixtures. Stop-offs also can be formed on the fixtures by heating at a high temperature in an atmosphere.

Dip Brazing

Dip brazing is done by immersing the brazing assembly and fixture into a molten bath of flux. The flux acts as both a heating mechanism to bring the parts to temperature, as well as a deoxidizer. Prior to immersion, the part and fixture must be preheated to remove moisture and prevent solidification of the flux during immersion. Preheating is done in a hot-air furnace at approximately 540 °C (1000 °F) for about 0.5 h. Duration of the preheat cycle varies with the complexity of the brazement, its size, and the size of the fixture. Nevertheless, even with small waveguide components and thin box brazements that require a decreased preheat time, using a preheat cycle time of 0.5 h is still recommended. Moisture removal is necessary to prevent steam explosions when the part is lowered into the bath. Steam explosions can be very hazardous to the operator.

Initial temperatures are determined by attaching a thermocouple to the aluminum assembly. Time and temperature readings are taken and used for subsequent parts as a mechanism to control the braze quality.

Adequate salt drainage is necessary for several reasons. Salt must be removed to prevent trapping and the possible corrosion of the parts. Adequate drainage is necessary to allow filler metal solidification. Retention of excess salt in the assembly depletes the level of the molten salt in the dip pot, necessitating more-frequent additions of dry flux to the bath and resulting in higher costs.

The bulk of the salt is removed by immersing the fixture and brazement in a bath of boiling water. Then, the brazement is separated from the fixture and put through a series of water baths to remove more salt. Final baths, which use distilled water, are changed at intervals until chemical tests show an acceptable limit of salt in the clear runoff water. Concurrently, the fixtures are further boiled and then blasted with water to remove any residual salt.

The molten flux bath is regularly dehydrated by immersing clean sheets of 1100 or 3003 series aluminum to remove water, oxides, and other contaminants for an amount of time that varies from bath to bath. The sheets must be cleaned and dried to maintain their effectiveness. They can be used repeatedly.

Furnace Brazing

Standard fluxes must be used in furnace brazing because of the oxide atmospheres. Flux can be applied by brushing, dipping, or spraying. Furnace brazing is used for large loads that require good temperature control. Stop-offs are often used on parts and fixtures to inhibit the flow of molten filler metal to certain areas and to prevent brazing to the fixtures.

Special fluxes can be used with special furnaces that have reduced-oxygen atmospheres. One such flux is NOCOLOK, which has modest cleaning and fluxing ability and requires well-cleaned parts. During the brazing process, the chamber is filled with flowing dry nitrogen. At the completion of brazing, the parts are coated with an inert residue from the flux. The parts do not require postbraze cleaning to remove the flux residue.

The temperature accuracy requirement for these aluminum brazing furnaces is usually ±5.5 °C (±10 °F). However, ±3 °C (±5 °F) is preferred, especially where critical components are being brazed.

Torch Brazing

Torch brazing is used in either manual or automatic fabrication, as well as in repair operations. Torch brazing ranges from simple tube-to-tube joints to more-complex and mechanized assemblies. Torch brazing is similar to oxyfuel gas welding in that the heat to effect the joint is applied locally. Oxyacetylene, oxyhydrogen, and oxy-natural gas are used in commercial torch brazing applications. Close temperature control is needed when using the typical BAlSi-3 and BAlSi-4 filler metals.

Because aluminum shows no change in color when hot, it is difficult to know when parts approach the brazing temperature. Fluxes that melt at a slightly lower temperature than the filler metal can serve as a temperature indicator. Joint areas are pointed with a slurry of brazing flux. A soft, slightly reducing flame is played over the entire area. Filler metal can be either preplaced or force fed. After brazing, residual flux chloride must be removed.

Brazing of Aluminum Alloys

Flux Removal Techniques

Whether a flux is used in torch brazing, furnace brazing, or dip brazing processes, it must be removed to prevent entrapment and the possibility of subsequent corrosion effects in the presence of moisture. Flux removal from dip-brazed assemblies was discussed in the dip brazing section of this article.

All fluoride fluxes are not safe to leave on the workpiece. If the flux residue remains in the inert form (for example, cryolite in the NOCOLOK process), it is considered to be an acceptable condition. However, under no circumstances should fluoride that can ionize remain on the surface because it can cause subsequent corrosion problems.

As much flux as possible should be removed by immersing torch-brazed and furnace-brazed parts in a bath of boiling water just after the filler metal has solidified. Scrubbing with a fiber brush in boiling water removes most of the flux. Pressure spray washers are often effective in opening passages that are plugged by flux. Agitation and turbulence, as well as ultrasound, help to remove flux from tight spaces. Acids (HNO_3, HNO_3-HF), as well as chromates, are often used in the final rinse water. Because of disposal problems, many companies avoid using chromates as corrosion inhibitors.

Testing for complete flux removal is done by monitoring the presence of chlorides in the final rinse water. An acidified solution of 5% silver nitrate is used to check the final rinse water for clarity. If white chloride residues cloud the water, then salt is still present. After several tests on subsequent rinses, the salt is considered removed if the water remains clear. Although this is a simple test, it is quite accurate.

Fluxless Vacuum Brazing

The main advantage of fluxless vacuum brazing is that no flux removal is necessary. If assemblies have been made using non-heat-treatable alloys, then they are ready for the next operation. If heat-treatable alloys are brazed, then a subsequent heat treatment will be necessary to reach the strengths required.

The required equipment is a vacuum furnace that can reach a vacuum of 133×10^{-5} Pa (10^{-5} torr) or lower, is leak tight, and is able to obtain temperature accuracy of ±3 °C (±5 °F) on the load being brazed.

Fluxless brazing is ideal for braze sheets where no flux is required and assemblies can easily be stacked and fixtured. Magnesium in some form is usually required to expedite the break-up of surface oxides and to facilitate the wetting mechanism. Magnesium is supplied by several techniques. It can be an integral part of the filler metal or base metal or it can be a part of other alloys used in the assemblies, such as the 5*xxx* series of aluminum-magnesium alloys. It can also be supplied in the form of chips or prealloyed aluminum-magnesium ingots.

Vacuum furnaces must be cleaned periodically to remove magnesium and magnesium oxide that condenses on the cold walls of the furnace and other appendages to those walls. These residues may, in time, short some of the electrodes and tend to be hygroscopic to water. Water is a contaminant that is very difficult to remove in vacuum.

Brazing of Aluminum Alloys

E.B. Gempler

Postbraze Heat Treatment

Dip-brazed heat-treatable assemblies can be spray quenched or immersion quenched after most of the salt has been drained and while the parts still remain at about 480 °C (900 °F). This puts the parts into a solution-heat-treated stage for subsequent precipitation hardening.

Heat-treatable assemblies usually are in the annealed or soft condition after furnace, torch, or fluxless brazing. Clean assemblies are usually heated at temperatures ranging from 480 to 515 °C (900 to 960 °F) for a period of time that allows the magnesium silicates to go into solid solution prior to quenching. The quenched parts are then aged for a period of time that allows precipitation hardening to take effect. The amount of time depends on the alloy system and on whether the parts are made from wrought or cast alloys. A typical precipitation heat treatment for 6061 shapes and tube is 160 °C (320 °F) for 16 to 20 h.

Brazing of Aluminum Alloys

E.B. Gempler

Safety Precautions

Exhaust fumes must be removed from the immediate vicinity of the operators. Suitable masks should be worn to prevent inhalation of these fumes.

Precautions are necessary when dip brazing. Operators must wear suitable burn-and heat-resistant coverings to protect themselves from splashes or burns and from inhaling flux fumes. As with all flux-type operations, fume exhaust is a necessity.

Lowering and removal of the parts and fixtures must be done at a rate that minimizes spatter from the molten bath. Parts to be brazed (including fixtures) must be preheated to prevent steam explosions as the part is lowered into the bath. Preheating also prevents the lower-temperature fixture and aluminum assembly from freezing out the molten salt as it is immersed.

The temperature of aluminum can be very deceptive, because this material does not turn red or glow when it is hot, like steel does. Precautions must be taken to prevent burns.

The cleaning of vacuum furnaces has already been discussed. When removing magnesium and magnesium oxides, nonsparking scraping tools should be used to prevent sparks that can ignite magnesium. Dust should be swept frequently into a metal container and removed from the vicinity of the furnace to prevent fires. The cleaning operators must work with adequate ventilation. Masks must also be used by the operators. The cleaning must be done by more than one operator as a precaution against accidents. Several buckets of appropriate materials, such as sand, as well as fire extinguishers, should be available at all times to douse potential fires.

Brazing of Refractory and Reactive Metals

Roy I. Batista, TRW, Inc.

Introduction

REFRACTORY METALS are metals that have melting points that are either higher than those of iron, nickel, and cobalt or exceed 2000 °C (3630 °F). Molybdenum, tungsten, niobium, and tantalum are the refractory metals discussed in this article. Reactive metals, which include titanium, zirconium, and beryllium, have in common the ability to form stable oxides at elevated temperatures. These diverse groups of metals have a wide range of mechanical and physical properties (Table 1).

(C) BETA TRANSUS

A vacuum atmosphere is suitable for brazing all of the refractory and reactive metals. Tungsten and molybdenum also can be brazed in reducing atmospheres and, in some applications, in air using a flux. The use of flux in the brazing of beryllium has been routine, but the preferred vacuum techniques are being developed. Inert gases with properly controlled purity are also useful atmospheres for the brazing of both refractory and reactive metals.

This article describes brazing filler metal selection and brazing procedures for each of these metals. The importance of fabricating samples to design requirements and then testing to the degree necessary to validate brazing procedures cannot be overemphasized. These materials do not have the data base that exists for alloys based on copper, iron, or nickel, and contradictions exist in the literature. Because specific details on brazing equipment, such as vacuum levels, type of vacuum equipment, quality of inert gases, and brazing cycles, are not reported in most of the development work on the refractory and reactive metals, verification is needed for specific braze designs.

The selection of filler metals presents a problem, because many recommendations are for materials that are not readily available. However, an attempt was made in this article to provide selections from commercially available compositions. Although these commercial alloys may not be optimal in all applications, they should be evaluated first to assess their suitability for specific designs. Consult the selected references at the end of this article for specific information on nonstandard brazing filler metals.

Brazing of Refractory and Reactive Metals

Roy I. Batista, TRW, Inc.

Refractory Metals

The four refractory metals that have the most commercial significance are molybdenum, tungsten, niobium, and tantalum. The brazing of these alloys is a complex subject, because their high melting points and specific mechanical, physical, and chemical properties have highly diverse applications, and the brazing procedures required by each application can be quite distinct. Molybdenum is used in high-temperature structures and electronic devices. Tungsten is most commonly associated with filaments, heating elements, and welding electrodes. Niobium is widely used in spacecraft propulsion systems and applications that require its corrosion resistance. The largest use of tantalum is for capacitors, followed by chemical processing equipment.

Ductile-to-Brittle Transition Temperature (DBTT)

DBTT is a metallurgical consideration that greatly influences the selection of brazing filler metals and the brazing environment. Tantalum and niobium are Group V metals and have a high solubility of interstitial elements and a low DBTT. Conversely, tungsten and molybdenum are Group VI metals and have a lower solubility for interstitial elements, but a high DBTT. Tungsten and molybdenum are specifically processed and alloyed to lower the DBTT. For both tungsten and molybdenum, a warm-worked structure has a lower DBTT than a recrystallized structure, and alloys have been developed to retard annealing. Annealed molybdenum has a DBTT that is near room temperature, whereas annealed tungsten may be brittle at temperatures below 315 °C (600 °F). Tantalum does not appear to have a ductile-to-brittle transition, and the DBTT of niobium can be as low as -200 °C (-330 °F).

Gas Reactions

The refractory metals are all sensitive to the absorption of, or reaction to, oxygen. Niobium and tantalum begin oxidizing at 200 and 400 °C (390 and 750 °F), respectively. Below 1370 °C (2500 °F), the oxides are nonvolatile, but the ductility of the parent metals is reduced, because of the absorption of oxygen.

Molybdenum starts to oxidize at about 500 °C (930 °F). At temperatures over 778 °C (1430 °F), which is the eutectic temperature of MoO_2-MoO, oxides become particularly volatile and the oxidation rate accelerates rapidly. Tungsten oxidizes rapidly at temperatures over 500 °C (930 °F), but not as rapidly as molybdenum. In general, oxygen absorption is not as much of a problem with tungsten and molybdenum as it is with tantalum and niobium.

Hydrogen exposure presents no problems to the use of molybdenum and tungsten. However, both tantalum and niobium will absorb hydrogen and form hydrides at moderate temperatures. The results can range from a loss of ductility at low concentrations to complete destruction, depending on time and hydrogen concentration. If it is not heavily contaminated, then hydrogen can be removed from tantalum and niobium by a high-temperature vacuum anneal.

Alloy Availability

Although there has been considerable development of the refractory metal alloys, their commercial availability in small quantities can be erratic. The alloys that are most common are identified in Table 1. Generally, tantalum, niobium, and their alloys are usually procured and used in the annealed condition. Tungsten and molybdenum are often used in the stress-relieved condition, because of higher strength and a lower DBTT. TZM is the most common alloy of molybdenum, and both molybdenum and tungsten are alloyed with rhenium to increase strength and ductility and to lower the DBTT. Molybdenum and tungsten may both contain dopants, such as potassium, to reduce grain growth at high temperatures, particularly in filament applications.

Brazing Filler Metal Selection

The wide range of applications and the high melting points of the refractory metals mean that a wide range of brazing alloys are available, but this also makes the selection process more complex. Alloys have been specifically developed for high-temperature, low-temperature, high-strength, or corrosion-resistant applications.

The higher the brazing temperature and the service temperature, the more difficult it becomes to select a brazing filler alloy. As temperature increases, adverse metallurgical reactions, erosion, and fixturing concerns are amplified. For example, nickel-containing alloys have resulted in brittle joints in both tungsten and molybdenum brazing, because of intermetallic formation. This brittleness can be minimized by short brazing cycles.

The refractory metals are not difficult to join. The objective of the selection process is to select an alloy that will provide the right combination of properties in service, such as high temperature, mechanical properties, or corrosion resistance.

Filler Metals for Brazing of Molybdenum. The commercially available alloys based on silver, gold, or palladium have all been evaluated for refractory metal brazing. In Ref 1, the 19 filler metals considered for molybdenum and the 32 considered for TZM are ranked on a wettability index. It was found that TZM was less-readily brazed than molybdenum, because of titanium oxide formation on its surface. As expected, higher brazing temperatures promoted wettability. Table 2 lists commercially available brazing filler alloys, as well as those alloys that may have special applications, but may not be commercially available.

(A) BRAZING RANGE

Examples of special-purpose brazing include the joining of thin foils, such as the honeycomb structure in which the alloy Ag-30Pd alloy was used. At a brazing temperature of 1160 °C (2120 °F), 0.025 mm (0.001 in.) molybdenum foils were joined without excess erosion. In a high-temperature application, a brazed Ti-25Cr-21V alloy (solidus temperature of 1160 °C, or 2120 °F) had a remelt temperature of 1600 °C (2910 °F) after a 16 h postbraze diffusion cycle at the solidus temperature. The other recommended alloy systems for high-temperature performance include Ti-48Zr-4Be (brazing temperature of 986 °C, or 1810 °F), Ti-25Cr-21V (brazing temperature of 1482 °C, or 2700 °F), and Ti-28Zr-8Ge (brazing temperature of 1327 °C, or 2420 °F). The TiCrV composition has. a high remelt temperature of 1920 °C (3490 °F) (Ref 2). The high remelt temperatures of the chromium-containing alloys may be a result of the volatilization of the chromium during brazing. Therefore, a vacuum environment may be required to achieve these remelt temperatures.

Other high-temperature brazing filler alloys are Ti-65V (brazing temperature of 1700 °C, or 3090 °F) and V-50Mo (brazing temperature of 2257 °C, or 4095 °F). After postbraze diffusion treatment, shear test specimens failed in the parent metal when tested at 1400 °C (2550 °F). Additions of base-metal powder to the brazing filler alloy were necessary to prevent Kirkendall void formation (Ref 3).

A Mo-20Ru brazing filler was used to braze a doped Mo-3Re filament to a tungsten post. Because of a requirement to minimize any recrystallization of the filament, a laser welder working in an argon atmosphere was used to heat the assembly. Excellent wetting of both the molybdenum and tungsten was achieved without recrystallization of the filament adjacent to the braze (Ref 4).

When using brazing alloy powders, the addition of elemental powders to act as a "diffusion sink" is an effective method of raising remelt temperatures. The diffusion sink material will either shorten the diffusion time to achieve a high remelt temperature or it may form higher-melting-point compounds within the brazed joint. An example of a diffusion sink combination is Ti-25Cr-13Ni alloy combined with molybdenum powder that brazes at 1260 °C (2300 °F), but remelts at 1710 °C (3110 °F).

Filler Metals for Brazing of Tungsten. The brazing filler alloys that are appropriate for use with molybdenum are generally well suited for use with tungsten. In addition, there has been development work for specific tungsten applications. Platinum-boron alloys containing from 1 to 4.5% boron were brazed at about 1100 °C (2010 °F), both with and without tungsten powder additions. Remelt temperatures of 2100 °C (3810 °F) were obtained. The use of a diffusion sink (tungsten powder) was not necessary when gaps were below 0.038 mm (0.0015 in.). The addition of a halide salt, NaF or KHF_2, reduced the possibility of W_2B compound formation, thus raising the remelt temperature to about 2300 °C (4170 °F) (Ref 5).

Three alloys were evaluated for use at temperatures up to 2500 °C (4530 °F): W-25Os (melting temperature of 2600 °C, or 4710 °F), W-50Mo (melting temperature of 2900 °C, or 5250 °F), and Mo-5Os (melting temperature of 2600 °C, or 4710 °F). At 2200 °C (3990 °F), base-metal strength values were reported (Ref 6).

The number of alloys evaluated for use with both tungsten and molybdenum is extensive. A review of the selected references is recommended if nonstandard alloys are indicated for a specific application.

Filler Metals for Brazing of Niobium. Niobium may be selected for its corrosion resistance in chemical and nuclear applications or for its low density and high melting point in aerospace structural and propulsion applications. The welding of niobium does not present the brittleness problems associated with tungsten and molybdenum. However, brazing must be considered when welding is inappropriate.

Although commercial brazing alloys based on silver, gold, and nickel will wet niobium, brittleness is often noted with their use. In addition, their low melting points make them unusable for many applications. The active-metal modifications (titanium additions) of the silver-copper and gold-nickel alloys may be useful for niobium joining, particularly if residual oxide on the surface presents a wetting problem.

A series of Ta-V-Nb and Ta-V-Ti alloys is compatible with niobium and will resist liquid sodium. They can be brazed at temperatures ranging from 1760 to 1925 °C (3200 to 3500 °F), and have shear strength values that range from 140 to 205 MPa (20 to 30 ksi). The alloy Nb-1Zr, when brazed with Ti-28V-4Be, was resistant to potassium vapor and liquid exposed for 1000 h at 815 °C (1500 °F). Honeycomb structures of Nb alloys were evaluated using Pd-30Cu and Ti-11Cr-13V-3Al brazing filler alloys. There was some erosion with the palladium alloy, but the titanium-base alloy produced joints with high ductility and minimum base-metal erosion.

Two diffusion-enhanced approaches have been explored to produce higher-temperature properties in niobium brazes. One method adds base-metal powder to the brazing alloy, that is, niobium powder added to a Ti-33Cr alloy brazed at 1485 °C (2705 °F). Another approach, which depends on diffusion between the braze and parent material, is niobium brazed with a Ti-30V-4Be alloy that was brazed at 1315 °C (2400 °F). Postdiffusion of the Ti-33Cr alloy raised the remelt temperature by over 300 °C (540 °F), with corresponding increases to high-temperature strength. The Ti-Cr-V alloy had about the same remelt temperature, but its strength was lower.

A 316L stainless steel sleeve was brazed to the inner diameter of a Nb-10Hf rocket engine thrust chamber using 82Au-18Ni filler metal. The joint failed shortly after removal from the vacuum furnace, because of residual stresses resulting from the difference in thermal expansion. The joint was redesigned so that the 316L material was the outer member. This configuration was successfully brazed and the engine was flight qualified (Ref 4). This example emphasizes the need to consider the thermal expansion of the brazement pieceparts to prevent failure after brazing. It was fortunate that the assembly failed shortly after brazing. The residual stresses in a mismatched joint could just as easily cause failure weeks or months after brazing.

Filler Metals for Brazing of Tantalum. The brazing of tantalum is not as well documented as the brazing of tungsten and molybdenum. This situation may exist because, like niobium, it is an easily weldable material without the brittleness problem encountered with welded tungsten and molybdenum. Many of the brazing filler alloys presented for tungsten and molybdenum, as well as all of the recommendations made for niobium, can be considered for use with tantalum.

The diffusion-sink titanium powder and a Ti-30V brazing filler alloy (braze temperature of 1760 °C, or 3200 °F) produced a remelt temperature of 2100 °C (3810 °F). A similar approach with a 33Zr-34Ti-33V (brazing temperature of 1427 °C, or 2600 °F) resulted in a remelt temperature of 1650 °C (3000 °F). Other approaches using hafnium-base alloys have been considered. These include Hf-7Mo, Hf-40Ta, and Hf-19Ta-2.5Mo.

Reactive Metals

Of the reactive metals, titanium and its alloys are the most likely to be fabricated outside of a specialized facility. It is a structural material that finds varied uses, ranging from aircraft to body implants. The use of zirconium is most common in nuclear applications. Beryllium has many specific aerospace applications, because of its low density and high modulus values, but is most commonly utilized in its pure form, in x-ray window applications. Only beryllium and titanium have useful properties after exposure to elevated temperatures in an oxidizing atmosphere.

Titanium Alloys

Titanium is the most commercially available material among both reactive and refractory metals, in terms of its number of alloys, available product forms, and metallurgical complexity. These factors all impact brazing recommendations.

Because of the cost of titanium, its use is usually confined to those applications that take advantage of its specific properties, such as high strength-to-weight ratio, corrosion resistance, and high-temperature strength. Aerospace applications include airframe and engine components for both aircraft and spacecraft. Applications that require its corrosion resistance include chemical/petrochemical processing, marine exposure, and medical uses, such as instruments and implants. There are also emerging applications in the automotive and consumer products industries.

Titanium alloys are available in commercially pure and alloy compositions. They are generally categorized into four groups, depending on the principal phases present in the microstructure:

- COMMERCIALLY PURE (CP) ALLOYS (HEXAGONAL CLOSE-PACKED, OR HCP)
- ALPHA ALLOYS (HCP)
- ALPHA-BETA ALLOYS
- BETA ALLOYS (BODY-CENTERED CUBIC, OR BCC)

In pure titanium, the transformation (beta transus) occurs at 888 °C (1630 °F). By alloying, the alpha phase can be stabilized to increase the beta transus. Other alloy compositions may stabilize the beta phase or result in a two-phase alpha-beta structure. These various structures have a marked effect on mechanical properties and their response to heat treatment.

Commercially Pure and Alpha Alloys. The alpha-stable compositions are the CP grades and those alloyed with alpha stabilizers. The variations in strength of the CP grades depend on purity, particularly in terms of oxygen, nitrogen, hydrogen, silicon, and iron. The control of oxygen and iron is specified in order to control strength. The other interstitials are minimized to avoid embrittlement. As a class, the CP alloys are usually specified for applications requiring corrosion resistance, but they have mechanical properties that are useful for structural applications. The Ti-0.2Pd and Ti-0.3Mo-0.8Ni grades are also considered to be CP grades and are specified for more-corrosion-resistant applications. These alloys are generally used in the annealed condition and cannot be strengthened by heat treatment.

Alpha alloys are stabilized with aluminum and tin/zirconium. These alloys have both high-temperature and cryogenic applications. Their creep strengths are higher than those of the alpha-beta and beta compositions. The extra-low-interstitial (ELI) grades are specified for severe applications. The alpha alloys also have good weldability, but poor forging properties and an inability to be strengthened by heat treatment.

Near-beta alloys, which contain small amounts of beta stabilizers, are included with the alpha alloys. They have enhanced creep strength and elevated-temperature properties.

Alpha-beta alloys contain both alpha and beta stabilizers. The beta stabilizers are generally vanadium, molybdenum, and manganese. Titanium 6Al-4V, a classic example of an alpha-beta alloy, represents over 40% of the titanium produced.

Although these alloys can be strengthened by heat treatment, some of them, including Ti-6Al-4V, are used in the annealed condition. The heat treatment consists of quenching from the solution heat-treating temperature, followed by aging (solution-treated and aged, or STA, condition). The phases that are present after quenching vary with the alloy, the solution temperature, the cooling rate, and the cross-section size, but a beta phase will always be retained. Aging decomposes the retained beta as a fine alpha structure in the retained beta matrix and, accordingly, strengthens the alloy. Aging temperatures are between 425 and 650 °C (795 and 1200 °F). The equiaxed annealed structure has higher ductility

and better low-cycle fatigue properties than the STA condition. An acicular structure results from the STA heat treatment and has higher creep resistance, higher fracture toughness, and higher stress-corrosion resistance than the annealed condition.

The beta alloys have high concentrations of beta stabilizers that slow the transformation from the beta to the alpha phase. After normal processing, the structure is nearly all beta. The beta phase partially transforms into a finely dispersed alpha structure while aging at temperatures from 450 to 650 °C (840 to 1200 °F). When these alloys are in the beta phase and are solution heat treated, their ductility is excellent and their abilities to be forged and formed are superior to those of the alpha-beta alloys. After aging, the beta alloys are generally stronger and have higher fracture toughness values than the alpha-beta alloys, but they have lower creep resistance and ductility.

Applications that utilize the high formability and strength of beta alloys include complex aerospace structures and fasteners. The compositions and physical properties of selected titanium alloys are shown in Table 1.

Restrictive Titanium Brazing Attributes. Because of the variety of titanium alloys and corollary heat treatments, there are brazing limitations that can avoid possible compromise of the mechanical properties after brazing. To maintain properties, the brazing alloys must be selected to ensure that the brazing temperature will be within the recommended heat treatments of the alloys being brazed. Commercially pure and alpha alloys should be brazed below the beta transus to prevent a coarse structure that reduces ductility. Although alpha-beta alloys are usually solution treated below the beta transus, the beta transus can be exceeded in order to obtain specific high-temperature properties. Brazing temperatures higher than those specified for beta alloys can result in grain coarsening and a loss in ductility.

For any titanium brazement, it is recommended that the design requirements for strength and ductility be reviewed to confirm the suitability of the selected alloy and of using a brazed approach. Certain combinations that require high-temperature brazing and/or quenching may not be acceptable. For example, the brazing of honeycomb sandwich, or any thin-sheet metal structure, is not practical with an alloy that requires quenching for the required properties. When possible, the brazing filler alloy should be selected to coincide with a standard heat treatment, such as an annealing or a solution heat-treating temperature.

Brazing filler metal selection should occur within the restraints noted above and with consideration to the environment to which the brazement will be exposed. Of particular concern is the possibility of galvanic corrosion. Although it is a reactive metal, oxidized titanium is noble to many structural alloys. In critical applications, braze samples should be exposed to the end-use environments to ensure that there is not preferential corrosion of the brazing filler alloy.

A review of titanium brazing literature reveals a considerable body of work that includes many compositions that would not be commercially available. Considerable effort was expended on silver, both pure and alloyed, with various combinations of lithium, copper, manganese, cadmium, and tin. Pure silver appears preferable to most of the silver alloys. The Ag-Cu-Li alloys were successful if the brazing cycles were short to prevent excessive erosion of the base metal and to minimize the formation of the brittle Cu-Ti intermetallic.

Aluminum alloys, including 3003 and 4043, are also available, if their lower melting points are acceptable. Pure aluminum (99.9%) forms a thicker intermetallic zone than the preferred alloys, because the alloy additions, particularly silicon, reduce intermetallic formation.

A 82Al-9Pd-9Ga alloy is commercially available. It easily wets titanium and has good strength and corrosion resistance. Base-metal erosion is minimal when short brazing cycles and minimum brazing temperatures are used.

A Ga-Pd-Ag brazing filler alloy was used on two structural joints on the Mars Viking landing instrument. One application was a triangular truss structure consisting of a socket comer fitting and three tubular legs. A cold-wall vacuum furnace was used in combination with a short brazing cycle, about 5 min at temperature. After brazing, the part did not meet dimensional tolerances because of an improperly machined fixture. The brazement was separated by immersion in HNO_3 until the brazing filler metal was dissolved. There was essentially no attack of the titanium by the molten filler and the assembly was rebrazed on modified fixtures. Because of the required close tolerances of the part, the fixtures were made of titanium to avoid potential problems with thermal expansion differences.

The second Viking application was a titanium thermal standoff that was brazed to 304L stainless steel. The stainless steel was electrolytically plated with nickel and the part was brazed in a cold-wall vacuum furnace. Although wetting of the stainless steel by the Ga-Pd-Ag filler was not satisfactory, the nickel plating was easily wet by the filler.

The Pd-Cu-Ag series of alloys is also reported to have superior wetting characteristics on titanium, but its use would be limited by a high copper content. Ti-Ni-Cu alloys are available in several compositions and are increasingly employed for titanium brazing. Commercially available titanium brazing alloys are identified in Table 3.

(A) BRAZING TEMPERATURE

Of the noncommercial alloys, there has been success with Ti-Zr-Be and Ag-Al-Mn alloys. The beryllium additions have potential health considerations and the section of this article that addresses beryllium should be reviewed before its use is considered.

For all but the most-benign applications, the selection of titanium filler alloys and brazing cycles should be supported by braze samples that simulate the fabrication and design requirements.

Zirconium Alloys

Zirconium is available in most common mill products, such as sheet, strip, bar, plate, and billet. It can be forged and extruded. Commercially pure material and alloys that contain tin or niobium are available. The commercial grades may contain up to 4.5% hafnium, a neutron absorber, which prohibits their use in nuclear applications. The successful use of zirconium as a nuclear material is due to its low thermal neutron cross section, good mechanical properties, and excellent hot-water and steam corrosion resistance. Its high corrosion resistance to both organic and inorganic acids and its immunity to attack by alkalies has led to applications in the petrochemical and food processing industries.

Pure zirconium is hexagonal close-packed (alpha phase) at room temperature. It transforms to body-centered cubic at about 870 °C (1600 °F). The commercially pure grades and the tin-containing alloys are alpha structures at room temperature. Niobium is a beta stabilizer, and its addition to zirconium results in an alpha-beta structure at room temperature with a beta transus at 854 °C (1570 °F).

During primary fabrication, zirconium alloys are worked in the beta region. This is followed by a solution heat treatment in the beta region, at approximately 1065 °C (1950 °F), and a water quench. Further processing is performed in the alpha region to preserve the interstitial distribution established by solution heat treatment. The retention of fine disbursement of interstitials is critical to the corrosion resistance of the zirconium. Subsequent heating near or over the beta transus will redistribute the intermetallics, with a resulting loss in corrosion resistance and mechanical properties.

The composition and physical properties of zirconium alloys are shown in Table 1.

Brazing Filler Metal Selection. The narrow commercial use of zirconium has limited the development of brazing alloys. Basic joints have utilized alloys of copper, silver, and phosphorus, but such a joint would not have the corrosion resistance of the parent material. The major effort in the area of zirconium brazing has centered on nuclear applications that require high strength, high temperature, and hot-water corrosion resistance.

The wetting of zirconium alloys is not a particular problem, but the brazing filler metal selection is critical, because of the demanding corrosion resistance of most zirconium applications, and testing in the proposed use environment is compulsory.

Brazing filler alloys that have demonstrated acceptable pressurized hot-water corrosion properties after 1450 h at 360 °C (680 °F) include Zr-5Be, Cu-20Pd-3In, and Ni-20Pd-10Si. Zircaloy brazed with Zr-50Ag or Zr-29Mn filler alloy has shown acceptable corrosion rates and mechanical properties after testing in pressurized hot water at 315 °C (600 °F) for nearly 3000 h.

Brazed zirconium components are predominantly used in nuclear applications, particularly fuel rods. One example is the brazing of Zr-1.5Sn alloy tube cap assemblies using Zr-5Be alloy. Another example was the brazing of Zr-1.5Sn alloy to molybdenum using a 48Ti-48Zr-4Be brazing filler metal. The 48Ti-48Zr-4Be alloy has also been effective in joining zirconium to alumina. Note that the beryllium content of these fillers limits their use to facilities that have the proper beryllium control procedures.

The filler metals shown in Table 3 for use with titanium are acceptable for use with zirconium.

Beryllium Alloys

Virtually all beryllium mill forms are based on powder metallurgy techniques. Ingot sheet from cast material has limited availability. Large blocks of beryllium that approach 1270 mm (50 in.) in diameter and 2995 kg (6600 lb) are produced by the vacuum hot pressing of beryllium powder. Because the beryllium is very active, the powder is oxidized. The resulting pressing contains a significant oxide content. It is partially through the control of this oxide that the final properties of the beryllium are achieved. Them are structural, optical, and instrument grades of beryllium to permit design optimization. Other forms of beryllium sheet, plate, or extrusions are fabricated from the block material.

Beryllium has a low density, 2.7 g/cm^3, and a high modulus of elasticity, 295 GPa (43 × 10^6 psi). It is this high specific stiffness that compels the use of beryllium for aerospace applications. Nuclear applications provide another large market for beryllium.

The design of beryllium hardware is not without problems. The high stiffness and low ductility values of the material may result in failures if proper design requirements are not followed. The elongation values of beryllium mill products range from 1 to 3% for block forms, 5 to 10% for plate and extrusions, and 20% for sheet. These elongations are for the longitudinal direction; wrought beryllium is very anisotropic. Transverse properties are significantly lower. Thus, the uniaxial tensile properties will not indicate how beryllium will perform under complex stress conditions.

The aluminum-beryllium alloy system has had considerable attention in an effort to increase ductility with some loss in stiffness. Lockalloy, a 38% aluminum alloy originally developed around 1961, has a ductility and weldability advantage, compared with unalloyed beryllium, but its applications were limited because of its lower stiffness. The Al-Be system is again becoming available in several compositions. Because the two metals are mutually immiscible, the alloys are

processed to produce a fine structure of aluminum and beryllium. Beryllium alloy compositions and physical properties are shown in Table 1.

Although beryllium has a hexagonal close-packed structure, it is unlike titanium and zirconium in that it does not undergo a phase change at elevated temperatures. Wrought products must be worked hot, at temperatures from 800 to 1000 °C (1470 to 1830 °F). The temperatures used during processing are adjusted to prevent recrystallization, and the strength of these products rises significantly with increasing warm work.

The annealing temperature varies with the amount of work, but is reported to be between 725 and 900 °C (1340 and 1650 °F). The mechanical properties are reduced by recrystallization and grain coarsening if the material is heated too much, but there are no thermal strengthening treatments for beryllium.

The brazing of beryllium is well established, partly because of the difficulties of other joining methods. Because of a brittle, coarse-grained structure, the properties of welded joints have low strength and ductility, and an increase in the DBTT. Although mechanical fasteners, such as bolts and rivets, are used, careful design is required to prevent cracking during assembly and use. The Al-Be alloys are ductile and can be welded.

Brazing Filler Metal Selection. Brazing filler alloys for beryllium are primarily selected from the zinc, aluminum, and silver alloys. The advantages of zinc are that no reactions with the beryllium occur, the brazing temperatures are low to prevent recrystallization, and adequate strengths are obtained. Strength decreases rapidly with elevated temperatures. Aluminum systems are the most widely used brazing filler alloys. They have the same advantages as zinc, but higher strength values at both room temperature and elevated temperatures. The silver systems provide higher joint strengths at elevated temperatures, but at some sacrifice to parent metal strength because of recrystallization.

The wettability of beryllium with any brazing filler metal is difficult, and the preplacement of aluminum fillers is recommended. With close-tolerance joints, capillary flow is possible with the silver alloys, but not always predictable. Although fluxless brazing is possible, the use of proprietary fluxes is common. With flux, joint tolerances are less critical, and wetting of the base metal is more predictable. However, the potential corrosion problems from residual flux must be considered in the design and postbraze cleaning of the brazed component.

Aluminum-silicon alloys are the most common aluminum-base filler metals, although pure aluminum is also recommended. Shear strength values that exceed 62 MPa (9 ksi) have been reported, and useful strengths are possible at 175 °C (345 °F). Silver brazing was an early development in the beryllium joining process and is still recommended for joints that require high-temperature strength. The 60Ag-30Cu-10Sn, Ag-7Cu-0.2Li and pure silver have both been used with success. The shear strength of silver-brazed beryllium strongly depends on the braze cycle, and strength values between 140 and 275 MPa (20 and 40 ksi) have been reported. Lower brazing temperatures and short brazing cycles favor higher strengths. Copper, silver, and copper/silver filler metals were evaluated using low pressure (2.1 MPa, or 300 psi) and extended braze cycles (up to 8 h) to evaluate joints for high-temperature operation. With this braze/ diffusion approach, shear-strength values of 140 MPa (20 ksi) were obtained in the temperature range from 540 to 650 °C (1000 to 1200 °F).

The brazing of aluminum-beryllium alloys would be similar to that of beryllium, but the brazing filler selection must be based on the melting point of the aluminum-base material and would be limited to the zinc and aluminum-silicon alloys.

Health and safety rules must be thoroughly understood before conducting brazing operations that involve beryllium. Breathing of beryllium oxide has caused a loss of lung capacity in a manner similar to coal dust. Beryllium particles that enter open wounds have caused chronic ulcerations. Any beryllium process that can generate dust must be controlled. In machining operations, this is usually accomplished by using vacuum cleaners with output filtration that precludes the exhaust of any beryllium particles. Any etching, fluxing, or other treatments that may leave a beryllium dust residue after drying also must be controlled. Approved procedures must be used to dispose of chips, scrap material, and solutions.

Beryllium handling guidelines can be found in the Code of Federal Regulations, Title 29, Part 1910. The Office of Safety and Health Administration (OSHA) has established limits of atmospheric contamination at 2 $\mu g/m^3$ averaged over an 8 h day. The Environmental Protection Agency (EPA) has established 10 g/day as the maximum beryllium emission into the atmosphere. The time and cost of meeting safety requirements may be prohibitive for random beryllium brazing operations.

The handling of bulk beryllium poses minimal safety issues. Elevated-temperature heating below 780 °C (1435 °F) does not produce volatile or nonadherent oxides. Brazing can be accomplished with standard equipment if the surfaces to be brazed are plated to permit wetting of the filler metals and if no flux is used. Either vacuum or inert gas atmospheres would be suitable for fluxless brazing, and no postprocess cleaning would be required. Although the preceding procedure should safely permit beryllium use under normal conditions, appropriate approvals must be obtained.

Roy I. Batista, TRW, Inc.

Brazing Procedures

The joint designs that are valid for brazing the more-common metals, such as stainless steel or copper, are equally suitable for the reactive and refractory metals. At brazing temperatures, joint clearances should be between 0.013 and 0.050 mm (0.0005 and 0.002 in.) when using fillers that have good capillary flow. As happens with other metals, increased porosity and lower strength result from excessive joint clearances. Filler metals that have minimal wettability with the base metal should be preplaced in the braze joint and, when possible, a small load should be applied to the joint to accommodate some of the gap at the brazing temperature.

Because of the low thermal expansion of this group of metals, the calculation of the gap at the brazing temperature is of particular concern when brazing dissimilar metals that have great differences in thermal expansion. In tubular joints, the high-expansion material should be on the outside, so that the joint is in compression upon cooling. If these joints must be thermally cycled, then thermal fatigue failure can be a likely result. Therefore, such applications should not be brazed. For example, shear specimens of Mo-50Re brazed to L-605 with 82Au-18Ni failed after 20 to 30 cycles after cycling to 700 °C (1290 °F).

Fixturing. Whenever possible, the design should incorporate provisions for self-fixturing. Fixturing becomes more difficult with increasing braze temperatures. Two techniques that could avoid the use of hard tooling are alignment pins and tack welding, if satisfactory equipment is available in the latter case.

The need to fixture refractory metal brazements is required, just as it is for the brazing of any metal. However, it is complicated for refractory metals, because of their low thermal expansion values. The expense of fabricating fixtures from refractory metals is probably prohibitive for small-volume jobs. At lower temperatures, steel tools with springs or flexures that are made from stainless steel, superalloys, or molybdenum can be used to control the position of the brazements. Higher-temperature brazing requires that the tools be made from refractory materials, metals, or ceramics.

Because very clean atmospheres are usually recommended for brazing the reactive and refractory metals, the fixture is likely to join to the brazement if stop-off materials are not provided. Oxide slurries are suitable, as are more-permanent solutions, such as ceramic pads or flame-sprayed coatings. Because of the reactivity of this group of metals, any stop-off materials should be high in purity and nonreactive with the brazement. Zirconium oxide may not be suitable in contact with zirconium alloys at high temperature.

Surface preparation techniques include prebraze cleaning, surface plating, or other measures that improve the brazeability of the design or accommodate less-than-ideal brazing conditions.

The direct brazing of reactive and refractory metal surfaces, as discussed in this article, is based on the assumption that the filler metals would wet these surfaces. Another approach is to plate the surfaces with a metal, such as nickel, and then to consider the braze as a nickel joint, rather than a refractory or reactive metal. Although the use of platings has value, it also has disadvantages, because platings can peel or blister and because they are not suitable for refractory metal brazed assemblies that must operate at high temperatures.

Beryllium forms the most refractory oxide in this group of metals and is the most difficult to braze. Techniques such as electroplating or vacuum depositing coatings such as nickel, copper, or titanium have been used to enhance wettability. When powdered brazing filler alloys are used, additions of titanium hydride have been made. During brazing, the hydride decomposes and plates the beryllium surfaces with titanium.

Because of the reactivity of the reactive and refractory metals, prebraze cleaning is more important than it is when iron-, nickel-, or copper-base alloys are used. The sequence below is one of many that can be used:

- *ALKALINE CLEAN*, WHICH CAN BE PRECEDED BY SOLVENT CLEANING, AS REQUIRED BY THE SURFACE CONTAMINANTS
- *WATER RINSE*, PREFERABLY WITH DEIONIZED WATER
- *ACID PICKLE*. FOR TITANIUM, ZIRCONIUM, AND BERYLLIUM, USE 30 TO 40% HNO_3 WITH 1 TO 5% HYDROFLUORIC ACID, FOR 1 TO 5 RAIN AT 60 °C (140 °F). FOR NIOBIUM, TANTALUM, TUNGSTEN, AND MOLYBDENUM, USE 40 TO 70% HNO_3 WITH 10 TO 30% HYDROFLUORIC ACID. THE HIGHER CONCENTRATIONS ARE MORE SUITABLE FOR TANTALUM AND NIOBIUM; USE AT 55 TO 65 °C (130 TO 150 °F).
- *HOT-WATER RINSE*, PREFERABLY WITH DEIONIZED WATER
- *DRY AND PACKAGE* TO PREVENT CONTAMINATION BEFORE BRAZING

Parts should be brazed as soon as possible after brazing to minimize oxide formation. All cleaning of titanium must exclude any chlorinated solutions and menthol alcohol. Titanium is prone to stress-corrosion cracking when exposed to these solutions.

Brazing of Refractory and Reactive Metals

Roy I. Batista, TRW, Inc.

Brazing Equipment

Strict control of the brazing atmosphere is mandatory for the successful brazing of the reactive and refractory metals. The use of marginal atmospheres will, at a minimum, reduce the quality of reactive metal brazements and can potentially destroy the refractory metals, because of oxidation.

A cold-wall, high-vacuum furnace is highly recommended for the brazing of reactive and refractory metals. At brazing temperatures, a vacuum of 0.013 Pa (10^{-4} torr) can be considered a minimum level, and the leak rate of the furnace should be less than 1 μm/h (40 μin./h). Refractory metal heating elements are preferred to those of carbon in order to minimize potential contamination. The use of a cryogenic cold trap in diffusion-pumped equipment is also highly desirable.

The potential contamination problems associated with the use of hot-wall vacuum furnaces make their use questionable for high-quality work.

Induction brazing is a preferred process when the size and design of the hardware permits its use. However, the control of the brazing atmosphere is still critical. Vacuum induction, at a level of 0.013 Pa (10^{-4} torr), is acceptable, as are inert gases such as argon. Bottled inert gases are often not as clean as labeled, and a gettering system is recommended to minimize residual water and oxygen. A stainless steel tube filled with zirconium or titanium turnings and operating at about 800 °C (1470 °F) will reduce water to a few parts per million. A liquid-argon source minimizes gas contamination problems.

Tungsten and molybdenum can also be furnace or induction brazed in a hydrogen atmosphere, if the filler metal is compatible with hydrogen. The hydrogen dew point should be below -50 °C (-60 °F).

It is recommended, when furnace or induction brazing, that the equipment be cycled to a temperature higher than the braze temperature before actual brazements are made. This technique will completely heat the equipment and minimize outgassing problems during the subsequent brazing operation. If the recommended brazing equipment is not available, then successful brazing may be possible by protecting the brazement with metal foil, such as tantalum, which reacts with water vapor and oxygen and thereby offers some protection to the brazement. To check this approach or to check any brazing equipment, a piece of tantalum foil can be processed through the braze cycle and then checked for foil ductility. A more-sensitive test would be to metallographically examine the foil for contamination or to run a carbon and gas analysis on the sample and compare it to the starting material.

Although torch brazing with fluxes has been used to join reactive and refractory metals, the likely contamination of the base metal and future corrosion problems associated with residual flux should discourage this approach. Heliarc torch brazing has been performed within a dry box using inert gas atmospheres that are purified, as for induction brazing. The heating of components in an electron-beam welder also can be useful when permitted by the component configuration.

The use of flux, with one exception, is not recommended. The exception is the brazing of beryllium, especially with the zinc- and aluminum-base filler metals. The beryllium oxide will prohibit wetting by these fillers without the use of flux.

Whatever braze equipment is used, the lowest temperature for the shortest amount of time that will achieve the desired joint properties should be used as a technique to reduce contamination and erosion in the base metal.

Brazing of Ceramic and Ceramic-to-Metal Joints

A.J. Moorhead and W.H. Elliott, Jr., Oak Ridge National Laboratory H.-E. Kim, Seoul National University

Introduction

THIS ARTICLE is intended to assist in the development of procedures for the brazing of ceramic-to-ceramic or ceramic-to-metal joints for service under one or more of the following conditions: elevated temperatures, mechanical or thermal stresses, or corrosive atmospheres. Also described in this article are those factors that must be considered when preparing a procedure for the brazing of graphitic materials. However, because the interest in joining graphite is not nearly as intense at this time as the interest in joining ceramics, the former topic will be given less attention.

There is worldwide interest in using ceramic materials for applications not previously considered, that is, engineering applications. In these proposed or actual applications, ceramic-to-ceramic or ceramic-to-metal joints must be compatible with elevated temperatures and environments that are either oxidizing or corrosive, and they must have significant mechanical properties, including strength and fracture toughness. In addition, the joints must have demonstrable thermal stability at the temperatures of interest.

Material scientists and engineers now have an increased awareness of the critical nature of joints, their microstructural complexity, and the possibilities for joining a given set of components for a specific application. It should be noted that the uses for ceramic materials are changing rapidly, with a major emphasis on structural applications. Furthermore, these materials are becoming more complex, in terms of being strengthened and toughened by transformation processes, the addition of other ceramic or metallic materials, or the development of performance-enhancing microstructures made possible by processing. The successful use of advanced ceramic materials requires the development of equally advanced joining materials and technology.

Although advanced or fine ceramics also include the electronic ceramics, such as those used as substrates and encapsulants, ionic conductors, piezoelectric devices, and high-critical-temperature superconductors, this category of materials and the related joining technology is outside the scope of this article.

A primary impetus behind the emphasis on structural ceramics is the desire for improved efficiency and increased component life in various internal-combustion engines. For example, recent reviews of current research on ceramic joining technology in Europe, the United States, and Japan (Ref 1, 2, 3) strongly emphasize the research and development efforts that are aimed at utilizing structural ceramics in advanced heat engines.

Ceramic components are either being considered or actually used in a wide range of applications in experimental and commercial automotive applications. These applications include:

- VARIOUS WEAR-REDUCING PARTS IN CONVENTIONAL GASOLINE OR DIESEL ENGINES (REF 4)
- IN-CYLINDER COMPONENTS FOR LOW-HEAT-REJECTION DIESEL ENGINES (REF 1)
- SMALL CERAMIC TURBINE ROTORS THAT CAN REACH 900 °C (1650 °F) AND ARE SUBJECT TO A COMBINED CENTRIFUGAL AND THERMAL STRESS OF 200 MPA (29 KSI) IN TURBOCHARGERS FOR CONVENTIONAL GASOLINE ENGINES (REF 5) OR LARGER ROTORS THAT ARE EXPOSED TO EVEN MORE SEVERE TEMPERATURE AND STRESS CONDITIONS IN RELATIVELY SMALL, HIGH-EFFICIENCY, ADVANCED GAS TURBINE ENGINES (REF 6, 7, 8)

Many of these applications require ceramic-to-ceramic or ceramic-to-metal joints.

A second major impetus, at least in the United States, is the development of ceramic heat exchangers to recover the waste heat that is traditionally lost in the high-temperature, corrosive exhausts of industrial furnaces (Ref 9, 10). It should be obvious that much of the present interest in using ceramics for high-temperature structural applications is based on the worldwide desire to reduce the use of fossil fuels through energy conservation.

Carbon and graphite are widely used as electrodes in metallurgical applications and as moderator materials in nuclear applications. Specialized uses include rocket nozzles, guide vanes, nose cones, electric motor brushes and switches, bushings and bearings, high-temperature heat exchangers, and plumbing, as well as heart valves, synthetic teeth posts, air-frame composites, and high-performance brake linings. An antenna used for heating the plasma in a fusion reactor experiment, a recent example of a successful application, is discussed later in this article.

It is important to note that in the very early stages of brazing procedure development, there must be a clear understanding of the type of ceramic or graphite involved, how it differs from the more-familiar metallic materials, and whether the ceramic or graphite is to be attached to the same material, a similar material, or a metal. Such an understanding will facilitate the selection of a brazing filler material, the selection and use of a transition material in ceramic-to-metal joints, and the selection of a thermal cycle that is compatible with the heat-treatment response of the materials to be joined. Therefore, the following two sections describe ceramics and graphites, respectively, in terms of how they are made and how they differ from metals. These sections are followed by a discussion of procedure development and the available brazing processes, as well as a brief description of factors that are important to ceramic-to-metal joints.

Brazing of Ceramic and Ceramic-to-Metal Joints

A.J. Moorhead and W.H. Elliott, Jr., Oak Ridge National Laboratory H.-E. Kim, Seoul National University

Ceramic Materials

Structural ceramics can be categorized as either monolithic materials or ceramic-matrix composites. The monolithic materials include the aluminas, mullites, silicon carbides, silicon nitrides, and Sialons. The ceramic-matrix composites can be subcategorized as those containing a random dispersion of particles or whiskers that am intended to improve fracture toughness and those containing semicontinuous fibers that are intended to carry the load during matrix-microcracking in a service-overload condition (Ref 11). Examples of oxide-matrix composites toughened by the dispersion of a second phase or material include the transformation-toughened zirconias (TTZ) (Ref 12), zirconia-toughened aluminas (Ref 13), and silicon carbide whisker-reinforced alumina and mullite (Ref 14). Examples of continuous fiber-reinforced composites include silicon carbide fiber-reinforced glass-ceramic composites (Ref 15); glass or glass-ceramic matrices reinforced with silicon carbide, alumina, or other fibers (Ref 16); and continuous and discontinuous fiber-reinforced oxide-matrix composites in which the matrix is formed from the hydrothermal decomposition of metal-organic precursors (Ref 17).

Materials that develop a microstructure that mimics the geometry and function of second-phase additions in ceramic-matrix composites represent a recent innovation. A principal example of these so-called self-reinforced ceramics is silicon nitride, in which a beneficial acicular microstructure is developed through the combined effects of chemical composition and thermal treatment (Ref 18, 19).

Generally, structural ceramics have lower coefficients of thermal expansion (CTE) than those of metals. For example, the CTE of silicon carbide ranges from 4 to 5×10^{-6}/K and that of silicon nitride ranges from 3 to $3.5 \times l0^{-6}$/K. Of the metals, tungsten has the lowest CTE of 4.5×10^{-6}/K, but it is generally not considered to be a structural metal, because it is brittle and subject to oxidation at low temperatures. Although differences in CTE values can introduce damaging thermal stresses, even in ceramic-to-ceramic joints brazed with metals or glasses, there are significantly greater potential risks associated with ceramic-to-metal joints. Although a thin metal or glass layer at the joint may be able to yield or even fail in a noncatastrophic manner, thereby reducing damaging residual stresses, such reductions may be precluded by the material, size, and geometry of a metallic component.

The general statement that structural ceramics have lower CTEs than structural metals does not apply to the TTZ ceramics, which have CTE values that range from approximately 8 to 11×10^{-6}/K. Such relatively high thermal-expansion behavior is similar to that of structural metals, including some cast irons and ferritic and martensitic stainless steels, as well as low-expansion superalloys, such as Incoloy 909. A potentially close CTE match improves the likelihood of success when zirconia ceramics are attached to metals. The damaging residual stresses associated with other ceramic-metal combinations that have significant CTE differences can be avoided by either designing the joint to always be subjected to compressive stresses or introducing one or more interlayers or graded joints between the ceramic and the metal. Such techniques for accommodating CTE differences will be discussed below.

Another important consideration when dealing with ceramics is that they are brittle and, therefore, less tolerant of tensile loads, stress intensifiers, and thermal shock than are most metals. For example, even advanced ceramic-matrix composites have fracture toughness values ranging from only 8 MPa $\sqrt{m}$ (7.3 ksi $\sqrt{in}$) for silicon carbide whisker-reinforced alumina to 14 MPa $\sqrt{m}$ (12.7 ksi $\sqrt{in}$) for some TTZ. These values are less than those of cast aluminum alloys or cast irons. Finally, because the structural ceramics tend to have greater thermo-dynamic stability than metals, it is difficult to form in ceramic joints strong chemical bonds that enhance adhesion. As will be seen in the section "Processing" in this article, this stability can be overcome by adding active elements to brazing filler metals, or by coating the ceramic surface with an active element prior to brazing with a conventional filler method.

Processing. In general, three processing routes prevail in the fabrication of high-performance ceramics. In the sintering process, powder particles in a "green" body coalesce in order to effect densification. Sintering can be accomplished in some materials either with or without pressure. However, a totally solid-state process that does not use sintering aids is unusual. The role of the sintering aids varies from material to material. Generally, these aids promote densification by modifying the diffusional process. In some systems, the sintering aid remains as a solid throughout the process. However, in the case of the silicon nitrides and Sialons, material is transported through a liquid phase (not by surface diffusion) that is formed by the reaction of metal-oxide sintering aids and the silicon dioxide that coats each of the silicon nitride grains. In most cases, at least some residue of the sintering aid remains at the grain boundaries after the ceramic densities. This residue, which in many cases is a glass, can significantly affect the joining process.

Reaction sintering and reaction bonding are two special processes that have been developed for fabricating silicon carbide or silicon nitride ceramics without the large volume decrease associated with conventional sintering. Reaction-bonded silicon nitride is fabricated by the nitridation of a compact of silicon powder that has been formed into the desired shape by a process such as isostatic pressing, slip casting, or injection molding. Reaction-sintered silicon carbide is fabricated by exposing a compact of silicon carbide powder and carbon to molten or vapor-phase silicon, which reacts with the carbon to form *in situ* silicon carbide that bonds the original silicon carbide particles together. Reaction-sintered silicon nitride has superior creep resistance, because it is densified without sintering aids. However, it retains about 15% open porosity, which can wick a brazing filler material away from the joint area. Reaction-sintered silicon carbide can have significant amounts of unreacted metallic silicon that can affect joining by reacting with the active element (such as titanium) in the filler metal. Such reactions reduce the amount of active element available to react with the silicon carbide, thus reducing wetting tendencies and resulting in the formation of excessive amounts of embrittling titanium silicides in the joint.

Table 1 identities some structural ceramic materials and the properties that are important to the joining process. It should he noted that most of these materials are still in the development stage, having been manufactured only since the late 1970s. Any tabulation of properties serves only as a general guideline and not as engineering data. The mechanical properties of ceramics heavily depend on specimen preparation and size, as well as the type of test being conducted. These factors can also explain why there is so much variation among data compilations. It is important to note that the type of test and the specimen geometry used to characterize the strength or toughness of a brazement also can have a very significant effect on the measured property values. These effects are discussed more extensively in Ref 28.

TABLE 1 SELECTED PROPERTIES OF VARIOUS CLASSES OF STRUCTURAL CERAMICS

	FLEXURAL STRENGTH		**FRACTURE TOUGHNESS**		**COEFFICIENT OF THERMAL EXPANSION, 10^{-6}/K**	**THERMAL CONDUCTIVITY**		REF
	MPA	**KSI**	**MPA $\sqrt{m}$**	**KSI $\sqrt{in}$**		**W/M · K**	**BTU/FT · H · °F**

(A) AT ROOM TEMPERATURE

It is also important to note that alumina, silicon carbide, and other materials that are often considered to be single-component materials are, in fact, families of materials that may respond very differently to the conditions imposed in a joining procedure. For example, there are a wide variety of high-alumina ceramics ranging in aluminum oxide content from 79 wt% (alumina-mullite) (Ref 29) to 99.9 wt% (Ref 30, 31). Because these materials readily densify without pressure, they are almost invariably fabricated by pressureless sintering. The aluminas not only vary widely in chemical composition (and, thus, in the amounts and composition of grain-boundary phases), but also in grain size and porosity. The various high-alumina ceramics can, therefore, be expected to respond very differently during joining or service. Differences during joining might include the formation of different interfacial reaction products, depending on chemical composition of the ceramic, or the wicking of filler metal away from a brazed interface, in the case of a porous ceramic or graphite body.

The materials that are sometimes referred to individually as silicon nitride or silicon carbide also are families of materials, in actuality. Again, the compatibility of these materials with a filler metal or glass and the responses of these materials to the brazing process may vary widely, because of differences in sintering aids, processing techniques, degree of densification, and microstructural features (such as the acicular grains in the self-reinforced silicon nitrides). Thus, as a brazing procedure is being developed, it is very important that the actual ceramic be used in all wetting, adherence, and strength or toughness studies.

Brazing of Ceramic and Ceramic-to-Metal Joints

A.J. Moorhead and W.H. Elliott, Jr., Oak Ridge National Laboratory H.-E. Kim, Seoul National University

---

Graphitic Materials

Carbon, graphite, and composites based on these materials are somewhat similar to structural ceramics and ceramic-matrix composites, but they are different enough to require a separate discussion. Although both material types have high melting points and relatively low CTE values, structural ceramics are compatible with oxidizing environments, whereas the carbon-based materials typically begin oxidizing at temperatures ranging from 400 to 650 °C (750 to 1200 °F), depending on the perfection of the carbon structure and its purity.

In addition, many structural ceramics have little or no open porosity, whereas many carbon materials have significant amounts of open porosity. Such porosity complicates the brazing process by wicking filler materials away from a joint. On the other hand, carbon materials have higher thermal conductivity values and, in tandem with their low CTE values,

are much less sensitive to thermal shock. Finally, the carbon materials are also more creep resistant than structural ceramics.

Carbon materials vary widely in degree of crystallinity and crystal orientation and in the size, quantity, and distribution of porosity in the microstructure. These factors strongly depend on the precursor materials and on processing and, in turn, govern the physical and mechanical properties of these products. This potential for variation in properties can be advantageous, because properties that are significant from a brazing standpoint (such as CTE) can be readily modified by processing. For example, CTE values can be varied from essentially zero in the fiber direction in fiber-reinforced composites to 8×10^{-6}/K for isostatically molded isotropic graphites.

Carbons and graphites can be manufactured by several processes that yield materials with a wide range of crystalline perfection and properties. In the most widely used process, polycrystalline graphites are made from natural pitch sources or from cokes produced from the residue that remains from petroleum after all volatile materials have been removed. The coke product is broken up and then calcined at temperatures ranging from 900 to 1400 °C (1650 to 2550 °F) to further reduce the volatile content and create a filler coke that will not shrink excessively during subsequent heat treatments.

The calcined coke is crushed, milled, and sized through screens into various fractions. The size of the particles in the coarse fraction may exceed 1 mm (0.04 in.) in large bodies and may be as small as 0.1 mm (0.004 in.) in smaller blocks, depending on the desired properties. The shape and properties of the crushed coke particles primarily depend on the coke source. Some cokes naturally break up into highly anisotropic particles with platelike or needlelike shapes, whereas others produce rounder isotropic particles.

The size fractions are mixed according to the properties that are desired in the final material, and then blended with a hot coal-tar pitch. The pitch creates a plastic mix that can be shaped by extrusion or molding. The shape of particles is important, because forming processes tend to preferentially align the anisotropic particles. Particles that are aligned in this manner as the result of extrusion or molding processes produce bodies with highly anisotropic properties.

The formed body is typically baked in large gas-fired floor furnaces to pyrolize the binder pitch at temperatures ranging from 800 to 900 °C (1470 to 1650 °F). During baking, the binder experiences a weight loss of approximately 50 to 60% and a volume loss that is even greater. The effect is a reduction in overall density and subsequently increased porosity. Density can be increased by rebaking after impregnation with low-melting-point, high-viscosity pitches. Special impregnants, such as thermosetting resins or mixtures of resins and pitches, can be used to control porosity. Final graphitization of carbon bodies is achieved at temperatures ranging from 2300 to 3000 °C (4170 to 5430 °F) in an electric furnace similar to those used to produce silicon-carbide grains.

Carbon-carbon composites consist of carbon or graphite fibers in a carbon or graphite matrix. The fibers have been made into yarns that are then woven into either two-dimensional fabrics or three-dimensional bodies of the desired shape. These preforms are then combined with a matrix to form a composite by either of two processes: liquid impregnation or chemical-vapor infiltration (CVI) (Ref 32). In the former, a preform is impregnated with liquid phenolic resin or pitch, baked to reduce porosity, and graphitized. The process of impregnation under pressure, carbonization, and high-temperature heat treatment is typically repeated five or more times in order to produce a composite that has a higher density and a stronger matrix.

In the CVI process, gaseous hydrocarbons, such as methane, are used to deposit an internal carbon matrix within a carbon-fiber preform. Several specialized procedures have been developed to overcome a major problem with the CVI process, which involves achieving a uniform deposition of the carbon matrix throughout a thick preform.

The carbon-carbon composite bodies that result from either process generally have very high tensile strength values, as well as low CTE values, which provide excellent resistance to thermal shock or stresses. However, these materials tend to be anisotropic, and their mechanical strength is much lower in directions that are not reinforced with fibers, such as between plies in two-dimensional bodies. In addition, for applications in which oxidation resistance of the composite is a concern, the materials are given a primary oxygen barrier consisting of an external coating of a ceramic, such as silicon carbide or silicon nitride, and internal inhibitors, such as compounds of boron, titanium, and silicon. At high temperatures, the latter materials form glassy oxide phases within the composite, which seal any CTE mismatch-induced cracks that form in the coating and restrict passage of oxygen through the porous matrix.

Of course, such oxidation-protection methods can significantly affect the brazing of these materials. One consideration, for example, would be whether the external coating is applied before or after brazing, because the coatings are applied at

temperatures from 1000 to 1400 °C (1830 to 2550 °F), depending on the process. The glass-forming inhibitors may also affect wetting and/or adherence of a brazing filler metal.

Brazing of Ceramic and Ceramic-to-Metal Joints

A.J. Moorhead and W.H. Elliott, Jr., Oak Ridge National Laboratory H.-E. Kim, Seoul National University

Procedure Development

Although ceramic joining technology has been highly developed since the 1940s, most of the effort has been directed toward the development of materials and techniques for applications involving "low" temperatures and low structural stress requirements. The technology of joining ceramics for use at elevated temperatures, at high stress levels, and in dirty environments is less well developed. By the careful selection of location or through judicious design, a joint in such applications may not be required to withstand the full intensity of the various service conditions. However, it is highly desirable that a ceramic-to-ceramic or ceramic-to-metal joint be capable of operation at near-peak conditions.

Wetting and adherence are the principal requirements for brazing. However, most ceramic and graphitic materials are inherently difficult to wet using the more-common filler metals. Most filler metals simply ball up when melted in contact with a structural ceramic or graphite. This problem can be overcome by either coating the ceramic surface with a suitable metal layer prior to brazing (indirect brazing) or using specially formulated filler metals that wet and adhere directly to an untreated ceramic surface (direct brazing).

Indirect Brazing. In this technique, the ceramic is first coated in the joint area with a material that can be wetted by a filler metal that will not wet the untreated surface. Coating techniques include sputtering (Ref 33, 34, 35, 36), vapor plating (Ref 37, 38, 39), and thermal decomposition of a metal-containing compound (Ref 40). The coating is usually, but not always, a metal. For instance, Hammond and Slaughter (Ref 41) re-acted chromium vapor with the surface of a graphite body to form a coating of chromium carbide. For graphite coated in this manner and then brazed with pure copper, the shear strength at room temperature and at 700 °C (1290 °F) was 140 MPa (5.8 ksi). Failure occurred at the chromium carbide and carbon interface.

The most widely used brazing technique for joining alumina ceramics is the molybdenum-manganese (Mo-Mn) process, in which a slurry consisting of powders of molybdenum and/or molybdenum trioxide (or tungsten/tungsten tri-oxide), manganese or manganese dioxide, and various glass-forming compounds is applied to the ceramic in the form of a paint. The coated ceramic is fired in a wet hydrogen atmosphere at a temperature of approximately 1500 °C (2730 °F). During firing, glassy material from the ceramic migrates into the molybdenum (or tungsten) powder layer, bonding it to the ceramic surface. Because the process depends on this glass migration out of the ceramic, it is also dependent on such factors as amount and viscosity of the glassy phases, ratio of grain size in the ceramic to the pore size in the molybdenum powder, and processing temperature and atmosphere. The molybdenum-manganese process is a well-developed commercial process that was thoroughly reviewed in a series of papers by Twentyman (Ref 42, 43, 44).

An example of using physical vapor deposition for coating is described by Santella (Ref 39), who coated cold isostatic pressed and sintered silicon nitride with a 1.0 μm (0.04 μin.) thick layer of titanium using vacuum evaporation, and then brazed the silicon nitride to itself and metals with standard (nonactive) filler metals. The room-temperature flexural strengths of some of the silicon nitride-silicon nitride brazements were comparable to that of the silicon nitride itself (Fig. 1). By depositing the titanium using vapor plating, Santella produced strong joints and overcame a problem that arose in earlier work.

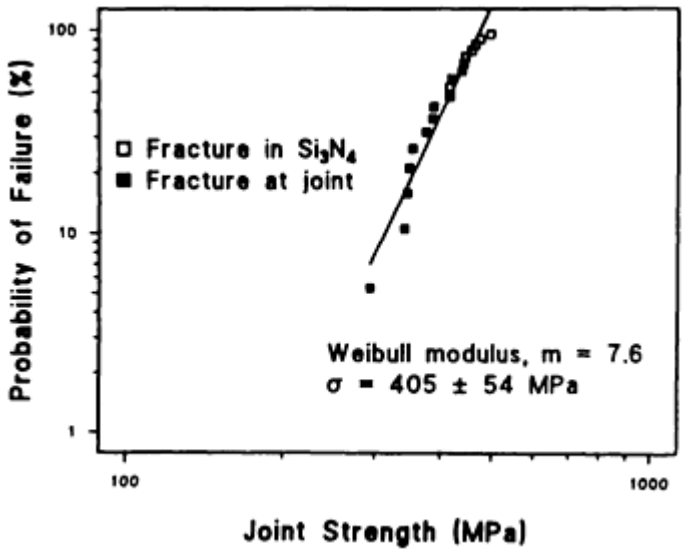

FIG. 1 FOUR-POINT FLEXURAL STRENGTH OF TITANIUM-VAPOR-COATED SILICON NITRIDE BRAZED TO ITSELF AT 1130 °C (2065 °F) WITH A AU-25NI-25PD, WT%, FILLER METAL. SOURCE: REF 39

In that earlier work (Ref 34), partially stabilized zirconia (PSZ) was coated by sputtering titanium and then brazed at 750 °C (1380 °F), either to nodular cast iron or to titanium with a commercial silver-copper-tin filler metal. Room-temperature shear strengths of both the PSZ/nodular cast iron and PSZ/titanium joints were about 140 MPa (20 ksi). However, at 400 °C (750 °F), the shear strength of the PSZ/ nodular cast iron brazement was only 28 MPa (4 ksi). Santella found that titanium coatings deposited by sputtering contain microporosity (apparently from trapped plasma gas) that coagulates during brazing and adversely affects high-temperature mechanical properties. Physical deposition of titanium by evaporation in a vacuum solved this problem.

Kohno *et al.* (Ref 45) coated silicon nitride by brazing at 1200 °C (2190 °F) with iron-nickel-chromium "paints" that contained silicon and carbon as melting-point depressants. They determined the adherence of the coatings by brazing the ceramic to itself at 1200 °C (2190 °F) with the paints themselves, and they achieved four-point bend strengths ranging from 125 to 200 MPa (18 to 29 ksi), depending on paint composition. However, the strength of similarly coated silicon nitride brazed to Kovar at 830 °C (1525 °F) with a silver-copper filler metal was only 50 MPa (7 ksi), apparently the result of damaging residual stresses.

Dunn *et al.* (Ref 46) studied the effects on mechanical properties of three silicon nitrides of various coatings applied by electron-beam evaporation. Polished bars were coated with hafnium, titanium, tantalum, or zirconium prior to being subjected to a thermal cycle simulating a brazing process (10 min at 980 °C, or 1795 °F, in vacuum) and then tested in four-point bending. The investigators found that zirconium and hafnium coatings did minimal damage to the silicon nitride. Titanium was found to be the coating most damaging to SNW-1000 (Si_3N_4-$13Y_2O_3$-$2Al_2O_3$), and it was even more severely damaging to AY6 (Si_3N_4-$6Y_2O_3$-$2Al_2O_3$). Interestingly, the effect of any of the coatings on PY6 material, which contains 6 wt% yttrium oxide, but no aluminum oxide, was minimal, which suggests a role for aluminum oxide in the property degradation of silicon nitride by active metal coatings. When silicon carbide was coated, heated, and tested in the same way, it was found that the hafnium coating was the most damaging.

Direct Brazing of Ceramics With Metallic Filler Metals. As mentioned above, most brazing filler metals will not wet structural ceramics and graphitic materials. Standard filler metals used to braze metals simply form a ball when melted in contact with a structural ceramic or graphite. This is due to the fact that the ceramic surface has very low surface energy, which means that there is no thermodynamic driving force for interface formation (wetting), as would be the case if a high surface energy surface were being wetted. However, for a number of years, it has been known that special alloying additions to conventional filler metals, such as the silver-copper eutectic composition, can promote wetting of and adherence to structural ceramics and graphite. The wetting of an untreated ceramic by a molten metal and the adhesion in such a system increases with the growing affinity of the metal constituents for the elements constituting the solid phase (Ref 47). Thus, the addition of chemically oxygen-active metals, such as titanium, zirconium, hafnium, aluminum, silicon, manganese, or lithium, should enhance both the wetting of and adherence to oxide ceramics, without the need for coating

the ceramic surface. In the same way, the wetting of and adherence to nonoxide ceramics, such as silicon carbide and silicon nitride, are aided by filler metals containing elements that strongly interact with silicon, carbon, or nitrogen. Whether the ceramic is an oxide, carbide, or nitride, the active metal reacts with the ceramic surface, forming an interfacial layer that can be wetted by the bulk of the filler metal.

Titanium is the most extensively studied and widely used active element added to filler metals formulated to directly braze structural ceramics and graphite (Ref 48, 49, 50, 51, 52). In the case of oxide ceramics brazed with titanium-containing filler metals, the critical interfacial reaction product is either titanium monoxide or dititanium trioxide, with appreciably higher adhesion resulting when titanium monoxide is formed (Ref 53). Titanium additions to filler metals have also been shown to enhance wetting of and adherence to silicon carbide (Ref 54), silicon nitride (Ref 55), and Sialon (Ref 56). The reaction products of the wetting process in the latter cases are titanium silicides, titanium carbides, and titanium nitride.

In recent years, there has been significant research in the use of another active element, aluminum, as a brazing material in joining silicon nitride and silicon carbide. In the case of silicon nitride, the reaction product after brazing with aluminum at 800 °C (1470 °F) was identified as a 500 nm (20 μin.) thick dual layer consisting of a fine-particle layer of β'-Sialon attached to the silicon nitride and an amorphous aluminum oxide layer (Ref 57, 58). The interfacial reaction product observed when silicon carbide is brazed with aluminum filler metal has been identified as aluminum carbide (Ref 59).

Some of the commercially available filler metals that have been developed for direct brazing of structural ceramics are shown in Table 2. Note that numerous active filler metals have been developed and, in many cases, patented, but only relatively few are commercially available. Generally, these filler metals consist of two types: those that have a relatively high active element content and will wet and flow on structural ceramics and graphite, and those that represent a new generation of materials that have a lower active element content and will wet and strongly bond to these ceramics, but only flow onto the ceramic surface very slowly, if at all (Ref 61). Therefore, filler metals in the latter category are preplaced between the mating components, rather than relying on capillary attraction to draw them into the joint. The filler metals with a high active element content are manufactured in the form of composites (such as a titanium core inside a sheath of silver-copper eutectic), because such high titanium contents form brittle and, therefore, unfabricable structures.

Direct Brazing With Nonmetallic Glasses. Numerous studies have been conducted to develop materials and techniques for joining structural ceramics, including alumina (Ref 62), PSZ (Ref 63), silicon nitride (Ref 64, 65, 66, 67, 68), and Sialon (Ref 69, 70) by brazing with nonmetallic glasses used as filler materials. The rationale for this approach is that many ceramics have amorphous phases remaining at the grain boundaries after the sintering process. Therefore, they would be expected to be wet by and compatible with similar glassy materials introduced at the joint. Glass viscosity and flow properties can be controlled over a wide range of temperatures. However, glasses have much lower toughness values than even monolithic ceramics, as well as low Young's modulus values, and are susceptible to stress corrosion (slow crack growth). As will be described below, some of the glasses, even those formulated to match the grain-boundary composition, have significantly different CTE values from that of the ceramic, which causes high residual stresses and cracking in the joint.

Generally, powdered glass in a slurry with a binder is applied to one or both of the mating components of a joint that is heated until the glass melts and reacts with the ceramic. In a variation of the process (Ref 66), the surface of one of the components was first coated with molten glass, and this glazed surface was ground to precisely control the thickness of the joining material. In another variation (Ref 64), aluminum foil was placed in a silicon nitride joint, along with sources of alumina and silicon dioxide, such as powders or oxidation layers on the aluminum and silicon nitride. The joints so produced had three-point bending strengths ranging from 35 to 210 MPa (5 to 30 ksi) at both room temperature and 1200 °C (2190 °F). In contrast to diffusion welding with high pressures applied to the joint area, brazing with glasses and metals uses relatively low pressures ranging from that provided by the weight of one of the parts being joined to 14 MPa (2 ksi) (Ref 63). Typical atmospheres are air (when joining oxides) and nitrogen (when joining silicon nitride).

The most extensive studies on brazing with glasses have been those on silicon nitride. The glasses include those similar to that which is found at the grain boundaries of a hot-pressed silicon nitride ($55SiO_2$-$35MgO$-$10Al_2O_3$) (Ref 66, 68, 69) and a very different CaO-TiO_2-SiO_2 (CTS) glass ($35CaO$-$25TiO_2$-$40SiO_2$) (Ref 67). Baik (Ref 65) stated that there are three potential problems when joining silicon nitride by brazing with glasses:

- A REACTION BETWEEN THE GLASS AND SILICON NITRIDE FORMS ACICULAR SILICON OXYNITRIDE CRYSTALS THAT PREVENT THE FORMATION OF A MICROSTRUCTURE TYPICAL OF A GRAIN BOUNDARY
- CTE MISMATCHES CAUSE CRACKING IN THE GLASS
- POROSITY FORMS IN THE GLASS LAYER DURING BRAZING OR UPON SUBSEQUENT HEATING TO ELEVATED TEMPERATURES

Such behavior was observed by Johnson and Rowcliff (Ref 66), who reported excellent strength (maximum of 400 MPa, or 58 ksi, within the optimum bonding conditions of 30 to 60 min and 1575 to 1650 °C, or 2870 to 3000 °F) in joints brazed with the composition similar to that found in the grain boundaries. However, significant cracking and porosity occurred in the joints. The cracking was attributed to differences in CTE, whereas the porosity was thought to result either

from the vaporization of silicon monoxide and magnesium or from the volume change associated with the formation of silicon oxynitride crystals.

Iwamoto (Ref 67) minimized the cracking problem by using a CTS glass that had a CTE value less than that of the silicon nitride and by mixing silicon nitride powder with the glass powder. At room temperature, the resulting joints had four-point bending strengths ranging from 235 MPa (34 ksi) with no silicon nitride powder in the glass to 272 MPa (44 ksi) with glass containing 30 wt% silicon nitride powder.

Baik (Ref 65) alleviated the porosity problem that he attributed to the decomposition of the silicon nitride to silicon and nitrogen by adding elemental silicon to a magnesium-silicon-oxynitride glass to increase the silicon activity and, thereby, retard the formation of nitrogen gas.

Neilson (Ref 69) and Coon (Ref 70) used glasses in the yttrium-silicon-aluminum-oxynitride system to bond a sintered Sialon at 1600 and 1725 °C (2910 and 3140 °F) under an applied load of 0.63 N (0.14 lbf) and nitrogen gas pressures of 138 and 207 MPa (20 and 30 ksi), respectively. Joint fracture toughness values (approximately 4.5 MPa$\sqrt{m}$, or 4 ksi$\sqrt{\text{in.}}$) and four-point flexure strengths (approximately 450 MPa, or 65 ksi) at temperatures to 1000 °C (1830 °F) were equal to that of the Sialon. At temperatures greater than 1000 °C (1830 °F), the strength of the joints made at 1600 °C (2910 °F), which contained significant amounts of glass (glass-filled joint), decreased rapidly until at 1100 °C (2010 °F) it was only 25 MPa (4 ksi). However, the joints produced at 1725 °C (3140 °F) (closed joint with little retained glass) had strengths of 200 MPa (29 ksi) at 1250 °C (2280 °F).

In addition to the above-mentioned study on the joining of silicon nitride, a CTS glass was also investigated for joining a magnesia-PSZ ceramic (Ref 63). The use of this type of glass was chosen because the system has several eutectic compositions with melting temperatures below the 1400 to 1500 °C (2550 to 2730 °F) annealing range of the ceramic. Therefore, the brazing step could be combined with the annealing treatment of this material. An applied pressure of 14 MPa (2 ksi) was used to distribute the molten glass through the joint. Unfortunately, the differences in the CTE values of the materials resulted in extensive cracking through the glass and interface when the joint area was large (20 cm^2, or 3 $in.^2$). Based on the work of Iwamoto (Ref 67), the CTE of the interlayer was made closer to that of the PSZ by adding 30 wt% zirconium oxide to the CTS interlayer powder. Using a thinner layer of the modified powder and a longer pressing time at 1420 °C (2590 °F), joints that had average four-point bending strengths of 66 MPa (10 ksi) were produced.

Several glass compositions were investigated for joining alumina ceramics (Ref 62). This work differed from that of the preceding studies in that one of the goals of these researchers was to initiate and control crystallization of the glass in the joint to increase fracture toughness and resistance to stress corrosion. Zirconium oxide powder was added to a magnesium aluminum silicate glass as a nucleating agent. Unfortunately, spontaneous crystallization occurred at the glass-alumina interface, limiting the desired degree of control over crystallization and resulting in large voids at the interface. Accordingly, the fracture toughness of the joint was only 1.8 MPa$\sqrt{m}$ (1.6 ksi$\sqrt{in}$) versus a value of about 4 MPa$\sqrt{m}$ (3.6 ksi$\sqrt{in}$) for the alumina (no joint strength data reported). The most successful joints (fracture toughness of 2.3 MPa$\sqrt{m}$, or 2.1 ksi$\sqrt{in}$) resulted when the alumina was joined at 1500 °C (2730 °F) with a mixture of 50 wt% talc (hydrated magnesium silicate) and 50% aluminum oxide. However, these joints contained a substantial number of pores that degraded the mechanical integrity of the joints. The authors suggested that the pores were caused by the evolution of adsorbed gases from the alumina body and, therefore, would be difficult to eliminate.

Alternate Brazing Techniques. Although brazing is typically accomplished through melting of a metallic alloy or glass-forming compound placed in the joint area, there are some other viable techniques for generating a liquid at an interface to effect a brazement. The most common of these, generally referred to as "eutectic brazing," relies on the reaction at the interface of an insert material or of the metallic member of a ceramic-metal joint with either the ceramic, another metal, or even a gaseous component of the atmosphere. Such reaction is based on the presence of a low-melting region (typically a eutectic reaction) of the respective phase diagram, and hence comes the name of the process.

The most widely studied of the eutectic brazing processes, known as gas-metal eutectic brazing, is based on the formation of a liquid skin on the metallic member as a result of reaction with the atmosphere (Ref 71, 72, 73). According to Burgess *et al.* (Ref 71), the idea is to form a liquid skin on a metal surface, with the requirement that the liquid wets both the ceramic and metal components being joined and forms a strong bond on cooling. Ideal for use as the liquid skin material are eutectics formed by the reaction of the brazing atmosphere with the metal component itself. Such a eutectic exists between copper and oxygen at 0.39 wt% oxygen. The melting point of this eutectic, 1065 °C (1950 °F), is sufficiently below the melting point of pure copper, 1083 °C (1980 °F), so that by careful temperature control an oxide ceramic can

be brazed to a copper component using this liquid. According to Yoshino (Ref 72) this technique is used in the electronics industry to manufacture copper-bonded alumina substrates for power semiconductor applications. Generally the copper is preoxidized prior to the joining operation, but Okamoto and coworkers (Ref 73)joined alumina to mild steel by simply using a copper filler metal foil in a slightly oxidizing atmosphere at 1200 °C (2190 °F). In addition to the copper-oxygen system, Burgess suggests that other beneficial metal-gas eutectics for joining might be iron-oxygen, nickel-oxygen, and cobalt-oxygen and even silver-phosphorus, nickel-phosphorus, copper-phosphorus, or molybdenum-silicon, and aluminum-silicon. The latter two types would be achieved by having small amounts of a phosphorus or silicon bearing compound (such as phosphine or silane) in the atmosphere.

A metal-metal eutectic was used by Naka and Okamoto (Ref 74) to braze an alumina (99.6 wt% Al_2O_3) to type 304 stainless steel. Titanium foil, which melts at 1670 °C (3040 °F), was placed between the two base materials and heated to 1400 °C (2550 °F) in vacuum of 0.13 mPa (1×10^{-6} mm Hg). The investigators suggest that the bond was made by the eutectic in the titanium-iron system at 68 at.% Ti at 1085 °C (1985 °F).

A recent and possibly very significant variation of the eutectic brazing process is one termed "partial transient liquid-phase" joining (Ref 75, 76). This process is based on the well-known transient liquid-phase bonding of nickel-base and cobalt-base superalloys (Ref 77). In this earlier work, a melting point depressant such as boron was added to a brazing filler metal and subsequently diffused into the base metals during brazing. Removal of the boron from the braze joint rids the brazement of embrittling compounds and results in a higher remelt temperature.

In the recent modifications of this process for joining of ceramics, three layers of metal are preplaced in the joint, with the outer two layers much thicker than the center layer. When the composite is heated, a thin film of low-melting-point liquid forms at the interfaces to make the braze, but the center layer is not totally consumed. Further holding at temperature results in diffusion of the liquid layer into the center layer, resulting in a more heat-resistant joint. The new process is termed "partial" transient liquid-phase joining because the transient liquid phase is formed only near the interface and the metal layer is not fully homogenized. One example of this process, cited by Iino (Ref 75), uses a thin layer of titanium on either side of a much thicker layer of nickel. According to the nickel-titanium phase diagram, when a nickel-titanium bilayer is heated at 1050 °C (1920 °F), a liquid phase occurs in the composition range of 60 to 75 wt% Ti. Because the titanium layer is much thinner than the nickel layer the liquid layer forms, the braze is made and then the liquid disappears as the titanium diffuses into the nickel and the local concentration of titanium falls below the liquidus line (below 60 wt%). If, by further diffusion, the titanium content falls below 30 wt%, the remelt temperature would be 1304 °C (2380 °F).

Shalz and coworkers (Ref 76) are considering a number of other possible material combinations for joining of ceramics such as alumina. Their work to date has included tri-layer compositions of copper/platinum/copper, copper/nickel/copper, copper/niobium/copper, and tin/ niobium/tin for joining alumina to alumina. The results of high-temperature postbonding anneals suggest that copper/platinum/copper and copper/ niobium/copper bonded alumina assemblies may be suitable for use at elevated temperatures in oxidizing and nonoxidizing environments, respectively.

Surface Preparation. Whether the filler material is a metal or glass, one of the initial decisions that must be made in brazing procedure development is the technique for preparing the ceramic surface. Although an as-fired surface is sometimes suitable for brazing, at least some machining is usually required to provide the contact surfaces necessary for joining. Because the machining of ceramic surfaces must generally be done by grinding with diamond-abrasive wheels, which is an inherently slow and costly process, surface preparation should be minimized. A surface preparation technique that is economically feasible, provides adequate surface finish and tolerances, and causes minimal damage to the ceramic is optimal. Unfortunately, ceramic machining itself is currently experiencing significant development, and it is not possible to recommend a set of grinding conditions (wheel grit, feeds, speeds, and such) that efficiently removes ceramic material while minimizing surface damage. However, enough information is available to state that the effect of a given preparation procedure on the ceramic is very material specific, even within a given family of ceramics.

For example, in working with an alumina ceramic containing 97.6% Al_2O_3, Mizuhara and Mally (Ref 50) found that grinding damage could be negated by retiring the ground parts at 1650 °C (3000 °F). Such a firing step, which apparently healed surface flaws induced during grinding, resulted in much higher peel strengths in Kovar/refired alumina joints brazed with silver-40 at.% copper plus titanium than in similar joints between Kovar and as-fired, ground, or ground/lapped alumina. However, a heat treatment of a higher-purity alumina (containing 99.5% Al_2O_3) after grinding did not have the same effect. Joints made with resintered samples of this alumina were much stronger than those made with ground material, but not as strong as those made with unground or ground/lapped alumina. It is assumed that the amount of glassy phase in the 99.5% alumina was insufficient to heal or blunt many of the grinding defects under the heat-treatment conditions used.

In the experience of the authors, a very different response to surface preparation has been observed among materials. For example, as shown in Fig. 2, it was found that the three-point bend strength of high-purity alumina (McDanel AD-998) ceramic-to-ceramic joints brazed in vacuum for 5 min at 800 °C (1470 °F) with an experimental filler metal were essentially the same, whether the joining surfaces were ground with a 180-grit diamond abrasive wheel or ground and then polished with 6 μm (240 μin.) and 3 μm (120 μin.) grit diamond pastes.

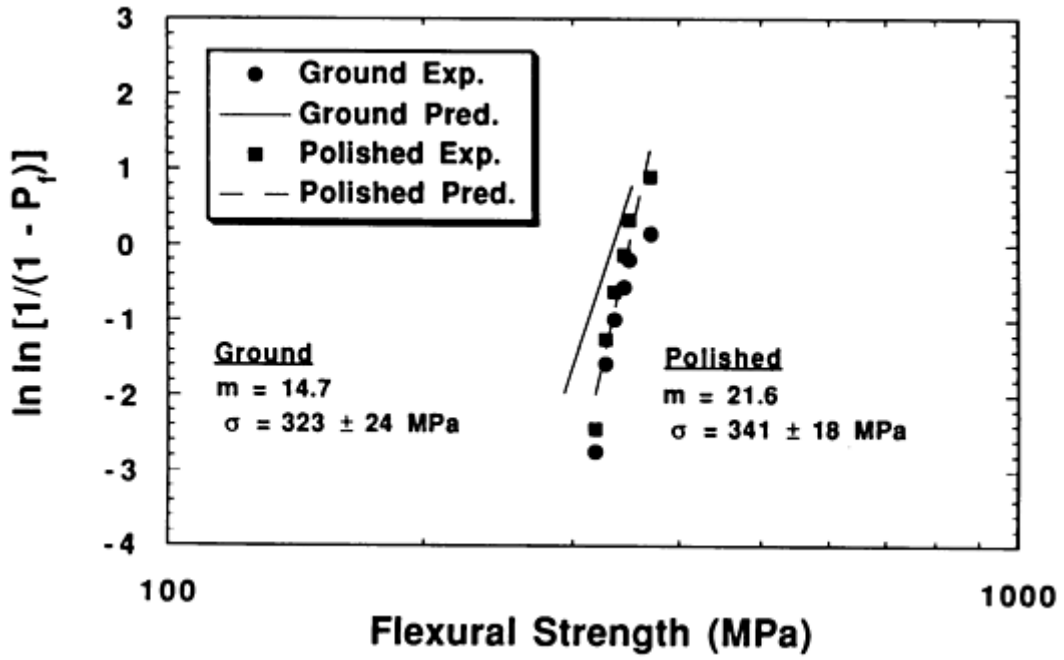

FIG. 2 EFFECT OF POLISHING INTERFACIAL AREA ON STRENGTH OF CU-41AG-3.5SN-7TI, AT.%, BRAZEMENT IN MCDANEL AD-998 ALUMINA

On the other hand, polishing the mating surfaces of coupons of silicon carbide whisker-rein-forced alumina prior to brazing led to significantly higher joint strengths, as shown in Fig. 3.

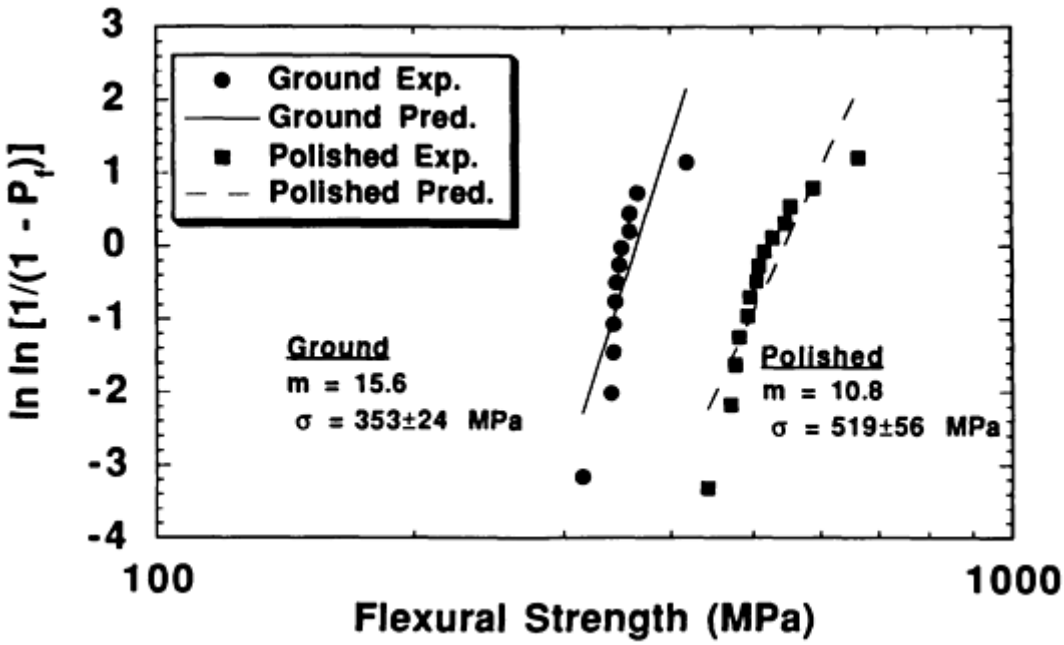

FIG. 3 EFFECT OF POLISHING INTERFACIAL AREA ON STRENGTH OF CU-41AG-3.5SN-7TI, AT.%, BRAZEMENT

IN SILICON CARBIDE WHISKER-REINFORCED ALUMINA

Examination of typically prepared coupons of both materials by scanning electron microscopy revealed that the morphologies of the ground surfaces were very different. As shown in Fig. 4(a), the ground alumina surface exhibited predominantly intergranular fracture, although some transgranular fracture was also evident, such as the grain just left of center. However, the most notable features in the alumina microstructure were the many cracks that appear to be both intergranular and transgranular. The microstructure of the ground composite (Fig. 5a) exhibited the general striations typically of grinding, with linear regions of predominantly transgranular fracture separated by areas with a "smeared" appearance suggesting plastic flow. Although the concept of plastic flow in an inherently brittle ceramic may seem incongruous, this behavior has been widely observed in machined ceramic surfaces. Despite the fact that the grain size in the alumina was much larger than that of the silicon carbide whisker-reinforced alumina material, the polished microstructures were somewhat similar (Fig. 4b, 5b), with both materials showing evidence of porosity and grain pullouts.

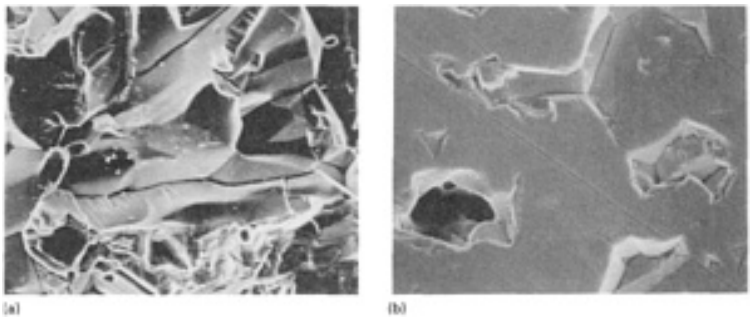

FIG. 4 SCANNING ELECTRON MICROGRAPHS OF SURFACE OF MCDANEL AD-998 ALUMINA AS PREPARED FOR JOINING. (A) GROUND, ROOT MEAN SQUARE (RMS) ROUGHNESS, R_Q, OF 0.63 μM (25 μIN.). (B) GROUND/POLISHED, R_Q OF 0.15 μM (6 μIN.). 3000×

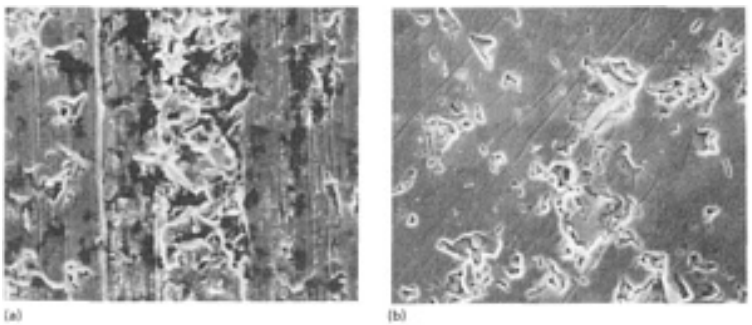

FIG. 5 TOPOGRAPHY OF SILICON CARBIDE WHISKER-REINFORCED ALUMINA SURFACES TO BE JOINED. (A) GROUND, R_Q OF 0.35 μM (14 μIN.). (B) GROUND/POLISHED, R_Q OF 0.04 μM (1.6 μIN.). 3000×

However, when the edges of the coupons were examined by scanning acoustic microscopy at 50 MHz before and after polishing, very significant differences were observed. Although the polishing of the composite material reduced the defect population, the procedure actually induced new subsurface defects in the alumina. A different set of grinding/polishing conditions might not produce the same results, but the importance of surface preparation on brazement strength should be obvious.

The brazing parameters themselves, that is, temperature, time at temperature (actually, the entire thermal cycle) and atmosphere, play a major role in the properties of a brazement and, therefore, are of critical importance in procedure development. Because strong bonds depend on chemical reactions at the ceramic/filler metal interface, one might assume that the strongest joints result from the highest temperatures and longest times. In many cases, it has been experimentally found that increasing a given parameter does, in fact, increase joint strength. However, this is true only up to a point. The

authors and other researchers have found that joint strengths tend to reach a maximum as temperature and/or time are increased and then decrease with further increases, as illustrated in Fig. 6.

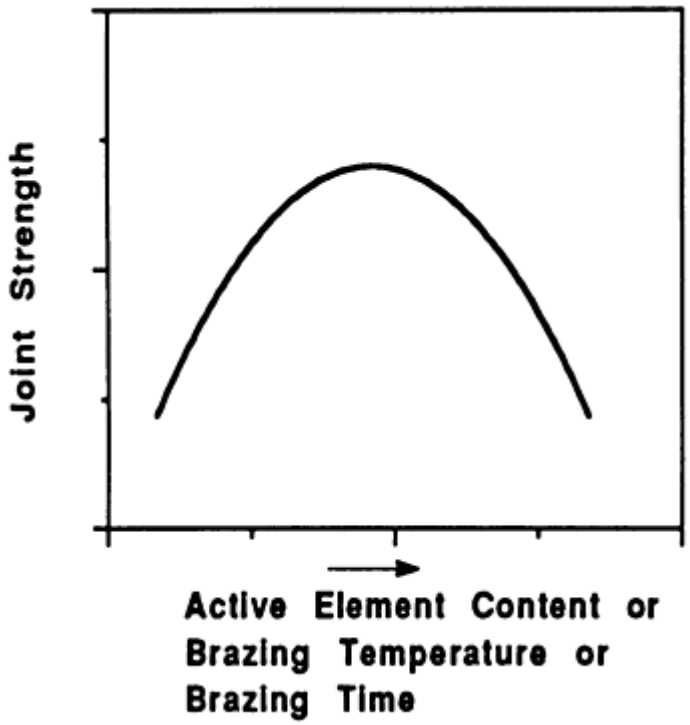

FIG. 6 RELATIONSHIP BETWEEN STRENGTH OF ACTIVE METAL BRAZEMENTS AND PRIMARY VARIABLES

For example, Kim and coworkers (Ref 78) observed this behavior when brazing a pressureless sintered silicon nitride with a series of copper-titanium filler metals. They found that the shear strengths of silicon nitride-silicon nitride joints were more affected by the morphology and thickness of the interfacial reaction layer than by wettability. As the titanium content of the binary filler alloys was increased, the equilibrium contact angle continually decreased, indicating improved wetting. As shown in Fig. 7, shear strength rapidly increased up to a relatively low titanium content of 5 wt% and then much more slowly afterwards. However, as shown in Fig. 8, the shear strengths initially increased and then decreased with further increases as temperature and time evidently exceeded optimum conditions. They attributed this behavior to excessive growth of the reaction layer, accompanied by the development of flaws in that layer.

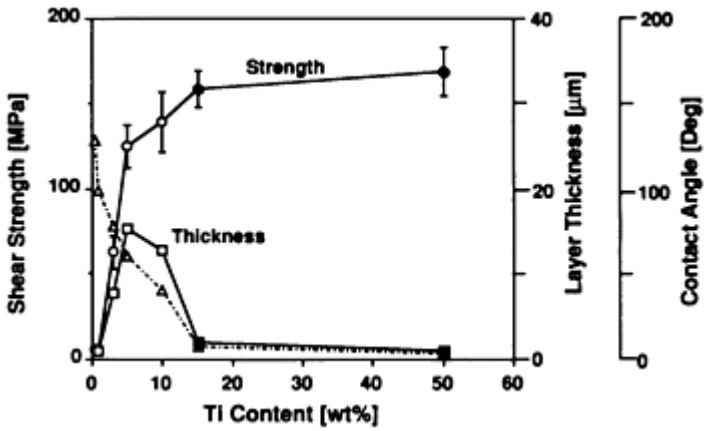

FIG. 7 EFFECT OF ACTIVE METAL CONTENT ON SHEAR STRENGTH, INTERFACIAL REACTION LAYER THICKNESS, AND WETTING ANGLE WHEN SILICON NITRIDE IS BRAZED WITH COPPER-TITANIUM FILLER METALS. OPEN DATA POINTS MEASURED AT 1100 °C (2010 °F), 1800 S; SOLID DATA POINTS MEASURED AT

1020 °C (1870 °F), 1800 S. SOURCE: REF 78

THE HOLDING TIME FOR THE BRAZEMENT OF (A) WAS 1800 S; THE SAMPLES FOR (B) WERE BRAZED AT 1130 °C (2070 °F). SOURCE: REF 78

The atmosphere used when brazing with active filler metals is also an important variable. Generally, a vacuum in the range of approximately 6 mPa (5×10^{-5} mm Hg) is used, but the literature of some manufacturers states that these filler metals can also be brazed in inert atmospheres, but of unspecified purity. Published reports have compared the strength of joints brazed in vacuum versus those brazed in inert gas, but little has been published on the effect of the actual magnitude of oxygen partial pressure on brazement wetting or adherence.

To facilitate an understanding of the effect of oxygen in the brazing atmosphere, the authors recently conducted a study that included PO_2 as one of the variables. A statistically designed experiment was conducted in order to objectively evaluate the role of certain parameters in the brazing of ceramic materials. An L9 orthogonal array and the Taguchi methodology were employed to examine four parameters at three levels on five different ceramic materials. The use of statistics in designing the experiment reduced the necessary number of brazing runs (for the five materials) from 320 to 45, while producing the same results. Each brazing run produced from six to twelve bend bars for testing. Therefore, the results were based on the average bend bar strength for each material and condition, or approximately 400 data points.

The materials were two aluminas (Coors AD-85, 85% Al_2O_3, and McDanel AD-998, 99.8% Al_2O_3), a silicon carbide whisker-reinforced alumina composite (Cercom PAD-AS30W), a sintered α-silicon carbide (Carborundum Hexoloy SA), and a sintered silicon nitride (GTE SNW-1000) that contained 13 wt% yttrium oxide (Y_2O_3) and 3 wt% Al_2O_3 as sintering aids. Material from a single lot of a commercially available brazing foil (GTE Wesgo's Cusil ABA, Ag-35Cu-2.0Ti, wt%) was used to join coupons of each ceramic material. The manufacturer recommends that this filler metal be brazed at temperatures ranging from 830 to 850 °C (1525 to 1560 °F), with a time at temperature of 3 to 10 min.

The mating edge of each coupon to be joined was prepared by one of three techniques: (1) Coarse grinding with a 180-grit diamond-impregnated grinding wheel; (2) Coarse grinding as in technique 1, followed by fine grinding with a 320-grit diamond wheel; or (3) Polishing the edges of some fine-ground coupons on a vibratory polisher using 6 μm (240 μin.) and 3 μm (120 μin.) grit diamond pastes. All of the grinding parameters, feeds, and speeds were held constant for coupons.

The brazing environments were flowing gases consisting of approximately 10, 100, and 1000 parts per million of oxygen in argon. The purity of the bottled argon was reduced to 10 ppm or less for each run by passing the gas through a commercial oxygen absorber. For the 100 and 1000 ppm runs, the $P\ O_2$ in the argon was controlled by mixing the purified argon with oxygen, and then measured with an oxygen analyzer with sensors located at the inlet and exit of the furnace tube.

The coupons were joined in a butt configuration in a silicon carbide fixture shown schematically in Fig. 9. The filler-metal foil was placed in the joint along with small, 38 μm (1.5 mil) thick tantalum shims on either end to prevent the joint

from closing completely under the slight end loading provided by 250 μm (0.01 in.) thick molybdenum sheet "springs." Both the shims and filler metal were held in place during assembly by small drops of a Nicrobraz cement.

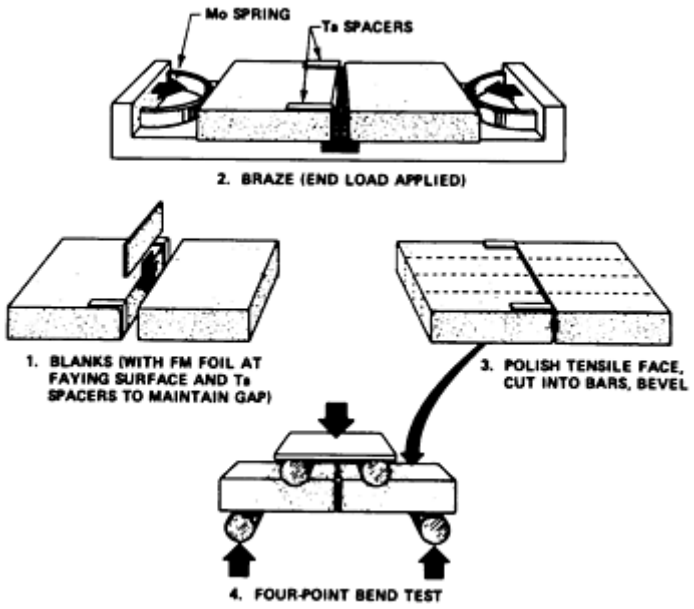

FIG. 9 SEQUENCE OF OPERATIONS FOR FABRICATING BRAZED FLEXURAL BARS FOR THREE- OR FOUR-POINT BENDING TESTS

It is important to note that because the filler metal was confined between the ceramic coupons, the authors do not know what the $P\,O_2$ actually was within that space. The filler metal that exuded from the joint during brazing was oxidized gray or black, but beneath the oxide layer, the filler metal was still bright and shiny. This observation was not surprising, because in a previous study on oxidation of titanium-containing brazing filler metals (Ref 79), the authors found that the oxidation followed a simple parabolic rate law. Such behavior is indicative of the formation of a nonporous, coherent oxide film acting as a physical barrier to restrict further oxidation. Although an arrangement that has the filler metal placed within the confines of the mating surfaces may not be typical for all brazements, the authors think it is typical for active-metal brazements made with filler metals containing relatively low amounts of the active species. The ability of these materials to flow through a capillary joint is restricted by their low titanium content, which requires that they be preplaced within the joint.

Brazing of the nine sets of coupons of each material was done in a resistance-heated, alumina-tube furnace. The brazing cycle consisted of heating to a brazing temperature of 800 °C (1470 °F), 850 °C (1560 °F), or 900 °C (1650 °F) in about 15 min, holding at that temperature for 6, 12, or 18 min, and then cooling to room temperature in about 90 min. After brazing, the coupons were attached to steel backing bars and ground on both faces using a 180-grit diamond-abrasive wheel with the grinding direction perpendicular to the braze joint. The ground blanks were polished (on what would become the tensile surface of the flexure bars) with 6 μm (240 μin.) and 3 μm (120 μin.) diamond pastes on a vibratory polishing machine. The polished brazed coupons were then sliced in a series of parallel cuts (Fig. 10) to produce 3 by 4 by 25 mm (0.12 by 0.16 by 1 in.) flexure bars with the brazed joint across the center of the bars. The long edges of the tensile face of each sample were beveled on a 6 μm (240 μin.) grit diamond lap. Each brazing run produced from six to twelve bend bars for testing. Testing was in four-point bending, with spans of 6.35 and 19.05 mm (0.25 and 0.75 in.) and a crosshead speed of 0.08 mm/s (3 mils/s).

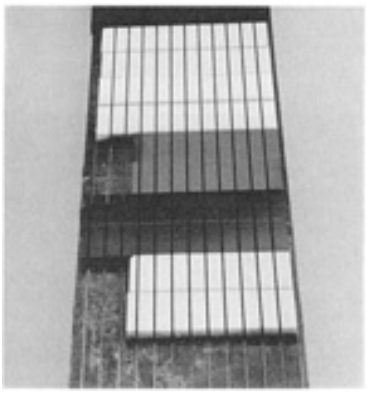

FIG. 10 POLISHED BRAZED COUPONS AFTER BEING SLICED IN A SERIES OF PARALLEL CUTS TO PRODUCE BARS FOR FLEXURAL STRENGTH TESTING

The results were very interesting and somewhat surprising. For example, very weak joints were produced in the sintered α-silicon carbide under many of the experimental conditions. In fact, the flexure bars from four of the nine brazements in this material failed after slicing. Because we have been able to prepare and test a number of bars with strengths of 20 MPa (3 ksi), we may assume that the failed bars had strengths less than that. As far as the effect of atmosphere is concerned, it was found that strong brazements could be produced in any of the materials, even when the oxygen partial pressure during brazing was 1000 ppm.

Figure 11 shows the ratios of the joint strength to ceramic strength for four of the materials. This figure illustrates that strong joints, with almost 50% of the bending strength of the respective ceramic, can be produced in each material, even in a relatively impure atmosphere. In order to make the comparisons valid, the strengths of the joints made with coarse-ground coupons brazed at 900 °C (1650 °F) for 12 min in an argon-1000 ppm O_2 atmosphere were used to calculate the ratios, not the maximum joint strength achieved for a given material. These were the conditions that produced the strongest brazement in the silicon carbide material, 256 ± 42 MPa (37 ± 6 ksi). The set of parameters, out of the nine sets of experimental conditions evaluated, that yielded the highest average joint strength for each material are given in Table 3. Interestingly, although these results may have been skewed by the failure of half of the silicon carbide brazements during bar fabrication, the recommended conditions (after statistical analysis of the results) that were predicted to produce optimum strength in the silicon carbide brazements were: 900 °C (1650 °F), 12 min, a coarse-ground finish, and 1000 ppm oxygen. In fact, two brazements in this material that were made in a vacuum of 4×10^{-3} Pa (3×10^{-5} mm Hg), which would be considered the "normal" atmosphere for active-metal brazing, for 6 min at 800 and 850 °C (1470 and 1560 °F), respectively, failed during flexure bar preparation.

TABLE 3 CONDITIONS FOUND TO PRODUCE THE HIGHEST AVERAGE JOINT STRENGTH WHEN BRAZING EACH OF FIVE STRUCTURAL CERAMICS WITH CUSIL-ABA IN AR-O_2 ATMOSPHERES

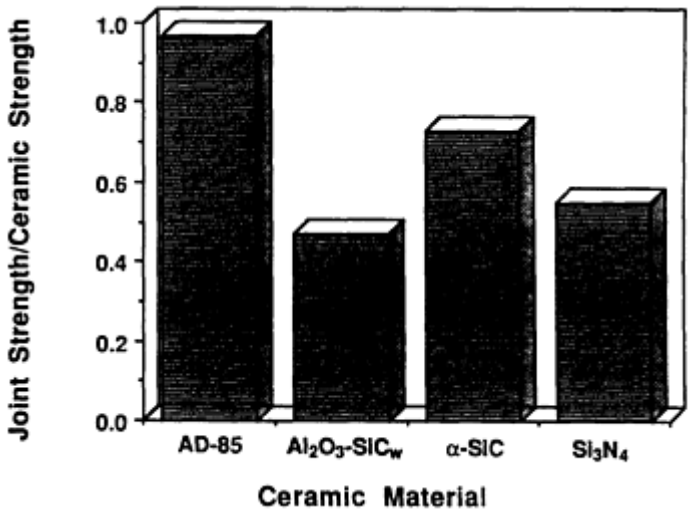

FIG. 11 RATIO OF JOINT STRENGTH TO CERAMIC STRENGTH FOR FOUR CERAMICS BRAZED WITH AG-35CU-2TI, WT%, FILLER METAL FOR 12 MIN AT 900 °C (1650 °F) IN AN AR-1000 PPM O_2 ATMOSPHERE

The statistical analysis also recommended the highest level of oxygen included in the experimental plan (1000 ppm), rather than 10 ppm, as one would anticipate, in the parameters *projected* to produce the highest strengths in brazements with this filler metal (Ag-35Cu-2.0Ti, wt%) in the AD-998 alumina and silicon nitride materials. The only material for which 10 ppm oxygen was recommended was the silicon carbide whisker-reinforced alumina composite. The necessary confirmatory braze runs have not been conducted, as of mid-1993, to determine whether even higher strengths are produced in the silicon carbide whisker-reinforced alumina and silicon nitride materials. The strengths of the alumina materials have already been exceeded by the strengths of the brazements made under several conditions.

However, the authors have conducted an interesting side study (outside the test matrix) that should provide some guidance to someone preparing a brazing procedure at this time. Coupons of the SNW-1000 silicon nitride ceramic were brazed as had been done before, but in a vacuum of 3 mPa (2×10^{-5} mm Hg), to determine whether that atmosphere had a significant effect on brazement strength. Very little differences in brazement strengths were observed. For example, the average strengths of the joints made with brazing conditions of 850 °C (1560 °F), 6 min, and a fine-ground joint surface were 505 ± 74 MPa (73.2 ± 10.5 ksi) and 496 ± 59 MPa (71.9 ± 8.5 ksi) for an atmosphere of vacuum and argon-1000 ppm O_2, respectively. These results suggest that atmosphere purity is not as critical as one might assume when brazing silicon nitride with an active filler metal (at least when the filler metal is preplaced in the joints).

Ceramic-to-Metal Joints

In addition to the factors considered above for ceramic-to-ceramic joints, there are specific factors that must be considered when developing a procedure for brazing ceramic-to-metal joints. One is that a thermal cycle must be chosen that does not degrade the properties of the materials being joined. Thermal exposure may be a problem for some structural ceramics, such as the magnesia-PSZ, the strength and toughness of which tend to be altered by exposure to temperatures of 1000 °C (1830 °F) and higher for only a few hours (Ref 80). However, most structural ceramics are thermally stable at temperatures typical of those used for brazing with active filler metals (see Table 2) or glasses. The problem, which has been deemed "thermal compatibility" by Pejryd (Ref 81), is generally more severe for the metallic member of a ceramic-to-metal joint. For example, he has shown (Fig. 12) that even a very modest thermal cycle can have a major effect on the mechanical properties of low-expansion superalloy Incoloy 909, which is often considered in the literature as a likely candidate metal in ceramic-to-metal joints. Such thermal behavior tendencies must be taken into account both during material selection and procedure development.

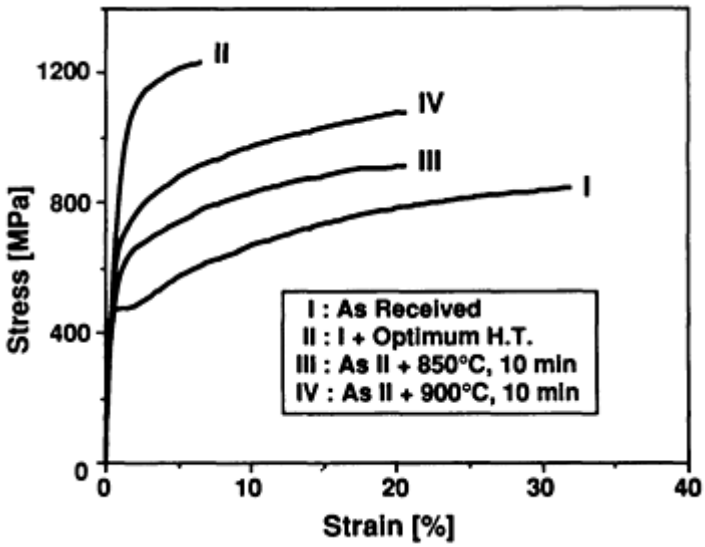

FIG. 12 TENSILE TEST CURVES FOR INCOLOY 909 SUBJECTED TO DIFFERENT BRAZING HEAT-TREATMENT CYCLES. SOURCE: REF 81

Another critical factor is the CTE mismatch of the materials. Differences in expansion behavior can generate significant thermal residual stresses in a ceramic-to-metal brazement, resulting in distortion and even failure during cooldown from the brazing temperature, as shown in Fig. 13.

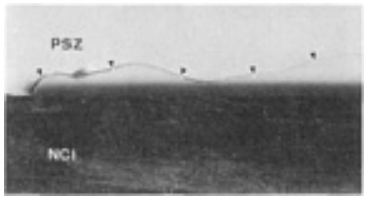

FIG. 13 FAILURE IN THE CERAMIC SIDE OF A CERAMIC-TO METAL BRAZEMENT RESULTING FROM A MISMATCH IN COEFFICIENTS OF THERMAL EXPANSION BETWEEN THE CERAMIC (MAGNESIA-PSZ) AND THE

METAL (NODULAR CAST IRON)

In this example, 2.5 by 4.5 by 26 mm (0.1 by 0.2 by 1 in.) coupons of nodular cast iron and magnesia-PSZ were joined along their long edges using an active filler metal. Upon cooling from the brazing temperature, failure occurred in the ceramic parallel to the interface. These materials are considered to have similar CTE values and had been successfully joined before. However, when thermal expansion data were taken for this particular piece of ceramic, an anomalous and large hysteresis loop was found, indicating that the material had been improperly heat treated during its manufacture, resulting in a different phase composition (and expansion behavior) than expected.

The obvious solution to the problem of CTE mismatch among the members of a ceramic-to-metal joint and the resulting damaging residual stresses is to select an alternate material for either the ceramic or the metallic member. When this cannot be done because of service requirements, or when the thermal expansion is still too great, there are several other alternatives. One is to design the joint such that the ceramic member and joint interfacial region are always in compression. Another is to use ductile metal, which elastically and plastically deforms, to relieve the residual stresses generated during cooldown (or thermal cycling during service), thereby avoiding joint failure. Both of these techniques are widely used by the commercial ceramic/metal or glass/metal seal industry (Ref 60, 82). A third option is to introduce one or more materials between the metal and ceramic components. These materials will serve as a transition between the properties of the two structural materials. The transition material can be one or more discrete layers of monolithic materials (Ref 83, 84, 85) or composite layers that can comprise varying proportions of the materials being joined (Ref 41, 86, 87).

The concept of monolithic transition layers, their compositions (and, thus, properties such as thermal expansion, modulus of elasticity, yield strength, and others), and the optimum thicknesses required are complex subjects. Readers are referred to the references cited above for the details of this approach.

The use of a series of composite layers (with a stepwise transition from one material to the next or a linear gradation in material composition) that are subsequently inserted in the braze joint area is not new. It has been applied successfully, as evidenced by the work of Hammond and Slaughter (Ref 41), who used a series of tungsten-nickel-iron inserts to braze graphite to a nickel-base alloy. In one example, seven transition inserts were used with compositions that varied from 97.5 wt% W and 2.5 wt% of 7Ni/3Fe, adjacent to the graphite, to 40 wt% W and 60 wt% of 7Ni/3Fe, in contact with the nickel alloy. The surface of the graphite was metallized with chromium carbide, and the entire assembly was brazed with pure copper as the filler material.

However, there are numerous cases in which this approach has led to failure. The recent work of Rabin and Heaps (Ref 80) provides a new understanding of how the geometry and micro-structure of the composite transition layer(s) affects the stress distributions in the materials. Using finite-element modeling of alumina-nickel functionally gradient materials, followed by experimental studies, they showed that it is desirable to have a continuous metal phase (high plasticity, low elastic modulus) in each of the transition pieces to best relieve the thermal residual stresses. From a practical standpoint, they were able to accomplish this by using different particle sizes of the alumina and nickel in the compacts. Thus, for the alumina, alumina-20% nickel, and alumina-40% nickel layers, they used 0.5 μm (20 μin.) doped aluminum oxide and 15 to 20 μm (600 to 800 μin.) nickel powders. For the nickel, 60% nickel, and 80% nickel layers, they used 22 μm (880 μin.) doped aluminum oxide and 3 to 7 μm (120 and 280 μin.) nickel powders. The "dopants" in this study were small amounts of manganese and titanium used as sintering aids.

Direct Brazing of Graphitic Materials. Most of the factors that are a concern when brazing ceramics to themselves or to metals are also valid when brazing the various graphites. Two major differences should be considered when these materials are to be joined. The first, which may be overcome through careful material selection, is the fact that the graphites generally tend either to be more porous than the structural ceramics or, if of similar bulk porosity, to have a much finer network of porosity. The effect of such fine porosity can be to draw the filler metal away from the interface, leaving insufficient metal to join the bodies (Ref 88). This effect is readily seen in the micrograph of Fig. 14(a), which shows extensive penetration of a porous graphite when brazed with GTE Wesgo's Ticuni (Ti-15Cu-15Ni, wt%) filler metal. Penetration of the graphite ranged in depth from 200 to 890 μm (0.008 to 0.035 in.) across the metallographic specimen. The solution to this problem was to use a graphite of much greater POCO AXF-5Q density (Fig. 14b), thereby minimizing the loss of filler metal into the component, resulting in the sound braze joint shown in Fig. 14(b).

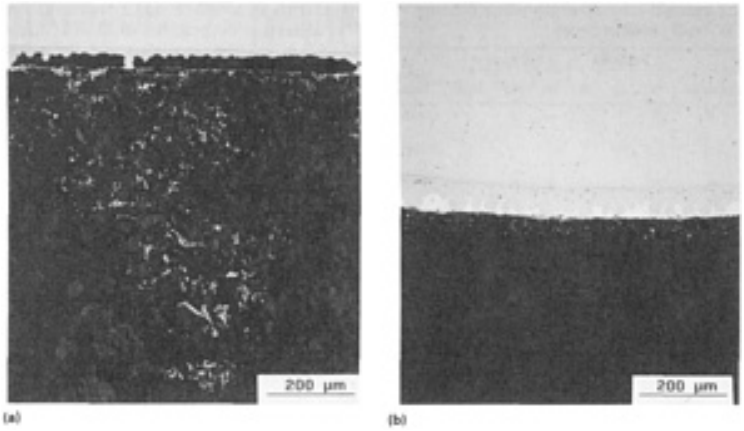

FIG. 14 EFFECT OF POROSITY ON ACTIVE METAL BRAZEMENTS OF GRAPHITE. (A) POROUS GRAPHITE HAS DRAWN THE MOLTEN FILLER METAL FROM THE JOINT, LEAVING A LARGE VOID. (B) MORE HIGHLY DENSE GRAPHITE HAS LEFT MOST OF THE FILLER METAL IN THE JOINT, RESULTING IN A SOUND BRAZEMENT. SOURCE: REF 88

The second major concern when brazing graphites is the stronger tendency for impurities, such as oxygen or water, to be either adsorbed on the surface or absorbed in the bulk of the material. Moisture retention always occurs to some extent, with levels as high as 0.25 wt%. This problem was overcome in one case (Ref 81) by cleaning and baking the graphite components in vacuum for 2 h at 1000 °C (1830 °F) prior to assembly, and then baking the subassemblies themselves (650 °C, or 1200 °F, for 10 min, followed by an overnight evacuation) as part of the brazing cycle.

Application of Clad Brazing Materials

Michael Karavolis, Sunil Jha, and James Forster, Texas Instruments, Inc.; Kris Meekins, Long Manufacturing Ltd.

Introduction

BRAZING, which is one of the most versatile joining techniques, is the preferred method for making a large number of joints in an assembly. The manufacture of heat exchangers, for example, requires the creation of leak-free joints between specific points and along contact surfaces and seams. The fabrication of high-density heat exchangers, which have a large heat transfer area and a compact size, is best accomplished by brazing (Fig. 1).

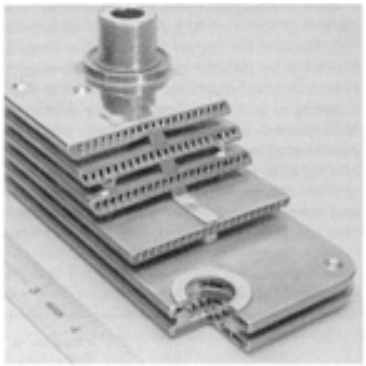

FIG. 1 AUTOMOTIVE ENGINE OIL COOLER MANUFACTURED WITH CLAD BRAZING MATERIALS

In a typical heat-exchanger assembly operation, the components are formed, cleaned, assembled, and fixtured prior to furnace brazing. During the assembly process, the brazing filler metal, which is often in the form of a wire, foil, paste, or powder sheet, is inserted at the appropriate locations. To simplify the assembly operation, the brazing filler metal can be clad to the materials to be brazed, as in aluminum-clad brazing sheet, where the brazing alloy is hot roll bonded to the aluminum alloy sheet (Ref 1). When the brazing filler metal is an integral part of the sheet or strip, the material is called a clad brazing material, because it can be brazed without the need for additional filler metal; that is, the brazing filler metal is already attached to the base material.

Although hot roll bonding is cited in the aluminum-clad brazing sheet example, many combinations of clad brazing materials are manufactured by cold roll bonding, a process that does not involve the explicit heating of the materials prior to the bonding operation. This material system is an economical solution for the fabrication of many high-volume, furnace-brazed products.

Additional information about the process involved in brazing with these materials is available in the article "Brazing With Clad Brazing Materials" in this Volume.

Material Selection

The design of heat exchangers for automotive applications varies widely, as does the manufacturing method. The selection of the base metal and brazing filler metal used in a specific heat exchanger depends on several factors, the most important of which are the performance and cooling requirements of the unit. Typical design parameters include space allotted for the heat exchanger, maximum weight of the unit, burst-pressure resistance, cooling capacity, pressure drop, life expectancy, and cost. These factors, among others, influence the size, type, and number of brazed joints in the heat exchanger, and all must be considered.

The materials chosen for a particular heat-exchanger application can vary greatly. In terms of the performance requirements that typically represent the starting point in base metal and brazing filler metal selection, the major concerns are durability and corrosion resistance. Although the need for compatibility with hot and cold fluids is obvious, consideration must also be given to the other materials that the heat exchanger may contact, in order to avoid premature failure that is due to corrosion by galvanic coupling. Some under-the-hood automotive heat exchangers may be exposed to the environment, whereas those that are contained within the engine block are exposed to a totally different environment and temperature range.

Other design considerations include:

- TOTAL NUMBER AND TYPES OF JOINTS
- APPLICATION OF ADDITIONAL CONNECTORS ON THE EXTERIOR OF THE UNIT
- APPLICATION OF A GREATER AMOUNT OF BRAZING FILLER METAL IN CERTAIN AREAS THAN IN THE REST OF THE LOCATIONS TO BE BRAZED
- FIXTURING METHODS NEEDED TO ENSURE PROPER JOINT CONTACT AT THE BRAZING TEMPERATURE DURING THE BRAZING CYCLE

Many engine oil coolers are currently made from stainless steel and use copper as the brazing filler metal. This base metal and filler metal combination is also available as a clad brazing material, where a copper brazing filler metal is clad to a stainless steel base material. Although the AISI 300 and 400 series of stainless steels have been the most widely used materials, low-carbon steels are being used in applications with less-strict corrosion-resistance and strength requirements.

Precautions that must be exercised during the brazing cycle, when using clad brazing materials, are identical to those that must be used when brazing the monolithic metals. For example, low-carbon versions of the 300 series of stainless steels are recommended to reduce the potential for sensitization during cooling from the brazing temperature. An excessively slow cooling rate should be avoided, because it can result in carbide precipitation in the grain boundaries of the stainless steel base material.

For a similar reason, a stabilized grade of 400 stainless steel is recommended to avoid the embrittlement phenomenon that also can result from improper cooling down from the brazing temperature. Typically, low levels of titanium, niobium, or a combination of the two, provide sufficient protection against embrittlement by minimizing the migration of carbon and any dissolved gases, without seriously reducing the wettability of the stainless steel. The niobium grades should be preferred because they are easy to braze, when compared to titanium-stabilized grades.

The copper brazing filler metal that is typically used in these applications conforms to the American Welding Society (AWS) filler-metal specification AWS A5.B, Class BCu-1. Past processing experience has shown that this type of filler metal performs very well in brazed heat exchangers that utilize both AISI 300 and 400 series stainless steels as base materials.

Application of Clad Brazing Materials

Michael Karavolis, Sunil Jha, and James Forster, Texas Instruments, Inc.; Kris Meekins, Long Manufacturing Ltd.

Fabrication of Clad Brazing Materials

The clad brazing materials described here are metals that are metallurgically joined by cold roll bonding. The technology and science of roll bonding and solid-phase welding have been described in detail elsewhere (Ref 2, 3, 4), but are summarized below.

As shown in Fig. 2, the process involves three basic steps:

- CLEANING OF THE MATING SURFACES BY CHEMICAL AND/OR MECHANICAL MEANS TO REMOVE DIRT, LUBRICANTS, SURFACE OXIDES, AND ANY OTHER CONTAMINANTS
- JOINING OF THE MATERIALS IN A BONDING MILL BY ROLLING THEM TOGETHER WITH A THICKNESS REDUCTION THAT RANGES FROM 50 TO 80% IN A SINGLE PASS, IMMEDIATELY AFTER WHICH, THE MATERIALS HAVE AN INCIPIENT, OR GREEN, BOND CREATED BY THE MASSIVE COLD REDUCTION
- SINTERING, A HEAT TREATMENT DURING WHICH THE BOND AT THE INTERFACE IS COMPLETED. DIFFUSION OCCURS AT THE ATOMIC LEVEL ALONG THE INTERFACE AND RESULTS IN A METALLURGICAL BOND THAT IS DUE TO A SHARING OF ATOMS BETWEEN THE MATERIALS. THE RESULTING BOND CAN EXCEED THE STRENGTH OF EITHER OF THE PARENT MATERIALS

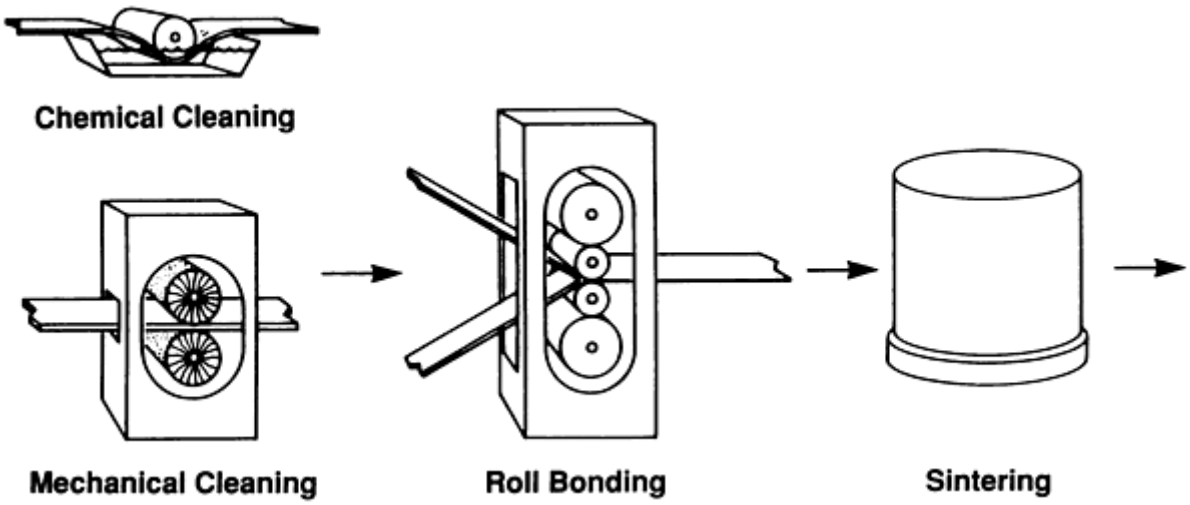

FIG. 2 PROCESS STEPS IN COLD ROLL BONDING

Upon completion of this three-step process, the resultant clad material can be treated in the same way as any other conventional monolithic metal. The clad material can be worked by any of the traditional processing methods for strip metals. Rolling, annealing, pickling, and slitting are typically performed to produce the finished strip to specific customer requirements, so that the material can be roll formed, stamped, or drawn into the required part.

Clad metals are defined by the materials that are present and the volume or thickness ratio of each layer. For example, a copper-clad stainless steel whose total thickness of 0.51 mm (0.020 in.) comprises 0.025 mm (0.001 in.) of copper, 0.46 mm (0.018 in.) of 301 stainless steel, and 0.025 mm (0.001 in.) of copper would be described as 5Cu/90/301SS/5Cu.

The thickness ratio can be determined by a number of techniques, including metallographic examination. A weigh/strip/weigh procedure can be used, where the material is weighed, the cladding is stripped by dissolving it in an appropriate solution such as an acid, and then the sample is weighed again. Another procedure utilizes the magnetic properties of the clad material. The volume ratio that is created during the roll-bonding operation remains through all subsequent finishing operations, including rolling. If appropriate starting material thicknesses and processing conditions are selected, then clad metals can be produced in an infinite number of layer ratios. It should be noted that it is not necessary that the cladding thickness be uniform on both sides of the core material, nor that the core material be clad on both sides. Nonsymmetrical material systems, as well as two-layer material systems, such as thermostat hi-metal, can also be produced. Figure 3 shows the cross section of a Cu/1008AK steel/Cu clad brazing material with a ratio of 5/90/5.

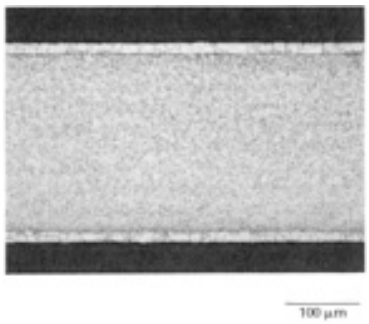

FIG. 3 PHOTOMICROGRAPH OF CU122/1008AK STEEL/CU122 CLAD BRAZING MATERIAL IN 5/90/5 RATIO, NO. 4 TEMPER

The amount of copper cladding is determined by the specific application and by the unit to be brazed. In areas where several hundred brazed joints can be made simultaneously, such as when a plate is joined to turbulator stock, a thicker copper layer (0.05 to 0.1 mm, or 0.002 to 0.004 in.) may be needed. In areas where only one or several joints are to be made, such as a can-to-lid or a plate-to-plate joint, a thinner copper layer (0.025 to 0.05 mm, or 0.001 to 0.002 in.) can be used. For applications in which a different number or different types of joints must be made on either side of a plate, different amounts of copper brazing filler metal can be clad on either side of the base metal. Nonsymmetrical layer ratio materials, such as 5/85/10 or 5/75/20, can be produced when needed.

Application of Clad Brazing Materials

Michael Karavolis, Sunil Jha, and James Forster, Texas Instruments, Inc.; Kris Meekins, Long Manufacturing Ltd.

Stamping, Cleaning, and Assembly

Clad metals should be considered to have the same forming characteristics as the core material. For example, a copper-clad 304L stainless steel system will have approximately the same ductility as the unclad 304L stainless steel. In some instances, the formability of the clad is better than that of the monolithic metal core because the copper on the surface of the stainless steel acts as a lubricant in the forming tool. The typical tensile properties of several copper-clad stainless steel clad brazing materials are shown in Tables 1 and 2.

TABLE 1 TWO-LAYER COPPER-CLAD BRAZING SYSTEMS

MATERIAL SYSTEM	LAYER THICKNESS RATIO	TENSILE STRENGTH		0.2% YIELD STRENGTH		ELONGATION IN 50 MM (2 IN.), %

C122/1008AK/C122	**10/80/10**	**295**	**43**	**215**	**31**	**39**

Notes: All properties shown are typical values for annealed materials, except for Cu122/1008AK/Cu122, which is in the No. 4 temper. Recommended brazing temperature for CDA-122 (AWS A5.8, Class B Cu-1) copper brazing filler metal is 1095 to 1150 °C (2000 to 2100 °F). Brazing atmosphere should be appropriate for the unclad core material.

The tooling that is used for stamping parts from clad metals can be the same as that used to make the monolithic metal core. Because the brazing filler metal is an integral part of the core material, additional stamping and forming operations associated with the production of the shim material are eliminated.

The parts must be cleaned after stamping, prior to assembly. The procedure for the clad metal parts should be similar to that used for cleaning the brazing filler metal shims or preforms. Copper-clad materials should be cleaned by a procedure that is appropriate for copper pans. Because the copper cladding is metallurgically bonded to the stainless steel core, wetting by the copper is ensured, as shown in Fig. 4, and the cleaning of any stainless steel parts is eliminated.

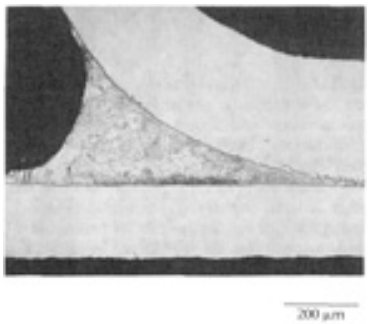

FIG. 4 PHOTOMICROGRAPH OF A TYPICAL BRAZED JOINT THAT WAS FORMED USING A CLAD BRAZING MATERIAL

As with any copper part, care must be taken to prevent oxidation during assembly prior to brazing. Because the copper brazing filler metal is bonded to the stainless steel, the number of pans to be assembled is significantly reduced and any handling of the thin, delicate brazing shim stock is eliminated. Unlike preform shims, which are usually used as flat, two-dimensional inserts, the brazing filler metal on the clad brazing material follows the complex surface topography that was stamped into the base material. Two examples are shown in Fig. 5 and 6. The former depicts a typical plate-type heat exchanger made from a clad brazing material, whereas the latter shows typical contoured joints that can be made easily with clad brazing materials.

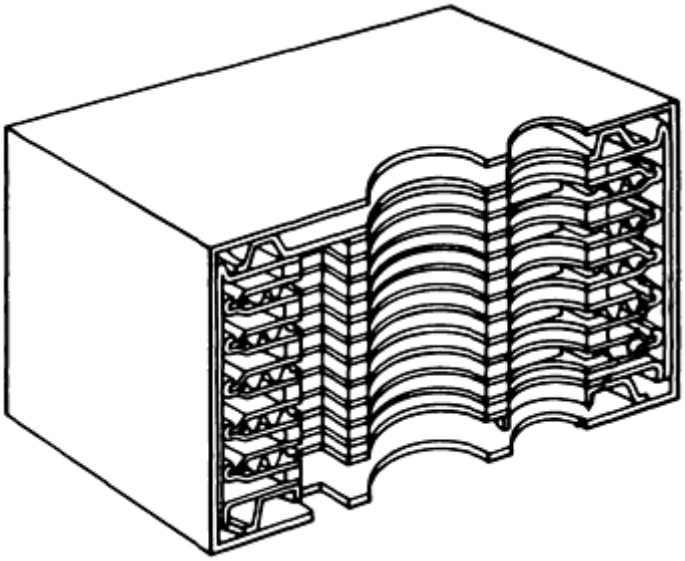

FIG. 5 CUTAWAY VIEW OF A TYPICAL PLATE-TYPE HEAT EXCHANGER

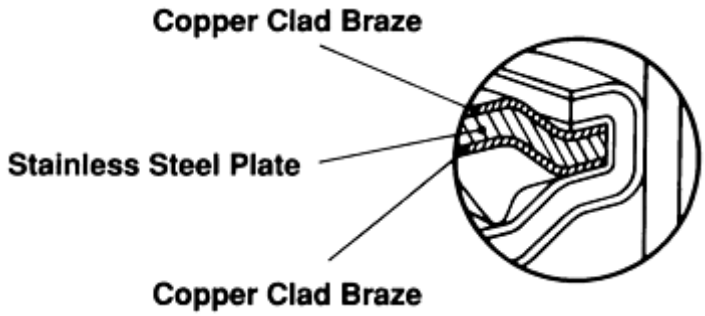

FIG. 6 CONTOURED JOINTS THAT CAN BE MADE EASILY WITH CLAD BRAZING MATERIALS

One design benefit of using clad brazing materials is a reduction of the clearance between the parts, because no allowance needs to be made for the insertion of thick shims, wires, or preforms.

Another benefit is that less copper brazing filler metal can be used, because the concerns associated with the handling of shim material have been eliminated. The thinner copper coating thickness, which typically ranges from 0.025 to 0.075 mm (0.001 to 0.003 in.), results in less shrinkage during brazing and is less likely to cause large brazing fillets. Consequently, the possibility that excess brazing filler metal will clog small passageways is greatly reduced. The typical joint shown in Fig. 7 illustrates the small-geometry passages that can be achieved and the capillary action of the brazing filler metal as it forms the fillets at the joints.

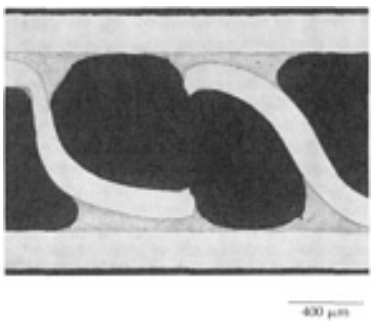

FIG. 7 PHOTOMICROGRAPH OF A PASSAGEWAY IN A HEAT EXCHANGER FABRICATED USING COPPER-CLAD STAINLESS STEEL CLAD BRAZING MATERIAL

Yet another benefit of using clad metals is that once the parts are assembled and fixtured, the brazing filler metal will not shift, move, or fall out as a result of the movement of fixtured assemblies prior to or during the brazing cycle.

Brazing Parameters

Brazing in a vacuum furnace is recommended for clad brazing materials, although the use of a protective gas atmosphere is also possible. Because stainless steel is typically used as the core material of heat exchangers, and because dissociation of the chromium oxide on the surface is essential, vacuum is the preferred brazing atmosphere. In many ways, vacuum furnace brazing with clad metals is similar to the vacuum brazing of stainless steel plates with copper shims. However, there are key differences. Furnace pressures from 0.0015 to 13.5 Pa (10^{-5} to 10^{-1} torr) are typical of the vacuum requirements for brazing with a stainless steel cored clad brazing material (Ref 5). The specific stainless steel alloy will determine the vacuum pressure that is required. No fluxes are needed, and the brazing operation can be considered to be a "clean" process.

Because the brazing filler metal is a pure, deoxidized copper, no additional time is needed to allow any binders to burn off or to outgas during the preheat stage. The heating rate is limited by the need to ensure a uniform temperature throughout the furnace load. Because the clad filler metal is metallurgically bonded to the core material, the wetting and rapid flow of the filler material is ensured. For these reasons, production costs can be lowered by reducing the total cycle time. Temperature control of ±5 °C (± 10 °F) is desired to ensure the proper flow of the brazing filler metal and to limit any filler metal-base metal penetration.

A fast cooling rate will help minimize any filler metal-base metal reactions, as well as production costs. Fast cooling rates are preferred for 300 series stainless steels, whereas slow cooling rates are preferred for the 400 series. The use of low-carbon 300 series and stabilized 400 series stainless steels, as described earlier, should result in a uniform, nonsensitized, non-embrittled core material.

General Soldering

Paul T. Vianco, Sandia National Laboratories

Introduction

SOLDERING TECHNOLOGY has been used in applications that range from the packaging of integrated circuit chips to the fabrication of industrial heat exchangers. Consequently, soldering applications are informally categorized as being either structural or electronic in nature. Regardless of these categories, soldering technology depends on certain underlying fundamental parameters and the issues associated with each. This article provides information about these topics:

- *SOLDER ALLOY.* A VARIETY OF ALLOYS AND THEIR PROPERTIES ARE DESCRIBED IN TERMS OF THE SELECTION PROCESS.
- *SUBSTRATE MATERIAL.* ALTHOUGH THE SELECTION OF THE SUBSTRATE BASE MATERIAL IS GENERALLY DETERMINED BY CRITERIA OTHER THAN THE JOINING TECHNIQUE, COATINGS CAN BE USED TO ENHANCE SOLDERABILITY.
- *FLUX.* FLUX SELECTION IS PRIMARILY BASED ON PROMOTING ADEQUATE WETTABILITY BY THE SOLDER. HOWEVER, THE NEED FOR POSTASSEMBLY CLEANING PROCEDURES MUST BE ADDRESSED WHEN THE CORROSIVITY OF THE FLUX RESIDUES JEOPARDIZES THE RELIABILITY REQUIRED OF THE WORKPIECE DURING SERVICE.
- *COMBINED SUBSTRATE, SOLDER, AND FLUX PROPERTIES.* THE COMBINATION OF PROPERTIES MUST BE CONSIDERED IN ORDER TO ESTABLISH THE JOINT DESIGN AND MANUFACTURING PROCEDURES THAT ARE NECESSARY TO SUCCESSFULLY CONSTRUCT THE WORKPIECE.

Each of these parameters is fully explored in this article, using examples of both structural and electronic applications. The article "Soldering in Electronic Applications" explores the latter topic in further detail.

Solder (Filler-Metal) Alloys

The primary criterion used to select a solder is its melting properties. Alloy selection is also determined by the heat sensitivity of the substrate material, the temperature conditions that are expected during service, and the pasty range of the alloy. The melting characteristics of solders are expressed as the solidus and the liquidus temperatures for the alloy. Solders composed of one metallic element, such as tin or indium, have a single melting temperature. Alloys with a eutectic composition have liquidus and solidus temperatures, but they are coincident, and the temperature value is referred to as the "eutectic temperature." The temperature spread between the solidus and liquidus temperatures define the pasty range of the alloy. Solders are commercially available with liquidus temperatures that are as low as 11 °C (51 °F), for the

ternary gallium-indium-tin alloy, to as high as 425 °C (795 °F), for the germanium-aluminum solder. Metal alloys with melting temperatures that exceed 450 °C (812 °F) are categorized as brazing filler metals. The pasty region can range from only a few degrees to nearly 100 °C (180 °F).

Other attributes of the solder include mechanical properties, such as strength and creep resistance; physical properties, such as thermal expansion or thermal conductivity; corrosion resistance; and cost. Because the solder provides a means of fastening two substrates together, its mechanical properties are of great importance. Besides their monotonic strength (tensile and shear) to resist overload stresses, solders must possess sufficient creep strength under sustained loads. This factor is particularly critical, because typical service environments (including room temperature) are actually high-temperature applications, relative to the low melting temperatures of the alloy. The resistance of the solder to fatigue deformation is important to both structural and electronic applications. The coefficient of thermal expansion (CTE) mismatch between the solder and substrate(s) can directly affect the long-term integrity of the solder joint. Thermal conductivity is important for joints that must meet heat-transfer specifications. Corrosion must be considered at all stages of solder joint design, because solder joints have dissimilar metals in intimate contact. Many solders are microstructurally heterogeneous and have other corrosion concerns.

Specifications and standards have established requirements for certain solder alloys in terms of composition limits, impurity levels, and a nomenclature for referencing particular compositions. In the United States, the specifications of solder alloy compositions are found in ASTM B 32 (Ref 1) and Federal Specification QQ-S-571E (Ref 2). Users in the European community prefer the International Organization for Standardization (ISO) specification (draft form) ISO/DIS 9453 (Ref 3). Candidate alloys must be submitted to the particular governing organization for consideration and acceptance as a "specified composition." It should be noted that the commercial availability of a solder material does not necessarily imply that it is included in these and other federal, military, or industrial standards and specifications. In the case of nonstandardized compositions, the user should insist that the vendors certify the composition (including impurities) of their products. Many government and military projects contractually require that the supplier or manufacturer used specified solder compositions in their products.

Although the U.S. standards are generally recognized by foreign industries, the expansion of trade with overseas companies will require that U.S. producers and manufacturers gain an increased familiarity with international standards.

The physical and mechanical properties of bulk solders and solder joints are discussed below. When designing a product, solder joint data are preferred to bulk solder properties. Generally, the use of bulk strength data will underestimate the loading capacity of the joint; that is, calculations will typically be conservative. Although they are not always available, the solder joint properties should include the joint thickness and the testing rate used to obtain the values. Solder selection is also guided by cost. The 1992 prices of metals commonly used in solder alloys are shown in Table 1.

TABLE 1 PRICES OF METALS COMMONLY USED IN SOLDERS

Tin-lead, tin-lead-antimony, tin-lead-silver, and lead-silver solder compositions, per ASTM B 32, are listed in Table 2. The values are similar in the QQ-S-571E specification. The ISO/DIS 9453 guidelines are given in Table 3. Antimony may be found in solders for any one of three reasons: as an impurity, that is, not intentionally added to the material; as a minor addition of 0.25 wt%, minimum, to try to prevent the formation of the low-temperature allotrope of tin (α of tin at 13.2 °C, or 55.8 °F); and as a principal component, representing 1 to 5 wt%, to improve monotonic and

creep strength of the solder. The levels of added antimony should be less than 7 wt% of the tin component of the solder (the solubility limit of antimony in tin) in order to prevent the formation of tin-antimony intermetallic compounds, which can severely impact the fluidity of the molten solder or reduce the ductility of the solidified joint. The ASTM designation for antimony levels in the solders are: Class A (alloys with tin content greater than 35 wt%), maximum of 0.12 wt%; Class B, 0.2 to 0.5 wt%; and Class C (tin content, 20 to 40 wt%), maximum of 6 wt% (Ref 5).

(A) LIMITS ARE MAXIMUM PERCENTAGES, UNLESS SHOWN AS A RANGE OR STATED OTHERWISE. FOR PURPOSES OF DETERMINING CONFORMANCE TO THESE LIMITS, AN OBSERVED VALUE OR CALCULATED VALUE OBTAINED FROM ANALYSIS SHALL BE ROUNDED TO THE NEAREST UNIT IN THE LAST RIGHT-HAND PLACE OF FIGURES USED IN EXPRESSING THE SPECIFIED LIMIT, IN ACCORDANCE WITH THE ROUNDING METHOD OF ASTM RECOMMENDED PRACTICE E 29.

(B) TEMPERATURES GIVEN ARE APPROXIMATIONS AND ARE FOR INFORMATION ONLY.

(A) TEMPERATURES GIVEN ARE FOR INFORMATION PURPOSES AND ARE NOT SPECIFIED REQUIREMENTS FOR THE ALLOYS.

(B) ALL SINGLE FIGURE LIMITS ARE MAXIMUM PERCENTAGES.

The thick, tenacious oxide of lead and the corrosion product layers that form on tin limit the extent of general corrosion to tin-lead solders. However, the lead-rich phase is particularly susceptible to corrosion in the presence of chloride ions, water, or carbon dioxide (from the atmosphere). The reaction by-product from the latter two is a white powder, identified as lead carbonate (Ref 6). The poor adhesion of lead carbonate to the lead causes it to drop away (known as "spalling"), exposing new metal to corrosion, until the solder film becomes a skeleton of tin-rich crystals.

The high-lead solders, which have a 5 to 20 wt% Sn content, are used extensively in micro-electronics packaging (flipchip or C^4 technology) or in high-temperature applications. Other applications include radiator assembly and automobile body repair, which utilize torch heating techniques. A drop in the liquidus temperature is obtained when tin content increases from 20 to 30 wt%. The 5 to 20 wt% Sn alloys have a wider pasty range that provides greater workability, whereas the higher tin content improves the wetting and flow of the solder. On the other hand, increased concentrations of tin also raise the price of the solder.

The most widely used solders are the eutectic 63Sn-37Pb and the near-eutectic alloys, 60Sn-40Pb and 50Sn-50Pb. These solders are used in electronics and structural applications, such as the assembly of conduit for nonpotable water, industrial fluids, compressed gas products, and vacuum assemblies. The narrow pasty range of these alloys limits their workability

prior to solidification. The largest use of the eutectic and near-eutectic solder is in the assembly of circuit boards for electronic products.

The alloys with higher tin contents of 65 to 100 wt% have more limited applications, because the melting temperatures and pasty range needed for structural applications can be provided by the less-expensive lead-rich compositions. However, the tin-rich alloys have improved wettability for hard-to-solder substrates.

The physical and mechanical properties of bulk tin-lead solders are given in Tables 4, 5, 6, 7, 8, and 9. The room-temperature physical properties of the tin-lead solders, ranked by tin content, are listed in Table 4. The CTE decreases with increasing tin content, whereas both thermal and electrical conductivities rise with tin content. Surface tension and viscosity data, which are indicative of capillary filling in holes and gaps by the solders, are listed in Table 5. The addition of flux will tend to *lower* the surface tension of the molten solder.

The mechanical properties of the tin-lead alloys are listed in Table 6. The tensile strength values were obtained at a strain rate of 0.5/min. The tensile and shear strength values of solders are very sensitive to the rate of testing, and they typically decrease with decreasing test rate. In fact, the percent decrease in strength is significantly *larger* at the elevated temperatures.

The room-temperature strength properties are a function of the time period between alloy solidification and testing. Annealing of the test sample (at room or higher temperatures) should be performed to stabilize the microstructure to ensure consistent, reproducible data. Tensile strength data of 63Sn-37Pb suggest that stability is reached by room-temperature aging for 60 days (Ref 8). Recommended high-temperature-aging treatments to accelerate stabilization have not been specified. The use of high-temperature annealing should be accompanied by microstructural evaluations to ensure that the aging mechanism is similar to that which exists at room temperature.

Strength data for the tin-lead alloys at cryogenic temperatures of -73 °C (-100 °F) and -196 °C (-320 °F) are included in Table 7. It is important to note that alloy ductility drops sharply at the lower temperatures. The Brinell hardness values of the tin-lead solders as a function of composition are given in Ref 9.

The mechanical properties of the tin-lead-antimony solders are listed in Table 8. Antimony additions of 2 to 4 wt% increase both the tensile and shear strengths and the creep resistance of the tin-lead alloys. Similar behavior is recorded with the addition of 1 to 3 wt% Ag, as occurs with the Sn62 (ASTM B 32) alloy. Impact strength is not significantly altered by antimony additions. Ductility varies with antimony content, reaching a maximum at approximately 2.5 wt% Sb.

Testing temperatures affect mechanical properties significantly. General trends can be obtained from the tensile strength and ductility data shown in Fig. 1 for 60Sn-40Pb and 90Pb-10Sn solders. Strength decreases and ductility increases as the test temperature increases. The tensile strength trend is not monotonic for the 60Sn-40Pb and 90Pb-10Sn solders. At approximately -129 °C (-200 °F), strength reaches a maximum.

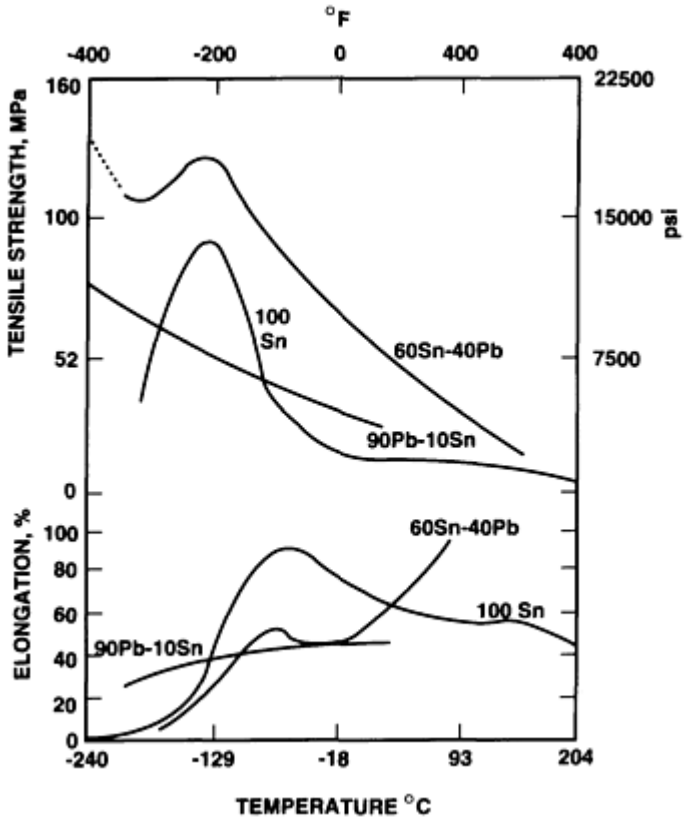

FIG. 1 TENSILE PROPERTIES OF BULK SOLDERS AS A FUNCTION OF TESTING TEMPERATURE

Table 9 gives the maximum creep stress values required to yield a life of 1000 h at temperatures of 20 °C (68 °F) and 100 °C (212 °F), as well as the maximum stress levels for the 10-year life of bulk tin-lead solders, as a function of tin content.

These data indicate that for a constant creep life, the stress value must decrease as the tin content increases. The addition of antimony improves the creep strength.

The fatigue life of bulk 60Sn-40Pb solder is shown in Fig. 2, whereas that of bulk 60Sn-40Pb solder as a function of testing rate is depicted in Fig. 3.

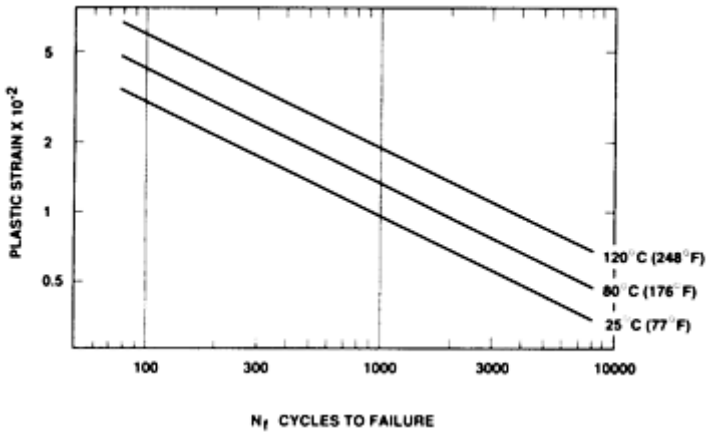

FIG. 2 ISOTHERMAL FATIGUE LIFE (PLASTIC STRAIN DEPENDENCE) OF BULK 60SN-40PB SOLDER. SOURCE: REF 10

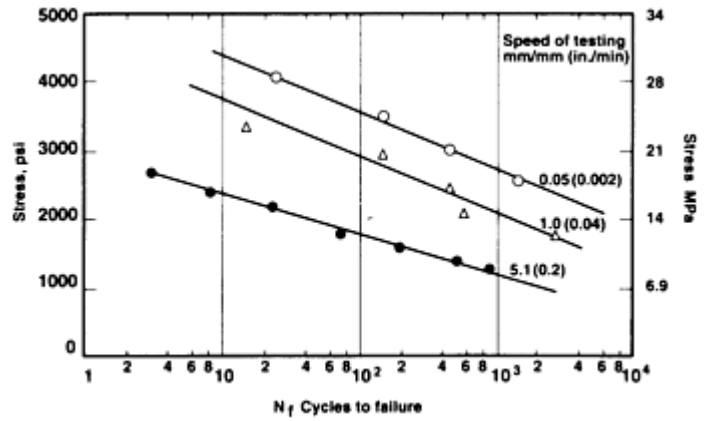

FIG. 3 ROOM-TEMPERATURE FATIGUE LIFE (STRESS DEPENDENCE) OF BULK 60SN-40PB SOLDER

The tin-lead-antimony solders demonstrate room-temperature aging of the microstructure and corresponding changes in the mechanical properties (Ref 11). Tensile strength data for the 60Sn-40Pb alloy following room-temperature aging are shown in Fig. 4. Strength and hardness do not decrease monotonically with time for alloys that have >3 wt% Sb. As shown in Fig. 5, a maximum in hardness is observed in the data for 47Sn-47Pb-6Sb.

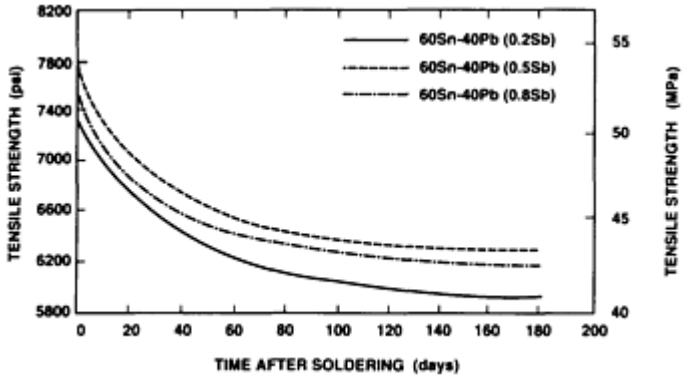

FIG. 4 TENSILE STRENGTH OF 60SN-40PB SOLDER AFTER ROOM-TEMPERATURE AGING. SOURCE: REF 8

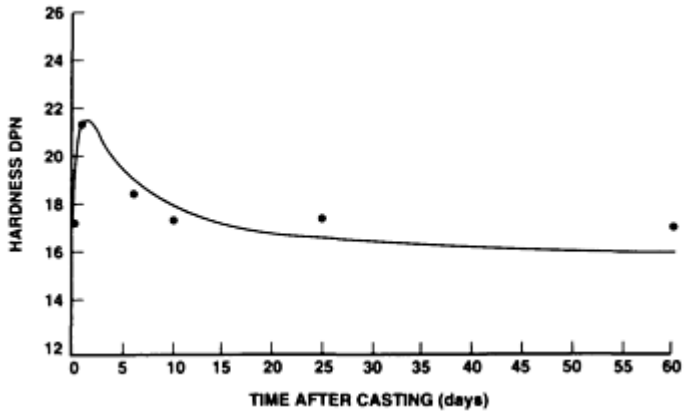

FIG. 5 HARDNESS OF 47SN-47PB-6SB SOLDER AFTER ROOM-TEMPERATURE AGING. SOURCE: REF 8

The effect of joint thickness on shear strength of copper substrates and 56Sn-44Pb solder is shown in Fig. 6. Typically, the maximum strength of solder joints is achieved with a thickness that ranges from 0.076 to 0.18 mm (3 to 7 mils).

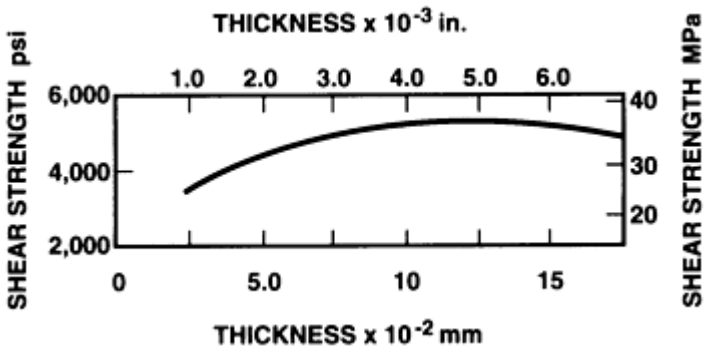

FIG. 6 SHEAR STRENGTH OF COPPER/56SN-44PB/COPPER SOLDER JOINTS AS A FUNCTION OF JOINT THICKNESS. SOURCE: REF 12

The primary sample geometries for the mechanical testing of solder joints are shown in Fig. 7. The appropriate ASTM test specifications for each configuration are D 1002, for the single-lap shear test; D 3528, for the double-lap shear test; F 1044, for the ring-in-plug test; D 897, for the tensile strength of joints; and D 1876, for the T-peel test. The sample

geometries test the joints in shear, the predominant loading mode for soldered joints. These test methods, along with those for measuring the creep and fatigue of adhesive joints, are listed in Table 10. The ring-in-plug test can be used for shear testing by tension (pulling the plug out of the ring) and by torsion (twisting).

Additional properties that are specific to the eutectic 63Sn-37Pb and near-eutectic 60Sn-40Pb solders are provided below. The properties of either group of these solders can be approximated with those of the other. The physical properties of 60Sn-40Pb are listed in Table 11, whereas creep-rapture data are given in Table 12.

The temperature dependence of the tensile strength, yield strength, and ductility of bulk 63Sn-37Pb solder at a test rate of 1.3 mm/min (0.05 in./min) is shown in Fig. 8; the temperature dependence of the tensile modulus and Poisson's ratio is shown in Fig. 9. These properties are particularly useful for finite-element modeling of solder joint residual stresses.

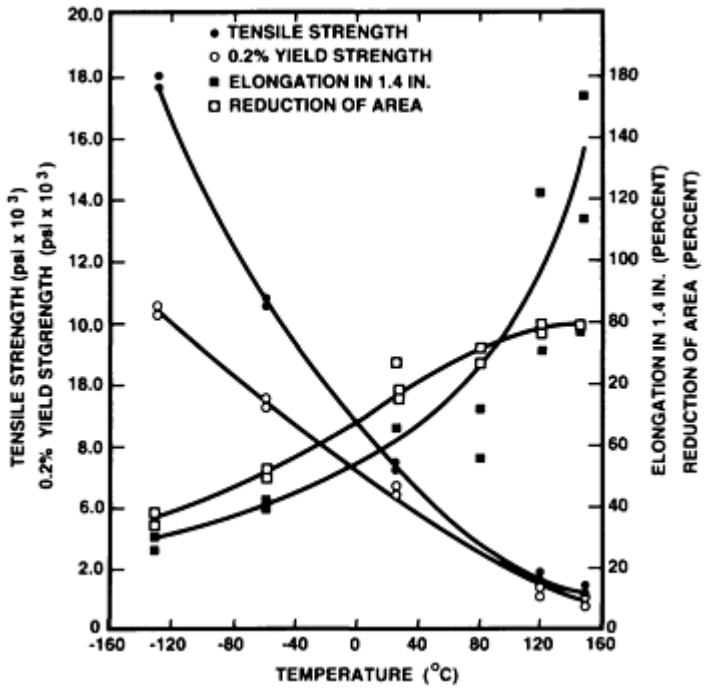

FIG. 8 TEMPERATURE DEPENDENCE OF TENSILE STRENGTH, YIELD STRENGTH, AND DUCTILITY OF 63SN-37PB

SOLDER. SOURCE: REF 14

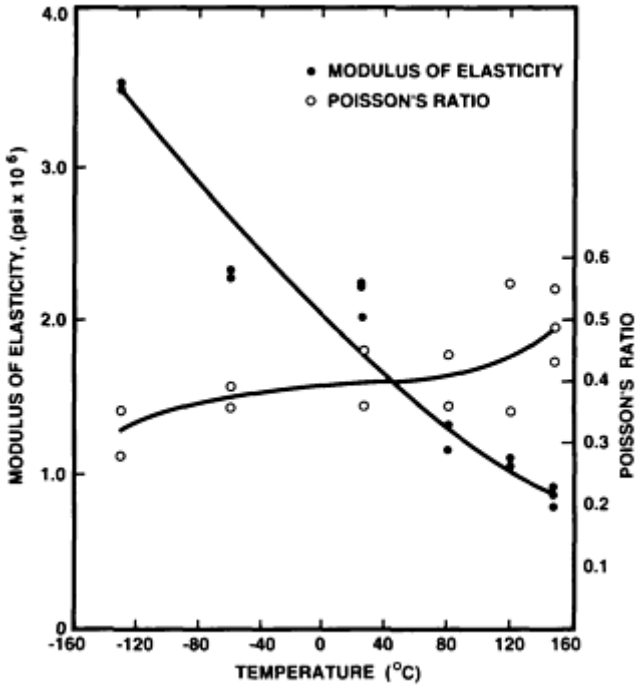

FIG. 9 TEMPERATURE DEPENDENCE OF TENSILE MODULUS AND POISSON'S RATIO OF 63SN-37PB SOLDER. SOURCE: REF 14

The room-temperature shear strength (copper ring-in-plug and single-overlap shear) of 60Sn-40Pb solder joints, as well as data from tests performed at elevated temperatures, are shown in Table 13. The single-lap joint gap thickness was 0.13 mm (0.005 in.). Thermal aging of the solder joints decreases the joint shear strength, and the effect on room-temperature data becomes much greater at higher strain rates (Ref 13).

Fatigue life data expressed as cycles to failure for a given load stress are presented in Fig. 3. Fatigue resistance can also be expressed as a function of the applied strain. Lap shear fatigue data from a variety of applied strain levels are shown in Fig. 10. Increasing the temperature above 20 °C (68 °F) generally decreases the number of cycles to failure. Isothermal fatigue life is also reduced by decreasing the frequency of cycles. The frequency effect is negligible for strains that exceed 4% and frequencies that exceed 0.01 Hz (Ref 16).

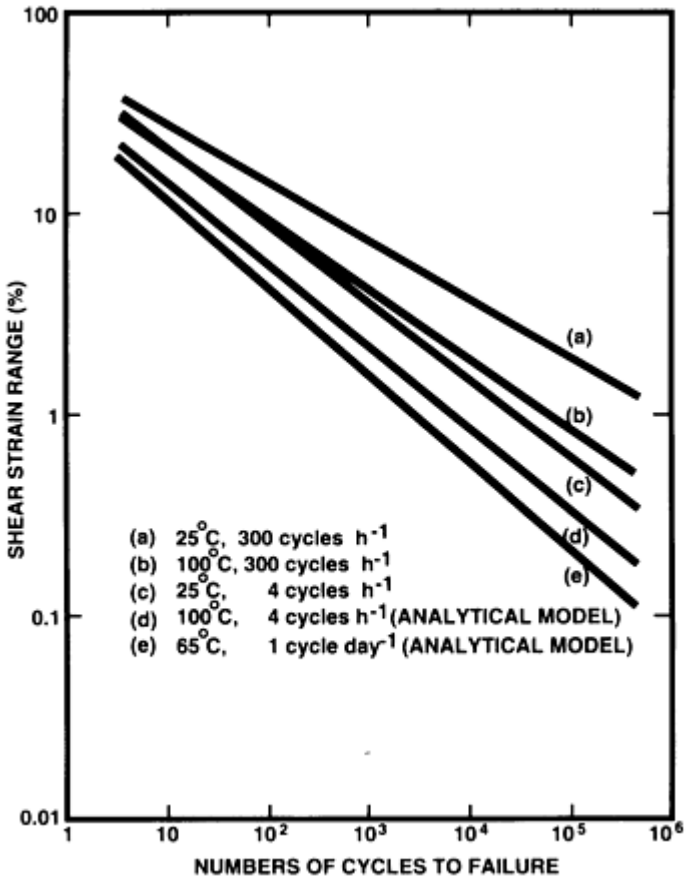

FIG. 10 FATIGUE LIFE OF 60SN-40PB SOLDER AS FUNCTION OF APPLIED STRAIN AMPLITUDE. SOURCE: REF 15

Resistance to creep diminishes as the temperature increases. Creep-rupture data at three temperatures are shown in Table 14.

(A) IACS, INTERNATIONAL ANNEALED COPPER STANDARD.

Alloys with 1 to 5 wt% Sb are commercially available. Antimony remains in solid solution in tin at levels up to 6 or 7 wt%. Higher amounts cause the precipitation of tin-antimony intermetallic crystals.

The tin-antimony-silver solder is certified in the ASTM specification. The silver improves the spreading of the solder, lowers the solidus and liquidus temperature, and extends the alloy pasty range. Tin-antimony solders exhibit excellent monotonic and creep strength levels for applications with high structural loads and elevated-temperature service, as well as in food handling equipment and potable water conduit and containers. Antimony additions above 0.3 wt% will deteriorate wetting and spreading. Solders with more than 0.2 to 0.5 wt% Sb can become embrittled when joined to aluminum, zinc, or zinc-coated parts because of the formation of aluminum-antimony and zinc-antimony intermetallic phases.

The room-temperature physical and mechanical properties of 95Sn-5Sb alloy are given in Table 18. The sensitivity of the room-temperature bulk tensile strength and copper ring-in-plug shear strength to testing rate (Table 19) is less than that for the tin-lead alloys. The tensile strength and elongation of tin-antimony solders also exhibit a smaller sensitivity to temperature (Fig. 11).

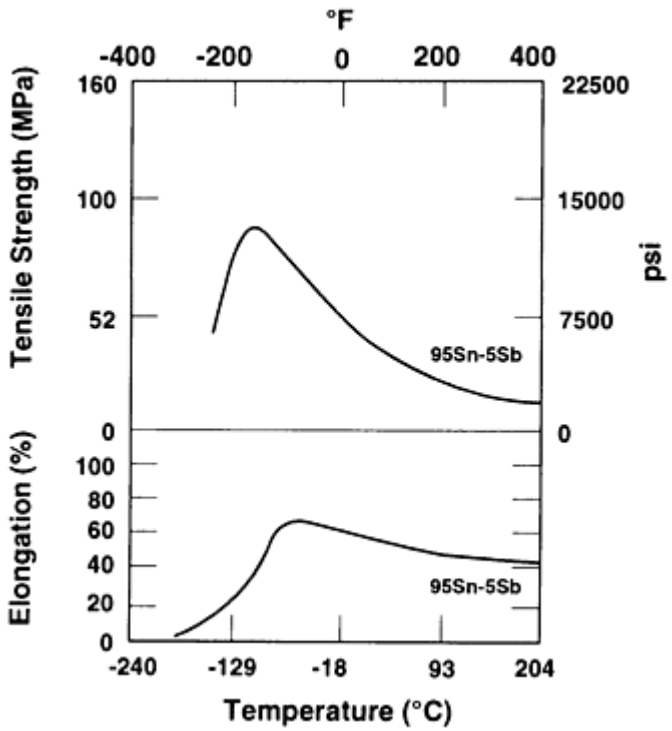

FIG. 11 TEMPERATURE SENSITIVITY OF TENSILE STRENGTH AND ELONGATION OF 95SN-5SB SOLDER

Bulk creep properties are illustrated in stress-rupture data in Table 20. Copper ring-in-plug creep-rupture data are shown in Table 21. Fatigue resistance is demonstrated by the results in Table 22 for cyclic compression/tension (zero mean stress). Both creep and fatigue properties of 95Sn-5Sb are superior to those of 60Sn-40Pb solder. The improved fatigue resistance is noted by the stress required to cause failure at 1000 cycles at a testing rate of 0.2 mm/min (0.008 in./min). The failure stresses at 20 °C (68 °F) are 21 MPa (3.05 ksi) for 95Sn-5Sb and 17 MPa (2.47 ksi) for 60Sn-40Pb.

Tin-silver solders include the tin-silver and tin-copper-silver compositions. The alloy compositions are listed in Tables 23, 24, and 25. ASTM B 32 recognizes the Sn96 solder as that composition which has a silver content of 3.4 to 3.8 wt%. The "same" alloy specified by QQ-S-571E has a composition of 3.6 to 4.4 wt% Ag. The ASTM document includes specifications for two additional tin-silver solders: Sn95, with 4.4 to 4.8 wt% Ag, and Sn94, with 5.4 to 5.8 wt% Ag. The tin-copper-silver alloy "E" included in ASTM B 32 contains 0.25 to 0.75 wt% Ag and 3.0 to 5.0 wt% Cu. Silver improves strength and spreading and lowers the melting temperature, when compared with pure tin. The addition of copper in the "E" alloy further improves its strength. Both the tin-silver (primarily, the eutectic 96.5Sn-3.5Ag) and the tin-copper-silver solders are used extensively in plumbing applications for potable water and in food handling equipment, where the use of lead-containing joints is restricted. Tin-silver alloys also form the high-temperature step of step-soldering processes with tin-lead alloys.

Tin-zinc and zinc-aluminum solders are used primarily in joints composed of aluminum-base metals in order to limit galvanic corrosion (Table 28). The eutectic tin-zinc composition, 91Sn-9Zn, has a melting temperature of 199 °C (390 °F), which makes it suitable for low-temperature applications that traditionally use the tin-lead solders. However, oxidation of the zinc constituent of the solder causes excessive dross formation and sluggish spreading when processed in air. As a precaution, the potential for galvanic corrosion between the zinc constituent of the solder and the base metal(s) should be thoroughly investigated prior to its use.

TABLE 28 PHYSICAL PROPERTIES OF TIN-ZINC AND ZINC-ALUMINUM SOLDERS

ALLOY	**DENSITY, G/CM^3**	EUTECTIC TEMPERATURE	
		°C	°F
91SN-9ZN	7.27	199	**390**

95ZN-5AL	**6.60**	**382**	**720**

Zinc-aluminum solders were also developed for aluminum soldering. The eutectic 95Zn-5Al has a melting temperature of 382 °C (720 °F) and is used in tube joining for heat-exchanger applications. Solder joint mechanical properties have been measured in ultrasonic soldering studies (Ref 17). These alloys are not included in the ASTM, ISO, or QQ-S-571E specifications.

Indium-containing solders are used for joining temperature-sensitive substrates or as the low-temperature step in multiple ("step") soldering processes to prevent reflow of the pre-existing solder joints (typically, tin-lead eutectic). Good plasticity at cryogenic temperatures make these alloys suitable for applications such as space vehicles and satellites. Selected properties of these solders are listed in Table 29.

(A) TOO SOFT TO MEASURE.

Indium is frequently added to tin-lead solders as a ternary addition in order to depress the melting temperature (for example, 40Sn-40Pb-20In and 70Sn-18Pb-12In). Indium also improves ductility and oxidation resistance. Indium-containing alloys have poor corrosion resistance in the presence of halide ions, such as those used for some activators in flux chemistries. The alloys 52In-48Sn and 97In-3Ag easily wet glass, fused silica, and other ceramics for glass-to-metal or glass-to-glass joints. These alloys also have very low vapor pressure, which makes them ideal for vacuum applications. The 501n-50Pb alloy is used in electronic applications to limit the scavenging of precious-metal substrates or coatings, which occurs very rapidly with tin-base solders. The indium-containing solder compositions are not certified by ASTM B 32 or QQ-S-571E. However, the latter document does give nominal compositions and melting temperatures. ISO/DIS 9453 does certify the composition of the 50In-50Sn alloy. The high cost of indium has limited the general use of these solders.

Low-melting fusible alloy solders, which contain bismuth, are used for soldering processes that involve temperature-sensitive substrates or devices, as well as the low-temperature part of step soldering procedures. Their ability to melt at low temperatures makes these materials ideal for thermal fuses. Compositions, mechanical, and selected physical properties are listed in Table 30.

(A) EXTENDED LIST AVAILABLE IN REF 6 (P 110).

Excessive oxidation of bismuth promotes dross formation and can limit spreading for soldering processes conducted in air. The eutectic 58Bi-42Sn alloy has found some applications in electronic assemblies. Bulk properties and copper ring-in-plug shear strength, creep, and fatigue data are listed in Table 31.

(A) SAMPLE SIZE, $N = 3$.

(B) SAMPLE SIZE, $N = 5$.

The ISO/DIS 9453 specification sets guidelines on the composition of 60Sn-38Pb-2Bi, 49Pb-48Sn-3Bi, and 57Bi-43Sn alloys. Alloys with greater than 47 wt% Bi exhibit varying degrees of expansion upon cooling after solidification, because of changes to the lattice structure of the alloys (Ref 18). Dimensional changes to the alloy also take place during room-temperature aging. Whether the dimensional change is due to contraction, expansion, or both, and the magnitude of this change, depends on the composition. These alloys can be used to eliminate solder-joint cracking during the cooling of two substrates that have vastly different degrees of thermal contraction.

Precious-metal solders include the gold-tin, gold-germanium, and gold-silicon compositions. Selected physical and mechanical properties are listed in Table 32. The high concentration of gold causes the alloys to be very expensive.

These solders are used for attaching integrated circuit chips to packages. They are also used in the construction and hermetic sealing of packages that house delicate sensors and instrumentation. Their high melting temperature also allows them to be used in the step-soldering process with conventional tin-lead and lead-indium solders.

An attribute of their precious-metal content is that the gold-tin, gold-germanium, and gold-silicon alloys exhibit excellent solderability without the need for a flux (including short-duration processes in air) when soldering gold-coated parts. However, spreading is limited by the high surface tension of the alloys, particularly in the absence of the flux. Mechanical pressure is frequently used to assist spreading of the molten solder in the joint. Gold, tin, germanium, and silicon can be thermally evaporated, making them suitable for thin-film soldering processes, such as the assembly of microsensors (Ref 20). Ultimate tensile strength and yield strength data are given in Fig. 14, which shows that the values far exceed those of the tin-lead alloys. Conversely, these solders show very low ductility (4 to 5%) at room temperature. The composition of the precious-metal solders are not described by the ASTM, QQ-S-571E, or ISO specifications.

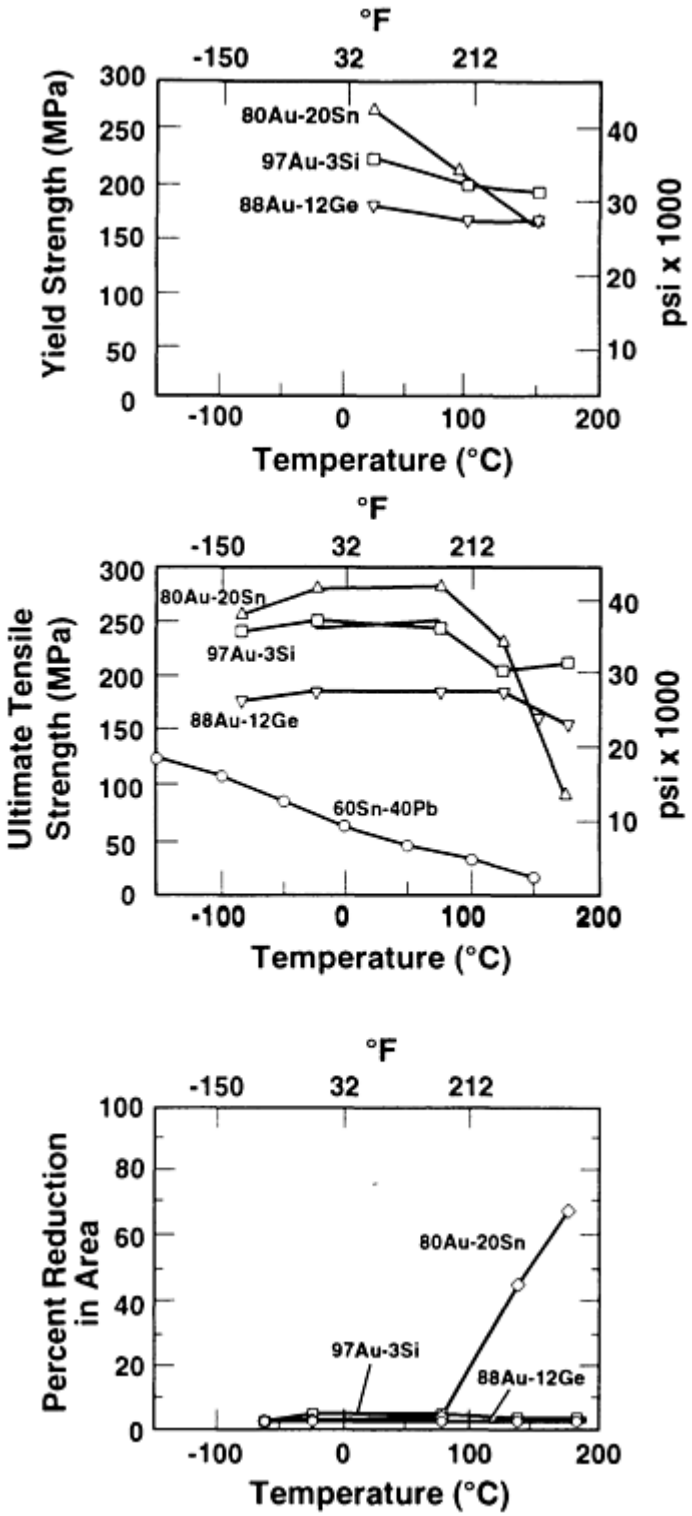

FIG. 14 TENSILE STRENGTH AND YIELD STRENGTH OF THE HIGH-MELTING-POINT PRECIOUS-METAL SOLDERS. SOURCE: REF 19

Cadmium-containing solders include special low-temperature alloys, such as 44In-42Sn-14Cd, which has a eutectic temperature of 93 °C (200 °F), as well as higher-temperature solders, such as the alloy 82.6Cd-17.4Zn, which has a eutectic temperature of 266 °C (511 °F). The corrosion protection offered by the cadmium permits these alloys to be used on aluminum or in corrosive service environments. The relatively high vapor pressure of cadmium precludes the use of cadmium-bearing solders in vacuum equipment. Generally, the use of cadmium-bearing solders is declining because of the health hazards associated with cadmium, particularly in terms of the vapors released during the soldering process. In fact, cadmium-bearing solders are now prohibited in numerous applications.

Available Solder-Metal Forms. In addition to alloy chemistry, the form of solder stock is also described by the ASTM, ISO, and QQ-S-571E specifications. Based on ASTM B 32, these forms include pig, 9.1 to 45 kg (20 to 100 lb); ingot, 1.4 to 4.5 kg (3 to 10 lb); bar, 0.22 to 0.91 kg (0.5 to 2.0 lb); and foil, sheet, or ribbon, which have various widths and thicknesses that are typically greater than 0.025 mm (0.001 in.). Solders that are contained in creams or pastes are specified according to solder powder size, metal content, flux, and viscosity. Solder wire without flux is specified by the wire diameter, which ranges from 0.25 to 6.35 mm (0.010 to 0.250 in.). Flux-cored wire must include flux type and quantity (percentage). Solder sheet may be cut or punched into particular shapes, and the stock is then referred to as a preform. The standard specifications also designate testing procedures to certify the composition and properties (flux activity of cored wire, viscosity of pastes, dimensions of wire and sheet, and so on) for the particular solder or solder-containing material.

Substrate Materials

A substrate is solderable if a metallurgical bond can be formed between the molten solder alloy and the substrate surface. Solderability deteriorates with the presence of organic contaminants and surface oxide layers that restrict the metallurgical reaction. Organic films and heavy oxide layers must be removed by precleaning procedures prior to soldering. Most fluxes are capable of removing only relatively light oxide (or tarnish) films. The tenacity of an oxide film is determined by its intrinsic chemical nature (including adhesion to the base metal) and its thickness.

Table 33 gives a qualitative ordering of solderability for several categories of materials. Generally, the noble metals (for example, gold and silver) are readily solderable, because of limited oxide formation and strong reactivity with the solder. The materials that are most difficult to solder are ceramics and refractory metals, which require metal coatings to promote solder wetting.

The solderability of marginal materials (nickel, beryllium-copper, steels, or heavily tarnished copper) can be improved by the use of stronger fluxes. However, the highly corrosive nature of the residues typically require postsolder process cleaning steps.

Preassembly Cleaning Procedures. Organic contaminants need to be removed by organic solvents or by semiaqueous or aqueous cleaning solutions. The list of frequently used organic solvents has changed, because the use of chlorofluorocarbon-base materials has been restricted by environmental laws and codes. Substitute materials include acetone, isopropyl alcohol, terpenes, alkaline detergent solutions (for example, 1 to 3% trisodium phosphate with surfactants), and newer semiaqueous compounds. Contamination removal by solvents can be assisted by vapor degreasing, although toxicity to workers and the potential fire hazard generated by fumes or aerosols must be adequately assessed.

Agitated baths and ultrasonics also can improve the cleaning capabilities of organic, semiaqueous, and aqueous cleaning material. However, possible damage to parts by sonic energy must always be assessed before using ultrasonic cleaning processes. The use of soft or distilled water is recommended for aqueous and semiaqueous solutions in order to limit residue formation. Regardless of the cleaning system, all cleaning solution residues must be thoroughly removed from the workpiece prior to storage or processing in order to prevent the formation of stubborn surface films.

Degreasing requirements can be significantly reduced through preventive measures, such as the use of gloves by workers handling parts, enclosing parts in bags or containers, and providing storage facilities that do not contain detrimental

materials or airborne particulates. Solderable surfaces should not contact silicon-base materials, because their residues (particularly silicone oils) are extremely difficult to remove and nearly always cause a significant deterioration in substrate solderability.

The removal of heavy oxide layers from metal surfaces is performed by chemical (or acid) cleaning when the chemical action of the flux is incapable of removing the oxide layer during the soldering process. Prior to acid cleaning, the surface must be completely cleaned of organic contaminants, to ensure the effectiveness of the cleaning process. Water-base solutions typically do not penetrate organic films. Surface layers other than oxides, such as sulfides, hydrides, or chlorides, may require specialized cleaning solutions. For increasingly thicker layers, whether an oxide film or another type of surface contaminant, longer cleaning periods or more aggressive chemicals are required for the removal process. However, either approach increases the chance of damage to the substrate.

Table 34 identifies some general solutions used to clean metal surfaces. Inhibitors are typically added to commercially available acid solutions to prevent pitting. Distilled or deionized water should be used in solutions to prevent unwanted deposits and residual films after cleaning. Electropolishing processes can also be used to remove metal-oxide layers (Ref 23). In such procedures, the substrate forms the anode.

Whether a chemical etch or an electropolishing procedure is used, the corrosive solutions must be thoroughly rinsed from the surfaces to prevent staining or latent corrosion. These artifacts may also deteriorate solderability in follow-up processing steps. Rinses with distilled water, followed by an alcohol rinse to remove the water, is a typical sequence. Workpieces should not be dried with unfiltered or undried "house" compressed air, because oil and water droplets from

the air line will quickly contaminate the surface. Once cleaned, the surface should be soldered as soon as possible to limit reoxidation, or measures should be taken to protect surfaces from further contamination.

Mechanical abrasion can be used to remove excessively thick oxide films. Techniques include using sandpaper, steel wool, or metal files, or blasting with particulates. However, solderability can be quickly degraded by abrasive media that become embedded in the substrate surface and are not readily wetted by the molten solder. Procedures that use abrasive particles (blasting or sandpaper) or steel wool should be followed by a chemical etching treatment to remove the layer of surface material containing the foreign particles. Metal files are used to prepare the surfaces of larger, more-rugged substrates, such as pipes and fittings, and they should be cleaned of contaminant materials prior to use.

Coatings. Metals and alloys that are difficult to solder (aluminum, chromium-nickel steels, cast irons, and others) may lose their solderability too quickly after precleaning and become unprocessible. In these instances, coatings can be applied to protect the base metal prior to final assembly. Methods of application include electroplating, electroless plating, evaporation, chemical vapor deposition, or dipping in a molten metal bath. Table 35 identifies 100Sn and tin-lead solder coatings that are used to protect base-metal solderability. These protective coatings can be electroplated on the surface or they can be applied by dipping the substrate into a hot solder or tin bath. Substrates with electroplated films can be heated above the melting temperature of the coating to "fuse" it, which provides an improved seal against air and contaminants, similar to the protection obtained with hot-dipped tin or solder coatings. Electroless tin processes, including "immersion" platings, are also used.

TABLE 35 TIN AND SOLDER COATINGS TO PRESERVE BASE-METAL SOLDERABILITY

COATING	**THICKNESS**		COMMENTS
	µM	**µIN.**	
ELECTROPLATED 100SN	7.6-13	300-500	**CONCERN FOR WHISKER GROWTH WITH MOISTURE AND RESIDUAL STRESSES; RECOMMENDED FUSING**

Source: Ref 24

For metals such as aluminum and magnesium, which simply cannot be kept solderable, or for ceramics that are intrinsically unsolderable, a metal layer is deposited on the substrate. The solder more readily wets this layer, which is often referred as to the "solderable" layer. These films must be adequately thick to avoid being consumed by the metallurgical reaction with the solder, and they must exhibit adequate adhesion to the base material. In some instances, an "adhesive" layer may be deposited between the base material and the solderable layer. A "protective" layer can also be deposited onto the solderable coating in order to prevent excessive oxidation or contamination. This protective layer is then consumed by the solder. Table 36 lists the coating materials and processing steps used for substrates that are commonly involved in solder processing.

	(SOLDERABLE OR BARRIER LAYER BARRIER LAYER)						

(A) THICKER LAYERS OF 2.5 TO 7.6 μM (100 TO 300 μIN.) PERMITTED FOR IMPROVED COVERAGE; ELECTROLESS NICKEL, 1.3 TO 3.0 μM (50 TO 120 μIN.) OR 2.5 TO 5.1 μM (100 TO 200 μIN.) PERMITTED ON NONFLEXIBLE SUBSTRATES; LAYER ADHESION AND SOLDERABILITY REQUIRE CLOSE MONITORING.

(B) THICKER LAYERS OF 2.5 TO 7.5 μM (100 TO 300 μIN.) PERMITTED FOR SOLDERABLE LAYER PROTECTION; HOWEVER, THINNER LAYERS ARE RECOMMENDED AND SOLDER JOINTS SHOULD BE MONITORED FOR EMBRITTLEMENT.

(C) MINIMUM.

(D) NOT CONTAINED IN MIL-STD-1276D

Gold plating layers should be removed by hot-solder dipping twice in a bath of molten solder if the calculated gold content of the solder joint will exceed 3 to 4 wt%, in order to prevent solder-joint embrittlement by gold-tin intermetallic formation. Electroplated gold layers should be pure gold, preferably type III, 99.9% pure, and grade A, according to MIL-G-45204C. Gold coatings alloyed with cobalt, nickel, or both (termed "hard gold"), which are used for wear resistance, are difficult to solder, because of oxidation of the cobalt or nickel component. Only matte finishes should be specified for soldering applications. "Bright" platings require organic additives in the bath, which then become entrapped in the gold coating and subsequently volatilize during soldering. This creates voids in the joints and poor wetting properties.

General Soldering

Paul T. Vianco, Sandia National Laboratories

Fluxes

The major role of the flux is the removal of thin tarnish layers during the initial stages of the soldering process, thereby permitting the molten solder to react with the substrate and to spread. Fluxes do not effectively displace organic contaminants, so the substrate underneath such films will remain untouched by the flux and will therefore be unsolderable. A degreasing step should precede flux application. Even the strongest fluxes cannot remove thick oxides or heavy scales, so a mechanical or chemical precleaning procedure may be required.

The flux has two additional functions. One is that it lowers the surface tension of the solder, allowing it to more readily fill gaps and holes by capillary action. The other function is that the flux coating protects the metal surface from reoxidation during the heating steps just prior to soldering.

Fluxes contain three principal ingredients: an active chemical compound, such as a halide, for oxide removal; wetting agents to improve surface coverage; and a vehicle to dilute and mix the cleaning compound and wetting agents together. The vehicle, which is removed by evaporation during the soldering process, is typically water, isopropyl alcohol, glycerin, glycol (for liquid fluxes), or petroleum jelly (for flux pastes or creams). Fluxes are characterized by their cleaning agent

and are assigned to one of these categories of increasing activity: rosin-base fluxes, organic-acid fluxes (also called "intermediate" or "water-soluble" fluxes), and inorganic-acid fluxes.

Flux specifications are most numerous for the rosin-base materials, because of the criticality of their properties in the assembly of electronic products. Sample specifications include military standards MIL-F-14256E and MIL-STD-2000; federal specification QQ-S-571 E; and the industry standards ASTM D 509, IPC-S-815A, and IPC-TM-650 (test methods). Fluxes are tested for bulk corrosivity (copper mirror test), concentrations of Cl^- and F^- (halide content), and solids content. Tests of residues left by the flux on the substrate (typically a printed wiring board) include surface insulation resistance, and ionic residues. The ISO/DIS 9454-1 document includes organic- and inorganic-acid flux specifications and test procedures (ISO/DIS 9455-X, where X = 1, 2, . . ., 14), in addition to rosin-base flux specifications.

The removal of flux residues depends on the specific application, as well as the potential corrosivity of the residues left behind. If residues are specified for removal, then the workpiece should be cleaned as soon as possible after processing. Rosin residues become particularly difficult to remove with time.

Rosin-base fluxes contain "water-white" rosin, a distillation product from pine tree sap. When used alone, rosin-base fluxes are referred to as a "nonactivated," or type R, grade. Rosin is solid, noncorrosive, and insulating at room temperature. Heating causes it to liquefy and become slightly chemically active, because of its abietic and pimaric acid components. The rosin is typically dissolved in an organic vehicle, such as isopropyl alcohol, to form the liquid solution.

The addition of an activator to rosin fluxes increases their chemical activity. Activators can be organic halogenated compounds, such as amine hydrohalides that contain chloride, fluoride, or bromide ion groups or "halide-free" activators, such as oleic, stearic, or lactic acids. Halide-free fluxes are recommended for materials that are sensitive to stress-corrosion cracking. The concentration of activators, which defines the corrosivity of the flux, determines the flux category as being one of the following: rosin-base, mildly activated (RMA), fully activated (RA), and superactivated (SA). Generally, rosin-base fluxes have poor high-temperature stability; that is, the fluxes degrade rapidly after excessive exposure to elevated temperatures (for example, >25 s at 260 °C, or 500 °F).

R-type fluxes are used on electronic assemblies, where the benign residues are left on the soldered assembly. However, the substrate(s) must have excellent solderability, because the weak activity of these fluxes offers a very small window of variability for oxide thicknesses. R-type fluxes are effective on lightly tarnished copper surfaces and on precious-metal substrates, as well as on tin- and solder-coated base metals. Residues can be removed by nonpolar solvents, organic solvents (isopropyl alcohol, 1,1,1-trichloroethane), semi-aqueous solutions (terpenes), and aqueous baths or detergent solutions.

The residues left by R-type fluxes can be reduced by dilution with an organic solvent (for example, isopropyl alcohol). Such fluxes are termed "low solids" because the solids, which are responsible for the residues, are significantly reduced so that cleaning steps are not required. These fluxes are also referred to as "no-clean;" however, the term "no-clean" covers a much wider range of flux formulations that must simply comply with residue corrosivity, irrespective of the solids content.

The increased activity of the RMA fluxes improves solder wetting on more heavily tarnished copper substrates. Residues are relatively benign and only require removal when the fluxes are used on high-reliability electronic systems (for example, in military applications) or when the fluxes contain potentially harmful halide activators. Residue cleaning is a two-step process. The first step requires the use of organic solvents to remove the nonpolar rosin, and in the second step, a polar solvent (water or polar alcohols) is used to rinse away activator residues. Aqueous and semi-aqueous products can perform both functions.

The greater corrosivity of RA and SA fluxes is due, primarily, to higher levels of the activators that are used in RMA fluxes. These fluxes are used on base metals such as nickel (and nickel plate), lightly tarnished low-carbon steels, copper, iron-base alloys, and copper-base alloys (brasses, bronzes, and beryllium copper). Residues of the RA and SA fluxes must be removed to prevent the corrosion of the substrate later in service. Cleaning procedures similar to those identified for RMA fluxes are used. Cleanliness testing for ionic residues should be implemented to verify the adequate removal of flux deposits, particularly for the stronger fluxes.

Organic-acid fluxes have a chemical activity range that varies from the levels associated with RMA fluxes to those that exceed the activity of RA fluxes. These fluxes contain one or more organic acids, such as lactic, oleic, or stearic acid.

Chemical activity can be enhanced by adding organic halogen compounds (amine hydrohalide, which may contain chloride and bromide derivatives) or nonhalogenated substances, such as one of the amines or amides (urea or thylene diamine). Typical vehicles include water, isopropyl alcohol, polyglycols, or petroleum jelly for pastes.

The organic-acid fluxes are used in many electronic applications involving machine processes and hand assembly, as well as the hot tin or solder dipping of nickel and iron-base alloy leads and devices. These fluxes are also used on structural applications with copper and copper alloy workpieces that have light to moderate tarnishes.

Whether the fluxes are used in structural or electronic applications, their residues should be removed. The water-soluble residues are typically removed by rinsing with water or a polar organic solvent. The organic acid fluxes have better high-temperature stability, when compared with the rosin-base materials, which makes them good candidates for solders with melting temperatures that exceed 200 °C (363 °F).

Inorganic-acid fluxes have the highest levels of chemical activity. There are two categories of these fluxes:

- PURE ACIDS, SUCH AS HYDROCHLORIC, HYDROFLUORIC, OR PHOSPHORIC ACIDS, WHICH HAVE SURFACTANTS ADDED TO ENHANCE COVERAGE.
- INORGANIC SALT MIXTURES OR SOLUTIONS, WHICH MAY ALSO CONTAIN SURFACTANTS.

The pure acids are very strong and are capable of removing heavy oxide layers and scales. However, they offer the clean surface limited protection from reoxidation during the soldering process. Binary inorganic salt "alloys" are formed from the combination of zinc chloride ($ZnCl_2$), ammonium chloride (NH_4Cl), stannous chloride ($SnCl_2$), or sodium chloride (NaCl) components. The inorganic salt combinations form simple eutectics with minimum temperatures near the melting point of solders. (The melting temperature of the single salts are too high for them to flow at typical soldering temperatures.) For example, the NH_4Cl:3 ($ZnCl_2$) eutectic composition has a eutectic temperature (T_e) of 177 °C (351 °F). Other eutectic salt combinations include: $SnCl_2$-CuCl, T_e = 170 °C (338 °F); AgCl-CuCl, T_e = 260 °C (500 °F); and CuCl-$ZnCl_2$, T_e = 230 °C (446 °F).

Proper flux selection is based on the salt mixture having a melting temperature that is less than that of the solder. The molten salt reduces the surface oxides and coats the base metal to prevent reoxidation during the soldering process. Flux activity is further increased by dissolving the flux in a water vehicle. The salts break down to release Cl^- ions, which combine with water to form a hydrochloric acid (HCl) "activator." The fluxes, particularly the water solutions, may contain surfactants to assist the complete coverage of the joint area. A paste form of the flux uses petroleum jelly as the vehicle.

The inorganic-acid fluxes are limited to structural applications, such as plumbing or mechanical assemblies. Their corrosive activity is unacceptable for electronic devices or substrates, or for their assembly. These fluxes are effective on nickel and nickel alloys, stainless steels, chromium, and heavily tarnished copper and copper alloys. The inorganic fluxes are very stable at high temperatures. The flux residues and the fluxes themselves are extremely corrosive and must be thoroughly removed after processing.

It should be noted that chloride-containing residues and small amounts of water are particularly damaging to aluminum and aluminum alloys, because of the potential for stress-corrosion cracking. Residues are removed with hot-water rinses and follow-up polar-solvent rinses. Neutralizing solutions (mild caustics) can be used on nonsensitive substrates. A list of selected inorganic flux solutions for particular base metals is provided in Table 37.

General Soldering

Paul T. Vianco, Sandia National Laboratories

Solder Joint Assembly

The configuration of a solder joint must have two basic attributes: It must meet the service requirements of the assembly, and it must be manufacturable to those requirements. Specifications and guidelines for the design of structural solder joints (for example, conduit) are limited, when compared with those used in electronic applications. Some British and European standards have been established, but few exist in the United States. Because standard joint design guidelines are not available, performance data are not well documented. However, the brazing community has several sets of standards that pertain to structural brazed joints (Ref 24). These specifications, which were established by the American Society of Mechanical Engineers (ASME), American National Standards Institute (ANSI), American Welding Society (AWS), and the Society of Automotive Engineers (SAE), cover joint construction, strength tests, and safety issues. Although these specific documents were developed for brazements, they can provide general guidelines for applying similar tests and criteria on solder joints. Under the circumstances, conservative design practices and inspection and test protocols that certify process quality have substituted for insufficient data. Additional information is available in the article "Evaluation and Quality Control of Soldered Joints" in this Volume.

Design for Service Requirements. Solder joint service conditions are typically represented by either electronic interconnect applications or structural applications. The former are described in the article "Soldering in Electronic Applications." Structural applications, which are described below, range from the assembly of small housings and containers to plumbing for fluid or gas conduit. Typical service requirements for structural joints include the support of mechanical loads (both high-temperature and cryogenic conditions), hermetic sealing for vacuum applications, and leak-tight joints for positive-pressure conduits and containers.

Several common structural solder joint configurations are shown in Fig. 15. It is recommended that solder joints be loaded in shear. Tensile loads should be avoided, because a slight deviation in the loading direction can place the joint in a peel-type fracture mode, which typically causes premature failure of the assembly. Lap-shear joints should have an overlap of approximately one-third of the base-metal thickness (Ref 25). Lap joints retain their strength over a range of gap thicknesses. However, the gap thicknesses of a single joint should be uniform for consistent capillary filling by the molten solder.

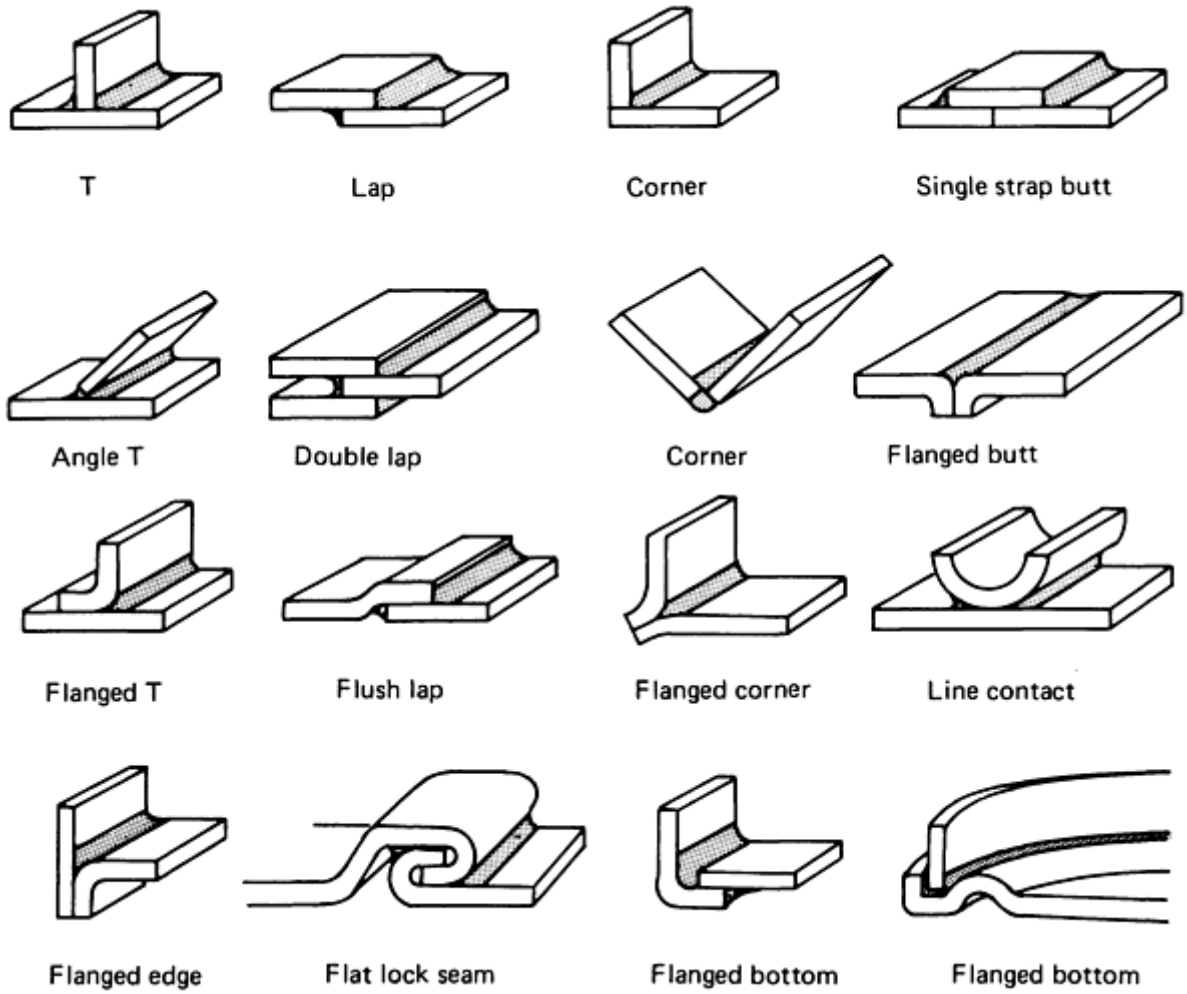

FIG. 15 COMMON STRUCTURAL SOLDER JOINTS

One of the first of the design criteria that pertains to the selection of a suitable solder is melting temperature, specifically the solidus and liquidus points. The solidus temperature is determined directly by the service conditions of the final assembly. Of course, the service temperature should never exceed the solidus point. However, how close the service temperature should be allowed to approach the solidus temperature depends on the level of monotonic or creep deformation and the fatigue life acceptable for the particular application. Tables of appropriate data either should be referred to or the necessary experiments performed.

A suitable liquidus temperature is primarily determined by the temperature sensitivity of the substrate materials during the soldering process. The molten solder working temperature should be approximately 25 to 50 °C (45 to 90 °F) greater than the liquidus temperature. A secondary factor in the selection of the liquidus and solidus temperatures is the desired pasty range for solder workability prior to solidification. Finally, multiple soldering processes require the solidus temperature of the first (high-temperature) soldering step to exceed the liquidus point by 30 to 50 °C (55 to 90 °F) of the second (low-temperature) step.

The mechanical properties of the solder must be considered in terms of the particular application. For example, the monotonic and creep strengths (shear or tensile) must be appropriate for the particular loading conditions and temperature environments to which the joint is subjected. Fatigue resistance is important for joints subjected to time-varying loads. Although such loads may be well below the ultimate monotonic or creep strength limits of the solder, they can result in significant cracking of the solder layer in a joint.

The size of the substrates and the thermal conductivity of the material from which they are constructed affect the joining process. A disparity of mass between the two substrates will result in the larger part heating up more slowly than the smaller one. Insufficient heat can result in a cold joint (that is, an absence of capillary flow and/or poor fillet formation

caused by premature solder solidification). Conversely, overheating the smaller workpiece may cause undesirable changes to the mechanical and physical properties of the base material. Similarly, two substrates with vastly different thermal conductivities (for example, stainless steel and aluminum) are difficult to uniformly heat, particularly in localized heating processes, such as soldering with an iron or torch.

When designing joints of dissimilar materials, the coefficient of thermal expansion (CTE) differences must be considered because sufficient stresses can build within the joint to cause catastrophic failure, particularly if the substrates are brittle. Time variations in environmental temperatures cause fatigue deformation to accumulate in the solder, thereby weakening the mechanical strength of the joint. An example of the method used to estimate the fatigue life of a 60Sn-40Pb solder joint can be made by calculations based on empirical data, as shown below. Unfortunately, data to support similar computations with other solders have not been compiled.

Laboratory tests of the isothermal fatigue life of 60Sn-40Pb over the temperature range from -50 to 125 °C (-58 to 257 °F) were used to develop the following equation for the fatigue life, N_f (Ref 16):

$$N_f = \left(\frac{1.14}{\Delta g_p} \right)^{1.96}$$

where N_f is the number of cycles to failure (50% load drop for equivalent strain) and $\Delta\gamma_p$ is the plastic strain level in the joint. A conservative estimate of $\Delta\gamma_p$ is made by using the total strain, $\Delta\gamma_t$, determined by:

$$\Delta g_t = \frac{(a_1 - a_2)\Delta TL}{t}$$

where α_i is the CTE of the two substrates (i = 1, 2), $\Delta T$is the temperature difference, L is the maximum dimension of the joint, and t is the joint thickness. The parameters and joint configuration are illustrated in Fig. 16. Solder fatigue cracks may be visible in the solder fillets, typically where L is a maximum.

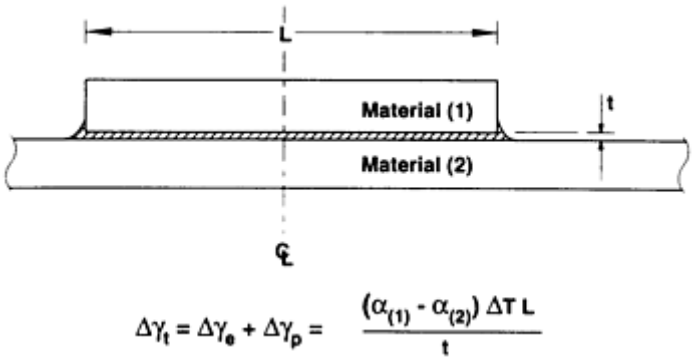

FIG. 16 PARAMETERS FOR THE CALCULATION OF TOTAL THERMAL MISMATCH STRAIN IN A GENERIC SOLDER JOINT CONFIGURATION. *T*, JOINT THICKNESS; *L*, MAXIMUM JOINT DIMENSION BETWEEN THE TWO SUBSTRATES

Thermal expansion mismatch between workpieces affects joint clearances during the soldering process. Consider the enclosed geometry tube-in-socket joint in Fig. 17. When the CTE of the outer part is larger than that of the inner part, the gap will increase with heating. An excessive gap will result in voids in the joint that are caused by an insufficient solder supply and/or poor capillary action. A sample calculation follows:

- INNER PART AT 20 °C (68 °F), COPPER; CTE (α_1), 17.0 × 10^{-6}/K; OUTER DIAMETER, 74.7 MM (2.94 IN.)
- OUTER PART AT 20 °C (68 °F), ALUMINUM; CTE (α_0), 23.5 × 10^{-6}/K; INNER DIAMETER, 75.0

MM (2.95 IN.)
- GAP AT 20 °C (68 °F), 0.15 MM (0.006 IN.)

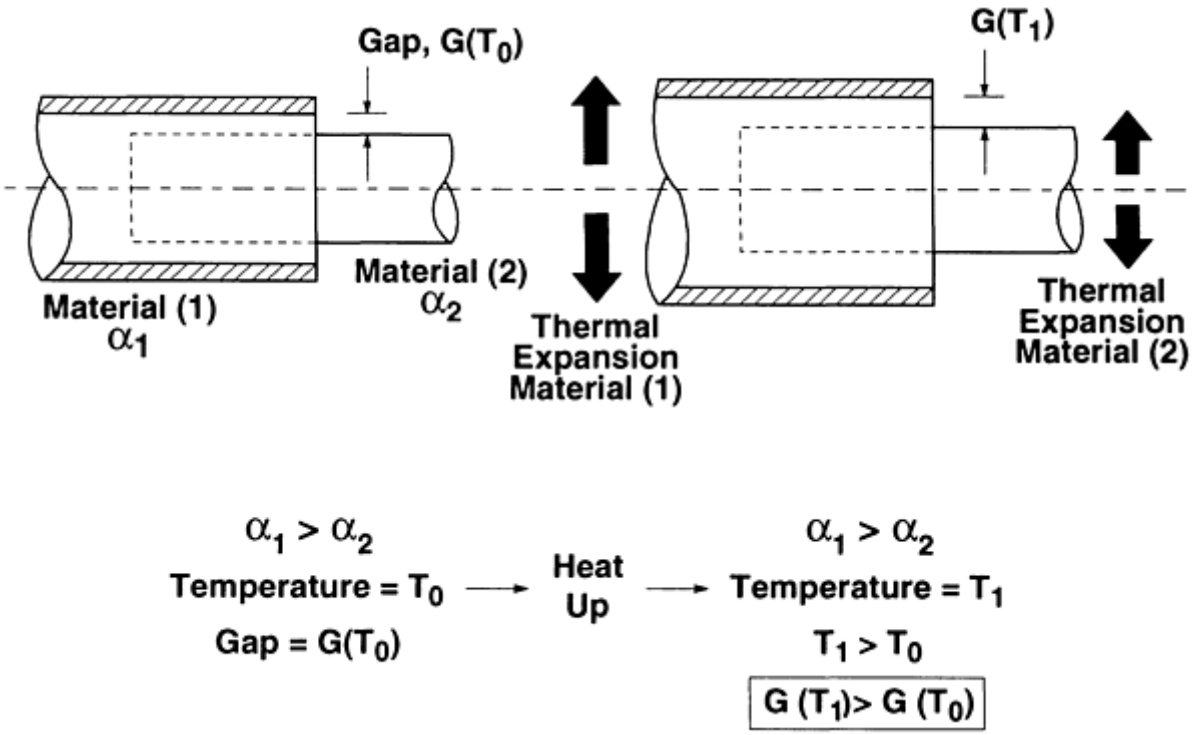

FIG. 17 EFFECTS OF HEATING ON THE JOINT GAP BETWEEN DISSIMILAR METALS

At 250 °C (482 °F), the new dimension, L_f, of the parts (the outer diameter of the aluminum and the inner diameter of the copper) are calculated by:

$$L_F = L_O + L_O \alpha \Delta T$$

where L_o is the dimension at 20 °C (68 °F), αis the CTE of the material, and ΔT is the temperature difference (T_f - T_o).

- T_F = 250 °C (482 °F), SO THAT ΔT = 230 °C (414 °F)
- INNER PART AT 250 °C (482 °F), COPPER; OUTER DIAMETER, 75.0 MM (2.95 IN.)
- OUTER PART AT 250 °C (482 °F), ALUMINUM; INNER DIAMETER, 75.4 MM (2.97 IN.)
- GAP AT 250 °C (482 °F), 0.2 MM (0.008 IN.)

In this example, the solder joint gap grew by 0.05 mm (0.002 in.). This computation can be applied to any geometry in which L_o is the dimension of the respective parts.

Conversely, an inner part with a CTE that is greater than that of the outer section will cause the gap to decrease with heating, causing voids and poor solder filling resulting from the inability of flux volatiles to escape from the joint.

Finally, consideration must be given to material compatibility. The first concern is that the substrate materials are not damaged by chemicals or the mechanical procedures used to preclean surfaces. Damage includes excessive metal removal, stress-corrosion cracking, or the deposition of hard-to-remove residues. Secondly, the corrosion potential of joining dissimilar metals, including the two base metals as well as the solder/base metal couples, must be adequately assessed. In the case of conduit for liquids or gases, the role of the carried medium, as an electrolyte in the corrosion of the joint, must also be considered. In many cases, references to the electromotive series or fundamental chemistry

textbooks (Ref 26) can provide corrosion information for a preliminary assessment. Finally, the assembled product must be compatible with the chemicals and processes used to remove flux residues after soldering.

Design for Processing Requirements. It is assumed that the substrates have adequate solderability for the selected solder alloy. Two processes must occur during product assembly to ensure an adequate joint: The solder must fill the gap area and flux volatiles and liquids must be ejected from the joint. Some general guidelines at the design stage will facilitate these processes.

First, the joint gaps should be in the range from 0.076 to 0.18 mm (0.003 to 0.007 in.). Workpiece design must also account for changes in gap dimensions caused by the heating/cooling of dissimilar substrates, surface roughness, plate flatness, eccentricity of circular-section workpieces, and consumption of the base metal or substrate coatings by the molten solder. Smaller gaps restrict solder flow and hinder the removal of flux volatiles, whereas larger gaps diminish the capillary effect required by the molten solder to fill the joint.

Second, the preferred gap geometry is a straight path opened to the atmosphere at two locations. One opening is used to supply flux and solder to the joint, while the other serves to vent flux volatiles and gases as the molten solder fills the gap. "Blind" gaps (or blind holes), which do not allow a vent path, should be avoided. A vent hole can be added and later filled in with a lower-melting-temperature solder if the design permits. Another rule of thumb is that solder has difficulty in "turning corners." Therefore, straight paths are preferred over sharp comers in the joint.

Third, ready access to the joint by a reservoir of solder containing an adequate quantity to fill the gap and to form the fillet must be provided. Inadequately filled gaps can be caused by an insufficient supply of solder to the joint. Poorly formed solder fillets reduce the monotonic strength, fatigue life, and creep strength of the joints, as well as limit the solderability assessment.

Fourth, solder joints that use preforms are always susceptible to void formation. Because the joint does not fill by capillary action, volatiles and gases have an increased likelihood of being trapped within the gap. Such joints must also be carefully assessed for corrosion potential by retained flux residues in those voids.

Fifth, the metallurgical reaction between the substrate and the solder during wetting necessarily consumes some of the substrate to form the reaction layer (typically, an intermetallic compound) at the interface. The dissolution of substrate material must be accounted for when soldering to very thin foils or coatings. The rate of dissolution will depend on substrate geometry (round or cylindrical sections dissolve slightly faster than flat plates), substrate composition, and the composition and volume of solder (flowing baths will remove more substrate metal than static baths). The temperature of the solder and the time of immersion (an increase of both raise the rate of substrate dissolution), are also factors. Dissolution data from unspecified geometries are determined from Fig. 18 and 19.

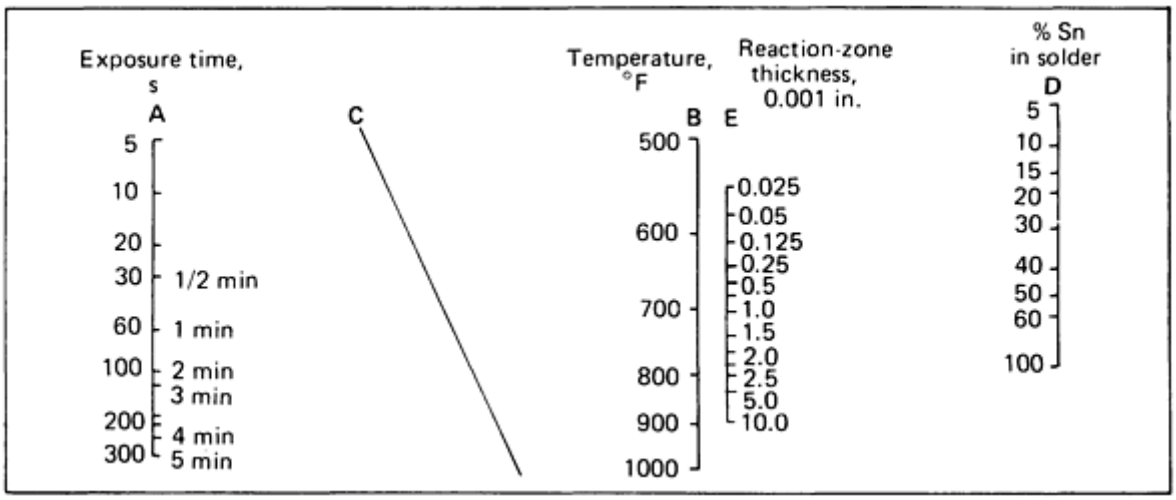

FIG. 18 NOMOGRAPH TO DETERMINE THE TIN-LEAD SOLDER REACTION ZONE THICKNESS FOR THE COPPER ALLOYS C10200 AND C26000 ALLOYS UNDER STATIC INFINITE-VOLUME CONDITIONS. SELECT THE EXPOSURE CONDITIONS ON SCALES A AND B. WITH A STRAIGHT EDGE BETWEEN THE CONDITIONS, FIND THE INTERSECTION WITH BASE LINE C. USING A STRAIGHT EDGE, CONNECT THIS POINT ON LINE C WITH THE

TIN CONTENT OF THE SOLDER ON SCALE D. READ THE REACTION-ZONE THICKNESS ON SCALE E. THE NOMOGRAPH CAN ALSO BE USED IN REVERSED SEQUENCE TO SELECT OPERATING CONDITIONS, GIVEN A PERMISSIBLE REACTION ZONE THICKNESS AND SOLDER COMPOSITION.

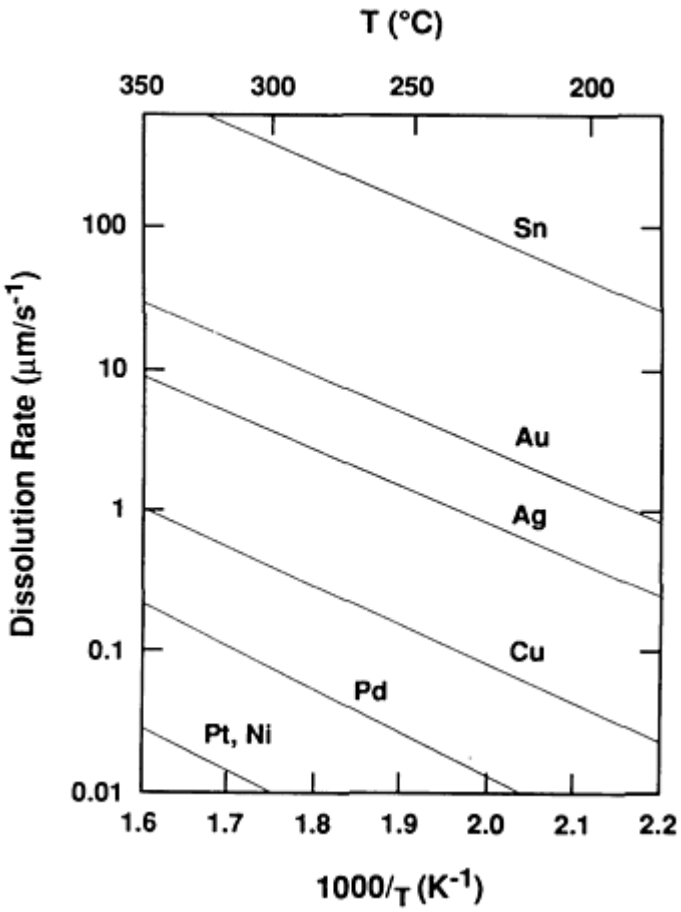

FIG. 19 METAL DISSOLUTION RATES FOR ELEMENTAL METALS AS A FUNCTION OF TEMPERATURE. SOURCE: REF 27

Intermetallic compounds represent the metallurgical reaction product between the solder and the substrate material. The compound formulations for common base metals and coatings with tin-bearing solders are:

- *COPPER:* CU_6SN_5 AND CU_3SN
- *NICKEL:* NI_3SN_4
- *GOLD:* $AUSN_4$ AND $AUSN_2$
- *IRON:* $FESN_2$
- *SILVER:* AG_3SN

These layers form when the solder is molten, as well as after solidification, by means of solid-state diffusion during storage or service at elevated temperature. In the solid state, the thickness is a function of the temperature and the time. Although intermetallic compounds are a necessary part of solder wetting, excessively thick layers can be detrimental to joint integrity or follow-up processing. Specifically, the brittle nature of intermetallic compounds can jeopardize the mechanical and fatigue strength of the joint, particularly at high loading rates, such as those that occur under impact or vibration conditions. Another detriment is that the solid-state growth of the layers consumes both the solder film and the base metal. Complete consumption of the tin or solder coating exposes the intermetallic surface to oxidation, making it very difficult to solder coat, even when using the strongest fluxes. The solid-state growth kinetics of several solders that were hot dip coated on copper are shown in Fig. 20. The typical as-soldered thickness of intermetallic compounds of

60Sn-40Pb on copper and nickel are 1 to 2 μm (39 μin.) and 0.5 μm (20 μin.), respectively. The layers grow very slowly at room temperature.

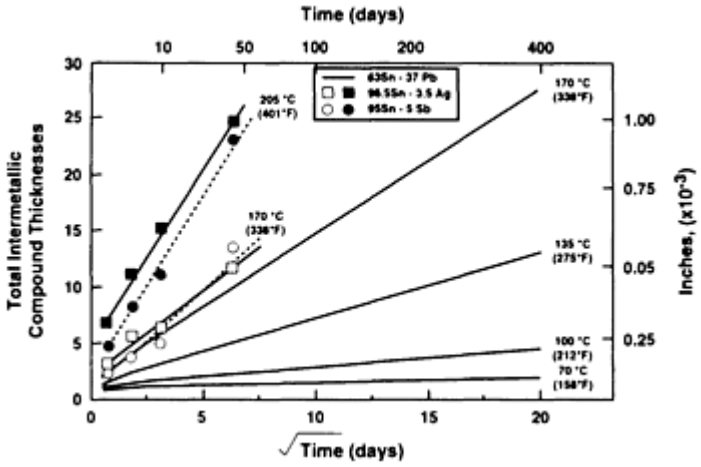

FIG. 20 SOLID-STATE INTERMETALLIC GROWTH KINETICS FOR HOT-DIPPED SOLDER COATINGS ON COPPER. SOURCE: SANDIA NATIONAL LABORATORIES

Joint design must include postassembly cleaning requirements. Materials compatibility between the cleaning agents and the workpiece, as well as the geometry of the workpiece, are important factors. Reentrant comers or hidden gaps and passages can entrap flux residues and prevent the flow of clean solvents into the areas.

The use of the high-temperature, precious-metal solders 80Au-20Sn or 88Au-12Ge on precious-metal substrates and coatings does not require a flux to remove the very limited oxide layers. The melting points of these solders preclude the use of rosin-base fluxes, because of significant high-temperature degradation. Other fluxes may also experience some degradation. The absence of a flux causes the surface tension of the solder to remain high, impeding capillary flow by the molten alloy. Therefore, the solders are typically introduced into the joint as preforms. Mechanical pressure on the joint is used to assist the spreading of the solder throughout the gap. Small quantities of oxide particles in the solder arise from the non-precious-metal component. Random spreading of the solder causes the joint to have a higher number of voids than is observed in a joint filled by capillary action.

Maintaining the position of the substrates during solder wetting is necessary for successful joint formation. Special fixturing can be designed to hold the workpieces for critical applications. Another approach is to design the joint itself to be self-jigging, in order to maintain the proper gaps and clearances during soldering (Fig. 21).

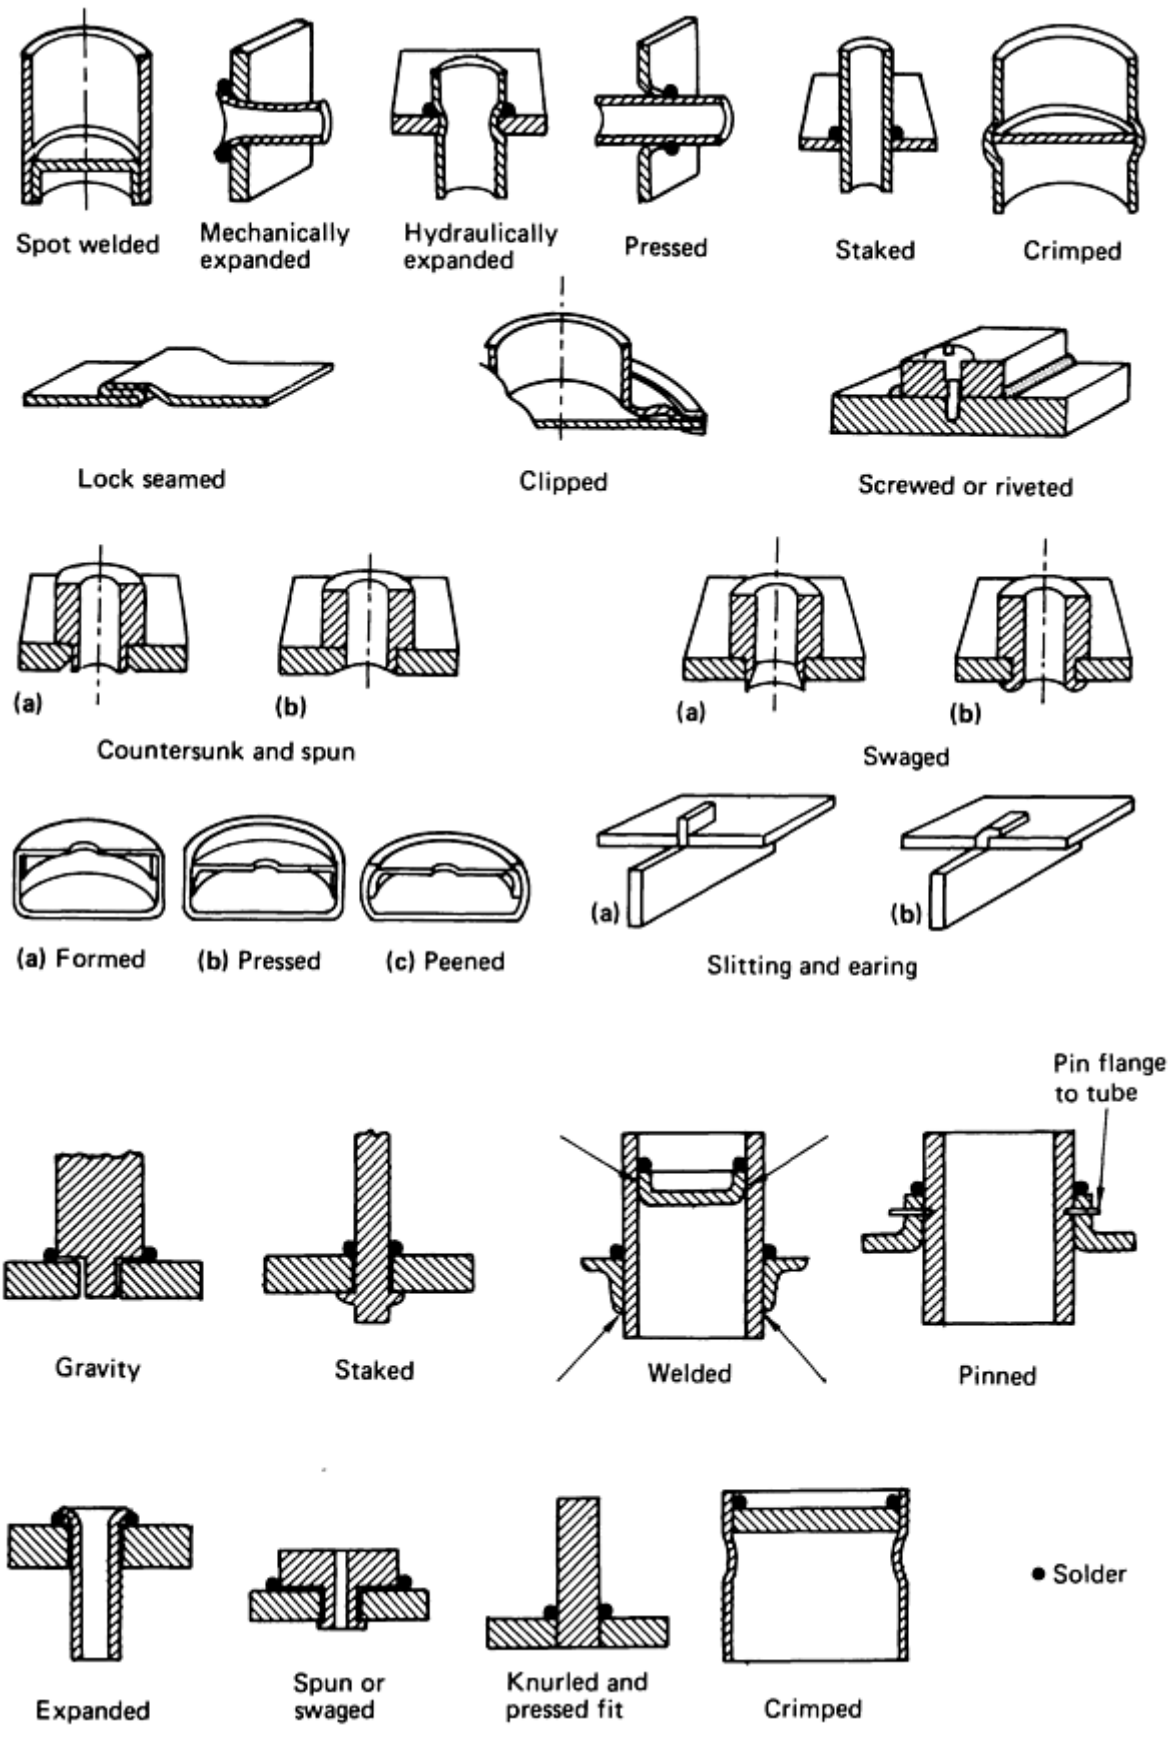

FIG. 21 SELF-JIGGING JOINT CONFIGURATIONS

Design for Inspection Requirements. The inspection techniques selected to qualify a solder joint will have particular requirements in terms of joint configuration. Visual inspection is typically used to determine whether the solder has flowed within the gap and on the external surfaces (fillets). For blind holes or gaps, witness holes can be drilled into the substrate(s). During soldering, the solder fills the witness hole to the outside surface, indicating to the operator that the solder has indeed filled the gap. Although they are not always practical, unobstructed views of the solder joint gap at the external surface vastly improve the visual inspection of the joint.

Soldering Techniques

The numerous soldering processes have the common goal of providing heat energy to the joint area in the presence of the flux and solder alloy. The heat energy (and subsequent temperature rise) must support activation of the flux cleaning activities, heating of the substrate, and melting of the solder alloy to permit wetting and joint formation. Too little heat limits solder wetting, whereas excessive heat chemically degrades the flux (which loses activity and deposits hard-to-remove residues), reoxidizes the substrate surface prior to completion of solder wetting, or causes heat damage to the substrate.

Heating techniques can be categorized as global processes, in which the entire substrate reaches the soldering temperature, and local techniques, in which only the immediate joint area is heated. Examples of global techniques include vapor-phase (condensation) reflow, furnace (infrared or convection) reflow, wave soldering, ultrasonic soldering (bath), as well as dip (including hot-air leveling) and drag soldering. Local heating techniques include the soldering iron (heat and heat plus ultrasonics), torch, hot gas reflow, focused infrared soldering, induction soldering, and laser soldering. Operator interaction depends on the particular process. For example, the entire process can be fully automated, as in furnace systems or specialized equipment used in electronic circuit board assembly. Nevertheless, operators must establish the proper zone temperatures, conveyor belt speeds, and heating rates. Thermocouple profiling of a prototype workpiece is essential to verifying that the proper thermal conditions will be achieved. Manual soldering, such as with the iron or torch, requires greater operator interaction and skill.

Control of the full sequence of heating, fluxing, and applying the filler metal is particularly critical in manual solder processes (whether iron, induction, torch, or hot-gas processes), because they are usually performed in air. Competing factors that occur during substrate heating are:

- NEED FOR AN INCREASE IN SUBSTRATE TEMPERATURE TO MAINTAIN THE MOLTEN STATE OF THE SOLDER
- ACTIVATION OF THE FLUX OXIDE REMOVAL PROCESS (OR PROCESSES)
- ACCELERATED OXIDATION OF THE SUBSTRATE SURFACE
- DEGRADATION OF SOME FLUX COATINGS

Circuit board soldering and structural applications are described below as general examples.

Circuit Board Soldering. First, flux is applied to the leads and circuit board, unless flux-cored soldering wire is used, in which case this step is omitted. The coated area should extend beyond the immediate joint to ensure adequate wetting by the solder. Next, the soldering iron is made to contact the lead (never the circuit board land), and the solder wire is fed so that it contacts the opposite side of the lead. Melting of the solder indicates that the lead has reached temperature. The wire, followed by the iron tip, is then removed from the joint area upon formation of the joint fillet.

Structural Applications. The larger thermal mass of typical workpieces requires preheating in order to bring the joint area to the working temperature. Then, the flux is applied to fully cover the hot surface. The joint is further heated and the filler metal is applied to the joint surfaces. Most inorganic and organic fluxes can tolerate the high temperatures required to supply heat to larger members. The rosin-base fluxes can quickly degrade, as indicated by the formation of thick, blackened residues on the surface. Heat and solder are removed when an adequate fillet forms at the joint opening, in order to ensure complete filling of the joint gap.

The hot dip coating of parts can be performed by ultrasonic activation, without using a flux. Ultrasonic energy is coupled to the sample through the solder bath (Fig. 22). Optimum coupling is a function of the sample geometry, power level, and workpiece-horn separation. Oxide removal does not occur through simple line-of-sight erosion by the horn (Ref 28). Rather, the oxide is disrupted by the ultrasonic energy that is transferred from the horn into the substrate. Therefore, hidden surfaces can also be coated by the solder. Hot-dipped coatings can be applied to large workpieces or to leads on small electronic devices. In the latter case, care should be taken to ensure that internal connections are not damaged by the ultrasonic energy. This technology has been used to assemble tube-socket joints on heat-exchanger equipment (Ref 29).

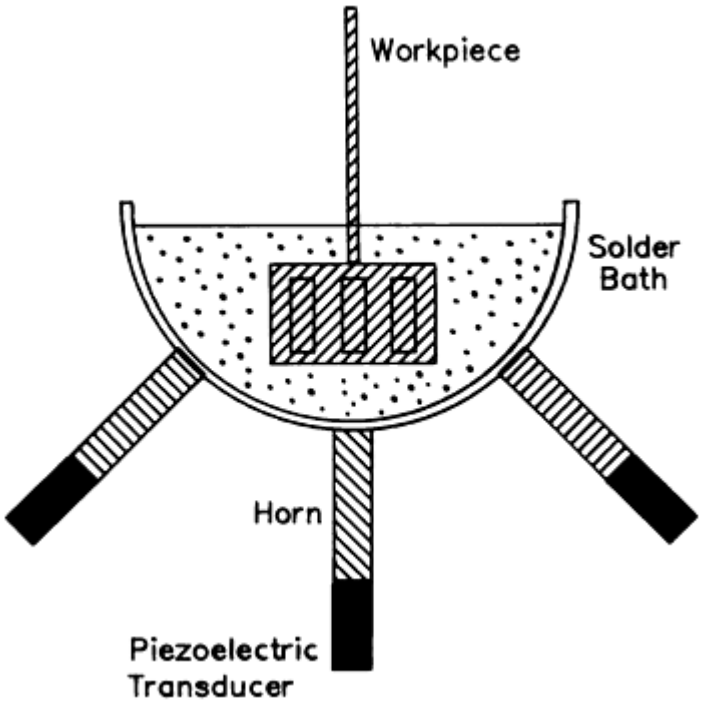

FIG. 22 ULTRASONIC SOLDERING BATH EQUIPMENT

An important component of the solder assembly process is the fixturing that is used to support the workpieces being assembled. Fixturing details are most critical for global heating processes in which the fixture will also be raised to the soldering temperature. The purpose of fixturing is to either anchor the two substrates to prevent movement while the solder is in the molten state or permit the controlled displacement of the substrates to establish specific joint gaps not achieved with the solder preform in the solid state. Lubricants include high-temperature petroleum products or solid lubricants (MoS_2 and graphite). Preloads on the workpieces are provided by springs (coil or Belleville configurations). The joint gap can be established by spacers between the workpieces or particles within the joint itself (Fig. 23). The spacer materials should not cause undesirable reactions with the solder or jeopardize the strength capacity of the joint.

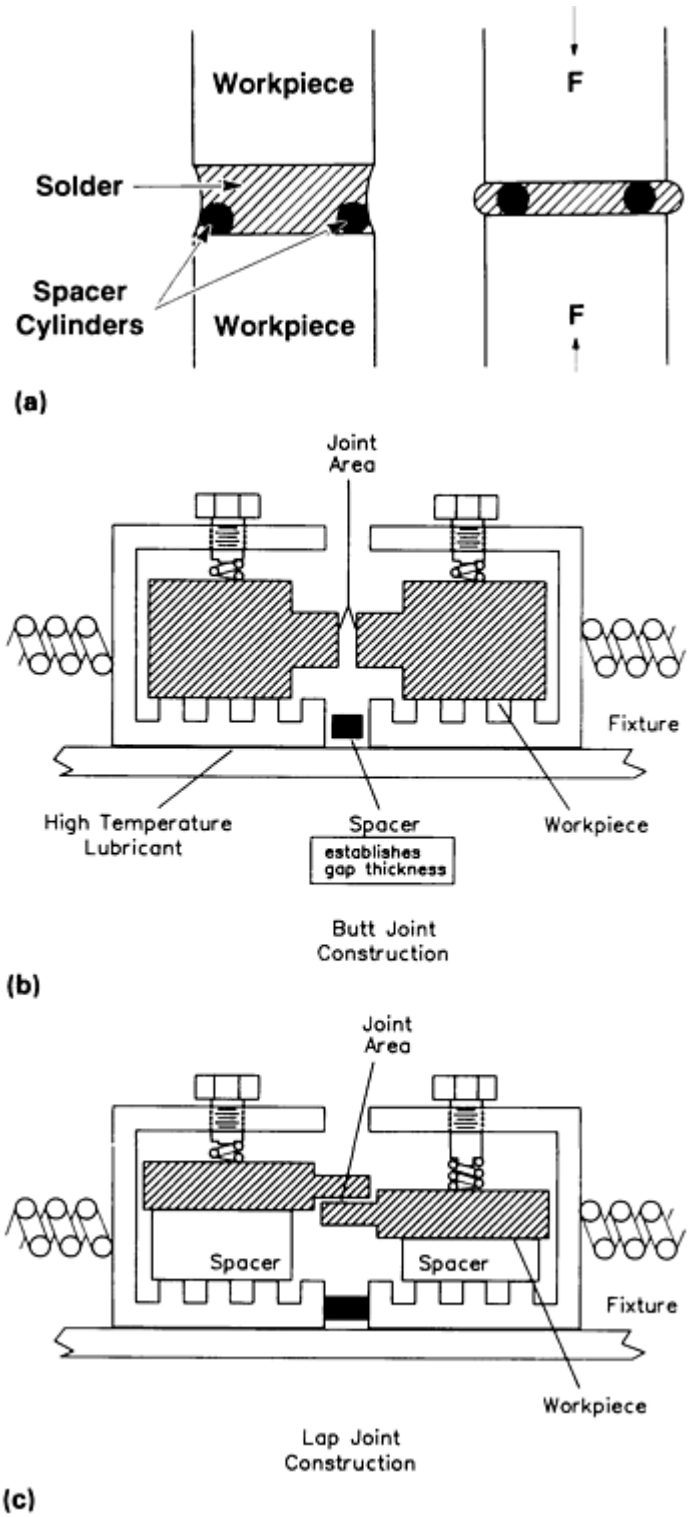

FIG. 23 TECHNIQUES TO MAINTAIN JOINT GAPS. (A) BUTT JOINT WITH SPACERS IN THE SOLDER. (B) BUTT JOINT WITH SPACER IN THE FIXTURE. (C) LAP JOINT CONSTRUCTION

Fixture materials should be carefully assessed. Although high vapor pressures generated by fixture metals is not of concern at the relatively low temperatures used in soldering, factors such as thermal expansion and fixture size should be considered. For example, a CTE mismatch between the workpiece and the fixture materials, with improperly designed dimensions, can cause the joint gap to grow or close at soldering temperatures. Fixtures with large thermal mass will lengthen the heating and cooling times for the workpiece, leading to possible flux degradation, base metal or coating erosion, and longer production time. Preferred fixturing materials include oxide ceramics (alumina, beryllia, or mullite), refractory metals (molybdenum, tungsten, or tantalum), and well-oxidized steels (low-carbon and stainless steels). These

materials will generally not be wetted by solder (and flux) spillage and can accommodate the elevated temperatures. Fixtures made of machined metals, such as aluminum, copper alloys, or steels, should be annealed in order to relieve any residual stresses that arise from the stock material or machining operations. These internal stresses may cause misalignment of the workpieces or the binding of moving parts, caused by warpage generated at soldering temperatures. Preoxidized surfaces will prevent inadvertent wetting by the solder.

Fixtures should be cleaned of organic residues to limit their outgassing in vacuum furnaces, prevent deposition of the contaminants onto the solderable surfaces, and limit spatter by their volatilization at soldering temperatures. Materials that contain or are coated with cadmium or zinc should not be used, because their high vapor pressures (even at soldering temperatures) may cause them to contaminate the joint area, as well as to poison vacuum and inert-atmosphere furnace systems.

The workpiece temperature should be monitored, at least in the prototype stages of process development, in order to document temperature conditions. In furnace operations, it is preferred that the controlling thermocouple contact the substrates to confirm the desired temperature profile at the joint area. The relatively low temperatures of soldering allow the use of inexpensive thermocouples, such as types J, T, and K, for many furnace cycles. The thermocouples should not interfere with the fixtures or the filling of the joint.

An undesirable spread of the molten solder on the substrate surface can be prevented by a number of "solder-stop" products. High-temperature tapes, which are popular in the electronics industry to prevent solder wetting of areas on printed circuit boards, are suited for many structural applications. Another product is a slurry made from powders that are mixed with water or alcohol and painted on the surface areas that are to be free of solder. The vehicle evaporates, leaving a coating that prevents spreading by the solder.

Detailed descriptions of the individual soldering processes, equipment, and applications are provided in the Section "Solid-State Welding, Brazing, and Soldering Processes" in this Volume.

Postassembly Cleaning Procedures

After the soldering operation, the workpiece is cleaned, primarily to remove flux residues that can cause corrosion of the part while in storage or during service. Other cleaning procedures include the removal of solder-stop materials, as well as stray solder particles, which can interfere with mechanical or electrical performance of the assembly. Flux residues should be removed as soon as possible after the soldering process, because their ability to be removed decreases with time, whereas their tenacity and potential for corrosive damage increase with time.

Cleaning fluids and solvents to be used are determined by the particular flux residues. Guidelines are presented in the section "Fluxes" in this article. The selection of organic solvents is rapidly changing as chlorofluorocarbon materials are phased out by environmental regulations and new materials (and processes) become qualified as replacements.

Some general practices must be considered when establishing cleaning procedures. First, assess the compatibility of substrate materials and filler metals with the cleaning solutions. Organic solvents are benign toward metal surfaces. Alkaline solutions used to neutralize strongly acidic fluxes can affect some base-metal finishes (for example, copper

alloys, iron alloys, and some steels). When in doubt, samples of the substrate should be exposed to the cleaning agent prior to use on final assemblies.

Second, determine whether the cleaning solutions leave undesirable residues. Mineral deposits from tap water can corrode or stain substrate surfaces (especially in the continued presence of water vapor). Tap-water rinses should be followed with rinses in either deionized or distilled water. All traces of water can be removed by a final alcohol rinse. Isopropyl alcohol is generally used. Denatured alcohol and acetone should be avoided, because they also can leave residues.

Third, the drying of solvent or other cleaning-solution residues should utilize dry, clean gas, such as bottled or cryogenic nitrogen gas. Compressed "house" air may contain water particles or compressor oils that can quickly recontaminate the workpiece.

Fourth, limit the contact of the assembly with oily rags and fingerprints. Many instances of cosmetic staining or pitting of the workpiece surface have been traced to fingerprints.

Fifth, test for the effectiveness of postcleaning operations. Unlike the well-specified procedures used by the electronics industry, such procedures are not well standardized for structural applications. Temperature-humidity chambers can be used to assess the propensity for corrosion on the workpiece (a destructive test).

Cleaning effectiveness can be enhanced by thermal and mechanical assistance. Cleaning solvents and solutions have higher solubility for residues at elevated temperatures. Caution should be observed when heating solutions because of the generation of vapors that can result in health or fire hazards. The use of solvent vapors at their boiling point in vapor degreasers can remove residues from remote locations on the workpiece. However, the solvents that have been popular for vapor degreasing are being restricted from use by environmental statutes.

Mechanical agitation of cleaning solutions is obtained by ultrasonic activation, high-energy sprays, and manual scouring procedures. Ultrasonics are very effective for loosening residues, particularly in hidden locations. Although generally safe for the cleaning of structural members, care must be exercised when using ultrasonics on electronic assemblies because of the possible damage to internal connections. The use of sprays or jets to force the cleaning solution into crevices and hidden areas of the workpiece can increase cleaning efficiency. Batch and in-line equipment based on spray and jet technology is currently available. Because the cleaning material passes through a jet, aerosols and mists are generated, which may create an explosion hazard.

Manual scouring can remove residues on exposed surfaces only. Cleaning with sandpaper or vapor blasting metal surfaces with abrasive particles should be avoided in the postprocess cleaning steps for three reasons: First, the base-metal oxide layer protects the surface from corrosion or excessive oxidation later in service. For example, stainless steels are particularly susceptible to corrosion attack after abrasive treatments, particularly those that use steel wool or a steel brush. Second, solders are generally much softer than the base metals. Therefore, inadvertent damage can be easily done to the joint fillets, possibly jeopardizing monotonic strength and fatigue resistance. Third, abrasive grit particles can become embedded in the substrate and, particularly, in the softer solder. Dislodged particles can damage mechanical actuators that are part of the soldered assembly. The abrasive particles can also deteriorate surface solderability of the workpiece during subsequent assembly, repair, or rework procedures. Damage occurs readily to circuit boards (solder masks, coatings, and the laminate itself) by abrasive particles.

Finally, storage of the parts must be considered. The extent of storage control depends on factors such as the type of assembly and its service requirements, the cost of rework, repair or scrapping of damaged parts, and the environment of the factory. Acute contamination or corrosion of finished parts can be prevented by their enclosure in bags. Popular containers are polyethylene plastic bags, which can provide short-term storage (<1 year) when properly sealed. Solderability may deteriorate for longer storage times because of the outgassing of polymer components contained in the plastic. Only new bags should be considered for the storage of solderable parts because contamination of the bag interior from previous usage may deteriorate solderability. Plastic bag material should be a minimum 0.1 mm (0.004 in.) thick. The bags can be filled with an inert gas (nitrogen) to further limit oxidation of solderable surfaces. Paper bags should be considered only for the transport of devices because their inability to be sealed from the environment, as well as contamination of solderable surfaces by chemicals in the paper, limit their appropriateness as storage containers. Metal foils can be used as storage media, although greater effort is required to seal the material. The use of desiccants that comply with MIL-D-3464E, "Desiccants, Activated, Bagged, Packaging Use and Static Dehumidification," is acceptable.

More elaborate and expensive storage measures include the construction of special facilities that control temperature, humidity, and air-particulate counts. The prevention of mechanical damage that results from the movement of inventory must also be addressed. Storage conditions are of particular concern for electronic devices and circuit boards in which solderability loss can severely hinder subsequent automated assembly processes.

The prevention of mechanical damage that results from the movement of inventory must also be addressed. Storage conditions are of particular concern for electronic devices and circuit boards in which solderability loss can severely hinder subsequent automated assembly processes.

General Soldering

Paul T. Vianco, Sandia National Laboratories

Inspection

Because inspection necessarily implies a determination of defects in the workpiece, the type and number of defects that jeopardize the service requirements of the product should be documented. The search for, and rework of, noncritical defects (such as unnecessary cosmetic attributes) simply increases product cost, the amount of scrapped product, as well as the likelihood of heat damage to the substrates. Defects and their acceptance limits should be defined in conjunction with the design engineer, who understands service requirements and codes, and the manufacturing engineer, who understands the process limitations. Several defect types and testing procedures are summarized below. The defects include:

- *INCOMPLETE FILLING OF THE JOINT,* CAUSED BY POOR SOLDERABILITY (NONWETTING OR DEWETTING), AN INADEQUATE QUANTITY OF FILLER METAL, LOW REFLOW TEMPERATURE, FLUX ENTRAPMENT (HOLES AND VOIDS), OR POOR JOINT DESIGN (REENTRANT CORNERS OR BLIND HOLES THAT PREVENT THE ESCAPE OF GASES)
- *POOR FILLET GEOMETRY,* CAUSED BY POOR SOLDERABILITY OF THE BASE METALS, AN INADEQUATE SUPPLY OF FILLER METAL FOR THE GIVEN JOINT GEOMETRY, OR INSUFFICIENT COVERAGE OF THE SURFACES BY THE FLUX COATING
- *CRACKS IN THE SOLDER FILLET,* WHICH SIGNIFY PART MOVEMENT DURING THE SOLIDIFICATION PROCESS, SOLIDIFICATION SHRINKAGE OF THE SOLDER METAL, OR, IN THE WORST CASE, A MAJOR FLAW IN THE JOINT DESIGN IN WHICH RESIDUAL STRESSES (FOR EXAMPLE, CTE MISMATCH) OVERLOAD THE SOLDER JOINT. THE LATTER CONDITION CAN CAUSE CRACKS IN THE SUBSTRATES, PARTICULARLY IN

BRITTLE MATERIALS, SUCH AS CERAMICS OR REFRACTORY METALS

- *GRAINY OR VERY DULL FILLET SURFACES,* WHICH INDICATE EXCESSIVE SOLDER CONTAMINATION, SUCH AS THAT ARISING FROM THE DISSOLUTION OF THE BASE-METAL MATERIALS AND SURFACE COATINGS, INADEQUATE HEATING OF THE SUBSTRATES, OR SUBSTRATE MOVEMENT DURING SOLIDIFICATION. (HOWEVER, SOME SOLDERS NORMALLY EXHIBIT A DULL FINISH UPON SOLIDIFICATION. SLOW COOLING, ESPECIALLY IN VAPOR-PHASE SOLDERING, CREATES DULL JOINTS)
- *FLUX RESIDUES,* WHICH SUGGEST INADEQUATE CLEANING PROCEDURES OR THE OVERHEATING OF THE FLUX TO PRODUCE VERY TENACIOUS RESIDUES. LARGER PARTICLES MAY BE EMBEDDED IN THE SOLDER FILLET.
- *DISCOLORATION IN THE BASE METAL,* WHICH SIGNIFIES EXCESSIVE HEAT EXPOSURE

Nondestructive inspection techniques range from visual assessment to elaborate tests involving complex equipment and procedures. The principal nondestructive testing methods are discussed below.

Visual inspection is the most widely used technique. Pictorial guides help the inspector qualify the particular joint configuration. Because the inspector can only infer joint quality from external observations, some destructive assessments should accompany the visual evaluations on early prototypes to correlate with subsequent inspector observations on the actual product. Low-power microscopes (<70×) are used.

Radiographic (x-ray) and ultrasonic inspection are used to visualize the interior sections of the joint. X-ray radiographs are used to detect mass differences in the joint, which indicate areas that are absent of solder, such as gas voids or entrapped flux. Ultrasonic techniques detect discontinuities in the path between the receiver and the transmitter (transmission mode) or in the reflected path (reflection mode). Besides unfilled sections of the gaps, this process also detects discontinuities such as poor bonding or cracks.

Infrared (thermal transfer) imaging is based on the transfer of heat across the joint gap. Voids and, to a lesser extent, cracks, have a lower thermal conductivity than the continuous base metal-solder-base metal path. The decreased thermal conduction of these defects is imaged by an infrared-sensitive camera that views the opposite side of a heated substrate. This technique has relatively poor resolution because of lateral heat conduction within the materials.

Proof testing involves subjecting the solder joint to a mechanical load that exceeds the service design load. The joint is then inspected for damage using nondestructive techniques. In the prototype phase of process development, this procedure may be considered "destructive."

Pressure and vacuum testing represent other nondestructive techniques. In pressure testing, which is detailed in the ASME Boiler and Pressure Vessel Code, a positive pressure is applied to conduit joints or soldered vessels. The joint is either coated with a soapy solution or submerged in a water bath before being pressurized. Leaks are identified by the formation of bubbles on the workpiece surface. Air can be replaced by helium or a halogen gas, and special detection equipment can be used to locate leaks in the joints. Vacuum checks of conduit also require special equipment to detect the leakage of trace gases, such as helium, into the conduit or vessel. Mass spectrometers can be used to detect and identify the passage of other gas species into the vacuum. The detector monitors the inside of the conduit (vacuum environment) while the gas is passed along the exterior walls.

Fluorescent dye penetration involves the introduction of a fluorescent dye to one side of the joint. The opposite side is then inspected for dye leakage, which would indicate a continuous path of cracks or voids.

Destructive testing techniques include all types of mechanical testing techniques as well as metallographic sectioning for microstructural examination.

Mechanical testing involves numerous techniques that have been standardized to examine tensile, shear, peel, impact, and torsion strengths, as well as the fatigue life of adhesive joints (Table 10). The various strength measurements can be extended to quantify defects in the joints, such as voids or cracks that cannot support a load, or a microstructural modification to the solder metal, which changes its strength. Inspection of the fracture surface provides critical information on the failure mechanism, as well as data on void content and nonwetting that are caused by poor solderability.

Additional information is available in the article "Evaluation and Quality Control of Soldered Joints" in this Volume.

General Soldering

Paul T. Vianco, Sandia National Laboratories

Environmental, Safety, and Health Issues

Both the materials and processes used in soldering present some general, as well as unique, environmental, safety, and health considerations. There is an increased awareness of the environmental damage caused by manufacturing processes. Applicable rules and regulations can be set by local, state, and federal legislation, as well as regulations developed through the Environmental Protection Agency (EPA). The environmental concerns that relate to soldering operations include:

- RELEASE OF CLEANING SOLVENTS AND SOLUTIONS INTO THE LIQUID WASTE STREAM
- VENTING OF SOLVENT FUMES INTO THE ATMOSPHERE
- DISPOSAL OF HEAVY-METAL SOLID WASTES, SUCH AS SOLDER DROSS AND SCRAP MATERIAL

Rules and regulations that govern worker safety are established by local, state, and federal employment statutes. The federal agency responsible for worker safety is the Occupational Safety and Health Administration (OSHA). Industrial organizations, such as the National Fire Protection Agency, the Underwriters Laboratory, and many insurance companies, have developed excellent safety guidelines for industrial practices. Some safety concerns in soldering operations include:

- BURNS FROM MOLTEN METAL AND ELEVATED-TEMPERATURE PROCESSING EQUIPMENT
- BURNS FROM THE IGNITION OF FLAMMABLE SOLVENTS USED IN CLEANING PROCESSES OR AS FLUX VEHICLES
- CHEMICAL BURNS FROM CORROSIVE ACIDS IN CLEANING SOLUTIONS AND FLUXES, THE LATTER OF WHICH INCLUDES SPATTER DURING SOME SOLDER PROCESSES
- CHEMICAL BURNS FROM ALKALINE MATERIALS USED IN POSTASSEMBLY CLEANING

An extensive effort has been made to identify and control the worker health risks of industrial soldering operations. Unlike safety issues, which tend to address acute dangers, health concerns can manifest themselves in accumulated toxicity to the worker which may not be identified for months or years. Besides the legislative bodies, regulations are also set by agencies such as OSHA, EPA, and the U.S. Mine Safety and Health Administration (MSHA). In addition, various guidelines are provided by organizations such as the Food and Drug Administration (FDA) and the National Institutes of Health--National Cancer Institute. Some of the health issues associated with soldering operations are:

- EXPOSURE TO ORGANIC SOLVENT FUMES (ACETONE, ALCOHOLS) IN FLUXES AND CLEANING COMPOUNDS OR THEIR HEAT-GENERATED BY-PRODUCTS (FOR EXAMPLE, ALDEHYDES FROM ROSIN-BASE FLUXES)
- ILLNESS FROM THE INHALATION OF ACID OR ALKALINE FUMES USED IN CLEANING SOLUTIONS
- HEAVY-METAL TOXICITY FROM MOLTEN SOLDER FUMES, BASE-METAL COATINGS, AND FROM THE BASE METALS THEMSELVES (AIRBORNE PARTICLES OF BERYLLIUM, CHROMIUM STEELS, AND SUCH)

Exposure to toxins occurs through skin absorption, ingestion, or inhalation. The use of protective clothing and face protection, as well as the practice of good hygiene habits, will prevent the absorption and ingestion, respectively, of toxic

materials. Because the most likely source of accidental exposure is inhalation, some guidelines and exposure limits are described below for materials and processes used in soldering operations. Air-sampling procedures have been established and should be used to certify compliance with these specifications. The exposure limits provide some insight into the relative hazard presented by each of the listed materials. It is important to note that regulations and exposure limits can change frequently as data are accumulated by the appropriate agencies. Therefore, it is recommended that the reader consult the necessary documents or agency representative to ensure compliance with the most recent guidelines.

The exposure limits are expressed as the time-weighted average (TWA), which is equivalent to the threshold limit value (TLV) established by the American Conference of Governmental Industrial Hygienists (ACGIH). The TWA limits were also accepted by OSHA in 1972 as the legal permissible exposure limits (PEL). The TWA value represents the time-averaged airborne concentration of the material over an 8-h period, which is assumed to be the exposure period per day.

Fluxes and Cleaning Agents. The primary concern when using rosin-base fluxes are the thermal breakdown products generated upon their exposure to the molten solder temperature. These reaction products are primarily the aliphatic aldehydes, typically measured by the equivalent formaldehyde concentration (Ref 30). The adopted TWAs for these substances, together with values for organic solvents used as flux vehicles or cleaning agents, are listed in Table 38. No limits are available for the typical constituents of organic acid fluxes (lactic acid, benzoic acid, or glutamic acid) or any suspected thermal breakdown products. The exposure levels of fumes from the inorganic acids, whether used as the flux or precleaning material, and from sodium hydroxide (neutralizing agent) are listed in Table 39. New regulations and exposure limits change as new data become available. The reader should remain aware of updates to these guidelines for current practices.

Solder and Base-Metal Constituents. The acute and chronic side effects of human exposure to metals are becoming better understood by the medical community. Toxicity hazards associated with the so-called "heavy" metals (lead, cadmium, antimony, tin, and others) used in the soldering processes are of particular concern to the health and regulatory agencies. Two mechanisms are responsible for airborne particulates: evaporation of metals by heat energy, which is applied to the molten solder or substrate, and mechanical agitation, which releases dust or abrasive particles.

Molten solder is generally used at temperatures well below the boiling point of either the solder or the substrate material. Exceptions are workpieces constructed with high vapor pressure metals or coatings, such as cadmium or zinc, or solders that contain these elements. Molten solders, like other liquids, release greater amounts of metal vapors as their temperature increases toward their vaporization point. Manual soldering processes, which exhibit the least degree of temperature control, are most susceptible to overheating of the solder and are therefore most likely to increase levels of toxic fumes in the atmosphere. Unfortunately, such processes also require the operator to be in close proximity to the workpiece. Therefore, proper ventilation must be maintained in the work area to minimize worker exposure.

Mechanical agitation of the molten solder for prolonged processing times, during which the solder is liquid, can accelerate the release of metal fumes. Airborne metal fumes and particulates are also caused by the agitation of solder dross and through abrasion of the solid metals. The dross that forms on the surface of solder baths can be a source of airborne particulates of tin, lead, or antimony, for example, when it is removed for disposal. Base-metal particles are generated by the use of abrasive precleaning techniques, such as grit or sand-blasting techniques. Base-metal particles and solder particles can also be generated when similar techniques are used to remove residues from the finished joints.

Table 40 gives the TWA values of metals that are used in solders or that compose substrate materials. Particulates of lead, cadmium, indium, platinum, silver, and chromium VI compounds are particularly hazardous, whereas those of zinc, copper, tin, and aluminum are relatively benign. Data are not available for bismuth and gold, a commonly used finish layer.

Lead regulations governing airborne lead concentrations in the workplace are very complex. The maximum airborne concentration (TWA) is 0.05 mg/m^3. However, an "action level" was established at 0.03 mg/m^3, above which a list of measures identified by OSHA regulations must be carried out. Below the action level, employees need only be monitored for lead exposure and receive adequate job training to minimize potential hazards.

Data were accumulated in the late 1970s that measured the blood lead levels of workers performing various soldering operations, as well as the airborne lead concentration of a number of soldering processes. Table 41 shows the blood lead levels of eight persons from a group of 37 who performed one of the tasks under the "job description." No significant difference was observed between these values (mean of the entire group of 37 was 11.7 µg/100 mL) and the blood lead level in the normal population with no occupational exposure to lead (10 to 30 µg/100 mL).

(A) VALUES CITED ARE TYPICAL FOR ALL 37 EMPLOYEES.

Airborne levels for several soldering operations and industries are shown in Table 42. None of the examples matched the maximum level of 0.05 mg/m^3. However, radiator manufacturing and repair typically exceeded the "action" level of 0.03 mg/m^3. This study emphasized that adequate ventilation of the work area was the most effective means to minimize airborne concentrations.

Soldering in Electronic Applications

Paul T. Vianco, Sandia National Laboratories

Introduction

SOLDERING represents the primary method of attaching electronic components, such as resistors, capacitors, or packaged integrated circuits, to either printed wiring boards (PWBs) or the ceramic substrates used for hybrid microcircuits.

Electronic miniaturization has fostered change in soldering technology as applied to electronic products. The increased functionality of electronic devices has placed a greater emphasis on solder joint integrity, not only in terms of increased reliability, but also with respect to limiting the cost of scrap product, inspection, or the repair of defective solder joints (especially on fine-pitch packages). The minimization of solder joint defects in electronic products depends on proper PWB design (for example, bonding pad geometries, conductor line layout, and laminate material), device packages (lead pitches and configurations or termination materials and finishes), and board assembly (flux and solder selection, process parameters and control, and cleaning).

This article discusses the categories that are most important to successful electronic soldering:

- SOLDERS AND FLUXES
- BASE MATERIALS AND FINISHES
- SOLDER JOINT DESIGN
- SOLDERABILITY TESTING

Additional information about the soldering processes discussed in this article can be found in the Section "Solid-State Welding, Brazing, and Soldering Processes" in this Volume.

Soldering in Electronic Applications

Paul T. Vianco, Sandia National Laboratories

Solders and Fluxes

Solders. The most commonly used solder alloys in electronics manufacturing are summarized in Table 1. Typical soldering temperatures in manufacturing operations are from 30 to 50 °C (55 to 90 °F) above the liquidus temperature to ensure adequate flow of the solder and proper heating of the substrate. The solder can be delivered to the joint area using numerous techniques. For example, the entire substrate can be placed in contact with the surface of a large molten solder bath, permitting the solder to either wet lands or fill holes. Solder wire can be directly heated at the joint by hand processes that use hot irons, gas jets, and other instruments. Preforms or solder paste can be placed at the joint area, and the substrate is either directly or indirectly heated, such as by an infrared (IR) furnace, causing the solder to melt and form the joint. Although solder pastes are often used in manual assembly or rework operations, their properties have been developed primarily for full-scale assembly processes.

TABLE 1 COMMONLY USED SOLDERS IN ELECTRONIC ASSEMBLIES

SOLDER ALLOY, WT%	SOLIDUS/LIQUIDUS TEMPERATURES	
	°C	°F
521N-48SN	118/118	244/244
50IN-50SN	118/125	244/257

58BI-42SN	138/138	281/281
43SN-43PB-14BI	143/163	289/325
97IN-3AG	143/143	289/289
70SN-18PB-12IN	162/162	324/324
63SN-37PB	183/183	361/361
60SN-40PB	183/190	361/374
62.5SN-36.1PB-1.4AG	170/179	354/354

96.5SN-3.5AG	221/221	430/430
95SN-5PB	233/240	451/464
97.5PB-1.5AG-1.0SN	304/309	588/588
90PB-10SN	268/299	514/570
95PB-5SN	270/312	518/594

Tin-Base Tin-Lead Solders. Pure tin, which has a melting temperature of 232 °C (450 °F), readily wets the substrate materials typically found in electronics applications. In fact, it is the tin component of electronic solders that forms the metallurgical bond with those materials. However, pure tin is not used for PWB assembly, because of its higher melting point, increased cost, and reduced flow, when compared with tin-lead alloys. Tin plate is sometimes used as a protective finish on device leads and terminations, although a solder dip coating is the preferred finish.

Tin-base tin-lead solders represent the most widely used solders for electronic assembly: eutectic 63Sn-37Pb, near-eutectic 60Sn-40Pb, and the eutectic 62.5Sn-36.1Pb-l.4Ag alloys. The solidus-to-liquidus (mushy zone) temperature range of 60Sn-40Pb makes this alloy preferable to the eutectic composition when used with some leaded surface-mount devices in order to prevent solder wicking (Ref 1) or to facilitate the filling of large holes and vias on PWBs. The silver content of 62.5Sn-36.1Pb-1.4Ag reduces the dissolution of silver coatings, such as electroplated finishes on base metals, or the silver conductor used in thick-film terminations on either surface-mount packages or in hybrid microcircuit thick-film networks. The tin-lead with silver composition will improve creep-rupture strengths and will slightly reduce reactions when soldering to silver or copper. These solders typically contain 0.25% Sb to prevent the formation of the low-temperature allotrope of tin ("tin pest") at 13.2 °C (56 °F).

Lead-base tin-lead alloys are not used in general PWB assembly, because they have poor flow and their melting temperatures are incompatible with PWB materials. These alloys can be applied to surfaces such as electroplated finishes, evaporated thin films, or hot dip coatings. They have excellent fatigue and creep properties. The alloys 95Pb-5Sn and 90Pb-10Sn are used in the controlled collapse chip component (C^4) attachment of silicon chips to package frames (Ref 2). Their elevated melting temperatures prevent reflow of the C^4 joints during subsequent joining of the unit to the PWB with eutectic tin-lead solder (step soldering).

Tin-Silver Alloys. The eutectic composition, 96.5Sn-3.5Ag, is generally used, although alloy compositions are available with silver contents of up to 5%. These alloys are used at the high-temperature attachment stage of step soldering processes with eutectic tin-lead solders. The tin-silver solders exhibit excellent wetting, strength, and fatigue properties that are generally superior to those of the tin-lead eutectic solder (Ref 3). No significant silver migration has been observed in solder joints fabricated with 96Sn-4Ag alloy (Ref 4). The combination of tin and silver forms Sn-Ag intermetallic compounds that are stable and are insensitive to electromigration reactions.

Tin-Antimony Alloys. The 95Sn-5Sb alloy is used at the high-temperature attachment portion of step soldering processes with tin-lead eutectic alloy. This solder type has excellent creep strength and wettability, comparable to the tin-silver solders. Localized heating methods (soldering iron, laser, and others) are preferred for applications that utilize this alloy because the high heat input required to melt the solder may damage some PWB substrates or heat-sensitive devices.

Indium-Tin Alloys. The eutectic and near-eutectic indium-tin solders (52In-48Sn and 50In-50Sn, respectively) are low-melting-point alloys used in the solder attachment of heat-sensitive devices or in the soldering steps that follow the use of tin-lead alloys. Because most electronic fluxes are unable to activate at lower working temperatures, there can be some wetting difficulties when indium-tin alloys are used. Indium-base alloys can wet several ceramic materials, including quartz, and some glasses. However, they can be susceptible to corrosion damage, and have poor mechanical properties, especially in creep. Although the relatively high cost of indium metal has discouraged more-extensive use of these

solders, the cost per device is not excessive, and indium-base alloys are finding increased usage where their properties are advantageous, such as in cryogenic applications.

Bismuth-containing alloys are also referred to as "fusible" solders. They are used on heat-sensitive devices or in step soldering processes. Upon solidification, bismuth-containing alloys exhibit either limited contraction or expansion, as in the case of solders with more than 47 wt% Bi (Ref 5). These alloys are prone to moderate oxidation in both the liquid and solid states, and they exhibit some difficulty in wetting because of limited flux activity at the lower working temperatures. These alloys have good mechanical properties and are used very successfully in a number of electronic applications.

Lead-indium alloys are used when soldering to precious-metal (gold, silver, platinum, palladium, or their alloys) substrates or coatings and when attaching components to hybrid thick-film networks. These solders have a lower rate of metal dissolution (and subsequent intermetallic compound formation), when compared with tin-containing alloys. Wettability is slightly poorer than that of the tin-lead solders. The lead-indium solders are also used in C^4 technology (Ref 6). Because of the relatively high cost of indium, these alloys are used on a limited basis. They are also susceptible to corrosion and interface voiding reactions (with high thermal gradients). However, they have excellent fatigue properties.

Solder Impurities. Solder alloys are available in reclaimed or virgin grades, and their purity is established by government, military, and industrial specifications. Excessive contaminant levels are detrimental to the quality of solder joints made by full-scale assembly equipment. Such processes, which use large baths as the solder source (wave, drag, or dip soldering), are particularly prone to impurity buildup from the dissolution of PWB and lead finishes (for example, copper, gold, or cadmium) or metals from the fixturing and soldering processes (aluminum or iron).

Table 2 provides contaminant limits for tin-lead solder material procurement (per federal specification QQ-S-571-E) and for tin-lead solder baths (per IPC-S-815A) that are for hot-dip coatings or PWB assembly. Amendment 6 to the QQ-571-E specification indicates a reduction in the maximum antimony content of powdered material to 0.120% in the upcoming QQ-571-F edition. The complete list of impurities is found in Amendment 6 of the QQ-571-E specification.

TABLE 2 RECOMMENDED IMPURITY LIMITS OF SOLDERS AT TIME OF PROCUREMENT AND IN OPERATIONAL TIN-LEAD BATHS

NICKEL	**. . .**	**0.025/0.01**

(A) PER QQ-S-571-E.

(B) PER IPC-S-815A

To prevent contamination, the recommended materials for solder pots are stainless steel or cast iron. Although solder dross in solder baths is not an impurity, excessive levels can impede the proper formation of solder joints. Organic contaminants from fluxes, soldering oils, and PWB residues can be picked up by solder joints on the printed boards. These materials polymerize under prolonged exposure to the solder temperatures and become difficult to remove using conventional cleaning measures. Ionic species remaining from flux residues can cause corrosion on assembled solder joints or leakage currents between conductors.

Solder paste is used primarily in PWB assembly based on surface-mount technology. Processes such as vapor-phase (condensation) and infrared (IR) furnace reflow are well suited to solder paste use. Solder paste is a mixture of solder particles with a binder composed of flux, rheological components (such as thickeners), and a solvent material. Solder particle shape, size distribution, and concentration, along with binder properties, determine the flow properties of the paste.

As shown in Fig. 1, the paste is deposited by screen printing, stencil printing, or bulk dispensing techniques. Paste properties (whether applied using screen or stencil) affect the number and kinds of defects observed on the finished solder joint. Printed circuit boards (PCBs) with 1.25 mm (50 mil) pitch require 0.20 to 0.25 mm (0.008 to 0.010 in.) of paste thickness, whereas fine-pitch PCBs (630 μm, or 25 mils, or less) typically use 0.08 to 0.20 mm (0.003 to 0.008 in.) of paste.

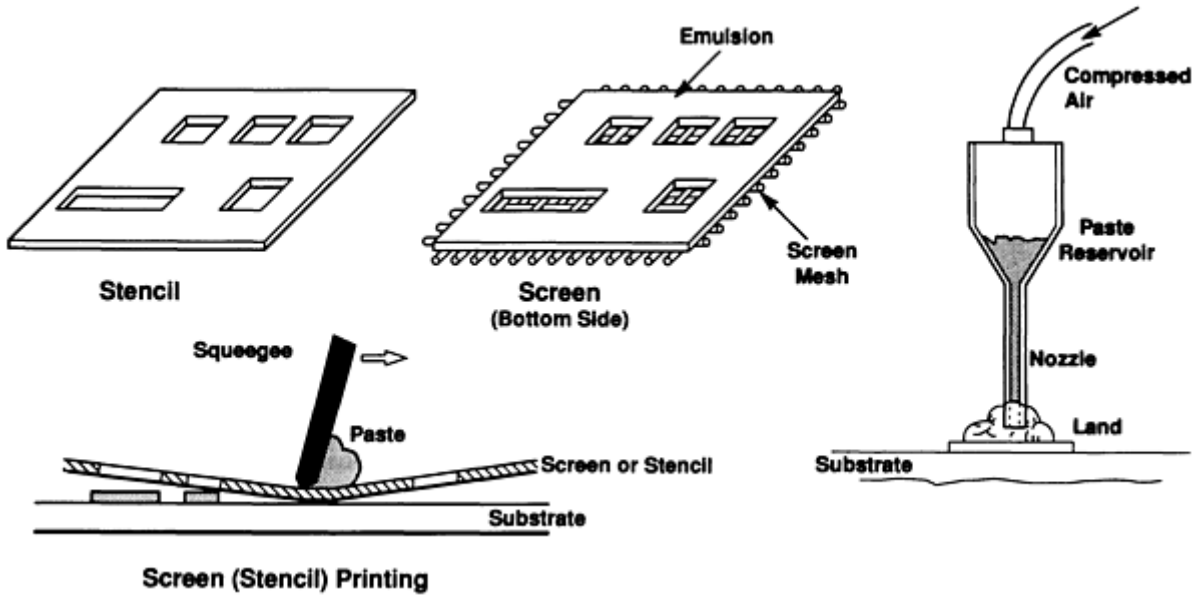

FIG. 1 STENCIL PRINTING, SCREEN PRINTING, AND BULK DISPENSING OF SOLDER PASTE

Printability can be affected by the distribution of the solder particles, metal content, slump, and viscosity of the paste. For example, smaller solder particles pass more easily through stencil or screen openings. However, the higher oxide content of the smaller particles (larger surface-to-volume ratio) creates a greater number of post-assembly solder balls, which are small spheres of solder that fail to coagulate with the larger solder mass in the joint (Fig. 2). Solder balls that are not removed by the cleaning process can cause short circuits during device electrical operation.

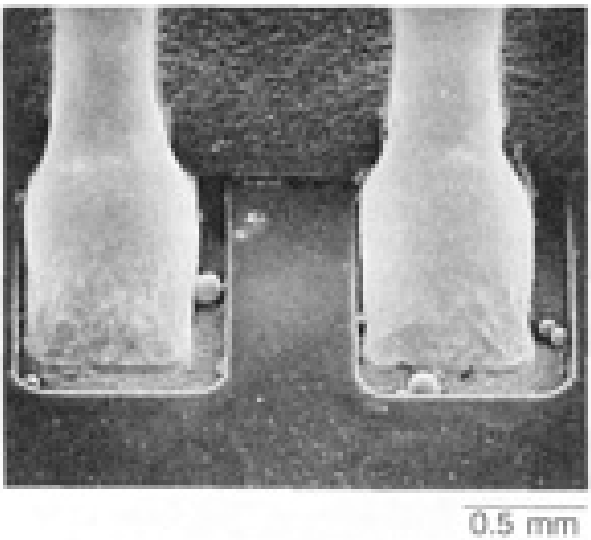

FIG. 2 SCANNING ELECTRON MICROGRAPH OF SOLDER BALLS ON A LEADLESS CERAMIC CHIP CARRIER SOLDER JOINT. COURTESY OF SANDIA NATIONAL LABORATORIES

Metal content refers to the mass percentage of the paste, that is, the solder component. Slump is a measure of the tendency of the paste to spread away from the deposited configuration prior to reflow. Excessive slump causes the deposits to contact one another (Fig. 3a), resulting in solder joint bridges (Fig. 3d), which can short circuit electrical signals (Ref 7).

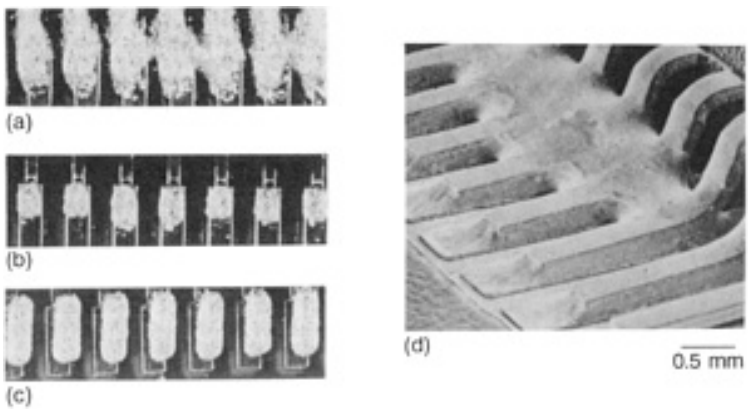

FIG. 3 DEFECTS OF SOLDER PASTE DEPOSITS. (A) APPEARANCE OF PASTE WITH POOR SLUMP (OPTICAL MICROSCOPY). (B) SKIPS IN PASTE DEPOSITS (OPTICAL MICROSCOPY). (C) PASTE DEPOSIT/LAND MISREGISTRATION (OPTICAL MICROSCOPY). (D) SOLDER BRIDGES (SEM). SOURCE: REF 1, 7

Viscosity determines the fluidity of the paste. When viscosity is too high, the paste will not pass through the screen or stencil, and will cause skips (Fig. 3b). When viscosity is too low, the paste will run out under the screen or stencil and will deteriorate the slump properties. Tackiness refers to the ability of the paste to hold devices onto the board prior to the reflow cycle. Paste with poor tackiness causes components to become displaced or to fall from the board during handling prior to reflow, resulting in part misalignment after assembly.

Test procedures that have been developed to quantify solder ball formation, slump, tackiness, and viscosity are identified in IPC-SP-819, "General Requirements and Test Methods for Electronic Grade Solder Paste."

Solder pastes deteriorate with storage time, which increases viscosity. The addition of thinners will reduce viscosity. Solder particles can further oxidize, leading to increased solder ball formation during reflow. Pastes that contain indium

deteriorate more quickly than those based on other alloys. The shelf life of solder pastes can be extended by storage under refrigerated (not freezing) conditions, where the paste surface is sealed from the atmosphere. Manufacturer recommendations should be strictly followed.

Process factors that affect the quality of the printed deposit are:

- STENCIL OR SCREEN THICKNESS
- DAMAGE AND WEAR TO THE STENCIL OR SCREEN
- SQUEEGEE STIFFNESS AND PRESSURE
- SNAP-OFF DISTANCE
- DRYING CONDITIONS FOLLOWING DISPENSING
- STENCIL (SCREEN) SUBSTRATE REGISTRATION (FIG. 3C)
- PRESSURE AND ORIFICE SIZE ON BULK DISPENSING EQUIPMENT

Table 3 provides typical solder paste properties for the noted delivery techniques (Ref 8, 9).

Fluxes. The role of fluxes in electronic soldering is to reduce thin tarnish layers on the substrates and solder, lower the surface tension of the solder to improve capillary flow and optimize fillet geometries, and protect the substrate surfaces from reoxidation during preheat prior to reflow. Electronic-grade fluxes for assembly processes can effectively remove only light oxide layers. Precleaning steps with chemical etchants should be used to remove heavy oxide films and scales prior to assembly. Surface oxide removal by the flux is inhibited by organic films that can be present on the surface. Therefore, surfaces must be degreased prior to application of the flux coating. In electronics applications, the least chemically active flux that satisfies production yields is preferred in order to minimize potential corrosion from unremoved residues.

Fluxes are applied to the PWB by spraying, immersing the board into a bath of flux, passing it through a flux wave, or coating it with a flux foam. The condition of the flux, which changes with use because of solvent evaporation and contamination buildup, is typically monitored by tracking its density. Density can also be used to indicate the viscosity of fluxes used in foaming applications, which in turn determines the ability of the flux to form a foam. Manufacturer recommendations should always be strictly followed because formulation variations are often proprietary.

Safety and health concerns should be considered in flux usage. Alcohol is a widely used solvent in fluxes, which makes the baths and vapors flammable. Fluxes, like corrosives, can cause acute and chronic irritation to the respiratory tract and skin. Because rosin-base fluxes break down at soldering temperatures to produce fumes of compounds from the aldehyde family, adequate ventilation of the work area is required.

Flux use must address three materials compatibility issues. First, the potential for damage to device packages (header material, glass-to-metal seals, and such), base materials, and plated surfaces prior to assembly will increase with more-active fluxes. Second, postassembly corrosion may arise from flux residues with high ionic contents, necessitating their removal by post-assembly cleaning measures. Third, the cleaning agents and processes used to remove flux residues must be compatible with the devices, substrates, and environmental regulations. Organic solvents, such as 1,1,1-trichloroethane and Freon, are very effective in removing rosin-base flux residues. However, these hazardous materials are being restricted from use due to potential environmental damage. Although aqueous and semiaqueous cleaning systems based

on water, polar alcohols, and terpenes can be very effective, their compatibility with all electronic materials has not been fully characterized. It should be noted that ultrasonic cleaning processes may damage active and passive devices. Therefore, the compatibility of this technique with assemblies must be verified prior to its implementation. Designers and process engineers must address these concerns at the early stages of process development to prevent costly production errors.

The most critical aspect of PWB cleanliness is ionic residues from the fluxes. When combined with atmospheric moisture, these residues can generate "structural" corrosion between the dissimilar metals found in the solder joint. The residues can also create metal whiskers by the electromigration of metal ions between lands or conductor lines at different voltage potentials, causing leakage currents that disrupt electrical performance. Ionic flux residues on PWBs are measured by the extraction method, in which the residues are rinsed into a bath, the resistivity of which is converted into the equivalent amount of ionics removed from the board (expressed as μg NaCl/cm^2 of board surface).

The potential for leakage currents, which are a function of substrate material, moisture, and the ionic content of the flux residues, is assessed by the surface insulation resistance (SIR) test. A conductive comb pattern is constructed on the test board. A voltage difference is applied between adjacent legs and the resistance breakdown is monitored under different temperature-humidity-time conditions. Ionic residue and SIR tests are recommended in the process development stages of soldered assemblies. Several industrial, military, and federal specifications that quantify flux activity and PWB cleaning procedures and criteria for electronic applications have been established (Table 4).

Rosin-base fluxes, which are based on the distilled products of pine saps, are the most widely used fluxes for electronics assemblies. Pure rosin (termed "water-white" rosin, after the test method for purity) is designated by the letter R. Because the R flux is a very weak acid, its residues are not corrosive in most applications. The activity of the rosin-base fluxes is strengthened by the addition of activators. Such fluxes are designated as mildly activated (RMA), fully activated (RA), and superactivated (RSA) (Ref 10).

RMA flux residues must be removed from most products designated for high-reliability applications. RA flux residues should be removed from all PWBs, except those used in low-end commercial electronic products. RSA fluxes are extremely corrosive, and their residues must by thoroughly removed from all products.

Activators are typically halide ions (Cl^-, F^-, and Br^-), which increase the activity of the rosin-base flux. However, "halide-free" activated fluxes are available and will lessen the corrosion potential of flux residues. Visible residues are tan or white in appearance (Ref 11). Black residues indicate that the flux has been exposed to excessive heat, and they are consequentially very difficult to remove. Ionic residue determination and SIR tests are strongly recommended for flux activities that exceed those of RMA materials.

No-Clean or Low-Solids Fluxes. Flux formulations for which the residues do not pose a corrosion concern after soldering--and thus do not need to be removed--are called "no-clean" fluxes. The fluxing activity of these materials can approach that of traditional RMA fluxes (Ref 12). A second approach to eliminating the need for postprocess cleaning is to use a "low-solids" flux, that is, a flux with limited solids content. (Solids form the residue after soldering.) However, low-solids fluxes have reduced oxide removal potential. Therefore, substrate tarnishes and contamination, flux density, and process conditions (inert atmospheres may be necessary) must be more tightly controlled to ensure consistent solderability.

Organic acid (OA) fluxes , which are also called water-soluble or intermediate fluxes, are water- or alcohol-base and have chemical activities greater than the rosin-base materials. OA fluxes improve the solderability of metals such as iron- or nickel-base alloys. Residues must be removed from the product using aqueous or semiaqueous cleaning methods. Flux activity can be provided by halide-containing compounds. The fluxes are also available in halide-free forms. Although they are more heat resistant than the rosin-base fluxes, the OA fluxes will char, producing hard-to-remove brown or black deposits. Ionic residue determination and SIR tests are strongly recommended for prototype development and lot sampling in assembly production to ensure adequate flux residue removal.

Inorganic acid (IA) fluxes either contain extremely corrosive acids (hydrochloric acid, phosphoric acid, and others) or are composed of metal chloride salts that form hydrochloric acid in the presence of water. Surfactants or wetting agents are also added. The residues are highly corrosive. These fluxes can be used for hot solder dipping of iron-base alloy or nickel leads, provided that adequate cleaning measures are taken to remove residues. These fluxes are not used in PWB assembly operations.

Base Materials, Finishes, and Storage/Corrosion Issues

The substrate can be characterized by the nature of the base material and the surface finish. The base materials of device leads are typically copper or one of the iron-base, low-expansion alloys. Leadless surface-mount devices have ceramic oxide base materials. Copper foil is used as the base material of PWB conductor lines and lands (bonding pads).

The surface layer of a substrate comprises the so-called *solderable layer* to which the molten solder metallurgically reacts and, frequently, an additional coating or *protective layer* to prevent the formation of excessive oxidation and/or contamination by organic films on the solderable layer. This solderable surface can be either the base material surface itself or a coating deposited by electroplating, electroless plating, evaporation, pretinning (solder dip coating), sputtering, or chemical vapor deposition (CVD). The protective layer is typically an electroplated film that is entirely consumed by the solder during wetting. It is primarily the condition of the surface of the solderable layer (base material or a separate coating) on the component lead, termination, and PWB lands that accounts for joint solderability during assembly. Base material bulk properties, such as thermal conductivity or heat capacity, indirectly affect solderability, particularly the time-dependent wetting performance.

Coatings that serve as the solderable layer must be sufficiently thick to ensure that:

- THE COATING COMPLETELY COVERS THE BASE MATERIAL SURFACE
- THE LAYER IS NOT DISSOLVED BY THE LIQUID SOLDER
- THE LAYER IS NOT CONSUMED BY SOLID-STATE GROWTH OF INTERMETALLIC COMPOUNDS WITH THE SOLDER

On the other hand, excessive thickness can lead to residual stresses that cause delamination of the coating and the entrapment of organic plating compounds and gases that in turn cause the deterioration of solderability. Coatings used as solderable surfaces are typically the elemental metals, that is, nickel or copper. Multi-elemental thick-film layers are used as solderable surfaces on ceramic substrates (for example, conductor networks for hybrid microcircuits or terminations on discrete leadless ceramic devices or chip carriers).

The protective layer must be of sufficient thickness to protect the wettability of the surface of the solderable layer. Nickel that has been coated by a protective coating can be wet by the molten solder using the rosin-base fluxes. An unprotected nickel film requires much more active fluxes to promote solder wetting. Because the protective coating is absorbed into the solder, its thickness must be limited to prevent excessive contamination of the solder, thereby affecting its physical and mechanical properties.

Protective layers are often made from precious metals, the most popular of which is gold. It is imperative that gold coatings be removed by hot solder dipping the leads twice in flowing or nonflowing solder baths prior to assembly in order to prevent solder joint embrittlement (MIL-STD-1276D). However, *three* immersions in solder at 250 °C (480 °F) are recommended to ensure the complete removal of all thicknesses of gold from beam-leaded, surface-mount devices (Ref 13). Additional information is provided in the section "Precious Metal and Alloy Base Materials" of this article.

Other protective layers include electroplated tin (the production of which is termed tin plating) and electroplated tin-lead solder (for example, 60Sn-40Pb). The tin and tin-lead solder platings can be heated above their respective melting temperatures of 232 °C (450 °F) and 183 °C (361 °F) to remove pores or gaps. These layers are then referred to as ***fused***

tin or *fused* tin-lead coatings, respectively. A protective layer of tin or tin-lead solder can also be added by applying flux to the solderable surface and immersing it into a molten bath of tin or tin-lead solder. These finishes are referred to as hot-dipped tin or hot-dipped solder layers, respectively.

Organic coatings, such as benzotriazole and imidazole, are used as protective finishes on solderable surfaces. They are popular for protecting bare copper surfaces on PWBs during storage prior to soldering.

Coating materials and their preferred thicknesses for solderable and protective finishes are specified by MIL-STD-1276D and MIL-M-3851OH. Examples are described below according to the base materials used most frequently in electronics applications. In general, properly prepared and protected solderable surfaces (base material or deposited layer) can be readily wetted by the solders listed in Table 1 using standard electronic fluxes and assembly practices.

Copper Alloys. Copper is used in electronic applications as wire leads (individual or as frames) on through-hole components, electroless/electroplated layers in PWB holes, or thin foil in the construction of lines and lands on PWB surfaces. In some PWB fabrication processes, copper foil surfaces can be built up with electroless and electroplated copper, as well. The thickness of copper layers that coat PWB through-holes is approximately 0.025 to 0.076 mm (0.001 to 0.003 in.). Typical foil thicknesses for PWB surface patterns range from 0.018 to 0.071 mm (0.0007 to 0.0028 in.). The most common thicknesses are termed 0.5 oz copper (0.018 mm, or 0.0007 in.), 1 oz copper (0.036 mm, or 0.0014 in.), and 2 oz copper (0.071 mm, or 0.0028 in.).

Copper is readily wetted by tin-lead solder using rosin-base fluxes, provided that the surface is not heavily oxidized. Oxide removal is performed by immersion in dilute hydrochloric acid or sulfuric acid solutions or another type of mixture. Compositions of acid solutions used for oxide removal are given in the article "General Soldering" in this Volume. Protective finishes for copper and copper alloys include layers of electroplated silver of a thickness from 3.8 to 8.9 μm (150 to 350 μin.), electroplated tin (7.6 to 13 μm, or 300 to 500 μin.), and electroplated tin-lead (7.6 to 23 μm, or 300 to 900 μin.). The latter two layers can be fused; the preferred thicknesses range from 2.5 to 13 μm (100 to 500 μin.). The silver coating is usually covered by a tarnish layer caused by a reaction with sulfur in the air. The resulting sulfide film causes the solderability to deteriorate with time of exposure. Silver coatings need to be removed just like the gold coatings to prevent embrittlement of the solder joint by silver-tin intermetallic formation.

A hot-dipped tin-lead finish (5.1 μm, or 200 μin., minimum) is most often specified for copper-base metal. A solid-state reaction takes place between copper and tin (or the tin component of solders) to form a layer of intermetallic compounds, Cu_3Sn and Cu_6Sn_5, at the solder-copper interface. The thickness of the intermetallic layer increases as exposure temperature and time increase. The total intermetallic layer thickness (Cu_3Sn + Cu_6Sn_5) as a function of time and temperature is shown in Fig. 4(a) for electroplated tin, Fig. 4(b) for electroplated tin-lead coatings, and Fig. 4(c) for hot-dipped tin-lead coatings. Growth kinetics at room temperature are illustrated in Fig. 4(d) (Ref 14, 15).

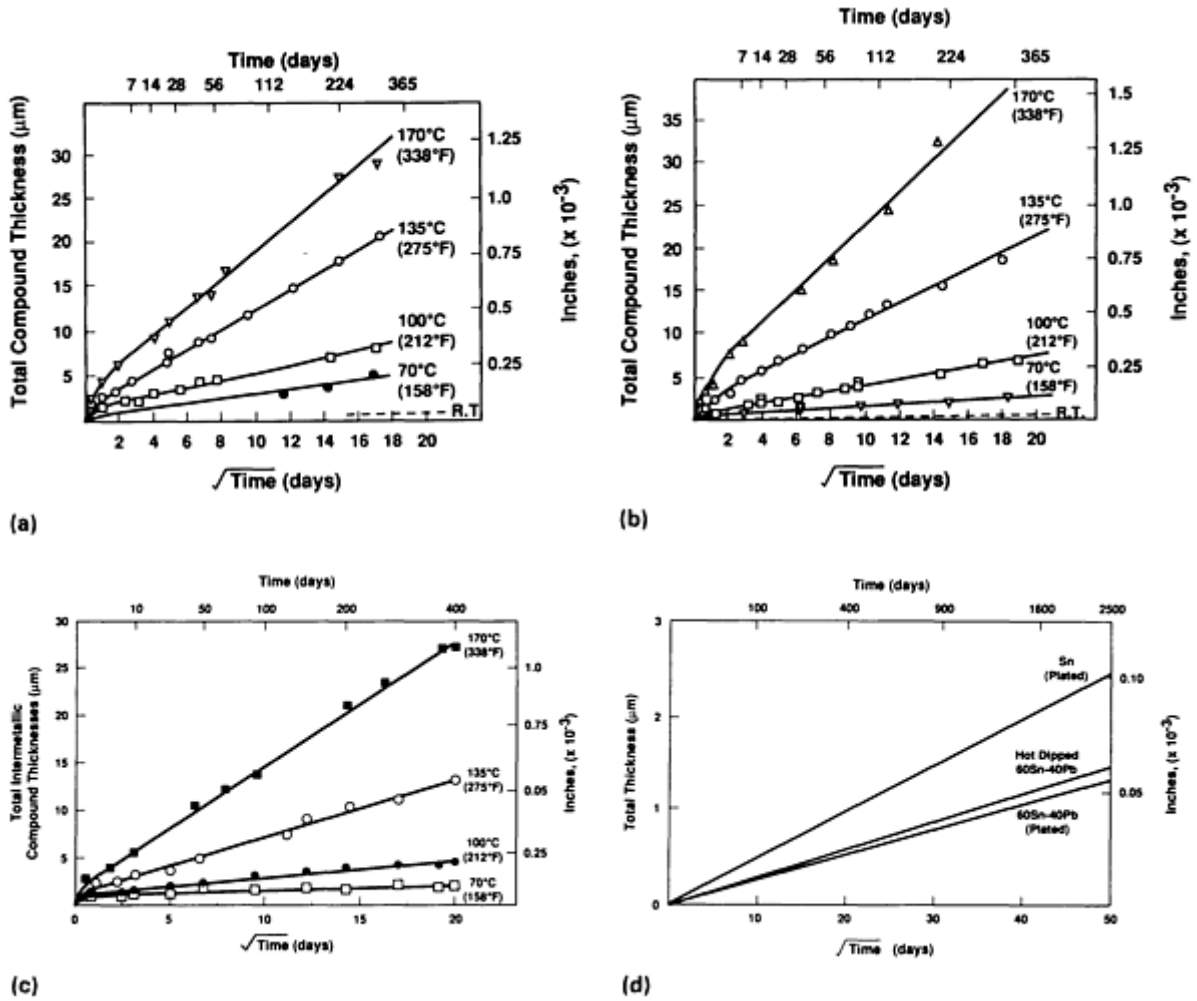

FIG. 4 COPPER-TIN INTERMETALLIC LAYER (CU_6SN_5 + CU_3SN) GROWTH KINETICS. (A) FOR ELECTROPLATED TIN COATING. (B) FOR ELECTROPLATED 60SN-40PB COATING. (C) FOR HOT-DIPPED 63SN-37PB COATING. (D) FOR TIN-LEAD COATINGS AT ROOM TEMPERATURE. SOURCE: INTERNATIONAL TIN RESEARCH INSTITUTE AND SANDIA NATIONAL LABORATORIES

Intermetallic layers have low ductility and, depending on their thickness, can affect the mechanical integrity of the solder joint (Fig. 5). In addition, the solid-state growth of the intermetallic film may consume very thin layers of tin or tin-lead alloy. The exposed intermetallic layer of Cu_6Sn_5 can readily oxidize and is difficult to wet with molten solder. Parts stored for over 1 or 2 years or those that will experience elevated temperatures (as in testing requirements) should be covered by a solderable layer of electroplated nickel (1.5 to 3.8 μm, or 60 to 150 μin.), followed by one of the above protective finishes. This coating structure will prevent the excessive formation of copper-tin intermetallic compounds at the solder-substrate interface, which may consume the tin or tin-lead protective finish and cause subsequent solderability to deteriorate.

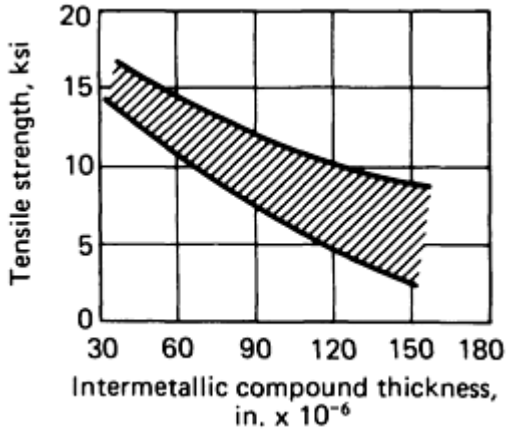

FIG. 5 EFFECT OF INTERMETALLIC COMPOUND THICKNESS ON ROOM-TEMPERATURE TENSILE STRENGTH OF SOLDER JOINTS (COPPER/COPPER BASE METALS)

Copper lines and lands on PWBs are protected with a hot-dipped solder coating that is generally applied by the hot-air leveling technique. The bare copper can also be protected with an organic inhibitor. Alloys of copper, including brasses, bronzes, copper-iron-zinc, copper-iron-tin, and copper-zinc-aluminum-cobalt, should be plated with a solderable layer (and protective coating) to overcome difficult-to-remove oxides or to act as a barrier against the diffusion of base metal constituents (for example, zinc) into the solder. Finishes include either a minimum 2.5 μm (100 μin.) of copper or a nickel layer with one of the protective coatings (described above).

Beryllium copper forms a tenacious oxide. Solder wetting with the use of activated rosin-base fluxes requires that the surface oxide be reduced by etching with strong acids. The soldering operation should immediately follow surface preparation steps to prevent reoxidation. Beryllium copper with very thin oxides can be wetted by solder if inorganic acid fluxes are used. However, a thorough cleaning of residues is required. The inorganic acid fluxes are used only to apply a protective layer of hot-dipped tin-lead solder. They are not recommended for PWB assembly.

Nickel and nickel-base alloys are used as the base metals on package leads. However, the most common electronics application is electroplated pure nickel used as the solderable coating on nickel-and iron-base lead materials that cannot be subjected to the cleaning measures and aggressive fluxes required to promote solderability. Nickel and its alloys are difficult to wet, because of the formation of a thin, tenacious oxide layer. Substrates must be chemically etched with aggressive solutions. The soldering operation or the application of a protective layer must immediately follow the etching treatment in order to minimize reoxidation of the surface. Freshly deoxidized leads made with nickel or nickel-containing alloys, or those that are electroplated with a solderable layer of nickel (1.3 to 3.8 μm, or 50 to 150 μin.), require one of the following protective layers prior to assembly on the PWB:

- ELECTROPLATED (MATTE) TIN (7.6 TO 13 μM, OR 300 TO 500 μIN.)
- ELECTROPLATED TIN-LEAD COATING (7.6 TO 23 μM, OR 300 TO 900 μIN.)
- HOT-DIPPED SOLDER COATING (5.1 μM, OR 200 μIN.)

The electroplated layers can be fused. The hot-dipped solder coating step may require the use of more-aggressive fluxes (organic acid or inorganic acid fluxes) to achieve a satisfactory finish. These fluxes must be compatible with the device package construction and their residues must be thoroughly removed after coating. It is very important that hot-dipped solder (or tin) layers on device leads and terminations contain neither "lumps" nor icicles, because these defects can interfere with the automated placement of components on the PWB, particularly with the use of fine-pitch devices. However, a properly applied hot solder dipped lead finish is superior to most tin or tin-lead plated surfaces.

The nickel solderable coating is protected by a finish of electroplated gold, particularly if the base metal is subject to temperatures that exceed the melting points of tin or tin-lead finishes prior to assembly. The MIL-G-45204C thickness recommendation for solderability is from 1.3 to 2.5 μm (50 to 100 μin.). However, general specification of gold thickness (MIL-STD-1276 D) can be as high as 2.5 to 7.6 μm (100 to 300 μin.) so that complete removal for soldering should be

verified if the thinner layers do not offer adequate protection. The previously described procedure regarding the removal of gold coatings pertains. Details are provided in the section "Precious Metal and Alloy Base Materials" in this article.

A less-expensive silver coating (3.9 to 8.9 μm, or 150 to 350 μin.) can also be used. However, silver tarnishes upon atmospheric exposure, causing a deterioration to solderability. As already mentioned, silver coatings need to be removed, just like gold coatings are.

Electroplated copper (3.8 to 7.6 μm, or 150 to 300 μin.), followed by one of the tin or tin-lead protective finishes, can also provide excellent solderability to nickel and nickel-alloy base metals. Although nickel forms an intermetallic compound layer with tin (primarily, Ni_3Sn_4), its growth rate is much slower than that of copper and tin. Therefore, it does not significantly affect the mechanical properties of solder joints in electronic assemblies. An ultrasonically activated solder pot can be used to apply a hot-dipped solder (or tin) coating to the lead without the use of aggressive fluxes. The ultrasonic energy disrupts the oxide layer, thereby allowing the solder to wet without the use of aggressive fluxes. Ultrasonics should not be used on devices that can be damaged by the ultrasonic energy.

Aluminum and its alloys are used as connector housings that attach cables to PWBs or other cable assemblies. A "strap" or lead is soldered to the housing to provide an electrical ground.

Aluminum alloys are difficult to wet, because of a tenacious surface oxide. Although aggressive fluxes, such as the inorganic acids, are required to promote solderability, they leave behind extremely corrosive residues that must be thoroughly removed to prevent corrosion in service.

Another issue when solder joining aluminum is galvanic corrosion between aluminum and a dissimilar substrate (for example, copper or nickel) or between aluminum and solder constituents (for example, tin). Solder alloys, such as 80Sn-20Zn (T_1 = 270 °C, or 518 °F; T_s = 198 °C, or 388 °F) and 95Zn-5Al (382 °C, or 720 °F), were developed for compatibility with aluminum. However, their high melting points require localized heating techniques and prohibit joining to organic materials or hybrid thick-film networks. The high thermal conductivity of aluminum alloys requires large heat input into the substrate to promote wetting.

Although solderable and protective finishes were not cited by the specifications noted above, adequate solderability can be obtained with coatings of electroplated nickel or copper to thicknesses of 1.3 to 3.8 μm (50 to 150 μin.) and 7.6 to 25 μm (300 to 1000 μin.), respectively. A zincate coating is applied to the aluminum prior to the nickel or copper finishes to promote adhesion. Once the soldering operation has been performed, it is recommended that the exposed nickel or copper layer be coated with an anodic finish (for example, cadmium or zinc) to reduce the potential for a corrosion couple with aluminum. Ultrasonic activation of the solder pot provides a means of depositing a hot solder or tin-dipped finish to aluminum substrates without a flux.

Iron-base alloys constitute the base materials for leads on a number of through-hole and surface-mount device packages. These alloys include Kovar, 29Ni-17Co-0.2Mn-balance Fe; alloy 52, 0.5Mn-0.25Si-50.5ONi-balance Fe; and alloy 42, 0.5Mn-O.25Si-5.5Cr-42Ni-balance Fe. Solder wetting of the iron-base alloys requires the removal of a thick, tenacious surface oxide by such procedures as the use of etchants and chemical brighteners or aggressive electropolishing treatments (Ref 16).

The hot-dipped solder coating may require the use of more-aggressive fluxes (organic acid or inorganic acid fluxes) to achieve a satisfactory finish. These fluxes must be compatible with the device package materials and their residues must be thoroughly removed after coating. Surfaces must be protected from reoxidation after surface preparation, typically by a hot-dipped tin or solder coating.

However, the most common technique to achieve solder wetting of these materials is the use of combined solderable and protective layers. The most frequent approach is to electroplate device leads with a solderable layer of nickel (1.3 to 3.8 μm, or 50 to 150 μin.), followed by a protective layer of electroplated (matte) tin (7.6 to 13 μm, or 300 to 500 μin.), electroplated tin-lead coating (7.6 to 23 μm, or 300 to 900 μin.), or hot-dipped solder coating (5.1 μm, or 200 μin., minimum). The electroplated layers can be fused. Silver (3.9 to 8.9 μm, or 150 to 350 μin.) can also be used as a protective finish. As previously mentioned, hot-dipped solder (or tin) finishes on package leads should not contain "lumps" or icicles, because they can interfere with the automated placement of components on the PWB.

The nickel solderable coating can be protected by a finish of electroplated gold, particularly if the base metal is subject to temperatures that exceed the melting points of tin or tin-lead prior to assembly. The recommended thickness for soldering

operations ranges from 1.3 to 2.5 μm (50 to 100 μin.), per MIL-G-45204C. Gold coatings must be removed in the manner previously described. Details are provided in the section "Precious Metal and Alloy Base Materials" in this article.

Alternative solderable coatings include electroless nickel (1.3 to 3.0 μm, or 50 to 120 μin.), palladium-nickel (1.3 to 2.5 μm, or 50 to 100 μin.), or copper (3.8 to 7.6 μm, or 150 to 300 μin.). Electroless nickel is not recommended for flexible or semirigid leads or substrates exposed to high-temperature testing procedures prior to PWB assembly. Phosphorus from the plating bath may become entrapped in the layer, resulting in film embrittlement or poor solderability because of its diffusion to the nickel surface at elevated temperatures. A palladium-nickel coating does not require a protective finish because the palladium component imparts oxidation resistance to the alloy coating. The electroless nickel and electroplated copper coatings require one of the protective finishes noted above.

Precious Metal and Alloy Base Materials. Excellent solderability of precious metals (gold, silver, palladium, platinum, and others) is achieved with tin-and indium-base solders, because of a strong metallurgical reaction at the solder/base metal interface. This metallurgical reaction results in the formation of intermetallic compounds at the interface. Their growth can take place when the solder is in either the liquid or solid state. In either case, intermetallic compound growth can quickly consume wires, leads, or the entire thick-film layer.

The dissolution rates of several precious metals in molten 60Sn-40Pb solder are shown in Fig. 6 (Ref 17). The excessive concentration of intermetallic compounds severely embrittles bulk tin-lead solder. In addition, thick intermetallic layers at the solder/base metal interface can drastically decrease solder joint ductility. Gold contents of 6 wt% decrease the ductility (reduction-in-area) by 50% (Ref 18); these data indicate that gold embrittlement is generally avoided in tin-lead solders by maintaining gold contamination to the joint at a level less than 4 wt%. (Some segments of the electronics industry have specified maximum gold contents of 1 wt%.)

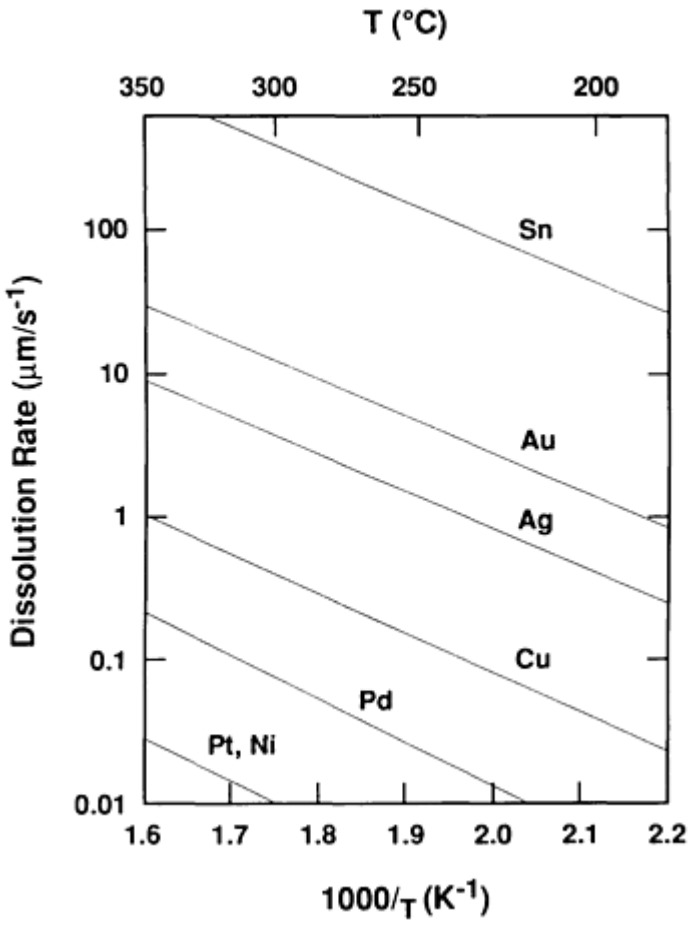

FIG. 6 DISSOLUTION RATES OF VARIOUS METALS IN MOLTEN 60SN-40PB SOLDER. SOURCE: REF 3

Silver wires or silver coatings on other metals have been used in place of gold to reduce cost. Silver has a lower dissolution rate in tin-lead solders than gold. The rate can be further diminished by adding from 1 to 2 wt% silver to the solder. However, silver rapidly tarnishes from airborne sulfur pollution, causing the surface to tarnish rapidly and lose solderability. The dissolution of precious metals is significantly less when lead-indium solders are used.

Wetting of precious metal base materials is assisted by the limited oxide layer that forms on them, which sometimes allows wetting by solders without the use of a flux. Wires or ribbons are used as jumper leads on PWBs by virtue of their low resistance. Pastes that contain precious metals or their alloys as the conductive component are used as thick-film networks for hybrid microcircuitry.

Ceramic materials used for electronic packages and substrates include alumina (Al_2O_3), beryllia (BeO), and silica (SiO_2), as well as several of the engineered ceramics, such as silicon nitride (Si_3N_4). Solders do not readily wet ceramic-base materials, because of the low surface energy of the substrate and the absence of a solder-ceramic metallurgical reaction.

Solderable surfaces are provided by thick-film metallization inks. These inks contain a powder of electrically conductive metals or alloys (for example, copper, nickel, gold-palladium-platinum, platinum-silver, platinum-gold, and others), an oxide powder and glass binder that bond the conductive component to the substrate by a high-temperature firing process, and an organic carrier comprising resin and solvents to give the ink "body" for printability on the substrate. The thick films have excellent solderability, because of their noble metal content. However, the 10 to 20 μm (100 to 800 μin.) thick film can be consumed by intermetallic formation with the tin component of the liquid solder, as well as through solid-state reaction at the solder-film interface of the solidified joint. The use of lead-indium solders greatly reduces the growth of intermetallic compounds. Copper and nickel thick films are not as quickly consumed by the tin-base solders and are less costly. However, these coatings must be protected from excessive oxidation during firing, solder processing, and contaminated atmospheres during storage.

Other thick-film systems are based on moly-manganese and refractory metals (Ref 19). The moly-manganese process uses an ink of molybdenum and manganese that is printed onto the selected location(s) and fired to bond the film to the ceramic. Next, a layer of copper or nickel is electroplated onto the moly-manganese film to form the solderable coating. Then, a protective layer of electroplated gold is added. Alternatively, some refractory metal thick-film systems use molybdenum or tungsten as the ceramic binder. Gold is electroplated onto the refractory metal binder. The resulting metallized layer is heated to partially consume the gold as gold-molybdenum or gold-tungsten alloy at the interface. The alloys form the solderable surface while the remaining gold serves as the protective finish. Electroplated nickel can be used to create the solderable surface in place of gold-molybdenum or gold-tungsten.

Storage. The base material or surface finish solderability is strongly affected by storage conditions (time, temperature, humidity, gases, and packing materials) and the integrity of the protective coating. Recommended electroplated and hot-dipped solder finishes that pass specified solderability tests are considered to preserve solderability for 1 to 2 years under typical industrial environments (Ref 20, 21). Longer periods may require special storage conditions, such as inert atmospheres in containers, controlled temperature and humidity levels, or additional solderability testing prior to assembly. Plasticizers and silicon-base mold releases in plastic containers, as well as sulfur compounds in paper products and factory atmospheres, can degrade solderability. Inventory control practices, including "first in, first out" and "just-in-time," can prevent solderability deterioration caused by excessive storage periods.

Corrosion. Solder alloys have necessarily dissimilar compositions, when compared with the base materials that they join together. Therefore, solder joints have a potential for corrosion activity. Water vapor from the atmosphere can provide the electrolyte medium, particularly given that most PWB laminates (and ceramic materials) are hygroscopic to varying degrees.

Sources of ionic species to form the electrolyte medium are flux residues, processing chemicals that remain in the PWB (laminate), or external contamination by handling or service environments. The electromotive series provides a preliminary estimate of corrosion "potential" for the metal systems in the joint. However, the series cannot describe the kinetics (rate) of corrosion.

Assembly processes for high-reliability electronics or those systems destined for harsh service conditions (for example, saltwater spray or high-humidity locations) must be thoroughly assessed for corrosion potential. Issues include: the compatibility of the solder and base material, the activity of the flux and the need for its residue removal after assembly,

and the use of either conformal (organic) coatings to exclude atmospheric moisture or coatings with metal finishes (zinc or cadmium electroplating) to act as sacrificial anodes.

Soldering in Electronic Applications

Paul T. Vianco, Sandia National Laboratories

Solder Joint Design

Solder joint performance depends on the package size of a device, the materials and layout of the PWB (or hybrid substrate), and the manufacturing processes used to assemble the PWB. Hardware package configurations and PWB layout guidelines have been established by several industrial standards organizations, such as the Electronics Industry Association (EIA), Institute for Interconnection and Packaging Electronic Circuits (IPC), American National Standards Institute (ANSI), and the Joint Electronic Devices Engineering Council (JEDEC). General solder joint configuration and performance recommendations are discussed below for through-hole technology, surface-mount technology, mixed technology (through-hole plus surface mount), and connector technology. Table 5 lists the numerous guidelines that provide details on these topics. (A list of industrial specifications can be obtained from IPC, 7380 N. Lincoln Ave., Lincolnwood, IL, 60646-1705; federal and military specifications are available from the Standardization Documents Order Desk, Building 4D, 700 Robbins Ave., Philadelphia, PA, 19111-5094.)

An assessment of solder joint performance requires knowledge of several physical and mechanical properties of the solder alloy, package, and substrate materials. Strength calculations based on bulk solder properties typically provide a conservative estimate of solder joint performance (Ref 22); more accurate predictions are made from solder joint properties. The properties of those materials commonly used in electronics packaging and substrates are summarized in Table 6.

(A) THERMAL EXPANSION OF CIRCUIT BOARD SUBSTRATES IN THE *Z* (THICKNESS) DIMENSION CAN BE AN ORDER OF MAGNITUDE GREATER THAN IN THE *XY* (PLANAR) DIMENSIONS.

Organic materials used in PWB laminates soften significantly at temperatures that exceed their glass transition point. Time periods at temperatures greater than the transition value should be minimized to prevent permanent warpage or twist to the PWB, which can cause debonded lands and conductor lines or fractured joints and packages due to misfit in cabinet frames.

Coefficients of thermal expansion (CTE) are required to assess the thermal fatigue resistance of solder joints, a principal source of failure for leadless surface-mount components. The CTEs of PWB laminates are specified for the in-plane dimensions. It is important to note that the through-thickness CTEs of PWB laminates can be as much as an order of magnitude larger than the in-plane values. Because PWB CTEs are very sensitive to the resin content, resin type, and fiber weave of the laminate, precise values should be obtained by measuring them directly, rather than relying on generic information from the manufacturer.

Thermal conductivity is important in solder joint design for high-power applications.

Excessive moisture retention by the PWB (organic laminate or ceramic) can lead to voids in solder joints that are due to water vapor formed at soldering temperatures or it can cause movement of surface-mount parts during reflow that results in misaligned packages on the assembly.

Through-hole technology typically refers to the use of leaded device packages. The leads are inserted into holes in the PWB and are soldered in place. Several package/lead configurations are shown in Fig. 7. Device leads are typically copper or one of the iron-base alloys (typically coated with a solderable layer). These lead-base materials have a protective finish of tin-lead alloy (plated, plated and fused, or hot dipped) to facilitate solder wetting during assembly on the PWB. Although the coatings can accommodate lead-forming operations, such practices should not be performed on leads with an electroless nickel solderable layer.

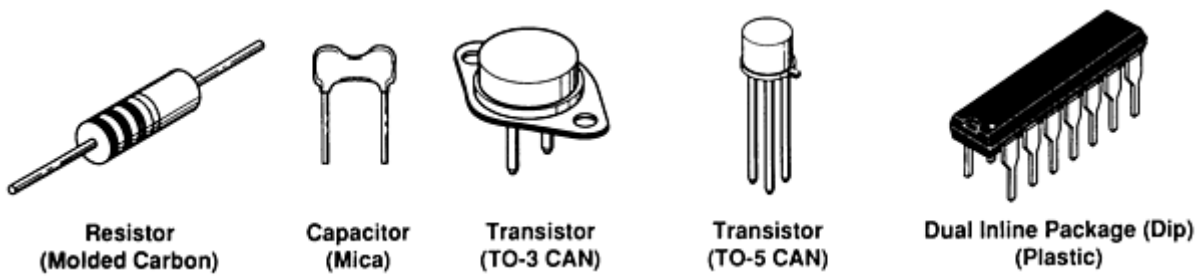

FIG. 7 PACKAGE AND LEAD CONFIGURATIONS FOR THROUGH-HOLE DEVICES

Substrates for through-hole technology include organic laminates, metal-clad substrates, and ceramics for hybrid microcircuits. Ceramic substrates are discussed below in the section on surface-mount technology. Through-hole PWBs are categorized as:

- SINGLE-SIDED, WITH CIRCUITRY ON ONE SURFACE ONLY
- DOUBLE-SIDED, WITH CIRCUITRY PLACED ON BOTH SURFACES
- MULTILAYER, WITH CIRCUIT LAYERS ON BOTH EXTERNAL SURFACES AS WELL AS CONDUCTIVE PATHS WITHIN THE LAMINATE

The solder joint configuration for each case is shown in Fig. 8. Lands (and conductor lines) are constructed of copper foil bonded to the laminate; the foil thicknesses are typically 0.017 mm (0.0007 in.), 0.035 mm (0.0014 in.), or 0.071 mm (0.0028 in.) and are designated as 0.5 oz, 1 oz, and 2 oz, respectively. The surfaces of lands (and lines) can be built up with a combination of electroless and electroplated copper to a thickness that ranges from 0.013 to 0.076 mm (0.0005 to 0.0030 in.) to satisfy final thickness requirements and enhance solderability.

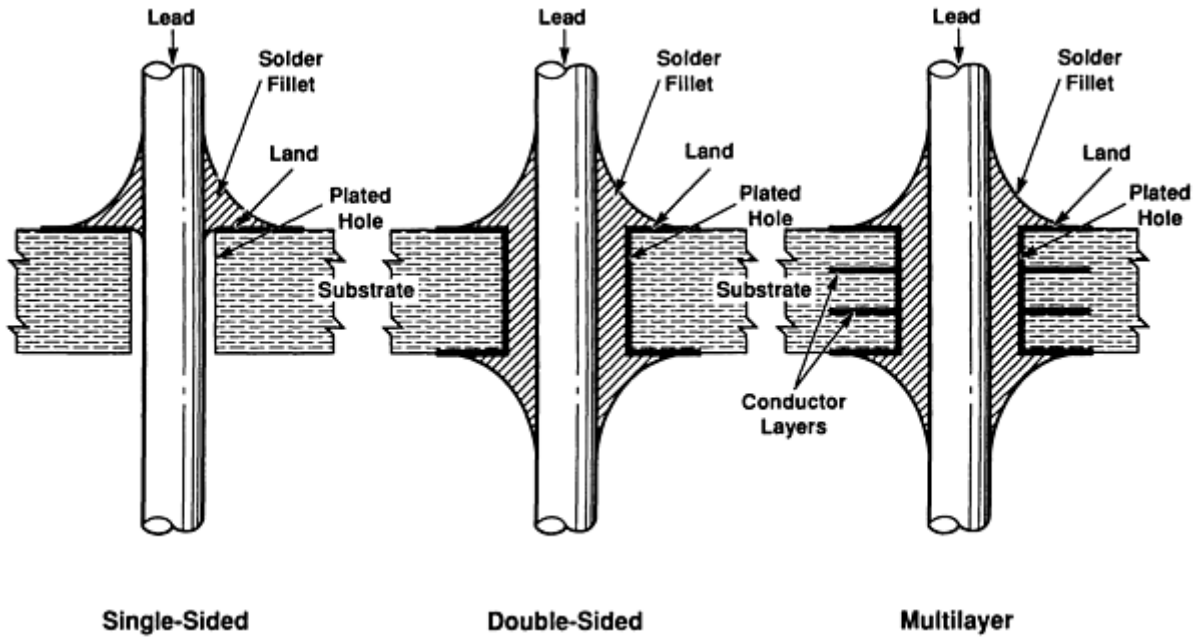

FIG. 8 SINGLE-SIDED, DOUBLE-SIDED, AND MULTILAYER SOLDER JOINT CONFIGURATIONS FOR THROUGH-HOLE TECHNOLOGY

Although the role of holes on single-sided circuitry is to mechanically secure the electronic devices, holes on double-sided and multilayer boards have an expanded role of providing electrical signal conduction between the two surfaces and internal layers. Holes used for interlayer signal transmission, but without a device lead, are termed "vias." The hole walls are deposited with copper to establish electrical conductivity and promote solder flow. The walls are coated with from 0.0003 to 0.0025 mm (0.0001 to 0.0001 in.) of electroless copper, followed by 0.025 to 0.076 mm (0.001 to 0.003 in.) of electroplated copper (Ref 23).

General guidelines for hole design are provided in Fig. 9. The hole size specified for a lead or wire should permit a gap of 0.15 to 0.20 mm (0.006 to 0.008 in.) to optimize the strength and capillary flow of the solder. Smaller gaps cause interference between the lead and hole, which can either damage the plating layer during insertion or generate voids caused by incomplete venting of flux gases produced during soldering. The recommended lead protrusion from the board underside is from 0.8 to 2.0 mm (0.03 to 0.07 in.). Values are kept small in order to minimize solder drainage from the fillet. The hole bonding land, or pad, should be round, and the outer diameter should be approximately three times the wire diameter. The annular width of the land should allow a lead height-to-pad width ratio of 1:1 for adequate fillet formation.

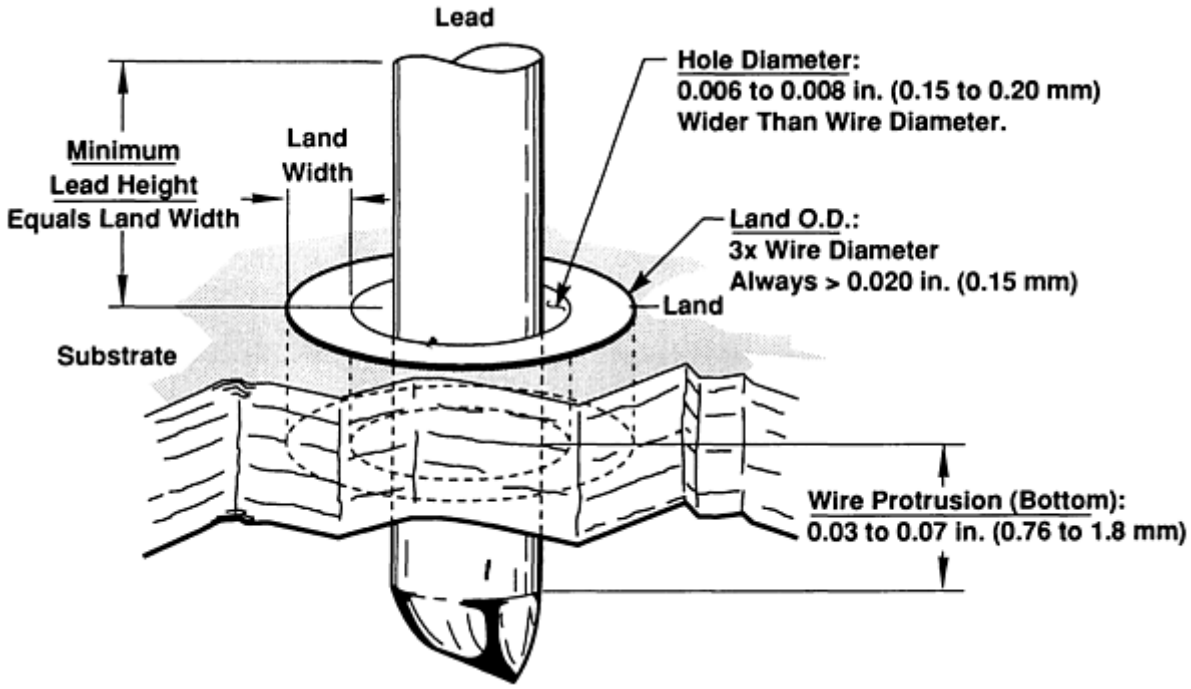

FIG. 9 GENERAL GUIDELINES FOR LEAD AND SUBSTRATE GEOMETRIES USED IN THROUGH-HOLE TECHNOLOGY

Loss of electrical continuity in the through-hole can arise from cracking (termed barrel cracking) of the hole plating layer because of the large CTE in the thickness dimension of the laminate (nearly a factor of 10 higher than in the laminate plane). This phenomena is particularly severe for via holes with large aspect ratios (the board thickness/hole diameter). Aspect ratios should be kept to a value smaller than 3 to ensure adequate reliability by typical assembly processes (Ref 24). The use of holes with larger aspect ratios requires additional attention to reliability.

Calculations have shown that the mechanical strength of the through-hole joint is limited primarily by PWB properties, specifically, the peel strength of the copper foil/laminate bond and the adhesion between the plating layer of the hole and the laminate (Ref 25). Similarly, the bond strength between the thick-film network and the ceramic substrate limits the strength of solder joints on hybrid microcircuits. Mechanical integrity can be lost through thermal fatigue. However, CTE mismatch between the device package and the PWB is not a principal source of thermal fatigue damage to through-hole solder joints, because the leads take up much of the displacement difference. Rather, thermal fatigue arises primarily from the difference between the lead CTE (for example, copper, at 9.4×10^{-6}/K, or 5.2×10^{-6}/°F) and the through-thickness thermal expansion value of PWB laminate (as much as 175×10^{-6}/K, or 98×10^{-6}/°F). Fatigue damage (Fig. 10) in through-hole solder joints is lessened by the CTE of the solder (25×10^{-6}/K, or 14×10^{-6}/°F), which is between those of the lead and PWB materials, as well as through proper assembly practices such as the incorporation of strain relief bends or loops placed in leads.

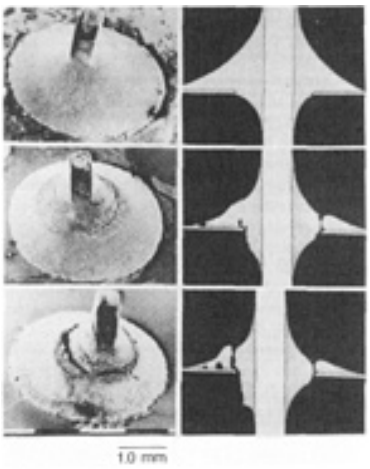

FIG. 10 PROGRESSION OF FATIGUE DAMAGE IN A THROUGH-HOLE SOLDER JOINT (OPTICAL MICROSCOPY AND SEM). SOURCE: REF 7

Plated-through holes are soldered from one side. Multilayer boards are more difficult to solder, because the interior conductor lines act as additional heat sinks that inhibit board heating. Solder assembly techniques for through-hole PWBs include hand soldering and larger-scale, automated processes such as dip, drag, or wave soldering. Solder pot working temperatures for the latter processes range from 240 to 260 °C (464 to 500 °F) for 63Sn-37Pb and 60Sn-40Pb solders. A good rule of thumb is to limit contact between the assembly and the molten solder to 3 to 10 s to minimize damage to the laminate and flux charring.

Heat damage to the attached device, neighboring components, and the substrate material must be considered when reworking through-hole solder joints. When a part is intended to be removed after assembly, it can be attached by hand soldering techniques with one of the lower melting temperature solders (Table 1). This technique is generally reserved for prototype assemblies; military and most commercial products specifications do not allow this operation.

Conformal coatings must be removed prior to reheating a solder joint. Clinched leads, that is, leads that are bent slightly on the opposite surface of the board to provide mechanical rigidity during assembly, hinder the removal of components. Generally, heat inputs will be greater when reworking a joint because the solder, lead, and land must be heated, which increases the likelihood of damage to the land/substrate bond or to the device. Cleanliness specifications must be followed after reworking to prevent functional failures caused by corrosion from flux residues.

The reliability of double-sided and multilayer circuit boards depends strongly on the plating quality of the hole walls. Water vapor and contaminants from the plating solutions can become entrapped in the deposited film. Plating layers should be free of embrittling contaminants that make them unable to adapt to board thermal expansion. The coating must have adequate thickness (and uniformity) so as not to be totally consumed by the metallurgical reaction with the solder. Contaminant materials vaporize at the soldering temperatures, causing cracks in the plating layer. Although plating cracks and voids, or delamination, do not necessarily jeopardize joint strength, they can interrupt electrical continuity between layers and surfaces.

A plated-through hole that is coated with a hot-dipped or plated-and-fused solder layer will have a very thin film of solder around its edge upon reflow. This phenomenon is a consequence of the surface physics of molten liquids. The limited protection offered by the thin solder film can cause nonwetting of the hole edge during assembly, in which case the joint is said to have a "weak knee." The effects of a weak knee on joint reliability are largely cosmetic for plated-through holes.

The traditional solders used in through-hole technology have been the tin-lead alloys. The solders with higher melting temperatures, such as tin-silver, tin-antimony, and lead-base tin-lead solders, have also been used in through-hole PWB systems designed for elevated-temperature service applications or step soldering processes. However, these solders are limited to specialized soldering assembly or those processes in which heat application is localized to the joint (for example, hot-air, hot-bar, fiber-optic infrared, or laser techniques), away from the electronic component. The higher heat inputs require that heat sinks be used on heat-sensitive devices. In addition, the higher reflow temperatures may

decompose the typical rosin-base fluxes. Synthetic-activated (SA) fluxes, which have activities comparable to those of RMA fluxes and water-soluble fluxes, can withstand the higher-temperature operations.

Surface-mount technology utilizes several types of assembly techniques. The technology generally refers to products that use conventional PWB assemblies, which include organic laminates, clad-metal substrates, as well as ceramic substrates for hybrid microcircuits. Although the architecture differs between organic laminates and hybrid substrates, the package configurations for electronic devices is similar. Surface-mount technology also includes chip (silicon)-on-board technologies (such as tape automated bonding, TAB), controlled collapse chip connection (C^4), or flip chip.

PWB Assemblies (Organic Laminate and Ceramic). Denser board populations and adaptability to fully automated assembly processes have increased the popularity of surface-mount technology. Figure 11 shows several leaded and leadless surface-mount packages. Lands on surface-mount PWBs are constructed with the same conduction layer material specifications used on boards with through-hole components:

- LAND THICKNESSES (COPPER) ARE BETWEEN 0.018 AND 0.071 MM (0.0007 AND 0.0028 IN.).
- PROTECTIVE FINISHES ON PWBS INCLUDE HOT-DIPPED SOLDER WITH HOT-AIR LEVELING OR ORGANIC COATINGS (INHIBITORS) ON BARE COPPER.
- THE CONTROL OF SOLDER THICKNESS ON HOT-AIR LEVELED LANDS IS CRITICAL WITH SURFACE-MOUNT PWBS.
- EXCESSIVE SOLDER QUANTITIES WILL INTERFERE WITH PART ALIGNMENT DURING PLACEMENT, DAMAGE FINE LEADS DURING AUTOMATED SETUP OF COMPONENTS ON THE BOARD, AND INCREASE THE LIKELIHOOD OF NONSYMMETRIC FILLETS ON DEVICES.
- NONSYMMETRIC FILLETS CAN LEAD TO MISALIGNMENT ("TOMBSTONING") OF DEVICES DURING AUTOMATED SOLDERING PROCESSES.

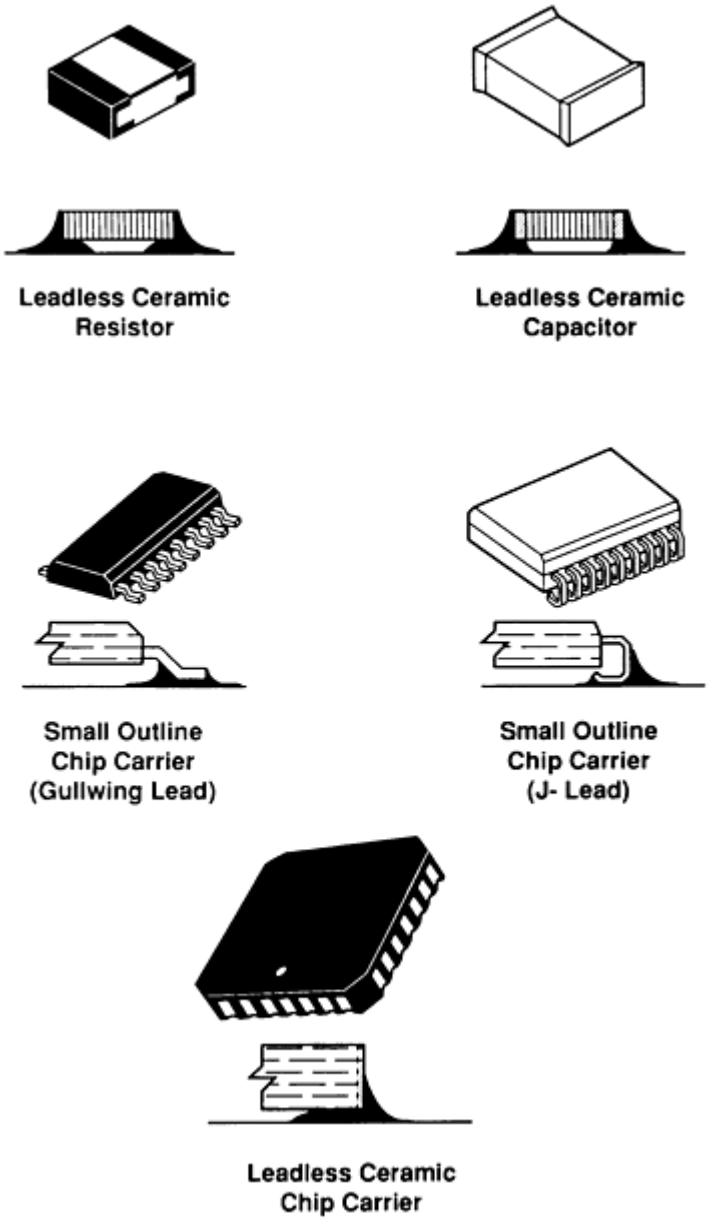

FIG. 11 PACKAGE AND LEAD CONFIGURATION OF SURFACE-MOUNT DEVICES, INCLUDING SOLDER JOINT PROFILES

A variety of land geometries are used in order to accommodate the range of package input/output (I/O) configurations. Holes, or vias, may be required on the PWB to permit signal transmission between the two external surfaces or between internal conductors of multilayer boards. In some cases, through-hole components are also found on the same PWBs. These assemblies are known as mixed technology. The quality of the plating layer in the hole is critical to system reliability, whether in vias for signal transmission or component holes for mixed technology applications.

Conductor lines and lands on ceramic boards are composed of one of the thick-film inks. The pattern is screen printed into the circuit configuration and fired to promote adhesion. Lines are usually formed from a single printed layer, with a thickness of approximately 0.01 mm (400 μin.). Lands to which soldering will take place may receive a second printing (double-printed), which improves solder joint reliability by reducing porosity in the film and limiting the dissolution of the conductive layer that is due to the formation of intermetallics between the solder and the precious metal. Double-printed layers are typically from 0.02 to 0.025 mm (0.0008 to 0.0010 in.) thick, depending on the porosity of the first layer.

Leadless surface-mount resistors and capacitors use terminations to form the solder interconnect. Terminations are regions on the package surface that are coated with a solderable layer to promote wetting by the solder. Leadless chip resistors and capacitors have a silver-bearing thick-film ink that is fired onto areas of the ceramic substrate; these areas are connected to the active electrical elements. Dissolution, or scavenging, of the thick film is reduced by adding more than 35% Pd to its composition (Ref 26). More commonly, the thick film is coated with a solderable nickel or copper finish to prevent the scavenging of silver by the solder. Candidate protective layers for the solderable finishes include electroplated tin or tin-lead and hot-dipped tin-lead solder.

Leadless ceramic packages for integrated circuits have multiple I/O terminations composed of metallized grooves on the package sides (castellation) and a metallized bonding area on the bottom of the package (blind lap joint). The metallized surfaces have a refractory layer (tungsten or molybdenum) that provides the electrical feedthrough to the interior. The refractory layer is then coated with a nickel solderable layer (1.3 to 8.9 μm, or 50 to 150 μin.). A protective layer of gold (1.3 to 2.5 μm, or 50 to 100 μin.) coats the nickel. The gold finish is removed by a hot-dipped solder coating step to prevent gold embrittlement of the solder joints. Gold embrittlement is of particular concern in surface-mount solder joints, because the limited amount of solder required to form the small joints can easily exceed the 4 wt% maximum Au content observed to degrade solder properties. Lower potential gold contents are preferred as a safety factor.

Leaded packages for surface-mount assembly have conductors fabricated from copper or one of the iron-base alloys and formed into the appropriate configuration (J-lead, gullwing, and others). A solderable layer of electroplated or electroless nickel, followed by a protective coating of electroplated gold, is deposited onto the iron-base alloy leads, per the recommended thicknesses (see the section "Base Materials, Finishes, and Storage/Corrosion Issues" in this article). The leads are hot dipped in tin-lead solder to remove the gold coating prior to assembly or to protect the copper solderable finish; however, tin or tin-lead electroplated coatings are preferred with fine-pitched leads and packages to eliminate the "crown" of solder on the lead. This crown causes the lead to deform and slide off of the similar crown of solder on the land when the part is placed on the PWB, causing component misalignment, solder joint distortion, or electrical failure.

The predominant solders used in surface-mount PWBs have been the tin-lead alloys. The tin-lead-silver solder (62.5Sn-36.1Pb-1.4Ag) has improved flow and a slightly improved isothermal fatigue life (for service conditions with limited temperature variations), when compared with the eutectic tin-lead alloy. The silver component of this solder improves creep strength. Silver-bearing solders also restrict the scavenging of silver from silver-bearing thick-film terminations on leadless ceramic devices that do not have a solderable (barrier) coating. A noneutectic tin-lead-silver alloy formed by the addition of 2% Ag, or the use of 60Sn-40Pb solder, will reduce the occurrence of solder wicking on leaded devices. Solder wicking is a phenomenon on leaded devices whereby the entire quantity of molten solder is drawn away from the pad to the lead because the lead heats up faster than the pad. This problem is particular to the vapor-phase reflow process and is compounded by leads that are noncoplanar with one another.

The noneutectic solders melt more slowly than eutectic alloys because they melt over a temperature range. This allows the lead and bonding pad surfaces to reach the same temperature, so that solder will simultaneously wet both surfaces. A longer melting sequence of the noneutectic alloys also decreases the incidence of "drawbridging," or "tombstoning," on leadless chip components (Fig. 12). A cause of drawbridging is the nonsimultaneous melting of the solder at the two terminations, causing the component to be drawn toward the molten joint by the surface tension of the solder. Other factors in drawbridging are paste tackiness, paste quantity, part location, and land design.

FIG. 12 DRAWBRIDGING OF A LEADLESS CERAMIC CHIP RESISTOR (OPTICAL MACROSCOPY). COURTESY OF SANDIA NATIONAL LABORATORIES

Other solders used for surface mounting include lead-indium alloys, which are used in hybrid microcircuit systems. The lead-indium solders limit the leaching of precious metals from thick-film networks and finishes on devices, and reduce the formation of brittle intermetallic compounds that jeopardize solder joint integrity. In addition, these alloys are more ductile than the tin-lead solders, thereby limiting the loads on the more-fragile thick-film/substrate ceramic bond. The low-temperature ductility of these solders provides a niche for them in cryogenic applications (for example, space vehicle electronics).

The low-melting-temperature tin-bismuth solders are used on PWBs with heat-sensitive devices or with those components that have to be removed and replaced on the board one or more times to satisfy testing or operational modes.

The high tin-silver solders are well suited for surface-mount assemblies because of their improved fatigue properties as compared to those of the tin-lead alloys. Their higher melting temperatures (96.5Sn-3.5Ag eutectic, 221 °C, or 430 °F) increase the service temperature window of assemblies, as well. It is critical that the finishes on substrate lands and device leads or terminations be compatible with the solder alloy. The mixture of different metals, which is due to nonsimilar pastes and finishes, can produce lower-melting-temperature phases that can deteriorate the physical and mechanical properties of the solder joints. For example, mixing bismuth-containing solders and lead finishes with tin-lead solder causes a low-melting-temperature tin-lead-bismuth phase that melts at 96 °C (205 °F).

The use of alternative solders implies solder joint cosmetics that are different from those of the tin-lead alloys. Cosmetics should not be relied upon to judge service performance. Typically, the tin-bismuth, lead-indium, and tin-silver solders have a grainy solder fillet. The fillets of lead-indium and tin-silver will be less concave than those of tin-lead, because of their higher surface tensions.

Typical fluxes used for surface-mount assembly are the rosin-base materials, usually the RMA forms. Water-soluble fluxes (organic acids) are being used increasingly in electronics, because of the variety of aqueous cleaning processes available to remove their residues. Although flux residue removal is determined by the reliability required of the assembly and flux activity, surface-mount technology requires additional attention to cleaning requirements and procedures. The high density of devices places conductors closer together, so that ionic residues are more likely to cause electrical shorts by the electromigration mechanism. In addition, flux residues can be easily entrapped in the 0.05 to 0.013 mm (0.002 to 0.005 in.) gap between the package and the substrate.

Surface-mount PWBs are manufactured by mass production techniques, such as vapor-phase reflow, heating in IR furnaces, or wave soldering. These processes, and numerous others, are described in separate articles in the Section "Joining Processes" in this Volume. Briefly, a typical assembly sequence for reflow techniques (that is, using vapor-phase or furnace processes) involves:

- DEPOSITING SOLDER PASTE ON THE SUBSTRATE LANDS BY EITHER SCREEN PRINTING, STENCIL PRINTING, OR BULK DISPENSING TECHNIQUES
- BAKING THE PASTE TO DRIVE OFF VOLATILES
- PLACING THE ELECTRONIC COMPONENTS ON THE PASTE DEPOSITS, OVER THE LANDS (MANUALLY OR WITH ROBOTICS)
- REFLOWING THE SOLDER
- CLEANING THE BOARDS OF FLUX RESIDUES, IF NECESSARY

The use of alternate solder alloys depends on their availability in paste form (with the optimum flux and flow properties). Preforms or wires of nontypical solders are more readily available. For vapor-phase reflow, working fluids that would accommodate solders with higher melting temperatures than tin-lead alloys may have limited availability. Infrared heating is more versatile in this regard. Damage to heat-sensitive components must be considered when higher-melting-temperature solders are used. Wave soldering utilizes a solder bath, which requires that an ingot form of the solder be available in order to fill the pot. Surface-mount parts are typically secured to the PWB with epoxies prior to being passed through the wave.

Some surface-mount PWBs are hand soldered. This technique is reserved for larger-pitch assemblies and runs of small quantities or for very high reliability electronic systems. It is also used as a means of repair and rework. For component placement, the conventional soldering iron tip has been replaced by hot bars or rectangles that conform to the various I/O configuration of surface-mount packages in order to simultaneously melt the solder in all joints. Heating rates should be

minimized on chip capacitors and resistors to prevent cracking of the ceramic chip or thick-film termination. Total heat input from the iron must not damage the land/substrate bond. An intermetallic layer formed between the copper land and molten tin-lead solder generally is not sufficient to restrict rework operations. However, solder removal that exposes the intermetallic layer to atmospheric oxidation can deteriorate solderability. Hand soldering processes may improve solder joint fatigue life by resulting in a finer solder microstructure, because of the fast cooling rate of joints after reflow (Ref 27). However, the fine microstructure coarsens with time and temperature, causing the strength advantage to be lost.

Solder joints for surface-mount technology fulfill electrical and mechanical attachment requirements. Adequate joint configurations have more than sufficient bonding strength to secure the device to the board. Shear tests (load application parallel to the board surface) are typically performed on leadless chip resistors and capacitors or on leadless ceramic packages to quantify the joint strength. Shear loads of chip resistors on polyimide-quartz PWBs are shown in Table 7 for as-fabricated, thermally cycled, and thermally shocked units (Ref 28). Leaded packages are more often tested in tension, that is, the load is applied perpendicular to the PWB surface.

TABLE 7 SHEAR STRENGTH OF SURFACE-MOUNT LEADLESS CERAMIC CHIP RESISTOR

TEST IDENTIFICATION	SHEAR STRENGTH	
	N	LBF
AS FABRICATED	84 ± 8	**19.0 ± 1.7**
300 THERMAL CYCLES	72 ± 6	**16.2 + 1.3**
100 THERMAL SHOCK CYCLES	**97 ± 4**	**21.9 ± 1.0**

Resistor dimensions, 2.67 × 1.27 × 0.457 mm (0.105 × 0.050 × 0.0018 in.); termination width, 0.25 mm (0.010 in.); thermal cycle, -55 to 125 °C (-67 to 257 °F), 120 min hold period, 6 °C/min (11 °F/min) ramp; thermal shock, -55 to 125 °C (-67 to 257 °F), 10 min hold period, liquid-to-liquid transfer; displacement rate, l0 mm/min (0.41 in./min).

A particular concern with surface-mount solder joints is thermal fatigue damage caused by the coefficient of thermal expansion (CTE) mismatch between the PWB laminate and the device package. Figure 13 shows scanning electron micrographs (SEM) of fatigue cracks on several different device packages. Thermal fatigue damage is of greater concern on leadless packages than on leaded configurations, because the latter can accommodate some of the displacement mismatch through the leads. For leadless packages (resistors, capacitors, or chip carriers), cracks begin under the package, as shown in Fig. 13(e), and grow toward the outer surface. Thus, cracks are well established prior to being visually detected on the fillet surface.

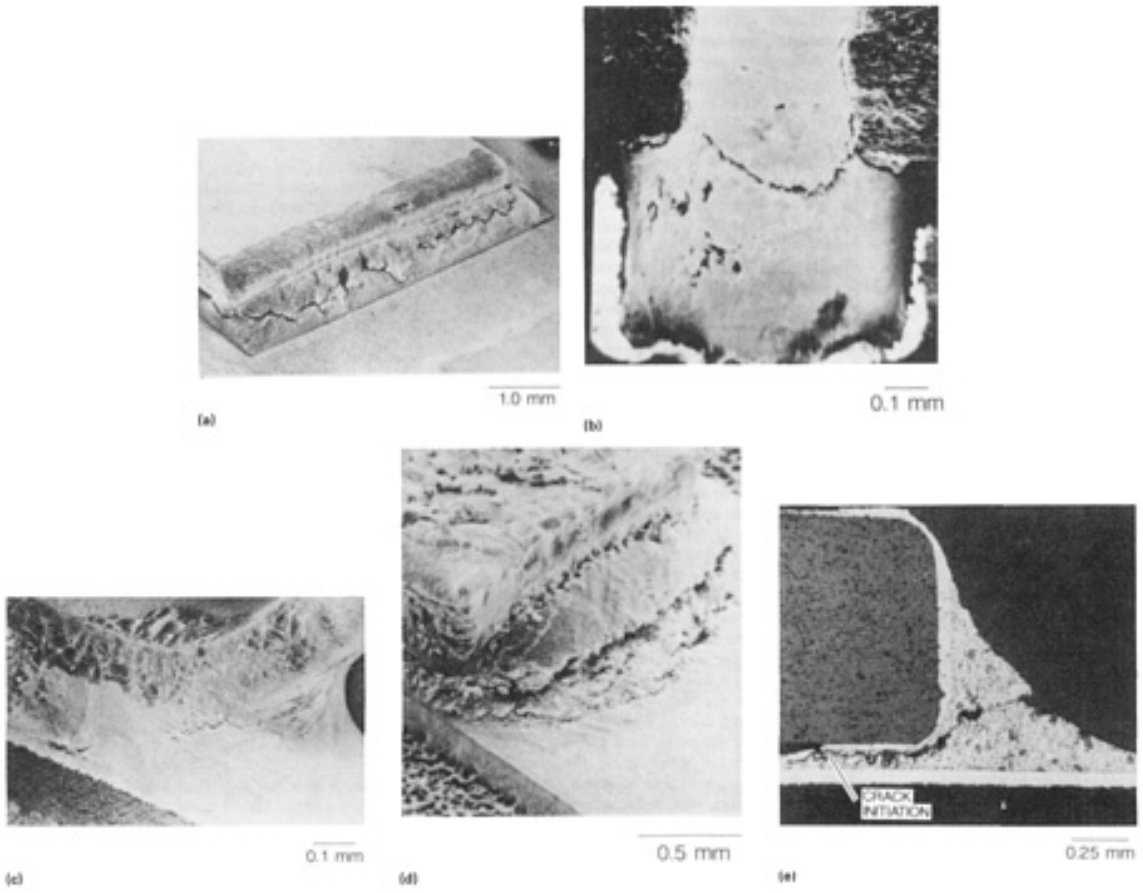

FIG. 13 FATIGUE CRACKS IN SURFACE-MOUNT SOLDER JOINTS. (A) LEADLESS CAPACITOR. (B) LEADLESS CERAMIC CHIP CARRIER. (C) J-LEADED PACKAGE. (D) GULLWING LEADED PACKAGE (SEM). (E) CRACKING IN A LEADLESS CERAMIC CHIP RESISTOR SOLDER FILLET. SOURCE: REF 7

Fatigue deformation that occurs under variable temperature conditions greatly complicates the prediction of solder joint failures. However, the thermal fatigue life of surface-mount solder joints can be estimated from isothermal fatigue test data when the microstructural damage is not strongly temperature dependent. Isothermal fatigue tests on surface-mount and leadless ceramic chip carrier 60Sn-40Pb solder joints at 35 °C (95 °F) and 125 °C (257 °F) show similar behavior. Tests at -55 °C (-67 °F) suggest a longer fatigue life, when compared with data from the higher-temperature tests (Ref 29). Therefore, isothermal fatigue test data on 60Sn-40Pb, taken at 35 °C (95 °F), can be used to estimate thermal fatigue performance over the temperature range from -25 to 125 °C (-77 to 257 °F).

The thermal fatigue life for eutectic and near-eutectic tin-lead solders can be predicted with the aid of Fig. 14. The configuration of the solder joint being tested (leadless ceramic chip resistor) is shown in Fig. 14(a). Let α_1 and α_2 be the CTEs of the package and PWB, respectively. ΔT is the absolute temperature range. The extension (or contraction) difference between the package and PWBs, Δx, is given as:

$$\Delta X = (\alpha_1 - \alpha_2)\, \Delta T L \qquad \textbf{(EQ 1)}$$

where L is the maximum separation between the solder joints, given the conservative assumption that all damage occurs to one joint.

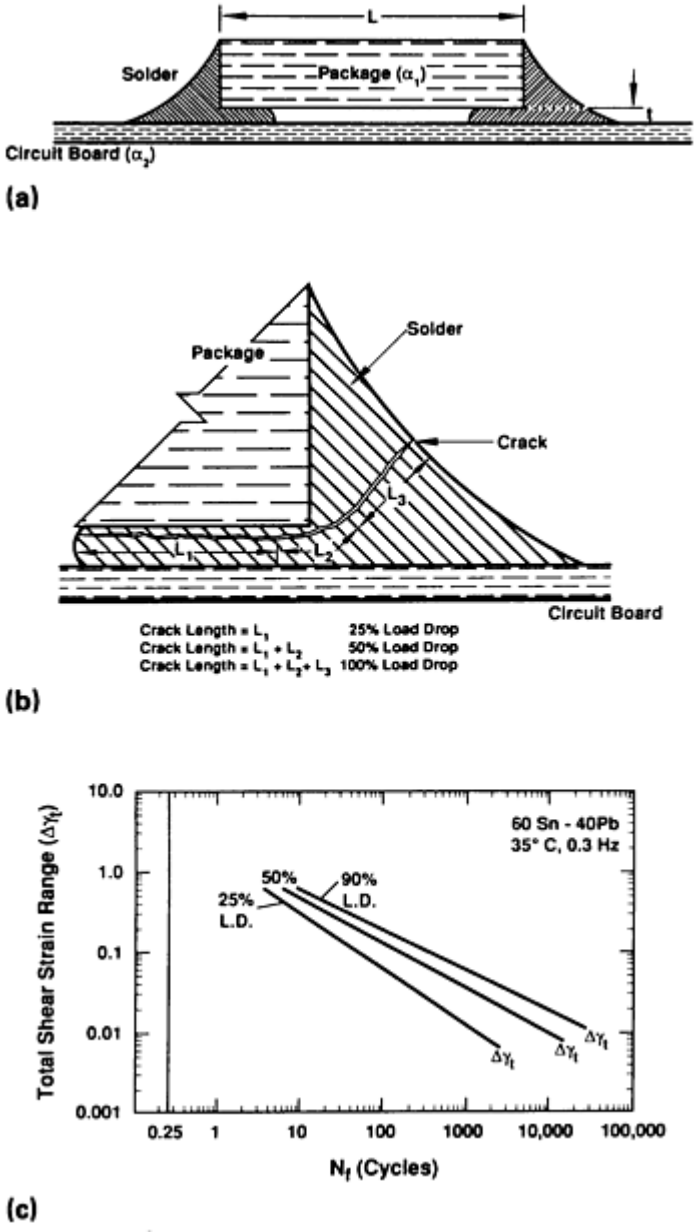

FIG. 14 ISOTHERMAL FATIGUE LIFE CALCULATION FOR THERMAL FATIGUE RESISTANCE APPROXIMATION. (A) PACKAGE/SOLDER JOINT GEOMETRY. L IS THE PACKAGE SIZE (DISTANCE BETWEEN SOLDER JOINTS), α_1 IS THE THERMAL EXPANSION COEFFICIENT, AND T IS THE SOLDER JOINT GAP. (B) FATIGUE LIFE VERSUS TOTAL SHEAR STRAIN RANGE PER LOAD DROP CRITERIA. (C) FATIGUE CRACK GROWTH CORRESPONDING TO PERCENT LOAD DROP CRITERIA FOR FATIGUE LIFE. SOURCE: REF 29, 30, AND 31

Equipartition of strain between the two joints requires the use of (L/2) in place of L. The total shear strain rate, $\Delta\gamma_t$, is:

$$\Delta g_t = \frac{\Delta x}{t} \qquad \textbf{(EQ 2)}$$

where t is the solder joint gap. For the crack extension (and associated load drop) depicted in Fig. 14(b), the value of $\Delta\gamma_t$ is found on the ordinate of Fig. 14(c), and the number of cycles to failure, N_f, is determined for each of the three failure criteria. The computed fatigue life is an approximation, that is, its accuracy is an order of magnitude. An in-depth treatment of the solder joint reliability issue is provided in Ref 32.

The data presented in Fig. 14(c) pertain to a cycle period of 3.3 s and are suitable for calculations of cycle times up to 1000 s (Ref 31). Periods in excess of 10,000 s/cycle cause the analysis described above to *overestimate* the fatigue life by nearly an order of magnitude.

Thermal fatigue life can be lengthened by matching the CTE of the substrate to that of the package material (note Table 6). Fatigue resistance is improved by increasing the standoff distance between the component and the substrate (that is, increase the value of *t*). Other techniques include the use of nonmelting balls in the solder paste or protrusions on the bonding surface of the package, both of which act as spacers to control the gap. In addition, it has been shown that fatigue life increases as the solder joint cooling rate is increased (Ref 33). The cooling rate can be controlled on automated assembly equipment such as IR furnaces and some vapor-phase units. However, thermal shock to the electronic devices and the substrate must be considered when increasing the cooling rate. Fast cooling rates are an inherent feature of localized heating techniques, such as hand soldering with an iron, hot gas or hot bar techniques, and laser soldering. However, room-temperature aging of the solder may counteract any fatigue life improvement.

Tape automated bonding (TAB) refers to bonding the silicon integrated circuit (IC) chip to a metal lead frame that, in turn, is soldered to the PWB. This technique is shown in Fig. 15. The Au_xSn_{1-x} solder inner lead bond, which attaches the silicon chip to the lead frame, is formed by the intermixing of gold and tin diffusing from corresponding metallizations deposited on the chip and lead, respectively, under elevated temperature and pressure. The outer lead bond, which attaches the silicon chip plus lead frame to the circuit substrate, is a tin-lead solder joint formed by one of the conventional assembly processes. A lead exists for each of the I/Os on the silicon chip. The thermal fatigue of solder joints is reduced by the lead, which takes up the thermal strain mismatch between the silicon IC and the substrate. Additional compliance is added to the lead by jogs or bends in the geometry.

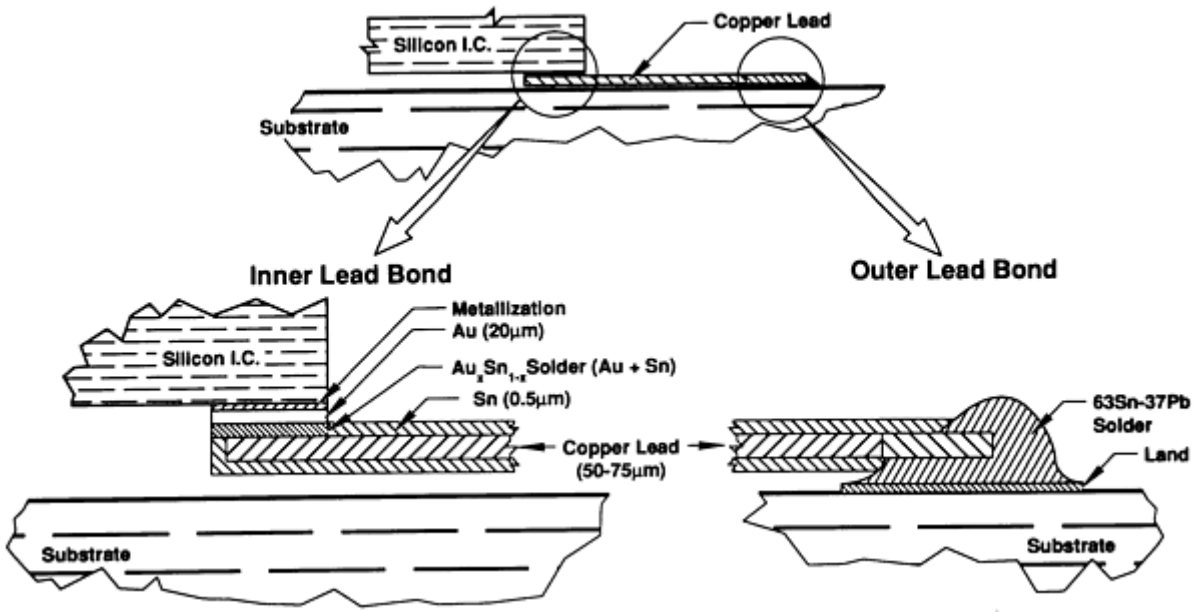

FIG. 15 TAPE AUTOMATED BONDING OF A SILICON CHIP TO THE SUBSTRATE

Controlled collapse chip connection (C^4) describes the process whereby the silicon IC chip is bonded directly to a ceramic substrate by small solder bumps that also serve as the signal I/O path (Fig. 16). This technique is widely used in computer assembly technology. The solderable surface on the silicon is a vacuum-deposited copper layer. A vacuum-deposited chromium film promotes adhesion of the copper to the SiO_2 layer. A gold layer (also vacuum-deposited) is the final protective finish. The ceramic substrate can be single-layered or multilayered.

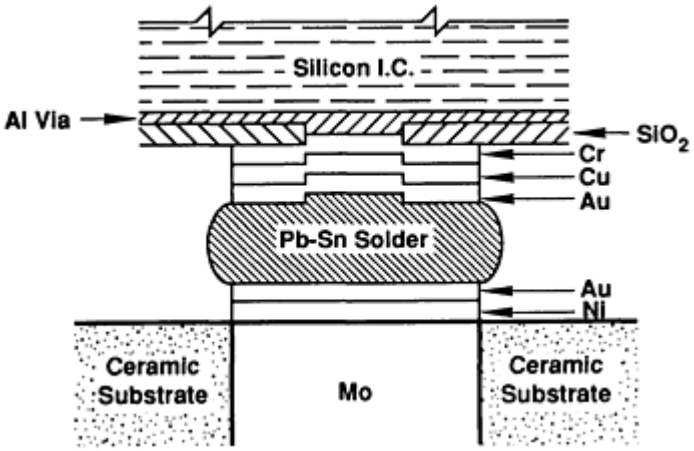

FIG. 16 SOLDER "BUMP" JOINT USED IN CONTROLLED COLLAPSE CHIP CONNECTION

When working with solder bumps to molybdenum vias, the molybdenum is coated with vacuum-deposited nickel and gold films, where nickel is the solderable surface and gold is the protective finish. The solder can be one of the lead-rich, tin-lead alloys (90Pb-10Sn or 95Pb-5Sn) or a lead-indium alloy (50In-50Pb). The lead-tin alloys are suited for assemblies that will later be processed with eutectic tin-lead soldering. The solder films are vacuum deposited onto the silicon chip in thicknesses ranging from 0.100 to 0.123 mm (0.004 to 0.005 in.). The units are passed through a belt furnace under a protective atmosphere to melt the solder.

The solder joints of C^4 interconnects must accommodate the thermal strain mismatch between the silicon IC and the substrate. Fatigue damage is reduced by maximizing and controlling uniformity of the silicon IC chip standoff distance above the substrate (hence the term, controlled collapse), limitation of the chip size, and the use of substrates with CTEs similar to that of silicon.

Connector Technology. In the signal analysis of an electronic product, the backplane forms the hub through which PWBs "talk" with one another and receive electrical power to operate devices mounted on them. As a result, the physical requirements placed on the backplane construction cause it to be a unique PWB. The backplane must mechanically support numerous PWBs and connector-cable assemblies that are frequently removed and reinserted in addition to heavier devices such as large capacitors or transformers. Therefore, the backplane is typically much thicker (2.4 to 3.2 mm, or 0.093 to 0.125 in.) than conventional PWBs (Ref 34). As the hub of electrical signal transmission, the backplane is often multilayered with thick conductor lines (0.071 to 2.8 mm, or 0.0028 to 0.11 in.), depending on the power transmission requirements of the system. Connector pins may be soldered on the substrate using preforms and vapor-phase assembly or manual processes. The thicker laminate and conductors as well as the multilayer construction can be a formidable heat sink to soldering processes in addition to being susceptible to warpage by overheating or inadequate support. Connector pins may also be press fit onto the substrate.

Signal transmission between devices that are not electrically connected via the PWB, between PWBs themselves, or between PWBs and the backplane, require the use of wires, cables, and connectors. Connectors are manufactured using attachment modes of soldering or a combination of soldering and mechanical fastening techniques. Examples of various connector techniques and design guidelines are shown in Fig. 17. The solder joints in connectors must be mechanically robust to accommodate loads caused by rigid, unyielding cables, as well as their frequent disconnection and reinstallation.

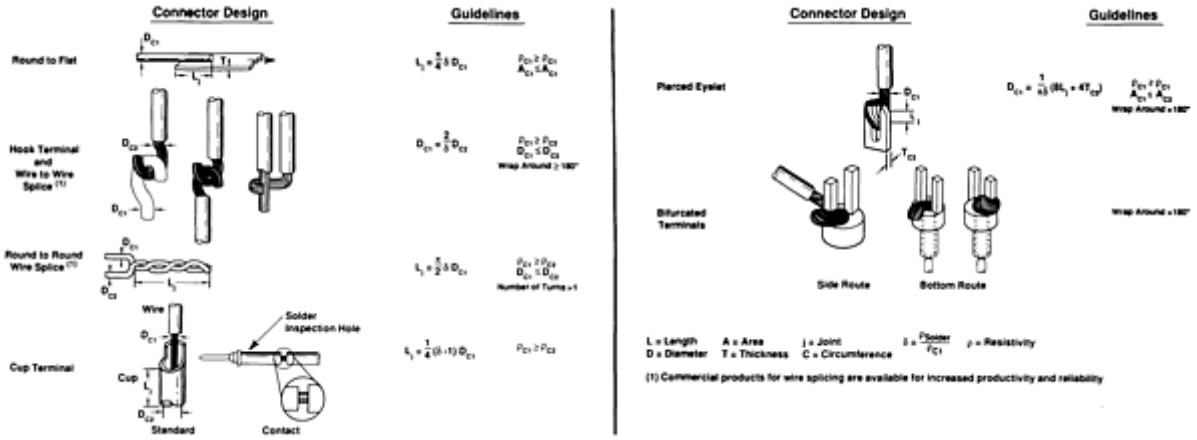

FIG. 17 CONNECTOR METHODOLOGIES

Base materials for connectors, wires, and cable conductors include copper alloys (for example, oxygen-free, high-conductivity copper and electrolytic pitch-grade copper, brass, beryllium copper, and others), iron-base alloys (Kovar, stainless steel, and others), and aluminum alloys. Preparation of the base metal and selection of solderable and protective finishes for solder attachment are described in the section "Base Materials, Finishes, and Storage/Corrosion Issues" in this article. Because connector assemblies typically use larger quantities of solder to form the joint, the electroplated gold that serves as the protective layer may not have to be removed by a hot-dipped solder coating prior to assembly. The solder joint may have a frosty appearance, because of the dissolved gold in the solder. However, a hot-dipped coating should be applied if the thickness of gold electroplating and the estimated quantity of solder used in the joint indicate a dissolved gold content in the solder that will potentially exceed the 4 wt% limit, which causes embrittlement in tin-lead solder joints.

Pins, which are part of a plug-and-socket connection, can be gold plated with so-called "hard coatings," that is, the gold electroplate contains approximately 0.3 wt% cobalt or nickel to improve abrasion resistance during removal and installation cycles of the connector. However, the cobalt or nickel additions can cause the solderability of the pin to be poor.

Silver coatings are preferred on some connector parts in order to lower contact resistance. Unfortunately, silver is tarnished by the formation of sulfides from airborne sulfur compounds, which also deteriorate solderability. For grounding applications, soldering processes to aluminum connector housings should be followed with an electroplated coating of zinc or cadmium to guarantee adequate corrosion resistance.

Solders used in connector assemblies are generally tin-lead alloys. Additional strength, particularly for products exposed to elevated temperatures or mechanical loads, is obtained with the tin-silver and tin-antimony solders. The higher melting temperatures, coupled with the generally massive structure of connectors (when compared with electrical components), requires greater heat input into the assembly for proper joint fabrication. Joining can be facilitated by first hot dipping the mating substrates in the particular solder prior to final assembly. The use of preforms can facilitate the introduction of solder into joints, particularly those of very small assemblies.

The preferred fluxes for connectors are the rosin-base materials. Residues from pure rosin need not be removed. Mildly activated (RMA) flux residues are removed for high-reliability applications. Residues of more-active fluxes (RA, SA, or water soluble) must be removed. Hand soldering with low-solids fluxes in air can give inconsistent solderability because only very thin layers of tarnish can be removed by the flux. The higher heat inputs required for connector structures can degrade rosin-base fluxes, necessitating the use of water-soluble and synthetic fluxes that will tolerate the higher working temperatures. In either case, the residues must be removed, because they are corrosive.

Connectors are typically assembled by localized heating, such as by soldering iron, hot gas jet, or hot bar techniques. The use of automated assembly processes that exploit vapor-phase reflow or IR furnaces is prohibited in order to prevent the exposure of heat-sensitive structural materials in the connector to elevated temperatures. Moreover, the generally cumbersome assemblies are not well suited for batch or continuous processes.

Solderability Testing in Electronics Applications

The formation of a solder joint that provides the necessary mechanical, electrical, and thermal properties for the particular device requires that all joint surfaces be wettable by the molten solder and that, upon solidification, a uniform solder film is retained. Solderability must be tightly controlled. Increased device functionality has placed greater demands on the performance of *each* solder joint. Full-scale manufacturing processes of PWBs, which can contain thousands of solder joints, make inspection and rework economically unfeasible.

The purpose of solderability testing is to quantitatively assess the wetting performance of component leads or terminations, as well as lands and holes of substrates, to ensure proper wetting performance by the solder at the time of PWB assembly. The goal is to prevent the expensive repair of solder joint defects on the assembled hardware and the operational failure of the device or entire electronic system. Solderability testing is typically performed on a lot sample with acceptance or rejection criteria that are based on the tested attribute(s).

Solderability tests, as well as lot sampling procedures and acceptance/rejection statistics, are specified by military and industrial specifications. Those specifications that control test procedures and acceptability criteria are listed in Table 8. The two predominant solderability tests are the dip-and-look evaluation and the wetting balance test.

TABLE 8 GUIDELINES AND SPECIFICATIONS FOR SOLDERABILITY TESTING OF ELECTRONICS APPLICATIONS

DOCUMENT	SUMMARY DESCRIPTION
MIL-STD-202F, METHOD 208F, SOLDERABILITY	**STRAND AND SOLID WIRES, LUGS, TABS, HOOK LEADS, AND SO ON, EVALUATED DIP-AND-LOOK TEST; INCLUDES STEAM AGING PROCEDURES**
MIL-STD-750C, METHOD 2026.5, SOLDERABILITY	**ELECTRONIC DEVICES EVALUATED BY DIP-AND-LOOK TEST PER MIL-STD-202F**
MIL-STD-883C, METHOD 2022.2, WETTING BALANCE SOLDERABILITY	**RIBBON LEADS EVALUATED BY THE WETTING BALANCE TEST; INCLUDES STEAM AGING PROCEDURES**
MIL-P-55110, GENERAL SPECIFICATION FOR PRINTED WIRING BOARDS	**INCLUDES SOLDERABILITY EVALUATION FOR RIGID PRINTED WIRING BOARDS**
MIL-P-50884C, PRINTED WIRING, FLEXIBLE AND RIGID-FLEX	**SOLDERABILITY EVALUATION OF FLEXIBLE AND RIGID-FLEX PRINTED WIRING BOARDS**
MIL-STD-883C, METHOD 5005.11, QUALIFICATION AND QUALITY CONFORMANCE PROCEDURES	**QUALITY CONFORMANCE AND CRITERIA FOR INSPECTION OF MICROELECTRONICS COMPONENTS USING INSPECTION TESTS (INCLUDING SOLDERABILITY TESTS)**
M1L-STD-150D, SAMPLING PROCEDURES AND TABLES FOR INSPECTION BY ATTRIBUTES	**SAMPLING PROCEDURES AND STATISTICS FOR ACCEPTANCE/REJECTION OF PARTS INSPECTED BY ATTRIBUTES (FOR EXAMPLE, SOLDERABILITY TESTING)**
MIL-STD-2000A, STANDARD REQUIREMENTS FOR SOLDERED ELECTRICAL AND ELECTRONIC ASSEMBLIES	**SPECIFIES SOLDERABILITY TESTS PER MIL-STD-202 AND CRITERIA FOR MAINTAINING SOLDERABILITY**
IPC-TM-650, TEST METHODS MANUAL	**SOLDERABILITY OF PRINTED WIRING BOARDS AND DIP-AND-LOOK PROCEDURE, AS WELL AS WAVE SOLDERING EVALUATION**
IPC-S-804, SOLDERABILITY TEST METHODS FOR PRINTED WIRING BOARDS	**SOLDERABILITY OF PRINTED WIRING BOARDS; EDGE DIP TEST ROTARY DIP TEST, WAVE SOLDERING TEST, THROUGH-HOLE SOLDER RISE TIME TEST; DIP-AND-LOOK TESTS**
IPC-S-805, SOLDERABILITY TESTS FOR COMPONENT LEADS AND TERMINATIONS	**SOLDERABILITY TESTS: DIP-AND-LOOK, WETTING BALANCE, AND GLOBULE TEST FOR COMPONENT LEADS AND TERMINATIONS; INCLUDES STEAM AGING PROCEDURES**
IPC-AJ-820, ASSEMBLY-JOINING HANDBOOK	**NO. 8.2.3, PROCEDURES FOR ACCELERATED AGING (IN CONJUNCTION WITH SOLDERABILITY TESTING)**
IPC-A-600C, GUIDELINES FOR	**INSPECTION CRITERIA FOR QUALITY ASSURANCE**

The dip-and-look test (for example, MIL-STD-883D, Method 2003.7) assesses the uniformity of the solder film that remains on a lead or termination after immersion in a solder pot. Shown in Fig. 18 are optical micrographs of samples demonstrating the three primary categories of wettability.

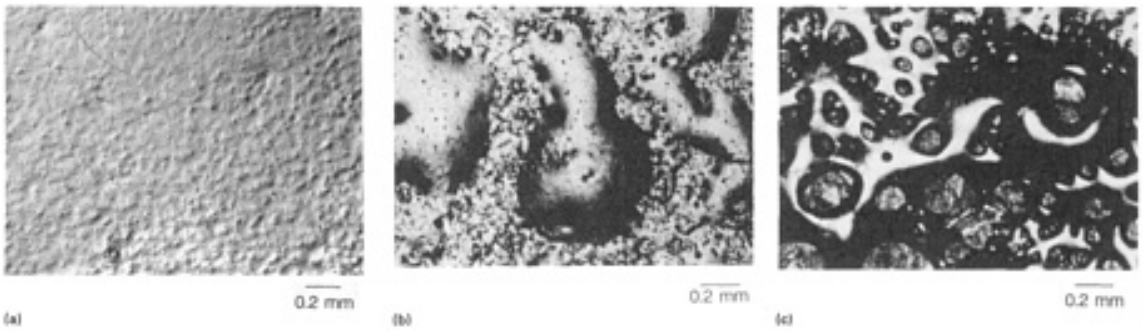

FIG. 18 OPTICAL MICROGRAPHS OF 60SN-40PB SOLDER ON SAMPLE SURFACES. (A) WETTING. (B) DEWETTING. (C) NONWETTING. SOURCE: SANDIA NATIONAL LABORATORIES

A less-subjective test is the wetting balance test (for example, MIL-STD-883C, Method 2022.2), in which a representative sample is attached to a force balance. The meniscus formed on the lead or termination causes a weight increase, which is detected by the balance. The typical wetting curve (force versus time) is shown in Fig. 19. The acceptability criteria of this test (by MIL-STD-883c), are the time for the trace to cross the zero line after the initial dip and the time required for the wetting force to reach two-thirds of its maximum. These parameters are also shown in Fig. 19. Variations to the wetting balance test procedure have been implemented to accommodate the wetting of terminations on leadless surface-mount devices. The wetting balance test should be accompanied by the dip-and-look procedure to verify the quality of the solder film. The wetting balance will *not* always detect dewetting of a solder film (Ref 34).

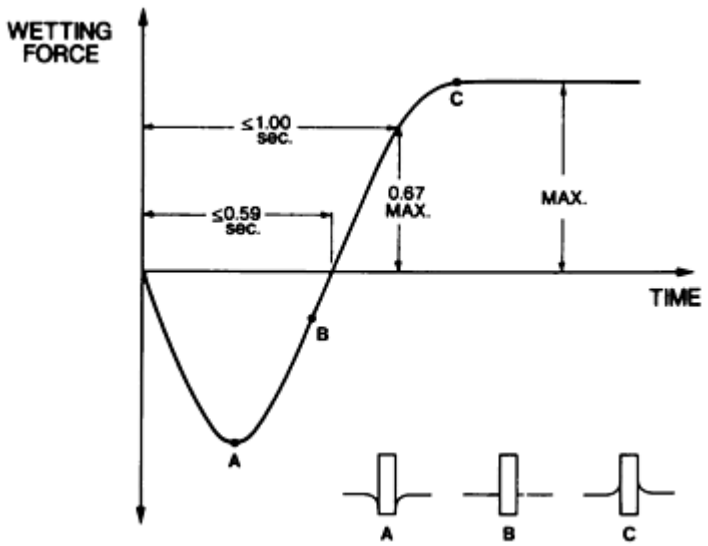

FIG. 19 WETTING BALANCE TRACE FOR SOLDERABILITY TESTS AND ACCEPTANCE CRITERIA PER MIL-STD-883C

Solderability tests for PWBs are typically dip-and-look tests, such as those specified in IPC-S-804 (J-STD-003) or the military specifications MIL-P-55110 and MIL-P-50804. Another test is the globule test, which measures the time for a solder globule to surround a horizontal wire or fill a hole (IPC-S-805).

The solderability of devices (and PWBs) deteriorates with time in storage. The tests noted above ensure adequate solderability within 120 days of the evaluation (MIL-STD-2000A). For longer periods, the steam aging treatment was instituted for the purpose of screening, on a lot sample basis, the leads, terminations, and other elements that would not be likely to retain adequate solderability under typical storage conditions prior to assembly. Steam aging (8.0 ± 0.5 h), followed by a successful solderability test, will indicate surfaces that can maintain adequate solderability for two years of "typical" storage conditions prior to use at the assembly level (MIL-STD-2000). Preferred storage conditions (see MIL-STD-2000; atmosphere, temperature, and humidity) can extend the storage time to 3 y. Parts that have exceeded the recommended storage life are considered to have questionable solderability and should be retested prior to use in an assembled product.

Introduction to Special Welding and Joining Topics

Hendrikus H. Vanderveldt, American Welding Society

Introduction

WELDING, BRAZING, AND SOLDERING are pervasive in our industrialized society, and it should come as no surprise that there are many unique aspects related to these.joining technologies that are not covered within the more traditional topic organization in the remainder of this Volume. It is the purpose of this "catchall" Section to provide coverage of some important topics that do not fit neatly in other sections of the book. However, no handbook--no matter how comprehensive--can exhaustively cover all subjects related to joining technology. This Section seeks to provide information about some of the more common, albeit unique, areas of interest and concern to the joining community. The articles that make up this Section provide overviews of these areas, point the reader towards more extensive literature, and help to identify additional areas of investigation.

The Section opens with an article on thermal spray coatings. The application of thermal spray aluminum and zinc coatings has seen a significant increase in the United States during recent years. The corrosion protection provided by these coatings can be as much as an order of magnitude greater than that obtained with traditional coating approaches. In addition, thermal spray coatings can be used to increase wear and abrasion resistance of in-service equipment and to repair and upgrade industrial components.

Introduction to Special Welding and Joining Topics

Hendrikus H. Vanderveldt, American Welding Society

Extreme Welding Environments

The next few articles in the Section provide information about extreme welding environments and service conditions. The construction of ships and offshore structures makes use of many of the same joining technologies used in shore-based construction industries, but also has its own set of unique requirements related to construction materials, fabrication environment, joining techniques, and so on. The article on underwater welding in this Section details some of the requirements involved during the original construction phase or later in-place repairs of large maritime structures; in addition, reference material is provided to point the reader to other sources of information.

Application of materials in cryogenic service (where temperatures can be as low as 4 K) provides opportunities to exploit special material properties associated with such low temperatures (superconductivity, for example). However, these opportunities must be weighed against some potential high penalties, such as the loss of structural properties exhibited at cryogenic operating temperatures. These problems can be significantly amplified in the joints produced for components intended for cryogenic service. The article "Welding for Cryogenic Service" discusses the impact of extremely low temperatures on the performance of welded structures.

The existence of long-term manned facilities in space is coming closer and closer to reality. Hence, the need to build structures or do repairs in space must be addressed. To date, very limited amount of work has been done to prepare ourselves for that day. The article "Welding in Space and Low-Gravity Environments" seeks to address what has been done and provide some guidance for future development efforts.

This Section also addresses the joining of nonmetallic and special-purpose materials. Although metals are generally the structural materials of choice, it is evident that increasing use is being made of plastics and composites in applications that include automotive parts and aerospace components, among many others. These materials are used because they exhibit high strength to weight and high stiffness, are producible as to properties, and have demonstrated reliability.

Experience related to joining of metals does not directly translate to joining of composite materials. The article "Joining of Organic-Matrix Composites" in this Section provides an extensive overview of this important topic as well as supplemental references to other sources of information. "Composite-to-Metal Joining" addresses the key factors involved in joining these dissimilar materials to one another.

The joining of plastics is generally accomplished by adhesive bonding or mechanical fastening. However, thermoplastic resins can be molded through the application of heat, and they can also be fusion welded. Various means of accomplishing such welding are discussed in the article "Welding of Plastics" in this Section.

Oxide-dispersion-strengthened materials provide high creep strength at very high temperatures and thus are used for applications such as gas turbine engines, high-temperature processing components, and so on. However, significant difficulties can be encountered in the processing of the oxide dispersions of these alloys. These can result in subsequent welding problems, such as porosity in the weldment and potentially in the adjacent heat-affected zone. The current state of the art in this area is high-lighted in the article "Joining of Oxide-Dispersion-Strengthened Materials" references are provided for further evaluation of this technology.

Computer technology has advanced to the stage where its application to welding and joining can make a major impact on the technical quality and cost of weldments, and this technology has the potential to revolutionize the entire joining manufacturing industry. The advent of personal desktop computer systems with high computational speed; the ability to model very complex parametric interrelationships without the need for exact theoretical understanding of those relationships; and the availability of comprehensive data base systems, computer-based engineering worksheets, and so on, all allow the modern manufacturing engineer to accomplish complex welding and joining tasks using minimal time and effort. The article "Intelligent Automation for Joining Technology" provides a general overview of this subject and detailed information about one particular development effort in this area. Related information is contained in the Section "Modeling of Joining Processes" in this Volume.

This Section concludes with an article on corrosion of weldments. Corrosion is a particularly difficult fabrication problem because it often appears only after significant in-service time has elapsed. A thorough understanding of corrosion phenomena can provide the designer of weldments with insight towards its avoidance. Additional information on this topic is available in *Corrosion,* Volume 13 of the *ASM Handbook.*

Thermal Spray Coatings

Herbert Herman, State University of New York, Robert A. Sulit, Sulit Engineering

Introduction

THERMAL SPRAY COATINGS (TSCs) are surface coatings engineered to provide wear-, erosion-, abrasion-, and corrosion-resistant coatings for original equipment manufacture and for the repair and upgrading of in-service equipment. In general, TSCs can be applied to a range of substrate materials, including metals, ceramics, plastics, and polymer composites. Thermal spray technology evolved and developed within the welding field because of similarities in the electrical and combustion equipment and the feedstock materials used in thermal spray with those used in welding and brazing. Accordingly, thermal spraying is classified as an allied welding process.

This article presents a general overview of the five thermal spray processes and the specific flame and arc spray processes used to preserve large steel components and structures. Also included are a TSC selection guide and an industrial process procedure guide for applying aluminum and zinc TSCs onto steel. Additional information on thermal spray processes is available in the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume.

Thermal spraying processes deposit finely divided metallic or nonmetallic feedstock surfing materials (wire, cored wires, ceramic rods, and powders) are heated to their plastic or molten state by combustion (flame, high-velocity oxygen fuel, and detonation) and by electric (arc and plasma) processes. The materials in their plastic or molten state are accelerated toward the substrate. The particles or droplets strike the surface, flatten, and form thin platelets (splats) that conform, adhere, and interlock with the roughened surface irregularities and with each other. As the sprayed particles impinge on the substrate, they cool and build up, particle by particle, into a lamellar-structured coating on the substrate. In general,

the substrate temperature can be kept at 200 °C (390 °F) or below to prevent metallurgical changes in the substrate material.

The properties of the TSC depend on such factors as its porosity, the cohesion between particles, adhesion to the substrate (including interface integrity), and the chemistry of the coating material. The particles bond to the substrate mechanically (the primary mechanism), metallurgically, or chemically. Particle impact velocity, particle size, substrate roughness, particle temperature, and substrate temperature influence bond strength. Figure 1 shows the lamellar structure of particle splats, oxide inclusions, and unmelted particles in a typical TSC cross section.

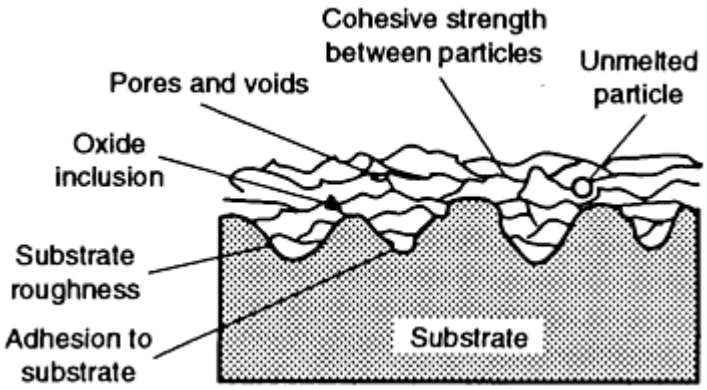

FIG. 1 SCHEMATIC SHOWING CROSS-SECTIONAL VIEW OF TSC LAMELLAR COMPONENTS THAT AFFECT COATING INTEGRITY

Aluminum and zinc TSCs have a long history of corrosion protection in structural steel work:

- BUILDINGS
- BRIDGES
- TOWERS
- RADIO AND TV ANTENNA MASTS
- STEEL GANTRY STRUCTURES
- HIGH-POWER SEARCH RADAR AERIALS
- OVERHEAD WALKWAYS
- RAILROAD OVERHEAD LINE SUPPORT COLUMNS
- ELECTRIFICATION MASTS
- TOWER CRANES
- TRAFFIC ISLAND POSTS
- STREET AND BRIDGE RAILINGS

On a smaller scale, aluminum-zinc TSCs have been successfully used to protect lawn furniture in corrosive seacoast environments.

Thermal Spray Coating Processes

Thermal spray processes differ in the feedstock materials used, the method of heating applied, and the method of propelling the material toward the substrate. The primary TSC feedstock materials can be classified as powder, wire,

cored wire, and ceramic rod. Thermal spray processes can be categorized into two basic groups (combustion or electrical) according to the method of heat generation (Table 1).

TABLE 1 CLASSIFICATION OF THERMAL SPRAY PROCESSES RELATIVE TO METHOD OF HEAT GENERATION AND FEEDSTOCK FORM

Table 2 gives typical characteristics of these thermal spray processes. The combustion flame and the electric arc processes are the main ones used for preserving steel. Recommended feedstock requirements, area coverage, and spray rates for flame and arc spraying are given in the section "Typical Process Parameters" in this article.

TABLE 2 TYPICAL PARAMETERS OF SELECTED TSC PROCESSES

Flame spraying is the simplest and most versatile process. All five feedstock forms can be sprayed with subsonic flame sp and most versatile process. All five feedstock forms can be sprayed with subsonic flame spray. The feed material is melted by an oxyfuel gas flame. In flame powder spraying (Fig. 2), powder particles are heated to 2200 °C (3990 °F), and impact the substrate at 30 m/s (100 ft/s). In flame wire spraying (Fig. 3), melted and vaporized wire particles are heated to 2800 °C (5070 °F), and impact the substrate at 180 m/s (590 ft/s). The higher gas flow used in flame wire spraying gives the droplets greater impact energy. The impact particle velocity in flame powder spraying is the lowest, resulting in reduced adhesion and increased porosity relative to the other thermal spray processes. Spray rates are usually in the range of 0.5 to 10 kg/h (1.1 to 22 lb/h) for both flame wire and flame powder spraying.

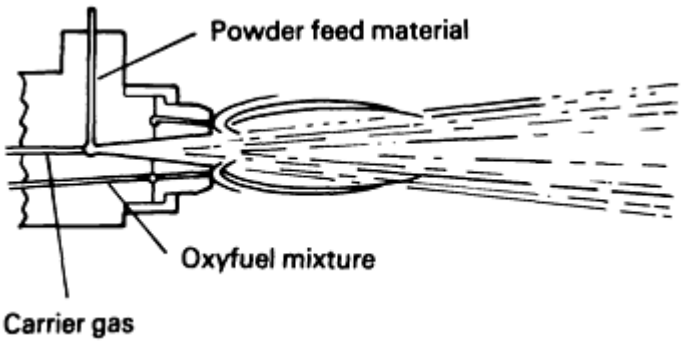

FIG. 2 CROSS-SECTIONAL VIEW OF A FLAME POWDER SPRAYING SYSTEM SHOWING POWDER FEED MATERIAL BEING TRANSPORTED BY THE CARRIER GAS AND THEN MELTED BY THE OXYFUEL MIXTURE

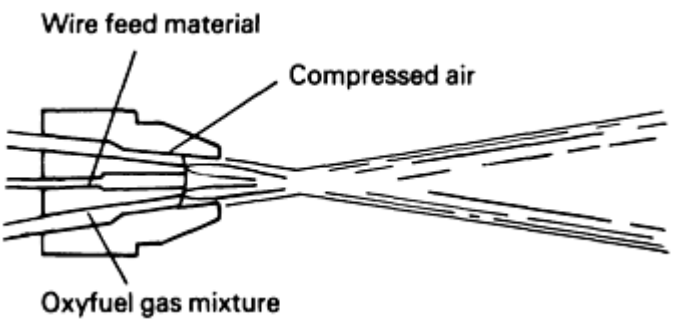

FIG. 3 ATOMIZATION OF WIRE FEEDSTOCK FROM THE NOZZLE OF A FLAME WIRE SPRAYING GUN

Detonation Gun. In the detonation gun (D-gun) process, oxygen and fuel gases are mixed with powder and cyclically injected into a constricted shotgunlike barrel and ignited. A spark ignites the mixture, producing a supersonic detonation wave that heats the powder particles to 2600 °C (4710 °F) and propels them at 900 m/s (2950 ft/s) onto the substrate.

The HVOF gun (Fig. 4) operates continuously and uses higher oxidant and fuel gas pressures, resulting in higher particle impact velocities, thus producing extremely dense, well-bonded TSCs.

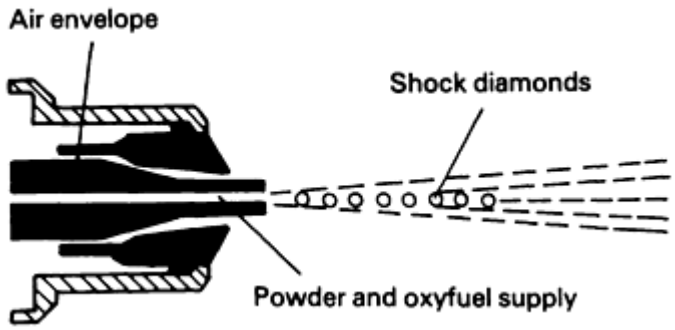

FIG. 4 CROSS-SECTIONAL VIEW SHOWING THE OUTPUT OF AN HVOF SPRAYING SYSTEM

Detonation Gun Versus HVOF Gun. High-velocity oxyfuel equipment is portable and can be transported to the job site, while the detonation gun equipment must be operated in fixed facilities. The HVOF gun can spray powder feedstock materials at the rate of 2 to 15 kg/h (4.4 to 33 lb/h).

Arc Spraying. Two oppositely charged consumable wires are fed into the gun (Fig. 5). Where they emerge from the nozzle, at their point of intersection, an arc is formed, melting the wire at 5000 °C (9030 °F). The molten metal is atomized and propelled by an air or gas stream, impacting the substrate at 240 m/s (785 ft/s). Metal and alloy wires and powders in metallic sheaths (cored wire) can be sprayed at rates of over 25 kg/h (55 lb/h).

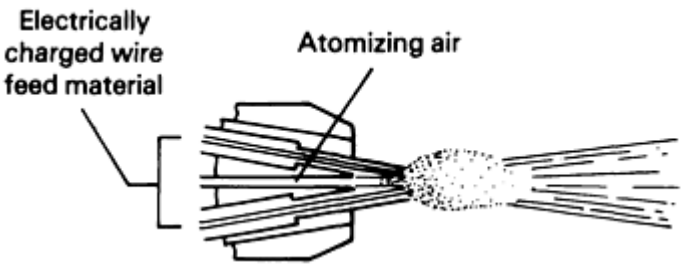

FIG. 5 SPRAY PATTERN GENERATED BY TWO ELECTRICALLY CHARGED WIRES MELTED AT THE NOZZLE OF AN ARC SPRAYING GUN

Plasma spraying uses a nontransferred arc gun to create the plasma jet that melts and propels the powder to the substrate (Fig. 6). The nontransferred plasma arc is contained in the gun. The arc is maintained between a thoriated tungsten cathode and a constricting nozzle anode (copper). An inert or reducing gas under pressure enters the annular space between the anode and the cathode, where it becomes partially ionized. The gas emerges from the nozzle as a high-temperature (up to 17,000 °C, or 30,600 °F) high-velocity jet. Powder feedstock material is injected into the hot gas stream, where it melts or softens, then impacts the substrate at 250 m/s (790 ft/s). Spray rates are 0.1 kg/h/kW (0.2 lb/h/kW). The usual power supplies range from 15 to 80 kW. Higher-power plasma guns, operating up to 200 kW can, in principle, spray ceramics at 25 to 50 kg/h (55 to 110 lb/h) and metals at an even higher rate.

Selection of TSCs to Preserve Integrity of Steels

Thermal spray coatings are extensively used for the corrosion protection of steel and iron in a wide range of environments. The long-term effectiveness (over 20 years) in rural, industrial, and marine environments is well documented. The corrosion tests carried out by the American Welding Society (Ref 1) and the 34-year marine-atmosphere performance report of the LaQue Center for Corrosion Technology (Ref 2) confirm the effectiveness of flame-sprayed aluminum and zinc coatings over long periods of time in a wide range of hostile environments. The British Standards Institution code of practice for the corrosion protection of steel specifies that only TSCs are able to give more than 20 years of protection before maintenance is necessary in the 19 industrial and marine environments considered. Only sealed, sprayed aluminum or zinc gives such protection in seawater immersion or splash zones (Ref 3). The Canadian Standards Association tabulates the life expectancy at more than 40 years for aluminum and zinc TSCs in various exposure environments (Ref 4).

The selection of a TSC depends on the service environment, the desired service life, operating duty cycle, and the maintenance and repair support to be provided during the life cycle. Tables 3 and 4 give current service life information for aluminum and zinc TSCs in various service environments. Figures 7 and 8 plot the required thickness specifications given in Tables 3 and 4, respectively. The service life estimates for 85/15 wt% Zn/Al alloy and the 90/10 vol% aluminum metal-matrix composites (MMCs) TSCs introduced in the late 1970s and 1980s, respectively, are based on accelerated laboratory tests and service applications through 1992. In a marine environment, powder TSC with higher aluminum content exhibits improved corrosion resistance (Ref 2). Where resistance to wear, abrasion, or both, is required in addition to corrosion protection, 90/10-MMC TSCs should be considered. The 90/10 MMC wire is composed of 90 vol% Al + 10 vol% Al_2O_3 (8 to 10 μm, or 320 to 400 μin., diameter).

Galvanic Properties. Aluminum and zinc and their alloys and composites provide broad atmospheric protection. Aluminum and zinc are anodic to steel and protect the ferrous substrate in electrolytic solutions. When applied in a nonthrough porosity thickness, they provide both barrier and cathodic protection. When cut through to the steel or when applied too thinly to role out through porosity, these TSCs provide galvanic protection to the steel. Aluminum corrodes less rapidly than zinc in highly acidic conditions, while zinc performs better in alkaline conditions. Aluminum TSCs immediately oxidize to form a loosely adherent Al_2O_3 protective film (as compared to the tightly adherent protective film on stainless steels) that prevent further oxidation. Thus, there is no advantage to applying aluminum TSCs greater than the non-through-porosity thickness of 150 to 200 µm (0.006 to 0.008 in.) unless wear or abrasion resistance is also required in addition to corrosion resistance. Aluminum TSCs have greater wear, abrasion, and erosion resistance than zinc TSCs.

Zinc alloyed with aluminum forms an effective corrosion-resistant coating, combining the attributes of both elements. The greater electrochemical activity of zinc provides greater galvanic protection than aluminum. Aluminum, with its lower electrochemical activity and a loosely adherent aluminum oxide film, provides long-term protection even through porous coatings and gives better wear, abrasion, and erosion resistance than zinc TSCs.

Aluminum and aluminum composite TSCs can be used where the temperature is greater than 200 °C (390 °F). Aluminum composite TSCs are used when wear, abrasion, and erosion resistance are required beyond that provided by aluminum and zinc TSCs.

Thermite Sparking Hazard (Ref 5, 6). Thermite sparking is caused by the reaction of rusted steel and aluminum (in the form of a finely divided smear) when this combustible mix is ignited by an impact. Aluminum smears may be generated on rusting steel by striking or dragging steel components and tools over bare aluminum surfaces or vice versa. Bare aluminum and bare aluminum TSCs should be avoided whenever there is a thermite sparking hazard. Situations where bare aluminum or bare aluminum TSCs and rusted steel will be near a combustion or explosion source can occur on a regular basis and should be avoided. There appears to be little risk of thermite sparking as a result of the impact of rusted steel on a sealed or painted aluminum, aluminum alloy, or aluminum composite TSC surface.

Porosity is an inherent feature of TSCs. When applied to nonthrough porosity thickness (nominally about 175 μm, or 0.007 in.) for flame-sprayed aluminum and 90/10 MMC, these TSCs will protect the substrate steel. When applied to a less than nonthrough porosity thickness, the TSC will retard substrate corrosion because of galvanic protection. The porosity of the TSC is a function of the feedstock material, the application method, and the spray parameters.

Role of Sealants and Topcoats. Thermal spray coatings are applied in a single application. They emit no volatile organic compounds, need no drying time, and provide galvanic protection to exposed steel substrates. The natural surface texture of TSCs provides an excellent base for paint and thermoplastic or thermosetting powder sealers as well as paint and powder-coating topcoats.

It is preferable to seal TSCs. The sealer fills the pores of the TSC, smooths the sprayed surface, and improves appearance and service life. Sealers also simplify maintenance, which is generally only the reapplication of the sealer. Sealers should be applied immediately after applying the TSC.

TSC paint sealers should have low viscosity to flow and should be absorbed into the natural pores of the TSC. The pigment particle size of colored paint sealers must be small enough to freely flow into the pores of the TSC, nominally a 5 fineness grind per ASTM D 1210. Thermoplastic and thermosetting powder sealers have fine particles but should be electrostatically applied to maximize penetration into the pores of the TSC. Furthermore, thermal sprayed components must be sufficiently heated to maximize outgassing of the pores prior to electrostatic application of the powder coating.

Thermal spray coatings should be topcoated only when:

- THE ENVIRONMENT IS VERY ACID OR VERY ALKALINE (THAT IS, WHEN THE PH IS OUTSIDE THE RANGE OF 5 TO 12 FOR ZINC TSCS, OR 4 TO 9 FOR ALUMINUM AND 90/10 MMC TSCS).
- THE METAL IS SUBJECT TO DIRECT ATTACK BY SPECIFIC CHEMICALS.
- THE REQUIRED DECORATIVE FINISH CAN BE OBTAINED ONLY WITH PAINT.
- ADDITIONAL WEAR, ABRASION, AND EROSION RESISTANCE ARE REQUIRED.

One or two coats of paint may be sufficient except in abnormally aggressive environments. Sealed TSCs are preferable to painted TSCs. Paints usually have a longer life on TSCs than on bare steel, because the TSC reduces or prevents rusting and pitting of the steel.

Zinc TSCs complement hot-dip galvanizing and should be considered when fabricated goods are excessively large or cannot be hot-dip galvanized. Zinc TSCs should also be considered for repairing galvanized coatings damaged during fabrication (for example, welding and cutting) and for maintenance recoating.

Zinc spraying can restore corrosion protection to areas where galvanizing is inadvertently removed during fabrication and assembly. This can occur on the threaded end of electrical conduits or along the welded seams inside galvanized barrels and drums. Zinc spray is particularly advantageous in such cases because it ensures the uniformity and reproducibility of the galvanized coating thickness.

Wellhead valve assemblies for offshore use have been coated for salt atmosphere protection since the 1950s. Aluminum TSCs have been used for flare stacks. Aluminum and zinc TSCs have been used for the external protection of oil and

propane gas storage tanks. The interiors of steel coal rail cars have been sprayed with aluminum for sulfuric acid corrosion protection and with aluminum composite for both corrosion and abrasion protection. The exteriors have been sprayed with zinc for atmospheric-corrosion protection. Thermal spray coatings have been used to protect pipelines against many environments. Pile couplings, valves, manhole covers, industrial gas bottles, and other small industrial items are candidates for protection by TSCs.

Zinc TSCs are used to protect potable water pipelines and storage tanks (Ref 7). Aluminum and zinc TSCs are used in sluice and canal lock gates in irrigation systems and in shipping canal lock gates. Once coated, these components require virtually no maintenance for decades.

Sealed zinc coatings improve the resistance of steel bridgework and railings to marine corrosion and deicing salts. Rebars in reinforced concrete can be zinc sprayed to retard corrosion. Reinforced concrete bridges and highways, especially those in marine and freezing environments where deicing salts are used, commonly suffer from chloride intrusion into the concrete, leading to rebar corrosion and concrete spalling. Zinc TSCs are sometimes used for rebar protection before concrete is poured. Zinc TSCs are sprayed directly onto bridge concrete substructures to provide a cathodic-protection coating or to serve as secondary anodes connected to an impressed-current cathodic-protection system.

In marine applications, the structural areas and components of ships are preserved with aluminum and zinc TSCs. The U.S. Navy routinely uses aluminum TSCs in new ship construction, in the maintenance of ship structures, and for a wide range of shipboard components, especially those in topside and wet spaces. The British, Australian, and New Zealand Navies use a duplex zinc (base) and aluminum (top) TSC system. Commercial ships and barges have used TSCs to preserve ship superstructures and various topside and interior components.

Sealed TSCs have a longer service life than unsealed TSCs, are easier to clean and maintain, and provide both barrier and galvanic protection. Sealer paints and powder coatings must be chemically compatible with the TSC material, the service environment, and the intermediate/topcoat paint. Sealers must be suitably thinned and have a fine pigment grind to effectively penetrate the TSC. As indicated above, sealed TSCs are preferable to painted TSCs. Descriptions and specifications of sealer and intermediate/topcoat paints are given in Ref 3 and 8.

Future Outlook. The suitability of a particular paint or thermoplastic/thermosetting powder (applied electrostatically or by thermal spray) must be evaluated when the coating is designed and specified. Such an evaluation is necessary in order to get the sealer/topcoat paint or powder system that best meets the service and life cycle cost (LCC) requirements compliant with the evolving environmental and safety regulations. Specific paint or powder systems can be ranked and validated with accelerated exposure tests simulating the service environment and duty cycle. The penetrability of the sealer into the TSC can be validated by metallographic analysis and the service life ranked by accelerated weathering tests.

Thermal spray coatings are supplementing and replacing paint coating systems because of their predictable service life, increased effectiveness, and lower life cycle costs. The LCC includes the initial installation cost plus the repair and maintenance costs incurred during the service life of the coating system. The installation cost of TSC systems may range up to one and one-half times that of high-performance paint systems, but the LCCs could be less than three-fourths the paint system LCC. Comparative TSC and painting system LCC may be estimated with the economic models in Ref 3 and 8.

Industrial Process Instruction for Applying TSCs on Steel

An industrial process instruction is an engineering procedure detailing the necessary equipment, consumables, method (step-by-step procedure), trained/certified personnel, and records required to accomplish the objective of that process with the requisite quality control, safety, and environmental compliance in a timely and cost-effective manner. The scope of an industrial process instruction for applying TSCs on steel should include (Ref 9):

- *DEFINITION* OF TERMS UNIQUE AND CRITICAL TO THE SAFE AND SUCCESSFUL ACCOMPLISHMENT OF THE PROCESS
- *SAFETY AND ENVIRONMENTAL COMPLIANCE* REQUIRED FOR OPERATOR, OBSERVERS, AND PASSERSBY. FOR THERMAL SPRAYING, AIRBORNE ALUMINUM AND ZINC DUST COULD BE AN EXPLOSIVE HAZARD IF NOT PROPERLY HANDLED. ALUMINUM AND ZINC FUMES PRODUCED IN THERMAL SPRAYING AND IN BLASTING DEBRIS FROM SURFACE PREPARATION, ESPECIALLY IF THERE WAS OLD LEAD-BEATING PAINT, REQUIRE PERSONNEL PROTECTION, CONTAINMENT, AND THE REQUISITE WASTE DISPOSAL
- *JOB AND CONTRACT DESCRIPTION* DETAILING THE FOLLOWING: THE THERMAL SPRAY WORK AREA BOUNDARY; WHAT IS AND WHAT IS NOT TO BE THERMAL SPRAYED; THE THERMAL SPRAY FEEDSTOCK AND TSC THICKNESSES; SEALING/TOPCOATING MATERIALS; AND THE INSPECTION AND ACCEPTANCE REQUIREMENTS
- *MATERIALS* REQUIRED, INCLUDING THERMAL SPRAY FEEDSTOCK (BASED ON THE NOMINAL AREA COVERAGE AND SPRAY RATES FOR THE SPECIFIED PROCESS EQUIPMENT), ABRASIVE BLASTING MEDIA FOR ROUGH AND FINAL ANCHOR-TOOTH BLASTING, SEALER AND TOPCOATING PAINTS OR THERMOPLASTIC/THERMOSETTING POWDER COATINGS, QUALITY CONTROL CONSUMABLES, AND ENERGY REQUIREMENTS (FUEL GASES, INERT GASES, AND OXYGEN)
- *EQUIPMENT FOR SURFACE PREPARATION AND THERMAL SPRAYING* TO INCLUDE SPRAY GUN QUALIFICATIONS, AIR COMPRESSOR, AND AIR DRYERS
- *QUALITY CONTROL EQUIPMENT* TO DETERMINE THE ACCEPTABILITY OF SURFACE PREPARATION (WHITE AND NEAR-WHITE METAL FINISH, BLASTING MEDIA CLEANLINESS, AND ANCHOR-TOOTH DEPTH) AND TSC APPLICATION (SUBSTRATE TEMPERATURE, AIR TEMPERATURE, DEW POINT AND HUMIDITY, TSC THICKNESS, AND TSC BEND TEST)
- *APPLICATION PROCESS:* SURFACE PREPARATION (INCLUDES NEW STEEL, OLD STEEL, MASKING, DEGREASING, AND SURFACE PROFILE WITH QUALITY CONTROL CHECK POINTS; POST BLASTING SUBSTRATE CONDITION AND THERMAL SPRAYING PERIOD; THERMAL SPRAYING (INCLUDES EQUIPMENT SETUP AND BEND TEST; PLANNING AND EXECUTING THERMAL SPRAY SEQUENCE AND CONTROLLING OVERSPRAY WITH TWO QUALITY CONTROL POINTS)

- *PROCEDURES* FOR SPRAYING EDGES OF MATERIALS OR INTO CAVITIES (THAT IS, HOLES)
- *SEALING AND TOPCOATING* WITH QUALITY CONTROL CONTROL CHECK POINTS
- *MAINTENANCE AND REPAIR OF TSCS* BASED ON DEGREE OF DAMAGE AND WEAR AS RELATED TO EXPOSURE OF THE UNDERLYING COATING OR SUBSTRATE STEEL AND THE SIZE OF THE DEGRADED AREA
- *DEBRIS* CONTAINMENT AND CONTROL
- *RECORDS,* INCLUDING A JOB CONTROL RECORD SUMMARIZING THE TSC JOB REQUIREMENTS, OPERATOR QUALIFICATIONS, AND A CHECK LIST OF THE NINE QUALITY CONTROL CHECK POINTS
- *OPERATOR TEST AND QUALIFICATIONS* PER ANSI/AWS C2.16-92 ("GUIDE FOR THERMAL-SPRAY OPERATOR QUALIFICATION")

Typical Process Parameters (Ref 9)

Table 5 gives the nominal thermal spray deposit efficiency and feedstock material required per unit area or unit thickness for representative materials sprayed onto a flat plate. Deposit efficiency is the percentage by weight of sprayed materials adhering to a large flat plate. Table 6 gives the typical spray rates and area coverage for flame and arc spraying on a flat plate. Additional feedstock will be required to spray complex geometrical shapes. Specific values vary with the shop or field job site, thermal spray equipment, spray parameters, process used, and the geometrical shape of the components being sprayed. The data in Tables 5 and 6 are technical data supplied by various equipment manufacturers and are given for comparison purposes and relative ranking; they are not intended for cost estimating.

Thermal spray coating applicators should develop their own shop and field deposit-efficiency data and production planning factors for their specific equipment and their method of operation. Past production records should provide a good information base for job cost estimating, production scheduling, and cost control.

Underwater Welding

S. Liu and D.L. Olson, Colorado School of Mines, S. Ibarra, Amoco Corporation Research

Introduction

UNDERWATER ARC WELDING is performed in either the wet environment or in a protective habitat (Ref 1). Although both environments experience increased pressure with depth (0.1 MPa, or 1 bar, for each 10 m, or 33 ft, increase in depth), the wet environment also significantly alters the cooling rate during welding, which affects the nature of the weld-metal phase transformation. Whereas shielded metal arc welding (SMAW) for surface welding has a time to cool from 800 to 500 °C (1470 to 930 °F), $\Delta t_{8/5}$, in the range of 8 to 16 s, a typical wet-welding procedure reportedly has $\Delta t_{8/5}$ values between 1 and 6 s, depending on heat input (0.8 to 3.6 kJ/mm) and plate thickness (Ref 2, 3, 4). The greater cooling rate produces significant amounts of heat-affected zone (HAZ) martensite in nearly all low-carbon steels. As the carbon equivalent (CE) of these steels approaches a value of 0.40 wt%, the fusion-line hardness usually exceeds 400 on the Vickers scale (98 N, or 10 kgf), where

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%(Cr + Mo + V)}{5} + \frac{\%(Ni + Cu)}{15} \qquad \textbf{(EQ 1)}$$

As the martensite content increases in the coarse-grained HAZ, the susceptibility to hydrogen cracking becomes a measurable concern.

When underwater arc welding is conducted directly in the water, the SMAW process is usually used, although more recently flux-cored arc welding (FCAW) has been used, as well. Wet underwater welding has been demonstrated to be an acceptable repair technique at depths of 100 m (330 ft). However, wet welds have been made on carbon steel structures at depths as low as 200 m (660 ft).

Welding that is performed in a dry, but high-pressure (hyperbaric) environment requires the construction of a chamber around the weld zone to create the dry habitat. The cost of hyperbaric welding is therefore much higher than that of wet welding. The setting up and tearing down of equipment can be very expensive in a deep-sea environment. Additionally, hyperbaric welding exhibits low mobility. Each fabrication situation often requires a customized setup. The gas-metal arc welding (GMAW) and gas-tungsten arc welding (GTAW) processes can both be used in hyperbaric welding, unlike wet welding.

Despite differences in process characteristics, the influences of water depth (pressure) on arc behavior are similar for both wet welding and hyperbaric welding (Ref 5, 6, 7). The specific technological features of each of these processes are provided in Ref 1. This article discusses the metallurgical aspects of the underwater welds.

Underwater Welding Pyrometallurgy

The pyrochemical behavior of underwater welds (both hyperbaric and wet) is reported (Ref 2, 8, 9, 10, 11) to be a function of depth (pressure) down to 300 m (990 ft). The variation of weld-metal manganese content as a function of depth is shown in Fig. 1. There is a sharp decrease in manganese content from 0.6 wt% for the surface weld to 0.25 wt% for the weld made at 30 m (90 ft). This decrease in weld-metal manganese content can be directly correlated to the rapid increase in weld-metal oxygen content for the same range of depth, as seen in Fig. 2. This observation suggests that manganese recovery in the weld pool is controlled by oxidation. Similar behavior was found for weld-metal silicon (Fig. 1). It is expected that all oxide-forming elements would react in this manner to an increase in oxygen.

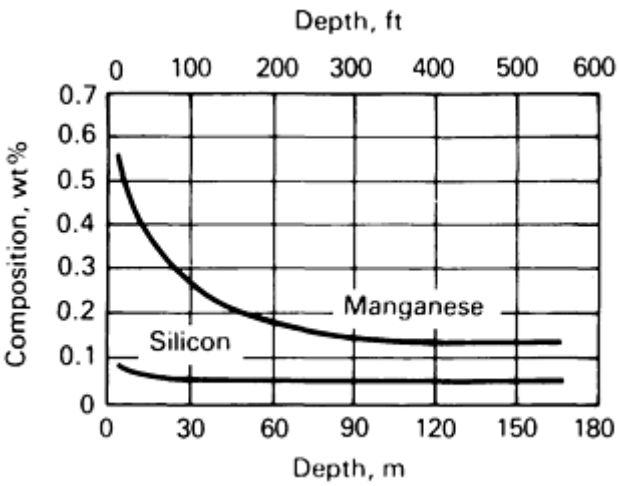

FIG. 1 WET UNDERWATER WELD-METAL MANGANESE AND SILICON AS A FUNCTION OF DEPTH. SOURCE: REF 11

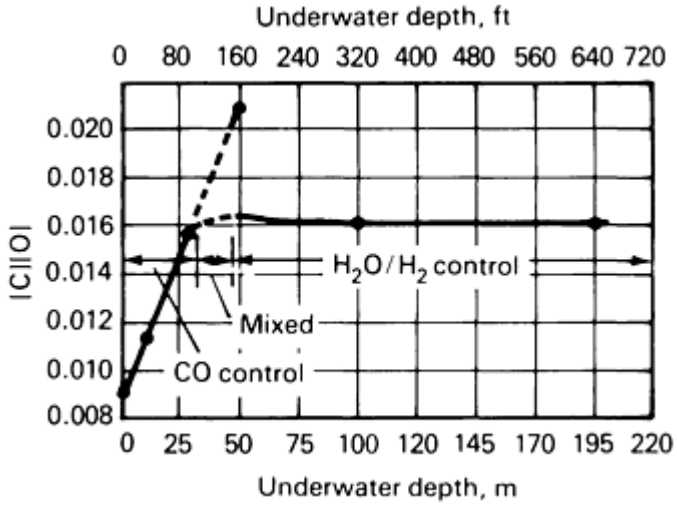

FIG. 2 PRODUCT OF WELD-METAL CARBON AND OXYGEN CONTENT AS A FUNCTION OF UNDERWATER DEPTH FOR WELD METAL PRODUCED WITH TREATED E6013 SMAW ELECTRODE. SOURCE: REF 11

The weld-metal carbon content, on the other hand, was found to increase significantly from the weld made at the surface to the welds made at 50 m (165 ft), as shown in Fig. 1. A linear relationship between the [C][O] product and the total pressure, *P*, or depth, has been found for both wet and hyperbaric SMAW processes, which suggests that the carbon monoxide reaction is a controlling mechanism. This behavior was observed for the hyperbaric SMAW process at depths equivalent to 300 m (990 ft). The carbon monoxide is a product of the decomposition of the calcium or magnesium carbonate that exists in the SMAW electrode coating to provide a working and protective welding plasma and cover. The resulting increases in weld-metal oxygen and carbon contents cause concern as to the use of a flux coating that contains carbonates for hyperbaric welding. Carbon pickup in the weld metal results in an increase in cracking susceptibility. Ferrosilicon additions to the flux did reduce weld-metal oxygen, but not sufficiently to alleviate this problem.

The carbon monoxide reaction was also found (Ref 10, 11) to be a controlling mechanism in wet underwater welding. The product of carbon and oxygen content, [C][O], for wet underwater welds was also plotted as a function of depth (pressure) in Fig. 2, which demonstrated an excellent linear correlation for the weld-metal carbon and oxygen product results down to 50 m (165 ft). This observation suggests that the carbon monoxide reaction controls the oxygen content down to 50 m (165 ft), and that the oxygencontent, in turn, controls the oxidation of manganese and silicon and, thus, the weld-metal contents of these elements. The actual depth to which the carbon monoxide reaction is a controlling factor is a function of the specific electrode composition.

In Fig. 2, the weld-metal oxygen and carbon contents become fairly constant between 50 and 100 m (165 and 330 ft). The weld-metal manganese and silicon contents are also fairly constant within this same range. These observations suggest that oxygen content still controls the weld-metal manganese and silicon contents, but that carbon monoxide formation is not the controlling reaction at depths greater than 50 m (165 ft).

The compositional results for depths greater than 50 m (165 ft) suggest that the H_2O decomposition reaction may be the controlling mechanism. At temperatures above 1000 °C (1830 °F), water vapor begins to dissociate into hydrogen and oxygen and dynamic equilibrium takes place (Ref 10, 11). For this reaction the weld-metal oxygen content is not a function of pressure (depth) and the [C][O] product will also remain constant. The diameter of the arc plasma column decreases with increasing pressure (depth). Thus, at depths greater than 50 m (165 ft), the water reaction becomes more dominant and the [C][O] product becomes less important and insensitive to depth, as seen in Fig. 2.

Another indication that hydrogen is more abundant in and involved with the rate-control chemistry is evident when considering arc stability, which decreases in extreme depth. In Fig. 3, the operating parameter space for underwater welding is shown to decrease with depth. This behavior can be explained by the high ionization potential for hydrogen, which makes it more difficult to sustain the welding arc.

Microstructural Development of Underwater Welds

Three types of ferrite are associated with low-carbon steel weld metal: grain-boundary ferrite (GBF), Widmanstätten, or sideplate, ferrite (SPF), and acicular ferrite (AF). Prior austenite grain boundaries can promote the formation of GBF and represent the sites for the nucleation of SPF, which protrudes from the grain boundaries into the prior austenite grains. Acicular ferrite is intragranular and has a much finer basket-weave structure. Other microconstituents, such as pearlite, cementite, and martensite, can also result. At faster cooling rates, the formation of bainite or ferrite with aligned carbide (AC) and martensite is possible. It is recognized that acicular ferrite is the microstructural constituent that gives a high resistance to cleavage fracture.

A typical wet (underwater) weld-metal microstructure, as a function of depth, is illustrated in Fig. 4. At shallow depths, the weld metal is primarily grain-boundary ferrite, with 10 to 20% aligned carbide. With increasing depths, the relative amount of grain-boundary ferrite decreases to about 50%, with increasing amounts of aligned carbide and sideplate ferrite. The major changes in microstructure occur in the first 50 m (165 ft) of depth. At depths greater than 50 m (165 ft), the weld-metal composition and microstructure remain fairly constant. This observation is also consistent with the constant weld-metal oxygen content described previously, which suggests a constant oxidation rate.

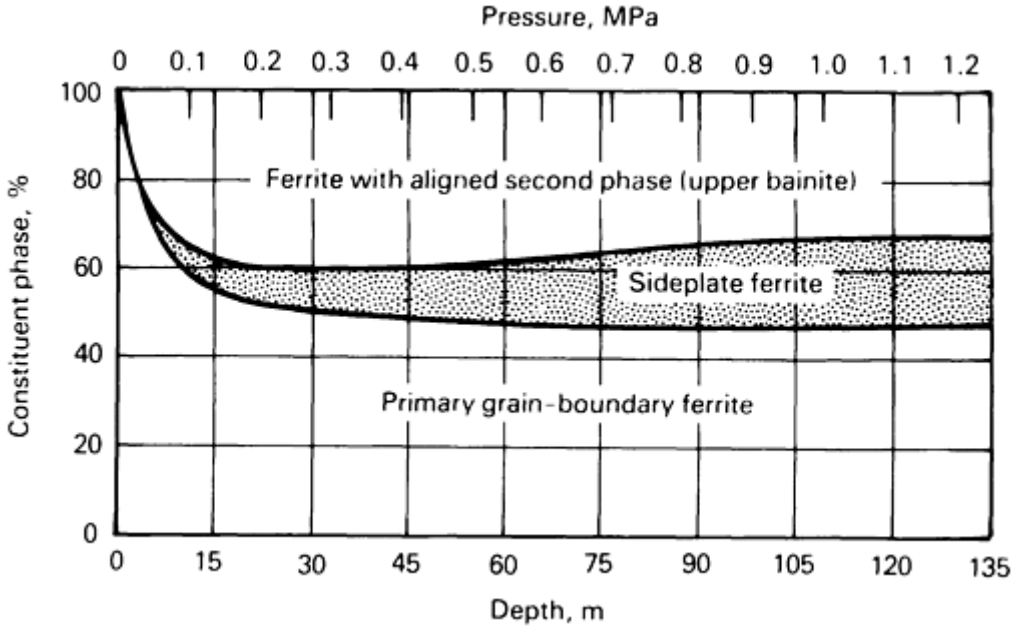

FIG. 4 PERCENTAGE OF WELD-METAL MICROSTRUCTURAL CONSTITUENTS FOR WET UNDERWATER WELDS AS A FUNCTION OF WATER DEPTH

The formation of acicular ferrite, instead of the significant sideplate ferrite content, is highly desirable in order to improve toughness. Acicular ferrite formation in underwater welds is possible, but only with specific weld-metal alloying additions, such as titanium or boron and with the proper weld-metal oxygen and manganese contents.

A diagram of weld-metal oxygen content versus effective weld-metal manganese content (Mn + 6C) has been used (Ref 8, 9, 10) to conceptually assist in selecting compositional modifications for the consumables of wet underwater welding, as shown in Fig. 5. Figure 5 represents a particular case in which deposits of an underwater wet E6013 electrode were constructed on the basis of microstructural and compositional analysis. This particular diagram represents the cooling rate typically found in wet welding.

Hydrogen Mitigation

Because moisture drastically increases the availability of hydrogen, the wet underwater welding of higher-strength steels is very susceptible to hydrogen cracking (Ref 12). Even during hyperbaric welding, after water has been removed from the chamber, the partial pressure of moisture is still high, causing the same effects as in wet welding.

The HAZ cracking that results from the wet welding of higher-strength steels is due to three necessary factors: hydrogen from the weld pool, microstructures that develop in the HAZ, and stress levels that develop in the weld joint. Hydrogen cracking can be reduced or managed by:

- USING CONSUMABLES THAT CAN HOLD A HIGH CONCENTRATION OF HYDROGEN IN MOLTEN WELD POOLS, AS WELL AS IN THE SOLIDIFIED WELD BEAD
- ALTERING THE FLUX COATINGS TO INTRODUCE ALTERNATE GASES IN THE WELDING PLASMA, THEREBY REDUCING THE HYDROGEN CONTENT
- SELECTING THE WELDING PARAMETERS THAT MINIMIZE WELD POOL HYDROGEN PICKUP

- DESIGNING THE WELD FOR MINIMUM STRESS

The use of ferritic-based weld deposits will cause the rejection of large amounts of hydrogen from the weld solidification. The hydrogen will go into the fully martensitic HAZ and will promote underbead cracking. A method that partially alleviates hydrogen susceptibility is to use an austenitic weld deposit that has a much larger solubility for hydrogen and, thus, a smaller tendency to transport hydrogen to the HAZ (Ref 13).

However, the use of an austenitic stainless steel consumable results in a deposit with a high coefficient of thermal expansion (CTE), relative to ferritic-based metal, as well as higher residual stresses and an increasing tendency for cracking. A solution to this problem, which is a compromise between high solubility for hydrogen and CTE mismatch, is to use high-nickel-content weld deposits, because nickel-base alloys have approximately the same CTE as ferritic steel and are capable of managing a large hydrogen content.

Although the nickel weld-metal deposit is virtually immune to the restraint cracking that was noted in the austenitic stainless steel welds, the use of nickel-base electrodes is restricted by their depth sensitivity. Although these electrodes are successful in preventing hydrogen cracking in the HAZ, the resulting welds can be porous and, in some cases, susceptible to embrittlement. Nickel-base welds at a depth of 30 m (100 ft) exhibited excessive porosity that was due to a lack of necessary heat input at this depth. These nickel-base wet-weld deposits have been successful only down to depths of 10 m (35 ft) when the SMAW process is used. Welding at greater depths, when using nickel-base electrodes, requires a higher level of heat input.

To reduce the influence of the plasma hydrogen content, other gases need to be introduced into the arc. Increasing the carbonate content of welding flux has been shown to increase the carbon monoxide content in the arc and, thus, to reduce the hydrogen content (Ref 14, 15). Carbonates (Ref 15) also increase the degree of oxidation of the deposited metal, which decreases weld-metal hydrogen content. The decomposition of carbonates results in higher oxygen and lower hydrogen contents.

The use of carbonates to reduce the plasma hydrogen content may not be as attractive when considering all the effects, because carbonates also promote weld-metal carbon and oxygen pickup with increasing pressure. Carbon has also been reported to reduce the hydrogen solubility in ferrite and to increase the hydrogen solubility in austenite. Thus, increasing carbon content will cause greater potential hydrogen supersaturation with the decomposition of austenite, thus reducing the favorable hydrogen reduction effects in the arc. This problem could limit the use of increased carbonate content to the shallower depths.

The influence of welding parameters on the underwater welding process and on the associated metallurgical reactions has been studied. The diffusible hydrogen content increases with increasing voltage, but decreases with increasing welding current. These results suggest that welding with lower potential and higher current will promote a significant reduction in the weld-metal diffusible hydrogen content (Ref 16). The diffusible hydrogen content in wet underwater welds decreases with increasing heat input for both SMAW and FCAW processes (Ref 17, 18).

The third factor that influences hydrogen cracking is the applied and residual stress states. The applied stress can be reduced by improving the fit-up on the weld joint to be used in the repair. In the underwater wet welding repair of platforms, scalloped sleeves are frequently fillet welded over the damaged area. Careful fabrication of the scalloped sleeve will result in improved fit-up and, thus, reduced stresses. The applied stress on a weldment can also be improved by using a larger weld-metal deposit. This practice will result in a larger HAZ, with a smaller applied stress.

The residual stresses are more difficult to manage in an environment that is not easily accessible to postweld heat treatment. Welding practices that can reduce residual stresses include:

- THE USE OF SMALL WELD DEPOSITS
- THE USE OF CONSUMABLES WITH CTES THAT ARE COMPATIBLE TO THAT OF THE BASE MATERIALS
- THE SELECTION OF EDGE PREPARATIONS THAT REDUCE THE SIZE OF THE TOTAL WELD DEPOSIT

The cross-sectional area of the total weld deposit is directly related to a shrinkage tendency. In designing an underwater weld joint, the concerns for applied stress and for residual stress must be balanced, because a different weld size is required in each case.

Temper Bead Practice. To further reduce stress and, thus, hydrogen cracking, the thermal experience(s) of the wet welding practice must be considered (Ref 8, 19). Although it is difficult to perform any significant preheat treatment procedures on the base material in wet, heavy-section welding, a temper bead practice that reduces the near-fusion-line hardness and cracking tendency has been perfected. A typical temper bead practice involves a weld deposition that is laid down over a previous weld deposit that has a less-susceptible cracking tendency than that of the base metal (Ref 20). As shown in Fig. 6, the second deposition, or temper bead, must be carefully located relative to the previous bead fusion line, such that its thermal experience tempers the near-fusion-line HAZ of the base material, which has a cracking-susceptible carbon equivalent (Ref 20).

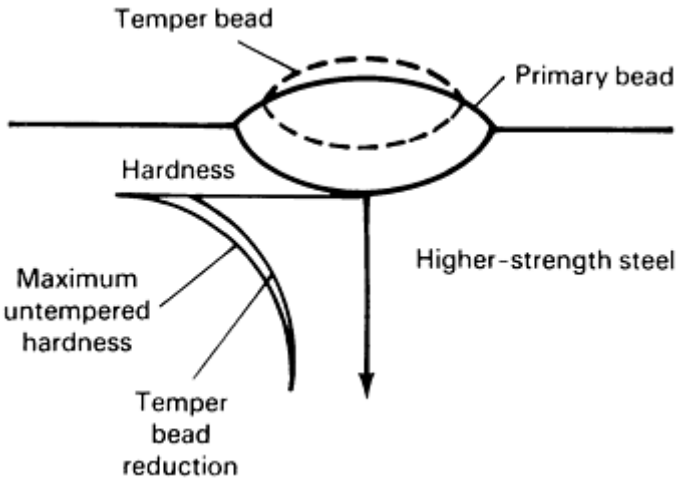

FIG. 6 USE OF TEMPER BEAD PRACTICE TO REDUCE HAZ HARDNESS AND SUSCEPTIBILITY FOR UNDERBEAD CRACKING. SOURCE: REF 11

There is evidence that temper weld beads can influence the properties of wet underwater welds. In the weld metal, Charpy V-notch toughness improved with an increasing number of weld passes (Ref 17, 18). This technique will reduce residual stresses, as well as hardness, and represents the optimum practice to wet weld the higher-CE steels. Another advantage to the temper bead practice is that while the temper bead is in the high-temperature austenitic condition, it is a favorable reservoir for hydrogen and, thus, it extracts some of the hydrogen from the more-crack-susceptible HAZ.

Welding consumables that generate chemical heat have been investigated as an additional heat source during underwater welding (Ref 8). Samples from a platform steel with a CE of 0.40 wt% were welded in a 10 m (35 ft) tank. A heat-generating thermit electrode weld was used after each pass to postweld heat treat the HAZ. Thermit-type reactions during arc welding have been used to improve the underwater temper bead practice in order to reduce the hydrogen cracking susceptibility of the HAZ.

Weld-Metal Porosity

Weld-metal porosity is a major concern in underwater welds. The amount of porosity determines whether a wet weld will meet the type A, B, or C weld specification (ANSI/AWS D3.6-83 specification). Pore formation results from entrapment, supersaturation of dissolved gas, or gas-producing chemical reactions. The nature and amount of weld-metal porosity involves at least four competing time-dependent processes (Ref 21): the nucleation, growth, transport, and coalescence of pores. The physical requirement for pore formation is that the sum of the partial pressure, P_g, of soluble gases must exceed the sum of the following pressure terms:

$$P_G > P_A + P_H + P_B \qquad \textbf{(EQ 2)}$$

where P_a is the atmosphere pressure, P_h is the hydrostatic pressure, and P_b is the pressure increase that is due to the curvature of the pore. For underwater welding, P_h is the controlling term, because it is directly related to depth.

The effect of water pressure on the formation of porosity in underwater gravity welding with electrodes of the ilmenite type, high titanium oxide type, and iron powder/iron oxide type and with SM41 steel base metals has been reported (Ref 22). The amount of porosity increased with water pressure (depth) (Fig. 7). The pore shape changed from spherical to long and narrow with increasing pressure, which indicates a change of the pore-formation mechanism. In wet underwater welds, the pores contained approximately 96 vol% H_2, 0.4 vol% CO, and 0.06 vol% CO_2. Other bubble compositions (Ref 6, 23) of 62 to 82% H_2, 11 to 24% CO, and 4 to 6% CO_2 have been reported (Ref 24). More-specific data on a rutile iron powder (E7014) electrode are 45% H_2, 43% CO, 8% CO_2, and 4% other. The variation in bubble composition indicates the broad nature of the chemical processes associated with wet underwater welding and is most likely due to variations in electrode covering compositions, energy input, and water depth.

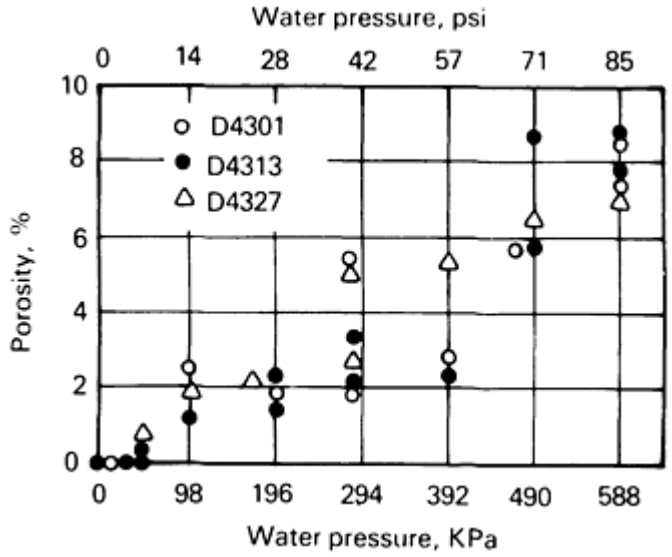

FIG. 7 EFFECT OF WATER PRESSURE ON POROSITY. SOURCE: REF 22

Two possible methods of reducing weld-metal porosity with depth, in the case of wet welding, are to add to the weld pool specific elements that getter the hydrogen by forming hydrides and to alter the welding parameters to reduce pore formation. At increasing travel speeds, the number of pores per volume of weld deposit goes through a maximum. A relationship between the product of travel speed (*S*) and bead area (*A*) and the amount of gas absorbed per unit volume of weld metal exists (Ref 25). This relationship suggests that for decreasing values of the product (*SA*), the gas absorbed per unit volume of weld metal increases for the same gas partial pressure. With small beads and a slow welding speed, the amount of gas absorbed per unit volume of weld metal is high. The faster freezing rate of the smaller, short-circuiting arc weld allows less time for gas desorption and causes more gas bubbles to be trapped before floating to the surface of the weld pool. This relationship holds significance for many of the practices used in wet underwater welding, which produce small weld deposits. In underwater welding, the relationship between porosity and welding current is strongly influenced by the type of moisture resistance coating on the electrode. The amount of gas pickup increases as the arc was lengthened (Ref 21). In general, the hydrogen absorption and, therefore, porosity levels in welding can be minimized by using a low current with direct current electrode positive (DCEP), a high current with direct current electrode negative (DCEN), a short arc, and a fast travel speed.

Fatigue as a Function of Porosity

The designers of offshore structures are usually concerned with the initiation and growth of fatigue cracks in fracture-critical members, because of noted decreases in fracture toughness, as well as the presence of varying amounts of porosity. Cyclic fatigue stresses will develop with any natural sea movement and will increase during storms.

Drilling the tip of a fatigue crack is a common field technique that is used to prevent further crack growth. In the same manner, the presence of porosity in weldments can be beneficial, because the pores act as pinning sites for fatigue cracks and can either retard or stop their growth. In particular, the presence of some amount of porosity retarded fatigue crack growth at low stress in surface habitat and wet underwater welds (Ref 26) (Fig. 8). The low-porosity dry habitat weld was shown to contain approximately 3% porosity on the fatigue fracture surface, whereas the high-porosity wet underwater weld contained approximately 12% porosity on the fatigue fracture surface.

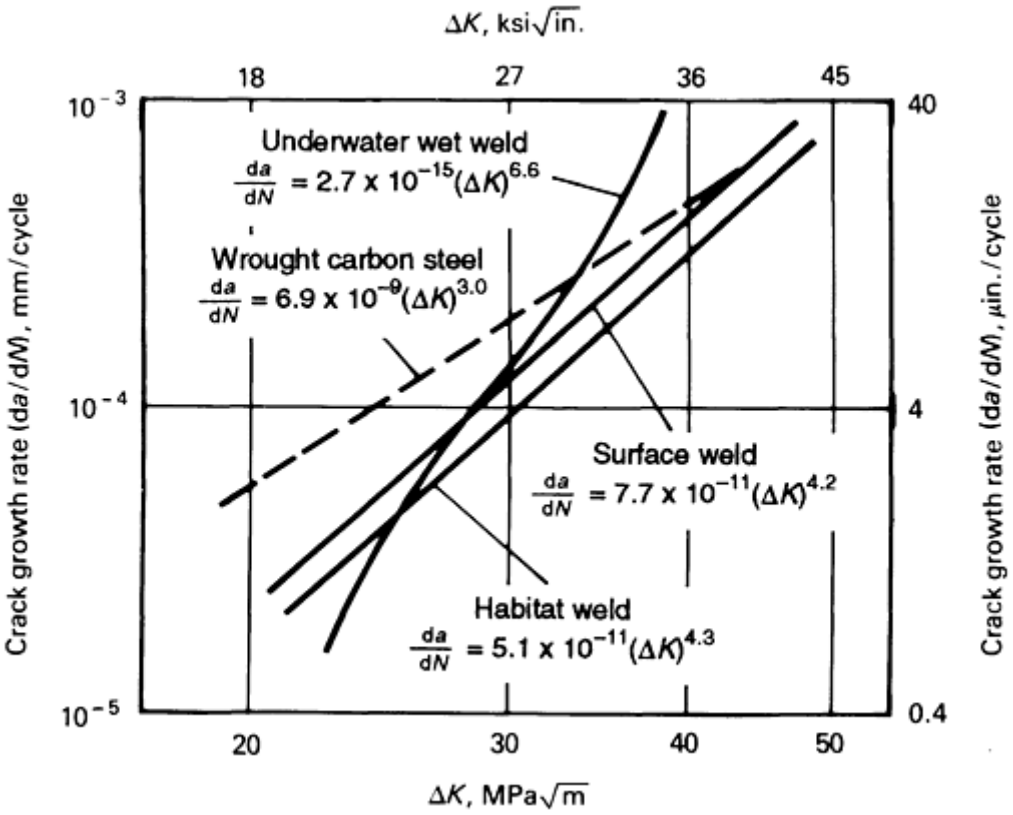

FIG. 8 COMPARISON OF EFFECTS OF POROSITY AND FREQUENCY ON THE FATIGUE CRACK GROWTH BEHAVIOR OF WELDS TESTED IN SEAWATER. SOURCE: REF 26

In comparison to normal wrought ferrite-pearlite steels, all experimental underwater welds exhibited lower growth rates for low values of ΔK, where ΔK is the cyclic variation in the stress intensity factor, K. However, the wet welds tended to have a higher fatigue crack growth rate than the wrought alloys at high values of ΔK, particularly in wet welds.

At low ΔK values, the wet underwater welds have the most fatigue crack growth resistance. The large number of pores act as pinning sites for the advancing fatigue crack front. Increased porosity in a weldment yielded lower fatigue crack growth at low ΔK values.

At high ΔK values, the crack growth rate is much greater for the higher-porosity content. At higher stress levels, the mechanical behavior of the sample is more like that experienced in a tensile test. The high numbers of pores act to reduce the cross-sectional area and, thus, allow the cracks to propagate at a high rate. The use of wet weld repairs in areas of high cyclic stress should be accompanied by caution and a load-reducing joint design.

Heat Sources

With increasing depth and, thus, pressure, the welding parameter space for sustaining a welding arc becomes more restricted. This effect necessitates a more careful selection of the welding voltage (gap) and current for a given size and type of welding electrode. The decreasing welding parameter space also reflects a shift of current to lower values and voltage to higher values (see Fig. 3), which changes the nature of the heat input. Electrode coating thickness can also influence the arc characteristics (Ref 16). Figure 9 illustrates that increasing coating thickness also raises the arc characteristic curves.

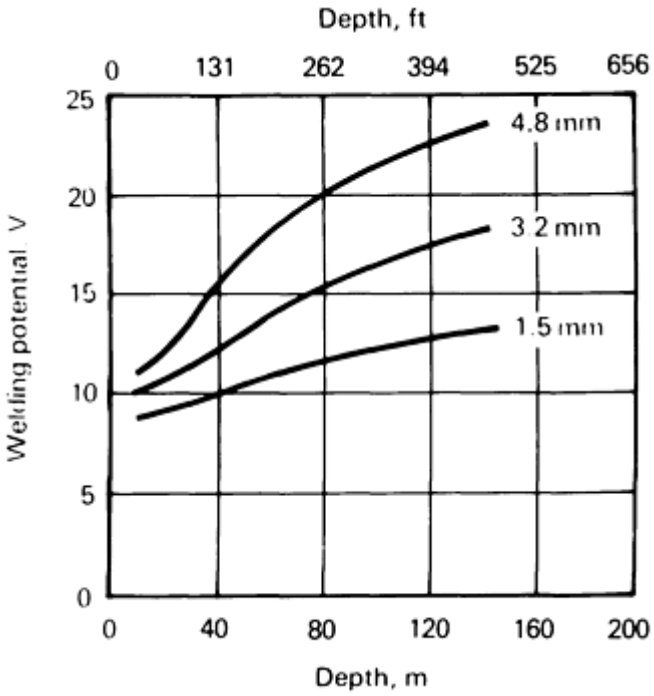

FIG. 9 EFFECTS OF DEPTH ON ARC VOLTAGE FOR THREE DIFFERENT GTAW ELECTRODE DIAMETERS. SOURCE: REF 29

With an increase in the welding depth, the duration and frequency of short circuits and arc extinctions were reported to grow significantly (Ref 28), and the process stability deteriorated. The observed rise of welding current is associated with the increase in the number of short circuits. The addition of rare earth metals into the charge of rutile-base flux-cored wire

provides considerable improvement in arc stability and reduces arc downtime (arc extinctions and short circuits) by nearly two times. The more-stable arc burning that occurs when welding with the rare earth metal-containing wire allows its use in any spatial position and within the depth ranges investigated.

An approach that separates the wet conditions from the weld pool has been demonstrated, in which a welding torch that produces a local gas cavity by controlling the fluid flow in the environment of the weld is utilized (Ref 29). This method hinders the water invasion by the momentum of the fluid jet and by the smooth exhausting of cavity gases by flow entrapment. The process allows near-surface welding conditions to exist and permits the flexibility of wet welding practices while achieving weld quality that is similar to dry-environment underwater welding.

Underwater Welding

S. Liu and D.L. Olson, Colorado School of Mines, S. Ibarra, Amoco Corporation Research

Practical Applications for Underwater Welding

Underwater welding techniques are used primarily for the repair of offshore platforms, particularly after the normal 5 year inspection period. However, these techniques have also been very useful during the installation of new offshore structures and undersea pipelines, the installation of hot taps, the repair of dock and harbor facilities, the modification of and addition to underwater structures, and the repair of nuclear facilities.

Examples of maintenance and repair applications are described below.

Offshore Structures. Underwater welding techniques are used to repair damages caused by corrosion or by fatigue cracking, and to repair members that have been damaged by ship impact. The repair or replacement of structural members damaged during installation by objects that have fallen overboard or by other accidents have also been reported. The underwater wet welding repair of these structures requires that the carbon equivalent of the steel be below 0.40 wt% (as calculated using the International Institute of Welding formula) to prevent hydrogen cracking. For steels with high carbon equivalents, the use of multiple temper bead techniques is required in order to reduce the hardness in the HAZ and eliminate the presence of hydrogen.

Undersea Pipelines. The repair or replacement of undersea pipelines is usually conducted in a hyperbaric dry chamber. Although sleeve repairs using wet welds have been tested successfully, their use has not been reported to date. Hyperbaric chambers are used regularly for underwater tie-ins and for repairs of defects.

Harbor Facilities. Corrosion and collision damage to sheet and pilings have been repaired. The repair and replacement of tubular dock braces, dock supports, and tanker moorings have also been reported.

Floating Vessels. Permanent and temporary repairs to holes in ship and barge hulls have been conducted. The hulls and pontoons of semisubmersible drill ships have also been repaired.

Nuclear Power Plants. The wet welding of nuclear power plant components is usually conducted with austenitic stainless steel electrodes in order to match the austenitic base metal used in the construction of these power plants. Damaged reactor internal components and leaks in pool liners are the usual types of repairs.

Specifications. The first underwater welding specification, known as ANSI/AWS D3.6, "Specification for Underwater Welding," was published in 1983 by the American Welding Society. This specification provides comprehensive information that enables engineers to select the welding method (wet or dry) that meets the established fitness-for-purpose requirements. The specification also provides a means for the engineer to make critical decisions in structural fabrication when underwater welding techniques are used. It is also a performance specification that is intended to assist the purchaser in specifying and obtaining the desired mechanical properties when using underwater welding techniques. The specification also allows contractors to prepare estimates and quotations for each project with a clear understanding of what is required. The original specification has been revised and reissued several times.

The AWS D3.6 specification defines four weld types, or classes. Each weld type has a specific set of quality requirements that must be verified during procedure qualification. The type of weld selected for a specific application is determined by the user.

Type A welds are represented by a set of requirements that produces an underwater weld comparable to a surface weld. Underwater welds that meet these requirements are usually hyperbaric (dry) welds.

Type B welds are usually reserved for wet underwater welds. They are intended for less-critical applications where reduced ductility and increased porosity can be tolerated. Typical applications include scallop sleeves on offshore structures.

Type C welds satisfy lesser requirements than type B welds and are intended for applications where load-beating function is not a primary consideration.

Type O welds usually meet the requirements of surface dry welds, as well as those of other codes and specifications.

Other underwater welding documents are developed by agencies such as the International Institute of Welding (IIW Doc SCUW 124-90), the American Society of Mechanical Engineers (ASME Section X/IWA 4550 for Underwater Welding of Nuclear Vessels), and the Norwegian agency Det Norske Veritas (DNV) (Document RP3604, Recommended Practices for Underwater Welding).

Welding for Cryogenic Service

T.A. Siewert and C.N. McCowan, National Institute of Standards and Technology

Introduction

CRYOGENIC TEMPERATURES cause many structural alloys to become brittle, which is an unacceptable condition in most structural applications. Therefore, structures built for service at low temperatures are typically made from alloys that maintain some ductility at the service temperatures. Cryogenic alloys include 9Ni steels, austenitic stainless steels, manganese stainless steels, maraging steels, titanium, aluminum, and nickel alloys. The choice of weld-metal alloy may depend solely on the strength of the alloy at a given temperature or on a combination of strength, toughness, fatigue resistance, thermal conductivity, magnetic permeability, and other considerations.

Wrought or cast alloy structural members are usually joined using filler materials with compositions that are similar, but not identical, to the parent material. The weld composition is optimized to compensate for the inherent differences in the properties of weld and parent material that are due to grain structure, inclusion content, and cooling rate differences. The goal is to match, as closely as possible, the mechanical and physical properties of the weld and parent material. When nonmatching weld compositions are most appropriate, differences between the welds and parent material in terms of thermal contraction, corrosion, and other factors must be considered. This article discusses these differences and explains how they affect the choice of the weld filler metal.

Welding for Cryogenic Service

T.A. Siewert and C.N. McCowan, National Institute of Standards and Technology

Effects of Cryogenic Service on Properties

Strength. As the temperature drops below room temperature, some cryogenic alloys strengthen appreciably. Unless some other property degrades and offsets this effect, such strengthening is very beneficial in reducing the required weight and thickness of structural members that are designed on the basis of load. Figure 1 shows this strengthening effect for several alloy systems, using data that are representative of both base and weld metal. Unfortunately, not all alloys strengthen at the same rate. Therefore, a comparison of the strengths at one temperature cannot be used to predict the relative strengths at a different temperature. Most literature data are for certain convenient test temperatures (4 K, 77 K, and 298 K). Data for intermediate temperatures indicate that strength is a smoothly varying function of temperature, whereas data for the three common test temperatures can be linked with curved lines. Because the behavior is very predictable, this discussion concentrates on the extreme temperature, 4 K, where the effects are most pronounced. Behavior at 77 K can be estimated by interpolation.

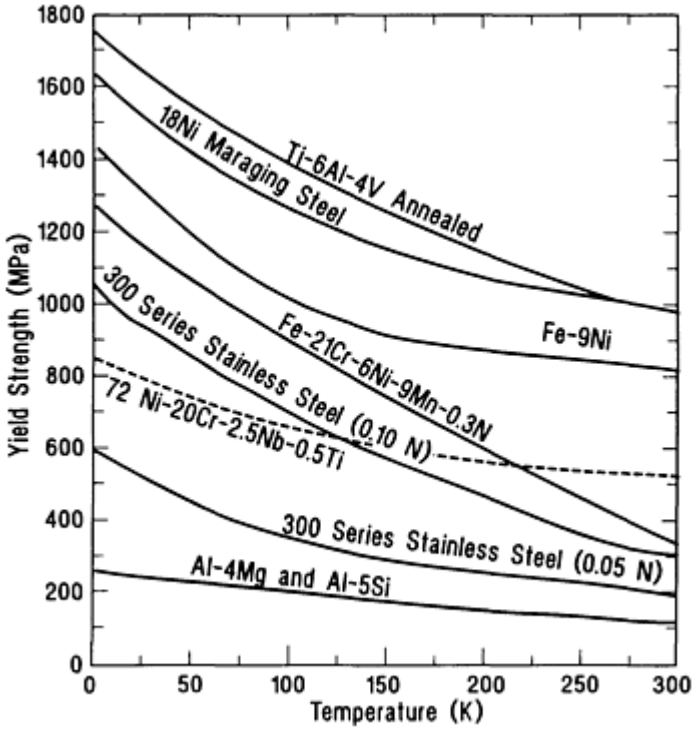

FIG. 1 YIELD STRENGTH VERSUS TEMPERATURE (4 TO 300 K) FOR VARIOUS BASE METALS AND WELD METALS THAT HAVE BEEN STUDIED FOR CRYOGENIC APPLICATIONS

As shown in Fig. 1, some alloys can reach very high yield strengths (well above 1000 MPa, or 140 ksi) at 4 K. Others, such as aluminum alloys, start from moderate or low strengths and respond mildly to a lowering of temperature (Ref 1, 2). Nine-percent nickel (Fe-9Ni) starts with a strength that is high at room temperature and rises from that point (Ref 1, 2). High-manganese steels, such as Fe-22Mn, and 21Cr-6Ni-9Mn stainless steel at 4 K approach the ultra-high-strength levels of 9Ni steel, maraging steel, and titanium (Ref 3, 4).

The austenitic (300 series) stainless steels offer medium strength at room temperature, but strengthen with decreasing temperature at a rate dependent on the nitrogen content of the alloy. As shown in Fig. 1, the strengthening of these alloys is a strong function of their nitrogen content: the trend line for the alloys with a higher nitrogen content shows much greater strengthening than the trend line for the alloys with a lower nitrogen content (Ref 5).

The maximum strength that can be reached is a function of the solubility limit of nitrogen in the stainless steel. This limit, in turn, is a function of composition and other factors. To control strength values, the nitrogen content of the weld must be carefully controlled, or else two effects can occur: pores may form in the weld during solidification (as the supersaturated liquid weld metal rejects nitrogen) or the weld pool may lose nitrogen through evaporation, weakening the weld. It should be noted that the strength of 21Cr-6Ni-9Mn is much higher than that of other austenitic steels because its nitrogen content is near 0.3 wt%. This higher level of strength is made possible by the improved nitrogen solubility in an alloy with a higher manganese content.

Equation 1 was developed to predict the strength of welds in austenitic stainless steel at a temperature of 4 K:

$$\sigma_Y(\text{MPA}) = 180 + 3200\ \text{N} + 33\ \text{Mo} + 32\ \text{Mn} + 13\ \text{Ni} \qquad \textbf{(EQ 1)}$$

where the elemental symbols represent their concentration in wt% (Ref 5). Equation 1 shows which elements have the greatest effect on strength and is very similar, in terms of elements and their coefficients, to an equation developed to predict the strength of austenitic stainless steel wrought material (Ref 6). Thus, it can be concluded that:

- AUSTENITIC WELD STRENGTH CAN BE ADJUSTED BY CHANGING THE COMPOSITION TO MEET THE NEEDS OF THE APPLICATION.
- WELD STRENGTH IS DETERMINED BY THE SAME FACTORS AS THOSE THAT DETERMINE THE BASE METAL STRENGTH.
- MATCHING THE COMPOSITION OF THE WELD TO THAT OF THE WROUGHT MATERIAL WILL RESULT IN NEARLY EQUIVALENT STRENGTHS.

Fracture Toughness at 4 K. Because many cryogenic structures are subject to fracture and other failure mechanisms, most designs must consider toughness, as well as strength. Unfortunately, toughness often degrades as the strength is increased or as the temperature decreases.

Figure 2 shows data for strength and fracture toughness at 4 K for some alloys that have been either proposed or actually used in cryogenic applications. The plotting of yield strength versus fracture toughness, K_{Ic}, provides an easy way to evaluate alloys, because these mechanical properties are common design criteria. A trend band or border was drawn around the data when warranted by the quantity of data. For some alloys, the data were so sparse that individual data points were plotted. Although most of these data are for base-metal alloys, data for selected welds are included to show that base-metal properties for important cryogenic alloys can be met or exceeded for high-toughness, fracture-critical applications.

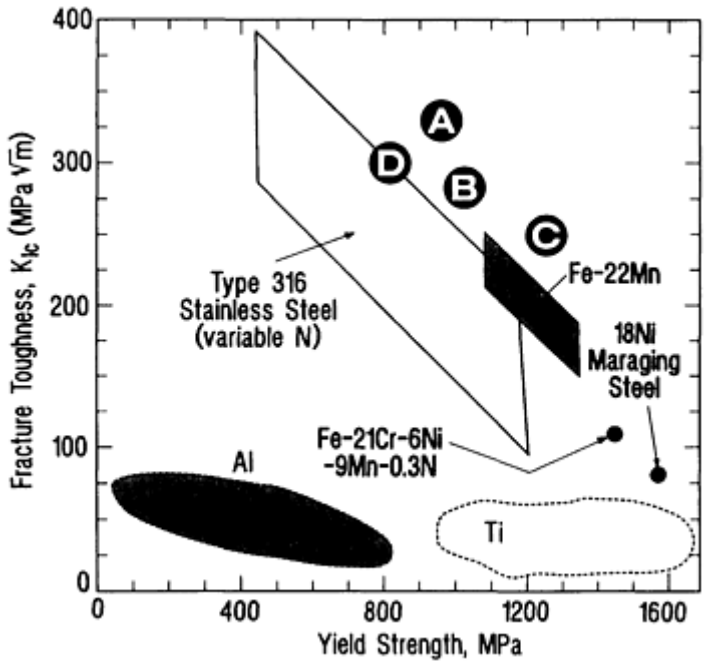

FIG. 2 YIELD STRENGTH VERSUS FRACTURE TOUGHNESS FOR VARIOUS BASE METAL ALLOYS AND SELECTED WELDS AT 4 K

Data for a Ti-6Al-4V alloy and an electron-beam (EB) weld showed an abrupt decrease in toughness at test temperatures below 125 K; toughness was lowest at the boundary between the heat-affected zone (HAZ) and the fusion zone of the weld (Ref 7). These data are grouped in the lower right corner of Fig. 2. Generally, titanium alloys and other ultrahigh-strength alloys, such as 18Ni maraging steel or 9Ni steel, exhibit low toughness at 4 K (as might be expected of an alloy with very high strength). Therefore, these alloys are most commonly used for compression loading or other applications where their limited ductility is acceptable (Ref 8, 9, 10). The 18Ni maraging steel and the titanium alloy do not show a transition from ductile to brittle fracture at low temperatures, as do 9Ni and other lower-nickel-content steels (Ref 1, 2, 9). No data for weld toughness were found for 18Ni maraging steels at 4 K.

Data for aluminum alloys and some welds are also included in Fig. 2 (Ref 11, 12). These data represent traditional aluminum alloys, as well as some of the new aluminum-lithium alloys. The zones indicated in Fig. 2 for the aluminum

and titanium alloys are intended to loosely identify mechanical property regions for the alloys, rather than to define limits for design purposes.

At a temperature of 4 K, considerable data exist for type 316L stainless steel wrought alloy (a common cryogenic structural material). Therefore, Fig. 2 includes a trend band for yield strength versus toughness (Ref 6). This alloy has a good balance of strength and toughness, and has found application as the structural case for large superconducting magnets. As its strength increases (through additions of nitrogen), its toughness decreases. This variation in strength with nitrogen content was shown in Fig. 1 as curves for two different nitrogen contents, whereas Fig. 2 shows the effect in terms of toughness as a function of strength at constant temperature. This trend shows the interrelationships between properties that must be considered by structural designers.

Although the trend line for the matching-composition electrodes is not included in Fig. 2, it extends over the same strength range, but at only 50 to 70% of the toughness of the base metal (Ref 4). This lower toughness for welding electrodes of matching composition has driven the search for electrodes of different compositions that can match the properties of these base metals. Two fully austenitic stainless steel weld compositions (shown as A and B in Fig. 2 and described in more detail in Table 1) have been proposed for joining AISI 316LN stainless steel (Ref 13, 14, 15).

TABLE 1 COMPOSITIONS FOR THE FOUR WELDS (A THROUGH D) INCLUDED IN FIG. 2

WELD	COMPOSITION, %								PROCESS
	FE	CR	NI	MN	N	C	S	P	
A	BAL	13	5	22	0.21	0.04	0.004	0.013	**EBW**
B	BAL	20	25	1.6	0.16	0.01	0.001	0.010	**GMAW**
C	BAL	18.1	20.4	5.4	0.16	0.03	0.007	0.006	**GMAW**
D	**1**	**20**	**BAL**	**3**	**. . .**	**0.02**	**. . .**	**. . .**	**GTAW**

Two other iron-base alloys, Fe-22Mn and 21Cr-6Ni-9Mn, have been used in structures that require high strength and toughness at 4 K. Figure 2 includes a trend line for a high-manganese alloy, Fe-22Mn, which is one of several iron-manganese alloys that have been developed since the early 1980s (Ref 3, 16). Its particular advantage is an ability to attain a strength higher than that of type 316 stainless steel. A matching-composition weld, shown as C in Fig. 2, was produced by electron-beam welding (EBW) (Ref 17). The strength of the weld was approximately 5% lower than that of the parent plate material, presumably because of the loss of nitrogen in the welding process. However, the fracture toughness of the weld exceeded the toughness of the plate material. Matching-composition welds have also been made using shielded metal arc welding (SMAW), gas-metal arc welding (GMAW), gas-tungsten arc welding (GTAW), and submerged arc welding (SAW) processes. The toughness of the welds produced by these other processes is lower than that of the EB weld, because their inclusion contents are higher (Ref 16).

Another common cryogenic alloy is 21Cr-6Ni-9Mn, for which one value is included in Fig. 2 (Ref 2). A trend band has not been developed, but the data would be expected to have a similar trend to those of Fe-22Mn and 316LN (but extending to a higher strength than that of 316LN, because the 21Cr-6Ni-9Mn can contain up to 0.4 wt% N). A nickel-base weld composition (weld D in Fig. 2) has been proposed for 21Cr-6Ni-9Mn. Although this nickel-base weld undermatches the strength, it overmatches the toughness. Thus, welds can be made in locations of lower stress, which permits the use of this high-strength alloy in the construction of structures.

Table 1 lists the compositions of the four welds included in Fig. 2. It shows that these welds (other than the Fe-22Mn composition) have more nickel than the iron-base alloys that they join. These weld composition data represent the best combinations of strength and toughness reported for the alloys. Because the matching-composition welds tend to have lower toughness than the parent plate, these nonmatching compositions are being considered for fracture-critical welds. Subsequent sections in this article describe how thermal expansion and other characteristics of the nonmatching compositions might affect the suitability of these alloys in particular applications.

Another common cryogenic temperature is 77 K, the normal boiling temperature of liquid nitrogen. Because toughness is higher at 77 K than at 4 K, higher-strength alloys can be considered for fracture-critical applications. Like other iron-base alloys that show a significant improvement in toughness with increasing temperature, Fe-21Cr-6Ni-9Mn is more suited for use at 77 K, where its high strength is an attractive option, when compared with that of 316LN alloy. For example, Fe-

21Cr-6Ni-9Mn base metal drops in strength from a level near 1450 MPa (210 ksi) at 4 K to near 1150 MPa (165 ksi) at 77 K, which is still a very respectable level of strength.

Charpy V-Notch Impact Energy at 77 K. Although not as useful in fitness-for-service calculations as K_{Ic} fracture toughness, the Charpy V-notch (CVN) test is a low-cost way to measure the resistance of an alloy to fracture. A literature search found that most data on fracture resistance at 77 K were reported as CVN data. In Fig. 3, CVN absorbed-energy data at 77 K are plotted versus the yield strength for a number of weld metals. The trends reiterate the effects of strength and nickel content on CVN toughness. Because many structural designs specify a minimum of 30 or 40 J (22 to 30 ft · lbf), numerous weld compositions can be considered at this temperature, including compositions that match that of the base plate.

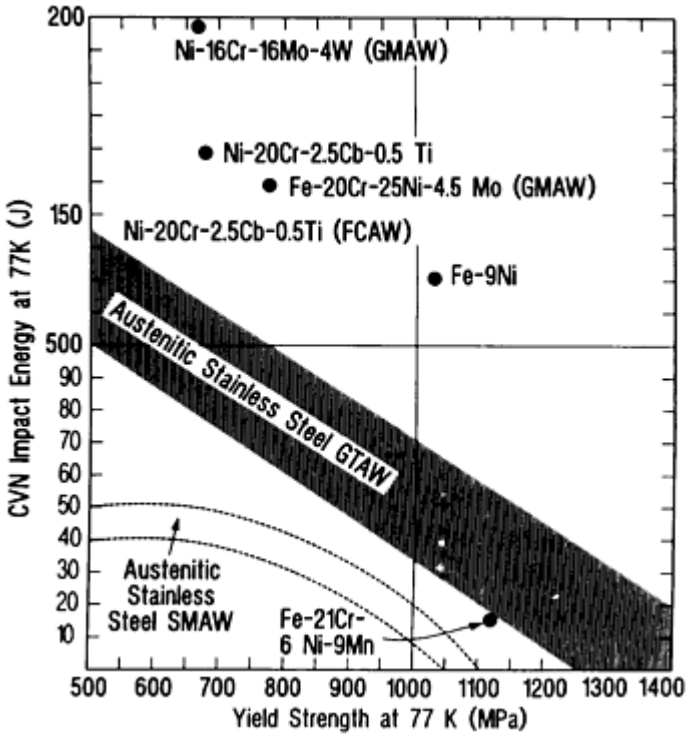

FIG. 3 CHARPY V-NOTCH ABSORBED ENERGY VERSUS STRENGTH FOR VARIOUS WELD METALS AT 77 K

In the lower right quadrant of Fig. 3 is a data point for a matching-composition weld for the Fe-21Cr-6Ni-9Mn steel (Ref 18). The low absorbedenergy indicates that the nickel-base undermatching weld compositions should be considered for applications with this composition at 77 K (Ref 19). Nickel-base weld compositions are also used for welding the Fe-9Ni alloy included in Fig. 3 (Ref 10).

For the austenitic (300 series) stainless steels, there are two trend bands. The lower band is for welds produced by the SMAW process, whereas the upper is for welds produced by the GTAW process. The difference is attributed to weld inclusions, as discussed in the next section of this article. Above the GTAW trend band are the four special weld compositions identified in Table 1. These higher absorbed energy levels are comparable to the level that type 316LN plate would develop at this temperature.

Equation 2 was developed to predict the absorbed energy at 77 K for the welds in austenitic stainless steel:

$$CVN(J) = 19 - 1.4\,FN - 890\,C^2 + 1.4\,NI \qquad \textbf{(EQ 2)}$$

where the elemental symbols represent the composition in wt%, and FN is a measure of the delta ferrite content (calculated by the Schaeffler diagram coefficients and allowed to be negative) in the weld (Ref 20).

This equation was not developed for weld compositions strengthened by nitrogen. Therefore, carbon represents the principal strengthening element. If carbon is considered as a generic strengthening term (combined effects of carbon, nitrogen, manganese, molybdenum, and others), then Eq 2 shows that increased strength and ferrite content lower the CVN toughness, and that nickel increases toughness. The effects of these factors on toughness are generally accepted to be true for stainless steel weld and base material. Because an increase in nickel content also decreases the ferrite content, nickel additions improve the toughness via two terms in Eq 2. This information on the effect of nickel confirms the reasons for the better toughness of the four nonmatching compositions (Ref 13, 14, 15, 17).

Inclusion Content. In austenitic stainless steels and manganese stainless steels, the fracture modes of both base metals and welds are usually quite ductile, and fracture originates at inclusions in the microstructure. A minor difference between the fracture surfaces of the base metal and weld metal is that those of the welds have a finer ductile dimple spacing. This finer spacing has been attributed to the higher inclusion content of the welds and explains why the welds are less tough than those of the matching-composition wrought material (Ref 21, 22, 23).

Figure 4 shows normalized toughness data versus inclusion spacings for both wrought materials and welds (Ref 21, 24). The vertical axis is known as a quality index, and it allows alloys with different strengths and nickel contents to be compared on a scale that has fracture toughness in the numerator (higher values are better). The similarity of the trend line for both sets of data supports the need to reduce the inclusion content of welds that require a higher fracture toughness. Most of the welds in Fig. 2 were produced using welding processes and procedures that minimize the inclusion content. The exceptions here are the nickel-alloy welds and the very high nickel content (greater than 20 wt%) stainless steel welds. Preliminary data indicate that the toughness of these compositions is less sensitive to inclusion content. Therefore, these materials could be more appropriate for welding at higher deposition rates.

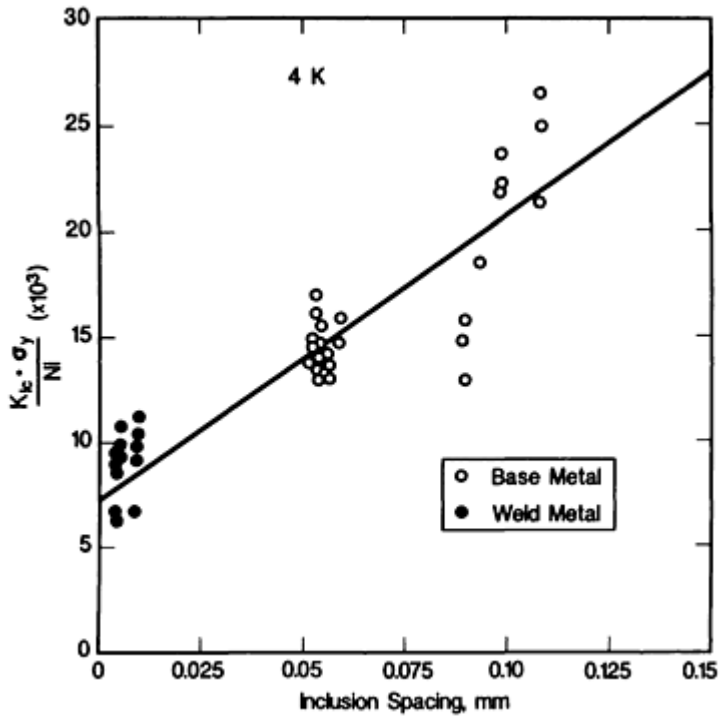

FIG. 4 NORMALIZED TOUGHNESS DATA (QUALITY INDEX) VERSUS INCLUSION SPACING FOR TYPE 316LN BASE METALS AND WELDS, SHOWING HOW THE WELD DATA FOLLOW THE SAME TREND AS THE BASE METAL, BUT A SMALLER INCLUSION SPACING RESULTS IN LOWER TOUGHNESS FOR THE WELDS

Fatigue Strength. Few data are available for the fatigue strength of cryogenic welds. However, the data that are available suggest that fatigue strength could limit the structural life in high-cycle applications. Table 2 lists data from a study that used the GTAW process to join a number of different materials (Ref 25). The data show that fatigue strength does not necessarily increase as temperatures decrease from 295 to 4 K. Expected yield strength data, extracted from Fig. 1, have been added for comparison.

TABLE 2 FATIGUE STRENGTH FOR GAS-TUNGSTEN ARC WELDS AT 4×10^4 CYCLES

SPECIMEN	ESTIMATED FATIGUE STRENGTH				YIELD STRENGTH AT 4 K	
	AT 295 K		AT 4 K			
	MPA	KSI	MPA	KSI	MPA	KSI
21CR-6NI-9MN TO 304L	380	55	360	52	1050	**150**
21CR-6NI-9MN TO 316L	420	60	390	57	1100	**160**
21CR-6NI-9MN BASE METAL	**370**	**54**	**290**	**42**	**1200**	**175**

The coefficient of thermal expansion (CTE) can have an important bearing on structural integrity. If the weld metal has a CTE that is very different from that of the base metal, cooling from room temperature to cryogenic temperature can introduce substantial stresses. These stresses can add to the residual stresses that exist around any weld and can permit the plastic deformation of the structure. Repeated thermal cycles could lead to work hardening of the microstructure or to fatigue failure, in the most severe cases. Other physical properties that are often important in cryogenic structures are phase stability and magnetic permeability.

Welding in Space and Low-Gravity Environments

Milo Nance, Martin Marietta Corporation; Jerald E. Jones, Colorado School of Mines

Introduction

WELDING AS AN ASSEMBLY PROCESS has become increasingly more attractive to designers of space structures for the same reasons welding is popular on earth. Welding applications in space are similar to those on earth in that they both involve the need to assemble structural components that will exhibit sufficient strength, endurance, and reliability during their service lives. In addition, ease of repair of welded structures is another consideration that makes various welding methods viable for space applications. Typical space welding applications generally fall into three categories:

- ON-ORBIT CONSTRUCTION OF LARGE STRUCTURES
- REPAIR WELDING ON-ORBIT AND FOR EXPLORATION FLIGHTS BEYOND THE VICINITY OF THE EARTH
- WELDING AND REPAIR OF STRUCTURES ON A LUNAR BASE

This article will review a variety of applications for welding in space and low-gravity environments, describe the unique aspects of the space environment, compare applicable welding processes, and examine the metallurgy of low-gravity welds. In addition, steps that must be taken to ensure the continued development of welding technology in space are discussed.

Welding in Space and Low-Gravity Environments

Milo Nance, Martin Marietta Corporation; Jerald E. Jones, Colorado School of Mines

Examples of Application

Welded joints have the potential to reduce the cost of fabrication and repair on-orbit. For example, large mechanical joints are planned for use on the U.S. Space Station Freedom. Each of these joints weighs approximately 1.36 kg (3 lb). When one considers that the cost for low earth orbit missions is several thousand dollars per pound of payload, it is easy to see how the replacement of these joints with a welded design would save significant amounts of weight and offer the potential to save large amounts of capital.

There are other applications for welding technology in space. These involve the modification and repair of structures and components in orbit. It has been suggested that structural material could be scavenged for reuse in orbit. An example of this is the Space Shuttle external tank (Fig. 1). On each shuttle mission the external tank is brought nearly into orbit. With minimal loss of payload capability, these tanks could be brought into orbit allowing the use of the tank structure for experimental platforms or for raw stock material. Cutting and joining technologies could enable the reuse of this valuable resource.

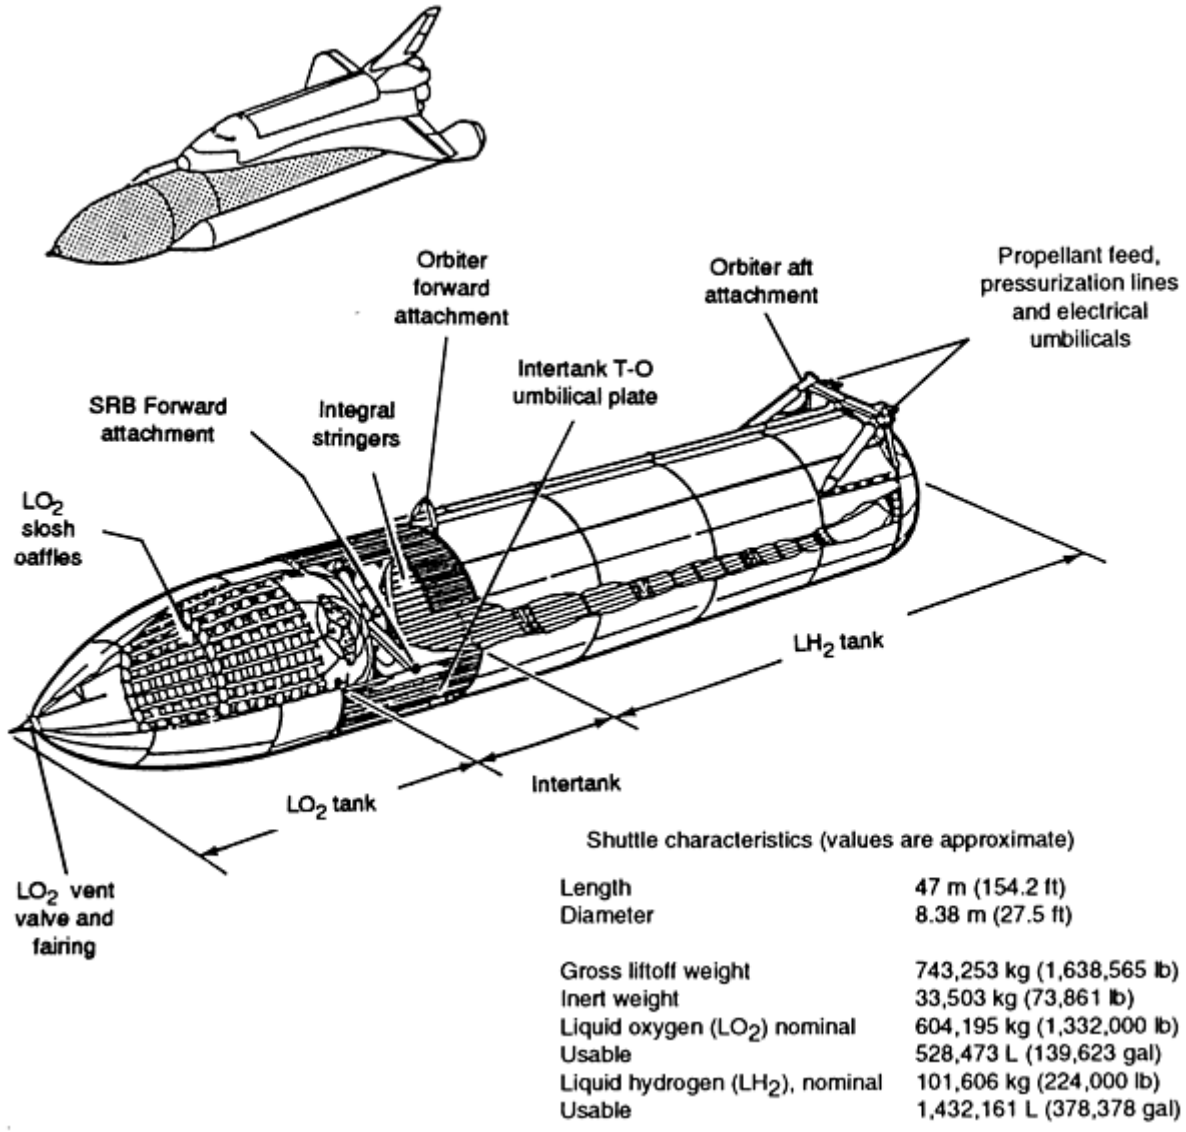

FIG. 1 SPACE SHUTTLE EXTERNAL FUEL TANK

Another application is the repair of major structures. Damage to space structures can result from many causes, including accidental misuse. However, one common cause of damage is "space debris," or miscellaneous small and large pieces of disintegrated satellites, material jettisoned from spacecraft, and other miscellaneous material. This debris is travelling at very high speeds, and may not be in the same orbital path and direction as a spacecraft. A resulting high-speed collision, even with a small piece of material, can cause significant damage. The amount of space debris in low earth orbit is increasing. Figure 2 shows the increase in concentration of debris in orbit from data collected by the Long Duration Exposure Facility (LDEF). The Space Shuttle has already been hit by at least one particle of debris, resulting in a damaged windshield, and there is speculation of impact damage to satellites.

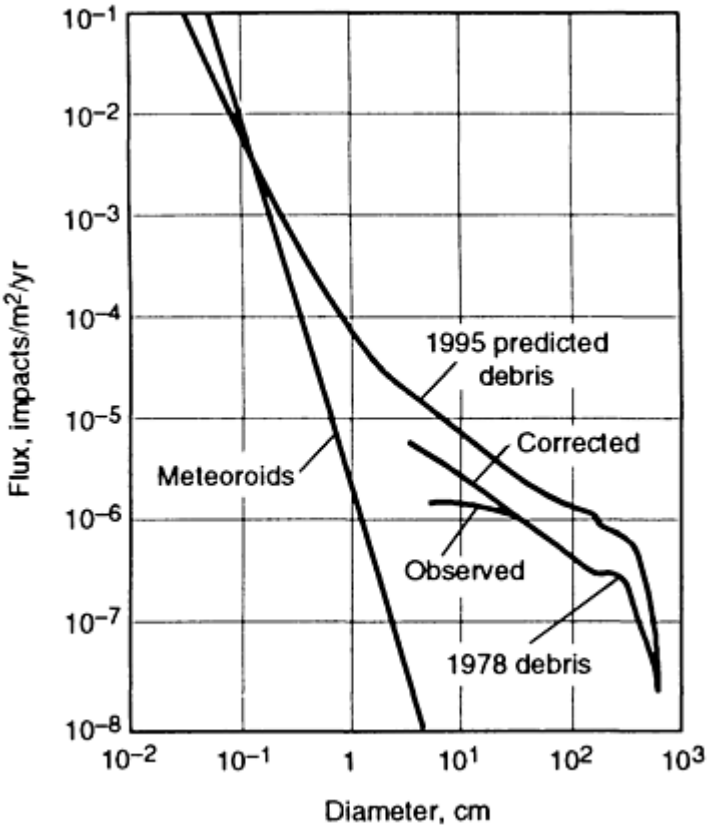

FIG. 2 DIAGRAM SHOWING THE INCREASE IN THE CONCENTRATION OF "SPACE DEBRIS" ENCOUNTERED IN ORBIT. COURTESY OF D.J. KESSLER, NASA JOHNSON SPACE CENTER

On-orbit repair of high-value, long-duration space-based assets has proven to be more effective than to return them to earth. On-orbit welding is a logical technology to assist in the repair of systems such as a space station. In other cases, such as a manned mission to Mars or the vicinity of the moon, it is impractical or impossible to return damaged structures to earth. The Soviet space program already has used welding to repair Soyuz space station tubing.

If a lunar base is established, structures will need to be economically constructed. Welding offers the potential for fast and cost-effective fabrication. In addition, repair of structures and equipment damaged by use and/or meteor collision will be necessary. Lunar dust contains many abrasive components, and wear of equipment will be inevitable. The cost of equipment replacement will probably be prohibitive, while repair by weld hardfacing and surfacing is a very cost-effective technology that is employed in earth-based applications subjected to wear. See the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in this Volume.

Both the United States and the former Soviet Union have carried out welding experiments in space. The United States used Skylab to weld 2219-T87 aluminum alloy, type 304 stainless steel, and pure tantalum samples. The Soviet program used the Soyuz to perform its experiments and still has its space welding technology available. Both efforts involved electron-beam welding. The findings from these experiments are discussed later.

Welding in Space and Low-Gravity Environments

---

Space Welding Environment

Space presents a unique welding environment and many technological challenges. The most obvious and dramatic factors are microgravity and high vacuum. Microgravity in earth orbit occurs due to the centrifugal force of the orbiting craft that counters the effects of gravity, making the spacecraft and all orbiting objects, including those within the spacecraft, in continual free fall until a force acts upon them. Typical gravitation accelerations are on the order of 10^{-6} G (acceleration due to gravity).

High vacuum is present around the spacecraft. Typical levels in low earth orbit are 1×10^{-4} to 1×10^{-16} Pa. This vacuum aids some welding processes, such as electron beam. Since virtually no atmosphere is present, there is no attenuation caused by scatter of the electron beam. In addition, for all welding processes there is no need to protect the metal from oxidation or other atmospheric contaminants with a vacuum chamber, flux, or an inert gas atmosphere.

The space environment also offers several technological challenges. One of the problems is the lack of a high-capacity electrical power supply. Electrical power generation is currently produced by one of three methods: batteries, fuel cells (power generation from the combination of oxygen and hydrogen to form water), and direct solar conversion. All three of these methods produce a relative small amount of power compared to the requirements of the typical earth-based welding system. Typically, power is limited to 4.5 kW for a period of a few minutes on board the Space Shuttle. This power constraint will be present for the foreseeable future. Larger-capacity generation systems based on thermal-nuclear generators are being developed, but have not yet been used in service with manned spacecraft.

A second problem is the lack of nondestructive testing methods qualified for space use. Many of the traditional methods of inspection will not operate well in a space environment. For example, there is no method of dye penetrant inspection developed to date that can be applied in a vacuum. Methods such as radiography and eddy current inspection may be feasible, but no space-qualified equipment has yet been developed. Even if such equipment was available, the competition for weight and volume onboard a spacecraft might prevent its usage.

The application of intelligent automation techniques that allow the production of high-quality welds with a high degree of reliability appears to be the most attractive alternative with regard to the available space and weight limitations (see the discussion of the future of space welding later in this article). In order to produce such welds, a clear and precise knowledge of the mechanisms involved in space welding must be developed as well as the equipment necessary to carry out such welds. There have been several advances made in the necessary sensor and control technologies for earth-based welding that can be used in space welding.

Welding in Space and Low-Gravity Environments

Milo Nance, Martin Marietta Corporation; Jerald E. Jones, Colorado School of Mines

Welding Processes

The space environment has constraints that limit the application of certain conventional welding processes. For example, submerged arc welding (SAW) generally depends on gravity to feed the granulated flux and hold it in place on the weld; this is not possible in low-gravity environments. The space environment also affects some of the basic physical processes involved in welding, making welding processes operate differently in space than in earth-based environments. In addition, the weight limitations of orbital payloads on spacecraft will impose constraints on the processes that can be feasibly used in space.

The three processes that appear to have good potential for space application are electron-beam welding (EBW), laser-beam welding (LBW), and gas-tungsten arc welding (GTAW). All three processes are often used for autogenous welding, thereby eliminating the need for transport of high-weight consumables. These processes are also amenable to welding in vacuum (with certain modifications to the GTAW process as discussed below). Also, all of these processes have relatively low power requirements when used for thin-section materials typical of spacecraft and space structures, making these processes most useful in space, where all utilities, including electricity, are limited.

Electron-Beam Welding (EBW)

The EBW process consists of an electron-beam gun that generates a high-energy stream of electrons. When directed through a series of focusing electromagnets, this high-energy stream has sufficient power density to melt metals. The

EBW process is described in detail in the articles "Electron-Beam Welding" and "Procedure Development and Practice Considerations for Electron-Beam Welding" in this Volume. In earth-based environments, EBW generally requires a vacuum since the electrons scatter in a gas atmosphere. In space, however, the natural vacuum environment is ideally suited for the EBW process.

Both the United States and the former Soviet Union have experimented with EBW and melting in space. The M512 metals melting experiments using an electron-beam gun, which were conducted by the United States in the Skylab in 1972, are described later in this article. In this case, the operations were performed in a vacuum chamber that was inside the spacecraft, but vented to the outside. At the time of the experiments, there was some concern as to the quality of the vacuum achievable. Often, certain gases and liquids are jettisoned from spacecraft that remain in the environment in the local vicinity of the vehicle and can produce contamination of the vacuum.

Advantages. The electron-beam gun is, perhaps, the most efficient of the processes proposed for on-orbit welding. Due to the power limitations of spacecraft, this process is the most capable for welding of thicker-section materials. For autogenous welding, no consumables are required, thereby eliminating the cost of including them in the spacecraft payload.

Limitations. The impingement of electrons onto a metal surface causes the emission of x-rays. The former Soviet Union experimented with a manual electron-beam welding gun for space application. However, x-ray shielding capacity is proportional to the mass of the shield; therefore, shielding of workers may be difficult due to the high cost of payload weight on spacecraft. Automated or robotic welding may be recommended due to the radiation exposure to workers, particularly for extended periods of welding activity.

Safety Considerations. Grounding of the part to be welded is very important. Without proper grounding, the part being welded will acquire a net negative charge from the absorbed electrons. This will cause the beam to be deflected and the weld will not form properly. In addition, if the part becomes charged, then it will discharge to anything that it comes in contact with. Such a discharge could be very dangerous for a worker, or could damage electronic equipment such as computers or communications equipment onboard the spacecraft. Although the inherent repulsion of the like-charged electrons will cause beam spread, the beam will remain a fairly concentrated heat source for some distance from the electron-beam gun. Care will be required, both for manual as well as automatic or robotic welds, to ensure that the gun is not activated except when directed at properly prepared components to be welded. Significant damage could occur to workers, to component parts, or to the spacecraft itself if the gun were activated when directed improperly.

Laser-Beam Welding

The LBW process consists of a laser and a series of lenses or mirrors that direct and focus the beam at the component to be welded. The process is described in detail in the articles "Laser-Beam Welding" and "Procedure Development and Practice Considerations for Laser-Beam Welding" in this Volume. While the LBW process, unlike the EBW process, does not require a vacuum, the inherent vacuum environment in space will help to prevent oxidation and other contamination of the weld. There are two types of lasers used for welding, gas (CO_2) and solid state (Nd:YAG). While the solid-state lasers are relatively low power, this power level is adequate for thin-section components that are likely to be welded in space.

Advantages. As with EBW, the LBW process provides a concentrated heat source that can quickly melt through thin materials without heating large sections of the workpiece. Thus, the necessary power is less than that required for many other processes. However, the laser system is inherently inefficient in the conversion of energy so the input power requirements will be much greater than for an equivalent output heating capacity when compared to EBW. Also, for autogenous welding, no consumables are necessary for LBW, so the payload cost will be low. In addition, the LBW process, unlike EBW, can be used to weld electrically nonconducting materials, including ceramics, glasses, and polymers.

Limitations. The inefficiency of the laser system is due to a significant amount of heat generated in the lasing process itself. This heat will need to be dissipated through the spacecraft radiators or using separate radiators for the laser system. Because heat radiation from low-temperature systems is fairly slow, this may require large radiators to be installed for the laser system; thus the cost and payload weight of the system is increased. Secondly, due to the power input and heat dissipation requirements, it is difficult to produce a laser system for portable application. Recent work with Nd:YAG lasers and fiber optics has resulted in optical fiber delivery of the laser beam at a location remote to the laser system.

However, the laser system generally should be approximately 10 to 30 m (30 to 100 ft) from the LBW torch. Also, great care must be taken to avoid any damage to the cable containing the optical fiber.

Safety Considerations. A laser beam will not spread and dissipate with distance as will an electron beam. Consequently, a misdirected laser beam has the potential to cause damage, even over large distances to workers, components, and to the spacecraft. The laser light itself is dangerous to workers if reflected into the eyes. Proper shielding for persons working around laser welding equipment is necessary.

Gas-Tungsten Arc Welding

The GTAW process consists of a tungsten electrode connected to one lead of a power source, the other lead of which is connected to the workpiece. When the power supply is activated, current flows to the tungsten electrode through an arc plasma to the workpiece, and returns to the power supply to complete the circuit. The arc plasma is the primary source of heat as electrons move from the metal surface, are accelerated through the plasma column, and impinge on the metal surface at the opposite side of the arc. This welding process is described in the article "Gas-Tungsten Arc Welding" in this Volume.

The arc plasma consists of a superheated gas of ions and electrons. To shield the weld from atmospheric contaminants and to provide a stable plasma, inert gas is used. Typically argon, helium, or a mixture of these is chosen for GTAW. Because of the vacuum in the space welding environment, it is not necessary to shield the weld from contaminants; however, a small amount of gaseous material is necessary to sustain a stable arc plasma. The GTAW torch to be used for space welding will be modified from the torch used for earth-based welding. Through the use of a hollow tungsten electrode, the small amount of gas needed to sustain the arc plasma can be provided. A non-reactive gas or gas mixture will be necessary to avoid contamination of the weld. This modified GTAW process is similar to the earth-based PAW process.

Advantages. The equipment used for GTAW is simpler and much less expensive to produce and maintain in comparison to EBW and LBW. Secondly, the arc plasma only exists as a part of the overall welding power circuit, therefore it is nearly impossible to direct the GTAW arc toward a component, worker, or spacecraft that is not connected to this power circuit. Thirdly, as the length of the plasma increases, the voltage required to initiate and maintain the arc increases. By limiting the available voltage in the welding power circuit, the distance that the arc can strike is limited, and the possible damage resulting from a misdirected arc is limited to near-vicinity (25 to 50 mm, or 1 to 2 in.) objects.

Limitations. The GTAW arc plasma requires a constant flow of gas. This gas supply, in the form of fairly heavy compressed gas cylinders, adds to the cost and weight of the spacecraft payload. In addition, this supply will need to be constantly replenished as welding progresses. If resupply is not available, the process will not be available for use. With both LBW and EBW, the welding process would always be available regardless of a resupplied source of welding gas.

The arc plasma is a much less concentrated heat source in comparison to EBW and LBW. This results in the need for a higher power feed from the spacecraft to produce a weld in the same thickness material.

Safety Considerations. The primary concern with arc welding is grounding and insulation for workers. Should the worker become part of the welding circuit, the power supply will generally be capable of delivering several kilowatts through the worker at a current level that can cause permanent disability and/or death. Secondly, in order to ionize the inert gas plasma and initiate the arc, a high voltage is usually applied. This is accomplished through the use of a high voltage pulse, or a superimposed high-frequency high-peak voltage signal. Either of these generates a significant amount of electromagnetic interference (EMI) radiation, which can result in damage or shutdown of such equipment as computers and other advanced electronics onboard the spacecraft.

Other Joining Processes

With a few exceptions (for example, SAW), virtually all welding processes could be used in space. The EBW, LBW, and GTAW generally have been based on weight limitations or on the inherent aspects of the space environment (for example, vacuum for EBW). The materials likely to be found in space that would be welded are typically welded with EBW, LBW, or GTAW in the earth-based environment. These include aluminum and titanium and their alloys. In addition, these processes are well understood, commonly used, and very controllable for thin-section aerospace applications.

Another process that takes advantage of the space environment is solar heat welding. Solar radiation in space is unshielded by the atmosphere. A spacecraft in low earth orbit typically receives 1.4 kW/m^2 (0.13 kW/ft^2) in daylight conditions. This energy can be taken advantage of by focusing the solar radiation on the workpiece through the use of a large collecting mirror and focusing lenses. Because the optics of the mirror need not be perfect, the cost would be reasonable and the system would not be a drain on the limited power capacity of the spacecraft.

Other joining processes that could be utilized include mechanical fastening, solid-state bonding, brazing, and adhesive bonding. However, each of these has inherent limitations that tend to make the three welding processes discussed above more attractive. For example, it may be difficult to use adhesives because they require curing by the application of heat and/or the use of hardening (curing) agents. As a result, adhesives may outgas and contaminate the local environment with volatile components. Mechanical fastening has been used extensively for some joining applications in space. However, mechanical fastening is generally not capable of producing pressurized seals, and mechanically fastened joints are more susceptible to external mechanical damage than are welds.

Metallurgy of Low-Gravity Welds

Influences of Microgravity. The microgravity environment that exists in space applications can have significant effect on the metallurgy of welds. Two important effects on the microstructure of a weld are cooling and fluid flow within the weld pool. In addition, certain other effects can be evident, including the deformation of the weld pool that occurs due to absence of gravity in the space environment. In the latter case, large weld pools in through-penetration or out-of-position welds will not droop or run, but instead their shape will be determined by surface energy and other forces.

Both the cooling rate and the liquid pool stirring behavior are influenced by gravity in earth-based welds. In space, the cooling rate will be different because convective flow is completely suppressed, and this affects the stirring forces in the pool. The principal heat loss from a weld is conduction into the surrounding solid metal. Because there is a significant temperature difference between the weld pool and its surroundings during the time the weld pool is at an elevated temperature, radiative cooling is also important. Generally, convective cooling from the weld surface is only a secondary cooling mechanism until the weld has dropped to a temperature at which little other cooling is occurring and further metallurgical transformation is unlikely to occur.

Both the conduction of heat into the surrounding metal and the radiation of heat from the weld pool are directly affected by the local surface temperatures of the weld pool. This includes the exposed surfaces as well as the interface between the liquid pool and the solid base metal. The conductive heat flow is governed by:

$$\boldsymbol{Q} = K \nabla \boldsymbol{T}$$

where ∇T is the temperature difference vector between the liquid metal and the solid metal at the interface and $\boldsymbol{q}$ is the heat flux vector. This same equation governs the loss of heat by convection from the exposed surface of the weld. However, the value of k is significantly less for heat flow across an interface into a gaseous medium than into a solid metal medium, and the k value for the convective heat transfer in a gas is much less still.

The equation for radiative heat flow is:

$$\boldsymbol{Q} = E\sigma(\nabla \boldsymbol{T})^4$$

where e is the emissivity of the emitting surface and σ is the Steffan-Boltzmann constant. Because the ∇T term is raised to the fourth power when the temperature difference vector is large, radiation heat transfer is a significant heat loss mechanism for the weld. It should be noted that the radiation of heat from the weld as well as the weld heat source may cause surrounding surfaces to heat, particularly if the weld is made in a vacuum such as outside the spacecraft

environment. The result might be damage to exposed components that are heat sensitive if appropriate shielding is not provided.

If convective pool stirring is suppressed, the temperature difference at the liquid-solid interface decreases. The liquid at that surface cools by conduction and the flow of hot liquid from the center of the pool is reduced. The result is a reduced cooling rate for the weld. This reduced cooling rate should tend to cause the grain size in the weld to increase. The opposite effect has, however, been observed and reported by investigators of space-based weld experiments.

The absence of gravitational forces also suppresses any buoyancy effects. Because of buoyancy forces, small particles of contaminants in earth-based welds will tend to either float to the weld surface or sink to the weld bottom depending on their density relative to the weld pool liquid. Surface energy effects may cause these particles to accumulate near surfaces. In low-gravity environments, it would be expected that these particles would remain suspended in the liquid pool as it solidifies. If these particles are good nucleants for metallurgical transformations in the weld metal, those transformations would tend to be enhanced. The result would be a difference in the microstructure between earth-based and space-based welds.

Differences between the distribution of inclusion particles in earth-based versus space-based welds has been observed. The effects of buoyancy and of cooling rate on actual welds were examined based on experiments conducted on Skylab in June of 1972. Some of those effects are discussed below.

Russian Welding Program. Space welding has long been a priority for the space program of the former Soviet Union. In 1969 Soyuz-6 performed the first welds in space on AMG6 and DM-20 aluminum alloys using the Vulkan apparatus. This work was carried on by the E.O. Paton Welding Institute of the Ukraine SSR Academy of Sciences. This work was conducted to develop methods of space repair and construction. Soon thereafter, the United States performed space welding experiments onboard the first manned Skylab Mission in June of 1973. Russian welding efforts have continued, and a portable EBW system has been developed. This hand-held EBW system is currently available for use on aircraft on the Mir space station.

United States M512 Experiments. The M551 EBW experiment was conducted in 1973 by astronaut Pete Conrad inside the multiple docking adapter of Skylab. Figures 3 and 4 show the Skylab spacecraft and the M512 material melting apparatus, respectively. The objectives of the M551 experiment, as described by McKannan and Poorman (Ref 1), were to demonstrate the feasibility of EBW in space and to investigate the differences caused by microgravity. The three materials tested included 2219T87 aluminum alloy, 304 type stainless steel, and tantalum. The aluminum and stainless steel alloys were chosen due to their commonality of use for aerospace applications; the tantalum was chosen as a nearly pure material with no complex phase transformations that would provide information on grain size and other physical and mechanical influences by microgravity. The density, melting point, thermal conductivity, and composition of these base metals are listed in Table 1. In this experiment, an electron beam was used to cut and also produce a weld bead on a 165 mm (6.5 in.) diam rotating disk that varied in thickness from 0.64 to 6.4 mm (0.025 to 0.250 in.) for the stainless steel and aluminum, and from 0.43 to 1.57 mm (0.017 to 0.062 in.) for the tantalum. Finally, the beam was directed at a stationary point on the disk to make a single dwell weld and tO produce a large molten pool. The electron-beam gun was held a constant distance of 38 mm (1.5 in.) with beam adjusted to 80 mA (70 mA for the tantalum sample) and 20 kV. These samples were then compared to samples welded with a duplicate earthbound apparatus using the same welding parameters. All the samples from this experiment were examined in depth at the Battelle Memorial Institute (Ref 2) and at NASA laboratories. In addition, several other organizations received samples for testing and evaluation.

TANTALUM	**GRAIN REFINEMENT** **DECREASED WELD POOL SAG** **INCREASED NUGGET SYMMETRY**

A subsequent investigation by Nance and Jones at the Colorado School of Mines has shown that both the grain size and the inclusion distribution were affected by the microgravity environment. This study concentrated on the tantalum material. It had been previously hypothesized that the grain size of the weld made in space would be larger due to the reduced cooling rate of the liquid pool. This hypothesis was contradicted by the observation of a 23% reduction in grain size observed in the Skylab tantalum welds in comparison to the earth-based welds. Figures 5(a) and 5(b) compare the grain size of the earth-based and Skylab tantalum welds. A similar grain size reduction was also noted in the aluminum and stainless steel alloys. The mechanism for grain size refinement in these alloys is complex, and it is difficult to draw

direct conclusions. For the pure tantalum samples, there were no solid-state transformations; however, the grain size change may be attributable to an inoculant nucleation mechanism.

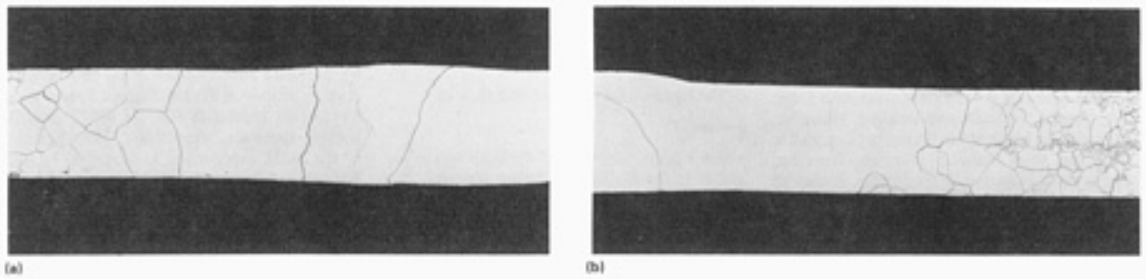

FIG. 5 COMPARISON OF (A) GROUND-BASED AND (B) SKYLAB-BASED WELDS IN PURE TANTALUM SAMPLES. NOTE THE LARGER GRAIN SIZE IN THE GROUND-BASED WELD. SOURCE: REF 2

Utilizing scanning electron microscopy (SEM) with energy dispersive x-ray analysis and scanning Auger spectroscopy (SAS), it was determined that oxide inclusions were well distributed throughout the Skylab welds. In the earth-based welds, these oxide particles, possibly due to the influence of gravity-induced buoyant forces, had floated to the top surface of the weld pool. Figure 6(a) is a SEM micrograph of the Skylab tantalum weld. There is a large carbide particle near the center of the SEM photomicrograph, as confirmed by the SAS carbon map shown in Fig. 6(b). Figure 6(c) is the SAS oxygen map, showing only a small accumulation of oxide particles near the surface of the weld, with a well-distributed oxide particle dispersion in the center of the weld. The earth-based weld showed virtually no oxide particles in the middle of the weld and a very heavy accumulation of oxides at the weld surface.

Future of Space Welding

The most important space-based welding application for long-duration manned spacecraft is repair welding. This technology offers the possibility of decreasing assembly time and decreasing the weight and cost of space structures. However, before welding technology can become commonplace in space, several steps must be taken. These involve the development of processes and controls that allow highly reliable welds to be performed in space. These steps include:

- DEVELOPMENT OF EQUIPMENT THAT HAS SUFFICIENT SENSOR TECHNOLOGY TO REPORT IN REAL TIME THE QUALITY OF WELDS AND TO FACILITATE REAL-TIME PROCESS CONTROL AND CORRECTION OF WELDS IN PROGRESS
- CHARACTERIZATION OF THE DIFFERENCES IN SPACE-BASED WELDS AND EQUIVALENT EARTH-BASED WELDS TO PROVIDE A BASIS FOR MODELING AND UNDERSTANDING OF THE DIFFERENCES IN THESE WELDS
- PROCESS DEVELOPMENT FOR WELDS CONDUCTED IN SPACE

If these three actions are taken, welding can potentially become the preferred method of joining metallic components in space and an important method for the long-term maintenance of structures, including large space-borne structures that are independent of earth.

The Need for Automation. Earth-based welding is a difficult task and requires both significant skill as well as time-consuming and tedious effort. If performed manually, space welding will be, at best, a very difficult task. The problems with space welding are compounded if the welding is to be done outside the spacecraft environment. Extra-vehicular activity (EVA) requires large numbers of ground personnel and considerable time and preparation by the mission specialist. In order for spacecraft crews to have the skill level required to make critical welds, considerable time and additional effort would have to be expended. Such training would be very expensive. Computer intelligent autonomous or semi-autonomous welding systems will probably be the most cost-effective means for space welding, particularly for EVA welding.

Intelligent Engineering/Planning Systems. Recently developed systems have demonstrated the possibility of coupling extensive databases with artificial-intelligence-based software to produce "intelligent" engineering and planning software that can make many routine engineering decisions for welding applications and guide a human user to optimum decisions for welding. These systems utilize expert system and neural network technology to provide accurate weld process models and engineering decision-making capability. This subject is addressed for earth-based welding applications in the article "Intelligent Automation for Joining Technology" in this Volume.

Intelligent engineering and planning workstations that are electronically coupled to automatic welding machines will substantially reduce the need for time-consuming work by mission specialists. The planning and development of welding schedules and procedures can be accomplished in a matter of a few minutes on a computer terminal rather than hours of work by hand. By having a complete set of databases and most of the routine engineering completed by the computer, the human user will need only to answer a few questions about the application, and the system will produce a complete welding plan and weld schedule that can be downloaded directly to the automated welding system. Such systems will offer considerable cost savings and manhour reduction while at the same time providing a carefully optimized welding plan and procedure.

Welding in Space and Low-Gravity Environments

Joining of Organic-Matrix Composites

L.J. Hart-Smith, McDonnell Douglas Aerospace

Introduction

SUCCESSFUL ADHESIVE BONDING of organic-matrix composites is dependent on the nature of the adherend surfaces. Factors that influence the integrity and durability of composite-to-composite bonds include wetting of the adherend, cleanliness of the substrate, chemical and physical properties of the adherends, and joint design. In this article, major emphasis is placed on the critical importance of proper surface preparation; both thermoset and thermoplastic composites are covered. The techniques used to analyze and design adhesively bonded composite joints are described in a companion article (Ref 1). Additional information can also be found in *Adhesives and Sealants,* Volume 3 of the *Engineered Materials Handbook* published by ASM International.

Joining of Organic-Matrix Composites

L.J. Hart-Smith, McDonnell Douglas Aerospace

Common Problems Encountered

The Importance of Proper Processing. It is well known that the adhesive bonding of metal structures requires strict adherence to the process specifications if the glue is to remain stuck for a long service life. It is also apparent that not all approved specifications are adequate. The Primary Adhesively Bonded Structures Technology (PABST) program (Ref 2) was conducted to demonstrate the tremendous benefits to metallic aircraft structures from good adhesive bonding, to associate previous problems in service with processing techniques that should be discontinued, and to validate the use of phosphoric acid anodizing with a corrosion-inhibiting primer as a reliable technique--as durable as the British chromic acid anodizing with Redux adhesive, and easier to use.

Only when the adhesive is stuck securely to the adherends is it possible to develop a bond strength that can be relied upon. Only then is it possible to use rational design procedures in which the joint can be designed for the bond to never fail, or if it does fail, for the failure to be characterized by cohesive failure of the adhesive layer itself. The interfacial failures associated with improper or inadequate processing are both unpredictable and variable--so variable, in fact, that

neither the strength nor fatigue life can be established. This poor processing is the source of the so-called "weak bonds" that are discovered only after the structure has fallen apart.

Industrial experience with bonding of both metals and composites has shown that it is very easy to fabricate defective bonds that are strong enough to pass all initial inspections, but that have only a small fraction of the strength to be expected from properly processed bonds. Techniques for creating suitable surface preparations must be followed to achieve the normal situation in which the bonds are so much stronger than the thin members they join that all failures will occur outside the joint. The necessary steps are not difficult, but are often omitted because of a failure to appreciate the need for them.

Unfortunately, the importance of surface preparation for the adhesive bonding of fibrous composites is not widely acknowledged. Robert Schliekelmann, the pioneer of Redux bonding at Fokker, was sufficiently concerned about this oversight to make a plea for more attention to this issue (Ref 3). Hart-Smith and co-workers at Douglas Aircraft Company prepared a document on surface preparation of fibrous composites to help the airlines until repair manuals were completed (Ref 4). When this document was reprinted in the Canadair house journal (Ref 5), every experiment had to be repeated to create new photographs and every phenomenon was duplicated in order to verify that the problems discussed in the Douglas Aircraft article really existed.

A similar concern was expressed in England, where Parker and Waghorn (Ref 6) reported on a far more comprehensive test program on the effects of surface preparations on adhesive bond strength for carbon-epoxy laminates. They also concluded that composite surfaces must be abraded to achieve strong adhesive-bonded joints. Pocius and Wenz (Ref 7) advocated the use of Scotchbrite pads with embedded abrasive particles as an effective and reliable surface preparation technique for achieving good composite bonds (Ref 7). The form of Scotchbrite giving the best results is of the consistency now used widely in floor-scrubbing pads, which is a little finer than that used in rotary discs for stripping rust from automobiles before repainting.

Sources of Defective Bonds. A major source of defective bonding of composite adherends is the omission of a thorough mechanical abrasion of the surface, either by a low-powered grit-blast machine or thorough sanding, following the removal of a peel ply from the surface of the laminate. Grit blasting is shown to lead to the best thermoset bonds, which are enhanced by the use of an adhesive film cured on the surfaces of the part as it is made. Although peel plies can protect against gross contamination, they do not create a surface that is easily wetted by adhesives. Despite the cautions about the many wrong ways to make bonded joints, correct processing is neither difficult nor expensive and results in strong durable structures.

Most, if not all, peel-ply surfaces are inadequate for adhesive bonding. This is a contentious issue because many bonded composite structures are so thin that the laminate or honey-comb core fails first during testing, even when the bond is less than 10% effective. However, that is often not the case in service. It has sometimes been found that when a part damaged in service is disassembled to provide access to abrade the surfaces for a bonded or co-cured repair, it is relatively easy to break the bonds apart without delaminating much of the composite. In such a case, all of the original bond area that was neither detected as defective during initial inspection, nor delaminated as the doublers and stiffeners were removed from the skin, should be regarded as weak (defective) bonds that could not be detected by ultrasonic inspection. This fraction of the bond area may be as high as 90% of the total if the original bonding had not been processed correctly. This condition is usually associated with virtually all of the adhesive on one surface or the other, when assessed locally, although the surface to which the adhesive adhered may vary throughout the total bond area. The local areas in which there was no adhesion are typically quite large and cannot be mistaken for porosity.

It is extremely rare to see half the bond completely covering each surface after disassembly; the cohesive strength of the adhesive layer, if it has been processed correctly, is usually so much greater than that of the adherends that trying to pry good bonds apart will result in delaminating the composite, not the adhesive layer. As a point of reference for the tremendous peel strength of most modern adhesives, attempts to salvage machined metal fittings from completed test panels for reuse on later panels in the PABST bonded metal fuselage program were largely fruitless, even when the structure was struck with sledge hammers and cold chisels after chilling the panels with liquid nitrogen. (Some older adhesives have so little peel strength at low temperature that it used to be possible to disassemble bonded metal structures by giving them a sharp rap after chilling them with dry ice.) It would seem to make more sense to heat bonded composite structures above the glass transition temperature for the adhesive, but below that of the parent laminate to facilitate safe disassembly. The disadvantage here would be that the working environment of some 120 °C (250 °F) would be rather unpleasant, unless it could be confined to the immediate vicinity of the area of prying by using a jet of hot air.

There is no history of bonds that were truly good at the time of manufacture deteriorating in service. There have, however, been numerous instances in which the interface of a metal bonded structure has corroded in service because it had not been properly prepared in the first place and was just sound enough to pass the initial inspection. Although poor composite bonds deteriorate by mechanisms other than corrosion, they share with poor metal bonding the characteristic that their short-term static strength is sufficient to conceal their deficiencies. Weak bonds have been notoriously difficult to detect prior to failure when only the parts have been examined; however, they are easy to identify after failure and can be recognized reliably from a straightforward reading of the process monitoring records and an on-site survey of the procedures followed (and ignored) during manufacture. The process monitoring records should always take precedence over successful test coupon results, even when it means rejecting and rebuilding (not reworking) complete assemblies.

The reason for the difficulty in bonding of polymer composites is that it is difficult to create strong chemical bonds between the adhesive and a cured (and therefore largely fully crosslinked) polymer matrix. The cured surface needs to be activated and, even then, chemical bonds may be degraded by absorbed water (Ref 8). The most durable bond strengths rely upon mechanical interlocking of the adhesive and the thermoset composite surface, just as with the primer and porous anodized surface on metal adherends. If the surface is not adequately roughened, the glue will not stick, even if the surface is not contaminated. The most common contaminants are industrial-grade cleaning solvents and coupling fluids for ultrasonic inspections. These are particularly difficult to remove from delaminations and areas of porosity. Failure to remove them completely results in a bond with inadequate adhesion to the adherend, just as is the case with a metal-bond surface that had been contaminated before the primer was applied.

Effects of Absorbed Moisture. Water is the most widespread and troublesome source of defective bonded joints and repairs in composite structures. It may be absorbed by the basic composite material before it is ever cured. If it is not removed by drying prior to curing or by venting during cure, it will result in porosity as well as harmful changes in the chemical structure of the polymer. Water may also be absorbed by uncured adhesive films that have been improperly stored or that have not thawed out before being unwrapped after removal from the freezer or that have been subjected to an extended layup time in a humid work environment. Adhesives vary in susceptibility to this problem, but most have a far greater affinity for water than do epoxy prepregs. The consequences are much the same, and just as detrimental. Water may also be absorbed within cured laminates that are to be secondarily bonded either during initial manufacture or as part of an in-service repair. If this water is not removed by slow drying prior to bonding, the water will react adversely with the adhesive and result in defective bonds. Cured epoxies have very low diffusion coefficients, so water is not absorbed very rapidly. However, they cannot be dried rapidly for the same reason.

A systematic series of tests to differentiate between the effects of different kinds of prebond moisture has not been carried out to date. However, a weak, porous adhesive that crumbles easily into powder when the fractured surface is handled after the adhesive layer has been exposed, but that has stuck to the adherends, can be associated with too much moisture absorbed by the adhesive before cure. A perfectly sound solid adhesive film that simply did not stick is more likely to be caused by precured laminates to be bonded that were not dried or by condensate on the surface of an otherwise dry adhesive film that was unwrapped too soon after removal from storage in the freezer. However, some film adhesives left out for several days in a humid layup area can absorb so much water that they will not stick even if they are not visibly covered by condensate during layup. Even then, there is a chance that the strength of the fillets at the edges of the bonds will be sufficient to disguise the weakness by preventing the parts from falling apart after completion of the cure.

Labor and Myhre (Ref 9) found that if they did not dry the parent laminate first, they could not attach even a single 0.13 mm (0.005 in.) thick carbon-epoxy tape without serrating the ends with pinking shears. With square-cut ends, the single layer would rapidly delaminate under fatigue loads of only about 25% of design limit load. Obviously, however, such weak bonds would have passed all nondestructive inspections at the time the repair was executed. The only way of knowing that the bond would have failed had it been placed in service was recognition that water definitely was present during the cure of the adhesive--water that was added deliberately to make the coupons representative of structures in service that were being quickly repaired without first being dried out slowly and carefully. In extreme cases, with a rapid temperature rise during bonding, the parent laminate may even split apart because of the steam generated by the water that was unable to escape fast enough. Figure 1 shows the dramatic reduction in the hot-wet strength of adhesively bonded joints caused by as little as 0.25% absorbed moisture in the composite laminates before bonding. Less than 20% of the room-temperature strengths were retained. Figure 2 shows equally dramatic losses in the fatigue life under slow-cycle testing of bonded aluminum joints as a function of different levels of prebond moisture in the adhesive film prior to bonding.

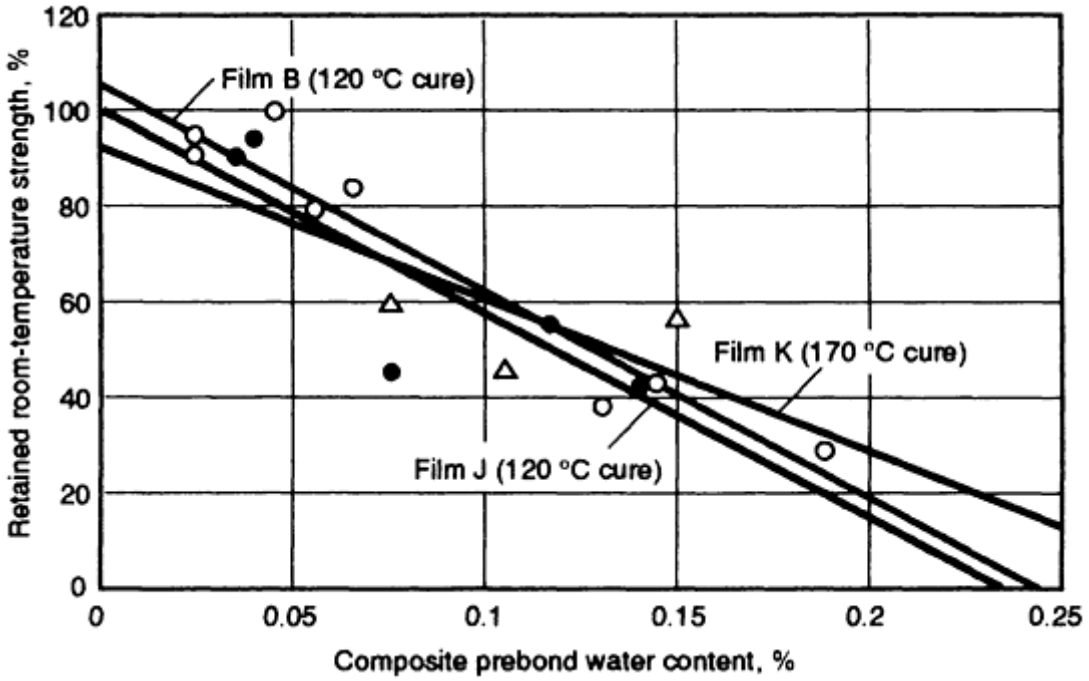

FIG. 1 EFFECT OF MOISTURE CONTENT ON THE HOT-WET BOND STRENGTH OF CARBON-EPOXY COMPOSITES. SOURCE: REF 10

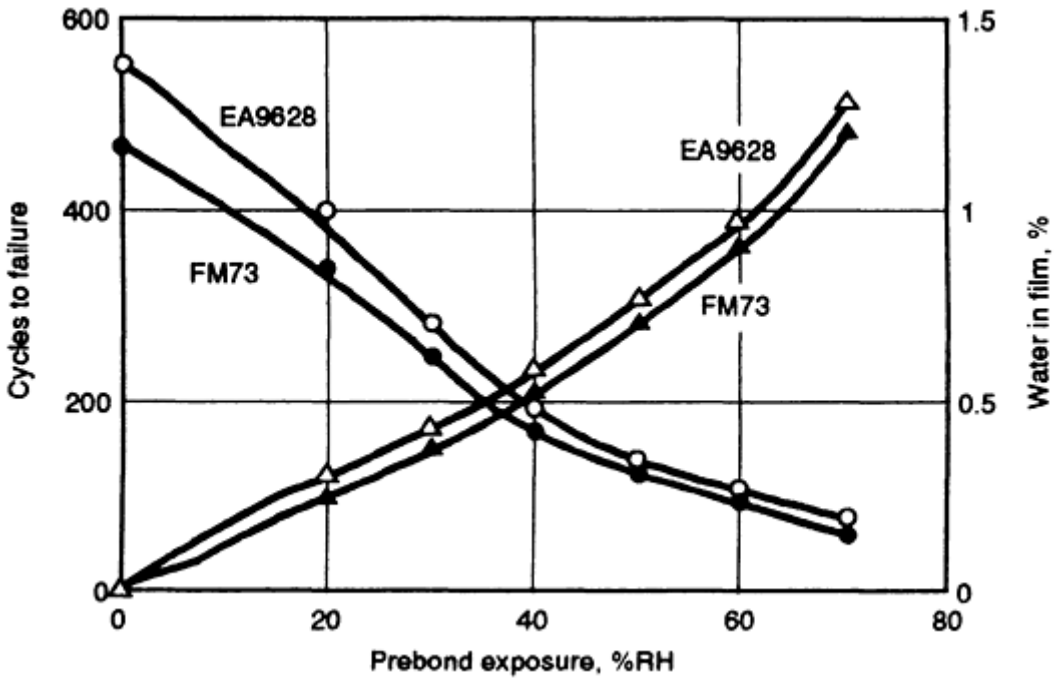

FIG. 2 EFFECT OF PREBOND MOISTURE ON FATIGUE STRENGTH OF ADHESIVELY BONDED ALUMINUM JOINTS. FILMS WERE PRECONDITIONED FOR 10 DAYS AT ROOM TEMPERATURE. RAAB SPECIFICATIONS, 10.3 MPA (1500 PSI), 4 CYCLES/H, 60 °C (140 °F), 100% RELATIVE HUMIDITY (RH). SOURCE: REF 11

Although the evidence is not yet absolutely conclusive, the epoxy resins may be more tolerant of absorbed moisture than is generally acknowledged if moisture can easily be driven off early in the cure cycle. However, if there are no vents to allow the steam (or solvents) to escape, as is often the case with no-bleed cure cycles, moisture cannot be driven off. There is conclusive evidence that the combination of the presence of moisture and a closed cure environment is

disastrous. However, there have been some instances with metal-bonded structures when water was known to be present in the uncured adhesive, yet the bonds appear to have been good (per service). In each case, the bonding tool permitted easy egress of the steam generated during cure. Companion panels manufactured with a different bonding tool that trapped the moisture in the adhesive from the very same rolls, passed all ultrasonic inspections but were found to be unbonded during assembly.

A similar problem arose with the two-stage bonding of a composite spoiler. Although water was present in some form during both bonds, there was adequate venting for the steam to escape while the first skin was bonded to an oversize block of honeycomb core, to stabilize it for subsequent machining of the aerodynamic profile (it is not known if the water was absorbed in the uncured adhesive film, if the Nomex honeycomb core had not been dried properly, or if the precured laminates had not been dried properly). This first bond was so strong as to give no warning of the problems to follow. When the second skin was bonded to the other side of the core, the water was trapped and the second bond had only a small fraction of the strength exhibited by the first bond. When tested, the second bond failed prematurely; it looked porous and weak, with poor filleting at the cell walls, while the first bond showed good filleting, as if the water had never been present.

The above examples are included not as an invitation to disregard the concerns about moisture present during the cure, but as encouragement to pursue this subject further to see if there are any consistently reliable alternatives to careful drying prior to bonding, which is obviously time consuming and costly. It is also intended to emphasize the need for venting during cure. There are other known instances in which simple thin laminates have suffered locally from very wavy fibers caused by the lack of an escape path for bubbles of gas created from the solvent used during the process of impregnating the fibers with resin. The bubbles lifted the fibers off the tool surface, pulling the ends in toward the bubbles. Eventually, the bubbles burst, causing the fibers to wrinkle as they were flattened out. There was no mechanism to push the fibers back to where they had been.

Difficulties in Detecting Defective Bonds. The most difficult aspect of defective bonds caused by prebond moisture or inadequate surface preparation is that the condition cannot be detected by ultrasonic inspection. It must be avoided by adherence to the correct procedures--which may differ from those specified--during processing because the weak bonds resulting from such errors cannot be repaired, even if they are detected before they fail. The parts must be disassembled, the surfaces cleaned and prepared again and the entire bonding cycle repeated. In general, it is easy to rework improperly manufactured mechanically fastened metallic structures and to restore 100% of the design strength. That is not true for either adhesively bonded metal or composite structures; the rework is difficult and the strength recovered far less than complete. This is why it is so important to do the job properly in the first place.

The cost of accepting defective parts is compounded as the original panels are embedded ever more deeply in the structural assemblies. It is bad enough when the defects are unrecognized because the end-item inspections are ineffective; inspection can exclude a few very bad parts, but cannot ensure the integrity of the great majority of assemblies. It is worse when parts are recognized as defective from a visual inspection, but are accepted anyway on the basis of coupon tests or ultrasonic inspections.

Bonding of Thermoplastic Composites. Thermoplastics are far more difficult to bond than are thermoset composites, but good results have been achieved by chemically etching the surface prior to bonding. The most promising approach for joining thermoplastic composites appears to be fusion bonding, using a compatible surface layer of plastic that melts at a lower temperature than that needed to melt the parent matrix. The ability of typical modified epoxy adhesives to bond chemically to the thermoplastic matrix is even less than for thermoset composites. Also, the thermoplastic surface is so resilient that it is very difficult to abrade sufficiently without breaking too many surface fibers in the process of creating the roughened bond surface. The best bonds made with layers of thermoset adhesives between thermoplastic adherends seem to have a strength of only about 80% of that of the best bonds using the same adhesive between thermoset adherends. One must conclude, therefore, that this loss of strength results from an interfacial bond strength that is weaker than the intrinsic cohesive strength of the adhesive layer. It follows, therefore, that the strength to be attained would be highly variable, as would the service life. Far better success has been achieved by chemically changing the surface to be bonded by oxidation using hot gases, by cold gas plasma treatment, or by corona discharge. The surface energy is increased by each of these techniques, permitting better wetting by the adhesive. However, these processes are rather slow if a large area has to be covered.

Success in bonding thermoplastics has also been achieved by fusion, or welding. The best success has been achieved when the original thermoplastic laminates have been fused together with a special surface layer of a different polymer that can be melted at a lower temperature than is needed to melt the base laminates. Direct fusion of thermoplastic laminates often results in considerable distortion, even if a structurally sound bond is achieved. Even making thermoplastic

composites using focused local heat to fuse each ply to the substrate has proved to be a slow process that is not well suited to large panels.

Similarly, it is common practice in making thermoset composite aircraft panels to include a surfacing layer of film adhesive co-cured with the parent matrix to both facilitate getting the paint to adhere and to provide a tough gel coat to compensate for the excessively dry surface plies in normal composite laminates. (The weight of this surfacing layer is less than that of the glazing that would otherwise need to be applied, by hand, to avoid pinhole porosity and an unacceptable paint finish.) Curiously, less use is made of this concept for preparing surfaces to be bonded, although an Australian firm has reported great success with it (Ref 12).

Examples of Good and Bad Adhesive Bonds

Properly Processed Bonds. Figure 3 shows the magnified fractured surface of a properly processed adhesive bond, with continuous coverage of the adherend. With composite adherends, this condition can occur only in test coupons deliberately designed with so little bond area that the bond will fail by shear. It is also necessary to suppress the generation of peel stresses at the ends of the overlap, by keeping the tip thickness of the adherends low. Properly designed structural joints will always fail outside the bond area, and while a coupon test based on such a joint can confirm the adequacy of the design, it cannot confirm that the processing was done properly because there is no fractured bond line to inspect. In properly designed bonded joints, the integrated shear strength of the bond should exceed the load needed to fail the adherends. It is almost impossible not to satisfy this condition for thin adherends, even for improperly processed bonded joints that will fail in service, but are strong enough to pass all the initial inspections. However, for thick adherends, it becomes necessary to use stepped-lap joints to prevent the bond from becoming a weak-link fuse.

FIG. 3 COHESIVE FRACTURE SURFACE IN A PROPERLY PROCESSED COMPOSITE-TO-COMPOSITE ADHESIVE BOND. VISIBLE FIBERS ARE THE RANDOM MAT CARRIER IN THE ADHESIVE FILM. 68×

Adhesion Failures. * Figure 4 shows a typical adhesion failure in which the adhesive almost totally failed to adhere to one of the adherends because the surface had not been adequately roughened. Although this photomicrograph is of the surface of the adhesive, not the composite, it clearly shows the imprint of the peel-ply woven surface to which it had not bonded over most of the surface. The comparison between the two modes of failure is dramatic. This failure of the adhesive to bond to a surface arises frequently when an attempt is made to bond directly to the surface that remains after removal of a peel ply, but it also occurs when one tries to bond directly to the other surface of the laminate, which is usually contaminated by release agents used to prevent the part from sticking permanently to the layup tool.

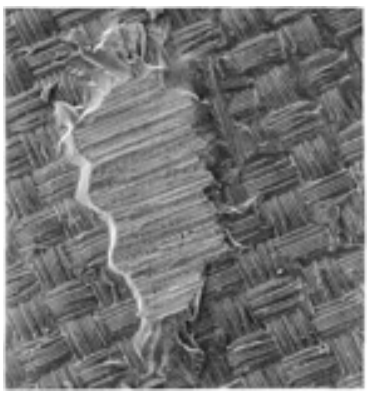

FIG. 4 ADHESION FAILURE SHOWING IMPRINT OF THE PEEL PLY AND FAILURE TO BOND OVER MOST OF THE SURFACE. A SMALL PIECE OF RESIN ADHERED AND IS IDENTIFIED BY THE IMPRINT OF THE FIBERS. 27×

In a different kind of adhesion failure, the adhesive does not remain in one continuous disbonded layer, but remains attached to one of the adherend surfaces in discrete full-thickness fragments. The underlying shiny peel-ply surface is clearly evident in the holes in the adhesive on both surfaces. Roughly half the adhesive is attached to each surface, but

only weakly. This kind of fracture has been observed in uncontaminated bond surfaces that had not been mechanically abraded to make the glue stick. It is the author's belief that this condition, in contrast to that shown in Fig. 4, can occur only in conjunction with small amounts of moisture trapped in the adhesive as it cures. Given that the interfacial bond is uniformly poor, it seems inconceivable that it could have been strong enough to tear a properly cured adhesive film from side to side. However, it is well known that a weak powdery bond results if the adhesive is cured in the presence of moisture. This moisture can either be absorbed by the adhesive film, through improper storage and handling, or by the laminate during service (with even more absorbed moisture, some adhesives will not stick at all). Actually, even the time involved between detail manufacturing and assembly can be sufficient to permit the absorption of sufficient moisture to create a weak powdery adhesive bond, even if the bond surfaces had been properly prepared by thorough abrasion. The laminates need to be stored in sealed containers until bonded or in a dehumidified air-conditioned room.

Inspection Methods. None of the structural deficiencies associated with weak or improperly cured adhesive bonds are detected by conventional ultrasonic nondestructive inspection (NDI), and it is most improbable that they could be detected prior to a gap being opened up by mechanical failure in service. Although the fillets at the ends of the bond overlap will be visibly porous for adhesives cured with trapped prebond moisture, it is usually only the hot-wet lap-shear tests that fail to meet the specified strengths. Consequently, the customary room-temperature tests that follow would not have caught this condition had it been on a real part. Figure 5 shows why visual inspections of adhesive bonds can be more informative and reliable than conventional ultrasonic NDI. More reliable results can be obtained from a visual inspection of the fillet than from either ultrasonic inspections or a defined "adequate" lap-shear test result on a coupon with abnormal fillets. Ironically, the ultrasonic signals are unreliable in the immediate vicinity of the edges of panels--which are the only locations where any significant load is transferred through bonded joints.

Note cited in this section

* *IT IS A COMMON MALPRACTICE TO USE THE WORDS "ADHESIVE FAILURES" EXCLUSIVELY TO DESCRIBE ONLY THOSE SITUATIONS IN WHICH THE ADHESIVE ITSELF HAS *NOT* FAILED, BECAUSE ADHESION IS A NOUN AND NOT AN ADJECTIVE. ACTUAL FRACTURE OF THE ADHESIVE ITSELF IS DESCRIBED AS A COHESIVE FAILURE. THE FORMER FAILURE OCCURS WHEN THE GLUE HAS NOT ADHERED TO ONE OR BOTH ADHERENDS. THE CURRENT MEANING ASCRIBED TO ADHESIVE FAILURES IS THUS VERY MISLEADING, EVEN IF IT IS GRAMMATICALLY CORRECT. IN THIS ARTICLE, THE WORD ADHESION IN PLACE OF ADHESIVE WILL BE USED IN THIS CONTEXT.

Surface Preparation for Thermoset Composite Adherends

While not always used in production, light grit blasting, thorough sanding, or some other form of mechanical abrasion are the best surface preparations for both adhesive bonding and painting of thermoset composites. This is confirmed by the test results shown in Fig. 6. As shown in this figure, the best example of sanding was as good as the grit-blasted coupons, but all other treatments were markedly inferior.

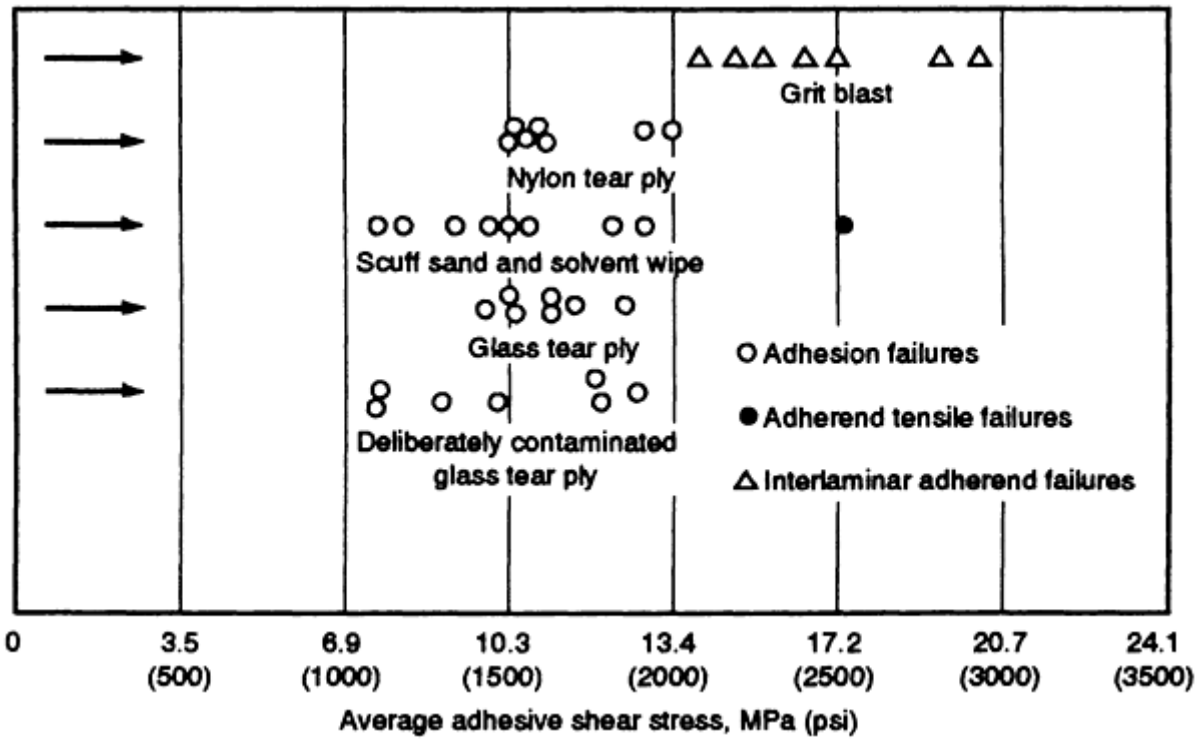

FIG. 6 EFFECT OF SURFACE PREPARATION ON THE STRENGTH OF DOUBLE-LAP GRAPHITE/EPOXY-TO-ALUMINUM ADHESIVE JOINTS (13 MM, OR $\frac{1}{2}$ IN., OVERLAP)

Peel-Ply Surfaces. While it is extremely difficult to ensure that a peel-ply surface will be satisfactory before the peel ply is removed, it is quite easy to evaluate the surface after removal in time to prevent bonding to an unsatisfactory surface. Figure 7 shows a magnification of the imprint of a nylon peel ply that had supposedly been corona treated to enhance its adhesion to the resin matrix to create a fresh fractured surface over the entire bond. Yet it is quite clear that, at the microscopic level, the surface is absolutely slick. The groove left by every fiber in the peel ply is clearly shown. The matrix is fractured over only an extremely small fraction of the surface, as shown in the higher magnification view of the same surface in Fig. 8. The adhesive will stick only to the fractured surface, not the obviously ultraslick surface so clearly evident in most of Fig. 8. The adhesive could bond to barely 10% of this surface and will not stick anywhere else. A reliable peel ply would leave an imprint so rough at the microscopic level that the weave of the peel ply so prominent in Fig. 7 would never be seen.

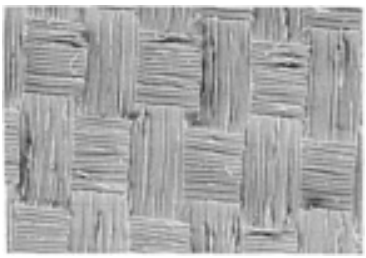

FIG. 7 IMPRINT OF A NYLON PEEL PLY LEFT AFTER REMOVAL FROM COMPOSITE LAMINATE. 58×

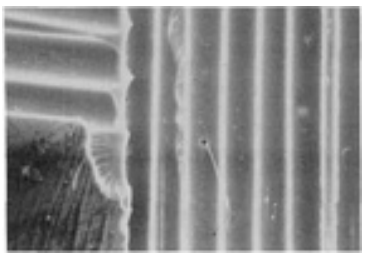

FIG. 8 IMPRINT OF A PEEL PLY SHOWING EXTREMELY SMALL FRACTION OF SURFACE COVERED BY FRACTURED RESIN MATRIX TO WHICH THE ADHESIVE COULD BOND. 580×

Figure 9 shows the imprint left by a different peel ply, that was believed to be producing satisfactory bonds, or at least much stronger bonds than had been achieved using another peel ply that left a surface like that shown in Fig. 7. There is clearly far less imprint visible in Fig. 9 than in Fig. 7, and far more fractured surface resin. Even so, one would be relying on good adhesion to no more than about 30% of the total area. Also, the surface in Fig. 9 is so rough as to be likely to trap pockets of air between the adhesive and the substrate. Fortunately, unless they coalesced, these air pockets would prevent contact only between the glue and those parts of the laminate to which it would not stick anyway.

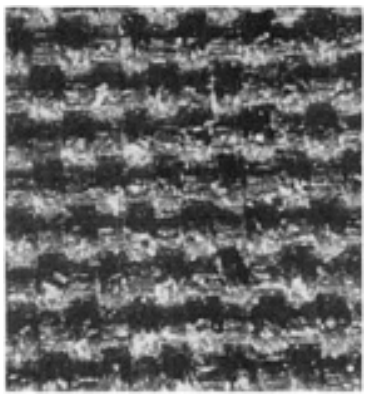

FIG. 9 IMPRINT OF A BETTER PEEL PLY ON A COMPOSITE SURFACE SHOWING A FAR GREATER FRACTION OF FRACTURED RESIN OF THE SURFACE. 34×

The real purpose of peel plies is to protect against gross contamination, which is removed as the peel ply is lifted off. Its removal must be followed by grit blasting or by sanding so thorough that all traces of the imprint from the peel ply have been removed. Figure 10 shows a scanning electron micrograph of a carbon-epoxy composite thoroughly sanded with 120 grit abrasive. There is no similarity with either Fig. 7 or Fig. 9. However, if the abrasion is so severe as to expose bare fibers, from which the surface treatment (coating) has been removed everywhere by sanding, the bond will be even

weaker. The solution to this problem is a resin-rich surface layer, like a conventional gel coat applied to simple fiberglass composite components before they are painted.

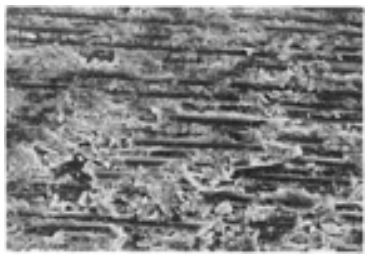

FIG. 10 SURFACE OF A CARBON-EPOXY COMPOSITE AFTER 120 GRIT ABRASIVE SURFACE PREPARATION. NOTE EXPOSED FIBERS AND SMALL AMOUNT OF DAMAGED FIBERS. 415×

Peel plies are either coated with release agents so that they will not delaminate the composite they are meant to protect or are so slick that the surface is like a mirror at the microscopic level. In either case, the glue cannot stick, except at the small nodules of fractured laminating resin in between the bundles of fibers in the weave of the peel ply. This increment of strength is often sufficient to bond successfully honeycomb cores in sandwich construction. Providing that all the remainder of the processing is done properly, even this limited bond strength is often enough to break the core away from the faces. In addition, this bond strength seems always to be enough to pass any ultrasonic NDI tests, even for faying-surface bonds. Another reason for thorough abrasion after removal of a peel ply is that the polymer molecules formed adjacent to the peel ply (or released tool surface) are oriented in such a way as to make them very difficult to be wetted by the adhesive. A stronger bond is possible in the more randomly oriented interior molecules.

Alternatives to Peel-Ply Surfaces. An alternative technique used to some extent in both Europe and North America is to not use a peel ply as such, but to add an extra layer of preimpregnated fine-weave aramid cloth to both surfaces of the composite laminate, using the same resin as for the primary laminate. This achieves two things. First, it avoids the acutely resin-starved surfaces left as the conventional dry peel plies absorb resin from the base laminate; second, it ensures a completely roughened surface to which to bond, without any trace of release agent from the caul plate.

Tests using fiberglass tear plies that were not intended to separate cleanly, but to remove a little resin from the entire surface, failed because the glass fibers were too brittle and broke repeatedly. The surface was contaminated, and possibly damaged as well, whenever razor blades were used to strip off the surface ply. Obviously, if the tear ply sticks too well, it will not come off alone, but will probably take one or two top plies from the laminate as well. This has been known to occur during the removal of metallic fittings from composite structures that had been installed with a layer of rubber-base sealant between the faying surfaces to prevent galvanic corrosion.

Grit Blasting. The objections to grit blasting are easier to recognize, even though they are not all valid. Grit blasting can create dust--black dust from carbon-epoxy laminates is perceived as a greater health hazard than white dust from fiberglass-polyester laminates. Also, it relies to some extent on operator skill, and if the only available grit-blasting machine must be borrowed from a nearby foundry where it is normally used to clean sand castings, it will be so powerful that it is easy to burn right through a laminate in a matter of seconds. Both of these objections can be overcome, as they were on the Lear Fan all-composite aircraft, by buying an inexpensive low-pressure machine in which the nozzle is surrounded by a ring of vacuum ports, which are themselves surrounded by a circular comb of soft bristles like those on domestic vacuum cleaners. It took only two to three days to properly train someone with no prior mechanical skills to operate such a machine. The bristles held the nozzle a fixed distance away from the work. An adequately blasted surface had a dull matt texture, which contrasted strongly against the shiny black unblasted areas nearby. The pressure was only 140 kPa (20 psi) instead of 700 kPa (100 psi), so it would take such a long time of holding the nozzle in one place to damage the composite surface that it would be obvious that something was wrong long before any damage actually occurred. The grit-blast machine was used in a room that was depressurized slightly with respect to the rest of the factory, but there was no need for protective clothing or respiratory masks. A fixed machine with many nozzles under which the parts pass on a roller table has also been developed. The nozzles may someday be computer controlled.

Currently, there are many forms of grit available, some of which are recyclable. Aluminum oxide (Al_2O_3) has been used traditionally, but is sufficiently expensive that recirculation of the used grit must be considered. It would seem that the use

of recirculated abrasives can be permitted on an otherwise uncontaminated peel-ply surface. However, so much release agent is transferred from caul plates to the adherend surface that no recirculation can be permitted on that kind of surface. Examples of inexpensive media are plastic beads, which can be separated from the debris by floatation in a water tank, biodegradable corn husks, and a number of powders, such as sodium bicarbonate, which can be recovered from aqueous solutions. Since chemical paint stripping is being outlawed, there is considerable pressure to come up with safe replacements. Grit blasting is certainly preferable to the use of jets of hot air, which have been observed to burn as many as two surface plies to the bare fibers in several places on thin-skinned fibrous composite parts.

Perhaps the most compelling argument in favor of using grit blasting is that none of the more widely used techniques for initial production can ever be used for repairs, whether by an airline during service or by the original manufacturer because of damage during manufacture. For example, a peel-ply surface cannot be recreated on a previously cured laminate--one is forced to abrade it.

Joining of Organic-Matrix Composites

L.J. Hart-Smith, McDonnell Douglas Aerospace

The Water-Break Test

The water-break test has long been a standard technique for verifying the adequacy of surface preparation for metal bonding. It can also be used for composite surfaces, as described in Ref 4. This is clear from Fig. 11, which compares the even wetting of a properly grit-blasted surface with the repelling of water on an untreated surface contaminated by the release agent on the lay-up tool. Although the water is on the surface for only a small time, and very little is absorbed into the laminate, some adhesives are so moisture-sensitive that it is necessary to dry even that moisture out before bonding. It would seem to make more sense to prime the composite surface after grit blasting so that it could be recleaned using solvents, than to use the water-break test on a surface known to have been prepared properly immediately beforehand. The benefit from the water-break test comes from confirming that a previously prepared panel has not been contaminated during storage.

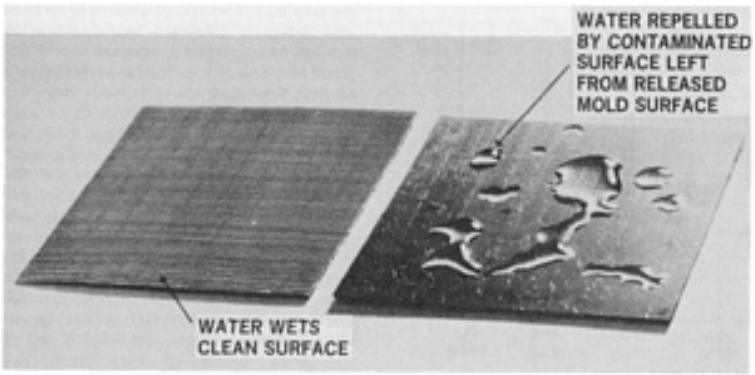

FIG. 11 COMPARATIVE WATER-BREAK TEST RESULTS. LEFT: PROPER PREPARATION. RIGHT: IMPROPER PREPARATION. COURTESY OF CANADAIR

Experience gained since the preparation of Ref 4 indicates that water-break tests are inappropriate for surfaces that have not been abraded. If water is applied to the surface left by removing a peel ply, the water will bridge between the small areas of fractured resin matrix and totally mask the unwettability of the majority of the surface. The test is ineffective in this case. Worse, it falsely creates the illusion that the surface has been prepared adequately for bonding, as well as the opportunity for someone to shift the blame for a poor bond from failure to dry out water absorbed from other sources to the microscopic traces of water left by the water-break test. Such traces are easily removed by a moderately hot air gun because the water is not on the surface long enough to permit significant absorption.

Matienzo *et al.* (Ref 13) indicate that lightly sanding the surface created by curing a laminate directly against a tool surface coated with mold release can be good enough to pass the water-break test, yet such surfaces cause bonds weaker than those achieved by untreated peel-ply surfaces. This indicates that even more emphasis must be placed on the thorough sanding or abrasion of the surface to be bonded and less on any subsequent verification. Unfortunately, their test data do not include baseline tests on anodized aluminum adherends against which the composite bonds could be assessed. One of their prime conclusions was that the simple removal of peel plies gave stronger bonds than were achieved with light sanding. However, it is significant that according to their test data, even higher average strengths were attained by deliberately contaminating one of the two peel plies by spraying it with mold release before the panel was cured. It should be pointed out that mold-release agents will stick like glue if they are not baked before a part is cured on the surface. This "contaminated" peel ply gave such better results than the uncontaminated peel ply that it is clear that the untreated peel-ply surfaces were capable of considerable improvement. Even a peel ply that showed no sign of silicon transfer gave slightly weaker average results than the spray-contaminated peel ply, although the highest individual strength was attained with the silicon-free peel ply. This peel ply was also effective in isolating the laminate from the silicon introduced from the mold release. However, as noted in their work, the use of peel plies on both sides of the part would not be applicable to compound-curved panels or to tool surfaces very much larger than available pieces of peel ply, which could not be lapped without unacceptable mark-off on the outside of the finished part. While even the highest strengths reported in Ref 13 are only about half what one might expect from a grit-blasted surface, the very low strengths they show from either gross contamination or from failure to make any attempt to remove the mold release indicate an irrefutable need for proper surface preparation for bonding polymer composites.

The change of surface texture between thoroughly abraded and bare surfaces is so great that, even though the water-break test works reliably, it is not always necessary. A visual inspection, which is capable of distinguishing between thorough and light sanding with the use of a magnifying glass, should suffice. This justification for omitting the water-break test is particularly relevant whenever the adhesive bonding follows immediately after the surface preparation and there is no opportunity for contamination. On the other hand, a drying cycle to remove water applied during the water-break test would also remove absorbed water from near the surface of the part. The omission of a compulsory drying cycle would demand great care in ensuring that the parts to be bonded had not absorbed water since their manufacture, even if they had been protected against the more widely recognized contaminants.

The water-break test would still seem to be very valuable for repairs to structures contaminated by chemicals absorbed during service or by coupling fluid for ultrasonic NDI of a porous or delaminated panel. It has already been shown to be effective in proving that most cleaning solvents applied to an unprimed surface actually contaminate the surface and need to be removed by water-soluble solvents such as alcohol. This issue is discussed in Ref 4, which includes photographs of the beach marks left as the solvent evaporates.

Experience with using the water-break test has revealed that the application of the least amount of water possible is preferable because a thick film of water can bridge a small local area of contamination and conceal a defect such as a thumb print. One needs to watch the film as it evaporates. A slow uniform drying out simultaneously over the entire surface is an indication of satisfactory surface preparation. If, on the other hand, a discrete dry area suddenly appears at some point during the evaporation, that is an indication of contamination.

Control of the Bonding Process for Thermoset Adhesives

The chemistry of creating a properly cross-linked adhesive bond is well understood by a large number of materials and process engineers. However, far fewer people who actually control autoclaves are knowledgeable of adhesive chemistry or have real-time access to such information. With the help of a polymer chemistry expert, an experienced process engineer can identify the cause of a problem and modify a cure cycle in progress to save a part that would otherwise need to be scrapped. Some of the more important process variables that need to be understood and controlled are outlined below.

Effects of Temperature Variations on Bond Strength. Some aspects of the process specification are almost so self-evident that their significance is underestimated. It is obvious that if an adhesive is heated up too slowly, it will not wet the surface to be bonded. The adhesive may eventually cure, but there will be a dry bond. Therefore, the process specifications include minimum heat-up rates. These vary with the adhesive, but are on the order of 3 °C (5 °F) per minute. Likewise, an adhesive can be made to boil if heated up very much faster, so there must be maximum heat-up rates and maximum temperatures as well. These limits present no problem when making a small, uniformly thick test panel. The problems arise when a large, complex assembly of variable thickness is either cured or bonded on a large tool having a variable heat sink. It then becomes very easy for some parts of the structure to be heated up too slowly while other parts are on the verge of being burned. For all but the simplest of parts, a proof-of-tool demonstrator should be carried out to ensure that the assembly can be properly cured the first time. It makes sense to save on the cost of this operation by using cheaper fibers with the same resin.

One solution for the problem of a large range in temperature within the composite part or assembly, once a cure is already in progress, is to put constant-temperature dwells in the cure cycle to give the various segments of the part time to equilibrate. This is best done early in the cure cycle, before any of the adhesive (or resin matrix) has gelled. Thus, in addition to maximum and minimum heat-up rates, there is a need for a maximum variation between high and low temperatures--measured on the part, not on the tool, even if that takes more time than it does to hook up a permanently wired thermocouple. In some cases, multiple dwells may be needed. There is a limit, however, since an excessive number of dwells will cause the adhesive to gel before it has a chance to wet the surface needing to be bonded.

Once such a problem is detected, blankets can be added for subsequently made parts to shield the hot spots and local heaters added to overcome the colder areas. It is not acceptable to simply disconnect the thermocouples giving the highest and lowest readings in subsequent cure cycles. It is better still to thermally isolate large heat sinks from the rest of the tool if this can be done without causing distortion of the part. A simple but effective solution to some such problems is to thermally isolate the tool from the bed of the autoclave and, wherever possible, to thermally isolate the tool surface contacting the part or assembly from the supporting structure. Other than the possibility of tool distortion, which may or may not adversely affect the product, no harm will come to the composite part or bonded assembly if it is heated correctly and only the tool support structure lags behind.

Most tools are made from metal because hand layed-up plastic tools tend to have internal voids that collapse and need patching. However, the metal tools expand and contract more than composite parts. A solution to this problem is to use autoclave-cured composite members to hold composite parts in the work station during a bond cycle. The composite holding frame is supported by the basic metal tool, but it is held at only one point and permitted to slide freely as the size of the metal tool changes. This enables linear dimensions to be held and avoids the problem of crushing the composite parts as the tool contracts during cool down. It also thermally isolates composite parts from the metal tools.

The problem of tools having excessive heat sinks arises because tool designers are used to extremely rigid tools rather than tools that are barely able to maintain their shape, but so simple and compact as to permit many of them to be loaded into a single autoclave cycle. For thin, flexible skins, it makes more sense to rack several caul plates in a single holding fixture than to make one massive lay-up and cure tool per part. The productivity of the autoclave is enhanced this way as well. While the caul plates may distort out-of-plane, they will retain their in-plane dimensions, and only light pressure will be needed to restore the profile of the parts as they are bonded into assemblies. For example, 9 m (30 ft) long Lear Fan unstiffened fuselage skin panels, which were mildly compound curved, were rolled up like giant cigars to stiffen

them for safer as well as easier handling as they were transported from the autoclave to the assembly room. The more common flat panels flex even more easily. Obviously, the entire shape must be well defined for the final bonding operation since the assembly will be too rigid to match the surrounding structure if it is made to the wrong shape. However, the bond cure cycle is typically 25 to 40 °C (50 to 100 °F) lower in peak temperature than the cure cycle for detail composite parts, so the problems of variable temperatures are diminished.

Effects of Prebond Moisture on the Strength of Bonded Joints. Another widespread problem is the need for the removal of volatiles before the start of cure and throughout its duration. Some manufacturers of composite and bonded structures want materials that are so tolerant of abusive cure cycles that it is permissible to: (1) apply full pressure from the start of the cure, flipping one switch for the heaters (with no automatic control system); and (2) to come back once during the cure at a preestablished time to cut back on the heat when the peak temperature has been attained and once more to switch the heat off when the cure is complete, preferably quickly enough not to need the services of a second shift of workers. Material development engineers have failed to create such forgiving materials, even though some process specifications permit parts to be made this way, so there are opportunities for using closed-loop control systems. Such systems, however, require experts to anticipate what should happen, what might happen, and what must not be permitted to happen--along with corrective responses.

The reliability of manufacture will be increased by demanding that all materials and parts be dried thoroughly immediately before each cure cycle. This refers also to Nomex honeycomb cores, which are known to have a great affinity for water and to absorb it rapidly if left in a humid environment. Wet cores result in weak glue fillets at honeycomb cell walls (Fig. 12). Such a goal of thorough drying exceeds the current practice at many composite manufacturing facilities today, whether or not the up-front savings exceed the consequently higher down-stream costs. But even if thorough drying were the norm, bagging procedures that permitted small amounts of moisture to be removed harmlessly during cure would also be desirable. The initial manufacturer also needs to be aware of the very high costs (to the consumer and/or the manufacturer) whenever a composite part or assembly is manufactured with sufficient trapped moisture to create an inferior part of unreliable service strength, but sufficient initial strength to be accepted after normal ultrasonic inspection. Under the prevailing circumstances, the original manufacturer is exposed to the consequences of improper processing only when there is sufficient residual strength in a rejected bonded panel to make it virtually impossible to disassemble the pieces for rebonding without destroying them by delaminations in the process.

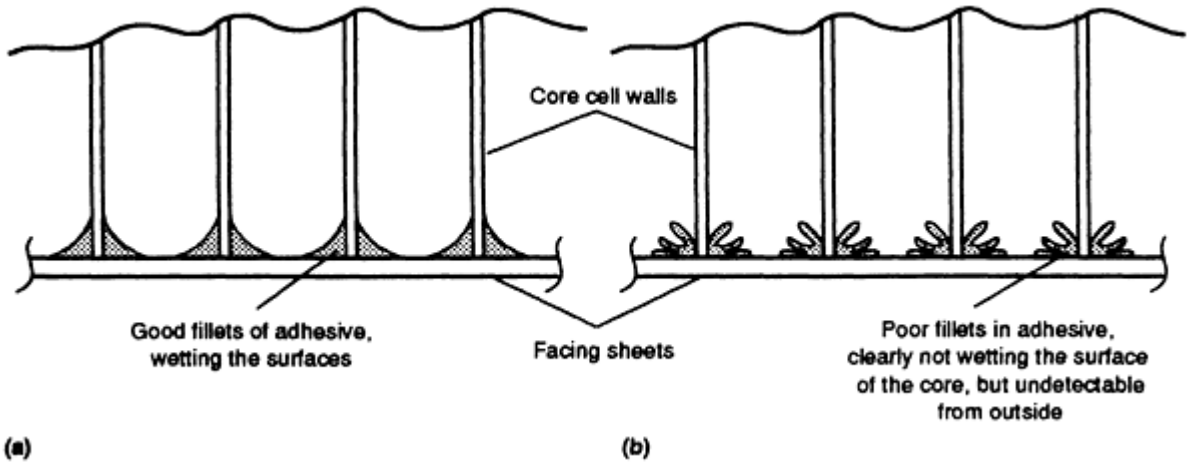

FIG. 12 EFFECT OF NOT PREDRYING ORGANIC HONEYCOMB CORES. (A) DRIED CORE. (B) UNDRIED CORE

Adhesives vary in their susceptibility to problems caused by moisture absorption. The first generation of modified epoxy adhesives introduced in the 1960s were discredited because of corrosion problems with bonded metal structures. These adhesives had a high permeability for moisture absorption after cure. This led to corrosion of the metal surfaces, which were usually only etched, not anodized, and were not protected by a corrosion-inhibiting primer. Ironically, these same adhesives have been used successfully with composite adherends that cannot corrode, but they have suffered limited application because of their bad reputation earned in a totally unrelated context. Actually, it was proved more than 20 years ago that the primary cause of such problems was inadequate surface preparation. However, other contemporary adhesives, cured at higher temperatures, lasted longer on the same poor surfaces and were then used in their place.

The second generation of modified epoxy adhesives, introduced in the late 1970s, were specially formulated to impede moisture migration and were used in combination with a phenolic-based primer baked on an aluminum alloy surface anodized with phosphoric acid. Their durability was established during the PABST program, and they have performed well in metal bonded structures. However, this class of adhesives has a great affinity for moisture in the uncured state. One of the first developed was so sensitive that it was withdrawn from sale. Other adhesives in this class are now associated with numerous problems with bonding composite laminates together and with the co-cure and bonding of composite patches. The problem, which was exposed and evaluated during the PABST program, occurs only when the adhesive is allowed to absorb moisture before bonding or when making sandwich panels with wet foam or Nomex honeycomb cores. The adhesive film can be restored by drying before use, but the best solution is to avoid the problem by limiting the exposure to humid environments or by regulating the atmosphere in the lay-up room.

It is vital that adhesives be stored in relatively small rolls so that the supply of material for an excessive lay-up period is not exposed to the atmosphere. They should be removed from frozen storage the day before they are to be used and allowed to thaw out overnight while still sealed, to prevent condensate from forming on the adhesive. If they do absorb moisture, they should be dried before further use. It is better to close down production for a day than to take a roll of adhesive straight out of the freezer, unwrap it, and start using it immediately while it is covered with condensate.

Laboratory experiments performed to prove that trapped moisture could actually prevent the adhesive from sticking, not merely degrade its properties, required fairly large blister panels to replicate the effect. It was shown that 150 mm (6 in.) square panels that were sealed around the edges would show the effect, but that smaller ones would not. It follows, therefore, that the conventional half-square-inch lap-shear test coupons used as travellers while parts are made cannot possibly expose this condition. If the adhesive has been exposed to high humidity and temperature for even the normal duration of a lay-up operation, or covered with condensate because it was unsealed before it had thawed out, the weak bonds will almost certainly be in the structure. If left out for an entire week, them is a good chance that the pieces will fall apart as they are removed from the bonding tool.

What is far worse than the above scenario is a degraded adhesive bond with sufficient residual strength that it does fall apart. There is then no way of characterizing the strength or the time taken for the bonds to fail in service. They will pass all ultrasonic inspections, unless there was so much trapped water that large blisters occurred during cure.

Better composite parts can be made more cheaply if the manufacturer starts with a slow vacuum-consolidation cycle, usually overnight, not in an autoclave, but possibly in a low-temperature oven or under an insulating styrofoam shelter. This enables trapped air bubbles to escape, solvents to be driven off, and some moisture to be expelled. Failure to do this, or the equivalent step of thoroughly drying detail parts to be bonded, as well as the adhesive itself if it is suspected of absorbing moisture, guarantees that all of these ingredients will be trapped inside the part once the autoclave pressure is applied. Full vacuum would be applied inside the bag until slightly short of the minimum viscosity point for the resin matrix, or until no further volatiles could be detected in the vent, if that occurred sooner. Most resins will boil if cured under high vacuum, so the bag needs to be vented to the atmosphere once the vent is no longer useful. The cure can then proceed, with the autoclave gage pressure holding the laminate down and the resin in the bag being subjected to the atmospheric pressure. After gelation, the pressure felt by the rosin will increase progressively toward that experienced inside the autoclave.

Partial-Vacuum Cures. A minor variation of the scheme above can eliminate the need for autoclaves, when curing simple parts that need little pressure to hold the laminates against the tool surface. After an unusually thorough consolidation cycle, the cure would start with a full vacuum inside the bag, using only an oven as a heat source. Once the point of minimum viscosity was reached, a regulated pressure of between one-third and two-thirds of an atmosphere would be maintained inside the bag, with the remaining differential pressure holding the laminate onto the tool. Many, but not all, resins should be capable of being cured this way. Phenolics, which generate steam during cure, are the most obvious exception.

There are new adhesives and resins being developed that will tolerate curing under full vacuum throughout the entire cycle, but the approach outlined above would produce better laminates and bonds even with such materials. It would also eliminate the need for an autoclave for many more resins and adhesives than a requirement for full vacuum would permit. It is a technique worthy of further study, particularly for repairs to thin composite sections. In-house assessments of both new and old adhesives at Douglas Aircraft have shown that the partial-vacuum cure achieves bond strengths almost as great as those produced by full autoclave pressure, and far better than those achieved under a full-vacuum cure of the same adhesive. This is true of adhesives specially developed for vacuum-bag curing as well as those formulated for autoclave cures and known to be totally unsatisfactory if cured under full vacuum. It is likely that the need for more heat

to maintain the heat-up rate on thicker panels, or with large tools that have not been thermally isolated from the work, would favor the use of an autoclave because the thermal conductivity of air increases as it is compressed.

Susman (Ref 14) has described the benefits of the dwell cycle for autoclave cures. Maintaining full vacuum while holding the temperature for about an hour at some 55 °C (100 °F) below the cure temperature permitted such a thorough removal of volatiles that the interlaminar shear strengths were doubled with respect to traditional cures. The worst laminates were made by the so-called straight-up cure, in which both full heat and full autoclave pressure were applied at the start of cure to minimize the cycle time.

Joining of Organic-Matrix Composites

L.J. Hart-Smith, McDonnell Douglas Aerospace

Bonding of Thermoplastic Composite Panels

Three different approaches have been evaluated for bonding thermoplastic composite components together. Adhesive bonding has been used, much as for thermoset composites, but needing different surface preparations. Fusing the panels together with or without an interlayer has also been used. This technique is of interest to engineers because it suggests that repairs could be performed far more easily than is possible with thermoset composites. However, there is the obvious disadvantage that it is difficult to melt such a localized area of resin without distorting the rest of the structure. Perhaps the most promising approach is that of coating the surfaces to be bonded with a different thermoplastic, which melts at a lower temperature than that in the basic laminate. Fusion bonding is then possible at a temperature low enough not to distort the part itself.

Bonding with Thermoset Adhesives. The reluctance of liquid polymers to wet solid thermoplastics is even greater than for thermosets. Having the surfaces free from contamination is but one of many criteria that must be met for one material to stick to another. Having the right surface energies is equally critical. An uncured resin or adhesive will typically not wet a cured surface having a far lower surface tension, as is achieved with release coatings. It is much more likely to adhere to a surface of far higher surface energy, as can be created by oxidation via corona treatment. Figure 13 shows how little corona energy is needed to almost double the surface energy of polyether ether ketone (PEEK). However, testing also showed that far more corona energy was needed to ensure a cohesive rather than interfacial failure (Ref 8). This supports the assessment that even after surface contaminants have been removed, there are still polymer layers of low surface energy between the bulk matrix and the surface created by curing against an inert tool surface. Much the same problem exists when trying to epoxy bond injection-molded thermoplastic inserts into honey-comb sandwich panels. The glue will not stick unless the initially inert plastic surface has been activated to form a chemical bond or etched to permit a mechanical bond.

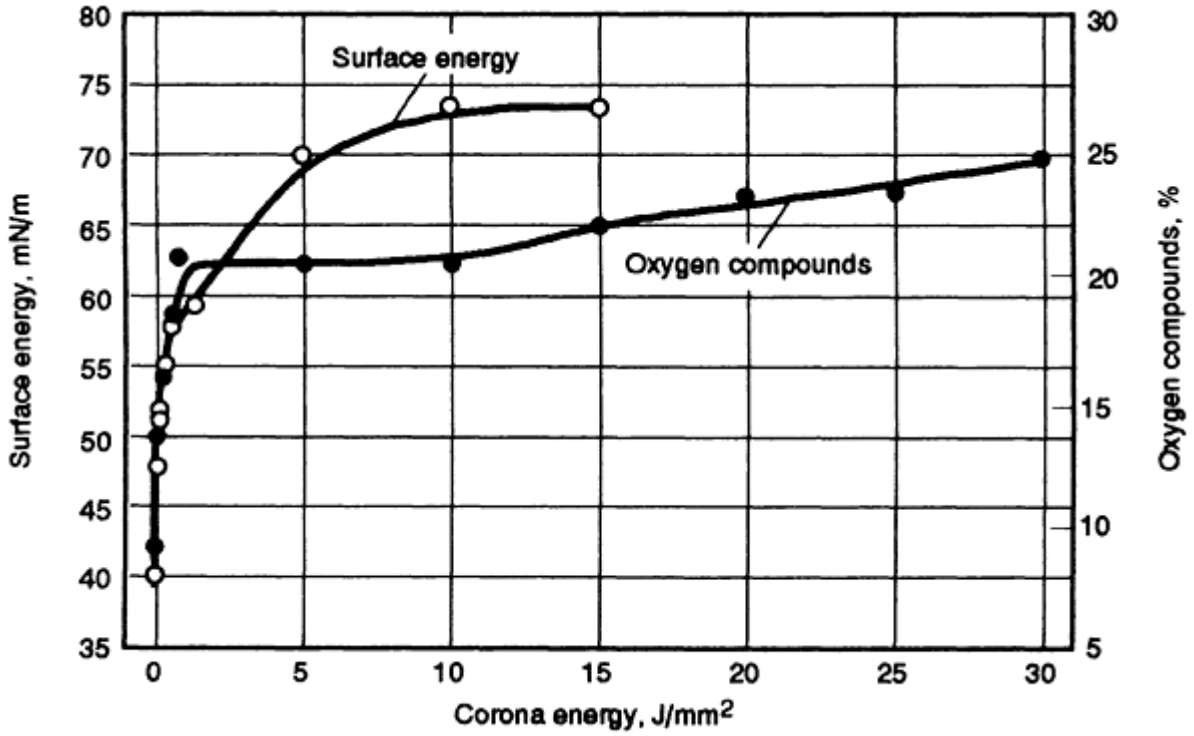

FIG. 13 EFFECT OF CORONA TREATMENT ON THE SURFACE ENERGY OF PEEK. SOURCE: REF 8

Wu *et al.* (Ref 15) describe the adhesive bonding of thermoplastic composites using several adhesives and a variety of surface treatments. Figure 14 shows results from their study. It is clear from Fig. 14 that weak interfacial failures are the inevitable result of failure to appreciate the need for proper surface treatment, for both the hot-bond epoxy FM-300 film adhesive and the BMI film adhesive EA-9673. Cohesive failures within the bond layer were achieved only for the chromic-sulfuric acid etch and plasma treatments. Significantly, these are the highest strengths obtained. While the highest average shear strengths are slightly less than one would expect on anodized aluminum coupons, they are credible for fibrous composite adherends having a quasi-isotropic fiber pattern and a slightly lower modulus. Higher strengths should have been obtained on unidirectional test coupons.

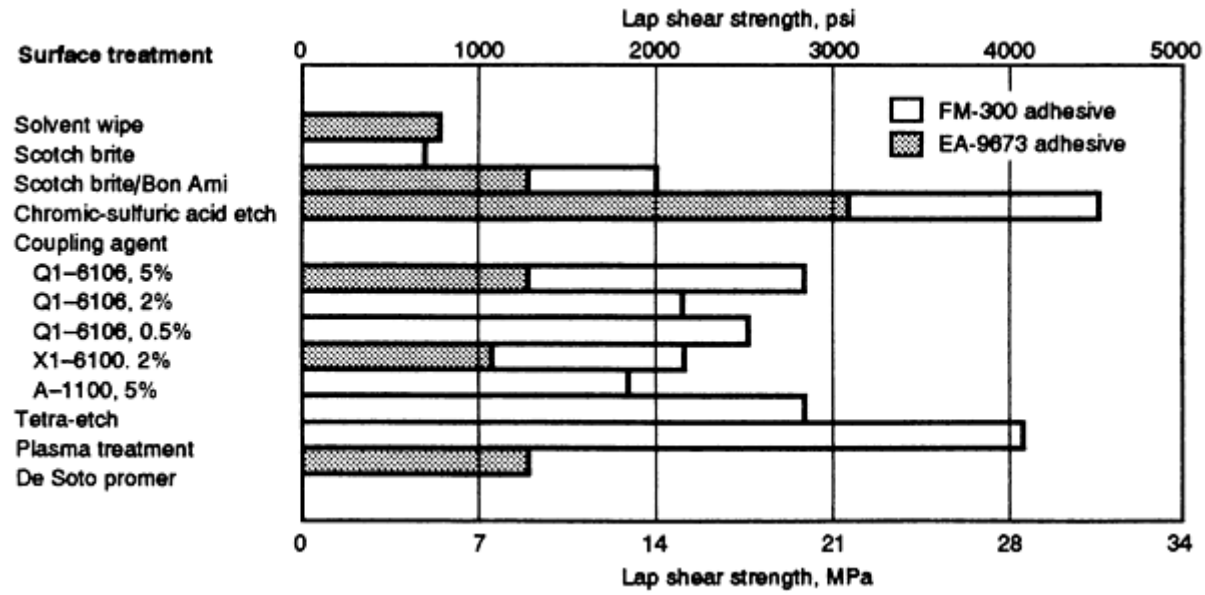

FIG. 14 EFFECT OF SURFACE TREATMENT ON THE LAP SHEAR STRENGTH OF AS4-APC-2 LAMINATE. SOURCE:

Other researchers have also reported success with plasma treatment, with various gaseous environments. While the technique is effective, and probably quite practical for small parts, the need to enclose the composite part in an evacuated chamber during the surface preparation would seem to render it impractical for very large components. On the other hand, the reliability of this process in comparison with others is of paramount concern. The acid etching would require a large tank, in any event, and the corona-discharge technique would require electrodes tailored for each part to achieve uniform treatment over the area if the thickness varied or if the part were contoured. The capital cost of the equipment for carrying out the process correctly is a small fraction of the cost of scrapping one or two large composite assemblies because the surfaces had not been prepared properly while there was access to the individual panels.

Figure 15 makes it clear that mere abrasive cleaning of thermoplastic adherends is unsatisfactory, no matter what thermoset adhesive is used, while the chromic-sulfuric acid etch is effective with all the adhesives tested. In other tests, Wu and co-workers found that extended etching did not increase the joint strength; worse, it pitted and degraded the surface. They also established by preliminary testing that them is a need to consider the environmental durability of bonds to thermoplastic adherends, just as them is with thermoset adherends.

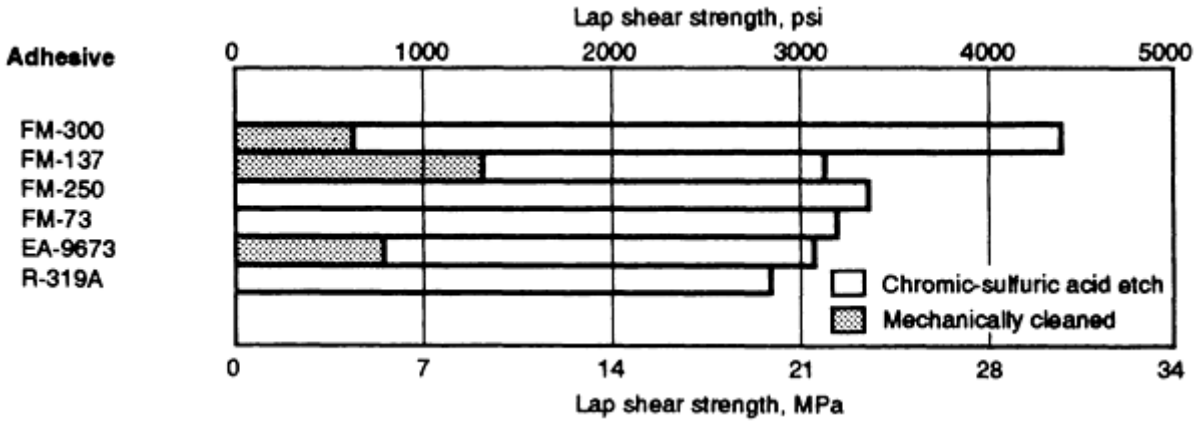

FIG. 15 EFFECT OF ABRASIVE CLEANING AND ACID ETCHING ON THE LAP SHEAR STRENGTH OF AS4/APC-2 LAMINATES. SOURCE: REF 15

Fusion Bonding of Thermoplastic Composites. Wu and co-workers also included some welded thermoplastic joints in their study (Ref 15). Lap-shear coupons that were bonded by ultrasonic welding exhibited good strengths for this process, whether the surface had been acid etched or merely abraded (Fig. 16). However, the procedure was not considered practical for large structures. Wu and co-workers examined such techniques as resistance welding, induction welding, laser welding, hot plate welding, and ultrasonic welding. It was determined that the high carbon-fiber content in the thermoplastic matrix and the high thermal and electrical conductivities of the fibers impose a tremendous amount of difficulty on fusion bonding processing. Uneven heating throughout the bonded area and delamination and distortion of the composite materials must be overcome with fusion bonding methods. In addition, such welding methods will change the crystalline structure of the resin because the remelting would be followed by cooling at a different rate from that experienced when the laminate was originally made.

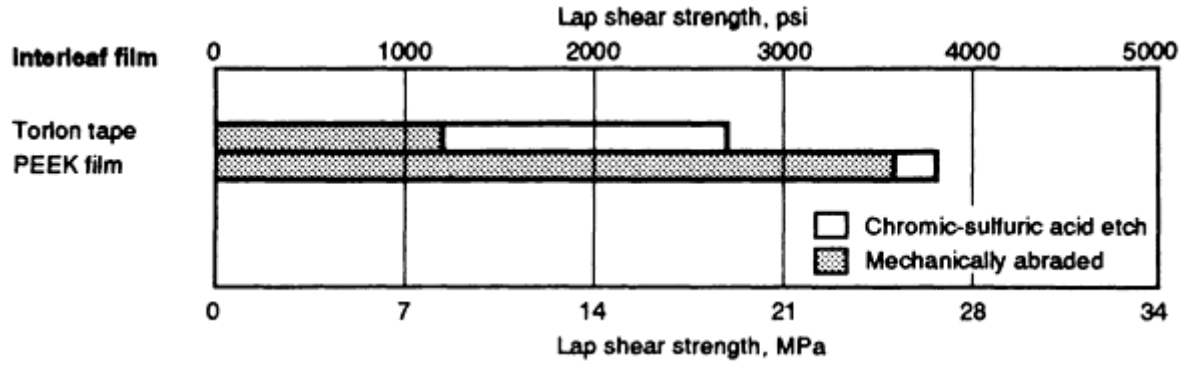

FIG. 16 EFFECT OF ABRASIVE CLEANING AND ACID ETCHING ON FUSION-BONDED AS4-APC-2 LAMINATES. TEST COUPONS WERE JOINED BY ULTRASONIC WELDING. SOURCE: REF 15

Fusion Bonding Using the Dual Resin Approach. The problems cited above can be avoided by using an interlayer that melts at a lower temperature than the parent thermoplastic matrix, but which is miscible with it. Several studies have been made using polyetherimide (PEI) to join PEEK laminates. Zelenak and Radford (Ref 16) cite success with a process in which a PEI film was melted onto the surface of APC2/PEEK tubes prior to joining. The PEI flowed into the PEEK parent, becoming a part of the parent material. This process occurred at the 320 °C (610 °F) processing temperature for the PEEK. To form the actual joint, another film of PEI was placed between the pieces to be joined as a filler. The joint was made under light pressure at a temperature of 300 °C (570 °F). This temperature is substantially above the glass transition temperature of PEI, which is 210 °C (410 °F), but below the melting temperature of PEEK (334 °C, or 633 °F). At this temperature the joint was formed by the PEI film bonding with the PEI in the parent material, which was intimately mixed with the PEEK material.

Unfortunately, the testing was marred by the limited strength of the structure outside the joint which, while it may have been able to carry the design loads, was not strong enough to fail either the laminate adjacent to the joint or the bond itself, except for two premature failures. Consequently, the absolute strengths of the joints were not established. However, in other regards, the use of PEI/PEEK as a miscible combination for bonding of structural PEEK matrix composites gives excellent joint performance with minimal susceptibility to surface contamination during bonding. While there remains the question of resistance to the environment, various chemicals, and age, this method is most promising. It would obviously be feasible to use the same technique to either repair damage in service or to add additional bonds as requirements changed, provided that the entire surface of the parts had been coated with PEI when the details were initially made.

Yoon and McGrath (Ref 17) have reported on bonding PEEK laminates with polyimide thermoplastic adhesive films. Their work is similar to that above in terms of processing at temperatures insufficient to melt the PEEK, but it differed significantly in that they bonded directly to the PEEK laminate. The absence of a compatible surface layer caused them to investigate the effectiveness of different surface treatments. They were able to make very good bonds without adhesive at 360 °C (680 °F), developing shear strengths of 47 MPa (6800 psi), which are not surprising given that their adherends were 24-ply thick unidirectional carbon-fiber reinforced laminates. However, they concluded that this temperature could not be used due to severe deformation. Their joints that fused together at 340 and 350 °C (645 and 660 °F) attained less than 20% of the highest strengths reached with adhesive films fused to treated surfaces that had been promptly primed with a solution of the adhesive to protect the surface. It was concluded that the highest practical temperature for the PEEK-graphite composite adhesion was around 340 °C (645 °F); however, high pressure was also required. Simple fusion of thermoplastic laminates does not seem to be a productive avenue at the present time.

It should be pointed out, however, that the work of Yoon and McGrath in activating the surface prior to bonding with thermoplastic adhesive closely parallels what was reported earlier for bonding with thermoset adhesives. Grit blasting showed a distinct improvement but clearly failed to enable the true material strengths to be exploited. The various gas plasma treatments were effective in producing cohesive failures, and the combinations of grit blasting and gas plasma treatments were better still, reaching nearly 41 MPa (6000 psi) and coming close to the strengths attained by fusion at 360 °C (680 °F).

Of the successful techniques described above, only one is applicable for joining large components. Fusion welding at a reduced temperature, made possible because the thermoplastic parts have been coated during fabrication with a miscible

plastic that melts at a lower temperature than does the base matrix, should enable full use to be made of the strength of the parent laminates. The plasma treatment and corona-discharge techniques are reliable for small parts. The other techniques for developing high strengths are nevertheless invaluable as a warning of how weak the structures will be if no attention is paid to the need for proper surface preparation. They establish the target that should be obtained by any method used in practice.

Solvent Bonding of Amorphous Thermoplastics. The difficulties cited above, when bonding aircraft-grade fiber-reinforced thermoplastic composites, apply specifically to crystalline thermoplastics. Amorphous thermoplastics have not been used widely for such structures because of their lower resistance to common solvents. However, this greater susceptibility to solvents can become an advantage for adhesive bonding. The extreme case of assembling polystyrene plastic model aircraft kits by local application of styrene monomer cement or methyl ethyl ketone solvent is well known. Solvent bonding of nonstructural thermoplastics is quite common in other industries. The same effect can also be used to enhance the bonding of amorphous thermoplastics by epoxy-type adhesives. Such adhesives do not normally bond well to these plastics. However, wiping the surfaces with a suitable solvent and bonding the parts together before the thermoplastic has time to revert to an inert state can produce adhesive bonds strong enough to tear honeycomb cores apart; that is, strength similar to good metal-bond structures. This has been demonstrated by the Ten Cate organization for their continuous-fiber-reinforced PEI thermoplastic bonded with 120 °C (250 °F) cured modified epoxy adhesives. They even advocate the direct use of solvent bonding for cosmetic repairs of local damage to such structures. This technique is no panacea, however, because some thermoplastics will craze after being subjected to the wrong solvent. Nevertheless, under suitable circumstances, solvent bonding or solvent-enhanced bonding can be a very useful technique.

Joining of Oxide-Dispersion-Strengthened Materials

David O'Donnell, Inco Alloys International Inc.

Introduction

OXIDE - DISPERSION - STRENGTHENED (ODS) MATERIALS utilize an extremely fine oxide dispersion for strengthening, such as yttria (Y_2O_3) or alumina (Al_2O_3). The majority of ODS alloys are produced by mechanical means, often referred to as mechanical alloying (MA), where elemental or alloyed powders are ball milled, or attrited. This mechanical working of different powders between large shot will cold weld particles and break them apart until a fine interlayered structure is produced. The powder is typically consolidated and homogenized by hot isostatic pressing or hot extrusion. Further consolidation is typically performed, producing a final product that is more than 99% dense (Ref 1, 2). The compositions of selected ODS alloys are given in Table 1.

TABLE 1 COMPOSITION OF SELECTED ODS ALLOYS

ODS ALLOY	COMPOSITIONS, %								TYPICAL APPLICATIONS

MA, mechanically alloyed; PM, powdered metal

A typical dispersoid diameter of Incoloy alloy MA 956, for example, is on the order of 30 nm (1.2×10^{-6} in.), which is too small for observation using optical metallographic techniques (Ref 3). The dispersion of stable oxides provides exceptional creep-rupture strength at temperatures above 980 °C (1800 °F) because carbides and many secondary phases used for strengthening conventional wrought alloys go into solution. The level of creep strength achieved at very high temperatures in ODS alloys has not been matched by similar wrought or cast alloys.

The processing techniques employed in the production of ODS alloys produce some entrapped gases, which tend to create porosity during fusion welding. Porosity can form either within the bulk of the fusion zone or near the fusion boundary, as a very fine porosity interface. This tendency is generally most severe in aluminum alloys and least evident in nickel-base alloys. The porosity tendency in iron-base alloys is between that of aluminum- and nickel-base alloys. The level of porosity that results from the fusion welding of aluminum ODS alloys is such that they are not generally considered to be fusion weldable.

Most ODS applications involve high temperatures and, possibly, corrosive environments. The first commercial applications were aircraft gas-turbine engines, followed by industrial engines. Vane airfoils are typically furnace brazed to platforms, both of which can be made from ODS alloys. Combustor parts can be riveted, resistance welded, or brazed. Some ODS alloys are being used to a significant extent in various components of molten glass handling equipment. Heat-treatment baskets, trays, shields, and furnace skid rails are also becoming common applications.

Joining of Oxide-Dispersion-Strengthened Materials

David O'Donnell, Inco Alloys International Inc.

Design Strategy

The high-temperature creep strength obtained from a cast weld structure, using ODS alloys, is generally comparable to that obtained with conventional wrought alloys and does not exhibit the same exceptional high-temperature creep strength of unwelded ODS materials. The stable oxides, or dispersoids, that are used in the ODS alloy systems have essentially no equilibrium solubility in the liquid phase. If melting occurs, then the dispersoids rapidly agglomerate, and buoyancy floats the oxide to an upper surface, if possible. In fusion welds, this results in the loss of the primary means of high-temperature strengthening. Agglomerated semicontinuous dispersoids in the partially melted zones of fusion welds are also suspected as contributing to early weld-service failures.

A number of successful strategies have been employed in joining ODS alloys. Conventional fusion welds or brazes are often placed in cooler locations in order to retain acceptable strength levels. A design is often altered so that conventional fusion welds are not the principal load-carrying members, but are attachments instead. Solid-state joining techniques can often be used, but the resulting grain structure must also be considered.

Grain Structure. At very high temperatures, grain boundaries become the weak link, so to speak, and fracture becomes intergranular. In order to minimize such a grain boundary strength limitation, ODS alloys are produced with a macro grain size, where the grain boundary area normal to the principal stresses are minimized without incurring the difficulties inherent in producing single crystals. This elongated grain structure is often referred to as a high grain aspect ratio (GAR). Welds or joints that significantly interrupt this large interlocked grain structure will fail prematurely at extreme temperatures, even if they are produced by solid-state means. A friction weld in a rod, where there is a straight grain boundary interface through the thickness and normal to the principal stresses, typically will not perform significantly better than a conventional fusion weld in which a similar structure is produced. The large, interlocking grain structure in such materials is a key attribute for good performance at extreme temperatures.

Because of grain-structure considerations, it is often preferable to use resistance welds, braze welds, or both in a lap joint, rather than a butt joint, where there is invariably a through-thickness noninterlocked grain structure normal to the principal stresses across the joint. When lap welds are used, double-lap joints outperform single-lap joints, which fail by peeling at lower stresses.

Postweld recrystallization anneals have been used with all types of welds to grow grains across the welds to the greatest extent possible. The best structural and strength results are generally obtained by joining base metals in a fine, unrecrystallized condition and by performing a grain-coarsening recrystallization anneal after welding. However, a postweld recrystallization anneal typically improves properties only in narrow joints, such as those commonly produced by electron-beam, diffusion, resistance, and friction welding techniques. Creep-rupture properties from wide-gap joints, such as those produced in gas-metal or gas-tungsten-arc welds can be reduced by such an anneal. This anneal is typically 1316 °C (2400 °F) for 1 h, when MA 754 and MA 956 alloys are used. The fine-grain approach, if adopted, requires coordination with materials suppliers, because most ODS alloys are typically supplied in the coarse-grained, recrystallized condition. However, some measure of improved properties may be obtained in narrow joints through postweld recrystallization, even where the base metal was joined in the coarse-grained condition. Table 2 provides transverse property data on selected alloys used in each of the welding processes discussed later in this article.

Other attributes of ODS alloys, relative to welding, are typical of their respective alloy groups. For example, ferritic ODS alloys will exhibit a ductile-to-brittle transition temperature (DBTT), and, because of their high alloy content, will have a marked sensitivity to delayed hydrogen cracking.

Iron-Base ODS Alloys

The alloy MA 956 utilizes a coarse, high-aspect grain structure as part of its high-temperature strengthening ability. This structure is achieved through processing and a final recrystallization anneal of 1316 °C (2400 °F) before service. The alloy has a high melting point of 1480 °C (2700 °F), and is often used in service at 1093 °C (2000 °F) and above. The alloy is quite ductile above its DBTT, which is near room temperature. All strain-forming operations, such as bend tests, friction welding, and explosion welding, should be performed after heating to 100 °C (212 °F) or higher. Below the DBTT, the alloy can be notch brittle. The MA 956 alloy undergoes no solid-state phase transformations between melting and cryogenic temperatures, and it cannot be quench hardened.

Iron-base ODS alloys are generally very sensitive to delayed weld zone and heat-affected zone (HAZ) hydrogen cracking. Good low-hydrogen welding practice should be followed for all fusion-welding processes, and only low-hydrogen fusion welding processes are recommended. For this reason, shielded metal arc welding or other flux-bearing welding processes are generally not recommended. Delayed cracking has been observed, even in heavy resistance welds, when no precautions were taken.

Fusion welding should utilize low-hydrogen practices, on the assumption that enough hydrogen will be present to cause cracking, and should incorporate preheating, minimum interpass temperatures, and a postweld hydrogen diffusion treatment prior to cooling in order to prevent cracking. Preheating and use of minimum interpass temperatures ranging from 149 to 204 °C (300 to 400 °F) have generally prevented cracking during welding. A postweld diffusion treatment before cooling at 300 °C (572 °F) for 10 h, or 400 °C (752 °F) for 6 h, has been effective in removing hydrogen in section thicknesses less than 11 mm (0.4 in.) thick. More information on hydrogen diffusion treatments for various thicknesses and temperatures is provided in Ref 4. The unique aspects of the different welding processes are described in the section "Welding Processes" in this article.

Nickel-Base ODS Alloys

Most of the nickel-base ODS alloys use a high GAR, but some are also highly textured to provide the best resistance to thermal fatigue. This structure is achieved in MA 754 through processing and a final recrystallization anneal of 1316 °C (2400 °F) before service. In MA 6000, zone annealing is used for an optimum longitudinal GAR.

The alloy MA 758 has been used increasingly in handling equipment for molten glass; such equipment is exposed to high temperatures, stress, and corrosive glasses. Welds have been made, primarily for attachment purposes, using the gas-metal arc, gas-tungsten arc, and shielded metal arc welding processes. Filler consumables that contain 30% Cr, such as Inconel filler metal 52 or Inconel welding electrode 152, are needed to provide corrosion resistance to most molten glasses.

The alloy MA 6000, an advanced gas-turbine blade material that utilizes both oxide-dispersion and γ' strengthening, is not typically fusion welded. Its aluminum content may make it susceptible to strain-age cracking, which can occur in fast precipitation-hardening alloys where significant residual stresses are present. These stresses can be caused by cold working or welding. If the piece is not heated rapidly to annealing temperatures after welding, then it may age fast enough for the locked-in stresses to exceed the rupture strength, at which point cracking will occur. Furnace brazing and diffusion welding should be performed after plating the joint area with a thin layer of nickel to prevent the oxidation of aluminum, which could cause incomplete bonding.

The alloy MA 754 is primarily a turbine vane material that is used for its exceptional combination of creep-rupture strength and thermal-fatigue resistance. Most applications involve vacuum furnace brazing to similar and dissimilar alloys, in situations where the joint is located in relatively cool locations or is subjected to reduced stresses (Fig. 1).

Welding Processes

Gas-tungsten arc welding of ODS alloys is typically carried out using minimal welding current and techniques that are designed to minimize melting of the alloys. When welding alloys with a significant aluminum content, such as MA 956, there is a high propensity for an aluminum-rich light gray oxide film to form on the weld-bead surface. The dispersoid from the melted base metal also floats to the weld-bead surface. These oxides should be removed by light abrasive techniques before subsequent weld beads are deposited, in order to prevent incomplete-fusion defects or oxide inclusions. Balanced-wave alternating current is generally not recommended, because the reverse current (electrode positive) part of the cycle attempts to "cathodically clean" the dispersoid oxides from the bulk of the base metal by arcing into the base metal. Power supplies for which the reverse-polarity cycle time can be minimized have been used with some success, producing only a weld-bead surface cleaning. Figures 2 and 3 show MA 956 products that have been gas-tungsten arc welded using different filler metals.

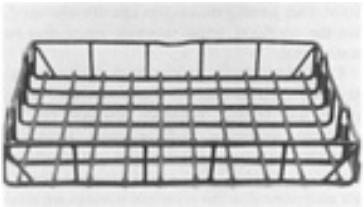

FIG. 2 GAS-TUNGSTEN ARC WELDED MA 956 HEAT TREAT BASKET. INCONEL 617 FILLER METAL WAS USED.

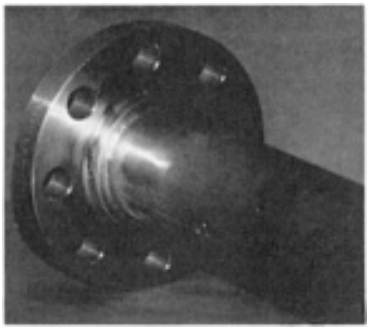

FIG. 3 MA 956 PIPE GAS-TUNGSTEN ARC WELDED TO A 304 STAINLESS STEEL FLANGE. 308 STAINLESS STEEL FILLER METAL WAS USED.

Because joint properties are representative of conventional wrought alloys, attempts should be made to either design welds as attachments that are subjected to reduced stresses or place the welds in cooler locations where they can withstand the stress. Table 3 lists typical filler-metal alloys for the ODS alloys discussed in this article.

Gas-metal arc welding of ODS alloys is typically implemented with pulsed or synergic power sources and low-to-average current settings to minimize the melting of the base metals. This typically amounts to an average welding current of 60 to 180 A, depending on the section thickness of the joint.

Electron-beam and laser-beam welding have been used to join MA 956, and the best results have been obtained in lap joints where the beam is oriented as close to parallel to the joint as possible. In butt joints, the best results can be obtained by inclining the joint and beam as much as possible from 90°. This will reduce the load per unit area on the weld fusion-boundary and centerline grain structure (Ref 5, 6). At the same time, melting should be minimized and the beam should be projected vertically to help prevent incomplete-fusion defects from dispersoid entrapment. Because MA 956 is magnetic, it should be demagnetized before electron-beam welding to prevent unwanted beam deflection.

Resistance welding of ODS alloys is typically implemented with parameters designed to minimize the thickness of the weld nugget and solidification time (high current, tip pressure, and minimum weld time). The typical lap joint produces a favorable grain orientation relative to the weld and principal stress, and the process is fast and repeatable. The overlap and number of spots are controlled to develop the required joint properties. Delayed hydrogen cracking can occur in iron-base

ODS alloys, particularly in thicker restrained pieces if preheat, minimum interpass temperatures, and postweld diffusion treatments are not employed.

Dedicated efforts to minimize melting or the thickness of the weld nugget have succeeded in producing solid-state, or very-near-solid-state, resistance welds. The commercial practicality and benefits of these techniques still need to be better defined.

Furnace brazing of ODS alloys has been extensively used by the aircraft industry. Iron- and nickel-base ODS alloys containing significant aluminum or titanium are typically plated with a very thin barrier of nickel to prevent oxidation of these elements during the brazing cycle. If oxidation occurs, then the flow of the brazing filler metals is inhibited. Brazing filler metals that are rich in silicon and lean in boron are preferred to avoid erosion of the ODS base metals during the brazing cycle. If significant erosion occurs, then dispersoids can form oxide inclusions or incomplete-fusion defects within the joint. For best results, joint gaps should be as narrow as possible without hampering filler-metal flow. Typical properties are shown in Table 4. Attempts to improve properties have utilized special techniques, such as diffusion brazing, transient liquid-phase bonding, and pressure brazing.

(A) STRESSES ARE BELIEVED TO BE BASED ON BASE METAL.

Although it has not yet been confirmed, the aluminum-base ODS alloys AL-905XL and AL-9052 should vacuum furnace braze well, by virtue of their magnesium content.

Friction welding is capable of creating sound solid-state joints in ODS alloys. The plastic deformation and flow at the bond interface typically produce a relatively straight grain-boundary interface through-thickness after annealing. This relatively flat grain-boundary interface normal to the principal stresses is undesirable, and it produces properties that are no better than most fusion processes. The best results have been obtained by welding fine-grained unrecrystallized rod and then performing a postweld recrystallization anneal.

Explosion welding generally creates a favorable grain structure by virtue of the lap joints used. In a limited study in which MA 956 was joined, the best results were obtained by bonding coarse-grained material and giving it a postweld diffusion treatment of 1100 °C (2012 °F) for 10 h.

Composite-to-Metal Joining

Raymond E. Bohlmann, McDonnell Douglas Aerospace-East

Introduction

SELECTING THE BEST METHODS and practices for joining composites to metals is highly dependent on the particular combination of composite and metal materials being joined and the design details and/or requirements of the joint. For example, if a carbon-epoxy laminate must be joined to an all-metal fitting through an adhesive bondline that should perform well in a hot-wet environment, aluminum would be a poor choice. To develop the hot-wet strength, the adhesive must be cured at elevated temperature. Because of the high coefficient of thermal expansion (CTE) of the aluminum and a low CTE for the carbon-epoxy composite, significant fabrication thermal stresses can occur in the adhesive bondline at room temperature after the elevated-temperature cure. These fabrication thermal stresses, which are at a maximum at the ends of the joint, can be sufficient to cause the adhesive to fail before any mechanical loads are applied. Also, the carbon-epoxy and aluminum combination is susceptible to galvanic corrosion. Titanium would be a better material selection for

the metal adherend--both for minimizing thermal stresses (CTE of titanium is less than one-half that of the aluminum) and for minimizing corrosion.

This article will discuss material combinations, design details, and fabrication processes that should be considered when joining resin-matrix composites to metals. Resin-matrix composites, also referred to as organic-matrix composites, can be divided into thermoset composites (resin chemical reaction during 120 to 175 °C, or 250 to 350 °F cure) and thermoplastic composites (resin melt fuse between 315 and 400 °C, or 600 and 750 °F). Thermoset composites can be joined to metals by adhesive bonding, whereas thermoplastic composites can be joined by adhesive bonding or through the use of a melt-fuse interface (amorphous bond). Themoplastics can be further divided into semicrystalline and amorphous materials. A semicrystalline thermoplastic material has a low moisture saturation level (0.25%) as compared to an amorphous thermoplastic (0.6%) and a typical thermoset (1.6%). Composite hot-wet properties and bonded-joint shear strengths (adhesive or amorphous bond) are reduced by the degree of absorbed moisture and the joining materials should be selected to minimize this effect.

Composite-to-Metal Joining

Raymond E. Bohlmann, McDonnell Douglas Aerospace-East

Bonded Joints

Design Issues. The analysis of adhesively bonded joints has advanced to the stage where it can legitimately be called a science. Hart-Smith has added nonlinear adhesive behavior to the analysis and design of adhesive bonded joints in the form of an elastic-plastic adhesive model (Ref 1, 2, 3). In addition, a series of digital computer programs has been developed for the analysis of bolted and bonded joints of various geometries (Ref 4, 5). As was stated earlier, selecting the best methods and practices for joining composites to metals depends on the particular combination of materials being joined and the design details/requirements of the joint.

The effect of several important design variables will be illustrated by application of the A4EI STEPLAP analysis computer program (Ref 5). The capabilities of the A4EI program include:

- ELASTIC OR ELASTIC-PLASTIC STRESS DISTRIBUTIONS
- STEPPED-LAP ADHESIVELY BONDED SPLICES OR DOUBLERS
- CHECKS FOR ADHEREND OR ADHESIVE FAILURE
- ACCOUNTS FOR ADHEREND STIFFNESS IMBALANCE, ADHEREND THERMAL MISMATCH, VARIABLE ADHEREND THICKNESS AND STIFFNESS, NONUNIFORM BONDLINE THICKNESS AND ADHESIVE PROPERTIES, AND TENSION, COMPRESSION, AND SHEAR LOADING

The STEPLAP computer procedure is based on a closed-form analysis, which, through an iterative scheme, provides the complete internal stress distribution of a stepped-lap joint (Fig. 1). Two program-detectable failure modes are adherend axial failure and adhesive shear failure. The elastic-plastic methodology represents a major improvement in stepped-lap joint analysis because it accounts for all significant variables in one procedure. In particular, the analysis accounts for adherend stiffness imbalance, adherend thermal mismatch, step thicknesses, number of steps, and adhesive ductility (in terms of an elastic-plastic model). This analytic capability allows the user to quickly identify the critical or limiting detail of a stepped-lap joint configuration and make changes in the joint design to maximize the stepped-lap joint strength. To apply these analyses procedures to a design requires the availability of the adhesive shear stress-strain data (Fig. 2), which are obtained by conducting a thick adherend test on the adhesive (Fig. 3). For design-limit loads (operating loads), the recommended procedure is to limit the bondline shear strain to the elastic knee of the shear stress-strain curve to prevent adhesive failure during repeated fatigue loading.

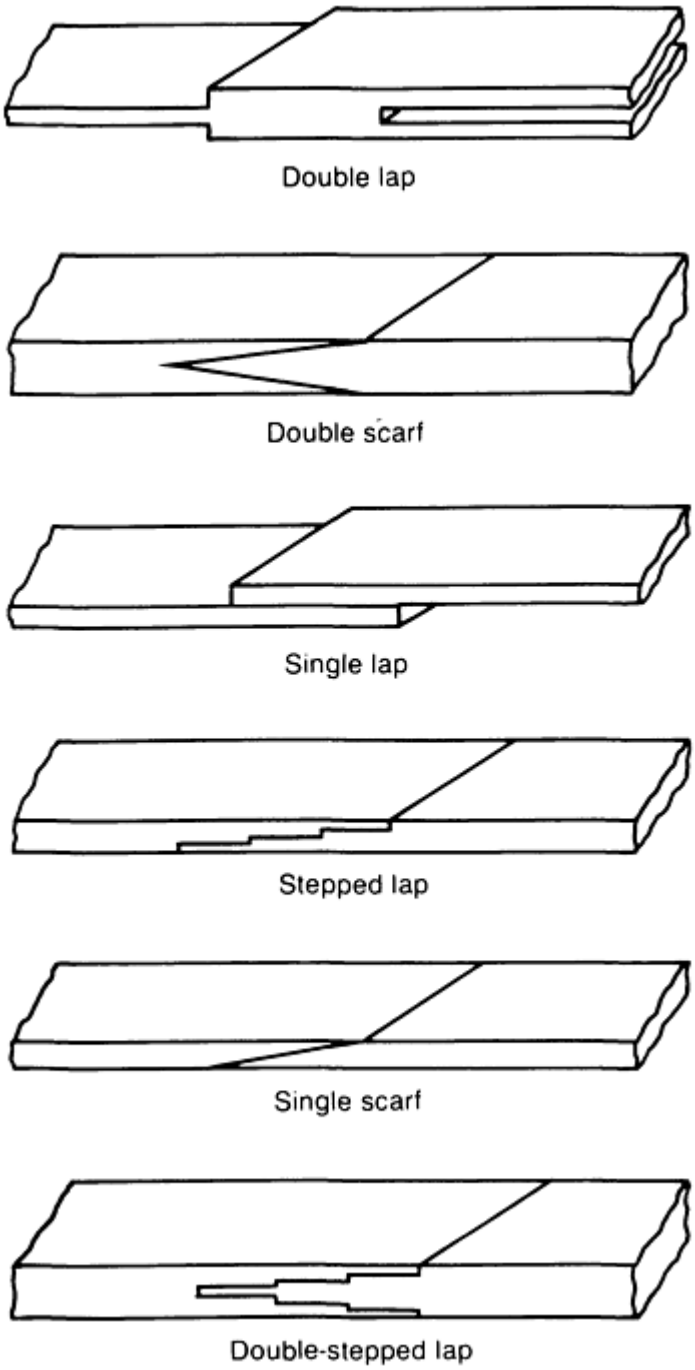

FIG. 1 JOINT DESIGNS USED FOR ADHESIVE BONDING

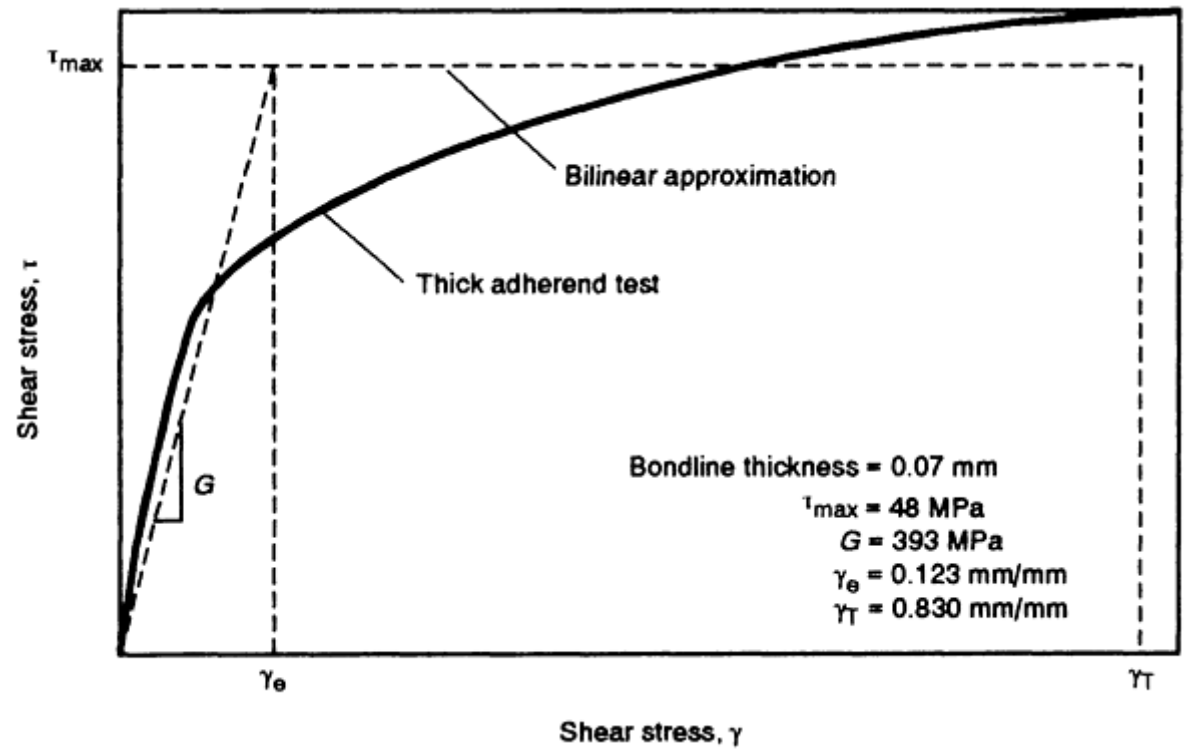

FIG. 2 STRESS-STRAIN CURVE DEVELOPED FROM A THICK ADHEREND (ROOM-TEMPERATURE/DRY) TEST USING FM300K ADHESIVE. *G*, SHEAR MODULUS; γ_E, ELASTIC STRAIN; γ_T, TOTAL STRAIN

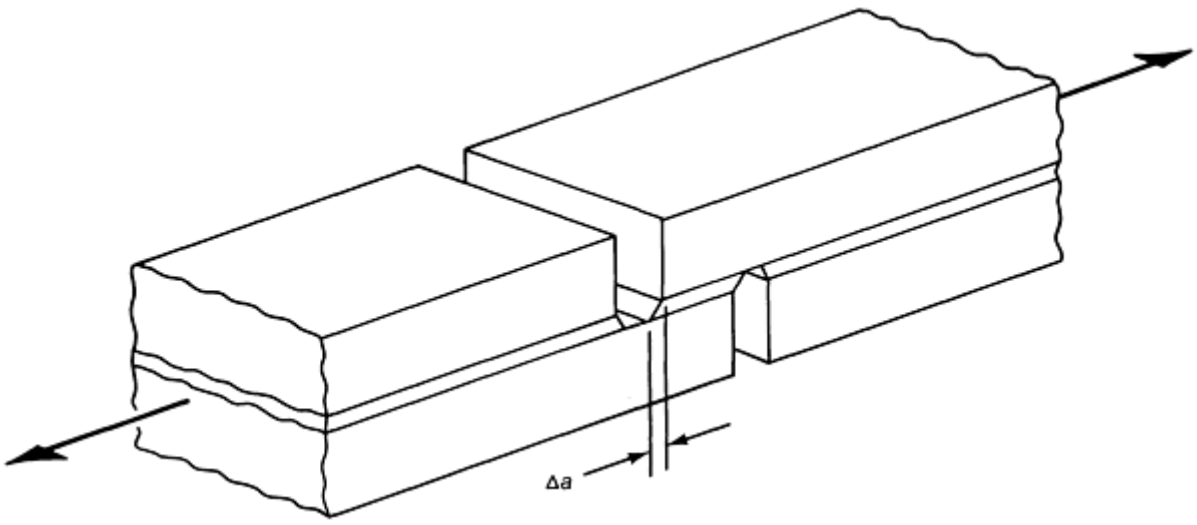

FIG. 3 THICK ADHEREND LAP-SHEAR SPECIMEN

The effect of adhesive bondline thickness on joint load capability is shown in Fig. 4 for a constant thickness composite-to-metal splice joint. The shear stress distributions along the bond length for two different bondline thicknesses were predicted by the computer program. The joint load capability is equivalent to the area under the curve. The curve for a bondline thickness of 0.13 mm (0.005 in.) has 60% more area under the curve and therefore can carry 60% more load than a 0.05 mm (0.002 in.) thickness. For a joint with an elastic distribution, the joint load-carrying capability increase is proportional to the square root of the bondline thickness increase. In this example, the joint load increased by $(0.005 \text{ in.}/0.002 \text{ in.})^{0.5}$, which is a 60% increase.

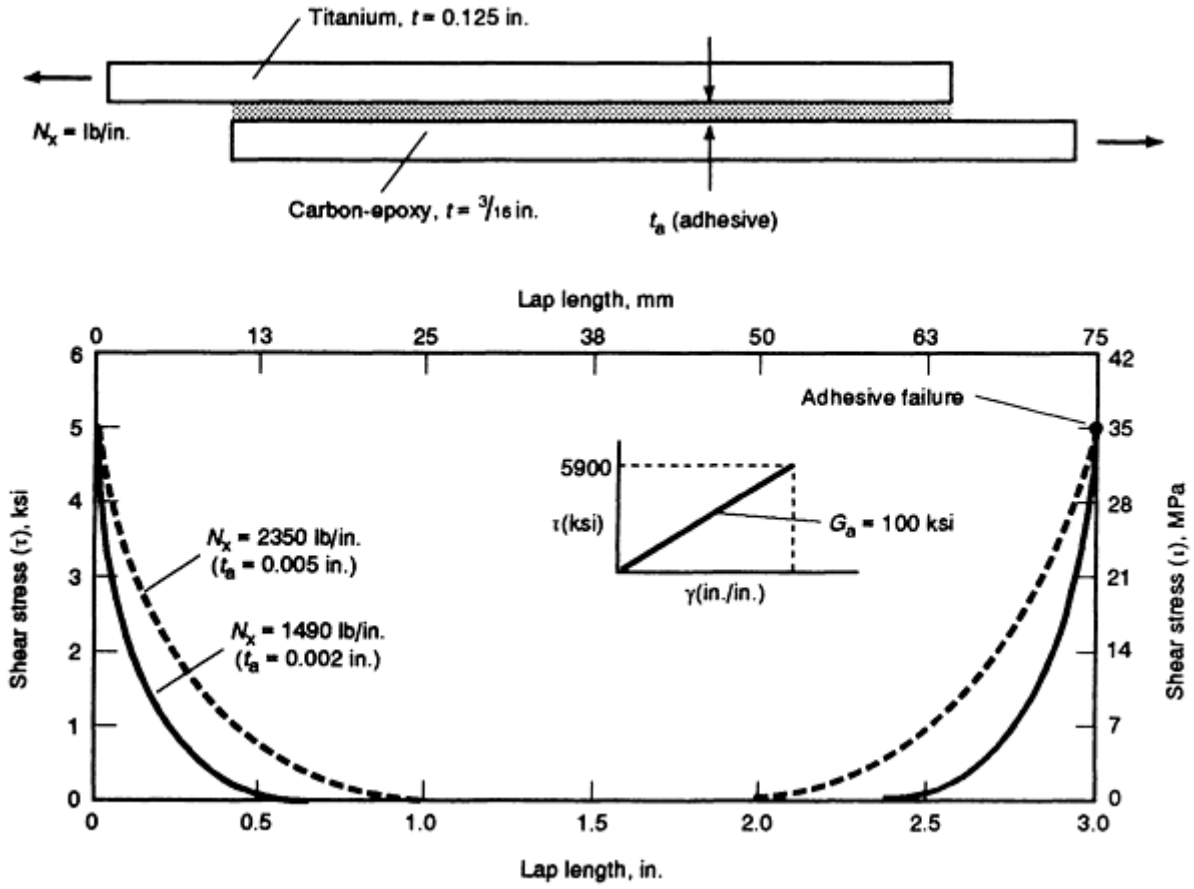

FIG. 4 THE EFFECT OF BONDLINE THICKNESS ON JOINT LOAD-CARRYING CAPABILITY. N_X, JOINT LOAD CAPABILITY; G_A, ADHESIVE SHEAR MODULUS; T_A, ADHESIVE THICKNESS; γ^{SU}, ADHESIVE PLASTIC SHEAR STRAIN (SU, SHEAR ULTIMATE). ORIGINAL SPECIMEN DIMENSIONS GIVEN IN INCHES

The benefits of tapering the adherend thickness are shown in Fig. 5. In the composite (carbon-epoxy)-to-titanium splice joint, two cases are compared using an elastic analysis. In the first case, both adherends are a constant thickness; in the second case, the titanium adherend is tapered as if the titanium is a repair patch that could be tapered prior to bonding. For the first case (adherend constant thickness), the shear stress in the adhesive is maximum on the right end of the joint. For the second case, tapering the thickness of the titanium patch on the right end of the joint reduces the maximum shear stresses in the adhesive, forcing the failure in the adhesive at the left end of the joint and increasing the joint load-carrying capability by 16%. The joint load capability can be further increased by tapering the carbon-epoxy laminate at the left end of the joint, which will further reduce the maximum shear stress in the adhesive. An additional benefit of tapering the ends is to reduce the peel stresses in the adhesive and the interlaminar tension in the laminate.

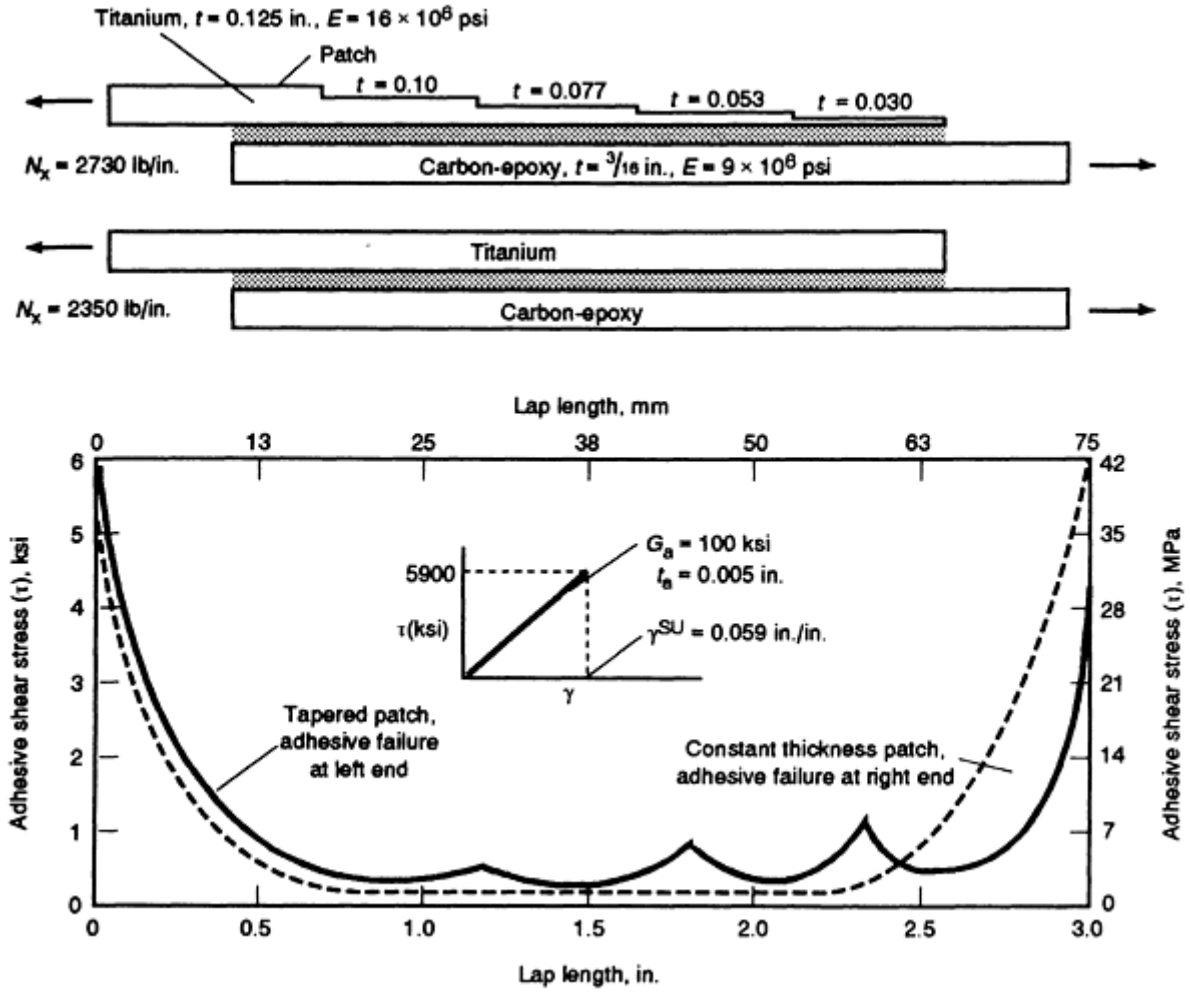

FIG. 5 THE EFFECT OF TAPERING THE ADHEREND THICKNESS ON JOINT LOAD-CARRYING CAPABILITY. SEE FIG. 4 FOR EXPLANATION OF SYMBOLS. ORIGINAL SPECIMEN DIMENSIONS GIVEN IN INCHES

Taking advantage of the adhesive plasticity will provide a significant increase in the area under the shear stress versus lap length curve and the resultant joint load capability (Fig. 6). The example shown in this figure is the same as the tapered-thickness titanium patch shown in Fig. 5 with the adhesive plasticity condition added. For the elastic case, the joint load capability is 49.5 kg/mm (2730 lb/in.). Increasing the adhesive shearing strain allowable from the elastic value of 0.059 mm/mm (in./in.) to the plastic value of 0.20 mm/mm (in./in.) increases the joint load to 118 kg/mm (6520 lb/in.) (a factor of 2.4). Increasing the adhesive plastic shear strain to 0.30 mm/mm (in./in.) further increases the joint load capability to 148 kg/mm (8140 lb/in.), which is a three-fold increase over the elastic condition. Adhesive plasticity will generally provide the added load-carrying capability needed between the operating loads (design limit) and the design ultimate loads when the operating loads (fatigue loading) are limited to the elastic knee in the adhesive shear stress-strain curve.

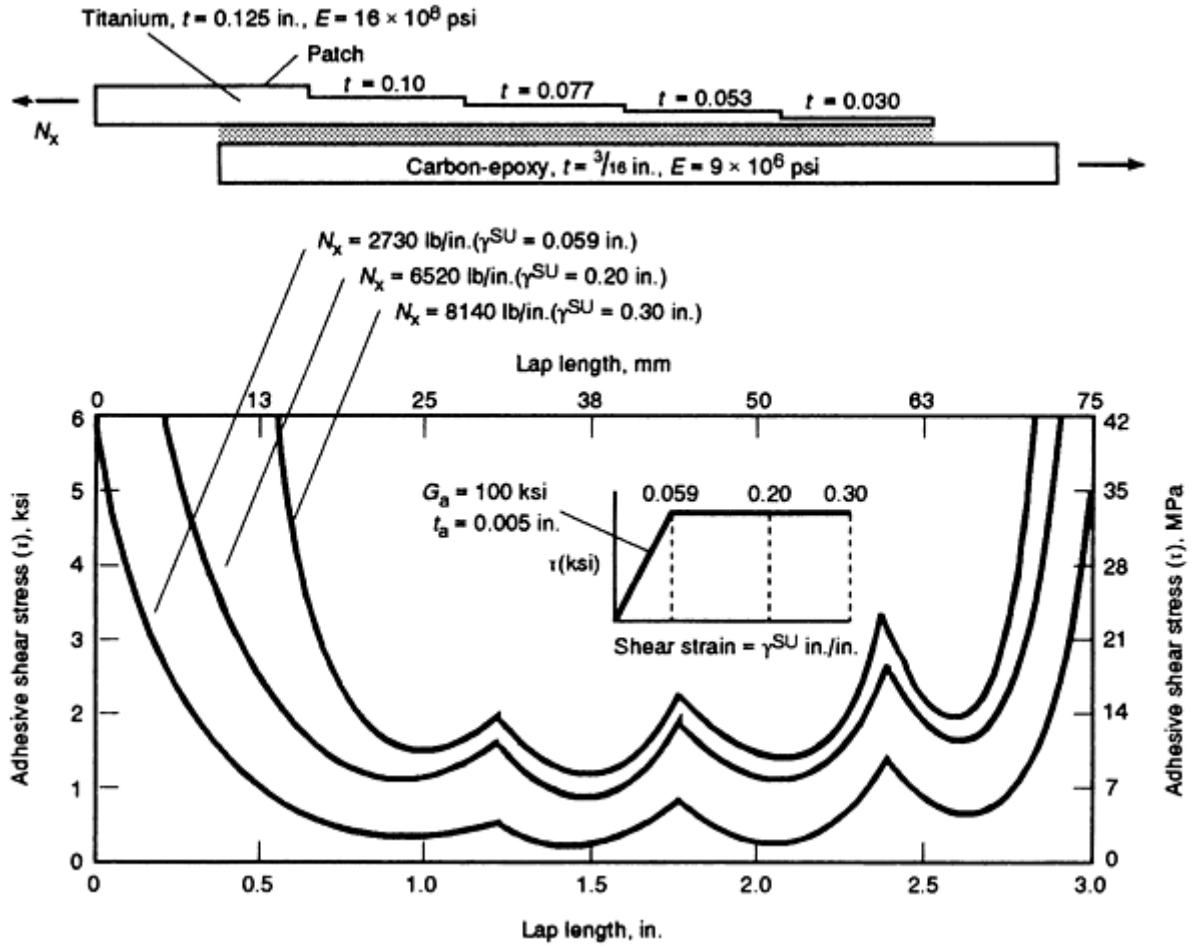

FIG. 6 THE EFFECT OF ADHESIVE PLASTICITY ON JOINT LOAD-CARRYING CAPABILITY. SEE FIG. 4 FOR EXPLANATION OF SYMBOLS. ORIGINAL SPECIMEN DIMENSIONS GIVEN IN INCHES

Thermoset Composites. (Carbon-epoxy)-to-titanium adhesively bonded splice joints are being utilized in aircraft primary structures. Joining carbon-epoxy to titanium using adhesive bonding has provided substantial weight savings. For these co-cured bonded joints, adhesive comparison testing led to the selection of FM300K, which is a film adhesive that contains an open-knit polyester carrier cloth to control bondline thickness. Figure 7 is a plot of the STEPLAP program output for typical joint analysis at room temperature. Joint configuration, ultimate loading, and adhesive strain are included. The adhesive strain plot illustrates the elastic trough on each step and the spike at each step end. Shear strains at the joint ends exceed the elastic strain of the bilinear FM300K stress-strain design curve (Fig. 4), and the shear stress plateaus at 39 MPa (5700 psi). For the room-temperature analysis, only a small length of the end steps is strained in the plastic range.

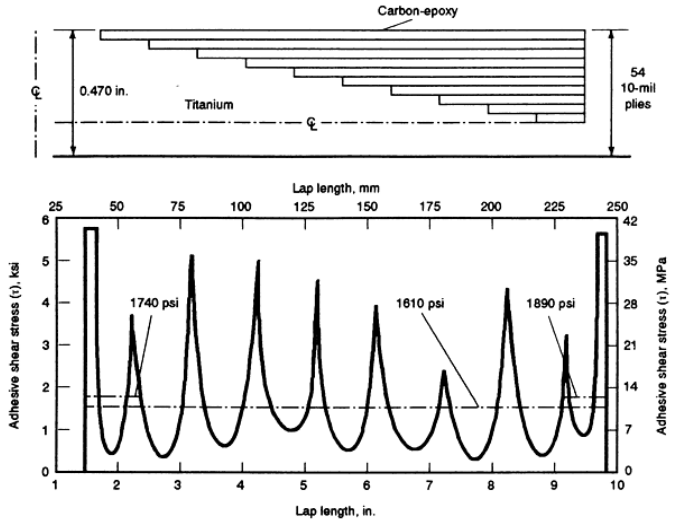

FIG. 7 ADHESIVE SHEAR STRESS DISTRIBUTION FOR AN ADHESIVELY BONDED STEPPED-LAP JOINT GENERATED USING THE STEPLAP COMPUTER PROGRAM

Thermoplastic Composites. AS4/APC-2 is one of the most frequently used and well characterized thermoplastic materials available. AS4/APC-2 is a semicrystalline material with excellent resistance to fluids (except fuel) and solvents and has low moisture absorption (AS4/APC-2 absorbs 0.25% moisture at 95% relative humidity). The two current methods used for bonding thermoplastics to metals or other composites are amorphous bonding and adhesive bonding. The primary joining technique used for thermoplastic semicrystalline adherends (such as AS4/APC-2) is to melt-fuse an amorphous thermoplastic film (Ultem) at the interface. This joining process (amorphous bonding) is accomplished by first adding a lower melt-fuse temperature resin onto the surface of the adherend to be subsequently joined (Fig. 8). Since the melting point of the amorphous film on the adherend surface and at the interface is about 300 °C (570 °F), the bonding does not affect the integrity of the AS4/APC-2 laminates, which are processed at 380 °C (720 °F). Amorphous bonded joints are structurally efficient and can produce room-temperature shear strengths in the 28 to 34 MPa (4000 to 5000 psi) range (Fig. 9). One limitation of amorphous joining is that the amorphous thermoplastic resin absorbs more water (1.3%) than semicrystalline thermoplastic composite laminates and the service temperature must be kept below 200 °C (390 °F) to prevent steam-pressure delamination damage of the joint (Fig. 10). A detailed explanation of the steam-pressure delamination phenomenon is described in Ref 6.

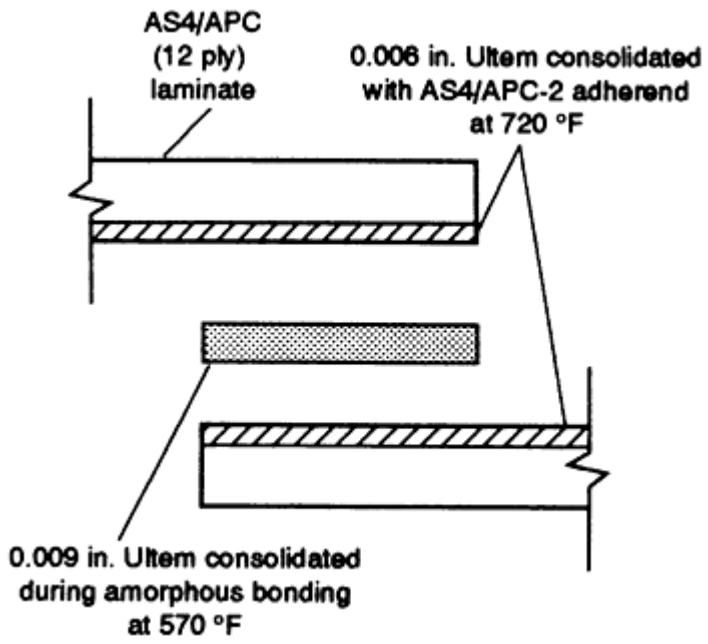

FIG. 8 SCHEMATIC OF THE AMORPHOUS BONDING PROCESS. ORIGINAL SPECIMEN DIMENSIONS GIVEN IN INCHES

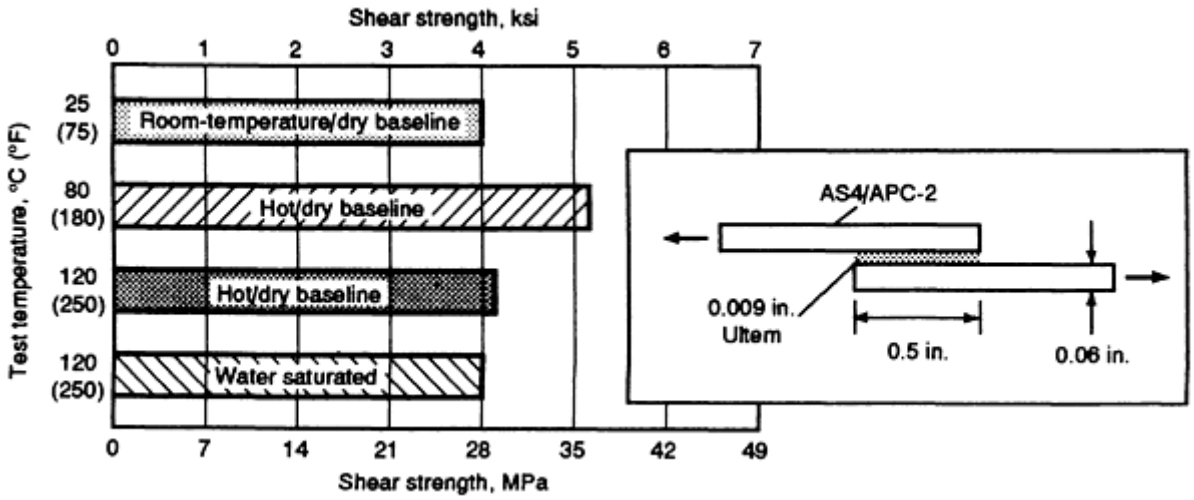

FIG. 9 SHEAR STRENGTHS OF SINGLE-LAP JOINTS PRODUCED BY AMORPHOUS BONDING

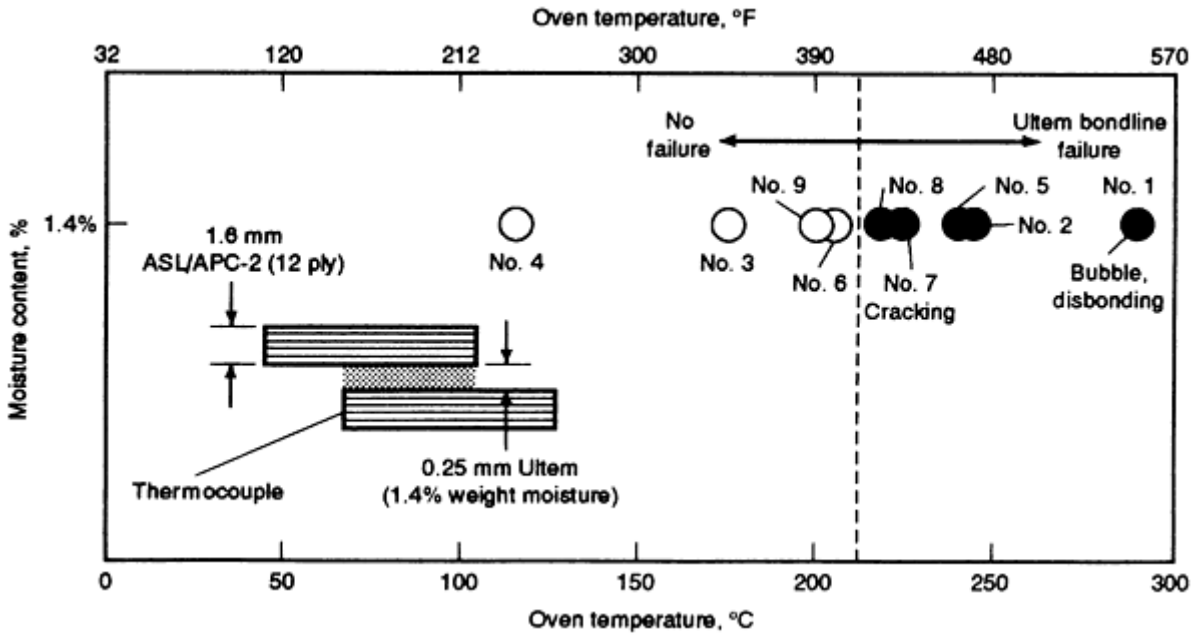

FIG. 10 THERMAL SHOCK (STEAM DELAMINATION) PROPERTIES FOR MOISTURE-SATURATED THERMOPLASTIC ADHERENDS JOINED BY AMORPHOUS BONDING WITH ULTEM. EACH CIRCLE REPRESENTS TESTING RESULTS OF ONE SPECIMEN. NUMBER INDICATES TESTING SEQUENCE.

Amorphous bonding of thermoplastics that requires an autoclave process (290 °C at ~700 kPa, or 550 °F at ~100 psi) is difficult to accomplish in a field-repair environment where minimal equipment is available. Therefore, adhesive bonding is a viable approach for attaching a metal or composite repair patch because the adhesive bond can be cured with a heating blanket (up to 175 °C, or 350 °F) and a vacuum bag. Epoxy adhesive systems do not bond as well to semicrystalline thermoplastics as to amorphous thermoplastics or thermoset composites. A test program was conducted to evaluate the benefit of adhesive bonding of an AS4/APC-2 thermoplastic with or without a layer of Ultem film. Two different adhesives were included in the evaluation --FM300 and FM73. The room-temperature dry test results indicated that the optimum combination was with the co-consolidated Ultem film and the FM73 adhesive. This combination

produced the highest lap shear strength (34 MPa, or 5000 psi), minimum test scatter, and a desirable cohesive failure mode. The quasi-isotropic AS4/APC-2 adherends used in the double-lap shear specimens (Fig. 1) were 2 mm (0.08 in.) thick. All adherends were surface treated by grit blasting followed by an isopropyl alcohol wipe and were bonded under vacuum bag pressure. The FM300 adhesive was processed at 150 °C (300 °F) for 4 h, and the FM73 adhesive was processed at 120 °C (250 °F) for 2 h. Prior to testing, all specimens were heated in a 95 °C (200 °F) oven until dry, stabilized weights were achieved.

Since previous shear strength tests of amorphous bonded thermoplastic joints showed that Ultem was sensitive to absorbed moisture, double-lap shear tests were conducted with and without Ultem for the FM73 adhesive at 25 °C (77 °F) and 60 °C (140 °F) in the dry condition and in the wet condition (95% relative humidity) at 60 °C (140 °F). The results summarized in Fig. 11 show that the moisture reduction factor is 28% at room temperature and 51% at 60 °C (140 °F) for the specimens with Ultem.

Bolted Joints

A composite-to-metal bolted joint was studied as an alternative to the high-load transfer bonded stepped-lap joint discussed earlier (Ref 7). The titanium seven-fastener design shown in Fig. 12 is 380 mm (15 in.) in length (about twice the length of the bonded design) and is 30% heavier than the baseline adhesively bonded joint design. A fastener load-distribution curve is shown in Fig. 13. The test specimen was designed for a zero margin at 150% of design limit load (DLL); failure occurred at 173% DLL. The specimen failed as predicted at the end fastener hole (fastener No. 1) in the high bypass strain area of the carbon-epoxy laminate.

Composite-to-Metal Joining

Raymond E. Bohlmann, McDonnell Douglas Aerospace-East

Submersible Thick Composite-to-Metal Joint

The optimum composite-to-metal joining method for a thick (>25 mm, or 1.0 in.) composite compression-loaded submersible is a block compression joint (Fig. 14). The type of loading for a submersible structure is primarily hydrostatic pressure, which results in biaxial compression loading of 2:1 for cylinders and equal biaxial loading for spheres. Bolted joints are not recommended for submersible structures because they provide a path for a potential water leak. Submersibles made from composites for significant depth operation require thick composite walls that cannot be readily joined by adhesive bonding. Bonded joints are best suited for joining thin structures (<2.5 mm, or 0.10 in.) where peeling

stresses are acceptable. Resin-matrix composites have good in-plane properties (fibers are in-plane) but low interlaminar properties and are weak in resisting peel-type loads.

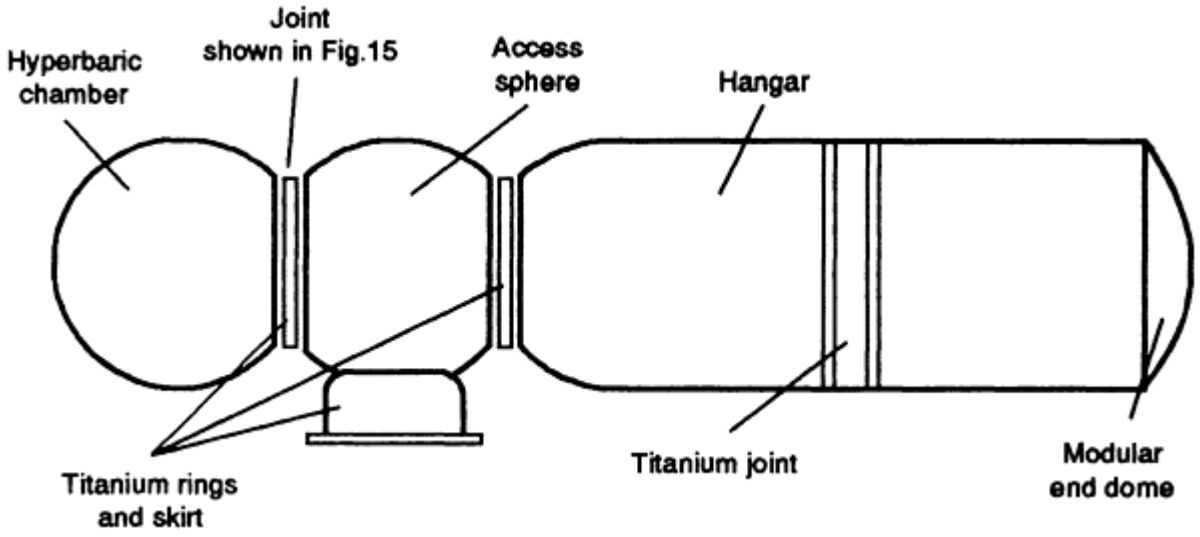

FIG. 14 SCHEMATIC OF THE MAN-RATED DEMONSTRATION ARTICLE (MRDA). SEE ALSO FIG. 15.

A Defense Advanced Research Projects Agency (DARPA) Man-Rated Demonstration Article (MRDA) is being developed (Ref 8). The MRDA is composed of a spherical hyperbaric chamber, a spherical access chamber, a cylindrical hangar section, and a modular end dome (Fig. 14). These components are joined to form a single structure; the joint assemblies used to join the composite spherical elements are made from titanium. The stress state in the regions where the titanium and composite material are in contact are very complex. Analysis of the joint region of the composite spheres indicates that small changes in manufacturing tolerances create significant strain concentrations in the composite spherical hyperbaric chamber. In this region, strains have been shown to be particularly high in the sphere at the point where it contacts the titanium joint. The joint region of concern is shown in Fig. 15.

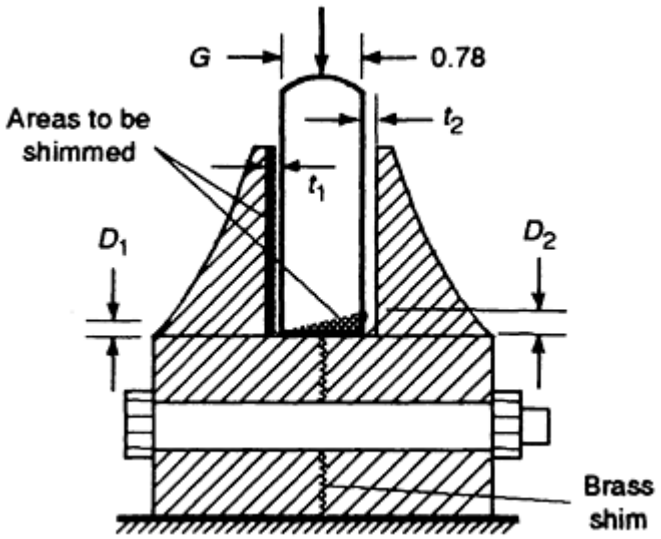

FIG. 15 CROSS-SECTIONAL VIEW OF THE MODULAR COMPOSITE SPHERE JOINT IN THE MRDA SHOWN IN FIG. 14

The tolerance variables considered in this investigation were the thickness of the fiberglass tabs and the perpendicularity between the composite sphere tabs and the composite sphere ends, as shown in the figure accompanying Table 1. Since the fiberglass tabs were to serve as sacrificial material to be machined for fit-up between the sphere and joint, two possible machining conditions were considered. The first condition was to have equal amounts of fiberglass (1.5 mm, or 0.060 in.) on each side of the composite sphere. The second condition was to have all machining performed on the inside of the sphere and resulting in full tab thickness on the outside of the sphere (~3 mm, or 0.12 in.) and essentially no tab material on the inside.

TABLE 1 TEST COUPON TOLERANCES USED TO STUDY COMPOSITE-TO-METAL JOINTS IN THE MRDA SHOWN IN FIG. 14

					T_1	T_2	
1A,B	BASELINE, NOMINAL CASE	0	0	0	0.06	0.06	**NO**
2	MAXIMUM END TAB THICKNESS	0	0	0	0.02	0.12	**NO**
3	EFFECT OF END TAPER	0	0	0.020	0.06	0.06	**NO**
4	EFFECT OF SEVERE END TAPER	0	0	0.040	0.06	0.06	**NO**
5	LATERAL GAP/LIQUID SHIM	0.02	0	0	0.06	0.06	**NO**
6	LATERAL GAP/TAPER LIQUID SHIM	0.02	0	0.020	0.06	0.06	**NO**
7	END TAPER AND LIQUID SHIM	0	0.06	0.080	0.06	0.06	**YES**
8	END TAPER AND LIQUID SHIM	0	0	0.020	0.06	0.06	**YES**
9	**BASELINE, TEST-TO-FAILURE**	**0**	**0**	**0**	**0.06**	**0.06**	**NO**

For the second tolerance condition, out-of-perpendicularity between the sphere end and the joint, which may result from machining or fitup, occurs where the end of the sphere sits in the titanium joint. For the best condition, the entire end of the sphere would contact the joint with no clearance in the fit. Considering the spherical geometry and size of both components, there is the possibility of a clearance in this region rather than intimate contact. To simulate both tolerance conditions, a series of rectilinear coupons to be loaded in uniaxial compression were machined. Table 1 summarizes the test coupon tolerances.

The quasi-isotropic AS4/3501-6 unidirectional tape thermoset compression specimens 20 mm (0.78 in.) thick were autoclave consolidated and then tested. The results of the complete test program are summarized in Ref 8. Only two of the nine specimens tested will be discussed here. These include test case No. 3 (see Table 1), which featured a 0.5 mm (0.02 in.) end taper and test case No. 9, which is a no-gap baseline specimen. The design goal of these tests was to evaluate the assembly up to a gage section strain of 6700 microstrain.

The results of test case No. 3 with the 0.5 mm (0.02 in.) showed significant strain variation at the load introduction end and only minor strain differences in the gage region. After unloading the specimen, no damage was observed. The results of test case No. 9, the baseline with no end taper, showed that the gage section strains were 13,500 microstrain when failure occurred in the gage region. A failed test specimen from test case No. 9 is shown in Fig. 16. An encouraging result of this test is that the 13,500 microstrain is the same level obtained in testing thin-section composites, indicating that thick-section compression properties are not reduced.

Welding of Plastics

Thomas H. North and Geetha Ramarathnam, University of Toronto

---

Introduction

POLYMERS AND POLYMERIC COMPOSITES are attractive because of their high strength-to-weight ratio, chemical inertness, and ability to be molded into complex shapes at relatively low cost. Polymers can be categorized as thermosets or thermoplastics.

In the case of thermoset resins, a chemical reaction occurs during processing and curing, that is, as a result of irreversible cross-linking reactions in the mold. Both molded thermoset and vulcanized elastomer components cannot be reshaped by means of heating, because degradation occurs. It follows that thermoset and vulcanized robber components can only be joined using adhesive bonding or mechanical fastening methods.

Thermoplastic resins, on the other hand, can be softened, as a result of the weakening of secondary van der Waals or hydrogen bonding forces between adjacent polymer chains. Therefore, thermoplastics can be remolded by the application of heat, and they can be fusion welded successfully.

Thermoplastics can be broadly divided into amorphous and crystalline resins, based on morphology, or structure. These materials are more attractive than thermosets because they:

- ARE CHEAPER
- ARE RECYCLABLE
- CAN BE JOINED USING FUSION WELDING
- HAVE GREATER DAMAGE TOLERANCE
- ARE EASY TO PROCESS
- HAVE GREATER IMPACT-RESISTANCE PROPERTIES

Table 1 lists the major thermoplastic resins. Filled thermoplastics are being increasingly used in semistructural applications. Fillers can reduce material cost, enhance mechanical properties, improve thermal properties, provide flame retardation, and so on.

Joining is generally the final step in any fabrication cycle. Some important review articles are represented by Ref 1, 2, 3, 4, 5, and 6. The effectiveness of the joining operation can have a large influence on the application of any polymer or composite material. A variety of polymer joining techniques are available. Figure 1 provides a classification of these different methods (Ref 4).

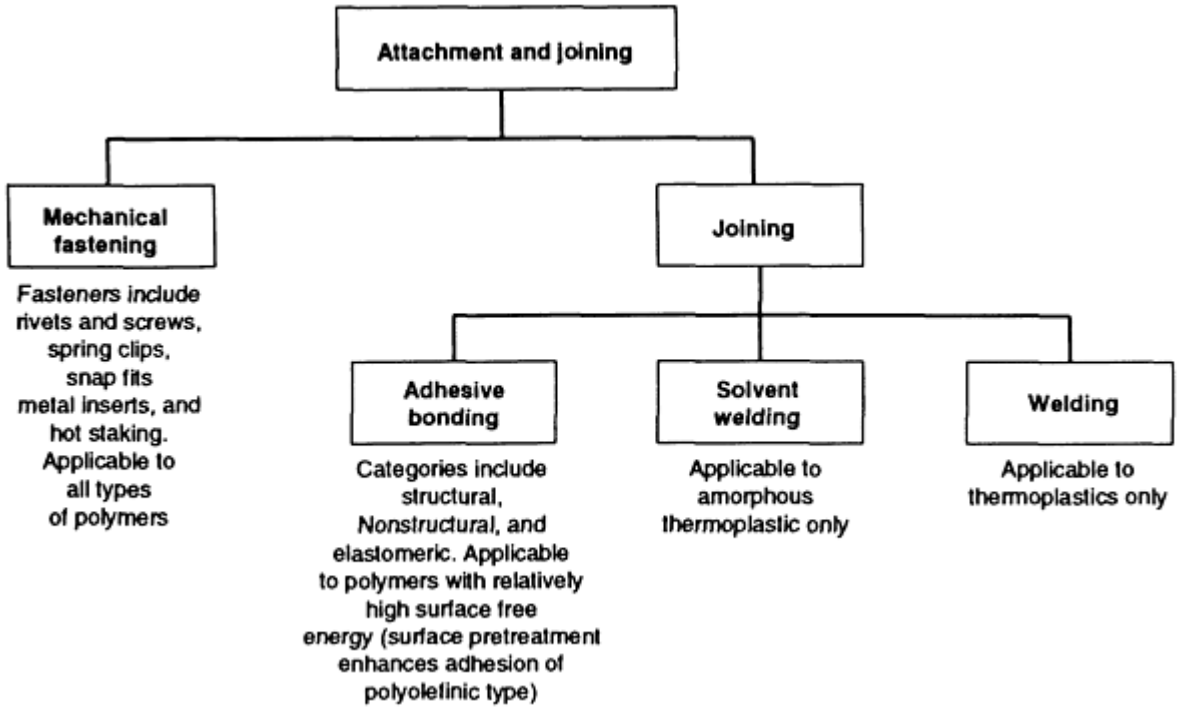

FIG. 1 CLASSIFICATION OF DIFFERENT JOINING METHODS. SOURCE: REF 4

Polymers are low-energy substrates, with surface free energies of less than approximately 50 mJ/m^2 (0.003 ft · lbf/ft^2) (Ref 7). The creation of a successful joint depends on four factors: the chemical nature of the polymer, the surface free energy, the surface topography, and contamination of the polymer surface by dust, oil, and grease. These factors markedly affect the effectiveness of the adhesive and solvent bonding methods. Fusion welding, however, is much more tolerant of aspects such as surface contamination and material variations from sample to sample.

Adhesives are thermoset-type polymers that are classified as structural, nonstructural, or elastomeric. Reference 7 provides additional details. Structural adhesives are generally used in load-bearing applications, in joints that have high strength-to-weight ratios. They are also used to improve resistance to both component fatigue and corrosion resistance. The principal disadvantages of adhesive bonding are that surface preparation is required prior to bonding, curing times can be long, the components cannot be disassembled following the joining operation, and health and/or safety hazards may be involved in their use. In spite of these problems, adhesive bonding is used extensively in numerous industries.

Mechanical fastening and adhesive bonding can be used to join both similar and dissimilar materials. For example, mechanical fastening is commonly used when joining a plastic to a metal (Ref 8), producing either permanent joints or connections that can be opened and sealed again. The advantages of this approach are that no surface treatment is required and disassembly of the components for inspection and repair is straightforward. The main limitations of this approach are increased weight, the presence of large stress concentrations around the fastener holes, and subsequent in-service corrosion problems (Ref 8). The typical applications of mechanical fastening are in the aerospace, automotive, and construction industry.

Polymeric materials that possess similar solubility parameters can be joined using solvent or fusion welding. Interdiffusion of polymer chains plays a major role in achieving intrinsic adhesion (Ref 9) and in promoting chain diffusion, either by applying a suitable solvent or by heating the polymer sample.

As mentioned previously, only thermoplastics can be joined using the fusion-welding process. The glass transition temperature, T_g, in amorphous polymers, and the melting temperature, T_m, in crystalline polymers must be exceeded so that the polymer chains can acquire sufficient mobility to interdiffuse. A variety of methods exist for welding thermoplastics and thermoplastic composites (Fig. 2). Thermal energy can be delivered externally via conduction, convection, and/or radiation methods, or internally via molecular friction caused by mechanical motion at the joint interface. In the case of external heating, the heat source is removed prior to the application of pressure, and longer

welding times are balanced by the greater tolerance to variations in material characteristics. Internal heating methods depend markedly on the material properties (Ref 10). Heating and pressure are applied simultaneously, and shorter welding times are generally involved during the joining process.

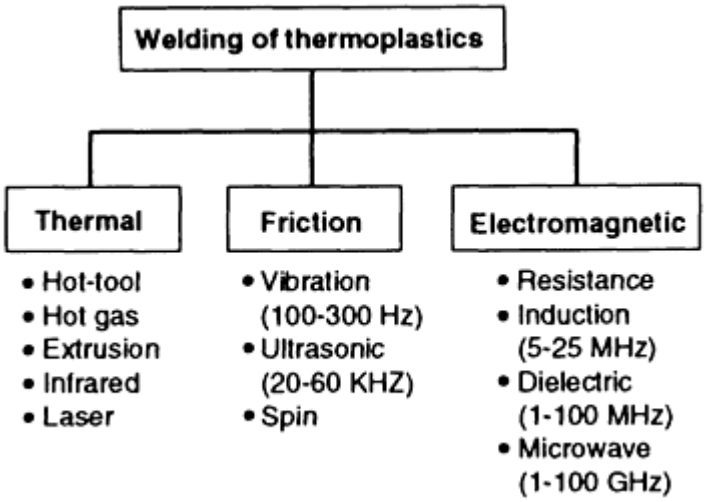

FIG. 2 CLASSIFICATION OF DIFFERENT WELDING METHODS FOR THERMOPLASTICS

Welding is accomplished in many stages. During the initial stage, the polymer-chain molecules become mobile and surface rearrangement occurs. This is followed by wetting and the diffusion of polymer chains across the interface. The final stage involves cooling and solidification. For linear random-coil chains, the mechanical energy required to separate the welded substrates, *G*, is given by the relation (Ref 11):

$$G = W(T,T,P,M) \qquad \textbf{(EQ 1)}$$

where *W* is the welding function to be determined, *t* is the time of contact, *T* is the temperature of welding, *P* is the pressure, and *M* is the molecular weight of the polymer.

In solvent welding, the application of a solvent at the bond line induces sufficient mobility for the polymer chains to interdiffuse (Ref 12, 13). Because the solvent must strongly plasticize the polymer surface, this joining technique is primarily applied to glassy amorphous thermoplastics, such as polycarbonate, acrylic, and polystyrene resins.

Fusion-Welding Techniques

The commonly available fusion-welding techniques will be described in terms of the basis of the joining method, the key joining parameters involved in the process operation, and the application areas of each joining method.

Hot-Tool Welding

Hot-tool welding occupies a central position among the different thermal fusion-welding techniques. This method can provide joint strength that is equal to that of the base material. The surfaces to be joined are brought to the melting or softening temperature by direct contact with a heated tool. Once the desired molten film thickness is produced, the heated tool is removed, the melted surfaces are brought together, and the joint is allowed to cool and consolidate under pressure. Typical welding times range from 10 s to 60 min, depending on the size of the component being joined.

The surfaces of the heated tool are usually coated with polytetrafluoroethylene (PTFE) to prevent the polymers from sticking to the platen. However, the PTFE coating generally restricts the maximum tool surface temperature to 260 °C (500 °F). Some research on heated-tool welding has involved hot-plate temperatures in excess of 350 °C (660 °F) for very short heating times (4 to 6 s). This thermal cycle has been made possible through the use of high-temperature aluminum-bronze heating elements (Ref 1).

The hot-tool welding process can be described by four phases (Fig. 3). During phase I, the surfaces of the material are brought in contact with the heated tool and are held under pressure. This pressure is maintained until a molten film appears. In phase II, the contact pressure between the heated tool and the substrate is reduced to increase the molten-film thickness. The rate of increase of melted-film thickness depends on the thermal conductivity of the polymer. Phase III is the change-over (removal of the hot tool) time, whereas phase IV is the joining and cooling under pressure. The amount of melted-polymer displacement from the weld zone is controllable. For example, computer-controlled machines will allow preselection of the pressure or displacement values that are applied during joining (Ref 15). In this connection, detailed mathematical analyses of the hot-tool welding process have already been carried out (Ref 15, 17).

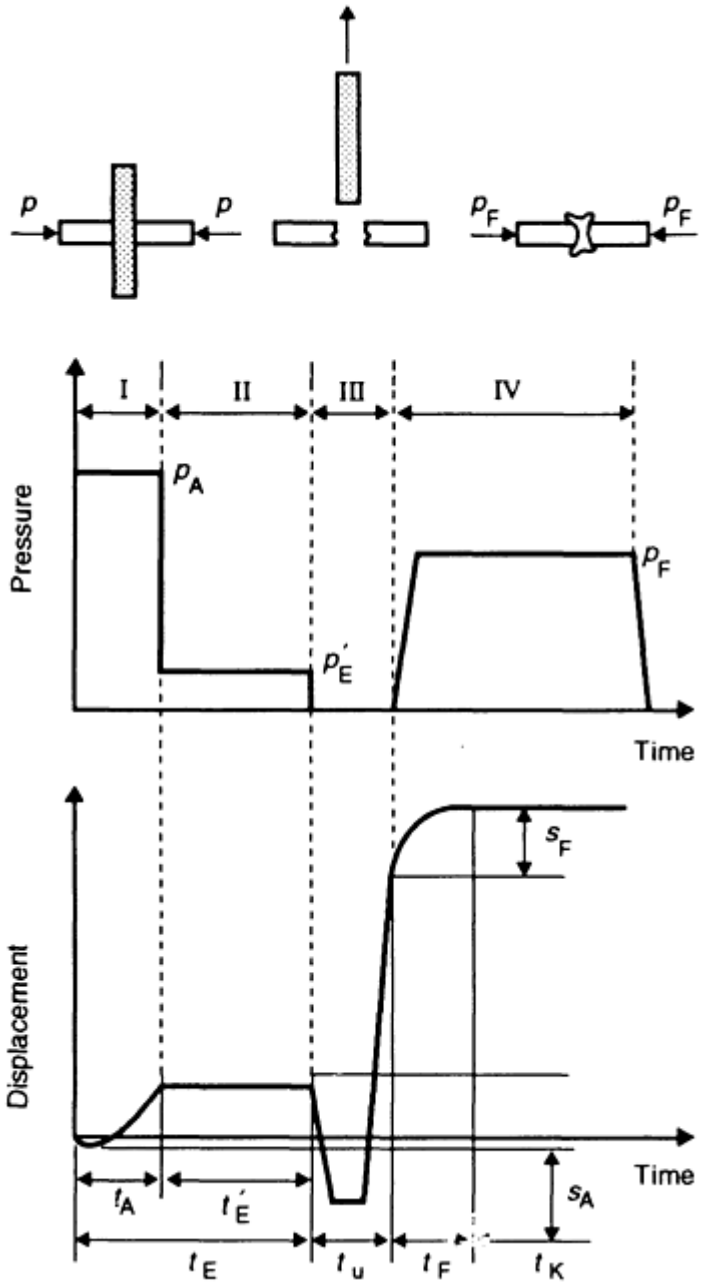

FIG. 3 PRESSURE-TIME AND DISPLACEMENT-TIME GRAPH SHOWING DIFFERENT PHASES OF HOT-TOOL WELDING PROCESS. P_A, P_E, AND P_F ARE MATCHING, HEATING, AND JOINING PRESSURES, RESPECTIVELY. T_E, T_U, T_F, AND T_K REPRESENT HEATING, CHANGE-OVER, JOINING, AND COOLING TIMES, RESPECTIVELY. S_F, REDUCTION IN LENGTH OF THE PART BEING JOINED; S_A, DISPLACEMENT PATH PRODUCED DURING TIME T_E. SOURCE: REF 16

The key joining parameters of hot-tool welding are:

- THE HEATED-TOOL TEMPERATURE, WHICH DEPENDS ON THE POLYMER BEING WELDED
- THE PRESSURE APPLIED AND THE DURATION OF PHASE I. (HOWEVER, HIGH PRESSURE DURING PHASE IV WILL PRODUCE TOO MUCH LATERAL FLOW AND POLYMER-CHAIN ORIENTATION IN THE COMPLETED JOINT, RESULTING IN ADVERSE MECHANICAL PROPERTY EFFECTS, AS DESCRIBED IN REF 15 AND 16)
- THE THERMAL CONDUCTIVITY AND SPECIFIC HEAT OF THE POLYMER AND THE SIZE

AND WALL THICKNESS OF THE PART BEING JOINED, WHICH ARE THE PARAMETERS THAT DETERMINE THE DURATION OF PHASE II

- THE TOOL TRANSFER, OR CHANGE-OVER, TIME, WHICH MUST BE MINIMIZED SO THAT COOLING OF THE MOLTEN LAYER DOES NOT OCCUR (TO AVOID INHIBITING POLYMER-CHAIN INTERDIFFUSION)

Applications. All thermoplastic materials can be joined using hot-tool welding. Components that have large, flat surface areas are commonly butt welded using this technique. It is also possible to join dissimilar materials through the use of two heated platens that are at different temperatures (Ref 14). The weldability factor, in this case, is the degree of compatibility.

Hot-tool welding can be readily automated. Portable equipment is primarily used for on-site weld repairs. Small amounts of joint misalignment prior to joining have negligible effects on the weld quality. Hot-tool welding is used in a variety of industrial applications. The automotive sector, for example, uses it to weld polypropylene (PP) copolymer cases for batteries and to weld rear-light casings of acrylonitrile-butadiene-styrene (ABS) joints to polymethyl methacrylate (PMMA) or polycarbonate (PC) lenses. Hot-tool welding is also employed when welding thermoplastic tanks and when joining large-diameter polyethylene (PE) pipeline to transport gas, water, and sewage wastes.

Hot-Gas Welding

A stream of hot air or gas (nitrogen, air, carbon dioxide, hydrogen, or oxygen) is directed toward the filler and the joint area using a torch (Ref 18). A filler rod or tape (of a similar composition to the polymer being joined) is gently pushed into the gap between the substrates (Fig. 4). A variety of nozzles are available for different applications, and either automated or manual welding can be carried out. During welding, the gas temperature can range from 200 to 600 °C (390 to 1110 °F), depending on the polymer being joined.

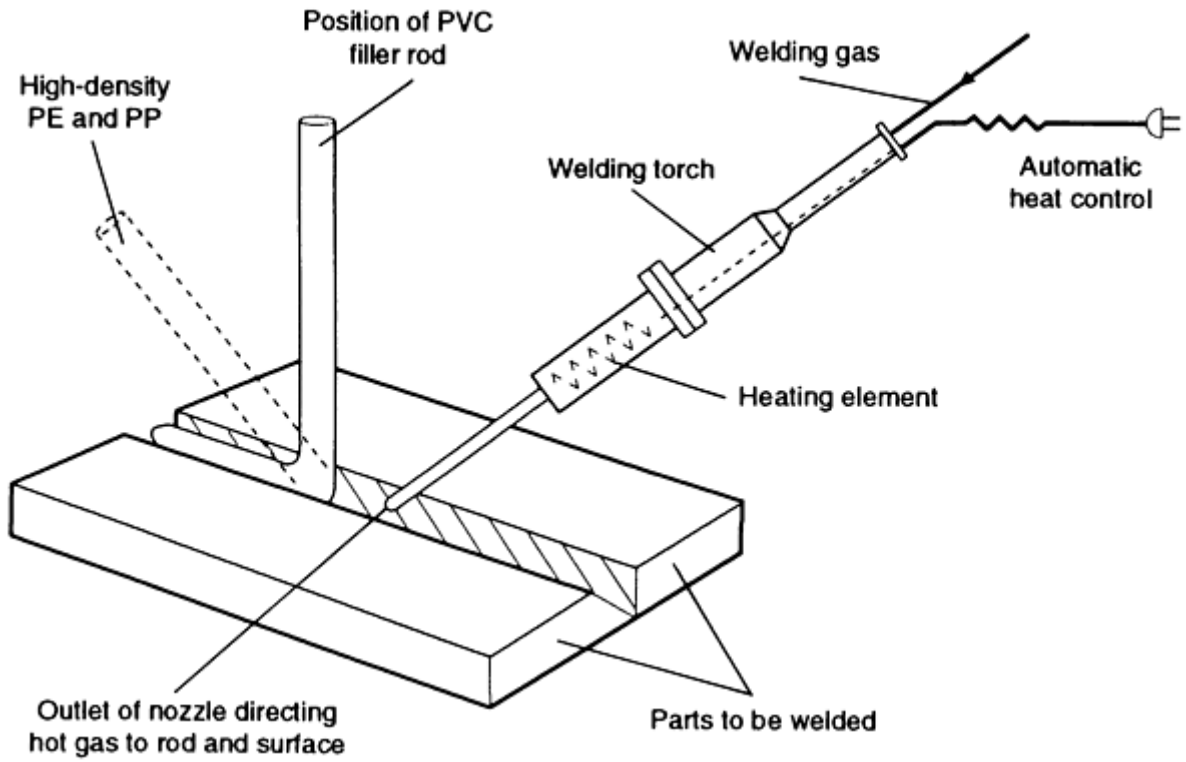

FIG. 4 SCHEMATIC OF HOT-GAS WELDING, SHOWING THE CORRECT POSITION OF TORCH AND FILLER ROD FOR DIFFERENT THERMOPLASTICS. SOURCE: REF 19

The key joining parameters of the hot-gas welding process are:

- GAS TEMPERATURE, WHICH DEPENDS ON THE TYPE OF POLYMER BEING JOINED, AND WHICH DETERMINES THE HEATING ELEMENT, NOZZLE DIMENSIONS, AND GAS/AIR FLOW RATES THAT ARE USED
- WELDING SPEED AND DOWNWARD PRESSURE OF THE WELDING ROD (MANUAL JOINING OPERATIONS)

Applications. The principal application areas involve the continuous welding of polyolefin tanks and containers, the welding of polyvinyl chloride (PVC), ABS, PE, and PP pipe sections, the sealing of packaging materials, and the field repair of PVC and other thermoplastic resins that are used in the construction and automotive industries. Hot-gas welding has a disadvantage in that the temperature of the hot gas/air is much higher than the melting point of the polymer being joined. Therefore, the process has poor energy efficiency, and degradation of the polymer substrate is possible unless care is taken. Polymers that oxidize at temperatures close to their melting points cannot be welded by this technique.

Extrusion Welding

Extrusion welding is similar to hot-gas welding. The weld area is heated using hot air, and plasticized filler material is extruded into V-shaped or lap seam joints under pressure by means of a welding shoe (Ref 20, 21). The preheating and welding-shoe assemblies are connected to the welding head, and the welding speed is kept constant by an automatic traversing unit that has adjustable motor speeds (Fig. 5).

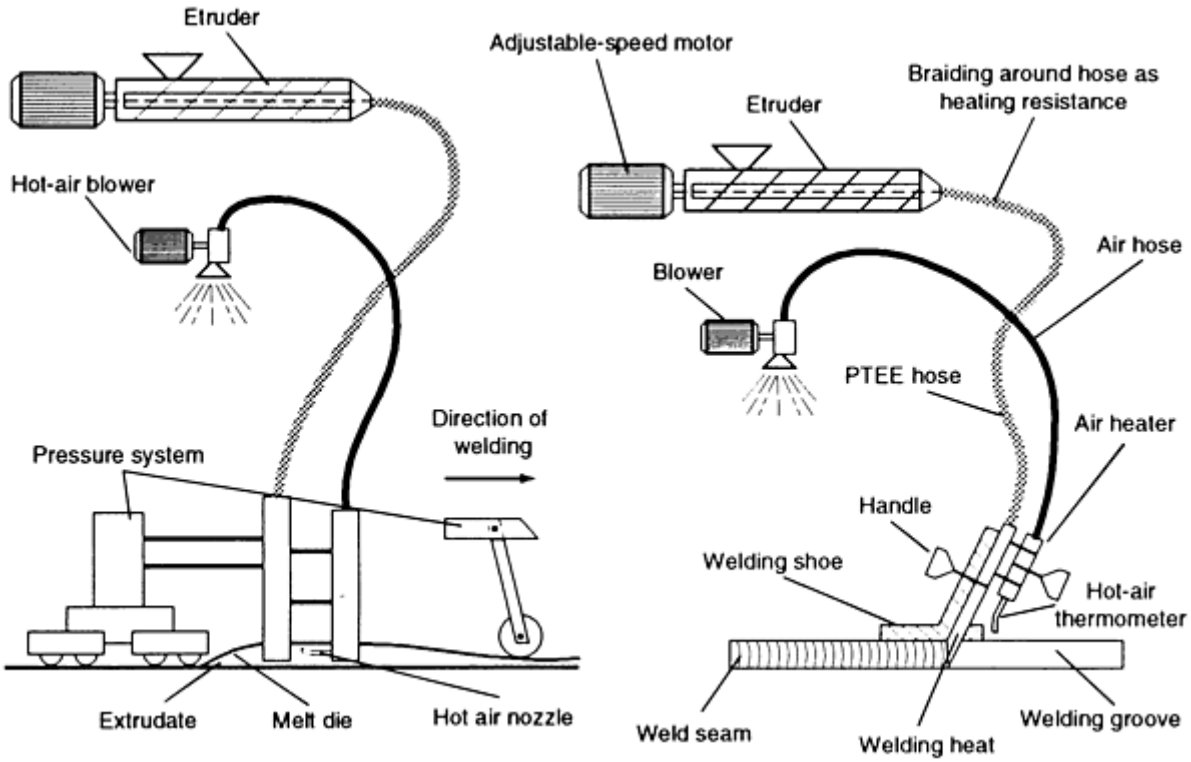

FIG. 5 SCHEMATIC OF VARIANTS OF EXTRUSION WELDING PROCESS. SOURCE: REF 20

The key joining parameters of this process are the:

- FEED ANGLE AND TEMPERATURE OF THE HOT GAS
- TEMPERATURE AND PRESSURE OF THE EXTRUDATE
- RELATION BETWEEN THE EXTRUDATE DELIVERY RATE AND THE WELDING SPEED
- HORIZONTAL AND VERTICAL FORCES APPLIED AT THE WELDING SHOE

- WELD LENGTH AND TIME REQUIRED TO COMPLETETHE JOINT

Applications. Extrusion welding is primarily used for producing long seams in thick-section polyolefin components. This joining technique is particularly useful when welding large container sections.

Focused Infrared Welding

This joining technique uses a quartz lamp and focuses the infrared (IR) radiation using highly polished, parabolic, elliptical reflectors. The focused IR method directs a precise, high-intensity reciprocating IR beam of a width that ranges from 1.5 to 3.0 mm (0.06 to 0.12 in.) onto the joint interface (Ref 22). A robotic fixture scans the IR beam back and forth over the two adherend surfaces, and when the joint line reaches the desired temperature, the heat source is removed and the substrates are forged together in a press. Sensors are mounted adjacent to the lamp fixture and are calibrated so that they selectively measure the adherend interface temperature only (Fig. 6).

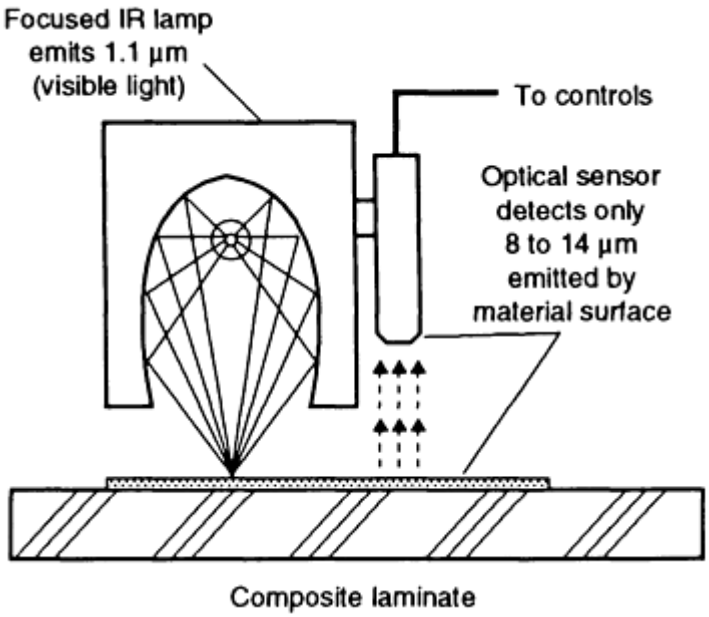

FIG. 6 SCHEMATIC OF FOCUSED IR LAMP AND OPTICAL SENSOR. SOURCE: REF 22

The welding of polyphenylene sulfide, using this IR technique, has been reported (Ref 23). Focused IR welding can be automated. Because this is a relatively new joining process, a detailed analysis of process operation has yet to be conducted.

The key joining parameters of this welding process are the:

- RADIATION DENSITY AND TIME OF IRRADIATION
- RADIATION ABSORPTION, REFLECTION, AND TRANSMISSION PROPERTIES OF THE POLYMER, WHICH DETERMINE THE RATE OF THE TEMPERATURE RISE IN THE IRRADIATED MATERIAL
- FLOW TEMPERATURE AND THERMAL CONDUCTIVITY OF THE IRRADIATED POLYMER
- RECIPROCATION RATE OF THE RADIATOR, WHICH DEPENDSON THE TYPE OF POLYMER BEING JOINED, AND ON THE PART SIZE
- RETRACTION RATE OF THE RADIATIVE HEAT SOURCE AND CLOSING SPEED OF THE PRESS (IN ORDER TO AVOID COOLING THE MELTED MATERIAL AT THE JOINT INTERFACE)

Applications. This technique can be used to join both simple and complex joint configurations when a noncontacting method of heating is essential. In addition, reinforced-fiber disruption can be minimized when advanced thermoplastic composites are joined.

Laser Welding

Limited information is available on laser welding. Carbon dioxide (CO_2) lasers induce excitation of the vibrational modes and, hence, heating of the irradiated organic material (Ref 24, 25). At low power input levels, satisfactory weld penetration can be achieved. The technique also provides high welding speeds and produces very small heat-affected zones (HAZ). Typical joining conditions involve an energy input of 100 W using a wavelength of 10.6 μm. The absorption of laser radiation depends on the relation:

$$I(Z) = I_0 \text{ EXP } (-\alpha Z) \qquad \textbf{(EQ 2)}$$

where z is the distance into the sample at which the laser intensity I (W/cm^2) is measured, I_0 is the laser intensity at the surface of the polymer sample (at $z = 0$), and α (1/cm) is the absorption coefficient. The laser power, P (watts) required for any given material to depth a (meters) can be derived using the relation (Ref 25):

$$p = \frac{vWa(\rho C_p T_m + \Delta H_m)}{0.484} \qquad \textbf{(EQ 3)}$$

where v is the welding speed (m/s), W is the weld width (m), ρ is the density of polymer (ks/m^3), C_p is the heat capacity (J/kg · °C), T_m is the melting temperature (°C), and ΔH_m is the latent heat of melting (J/m^3).

There is not much that has been published concerning the commercial application of this joining method.

Friction Welding

Frictional heating is important in the ultrasonic, vibration, and spin-welding methods. In ultrasonic welding, heat generation depends on the storage and loss moduli of the polymer. In the cases of vibration and spin welding, heat generation depends on the frictional coefficient of the polymer material, and on the storage and loss moduli values (Ref 10). As would be expected, joining processes that depend on direct heat generation at the bond line are more efficient in terms of energy utilization, and the heating and pressure cycles are applied simultaneously.

Vibration Welding

Samples are clamped together and vibrated using an oscillating motion under pressure (Fig. 7). Frictional heating is due to one solid being rubbed against the other, and to the shear heating of the melt. Vibratory motion is applied until the polymer melts at the bond line. Then, the motion is terminated and melted polymer at the joint interface is cooled under pressure.

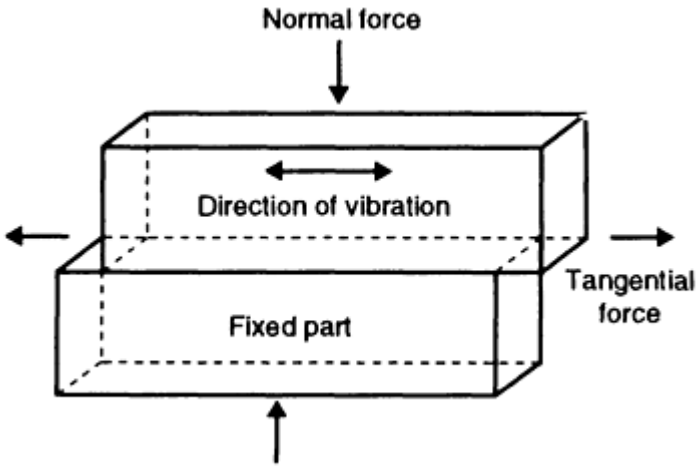

FIG. 7 SCHEMATIC OF VIBRATION WELDING PROCESS

Two types of vibration welding machines are available: linear machines, in which the center of motion lies outside of the molded part; and angular machines, in which the center of motion lies within the molded part (Ref 3). Linear vibration welding is more popular, because of its ability to weld long and narrow molded parts.

During welding, the samples are fixed to upper and lower platens, and the lower platen is kept fixed while the upper platen is vibrated using an electromagnetic or hydraulic drive system at frequencies ranging from 100 to 500 Hz. The vibrational amplitude ranges from 0.1 to 5.0 mm (0.004 to 0.2 in.), depending on the frequency used (Ref 26, 27).

The detailed features of the vibrational welding process have been studied, along with welding parameter optimization, by a number of investigators (Ref 28, 29, 30). It has been shown that the vibration welding process involves four distinct phases (Fig. 8). Phase I comprises the initial heating of the interface to the melting point as a result of coulomb friction. Phase II involves melting and unsteady material flow in the lateral direction. In phase III, melting and flow are at a steady

state, and weld penetration (the decrease in the melted zone width that is due to lateral flow) increases linearly with time. When the vibratory motion is terminated, weld penetration continues to increase until the material solidifies, which represents phase IV.

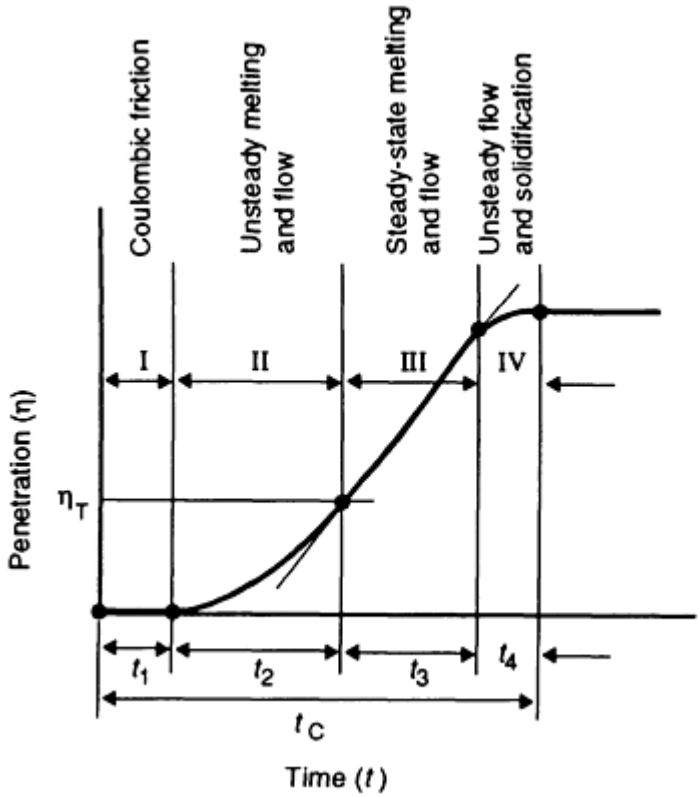

FIG. 8 SCHEMATIC OF PENETRATION-TIME GRAPH SHOWING THE FOUR PHASES OF VIBRATION WELDING PROCESS. SOURCE: REF 26

The key joining parameters of this process are the:

- AMPLITUDE, FREQUENCY, AND TIME OF VIBRATION APPLIED DURING WELDING
- PRESSURE APPLIED DURING THE JOINING OPERATION

It has been reported that the use of a process-controlled pressure profile (high pressures during phase I and lower applied pressures during the subsequent phases) will improve final joint mechanical properties and decrease the welding time, when compared with the time used in a constant weld pressure cycle (Ref 29).

Applications. The success of vibration welding lies in the fact that it can be used to join large parts and is limited by machine size. The joining process, which can be readily automated, can be applied to a variety of plastics, particularly semicrystalline polymers such as PP, PE, acetal, and nylon, which are difficult to weld using ultrasonic welding. Butt weld joints are the principal type of joint geometry that is used. The primary application areas are in the automotive, aeronautical, and household appliance sectors.

Spin Welding

Spin welding is ideally suited for joining cylindrical or circular parts. One half of the component is fixed, and the other half rotates at a prescribed angular velocity while pressure is applied (Fig. 9). Once a desired melted polymer thickness is achieved, the rotational motion is terminated and the parts are pressed together and cooled.

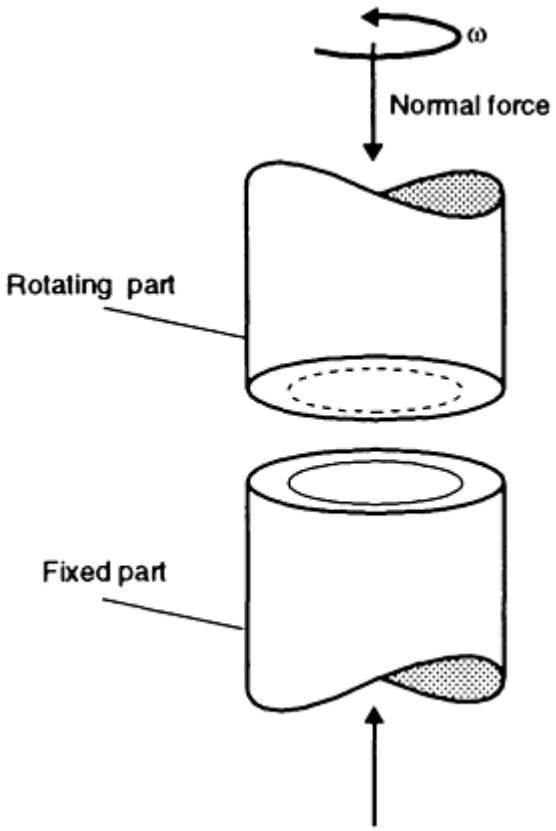

FIG. 9 SCHEMATIC OF SPIN WELDING PROCESS

Spin-welding machines can contain a range of sensors that indicate the rotational speed, axial pressure, weld penetration, velocity, and torque during the joining operation (Ref 31). The joining process can be described as having five distinct phases (Fig. 10). Solid (coulombic) friction, followed by friction and generation of wear particles, occurs during phases I and II. Phase III is the melting transition. Shearing of the melt produces further heat generation, and the weld penetration increases linearly with time in phase IV. Phase V involves cooling and consolidation of the joint under pressure.

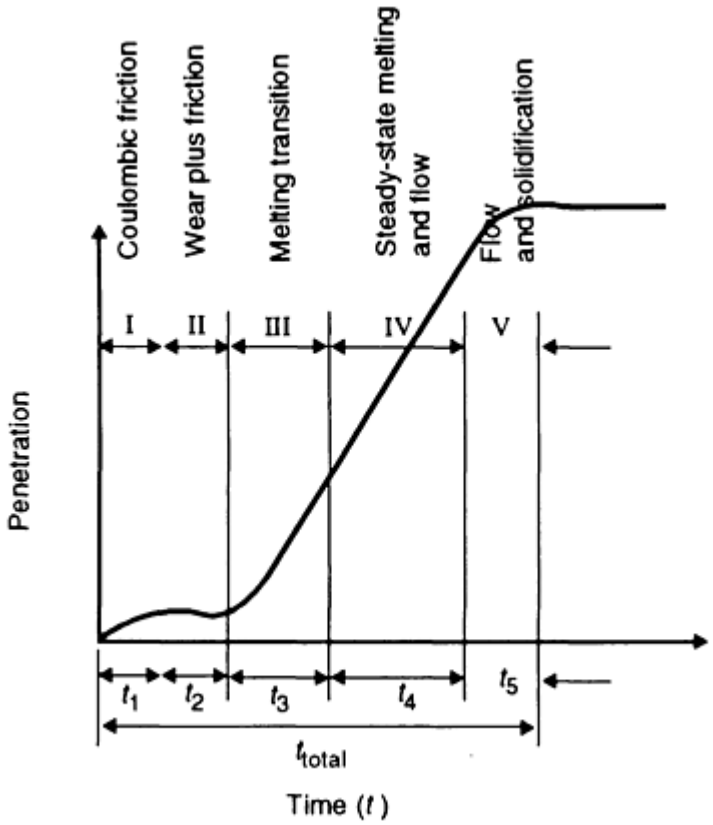

FIG. 10 PENETRATION-TIME GRAPH OF THE SPIN-WELDING PROCESS. SOURCE: REF 32

The key welding parameters are the:

- AXIAL FORCE APPLIED DURING THE WELDING OPERATION, WHICH DETERMINES THE ORIENTATION OF POLYMER CHAINS THAT DEVELOP IN THE COMPLETED JOINT AND MARKEDLY AFFECTS JOINT MECHANICAL PROPERTIES (REF 33)
- TIME REQUIRED TO COMPLETE THE WELDING OPERATION
- ROTATION SPEED EMPLOYED DURING SPIN WELDING

Applications. This inherently simple joining technique is capable of joining large-diameter sections, although it is applicable only to rotationally symmetric components. In the automotive sector, a typical application involves the joining of small, circular parts to large, blow-molded or injection-molded sections. Other automotive-related examples are the joining of ventilation fittings to blow-molded fuel tanks and the welding of gasoline filters and carburetor housings. Spin welding is also used in the manufacture of floats and aerosol bottles in the packaging industry.

Ultrasonic Welding

Ultrasonic welding is the most widely used polymer joining process. Numerous published papers describe the basic features of this joining technique. In this welding process, the sonotrode delivers low-amplitude (15 to 60 μm), high-frequency sinusoidal vibration in a direction perpendicular to the bond line. Although ultrasonic welding machine frequencies range from 10 to 50 kHz, the commonly available devices apply frequencies that are between 20 and 40 kHz.

Ultrasonic-welding machines generally comprise an actuator that contains the converter, booster, horn, and other pneumatic controls (Fig. 11). The ultrasonic vibrations are generated by exciting piezoelectric or magnetostrictive transducer crystals using electrical energy from a power supply. The transducer assembly is rigidly attached to a booster rod that increases or decreases the vibrational amplitude. Finally, the booster is connected to the sonotrode, which

transfers the vibratory motion to the workpiece. The converter, booster, and horn must be resonant at the operating frequency.

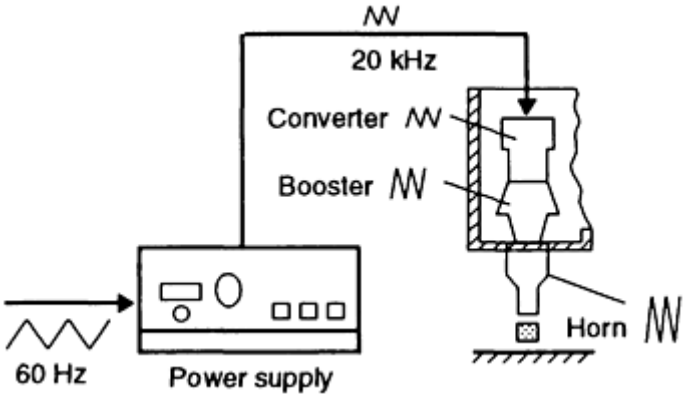

FIG. 11 SCHEMATIC OF ULTRASONIC-WELDING COMPONENTS

The weldability of any polymer depends on the damping capacity, or attenuation characteristics, and size of the component being joined. Depending on the distance between the sonotrode and the bond line, ultrasonic welding is classified as being either near-field (for distances under 6 mm, or 0.24 in.) or far-field (for distances over 6 mm, or 0.24 in.) welding.

It follows that the component geometry has a crucial influence on energy transmission, heat generation, and polymer melting at the joint interface. The transmission of ultrasonic vibrations through the workpiece sets up standing-wave patterns and regions of maximum and minimum displacements (Ref 34). The material fuses in regions of maximum strain or stress.

Amorphous thermoplastics are more readily weldable when an energy director is used. A triangular projection is molded onto one of the specimen surfaces, usually the one that contacts the sonotrode (Fig. 12a). Ultrasonic welds in semicrystalline resins are commonly produced using an interference, or shear joint, design (Fig. 12b). A novel technique that utilizes a tielayer at the interface has been developed recently (Fig. 12c) for use during the ultrasonic welding of flat contacting surfaces.

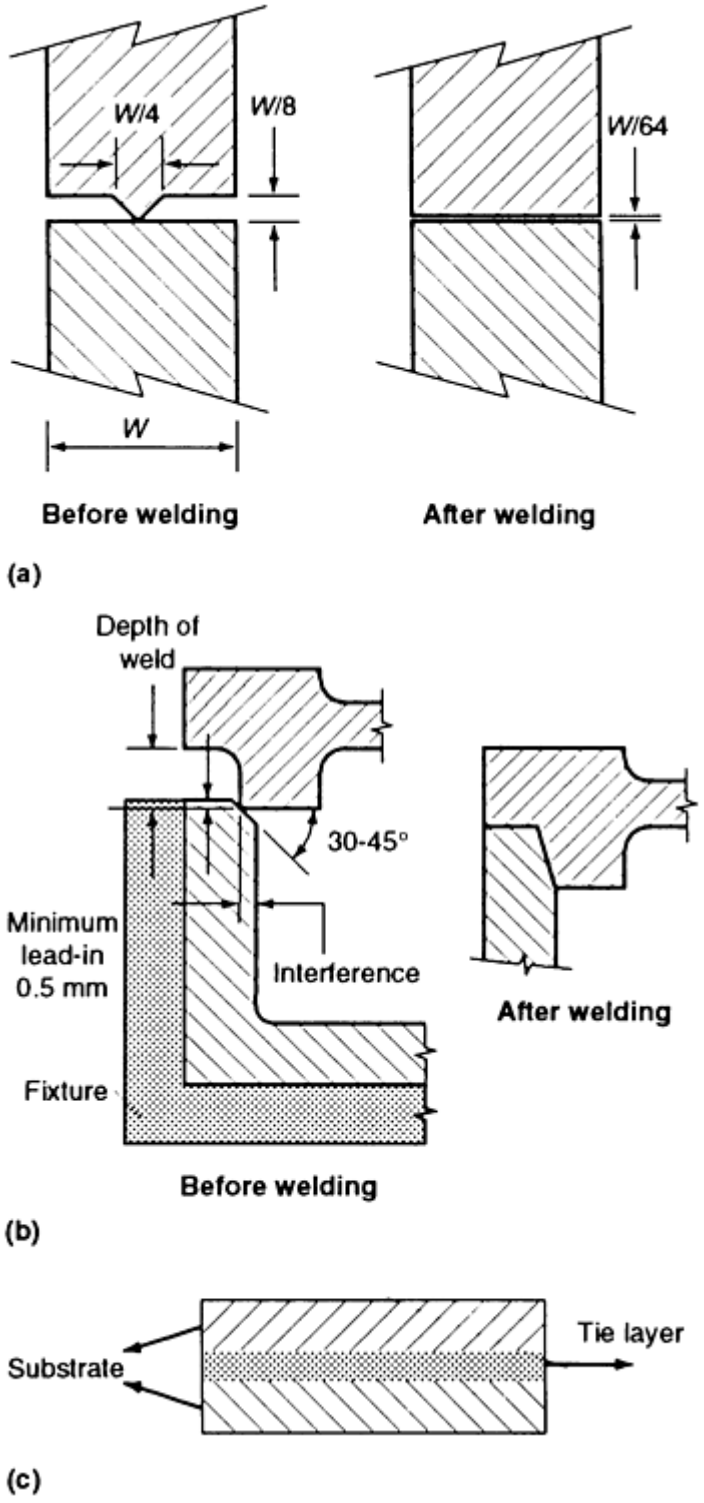

FIG. 12 SCHEMATIC OF ULTRASONIC CONFIGURATION. (A) ENERGY DIRECTOR DESIGN. (B) SHEAR JOINT DESIGN. (C) TIE-LAYER DESIGN. SOURCE: REF 35 AND 36

Energy generation and welding-parameter optimization during the ultrasonic welding of polystyrene (PS), a blend of PC and polybutylene terephthalate, and a composite of polyetherether ketone (PEEK) and graphite APC-2 have been analyzed in detail by different authors (Ref 37, 38, 39). The joining process comprises four distinct phases when tie layers are employed (Fig. 13). The rapid increase in temperature up to the polymer melting point results from frictional heating at surface asperities and, to a much lesser extent, viscoelastic dissipation. In phase II of the ultrasonic-welding process, bulk melting of the interface region predominantly results from viscoelastic energy dissipation. Further heating is due to viscous dissipation during phase III. In phase IV, the joint cools under pressure.

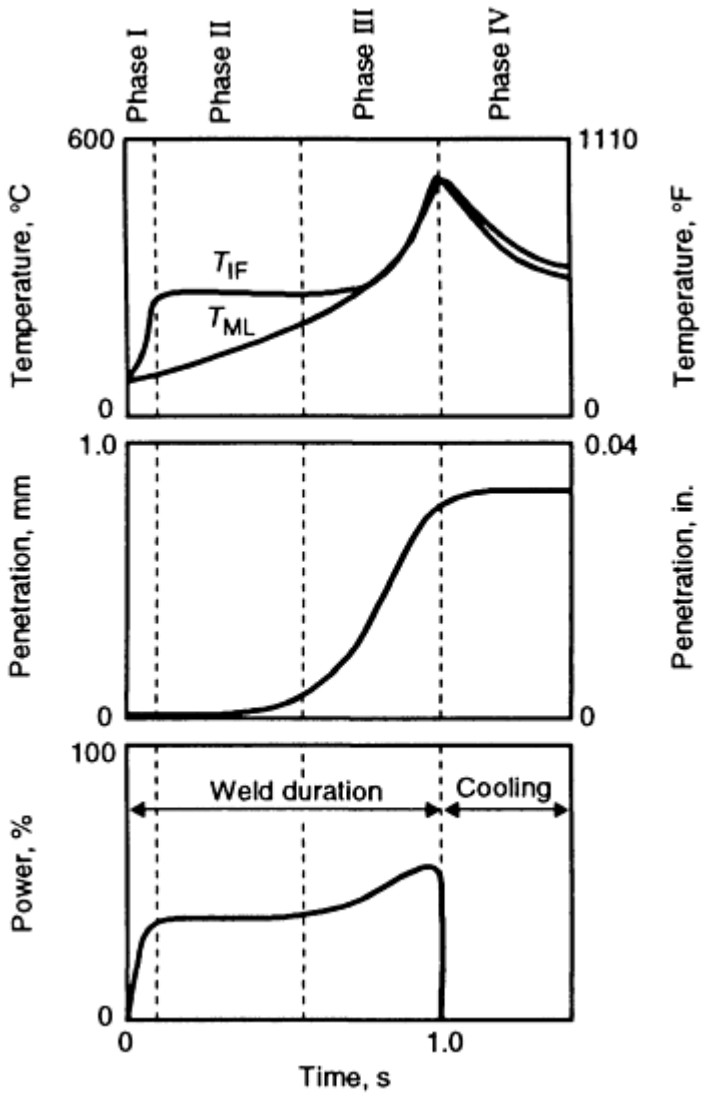

FIG. 13 TYPICAL PROCESS DATA TRACES-TIME GRAPH OF ULTRASONIC-WELDING PROCESS WHEN USING TIE LAYERS AT THE INTERFACE. SOURCE: REF 40

The weldability of a thermoplastic can be defined using the following relationships (Ref 3):

$$f = \int_{T1}^{T2} \frac{r\,c}{\left\{ E' \frac{\tan d}{2} + \frac{0.25}{p}\left[1 - \left(\frac{P}{P_x}\right)^{0,7}\right] v \right\}} dt \qquad \textbf{(EQ 4)}$$

$$\wedge = \pi \mathrm{TAN}\,\delta \qquad \textbf{(EQ 5)}$$

where f is the energy index, T_1 is the ambient temperature, T_2 is the softening point or crystalline melting point of the polymer, ρ is the density, c is the specific heat, E' is the real component of the complex elastic modulus, tan δ is the mechanical loss factor, P and P_x are the joining and critical joining pressure values, respectively, v is the coefficient of friction, and $\wedge$ is the logarithmic damping decrement. When the f value increases, more energy is required during the ultrasonic-welding process. When the logarithmic decrement factor $\wedge$ has a low value, more energy arrives at the joint interface. The f and $\wedge$ indexes are plotted in Fig. 14.

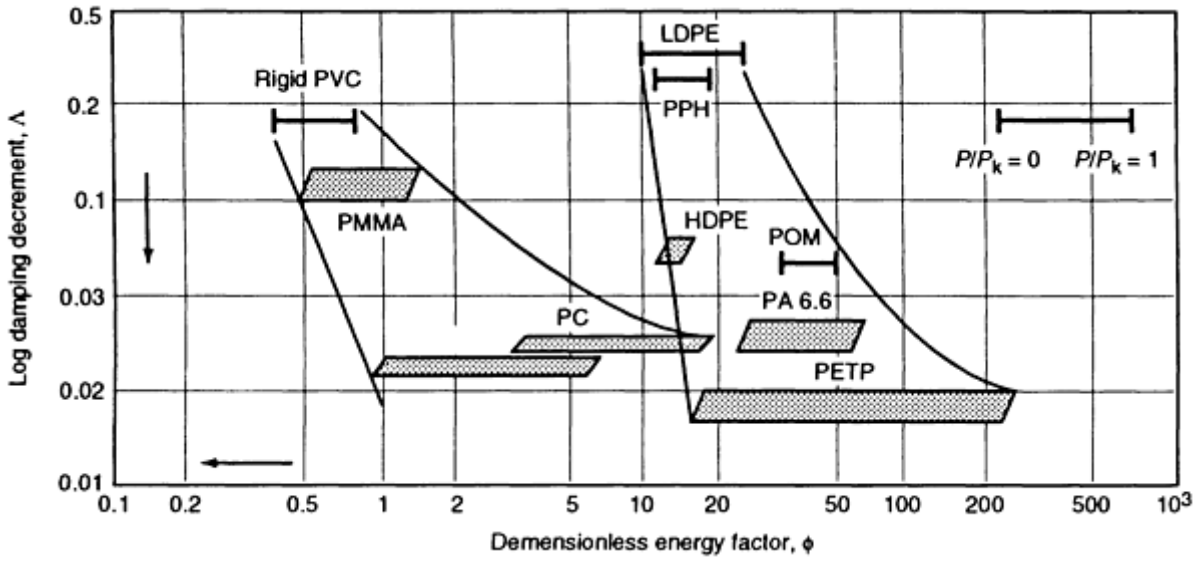

FIG. 14 DIAGRAM FOR ASSESSMENT OF WELDING CAPACITY OF THERMOPLASTICS. ARROW DIRECTION SHOWS INCREASE IN WELDABILITY BY THE INDIRECT METHOD. LDPE, LOW-DENSITY POLYETHYLENE; HDPE, HIGH-DENSITY POLYETHYLENE; PA, POLYAMIDE; POM, POLYOXYMETHYLENE. SOURCE: REF 34

The key joining parameters of ultrasonic welding are the:

- AMPLITUDE OF VIBRATION DURING JOINING
- PRESSURE APPLIED DURING THE WELDING OPERATION
- JOINT GEOMETRY WHEN WELDING AMORPHOUS AND SEMICRYSTALLINE POLYMERS
- WELDING TIME AND ENERGY APPLIED DURING THE WELDING PROCESS
- TRIGGER PRESSURE/FORCE RELATIONSHIP (THE PRESSURE AT WHICH ULTRASONIC VIBRATIONS ARE INITIATED)

Applications. The success of ultrasonic welding lies in the fact that the process is very fast (welding times are approximately 1 s), the equipment is compact, the process can be readily automated, and consistently acceptable weld quality can be produced. Ultrasonic welding is commonly used to join components in the automotive, toy, domestic appliance, and packaging industries. It is also the method of choice when welding many medical plastic components. The only limitation is that large parts cannot be welded using this method.

Electromagnetic Welding

The joining techniques described in this section include resistance, induction, dielectric, and microwave welding.

Resistance or Implant Welding

In this technique, a conducting wire or mesh is inserted at the interface between the parts being welded. This insert is resistively heated by the passage of electric current (Fig. 15a), which melts the thermoplastic surrounding the insert, forming a weld. It should be noted that the implant remains in the completed joint. Electrofusion is a technique whereby the two ends of the pipe to be welded are inserted into a fitting/collar/coupler, the inside of which constitutes the heating element (Ref 41, 42). The electric current that passes through the heating element promotes melting on the inside surface of the fitting. Figure 15(b) shows a typical rectangular cross section of an electrofusion weld.

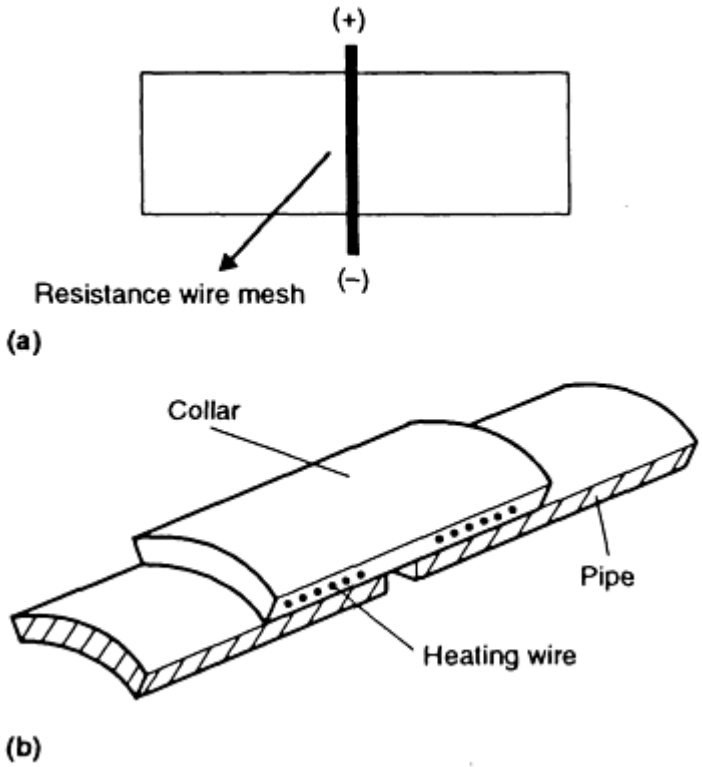

FIG. 15 (A) ELECTROFUSION (RESISTANCE) WELDING PROCESS. (B) ELECTROFUSION WELDING PROCESS. SOURCE: REF 42

The key joining parameters are the:

- APPLIED VOLTAGE AND APPLIED CURRENT, WHICH CAN BE AS HIGH AS 150 A
- CLAMPING PRESSURE DURING WELDING
- HEATING TIME
- AVOIDANCE OF CONTACTING SURFACE CONTAMINATION. BECAUSE MELT FLOW IS RESTRICTED DURING WELDING, IMPURITIES CAN BE TRAPPED AT THE JOINT INTERFACE, REDUCING THE STRENGTH OF THE WELD

Applications. The principal advantage of this joining method is that the equipment is relatively simple and portable. Therefore, it can be used in on-site repair situations. The primary application area for electrofusion welding is the joining of PE pipes with diameters less than 180 mm (7 in.), which are used for water transportation and natural gas distribution (Ref 42).

Induction Welding

In this joining method, a layer of electromagnetic material in the form of a tape or a thin sheet is placed at the joint interface. This insert material is heated using a high-frequency (2 to 10 MHz) inductive supply (Ref 43, 44). The electromagnetic tapes contain conductive and ferromagnetic particles. The particle size, type, and concentration depend on the application desired. The welding equipment comprises a high-frequency induction generator, a water-cooled copper working coil, and press fixtures, which hold the polymer component so that it can be heated and loaded.

Heating results from eddy currents that are induced in the thermoplastic tape containing the ferromagnetic particles (Fig. 16), and energy generation is proportional to I^2R. Heat generation during electromagnetic welding has been modeled, particularly for cross-ply carbon fiber thermoplastic composites (Ref 45, 46).

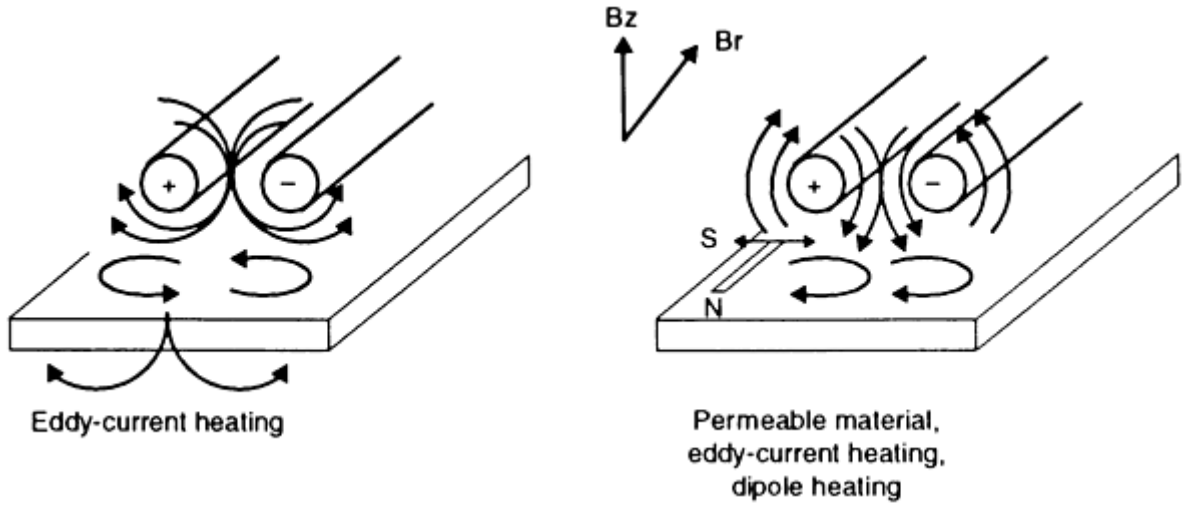

FIG. 16 INDUCTION-HEATING MECHANISM. SOURCE: REF 5

The key joining parameters of this technique are the:

- COIL DESIGN, WHICH MUST BE CAREFULLY TAILORED TO SUIT THE END USE AND TO PRODUCE A UNIFORM RADIO-FREQUENCY (RF) FIELD. A RANGE OF COIL DESIGNS (SINGLE TURN, MULTITURN, HELICAL, BENT HAIRPIN, AND SO ON) ARE ALL POSSIBLE
- FREQUENCY AND POWER OUTPUT OF THE INDUCTION GENERATOR
- PARTICLE SIZE AND TYPE OF FILLER USED IN ELECTROMAGNETIC TAPE MANUFACTURE
- DISTANCE BETWEEN THE INDUCTOR COILS AND THE BOND LINE

Applications. The principal advantage of this joining method is that it can handle components of complex geometry. The process is also suitable for joining filled thermoplastic materials. The primary applications are in the automotive, packaging, and appliance industries. In the medical field, electromagnetic induction welding has been employed for joining PC blood oxygenators and arterial filter components.

The principal disadvantages of this joining process are the high cost of the equipment, the recurring costs associated with the purchase of ferromagnetic-filled tapes, and the care that is required in the design and construction of the inductive heating coils.

Dielectric Welding

In dielectric welding, the joint interface is subjected to much higher RF electrical energy. The process utilizes these major components:

- A GENERATOR THAT PRODUCES A FREQUENCY RANGING FROM 13 TO 100 MHZ (27.12 MHZ IS TYPICAL) OF ELECTRICAL ENERGY AT AN OUTPUT OF 1 TO 25 KW
- A PRESS THAT CLAMPS THE SECTIONS TOGETHER DURING THE HEATING AND SUBSEQUENT COOLING CYCLES
- A BRASS ELECTRODE OR DIE THAT IS MOUNTED ON AN ALUMINUM PLATE, WHICH APPLIES THE ELECTRICAL ENERGY DIRECTLY TO THE PLASTIC (REF 47)

The key joining parameters of this process are the:

- DIELECTRIC LOSS FACTOR OF THE POLYMER OR THE PRESENCE OF A DIPOLE, BECAUSE A HIGH DIELECTRIC LOSS FACTOR INCREASES THE EFFECTIVENESS OF THE JOINING OPERATION
- THICKNESS OF THE MATERIAL BEING JOINED
- OUTPUT POWER AND FREQUENCY OF THE GENERATOR EMPLOYED DURING WELDING

Applications. Dielectric welding is a fast, efficient joining method for sealing thin polymer films and sheet materials. The equipment can be readily automated. However, the process can only be used on materials that have a high dielectric loss factor, such as rigid or flexible PVC, ABS, and thermoplastic polyurethane materials. The principal application area is in the packaging industry, where the process is used to join medical components, such as blood-pressure cuffs, medical bags, rainwear, pool liners, and so on.

The primary disadvantage of this joining technique is that the initial equipment cost is high.

Microwave Joining

This joining technique depends on the heat produced by microwave-frequency radiation. The parts being joined are held together under a slight pressure of 35 to 70 kPa (5 to 10 psi), and then the interface is irradiated by electromagnetic (EM) radiation using well-focused horn antennas. In order to absorb EM energy, the polymer must contain polar groups. To attain viable heating, either a nonconducting or a low-conductivity polymer may have to be doped with conducting polymer or, as an alternative, an adhesive film that contains polar and/or electron-withdrawing groups can be placed at the joint interface (Ref 48).

This joining method is relatively new and is still in the experimental stage. The experimental equipment (Ref 48) consists of a magnetron tube that generates the microwave energy, a ferrite isolator that shields the magnetron and promotes the efficient transmission of power with very little attenuation, a forward/reflected-power indicator that monitors the whole system while it is in operation, a tuner that can be adjusted to minimize the reflected power and aid in the maximum transfer of power from the source to the workpiece, a variable-coupling iris that optimizes and adjusts the power coupled to the load, and, finally, an applicator that concentrates the microwave power at the joint region.

The key joining parameters of this process are the:

- MICROWAVE PROPERTIES OF THE MATERIAL, SUCH AS PERMITTIVITY AND PERMEABILITY
- FREQUENCY AND ENERGY OF THE MICROWAVE SUPPLY

Applications. This welding technique is simple, fast, clean, and very efficient in terms of energy conversion. Consequently, short welding times are involved. Dissimilar materials can be joined, and the use of a microwave-absorbing adhesive will permit the repair of thermoset- or thermoplastic-based composite materials. This joining method can be very useful for in-situ repairs of structures, especially on space vehicles and other aircraft.

Evaluation of Welds

Because polymers are being used increasingly for semistructural and load-bearing applications, the testing of the welded joints is important. The mechanical properties of welded plastics can be evaluated by performing standard destructive tests, such as tensile, peel, wedge, and four-point bending. Of particular interest is the development of short-term tests (Ref 49), where a hole is notched in the weld area (to create multiaxial stress). These short-term tests are for quality-assurance purposes only.

For long-term applications, creep tests are much more favored. The measurement of thermal and residual stress has been evaluated using the Moire interferometric method (Ref 50).

The microstructure of the weld zone can be examined using light microscopy, scanning electron microscopy (SEM), or x-ray techniques (Ref 32, 51, 52). The microstructural examination of bonded regions is important because it allows:

- MEASUREMENT OF THE WELD ZONE AND HEAT-AFFECTED ZONE DIMENSIONS AND THEIR UNIFORMITY ALONG THE WELD LINE
- EVALUATION OF THE DEVELOPMENT OF CRYSTALLINITY, ESPECIALLY THE TRANSCRYSTALLINE REGION
- EVALUATION OF THE CHAIN ORIENTATION, ESPECIALLY PARALLEL TO THE BOND-LINE REGION
- ESTIMATION OF THE FAILURE MODES OF MECHANICALLY TESTED WELD SECTIONS
- OPTIMIZATION OF WELDING CONDITIONS IN ORDER TO CONSISTENTLY PRODUCE JOINTS OF OPTIMUM STRENGTH

Nondestructive evaluation (NDE) techniques for the detection of flaws in metal joints are well established. However, in the case of plastic joints, much work is still required to optimize the application of NDE techniques (Ref 53).

Intelligent Automation for Joining Technology

Xiaoshu Xu and Jerald E. Jones, American Welding Institute

Introduction

AS JOINING TECHNOLOGY IMPROVES, industry is incorporating more types of automatic joining equipment and is expending significant efforts to make automated equipment more efficient. One of the most important approaches being used is called "intelligent automation." This approach combines automatic joining equipment, the knowledge of human experts in terms of joining, and a modem computer technique known as artificial intelligence (AI).

Artificial intelligence traditionally covers several application areas. AI techniques that can be applied to the intelligent automation of joining include expert systems, intelligent data-base systems, image processing, signal analysis, fuzzy-logic systems, and artificial neural networks.

An intelligent automation system usually includes an off-line planning system and a real-time adaptive control system that are connected through a computer communications interface. In the off-line planning system, the user develops a plan, with computer assistance, for the specific joining application, such as designing the joint, determining the process control parameters, or planning the robot path. The plan is then sent to the real-time control system through the interface. The real-time controller, using this down-loaded plan, controls the operation of the equipment. During execution, several sensors monitor the process and feed back information to the real-time controller. Using the feedback information, the real-time adaptive controller will adjust the robot trajectory, process parameters, and other controllable variables to correct any run-time errors.

Intelligent automation systems that vary in complexity are being developed by several organizations, as of 1993. Less-complex systems should be released in the near future by welding robot vendors. Currently, an intelligent automation system for arc welding, called WELDEXCELL, is being developed for the U.S. Navy at the American Welding Institute (AWI).

A graphical overview of the WELDEXCELL system is shown in Fig. 1. This system, which is relatively complex, utilizes most of the intelligent system techniques. For this reason, and because the authors are very familiar with it, WELDEXCELL is used for the examples described in this article. Although the discussion concentrates on the application of intelligent automation to arc welding processes, the technique also can be used for other joining processes.

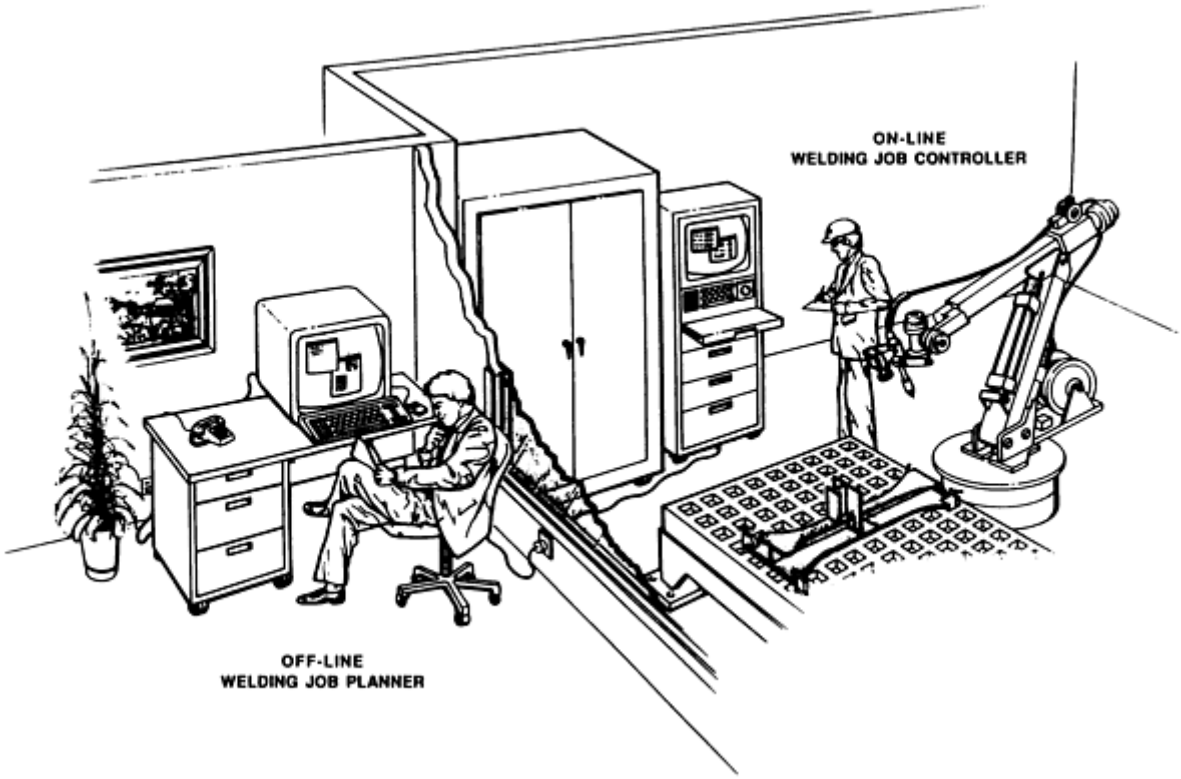

FIG. 1 INTELLIGENT AUTOMATED WELDING SYSTEM

Xiaoshu Xu and Jerald E. Jones, American Welding Institute

Off-Line Planning System

An intelligent off-line planning system comprises several modules. WELDEXCELL, for example, contains four: the parts designer, path planner, welding schedule developer, and system integrator (Fig. 2).

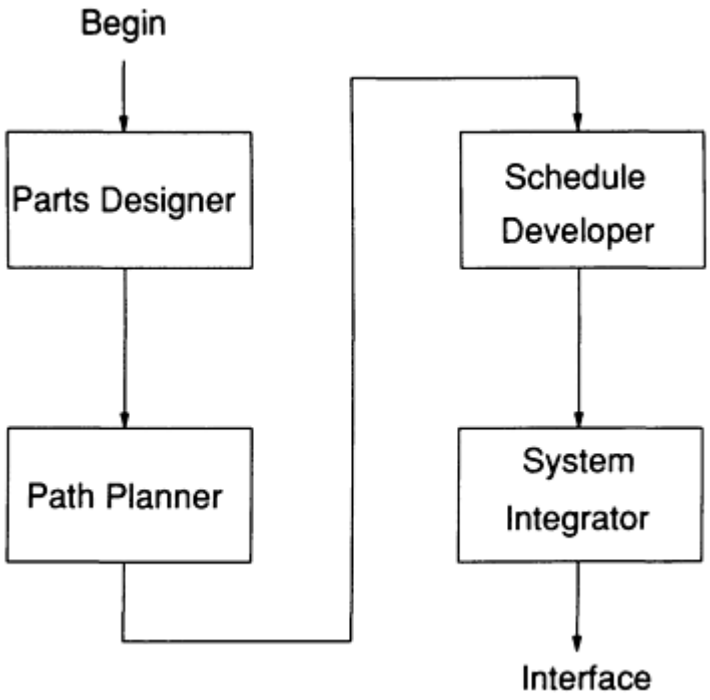

FIG. 2 SEQUENTIAL OPERATION OF AN OFF-LINE PLANNING SYSTEM

Parts Designer. The parts to be joined should first be drawn in a three-dimensional (3-D) computer-aided design (CAD) system. Many suitable commercial CAD systems are available. For a CAD system to be used in an off-line planning system, the required functions include:

- DRAWING FUNCTIONS THAT DRAW EITHER 3-D OR PSEUDO 3-D OBJECTS, INCLUDING LINES, CIRCLES, ARCS, POLYGONS, AND ELLIPSES
- EDIT FUNCTIONS THAT ERASE, MOVE, OR COPY DRAWN OBJECTS
- A FUNCTION THAT CHANGES THE COORDINATE SYSTEM, INCLUDING THE ORIGIN AND THE VIEW POINT (IMPORTANT FOR THE USER INTERFACE, AS WELL AS FOR LATER ROBOT GUIDANCE)
- OUTPUT DRAWING FILES IN ONE OF THE STANDARD VECTOR GRAPHICS REPRESENTATION FORMATS

In the WELDEXCELL system, the user superimposes the weld segments on a separate layer of the CAD part representation. A weld segment is a portion of a weld, and a series of one or more weld segments will produce a single weld on the part. It can be a single- or a multiple-pass weld. However, it has to satisfy the following two restrictions. First, the welding segment must contain a continuous trajectory, which can be a straight line, polyline, circle, arc, or spline in 3-D space. Second, the welding process, position, and all other non-real-time adjustable parameters, such as filler-metal diameter or type of shielding gas, must be kept constant during each weld pass when welding the defined segment.

In the parts designer module, the user is able to set any required welding restrictions for any welding segment. After the parts are designed and the weld segments are defined, they are stored by the CAD system in a vector-based format. This allows the later retrieval of any points that are located on the parts, especially the weld segments and associated restrictions.

- *THE PATH PLANNER* IS AN INTELLIGENT, OFF-LINE, WELD PLANNING SYSTEM COMPRISING TWO PARTS: PATH GENERATION AND ROBOT SIMULATION. FIRST, THE INITIAL ROBOT WELDING PATH IS DETERMINED. THIS PATH INCLUDES THE

TRAJECTORY OF THE ROBOT, AS WELL AS THE MOVEMENT OF A POSITIONING TABLE (IF APPLIED). THE PATH CONTAINS THREE MAJOR SECTIONS.

The start section represents the path from the home (or start) position of the robot to the beginning of the first weld segment.

The welding section, which is the most important section of the path plan, includes the path for each weld segment and the transition path between segments and between welding passes for each segment (in the case of a multiple-pass weld). Because the number of passes and the offset of each pass from the joint centerline for each segment are not known until the welding schedules are later developed, the initial path plan does not take multiple passes into consideration.

The end section represents the path from the end of the last weld segment back to the robot home position.

After the initial path is generated, it can then be sent electronically to the robot simulation model for execution. The simulation environment on the computer should include an animated robot and its environment. Objects that the robot could collide with, such as the welding torch, positioning table, parts to be welded, fixtures to secure the part, and others, should be included in the robot simulation environment (Fig. 3). The simulation will run through the designated path to ensure that no collision occurs between the robot arm and any environmental object and that the path is smooth and satisfies the requirements of the user. The simulation should provide a full 3-D or pseudo 3-D representation and should allow viewing from various positions. Them may be a system inside the simulation that can automatically correct or even optimize the robot trajectory to avoid any possible collision.

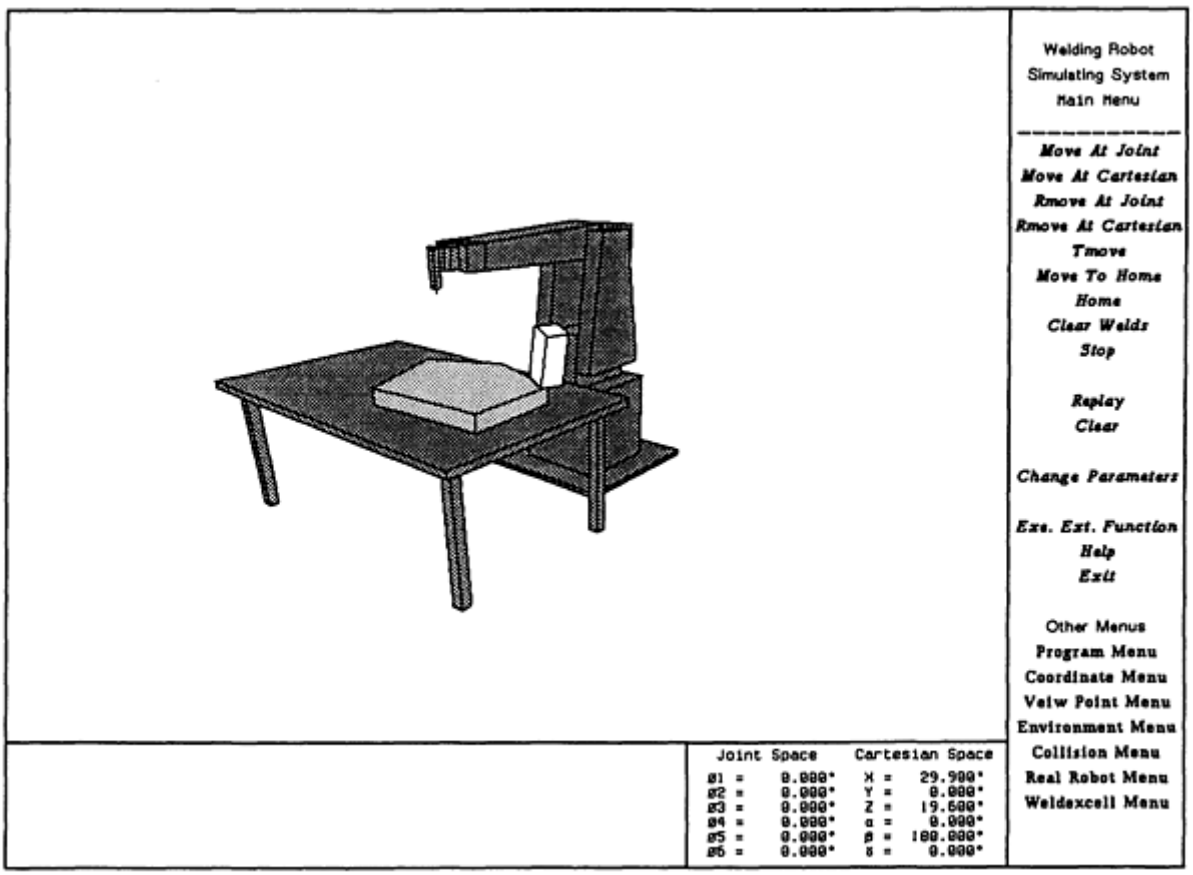

FIG. 3 PATH PLANNER AND ROBOT SIMULATOR IN THE WELDEXCELL SYSTEM

Based on the results of this simulation, either the system or the user can modify the path by using any extra degrees-of-freedom of the robot and/or by rotating the positioning table to adjust the trajectory. If necessary, the welding position can be changed for some weld segments. If the welding position has been restricted by the user, then input from the user is

needed to modify that portion of the path plan. This modified path can then be sent to the robot simulation to run again. Several iterations of this cycle may be required before a satisfactory path plan can be attained. Note that the path generated here is not complete. Multiple-pass welding segments have not been planned, nor has the velocity been set. Final path planning will occur in the system integrator module.

Schedule Developer. A welding schedule is developed for each individual welding segment. All welding variables, except for welding position (determined in the path planner module), are determined by the schedule developer (in combination with user input). These variables include welding process, number of welding passes, consumable type and size, welding current, voltage, wire feed rate, travel speed, shielding gas type and flow rate, required heat treatment, and others.

Several modules in the WELDEXCELL system are used to develop a welding schedule for each segment. These modules, called knowledge sources, will determine the individual variables. The knowledge sources include expert systems, neural networks, and CAD systems. A distributed data base system that contains several data bases is required to support these knowledge sources.

Data Base Systems. Several data bases should be available to the off-line planner. Data can be directly used by either the human user, to develop the welding schedule, or the intelligent off-line planner, in which case the data are available to the other knowledge sources. The data base system should include:

- A BASE-MATERIAL DATA BASE, WHICH STORES THE DESIGNATION AND THE CHEMICAL, THERMOPHYSICAL, AND MECHANICAL PROPERTIES OF THE BASE MATERIALS
- A FILLER-MATERIAL DATA BASE, WHICH STORES THE DESIGNATIONS, CHEMICAL PROPERTIES, AND MECHANICAL PROPERTIES OF THE FILLER MATERIALS
- A JOINT DATA BASE, WHICH STORES JOINT DESIGNS THAT ARE STANDARD (SUCH AS THOSE FROM THE AWS/ANSI STRUCTURAL WELDING CODE D 1.1) AND NONSTANDARD (USER), AS WELL AS DIMENSION INFORMATION, INCLUDING GRAPHICAL (CAD) REPRESENTATIONS
- A WELDING PROCEDURE SPECIFICATION (WPS) DATA BASE (REFER TO REF 1 FOR AN EXPLANATION OF WPS)
- A PROCEDURE QUALIFICATION RECORD (PQR) DATA BASE (REFER TO REF 1)
- A WELD-SCHEDULE DATA BASE, WHICH MAINTAINS THE WELD SCHEDULES ONCE THEY ARE DEVELOPED

An expert system consists of a "knowledge base," which stores information on a subject from a human expert, and an "inference engine," which contains a set of logic processes that is useful in applying the information in the knowledge base. The separation of the knowledge from the logic processes is one way in which expert systems differ from conventional software.

In the field of artificial intelligence, several methodologies have been developed for the representation of knowledge. Some of these have been used to develop computerized applications. Two of the methodologies, specifically "frames" and "production rules," have been successfully used to develop expert systems.

In this type of expert system, the knowledge of the human expert is stored in the production rules. These rules are written in the form of: if (A), then (C); where (A) is known as the antecedent and (C) is known as the consequent. For organizational purposes, and to aid in the application of the logic processes, the rules are then grouped together in a frame structure that is hierarchical in nature.

The expert system operates by selectively choosing rules that generate conclusions or formulate parts of answers to questions. This process is accomplished by the inference engine as the antecedent of a rule is shown to be true by either user input or data derived from a data base for a specific situation.

Sometimes, these rules are also associated with certainties. This gives the final result, or a set of results from an expert system operation, a certainty value. A detailed discussion of expert systems can be found in Ref 2 and 3. As the logic system applies specific rules to generate conclusions, those rules are "chained" together. If the system is designed to form a conclusion, then "backward" chaining is used (that is, working backward from a possible conclusion to show whether it is true or false). Forward chaining is applied if the purpose is to synthesize information, such as to generate a welding procedure.

In a schedule developer, the expert system usually includes such tasks as: select suitable filler-metal type and size, determine preheat and postweld heat-treatment schedule, determine welding parameters, and others.

The WELDEXCELL system, for example, contains several expert systems in the area of arc welding, which can be used in the off-line planning activity. Examples of these include:

- WELDSELECTOR: AN EXPERT SYSTEM TO HELP SELECT AN ELECTRODE (FILLER MATERIAL) AND ELECTRODE DIAMETER. THIS SYSTEM HAS A CERTAINTY-FACTOR-BASED, BACKWARD CHAINING, INFERENCE ENGINE AND GIVES A RANKED LIST OF ELECTRODES FOR A GIVEN APPLICATION. THIS WAS THE FIRST PERSONAL-COMPUTER-BASED EXPERT SYSTEM COMMERCIALLY AVAILABLE IN THE UNITED STATES.
- FERRITEPREDICTOR: AN EXPERT SYSTEM THAT PERFORMS THE FERRITE ANALYSIS FOR STAINLESS STEEL WELDING. FOUR CONSTITUTION DIAGRAMS CAN BE CONSULTED: SCHAEFFLER, DELONG, AND THE 1988 AND 1992 WELDING RESEARCH COUNCIL (WRC) DIAGRAMS. FIGURE 4(A) SHOWS THE GENERAL USER INTERFACE, WHEREAS FIG. 4(B) SHOWS THE WRC DIAGRAM ANALYSIS.
- WELDHEAT: AN EXPERT SYSTEM THAT DETERMINES THE PREHEAT, INTERPASS TEMPERATURE, AND POSTWELD HEAT TREATMENT. THE WELDHEAT EXPERT SYSTEM USES FOUR DIFFERENT METHODS: INTERNATIONAL INSTITUTE OF WELDING (IIW) CARBON EQUIVALENT, WRC PREHEAT AND POSTWELD HEAT TREATMENT TABLE (FROM REF 4), AND A MATHEMATICAL MODEL PREDICTION BASED ON THE WORK DONE BY N. YURIOKA AND M. OKUMURA (REF 5, 6, 7).
- WELDPROSPEC: A SYSTEM THAT INTELLIGENTLY SEARCHES THE PQR DATA BASE, BASED ON A SPECIFIED WELDING CODE, SUCH AS THE AWS/ANSI STRUCTURAL WELDING CODE D1.1. THE WELDPROSPEC SEARCHES THE PQR(S) IN THE PQR DATA BASE THAT CAN QUALIFY THE CURRENT WELD SCHEDULE. IF NECESSARY, WELDPROSPEC CAN CREATE A WPS FROM SELECTED PQR(S) TO SUPPORT THE CURRENT WELD SCHEDULE.

FIG. 4 EXAMPLES OF EXPERT SYSTEM SCREEN DISPLAYS. (A) USER INTERFACE OF THE FERRITEPREDICTOR EXPERT SYSTEM FOR STAINLESS STEEL FERRITE ANALYSIS. (B) A FERRITE ANALYSIS OF A DISSIMILAR METAL STAINLESS STEEL WELD (BASE METALS, 304 AND 316; FILLER METAL, ER308) USING THE 1988 WRC DIAGRAM IN THE FERRITEPREDICTOR EXPERT SYSTEM

A *neural network system* (NNS) is a computer hardware and software technique that simulates an interconnected network of biological neurons, similar to a portion of the human brain. A neural network can be trained with given patterns, called training sets. After the NNS "learns" from the training set, the network can retrieve these patterns and can make generalizations for patterns that are not included in the training set. Neural networks can be used in associative memory, object or pattern classification, process modeling and control, and signal processing. A detailed discussion of neural networks can be found in Ref 8 and 9.

The important NNSs contained in the WELDEXCELL off-line planner are WELDBEAD and HEATFLOW. WELDBEAD, a neural network model of the welding process, predicts bead geometry, such as the bead width, height, and penetration, for a given set of welding parameters and a specific joint configuration. Figure 5 shows the user interface for the WELDBEAD software. A more detailed discussion of the WELDBEAD system can be found in Ref 10.

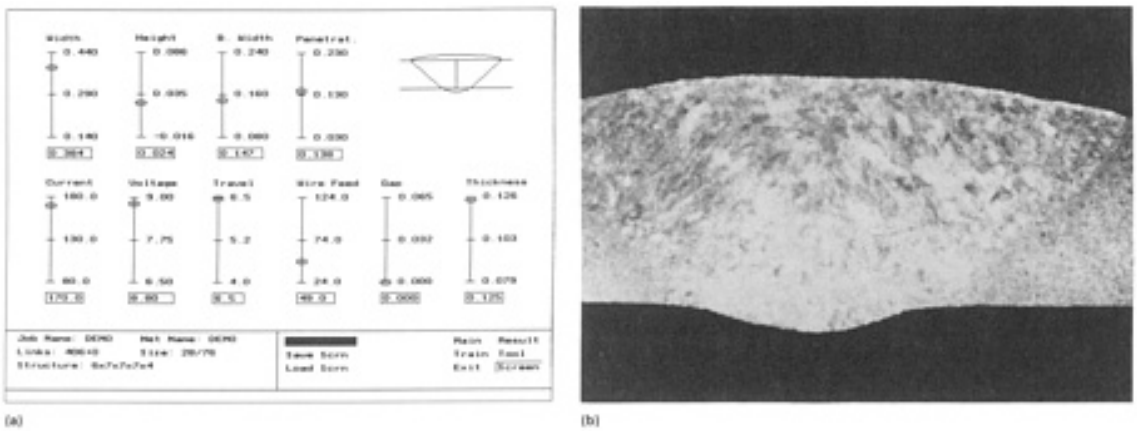

FIG. 5 NEURAL NETWORK SYSTEM FOR AUTOMATED WELDING. (A) USER INTERFACE OF WELDBEAD NEURAL NETWORK WELD MODEL FOR A GTAW WELD IN THIN-SECTION STAINLESS STEEL. (B) MACROGRAPH OF THE RESULTING TEST WELD CORRESPONDING TO THE PREDICTION BY THE WELDBEAD NEURAL NETWORK, SHOWN IN (A)

The HEATFLOW system is used to predict the temperature distribution in the weld. This neural network is a model of the heat flow during welding. When given the voltage, current, wire speed, and travel speed, it can predict the size and shape of the liquid weld pool, as well as provide a map of isothermal lines. This system produces information that is helpful in selecting the proper preheat and postweld heat treatment schedule. Figure 6 shows the WELDHEAT user interface. Reference 11 provides more information.

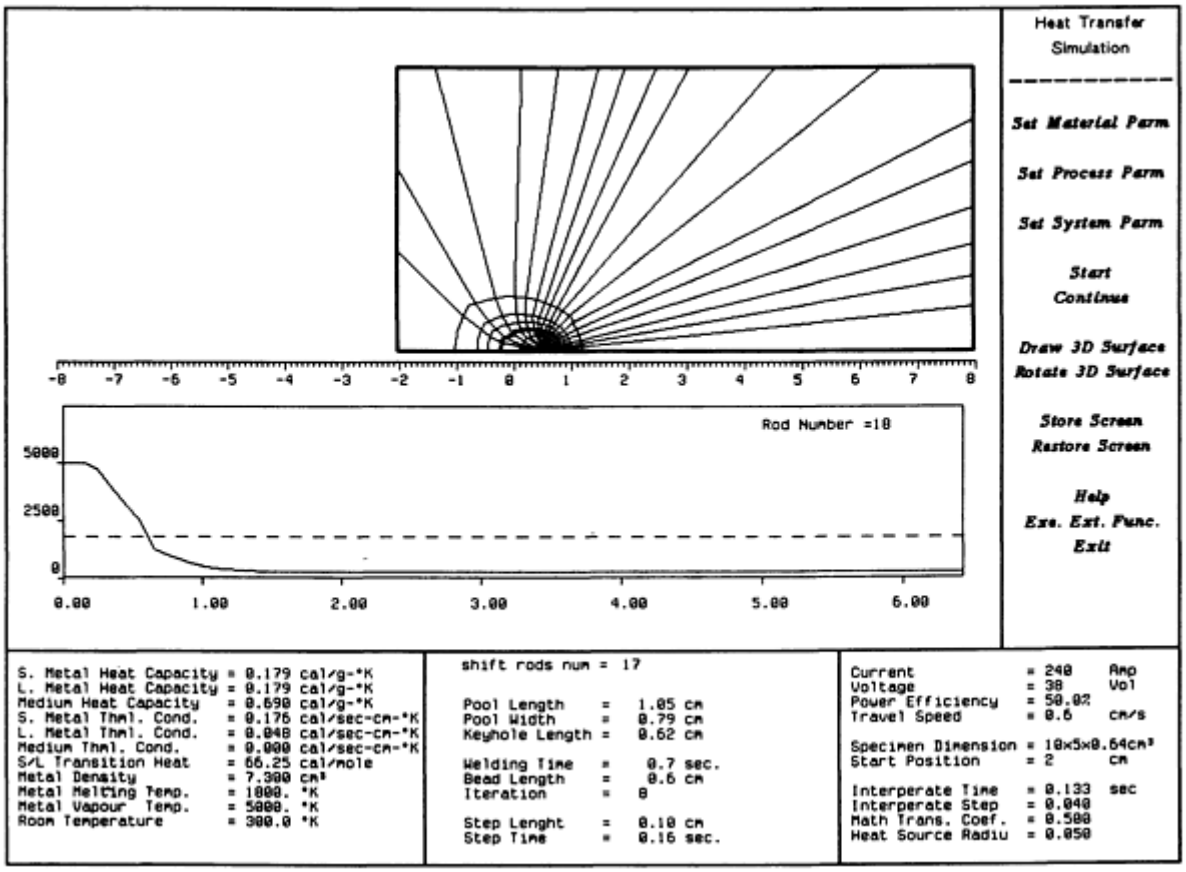

FIG. 6 WELDHEAT PROGRAM USER INTERFACE

In a complex computer software system, such as intelligent welding off-line planning, supervisory software is needed to coordinate the system. One type of supervisory system, known as a "blackboard," was first developed in the 1980s (Ref 12, 13). The computer blackboard architecture has proven to be an efficient system for controlling multiple-knowledge sources, including expert systems, data base systems, neural network systems, and human users. The blackboard integrates and organizes the actions of the various software systems. Often, a blackboard will have an expert system as the principal control element. As an example, the structure of the WELDEXCELL schedule developer is shown in Fig. 7 with the blackboard as the central controller.

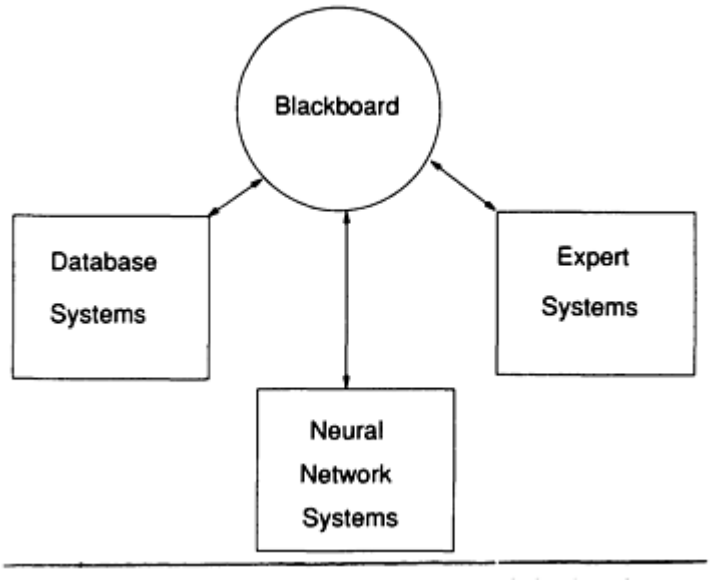

FIG. 7 OPERATION OF THE WELDING SCHEDULE DEVELOPER FROM THE WELDEXCELL SYSTEM

System Integrator. Once an initial weld path has been established and the welding schedule determined, the two separate sets of information must be integrated. Then, the automated welding system will be able to control the process and the torch motion simultaneously to produce a weld.

The first task of this module is to develop a complete robot path. Using the previously developed initial path, this module expands the welding portion to include all passes of a multiple-pass weld. Torch velocity is also assigned to each segment based on the travel speed specified in the schedule developer model. The final welding instruction (path and process control information) can then be sent to the robot simulation, where final modifications can be made by the human user, based on the performance of the simulation execution.

The other task of this module is to combine all of the information, such as pass number(s) and welding parameters, into a set of interface files. These interface files can then be sent to the real-time control system for execution.

Interface Between Off-Line Planners and Real-Time Control Systems

The interface is the communication link between the off-line planner and the real-time control system. This interface is based on computer files, which include the:

- *JOB DESCRIPTION FILE* (*JDF*). THIS FILE CONTAINS THE NAMES OF THE OTHER FILES THAT ARE ASSOCIATED WITH A SPECIFIC WELD JOB.
- *PART SEGMENT FILE* (*PSF*). THIS FILE PROVIDES A DESCRIPTION OF EACH PART SEGMENT TO WELD.
- *JOB TASK FILE* (*JTF*). THIS FILE CONTAINS A SEQUENCE OF TASKS DESCRIBING THE EXECUTION SEQUENCE OF A WELD JOB.
- *WELD SET FILE* (*WSF*). THIS FILE CONTAINS ALL OF THE WELD SETS TO BE USED FOR THE JOB. (WELD SETS ARE DESCRIBED BELOW.)
- *WELD PASS FILE* (*WPF*). THIS FILE PROVIDES INFORMATION FOR CONTROLLING THE MOVEMENTS OF THE ROBOT ALONG EACH PASS.
- *ROB TRAJECTORY FILE* (*RTF*). THIS FILE DEFINES THE ROBOT TRAJECTORY AND POSITIONER MOVEMENT.
- *PART SETUP FILE* (*PSF*).THIS FILE CONTAINS INFORMATION FOR POSITIONING THE PART TO BE WELDED ON THE PART POSITION TABLE, AND FOR LOCATING THE PART RELATIVE TO THE WORLD COORDINATE FRAME OPERATOR.
- *JOB PICTURE FILE* (*JPF*). THIS FILE CONTAINS PIXEL-MAP IMAGES SHOWING THE CROSS-SECTIONAL VIEW OF ALL WELDED JOINTS.
- *JOB NOTES FILE* (*JNF*). THE JNF CONTAINS NOTES OR COMMENTS ABOUT THE WELDING PROCEDURE AND PROVIDES FOR COMMUNICATION BETWEEN THE ENGINEER AND THE WELDING SYSTEM OPERATOR.
- *JOB INTERMEDIATE FILE* (*JIF*). THIS FILE REFLECTS THE JOB STATE AND CONTAINS ANY CHANGES DETERMINED BY THE OPERATOR IN THE SETUP PROCEDURE.
- *JOB RESULTS FILE* (*JRF*). THIS FILE REFLECTS THE FINAL JOB STATE, AS IT WAS ACTUALLY EXECUTED.

This set of files has been proposed to the American Welding Society (AWS) A9 Committee as part of a standard (A9.3) for such interfaces.

The JDF, JTF, PSF, WSF, WPF, RTF, PSF, JPF, and JNF are generated by the off-line planner and sent to the real-time controller. The JIF and JRF store information retrieved during weld job execution from the real-time controller. These files are then sent back to the off-line planner in order to update it and to provide additional training examples for the neural network systems. Many automated welding systems that are computer controlled utilize a "weld set."

- THE FOLLOWING INFORMATION SHOULD HELP TO CLARIFY THE DESCRIPTION OF THE INTERFACE:
- *WELD SET.* A WELD SET IS A COLLECTION OF WELDING PARAMETERS THAT INCLUDES CURRENT, VOLTAGE, TRAVEL SPEED, WIRE FEED SPEED, AND WELDING TORCH ANGLE. WELD SETS ARE IDENTIFIED BY A DESIGNATOR SUCH AS A WELD SET NUMBER (WSN).
- *TRAJECTORY.* A TRAJECTORY IS A CONTINUOUS MOVEMENT OF THE ROBOT WITH THE FOLLOWING RESTRICTIONS: FIRST, A TRAJECTORY HAS EITHER ONE WELD PATH ASSOCIATED WITH IT OR NO PATH, AS IN THE CASE OF A TRANSITION FROM ONE WELD SEGMENT TO AN ADJACENT WELD SEGMENT. SECOND, A TRAJECTORY HAS ONE MOVE PATTERN. THE MOVE PATTERN CAN BE A 3-D STRAIGHT LINE, ARC, SPLINE, OR NONE. NONE, IN THIS CONTEXT, MEANS THAT NO SPECIFIC MOVE PATTERN IS REQUIRED. FOR ROBOTS OF THE PRESENT TIME, THE MOVING VELOCITY HAS TO BE CONSTANT. IT IS LIKELY THAT THIS WILL NOT BE TRUE OF FUTURE ROBOT SYSTEMS. A TRAJECTORY IS IDENTIFIED BY AN IDENTIFIER, SUCH AS A TRAJECTORY NUMBER. BASED ON THIS DEFINITION, EACH PASS IS ASSOCIATED WITH ONE UNIQUE TRAJECTORY.
- *WELD JOB.* A WELD JOB CAN HAVE SEVERAL WELD SCHEDULES. THIS MEANS THAT IN THE EXECUTION OF A WELD JOB, THE WELDING PARAMETERS IDENTIFIED ABOVE CAN BE VARIED. PARAMETERS THAT CANNOT BE ADJUSTED DURING WELDING, SUCH AS FILLER-METAL TYPE AND SIZE OR GAS TYPE AND FLOW RATE, REMAIN CONSTANT FOR ANY CONTINUOUS OPERATION. HOWEVER, THESE PARAMETERS MAY CHANGE FROM ONE PASS TO ANOTHER.

Intelligent Automation for Joining Technology

Xiaoshu Xu and Jerald E. Jones, American Welding Institute

Real-lime Intelligent Control System

The real-time controller for an intelligent automated welding system has several functions. First, it must control the motion of the welding torch. Second, the control of the welding process equipment must be coordinated with the location of the torch in the weld joint. Third, software and hardware are needed to process and interpret the signal data from one or more sensors. Fourth, the controller must have an adaptive process planning and control modification system for making adjustments to the control parameters based on the interpreted sensor data and process models. Finally, for process control and planning improvement, the real-time controller is a platform for the collection of data about the weld that can be up-loaded electronically to the off-line planning system.

Standards

In order for the real-time controller to communicate with the welding process systems and with the off-line planner, it is important that standards be established for the storage and communication of computerized welding information. The AWS A9 and D16 Committees are developing such standards, and the reader is referred to AWS/ANSI A9.1-92 and A9.2-92, as well as the soon to be published standards, such as AWS/ANSI A9.3 and A9.4, and ASTM E49 Committee standards.

Real-Time Control System

The real-time control system comprises six major modules:

- THE INTERFACE TO A JOB DATA FILE OR AN OFF-LINE PLANNER
- THE JOB INTERPRETER
- THE JOB EDITOR AND USER INTERFACE
- THE HARDWARE CONTROLLER OF THE WELDING CELL
- THE HARDWARE OF THE WELDING CELL AND THE ASSOCIATED SENSORS
- THE SENSOR DATA PROCESSOR

Figure 8 shows the structure of a typical real-time intelligent welding control system. Such a system generally consists of a stand-alone computer system and video display device that are built into a shop floor "hardened" cabinet. The cabinet also includes the necessary computing hardware (that is, backplane, processor boards, and other special-purpose electronics) for the real-time control of the welding cell hardware and sensor data input.

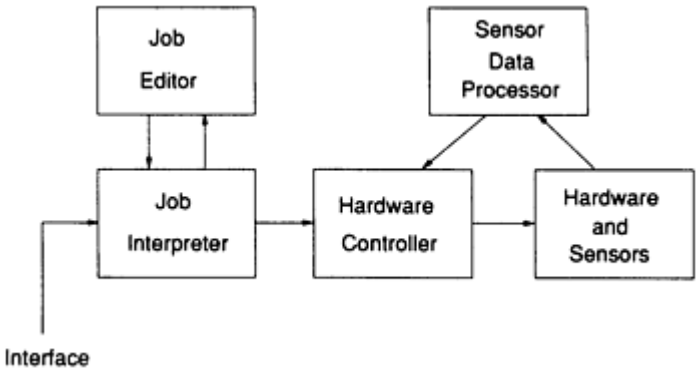

FIG. 8 TYPICAL REAL-TIME CONTROL SYSTEM

The interface module is capable of bidirectional data transfer between the real-time control system and external job data. The job data can reside in a simple data base, for example, on a central data storage device in a network. The interface may only need to download this data. Alternatively, the job data can be obtained by direct communication with the off-line planning system.

The job interpreter reads the interface files and generates the control information. The files that are sent from the interface are used to develop all of the "low-level" control-system parameter values, such as the trajectory for the robot controller and welding parameters for the welding power supply controller. This information is then sent electronically to the welding cell hardware controller subsystem. In addition, the control information is presented to a user interface video screen that the welding cell operator can access. The job interpreter translates the control parameters into data that can be understood by the operator.

The job editor provides an interface for the operator to modify the set points of the welding parameters and robot trajectory prior to the execution. An "intelligent" system will provide software that ensures that these modifications cannot exceed the given minimum and maximum limitations, as specified by the welding engineer or the applicable codes and specifications.

Hardware Controller. A controller is provided for each piece of controllable hardware, such as the robot, welding power supply, wire feed system, gas solenoid and pressure regulators, and others. These hardware controllers typically consist of a digital signal processing integrated circuit that is fast enough to provide control signals to the cell hardware components. These controllers receive information from a software system that interprets sensor data, combines the data with information from the job interpreter, and sends the corresponding commands to the hardware controllers to perform the proper task. Such software systems can be simple set-point or proportional-integral-differential (PID) control systems, or they can be very complex, adaptive, model-based control systems or fuzzy-logic-based control systems.

Basic software control systems attempt to control specific variables based on predefined set-point values. The simplest is an on/off type that turns either on or off, depending on the current value of a control parameter. For example,

if the voltage is less than the set-point value, then an on/off type controller would step up the voltage by the difference between the current value and the set-point value. A more complex controller, the PID type, would make an adjustment to the voltage, but would try not to "overshoot" the value by making small changes to the voltage that were "proportional" to the difference between the current value and the set-point value.

Intelligent adaptive software control systems change the values of one or more control parameters simultaneously, according to the desired "result" of the weld. That is, if a sensor indicated that the weld was not penetrating completely through a root pass, then an intelligent adaptive system would simultaneously change the values of the voltage, current, and travel speed to achieve the end result of increasing the weld penetration. These systems represent a significant improvement in the control capability of the welding process and will, in the future, offer the ability to improve quality and productivity while reducing costs and postweld inspection requirements.

Intelligent adaptive control depends on accurate models of the welding process and, in turn, good theoretical research and empirical results from adequate experimentation. One system design that appears to offer a good methodology for solving the intelligent adaptive control problem is the "hierarchical" architecture. In a hierarchical system, one or more control loops exercise supervisory control over the bottom-level process parameter control system (generally, a PID-type controller).

For example, there could be two supervisory control loops. A neural-network-based inner loop could make direct modifications to the weld control parameter set points for the PID controller. An expert-system-based outer loop would make longer-range control decisions, such as overall weld size for adaptive fill, or overall heat-input changes to account for large dimensional changes to the material being welded. The inner loop would take input from sensors, such as a penetration sensor, and make adjustments quickly to account for penetration variations. The outer loop would accept input from sensors, such as a laser scanner joint profiler, and make changes to the weld deposit size and shape inputs to the inner loop.

Welding Cell Hardware and Sensors. The welding cell includes a set of equipment designed to produce automated welds. This equipment consists of a welding torch manipulation system (for example, a robot), a fixturing and positioning system, a parts transport system, a welding power supply, welding consumable supply systems (wire feeder, flux feeder, gas control equipment, and others), control hardware as described above, fume/consumable removal systems (flux vacuum, fume extraction, and others), sensor systems, and other cell-servicing systems (for example, an automated torch cleaning system).

Robot System. The torch manipulation system must be capable of positioning the torch correctly for the welding operation, moving the torch along the weld in a smooth and controllable manner, operating at useful speeds for the welding operations, and positioning the torch for service (for automatic cleaning, for example). Because not all robot systems can move in continuous paths at the appropriate speeds for welding, the choice of robot hardware is important when setting up an automated welding manufacturing cell. Although a robot system is capable of traversing continuous paths at the appropriate speeds, the robot control software and programming language may not be amenable to welding. The software should be designed to easily produce continuous smooth-path motions, including automatic straight line, arc, and spline interpolation and speed control.

The range of motion of the robot should be considered. Its required motion can be very dependent on the motion capability of the welding part fixture and positioning system. The "operating window" of the robot can easily be obtained from its manufacturer and should be carefully examined to determine the suitability of the robot for the parts to be produced. Because robots can have extended lifetimes, all of the anticipated uses of the robot during its expected life should be considered.

The weight-carrying capacity of the robot and the influence of weight on robot accuracy and repeatability should also be considered. The manipulator must be able to lift the weight of the welding torch; the gas, water, and electrode supply tubes; the sensor systems; the flux supply system; and other equipment. As the weight on the robot end effector increases, the accuracy and repeatability of the robot may degrade.

Robot accuracy is a measure of the ability of the robot hardware and associated control system to position the robot at a specific location in 3-D space, given the coordinates of that position. Robot repeatability is the measure of the ability of the robot to return to the same position in space at a later time. Both of these values will affect the ability of the robot to repeatedly position the welding electrode and sensors in the correct positions for welding during the life of the system. These values can be obtained from the robot vendor. Often, these values are also affected by the speed of the robot, and

either the vendor or an independent testing laboratory can test the degradation of accuracy and repeatability under dynamic conditions. For welding purposes, it is important to obtain information about the dynamic response of the system, because robot accuracy and repeatability will change as the speed increases. Furthermore, during the welding process, the robot will always be moving (except in the case of spot resistance welds).

Fixturing and Positioning System. The parts to be welded must be held in position for welding. The robot is capable of being programmed to travel along a complex path and to position the welding torch in that preplanned path. However, the accuracy of that positioning not only depends on the robot system and its controller, but on the accuracy of the part location, as well. The positioning system must accurately locate the weld joint so that the robot can "find" the joint. It is difficult and often costly to have a sensor system (for example, a camera) that can locate the part for the robot. Therefore, it is advantageous to utilize a positioning system that can locate the part with sufficient accuracy and repeatability for the weld being made.

Often, it is advantageous to have a positioning system that can move the part to the robot operating window. Such positioners may have several "indexed" positions. An indexed positioner could have four positions: one for loading the part, one for inspecting the part to be welded, one for the welding operation, and one for postweld inspection.

Finally, moving positioners are capable of positioning the weld dynamically during the welding process. In this way, the weld can be maintained in the same welding position (for example, flat) throughout the welding operation. Flat welding often will provide greater weld quality and consistency. Consequently, positioners of this type represent a useful addition to an automated welding cell. Such a system, however, is much more complex than a simple indexed positioner. The motion of the robot and of the positioner must be coordinated. Generally, the positioner has a completely separate controller. Therefore, either the robot controller or a separate computer system must integrate the actions of the positioner with the robot.

Parts Transport System. The parts to be welded must be transported to and from the automated welding cell. Because of the expense of the cell, it should weld as many parts as possible per unit time. To accomplish this, parts need to be transported to and from the weld cell at rates and times that provide the most efficient operation. Thus, if an automated transport system is used, it should be electronically or mechanically coordinated to operate in conjunction with the robot cell positioner and welding operation cycle time.

Welding Power Supply. The choice of welding power supply is important to the success of an intelligent automated welding system. Because the adaptive control system will need to both change the welding parameters during the welding process and control the power supply, a communications link is essential. The power supply must be controllable by an external computer system through this communications link, and must allow modification of voltage and/or current set-point values during the welding process.

Most robots are operated by electric motors with sensitive controls. If the power supply emits high-frequency electromagnetic noise (for example, a high-frequency start or a pulsed-voltage start for gas-tungsten arc welding) or other types of electromagnetic noise, then the robot system may not be able to operate. This type of electronic noise can cause the robot computer to "crash." More serious damage to the robot or the cell controller can also result.

Welding Consumable Supply Systems. The intelligent automated welding cell requires equipment that can supply welding consumables to the welding operation. This includes devices such as a flux feeder, gas supplies, wire/electrode feed system, and others. Each of these components should have a digital (computer) or analog control communications link that can be accessed by the control system. These can be as simple as turning the gas flow on and off or as complex as fully computer controlled linear mass flow metering for accurate gas mixing and flow control. The systems selected should reflect the type of welding that needs to be performed and the necessary control communication links.

Control hardware, as described above, needs to be in a shop floor "hardened" cabinet that may require external cooling. The cabinet also should be shielded from any electromagnetic noise that is generated by the weld or any associated equipment.

Fume/Consumable Removal Systems. Many welding fume components are now recognized as being hazardous or noxious. Therefore, the welding fumes should be removed from the weld at a point that is as close to the weld as possible in order to minimize the volume of air that requires filtering. Fume extraction systems should be obtained and fitted so that they minimally interfere with the operation and motion of the robot and welding torch. For submerged arc welding, flux vacuum systems can provide flux recovery, and the reuse of used flux can provide some cost savings. In some cases,

the flux can easily be screened and reused. Because some specifications put limits on the number of times a flux can be recycled, a used-flux management system may need to be developed for the recovery system.

Sensor Systems. A wide variety of sensor systems can be employed in an intelligent automated welding cell. Types of sensors are described below.

Laser scanning sensors use reflected light information from a scanned laser stripe or region to provide data for weld seam guidance, dynamic calculation of the amount of fill required, and location of the part and weld joint for purposes of robot orientation.

A charge-coupled device (CCD) video camera provides information that can be used to determine weld pool size and shape, welding joint guidance (Fig. 9), and collision detection. The camera can be placed inside of a gas-tungsten arc welding (GTAW) torch in order to decrease the sensor package size and to obtain weld pool data. It can be combined with a laser stripe to provide joint geometry and fill information. In addition, a camera has been used to "look" at the back side of a weld and to determine, through measurements of total light intensity, the penetration or lack thereof by the liquid weld pool.

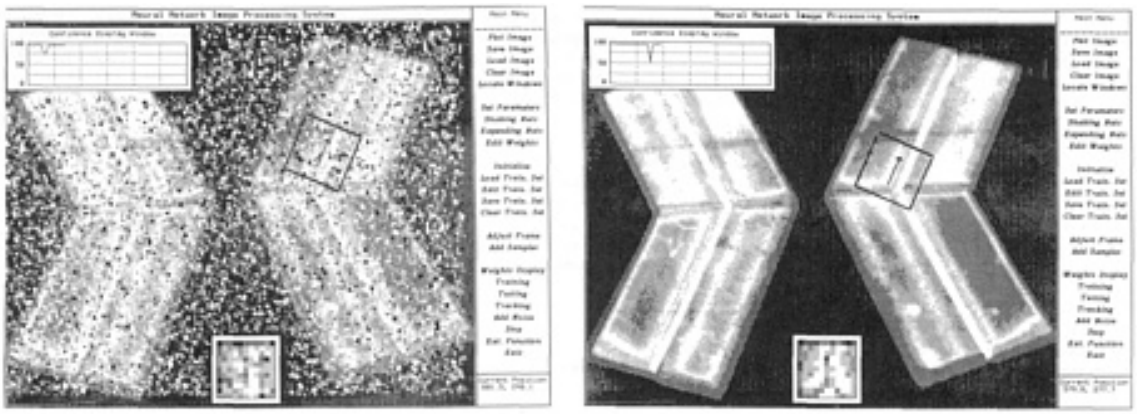

FIG. 9 NEURAL-NETWORK-BASED SEAM-TRACKING SYSTEM. (A) SYSTEM UTILIZING A CCD ARRAY CAMERA TRACKING A CLEAR IMAGE. (B) SYSTEM UTILIZING A CCD ARRAY CAMERA TRACKING AN IMAGE WITH SIMULATED SMOKE AND SPATTER FROM A FCAW PROCESS

Ultrasonic sensors, of both the contacting (piezoelectric crystal) and noncontacting (electromagnetic acoustic transducer) varieties, have been used in the laboratory to evaluate the penetration characteristics of the weld. Other uses also are being investigated.

Acoustic emission sensor data have been used in the laboratory and in limited production applications to determine the formation of welding discontinuities. This sensor has been reported to be able to detect cracking, incomplete fusion, inadequate penetration, and porosity formation.

Through-the-arc voltage/current sensors can detect voltage changes. In a weaving-type weld, the arc gap decreases as the sides of the joint are approached, causing a detectable change in voltage. This voltage change can be used to "guide" the robot along a weld seam in a prepared joint groove. This type of sensor can also determine the transfer modes for gas-metal arc welding and flux-cored arc welding (FCAW), as demonstrated in the laboratory. In addition, it can detect inadequate penetration defect formation through the use of advanced signal processing technology.

Airborne acoustics information (that is, the sound that the weld makes) has been used to diagnose the formation of defects and to determine metal-transfer modes. This type of sensor has been demonstrated in the laboratory. Through the use of multiple sensors and a triangulation algorithm, airborne acoustic data also have been used to locate the position of the welding torch in laboratory demonstrations.

An emission spectroscopic sensor has been developed by the U.S. Army and is patented for use in detecting hydrogen contamination of the welding arc plasma. This sensor can detect the presence of excessive amounts of hydrogen that cause cracking in higher-strength welds.

Infrared thermal area-type cameras have been used in the laboratory and in limited production applications to determine the shape and size of the weld pool and to provide some cooling rate data. A point-type camera also has been used, in conjunction with an AI-based heat-flow model, to determine thermal information and to control the cooling rate of welds.

A low-voltage "touch" sensor operates by energizing the electrode with a very low voltage, which enables the reasonably accurate detection of the electrode when it is brought in very close proximity to the part. This type of sensor also has been used to allow a GTAW electrode to be withdrawn an accurate and small distance from the part and then to energize the arc plasma. This eliminates the need for a high-frequency or high-voltage pulse starter for the automated GTAW process. Experimentally, such sensors are being developed to locate the joint or other locating positions on a part for robot spatial orientation.

An eddy current seam locator (probe) has been used in the laboratory and in limited production applications to scan the surface of a weld joint just ahead of the weld torch in order to "find" the weld seam and track the automated welding system along the joint. This is particularly useful for tracking square butt joints in shiny materials (for example, polished aluminum) that are tightly closed and not visible in CCD camera images.

Other cell services may be required in order to keep the welding equipment operational. For example, automated torch cleaning systems utilize rotating wire brushes or other devices to clean the spatter from GMAW and FCAW welding torches.

Automated welding cell utility services provide adequate power for the welding power supply and for the operation of other equipment; water as a coolant; welding gas; compressed air (for pneumatic devices on the robot or positioner); and network communication links to the computer-integrated manufacturing system.

Corrosion of Weldments

A. Wahid, D.L. Olson, and D.K. Matlock, Colorado School of Mines; C.E. Cross, Martin Marietta Astronautics Group

Introduction

WELDMENTS exhibit special microstructural features that need to be recognized and understood in order to predict acceptable corrosion service life of welded structures (Ref 1). This article describes some of the general characteristics associated with the corrosion of weldments. The role of macrocompositional and microcompositional variations, a feature common to weldments, is emphasized in this article to bring out differences that need to be realized in comparing corrosion of weldments to that of wrought materials. A more extensive presentation, with data for specific alloys, is given in Volume 13 of the *ASM Handbook* (Ref 2).

Weldments inherently possess compositional and microstructural heterogeneities, which can be classified by dimensional scale. On the largest scale, a weldment consists of a transition from wrought base metal through a heat-affected zone and into solidified weld metal and includes five microstructurally distinct regions normally identified (Ref 3) as the fusion zone, the unmixed region, the partially melted region, the heat-affected zone, and the base metal. This microstructural transition is illustrated in Fig. 1. The unmixed region is part of the fusion zone, and the partially melted region is part of the heat-affected zone, as described below. Not all five zones are present in any given weldment. For example, autogenous (that is, no filler metal) welds do not have an unmixed zone.

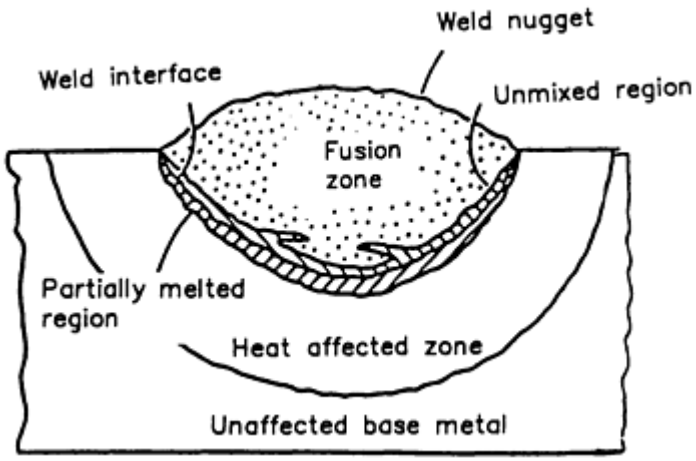

FIG. 1 SCHEMATIC SHOWING THE REGIONS OF A HETEROGENEOUS WELD. SOURCE: REF 3

The fusion zone is the result of melting which fuses the base metal and filler metal to produce a zone with a composition that is most often different from that of the base metal. This compositional difference produces a galvanic couple, which can influence the corrosion process in the vicinity of the weld. This dissimilar-metal couple can produce macroscopic galvanic corrosion.

The fusion zone itself offers a microscopic galvanic effect due to microstructural segregation resulting from solidification (Ref 4). The fusion zone also has a thin region adjacent to the fusion line, known as the unmixed (chilled) region, where the base metal is melted and then quickly solidified to produce a composition similar to the base metal (Ref 5). For example, when type 304 stainless steel is welded using a filler metal with high chromium-nickel content, steep concentration gradients of chromium and nickel are found in the fusion zone, whereas the unmixed zone has a composition similar to the base metal (Fig. 2).

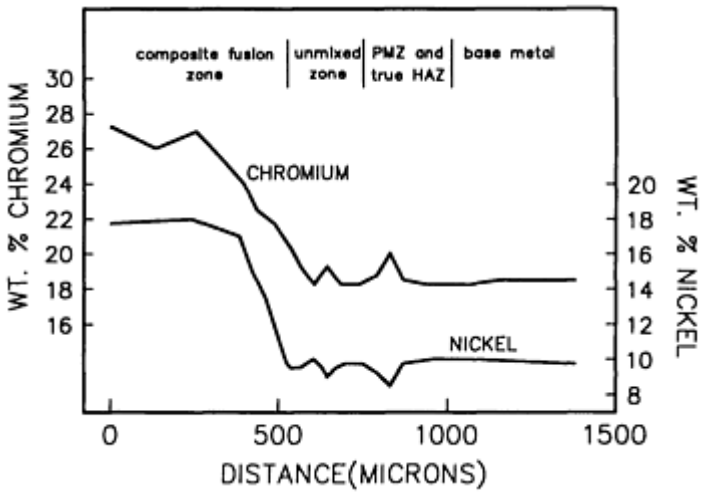

FIG. 2 CONCENTRATION PROFILE OF CHROMIUM AND NICKEL ACROSS THE WELD FUSION BOUNDARY REGION OF TYPE 304 STAINLESS STEEL. SOURCE: REF 5

Heal-Affected Zone. Every position in the heat-affected zone relative to the fusion line experiences a unique thermal experience during welding, in terms of both maximum temperature and cooling rate. Thus, each position has its own microstructural features and corrosion susceptibility.

The partially melted region is usually one or two grains into the heat-affected zone relative to the fusion line. It is characterized by grain boundary liquation, which may result in liquation cracking. These cracks, which are found in the grain boundaries one or two grains below the fusion line, have been identified as potential initiation sites for hydrogen-promoted underbead cracking in high-strength steel.

Microstructural Gradients. On a fine scale, microstructural gradients exist within the heat-affected zone due to different time-temperature cycles experienced by each element of material. Gradients on a similar scale exist within solidified multi-pass weld metal due to bead-to-bead variations in thermal experience. Compositional gradients on the scale of a few microns, referred to as microsegregation, exist within individual weld beads due to segregation of major and trace elements during solidification (Ref 4).

Forms of Weld Corrosion

Weldments can experience all the classical forms of corrosion, but they are particularly susceptible to those affected by variations in microstructure and composition. Specifically, galvanic corrosion, pitting, stress corrosion, intergranular corrosion, and hydrogen cracking must be considered when designing welded structures.

Galvanic Couples. Although some alloys can be autogenously welded, filler metals are more commonly used. The use of filler metals with compositions different from the base material may produce an electrochemical potential difference that makes some regions of the weldment more active. For example, Fig. 3 depicts weld metal deposits that have different corrosion behavior from the base metal in three aluminum alloys (Ref 6).

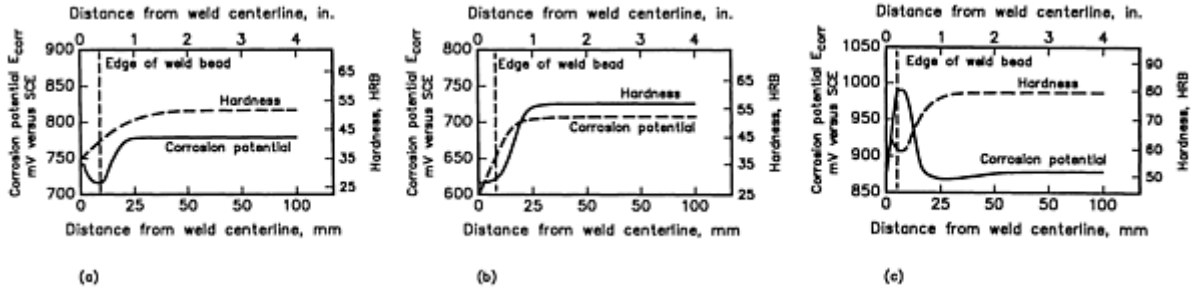

FIG. 3 EFFECT OF WELDING HEAT ON MICROSTRUCTURE, HARDNESS, AND CORROSION POTENTIAL OF THREE ALUMINUM ALLOY WELDED ASSEMBLIES. (A) ALLOY 5456-H321 BASE METAL WITH ALLOY 5556 FILLER. (B) ALLOY 2219-T87 BASE METAL WITH ALLOY 2319 FILLER. (C) ALLOY 7039-T651 BASE METAL WITH ALLOY 5183 FILLER. SOURCE; REF 6

For the majority of aluminum alloys, the weld metal and the heat-affected zone become more noble relative to the base metal, as demonstrated in Fig. 3(a) and 3(b) for a saltwater environment (Ref 6). Certain aluminum alloys, however, form narrow anodic regions in the heat-affected zone and are prone to localized attack. Alloys 7005 and 7039 are particularly susceptible to this problem (Fig. 3c).

There are a number of other common weld deposit/base metal combinations that are known to form galvanic couples. It is common practice to use austenitic stainless steel welding consumables for field repair of heavy machinery, particularly those fabricated from high-strength low-alloy steel. This practice leaves a cathodic stainless steel weld deposit in electrical contact with the steel. In the presence of corrosive environments, hydrogen is generated at the austenitic weld metal cathode, which is capable of maintaining a high hydrogen content without cracking. However, the cathodic behavior of the austenitic weld deposit may increase the susceptibility for stress-corrosion cracking in the heat-affected zone of the high-strength steel. A 40% thermal expansion mismatch between the austenitic stainless steel and ferritic base metal produces a significant residual stress field in the weldment; this residual stress field also contributes to cracking susceptibility. A similar, but more localized, behavior may explain the correlation between stress-corrosion cracking susceptibility and the presence of retained austenite in high-strength steel weld deposits.

Another common dissimilar metal combination involves the use of high-nickel alloys for weld repair of cast iron. Fe-55Ni welding electrodes are used to make weld deposits that can hold in solid solution many of the alloying elements common to cast iron. Furthermore, weld deposits made with Fe-55Ni welding consumables have an acceptable thermal expansion match to the cast iron. Because cast iron is anodic to the high-nickel weld deposit, corrosive attack occurs in the cast iron adjacent to the weld deposit. It is suggested that cast iron welds made with high-nickel deposits be coated (painted) to reduce the susceptibility to selective corrosion attack.

Plain carbon steel weldments can also exhibit galvanic attack. For example, the E6013 welding electrode is known to be highly anodic to A285 base metal in a seawater environment (Ref 7). It is important to select a suitable filler metal when an application involves a harsh environment.

Weld Decay of Stainless Steel. During welding of stainless steels, local sensitized zones (i.e., regions susceptible to corrosion) often develop. Sensitization is due to the formation of chromium carbide along grain boundaries, resulting in depletion of chromium in the region adjacent to the grain boundary (Ref 8, 9, 10, 11, 12, 13, 14). This chromium

depletion produces very localized galvanic cells (Fig. 4). If this depletion drops the chromium content below the necessary 12 wt% that is required to maintain a protective passive film, the region will become sensitized to corrosion, resulting in intergranular attack. This type of corrosion most often occurs in the heat-affected zone. Intergranular corrosion causes a loss of metal in a region that parallels the weld deposit (Fig. 5). This corrosion behavior is called weld decay (Ref 13).

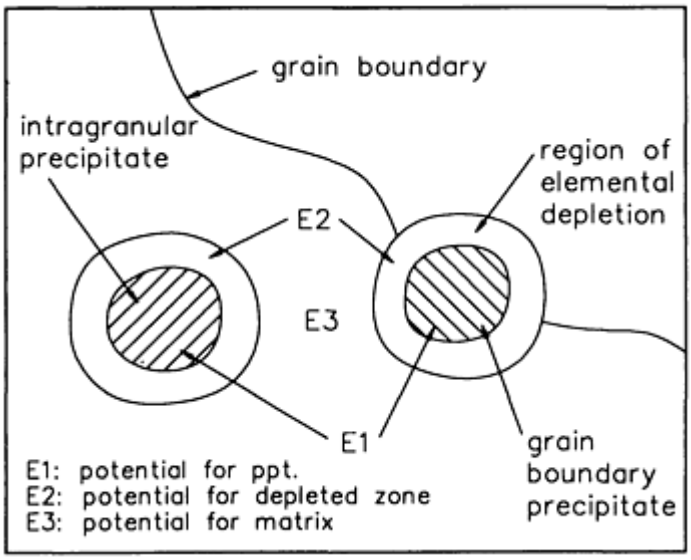

FIG. 4 DEPLETED REGIONS ADJACENT TO PRECIPITATES. THESE REGIONS CAUSE AN ELECTROCHEMICAL POTENTIAL (E) DIFFERENCE THAT CAN PROMOTE LOCALIZED CORROSION AT THE MICROSTRUCTURAL LEVEL.

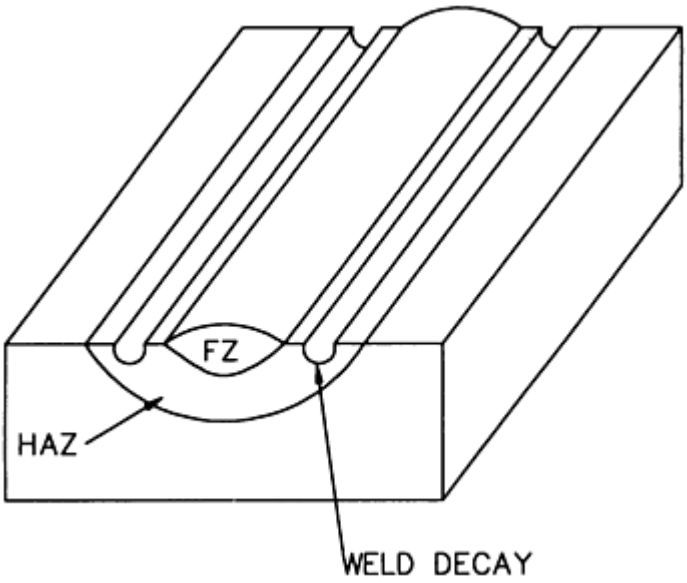

FIG. 5 INTERGRANULAR CORROSION (WELD DECAY) OF STAINLESS STEEL WELDMENTS. FZ, FUSION ZONE

The formation of sufficient chromium carbide to cause sensitization can be described by the C-shaped curves on the continuous cooling diagram illustrated in Fig. 6. The figure shows susceptibility to sensitization as a function of temperature, time, and carbon content (Ref 15). If the cooling rate is sufficiently great (curve A in Fig. 6), the cooling curve will not intersect the given C-shaped curve for chromium carbide and the stainless steel will not be sensitized. By decreasing the cooling rate, the cooling curve (curve B) eventually intersects the C-shape nucleation curve, indicating that sensitization may occur. At very low cooling rates, the formation of chromium carbide occurs at higher temperature and allows for more nucleation and growth, resulting in a more extensive chromium-depleted region.

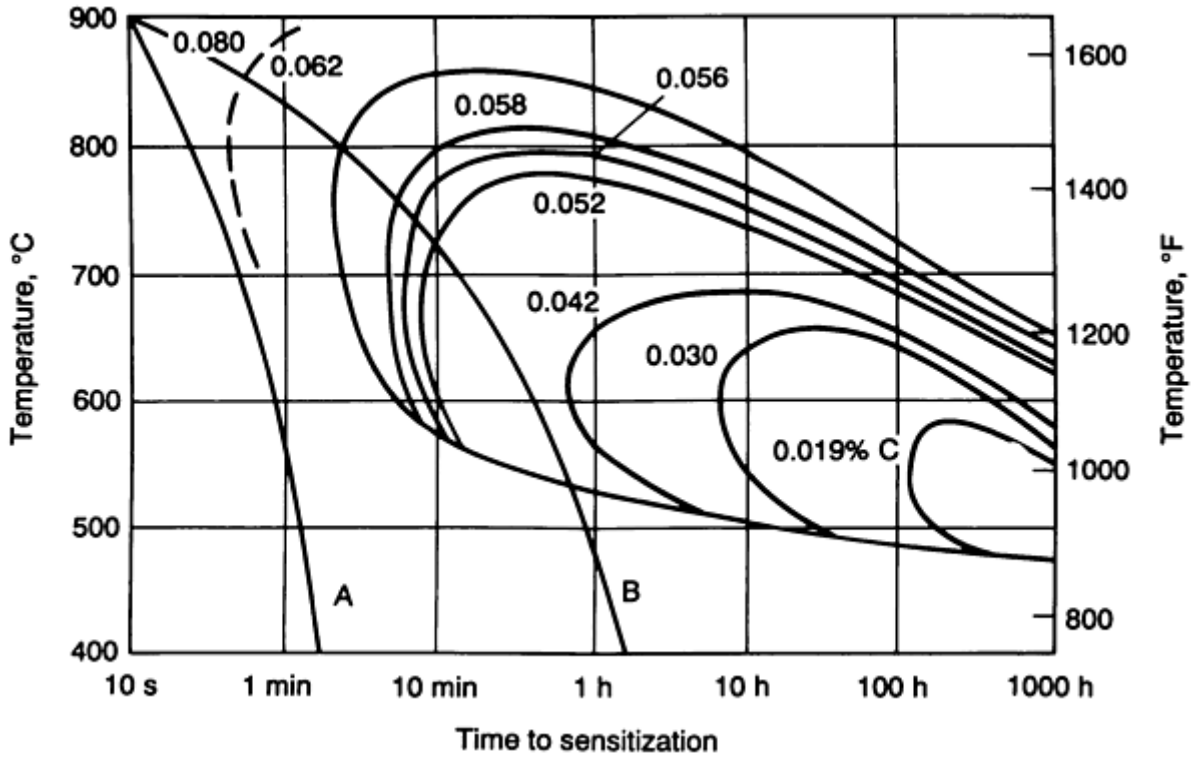

FIG. 6 TIME-TEMPERATURE-SENSITIZATION CURVES FOR TYPE 304 STAINLESS STEEL IN A MIXTURE OF $CUSO_4$ AND HSO_4 CONTAINING COPPER. SOURCE: REF 15. CURVES A AND B INDICATE HIGH AND MEDIUM COOLING RATES, RESPECTIVELY.

The minimum time required for sensitization as a function of carbon content in a typical stainless steel alloy is depicted in Fig. 7. Because the normal welding thermal cycle is completed in approximately two minutes, for this example the carbon content must not exceed 0.07 wt% to avoid sensitization. Notice that the carbide nucleation curves of Fig. 6 move down and to longer times with decreasing carbon content, making it more difficult to form carbides for a given cooling rate.

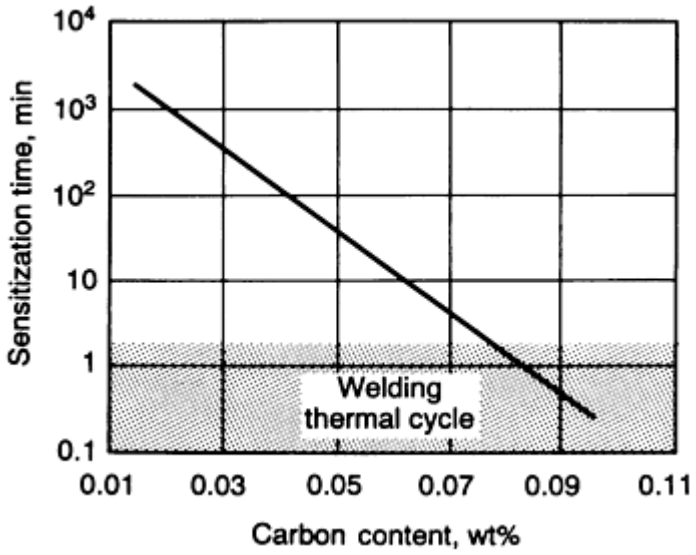

FIG. 7 MINIMUM SENSITIZATION TIME FROM A TIME-TEMPERATURE-SENSITIZATION DIAGRAM AS A FUNCTION OF CARBON CONTENT FOR A TYPICAL 300-SERIES STAINLESS STEEL ALLOY. SOURCE: REF 15

The control of stainless steel sensitization may be achieved by using:

- A POSTWELD HIGH-TEMPERATURE ANNEAL AND QUENCH TO REDISSOLVE THE CHROMIUM AT GRAIN BOUNDARIES, AND HINDER CHROMIUM CARBIDE FORMATION ON COOLING
- A LOW-CARBON GRADE OF STAINLESS STEEL (E.G., 304L OR 316L) TO AVOID CARBIDE FORMATION
- A STABILIZED GRADE OF STAINLESS STEEL CONTAINING TITANIUM (ALLOY 321) OR NIOBIUM (ALLOY 327), WHICH PREFERENTIALLY FORM CARBIDES AND LEAVE CHROMIUM IN SOLUTION. (THERE IS THE POSSIBILITY OF KNIFE-LINE ATTACK IN STABILIZED GRADES OF STAINLESS STEEL.)
- A HIGH-CHROMIUM ALLOY (E.G., ALLOY 310)

Role of Delta Ferrite in Stainless Steel Weld Deposits. Austenitic weld deposits are frequently used to join various ferrous alloys. It has been well established that it is necessary to have austenitic weld deposits solidify as primary ferrite, also known as a δ ferrite, if hot cracking is to be minimized (Ref 16, 17). The amount and form of ferrite in the weld metal can be controlled by selecting a filler metal with the appropriate chromium and nickel equivalent. A high chromium/nickel ratio favors primary ferrite formation, whereas a low ratio promotes primary austenite (Fig. 8). An optimum condition can be attained for ferrite contents between 3 and 8 vol% in the weld deposit. Ferrite contents above 3 vol% usually guarantee primary ferrite formation and thus reduce hot cracking susceptibility. However, ferrite above 10 vol% can degrade mechanical properties at low- or high-temperature service. At low temperatures, excess ferrite can promote crack paths when the temperature is below the ductile-brittle transition temperature. At high temperatures, continuous brittle sigma phase may form at the interface between the austenite and the ferrite. The ferrite content can be confirmed using magnetic measuring equipment (Ref 16, 17).

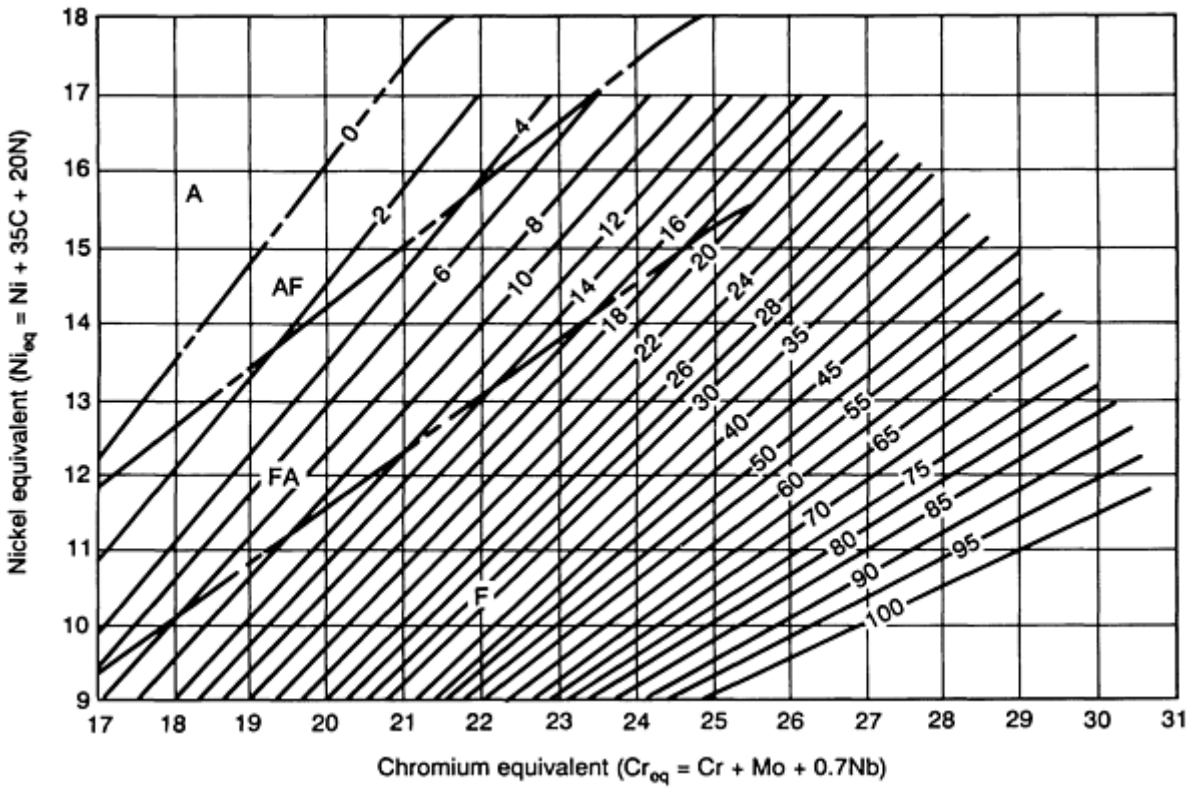

FIG. 8 WELDING RESEARCH COUNCIL (WRC-1988) DIAGRAM USED TO PREDICT WELD METAL FERRITE CONTENT. SOURCE: REF 18

Figure 8 can be used to predict the type of ferrite (primary or eutectic) and the ferrite content when a difference exists between the stainless steels being joined, such as when welding type 304 to type 310 stainless steel (Ref 18). This diagram shows the compositional range for the desirable primary solidification mode. The dotted lines on the diagram indicate the various transitions in the primary solidification phase. Because not all ferrite is primary ferrite (i.e., some is a phase component of a ferrite-austenite eutectic), this diagram can be used to ensure that ferrite is the first solid (primary) phase to form. This condition occurs when the weld deposit has a composition in the range labeled FA in Fig. 8. Because primary ferrite is the preferable microstructure, use of this diagram should reduce problems of hot cracking during welding. Also, the corrosion behavior of stainless steel weld deposits and castings is measurably different depending on whether the stainless steel has a microstructure generated with primary ferrite or primary austenite (Ref 19, 20, 21, 22, 23, 24, 25). Thus, knowledge of the weld metal ferrite content and form is necessary in order to be able to properly characterize and predict corrosion behavior.

Pitting is a form of localized attack caused by a breakdown in the thin passive oxide film that protects material from the corrosion process. Pits are commonly the result of a concentration cell established by a variation in solution composition that is in contact with the alloy material. Such compositional variations result when the solution at a surface irregularity is different from that of the bulk solution composition. Once a pit has formed, it acts as an anode supported by relatively large cathodic regions. Pitting has a delay time prior to nucleation and growth, and nucleation is very site-selective and microstructure-dependent. Pits are often initiated at specific microstructural features in the weld deposit (Ref 26). Pitting occurs when the material/solution combination achieves a potential that exceeds a critical value, known as the pitting potential. The tendency for a given alloy/solution combination to pit can often be characterized by critical potentials for pitting and repassivation determined by a cyclic potentiodynamic polarization technique.

Pits develop more readily in metallurgically heterogeneous materials. For example, when austenitic stainless steel is heated to temperatures where sensitization takes place (Ref 26, 27), the resulting chromium-depleted region is subject to pitting. Pits may also initiate at the austenite-ferrite interfaces in stainless steel weld metal.

Although weld metal has a higher probability of being locally attacked because of microsegregation in the dendritic structure, filler metals are now available that have better pitting resistance than their respective base metals; information about these filler metals can be obtained from consumable suppliers. However, even when the proper filler metal is used, pitting may still occur in the unmixed zone.

Duplex stainless steels, with ferrite contents in the range of 40 to 50 vol%, are often used to decrease the tendency of stress-corrosion cracking in chromium-nickel high-alloy steels. The welding practice for duplex stainless steels must be given special attention (Ref 20, 21, 22, 24, 25, 27) to avoid reduction in corrosion resistance. The combination of a low carbon content and a carefully specified nitrogen addition have been reported to improve resistance to pitting corrosion, stress-corrosion cracking, and intergranular corrosion in the as-welded condition. The low carbon content helps avoid sensitization, while the addition of nitrogen slows the precipitation kinetics associated with the segregation of chromium and molybdenum during the welding process (Ref 1). On rapid cooling from high temperature, nitrogen also has been reported to form deleterious precipitates (for example, Cr_2N) in the ferrite, thus reducing the corrosion resistance (Ref 28). Nitrogen also increases the formation of austenite in the heat-affected zone and weld metal during cooling. A minimum pitting corrosion rate is achieved at a ferrite content of about 50 vol%.

Stress-Corrosion Cracking. Weldments can be susceptible to stress-corrosion cracking under specific environmental conditions. This cracking requires the proper combination of corrosive media, susceptible microstructure, and tensile stress. Welds are often loaded in tension (due to residual stress) to a level approaching the yield strength of the base metal. A weld, with its various heterogeneous microstructural features, thus becomes an excellent candidate for stress-corrosion cracking.

Stress-corrosion cracks have an anodic crack tip and often leave apparent corrosion products along the fracture. Cracking is often characterized by crack branching and usually has a delay time prior to crack initiation, with initiation occurring at corrosion pits. Increasing the ferrite content in stainless steel weld metal reduces stress-corrosion cracking susceptibility. Approximately 50 vol% ferrite gives optimum stress-corrosion cracking resistance.

Welding parameters influence the amount and distribution of residual stress, because the extent of the stressed region and the amount of distortion are directly proportional to the size of the weld deposit; this deposit is directly related to the heat input. The thermal experience of welding is often very localized, resulting in strains that can cause distortion and residual stress. These residual stresses can be important in the initiation and propagation of environmentally assisted cracking. The use of small weld deposits reduces the stress and thus reduces the susceptibility of environmentally enhanced cracking.

It is known that postweld heat treatment can reduce stress-corrosion cracking by redistributing the localized load and by reducing the magnitude of the residual tensile stress available to induce corrosion cracking (Ref 29). In a recent study on a cast austenitic stainless steel, post-solidification heat treatments were also shown to modify the local composition gradients, significantly altering the susceptibility of the solidified microstructure to stress-corrosion cracking (Ref 30).

Hydrogen damage results from the combined actions of hydrogen and stress (Ref 31); the stress can be residual or applied. The weld pool in the liquid state has a much higher solubility for hydrogen than solid metal, and during solidification the hydrogen content becomes supersaturated in the weld pool as hydrogen attempts to transport from the weld deposit. While some of the hydrogen leaves the weldment, significant amounts transport through the fusion line and into the heat-affected zone.

The fusion line region also has the highest cooling rate, which may lead in some alloys to fracture-sensitive microstructures (e.g., martensite). The combination of high hydrogen content and brittle microstructures can produce cracking. The result is underbead cracking, characterized by delayed slow propagating cracks that travel adjacent to the fusion line in the heat-affected zone. The typical hydrogen crack travels one or two grains from the fusion line in the heat-affected zone.

Weld metal hydrogen cracking often takes the form of chevron cracks (Ref 32, 33, 34). Chevron crack formation and propagation are influenced by the combination of stress and orientation of the columnar grain boundaries. Chevron cracking occurs at high hydrogen content levels and appears to be inactive at low levels. This type of cracking appears to be sensitive to reheating during multi-pass deposition of welding beads. Chevron cracking is most likely found with flux-related welding processes.

Microbiologically Influenced Corrosion (MIC) is a phenomenon in which microorganisms play a role in the corrosion of metals. This role may be to initiate or accelerate the corrosion process. For example, water and some organic media may contain certain microorganisms that can produce a biofilm when exposed to a metal surface. The resulting nonuniform coverage may lead to a concentration cell and eventually initiate corrosion. In addition, the metabolic process of the microorganism can produce a localized acid environment that changes the corrosion behavior of the exposed metal by, for example, altering anodic and cathodic reactions, destroying protective films, or creating corrosive deposits (Ref 35).

In austenitic stainless steel weldments, the effects of MIC are usually observed as pitting on or adjacent to welds (Ref 36, 37). MIC attacks either γ or α phases, and chlorides am sometimes found in a pit, even when the water has extremely low chloride content. Pits are found in regions of the heat-affected zone at the fusion line, and in the base metal near the weld for reasons not well understood. Them is some evidence that MIC takes place along with stress-corrosion cracking in weldments of austenitic stainless steel. Welding design and plant operation can minimize MIC attack, mainly by preventing an acceptable environment for microorganisms.

Heat-Tint Oxide Formation. The welding process, especially with poor gas shielding, can produce a variation in the thickness of the passivating oxide. The variation in oxidation will result in a gradient in the degree of chromium depletion adjacent to a stainless steel weld. This behavior will cause some tendency for localized corrosion (Ref 1). An indication of this problem can be seen by the heat-tint oxide formation (Ref 38).

Welding Practice to Minimize Corrosion

Several methods are available to minimize corrosion in weldments (Ref 39). The most important of these are discussed below.

Material and Welding Consumable Selection. Careful selection of materials and welding consumables can reduce the macro- and micro- compositional differences across the weldment and thus reduce the galvanic effects.

Surface Preparation. A properly selected cleaning process can reduce defects that are often sites for corrosive attack in aggressive environments. However, the cleaning process can also be a source of trouble. For example, any mechanically cleaned surface (i.e., cleaned by sand blasting or grinding) can leave impurities on the surface. The type of wire brush used can also be an important consideration (Ref 39). Stainless steel brushes are generally preferred because they do not form corrosion products capable of holding moisture.

Welding design should promote deposits that have relatively flat beads with low profiles and have minimal slag entrapment. A poor design can generate crevices that trap stagnant solutions, leading to pitting and crevice corrosion. Irregular weld deposit shapes can promote turbulent flow in a tubular product and result in erosion corrosion.

Welding Practice. Complete penetration is preferred to avoid underbead gaps. Slag should be removed after each pass with a power grinder or power chipping tool. If the welding method uses flux, the geometry of the joint must permit thorough flux removal, because many flux residues are hydrophilic and corrosive.

Weld Surface Finishing. The weld deposit should be inspected visually immediately after welding. Maximum corrosion resistance usually demands a smooth uniformly oxidized surface that is free from foreign particles and irregularities (Ref 37). Deposits normally vary in roughness and in degree of weld spatter, a concern that can be minimized by grinding. For smooth weld deposits, wire brushing may be sufficient. For stainless steel, however, brushing disturbs the existing passive film and may aggravate corrosive attack.

Surface Coating. When a variation in composition across the weld metal can cause localized attack, it may be desirable to use protective coatings. The coating needs to cover both the weldment and the parent metal and often requires special surface preparation.

Postweld Heat Treatment. A postweld heat treatment can be an effective way to reduce corrosion susceptibility. This improved corrosion resistance is accomplished through a reduction in residual stress gradients that influence stress-corrosion cracking growth. Postweld heat treatment can assist in the transport of hydrogen from the weldment and reduce susceptibility to hydrogen cracking. The treatment can also reduce compositional gradients (i.e., microsegregation) and corresponding microgalvanic cells.

Preheat and Interpass Temperature. The selection and use of proper preheat treatment and interpass temperature may prevent hydrogen cracking in carbon and low-alloy steel.

Passivation Treatment. A passivation treatment may increase the corrosion resistance of stainless steel welded components.

Avoidance of Forming Crevices. Slag that is still adhering to the weld deposit and defects such as lack of penetration and microfissures can result in crevices that can promote a localized concentration cell, resulting in crevice corrosion. Proper selection of welding consumables, proper welding practice, and thorough slag removal can alleviate this form of corrosion damage.

Removing Sources of Hydrogen. Through proper selection of welding consumables (that is, low-hydrogen shielded metal arc welding electrodes), proper drying of flux, and welding clean surfaces, the hydrogen pickup can be drastically reduced.

Overview of Weld Discontinuities

Introduction

DISCONTINUITIES are interruptions in the desirable physical structure of a weld. A discontinuity constituting a danger to the fitness-for-service of a weld is a defect. By definition, a defect is a condition that must be removed or corrected (Ref 1). The word "defect" should therefore be carefully used, because it implies that a weld is defective and requires corrective measures or rejection. Thus, repairs may be made unnecessarily and solely by implication, without a critical engineering assessment. Consequently, the engineering community now tends to use the word "discontinuity" or "flaw" instead of "defect."

The significance of a weld discontinuity should be viewed in the context of the fitness-for-service of the welded construction. Fitness-for-service is a concept of weld evaluation that seeks a balance among quality, reliability, and economy of welding procedure. Fitness-for-service is not a constant. It varies depending on the service requirements of a particular welded structure, as well as on the properties of the material involved. (See the article "Fitness-for-Service Assessment of Welded Structures" in this Section for more information.)

Neither construction materials nor engineered structures are free from imperfections. Welds and weld repairs are not exceptions. Weld acceptance standards are used when a discontinuity has been clearly located, identified, sized, its orientation determined, and its structural significance questioned. Critical engineering assessments of weld discontinuities are performed to define acceptable, harmless discontinuities in a structure that will not sacrifice weldment reliability. One of the major reasons for understanding the engineering meaning of weld discontinuities is to decrease the cost of welded structures by avoiding unnecessary repairs of harmless weld discontinuities (Ref 2). Welders, of course, must constantly be encouraged to make sound (perfect) welds independent of prevailing acceptance standards.

This article describes the types of weld discontinuities that are characteristic of the principal welding processes. In addition, information is provided about the common inspection methods used to detect these discontinuities. More detailed descriptions of these inspection methods can be found in the article "Inspection of Welded Joints" in this Section of the Handbook.

Classification of Weld Discontinuities

Discontinuities may be divided into three broad classifications: design related, welding process related, and metallurgical. Design-related discontinuities include problems with design or structural details, choice of the wrong type of weld joint for a given application, or undesirable changes in cross section.

Process-related discontinuities include:

- *UNDERCUT:* A GROOVE MELTED INTO THE BASE METAL ADJACENT TO THE TOE OR ROOT OF A WELD AND LEFT UNFILLED BY WELD METAL
- *SLAG INCLUSIONS:* NONMETALLIC SOLID MATERIAL ENTRAPPED IN WELD METAL OR BETWEEN WELD METAL AND BASE METAL
- *POROSITY:* CAVITY-TYPE DISCONTINUITIES FORMED BY GAS ENTRAPMENT DURING SOLIDIFICATION
- *OVERLAP:* THE PROTRUSION OF WELD METAL BEYOND THE TOE, FACE, OR ROOT OF THE WELD
- *TUNGSTEN INCLUSIONS:* PARTICLES FROM TUNGSTEN ELECTRODES THAT RESULT FROM IMPROPER GAS-TUNGSTEN ARC WELDING PROCEDURES
- *BACKING PIECE LEFT ON:* FAILURE TO REMOVE MATERIAL PLACED AT THE ROOT OF A WELD JOINT TO SUPPORT MOLTEN WELD METAL
- *SHRINKAGE VOIDS:* CAVITY-TYPE DISCONTINUITIES NORMALLY FORMED BY SHRINKAGE DURING SOLIDIFICATION
- *OXIDE INCLUSIONS:* PARTICLES OF SURFACE OXIDES THAT HAVE NOT MELTED AND ARE MIXED INTO THE WELD METAL
- *LACK OF FUSION (LOF):* A CONDITION IN WHICH FUSION IS LESS THAN COMPLETE
- *LACK OF PENETRATION (LOP):* A CONDITION IN WHICH JOINT PENETRATION IS LESS THAN THAT SPECIFIED
- *CRATERS:* DEPRESSIONS AT THE TERMINATION OF A WELD BEAD OR IN THE MOLTEN WELD POOL
- *MELT-THROUGH:* A CONDITION RESULTING WHEN THE ARC MELTS THROUGH THE BOTTOM OF A JOINT WELDED FROM ONE SIDE
- *SPATTER:* METAL PARTICLES EXPELLED DURING WELDING THAT DO NOT FORM A PART OF THE WELD
- *ARC STRIKES (ARC BURNS):* DISCONTINUITIES CONSISTING OF ANY LOCALIZED REMELTED METAL, HEAT-AFFECTED METAL, OR CHANGE IN THE SURFACE PROFILE OF ANY PART OF A WELD OR BASE METAL RESULTING FROM AN ARC
- *UNDERFILL:* A DEPRESSION ON THE FACE OF THE WELD OR ROOT SURFACE EXTENDING BELOW THE SURFACE OF THE ADJACENT BASE METAL

Metallurgical discontinuities include:

- *CRACKS:* FRACTURE-TYPE DISCONTINUITIES CHARACTERIZED BY A SHARP TIP AND HIGH RATIO OF LENGTH AND WIDTH TO OPENING DISPLACEMENT
- *FISSURES:* SMALL CRACKLIKE DISCONTINUITIES WITH ONLY A SLIGHT SEPARATION (OPENING DISPLACEMENT) OF THE FRACTURE SURFACES
- *FISHEYE:* A DISCONTINUITY FOUND ON THE FRACTURE SURFACE OF A WELD IN STEEL THAT CONSISTS OF A SMALL PORE OR INCLUSION SURROUNDED BY A BRIGHT, ROUND AREA

- *SEGREGATION:* THE NONUNIFORM DISTRIBUTION OR CONCENTRATION OF IMPURITIES OR ALLOYING ELEMENTS THAT ARISES DURING THE SOLIDIFICATION OF THE WELD
- *LAMELLAR TEARING:* A TYPE OF CRACKING THAT OCCURS IN THE BASE METAL OR HEAT-AFFECTED ZONE (HAZ) OF RESTRAINED WELD JOINTS THAT IS THE RESULT OF INADEQUATE DUCTILITY IN THE THROUGH-THICKNESS DIRECTION OF STEEL PLATE

The observed occurrence of discontinuities and their relative amounts depend largely on the welding process used, the inspection method applied, the type of weld made, the joint design and fit-up obtained, the material utilized, and the working and environmental conditions. The most frequent weld discontinuities found during manufacture, ranked in order of decreasing occurrence on the basis of arc-welding processes are:

SHIELDED METAL ARE WELDING (SMAW)
SLAG INCLUSIONS
POROSITY
LOF/LOP
UNDERCUT
SUBMERGED ARE WELDING (SAW)
LOF/LOP
SLAG INCLUSIONS
POROSITY
FLUX-CORED ARC WELDING (FCAW)
SLAG INCLUSIONS
POROSITY
LOF/LOP
GAS-METAL ARC WELDING (GMAW)
POROSITY
LOF/LOP
GAS-TUNGSTEN ARC WELDING (GTAW)
POROSITY
TUNGSTEN INCLUSIONS

The commonly encountered inclusions-as well as cracking, the most serious of weld defects--will be discussed in this Section.

Gas porosity can occur on or just below the surface of a weld. Pores are characterized by a rounded or elongated teardrop shape with or without a sharp point. Pores can be uniformly distributed throughout the weld or isolated in small groups; they can also be concentrated at the root or toe of the weld. Porosity in welds is caused by gas entrapment in the molten metal, by too much moisture on the base or filler metal, or by improper cleaning of the joint during preparation for welding.

The type of porosity within a weld is usually designated by the amount and distribution of the pores. Some of the types are classified as follows:

- *UNIFORMLY SCATTERED POROSITY:* CHARACTERIZED BY PORES SCATTERED UNIFORMLY THROUGHOUT THE WELD (FIG. 1)
- *CLUSTER POROSITY:* CHARACTERIZED BY CLUSTERS OF PORES SEPARATED BY POROSITY-FREE AREAS (FIG. 1B)
- *LINEAR POROSITY:* CHARACTERIZED BY PORES THAT ARE LINEARLY DISTRIBUTED (FIG. 1C). LINEAR POROSITY GENERALLY OCCURS IN THE ROOT PASS AND IS ASSOCIATED

WITH INCOMPLETE JOINT PENETRATION

- *ELONGATED POROSITY:* CHARACTERIZED BY HIGHLY ELONGATED PORES INCLINED TO THE DIRECTION OF WELDING. ELONGATED POROSITY OCCURS IN A HERRINGBONE PATTERN (FIG. 1D)
- *WORMHOLE POROSITY:* CHARACTERIZED BY ELONGATED VOIDS WITH A DEFINITE WORMLIKE SHAPE AND TEXTURE (FIG. 2)

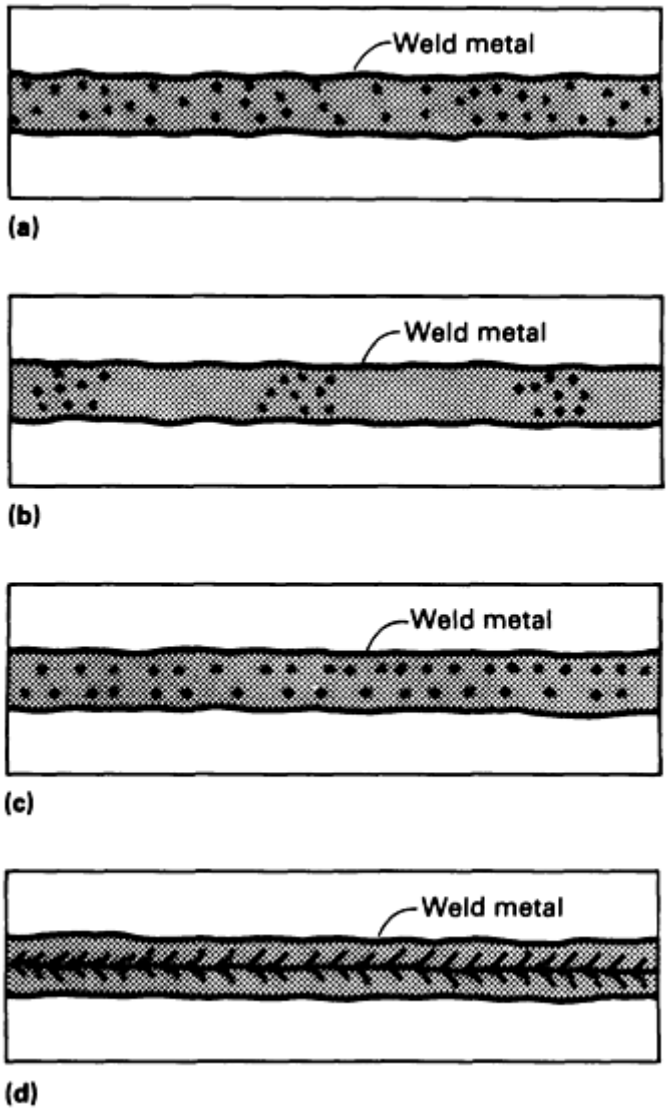

FIG. 1 TYPES OF GAS POROSITY COMMONLY FOUND IN WELD METAL. (A) UNIFORMLY SCATTERED POROSITY. (B) CLUSTER POROSITY. (C) LINEAR POROSITY. (D) ELONGATED POROSITY

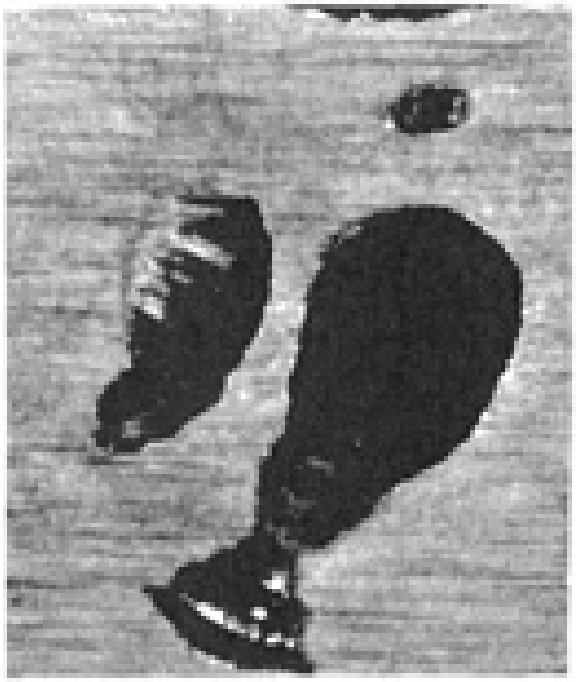

FIG. 2 WORMHOLE POROSITY IN A WELD BEAD. LONGITUDINAL CUT. 20×

Radiography is the most widely used nondestructive method for detecting subsurface gas porosity in weldments. The radiographic image of round porosity appears as round or oval spots with smooth edges, and elongated porosity appears as oval spots with the major axis sometimes several times longer than the minor axis. The radiographic image of wormhole porosity depends largely on the orientation of the elongated cavity with respect to the incident x-ray beam. The presence of top-surface or root reinforcement affects the sensitivity of inspection, and the presence of foreign material, such as loose scale, flux, or weld spatter, may interfere with the interpretation of results.

Ultrasonic inspection is capable of detecting subsurface porosity. However, it is not extensively used for this purpose except to inspect thick sections or inaccessible areas where radiographic sensitivity is limited. Surface finish and grain size affect the validity of the inspection results.

Eddy current inspection, like ultrasonic inspection, can be used for detecting subsurface porosity. Normally, eddy current inspection is confined to use on thin-wall welded pipe and tubing because eddy currents are relatively insensitive to flaws that do not extend to the surface or into the near-surface layer.

Magnetic particle inspection and liquid penetrant inspection are not suitable for detecting subsurface gas porosity. These methods are restricted to the detection of only those pores that are open to the surface.

Slag inclusions may occur when using welding processes that employ a slag covering for shielding purposes. (With other processes, the oxide present on the metal surface before welding may also become entrapped.) Slag inclusions can be found near the surface and in the root of a weld (Fig. 3a), between weld beads in multiple-pass welds (Fig. 3b), and at the side of a weld near the root (Fig. 3c).

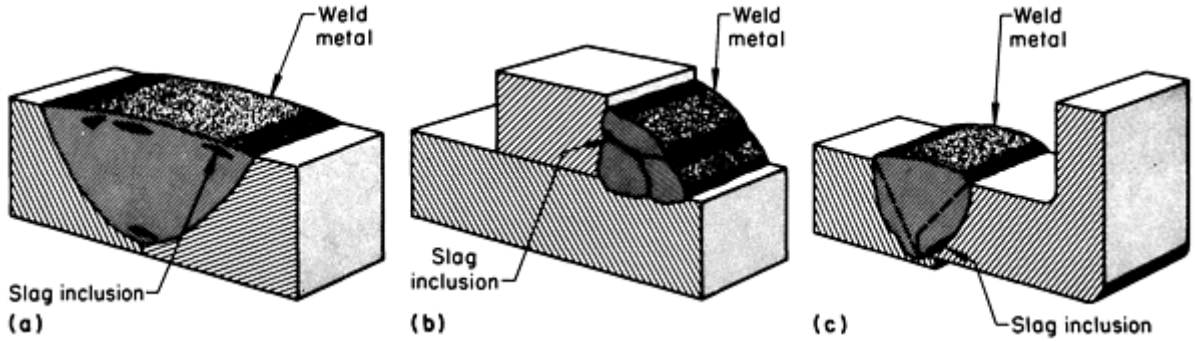

FIG. 3 SECTIONS SHOWING LOCATIONS OF SLAG INCLUSIONS IN WELD METAL. (A) NEAR THE SURFACE AND IN THE ROOT OF A SINGLE-PASS WELD. (B) BETWEEN WELD BEADS IN A MULTIPLE-PASS WELD. (C) AT THE SIDE OF A WELD NEAR THE ROOT

During welding, slag may spill ahead of the arc and subsequently be covered by the weld pool because of poor joint fit-up, incorrect electrode manipulation, or forward arc blow. Slag trapped in this manner is generally located near the root. Radical motions of the electrode, such as wide weaving, may also cause slag entrapment on the sides or near the top of the weld after the slag spills into a portion of the joint that has not been filled by the molten pool. Incomplete removal of the slag from the previous pass in multiple-pass welding is another common cause of entrapment. In multiple-pass welds, slag may be entrapped any number of places in the weld between passes. Slag inclusions are generally oriented along the direction of welding.

Three methods used for the detection of slag below the surface of single-pass or multiple-pass welds are magnetic particle, radiographic, and ultrasonic inspection. Depending on their size, shape, orientation, and proximity to the surface, slag inclusions can be detected by magnetic particle inspection with a dc power source, provided the material is ferromagnetic. Radiography can be used for any material, but is the most expensive of the three methods. Ultrasonic inspection can also be used for any material and is the most reliable and least expensive method. If the weld is machined to a flush contour, flaws as close as 0.8 mm ($\frac{1}{32}$ in.) to the surface can be detected with the straight-beam technique of ultrasonic inspection, provided the instrument has sufficient sensitivity and resolution. A 5 or 10 MHz dual-element transducer is normally used in this application. If the weld cannot be machined, near-surface sensitivity will be low because the initial pulse is excessively broadened by the rough as-welded surface. Unmachined welds can be readily inspected by direct-beam and reflected-beam techniques, using an angle-beam (shear-wave) transducer.

Tungsten inclusions are particles found in the weld metal from the nonconsumable tungsten electrode used in GTAW. These inclusions are the result of:

- EXCEEDING THE MAXIMUM CURRENT FOR A GIVEN ELECTRODE SIZE OR TYPE
- LETTING THE TIP OF THE ELECTRODE MAKE CONTACT WITH THE HOT TIP OF THE ELECTRODE
- USING AN EXCESSIVE ELECTRODE EXTENSION
- INADEQUATE GAS SHIELDING OR EXCESSIVE WIND DRAFTS, WHICH RESULT IN OXIDATION
- USING IMPROPER SHIELDING GASES SUCH AS ARGON-OXYGEN OR ARGON-CO2 MIXTURES, WHICH ARE USED FOR GMAW

Tungsten inclusions, which are not acceptable for high-quality work, can only be found by internal inspection techniques, particularly radiographic testing.

Lack of fusion and lack of penetration result from improper electrode manipulation and the use of incorrect welding conditions. Fusion refers to the degree to which the original base metal surfaces to be welded have been fused to the filler metal; penetration refers to the degree to which the base metal has been melted and resolidified to result in a deeper throat

that was present in the joint before welding. In effect, a joint can be completely fused but have incomplete root penetration to obtain the throat size specified. Based on these definitions, LOF discontinuities are located on the sidewalls of a joint, and LOP discontinuities are located near the root (Fig. 4). With some joint configurations, such as butt joints, the two terms can be used interchangeably. The causes of LOF include excessive travel speed, bridging, excessive electrode size, insufficient current, poor joint preparation, overly acute joint angle, improper electrode manipulation, and excessive arc blow. Lack of penetration may be the result of low welding current, excessive travel speed, improper electrode manipulation, or surface contaminants such as oxide, oil, or dirt that prevent full melting of the underlying metal.

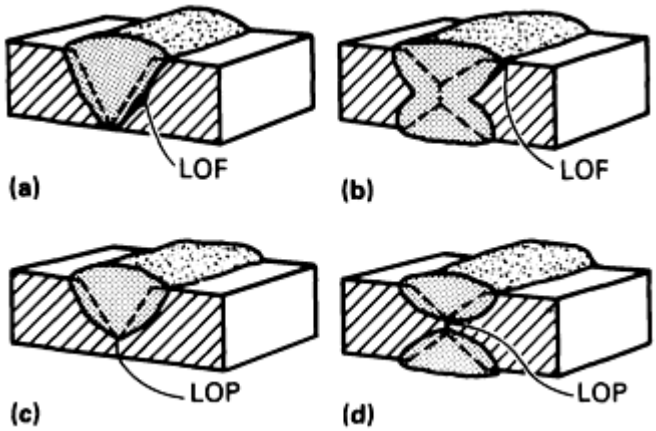

FIG. 4 LACK OF FUSION IN (A) A SINGLE-V-GROOVE WELD AND (B) DOUBLE-V-GROOVE WELD. LACK OF PENETRATION IN (C) A SINGLE-V-GROOVE WELD AND (D) A DOUBLE-V-GROOVE WELD

Radiographic methods may be unable to detect these discontinuities in certain cases, because of the small effect they have on x-ray absorption. As will be described later, however, lack of sidewall fusion is readily detected by radiography. Ultrasonically, both types of discontinuities often appear as severe, almost continuous, linear porosity because of the nature of the unbonded areas of the joint. Except in thin sheet or plate, these discontinuities may be too deep-lying to be detected by magnetic particle inspection.

Geometric weld discontinuities are those associated with imperfect shape or unacceptable weld contour. Undercut, underfill, overlap, excessive reinforcement, fillet shape, and melt-through, all of which were defined earlier, are included in this grouping. Geometric discontinuities are shown schematically in Fig. 5. Radiography is used most often to detect these flaws.

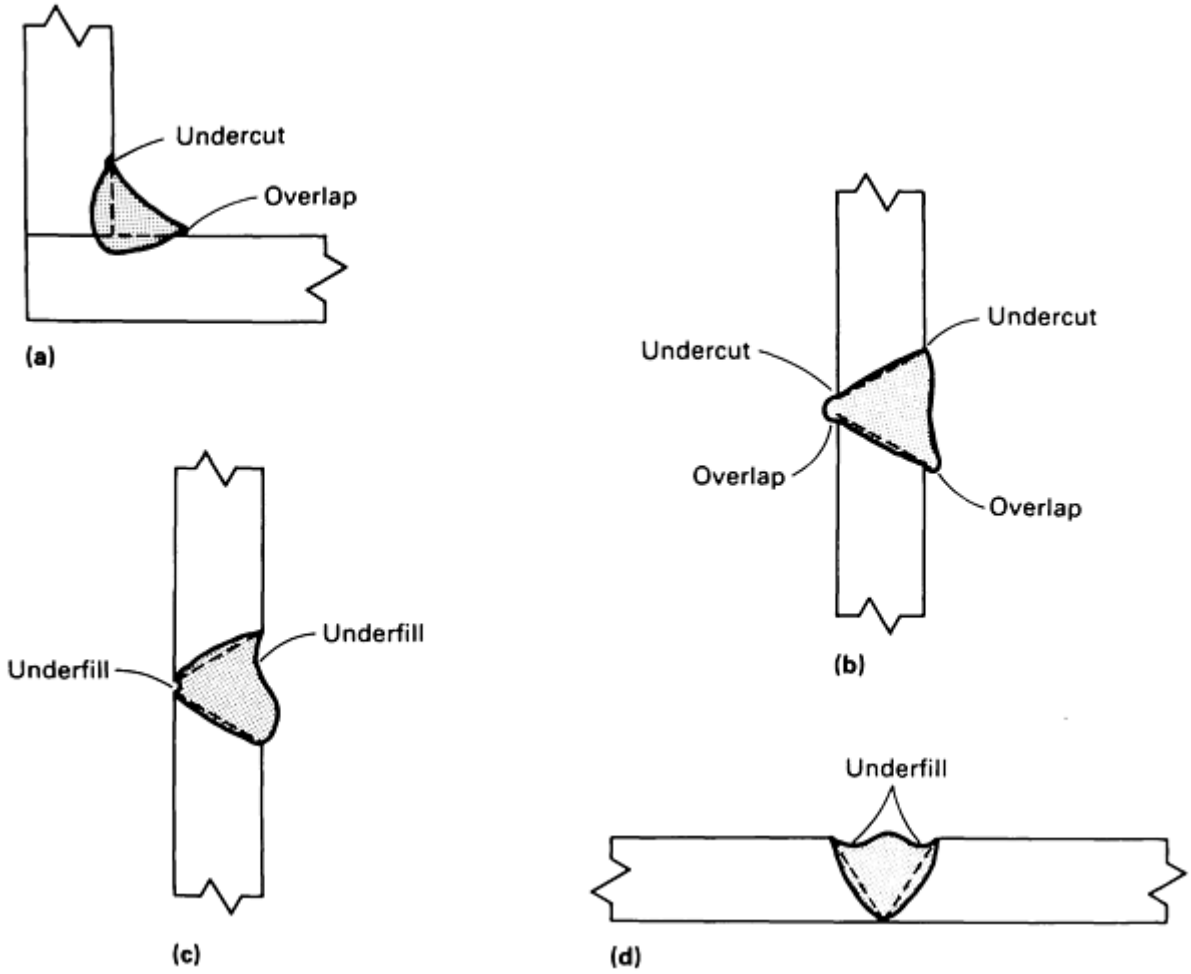

FIG. 5 WELD DISCONTINUITIES AFFECTING WELD SHAPE AND CONTOUR. (A) UNDERCUT AND OVERLAPPING IN A FILLET WELD. (B) UNDERCUT AND OVERLAPPING IN A GROOVE WELD. (C) AND (D) UNDERFILL IN GROOVE WELDS

Cracks can occur in a wide variety of shapes and types and can be located in numerous positions in and around a welded joint (Fig. 6). Cracks associated with welding can be categorized according to whether they originate in the weld itself or in the base metal. Four types commonly occur in the weld metal: transverse, longitudinal, crater, and hat cracks. Base metal cracks can be divided into seven categories: transverse cracks, underbead cracks, toe cracks, root cracks, lamellar tearing, delaminations, and fusion-line cracks.

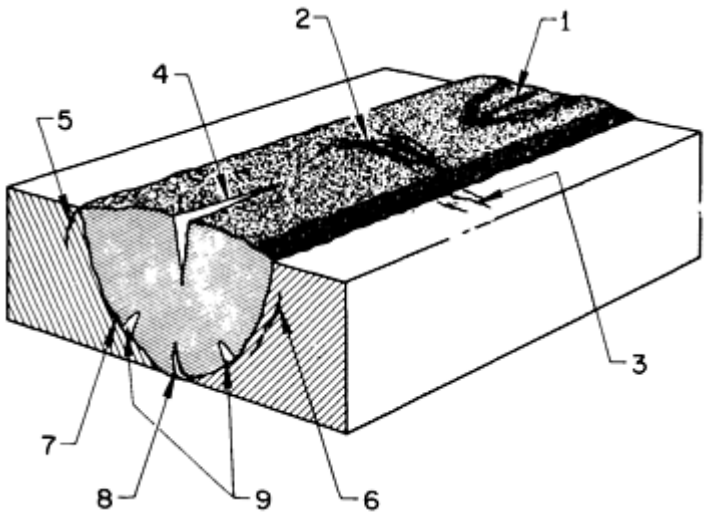

FIG. 6 IDENTIFICATION OF CRACKS ACCORDING TO LOCATION IN WELD AND BASE METAL. 1, CRATER CRACK IN WELD METAL; 2, TRANSVERSE CRACK IN WELD METAL; 3, TRANSVERSE CRACK IN HAZ;, 4, LONGITUDINAL CRACK IN WELD METAL; 5, TOE CRACK IN BASE METAL; 6, UNDERBEAD CRACK IN BASE METAL; 7, FUSION-LINE CRACK; 8, ROOT CRACK IN WELD METAL; 9, HAT CRACKS IN WELD METAL

Weld metal cracks and base metal cracks that extend to the surface can be detected by liquid penetrant and magnetic particle inspection. Magnetic particle inspection can also detect subsurface cracks, depending on their size, shape, and proximity to the surface. Although the orientation of a crack with respect to the direction of the radiation beam is the dominant factor in determining the ability of radiography to detect the crack, differences in composition between the base metal and the weld metal may create shadows to hide a crack that otherwise might be visible. Ultrasonic inspection is generally effective in detecting most cracks in the weld zone.

Transverse cracks in weld metal (No. 2, Fig. 6) are formed when the predominant contraction stresses are in the direction of the weld axis. They can be hot cracks, which separate intergranularly as the result of hot shortness or localized planar shrinkage, or they can be transgranular separations produced by stresses exceeding the strength of the material. Transverse cracks lie in a plane normal to the axis of the weld and are usually open to the surface. They usually extend across the entire face of the weld and sometimes propagate into the base metal.

Transverse cracks in base metal (No. 3, Fig. 6) occur on the surface in or near the HAZ. They are the result of the high residual stresses induced by thermal cycling during welding. High hardness, excessive restraint, and the presence of hydrogen promote their formation. Such cracks propagate into the weld or beyond the HAZ into the base metal as far as is needed to relieve the residual stresses.

Underbead cracks (No. 6, Fig. 6) are similar to transverse cracks in that they form in the HAZ because of high hardness, excessive restraint, and the presence of hydrogen. Their orientation follows the contour of the HAZ.

Longitudinal cracks (No. 4, Fig. 6) may exist in three forms, depending on their positions in the weld. Check cracks are open to the surface and extend only partway through the weld. Root cracks extend from the root to some point within the weld. Full centerline cracks may extend from the root to the face of the weld metal.

Check cracks are caused either by high contraction stresses in the final passes applied to a weld joint or by a hot-cracking mechanism.

Root cracks are the most common form of longitudinal weld metal crack because of the relatively small size of the root pass. If such cracks are not removed, they can propagate through the weld as subsequent passes are applied. This is the usual mechanism by which full centerline cracks are formed.

Centerline cracks may occur at either high or low temperatures. At low temperatures, cracking is generally the result of poor fit-up, overly rigid fit-up, or a small ratio of weld metal to base metal.

All three types of longitudinal cracks are usually oriented perpendicular to the weld face and run along the plane that bisects the welded joint. Seldom are they open at the edge of the joint face, because this requires a fillet weld with an extremely convex bead.

Crater cracks (No. 1, Fig. 6) are related to centerline cracks. As the name implies, crater cracks occur in the weld crater formed at the end of a welding pass. Generally, this type of crack is caused by failure to fill the crater before breaking the arc. When this happens, the outer edges of the crater cool rapidly, producing stresses sufficient to crack the interior of the crater. This type of crack may be oriented longitudinally or transversely or may occur as a number of intersecting cracks forming the shape of a star. Longitudinal crater cracks can propagate along the axis of the weld to form a centerline crack. In addition, such cracks may propagate upward through the weld if they are not removed before subsequent passes are applied.

Hat cracks (No. 9, Fig. 6) derive their name from the shape of the weld cross section with which they are usually associated. This type of weld flares out near the weld face, resembling an inverted top hat. Hat cracks are the result of excessive voltage or welding speed. The cracks are located about halfway up through the weld and extend into the weld metal from the fusion line of the joint.

Toe and root cracks (No. 5 and 8, Fig. 6) can occur at the notches present at notch locations in the weld when high residual stresses are present. Both toe and root cracks propagate through the brittle HAZ before they are arrested in more ductile regions of the base metal. Characteristically, they are oriented almost perpendicular to the base metal surface and run parallel to the weld axis.

Lamellar tearing is the phenomenon that occurs in T-joints that are fillet welded on both sides. This condition, which occurs in the base metal or HAZ of restrained weld joints, is characterized by a steplike crack parallel to the rolling plane. The crack originates internally because of tensile strains produced by the contraction of the weld metal and the surrounding HAZ during cooling. Figure 7 shows a typical condition.

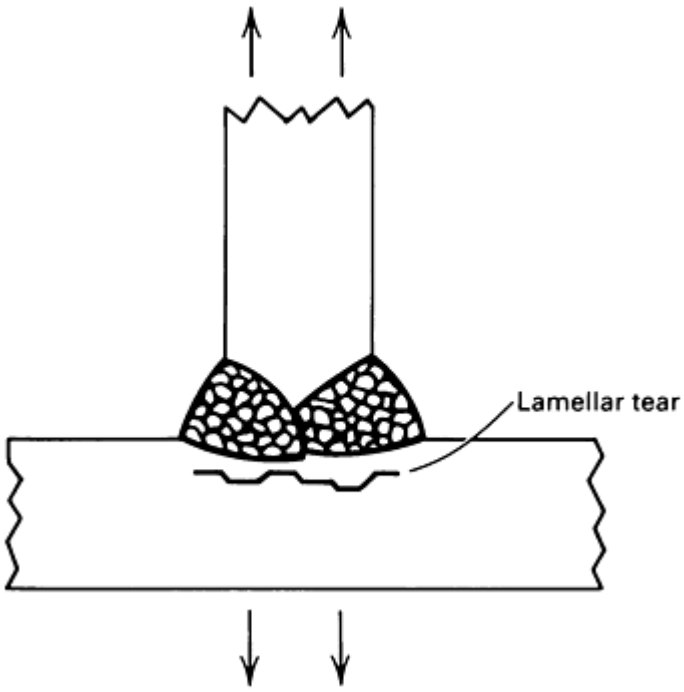

FIG. 7 LAMELLAR TEAR CAUSED BY THERMAL CONTRACTION STRAIN

Fusion-line cracks (No. 7, Fig. 6) can be classified as either weld metal cracks or base metal cracks because they occur along the fusion line between the two. There are no limitations as to where along the fusion line these cracks can occur or how far around the weld they can extend.

Discontinuities Associated With Specialized Welding Processes

The preceding section has dealt mainly with the discontinuities common to conventional arc-welding processes. In addition, there are certain more specialized welding methods that may have discontinuities unique to them. These methods include electron-beam, plasma arc, electroslag, friction, and resistance welding. In general, the types of discontinuities associated with these processes are the same as those associated with conventional arc welding; however, because of the nature of the processes and the joint configurations involved, such discontinuities may be oriented differently from those previously described, or they may present particular problems of location and evaluation.

Electron-Beam Welding

In electron-beam welding, as in all other welding processes, weld discontinuities can be divided into two major categories:

- THOSE THAT OCCUR AT, OR ARE OPEN TO, THE SURFACE
- THOSE THAT OCCUR BELOW THE SURFACE

Surface flaws include undercut, mismatch, underfill, reinforcement, cracks, missed seams, and LOP. Subsurface flaws include porosity, massive voids, bursts, cracks, missed seams, and LOP. Figure 8 shows poor welds containing these flaws, and a good weld with none of them.

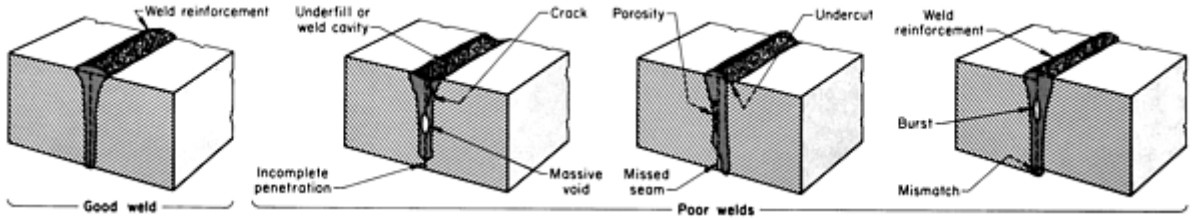

FIG. 8 ELECTRON-BEAM WELDS SHOWING FLAWS THAT CAN OCCUR IN POOR WELDS AND THE ABSENCE OF FLAWS IN A GOOD WELD WITH REINFORCEMENT

Surface discontinuities such as undercut, mismatch, reinforcement, and underfill are macroscopic discontinuities related to the contour of the weld bead or the joint. As such, they are readily detected visually or dimensionally. Surface discontinuities such as cracks are usually detected visually using liquid penetrant inspection or using magnetic particle inspection if the material is ferromagnetic.

When liquid penetrants are used to inspect a weld for surface discontinuities such as cracks, missed seams, and LOP, the surface to be inspected must be clean and the layers of metal smeared from machining or peened from grit- or sandblasting must be removed. Generally, some type of etching or pickling treatment works well, but the possibility of hydrogen pickup from the treatment must be considered.

Occasionally, special inspection procedures must be employed to detect some types of surface discontinuities in electron-beam welds. Missed seams and LOP are often difficult to detect because they are frequently associated with complex weld joints that prevent direct viewing of the affected surface.

Because of this difficulty, missed seams are often detected using a visual witness-line procedure in which equally spaced parallel lines are scribed on both sides of the unwelded joint at the crown and root surfaces. Missed seams, which result from misalignment of the electron beam with the joint such that the fusion zone fails to encompass the entire joint, are detected by observing the number of witness lines remaining on either side of the weld bead. By establishing the relationship between the width of the fusion zone and the spacing of the witness lines, reasonably accurate criteria for determining whether the joint has been contained within the weld path (and therefore whether missed seams are present) can be developed.

Lack-of-penetration discontinuities occur when the fusion zone fails to penetrate through the entire joint thickness, resulting in an unbonded area near the root of the joint. These discontinuities are best detected by etching the root surface and observing the macroscopic shape and width of the fusion zone for full and even penetration.

An alternative method for inspecting complete weld penetration is that of immersion pulse-echo ultrasonic testing. The planet gear carrier assembly shown in Fig. 9(a) consists of three decks (plates) and eight curved spacer sections. The assembly, which is made from SAE 15B22M boron-treated structural steel, is held together by 16 welds. Weld integrity is monitored by ultrasonic methods.

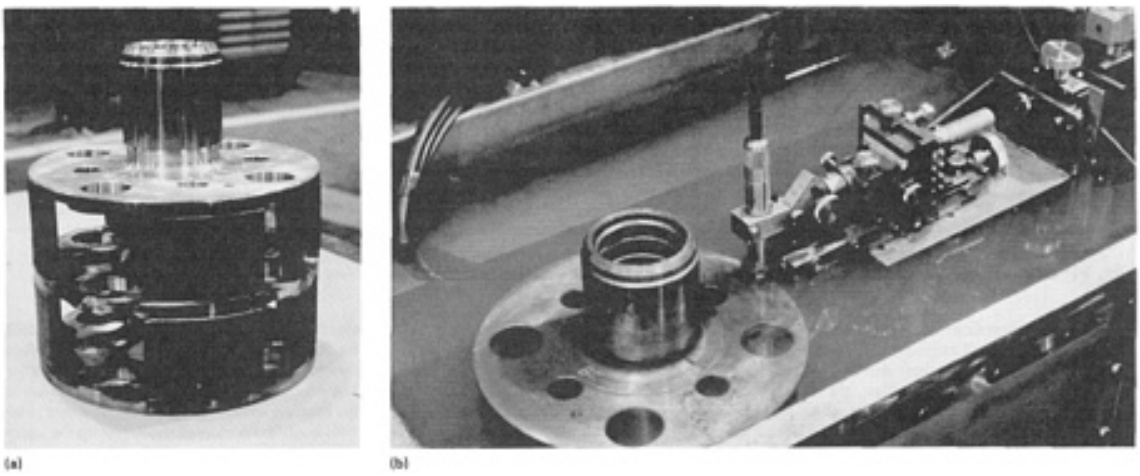

FIG. 9 PLANET GEAR CARRIER ASSEMBLY (A) SHOWING THE FOUR WELDS IN ONE STACK THAT CONNECT THE THREE DECKS. THE TOP AND TOP-CENTER WELDS ARE TESTED BY THE TOP ULTRASONIC TRANSDUCER, AND THE BOTTOM AND BOTTOM-CENTER WELDS ARE INSPECTED BY THE BOTTOM TRANSDUCER. (B) CLOSE-UP OF UPPER TRANSDUCER IN POSITION TO TEST THE WELDS. COURTESY OF CATERPILLAR, INC.

The parts are mounted on a turntable on a locating fixture so that the welds along the outside diameter are accessible. Two transducers, located above and below the assembly, are used. Figure 9(b) shows the upper transducer in position to test the welds. An overall view of the tank, turntable, controls, and reject/accept light panel is shown in Fig. 10. The use of such a system involves little downtime and enables a high quality level to be maintained. More information on ultrasonic test methods is presented later in this article.

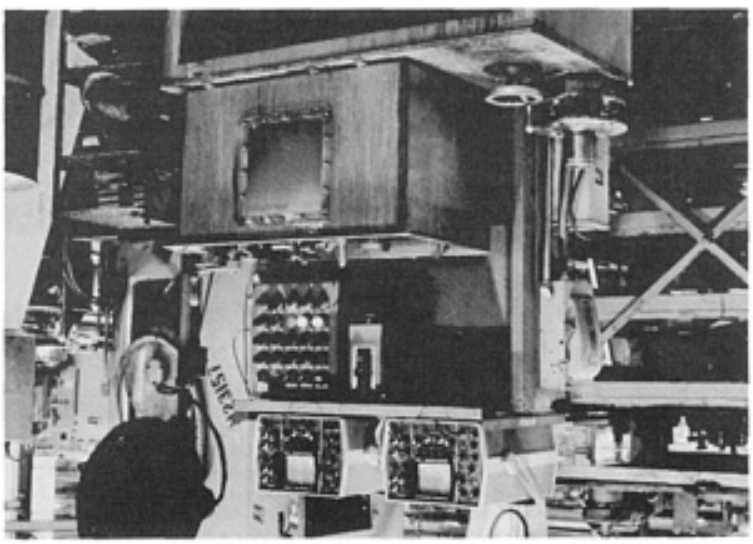

FIG. 10 OVERALL VIEW OF THE ULTRASONIC UNIT USED TO TEST THE ELECTRON-BEAM WELDED ASSEMBLY

SHOWN IN FIG. 9. COURTESY OF CATERPILLAR, INC.

Subsurface discontinuities in electron-beam welds are generally considerably more difficult to detect than surface discontinuities because observation is indirect. The two most reliable and widely used nondestructive inspection methods are radiography and ultrasonics.

Volume-type discontinuities such as porosity, voids, and bursts are detected by radiographic inspection, provided their cross sections presented to the radiating beam exceed 1 to 2% of the beam path in the metal. Discontinuities that present extremely thin cross sections to the beam path, such as cracks, missed seams, and LOP, are detectable with x-rays only if they are viewed from the end along their planar dimensions.

Ultrasonic inspection can detect most volume discontinuities as well as planar discontinuities. Planar discontinuities are best detected normal to the plane of the discontinuities, but missed seams and LOP often appear as continuous porosity when viewed looking down from the crown to the root of the weld in the plane of the discontinuity.

Because of the inherent dependence of both radiographic and ultrasonic inspection on the shape and orientation of flaws because each of the two methods can generally detect those flaws that the other misses, it is most advisable to complement one method with the other. Furthermore, to increase the likelihood of properly viewing a flaw, one of the methods should be employed in at least two (preferably perpendicular) directions.

Plasma Arc Welding

Discontinuities that occur in plasma arc welds include both surface and subsurface types, as shown in Fig. 11.

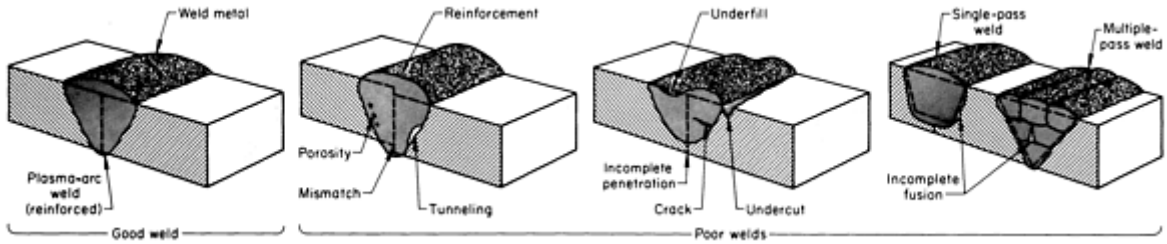

FIG. 11 PLASMA ARC WELDS SHOWING FLAWS THAT CAN OCCUR IN POOR WELDS AND THE ABSENCE OF FLAWS IN GOOD REINFORCED WELD

Surface discontinuities such as irregular reinforcement, underfill, undercut, and mismatch that are associated with weld bead contour and joint alignment are easily detected visually or dimensionally. Lack of penetration is also detected visually through the absence of a root bead. Weld cracks that are open to the surface are detected with liquid penetrants. Surface contamination, which results from insufficient shielding-gas coverage, is detected by the severe discoloration of the weld bead or adjacent HAZ.

Subsurface discontinuities are generally more prevalent in manual than in automatic plasma arc welding and are detected primarily by radiographic or ultrasonic inspection.

Porosity is by far the most commonly encountered discontinuity. Radiographic inspection is limited to detecting pores greater than approximately 1 to 2% of the joint thickness. Visibility is greater if both the crown and root beads are machined flush. Ultrasonic inspection can detect porosity if the joint is machined flush and joint thickness exceeds approximately 1.3 mm (0.050 in.).

Tunneling, as shown in Fig. 11, is a severe void along the boundary of the fusion zone and the HAZ. This discontinuity results from a combination of torch alignment and welding conditions (particularly travel speed). Tunneling is readily detectable by radiographic inspection.

Lack-of-fusion discontinuities occur in either single-pass or multiple-pass repair welds (Fig. 11). These discontinuities result from insufficient heat input to permit complete fusion of a particular weld bead to the part. Incomplete fusion can be detected by radiographic or ultrasonic inspection. Depending on the orientation of the discontinuity, one method may have an advantage over the other, so both should be used for optimum inspection.

Subsurface weld cracks, regardless of their cause, are detectable by radiographic and ultrasonic inspection.

Subsurface contamination in plasma arc welding results when copper from the torch nozzle is expelled into the weld. This is caused by excessive heat, usually produced in manual repair welding when the torch nozzle is placed too close to the weld, particularly in a groove. The resulting contamination, which may be detrimental, is undetectable by conventional nondestructive inspection methods. The only way of detecting copper contamination is by alerting the operator to watch for copper expulsion, which then must be machined off.

Electroslag Welding

Electroslag welding involves the use of copper dams over the open surfaces of a butt joint to hold the molten metal and the slag layer as the joint is built up vertically. Wire is fed into the slag layer continuously and is melted by the heat generated as current passes through the highly resistant slag layer.

Generally, electroslag welds are inspected with the same nondestructive examination methods as other heavy-section welds. With the exception of procedure qualification, all testing is nondestructive because of the sizes used. Techniques such as radiography and ultrasonic inspection are most often used, while visual, magnetic particle, and liquid penetrant testing are used also. Internal defects are generally more serious. Radiography and ultrasonic tests are the best methods for locating internal discontinuities.

Because of the nature of the process, LOF is rare. If fusion is achieved on external material edges, then fusion is generally complete throughout. Cracking may occur either in the weld or the HAZ. Porosity may either take the form of a rounded or a piped shape; the latter is often called wormhole porosity. Ultrasonic inspection is probably the quickest single method for inspecting any large weldment. If defects should occur, they appear as porosity or centerline cracking. Ultrasonic inspection is effective for locating either type of detect; however, only well-qualified personnel should set up the equipment and interpret the test results.

Electroslag welding results in large dendritic grain sizes because of the slow cooling rate. Inexperienced personnel often use high sensitivity and actually pick up the large coarse grains; when such welds are sectioned, usually no defects are present. Inspectors must learn to use low sensitivity to obtain good results when inspecting electroslag welds. Magnetic particle inspection is not a particularly good inspection method, because the areas examined by this technique are primarily surface or near surface. This is only a small percentage of the total weld; the only useful information is either checking the ends for craters, cracks, or centerline cracking or possibly for lack of edge fusion on the weld faces. Usually, a visual examination gives the same result unless the defect is subsurface. Visual examinations are only effective for surface defects, which are not common in this process.

Friction Welding

If impurities are properly dispelled during upsetting, friction or inertia welds are generally free of voids and inclusions. Incomplete center fusion can occur when flywheel speed is too low, when the amount of upset is insufficient, or when mating surfaces are concave. Tearing in the HAZ can be caused by low flywheel speed or excessive flywheel size. Cracks can occur when materials that are prone to hot shortness are joined. The penetration of a split between the extruded flash into the workpiece cross section is most prevalent during the welding of thin-wall tubing using improper conditions that do not allow for sufficient material upset.

The area where LOF generally occurs is at or near the center of the weld cross section. Because this is a subsurface discontinuity, detection is limited to radiographic or ultrasonic inspection; ultrasonic inspection is more practical. The longitudinal wave test (either manual-contact or immersion method) with beam propagation perpendicular to the area of LOF gives the most reliable results. This test can be performed as long as one end of the workpiece is accessible to the transducer.

Penetration of the split between the extruded flash on the outer surface of a tube is readily detected by liquid penetrant or magnetic particle inspection after the flash has been removed by machining. A split between the weld flash on the inner

surface of the tube can be detected by ultrasonic inspection using the angle-beam technique with manual contact of the transducer to the outside surface of the tube. The transducer contacts the tube so that the sound propagates along the longitudinal axis of the tube through the weldment.

Resistance Welding

Resistance welding encompasses spot, seam, and projection welding, each of which involves the joining of metals by passing current from one side of the joint to the other. The types of discontinuities found in resistance welds include porosity, LOF, and cracks. Porosity will generally be found on the centerline of the weld nugget. Lack of fusion may also be manifested as a centerline cavity. Either of these can be caused by overheating, inadequate pressure, premature release of pressure, or late application of pressure. Cracks may be induced by overheating, removal of pressure before weld quenching is completed, improper loading, poor joint fit-up, or expulsion of excess metal from the weld.

Weld Appearance. On the surface of a resistance spot welded assembly, the weld spot should be uniform in shape and relatively smooth, and it should be free of surface fusion, deep electrode indentations, electrode deposits, pits, cracks, sheet separation, abnormal discoloration around the weld, or other conditions indicating improper maintenance of electrodes or functioning of equipment. However, surface appearance is not always a good indicator of spot weld quality, because shunting and other causes of insufficient heating or incomplete penetration usually leave no visible effects on the workpiece.

The common practice for monitoring spot weld quality in manufacturing operations is the teardown method augmented with pry testing and visual inspection (Ref 3). In visual inspection, the operator uses the physical features of the weld surface, such as coloration, indentation, and smoothness, for assessing the quality of the weld. In pry testing, a wedge-shaped tool is inserted between the metal sheets next to the accessible welds, and a prying action is performed to see if the sheets will separate in the weld zone. The teardown method consists of physically tearing apart the welded members with hammers and chisels to determine the presence and size adequacy of fused metal nuggets at the spot weld site. The specifications require that the parent metal be torn and that the weld nugget remain intact. The destructiveness and/or inadequacy of these common inspection methods has long been recognized, and as a result, nondestructive methods have been extensively studied. The pulse-echo ultrasonic inspection of spot welds is now feasible.

Diffusion Welding

Diffusion welding (also known as diffusion bonding) is a metal joining process that requires the application of controlled pressures at elevated temperatures and usually a protective atmosphere to prevent oxidation. No melting and only limited macroscopic deformation or relative motion between the faying surfaces of the parts occur during bonding. As such, the principal mechanism for joint formation is solid-state diffusion. A diffusion aid (filler metal) may or may not be used. Diffusion welding has the advantage of producing a product finished to size, with joint efficiencies approaching 100%.

Discontinuities in Diffusion Welds. In the case of fusion welds, the detection of discontinuities less than 1 mm (0.04 in.) in size is not generally expected. In diffusion welding, in which no major lack of bonding occurs, individual discontinuities may be only micrometers in size. To understand how discontinuities form in diffusion-welded structures, it is first necessary to consider the principles of the process.

As illustrated in Fig. 12, metal surfaces have several general characteristics:

- ROUGHNESS
- AN OXIDIZED OR OTHERWISE CHEMICALLY REACTED AND ADHERENT LAYER
- OTHER RANDOMLY DISTRIBUTED SOLID OR LIQUID PRODUCTS SUCH AS OIL, GREASE, AND DIRT
- ADSORBED GAS, MOISTURE, OR BOTH

Because of these characteristics, two necessary conditions that must be met before a satisfactory diffusion weld can be made are:

- MECHANICAL INTIMACY OF METAL-TO-METAL CONTACT MUST BE ACHIEVED
- INTERFERING SURFACE CONTAMINANTS MUST BE DISRUPTED AND DISPERSED TO

PERMIT METALLIC BONDING TO OCCUR (SOLVENT CLEANING AND INERT GAS ATMOSPHERES CAN REDUCE OR ELIMINATE PROBLEMS ASSOCIATED WITH SURFACE CONTAMINATION AND OXIDE FORMATION, RESPECTIVELY)

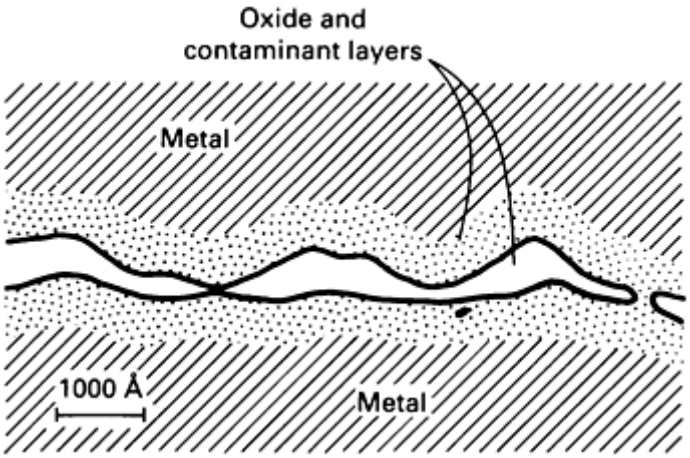

FIG. 12 CHARACTERISTICS OF A METAL SURFACE SHOWING ROUGHNESS AND CONTAMINANTS PRESENT. SOURCE: REF 7

For a given set of processing parameters, surface roughness is probably the most important variable influencing the quality of diffusion-welded joints. The size of the discontinuities (voids) is principally determined by the scale of roughness of the surfaces being bonded. The degree of surface roughness is dependent on the material and fabrication/machining technique used. It has been shown that bonding becomes easier with finer surface roughness prior to bonding. Figure 13 compares the surface roughness values produced by a variety of fabrication methods. More detailed information on surface roughness can be found in the article "Surface Finish and Surface Integrity" in *Machining,* Volume 16 of the *ASM Handbook.*

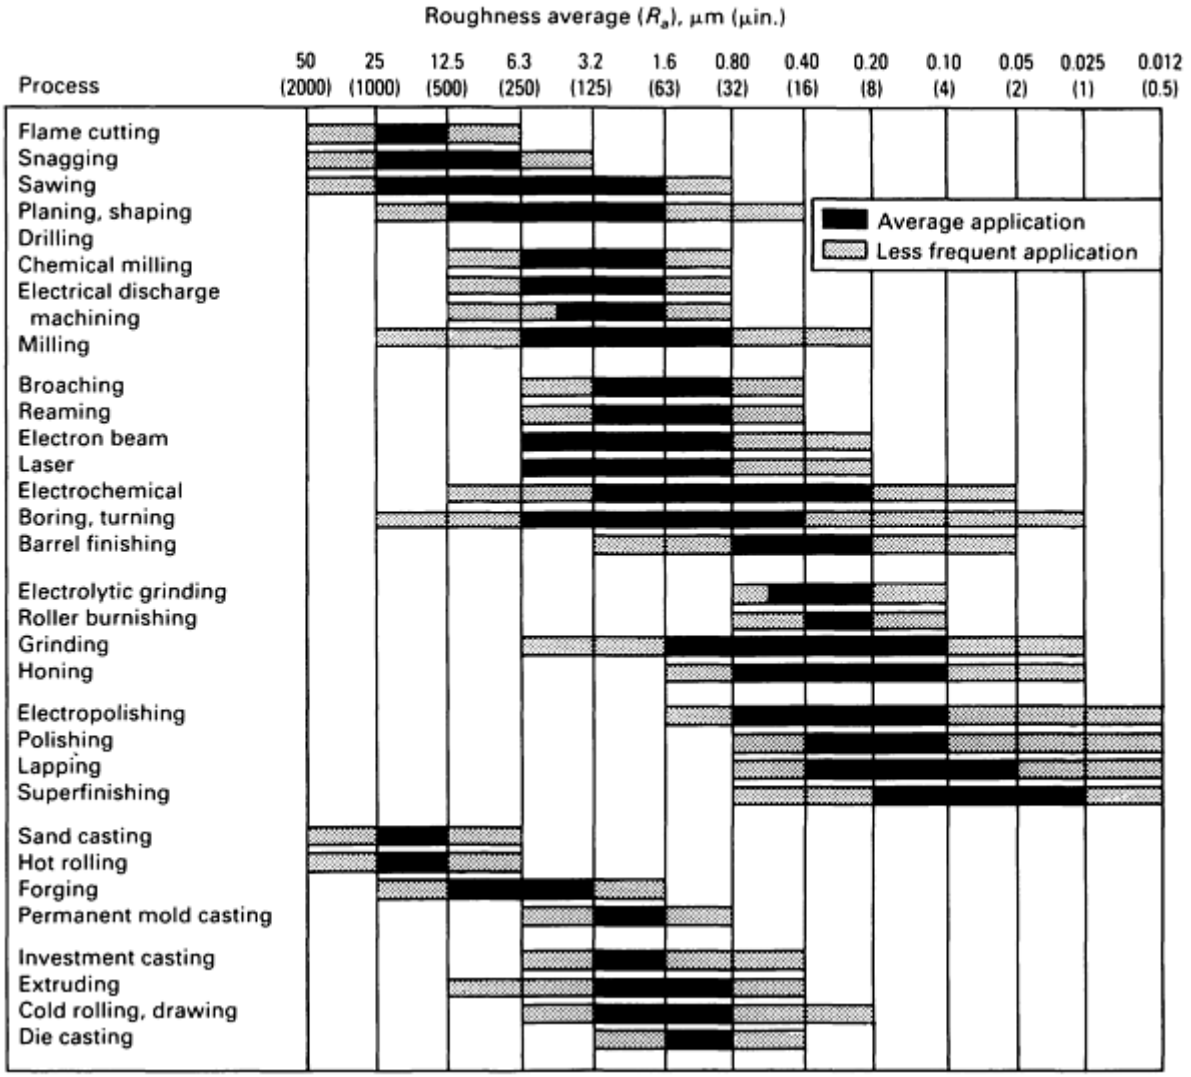

FIG. 13 SURFACE ROUGHNESS PRODUCED BY COMMON PRODUCTION METHODS. THE RANGES SHOWN ARE TYPICAL OF THE PROCESSES LISTED. HIGHER OR LOWER VALUES CAN BE OBTAINED UNDER SPECIAL CONDITIONS.

The mechanism of bond formation in diffusion welding is believed to be the deformation of the surface roughness in order to cause metal-to-metal contact at asperities, followed by the removal of interfacial voids and cracks by diffusional and creep processes. For conventional diffusion bonding without a diffusion aid, the three-stage mechanistic model shown in Fig. 14 describes bond formation. In the first stage, deformation of the contacting asperities occurs primarily by yielding and by creep deformation mechanisms to produce intimate contact over a large fraction of the interfacial area. At the end of this stage, the joint is essentially a grain boundary at the areas of contact with voids between these areas. During the second stage, diffusion becomes more important than deformation, and many of the voids disappear as the grain-boundary diffusion of atoms continues. Simultaneously, the interfacial grain boundary migrates to an equilibrium configuration away from the original plane of the joint, leaving many of the remaining voids within the grains. In the third stage, the remaining voids are eliminated by the volume diffusion of atoms to the void surface (equivalent to diffusion of vacancies away from the void). Successful completion of stage three is dependent on proper surface processing and joint processing.

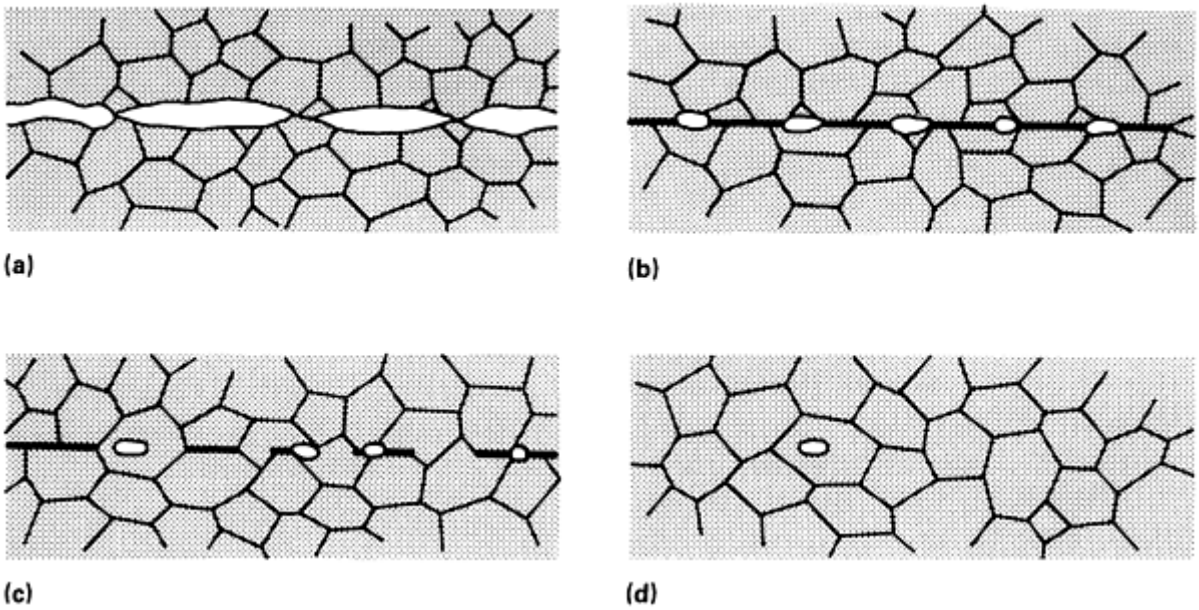

FIG. 14 THREE-STAGE MECHANISTIC MODEL OF DIFFUSION WELDING. (A) INITIAL ASPERITY CONTACT. (B) FIRST-STAGE DEFORMATION AND INTERFACIAL BOUNDARY FORMATION. (C) SECOND-STAGE GRAIN BOUNDARY MIGRATION AND PORE ELIMINATION. (D) THIRD-STAGE VOLUME DIFFUSION AND PORE ELIMINATION. SOURCE: REF 7

Successful nondestructive evaluation of diffusion-welded joints requires that the maximum size and distribution of discontinuities be determined. However, many conventional NDE methods and equipment are not adequate for discontinuity determination. Fluorescent penetrants provide excellent detection capability for lack of bonding as long as the interfacial crack breaks the surface. They are completely ineffective for defects that have no path to the surface.

Conventional film radiography is not suitable for detecting the extremely small defects involved in diffusion welding, but the use of x-ray microfocus techniques coupled with digital image enhancement offers an improvement in resolution. Discontinuities as small as 50 μm (0.002 in.) have been detected.

Conventional ultrasonic testing has some applications, although only significant lack of bonding or clusters of smaller defects can be reliably detected. High-resolution flaw detection involving frequencies approaching 100 MHz appears to have distinct advantages over conventional testing. Scanning acoustic microscopy also appears to offer excellent possibilities in diffusion bond inspection. Eddy current and thermal methods are relatively unsatisfactory for most applications.

Inspection of Welded Joints

G.R. Edwards, The Welding Institute

Introduction

WELDED JOINTS in any component or structure require thorough inspection. The role of nondestructive evaluation (NDE) in the inspection of welds is very important, and the technology has become highly developed as a result. This article describes the applications, methods, and limitations of NDE, and provides guidance as to method selection.

Nondestructive evaluation comprises a range of test methods for detecting discontinuities in a material, component, or structure, without causing damage. Therefore, the principal advantages of nondestructive tests, as opposed to alternative destructive proof tests, are that a 100% inspection can be performed at manufacture and that monitoring of the structure or component can continue while it is in service. The principal disadvantage of NDE is that the measurements obtained are only indirectly related to the presence and severity of the flaws, and much subjective interpretation is necessary.

Any discussion of NDE requires a clear definition of the term "defect." A defect is a discontinuity that creates a substantial risk of failure in a component or structure during its service life. Although the aim of NDE is to detect defects, it provides evidence of flaws, as well. The significance of these flaws and whether or not they are actually defects must then be determined. The development of NDE procedures often includes a collaboration between the NDE, engineering, and design functions to investigate the significance of defects.

There are five principal test methods: penetrant testing, magnetic-particle testing, eddy-current testing, radiographic testing, and ultrasonic testing. Although visual inspection is not strictly a test method, it does have an important role in NDE procedures and is often the only inspection method used. Acoustic emission (AE) testing and leak testing are described separately, because they are somewhat different in character and are not used as widely. There are other NDE methods that have been omitted, because they are very specialized.

Inspection of Welded Joints

G.R. Edwards, The Welding Institute

Applications

A useful distinction can be made between those NDE methods that are applied to welds during manufacturing and those that are applied to welds as part of plant and machinery maintenance. Although the same methods and techniques can be applied in both areas, there are important differences in inspection goals and, therefore, in test procedures.

In manufacturing, NDE is one of a series of quality-control techniques. The integration of these techniques into the manufacturing process is an important management subject. The first step is to decide at what stage or stages the NDE is to be carried out. Components that are brought in-house can be inspected prior to welding. An ultrasonic examination of a parent plate, for example, will show areas that contain laminations. Although these laminations may not be defects in themselves, lamellar tears could result where they occur near the weld in a specific orientation.

During the welding of thick sections, the magnetic-particle testing (MPT) of the root-pass and hot pass, in an attempt to find cracks before filling the weld groove, could save on repair costs. Using dry powder techniques, MPT can be carried out while surfaces are still hot.

Attempts have been made to incorporate NDE techniques with continuous monitoring of the weld process. Eddy-current testing, for example, has been used on small-bore induction-welded tube to provide feedback to control the welding process. However, total automation with real-time evaluation of test results is still not generally available, except in very simple applications, where results can be evaluated with simple go/no-go acceptance criteria.

Nondestructive evaluation is usually conducted at the end of a manufacturing process. In that capacity, it functions as part of the specification requirements and thus provides a safeguard against sending defective components or structures to customers. Unfortunately, conducting NDE after welding has been completed is not satisfactory. The necessity of repairs has given NDE a negative image in the manufacturing process. The early implementation of NDE in the process and the consequent actions to reduce repair rates is a more positive use.

NDE techniques have been used increasingly in plant and machinery maintenance, as a result of numerous industrial trends. The trend toward improved safety of operation, particularly in aircraft and nuclear power plants, is an obvious example. In times of economic recession, the operating life of a plant tends to be extended, and NDE has been utilized with increasing frequency. Environmental issues also have provided a stimulus to NDE activity. The inspection of storage tanks at refineries, where corrosion needs to be detected before leaks develop, is a good example.

As already noted, the performance capability required of NDE during the manufacturing process can be quite different from that needed during plant maintenance. Generally, the sizing accuracy is more important in maintenance, whereas the reliability of detection is more important in manufacturing. Because of the inherent unreliability of many techniques, a wide tolerance between critical defect size and flaw detection threshold is needed in manufacturing. However, the incorporation of fitness-for-purpose philosophies into quality control is having the effect of reducing this tolerance and placing greater emphasis on NDE sizing accuracy in all applications.

Inspection of Welded Joints

NDE Methods

A variety of NDE methods are briefly described below, along with some of the operating problems that can be encountered. The limitations of NDE methods are further described in the section "NDE Performance" in this article.

Visual inspection, although not itself a test method, is the most common NDE method and, arguably, the most important. Indeed, a thorough visual examination is a prerequisite of successful NDE. Much can be inferred from the surface of the weld, including information about its internal condition, although a good weld surface does not necessarily indicate a defect-free weld.

Mechanical gages are available for measuring such dimensions as the height of the weld bead, the depth of the undercut, and the weld size (Fig. 1). When surfaces are not accessible, it may be possible to use boroscopes and flexible endoscopes to view the weld. Their use does require some familiarization, because they give a very flat field of view in which important features can be lost unless the surface is illuminated carefully.

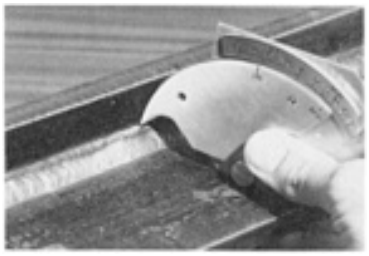

FIG. 1 WELD GAGE

Penetrant Testing. Penetrants provide a method of enhancing the visibility of flaws. A strongly colored, or fluorescent, liquid is applied liberally to the test surface and left to infiltrate surface-breaking cavities and cracks. The surface contact time is typically about 15 min. The excess liquid is then wiped from the surface, using some solvent, and a fine white developer powder is applied, usually as an aerosol in a volatile solvent. As the solvent evaporates, the penetrant liquid that is trapped in the flaws is drawn into the dry developer powder by a reverse-capillary action. For a cavity, this process may take no more than 1 s, but for a fine hairline crack, it may be necessary to wait more than 1 h for a visible indication.

The several penetrant types that exist can be distinguished on the basis of color, method of removal, and the form of the developer. Red penetrants, which are the most commonly used, require good daylight viewing conditions and a white background to improve contrast. Fluorescent penetrants are used when high sensitivity to fine flaws on relatively smooth surfaces is needed. They require black-light viewing conditions.

Solvent-removable red penerrants are the most convenient for site use. They can be provided in three aerosol cans of penetrant, cleaning fluid, and developer. Unfortunately, solvents are a health hazard and should be applied only in well-ventilated areas. A safer alternative is the water-washable penetrant.

When the geometry of the test piece is too complicated for an even coating to be applied using a spray, the developer can be applied directly as a dry powder. A dry powder is more suited to fluorescent penetrants, because it does not provide a white background, and the thickness of the coating reduces the blotting action and sensitivity, but improves image definition.

The compatibility of the penetrant with the test material must be considered. Residues of penetrant can be difficult to remove after the test. Traces of chlorine will corrode stainless steels and hydroxides will attack aluminum. The trace element content is provided by the manufacturer of the penetrant.

Although it is the most common NDE method, penetrant testing is widely misused. The test surfaces are often inadequately cleaned, the penetrant contact time with the surface is too short, or the excess penetrant is removed carelessly from flaws, as well as from the surface. In addition, because the method only detects flaws that are open to the surface, abrasive cleaning methods may peen over fine, surface-breaking cracks. This problem can arise when penetrants are used to chase fine hairline cracks or incomplete fusion with grinding.

Magnetic particle testing is the preferred method for detecting surface-breaking and, under certain circumstances, near-surface flaws in situations where a test material can be magnetized.

This method depends on the flaw disrupting the magnetic flux generated along the surface of the weld by a permanent magnet or electromagnets, or by electric-current-carrying electrodes and cables. Flux leakage from the surface creates magnetic poles, which attract the magnetic particles, creating a clearly visible image of the flaw. The method is particularly sensitive to the detection of cracks, where, like penetrants, the particles identify flaws with well-defined features. However, the flux leakage may be absent altogether, if the crack runs parallel with the magnetic field. It is therefore vital that the inspection surface be magnetized in two directions at right angles to each other.

Important considerations associated with MPT are the method of magnetization, the detecting medium, and the ways in which the field direction and strength can be measured. A very convenient method of magnetization is to use permanent magnets, which do not need a power source. Because the magnetic field is in a constant direction and does not alternate, it penetrates the surface to give some sensitivity to subsurface flaws. However, permanent magnets are difficult to

manipulate in confined spaces. If proper contact between the feet of the magnet and the test surface is not achieved, then the density of magnetic flux in the test piece is weakened, and the test sensitivity is reduced.

Electromagnets are easier to use and can generate magnetic fields with alternating current (ac) (Fig. 2). The skin effect caused by ac concentrates the flux at the surface, improving the sensitivity to surface-breaking flaws, particularly on contoured surfaces.

FIG. 2 MAGNETIC-PARTICLE TESTING OF A WELD WITH AN ELECTROMAGNET

Prod magnetization, in which electrodes carrying a high-amperage, low-voltage current are pressed onto the test surface to induce a distorted, circular magnetic field, provides the most controlled method of magnetization. Although the electrodes can be manipulated more easily into tight corners, they do have two major disadvantages, which can preclude their usefulness. First, the arc strikes that can occur at the prod contact points can damage the test surface. Second, the electrodes may require a two-man operation.

Cable magnetization is common in diver inspections of underwater node welds on oil platforms. The cables are wrapped around the pipe adjacent to the weld. The induced field, which is directed across the weld, is sensitive to longitudinal cracks only.

The fine particles that are applied to the magnetized surface to detect the flux-leakage fields must be highly magnetic. Materials commonly used are black iron and red or yellow iron oxides. The iron particles can be coated with a fluorescent material and viewed in black light. Before black particles are applied, the surface can be coated with a thin, white lacquer to improve contrast. Although the particles are typically sprayed on the surface as a suspension in water or solvent, they also can be applied as a dry powder. Dry powders can be used on hot surfaces or in cases where contamination is an issue.

To ensure that the magnetic flux is adequate, indicators such as the Berthold gage can be placed on the test surface. This type of indicator contains fine graticules of a highly magnetic material set in a nonmagnetic base. The graticules are made visible when the particles are applied and the magnetic field is of sufficient strength in a right-angled direction to the graticule. However, the indicators are influenced more by the tangential field across the test surface than by the magnetic field within the test piece. Therefore, as an indicator of test sensitivity, they should be treated with circumspection. It is possible to see defects, even when the indicator has been placed on a nonmagnetic material, where there is obviously no defect sensitivity at all.

The MPT process can leave residual fields that interfere with welding processes, Demagnetization can be achieved by slowly wiping the surface with an ac yoke.

Eddy-current testing techniques have been used widely in automated tube-testing systems and material sorting, as well as in the inspection of aircraft components and structures. For the testing of welds, there is a growing interest in using eddy-current testing as an alternative to MPT and penetrant testing, because the method is able to detect cracks beneath a thick layer of paint.

Like MPT, eddy-current testing relies on the flaw disrupting the energizing field, which is electrical, circular, and induced by a small coil carrying high-frequency alternating current. Therefore, the orientation of vertical planar flaws is not important, but the coil has to be scanned intensively over the test surface to ensure coverage. Laminar flaws are not detectable.

The method relies on detecting changes in the impedance of a coil that are caused by deflections in the eddy-current field around a flaw. The eddy-current field is affected by changes in material properties, surface geometry, edges, and many other factors that are unrelated to flaws. For this reason, the analysis of eddy-current test results can be difficult. The important components of the test equipment are the instrument, the probe containing the coil, and the calibration block containing slots or other artificial flaws.

Meter-reading instruments may be adequate for simple tests, but for more complex applications, such as weld testing, a cathode-ray tube with a vector point display is needed for analyzing the induced coil current (Fig. 3). The vector point provides information about the impedance of the coil. This is a complex quantity, which measures the amplitude and phase of the coil current. Certain directional movements in the vector point on the screen representing phase changes between coil current and voltage are associated with well-defined effects, such as lift-off effect (the up and down movement of the coil) and the edge effect (coil approaching an edge of the test piece). These can be distinguished from vector movements in other directions that are caused by cracks.

FIG. 3 EDDY-CURRENT TEST INSTRUMENT WITH VECTOR POINT DISPLAY

For weld testing, the coils are housed in pencil-like probes, which can be scanned along the weld cap. Coil arrangements can be varied to improve performance. Simple absolute coils, for example, are generally too noisy for testing welds. Alternative differential coil arrangements have been developed, which almost remove the lift-off noise completely as the probe scans the rough surface of the weld cap.

A measurement of crack depth is achieved by comparing the crack signal with the signal from a slot of known depth in a calibration block. This can be regarded only as a very approximate measure. It does not consider the crack width and inclination to the surface.

On the vector point display, the phase separation between lift-off and crack signals depends on the frequency of the coil current, as well as the coil design. The test frequency also determines the depth of penetration of the eddy-current field and, therefore, the sensitivity to subsurface flaws. At test frequencies below 1 kHz, the field can penetrate aluminum to a depth of several millimeters. However, for ferromagnetic materials, the overriding factor determining depth of penetration is the magnetic permeability, which restricts the eddy-current field to the surface unless it is removed by saturating the material with magnetism.

Radiographic testing, in the past, has formed the basis of weld inspection for internal flaws. However, it is an expensive method, and increasing restrictions on the use of ionizing radiation has led to a shift toward alternative ultrasonic testing techniques.

The radiographic technique uses radiation, either as x-rays or gamma rays, to penetrate the weld to create a latent image on radiographic film. The test piece absorbs radiation, but when flaws are present, less is absorbed than the amount

absorbed by the parent material, which produces a localized darkening of the film. If the radiation source is sufficiently far from the object, then the image of the flaw will be sharp. Cavities with a through thickness of the order of only 1% of wall thickness can be discerned.

Most radiography is carried out with x-rays from tubes that operate in a voltage range between 120 and 400 kV. Higher voltages can be achieved using special equipment. As the thickness of the test object increases, the amount of kilovolts also must increase to keep the exposure time down to 4 to 6 min, typically, to avoid shortening the tube service life. However, high voltages reduce the image quality.

Gamma rays are produced by the radioactive decay of isotopes and do not need an electric power supply. Therefore, they are used extensively in site work. Iridium 192 is the usual isotope choice. However, for thick sections (72 in.), Cesium 137 and Cobalt 60 provide higher energy, whereas for thin sections, Ytterbium 169 is suitable. Generally, the quality of gamma radiographs is not as good as that of x-radiographs.

The test results are viewed in a radiograph. The radiographic films are chosen to achieve optimum definition and contrast within practicable exposure times. Faster films are needed where sections are thick, but at the sacrifice of image definition. Speed can be increased by replacing lead-intensifying screens that are in contact with the film with fluorescent ones, but this will result in a loss of definition.

The radiographs are viewed as negatives. The highest contrast is attained at image densities of the order of 3.0 on a log scale and, therefore, the radiographs can only be viewed in high-intensity transmitted light. If the image can be viewed with the film held up in front of normal light bulbs, then the density is much too low.

As an alternative to film radiography, where it can take 20 min to develop a radiograph that can be viewed, radioscopy offers images in real time. The images are created on x-ray-sensitive screens that can be intensified and scanned with a camera for visual display. However, screen resolution and contrast are not as high as with film radiography.

Obviously, taking a conventional radiograph necessitates access to both sides of the object. Thus, there is a variety of techniques for inspecting pipe welds. For pipe diameters that exceed 750 mm (30 in.) and allow access to the center, panoramic techniques are the most efficient (Fig. 4). For smaller pipes that do not allow internal access, both film and source must be on the outside. Exposure times are increased because the radiation must penetrate two walls. Inspection rates are reduced further, because the pipe has to be covered in multiple exposures.

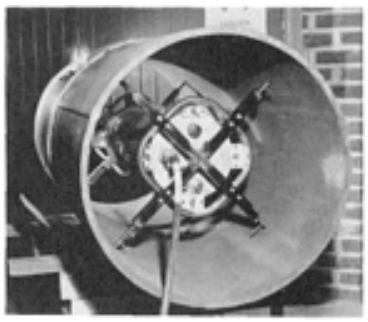

FIG. 4 RADIOGRAPHIC TESTING OF A PIPE WITH A PANORAMIC TECHNIQUE

If the pipe diameter is less than 75 mm (3 in.), then the number of exposures can be halved by putting the source at a sufficient distance away from the pipe to provide images of both the near and the far sides of the weld. The so-called double-wall, double-image technique is often used on welds in steam-generator pipes and condenser tubes.

Radiography can be used on welds in more complex geometries, such as nodes and T-joints, but only for detecting large volumetric flaws. Film cassettes that are double loaded with one fast and one slow film are used to accommodate the large variation in penetrated thickness across the weld.

The sensitivity of the radiograph is assessed using image quality indicators (IQIs), which can either be fine wires placed across the weld or plaques with small drilled holes placed adjacent to the weld. The dimension of the smallest visible hole

or wire in the radiograph is a measure of its sensitivity. These are described in greater detail in the section "Sensitivity" in this article.

Ultrasonic testing receives more attention in the literature than any other NDE method, because of its use in critical applications, such as in the nuclear industry, and because it requires the highest level of skill. Like sonar, the method relies on propagating pulses of sound through a medium and then picking up reflected echoes. However, because the sound is of an ultrasonic frequency, the pulses are propagated along a narrow beam in a fixed direction, typically at refraction angles of 0, 45, 60, or 70° from the probe placed on the surface. To achieve coverage, the beam must therefore be scanned in a tight raster fashion over the test surface.

The surface of the flaw will have an important effect on the echo. Planar specular reflectors will only reflect the sound back to the probe if they lie in a plane perpendicular to the beam. Therefore, the detection of incomplete fusion in the sidewall of groove welds will require the judicious selection of probe beam angles. On the other hand, the echo amplitude is independent of beam direction for spherical reflectors, such as pores.

In conventional ultrasonic testing, the information collected by manually scanning the probe up to the weld and, where the cap has been removed, across the weld, is displayed on a cathoderay oscilloscope in an A-scan display (Fig. 5). This provides information about the amplitude of the echo and the distance of the reflector from the probe. Interpretation of the A-scan requires a high level of skill. It does not provide a permanent record of the test, which is, perhaps, the most important disadvantage of ultrasonic testing. On the other hand, the A-scan does provide information about the nature, size, and location of the flaw, which is further described in the section "NDE Performance" in this article.

FIG. 5 ULTRASONIC EXAMINATION OF A NOZZLE WELD

The A-scan is viewed with the ultrasonic flaw-detector instrument, which has controls to adjust range, delay, and gain. Recently, instruments with digitally created A-scans have started to replace those based on analog. They are capable of making print-outs of the screen, but with some loss in resolution.

In addition to the beam angle mentioned above, probes can be selected according to ultrasound frequency, transducer diameter, and wave mode (shear or compression). Lower frequencies, such as 1 to 2.5 MHz, are used on thick sections.

An important aspect of ultrasonic testing is calibration. The time base of the A-scan must be calibrated for distance in millimeters or inches, and the amplitude of signals must be calibrated in dB, relative to some reference reflector. This is achieved using standard calibration blocks that are made from the same material as the test piece and contain reflectors at known distances and of known dimensions. To calibrate the amplitude of the A-scan, side-drilled holes are typically used in a range of distances. By observing the fall-off in signal amplitude with distance, the important distance-amplitude correction (DAC) can be applied to the A-scan.

Besides the flaw detector, probes, and calibration blocks, thick liquid couplants are needed to transmit the ultrasound from the probe into the test piece. The test surface has an important bearing on coupling efficiency. It should be smooth and free from loose debris. Although ultrasonic tests can be carried out on painted surfaces, the instrument gain should be increased to account for transfer losses.

One of the most common problems with ultrasonic testing is insufficient access for probe scanning. The width of scanning surfaces should be considered carefully at the weld design stage.

Other NDE methods also exist. Acoustic emission (AE) and leak testing are worth mentioning here because of their use in weld testing. Acoustic emissions are stress waves generated from crack growth and plastic deformation. Therefore, the weld has to be loaded. The emissions range in frequency from 20 to 1200 kHz and are picked up with piezoelectric transducers fixed to the structure in arrays that are from 1 to 6 m (3.3 to 19.7 ft) apart. The emissions generally occur in bursts and are of very low amplitude. The instruments are able to amplify the signals and filter out the high levels of associated noise, producing a record of emissions over time. The emissions are difficult to define, because of their wide amplitude and frequency range. Moreover, the response of the transducers has an overriding effect on the signals. In most conventional systems, the analysis of emissions is simplified to include the number of counts (emissions exceeding a threshold level), their amplitude, and the rise time of pulses.

Acoustic emission testing has three important applications in the welding field: the in-process monitoring of resistance welds, the detection of leaking welds in storage tanks, and the proof testing of welded pressure vessels.

In the first of these applications, the AE is produced by the thermal stresses created as the weld cools and solidifies. Each weld process has a particular AE signature, which can be monitored to indicate suboptimal performance.

Leaks that produce turbulent flow in the escaping fluid also produce stress waves. Therefore, AE provides a noninvasive method of detecting leaks in storage tanks. By taking triangulation measurements from points around the tank, the source can be located.

Perhaps the most effective use of AE is in the proof testing of pressure vessels. The AE process was originally developed for use with pressure tests of vessels in glass fiber reinforced plastic. In effect, it sensitizes the proof test, so that subcritical defects, which do not lead to failure in the test, but which may lead to subsequent failure, are revealed.

Most AE problems are associated with noise. Site testing requires quiet environmental conditions, without rain or wind. In addition, great care has to be taken when loading structures to avoid flaw propagation to critical levels. The past loading history of the structure affects its AE signature. For this reason, effective AE tests of pressure vessels can only take place with the initial pressure test. After the first loading, some information about flaws will be lost.

As already mentioned, leak testing can be carried out using AE methods. However, there are simpler methods that can be used in the field for inspecting welds. For example, penetrant testing can be adapted by applying the liquid to one surface and observing the development of flaws on the other.

The most common method of leak testing is the bubble test, in which a bubble-forming solution is sprayed onto the surface. To create the pressure difference across the weld, which is necessary to form the bubbles, the test area is either encased in a transparent vacuum box or a positive pressure is applied to the opposite side of the component.

For very small leaks, it is necessary to use tracer gases with specialized detection equipment and probes to locate the position of the leak. Gases of small molecular size, such as helium, are used for this purpose.

Inspection of Welded Joints

G.R. Edwards, The Welding Institute

Test Procedures

A very important aspect of NDE is the development of test procedures. These are control documents, which state how the test is to be performed and how the results are to be evaluated and recorded. Written by an NDE specialist, the procedure attempts to provide the test operator with information to ensure that the defects being sought are detected in a repeatable manner.

NDE procedures can be classified as either routine or special. The routine procedure is written in accordance with a specification or code. The special procedure is written to meet a particular requirement, which is not covered by a specification. Special procedures are more prevalent during in-service monitoring and may require validation trials on specimens that possess simulated defects.

A good procedure will be clear and concise, and it will provide adequate coverage within the constraints set by cost and time for inspection. The procedure will start with a title page that includes a reference number as part of a quality-assurance system. At times, the procedures may be amended, and the system must be able to cope with this. In addition to the name of the person who wrote the procedure, someone in authority, who must also print his or her name and sign and date the document, must approve the procedure. The next section of the procedure will list the precise details of the equipment to be used, listing alternatives, if possible.

The level of competence required of the test operators must also be defined. In situations where nationally accepted schemes, such as the American Society of Nondestructive Testing (ASNT), are mentioned, finding an equivalent scheme can be a problem. Attempts are being made to formalize agreements among national certification schemes.

The section of the procedure that is known as the technique comprises equipment setup and test operation. This is at the core of the procedure document and requires the most careful preparation. It is not uncommon to list several techniques within one procedure document, where each refers to a different type of weld in a structure, but is covered by the same equipment, personnel, calibration, evaluation, and recording requirements as the other techniques.

The methods used to evaluate the test results must be described carefully. They should consider the way in which the results are presented, that is, images or signals. It may be appropriate to evaluate the porosity visible in a radiographic image in terms of density as a percentage of area. However, with ultrasonic testing, the signals on the A-scan cannot be interpreted in this way.

The final section of the document deals with the recording of results. Written evidence is always required to document how the test was carried out, so that it can be repeated. Report forms must be designed carefully to include serial numbers of equipment, for example. Radiography is the only routine method that provides a permanent record of the test results. Although photographs can be taken of flaws found by penetrant and magnetic-particle testing, the results of eddy-current and ultrasonic tests are more difficult to record. The information about signal amplitude and position can be logged in a table and plotted onto diagrams of the weld, but it is the skill of the test operator that ultimately determines the quality of the report.

Inspection of Welded Joints

Test-Operator Training

The training and certification of NDE operators receives a great deal of attention. The approach established by the American Society of Nondestructive Testing (ASNT) has been adopted by many national schemes, but with important differences. Broadly speaking, there are three levels of competence for each method. At Level I, the test operators have progressed from trainees to a stage at which they can conduct tests under supervision. At Level II, they are able to conduct tests independently, write test procedures, and generally provide the base manpower for NDE operations. At Level III are supervisors and managers responsible for the NDE function. They have a more general knowledge of NDE and quality control and are in a position to approve NDE procedure documents, for example. At each level, the technician will have passed a written examination and demonstrated practical proficiency in conducting tests.

The situation is complicated by the need to qualify test operators not only for the method, but for the application. Personnel involved in the inspection of groove welds in plate, for example, may not have received training for the inspection of groove welds in T-joints. This led the ASNT to establish schemes that were company specific. Each company establishes its own training and certification scheme according to the document SNT-TC-1A, "Recommended Practice for Qualification and Certification in NDT." This is subject to external audit.

European certification schemes such as PCN (United Kingdom), COFREND (France), and NORDTEST (Scandinavia) also have three levels of competence, but the approvals are conducted at independent test centers.

G.R. Edwards, The Welding Institute

NDE Performance

NDE detects and evaluates flaws indirectly by the way in which the flaw interrupts a magnetic field or reflects ultrasound, for example. Measuring the performance of NDE in carrying out this task is difficult, because of ambiguities in the interpretation of test results. Nondestructive evaluation is not an exact science.

The detection capability of the test is expressed in terms of its sensitivity, but the test may also provide information about the nature, size, and location of the flaw. These are all important attributes in determining whether or not a flaw is significant.

Nature of the Flaw. NDE methods can be segregated in terms of those that provide images of the flaw (visual inspection and penetrant, magnetic particle, and radiographic testing) and those that provide signals from the flaw (ultrasonic and eddy-current testing).

The nature of the flaw can be more easily assessed from images than from signals. However, interpreting images is not always straight-forward. Penetrant tests, for example, indicate flaws that are a result of a blotting action. This can have the effect of forming a line of rounded flaws from a linear flaw. Cleaning away the developer and closely examining the purported flaw with a magnifying glass is usually sufficient to assess ambiguity.

With MPT, the sharp change in contour that occurs at the weld toe produces a flux-leakage field that attracts magnetic particles. This indicates a flaw that can be mistaken for a toe crack. Generally, however, the flaw is weak and can be blown away from the surface. Grinding the weld toe to a favorable profile can improve accuracy.

Because radiographic testing provides a two-dimensional image of a three-dimensional object, images from the surface can be confused with those from internal flaws. Visual inspection may be necessary to distinguish an undercut from a slag inclusion, for example.

The identification of flaws from signals is severely limited. With eddy-current testing, an observation of vector displacements on the cathode-ray tube may distinguish surface from subsurface cracks, for example, but only after careful selection of the test frequency.

The signals displayed in the A-scan of an ultrasonic flaw detector provide more information, including distance and amplitude information collected as the probe scans the surface. These so-called echo dynamic patterns make it easier to characterize a flaw using an ultrasonic test than it is with an eddy-current test. Flaw characterization based on ultrasonic tests is currently a matter of much interest.

Flaw Size. After a flaw has been detected and its nature determined, the next step is to measure its dimensions. Measuring the length of a flaw is straightforward. However, the blotting effects of penetrants must be taken into account. Other problems can arise in radiography, where the full extent of a fine linear flaw can be seriously underestimated if its plane moves out of parallel with the radiation beam.

In an eddy-current or ultrasonic test, the length of probe movement between the indication end points is what is being measured. The definition of the end points can be a problem. The most common method employed in ultrasonic tests is the 6 dB drop sizing method, in which the probe is moved off the edge of the flaw to the point where the signal has dropped in amplitude by 6 dB or half its original amplitude. The axis of the sound beam is now half on and half off the flaw and can be taken as delineating the flaw edge. This can be done to an accuracy of ±5 mm (0.2 in.).

The width of a flaw also can be measured in an image, but it is generally too small to be measured by eddy-current or ultrasonic test methods.

After length, the next most important dimension in assessing the significance of a flaw is its height in the through-wall direction. Here, the performance of imaging methods is severely limited. Only qualitative assessments can be made from

the density of a defect indicated by penetrant, magnetic particle, or radiographic testing. On the other hand, eddy-current and ultrasonic tests do provide quantifiable information.

Comparisons with slots of known depth in a reference block serve to calibrate the vector displacements on an eddy-current instrument. Cracks to a depth of 3 mm (0.12 in.) can be measured with an accuracy of 0.5 mm (0.02 in.) in this way.

Ultrasonic tests can provide a measure of the through height of an internal flaw. There are four methods, the simplest of which involves comparing the amplitude of the echo signal from the flaw with the echo signal from a side-drilled or flat-bottomed hole. This can only be applied if the dimension is smaller than the width of the ultrasound beam (typically, 5 to 10 mm, or 0.2 to 0.4 in.). More importantly, when dealing with planar flaws, the orientation must be taken into account. If the plane of the flaw is more than 20° off perpendicular to the axis of the sound beam, then the echo will not be reflected back to the probe and it even may go undetected.

For small planar flaws with a height of more than 3 mm (0.12 in.), the preferred ultrasonic sizing method is the 20 dB drop method. This involves scanning the beam across the flaw and finding the 20 dB drop points. The beam path and probe positions at these points are plotted on a diagram of the weld using a cursor or overlay with the 20 dB beam profile to give the flaw edges. An accuracy of ±3 mm (0.12 in.) is achievable.

For planar flaws with large through-wall dimensions, such as cracks, the maximum-amplitude method involves plotting the facets of a flaw to indicate its orientation and dimension.

The location of the flaw in the through dimension of the weld is important in determining its significance. Flaws that are near a surface are more significant than flaws in the center of a weld. In a radiograph, this can only be inferred. Root flaws may appear in the center of the weld image, but may be confused with flaws that are near the weld cap. Only ultrasonic testing can provide definitive information about the through-wall location of a flaw. Indeed, it is often necessary to supplement radiographic tests with ultrasonic tests for this purpose.

Flaw location is, perhaps, the most reliable function of ultrasonic tests. To locate an echo signal, the time base of the A-scan must be accurately calibrated for distance. Variations in the velocity of ultrasound are not uncommon, but generally an accuracy to within 1 mm (0.04 in.) can be expected. The angle of the ultrasound beam and the probe index point must also be checked regularly with a calibration block. Shoe wear can lead to inaccuracies.

Finally, the position of the probe on the test surface at the point of maximum signal amplitude must be measured from the weld centerline, which should always be marked clearly on the test surface. However, the reliability of flaw location with ultrasonic testing depends on the skill of the operator. Carelessness can lead to errors, for example, in plotting the flaw on the wrong side of the weld.

Sensitivity. When dealing with images, sensitivity is expressed in terms of contrast and definition. When dealing with signals, it is the separation of signals from the background noise or signal/noise ratio.

The contrast and definition of penetrant testing and MPT can be enhanced by using fluorescent materials. Variations in contrast can be recognized more easily than with colored materials, and finer details in the flaw can be observed. However, on rough surfaces, background color can lead to a loss in sensitivity.

The contrast in a radiographic image is improved by decreasing the energy of the radiation and increasing the density of the image. In gamma radiography, the energy is fixed by the type of isotope, whereas in x-radiography, it can be varied with the tube voltage. The radiation from Iridium 192 has an x-ray equivalent in the 500 kV to 1 MeV range and, therefore, image quality is not as good as it is with x-rays in the usual 150 to 400 kV range. Ytterbium 169 has a much lower energy level, producing nearly x-ray image quality, but it suffers from a short half life and low output.

Although radiographic definition is also reduced by using higher-energy radiation, the most important factor that affects definition is the unsharpness, or penumbra, effect. This is caused by having a source, or x-ray focal spot, of finite size, typically 3 to 4 mm (0.12 to 0.16 in.). It is reduced by moving the object away to a distance of 0.5 to 1 m (1.6 to 3.3 ft) from the source, depending on object thickness, or by using special minifocused or microfocused x-ray tubes.

The contrast and definition of a radiograph can be assessed using a penetrameter or an image quality indicator (IQI). The size and type of penetrameter are specified by standards such as ASTM 747, "Method for Controlling Quality of

Radiographic Examination Using Wire Parameter." This instrument is placed near the weld or, in the case of a wire-type IQI, across the weld, on its source side at the time the radiograph is taken. The IQI comprises carefully dimensioned wires or steps with holes. By counting the number of wires or stepped holes that are visible on the radiograph, the sensitivity can be calculated as a percentage of wall thickness, or *T* value. If calculated as a percentage, then a value of 1 to 2% is normally acceptable. A higher percentage indicates a lower sensitivity.

Despite a high level of sensitivity, fine planar flaws can be missed if they are not oriented almost parallel with the radiation beam. Radiography is not effective at detecting incomplete side-wall fusion in metal-inert gas welds with a 30° chamfer angle, for example, unless the radiographic source is aligned with the angle, which requires multiple exposures.

In eddy-current testing, improving the signal/noise ratio is based on selecting appropriate coil configurations, test frequencies, and *y*/*x* potential ratios on the vector point display. A phase separation approaching 90° between the impedance vector caused by noise as the probe moves along the weld surface (lift-off) and the impedance vector from cracks can be achieved. Further reductions in noise can be made using signal filters, but the probe then has to be scanned at a constant speed.

The test frequency also affects the signal-to-noise separation in ultrasonic testing. As the frequency increases, the ultrasound attenuation rises, and the reduced ultrasound wavelength is scattered to produce more noise. Generally, the optimal frequencies for ultrasonic testing of welds in ferritic steels range from 4 to 5 MHz. The frequencies are higher for welds that are less than 10 mm (0.4 in.) thick, and lower for welds that are more than 50 mm (2 in.) thick. It should be noted, however, that some test procedures call for lower frequencies, because their flaw evaluation is based on echo amplitude only. At lower frequencies, beam spread is greater and, therefore, signal amplitude is less dependent on flaw orientation.

Inspection of Welded Joints

G.R. Edwards, The Welding Institute

Evaluation of Test Results

The evaluation of test results and the setting of accept/reject criteria for weld flaws are the subjects of much current debate. This is because of the empirical way in which the criteria were derived in the past. As new developments in defect assessment, such as fracture mechanics, set the trend toward more sophisticated methods of evaluating NDE results, the discrepancies in current practice become more apparent. This is particularly true of ultrasonic testing.

In general, the accept/reject criteria used in national standards draw a distinction between rounded and elongated flaws, as well as volumetric and planar ones. With NDE methods that produce an image of the flaw, this is a simple task. An elongated flaw is usually defined as one in which the length is more than three times the width.

Flaws rarely occur in isolation, and their distribution and proximity to each other are important characteristics. Porosity may be isolated, clustered, or aligned. If it is aligned, then it is more significant than if it were random, because there is likely to be incomplete fusion.

The NDE methods that produce signals from the flaw are the most difficult to evaluate. In ultrasonic tests, the simplest method of evaluation is to use echo amplitude and length criteria only. This can lead to planar flaws being undersized, if they are poorly oriented in the ultrasound beam. It is therefore important, in an ultrasonic test, to first characterize the flaw and, in particular, to distinguish planar flaws from volumetric ones. The identification of planar flaws such as cracks and incomplete fusion primarily depends on the skill of the test operator, who considers the signal location, shape, response to probe movement, and relative amplitude from different sides of the weld and with different probe beam angles.

Volumetric flaws, on the other hand, can be evaluated in terms of signal amplitude and length. In some specifications, for example, if the signal amplitude exceeds the DAC set-off 3 mm (0.12 in.) diameter holes, and the dB-drop length of the flaw exceeds the wall thickness of the weld, then the flaw is rejected as a defect.

The accept/reject criteria are usually set by a fabrication or manufacturing standard. In the past, these standards have been application specific. For example, ASME Section VIII has governed the manufacture of unfired pressure vessels. In the new European standards, however, the move is toward blanket quality levels, where each quality level defines the NDE procedures and defect accept/reject criteria and is selected according to the application.

G.R. Edwards, The Welding Institute

Selection of the NDE Method

The selection of the appropriate NDE method is influenced by a number of factors related to the test conditions. Those described here are not exclusive. There may be other constraints on selection, such as availability of trained personnel or costs. The methods shown in Tables 1, 2, and 3 are rated according to their applicability. This rating is not easily quantifiable, because it must account for the ease of test operation, its efficacy in finding flaws common to the application, and whether or not it is the only applicable NDE method.

Source: ISO 6520

There are various techniques for applying each NDE method, some of which are more appropriate than others and might therefore alter the rating. It is often the case that two methods are complementary to each other. For example, radiographic testing will detect volumetric flaws and ultrasonic testing will detect planar ones. The method of selection discussed below is based on the material, weld geometry, and type of flaw.

Material. For NDE purposes, the material being tested can be categorized as shown in Table 1. First, a distinction is drawn between metal and nonmetal.

NDE methods are being increasingly applied to welds in thermoplastics, which can take the form of bulk plastics or composites with reinforcing fibers. Electrical and magnetic testing methods cannot be applied to bulk plastics, of course. Eddy-current techniques have been used on carbon fiber reinforced plastics, because of the conductive properties of the fibers. Penetrants also can be used, but care must be taken to ensure that solvents do not attack the plastic.

Radiographic techniques can be applied using low-kilovolt techniques, which are necessary because of the low absorption coefficient for x-rays of plastics. Typical values are between 10 and 25 kV. This can introduce problems such as cassette pick-up and air absorption.

Plastics are highly attenuative of ultrasound, and they will only propagate compressional waves to any distance. However, ultrasonic techniques have been used with some success for the inspection of hot-plate groove fusion welds in polyethylene pipe.

Metals can be subcategorized as being either magnetic or nonmagnetic, dense or light, and isotropic or anisotropic. Obviously, MPT cannot be used on nonferrous metals, but there are also many high-alloy steels that are too weakly magnetic to be magnetized. Other ferrous steels that are often used in the aerospace industry are ferromagnetic, but require stronger magnetizing fields to create adequate flux leakage from flaws. These also tend to have high magnetic retentivity and are difficult to demagnetize after the inspection.

The density and anisotropy in metals have the greatest effect on test sensitivity in radiographic and ultrasonic tests.

In general, radiation is absorbed more by dense materials, such as austenitic steel, than by less-dense materials, such as aluminum. Because higher-energy radiation is needed to penetrate the same thickness of material, it has the effect of decreasing image contrast and, therefore, test sensitivity. Anisotropy that is due to a large grain structure also results in radiation scattering and, sometimes, the appearance of diffraction mottling in the radiographs.

The velocity and attenuation of ultrasound is affected by changes in material composition or structure. This can be particularly apparent in aluminum welds and duplex stainless steel. In addition, large grain size can distort ultrasonic signals.

Eddy-current tests are particularly susceptible to interference from quite minor changes in the material. For example, the change in magnetic permeability at the heat-affected zone of a weld in low-carbon steel can create noise that obscures signals from toe cracks.

Weld geometry also has an important effect on test method selection. The factors that need to be considered include joint type and thickness, whether or not there is access to both sides, and, in the case of groove welds, the inclination of the weld groove faces (Table 2).

Visual inspection is applicable to all weld geometries, but is particularly applicable to fillet welds and welds in thin sections. Penetrant testing and MPT serve to enhance visual inspection.

Eddy-current testing is the least applicable of the test methods for weld inspection, but it is being used increasingly in underwater node inspection as an alternative to MPT. For thin-section welds in nonmagnetic materials, it has sufficient penetrating power to offer an alternative to ultrasonic testing.

Radiographic testing is of limited use in testing welds that have a complex geometry, as well as thick-section welds. Access to both sides of the weld is essential.

Ultrasonic testing does not suffer from as many geometric restrictions as radiographic testing, but the method is difficult to use on small fillet welds and thin sections, where A-scan interpretation is complicated by the numerous geometric echo signals.

Type of Flaw. Visual inspection is not applicable to internal flaws, but it is the only method that can be used with most geometric flaws (Table 3). Microflaws will only be visible with the aid of magnification.

Penetrant testing and MPT enhance visual inspection, but are particularly sensitive to surface-breaking cracks and incomplete fusion. Undercut and other shallow and open flaws usually give weak images, whereas overlap can be difficult to distinguish from the sharp change in contour at the weld toe. Eddy-current tests are very sensitive to planar flaws at the surface, but not to volumetric flaws.

There are very few flaws that cannot be detected by radiographic testing. Planar flaws must be oriented favorably in the radiation beam, and it can be difficult to distinguish surface from subsurface flaws, because of the two-dimensional nature of the image. The angular "cusp" shapes of an undercut can, for example, be indistinguishable from inclusions. In addition to magnification by way of microfocus radiographic techniques, microflaws need very high levels of contrast and definition in the radiograph, in order to be detected.

Ultrasonic testing is often regarded as being complementary to radiographic testing. Planar flaws need to be oriented in a perpendicular plane to the ultrasound beam, but because a range of beam angles can be utilized, ultrasonic testing is generally regarded as more sensitive to cracks and incomplete fusion than radiography. However, the characterization of different types of flaw, both planar and volumetric, is extremely difficult. Porosity produces low-amplitude echo signals that barely exceed the recording threshold levels in most procedures.

Inspection of Welded Joints

G.R. Edwards, The Welding Institute

Advanced Methods

As with all technologies, advances in NDE are being dominated by the introduction of computers. The emphasis has been on the acquisition and recording of data to aid the test operator and interpreter. In the future, it is likely that computers may complete the analysis and evaluation of test results, although the problems in interpreting the results of even the simplest NDE procedure should not be underestimated.

In radiographic testing, the replacement of films by real-time imaging systems has been aided by the introduction of image processing software that is able to improve the image quality to almost film-like levels.

In eddy-current testing, the characterization of different types of flaws by their effect on the impedance at mixed coil frequencies is a complex problem that is being tackled with neural network software.

The greatest advances have been made in ultrasonic testing. Digitally controlled flaw detectors make calibration more consistent and can provide print-outs of the A-scan display. With probe scanners, ultrasonic images can be created to provide a hard copy of test results. Digitized signals can be processed at much higher gain settings to reveal diffracted echoes in accurate flaw sizing.

Weld Procedure Qualification

Harvey R. Castner, Edison Welding Institute

Introduction

WELDING CODES AND STANDARDS usually require the qualification of welding procedures prior to being used in production to ensure that welds will meet the minimum quality and mechanical property requirements for the application. This article provides an overview of welding procedure qualification guidelines and test methods. The reader is referred to codes, standards, and specifications that govern the design and fabrication of welded structures for the procedure qualification details that are appropriate for the given application.

Some of the most widely recognized codes, standards, and specifications that cover welding procedure qualification include:

- SECTION IX OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS (ASME) BOILER AND PRESSURE VESSEL CODE
- AMERICAN NATIONAL STANDARDS INSTITUTE/AMERICAN WELDING SOCIETY (ANSI/AWS) B2.1, STANDARD FOR WELDING PROCEDURE AND PERFORMANCE QUALIFICATION
- ANSI/AWS D1.1, STRUCTURAL WELDING CODE FOR STEEL
- ANSI/AWS D1.2, STRUCTURAL WELDING CODE FOR ALUMINUM
- ANSI/AWS D1.3, STRUCTURAL WELDING CODE FOR SHEET STEEL
- ANSI/AWS D1.5, BRIDGE WELDING CODE
- ANSI/AWS D1.4, STRUCTURAL WELDING CODE FOR REINFORCING STEEL
- MILITARY STANDARD 248, WELDING AND BRAZING PROCEDURE AND PERFORMANCE QUALIFICATION
- AMERICAN PETROLEUM INSTITUTE (API) 1104, STANDARD FOR WELDING PIPELINES AND RELATED FACILITIES
- INDUSTRIAL SPECIFICATIONS, SUCH AS ANSI/AWS D14.1, SPECIFICATION FOR WELDING INDUSTRIAL AND MILL CRANES AND OTHER MATERIAL HANDLING EQUIPMENT; ANSI/AWS D14.3, SPECIFICATION FOR WELDING EARTHMOVING AND CONSTRUCTION EQUIPMENT; ANSI/AWS D14.5, SPECIFICATION FOR WELDING OF PRESSES AND PRESS COMPONENTS; ANSI/AWS D14.6, SPECIFICATION FOR WELDING ROTATING ELEMENTS OF EQUIPMENT; AND ANSI/AWS D15.1, RAILROAD WELDING SPECIFICATION

Additional information about standards and specifications for particular welding applications is available in the Section "Material Requirements for Service Conditions" in this Volume.

Procedure qualification is an important part of any total weld quality management program, because it confirms that the welding procedure will meet the mechanical design requirements. Therefore, some form of welding procedure

qualification should be performed for all critical welding operations, regardless of whether the application is covered by a code or standard.

Purpose of Qualification and Responsibility for the Task

Fabricators, manufacturers, and contractors are responsible for the selection, definition, and control of the welding procedures they use. This control normally includes the preparation of detailed written instructions known as welding procedure specifications (WPS), and may include the qualification of both welding procedures and personnel. The purpose of qualifying a welding procedure is to demonstrate that the resulting welds will meet prescribed quality standards and have the requisite mechanical properties for the intended application. A sample WPS form is shown in the article "Welding of Carbon Steels" in this Volume.

Some codes allow the use of prequalified welding procedures, if they meet all of the requirements contained in the code. The use of prequalified procedures does not lessen the responsibility of the fabricator or contractor to ensure that the welding procedures are satisfactory for the application.

The qualification of welders, welding operators, and tack welders is another important part of weld quality control. The qualification of personnel demonstrates the ability to produce satisfactory welds when the prescribed welding procedure is used.

Procedure qualification involves examining the welds according to the specified welding procedure, testing specimens taken from these welds, and documenting the results on a procedure qualification record. The fabricator, manufacturer, or contractor must supervise and control the preparation of the qualification test welds. Many codes permit another organization to assist in the removal and assessment of test specimens. However, the contractor or fabricator is ultimately responsible for the procedure qualification tests, the results of these tests, and the control and application of the procedures in production. A single welding procedure qualification test may support a number of WPSs, or a single WPS may be supported by several procedure qualifications.

Weld Procedure Qualification

Harvey R. Castner, Edison Welding Institute

Types of Tests

Welding procedure qualification tests can be categorized as either standard or special tests. Standard tests include visual, metallurgical, and nondestructive examinations; chemical analysis; crack susceptibility tests; and tests to determine mechanical properties. The mechanical property tests can include tension, bend, and hardness tests, as well as tests to determine notch toughness.

Although the use of standard tests to qualify a WPS demonstrates the ability of the procedure to produce sound welds that meet the minimum required properties, these tests may not ensure that the welding procedure is suitable for all applications. Standard test plates are relatively small and are normally welded under laboratory, rather than production, conditions.

The fabricator, designer/owner, or operator of the welded structure or component may determine that additional special qualification tests are required in order to establish the acceptability of a welding procedure for the application and to ensure that the welded structure will meet the mechanical requirements. Special tests may involve welding mock-up or prototype structures and then subjecting these structures to static or dynamic tests, corrosion tests, high-temperature tests, macrosectioning, or other tests.

Standard Tests

Standard procedure qualification test weldments represent the type of weld and weld joint that are to be used in production. Groove welds in butt joints in plate and pipe are shown in Fig. 1 and 2, respectively. Two examples of fillet welds in T-joints are shown in Fig. 3. Fillet welds can also be deposited on lap, corner, or edge joints. A partial penetration weld in a T-joint is shown in Fig. 4, whereas a plug weld test specimen is shown in Fig. 5. The latter could be a slot weld as well, and a similar weldment could be used for spot welds.

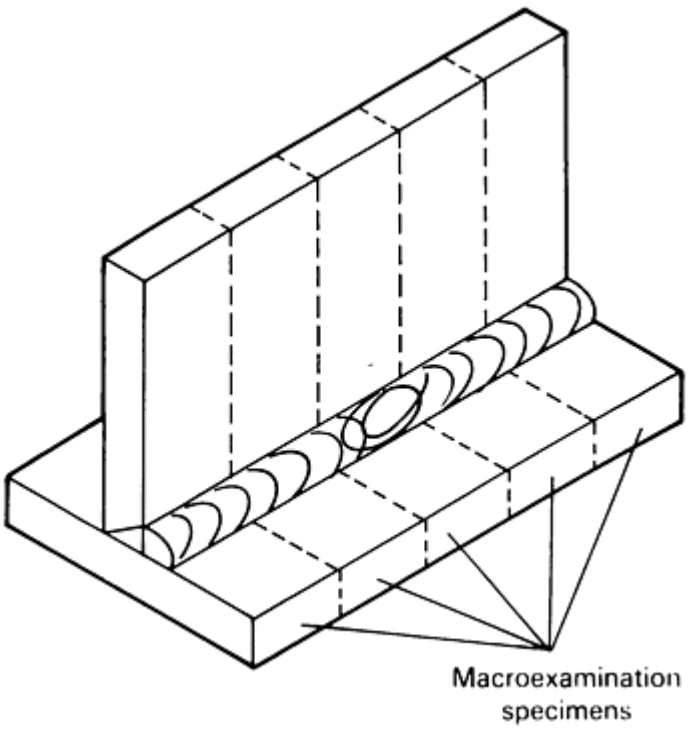

FIG. 4 PARTIAL-PENETRATION WELD SPECIMEN

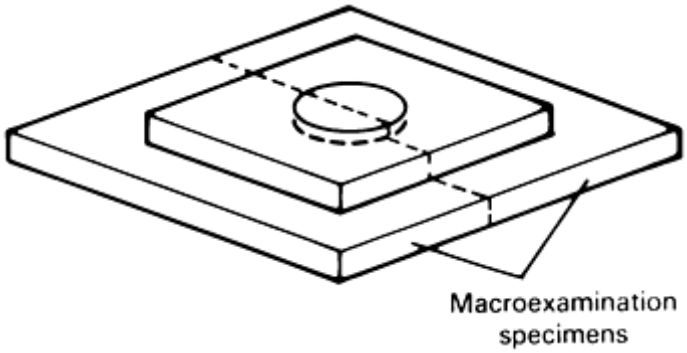

FIG. 5 PLUG WELDS QUALIFIED BY GROOVE WELD TEST

Resistance spot and seam welds are typically made on lap joints. Other weldments are appropriate for friction, laser-beam, electron-beam, and stud welding, or for surfacing weld deposits. The thickness of test weldments should be selected after considering the thickness of materials used in actual fabrications and the thickness limitations of the code or standard. The length and width of the test weldment should be sufficient to permit removal of the necessary test specimens.

The test weldment is prepared and welded using the methods that are detailed in the WPS. Standard test requirements vary, depending on the code or standard being used. However, it is common to examine the completed weldment by visual and nondestructive examination methods. It is also common to section the weldment and remove specimens for mechanical property tests or other examinations.

Tests for full-penetration groove welds include tension, bend, and toughness tests. It is also common to subject weldments to chemical analysis, hardness tests, and metallurgical examinations. Figures 1 and 2 indicate the location of tension and bend specimens in plate and pipe test weldments, respectively. Figure 6 shows the configuration of tension and bend specimens. The details of specimen size, orientation, removal, testing, and acceptance are provided in the welding codes and standards listed above, in ASTM test standards, or in ANSI/AWS B4.0.

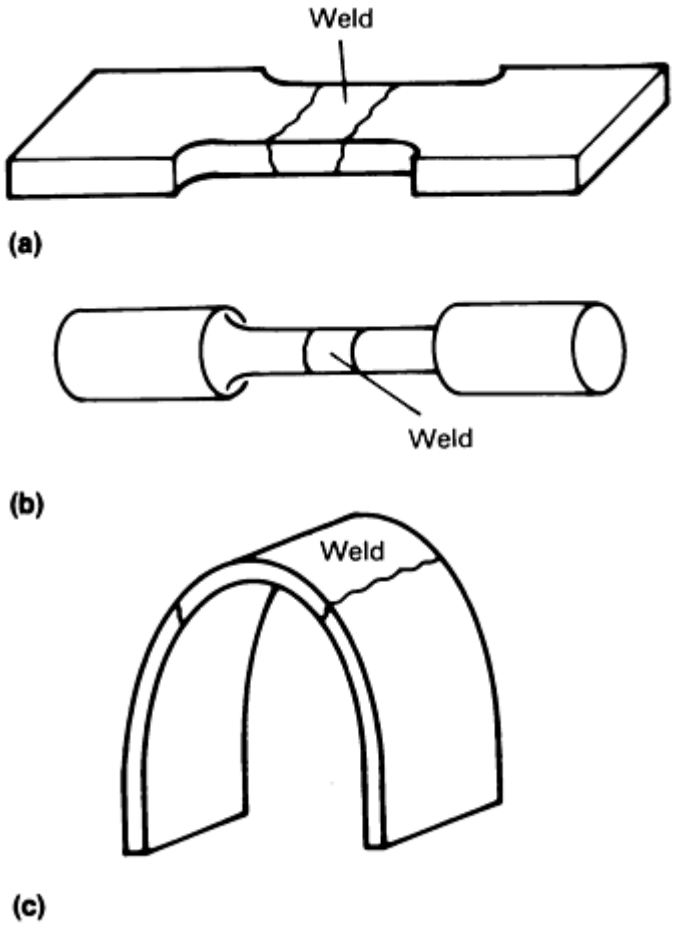

FIG. 6 TENSION AND BEND SPECIMENS FOR TESTING OF FULL-PENETRATION GROOVE WELDS. (A) REDUCED-SECTION TENSION SPECIMEN. (B) ROUND TENSION SPECIMEN. (C) BEND SPECIMEN

Transverse tension tests are performed on full-penetration groove welds to determine the tensile strength of the weld region. The specimens can be one of several configurations: full-section specimens, reduced-section specimens, or round specimens (see Fig. 6). Multiple tension specimens can be used for plates that are more than 25 mm (1 in.), as shown in Fig. 7, in order to test the entire thickness. The acceptance of the tension test results normally is based on a tensile strength that is either equal to or greater than the minimum specified tensile strength of the base metal being welded. If the weld metal has a lower specified strength than the base metal, then the tension test must exceed the specified minimum tensile strength of the weld metal. Some codes permit the strength of the tension specimen to be 5% below the specified minimum tensile strength of the base metal if the specimen breaks outside of the weld or fusion line. If all-weld-metal tension tests are required, then round specimens are typically removed from the center of the weld and oriented parallel to the weld axis.

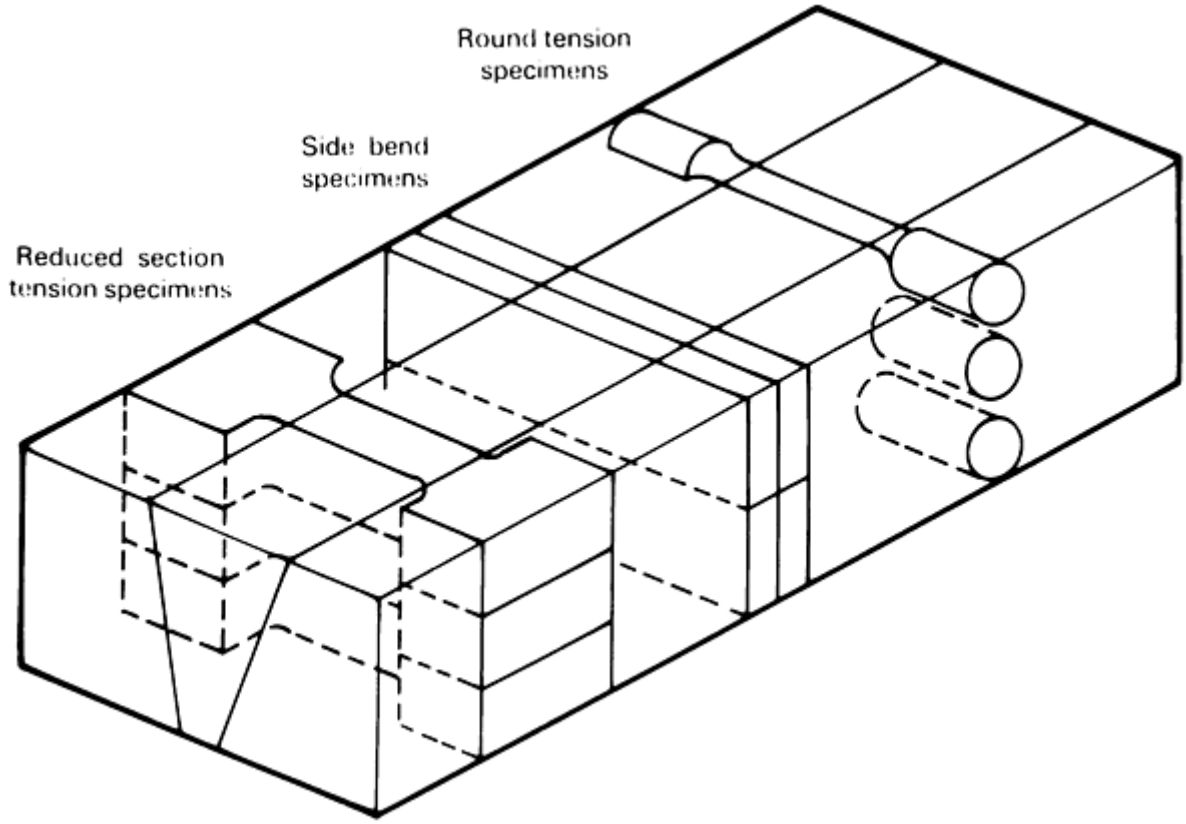

FIG. 7 REMOVAL OF MULTIPLE BEND AND TENSION SPECIMENS FROM THICK TEST PLATES

Bend tests are performed to verify the soundness and ductility of the weld and the heat-affected zone (HAZ), as shown in Fig. 6. Figures 1, 2 and 7 show bend specimens that are typically oriented transverse to the weld axis, with the center of the weld in the center of the specimen. Under some circumstances, longitudinal bends are removed with their length parallel to the axis of the weld. Longitudinal bend specimens are used for welds of dissimilar metal, where there is a large difference in bend properties between the two base metals or between the weld metal and the base metal.

The face of the weld (face-bend), the root of the weld (root-bend), or the cross section of the weld (side-bend) can be placed on the convex face of the bent specimen. Face-bend and root-bend specimens are typically specified for base-metal thicknesses of less than 9.5 mm (0.375 in.). Side-bend specimens are required for thicker test plates in order to test the entire weld cross section. Plates that are more than 38 mm (1.5 in.) thick may require multiple side-bend specimens to ensure that the entire weld thickness is tested (see Fig. 7).

Guided bend specimens are forced into a specified curvature (Fig. 6) by either applying a load to a plunger or forming the specimen around a fixed mandrel. The width and thickness of the specimen and the radius of the plunger or mandrel are designed to produce a minimum specified elongation (approximately 20%) in the outer surface of the specimen. It is important to follow the recommendations for specimen dimensions, because width and thickness influence test performance. The most common bend specimen is 9.5 mm (0.375 in.) thick and is formed around a 19.1 mm (0.75 in.) radius. However, codes specify larger radii for low-ductility base metals and for weld metals that are not capable of being bent to a small radius. Acceptable bend specimens must not fracture or have cracks or other open defects that exceed a specified maximum size (usually, 3.2 mm, or 0.125 in.) on their convex surface.

Notch Toughness Tests. Charpy V-notch impact tests are used to measure the toughness of weld metals and HAZs. Charpy V-notch specimens are usually removed from the weld metal and HAZ, with the notch oriented normal to the surface. One face of the V-notch specimen is located within 1.6 mm ($\frac{1}{16}$ in.) of the surface of the material. Thick materials require additional specimens at subsurface locations. The number of specimens, their location and orientation, and the test temperature are determined by the design requirements or material specifications. Acceptance criteria may be

a minimum specified absorbed energy in joules (ft · lbf), a minimum percentage of shear fracture appearance, or a minimum specified lateral expansion opposite the notch.

Drop-weight notch toughness tests are sometimes used to determine the minimum nil-ductility transition temperature for ferritic steel weld metal and HAZs. The assessment of toughness, in terms of the stress-intensity factor, *K*, the J integral, or crack tip opening displacement, may be required for some welding procedures. Codes and specifications describe how specimens can be removed from the weld metal and HAZs to permit the measurement of each of these fracture-toughness properties.

Tests for Fillet Welds, Partial-Penetration Groove Welds, and Spot and Plug Welds. The procedure qualification of fillet welds typically involves T-joint test weldments, like those shown in Fig. 3. Some codes and specifications permit lap joints, comer joints, or other joint configurations that represent the actual joint used in production.

Procedures for partial-penetration groove welds can be qualified by making test weldments that represent the joint used for the application. Figure 4 shows a T-joint test weldment for a partial-penetration groove weld. Figure 5 shows the configuration of the test weldment for the qualification of plug or slot welds.

Completed fillet, partial-penetration, and plug or slot weldments are usually examined visually and by nondestructive methods to ensure that they meet the acceptance requirements of the weld quality specification. These welds do not normally lend themselves to mechanical property testing, although tension-shear tests and weld-break tests can be conducted on them. The required mechanical properties must be determined from a standard groove weld test. Macrosections are removed to verify root penetration.

Figures 3 and 4 show how macroexamination specimens are removed from fillet or partial-penetration welds. Figure 5 illustrates how plug or slot welds are cut through their center to produce macroetch specimens. The faces of macroetch specimens are ground smooth, etched, and then examined. Acceptable welds must have:

- THE DESIGNATED WELD SIZE AND PROFILE
- FUSION TO THE ROOT OF THE JOINT
- NO CRACKS
- COMPLETE FUSION BETWEEN ADJACENT LAYERS OF WELD METAL, AS WELL AS BETWEEN WELD METAL AND BASE METAL

Shear tests can also be used to measure the strength of fillet, partial-penetration, plug, or slot welds. Usually, an acceptable shear strength is at least 60% of the minimum specified tensile strength of the base metal.

Weld-break or fracture tests may also be required for fillet and partial-penetration welds. These specimens are removed from the weld, as shown in Fig. 3, and loaded so that the root of the weld is in tension until the specimen fractures or bends flat upon itself. Acceptance of a fractured specimen is determined by examining the fractured surface for complete fusion, the required depth of penetration, and porosity and inclusion levels that do not exceed a specified maximum size. The specimen is also acceptable if it bends flat upon itself without fracturing.

Procedure qualification tests for arc and resistance spot welds include tension-shear, torsion, peel, and hardness tests, as well as macroexaminations. Tension, torsion, and peel test specimens are examined to determine the location of failure and the size and soundness of the weld nugget.

Tests For Stud Welds. The qualification of stud welding procedures can involve the macroexamination of cross sections, bend tests, tensile tests, or torsion tests. Sectioning and macroexamination can determine whether or not the welds and HAZs have the proper fusion and are free of cracks. Bend tests for stud welds involve bending the stud through a minimum angle, usually 15°, and then bending it back to the original position. An alternative test is to bend the studs by hammering them flat onto the test plate. The bent studs must be free of visible separation or fracture. Stud welds also are tested by applying torque or tension loads.

Tests For Weld Cladding and Surfacing. The qualification of weld cladding procedures involves chemical analysis of the deposit, macroexamination of cross sections, and bend tests. The qualification for hard-surfacing welding procedures can include hardness tests, in addition to chemical analysis of the deposit and macroexamination of cross sections.

Special Tests

Special tests for welding procedure qualification often utilize prototype structures or mock-up components that are fabricated per the specified welding procedure. These structures or components can then be subjected to loads that simulate the actual conditions encountered in service. Tests can include static or dynamic tensile loads, bending loads, fatigue loads, or impact loading. After load testing, the structure can also be tested destructively; welds can be sectioned and the cross sections examined for proper penetration, bead placement, profile, and so on. An example of this type of testing, for roll-over protection structures, is described in ANSI/AWS D14.3.

Weld Procedure Qualification

Harvey R. Castner, Edison Welding Institute

Limitations on Procedure Qualification

A new welding procedure must be qualified if it differs significantly from another procedure that has already been qualified. The application range of a welding procedure qualification is determined by placing limits on the welding variables specified in a welding procedure. Codes define these limiting variables as "essential variables," because the WPS must be requalified if the values are changed so that they exceed the specified limits.

Supplementary essential variables are the variables that affect notch toughness. Supplementary variables become essential variables when notch toughness tests are required.

Nonessential variables are the remaining variables that are contained in the WPS, but that can be changed without requiring requalification. An essential variable for one process may be nonessential for another process.

Although there are differences in how codes and standards define essential variables, the variables described below are considered to be essential by most codes and standards.

Welding Process. A change of welding process will require requalification, because the process has a significant effect on the mechanical properties and metallurgical structure of the weld.

Base Metal. Changing from one type of base metal to another can affect weldability, as well as the metallurgical and mechanical properties of the weld. For certain welding processes, changes in base metals also can cause differences in penetration and weld fusion characteristics. Therefore, significant changes in base-metal type, composition, heat treatment, or processing will require requalification.

Some codes require separate welding procedure qualifications for pipe and plate. Although a procedure qualification on pipe may also cover plate, a procedure qualification on plate might be restricted to the welding of large-diameter pipes. Base-metal thickness influences cooling rate and, therefore, metallurgical and mechanical properties. The composition of a metal may also change with thickness. Some codes require qualification on the exact thickness of metal that is to be used for production welds. Other codes require qualification on the thinnest and thickest metals that are used in production. Most codes permit qualification on one thickness of test specimen to cover a range of base-metal thicknesses.

Codes often group together those base metals that have similar weldability characteristics, metallurgical properties, chemical compositions, or mechanical properties. The grouping of base metals reduces the number of required qualifications by allowing the qualification of one of the materials in the group to qualify the other base metals in that group.

Filler Metal. Codes group filler metals and welding electrodes with similar chemical compositions and operating characteristics together. Grouping reduces the number of tests by allowing the qualification of one of the filler metals in

the group to also qualify the others in that group. Ferrous filler metals can be grouped by both chemical composition and usability. The addition or deletion of a consumable insert is an essential variable.

Position is not an essential variable for all codes and specifications, which may allow qualification in one position to cover qualification in another position. For example, qualification in the horizontal position may also qualify for the flat position.

Joint design is an essential variable for some codes, but not for others. Weld joint design should be an essential variable for processes in which joint changes affect metallurgical structures and weld properties. These processes include stud, laser-beam, electron-beam, and friction welding.

Electrical Characteristics. Variations in the type of welding current (alternating or direct, for arc welds) or in polarity normally require requalification. A small change in welding current or voltage does not typically require requalification. Many codes limit changes to ± 10% from the mean value, without necessitating requalification. The use of current pulsation and the pulse parameters may be essential variables. For example, beam current or beam power are essential variables for both laser- and electron-beam welding.

Shielding. The use and the composition of a shielding gas are essential variables for arc welding, friction welding, and laser-beam welding processes. An essential variable for electron-beam welding is the use of a vacuum.

Preheat and Interpass Temperatures. Significant changes in preheat or interpass temperatures will affect properties and, therefore, will require requalification. Codes and standards differ on the size of the change in temperature that is permitted. Some codes limit changes to a maximum of 14 °C (25 °F), whereas others permit an increase or decrease of up t 56 °C (100 °F) before requalification is required.

Postweld Heat Treatment. The use of postweld heat treatment, as well as changes in the postweld heat-treatment temperature or time at temperature, will require requalification.

Other variables that affect the soundness, metallurgical structure, or mechanical properties of the weld are essential variables. These variables depend on the welding process being used. Examples of other essential variables include:

- CHANGES IN MEAN TRAVEL SPEED OF MORE THAN 10%
- CHANGING FROM A STRINGER TO A WEAVE BEAD, OR CHANGING THE DIRECTION OF WELDING FOR VERTICAL ARC WELDING PROCEDURES
- CHANGES IN ELECTRODE COMPOSITION OR CONFIGURATION FOR RESISTANCE WELDING
- CHANGES IN FILAMENT TYPE, SIZE, OR SHAPE, AND IN GUN-TO-WORK DISTANCE FOR ELECTRON-BEAM WELDING
- CHANGES IN FOCAL LENGTH, FOCUS POSITION, OR SPOT SIZE FOR LASER-BEAM WELDING
- CHANGES IN ENERGY, APPLIED LOADS, OR THE AMOUNT OF UPSET FOR FRICTION WELDING

Limitations on Procedure Qualification

A new welding procedure must be qualified if it differs significantly from another procedure that has already been qualified. The application range of a welding procedure qualification is determined by placing limits on the welding variables specified in a welding procedure. Codes define these limiting variables as "essential variables," because the WPS must be requalified if the values are changed so that they exceed the specified limits.

Supplementary essential variables are the variables that affect notch toughness. Supplementary variables become essential variables when notch toughness tests are required.

Nonessential variables are the remaining variables that are contained in the WPS, but that can be changed without requiring requalification. An essential variable for one process may be nonessential for another process.

Although there are differences in how codes and standards define essential variables, the variables described below are considered to be essential by most codes and standards.

Welding Process. A change of welding process will require requalification, because the process has a significant effect on the mechanical properties and metallurgical structure of the weld.

Base Metal. Changing from one type of base metal to another can affect weldability, as well as the metallurgical and mechanical properties of the weld. For certain welding processes, changes in base metals also can cause differences in penetration and weld fusion characteristics. Therefore, significant changes in base-metal type, composition, heat treatment, or processing will require requalification.

Some codes require separate welding procedure qualifications for pipe and plate. Although a procedure qualification on pipe may also cover plate, a procedure qualification on plate might be restricted to the welding of large-diameter pipes. Base-metal thickness influences cooling rate and, therefore, metallurgical and mechanical properties. The composition of a metal may also change with thickness. Some codes require qualification on the exact thickness of metal that is to be used for production welds. Other codes require qualification on the thinnest and thickest metals that are used in production. Most codes permit qualification on one thickness of test specimen to cover a range of base-metal thicknesses.

Codes often group together those base metals that have similar weldability characteristics, metallurgical properties, chemical compositions, or mechanical properties. The grouping of base metals reduces the number of required qualifications by allowing the qualification of one of the materials in the group to qualify the other base metals in that group.

Filler Metal. Codes group filler metals and welding electrodes with similar chemical compositions and operating characteristics together. Grouping reduces the number of tests by allowing the qualification of one of the filler metals in the group to also qualify the others in that group. Ferrous filler metals can be grouped by both chemical composition and usability. The addition or deletion of a consumable insert is an essential variable.

Position is not an essential variable for all codes and specifications, which may allow qualification in one position to cover qualification in another position. For example, qualification in the horizontal position may also qualify for the flat position.

Joint design is an essential variable for some codes, but not for others. Weld joint design should be an essential variable for processes in which joint changes affect metallurgical structures and weld properties. These processes include stud, laser-beam, electron-beam, and friction welding.

Electrical Characteristics. Variations in the type of welding current (alternating or direct, for arc welds) or in polarity normally require requalification. A small change in welding current or voltage does not typically require requalification. Many codes limit changes to ± 10% from the mean value, without necessitating requalification. The use of current pulsation and the pulse parameters may be essential variables. For example, beam current or beam power are essential variables for both laser- and electron-beam welding.

Shielding. The use and the composition of a shielding gas are essential variables for arc welding, friction welding, and laser-beam welding processes. An essential variable for electron-beam welding is the use of a vacuum.

Preheat and Interpass Temperatures. Significant changes in preheat or interpass temperatures will affect properties and, therefore, will require requalification. Codes and standards differ on the size of the change in temperature that is permitted. Some codes limit changes to a maximum of 14 °C (25 °F), whereas others permit an increase or decrease of up t 56 °C (100 °F) before requalification is required.

Postweld Heat Treatment. The use of postweld heat treatment, as well as changes in the postweld heat-treatment temperature or time at temperature, will require requalification.

Other variables that affect the soundness, metallurgical structure, or mechanical properties of the weld are essential variables. These variables depend on the welding process being used. Examples of other essential variables include:

- CHANGES IN MEAN TRAVEL SPEED OF MORE THAN 10%
- CHANGING FROM A STRINGER TO A WEAVE BEAD, OR CHANGING THE DIRECTION OF WELDING FOR VERTICAL ARC WELDING PROCEDURES
- CHANGES IN ELECTRODE COMPOSITION OR CONFIGURATION FOR RESISTANCE WELDING
- CHANGES IN FILAMENT TYPE, SIZE, OR SHAPE, AND IN GUN-TO-WORK DISTANCE FOR ELECTRON-BEAM WELDING
- CHANGES IN FOCAL LENGTH, FOCUS POSITION, OR SPOT SIZE FOR LASER-BEAM WELDING
- CHANGES IN ENERGY, APPLIED LOADS, OR THE AMOUNT OF UPSET FOR FRICTION WELDING

Documentation of Procedure Qualification

Record keeping is an essential part of welding procedure qualification. The WPS defines the variables and methods to be used for welding. As noted earlier, a procedure qualification record is used to document the actual welding variables that are used for the procedure qualification test weldment, as well as the results of the tests. The manufacturer or contractor should have these records available for review by customers or authorized inspectors.

Introduction

COMPLEX THERMAL STRESSES occur in parts during welding due to the localized application of heat. Residual stresses and distortion remain after welding is completed. Transient thermal stresses, residual stresses, and distortion sometimes cause cracking and mismatching of joints. High tensile residual stresses in areas near the weld can cause premature failures of welded structures under certain conditions. Distortion, especially out-of-plane distortion, and compressive residual stresses in the base plate can reduce the buckling strength of a structural member subjected to compressive loading. Correction of unacceptable distortion is costly and, in some cases, impossible. The subjects related to residual stresses, distortion, and their consequences are too broad to be discussed in depth in this article. Those who need more detailed information are advised to refer to the references, especially Ref 1, 2, 3.

Residual Stresses and Distortion

Koichi Masubuchi, Massachusetts Institute of Technology

Formation of Residual Stresses and Distortion

Residual stresses, also referred to as internal stresses, initial stresses, inherent stresses, and locked-in stresses, are stresses that exist in a body after all external loads are removed. Residual stresses also occur when a body is subjected to nonuniform temperature changes; these stresses are called thermal stresses. The intensity of stress is usually expressed in load or force per unit area, such as newtons per square meter (N/m^2) or pascals (Pa), kilograms force per square millimeter (kg/mm^2), or pounds per square inch (psi).

Residual stresses in metal structures occur for many reasons during various manufacturing stages, including casting, rolling, bending, flame cutting, forging, machining, and grinding. Heat treatments at various stages also influence residual stresses. For example, quenching treatments produce residual stresses, while stress-relieving heat treatments may reduce such stresses. Areas in which residual stresses exist vary greatly--from microscopic areas to large sections of the metal structure. This article focuses primarily on macroscopic residual stresses. Residual stresses can be classified into two groups according to the mechanisms that produce them:

- STRESSES PRODUCED BY STRUCTURAL MISMATCH
- STRESSES PRODUCED BY AN UNEVEN DISTRIBUTION OF NONELASTIC STRAINS, INCLUDING PLASTIC AND THERMAL STRAINS

Thermal Stresses and Metal Movement During Welding

Because a weldment is locally heated by the welding heat source, the temperature distribution is not uniform and changes as welding progresses. During the welding thermal cycle, complex transient thermal stresses are produced in the weldment and the surrounding joint. The weldment also undergoes shrinkage and deformation during solidification and cooling.

Thermal Stresses During Welding. Figure 1 schematically shows changes in temperature and resulting stresses that occur during welding by examining a bead-on-plate weld of a thin plate made along the *x*-axis. The welding arc, which is moving at a speed *v*, is presently located at the origin, *O*, as shown in Fig. 1(a). The area where plastic deformation occurs during the welding thermal cycle is shown by the shaded area, *M-M '*, in Fig. 1(a). The region where the metal is molten is

indicated by the ellipse near *O*. The region outside the shaded area remains elastic throughout the entire welding thermal cycle.

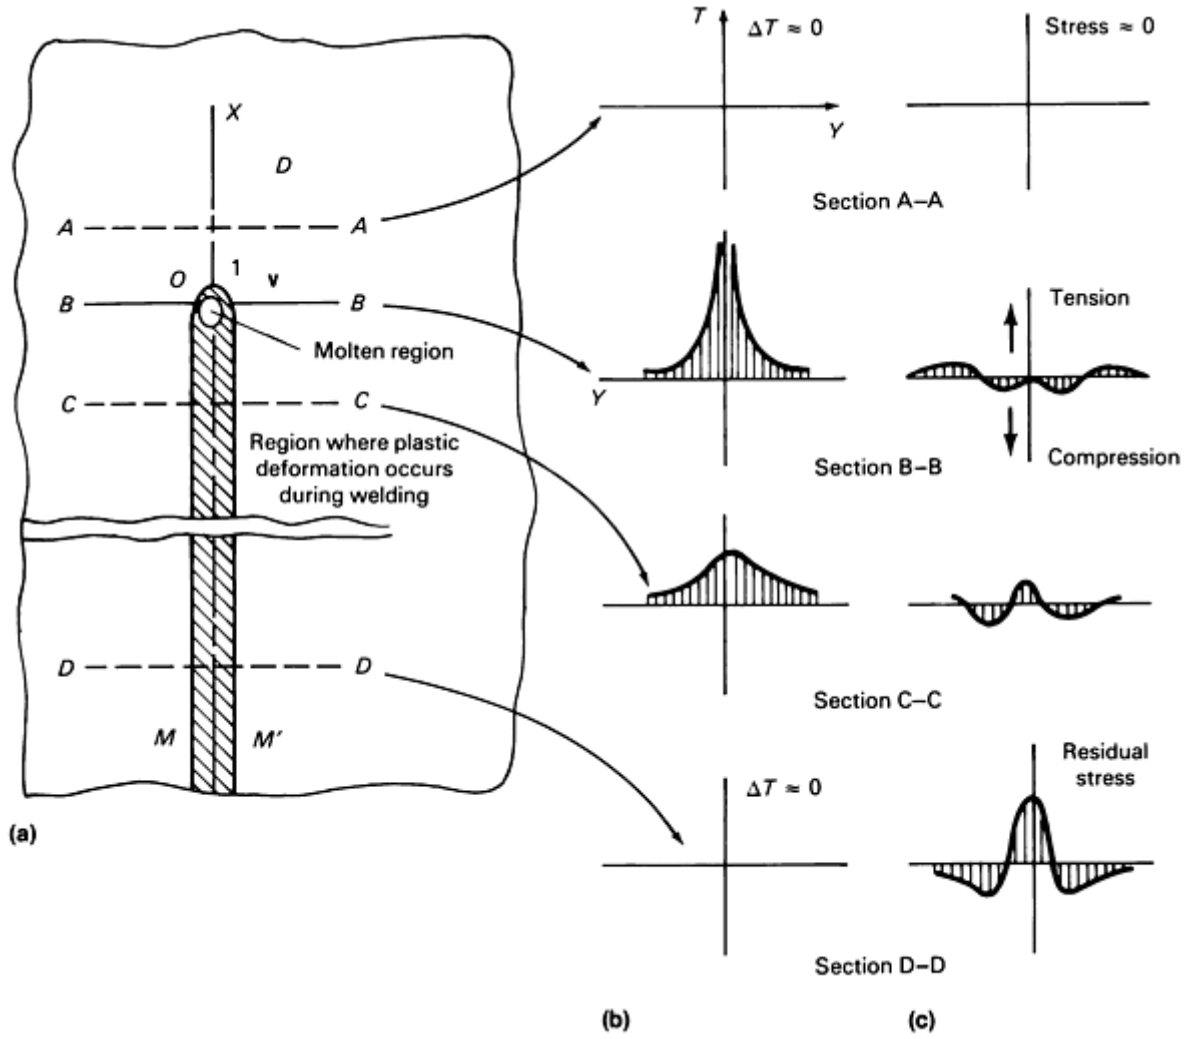

FIG. 1 SCHEMATIC REPRESENTATION OF CHANGES IN TEMPERATURE AND STRESSES DURING WELDING. (A) WELD. (B) TEMPERATURE CHANGE. (C) STRESS, σ_x. STRESS DISTRIBUTION IS SHOWN IN THE PLANE STRESS CONDITION. THEREFORE, STRESSES ARE REGARDED AS BEING UNIFORM IN THE THICKNESS DIRECTION. SOURCE: WELDING RESEARCH COUNCIL

Temperature gradients along several cross sections through the weld bead path are indicated in Fig. 1 (b). In the base metal ahead of the welding arc (denoted as section A-A), the slope of the temperature gradient due to welding ($\Delta T/\Delta Y$) is almost zero. However, along section B-B, which crosses the welding arc, the slope becomes very steep. Along section C-C, somewhat behind the welding arc, the slope becomes less steep. The slope of the temperature gradient due to welding once again approaches zero along section D-D, which is some distance behind the welding arc. Figure 1(c) shows the distribution of normal stress in the *x*-direction (σ_x) along the cross sections. Normal stress in the *y*-direction (σ_y) and shearing stress (t_{xy}) also exist in a two-dimensional stress field. In a three-dimensional stress field, six stress components exist: σ_x, σ_y, σ_z, t_{xy}, t_{yz}, and t_{zx}.

Figure 1(c) shows the distribution (along the *y*-axis) of normal stress in the *x*-direction (σ_x) due to welding (that is, thermal stress). Along section A-A, the stresses are almost zero. The stress distribution along section B-B is complicated. Beneath the welding arc, stresses are close to zero, because molten metal does not support shear loading. Moving away from the arc, stresses become compressive, because expansion of the metal surrounding the weld pool is restrained by the base metal. Because the temperatures of these areas are quite high, the yield stress of the material becomes quite low. In other words, a situation occurs in which stresses in these areas are as high as the yield stress of the base metal at corresponding temperatures. The magnitude of compressive stress passes through a maximum with increasing distance

from the weld or with decreasing temperature. However, stresses occurring in regions farther away from the welding arc are tensile in nature and balance with compressive stresses in areas near the weld pool.

Figure 1(b) shows that along section C-C the weld-metal and base-metal regions have cooled. As they shrink, tensile stresses are caused in regions in and adjacent to the weld (Fig. 1c). As the distance from the weld increases, stresses become compressive. High tensile stresses exist along section D-D in and adjacent to the weld. Compressive stresses are produced in areas away from the weld.

Equilibrium Condition of Residual Stresses. Because residual stresses exist without external forces, the resultant force and the resultant moment produced by the residual stresses must vanish on any plane section:

$$\int \sigma \cdot DA = 0 \qquad \textbf{(EQ 1)}$$

$$\int DM = 0 \qquad \textbf{(EQ 2)}$$

where *dA* is area and *dM* is the resultant moment. Residual stress data must be checked in any experiment to ensure that they satisfy the above condition.

Metal Movement During Welding. During welding, the weldment undergoes shrinkage and deformation. The transient deformation, or metal movement, is most evident when the weld line is away from the neutral axis of the weldment, causing a large amount of bending moment. Figure 2 schematically shows how a rectangular plate distorts when its longitudinal edge is heated by a welding arc or an oxyacetylene torch (for cutting, welding, or flame heating). Areas near the heat source, or the upper regions of the rectangular plate, are heated to higher temperatures and thus expand more than areas away from the heat source, or the lower regions of the plate. Therefore, the plate first deforms as shown by curve *AB*.

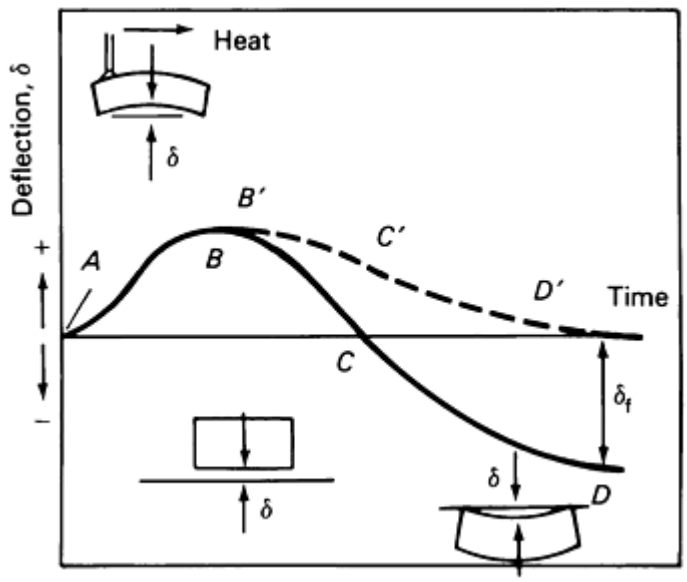

FIG. 2 CHANGES OF DEFLECTION AT THE CENTER OF THE LOWER EDGE OF A RECTANGULAR PLATE DUE TO HEATING BY A HEAT SOURCE MOVING ALONG THE UPPER EDGE AND SUBSEQUENT COOLING

If all the parts of the material remained completely elastic during the entire thermal cycle, thermal stresses produced during the heating and cooling cycle would disappear when the temperature returned to the initial temperature. Deformation of the plate during the welding process would be indicated by curve *AB'C'D'*, resulting in no deformation after the thermal cycle. However, in most practical materials, plastic strains are produced in areas heated to elevated temperatures, causing plastic upsetting. The thermal stresses do not disappear when the temperature returns to the initial temperature, causing residual stresses. Transient deformation of the plate during heating and cooling is shown by curve *ABCD*. After the plate cools to the initial temperature, final deformation in the amount δ_f remains, which also is called

distortion. The metal movement (that is, transient distortion or transient deformation) during welding and the distortion after welding is completed occur in opposite directions, generally with the same order of magnitude.

In summary, some basic characteristics of residual stresses and distortion are (Ref 4):

- THE METAL MOVEMENT DURING WELDING (EXPANSION) IS OPPOSITE TO THE DISTORTION THAT REMAINS AFTER WELDING.
- ALTHOUGH WELDING IS COMPLETED IN A SHORT PERIOD (IN A FEW MINUTES, FOR EXAMPLE), RESIDUAL STRESSES AND DISTORTION TAKE A RELATIVELY LONG TIME TO DEVELOP COMPLETELY (30 MIN TO 1H)
- BECAUSE MOST OF THE NONELASTIC STRAINS THAT CAUSE RESIDUAL STRESSES AND DISTORTIONS ARE PRODUCED DURING WELDING, NECESSARY ACTIONS MUST BE PERFORMED DURING WELDING TO EFFECTIVELY CONTROL AND REDUCE RESIDUAL STRESSES AND DISTORTION.

Analyses of Residual Stresses and Distortion in Weldments

Residual stresses and distortion in welded structures have been recognized and studied since the 1930s. Analyses of these subjects require complex computation; therefore, most early studies were primarily empirical or limited to the analysis of simple cases. With the advancement of modern computers and computational techniques (for example, the finite-element and finite-difference method), a renewed effort has been made in recent years to study residual stresses and related phenomena. Therefore, it is now possible using computer programs to simulate the transient thermal stresses and metal movement during welding as well as the residual stresses and distortion that remain after welding is completed (Ref 5, 6, 7, 8, 9). However, because these analysis methods are very complex, most are not practical for analyzing and controlling residual stresses and distortion in weldments.

Techniques for Measuring Residual Stresses

Many techniques have been used to measure residual stresses in metals (Ref 1, 10, 11). Table 1 lists most of the presently available measurement techniques and classifies them as follows:

- STRESS-RELAXATION TECHNIQUES
- X-RAY DIFFRACTION TECHNIQUES
- TECHNIQUES USING STRESS-SENSITIVE PROPERTIES
- CRACKING TECHNIQUES

Source: Ref 12

In the stress-relaxation technique, residual stress is determined by measuring the elastic-strain release that takes place when a specimen is cut into pieces or has a piece removed. In most cases, electric or mechanical gages are used for measuring this strain release (group A-1 in Table 1). A variety of such techniques exist (that is, there are many ways to section a specimen to determine residual stresses). Certain techniques are used to study stresses in a plate, while others are used for cylinders, tubes, or three-dimensional solids. Strain release caused by stress relaxation can also be determined by using grid systems, brittle coatings, or photoelastic coatings (group A-2 in Table 1). An inherent disadvantage of stress-relaxation techniques is that they are destructive (that is, the specimen must be partially or entirely sectioned). Nevertheless, the stress-relaxation techniques provide reliable quantitative data and are the most widely used method for measuring residual stresses in weldments.

In metals with crystalline structures, elastic strains can also be determined by using x-ray diffraction to measure the lattice parameter. Because the lattice parameter of a metal in the unstressed state is known or can be determined separately, elastic strain in the metal can be measured nondestructively without machining or drilling. Two methods are presently available: the x-ray film technique and the x-ray diffractometer technique. With x-ray diffraction, surface strains can be determined within a small area--for example, to a depth of 0.025 mm (0.001 in.) and a diameter of 0.0025 mm (0.0001 in.). Modern x-ray diffraction stress measurement instrumentation can provide one complete measurement in time scales as short as a fraction of a second, and typically less than 1 min. However, x-ray diffraction techniques have some disadvantages. They are time consuming, and they are not accurate, especially in situations where high temperatures have distorted the atomic structure of the material. Studies have recently been made using diffraction of neutrons, which can penetrate deeper into the metal than x-rays (Ref 13).

Attempts have been made to determine the residual stresses in metals by measuring their stress-sensitive properties. The following stress-measurement techniques have been proposed:

- ULTRASONIC TECHNIQUES, SUCH AS THE POLARIZED ULTRASONIC WAVE TECHNIQUE (WHICH MAKES USE OF STRESS-INDUCED CHANGES IN THE ANGLE OF POLARIZATION OF POLARIZED ULTRASONIC WAVES) AND THE ULTRASONIC ATTENUATION TECHNIQUE (WHICH MAKES USE OF STRESS-INDUCED CHANGES IN THE RATE OF ABSORPTION OF ULTRASONIC WAVES)
- HARDNESS TECHNIQUES, WHICH MAKE USE OF STRESS-INDUCED CHANGES IN HARDNESS

However, none of these techniques has been developed beyond the laboratory stage, and they have not been used successfully for the measurement of residual stresses in weldments.

Another technique developed for the study of residual stresses involves the close observation of cracks induced in the specimen by hydrogen embrittlement or stress-corrosion cracking (SCC). Cracking techniques are useful when studying residual stresses in complex structural models in which the distribution of residual stresses is complicated, but these techniques provide only qualitative, not quantitative, data.

Magnitude and Distribution of Residual Stresses in Weldments

A number of investigators have studied distributions of residual stresses in various types of weldments. Most of the data presented in this section relates to single welds as opposed to multipass welds. References 1, 2, and 3 present detailed information.

Residual Welding Stresses, Reaction Stresses, and Stress Distributions in a Groove Weld. As stated earlier, residual stresses can be classified as (1) stresses produced by structural mismatch or displacement and (2) stresses produced by uneven distribution of nonelastic strains. The same method of classification is applicable to residual stresses in weldments: (1) reaction stresses caused when the weldment is restrained externally and (2) residual stresses produced in an unrestrained weldment.

Figure 3 shows a typical distribution of residual stresses in a groove weld. The significant stresses are those parallel to the weld direction, designated σ_x, which are usually called the longitudinal stresses, and those transverse to σ_x, designated σ_y, which are called the transverse stresses. The distribution of the longitudinal stress is shown in Fig. 3(b). Near the weld, tensile stresses of high magnitude are produced. These taper off quickly and become compressive at a distance equal to several times the width of the weld metal. The stress distribution is characterized by two parameters:

- THE MAXIMUM STRESS AT THE WELD REGION, σ_M
- THE WIDTH OF THE TENSION ZONE OF RESIDUAL STRESS, B

The distribution of longitudinal residual stress, σ_x, can be approximated by:

$$s_x(y) = s_m\left[1-\left(\frac{y}{b}\right)^2\right]e^{-[1/2(y/b)^2]} \qquad \textbf{(EQ 3)}$$

Equation 3 satisfies the equilibrium conditions given in Eq 1 and 2.

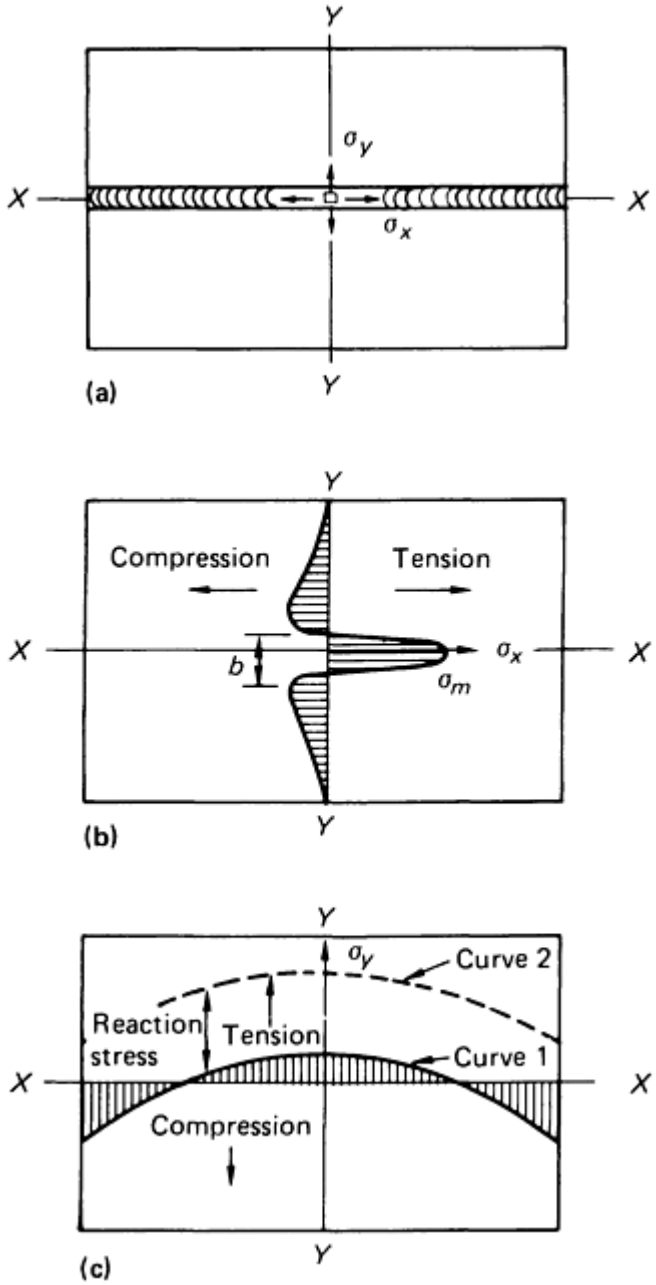

FIG. 3 TYPICAL DISTRIBUTIONS OF RESIDUAL STRESSES IN A GROOVE WELD. (A) GROOVE WELD. (B) DISTRIBUTION OF σ_x ALONG *YY*. (C) DISTRIBUTION OF σ_y ALONG *XX*. SOURCE: WELDING RESEARCH COUNCIL

Curve 1 of Fig. 3(c) shows the distribution of transverse stress,σ_y, along the length of the weld. In the center of the joint, tensile stresses of relatively low magnitude are produced. Compressive stresses are produced at the ends of the joint. If an external constraint is used to restrain the lateral contraction of the joint, approximately uniform tensile stresses along the weld are added, resulting in curve 2 of Fig. 3(c). However, an external constraint has little influence on the distribution of residual stress (σ_x).

Residual Stresses in a Plug Weld. Figure 4 shows the distribution of both the theoretical and experimental residual stresses in a circular plug weld (Ref 14). Tensile stresses, as high as the yield stress of the material, are produced in both radial and tangential directions in the weld and adjacent areas. In areas away from the weld, radial stresses (σ_r) are tensile, and tangential stresses ($\sigma\theta$) are compressive; both stresses decrease with increasing distance from the weld (*r*).

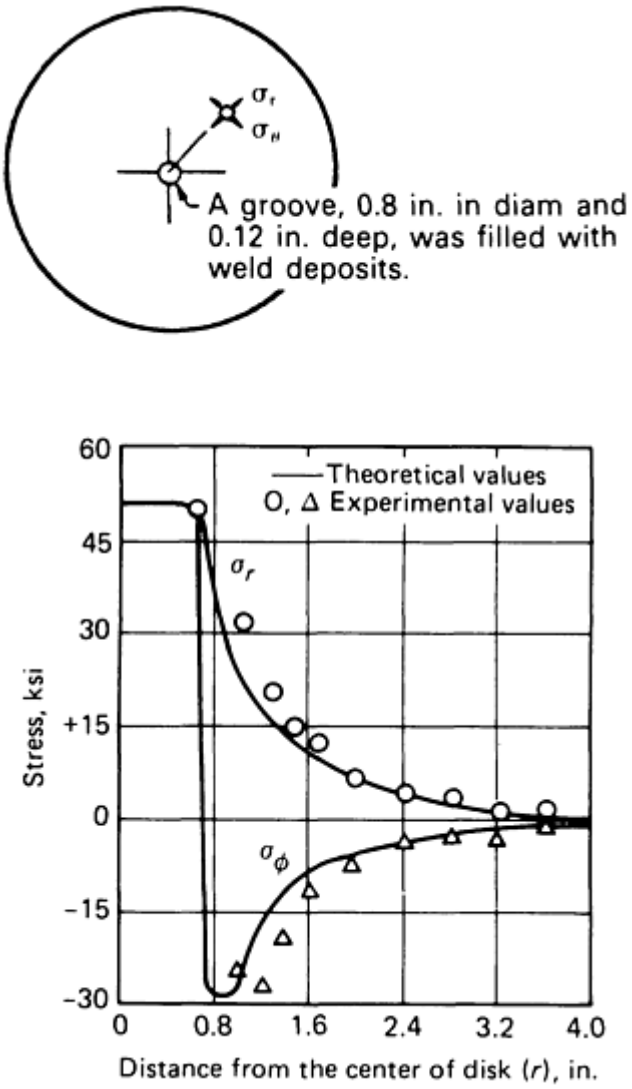

FIG. 4 THEORETICAL AND EXPERIMENTAL DISTRIBUTIONS OF RESIDUAL STRESSES IN A PLUG WELD

Residual Stresses in a Welded Shape and a Column. Figure 5 shows typical distributions of residual stresses and distortion in various welded shapes (Ref 15). As shown in section *xx* of Fig. 5(a), high tensile residual stresses are produced in areas near the weld, in the direction parallel to the weld line (axis). In the flange, longitudinal stresses are compressive (-) in areas away from the weld and tensile (+) in areas near the weld. Tensile stresses in areas near the upper edge of the web are caused by longitudinal bending distortion of the T-shape, which are caused by the longitudinal shrinkage of the weld. Angular distortion also is produced.

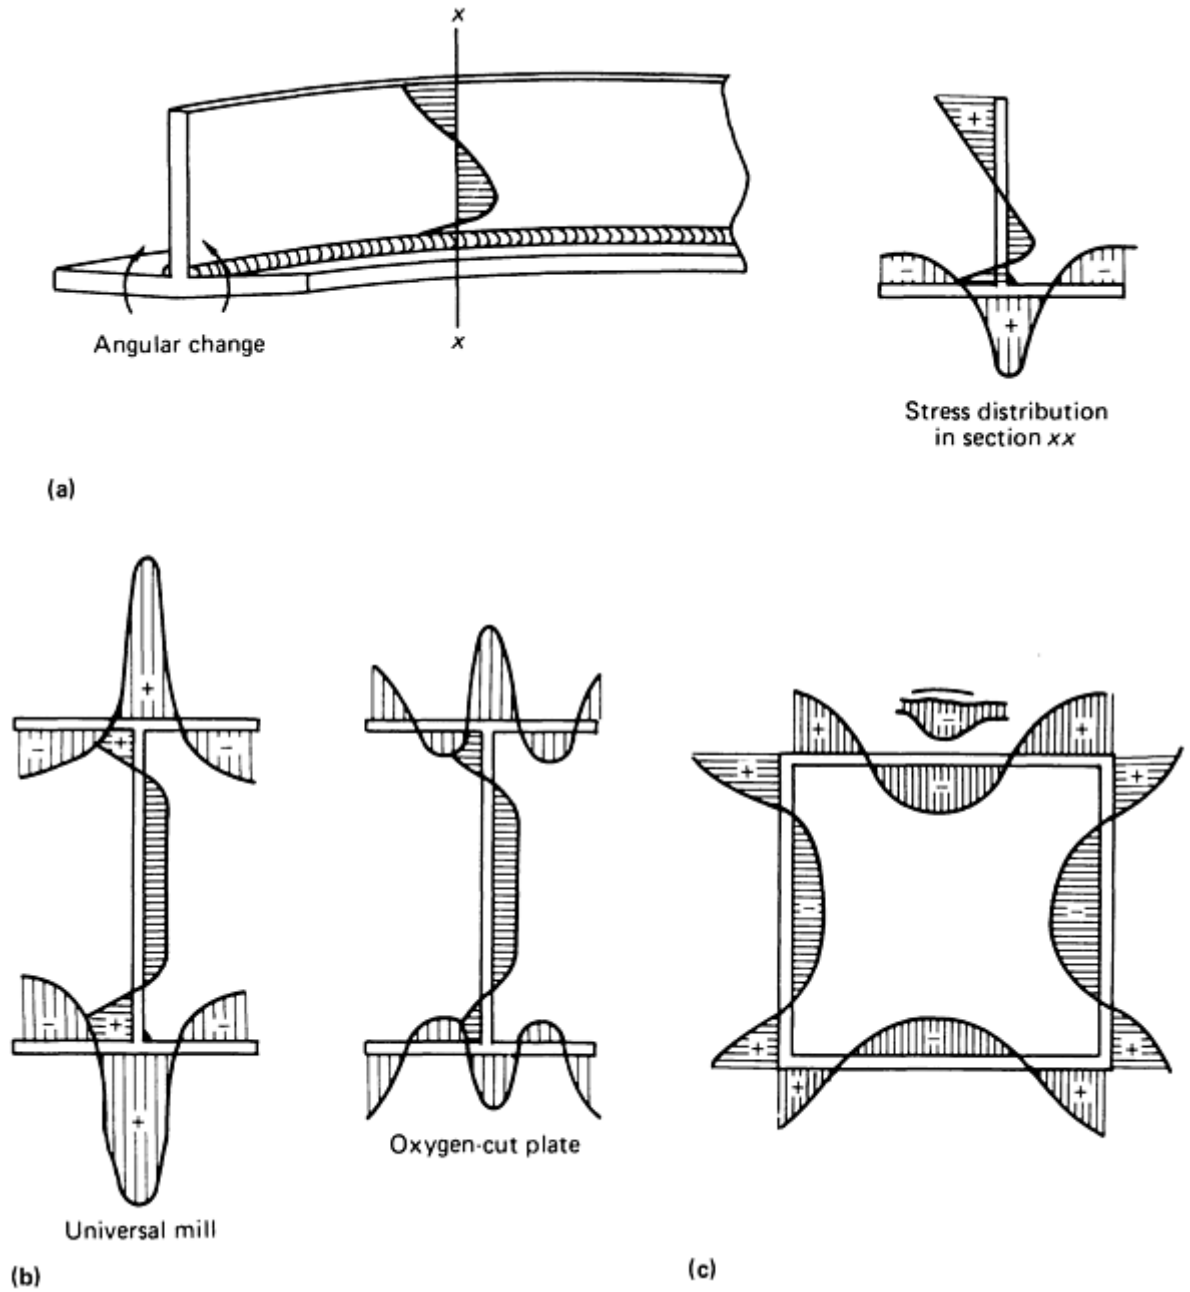

FIG. 5 TYPICAL RESIDUAL STRESSES IN WELDED SHAPES. (A) T-SHAPES. (B) H-SHAPES. (C) BOX SHAPES. COMPRESSIVE STRESS, -; TENSILE STRENGTH, +

Figures 5(b) and 5(c) show typical distributions of residual stress in H-shapes (I-beams) and in a welded box shape, respectively. Residual stresses are shown parallel to the weld line (axis); they are compressive in areas away from the welds and tensile in areas near the welds.

Residual Stresses in Weldments of Selected Materials. Distributions of residual stresses in welds in various metals are similar to those in low-carbon steel welds, discussed above. In most cases, the maximum residual stresses are as high as the yield stress of the material. One exception is ultrahigh-strength steels, such as 4130, D-6a, and H13 (Ref 1). For such steels, peak values of residual stresses in some areas can be as high as the yield stress (or even higher in the case of triaxiality); however, average values of residual stresses in the weld metal are considerably lower than the yield stress.

Distortion in Weldments

Distortions found in fabricating structures are caused by three fundamental dimensional changes:

- TRANSVERSE SHRINKAGE
- LONGITUDINAL SHRINKAGE PARALLEL TO THE WELD LINE
- ANGULAR DISTORTION AROUND THE WELD LINE

These dimensional changes are shown in Fig. 6.

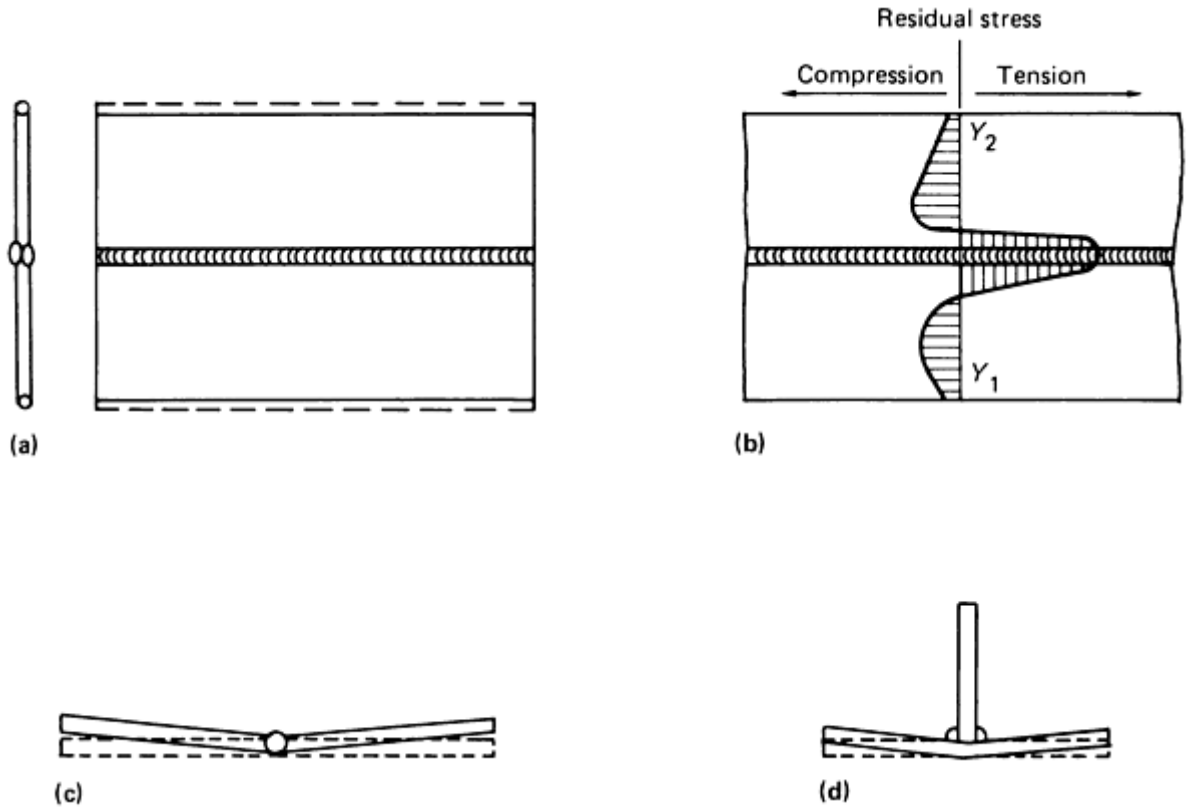

FIG. 6 DIMENSIONAL CHANGES OCCURRING IN WELDMENTS. (A) TRANSVERSE SHRINKAGE IN A GROOVE WELD. (B) LONGITUDINAL SHRINKAGE IN A GROOVE WELD. DISTRIBUTION OF LONGITUDINAL RESIDUAL STRESS, σ_x, IS ALSO SHOWN. (C) ANGULAR CHANGE IN A GROOVE WELD. (D) ANGULAR CHANGE IN A FILLET WELD. SOURCE: WELDING RESEARCH COUNCIL

The shrinkage and distortion that occur during fabrication of actual structures are far more complex than those shown in Fig. 6. For example, when longitudinal shrinkage occurs in a fillet joint, the joint bends longitudinally unless the weld line is located along the neutral axis of the joint. A common structural element is a stiffened panel structure in which longitudinal and transverse stiffeners are fillet welded to a flat plate. Angular changes that occur in the fillet welds cause out-of-plane distortion in the plate, resulting in a shape which looks like a "hungry horse." Presented below are brief discussions of:

- TRANSVERSE SHRINKAGE OF GROOVE WELDS
- ANGULAR DISTORTION OF GROOVE WELDS
- OUT-OF-PLANE DISTORTION CAUSED BY ANGULAR DISTORTION OF FILLET WELDS
- LONGITUDINAL DISTORTION OF BUILT-UP BEAMS
- BUCKLING DISTORTION

Transverse Shrinkage of Square Groove Welds. In Fig. 6(a), shrinkage is uniform along the weld; however, transverse shrinkage that occurs in a groove weld, especially in a long groove weld, is not uniform and is typically much more complex. The major factors causing nonuniform transverse shrinkage in a groove weld are rotational distortion and joint restraint. When two separate planes are joined progressively from one end to the other, the plate edges of the unwelded portion of the joint move, causing a rotational distortion. This can be understood from Fig. 2. The rotational distortion is affected by welding conditions and the location of tack welds. In many practical joints, the degree of joint restraint is not uniform along the weld. Because the amount of transverse shrinkage is less when the joint is more severely restrained, nonuniform distribution of the magnitude of restraint results in an uneven distribution of transverse shrinkage.

Mechanisms of Transverse Shrinkage. The most important finding of mathematical analyses of mechanisms of transverse shrinkage is that the major portion of the transverse shrinkage of a groove joint is caused by contraction of the

base plate adjacent to the weld. The base plate near the weld expands during welding. When the weld metal solidifies, the expanded base metal must shrink; this shrinkage accounts for the major part of transverse shrinkage. Shrinkage of the weld metal accounts for about 10% of the actual total shrinkage. Therefore, most formulas developed for computing transverse shrinkage of a square groove weld are composed of two parts:

- SHRINKAGE OF THE ADJACENT BASE PLATE
- SHRINKAGE OF THE WELD METAL

Transverse Shrinkage During Multipass Welding. Welding of a square groove joint in a thick plate commonly requires a number of passes. Figure 7(a) shows how transverse shrinkage increases during multipass welding of a groove joint in 19 mm ($\frac{3}{4}$ in.) thick low-carbon steel plates. Shrinkage is pronounced during the early weld passes, but diminishes during later passes because of the resistance to shrinkage that increases as the weld metal is increased. The effects of transverse shrinkage on various factors, including root opening, joint design, electrode diameter, and degree of restraint, have been studied extensively (Ref 1).

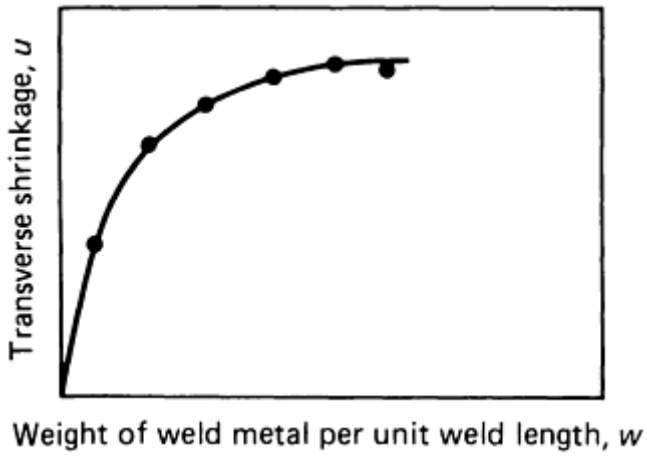

FIG. 7 INCREASE OF TRANSVERSE SHRINKAGE DURING MULTIPASS WELDING OF A GROOVE JOINT. SPECIMENS WERE 19 MM ($\frac{3}{4}$ IN.) THICK LOW-CARBON STEEL PLATES.

Transverse Shrinkage in a Square Groove Weld in Aluminum. As stated earlier, the major portion of transverse shrinkage of a square groove weld is caused by contraction of the base plate adjacent to the weld. Compared with steel, aluminum has a much higher heat conductivity and coefficient of thermal expansion; therefore, transverse shrinkage of an aluminum groove weld is approximately three times greater than that of a steel groove weld of similar dimensions (Ref 1). Because the value of thermal conductivity of aluminum is much greater than that of steel, heat generated by the welding arc dissipates faster in aluminum than in steel, resulting in a broader HAZ (Ref 2).

Angular Distortion of Groove Welds. In a groove weld, when transverse shrinkage is not uniform in the thickness direction, angular distortion often occurs. The angular change of a weld in a thick plate can be minimized by properly selecting the ratio of the size of the weld groove on the front surface to that of the back surface (Ref 1).

Out-of-Plane Distortion Caused by Angular Distortion in Fillet Welds. A stiffened panel composed of a flat plate with longitudinal and transverse stiffeners fillet welded to the plate is widely used for many structures. Angular changes that occur at fillet welds cause out-of-plane distortion of the flat plate (Ref 1). Figure 8 compares values of distortion at the panel center (δ_m) for steel and aluminum welded structures on the basis of the same fillet size (D_f) for selected plate thicknesses. Distortion in aluminum structures is less than in steel structures because the temperature distribution in the thickness direction is more uniform in an aluminum weld than in a steel weld (Ref 2).

Longitudinal Distortion of Built-up Beams. Figure 9 compares values of longitudinal distortion expressed in terms of the radius of curvature of built-up beams in steel and aluminum. In this instance, aluminum welds distorted less than steel welds, perhaps because the temperature distribution in the *z*-direction is more uniform in an aluminum weld than in a steel weld.

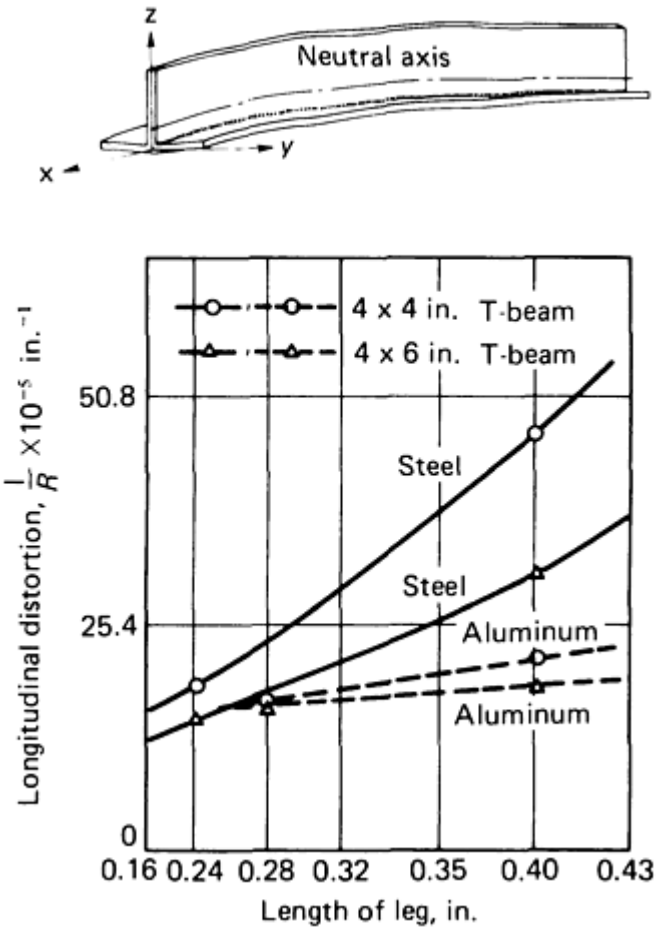

FIG. 9 RELATIONSHIP BETWEEN LENGTH OF LEG AND CURVATURE OF LONGITUDINAL DEFLECTION IN T-SECTION BEAM. SOURCE: REF 1, 16

Buckling Distortion. In any weldment, longitudinal residual stresses are compressive in areas away from the weld, as shown in Fig. 3. When the plate is thin, it may buckle due to these compressive residual stresses. Buckling distortion differs from bending distortion in that the amount of distortion in buckling is much greater. Also, there may be more than one stable deformed shape in buckling distortion. The most effective method for dealing with buckling distortion is prevention by proper selection of plate thickness, length of free span, and welding heat input.

When stiffeners are fillet welded to thin plate, the plate may buckle because of the compressive residual stresses that occur in the plate. Figure 10 shows relationships between distortion at the center of the panel and heat input for square panels 500 mm (20 in.) long made with plates 4.6 to 10 mm (0.18 to 0.4 in.) thick. For example, in the case of a 500 × 500 mm (20 × 20 in.) panel with a plate 6 mm (0.24 in.) thick, the plate deflection increases suddenly when the heat input exceeds approximately 3700 cal/cm^2. This indicates that the critical heat input is approximately 3700 cal/cm^2. When the plate is 4.6 mm (0.18 in.) thick, this critical heat input is only approximately 2000 cal/cm^2. The following formula can be used to determine the critical heat input, H_{cr}, above which excessive buckling distortion occurs:

$$H_{cr} = \frac{Q}{t^3} \quad b \geq \sim 4x10^5 cal/cm^3 \qquad \textbf{(EQ 4)}$$

where *b* is the length of the panel and *t* is the plate thickness, both in millimeters. The above parameter, H_{cr}, is also called the critical heat input index.

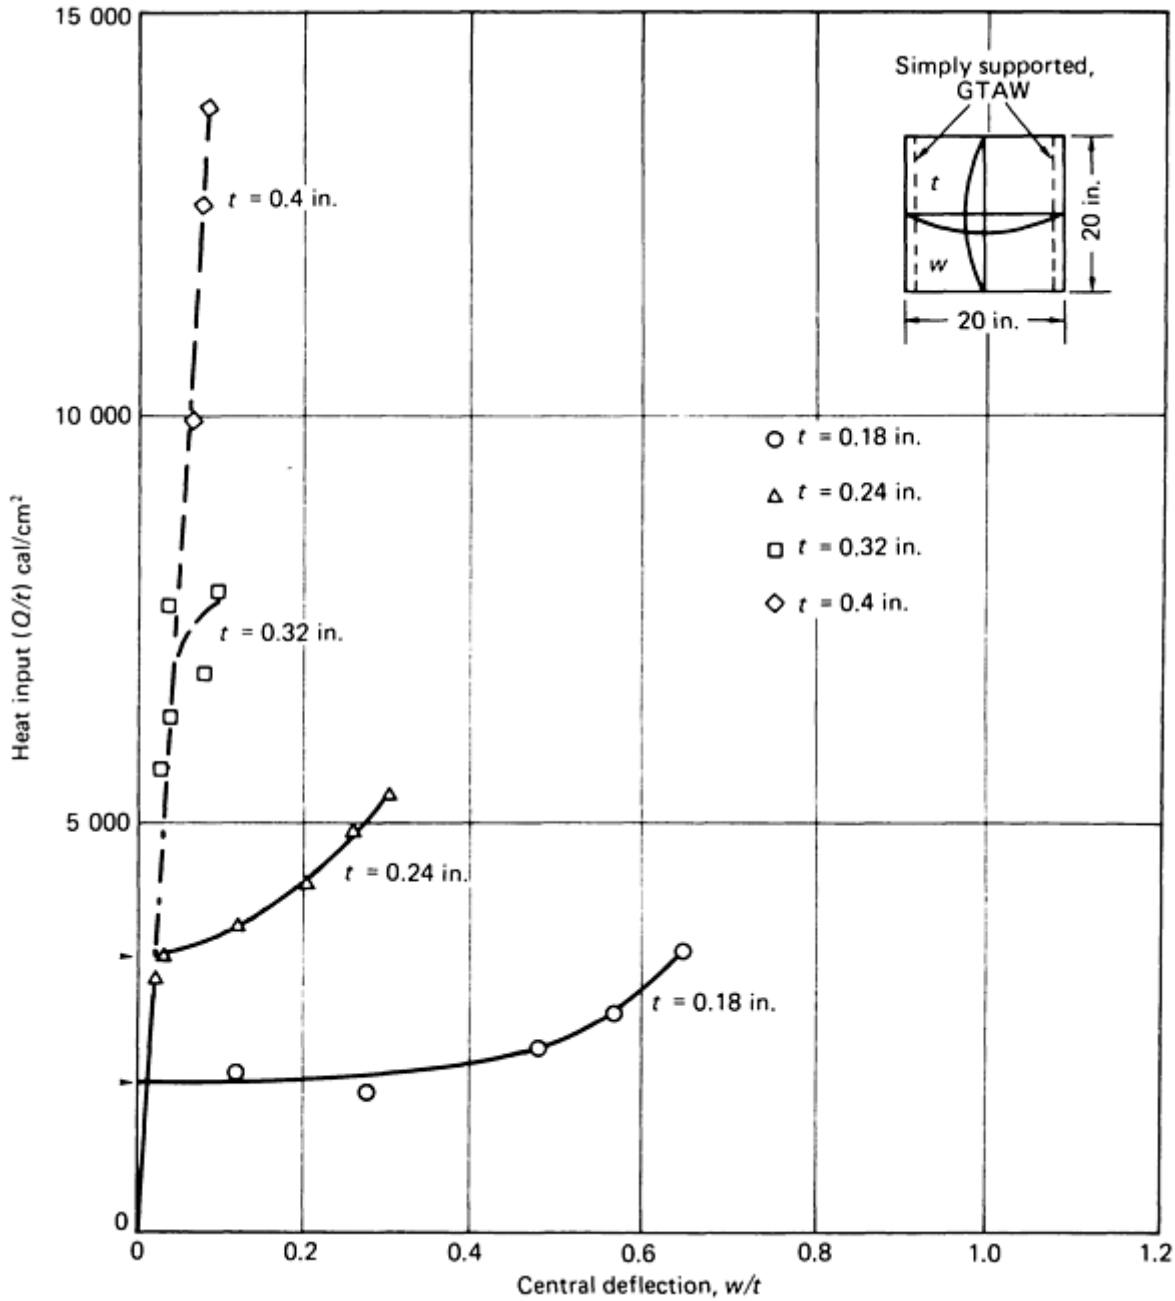

FIG. 10 PLOT OF HEAT INPUT VERSUS DEFLECTION FOR 500 × 500 MM (20 × 20 IN.) LOW-CARBON STEEL PANELS AS A FUNCTION OF PANEL THICKNESS

Thermal Treatments of Weldments

Thermal treatments are often necessary to maintain or restore the properties of base metal affected by the heat of welding. Thermal treatment may also affect the properties of the weld metal. The extent of changes in the properties of the base metal, weld metal, and heat-affected zone (HAZ) are determined by several factors, including the soaking temperature, time, cooling rate, and material thickness. Further detailed information is available in Ref 2 and 3.

Preheat is the most common thermal treatment applied to weldments. Proper use of preheat can minimize residual stresses and distortion that would normally occur during welding as a result of lower thermal gradients around the weld. Preheat also has the beneficial effect in steels of reducing the tendency for the formation of a HAZ and weld metal cracking.

Postweld Thermal Treatments. A properly executed postweld heat treatment results in uniform mechanical properties and reduced residual stresses. The effects of time at temperature and the stress-relieving temperature on residual stresses are shown in Fig. 14(a) and 14(b), respectively (Ref 3). When thick weldments require a postweld machining operation, a stress-relief treatment is usually necessary to achieve normal machining tolerance.

Repair Welding

Vern Sutter, American Welding Institute; Robert J. Dybas, General Electric Company

Introduction

REPAIR AND MAINTENANCE of parts and components is a multibillion dollar industry. Repair welding can be carried out as a logical procedure that ensures the production of a usable and safe component or it can be approached haphazardly. The latter approach results in poor-quality workmanship and can lead to failed parts, large warranty claims, and dissatisfied customers.

It is to the advantage of the individual welder, job shop owner, end user, and others who depend on the weld repair industry to approach each repair with a thorough knowledge of component history in terms of:

- COMPONENT FUNCTION
- MATERIAL COMPOSITION
- COMPONENT SURFACE OR THROUGH HARDNESS
- PART ORIGINALLY CAST, FABRICATED, OR WELDED

Repair welding can fall into one of three general categories: repair of weld defects, repair of failed parts, and repair of worn parts. This article describes the repair of weld defects and structural failures. Welding buildup of worn parts is described in the article "Cladding, Hardfacing, and Dissimilar Metal Joining" in this Volume.

Requirements and repair techniques discussed in this article apply to arc and oxyfuel welding processes. Materials can be any that are usually joined successfully using arc or oxyfuel welding processes. Generally, the repair welding procedures will apply whether the structure is built under code construction specifications or not. Many construction codes require that a written procedure be prepared prior to any repair welding. Code or contractual requirements supersede any statements made in this article.

If the component to be repaired was originally a welded fabrication, then data and information on the original process are important to a successful repair. If access to this information is not practical, then an analysis of the base material, including previous weld deposits, becomes mandatory. If dimensions require close tolerances or if flatness is critical, then benchmarks that will aid the repair without causing excessive and expensive damage to the workpiece must be established.

Understanding the basics of each group of metals covered in this article helps to ensure a successful repair. All references and sources of information should be exhausted before any job commences. Excellent sources include filler-metal manufacturers and manufacturers of bar, plate, forgings, and castings. Either of these producers can supply key information on the weldability of the workpiece alloys.

Depending on the specific application, all of the common welding processes can be used for repair welding:

- SHIELDED METAL ARC WELDING (SMAW)
- GAS-METAL ARC WELDING (GMAW)
- GAS-TUNGSTEN ARC WELDING (GTAW)
- SUBMERGED ARC WELDING (SAW)
- PLASMA ARC WELDING (PAW)

For the highest-quality welds, the GTAW and PAW processes find the widest application. For long runs or when a large amount of weld metal must be deposited and mechanization is feasible, the SAW process or, to a lesser extent, the GMAW process, is utilized. For general repairs, the SMAW process still enjoys the widest range of applications for out-of-position welding and for short runs, especially when time is critical and when readily portable equipment is utilized. Electrodes are easily transported in sealed 4.5 kg (10 lb) containers.

In addition to the SMAW process, the GMAW process has been gaining wider support and utilization since the introduction of the flux-cored arc welding (FCAW) process, a core wire variation of solid-wire welding. The cored wires are manufactured in smaller diameters to make the wires suitable for out-of-position welding and, especially, for many field and construction applications.

Repair Welding

---

Preliminary Assessment

Before attempting a repair, three factors must first be considered: material weldability, nature of the failure that prompted the repair, and involvement of any code requirements.

Base Metal Weldability

If the item to be repaired was not welded previously, then a special investigation may be necessary to determine weldability. Original documents and drawings are helpful in determining the specifications or description of the base metal. Some tests that can determine degree of weldability include the spark test, chemical analysis test, and simulated weld tests.

The spark test determines the approximate base metal chemistry for carbon steels. Full chemical analysis using drillings can accurately determine chemistry, but not necessarily the heat treatment history of the base metal. Simulated weld tests can determine some practical approaches to repair welding, but seldom give any absolute requirements. These tests require samples of some of the base metal from the workpiece to be repaired.

Nature of Failure

When designing and producing a successful repair, it is often necessary to assess the reasons that a repair is required. Failures can be grouped into four major categories:

- BASE-METAL DEFECTS
- BASE-METAL STRENGTH DEFICIENCIES
- FAILURES INTRODUCED DURING FABRICATION
- DEFECTS CAUSED BY ABRASION, CAVITATION, CORROSION, OR EROSION

Base-Metal Defects. During or subsequent to fabrication, defects in the base metal may be detected. Defects can include pits, stringers, slivers, and a variety of internal discontinuities, the latter of which may be discovered when sawing through the base metal or subjecting the base metal to nondestructive testing (NDT).

Base-Metal Strength Deficiencies. Weld repair alone may not adequately repair a structure that has been overloaded. Reduction of load and additional reinforcing may be necessary. The loading and member arrangement should be thoroughly investigated. Repair of a crack or other structural discontinuity may involve repairing the crack as a weld repair and adding reinforcing plates or members to the workpiece by welding.

Weld Failure if Fabricated. Repair may be required on weld joints that have failed structurally or have undergone nondestructive evaluation (NDE), but do not meet soundness criteria. In these cases, it is usually prudent to prepare the joint for rewelding with procedures similar to the original welding operations.

Defects Caused by Abrasion, Cavitation, Corrosion, and Erosion. Buildup of the workpiece to repair surface damage that is due to abrasion, cavitation, corrosion, or erosion can be carried out as a weld repair. These conditions may or may not be associated with an original weld. The same weldability problems associated with structural repairs are encountered with the defects induced by these conditions. The article "Cladding, Hardfacing, and Dissimilar Metal Joining" in this Volume addresses the conditions that produce these defects in much more detail.

Codes and Standards

Repairs may be governed by welding or construction standards. Some codes address repair welding requirements as a specific subject and others simply require welding qualification that would apply to both new and repair welding. Organizations such as the American Society of Mechanical Engineers (ASME), American Welding Society (AWS), American Petroleum Institute (API), and military standards (MIL-STD) publish their own codes. Owner or engineer approval of repair welding procedures may be required by contract specifications.

Welding Process Selection

When selecting a welding process for a specific application, several factors that affect productivity and weld quality must be balanced. Selection can be difficult because each process has a number of conflicting advantages and limitations in specific situations.

Productivity is usually not an important consideration on most repair jobs. Each process can be ranked in terms of its deposition rate in kilograms (pounds) of weld metal deposited per hour. However, there are other factors that must be considered, as a minimum, before selecting a welding process:

- BASE-METAL TYPE
- JOINT DESIGN AND THICKNESS
- WELDING POSITION
- ENVIRONMENTAL CONDITIONS

- EQUIPMENT AVAILABILITY

Base-Metal Type. Some processes are better suited for use with certain base materials. The maximum heat input must be limited on certain types of materials, such as heat-treated materials that have been quenched, tempered, and age hardened, as well as other heat-treated or cold-worked materials. Processes that derive their advantage from high productivity and high heat input may be unsuitable for these applications.

Joint Design and Thickness. As section thickness increases, welding productivity becomes more important, which should be reflected in the process selection. The length of the weld must also be considered, because a higher-productivity process may not realize this advantage, particularly if the operator must frequently stop the process in order to set up the next pass, as would be necessary with a small repair. Because some processes require more access to the joint root to avoid fusion defects, the selection of some processes may also require a joint design change.

Welding Position. The weld joint position is very important in terms of process selection, because many processes are limited to only a few positions. Whenever possible, the joint should be in the flat (1G) position, because the highest productivity and weld quality are attained when welding is accomplished in this position. Because most field repair work is done on large weldments that cannot be repositioned and because access to the joint is limited, the use of high-productivity processes and filler materials is also limited.

Environmental Conditions. Wind and rain are the two conditions that typically affect field welding. It takes very little wind to disturb the gas shield that is critical for high-quality GMAW and GTAW processes. This restricts their use outside of sheltered containments. The SMAW and FCAW processes can also be affected by wind, but to a lesser degree. Because no process ever tolerates direct exposure to rain, the proper placement of tarps, dams, or other temporary containments is in order.

Availability of Equipment. Most large welding shops have access to the welding equipment required for the processes discussed. However, there are occasions when new equipment must be evaluated to determine if its increased productivity or versatility would offset the capital expense of its initial cost and training.

A general comparison of the most commonly used processes relative to some of the factors discussed above is provided in Table 1. Although some of the ratings are very subjective, they do provide a general guideline for many applications.

TABLE 1 RATING OF SELECTED WELDING PROCESSES AS A FUNCTION OF WELD PARAMETERS AND CHARACTERISTICS

PARAMETER OR CHARACTERISTIC	PROCESS				
	SMAW	**GTAW**	**GMAW**	**FCAW**	SAW
WELD QUALITY	GOOD	EXCELLENT	EXCELLENT	GOOD	**EXCELLENT**
WELD DEPOSITION RATE	FAIR	POOR	GOOD	GOOD	**EXCELLENT**

Base-Metal Preparation

Methods of preparing base metal for repair welding may vary, depending on the specific metal to be welded. Generally, all coatings in the vicinity of the repair weld should be removed. Coatings can cause defective welds and can become surface contaminants when heated to the temperatures required for welding.

Where cracks are to be excavated and the part rewelded, a welding groove should be prepared. Most base metals can be cut or grooved using air-carbon arc cutting (CAC-A). Table 2 shows some parameters for carbon arc cutting, whereas Fig. 1 shows a typical joint preparation using the CAC technique. It should be noted that the groove must be prepared in such a way as to allow adequate access to the root of the joint. This preparation is sometimes described as "canoe-shaped." Additional information on this cutting process is provided in the article "Air-Carbon Arc Cutting" in this Volume.

TABLE 2 RECOMMENDED CURRENT RANGE FOR SELECTED SIZES OF AC AND DC ELECTRODES USED FOR CARBON ARC GOUGING AND CUTTING IN AIR

ELECTRODE DIAMETER		CURRENT, A
MM	**IN.**	
DIRECT-CURRENT ELECTRODES (DCEP POLARITY)		
3.2	$\frac{1}{8}$	**30-60**
4.0	$\frac{5}{32}$	**90-150**
4.8	$\frac{3}{16}$	**200-250**
6.4	$\frac{1}{4}$	**300-400**
7.9	$\frac{5}{16}$	**350-450**
9.5	$\frac{3}{8}$	**450-600**

(A) FLAT

FIG. 1 USE OF AIR-CARBON ARC CUTTING TO PRODUCE A GROOVE IN A PLATE. ELECTRODE HOLDER IS EQUIPPED WITH A JET OF COMPRESSED AIR IN LINE WITH THE ELECTRODE TO BLOW AWAY THE MOLTEN METAL.

Grooves can also be prepared by grinding. However, grinding particles left on a groove surface can cause problems, especially in nonferrous materials. The proper grinding wheels must be carefully selected. Carbon arc cutting usually leaves some undesirable by-product on the cut surfaces. A grinding operation following CAC is necessary to remove this layer.

Repair Welding

Guidelines for Various Base Metals

Each group of base metals has specific general repair guidelines that must be followed to ensure successful weld repairs of both ferrous (carbon steels, cast irons, and stainless steels) and nonferrous (for example, titanium) base metals.

Low-Carbon Steel

The most commonly welded group of materials is that which has a carbon-manganese-iron base and is known as mild, or low-carbon, steel. They constitute the bulk of construction materials used today and are the common choice for equipment and fabricated component assemblies, because of their weldability.

Mild steels (up to 0.25% C) are readily weldable and, in cross sections of less than 50 mm (2 in.), usually do not require any preheat or postweld heat treatment. Hardened heat-affected zones (HAZ) are not a problem, and cracking is nonexistent when electrodes are used from fresh containers or electrode storage ovens and are dry. American Welding Society specification A5.1, "Carbon Steel Electrodes for Shielded Metal Arc Welding," covers the filler metals of choice for greater than 50% of all welding fabrication and repair work performed in the world. With the greater demand for higher-production deposition rates, continuous welding wire has grown in usage and application areas.

AWS specifications A5.17 ("Carbon Steel Electrodes and Fluxes for Submerged Arc Welding"), A5.18 ("Carbon Steel Filler Metals for Gas-Shielded Arc Welding"), and A5.20 ("Carbon Steel Electrodes for Flux-Cored Arc Welding") have gained wide support for automatic, semiautomatic, and mechanized welding processes.

Electrodes that are not suitably protected nor kept dry in an electrode storage oven can absorb moisture, which is released as hydrogen gas during the welding process. This hydrogen gas is entrapped in the solidifying weld metal, resulting in immediate or delayed cracking and expensive repairs. When abrasion, friction, or sliding wear is the reason for equipment downtime, either AWS specification A5.13 ("Solid Surfacing Welding Rods and Electrodes") or A5.21 ("Composite Surfacing Welding Rods and Electrodes") is the first choice in the selection process to deposit and build up a resistant

surface capable of withstanding the original wear phenomena in the most severe working environment. In addition, there are numerous electrodes of proprietary composition on the market that perform satisfactorily in service. These electrodes require evaluation and testing before being used.

Base-metal preparation usually consists of removing paint, mill scale, rust, or grease, because they contribute to porous welds. When making field repairs, especially in high-humidity areas, it is always a good practice to apply a preheat in the range from 120 to 150 °C (250 to 300 °F). Postweld heat treatment, though normally not required on mild steels, is sometimes used to ensure dimensional stability where close, flat tolerances are required.

Medium-Carbon Steels

Steels containing from 0.25 to 0.60% C and 0.25 to 1.65% Mn are classified as medium-carbon steels. Based on their base-metal mechanical properties, the electrodes in AWS specification A5.1 usually suffice in most applications.

The use of preheat, interpass temperature, and postweld heat treatment is always required to ensure fusion of the base metal and the weld metal, to prevent distortion, and to ensure dimensional stability of the finished product. Depending on chemical composition, the preheat temperature ranges from 120 to 205 °C (250 to 400 °F). Postweld heat treatment for this group of materials ranges from 595 to 620 °C ± 14 °C (1100 to 1150 °F ± 25 °F). The AWS electrode specifications listed for mild steels are suitable for repairing medium-carbon steels.

High-Carbon Steels

High-carbon steels have a carbon content ranging from 0.60 to 1.00% C. These metals require preheats in the range from 205 to 260 °C (400 to 500 °F), interpass temperatures from 205 to 290 °C (400 to 550 °F), and postweld heat treatments from 620 to 650 °C (1150 to 1200 °F).

Because of the higher carbon content of these steels, greater care must be exercised when welding and during subsequent heat treatment. The HAZ has a higher hardness and cooling must be controlled to preclude any chilling effects that could result in fusion line cracking.

For steels in the annealed or normalized condition, the welding electrodes listed for mild steels will suffice, based on mechanical properties. In the heat-treated condition (that is, higher strength levels), the repair may require stronger filler metal as provided by AWS specifications A5.5 ("Low Alloy Steel Covered Arc Welding Electrodes"), A5.23 (Low Alloy Steel Electrodes and Fluxes for Submerged Arc Welding"), A5.28 ("Low Alloy Steel Filler Metals for Gas-Shielded Arc Welding"), and A5.29 ("Low Alloy Steel Electrodes for Flux Cored Arc Welding").

Cast Irons

Cast irons are a family of high-carbon iron-base alloys containing from 2 to 4% C, 0.50 to 2% Si, and varying amounts of added manganese and chromium strengtheners, in addition to other elements that control graphite formation.

The most common members of this family are the gray cast irons (flake graphite) described in ASTM specification A 48. They are primarily carbon-manganese-silicon in content and no other elements are deliberately added. These materials have tensile strengths ranging from 140 to 415 MPa (20 to 60 ksi) with nil yield ductility and elongations less than 0.5%. Because of this characteristic, they are most difficult to weld and usually suffer from fusion line cracking, because of the presence of carbides formed by the flake graphite. If the broken area (cracked zone) can be placed in compression, then the chance of a successful repair is significantly improved.

Ductile cast irons, clearly identified by the presence of nodular graphite in their microstructure, are sometimes called nodular irons or spheroidal-graphite cast irons. ASTM A 536 grades 60-40-18 through 120-90-02 (designations indicate tensile strength in units of ksi, yield strength in ksi, and elongation in percent, respectively) have better ductility, which makes them more readily weldable by the higher-strength filler metals.

Malleable irons, described in specification ASTM A 47 (ferritic malleable iron castings), A 220 (pearlitic malleable irons), and A 602 (automotive malleable iron castings), are generally weldable and do not suffer the same problems that gray irons have.

The welding processes suitable for repair work are identified in AWS specification D11.2 ("Guide for Welding Iron Castings"):

- SHIELDED METAL ARC WELDING
- GAS-METAL ARC WELDING
- FLUX-CORED ARC WELDING
- GAS-TUNGSTEN ARC WELDING
- SUBMERGED ARC WELDING

The gas processes used for the repair of iron castings are oxyfuel welding (OFW) and braze welding, which utilizes specific filler metals of AWS specification A5.8 ("Filler Metals for Brazing"). The group of welding electrodes used for the arc welding of cast irons is described in AWS specification A5.15 ("Welding Electrodes and Rods for Cast Iron").

Stainless Steels

Stainless steel is a generic term encompassing three distinct families of iron-base alloys:

- AUSTENITIC STAINLESS STEELS
- FERRITIC STAINLESS STEELS
- MARTENSITIC STAINLESS STEELS

The rules for the repair welding of stainless steels will vary with the composition and physical characteristics of the material.

Austenitic stainless steels can be welded by the SMAW process, using electrodes listed in AWS specification A5.4 ("Stainless Steel Electrodes for Shielded Metal Arc Welding"). The GMAW, GTAW, FCAW, SAW, and PAW processes use electrodes listed in AWS specification A5.9 ("Bare Stainless Steel Welding Electrodes and Welding Rods"). SAW process fluxes of proprietary composition are available from manufacturers.

Austenitic stainless steels are usually not preheated and are readily weldable, but they must be clean and free from contamination to ensure weld-metal quality. The free-machining sulfurized grades and those containing selenium or phosphorus are generally not weldable. The titanium or niobium-plus-tantalum stabilized grades of types 318, 321, 347, and 348 have altered chemistries to prevent intergranular precipitation upon heating to a temperature-sensitizing range, such as occurs in welding. The selection of a suitable electrode is critical, and the steel manufacturer or electrode manufacturer should be consulted for the latest technology. Because of their lower thermal conductivity and higher electrical resistivity, stainless steel welds require from 20 to 30% less heat input to prevent weld cracking, loss of corrosion resistance, warping, and undesirable changes in mechanical properties.

The GMAW and GTAW processes use argon gas for a cool, stable arc and helium for a hotter, deeper-penetrating, but somewhat unstable arc. Table 3 lists various combinations of base metal and filler metal that are suitable for a variety of service conditions. This table is an excellent starting point for any repair.

TABLE 3 ELECTRODES OR WELDING RODS AS FILLER METALS FOR USE IN ARC WELDING OF STAINLESS STEELS

Source: Ref 1

(A) 1, AS WELDED; 2, ANNEALED; 3, HARDENED AND STRESS RELIEVED; 4, STRESS RELIEVED; 5, STABILIZED AND STRESS RELIEVED.

(B) PREFIX E OR ER OMITTED.

(C) TYPE 308 WELD METAL IS ALSO REFERRED TO AS 18-8 AND 19-9 COMPOSITION. ACTUAL WELD ANALYSIS REQUIREMENTS ARE: 0.08% C MAX, 19.0% CR MIN, AND 9.0% NI MIN.

(D) TYPE 310 (1.50% SI MAX) MAY BE USED AS FILLER METAL, BUT THE PICKUP OF SILICON FROM THE BASE METAL MAY RESULT IN WELD HOT CRACKING.

(E) FREE-MACHINING BASE METAL WILL INCREASE THE PROBABILITY OF HOT CRACKING OF THE WELD METAL. TYPE 312 FILLER METAL PROVIDES WELD DEPOSITS THAT CONTAIN A LARGE AMOUNT OF FERRITE TO PREVENT HOT CRACKING.

(F) WELDS MADE WITH TYPES 316, 316L, 317, AND 317CB ELECTRODES OR WELDING RODS MAY OCCASIONALLY DISPLAY POOR CORROSION RESISTANCE IN THE AS-WELDED CONDITION. IN SUCH CASES, CORROSION RESISTANCE OF THE WELD METAL MAY BE RESTORED BY THE FOLLOWING HEAT TREATMENTS: FOR TYPES 316 ANE 317 BASE METAL, FULL ANNEAL AT 1065 TO 1120 °C (1950 TO 2050 °F); FOR TYPES 316L AND 317L BASE METAL, 870 °C (1600 °F) STRESS RELIEF; FOR TYPE 518 BASE METAL, 870 TO 900 °C (1600 TO 1650 °F) STABILIZING TREATMENT. WHERE POSTWELD HEAT TREATMENT IS NOT POSSIBLE, OTHER FILLER METALS MAY BE SPECIALLY SELECTED TO MEET THE REQUIREMENTS OF THE APPLICATION FOR CORROSION RESISTANCE.

(G) TYPE 321 COVERED ELECTRODES ARE NOT REGULARLY MANUFACTURED, BECAUSE TITANIUM IS NOT READILY RECOVERED DURING DEPOSITION.

(H) CAUTION IS NEEDED IN WELDING THICK SECTIONS, BECAUSE OF CRACKING PROBLEMS IN HEAT-AFFECTED ZONES.

(I) IN BASE METAL AND WELD METAL, FOR NUCLEAR SERVICE, TANTALUM IS RESTRICTED TO 0.10% MAX AND COBALT TO 0.20% MAX.

(J) ANNEALING SOFTENS AND IMPARTS DUCTILITY TO HEAT-AFFECTED ZONES AND WELD. WELD METAL RESPONDS TO HEAT TREATMENT IN A MANNER SIMILAR TO THE BASE METAL.

(K) THESE AUSTENITIC WELD METALS ARE SOFT AND DUCTILE IN AS-WELDED CONDITION, BUT THE HEAT-AFFECTED ZONE WILL HAVE LIMITED DUCTILITY.

(L) REQUIRES CAREFUL PREHEATING AND POSTWELD HEAT TREATMENT TO AVOID CRACKING.

(M) REQUIRES CAREFUL PREHEATING. SERVICE IN AS-WELDED CONDITION REQUIRES CONSIDERATION OF HARDENED HEAT-AFFECTED ZONES.

(N) ANNEALING INCREASES DUCTILITY OF HEAT-AFFECTED ZONES AND WELD METAL. TYPE 405 WELD METAL CONTAINS NIOBIUM, RATHER THAN ALUMINUM, TO REDUCE HARDENING.

(O) ANNEALING IS EMPLOYED TO INCREASE DUCTILITY OF THE WELDED JOINT.

(P) TYPE 308 FILLER METAL WILL NOT DISPLAY SCALING RESISTANCE EQUAL TO THAT OF THE BASE METAL. CONSIDERATION MUST BE GIVEN TO DIFFERENCES IN THE COEFFICIENTS OF THERMAL EXPANSION OF THE BASE METAL AND THE WELD METAL.

Ferritic stainless steels (types 446, 430, 405, and 409) are generally less weldable than the austenitic grades. Preheat temperatures ranging from 150 to 230 °C (300 to 450 °F) are necessary to prevent weld cracking, warping, and other serious repair problems. Postweld heat treatment ranging from 790 to 815 °C (1450 to 1500 °F) is necessary to transform a mixed structure to a wholly ferritic structure and to restore the mechanical properties and corrosion resistance that were seriously affected by the heat of welding. The filler metals in Table 3 apply to these grades of stainless steels, as well.

Martensitic stainless steels (types 403, 410, 414, 420, and the 440 series) are weldable with adequate preheat and interpass temperature control ranging from 205 to 315 °C (400 to 600 °F). To restore mechanical properties and reduce the hardened HAZ, a postweld heat treatment ranging from 650 to 675 °C (1200 to 1250 °F) is commonly used to restore properties and reduce internal welding stresses. Austenitic electrodes are used for minor repairs or when properties are not the prime consideration (see Table 3).

Precipitation-hardening stainless steels are divided into three groups on the dual basis of characteristic alloying additions, particularly the elements added to promote precipitation hardening (PH), and the matrix structures of the steels in the solution-annealed and aged condition. Differences among the steels have a direct bearing on the behavior of the steels in welding.

Martensitic Precipitation-Hardening Steels. These steels have a predominantly austenitic structure at the solution-annealing temperature of approximately 1040 to 1065 °C (1900 to 1950 °F), but they undergo an austenite-to-martensite transformation when cooled to room temperature. These steels can be readily welded. The welding procedures resemble those ordinarily used for the 300-series stainless steels, despite differences in composition and structure between the two classes.

The selection of filler metal depends on the properties required for the welded joint (Table 4). If strength comparable to that of the base metal is not required at the welded joint, then a tough 300-series stainless steel filler metal may be adequate. When a weld having mechanical properties comparable to those of the hardened base metal is desired, the filler metal must be of comparable composition, although slight modifications are permissible to obtain better weldability.

TABLE 4 RECOMMENDED FILLER METALS FOR WELDING PRECIPITATION-HARDENING STAINLESS STEELS

Source: Ref 2

Semiaustenitic Precipitation-Hardening Steels. Unlike martensitic PH steels, semiaustenitic PH steels are soft enough in the annealed condition to permit cold working. When cooled rapidly from the annealing temperature to room temperature, they retain their austenitic structure, which displays good toughness and ductility in cold-forming operations.

The semiaustenitic PH steels are normally welded in the annealed condition. The tough austenitic structure imparts welding characteristics similar to those of 300-series stainless steels. The semiaustenitic PH steels are not susceptible to cracking when welded after transformation to martensite, because the low-carbon martensite developed is not of high hardness or low ductility. Also, cold cracking does not occur in the base metal adjacent to the weld because the HAZ is austenitized during welding and remains substantially austenitic as the joint cools to room temperature.

The choice of filler metal depends largely on the weld properties desired. The filler metal can be an alloy of precipitation-hardening composition that is capable of developing mechanical properties comparable to those of the base metal (Table 4). If high strength is not required, then the filler metal can be a 300-series austenitic stainless steel. When these steels are welded in the annealed condition, certain microstructural relations are generally obtained as a result of relatively rapid heating and cooling at the joint:

- WELD METAL CONTAINS SMALL AMOUNTS OF FERRITE IN AN ESSENTIALLY AUSTENITIC MATRIX; HARDNESS IS APPROXIMATELY 90 HRB
- BASE METAL IMMEDIATELY ADJACENT TO THE WELD DISPLAYS HIGH-TEMPERATURE ANNEALED (AUSTENITIC) STRUCTURE; HARDNESS IS APPROXIMATELY 90 HRB
- BASE METAL IN THE NARROW ZONE JUST BEYOND THE ANNEALED ZONE NEXT TO THE WELD IS HARDENED SLIGHTLY; HARDNESS IS APPROXIMATELY 90 TO 98 HRB

Austenitic Precipitation-Hardened Steels. The alloy content of these steels is high enough to maintain an austenitic structure after annealing and after any aging or hardening treatment. Although the austenitic PH steels remain austenitic during all phases of forming, welding, and heat treatment, some contain alloying elements (for precipitation-hardening purposes) that greatly affect behavior in welding.

The austenitic PH stainless steels can be welded using the arc welding techniques applied when welding the austenitic stainless steels. The major difference is that these steels are usually heat treated after welding to achieve the required mechanical properties, which is usually unnecessary with austenitic PH stainless steels. Austenitic PH stainless steels can be welded with matched or dissimilar filler metals or without filler metals, as in the case of most stainless steels. There is a wide variety of hardenable filler metals available for these PH grades through the manufacturer of consumables. The most commonly used grade is the AWS A5.4 Class E630/AWS A5.9 Class ER630 alloy, the only one currently included in the AWS specifications. Its composition is shown in Table 5.

TABLE 5 COMPOSITION OF WELDING CONSUMABLES FOR PRECIPITATION-HARDENING STAINLESS STEELS

All data are maximum percentages.

AWS CLASSIFICATION	COMPOSITION, %									
	C	**Cr**	**Ni**	**Mo**	**Nb + Ta**	**Mn**	**Si**	**P**	**S**	Cu
E630[A], ER630[B]	**0.05**	**16.0-16.75**	**4.5-5.0**	**0.75**	**0.15-0.30**	**0.25-0.75**	**0.75**	**0.04**	**0.03**	**3.25-4.00**

Duplex Stainless Steels (Ref 3, 4, 5). The physical and mechanical properties of duplex (ferritic-austenitic) stainless steels affect the welding process. Because of their better stress-corrosion cracking resistance and appreciably higher yield and tensile strengths, these steels are currently used as direct substitutes for austenitic stainless steels when service above about 260 to 315 °C (500 to 600 °F) is not required.

Because duplex stainless steels generally have a higher thermal conductivity and a lower coefficient of thermal expansion than austenitic stainless steels, they generally exhibit less distortion during welding than do austenitic stainless steels.

The general welding characteristics of the duplex alloy steels are very similar to those of austenitic stainless steels. They can be welded by any of the conventional arc welding processes (SMAW, GTAW, GMAW, PAW, and SAW). In addition, electron-beam and laser-beam welding are used, as well as resistance welding. Heat input should be low enough to minimize intergranular carbide precipitation. Surface cleanliness is a must when welding duplex stainless steels. It is necessary to eliminate any source of hydrogen in the welding operation. For the gas-shielded processes, particularly on pipe, argon-helium purge gas should be used.

Filler metal selection is critical. A filler metal with matching composition may result in a higher ferrite content than that of the base metal. Gooch (Ref 4) and others have shown that filler metals of duplex stainless steel with higher nickel and/or nitrogen are preferred. Weld metal cracking in duplex steels has rarely been identified. Because extensive austenite-to-ferfite and ferrite-to-austenite transformations occur in the HAZ, along with grain growth, the welding procedure must be carefully controlled. The extent of the above transformations greatly depends on the composition and the precise weld thermal cycle experienced by the HAZ during welding. Because of their high chromium level, these steels are prone to σ phase and 475 °C (885 °F) embrittlement. Though the weld thermal cycle is too short for σ-phase formation of 475 °C (885 °F) embrittlement to occur, care must be exercised in welding heavy-section steels of this type.

Titanium

Titanium is a reactive metal that requires special considerations before and during the welding cycle. The metal must be cleaned at least 50 mm (2 in.) beyond any gas shield. Abrasive blasting is an acceptable cleaning method. Chlorinated solvents (for example, trichloroethylene), should not be used for degreasing titanium alloys because the chlorine residues can result in intergranular cracking during subsequent heating operations.

Titanium alloys are most successfully welded in sealed chambers, although welding in air can be accomplished with a suitable trailing gas shield. Argon gas is the preferred gas for welding and is also used for welding in argon atmosphere chambers to protect the molten metal from oxidation.

The most commonly used process for repairing titanium components is GTAW, using AWS specification A5.12 Class EWTh2 and EWTh1 tungsten electrodes. Helium and argon-helium gas mixtures are also used when higher heat inputs are necessary for deeper penetration and when welding thicker sections. The GMAW process is also effectively applied on thicker parts (6.35 mm, or 0.25 in.) and large parts or when significant amounts of weld metal is to be deposited. Thirteen filler metals of pure and alloyed titanium are classified in AWS specification A5.16 ("Titanium and Titanium Alloy Welding Electrodes and Rods").

All grades of unalloyed titanium are welded in the annealed condition because annealing offsets the effect of cold working with its attendant loss of strength. Metastable beta alloys are welded in the annealed or solution-treated condition, where the welds are low in strength, but ductile. To obtain full strength, the weld is cold worked by peening or planishing and the weldment is solution treated and aged. Additional information can be found in the article "Welding of Titanium" in this Volume.

Fitness-for-Service Assessment of Welded Structures

J.R. Gordon, Edison Welding Institute

Introduction

IT IS GENERALLY ACCEPTED THAT all welded structures enter service containing flaws that can range from volumetric discontinuities, such as porosity or slag inclusions, to planar defects, such as a lack of side-wall fusion or

hydrogen cracks. For this reason, most welding codes include clauses that cover the inspection of production welds and set acceptance standards for the discontinuities that may be found. Any flaws that are not acceptable are repaired.

The acceptance standards included in the majority of codes are based on good workmanship practices. Although this is a very useful basis, in some cases it can result in the repair of relatively harmless flaws, with the possibility that the repair weld (often made under more-demanding conditions than the production weld) will contain a more-serious flaw. Since the early 1980s, a number of fracture mechanics-based assessment procedures have been developed that enable the significance of weld discontinuities to be assessed on a "fitness-for-service" basis. Using this concept, a structure is considered to be fit for service if it can be operated safely throughout its design life. The adoption of fitness-for-service concepts in several codes has resulted in the development of more-rational flaw-acceptance criteria.

Fitness-for-service assessment procedures also can be used to assess the integrity, or remaining life, of components in service. Indeed, one of the most widespread uses of fitness-for-service concepts is the justification of life extension, which is a term that has often been misunderstood. The purpose of life-extension activities is not to continue the operation of a plant beyond its useful life but merely to ensure full utilization up to its useful life. The idea is to avoid premature retirement of plants and plant components, on the basis of the so-called design life, because actual useful lives can often exceed the design life.

Overview of Failure Modes. Depending on the operating environment and the nature of the applied loading, a structure can fail by a number of different modes, including:

- BRITTLE FRACTURE
- DUCTILE FRACTURE
- PLASTIC COLLAPSE
- FATIGUE
- CREEP
- CORROSION
- BUCKLING

These failure modes can be broken down into the following broad categories:

- FRACTURE
- FATIGUE
- ENVIRONMENTAL CRACKING
- HIGH-TEMPERATURE CREEP

Fracture includes the conventional static failure modes, such as brittle fracture, ductile fracture, plastic collapse, buckling, as well as dynamic fracture. Fatigue failure is caused by cyclic loading. Environmentally assisted cracking includes corrosion, stress-corrosion cracking, hydrogen-induced cracking, and other environmentally assisted failure modes. High-temperature creep includes creep rupture and creep crack growth. This article discusses each of these categories, as well as the benefits of a fitness-for-service approach.

Fitness-for-Service Assessment of Welded Structures

J.R. Gordon, Edison Welding Institute

Fracture

Of all the conventional failure modes, brittle fracture is undoubtedly the most spectacular and dangerous mode of fracture, frequently occurring with no prior warning and with the potential to produce devastating consequences. The notched-bar impact test was one of the earliest tests developed to study the fracture behavior of steel. The most widely used impact

test, as of the early 1990s, is the Charpy impact test, the results of which are most useful when presented as a plot of absorbed energy or percentage shear fracture against test temperature (Fig. 1).

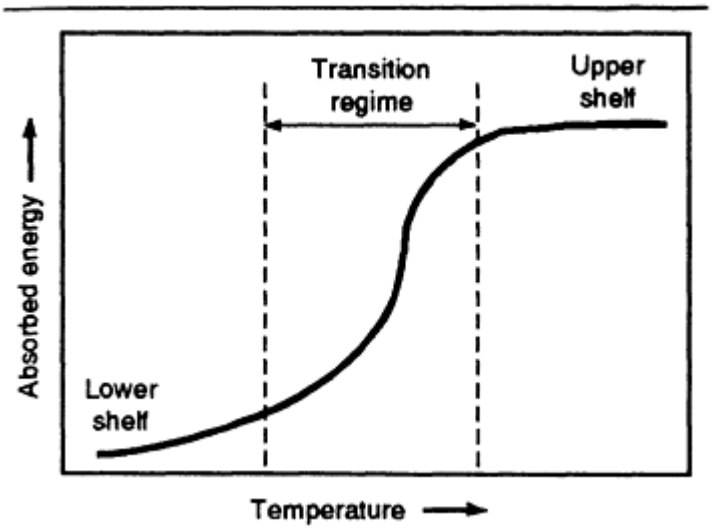

FIG. 1 TYPICAL CHARPY IMPACT ENERGY TRANSITION CURVE

In the case of ferritic steels, the subsequent results show fracture behavior that ranges from low-energy brittle fracture (lower shelf) to high-energy ductile fracture (upper shelf). Between these two modes of fracture, there is a transition regime, in which the fracture mode changes from brittle to ductile fracture as the temperature increases. In design, Charpy impact data are used to ensure that the material exhibits good toughness properties (that is, upper-transition or upper-shelf behavior) at the minimum operating temperature. Most design codes include Charpy impact toughness requirements to minimize the risk of structures failing by unstable fracture.

Although the Charpy impact test has received widespread acceptance, it has a number of drawbacks. First, unlike a tensile test, the results from notched-bar impact tests are highly dependent on specimen size. Larger specimens translate the transition curve to higher temperatures because of increased specimen constraint and sampling size.

Second, toughness is also a function of loading rate. In most structural applications, this rate is relatively low, whereas in a Charpy test, the specimen is subjected to impact loading. If Charpy specimens were tested under loading rates that were more representative of structural applications, then the transition curve could be translated to a lower temperature.

Third, Charpy specimens contain 2 mm (0.8 in.) deep V notches, which are relatively blunt. In comparison, structures can contain much sharper cracks, such as fatigue cracks. Increasing the notch acuity in a Charpy specimen would cause the transition curve to shift to a higher temperature.

Fracture comprises two phases: initiation and propagation. Initiation is defined as the first extension of an existing defect, whereas propagation is the continued extension thereafter. Which of these phases is the most important depends on the material and the structural application. Unfortunately, the Charpy impact test does not distinguish between these two phases; that is, it just provides an indication of the energy necessary to initiate and propagate a crack.

Thus, although the Charpy impact test is widely accepted by engineers and designers because it can indicate the "quality" of a material, its most-significant shortcoming is that the results cannot be used in any quantitative sense to assess the significance of flaws in a structure. Fracture mechanics can, to a certain extent, bridge the gap between the measurement of material properties and their application to design.

Fracture Mechanics Assessment Procedures. As shown in Fig. 2, fracture mechanics seeks to relate the three parameters that combine to control the fracture process. These parameters are: the size of the discontinuity, material toughness, and the applied stress.

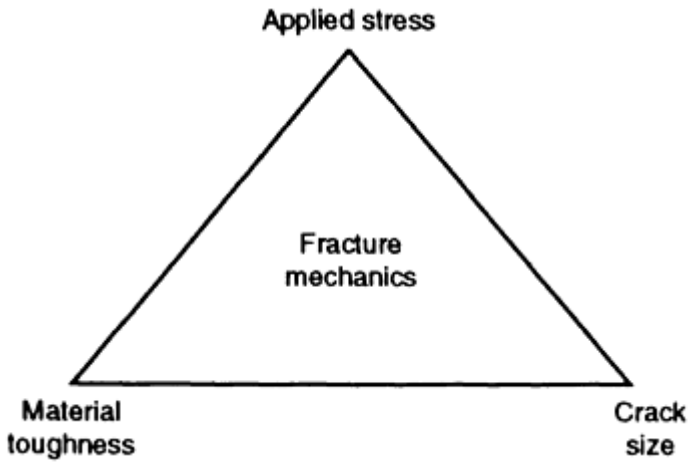

FIG. 2 ROLE OF FRACTURE MECHANICS

If any two of these three parameters are known, then it is possible, using the principles of fracture mechanics, to estimate the value of the third parameter that will elicit the failure of the structure. Alternatively, if all three parameters are known, then it is possible to predict whether or not the structure is fit for service, and, if it is, estimate the margin of safety.

Figure 3 summarizes the different loading paths that can result in the failure of a structure (assuming that fatigue, creep, and corrosion effects are not significant). The loading paths range from brittle fracture under nominally elastic loading (applied stresses well below yield) to plastic collapse (overload of remaining ligament). In cases where brittle fracture occurs at low applied stresses, the concept of linear-elastic fracture mechanics (LEFM) can be applied, that is, a stress-intensity factor, *K*, approach. At the other extreme, when the failure mechanism is plastic overload, then assessments should be performed using limit load or plastic-collapse analyses.

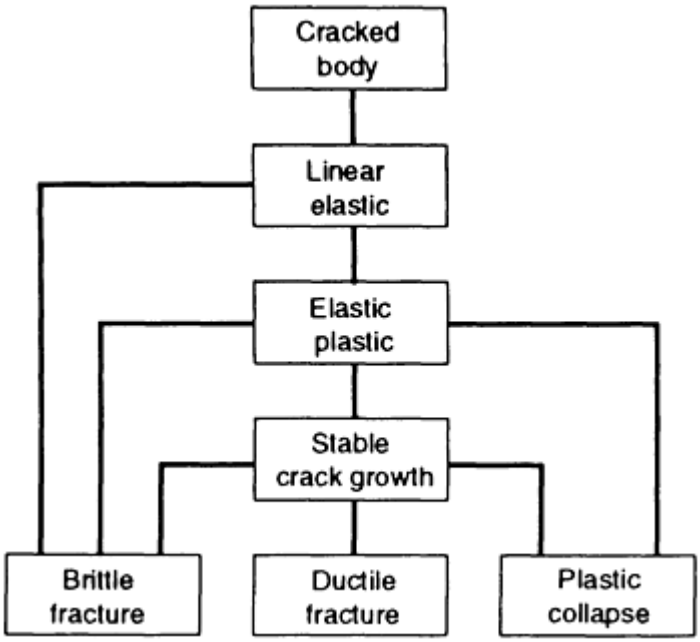

FIG. 3 SUMMARY OF LOADING PATHS TO FAILURE

Between these two extremes, elastic-plastic fracture mechanics (EPFM) methods can be applied to assess the integrity of structures. The two most common EPFM fracture-characterizing parameters are the crack-tip opening displacement (CTOD) and the J-integral, *J*. Fitness-for-service methodologies have been developed using both of these parameters.

A number of different fitness-for-service assessment methodologies for calculating allowable or critical flaw sizes are currently in use throughout the world, such as those cited in Ref 1, 2, 3, 4, 5.

Failure-Assessment Diagrams. The concept of performing fitness-for-service assessments using a failure-assessment diagram (FAD) was first proposed in 1975. These diagrams provide a convenient method of assessing the risk of failure by brittle fracture, ductile fracture, or plastic collapse, that is, all the loading/failure paths presented in Fig. 3. As a result, most of the widely used fracture assessment methodologies are now based on FADs. Although the exact form of the FADs in the different assessment procedures can vary, the basic concept of the FAD is identical; that is, the *y*-axis (K_r axis) of a FAD provides an indication of the resistance of the structure to brittle fracture, whereas the *x*-axis (S_r axis) assesses resistance to plastic collapse. The failure-assessment curve interpolates between these two limiting failure modes, as shown in Fig. 4.

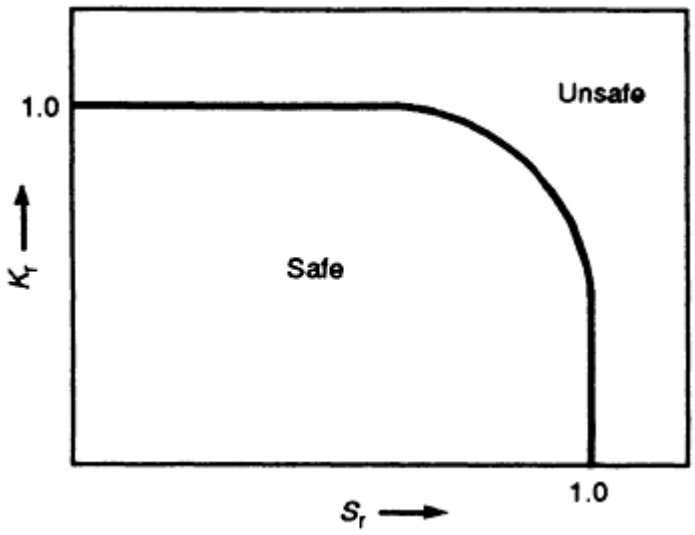

FIG. 4 BASIC CONCEPT OF FAILURE-ASSESSMENT DIAGRAM

To perform a structural integrity assessment, the user plots assessment points on the FAD. The location of each point is a function of the applied loading conditions, flaw size, material properties, and other factors.

Although the exact procedures for calculating assessment points can vary from procedure to procedure, the general procedure to determine an assessment point is as follows:

$$K_t = \frac{k_I}{k_{mat}} \qquad \textbf{(EQ 1)}$$

$$S_t = \frac{s}{s_{pc}} \qquad \textbf{(EQ 2)}$$

where K_I is the applied stress intensity for crack under consideration subjected to the primary and secondary loading conditions of interest; K_{mat} is the material toughness (for example, K_{Ic}); σis the applied primary stress; and σ_{pc} is the plastic collapse stress for the component under consideration.

It should be noted from the above equations that secondary stresses (for example, welding residual stresses or thermal stresses) are incorporated in the calculation of the K_r coordinate but are not included in the calculation of S_r because, by definition, secondary stresses are self-equilibrating and, as a result, cannot contribute to plastic collapse.

Although fracture assessment procedures have improved significantly in recent years due to the advances in fracture mechanics, there are still a number of issues, particularly with regard to performing fracture assessments of welded structures, that have not been fully resolved. It should be noted that the current fracture assessment procedures are

generally unsafe. The unresolved issues tend to make current predictions conservative. A better understanding of these complexities would merely make analyses of critical conditions more accurate.

The major unresolved issues with regard to applying fracture mechanics assessment procedures to welded structures are undoubtedly weld metal mismatch and welding residual stresses. When designing a welded structure, it is normal practice to specify welding consumables with a higher yield strength than the surrounding parent material to avoid the possibility of localized plastic straining in the weld metal. Conversely, there are a number of materials that can only be welded successfully with consumables that will give rise to undermatching welds. This is becoming more common with the increasing use of high-heat-affected zone (HAZ), and parent material cannot be taken into account in the currently available fracture assessment models, it is normal practice to assume the tensile properties of the material in which the defect is located (that is, if a crack is located in the weld metal, the assessment is performed assuming the tensile properties of the weld metal). In reality, the difference in tensile properties between the different weld regions will influence how plasticity develops at defects and, hence, the relationship between crack driving force and applied loading. This can lead to significant errors in a fracture assessment.

At present, the only method of performing an accurate fracture assessment of under or overmatched welded joints is to perform a detailed finite-element analysis to compute the applied crack driving force. This level of sophistication is clearly excessive in situations where assessments of simple welded components are required on a regular basis. Research is required to investigate the effect of weld metal mismatch on the accuracy of fracture prediction models. Results from such research will hopefully lead to the proposal of modifications to fracture assessment models to account for weld metal mismatch.

Another unresolved issue, which, again, is particularly relevant to welded structures, concerns the estimation (prediction) and incorporation of residual stresses (or secondary stresses) in fracture assessment models. The major problem is that there is no quick or convenient method of measuring or predicting the through-thickness variation of residual stresses in a welded joint. Consequently, in the absence of definitive measurements, it is common practice to assume that residual stresses in an as-welded structure are both tensile and yield strength in magnitude. Moreover, it is common practice to assume that the residual stresses are uniform across the section under consideration, despite the fact that the assumed residual stress distribution is not self-equilibrating. This, undoubtedly, leads to extremely conservative assessments, particularly when it is considered that the residual stress components frequently play a major role in an assessment. The other area of concern with regard to residual stresses is the relaxation of residual stresses with increasing primarily load (that is, mechanical stress relief). Although the latest version of PD 6493 includes a procedure for calculating the relaxation of secondary stresses with increasing primary load, there is concern that the method may still overestimate the subsequent residual stress levels.

If the assessment points lie within the area bounded by the axes of the failure-assessment diagram and the failure-assessment curve, then the structure is deemed to be safe. Alternatively, if the assessment points lie outside the FAD, then the structure is considered to be unsafe. This approach also can be used to determine the limiting flaw size by plotting a series of assessment points for different crack sizes. The limiting flaw size corresponds to the flaw size that results in the assessment locus intersecting the FAD, as shown in Fig. 5.

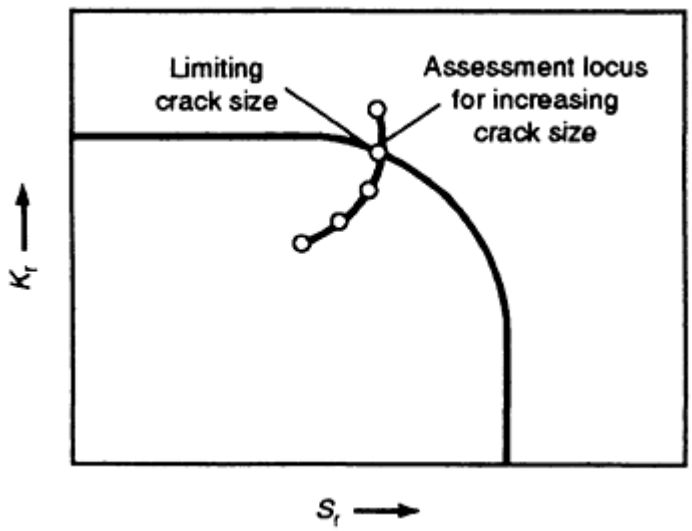

FIG. 5 ASSESSMENT PROCEDURE TO DETERMINE LIMITING CRACK SIZE

When performing fracture assessments, it is essential that the fracture-toughness values used in the assessment are representative of the material in which the crack is located (for example, parent material, weld metal, or heat-affected zone). Furthermore, the fracture-toughness values should be representative of the condition of the material or the welded joints in the structure. For example, if the material has suffered degradation, such as temper or hydrogen embrittlement, then tests should be performed on material/welded joints in the same condition. Finally, to ensure conservative assessments, the fracture-toughness tests should be performed at the minimum operating temperature of the structure.

Application of Fracture-Assessment Procedures. Fitness-for-service design philosophies can be applied to welded structures in several different ways. The most widely used approach is to develop relaxed flaw-acceptance criteria. These are typically derived by assuming a minimum toughness level that is incorporated in a weld procedure qualification. These relaxed flaw-acceptance criteria can result in significant economic savings and can accelerate construction schedules through a dramatic reduction in the number of repairs. Nevertheless, it should be emphasized that the adoption of fitness-for-service concepts should never be used to condone poor workmanship. The general quality of fabrication should remain constant, regardless of whether fitness-for-service concepts are applied.

Fitness-for-service concepts also can be used to develop inspection criteria, including sensitivity requirements. These concepts also can be used to demonstrate that flaws that may escape detection will not impair overall structural integrity, even under accident or overload conditions.

Fitness-for-Service Assessment of Welded Structures

J.R. Gordon, Edison Welding Institute

Fatigue Design

The fatigue life of a welded structure is almost invariably limited by the fatigue life of the weld details. As a result, the design stresses in welded structures that are subjected to cyclic loading are limited by the fatigue strength of the weld details. For this reason, extensive research has been undertaken in recent years to study the fatigue behavior of welded joints. This has culminated in a number of proposed methodologies to assess the fatigue behavior of different welded joint geometries. The most widely used procedure for assessing the fatigue performance of welded joints is the *S-N* curve approach.

In general, the fatigue life of a component is comprised of initiation and propagation phases. For smooth components, the crack-initiation period represents the bulk of the total fatigue life. This is particularly noticeable with high-fatigue applications, where the fatigue crack-initiation period may exceed 95% of the fatigue life. In the case of machined components, once a fatigue crack has grown to a detectable size, the component is virtually at the end of its useful life and would normally be withdrawn from service. In the case of welded joints, there is practically no crack-initiation period, because of the presence of weld-toe discontinuities, which behave as preexisting cracks. As a result, the bulk of the fatigue life of a welded joint can be attributed to fatigue-crack propagation.

The fatigue strength of unwelded components increases with material tensile strength. In the case of welded joints, however, the fatigue strength is relatively unaffected by material tensile strength, as shown in Fig. 6. This is because the bulk of the fatigue life of a welded joint is spent in the propagation phase and, although crack-propagation rates can change from one material to another, there is no consistent trend with regard to tensile strength. This indicates that the improved fatigue performance produced by increasing material tensile strength is limited primarily to the crack-initiation phase. As a result, increasing the material tensile strength will not improve the fatigue performance of welded joints.

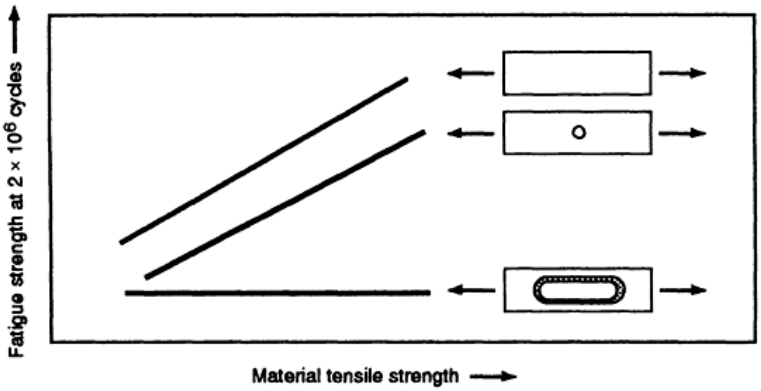

FIG. 6 EFFECT OF MATERIAL TENSILE STRENGTH OR THE FATIGUE STRENGTH OF WELDED AND UNWELDED SPECIMENS

The potential initiation sites at which fatigue cracks may develop in welded joints depends on the geometry of the joint details. Nevertheless, the most common initiation site, by far, is the weld toe. This is a particularly severe location, because of the geometric discontinuity that gives rise to a local stress concentration and the possible presence of undercutting and weld-toe intrusions (Ref 6, 7, 8, 9). The weld-toe intrusions that form as a result of the welding process are generally angular in nature and protrude below the plate surface. The precise origin of these discontinuities is not fully understood, although it has been suggested that they may be caused by slag or impurities in the steel.

Limited studies (Ref 6, 7, 8, 9) have indicated that the weld-toe discontinuities range in depth from 0.1 to 1.0 mm (0.004 to 0.04 in.). The depth of the weld-toe intrusions depends on a number of variables, including welding process, welding consumables, flux, and welding parameters. These studies have indicated that the average root radius of intrusions is from 2 to 3 μm (80 to 120 μin.), although root radii of less than 1 μm (40 μin.) have been recorded. In addition to the local stress concentration and the presence of sharp weld-toe discontinuities, the weld-toe region is also subjected to tensile residual stresses that form as a result of the thermal cycle associated with welding. Thus, the weld toe is a location of high local stress with preexisting crack-like discontinuities and large tensile residual stresses, which means that it is a prime source for fatigue cracks.

For this reason, the fatigue performance of welded joints is generally much lower than the fatigue performance of unwelded components, even if they contain stress concentrations (Fig. 7).

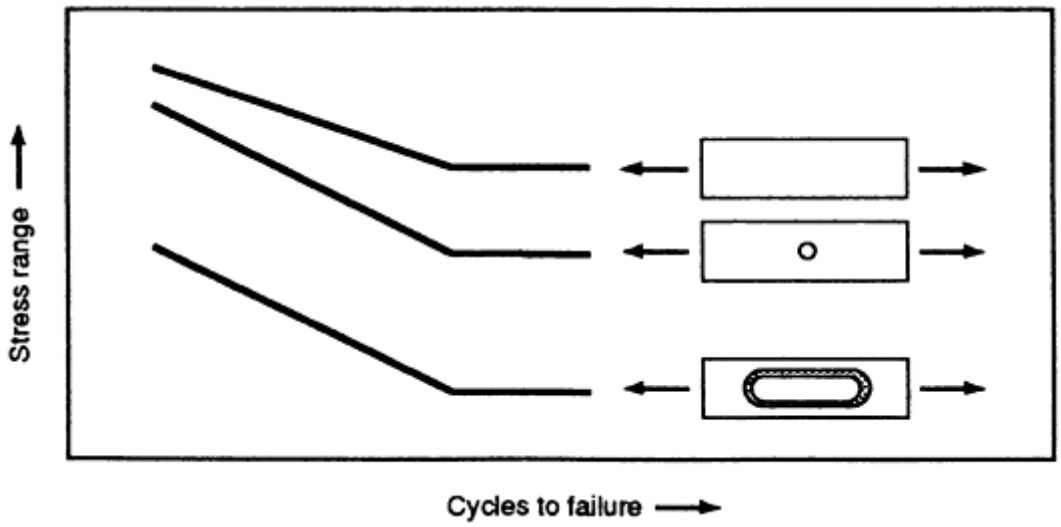

FIG. 7 RELATIVE FATIGUE BEHAVIOR OF WELDED JOINTS AND UNWELDED COMPONENT (WITH AND WITHOUT STRESS CONCENTRATORS)

The *S-N* curve approach is probably the most widely used method of assessing the fatigue performance of welded structures. The fatigue design rules proposed by Gurney in 1976 (Ref 10) provide a framework to assess the fatigue behavior of welded joints. Based on the results of an extensive welded joint fatigue test program, a series of *S-N* curves that incorporate a wide range of welded joint details was developed. Similar design approaches have now been included in many national and international codes and standards (Ref 11, 12, 13, 14). In a typical set of fatigue design curves (Fig. 8), the different classifications correspond to different welded joint geometries.

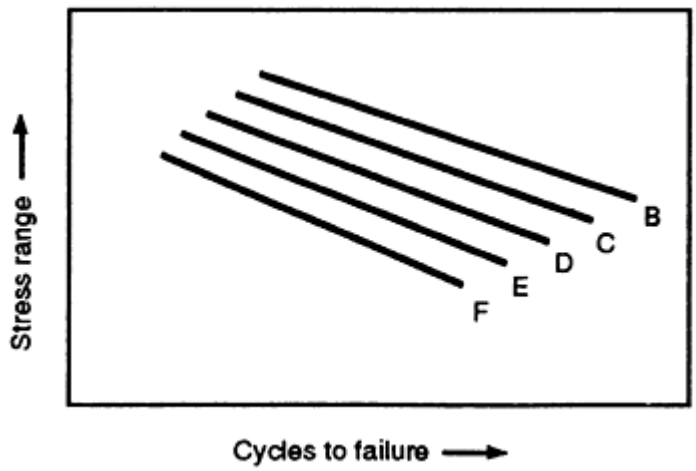

FIG. 8 SCHEMATIC OVERVIEW OF TYPICAL FATIGUE DESIGN RULES

Although the exact classification system can vary from code to code, the general approach is consistent. Most codes adopt a weld joint classification system that uses letters to denote different classes. In the original fatigue design rules proposed by Gurney, the following nine weld joint classifications were adopted: A, B, C, D, E, F, F2, G, and W; where class A is the parent material *S-N* curve obtained from uniform, machined, and polished specimens; class W is the welded joint *S-N* curve based on nominal shear stress on the minimum weld throat area; and classes B through G are the welded joint *S-N* curves for joints of decreasing fatigue performance.

S-N curves are used in design either to determine the maximum allowable cyclic stress for a given fatigue design life or to estimate design life for a given set of operating conditions.

Fracture-Mechanics Assessment Procedures. As already mentioned, the majority of the fatigue life of a welded joint is spent in the crack-propagation phase. Consequently, the analysis of fatigue cracking in welded joints is well suited to fracture mechanics, which can be used to predict the fatigue strength of nominally sound welds by considering the propagation of a fatigue crack from the inherent discontinuities that exist at the weld toe and the weld root. Fracture mechanics also can be used to predict the life of a joint with a weld discontinuity. The most widely accepted fatigue crack growth relationship is the Paris law (Ref 15), which can be expressed as:

$$\frac{da}{dN} = C(\Delta K)^m \qquad \textbf{(EQ 3)}$$

where ΔK is the applied stress-intensity factor range, a is the crack size, N is the number of cycles, and C and m are constants that depend on the material and environment.

Maddox (Ref 16) has carried out a series of fatigue crack propagation tests on various parent steels, weld metals, and heat-affected zone (HAZ) microstructures. He found that there was no significant variation in crack-propagation rates among any of the materials tested. The upper-bound crack-growth rate constants for ferritic steels operating in nonaggressive environments are given by:

$$C = 3.0 \times 10^{-13} \text{ AND } M = 3.0 \qquad \textbf{(EQ 4)}$$

For structural ferritic steels operating in marine environments up to 20 °C (68 °F), the following crack-growth constants can be used:

$$C = 2.3 \times 10^{-13} \text{ AND } M = 3.0 \qquad \textbf{(EQ 5)}$$

For design purposes, it is sometimes necessary to estimate the limiting flaw size that will not extend by fatigue during service. The limiting crack size, below which fatigue crack growth will not occur, can be calculated using fatigue-threshold concepts. The following threshold stress-intensity factor ranges have been proposed for carbon and carbon-manganese steels operating in air or seawater environments (Ref 1, 2):

$$\Delta K_0 = 5.44 - 6.85R \text{ MPA } \sqrt{m} \text{ FOR } 0 \le R \le 0.5$$
$$K_0 = 63 \text{ N}\sqrt{mm} \text{ FOR } 0.5 \le R \qquad \textbf{(EQ 6)}$$

where R is the stress ratio (that is, minimum stress divided by maximum stress). It should be noted that welding residual stresses must be taken into account when calculating the stress ratio. Using the above expressions, it is possible to calculate the limiting flaw size that will not extend by fatigue during service.

Fracture mechanics-based fatigue-assessment procedures can also be used to define inspection criteria and, in particular, inspection intervals. This is achieved by assuming the maximum flaw size that may escape detection and by specifying a critical crack size that should be detected to avoid unnecessary damage to the structure or the risk of failure. Using fracture mechanics-based fatigue crack growth procedures, the user can determine the number of cycles (or time) needed for the crack to extend from the initial size to the critical size.

The time for the crack to extend from its initial size to the critical size represents the maximum inspection interval (that is, if an inspection is not performed during this period, the structure could conceivably fail without any obvious warning). To guard against premature failure, it is normal practice to set inspection intervals that are considerably less than the maximum inspection interval. This will enable the operator to determine if cracks have initiated or extended during service before they have the potential of reaching a critical size.

After inspecting the component and sizing any defects/cracks that are present, the operator can determine a new maximum inspection interval for the component by calculating the time needed for the current cracks to extend to a critical size. Using this approach, an operator may specify decreasing inspection intervals for a component that is experiencing in-service cracking. Another reason for specifying inspection intervals that are considerably less than the

maximum inspection interval is that it provides the operator with an opportunity to evaluate the validity of the assessment and the initial assumptions.

Introduction

THE HEAT THAT IS SUPPLIED TO THE WORKPIECE, which then is transferred within the workpiece to produce melting, forms the basis of every welding process. The heat-transfer process, or thermal cycle, in the weldment has many consequences, including the complex metallurgical changes that take place in the fusion zone, where the metal is liquified and subsequently solidified, and in the adjacent heat-affected zone, where material is heated to temperatures that are below the melting point, but are sufficiently high to produce changes in the microstructure and in mechanical properties.

The description of the input-energy source is basic to any numerical modeling formulation designed to predict the outcome of the welding process. Both the magnitude and distribution of the source are fundamental and unique to each joining process, and the resultant output of any numerical model is therefore affected by the initial description of the heat source. An understanding of both the physics and the mathematical simulation of these sources is essential for characterizing the heat source. This article briefly reviews the physical phenomena that influence the input-energy distribution and discusses several simplified and detailed heat-source models that have been used in the modeling of arc welding, high-energy-density welding, and resistance welding processes.

Characterization and Modeling of the Heat Source

S.S. Glickstein and E. Friedman, Westinghouse Electric Corporation

Simplified Modeling of the Heat Source

Analytical modeling of the welding heat source is generally complex, because of the nature of energy transfer to the workpiece, whether the source of that energy is an arc, a high-energy-density beam of electrons or laser light, or joule heating. For numerical modeling purposes, heat input to the weldment is usually applied as a distribution of surface flux, a distribution of heat generated internally, or a combination of both. Many analytical treatments, however, have sought to simplify the characterization of the heat source by assuming that the effective thermal energy supplied by the heat source is deposited in such a narrow band of material that it may be idealized mathematically as a point or a line source, depending on the geometry of the weldment (Ref 1). Heat input idealizations of this sort lend themselves to the derivation of closed-form welding temperature solutions and the avoidance of developing numerical finite-element or finite-difference models to calculate temperatures. These solutions are valid only for simple geometries and in regions removed from the fusion and heat-affected zones, where details of the distribution of heat input from the source and accurate representations of the thermal energy transferred from the weld bead to the rest of the weld joint are not important.

The fundamental simplified heat-source model is developed for a flat plate of infinite extent bounded by the planes $z = 0$ and $z = h$. Heat is input at a point that is either stationary or is moving at uniform speed, v, in the x direction on the surface $z = 0$, so that at any time, t, the point source is located at $x = vt$ (Fig. 1). If the end effects that result from the initiation or termination of the heat source or the finite dimensions of the weldment are neglected, then the resulting temperature distribution associated with the moving source is stationary with respect to a moving coordinate system, the origin of which coincides with the point of application of the heat source. This class of temperature response is termed "quasi-stationary."

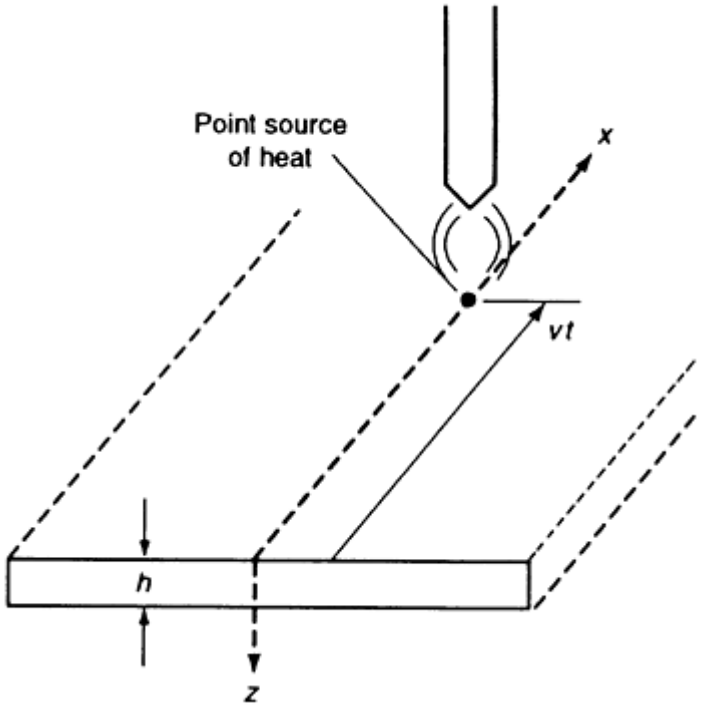

FIG. 1 MOVING POINT SOURCE IN INFINITE PLATE

In general, for either a stationary or a moving point source, heat is conducted through the plate without hindrance until the insulating effect of the ideally adiabatic surface at $z = h$ is felt. For a sufficiently thick plate, the temperature rise at $z = h$ is so small that the solution for an infinitely thick plate, which is associated with a single source of heat, is applicable. For a moderately thick plate, the temperature rise at $z = h$ from the infinitely thick plate point source solution is large enough to result in nonzero heat flow at $z = h$. An image source of the same strength applied at $z = 2h$ ensures that the surface $z = h$ is adiabatic. However, the image source produces nonzero heat flow at $z = 0$, and another image source applied at $z = -2h$ is now required to satisfy conditions at $z = 0$.

Carrying this imposition of image point sources of heat along ad infinitum (Fig. 2), an infinite distribution of image sources superposed with the original source at $z = 0$ yields the desired adiabatic conditions at both the $z = 0$ and $z = h$ surfaces. The temperature solution for this series of image sources is in the form of an infinite series (Ref 2), which converges more rapidly for thicker plates. The solution for the moderately thick plate applies to thin plates as well, but convergence of the infinite series would be extremely slow. As an alternative, the heat source can be applied as a line source distributed uniformly through the thickness (Ref 3). This approach eliminates any variation of the temperature distribution through the thickness, and is often used to model high-energy-density welding processes that result in the formation of a keyhole, as will be discussed later.

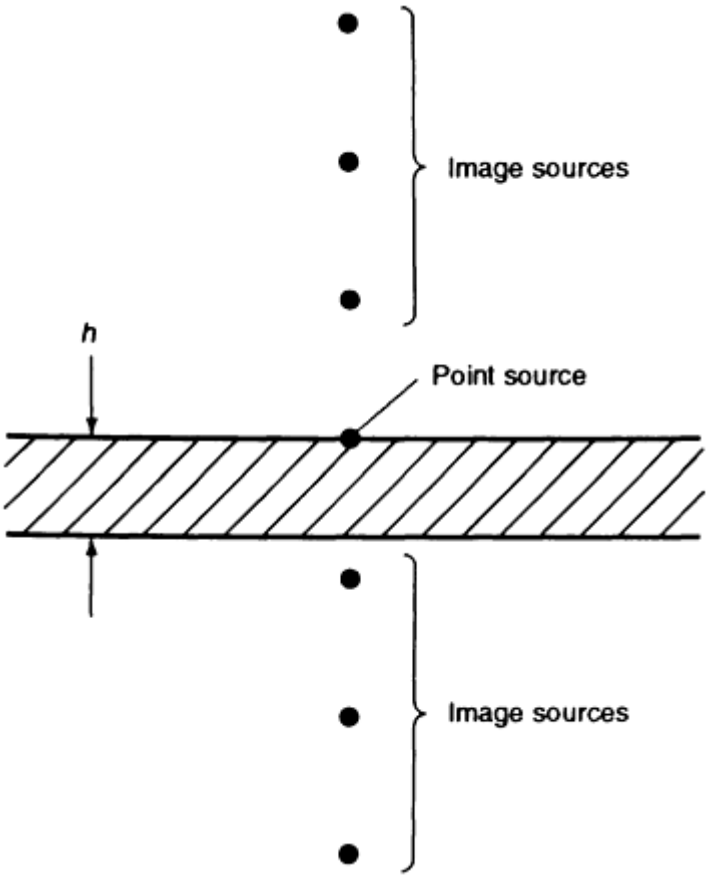

FIG. 2 SUPERPOSITION OF IMAGE SOURCES IN FINITE-THICKNESS PLATE

Offshoots of these cases also have been developed. These include considerations of plates of finite width, in which case sets of image sources are needed to ensure adiabatic conditions at the edges (Ref 4); line sources of heat traveling on a circular path (Ref 5); and conditions that simulate either initiation or termination of the heat source (Ref 6). Variations of the moving point source approach have been employed (Ref 7) to calculate the temperatures needed for weld-induced residual stress calculations in piping.

Characterization and Modeling of the Heat Source

S.S. Glickstein and E. Friedman, Westinghouse Electric Corporation

Arc Welding

Gas-tungsten arc welding (GTAW) is the most frequently modeled arc-welding process in which the heat source is a nonconsumable electrode. In the direct current electrode negative GTAW process, the pieces of material are joined together by energy that is transferred to the workpiece by four primary mechanisms (Ref 8):

- KINETIC ENERGY OF THE ELECTRONS THAT CONSTITUTE THE ARC CURRENT
- HEAT OF CONDENSATION OF THE ELECTRONS (WORK FUNCTION) PENETRATING THE SOLID WORK SURFACE
- RADIATION FROM THE ARC
- THERMAL CONDUCTION FROM THE ARC PLASMA TO THE WORKPIECE

The first two mechanisms constitute the major source of energy to the weldment (Ref 9).

Because of the complicated nature in which energy is transferred from the arc, heat input to the weldment can be modeled by one of the point- or line-source approaches discussed in the preceding section of this article. If none of these treatments is appropriate for the particular application, then a more realistic approach is to input the energy by a distribution of surface flux, a distribution of heat generated internally, or a combination of the two. If an internal heat distribution is confined to a thin layer of material adjacent to the heated surface, then the choice of heat-input model is immaterial (Ref 10). The magnitude of heat input to the workpiece is expressed simply as the product of what has traditionally been defined as the arc power (that is, the product of the voltage drop across the arc and the arc current) and a factor called the arc efficiency, which accounts for energy losses from the arc.

Estimates of arc efficiency can be made by correlating computed temperatures with thermocouple readings from test welds, making calorimeter measurements for a specific set of welding conditions, or utilizing some other observable response to the welding thermal cycle. Because the voltage used is usually determined from measurements at some point within the power supply, estimates need to be made to account for losses within the electrode and other parts of the system (Ref 11). Changes in welding process variables, such as shielding gas, electrode configuration, arc gap, and minor element additions to the arc, all affect arc efficiency, as does the material that is being welded.

The magnitude of heat applied to the weldment surface is usually not known with great accuracy, and the distribution of the heat input is even more uncertain. Input-energy distribution depends on factors related to the electrode and the physics of the arc, as well as on the interaction of the arc with the molten weld pool. For example, the arc characteristics and the depth-to-width ratio of the weld puddle will change as the vertex angle of the conical tip of the electrode is altered (Fig. 3). As the arc becomes more constricted, the heat source becomes more concentrated, thus increasing weld penetration. Changes in heat-source distribution (that is, input current) will affect the electromagnetic forces in both the arc and the weld puddle, resulting in changes in weld-puddle motion, which can promote alterations in convection heat transfer within the weld puddle. Shielding gas composition and minor alloying elements also can influence the distribution of input energy.

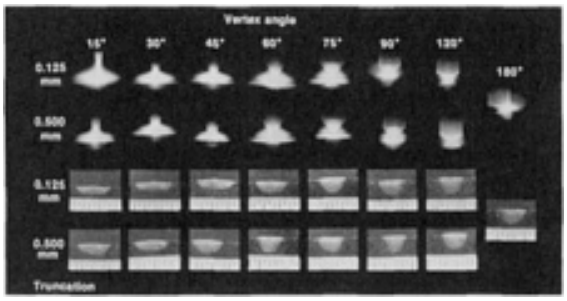

FIG. 3 ARC SHAPE AND WELD-BEAD GEOMETRY AS A FUNCTION OF ELECTRODE TIP ANGLE IN A PURE ARGON SHIELD FOR 2.38 MM (0.10 IN.) DIAMETER ELECTRODES TRUNCATED TO 0.125 AND 0.500 MM (0.005 AND 0.2 IN.); ARC GAP, 1 MM (0.04 IN.). SOURCE: REF 12

When welding at low currents and high voltages, the perturbation of the weld-puddle surface may be considered to have a small effect on the heat-input distribution, and a model that considers heat to be applied as a surface flux is usually satisfactory. However, as the current increases (particularly when the arc voltage is small, indicating a short electrode-to-work surface distance), the arc jet can depress the weld-puddle surface and affect the configuration of the distribution on the surface of the weldment (Fig. 4). The effects of depressing the weld puddle can be accommodated empirically by postulating some or all of the heat from the arc to be deposited internally. However, the specification of an internal heat-generation distribution is more complex than that of a surface flux.

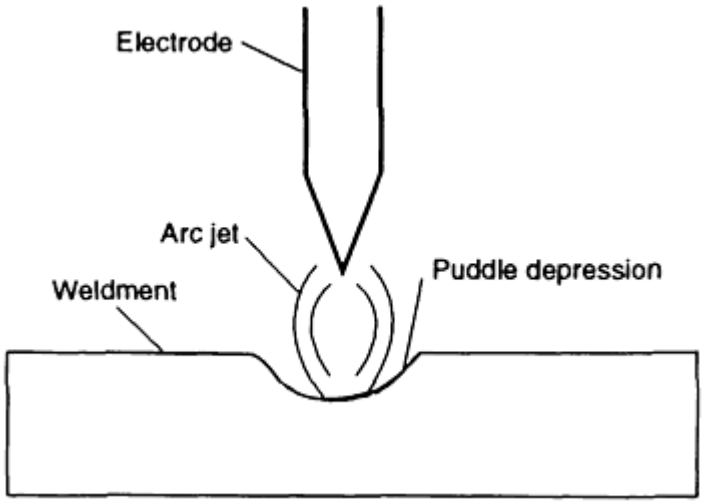

FIG. 4 EFFECT OF ARC JET ON DEPRESSION OF WELD POOL

For models in which heat from the welding arc is postulated to be deposited on the surface of the weldment, the input energy is often assumed to be a radially symmetric, normally distributed surface flux at any instant in time (Ref 13). The incident heat flux, *q,* can be expressed conveniently as an exponential, or Gaussian, function such that:

$$Q\,(R) = (3Q/\pi R'^2)\ \mathrm{EXP}[-\,3(R/R')^2] \qquad \textbf{(EQ 1)}$$

where Q is the magnitude of the heat input per unit time, r is the distance from the center of the heat source to the surface, and r' is a characteristic radial dimensional distribution parameter that defines the region in which 95% of the heat flux is deposited. In the limit as $r' \rightarrow 0$, the heat input becomes a point source of strength Q on the surface. The applicability of point sources to characterize energy input for laser-beam welding processes will be explored later in this article.

Equation 1 describes the heat-input distribution from a stationary arc. Only the magnitude of the heat input, the distribution parameter, and the duration of heating are necessary to fully characterize the input energy. Figure 5 shows typical variations of the weld bead depth and width for stationary spot welds on 6.5 mm (0.25 in.) thick plates with both the distribution parameter, *r*', and the duration of heating, *t**.

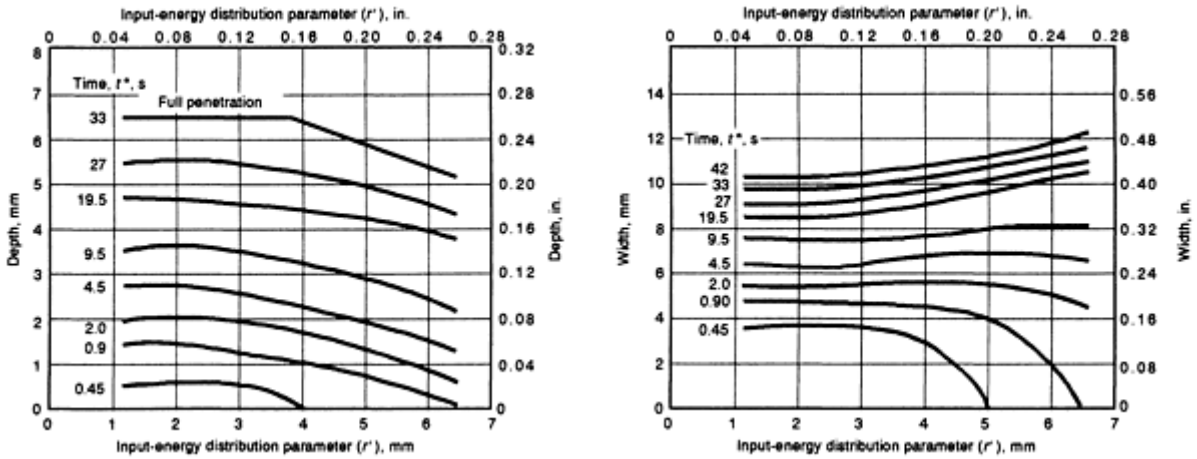

FIG. 5 WELD-BEAD DIMENSIONS FOR DIFFERENT DURATIONS OF HEATING, *T, AND INPUT-ENERGY DISTRIBUTION PARAMETER, *R*'. Q_O = 1060 W. SOURCE: REF 10**

Other forms of the heat-input distribution also can be used. These include ramp, or triangular, distributions; uniform heat-input distributions over finite areas (for example, the area of the weld puddle surface); or combinations of the two (that is, trapezoidal distributions).

The axisymmetric characterization of heat input for stationary arcs enables temperatures in the weldment to be calculated using axisymmetric thermal analysis methods, if the weldment geometry justifies such an analysis. On the other hand, if the heat source is moving, then the resultant flow of heat is three-dimensional, that is, temperature gradients develop through the thickness of the weldment, as well as in directions parallel to and transverse to the welding direction. If the weldment geometry is regular (for example, flat plate), then the heat source from the arc is moving at a constant, sufficiently high speed, *v*, and if end effects such as the starting and stopping of the arc are neglected, then transient two-dimensional thermal analyses at cross sections normal to the welding direction may be satisfactory (Ref 14). The heat input at a section transverse to the direction of arc travel is given by:

$$Q\,(X,T) = (3Q/\pi R'^2)\ \mathrm{EXP}[-3(X/R')^2]\ \mathrm{EXP}[-3(VT/R')^2] \qquad \textbf{(EQ 2)}$$

where *x* is the distance from the centerline of the weld and *t* is the time measured from the moment the center of the heat source passes over the weld section being analyzed. The three heat-input parameters characterizing a moving arc (*Q*,*r*',*v*) are embodied in this formulation. The inverse of the speed of a moving arc is akin to the duration, *t**, of a stationary arc, because a moving arc supplies a heat input, *Q*/*v*, per unit length of weld, whereas a stationary arc provides a total amount of heat, *Qt**, to the weldment.

For models in which heat is deposited internally, rather than as a surface flux, the input energy can be assumed to be deposited within a spheroidal or ellipsoidal region that is similar in shape to the weld puddle. As described by Ref 15, the heat input can be taken to vary exponentially as a Gaussian distribution in all directions within the ellipsoid. Thus, the energy-input distribution is completely specified by the dimensions of the ellipsoid. More elaborate models can be formulated by prescribing either double-ellipsoid heat-input regions that better match weld-puddle shape or conical regions of internal energy deposition. Regardless of the methodology chosen to characterize the distribution of the heat input, the geometric parameters of the distribution should be established, at this stage of computer-modeling development, by correlating calculated thermal-response characteristics, such as the weld bead and heat-affected zone dimensions, with measured values.

Gas-metal arc welding (GMAW) modeling is more complex than that of the GTAW process, because of the need to consider thermal energy that is transferred to the workpiece not only by mechanisms similar to those associated with the GTAW process, but, more importantly, by heat contained in the molten metal drops that are transferred as filler metal from the consumable electrode wire to the workpiece. Refer to Ref 16 for additional details. Because the GMAW process utilizes direct current electrode positive, the heat associated with the kinetic energy of the electrons and the heat of condensation is now input to the electrode. The energy previously input to the weldment is replaced by the energy of positively charged ions, which contribute a much smaller amount of heat to the weldment.

In addition, the radiation and conduction via the arc plasma make minor contributions to the heat input to the weldment. The more-important source of heat is derived from the mass of molten material and is related directly to both the temperature and the melting rate of the electrode wire. The melting rate of the electrode is governed primarily by joule heating and by arc heating similar to that of the GTAW process. The transfer of material to the workpiece can be globular, such that the metal is deposited in droplets, the diameters of which are greater than that of the electrode, or in a spray, in which mass is transferred to the weld puddle as droplets with diameters that are smaller than that of the electrode.

The thermal energy applied to the workpiece therefore consists of two sources: the arc-energy distribution generated at the cathode area (workpiece) and the thermal energy of the metal drops transferred from the filler wire. The arc input energy has a significant effect on the width of the weld puddle and, thus, of the solidified weld bead, whereas the energy in the molten metal contributes significantly to the melting of the workpiece (Ref 17). Furthermore, the impingement of the metal drops on the puddle significantly affects the depth of penetration (Ref 18), because the impact of each drop causes a distinct indentation in the weld puddle, especially at high currents.

Modeling of the heat input from the GMAW process should generally include the effects of heat input from the filler-metal droplets, the addition of new weld material from the filler wire, and, in many cases, the significant indentation of the weld-puddle surface, as well as a spatially distributed heat flux on the surface to represent radiation energy from the arc and positive ion impingement. Accurate representations of these phenomena are so complex that alternate treatments are essential. In Ref 19, the heat input from the GMAW process was modeled as a Gaussian distribution and accounted for the energy necessary to melt the electrode wire. In Ref 20, a model in which heat is input partly in the weld puddle and partly as a surface flux was developed. A more common approach is to model the addition of filler metal by "creating" new metal in an analytical model.

In finite-element treatments, for example, new metal is simulated by adding sets of elements to the model. For three-dimensional models, these elements can be introduced in distinct increments of time, whereas for a two-dimensional analysis of a cross section normal to the welding direction, a set of elements corresponding to a weld bead cross section can be created. More recently, the contour outlining the weld bead has been determined experimentally and then used as the starting boundary condition for the thermal modeling of welds. As an example, the boundary condition can be a time-dependent temperature that may reach or exceed the melting temperature of the material.

Other Arc-Welding Processes. Shielded metal arc welding (SMAW), submerged arc welding (SAW), and flux-cored arc welding (FCAW) are other processes in which energy is transferred to the workpiece both from the arc and from an overheated consumable electrode. The previously outlined semiempirical methodology for simulating the heat input for the GMAW process also appears to be well suited for the flux welding processes, although the introduction of a slag layer, whether it develops from the melting and solidification of electrode-covering material or from a flux feeding tube, presents another factor to be considered when calculating weld-induced temperatures.

Characterization and Modeling of the Heat Source

S.S. Glickstein and E. Friedman, Westinghouse Electric Corporation

High-Energy-Density Welding

In modeling the heat source for high-energy-density welding, one first needs to determine the type of welding process being formulated. Depending on the weld parameters, high-energy-density welding can simulate either a conduction-mode weld process or a keyhole weld process. If a strict conduction-mode weld process is being modeled, then the energy density will be low enough to prevent intense vaporization of the material. All of the energy of the beam is deposited directly on the surface of the weldment as a heat flux, similar to that discussed in terms of the GTAW process. The major difference between this mode of welding and that of arc welding is in the magnitude and distribution of the heat source. In laser-beam welding, the input-energy distribution is very dependent on the operational mode of the laser system.

Figure 6 shows several shapes of the source distribution that can be present at any one time. The fundamental transverse electromagnetic mode, TEM_{00} (a Gaussian distribution), is often selected as the heat-input description for conduction welding. It is also assumed to be the source distribution for electron-beam welding. The exact determination of the Gaussian width parameter, r', depends on the optics of the laser-or electron-beam welding system. In many cases, a point source on the surface is an excellent approximation. In laser-beam welding, if the energy is delivered via a fiber-optic system, then the output source distribution is often described as a truncated Gaussian source distribution of specified width. However, the beam exiting a fiber-optic system has been examined (Ref 21), and the output-energy distribution is reported to depend on the incident angle of the beam into the fiber. A variety of output configurations can be obtained as a function of the angle.

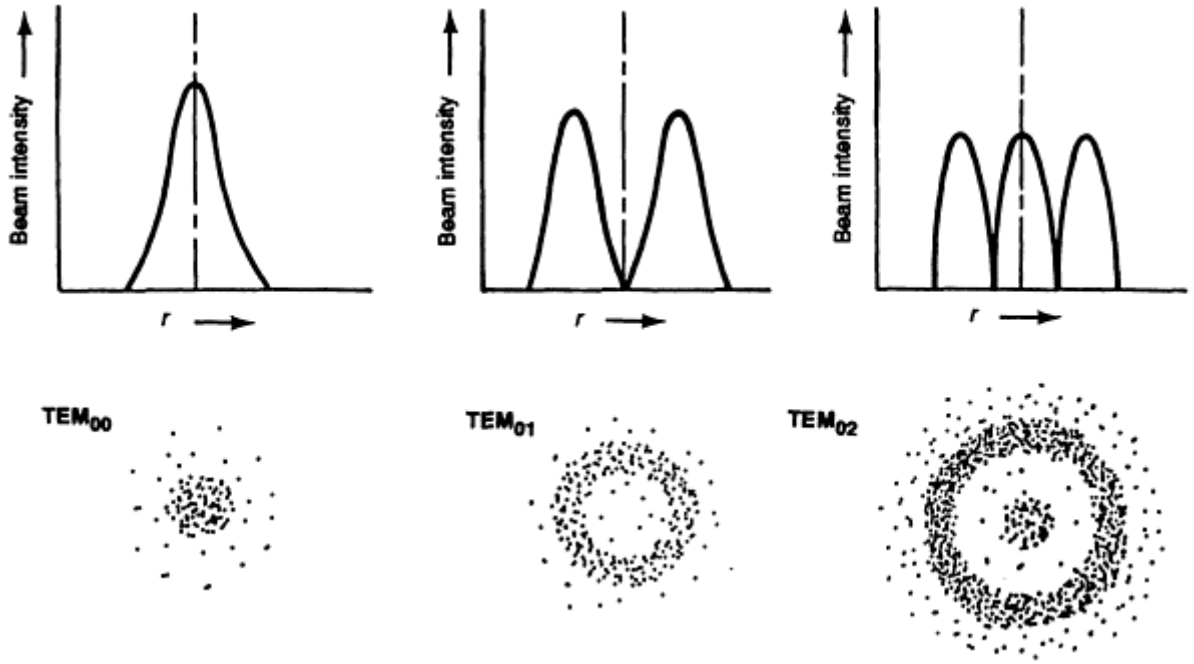

FIG. 6 APPEARANCE OF LASER BEAM FOR THREE DIFFERENT TRANSVERSE ELECTROMAGNETIC MODES (TEM). HORIZONTAL AXIS SHOWS INCREASING DISTANCE FROM THE CENTER OF THE HEAT SOURCE TO THE SURFACE.

Some laser systems, such as the multikilowatt carbon-dioxide laser, operate with the TEM_{01} as the dominant mode. This donut shape (Fig. 6) has been used very effectively for specific welding operations. Other laser systems may display a combination of these modes (for example, TEM_{02}), as well as higher-order modes. Beam analyzers are currently being employed to measure the precise distribution of the laser input energy to the weldment.

If a keyhole mode of welding is being formulated, then modeling of the input-energy distribution is complicated. Several different formulations have been discussed in the literature. In the keyhole mode, the energy density is sufficiently high to cause material ablation near the center of the beam, resulting in beam penetration further into the weldment. A hole created in the maternal is maintained by equilibrium between vapor pressure in the keyhole, surface tension, and hydrodynamic pressure in the surrounding melt. The exact distribution of energy deposited in the hole is complicated and depends on the scattering and absorption of the beam through the weldment, as well as on the focal parameters of the system. Several different models have been used to simulate these conditions.

The simplest model for the keyhole mode of welding is that of a moving line source through the weldment (Ref 22). The appropriate solution of the heat equation was obtained by Rosenthal (Ref 23). The model does not describe the typically observed semicircular part of the weld cross section at the top, because it corresponds to a liquid region, the size of which does not vary through the thickness of the workpiece. This simple model has been found to be very useful, however, in providing relations between such quantities as the power absorbed and the width of the weld.

A thermal analysis of the laser process has been derived for a Gaussian source moving at a constant velocity over a large range of conditions, from simple heat treating to deep-penetration welding (Ref 24). To obtain a more realistic weld shape, the simple line-source approach was modified (Ref 25) by adding a point source close to the surface of the workpiece to the line source distributed uniformly through the thickness. The line-source models uniform absorption of heat by the workpiece with depth, whereas the point source corresponds to a much more concentrated region of absorption in the vicinity of the laser focus, which contrasts with the absorption from multiple reflections that occur in the main part of the keyhole. The temperature distribution from this combined-source model yields a vertical weld seam shape that reflects the general shape of that found from experimental investigations (Fig. 7).

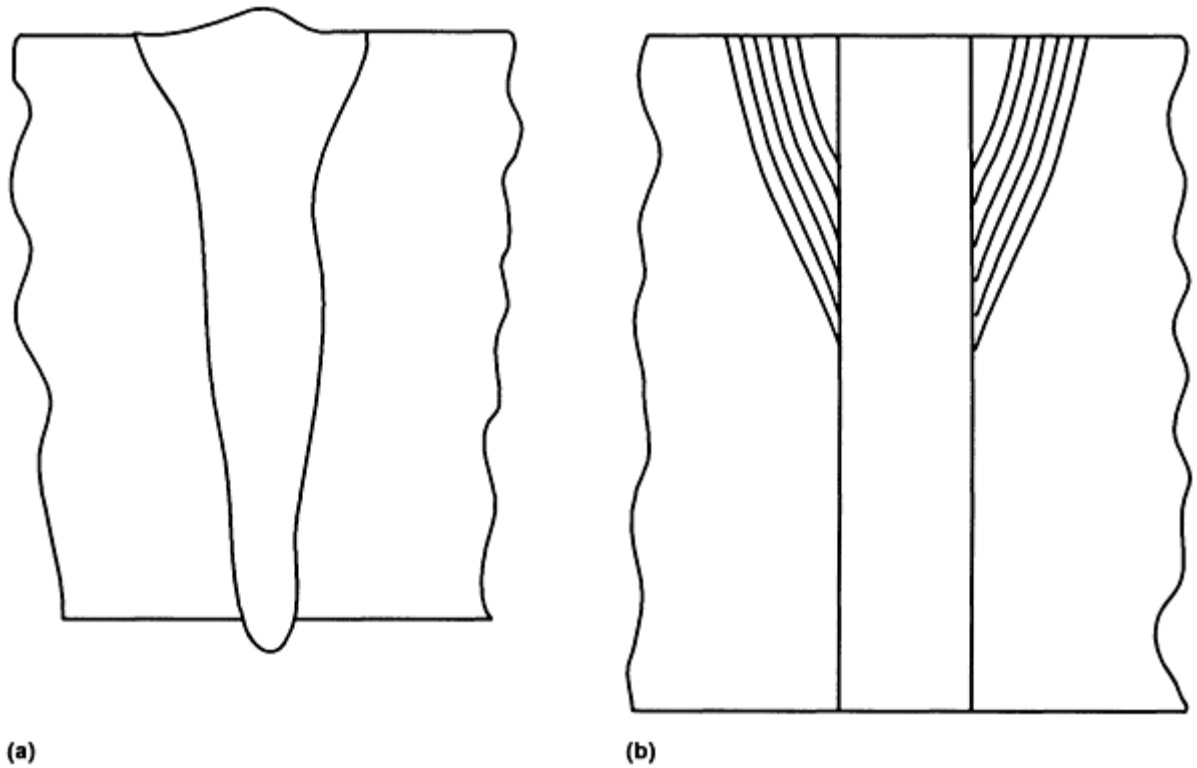

FIG. 7 OUTLINES OF CROSS SECTIONS OF (A) EXPERIMENTAL AND (B) CALCULATED KEYHOLE WELDS. CALCULATED RESULTS SHOWN FOR SEVERAL DIFFERENT POINT SOURCES ADDED TO THE LINE SOURCE. SOURCE: REF 25

A simple description of the input energy avoids the problem of defining the exact nature of the energy-transfer process in the keyhole itself. A more sophisticated model is necessary to characterize this effect. The attenuation of the laser beam in the vertical direction has been accounted for (Ref 26) by calculating the temperature at a depth, *d*, below the surface. If the temperature at depth, *d*, exceeds the boiling point of the material, then point *d* is deemed to be transparent. The incident power is then applied at a point below it, after suffering some absorption. This sequence continues through the substrate. The transparent grid points keep their high temperatures as if the keyhole were filled with a hot plasma.

This brief overview of several of the approaches used to model the high-energy-density welding process points out the difficulty in defining a unique methodology. Experimental data must be used for specific welding conditions to establish the overall approach, as well as the magnitude and distribution of the input source energy.

Characterization and Modeling of the Heat Source

S.S. Glickstein and E. Friedman, Westinghouse Electric Corporation

Resistance Spot Welding

The electrical resistance spot welding process for joining two materials at their common interface involves a complicated interaction of electrical, thermal, mechanical, metallurgical, and surface phenomena. Figure 8, a simplified representation of the process, shows some essential features for producing a weld.

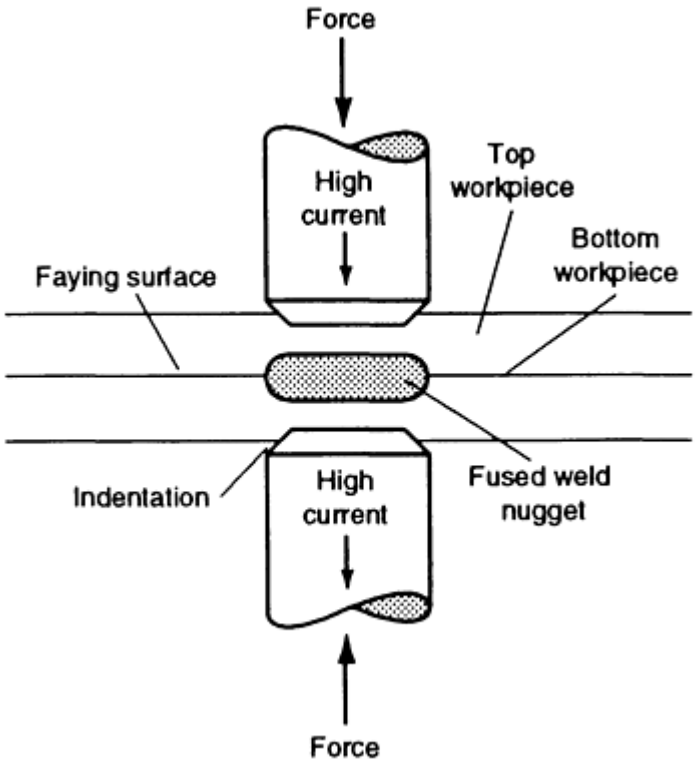

FIG. 8 RESISTANCE SPOT WELDING PROCESS

In this welding process, the faying surfaces of two or more workpieces are fused and joined at a spot by electric current flowing through the weldment (joule heating). The weldment is actually held together by the compressive force exerted by the electrodes. Because the input energy in this weld process is due to joule heating, the spatial distribution of the current and the electrical resistance within the workpiece must be determined when modeling the heat source. Most importantly, the contact resistance at the surfaces of both the electrode and the work-piece, as well as the interfaces of the work-pieces, must be established. The electrical contact resistance depends on the surface condition of the material, its hardness, the degree of oxidation, the amount and kind of impurities, as well as the apparent pressure at the surfaces and the temperature. The fact that these quantities are time dependent is another complication, because the joule heat source must be considered as a time-dependent parameter.

A detailed description of the process is presented in the article "Resistance Spot Welding" in this Volume. Literature reviews of the resistance spot welding process simulation are provided in Ref 27 and 28. The brief overview provided below of some important findings in the literature on resistance welding highlights several points that need to be considered when developing a model of the heat source.

In 1958, experimental and analytical investigations of the resistance spot welding process were performed (Ref 29). The researchers reported current-density singularities at the outer rim of the contact area from theory and correlated this phenomenon with experimental results that showed heat concentration at the periphery. They concluded that the bulk of the material near the contact region was not heated appreciably by the flow of current through it, but was heated indirectly by conduction from the peripheral region of the contact area. However, further study indicated that the contact area plays a major role only in the early stages of heat production and becomes less influential in later stages of weld-nugget formation. This fact reinforces the earlier remarks that the modeling of the heat source must consider not only the spatial distribution of the heat source, but its time dependence.

Further reinforcing this idea, it was found (Ref 30) that in the beginning of the welding process, most of the voltage drop occurred at the interface between the electrode and the weldment and in the interface of the two workpieces (21% and 66%, respectively). The researchers determined that after six cycles from the instant that weldment fusion begins, most of the voltage drop takes place in the base metal (87%). This occurs because the interfacial resistance decreases as the temperature rises, which is due to melting at the interface, and because the resistivity of the base metal increases with increased temperature.

Complicating the modeling process is the unknown, but very important, contact diameter at the faying surface. This parameter depends on the geometry of the electrodes, the surface conditions, and, most importantly, the mechanical load applied by the electrode. Recent work (Ref 28) in modeling this process uses the diameter of the electrode face as the contact diameter between the electrode and the workpiece, but a slightly larger diameter is used to represent the contact diameter at the interface of the work-pieces. Figures 9 and 10 show the current density and joule heating as functions of the nondimensional radius R/R_c, where R_c is the assumed contact radius.

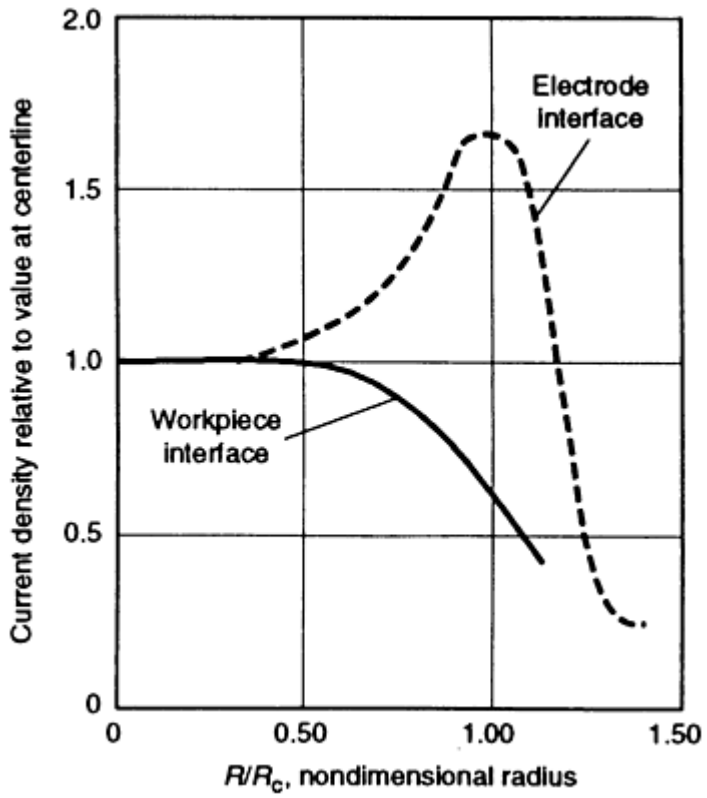

FIG. 9 CURRENT DENSITY RATIO VERSUS NONDIMENSIONAL RADIUS. TIME, 2 CYCLES; R_C, RADIUS OF CONTACT. SOURCE: REF 27

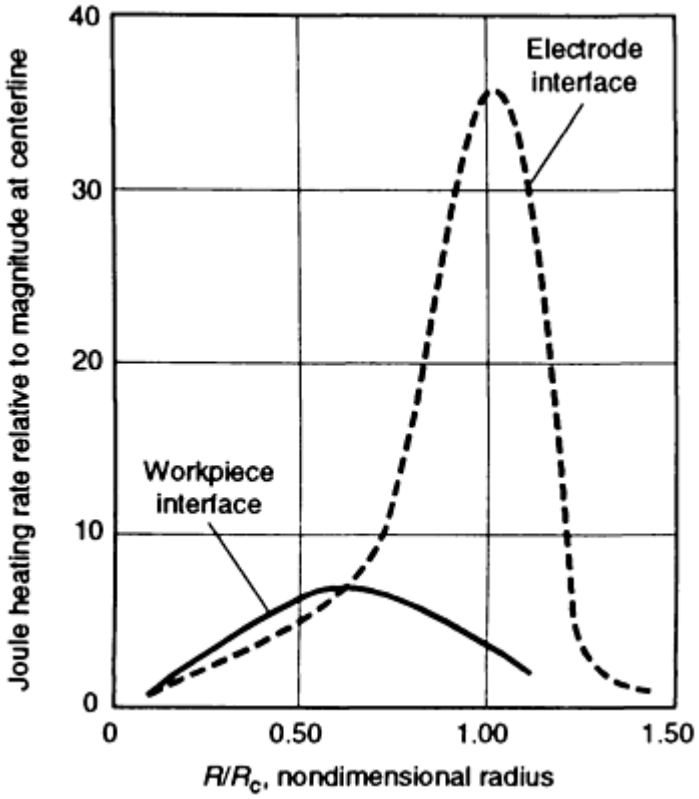

FIG. 10 JOULE HEATING RATE RATIO VERSUS NONDIMENSIONAL RADIUS. TIME, 2 CYCLES; R_C, RADIUS OF CONTACT. SOURCE: REF 27

The authors of both Ref 27 and 28 stress the importance of developing a thermomechanical coupling model that will account for changes in resistance and current distributions during the welding process. This article has tried to point out that the input description of the heat source for resistance welding is extremely complicated. It depends on the electrode geometry, the weldment material, and the weldment surface condition, as well as the weld parameters (including the mechanical forces on the electrode) that must be considered as being time dependent.

Validation Strategies for Heat-Affected Zone and Fluid-Flow Calculations

J. Mazumder, University of Illinois at Urbana-Champaign

Introduction

FUSION WELDING PROCESSES involve all four phase changes: solid-solid state, solid-liquid, liquid-vapor, and vapor-plasma. Attempts to model the associated heat transport and related phenomena have been ongoing for more than half a century. The temperature history and the peak temperature determine the nature and extent of the phase change. One of the earlier analytical models for heat conduction in welding developed by Rosenthal (Ref 1) is still being used by many welding practitioners to estimate the heat-affected zone (HAZ). Although the existence of convection and its effect on molten weld pools were first reported in mid-1950s (Ref 2, 3), major modeling efforts on convection in welding started after the work reported by Heiple and Roper (Ref 4) on the effect of surface-tension-driven flow in the weld pool. During the past decade, several research groups developed two- and three-dimensional models for convection in the weld pool (Ref 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15). Of course, these convection models also predict the thermal history of the weld. Another effect of thermal history is the generation of residual stress and strain due to thermal expansion and solid-state phase transformation. Due to the importance of residual stress on the mechanical performance of welded joints, several groups also became involved in modeling the stress/strain history of welds (Ref 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35).

Each model has its own sets of assumptions. Validation of a model requires careful experiments to satisfy the underlying assumptions for that particular model. For example, Rosenthal's two-dimensional model is only valid for thin-plate welding and temperature prediction (Ref 1). Prediction for the center of the heat source for his three-dimensional model is erroneous because the assumption of a point heat source will lead to infinitely high temperatures, which is physically impossible. Also, lack of physics such as latent heat of fusion, radiative and convective heat loss, convection in the weld pool, and vaporization heat loss will lead to significant error in the melt pool prediction. Therefore, the only reasonable strategy for validation of such an analytical model will be temperature measurement at the HAZ, preferably away from the liquid-solid interface.

In designing experiments for validation of any analytical or numerical models for thermal, momentum, or stress history, one should clearly be aware of the model assumptions and boundary conditions. In this article, some important techniques to validate temperature, momentum, and stress history observed in welded materials will be discussed.

Validation Strategies for Heat-Affected Zone and Fluid-Flow Calculations

J. Mazumder, University of Illinois at Urbana-Champaign

Validation of Fluid-Flow Calculation

Convection is the single most important factor influencing the geometry of the weld pool including pool shape, aspect ratio, and surface ripples, and can result in defects such as variable penetration, porosity, and lack of fusion. Convection is also primarily responsible for mixing and, as a result, also affects the composition of the weld pool.

Recently, the sophistication of fluid-flow modeling has reached a stage where most of the important physics are considered. Buoyancy, surface tension, and electromagnetic forces are the three driving forces for convection. Electromagnetic force is important for arc welding. Initial work by Orepar, Eager, and Szekely (Ref 36) showed that even for arc welding, surface-tension-driven flow is dominant until the current level is very high (exceeding 250 A). Recently, several authors published models for thermocapillary flow (surface-tension-driven flow) for welding (Ref 6, 7, 8, 9, 10, 11, 12, 13, 14, 15). For validation of fluid-flow models, free surface models are the best candidates since they incorporate the most physics of the welding process. However, until recently, measurement of free surface deformation was difficult to perform. A new technique utilizing the specular reflection of a 488 nm argon-ion laser beam from the melt pool is employed to measure the free surface deformation (Ref 37, 38). Another challenge for validation of the fluid flow model is the measurement of liquid-metal velocity during welding. Temperature measurement techniques for the weld pool were recently reviewed by Kraus (Ref 39). Important techniques for the measurement of free surface deformation, fluid velocity, and pool temperature are discussed below.

Validation Strategies for Heat-Affected Zone and Fluid-Flow Calculations

J. Mazumder, University of Illinois at Urbana-Champaign

Measurement of Free Surface Deformation

Measurement of free surface deformation during welding is extremely complicated due to melt pool characteristics such as the specular pool surface, the wide range of deformation slopes possible, vaporization of metal from the pool surface, shielding gas, radiation of many wavelengths from the hot surface and plasma, small pool size, high temperature, and the incoming processing beam. Various optical techniques have been considered, but were found inadequate for characterizing the aforementioned characteristics (Ref 40). Since none of the classic methods were appropriate, a new technique was developed based on the specularity and steepness of the surface of the weld pool.

The fundamental step of this method is to reflect light off of a specular surface and measure the slope of the surface where the reflection is observed. This slope is measured indirectly by measuring the difference between the angles of the incident light when it reflects into a camera at a location on a flat surface and the corresponding location of the melt pool. If the angle of incidence is varied over a large enough range, each portion of the pool will at some time reflect the incident light into the camera, thereby revealing its slope. This will result in a known slope for every portion of the melt pool surface. If the slope between the areas of interest and the edge of the pool is known, it can be integrated to obtain the surface elevation. This is the basic idea behind the melt pool surface contour measurement method (Ref 38, 40). Figure 1 shows a schematic of the surface contour measurement system.

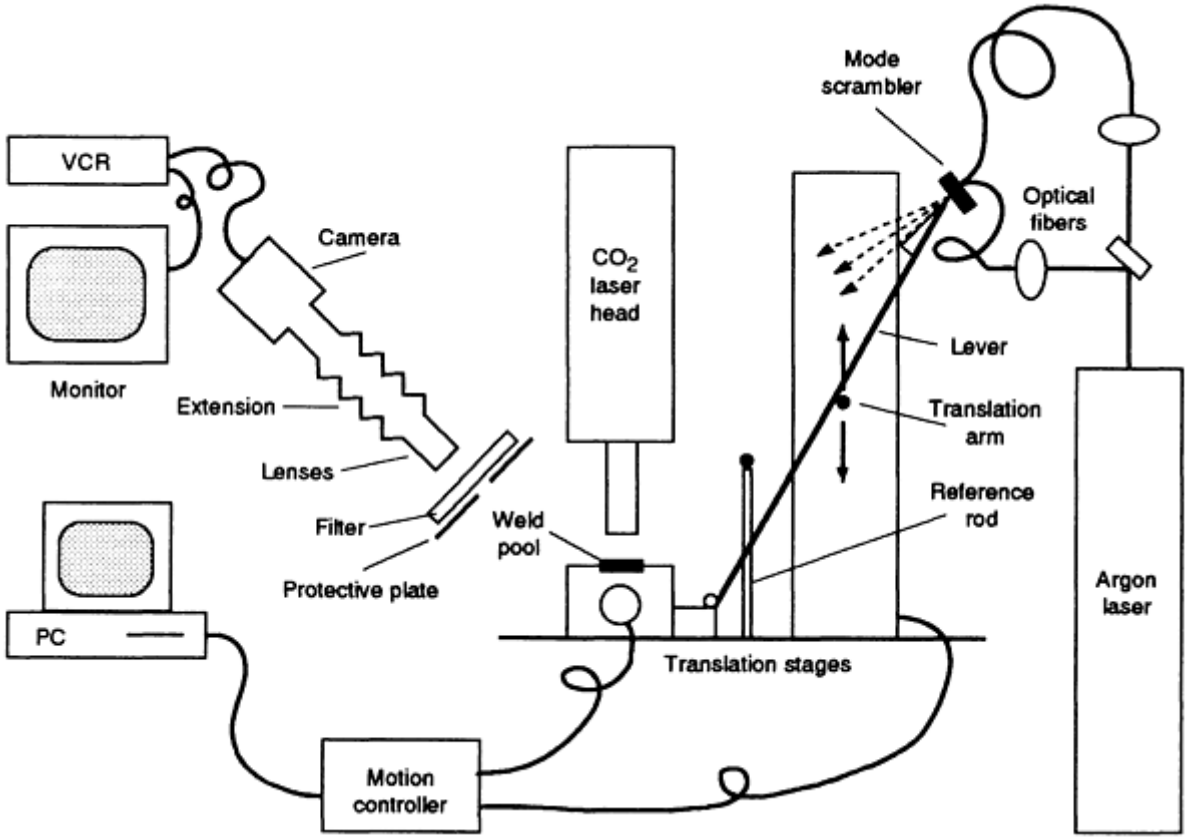

FIG. 1 SCHEMATIC OF THE SPECULAR SURFACE CONTOUR MEASUREMENT SYSTEM

Figure 2 shows a typical laser weld pool free surface measured by the "reflective topography" technique described above. This technique has shown the capability of measuring all types of free surface shapes including convex, concave (Ref 37), and complicated shapes with a lip as shown in Fig. 2.

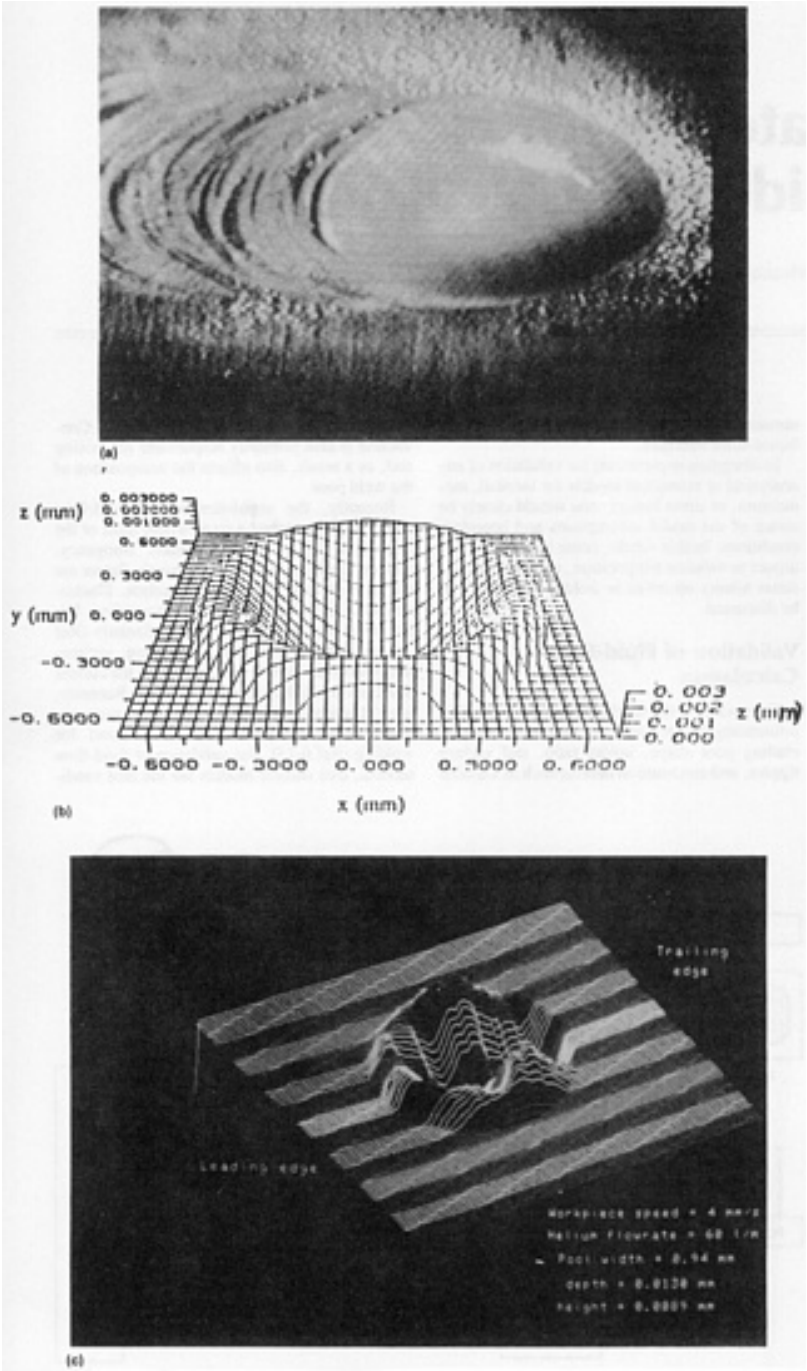

FIG. 2 LASER WELD POOL FREE SURFACE MEASURED BY THE REFLECTIVE TOPOGRAPHY TECHNIQUE. (A) VISUALIZED PICTURE. (B) PREDICTED MODEL. (C) REFLECTIVE TOPOGRAPHY IMAGE

There are several uncertainties in the modeling of free surface deformation of the weld pool. Most common for weld modeling is the paucity of temperature-dependent thermophysical property data. For the free surface deformation problem in particular, the nature of the surface tension gradient as a function of temperature and composition is poorly understood, and very little data are available. Presently, a linear dependence on temperature is assumed by most researchers. Recently, experimental measurements carried out by Sahoo *et al.* (Ref 41) and McNallan *et al.* (Ref 42), indicate a nonlinear relationship which may affect the free surface contour significantly. Also, there is controversy over the role of plasma, which is often present in welding, on the surface tension characteristics. The effect of vaporization on the pressure boundary condition also needs attention. Although significant progress has been made in modeling the melt pool free surface, there is considerable controversy over the basic assumptions for process phenomena and the physics of the process.

Various researchers have used metallographic techniques to measure the weld pool aspect ratio for the solidified weld and compared that with modeling data for model validation. This technique provides a qualitative validation of the overall model. However, comparison of the surface contour measurement of the solidified weld pool using a stylus profilometer with that of the liquid metal free surface measured by the reflective topographic technique reveal that the assumption of similar liquid and resolidified surface contours, which is sometimes suggested because the pool is expected to resolidify quickly, is not an accurate assumption for model validation (Ref 37). Therefore, for more accurate validation of the physics of the model, reflective topography accompanied with velocity measurement by x-ray radiography is more desirable.

Velocity Measurement

Heiple and Roper (Ref 4) used a high-speed movie to track the flow of Al_2O_3 particles on the weld pool surface to measure surface velocity. To validate the nature and velocity of the recirculating flow at the weld pool, x-ray radiography must be utilized. A schematic diagram of the experimental arrangement used by Mazumder *et al.* (Ref 43) is shown in Fig. 3. The substrate material used for this arc welding experiment is aluminum. Tungsten particles are used as tracers to provide contrast. A microfocused x-ray beam is directed through the test sections and an image intensifier is located on the back of the sample to receive the image. This image is processed and stored on videotape. Because of the density difference between aluminum and tungsten, the tungsten particles can be traced as they travel with the moving molten aluminum. Because the frame speed of the television camera is known, the relative position of the tungsten particles will provide the velocity of the weld pool, assuming the particles flow with the same velocity as the liquid metal (Ref 43).

Temperature Measurement

Thermocouples. Temperature measurement for model validation is probably the most mature arena for model validation. An excellent review of the field has been published by Kraus (Ref 39). Most of the earlier work for temperature measurement for welding was with thermocouples. Sundell *et al.* (Ref 44) used tungsten-rhenium thermocouples to measure the temperature for low-alloy steel, type 316L stainless steel, and Inconel 718 weld pools created during gas-tungsten] arc welding (GTAW). Thermocouples were inserted from the underside of the work-piece in holes drilled to within 0.38 mm (0.015 in.) from the surface in order to measure weld pool surface temperatures. Some thermocouples were found to protrude beyond the free surface due to the weld pool surface deformation. Draw-backs for thermocouple measurements are the several-millisecond time constant for temperature measurement and weld pool temperature and flow field perturbations. However, the response time constant can be reduced by 3 to 4 times using the procedure reported by Dantzig (Ref 45), which entails calibration of the thermocouple and signal conditioning.

Thermography. Infrared (IR) thermographic cameras are now commercially available. A number of research groups have used them for weld pool temperature measurement (Ref 46, 47, 48, 49, 50, 51). Thermographic cameras can be used for high-resolution measurements of relative emissive power of the weld pools, but lack of emissivity data prevents their use for accurate absolute temperature measurement (Ref 39). Lukens and Morris (Ref 49) correlated the IR emission intensity measurements with temperatures measured by thermocouples embedded 2 mm (0.08 in.) below the surface. Although this provides some idea about the average temperature of the weld pool, it fails to validate the surface temperature observed by the thermographic camera. However, this technique can be applied for weld control and monitoring of weld cooling rate (Ref 49).

Narrow-band IR pyrometry was used for weld pool temperature measurement by Schaver *et al.* (Ref 52) for translating electron-beam welds, and Giedt *et al.* (Ref 53) for stationary welds. They used a 1.4 μm wavelength, and spectral emissivity was measured at the gas-tungsten arc at the melting point of the metals welded.

Hunter, Allemand, and Eager (Ref 54, 55) developed techniques for temperature measurement using multiwavelength pyrometry to alleviate the emissivity variation problem. However, so far the only proof of the concept was demonstrated using a heated platinum substrate. This could be a valuable tool for surface temperature measurement. Spatial resolution of 100 μm with 5% accuracy in temperature measurements above 1100 K is possible in this technique. They reported measurement of spectral radiance at approximately 200 wavelengths in a range of 0.6 to 0.8 μm. In real life, measurement of 5 or 6 wavelengths is adequate.

Optical Spectral Radiometric/Laser Reflectance (OSRLR). Kraus (Ref 56, 57) developed the OSRLR technique for high-resolution weld pool surface temperature measurements. This technique combines high-speed-film radiographic measurements of weld pool spectral directional thermal emissive power with spectral directional emissivity measurements to enable temperature calculation up to a point (Ref 39). However, this method requires knowledge of the weld pool free surface topology as well as an oxide-free weld pool surface because the surface has to reflect a focused laser beam. High resolution with spot sizes up to 60 μm have been achieved using this technique. Figure 4 shows the experimental setup for measurement of spectral directional emissivity in the weld pool. The details of the application of this technique for weld pool surface temperature measurements using OSRLR for gas-tungsten arc welds in types 304 and 316 stainless steels and AISI 8630 alloy steel are provided in Ref 58. Similar temperature measurements based on laser line reflection were also applied by Fuchs *et al.* (Ref 51) for weld pool surface temperature measurement of gas-metal arc welds.

Validation Strategies for Heat-Affected Zone and Fluid-Flow Calculations

J. Mazumder, University of Illinois at Urbana-Champaign

Model Validation and Boundary Condition

The importance of matching the boundary condition during the experimental measurement for model validation cannot be overemphasized. One of the concepts employs various measurement techniques at different parts of the weld pool to define the boundary conditions as tightly as possible (Ref 51). Another approach uses a cold plate, as shown in Fig. 5, which was specially designed to hold the specimens in order to achieve symmetry of temperature and electromagnetic boundary conditions.

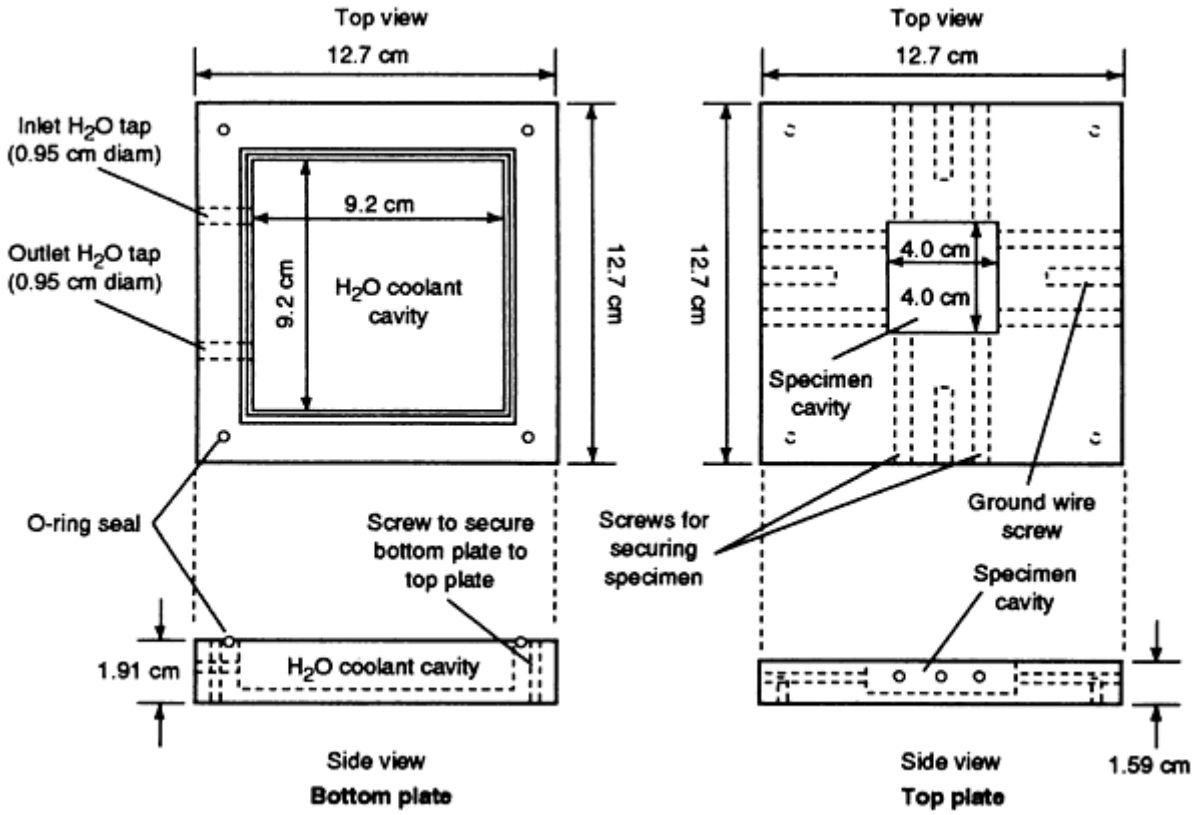

FIG. 5 SCHEMATIC OF THE COLD PLATE USED FOR SECURING SPECIMENS IN ORDER TO ACHIEVE SYMMETRY OF TEMPERATURE AND ELECTROMAGNETIC BOUNDARY CONDITIONS DURING MODEL VALIDATION

Validation Strategies for Heat-Affected Zone and Fluid-Flow Calculations

J. Mazumder, University of Illinois at Urbana-Champaign

Validation of Residual Strain Calculation

Residual strains for weld HAZs are often measured by strain gages (Ref 35). Nonobtrusive techniques such as interferometry are also employed by some researchers (Ref 59, 60). For postweld residual strain measurements, x-ray diffraction is the most popular. Recently, neutron scattering techniques have been employed by some groups (Ref 61, 62). From the strain measurement data, stress data can be calculated provided modulus data for the particular material at the temperature range of interest are available.

Strain gages are essentially Wheatstone bridges that use the change of electrical resistance of a wire under strain to measure pressure. Strain gages generally consist of an array of four metal thin-film resistors. When they are deformed due to strain, the difference of output voltage is the measure of strain. Output voltages are generally very small; for example, 3 mv per volt of excitation for full-scale deformation with accuracies ranging from 1% to 0.1% (Ref 63). Therefore, one needs an amplifier to either plot the data on a chart recorder or to send it to the input/output board of a computer. Strain gages are generally mounted on the weld specimen with bonding agents (adhesives). Because both bonding agents and

strain gages are very sensitive to high temperatures, strain measurement is limited to a region substantially outside the immediate vicinity of the HAZ.

Interferometry. All interferometric techniques are based on the interference of two coherent light wave trains. Masubuchi *et al.* (Ref 59) measured out-of-plane displacement using laser interferometer. Chavez *et al.* (Ref 60) used Moire interferometry to obtain full-field strain data across welds in stainless steel plates with Ferralium or nickel filler. Moire interferometry provides full-field surface displacement data with displacement resolution on the order of 1 μm. Holographic interferometric techniques can provide a higher resolution, whereas the Moire technique can be used in situations involving large strain variations such as occur during welding. Norvell (Ref 64) found strain variation for a 1 °C (1.8 °F) change in temperature can be measured by holographic interferometry; thus this method is too sensitive for welding. On the other hand, Moire interferometry is much more forgiving. Another interferometric technique called shearography seems to be more promising because the interference pattern is created simply by shearing the image by placing an optical wedge in front of the camera (Ref 65). Although Fourier transformation is required to deduce the strain data, unlike other interferometric techniques, shearography provides a strain field directly and minimizes data reduction.

X-Ray and Neutron Diffraction Methods. Both x-ray and neutron diffraction follow Bragg's law:

$$\lambda = 2D_{HKL} \text{ SIN } \theta_{HKL}$$

where λ is the wavelength, d_{hkl} is interplanar spacing of the plane ***hkl,*** and θ_{hkl} is the scattering angle.

An advantage of neutron diffraction is that it can penetrate to much greater depths. For example, a penetration depth in excess of 16 mm (0.63 in.) was observed for steel (Ref 61). For an x-ray, one needs to section off a specimen layer by layer, assuming that machining or chemical etching will not introduce any additional strain. This increased penetration depth is due to the extremely small wavelength (~0.165 nm) for neutrons. Root *et al.* (Ref 62) have determined the longitudinal, normal, and transverse strain components at 1.5 mm (0.06 in.) from inside the bottom surface of a multipass ferritic weldment. However, the major draw-back is that one needs a nuclear reactor for the neutron source. Penetration depth provides a unique opportunity to compose the prediction from three-dimensional models.

Oxyfuel Gas Cutting

Introduction

OXYFUEL GAS CUTTING (OFC) includes a group of cutting processes that use controlled chemical reactions to remove preheated metal by rapid oxidation in a stream of pure oxygen. A fuel gas/oxygen flame heats the workpiece to ignition temperature, and a stream of pure oxygen feeds the cutting (oxidizing) action. The OFC process, which is also referred to as burning or flame cutting, can cut carbon and low-alloy plate of virtually any thickness. Castings more than 760 mm (30 in.) thick commonly are cut by OFC processes. With oxidation-resistant materials, such as stainless steels, either a chemical flux or metal powder is added to the oxygen stream to promote the exothermic reaction.

The simplest oxyfuel gas cutting equipment consists of two cylinders (one for oxygen and one for the fuel gas), gas flow regulators and gages, gas supply hoses, and a cutting torch with a set of exchangeable cutting tips. Such manually operated equipment is portable and inexpensive. Cutting machines, employing one or several cutting torches guided by solid template pantographs, optical line tracers, numerical controls, or computers, improve production rates and provide superior cut quality. Machine cutting is important for profile cutting--the cutting of regular and irregular shapes from flat stock.

Principles of Operation

Oxyfuel gas cutting begins by heating a small area on the surface of the metal to the ignition temperature of 760 to 870 °C (1400 to 1600 °F) with an oxyfuel gas flame. Upon reaching this temperature, the surface of the metal will appear bright red. A cutting oxygen stream is then directed at the preheated spot, causing rapid oxidation of the heated metal and generating large amounts of heat. This heat supports continued oxidation of the metal as the cut progresses. Combusted gas and the pressurized oxygen jet flush the molten oxide away, exposing fresh surfaces for cutting. The metal in the path of the oxygen jet burns. The cut progresses, making a narrow slot, or kerf, through the metal.

To start a cut at the edge of a plate, the edge of the preheat flame is placed just over the edge to heat the material. When the plate heats to red, the cutting oxygen is turned on, and the torch moves over the plate to start the cut.

During cutting, oxygen and fuel gas flow through separate lines to the cutting torch at pressures controlled by pressure regulators, adjusted by the operator. The cutting torch contains ducts, a mixing chamber, and valves to supply an oxyfuel gas mixture of the proper ratio for preheat and a pure oxygen stream for cutting to the torch tip. By adjusting the control valves on the torch handle or at the cutting machine controller, the operator sets the precise oxyfuel gas mixture desired. Depressing the cutting oxygen lever on the torch during manual operation initiates the cutting oxygen flow. For machine cutting, oxygen is normally controlled by the operator at a remote station or by numerical control. Cutting tips have a single cutting oxygen orifice centered within a ring of smaller oxyfuel gas exit ports. The operator changes the cutting capacity of the torch by changing the cutting tip size and by resetting pressure regulators and control valves. Because different fuel gases have different combustion and flow characteristics, the construction of cutting tips, and sometimes of mixing chambers, varies according to the type of gas.

Oxyfuel gas flames initiate the oxidation action and sustain the reaction by continuously heating the metal at the line of the cut. The flame also removes scale and dirt that may impede or distort the cut.

The rate of heat transfer in the workpiece influences the heat balance for cutting. As the thickness of the metal to be cut increases, more heat is needed to keep the metal at its ignition temperature. Increasing the preheat gas flow and reducing the cutting speed maintains the necessary heat balance.

Oxygen flow also must increase as the thickness of the metal to be cut increases. The jet of cutting oxygen must have sufficient volume and velocity to penetrate the depth of the cut and still maintain its shape and effective oxygen content.

Quality of Cut. Oxyfuel gas cutting operations combine more than 20 variables. Suppliers of cutting equipment provide tables that give approximate gas pressures for various sizes and styles of cutting torches and tips and recommended cutting speeds; these variables are operator controlled. Other variables include type and condition (scale, oil, dirt, flatness) of material, thickness of cut, type of fuel gas, and quality and angle of cut.

Where dimensional accuracy and squareness of the cut edge are important, the operator must adjust the process to minimize the kerf, the width of metal removed by cutting, and to increase smoothness of the cut edge. Careful balancing of all cutting variables helps attain a narrow kerf and smooth edge. The thicker the work material, the greater the oxygen volume required and therefore, the wider the cutting nozzle and kerf.

Process Capabilities

Oxyfuel gas cutting processes are used primarily for severing carbon and low-alloy steels. Other iron-base alloys and some nonferrous metals can be oxyfuel gas cut, although process modification may be required, and cut quality may not be as high as is obtained in cutting the more widely used grades of steel. High-alloy steels, stainless steels, cast iron, and nickel alloys do not readily oxidize and therefore do not provide enough heat for a continuous reaction. As the carbon and alloy contents of the steel to be cut increase, preheating or postheating, or both, often are necessary to overcome the effect of the heat cycle, particularly the quench effect of cooling.

Some of the high-alloy steels, such as stainless steel, and cast iron can be cut successfully by injecting metal powder (usually iron) or a chemical additive into the oxygen jet. The metal powder supplies combustion heat and breaks up oxide films. Chemical additives combine with oxides to form lower temperature melting products that flush away.

Applications. Large-scale applications of oxyfuel cutting are found in shipbuilding, structural fabrication, manufacture of earthmoving equipment, machinery construction, and in the fabrication of pressure vessels and storage tanks. Many machine structures, originally made from forgings and castings, can be made at less cost by redesigning them for OFC and welding with the advantages of quick delivery of plate material from steel suppliers, low cost of oxyfuel gas cutting equipment, and flexibility of design.

Structural shapes, pipe, rod, and similar materials can be cut to length for construction or cut up in scrap and salvage operations. In steel mills and foundries, projections such as caps, gates, and risers can be severed from billets and castings. Mechanical fasteners can be quickly cut for disassembly using OFC. Holes can be made in steel components by piercing and cutting. Machine OFC is used to cut steel plate to size, to cut various shapes from plate, and to prepare plate edges (bevel cutting) for welding.

Gears, sprockets, handwheels, clevises and frames, and tools such as wrenches can be cut out by oxyfuel gas torches. Often, these oxyfuel cut products can be used without further finishing. However, when cutting medium- or high-carbon steel or other metal that hardens by rapid cooling, the hardening effect must be considered, especially if the workpiece is to be subsequently machined.

Thickness Limits. Gas can cut steels less than 3.2 mm ($\frac{1}{8}$ in.) thick to over 1525 mm (60 in.) thick, though some sacrifice in quality occurs near both ends of this range. With very thin material, operators may have some difficulty in keeping heat input low to avoid melting the kerf edges and to minimize distortion. Steel under 6.4 mm ($\frac{1}{4}$ in.) thick often is stacked for cutting of several parts in a single torch pass.

There are a number of advantages and disadvantages when OFC is compared to other cutting operations such as arc cutting, milling, shearing, or sawing. The advantages of OFC are:

- METAL CAN BE CUT FASTER BY OFC. SETUP IS GENERALLY SIMPLER AND FASTER THAN FOR MACHINING AND ABOUT EQUAL TO THAT OF MECHANICAL SEVERING (SAWING AND SHEARING).
- OXYFUEL GAS CUTTING PATTERNS ARE NOT CONFINED TO STRAIGHT LINES AS IN SAWING AND SHEARING, OR TO FIXED PATTERNS AS IN DIE CUTTING PROCESSES. CUTTING DIRECTION CAN BE CHANGED RAPIDLY ON A SMALL RADIUS DURING OPERATION.
- MANUAL OFC EQUIPMENT COSTS ARE LOW COMPARED TO MACHINE TOOLS. SUCH EQUIPMENT IS PORTABLE AND SELF-CONTAINED, REQUIRING NO OUTSIDE POWER AND WELL SUITED FOR FIELD USE.
- WHEN PROPERTIES AND DIMENSIONAL ACCURACY OF GAS CUT PLATE ARE ACCEPTABLE, OFC CAN REPLACE COSTLY MACHINING OPERATIONS. IT OFFERS REDUCED LABOR AND OVERHEAD COSTS, REDUCED MATERIAL COSTS, REDUCED TOOLING COSTS, AND FASTER DELIVERY.
- WITH ADVANCED MACHINERY, OFC LENDS ITSELF TO HIGH-VOLUME PARTS PRODUCTION.
- LARGE PLATES CAN BE CUT QUICKLY IN PLACE BY MOVING THE GAS TORCH RATHER THAN THE PLATE.
- TWO OR MORE PIECES CAN BE CUT SIMULTANEOUSLY USING STACK CUTTING METHODS AND MULTIPLE-TORCH CUTTING MACHINES.

The limitations of the OFC process include:

- DIMENSIONAL TOLERANCES ARE POORER THAN FOR MACHINING AND SHEARING.
- BECAUSE OFC RELIES ON OXIDATION OF IRON, IT IS LIMITED TO CUTTING STEELS AND CAST IRON.
- HEAT GENERATED BY OFC CAN DEGRADE THE METALLURGICAL PROPERTIES OF THE WORK MATERIAL ADJACENT TO THE CUT EDGES. HARDENABLE STEELS MAY REQUIRE PREHEAT AND/OR POSTHEAT TO CONTROL MICROSTRUCTURE AND MECHANICAL PROPERTIES.
- PREHEAT FLAMES AND THE EXPELLED RED HOT SLAG POSE A FIRE HAZARD TO PLANT AND PERSONNEL.

Oxygen consumption and flow rates vary depending on whether economy, speed, or accuracy of cut is desired. For average straight-line cutting of low-carbon steel, consumption of cutting oxygen per pound of metal removed varies with thickness of the metal and is lowest at a thickness of 100 to 125 mm (4 to 5 in.).

By assuming that for every unit mass of iron oxidized an equal mass of iron melts, one can calculate the amount of heat generated by the cutting reaction--heat emitted is 6680 kJ/kg (2870 Btu/lb) of iron oxidized. Melting of 0.5 kg (1 lb) of iron takes 715 kJ (680 Btu), based on a melting point of 1540 °C (2800 °F), 0.8 kJ/kg · K (0.2 Btu/lb · °F) as the specific heat, and 272 kJ/kg (117 Btu/lb) as the heat of fusion. Only a small amount of the heat melts the iron; most of it, about 4900 kJ/kg (2100 Btu/lb), goes into the reaction. Some of this superheats the molten metal, some soaks into the workpiece, and some leaves by radiation and convection. Most of it leaves with the slag and hot exhaust gases.

As cutting oxygen flows down through the cut, the quantity available for reaction decreases. If the flow of oxygen is large and well collimated, the rate of cutting through the depth of the cut is approximately constant. The cutting face remains vertical if the oxygen is in excess and if cutting speed is not excessive.

If oxygen flow is insufficient, or cutting speed too high, the lower portions of the cut react more slowly, and the cutting face curves behind the torch. The horizontal distance between point of entry and exit is called drag (see Fig. 1).

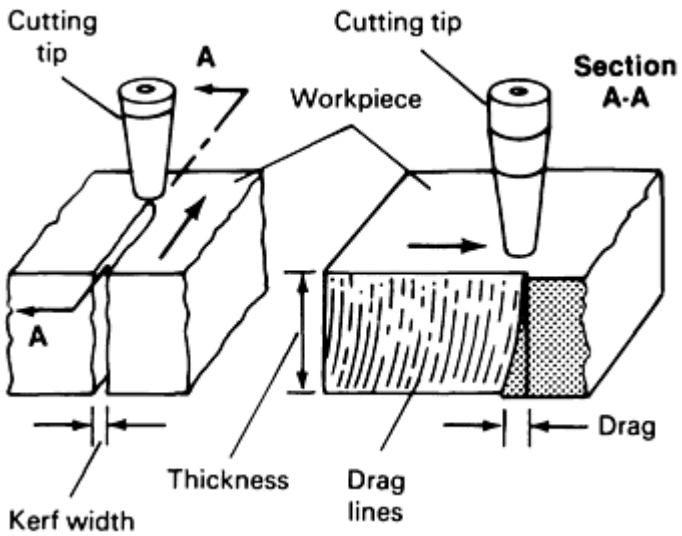

FIG. 1 SCHEMATIC CROSS SECTION OF WORK METAL DURING OFC SHOWING DRAG ON CUTTING FACE

Drag influences edge quality. Optimum edge quality results from zero drag--the oxygen stream enters and leaves the cut in a straight line along the cutting tip axis. This is called a "drop-cut," designating a clean, fully severed edge. Increasing cutting speed or reducing oxygen flow makes less oxygen available at the bottom of the cut, causing the bottom of the cut to "drag" behind the top of the cut. A drag of 20% means that the bottom of the cut edge lags the top surface by 20% of the material thickness. Drag lines appear as curved ripples on the cut edge. For fast, rough cuts, some drag is acceptable.

Drag is a rough measure of cut quality and of economy in oxygen consumption. In metal thicknesses up to 50 to 75 mm (2 or 3 in.), 10 to 15% drag indicates good quality of cut and economy. The key to quality cuts is control of heat input. Higher quality demands less drag; more drag indicates poorer quality and low oxygen consumption. Excessive drag may lead to incomplete cutting.

In very thin sections, drag has little significance. In very thick sections, the goal is to avoid excessive drag.

Preheating may consist of merely warming a cold workpiece with a torch or may require furnace heating of the work beyond 540 °C (1000 °F). For some alloy steels, preheat temperatures are 205 to 315 °C (400 to 600 °F). Carbon steel billets and other sections occasionally are cut at 870 °C (1600 °F) and higher.

In OFC, preheating is accomplished by means of the oxyfuel gas flame, which surrounds the cutting oxygen stream. At cut initiation, the preheat flame, the result of oxygen and fuel gas combustion, brings a small amount of material to ignition temperature so that combustion can proceed. After cutting begins, the preheat flame merely adds heat to compensate for heat lost by convection and radiation or through gas exhausted during cutting. The flame also helps to remove or burn off scale and dirt on the plate surface; the hot combusted gases protect the stream of cutting oxygen from the atmosphere.

Preheating may also be applied over a broader area of the work. It may include soaking the entire workpiece in a furnace to bring it up to 95 to 205 °C (200 to 400 °F), or a simple overall warm-up with a torch to bring cold plate to room temperature. A preheat improves cutting speed significantly, allowing faster torch travel for greater productivity and reduced consumption of fuel gas. Broader preheat smooths the temperature gradient between the base metal and the cut edge, possibly reducing thermal stress and minimizing hardening effects in some steels.

Properties of Fuel Gases

Each cutting job entails a different type or volume of work to be completed. Consequently, the best gas for all cutting in a fabricating plant is found through experimentation. Evaluating a gas for a single job requires a test run that monitors fuel gas and oxygen flow rate, labor costs, overhead, and the amount of work performed. If plant production varies from week to week, gas performance should be measured over a long enough period to achieve an accurate cost analysis. Any of the fuel gases may perform well over a range of flow rates. When comparing gases, performance should be rated at the lowest flow rate that gives acceptable results for each gas.

Gas manufacturers provide comprehensive data on flame temperature, heat of combustion, oxygen-to-gas consumption ratio, heat transfer, and heat distribution in the flame. Gas properties can be rated on a weight or volume basis. Flow rates, for example, commonly are given in terms of volume. Gas may be sold, however, by weight or by volume, and specifications may state properties in terms of one or the other to make the product seem as attractive as possible. For example, acetylene occupies more volume per pound than does propane. Consequently, cost based on weight makes propane liquid seem inexpensive. Cost based on volume makes the lighter fuels, such as acetylene, seem less costly. The user must understand these ratings and comparisons.

Heat Distribution in the Flame. Combustion of fuel gas produces the preheat flame, which initiates cutting action and helps sustain the operation. These flames heat the surface of the work to ignition temperature to (1) initiate cutting, (2) descale and clean the work surface, (3) supply heat to the work and the cutting oxygen stream to maintain the heat needed for continuous cutting, and (4) shield the cutting oxygen stream from surrounding air. Preheat gases consist of hydrocarbons, which produce water vapor and carbon dioxide as products of chain reactions. These reactions occur in cones within the flame, usually visible as an inner and outer flame. A gas whose inner flame has a high temperature and high heat release provides the most concentrated heat. These gases are superior for fast starts in flame cutting of high-alloy steels that are difficult to cut.

When low heat release is accompanied by high flame temperature, even though it is above the melting point of steel, heat is diffused and gives slow starts in flame cutting. Gases, such as natural gas, that release most of their heat in the outer flame are well suited to heating and heavy cutting. Heat distribution is a good indication of the potential performance of a particular gas.

Acetylene

Acetylene is the most widely used cutting gas. It burns hotter than any of the other common fuel gases, making it indispensable for certain jobs. The volume of oxygen consumed per volume of acetylene is $2\frac{1}{2}$. Combustion occurs in stages. In the small inner cone at the tip of the torch, acetylene burns with feed-line oxygen. This reaction gives off a blistering amount of heat; the tip of the inner cone is the hottest part. Burning continues in the outer envelope of the flame, in a cooler, blue-colored region.

Most oxygen for this reaction comes from the air surrounding the flame. Of the $2\frac{1}{2}$ parts of oxygen needed for acetylene to burn completely, about $1\frac{1}{2}$ comes from the air and 1 part from line oxygen. A neutral flame, recommended for manual cutting, consumes equal volumes of line oxygen and acetylene. In practice, operators may raise the line oxygen ratio to $1\frac{1}{2}$, a proportion that produces an oxidizing flame. The inner cone contracts and becomes sharply defined. This is the hottest flame attainable with acetylene or with any other raw fuel gas. The triple bond in acetylene makes it the hottest burning gas. In cutting of steel, operators should adjust the acetylene-to-oxygen ratio to produce a neutral flame, even though it is below the highest possible temperature. A neutral flame minimizes oxidation and carburization of the base metal. Users sometimes use the hotter oxidizing flame for piercing at the start of a cut.

Acetylene is unstable at room temperature and moderate pressure and can explode under a blow even without the presence of air or oxygen. For safe storage and handling, it is dissolved in acetone. A typical cylinder is filled with heavy porous clay, which holds the acetone. Acetylene, forced into the cylinder, saturates the acetone. When the cylinder valve opens, acetylene vaporizes above the acetone solution. The regulator limits outlet pressure to 105 kPa gage pressure (15 psig) or less.

Cylinders for acetylene should be handled with care. Safety requires them to be placed upright to prevent acetone solvent from entering the regulator. The ratio of line oxygen consumption to acetylene consumption is lower than that for the other fuel gases. Acetylene uses less oxygen at its maximum flame temperature, so that handling of oxygen cylinders may be reduced, thus offsetting the inconvenience of the acetylene cylinder.

Cost of acetylene as a fuel gas changes with consumption. Large-volume users of acetylene often install bulk trailers that hook up to manifold piping systems. When volume justifies, users may install acetylene-generating plants, thus reducing handling costs.

Heat content of acetylene (kJ/m^3, or Btu/ft^3) is lower than all gases except natural gas. Although acetylene burns at a high temperature, it has to burn at higher flow rates than other gases to deliver the same amount of heat. Acetylene releases heat rapidly in a small, concentrated area. Acetylene is a poor choice for cutting a large block of metal because of high fuel cost and the need for large volumes of the fuel to obtain required total heat. To concentrate heat on a limited area, as in cutting thin plate, acetylene is a good choice. It burns faster than other gases, and it burns close to the torch tip. Heat energy concentrates at the tip of the tiny cone.

Acetylene gives a narrow heat-affected zone (HAZ) and possibly less distortion (depending on the volume and shape of the work) than a wider spreading heat. It is particularly well suited to fast cutting of plate under 13 mm ($\frac{1}{2}$ in.) thick. The hot flame cuts through heavy mill scale or rust and can make a bevel quickly with good edge quality. Acetylene facilitates short, stop-and-start cutting jobs, such as cutting structural members and reinforcing bars, because of its short preheat time. For stack cutting and for cutting heavy sections--operations requiring large heat input into a deep kerf--acetylene does not perform as well as other gases. This type of work calls for a fuel gas with high heat output in the secondary flame, such as propane or methylacetylene-propadiene-stabilized (MPS or MAPP) gas.

However, manual cutting is cooler with acetylene than with other gases; less heat rises into the operator's face. It is one of the most versatile and convenient fuels for shops that perform a wide range of fuel gas operations and for shops that cannot justify handling more than one gas. Data for both machine and manual oxyacetylene cutting (OFC-A) of carbon steel plate of varying thickness are given in Tables 1 and 2.

(A) VALUES DO NOT NECESSARILY VARY IN EXACT PROPORTION TO PLATE THICKNESS, BECAUSE STRAIGHT-LINE RELATIONS DO NOT EXIST AMONG PRESSURE, SPEED, AND ORIFICE SIZES.

(B) LOWEST SPEEDS AND HIGHEST GAS CONSUMPTIONS ARE FOR INEXPERIENCED OPERATORS, SHORT CUTS, DIRTY OR NONUNIFORM MATERIAL. HIGHEST SPEEDS AND LOWEST GAS CONSUMPTIONS ARE FOR EXPERIENCED OPERATORS, LONG CUTS, CLEAN AND UNIFORM MATERIAL.

(C) PRESSURE OF ACETYLENE FOR THE PREHEATING FLAMES IS MORE A FUNCTION OF TORCH DESIGN THAN OF THE THICKNESS OF THE PART BEING CUT. FOR ACETYLENE PRESSURE DATA, SEE CHARTS FROM MANUFACTURERS OF APPARATUS.

(A) VALUES DO NOT NECESSARILY VARY IN EXACT PROPORTION TO PLATE THICKNESS, BECAUSE STRAIGHT LINE RELATIONS DO NOT EXIST AMONG PRESSURE, SPEED, AND ORIFICE SIZES.

(B) LOWEST SPEEDS AND HIGHEST GAS CONSUMPTIONS ARE FOR INEXPERIENCED OPERATORS, SHORT CUTS, DIRTY OR NONUNIFORM MATERIAL. HIGHEST SPEEDS AND LOWEST GAS CONSUMPTIONS ARE FOR EXPERIENCED OPERATORS, LONG CUTS, CLEAN AND UNIFORM MATERIAL.

(C) PRESSURE OF ACETYLENE FOR THE PREHEATING FLAMES IS MORE A FUNCTION OF TORCH DESIGN THAN OF THE THICKNESS OF THE PART BEING CUT. FOR ACETYLENE PRESSURE DATA. SEE CHARTS FROM MANUFACTURERS OF APPARATUS.

Natural Gas

The composition of natural gas varies, depending on its composition at the well, but its main component is methane (CH_4). One volume of methane requires two volumes of oxygen. The combustion ratio is 2 to 1.

Although available in pressurized cylinders, natural gas usually is supplied through low-pressure lines from a local utility. Torchmakers overcome low line pressure through torch design. A siphon stream in the mixing chamber pulls the gas in at the required rate for complete combustion. Torches operate at pressures as low as 2 kPa (4 ozf/in.^{2}) gage line pressure.

A natural gas flame is more diffuse than an acetylene flame--heat intensity is lower, and adjustment for reducing (carburizing), neutral, and oxidizing flames is less clearly defined. Preheating time is longer.

Because heat content is low and heat emission is diffuse, natural gas cannot be used to weld steel. Consequently, if cutting and welding must be performed with a single fuel gas, natural gas cannot be used.

Despite these disadvantages, use of natural gas for cutting has increased. It is the lowest cost commercial fuel gas and, with careful torch adjustment, produces excellent cuts in light- to heavy-gage material. Data for manual oxynatural gas straight-line cutting of carbon steel plate of varying thickness are given in Table 3. Table 4 gives data for oxynatural gas shape cutting of carbon steel plate. Table 5 gives data for machine oxynatural gas drop cutting of shapes from thick carbon steel plate.

(A) PRESSURE MEASURED AT TORCH INLET

Methylacetylene-Propadiene-Stabilized Gas

The common trade name of methylacetylene-propadiene-stabilized gas is MAPP gas. Methylacetylene-propadiene-stabilized mixtures are by-products of the manufacture of chemicals such as ethylene. These mixtures combine the qualities of an acetylene flame with a more even heat distribution in a fuel that is less prone to explosion and less costly than acetylene. It is supplied as a liquid, in large tanks or in portable cylinders.

Methylacetylene-propadiene-stabilized gases contain a mixture of several hydrocarbons, including propadiene (allene), propane, butane, butadiene, and methylacetylene. Methylacetylene, like acetylene, is a high-energy triple-bond compound. It is unstable, but other compounds in the mixture dilute it sufficiently to enable safe handling.

Compositions of MPS mixtures are proprietary and may vary; consequently, an exact combustion equation cannot be specified. The mixture bums hotter than propane or propylene. It also affords a high release of heat energy in the primary flame cone, characteristic of acetylene. The outer flame gives relatively high heat release, similar to propane and propylene. The overall heat distribution in the flame is the most even of any of the other gases. The inner cone releases 19.3 MJ/m^3 (517 Btu/ft^3), and the outer flame releases 70.37 MJ/m^3 (1889 Btu/ft^3). The coupling distance is therefore less exacting than for acetylene. The best coupling distance for MPS fuel places the outer cone on the plate; however, a shorter coupling distance also delivers considerable heat.

The neutral MPS gas-oxygen flame generates 89.62 MJ/m^3 (2406 Btu/ft^3) with a 2925 °C (5300 °F) flame with a ratio of 3.5 to 4 parts oxygen to 1 part fuel. Values vary with the composition of the gas. The carburizing flame, 2.2 parts or less oxygen to 1 part fuel, can weld alloys, such as aluminum, which oxidize readily. A neutral flame, with a ratio of 2.3 parts line oxygen to 1 part fuel gas, can weld steel. At 2.8 line oxygen ratio, the flame becomes oxidizing, unsuitable for welding. Methylacetylene-propadiene-stabilized gas produces its hottest flame at 3.3 line oxygen-to-gas ratio.

In comparing the cost of MPS gas with the cost of acetylene, differences in cylinder yield and consumption rate must be considered. A 54 kg (120 lb) cylinder of MPS gas yields 17.5 m^3 (620 ft^3) of gas; a 115 kg (240 lb) cylinder of acetylene yields only 7.4 m^3 (260 ft^3) of gas. In addition, acetylene bums faster. Thus, storage, transportation, and time and labor for changing cylinders become important cost factors.

Methylacetylene-propadiene-stabilized gas competes with acetylene for almost every job that uses fuel gas. Its most unusual use perhaps is in deep water cutting. Because acetylene outlet pressure is limited to 105 kPa gage pressure (15 psig), it cannot be used below 9 m (30 ft) of water. The Navy and several shipyards use MPS gas for underwater work. Table 6 provides data for oxy/MPS gas cutting of carbon steel plate.

Note: All recommendations are for straight-line cutting with a three-hose torch perpendicular to work.

(A) ALL TIPS ARE OF DESIGN RECOMMENDED BY THE SUPPLIER.

(B) PRESSURE OF CUTTING OXYGEN MEASURED AT THE TORCH.

Effect of Oxyfuel Cutting on Base Metal

During cutting of steel, the temperature of a narrow zone adjacent to the cut face is raised considerably above the transformation range. As the cut progresses, the steel cools through this range. Cooling rate depends on the heat conductivity and the mass of the surrounding material, on loss of heat by radiation and convection, and on speed of cutting. When steel is at room temperature, the rate of cooling at the cut is sufficient to produce a quenching effect on the cut edges, particularly in heavier cuts in large masses of cold metal. Depending on the amount of carbon and alloying elements present, and on the rate of cooling, pearlitic steel transforms into structures ranging from spheroidized carbides in ferrite to harder constituents. The HAZ may be 0.8 to 6.4 mm ($\frac{1}{32}$ to $\frac{1}{4}$ in.) deep for steels 9.5 to 150 mm ($\frac{3}{8}$ to 6 in.) thick. Approximate depths of the HAZ in oxyfuel gas cut carbon steels are given in Table 7. Some increase in hardness usually occurs at the outer margin of the HAZ of nearly all steels.

TABLE 7 APPROXIMATE DEPTHS OF HAZ IN OXYGEN CUT CARBON STEELS

PLATE THICKNESS		HAZ DEPTH	
MM	IN.	MM	IN.
LOW-CARBON STEELS			
<13	$<\frac{1}{2}$	<0.8	$<\frac{1}{32}$
13	$\frac{1}{2}$	0.8	$\frac{1}{32}$
150	6	3.2	$\frac{1}{8}$
HIGH-CARBON STEELS			
<13	$<\frac{1}{2}$	<0.8	$<\frac{1}{32}$
13	$\frac{1}{2}$	0.8-1.6	$\frac{1}{32}$-$\frac{1}{16}$
150	6	3.2-6.4	$\frac{1}{8}$-$\frac{1}{4}$

Note: The depth of the fully hardened zone is considerably less than the depth of the HAZ. For most applications of gas cutting, the affected metal does not have to be removed.

Low-Carbon Steel. For steels containing 0.25% C or less cut at room temperature, the hardening effect usually is negligible, though at the upper carbon limit it may be significant if subsequent machining is required. Short of preheating or annealing the workpiece, hardening may be lessened by ensuring that (1) the cutting flame is neutral to slightly oxidizing, (2) the flame is burning cleanly, and (3) that the inner cones of the flame are at the correct height. By increasing the machining allowance slightly, the first cut usually can be made deep enough to penetrate below the hardened zone in most steels. Mechanical properties of low-carbon steels generally are not adversely affected by OFC. Typical data for OFC of low-carbon steel plate are given in Tables 1, 2, 3, 4, 5, and 6.

Medium-Carbon Steels. Steels having carbon contents of 0.25 to 0.45% are affected only slightly by hardening caused by OFC. Up to 0.30% C, steels with very low alloy content show some hardening of the cut edges, but generally not enough to cause cracking. Over 0.35% C, preheating to 260 to 315 °C (500 to 600 °F) is needed to avoid cracking. All medium-carbon steels should be preheated if the gas cut edges are to be machined.

High-Carbon and Alloy Steels. Oxyfuel gas cutting of steels containing over 0.45% C and of hardenable alloy steels at room temperature may produce a thin layer of hard, brittle material on the cut surface that may crack from the stress of cooling. Preheating and annealing may alleviate hardening and the formation of residual stress.

Preheating to 260 to 315 °C (500 to 600 °F) is sufficient for high-carbon steels; alloy steels may require preheating as high as 540 °C (1000 °F). Preheat temperature should be maintained during cutting. Thick preheated sections should be cut as soon as possible after the piece has been withdrawn from the furnace.

Local preheating heats the volume of the workpiece enclosing the HAZ of the cut. If the volume of material to be heated is small, the flame of a cutting. torch can be used for preheating. When the workpiece is thick and broad, a special heating torch may be necessary. Workpieces must be heated uniformly through the section to be cut, without excessive temperature gradient.

Distortion, which is the result of heating by the gas flame, can cause considerable damage during (1) cutting of thin plate (less than 7.9 mm, or $\frac{5}{16}$ in., thick), (2) cutting of long narrow widths, (3) close-tolerance profile cutting, and (4) cutting of plates that contain high residual stresses. The heat may release some of the restraint to locked-in stress, or may add new stress. In either case, deformation (warpage) may occur, thus causing inaccurate finished cuts. Plates in the annealed condition have little or no residual stress.

Deformation. In cuts made from large plates, the cutting thermal cycle changes the shape of narrow sections and leaves residual stress in the large section (see Fig. 2). The temperature gradient near the cut is steep, ranging from melting point at the cut to room temperature a short distance from it. Plate does not return to its original shape unless the entire plate is uniformly heated and cooled.

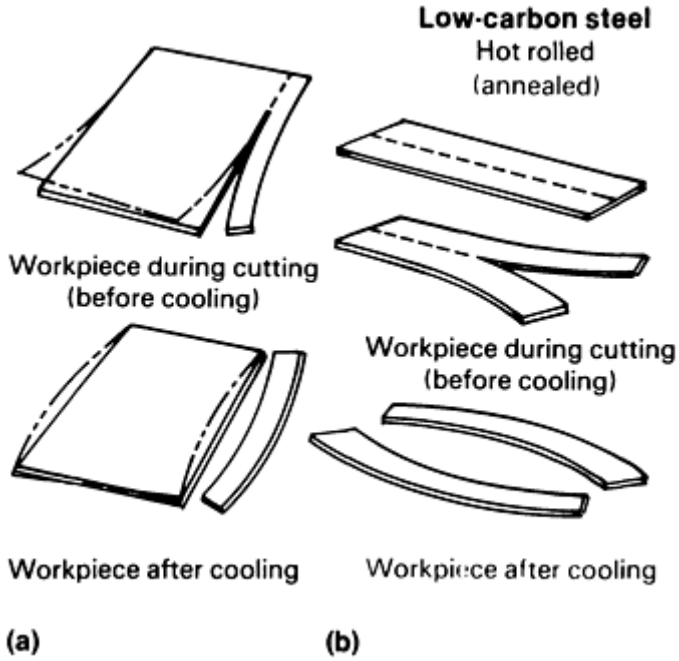

FIG. 2 EFFECTS OF OFC THERMAL CYCLE ON SHAPE OF SECTIONS. (A) PLATE WITH LARGE RESTRAINT ON ONE SIDE OF KERF, LITTLE RESTRAINT ON THE OTHER SIDE. PHANTOM LINES INDICATE DIRECTION OF RESIDUAL STRESS THAT WOULD CAUSE DEFORMATION EXCEPT FOR RESTRAINT. (B) PLATE WITH LITTLE RESTRAINT ON EITHER SIDE

As the metal heats, it expands and its yield strength decreases; the weakened heated material is compressed by the surrounding cooler, stronger metal. The hotter metal continues to expand elastically in all directions until its compressive yield strength is reached, at which point it yields plastically in directions not under restraint. The portion of this upset metal above 870 °C (1600 °F) is virtually stress-free; the remainder is under compressive stress that is equal to its yield strength. Metal that expands but does not upset is under compressive strength below yield. The net stress on the heated side of the neutral axis causes bowing of a narrow plate during cutting, as shown in Fig. 2.

As the heated metal begins to cool, it contracts, and its strength increases. First, the contraction reduces the compressire stress in the still-expanded metal. When the compressive stress reaches zero and the plate regains its original shape,

previously upset metal also has regained strength. This metal is now in tension as it cools, and its tensile yield strength increases. Tension increases until the metal reaches room temperature. Residual tensile stress in the cooling side of the neutral axis causes the bowing of narrow plates after cooling (see Fig. 2). Controlled upsetting is the basis of flame straightening.

Control of Distortion. Preheating the workpiece can reduce distortion by reducing differential expansion, thereby decreasing stress gradients. Careful planning of the cutting sequence also may help. For example, when trimming opposite sides of a plate, both sides should be cut in the same direction at the same time. When cutting rings, the inside diameter should be cut first; the remaining plate restrains the material for the outside-diameter cut. In general, the larger portion of material should be used to retain a shape for as long as possible; the cutting sequence should be balanced to maintain even heat input and resultant residual stresses about the neutral axis of plate or part.

Oxyfuel Gas Cutting

Equipment

Commercial gases usually are stored in high-pressure cylinders. Natural gas--primarily methane--is supplied by pipeline from gas wells. The user taps into local gas lines. Acetylene, dissolved in acetone, is available in clay-filled cylinders. High-volume users often have acetylene generators on site. For heavy consumption or where many welding and cutting stations use fuel gas, banks of gas cylinders are maintained at a central location in the plant, and the gas is manifolded and piped to the point of use.

Manual gas cutting equipment consists of gas regulators, gas hoses, cutting torches, cutting tips, and multipurpose wrenches. Auxiliary equipment may include a hand truck, tip cleaners, torch ignitors, and protective goggles. Machine cutting equipment varies from simple rail-mounted "bug" carriages to large bridge-mounted torches that are driven by computer-directed drives.

Gas regulators reduce gas pressure and moderate gas flow rate between the source of gas and its entry into the cutting torch to deliver gas to the cutting apparatus at the required operating pressure. Gas enters the regulating device at a wide range of pressures. Gas flows through the regulator and is delivered to the hose-torch-tip system at the operating pressure, which is preset by manual adjustment at the regulator and at the torch. When pressure at the regulator drops below the preset pressure, regulator valves open to restore pressure to the required level. During cutting, the regulator maintains pressure within a narrow range of the pressure setting.

Regulators should be selected for use with specific types of gas and for specific pressure ranges. Portable oxyacetylene equipment requires an oxygen regulator on the oxygen cylinder and an acetylene regulator on the acetylene cylinder, which are not interchangeable.

High-low regulators conserve preheat oxygen when natural gas or liquefied petroleum gas (LPG) is the preheat fuel used in OFC. These gases require a longer time to start a cut than acetylene or MPS. High-low regulators reduce preheat flow to a predetermined level when the flow of cutting oxygen is initiated. When the regulator switches from high to low, preheat cut-back may range from 75 to 25% as plate thicknesses increase from 9.5 to 205 mm ($\frac{3}{8}$ to 8 in.). High-low regulators are used for manual and automatic cutting with natural gas and with LPG.

Hose. Flexible hose, usually 3.2 to 13 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) in diameter, rated at 1.4 MPa gage pressure (200 psig) maximum, carries gas from the regulator to the cutting torch. Oxygen hoses are green; the fittings have right-hand threads. Fuel gas hoses are red; the fittings have left-hand threads and a groove cut around the fittings. For heavy cutting, two oxygen hoses may be necessary--one for preheat and one for cutting oxygen. Multi-torch cutting machines often have three-hose torches.

Cutting torches, such as the one shown in Fig. 3, control the mixture and flow of preheat oxygen and fuel gas and the flow of cutting oxygen. The curing torch discharges these gases through a cutting tip at the proper velocity and flow rate. Pressure of the gases at the torch inlets, as well as size and design of the cutting tip, limits these functions, which are operator controlled.

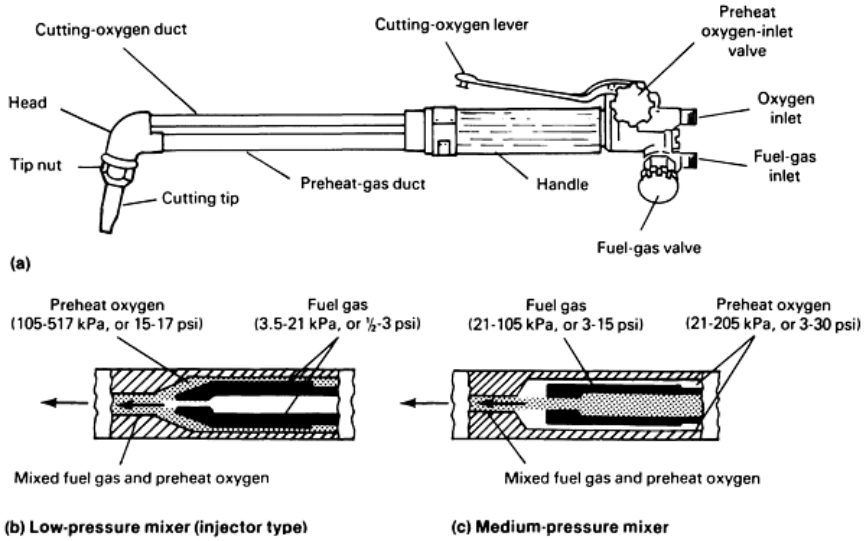

FIG. 3 TYPICAL MANUAL CUTTING TORCH IN WHICH PREHEAT GASES ARE MIXED BEFORE ENTERING TORCH HEAD. (B) AND (C) SECTIONS THROUGH PREHEAT GAS DUCT SHOWING TWO TYPES OF MIXERS COMMONLY USED WITH THE TORCH SHOWN. AFTER THE WORKPIECE IS SUFFICIENTLY PREHEATED, THE OPERATOR DEPRESSES THE LEVER TO START THE FLOW OF CUTTING OXYGEN. VALVES CONTROL THE FLOW OF OXYGEN AND FUEL GAS TO ACHIEVE REQUIRED FLOW AND MIXTURE AT THE CUTTING TIP.

Oxygen inlet control valves and fuel gas inlet control valves permit operator adjustment of gas flow. Fuel gas flows through a duct and mixes with the preheat oxygen; the mixed gases then flow to the preheating flame orifices in the cutting tip. The oxygen flow is divided--a portion of the flow mixes with the fuel gas, and the remainder flows through the cutting oxygen orifice in the cutting tip. A lever-actuated valve on the manual torch starts the flow of cutting oxygen; machine cutting starts the oxygen from a panel control.

Fuel gases supplied at low pressure, such as natural gas tapped from a city line, require an injector-mixer (Fig. 3b) to increase fuel gas flow above normal operating pressures. Optimum torch performance relies on proper matching of the mixer to the available fuel gas pressure.

Cutting tips are precision-machined nozzles, produced in a range of sizes and types. Figure 4(a) shows a single-piece acetylene cutting tip. A two-piece tip used for natural gas (methane) or LPG is shown in Fig. 4(b). A tip nut holds the tip in the torch. For a given type of cutting tip, the diameters of the central hole, the cutting oxygen orifice, and the preheat ports increase with the thickness of the metal to be cut. Cutting tip selection should match the fuel gas: hole diameters must be balanced to ensure an adequate preheat-to-cutting oxygen ratio. Preheat gas flows through ports that surround the cutting oxygen orifice. Smoothness of bore and accuracy of size and shape of the oxygen orifice are important to efficiency. Worn, dirty bores reduce cut quality by causing turbulence in the cutting oxygen stream.

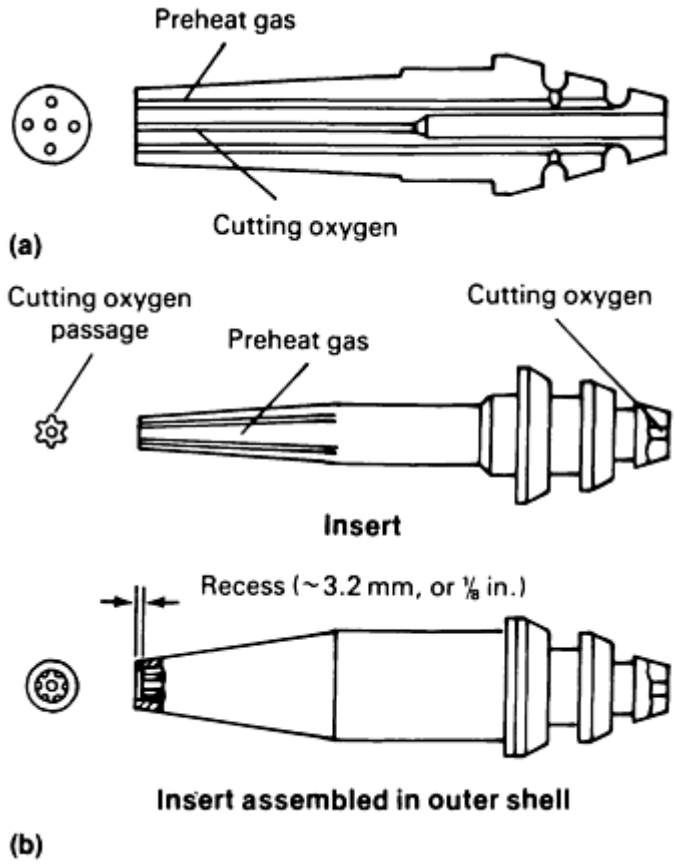

FIG. 4 TYPES OF CUTTING TIPS. (A) SINGLE-PIECE ACETYLENE CUTTING TIP. (B) TWO-PIECE TIP FOR NATURAL GAS OR LPG. FUEL GAS AND PREHEAT OXYGEN MIX IN TIP. RECESSED BORE HELPS PROMOTE LAMINAR FLOW OF GAS.

The size of the cutting tip orifice determines the rate of flow and velocity of the preheat gases and cutting oxygen. Flow to the cutting tip can be varied by adjustment at the torch inlet valve or at the regulator, or both.

Increasing cutting oxygen flow solely by increasing the oxygen pressure results in turbulence and reduces cutting efficiency. Turbulence in the cutting oxygen causes wide kerfs, slows cutting, increases oxygen consumption, and lowers quality of cut. Consequently, larger cutting tips are required for making heavier cuts.

Standard tips, as shown in Fig. 5(a), have a straight-bore oxygen port. Oxygen pressures range from 205 to 415 kPa (30 to 60 psi) and are used for manual cutting. High-speed tips, or divergent cutting tips (Fig. 5b), use a converging, diverging orifice to achieve high gas velocities. The oxygen orifice flares outward. High-speed tips operate at cutting oxygen pressures of about 670 kPa (100 psi) and provide cutting jets of supersonic velocity. These tips are precision made and are more costly than straight-drilled tips, but they produce superior results--improved edge quality and cutting speeds 20% higher than standard tips. Best suited to machine cutting, high-speed tips produce superior cuts in plate up to about 150 mm (6 in.) thick. Above this thickness, advantages of their use decrease; they are not recommended for cutting metal more than 255 mm (10 in.) thick.

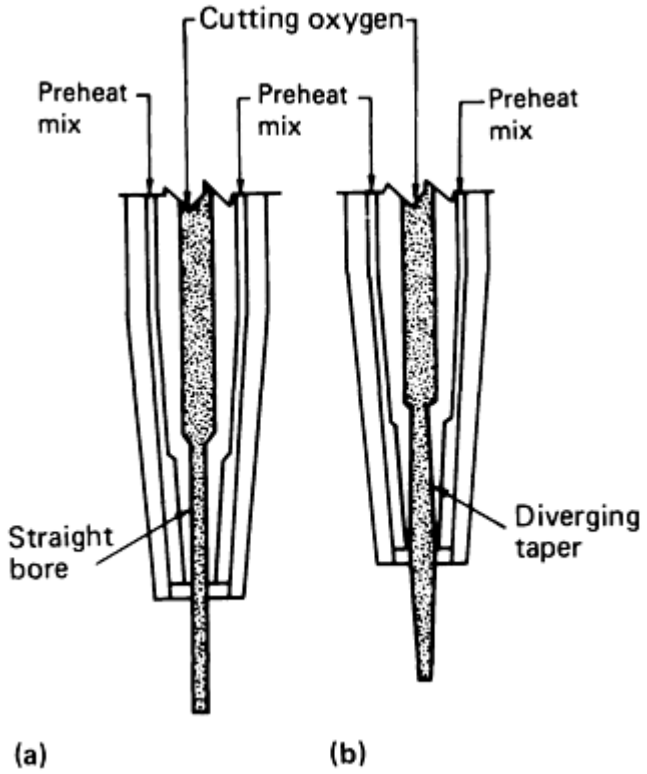

FIG. 5 OXYFUEL CUTTING TIPS. (A) STANDARD CUTTING TIP WITH STRAIGHT-BORE OXYGEN ORIFICE. (B) HIGH-SPEED CUTTING TIP WITH DIVERGENT-BORE OXYGEN ORIFICE

Equipment Selection Factors. Natural gas and liquefied petroleum gases operate most efficiently with high-low gas regulators, injector-type cutting torches, and two-piece, divergent, recessed cutting tips. Acetylene cutting is most efficient with divergent single-piece tips. If acetylene is supplied by low-pressure generators, an injector-type torch is best suited to most cutting applications.

Two-piece, divergent cutting tips are best suited for use with MPS gas; the tip recess should be less than for use of natural gas or propane. Injector-type torches and high-low regulators are not required with MPS gas.

Starting the Cut

To start a cut at the outer edge of the workpiece, the operator should place the cutting torch so that the ends of the inner cones in the preheating flame just clear the work metal. When a spot of metal at the top of the edge is heated to bright red, the stream of cutting oxygen is turned on. The reactions form a slot in the plate edge, and the torch can move along the desired line of cut. Piercing starts are necessary to cut holes, slots, and shapes.

In manual piercing, the spot should be heated to bright red. Then the torch should be raised to 13 mm ($\frac{1}{2}$ in.) above the normal cutting distance, and cutting oxygen should be turned on slowly. As soon as the metal is penetrated, the torch is lowered to cutting height and cutting action is started.

Machine torch piercing is similar to manual operations, except that torch travel begins after the cutting oxygen is slowly turned on and the flame starts to eject molten slag. Initial piercing action does not completely penetrate the plate, so that the completed pierce covers a short distance (depending on plate thickness) and forms a sloping trough with molten slag ejected from the torch. Length of the lead-in should be increased for heavy plate.

Light Cutting

Light cutting (material less than 9.5 mm, or $\frac{3}{8}$ in., thick) requires extra care in tip selection, tip cleanliness, and control of gas pressure. Quality of cut when oxyfuel gas cutting steel thinner than 3.2 mm ($\frac{1}{8}$ in.) is virtually impossible to control. Wide, uneven kerf, ragged edge, and distortion result from heat buildup.

For straight or large-radius cuts in thicknesses 3.2 mm ($\frac{1}{8}$ in.) and over, angling the cutting torch forward increases the distance through the cut and may help to deflect some of the heat input. When cutting shapes, however, the torch must be vertical.

One of the most important techniques for cutting of thin sections is stack cutting (see the section of this article on stack cutting for more detailed information on this process). This technique avoids the difficulties inherent in light cutting and also increases production. Sections stacked for cutting must be flat and tightly clamped together.

Oxyfuel Gas Cutting

Medium Cutting

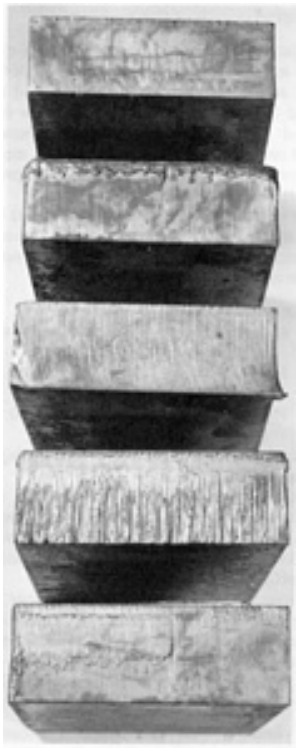
In cutting plate 9.5 to 255 mm ($\frac{3}{8}$ to 10 in.) thick, OFC achieves its highest efficiency and produces the most satisfactory cuts. Conditions for medium cutting of carbon steel plate using a variety of oxyfuel combinations are presented in Tables 1, 2, 3, 4, 5, and 6. Commercial cuts must meet these requirements:

- DRAG IS SHORT, MARKINGS ON THE FACE OF THE CUT APPROACH VERTICAL.
- SIDE OF THE CUT IS SMOOTH, NOT FLUTED, GROOVED, OR RAGGED.
- SLAG SHOULD NOT ADHERE TO THE BOTTOM OF THE CUT.
- UPPER AND LOWER EDGES SHOULD BE SHARP.
- COST IS MODERATE.

The following variables require adjustment to obtain satisfactory commercial cuts:

- SUITABLE CUTTING TIP, WITH CUTTING ORIFICE OF CORRECT TYPE AND SIZE, AND PROPER DEGREE OF PREHEAT
- SUITABLE OXYGEN AND FUEL GAS PRESSURES
- CORRECT CUTTING SPEED
- UNIFORM TORCH MOVEMENT
- CLEAN, SMOOTH-BORE CUTTING ORIFICE AND PREHEAT HOLES
- HIGH-PURITY OXYGEN
- PROPER ANGLE OF THE CUTTING JET IN RELATION TO THE UPPER EDGE OF THE CUT

Surface finish for gas cut production parts is compared with sample cuts. One such group of machine cut samples is shown in Fig. 6. Sample A represents high quality, with drag varying about 2 to 7%. Samples B, C, D, and E show typical defects resulting from improper cutting speed or torch settings. The American Welding Society (AWS) provides standard plastic samples of cut edges.



TORCH SETTINGS FOR BAR A[(A)]	
PREHEAT OXYGEN PRESSURE:	
HIGH (EDGE STARTING)	310 KPA (45 PSI)
LOW (CUTTING)	55-83 KPA (8-12 PSI)
PREHEAT NATURAL GAS PRESSURE:	
HIGH (EDGE CUTTING)	21 KPA (3 PSI)
LOW (CUTTING)	UNDER 430 PA (1 OZ/IN.^{2})
CUTTING OXYGEN PRESSURE	670 KPA (100 PSI)
CUTTING SPEED	255-380 MM/MIN (10-15 IN./MIN)

(A) SETTINGS FOR BARS B, C, D, AND E WERE VARIED AS NOTED IN THE LEGEND ABOVE. ALL BARS WERE CUT WITH TWO-PIECE DIVERGENT-NOZZLE (HIGH-SPEED) TIPS WITH 1.37 MM (0.054 IN.) DIAM CUTTING OXYGEN ORIFICE. ALL CUTTING WAS DONE WITH LOW PREHEAT SETTINGS, EXCEPT FOR BAR B, WHICH WAS CUT WITH BOTH PREHEAT

FIG. 6 COMPARISON OF SURFACE FINISH OF GAS CUT SPECIMENS. (A) PROPER SPEED, PREHEAT, AND CUTTING-OXYGEN PRESSURE. NOTE CLEAN FACE AND NEARLY STRAIGHT DRAG LINES. (B) PROPER SPEED AND CUTTING-OXYGEN PRESSURE, TOO MUCH PREHEAT. NOTE EXCESSIVE SLAG AND ROUNDING OF TOP EDGE. (C) PROPER PREHEAT AND CUTTING-OXYGEN PRESSURE, BUT TOO MUCH SPEED. NOTE INCREASE IN DRAG AND UNCUT CORNER AT LOWER LEFT. (D) PROPER SPEED AND PREHEAT, BUT TOO MUCH CUTTING-OXYGEN PRESSURE. SURFACE IS ROUGH AND TOP EDGE IS MELTED. (E) PROPER PREHEAT AND CUTTING-OXYGEN PRESSURE, BUT SPEED TOO LOW. BURNED SLAG ADHERES TO CUT SURFACE.

Tip Design. General-purpose cylindrical-bore tips operate best with cutting oxygen pressures of 205 to 415 kPa (30 to 60 psi); a pressure of 275 kPa (40 psi) is a good initial setting. Divergent-orifice tips operating with cutting oxygen pressures of about 690 kPa (100 psi), with variations of ± 140 kPa (±20 psi) may provide better results. Because tip size controls kerf width, a smaller tip should be used for a narrower kerf; the part may not drop free, and slower speed must be used. Larger-than-normal tips may be used when the metal is covered with thick scale.

Cutting Speed. Within recommended speed ranges, slow cutting produces the best results; higher speeds are used for maximum output. Optimum cutting speed may be determined by observing the material that is expelled from the underside of the workpiece. When speed is too slow, the cutting stream forms slag drippings. At excessive speed, a stream trails at a sharp angle to the bottom of the workpiece. Highest quality cutting occurs when a single, continuous stream is expelled from the underside for about 6.4 mm ($\frac{1}{4}$ in.), then breaks into a uniform spray. This condition is accompanied by a sound similar to that of canvas ripping.

Preheat. Less preheat is needed to continue a cut than to start it. When optimum quality is desired, the amount of preheat should be reduced after starting the cut. Commercially available devices automatically reduce preheat after cutting begins.

In thicknesses up to 50 mm (2 in.), excessive preheat may cause the top corner to melt and roll over. Insufficient preheat results in loss of cut. Correct preheat provides a continuous reaction with a sharp, clean top edge of the cut.

Kerf compensation, or the allowance of half the kerf width on the outline of the template, is the amount added for outside cuts and subtracted for inside cuts. In straight-line cutting or in following a layout, the operator may compensate for this measurement; in machine cutting, kerf compensation should be incorporated in the template. Many automatic machines incorporate kerf compensation in their controllers.

Machine Accuracy. When a machine is properly maintained, the guidance system controls accuracy. Mechanical followers are very accurate when properly adjusted. Compensation for the diameter of the follower wheel or spindle must be made in the same manner as for kerf width when making a template.

Kerf angle, the small deviation of the kerf wall from a right angle, may be caused by failure to set the torch perpendicular to the work. It may also be the result of widening of the cutting oxygen stream. In the latter case, the width of the kerf increases from the top to the bottom of the cut; this may be corrected in straight cutting by angling the torch slightly to make one wall of the kerf perpendicular. In shape cutting, where this cannot be done, kerf angle can be corrected by slightly reducing cutting oxygen pressure.

Plate movement may be vertical, caused by warp, or lateral, caused by planar expansion and contraction of the part. Vertical movement requires either manual or automatic control of torch height. A very slight allowance can be made in the initial setting of the tip-to-work distance. Lateral movement can be controlled by fixing the part to be cut on the plate support, wedging the cut within the stock plate, or allowing only a small amount of scrap trim around the part so that the scrap will move instead of the workpiece.

Heavy Cutting

Cutting of metal 255 mm (10 in.) or more in thickness requires attention to gas flow, preheat flame setting, drag, and starting technique. Standard cutting torches may be used to cut steel up to 455 to 510 mm (18 to 20 in.) thick; heavy-duty torches are necessary for sections up to 1525 mm (60 in.) thick.

Gas Flow Requirements. Heavy cutting requires a uniform supply of high-purity oxygen and fuel gas at constant pressure, and an adequate volume of cutting oxygen. Torches should have three hoses--one for the cutting oxygen, one for the preheat oxygen, and one for the fuel gas. This allows setting of proper pressures independently for preheating and cutting. Cutting oxygen hose should be at least 13 mm ($\frac{1}{2}$ in.) in diameter to ensure an adequate volume of oxygen at low pressure settings. Regulators should be used that are capable of providing the large volumes of gas required. Cutting oxygen flow requirements (ft^3/h) vary from 80 to 120 times (80*t* to 120*t*) the thickness to be cut measured in inches. Cutting oxygen consumption for shape cutting approaches 120*t* or higher; for straight-line cutting, it is between 80*t* and 100*t*. Pressures are 140 to 415 kPa (20 to 60 psi) at the torch.

Preheating. In heavy cutting, the preheat flame must extend almost to the bottom of the thickness to be cut to avoid excessive drag. If the cutting torch cannot deliver enough heat, an extra torch may be needed, or the workpiece may be furnace heated. A temperature boost of 95 to 150 °C (200 to 300 °F) assists cutting action considerably. Tip height above the work is important; if the tip is too close, excessive melting and rounding of the top edge occur. If too high, preheat will be insufficient and cutting will be slowed. Generally, 25 to 50 mm (1 to 2 in.) of separation is satisfactory.

The starting edge should be thoroughly preheated, with the preheated zone extending far down the face as shown in Fig. 7(a). As soon as the metal begins to melt, the flow of cutting oxygen and the cutting motion should proceed simultaneously, cutting at normal speed. The cut should progress down the face at a constant rate until it breaks through the bottom. Drag will be long at first, but it will shorten as soon as the cut is confined. Too slow a speed causes a shelf part way through the cut edge (Fig. 7e). Too high a speed results in incomplete penetration or in extremely long drag, as shown in Fig. 7(f).

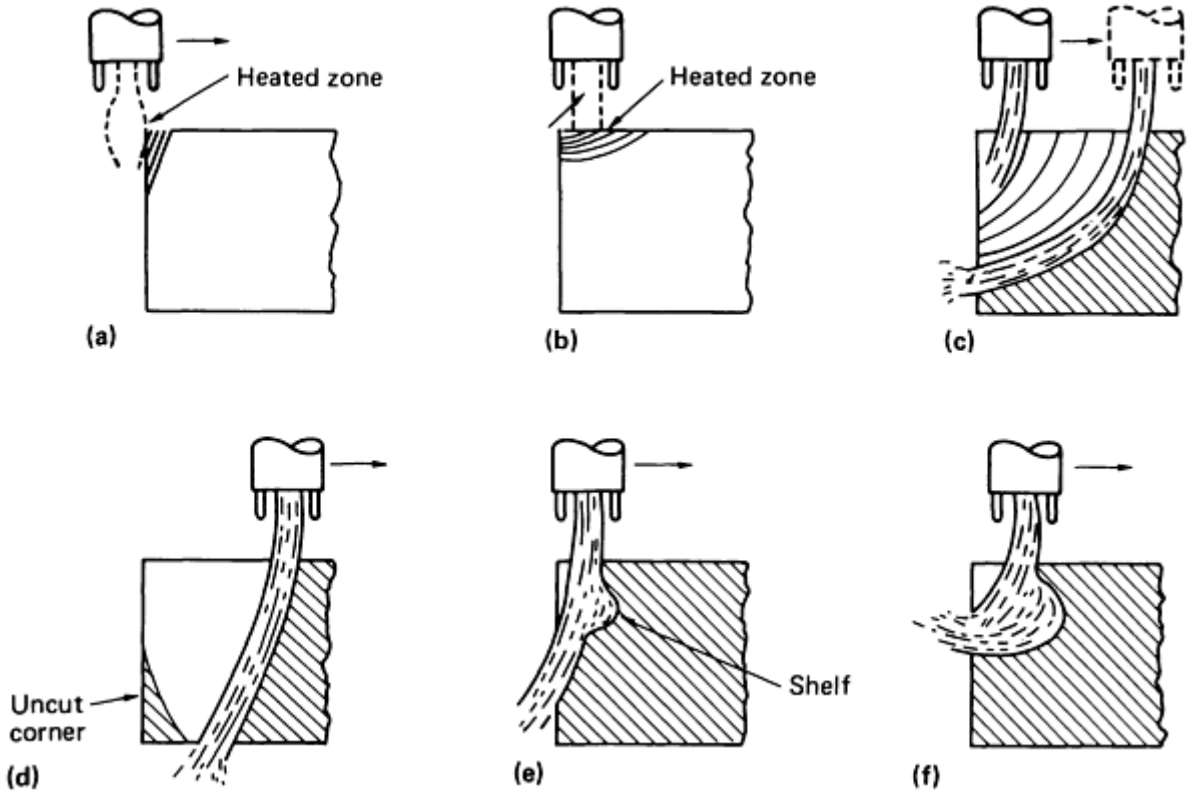


FIG. 7 PROPER AND IMPROPER TECHNIQUES FOR HEAVY CUTTING. (A) PROPER TORCH POSITION; PREHEAT IS PRIMARILY ON STARTING FACE. (B) IMPROPER START; OXYGEN STREAM IS TOO FAR ONTO WORK, WHICH RESULTS IN ACTION OF CUT AS SHOWN IN (C) AND IN UNCUT CORNER AS SHOWN IN (D). (E) EXCESSIVE OXYGEN PRESSURE OR ACTION OF CUT AT TOO LOW A SPEED. (F) INSUFFICIENT OXYGEN PRESSURE OR ACTION OF CUT AT TOO HIGH A SPEED

Drag. To successfully complete the cut (drop cutting), minimum drag conditions must exist, as shown in Fig. 8(a). Too much drag leaves an uncut corner at the end of the cut (Fig. 8b and c). Angled cutting may be used in straight-line work to counter drag (Fig. 8d and e), but for shape cutting, the torch must be perpendicular to the work.

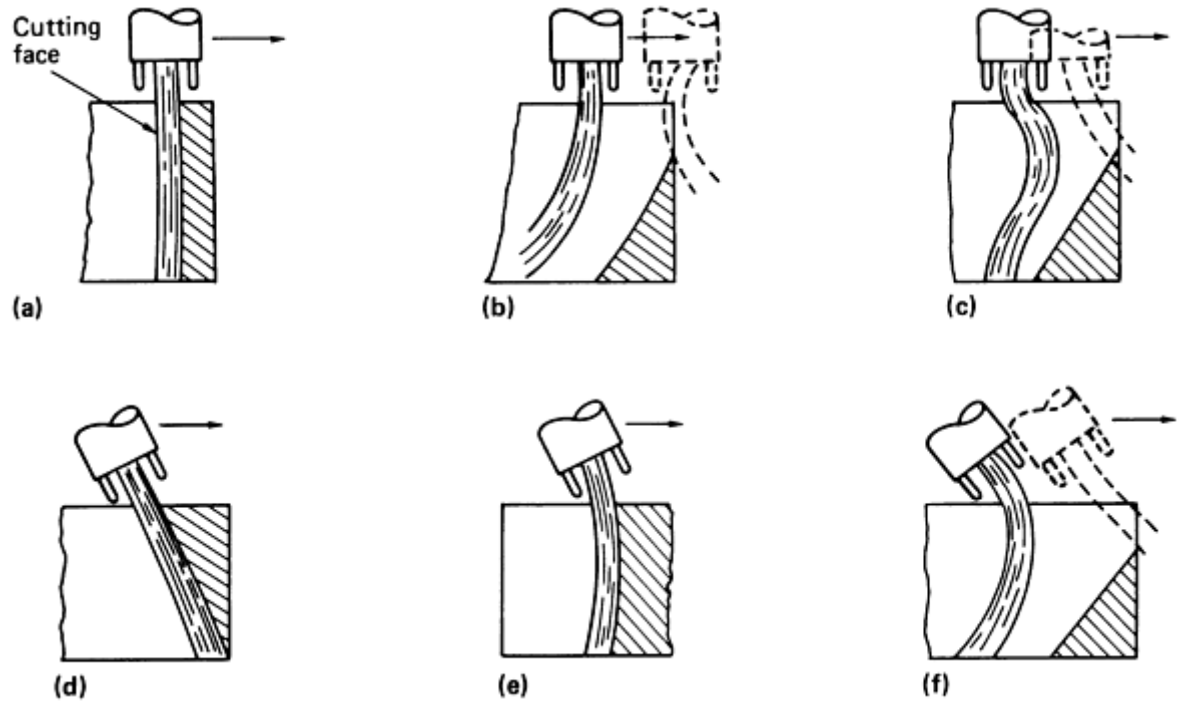

FIG. 8 PROPER AND IMPROPER TECHNIQUES FOR A HEAVY CUT. (A) MINIMUM DRAG (TYPICAL AT BALANCED CONDITIONS) PERMITS FLAME TO BREAK THROUGH CUTTING FACE UNIFORMLY AT ALL POINTS. (B) EXCESSIVE DRAG, TYPICALLY CAUSED BY INSUFFICIENT OXYGEN OR EXCESSIVE SPEED, RESULTS IN UNDERCUT. (C) FORWARD DRAG RESULTING FROM EXCESSIVE OXYGEN PRESSURE OR TOO LITTLE SPEED. (D) AND (E) FORWARD ANGLING OF TORCH TO MINIMIZE DRAG AND THUS AVOID AN UNCUT CORNER. (F) EXCESSIVE FORWARD ANGLING OF TORCH, RESULTING IN UNDERCUT

Starting. Extra care is needed in starting a heavy cut to avoid leaving an uncut corner or pocketing the flame in the lower portion of the cut. Starting sometimes is facilitated by first undercutting the forward edge of the material with a hand torch.

Cutting of Bars and Structural Shapes

To cut round steel bars, gas pressure should be adjusted for the maximum thickness (diameter), and the cut should be started at the outside. As the cut progresses, the torch should be raised and lowered to follow the circumference. The bar should be nicked with a chisel to make a burr at the point where the cut is to begin. Oxyfuel gas cutting of round bars is usually manual, so that the cut surface is rough. The chief advantage of OFC over sawing is that the torch can be brought to the work. The same advantage applies to OFC of various structural shapes.

Close-Tolerance Cutting

Shapes can be oxyfuel gas cut to tolerances of 0.8 mm ($\frac{1}{32}$ in.) in plate up to 64 mm ($2\frac{1}{2}$ in.) thick with multi-torch pantograph or coordinate-drive machines. Conditions must be optimum:

- OPERATORS MUST BE WELL TRAINED AND EXPERIENCED.
- MACHINES MUST BE PROPERLY ADJUSTED SO THAT THEY CAN TRACE AND RETRACE A PATTERN WITH ACCURACY OF ±0.13 MM (±0.005 IN.) IN A GIVEN DIRECTION.
- WORKPIECE MUST BE FLAT AND FREE OF DIRT, SCALE, GREASE, AND OIL.

- WORKPIECE SHOULD BE SUPPORTED OR RESTRAINED TO PREVENT MOVEMENT OF THE SHAPE DURING CUTTING.
- CUTTING TIP MUST BE CLEAN (SELECTED FOR HIGH-QUALITY, NARROW-KERF CUTTING).
- CUTTING SPEED AND GAS PRESSURES SHOULD BE TUNED TO SPECIFIC PRODUCTION CONDITIONS.

Optical tracing devices can follow an ink line 0.64 mm (0.025 in.) wide on paper. If cutting speed does not exceed 760 mm/min (30 in./ min), a template with an outside corner radius of 2.4 mm ($\frac{3}{32}$ in.) will produce a sharp corner. A 2.4 mm ($\frac{3}{32}$ in.) inside radius on the template produces a somewhat larger radius in the workpiece, depending on thickness and cutting tip. Numerical control tracing, whether punched tape or computer assisted, offers the greatest accuracy. Inaccuracies introduced by distortion of templates are avoided, and electronic directions are more exacting than those generated by mechanical cutting machines, which set limits on cutting speed.

Oxyfuel Gas Cutting

Safety*

The hazards of combustion or possible explosion associated with the gases used in OFC, as well as the presence of toxic gases and dust, make it necessary for the user to follow established safety precautions. The three areas of most concern, dealt with in this section, are protective clothing, handling and storage of gas cylinders, and the working environment.

Protective Clothing. Size, nature, and location of the work to be cut dictate the necessary protective clothing. The operator may require some or all of the following:

- TINTED GOGGLES OR FACE SHIELD:

- LIGHT CUTTING, UP TO 25 MM (1 IN.)--SHADE NO. 3 OR 4
- MEDIUM CUTTING, 25 TO 150 MM (1 TO 6 IN.)--SHADE NO. 4 OR 5
- HEAVY CUTTING, THICKER THAN 150 MM (6 IN.)--SHADE NO. 5 OR 6

- HARD HAT AND SOMETIMES A CLOSE-FITTING HAT BENEATH
- SAFETY GLASSES
- FLAME-RESISTANT JACKET, COAT, HOOD, APRON; WEAR WOOLEN CLOTHING, NOT COTTON OR SYNTHETIC FIBER; KEEP SLEEVES AND COLLARS BUTTONED, NO CUFFS; BUTTON-DOWN POCKETS
- PROTECTIVE GLOVES, WRISTLETS, LEGGINGS, AND SPATS. WHEN CUTTING PLATED OR COATED STOCK, RESPIRATORY PROTECTION SHOULD BE USED IF NECESSARY
- CLOTHING SHOULD BE FREE OF GREASE AND OIL, AND FREE OF RAGGED EDGES

Cylinders. Fuel gas cylinders should be placed in a location where they cannot be knocked over. Cylinders should be kept upright with valve ends up to avoid hazardous liquid withdrawal; the protective caps should never be removed except when the cylinders are connected for use. Cylinders should never be exposed to high heat or open flame, which could cause them to explode.

Cylinders should not be placed where they might complete an electric circuit, such as against a welding bench. They should not be used as an electrical ground or as a surface on which to strike an arc.

Damage to cylinders by impact should be avoided. Regulators should be removed before cylinders are moved, except on portable outfits. Slings or magnets should not be used as supports or rollers.

Damaged or defective cylinders should be removed from service immediately, tagged with a statement of the problem, and returned to the supplier. Leaking cylinders should be transported to an isolated location outdoors, the supplier notified, and his instructions for disposal followed.

No attempt should be made to fill a small cylinder from a large one. Filling requires special equipment and training.

Before storing, valves should be closed and caps replaced on empty or unused cylinders. Empty cylinders should be marked accordingly and kept separate from filled ones. Unused oxygen or fuel gas should not be drained from cylinders, and oxygen cylinders should be kept away from fuel gas cylinders.

Working Environment. Torches should not be used around chlorinated solvent vapors; heat forms phosgene and other corrosive, toxic products from them. Adequate ventilation must be provided, especially when alloys containing lead, cadmium, zinc, mercury, beryllium, or other toxic elements are being cut. A flame should not be used in a closed vessel or pipeline that has held flammable or explosive material, such as gasoline. Adequate ventilation should also be provided when work is being performed in a confined area. Under such conditions, the person doing the cutting should have an assistant in case trouble occurs.

Fire prevention warnings in "Safety in Welding and Cutting" (ANSI/AWS 249.1), which have legal status as Occupational Safety and Health Administration (OSHA) regulations, should be heeded. Workers should know the locations and operating procedures of the nearest fire extinguishers.

If cutting is to be done over concrete, it should be protected with metal or another suitable material; concrete spalls explosively when overheated. Hoses should be protected from sparks, hot slag, hot objects, sharp edges, and open flame.

Additional information is available in the article "Safe Practices" in this volume.

Plasma Arc Cutting

Chuck Landry, Thermal Dynamics Corporation

Introduction

PLASMA ARC CUTTING (PAC) is an erosion process that utilizes a constricted arc in the form of a high-velocity jet of ionized (electrically conductive) gas to melt and sever metal in a narrow, localized area.

Process Description. In the PAC process, a cool and inert gas, such as compressed air, is forced under pressure through a small orifice in the front of the cutting torch. This torch is connected by leads to a direct-current (dc) power supply. In the torch, a portion of the inert gas is changed into a plasma (ionized gas) by heat created by the discharge of a high-voltage arc from the power supply. This arc is created between an electrode (dc negative) in the torch and the tip (nozzle) of the torch through which the gas flows.

When a small amount of dc from the power supply is imposed on this high-voltage arc, it achieves a pilot arc that extends approximately 13 mm ($\frac{1}{2}$ in.), as a plasma jet from the tip orifice. This pilot arc acts as a path that establishes the main cutting arc to the workpiece. When the pilot arc is brought in contact with the metal workpiece, which is connected to the positive side of the dc power supply, the transferred (main) arc occurs and the pilot arc is shut off. The cutting torch is

then usually operated with a standoff, that is, the distance between torch and workpiece, of approximately 3 to 10 mm ($\frac{1}{8}$ to $\frac{3}{8}$ in.).

However, in some applications, the torch tip can actually be dragged along the workpiece. The transferred plasma arc heats the metal by the combined effects of the electric arc from the power supply, the high-temperature plasma created by constriction of the arc by the orifice, and the reassociation of the gas molecules at the workpiece. The molten metal is blown out of the cut, or kerf, by the high-velocity, well-columnated plasma jet, resulting in fast, clean cuts.

Plasma Arc Cutting

Chuck Landry, Thermal Dynamics Corporation

Equipment

The required equipment for the PAC process comprises:

- A TORCH DESIGNED FOR EITHER MANUAL OR MECHANIZED OPERATION
- TORCH LEADS THAT CARRY THE ELECTRIC POWER, GAS, AND COOLANT TO THE TORCH
- A COOLANT SYSTEM FOR THE TORCH
- A POWER SUPPLY THAT PROVIDES THE PROPER CURRENT AND VOLTAGE FOR THE PLASMA ARC
- A MANIFOLD SYSTEM FOR COMBINING POWER, GAS, AND COOLANT FOR CONNECTION TO THE TORCH
- A CONTROL SYSTEM THAT CONSISTS OF SWITCHES, GAGES, DIALS, METERS, AND OTHER CONTROLS FOR OPERATING THE PAC SYSTEM AND THE GAS SUPPLY

In its simplest form, a PAC system includes a gas-cooled torch with leads that connect to a power supply.

All PAC torches possess the same basic components (Fig. 1). The tip, or nozzle, of the torch contains the orifice that constricts the arc. The diameter of the orifice, which ranges from 1 to 6.4 mm (0.038 to 0.250 in.), determines the maximum cutting current that can be used with that tip. The larger the orifice, the more current that can be forced through it.

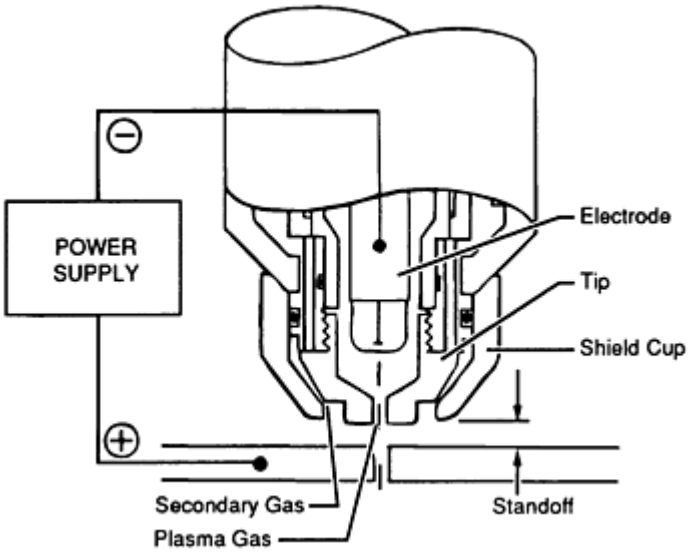

FIG. 1 TYPICAL PAC TORCH

Tips are designed so that the orifice provides maximum arc constriction. If a tip orifice is overpowered, then it will become gouged or washed out, resulting in a change of arc characteristics and in the deterioration of cut quality and cutting speed. To attain optimal cutting conditions, tips are used at or very near their maximum cutting rating. Torch tips are either water cooled, through internal passages connected to a closed-loop coolant system, or indirectly cooled, by good thermal contact with other torch parts that are either water or gas cooled.

The electrode, or cathode, in a PAC torch is the surface from which the plasma arc is generated. This electrode is in electrical contact with the negative potential in the power supply. Both electrode material and design are quite varied. For most applications that use nitrogen or argon-hydrogen as the plasma gas, a 2% thoriated tungsten is used as the electrode. Hafnium and zirconium are commonly used as electrode materials for both air and oxygen plasma cutting.

In terms of its construction, the electrode can be solid, such as a rod of tungsten or a tungsten element held in a solid-copper holder, or it can be hollow and have two pieces (copper and the electrode element) that allow direct water or gas cooling. Because proper cooling will promote both tip and electrode life, PAC torches designed for cutting above 150 A are usually water cooled.

In the area between the electrode and the tip orifice, which is called the plenum, the initial ionization or plasma formation takes place. The plasma gas enters the plenum in either a straight (laminar) flow pattern or a tangentially swirling pattern. Although torch design depends on several factors, pointed electrodes usually utilize laminar flow patterns, whereas flat or blunt-ended electrodes utilize a swirling gas to keep the arc attachment point moving around the center of the electrode. The swirl is most commonly imparted on the gas by a gas distributor, or swirl ring, that is located near the end of the electrode.

Other parts that are common to most PAC torches include internal ceramic or high-temperature plastic insulators for electrical insulation, collets or other mechanisms for retaining the electrode, and shield cups to insulate the front end of the torch from the workpiece.

Leads. The PAC torch is connected to the other system components by means of a leads package that consists of hoses, fittings, and wires. The leads supply the electric power, gases, and cooling medium to the torch. Lead lengths vary from 3 to 68 m (10 to 225 ft), depending on the application. Simple extension kits can be used to join leads packages together for increased length.

Cooling of PAC torches that operate at less than 150 A can be simply accomplished by properly channeling the gases used in torch operation. High-powered systems require a water-based coolant system, which consists of a reservoir, pump, and heat-exchanger assembly. Because this type of coolant is often in contact with both negative and positive electric potentials within the torch, it is important to use a deionized (nonconductive) coolant.

The power supply for a PAC system must have a dc output with the negative side connected to the electrode in the torch and the positive side connected to the workpiece. Systems that include a pilot arc also have a positive connection, limited in current through a resistor, to the tip in the torch. Power supplies are usually of a constant-current, dropping volt-amp curve design, and they have higher open-circuit voltages (up to 400 V) than those found in common welding power supplies, in order to accommodate the high operating voltage (90 to 200 V) of the torches. The amperage output of power supplies can be designed to have one fixed level, or several switchable fixed settings, or an infinitely adjustable output by means of a control potentiometer.

The manifold assembly combines the dc power, gas, coolant, and high-voltage starting circuitry and provides it to the cutting torch via the leads package.

Controls for starting and stopping the cutting operation, selecting the proper amperage output, adjusting gas flows, and regulating other system functions can be located on the manifold box, on the power supply, or in a dedicated control cabinet for convenient mounting near an operator station.

All-in-one packaged PAC systems that combine the coolant system, power supply, manifold assembly, and controls in one unit are available. These systems offer improved portability, simplicity of operation, and reduced costs.

Optional equipment for manual PAC systems includes drag-type shield cups with protrusions, or feet, that enable direct contact with the workpiece to allow the operator to maintain a constant standoff. Wheels that can be attached to the torch for manual guidance, as well as circle-cutting attachments that include an adjustable radius rod to allow the cutting of various-sized holes, are also available.

Optional equipment for mechanized PAC systems includes torch-standoff controls that automatically find and maintain the proper standoff for the cutting operation. Water-shrouded systems are also available. When used in conjunction with water tables, these systems provide a blanket of water around the front of the torch during the cut, in order to minimize smoke, fumes, noise, and arc glare.

Plasma Arc Cutting

Chuck Landry, Thermal Dynamics Corporation

Gases

The plasma or secondary shielding gases that are used in PAC systems are inert, and they are usually supplied from high-pressure cylinders, bulk tanks, or air compressors. Pressure regulators are adjusted to provide from 140 to 560 kPa (20 to 80 psi) of gas, depending on system requirements.

If water is used in place of a secondary gas, then it is usually supplied from a filtered, in-plant water system at a flow rate of 0.63 to 1.9 L/min (10 to 30 gal/h), again, depending on system requirements.

The purity of plasma gases is usually of a welding grade or higher. The plasma gas can be compressed air, which is inexpensive and provides fast, clean, high-quality cuts on carbon steels, but a relatively short electrode life, because of the rapid oxidation that occurs at high temperatures. If purity from an in-plant compressor is a problem, then either charcoal filters that remove oil vapors and moisture traps or dryers can be added into the line. As an alternative, clean, dry, compressed air can be obtained in cylinder form.

Another choice is nitrogen, which is relatively inexpensive and provides good-quality cuts on stainless steels and aluminum. It also provides good electrode life.

Argon-hydrogen, which is usually supplied in a 65 or 70% Ar and a 35 or 30% H mixture, operates at a higher temperature. It can reduce the quantity of smoke and fumes created during the cutting operation and provide a higher-quality surface finish on aluminum and stainless steels that are more than 12 mm (0.5 in.) thick. However, argon-hydrogen is usually from two to three times more expensive than nitrogen. In addition, it is not as readily available and requires more-critical adjustment of the operating parameters.

Oxygen plasma provides the same benefits as air plasma when cutting carbon steels. Because of the absence of nitrogen, it can minimize the amount of nitrides in the cut surface, thereby enabling better-quality welds on "as-cut" pieces that have not undergone additional finishing operations. Like air plasma, oxygen causes more-rapid electrode erosion than does nitrogen or argon-hydrogen plasma.

Operating Sequence

A routine check of the PAC system before power is applied involves examining the torch to ensure proper assembly, verifying adequate coolant and gas supplies, and inspecting all components of the system to verify that they are in order.

The disconnect switch can then be turned on, which applies power to the system. Gas supplies should be turned on and adjusted according to the recommended pressure or flow. The plasma gas should be allowed to purge for an additional 2 to 3 min in order to eliminate any traces of moisture that accumulated within the plasma lines. This moisture is usually the result of condensation that forms when the system is off for prolonged periods of time.

The "start-cut" signal can be supplied by either an operator who simply pushes a start button on a mechanized control station to energize the switch on a manually operated torch or by a computer-generated signal on a fully automated system. The start-cut signal will cause the main contactor in the power supply to energize and initiate a gas prepurge. The prepurge ensures that gas is at the torch before an arc is struck and can last from 2 to 10 s if extra-long torch leads are used. At the end of the prepurge, the high-frequency arc and pilot arc circuits are energized, establishing the pilot arc at the torch. The pilot arc duration can be controlled by a timing circuit, limiting it to approximately 5 s, or it can be continuous, thereby shutting off only after an actual cut is established. Some PAC systems include circuitry for an automatic restart pilot, which enables automatic cycling between the pilot and cut modes as long as the start signal is present. This type of operation is valuable when cutting expanded metal, grating, or other material with an interrupted cut line.

The cutting arc will begin as soon as the torch and pilot arc are brought close enough to the workpiece (usually, 13 to 25 mm, or $\frac{1}{2}$ to 1 in.) to allow main arc transfer. However, some systems do not use a pilot arc to start the torch. Rather, they only use high frequency, and require that the torch be placed within 1 mm (0.038 in.) to establish a cutting arc. The cutting action will continue as long as there is metal to which the arc can transfer. If the cutting speed is too fast, then the arc will not fully penetrate the metal, and an incomplete cut or gouge will occur. If the cutting speed is too slow, then the kerf will widen as available metal is blown away and, eventually, the arc will be extinguished.

When the "start signal" is removed, or when a stop signal is provided, the cutting arc or pilot arc will shut off and the system will enter a postpurge mode, which is a continuation of plasma gas flow for 2 to 40 s to ensure that the electrode cools in a good atmosphere and to remove any residual heat within the torch.

The system is then ready for the next start signal to begin the cutting sequence again. Some systems include circuitry that allows immediate starting of the pilot or cutting sequence at any time during the postpurge.

For manual operation, the torch is usually held with two hands to provide optimum comfort and speed control. An exception to this rule occurs when small, lightweight torches are used in conjunction with templates or a straight edge that requires one hand to be used for positioning while the other hand operates the torch.

There are two means of starting the cut in manual PAC systems: edge starts and pierce starts. For edge starting, the torch tip is usually placed directly over the edge of the workpiece. Resting the torch at the start position ensures that the cut will begin at the proper location. The torch switch is pressed and the torch is moved along the cut line as soon as the arc is established.

Piercing is best accomplished by slightly angling the torch over the starting point so that the molten metal is directed away from the torch. After starling the arc, the torch is moved to the vertical position and the cut proceeds along the cut

line. This technique prevents molten metal from blowing back at the torch and causing damage. Thicker metals may require that the torch be left stationary over the start point for a few seconds to ensure full arc penetration. Because a pierce will sometimes result in a blow hole that is larger than the normal kerf width, it is good practice to start the pierce off the cut line in the scrap piece to eliminate discontinuities in the cut surface of a good piece.

In mechanized applications, edge starts are accomplished by lining the torch up with the cut line. Pierce starts cannot be done in the same way as they are in manual cutting, because the torch cannot be conveniently angled and then brought back to a vertical position. Best results are achieved with a slow-moving pierce, in which the torch motion begins when the arc is struck. This allows the molten metal to flow back along the cut line until full penetration is achieved. Some allowance should be made for the start of a moving pierce to ensure that the entire piece is cut out.

A third means of starting the arc in mechanized applications is the running-edge start. In this mode, the torch is positioned off the workpiece, the pilot arc is established, and then the torch is put in motion. The cutting arc is established as soon as the pilot hits the edge of the work.

For either manual or mechanized operation, the best cut quality is usually achieved with a torch standoff of 3 to 10 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.). Thinner metals, under 3 mm ($\frac{1}{8}$ in.) thick, require a closer standoff. At low power levels (below 40 A), good-quality cuts can be obtained by dragging the torch tip in contact with the work.

The proper cutting speed for achieving the best quality is determined by the angle that the arc makes with a vertical plane as it exits the workpiece (Fig. 2). The optimal speed for air cutting is usually achieved when the arc is vertical (0°). Nitrogen and argon-hydrogen cuts are optimized by adjusting speed to obtain a 5 to 10° trailing arc. The best oxygen cuts are made using a speed that provides a slight (1 to 2°) leading arc. The PAC torch should always be kept square with the workpiece to provide maximum arc penetration and to obtain consistent quality when contour cutting.

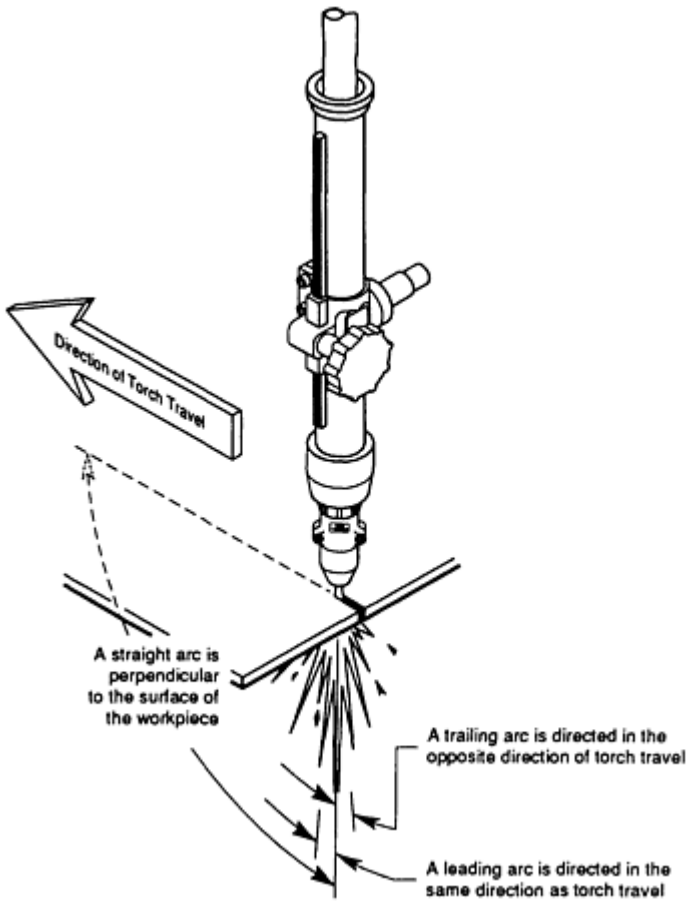

FIG. 2 ARC CHARACTERISTICS OF PAC TORCH

Chuck Landry, Thermal Dynamics Corporation

Process Considerations

Process Variations. The major difference between a conventional PAC process, which utilizes the basic system components described earlier, and other process variations is that the conventional PAC torch uses only a single gas, and the orifice in its tip represents the only gas exit. Because these torches do not incorporate any secondary gas, they must be liquid cooled.

Gas-shielded plasma arc cutting utilizes the traditional plasma gases plus a secondary gas that forms a shield around the plasma arc. The torch design provides special passages for this secondary gas. The functions of the secondary gas are to:

- ASSIST THE PLASMA IN BLOWING AWAY MOLTEN METAL
- ENABLE FASTER AND CLEANER CUTS
- PROVIDE BETTER COOLING OF THE TORCH FRONT END
- REDUCE ACCUMULATION OF METAL SPATTER ON THE TORCH
- REDUCE TOP-EDGE ROUNDING OF THE WORKPIECE
- PERMIT EASIER PIERCING
- MINIMIZE DOUBLE ARCING

In gas-cooled, rather than liquid-cooled, torches, it is the secondary gas that provides the cooling action. The choice of secondary gas can also affect cut quality, cutting speed, and the amount of smoke and fumes produced during the PAC process.

Water-shielded plasma arc cutting is a variation of the gas-shielded process that is only used in mechanized applications. The water, which can be provided from standard plant water systems at a rate of 0.63 to 0.95 L/min (10 to 15 gal/h), is substituted for the secondary gas in torches designed for this type of operation. Using a water shield, rather than a gas shield, is less expensive, because water is virtually free. It also results in reduced top-edge rounding, a reduced amount of smoke and fumes, and a clean, shiny, cut surface.

Water-injection plasma arc cutting is similar to the water-shielded process, except that the water is forced into the plasma stream, at approximately 1.26 L/min (20 gal/h), just after the arc exits the tip orifice and just before it leaves the ceramic piece on the front end of the torch (Fig. 3). The impinging water increases the constriction and density of the plasma arc, resulting in improved cut squareness and increased cutting speed. Because of the entry of water at the tip orifice in a water-injection torch, the quality of water is more critical than that used in water-shielded cutting. A plant water system that has high levels of dissolved minerals may require water softeners in conjunction with the system in order to avoid rapid deterioration of part lifetimes. Water-injection cutting is only used in mechanized setups.

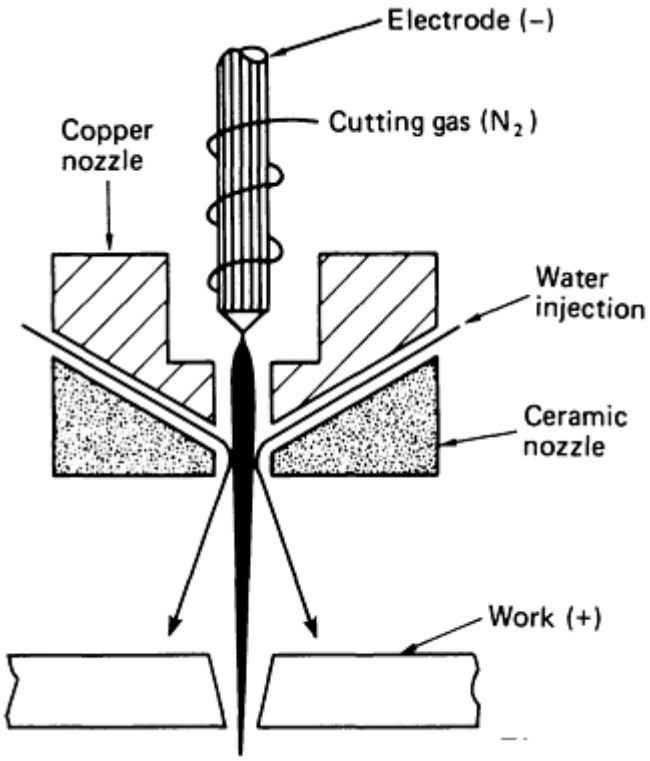

FIG. 3 WATER-INJECTION PAC TORCH

Process Capabilities. Plasma arc cutting is unique in its ability to make fast, clean cuts on both ferrous and nonferrous metals. When compared with the oxyfuel cutting of ferrous metals, the major advantage of this process it its speed, which can be from 4 to 5 times greater than the speed of oxyfuel cutting. For example, when cutting 6 mm ($\frac{1}{4}$ in.) carbon steel with an oxyfuel process, a speed of 0.68 m/min (27 in./min) is used, but when using a 150 A PAC system with air plasma, the speed goes up to 3.81 m/min (150 in./min) (Fig. 4). Because labor and overhead represent the primary costs of operating a mechanized cutting system, reducing the time to cut a part will, in turn, reduce the cost of the part itself. The five-fold increase in cutting speed of the PAC process, versus that of the oxyfuel process on carbon steel, will translate to a part cost of only one-fifth that achieved with the oxyfuel process.

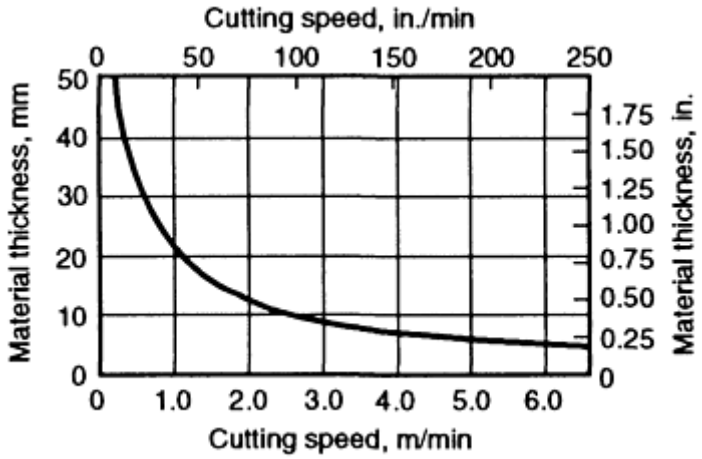

FIG. 4 CUTTING SPEEDS VERSUS MILD STEEL THICKNESS (150 A, AIR PLASMA)

Because the speed of the PAC process, like that of the oxyfuel process, is dependent on metal thickness, increasing thickness will diminish the speed advantage. Therefore, other factors that favor the PAC process have to be determined when comparing it with the oxyfuel process for cutting carbon steel that is more than 50 mm (2 in.) thick.

Another advantage of the PAC process, versus the oxyfuel process, is its ability to cut carbon steel with virtually no distortion, because of the fast travel speed and narrow, localized heating of the metal. This same high-speed localized heating results in a much narrower heat-affected zone (HAZ), that is, the depth of metallurgical change from the cut surface, than that of the oxyfuel process. Typical HAZs of up to 1.78 mm (0.070 in.) from oxyfuel cuts on carbon steel have been measured, whereas the PAC process produces HAZs of only 0.51 mm (0.020 in.). The HAZ will have an effect on the overall strength, corrosion resistance, and susceptibility to surface cracking of the cut part. If the application is such that the cut part must undergo machining to remove the HAZ, then the depth of machining required is much less with the PAC process.

Normally, PAC surfaces do not require any additional finishing operations before they are welded, although this usually depends on the final application and the codes to which the cut part being welded must conform.

The PAC process has the ability to make both edge starts and pierce starts without a preheat, as is required for oxyfuel cutting. This advantage becomes quite dramatic when the application calls for interrupted cuts, such as on grating or expanded metal.

These same capabilities apply to the cutting of stainless steel and aluminum. No preheat is required, and there is no distortion of the cut part. For plasma arc cuts on stainless steel and aluminum, respectively, the HAZ has been measured at 0.25 and 2.03 mm (0.010 and 0.080 in.).

Process Mechanization. Plasma arc cutting can be mechanized in several ways, the simplest of which takes the form of portable carriages or tractors. These devices can travel along a track to achieve straight-line cutting or along an arc guided either by a radius rod or by hand to cut curves. Although tractors are primarily used for simple cut-off, squaring, and trimming operations, they are also used as parts of large fixtures for cutting cast and rolled metals.

Pattern/follower wheel-shaped cutting machines or pantographs are used for the plasma arc cutting of relatively small, simple shapes. A scale model of the desired piece is held and traced by a follower that is connected, through a series of arms, to the torch, which cuts either an identical or a larger-scale part.

Optical tracing or electric-eye machines are used to trace part shapes that are in the form of templates or, more commonly, in the form of line drawings that are the same scale as the desired part. A mechanized PAC setup that uses optical tracing is shown in Fig. 5. The speed of an optical tracing machine is limited by the capability of the electric eye to follow a line. Low-speed machines that operate at speeds up to 1.52 m/min (60 in./min), which were originally designed for use with oxyfuel torches, are compatible with lower-amperage PAC systems. New high-speed machines, with speeds of up to 12.7 m/min (500 in./min), have been developed for operation with high-amperage plasma cutting systems.

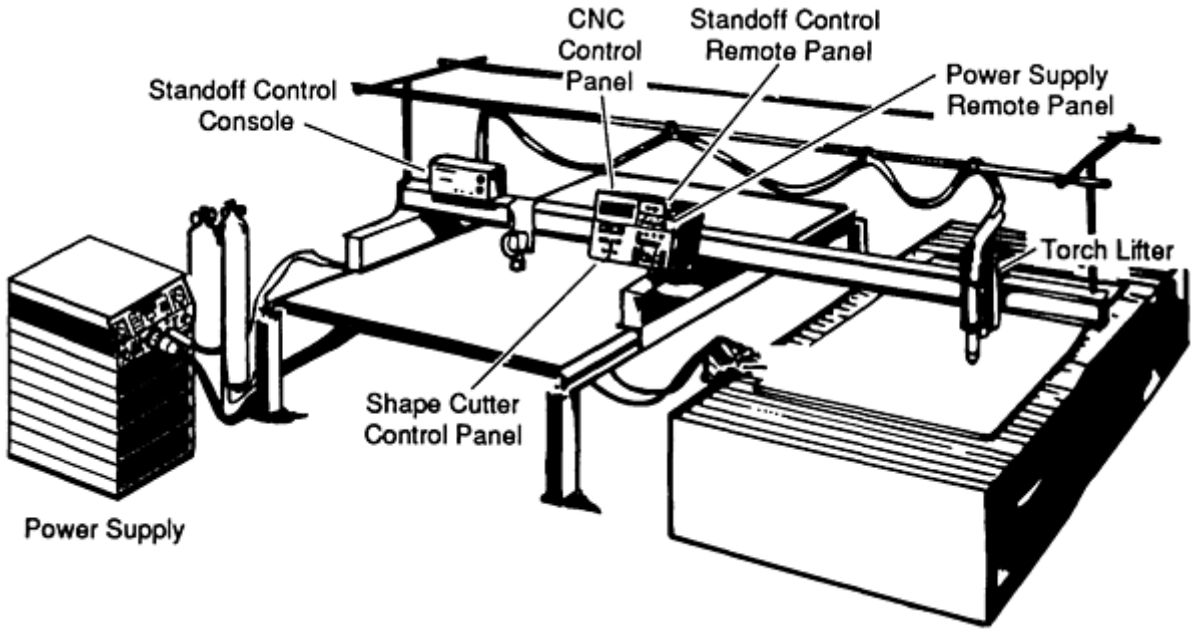

FIG. 5 MECHANIZED PAC SYSTEM THAT USES OPTICAL TRACING OF PART SHAPES

Computer numerical control (CNC) shape-cutting machines with speeds of up to 25.4 m/min (1000 in./min) represent the state of the art in automated cutting. CNC machines are much more reliable, have greater capabilities, and are lower priced than their numerical (tape) control machine predecessors, which are now considered obsolete. CNC machines can be connected directly into the central processor (direct numerical control) of a plant for complete integration of product design, material requirements, work in process, and other functions. Because the evolution of CNC machines paralleled that of mechanized PAC systems, their combination represents the highest level of productivity available in metal cutting today.

Automated material handling systems are sometimes used to keep up with the speed of CNC PAC systems. Typical systems utilize a raw material loading station, a cutting station, and a finished parts station. While the cutting operation is taking place, the operator is loading raw material and unloading finished parts. Upon completion of the cutting sequence, a conveyor moves the finished parts off the cutting area as it moves raw material onto the cut station. The operator signals the start-cut sequence and the cycle is repeated.

Robots are being used in increasing numbers for PAC operations involving the contour cutting of pipe and vessels, the removal of sprues and risers from castings, and the cutting of shapes in various planes of cast or formed parts. Material handling is also a great concern in robotics applications. Multiple work stations are the rule, because they allow an operator or another robot to load unfinished work and remove finished parts while the cutting operation is ongoing.

Cut Quality. Besides the HAZ, which was discussed above, several other factors (Fig. 6) that also must be considered in determining the quality of a plasma arc cut are the:

- CUT ANGLE
- DROSS
- SURFACE FINISH
- TOP-EDGE SQUARENESS
- KERF WIDTH

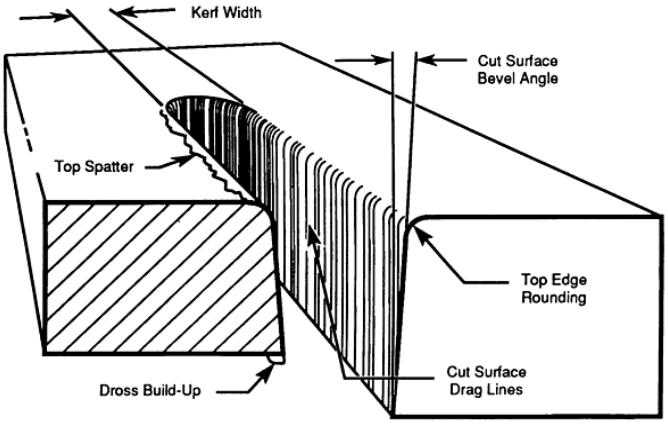

FIG. 6 CHARACTERISTICS OF A PLASMA ARC CUT

Cut Angle. Plasma arc cutting will usually result in an angle on the cut surface of approximately 1 to 3° on the "good" side and 3 to 8° on the "bad" side, when using torches that swirl the plasma. With laminar-flow torches, the angle on both sides is usually about 4 to 8°. These angles are most noticeable in mechanized applications where the torch is square to the workpiece. The good and bad sides of the cut are determined by torch travel direction and plasma gas swirl. With a clockwise gas swirl, the good side of the cut will be on the right with respect to torch motion. Therefore, in the cutting of a ring or flange in which the minimum angle is desired on both the inside and outside diameters, the outside would be cut in the clockwise direction, while the inside would be cut counterclockwise (Fig. 7). This change in angle from good side to bad side of the cut is the result of the arc attachment point on the cut surface and the release of energy on the good side before contact with the bad side occurs.

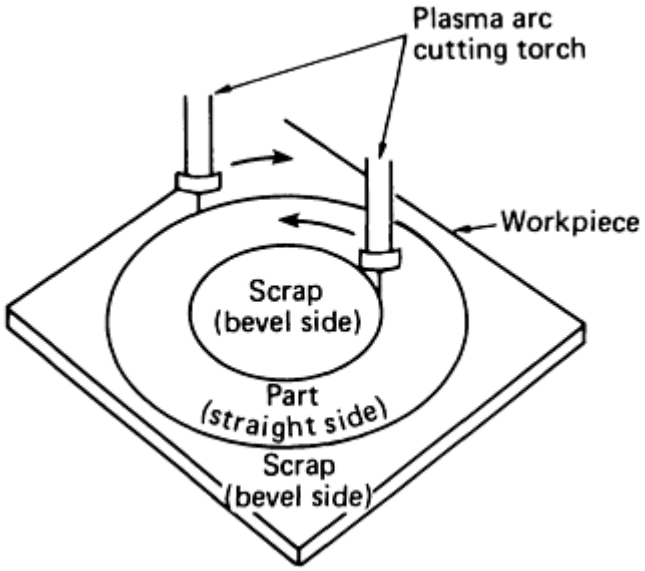

FIG. 7 PAC TORCH DIRECTION THAT ACHIEVES BEST QUALITY

Changing an internal torch part, such as the electrode or gas distributor, can enable those plasma cutting torches that create a gas swirl to change from a clockwise to a counterclockwise swirl direction. This then enables mirror-image cutting when using two torches in a mechanized setup, such as in strip-cutting applications.

Dross is the resolidified metal that adheres to the bottom edge of the plasma cut. The concentration of dross will be heavier on the bad side of the cut. The amount of dross that forms is a result of the type of metal being cut, the cutting speed, and the arc current. Dross can be formed from either too high or too low a cutting speed, but there is a "window"

between these two extremes in which dross-free cuts can usually be achieved. The dross-free range is greater on stainless steel and aluminum than it is on carbon steel and copper alloys. If dross-free cuts cannot be achieved, then a minimum amount of low-speed dross is more desirable, because it is more easily removed than the high-speed variety.

Surface Finish. The cut surface from the plasma arc process is normally rougher than that achieved by oxyfuel cutting on carbon steels, and it is definitely more rough than most machining processes. In most metals, this roughness usually appears as a ripple along the cut surface. This is partly due to the output waveform of the dc power supply (the smoother the output, the smoother the cut), but it is also determined to an extent by the gases used and the torch design. Water-shielded and water-injection plasma arc cutting provide much smoother cuts than do gas-shielded or conventional plasma techniques. The use of argon-hydrogen as a plasma or a shielding gas will result in smoother cut surfaces on most metals than when using nitrogen plasma or any other gas shield.

Top-Edge Squareness. Most metals experience some top-edge rounding when the PAC process is applied. Top-edge rounding is more pronounced on the thinner metals. This rounding is due to a higher heat concentration at the top of the cut, and can be minimized by using a gas-shielded PAC process. It can be even better controlled when water-shielded or water-injection plasma arc cutting is used.

The kerf width obtained by plasma arc cutting will be greater than that achieved by oxyfuel cutting on carbon steel, but not as great as that obtained by other processes, such as abrasive cutting or arc gouging. The rule of thumb for estimating the kerf in plasma arc cutting is that its width will be approximately 1.5 to 2 times the tip orifice diameter.

Plasma Arc Cutting

Chuck Landry, Thermal Dynamics Corporation

Applications

Plasma arc cutting is used in a variety of industries. End users of smaller systems with output capabilities of 100 A or less include:

- SMALL JOB SHOPS THAT MUST FABRICATE SPECIALTY AND SUBCONTRACTED ITEMS FROM STAINLESS STEEL, ALUMINUM, BRASS, COPPER, CARBON STEEL, GALVANIZED METAL, AND OTHER METALS
- MANUFACTURERS AND INSTALLERS OF DUCTWORK FOR HEATING, VENTILATING, AND AIR CONDITIONING, WHO MUST CUT GALVANIZED METALS
- MANUFACTURERS OF FOOD PROCESSING AND INSTITUTIONAL KITCHEN EQUIPMENT, WHO MUST CUT STAINLESS STEELS
- AUTOMOBILE MANUFACTURERS, AUTO BODY REPAIR SHOPS, AND DISMANTLERS, WHO MUST CUT HIGH-STRENGTH STEELS USED IN UNIBODY CONSTRUCTION
- MANUFACTURERS AND REBUILDERS OF OVER-THE-ROAD LIQUID TRANSPORT TRAILERS USED TO HAUL PETROLEUM, CHEMICALS, MILK, AND FERTILIZERS, WHO MUST CUT STAINLESS STEELS AND ALUMINUM
- CONTRACTORS AND MAINTENANCE DEPARTMENTS THAT ERECT AND MAINTAIN ALL KINDS OF PLANTS, INCLUDING FOOD PROCESSING, PETROLEUM, CHEMICAL, PULP AND PAPER MILLS, POWER PLANTS, AND MINING OPERATIONS

The end users of PAC systems with an output greater than 100 A include:

- LARGE SHOPS THAT FABRICATE SPECIALTY AND SUBCONTRACTED PARTS FROM VIRTUALLY ANY METAL
- STEEL WAREHOUSES AND SERVICE CENTERS THAT SIZE AND SHAPE-CUT BOTH FERROUS AND NONFERROUS METALS, AS WELL AS THOSE THAT SIZE SCRAP

- PIPE FABRICATORS AND PIPING CONTRACTORS, WHO MUST SIZE, BEVEL, AND MAKE INTERSECTION CUT-OUTS ON CARBON AND STAINLESS STEEL PIPE
- STRUCTURAL FABRICATORS, WHO MUST PERFORM HIGH-SPEED SLITTING OF H AND I BEAMS AND THE SIZING AND SLITTING OF PLATE
- MANUFACTURERS OF SHIPS, BARGES, AND OFF-SHORE RIG PLATFORMS, WHO MUST PERFORM PLATE SIZING, PIPE CUTOFF, BULKHEAD FABRICATION, AND PROPELLER TRIMMING
- ALUMINUM, STEEL, AND COPPER MILLS THAT SIZE AND STRIP ROLLED PLATE AND SHEET, OR THAT SIZE SCRAP, OR THAT PERFORM PLANT EQUIPMENT MAINTENANCE
- SCRAP YARDS THAT PERFORM HIGH-SPEED SIZING OF STAINLESS STEEL, COPPER, BRASS, ALUMINUM, AND OTHER METALS

Plasma Arc Cutting

Chuck Landry, Thermal Dynamics Corporation

Safety

Operators of PAC equipment should be aware of seven areas of potential hazards that are associated with the process. The proper operation of the equipment and adherence to certain precautions will minimize the risks involved.

Gases and Fumes. Potentially hazardous gases associated with the PAC process include ozone, nitrogen dioxide, and phosgene (caused by the breakdown of chlorinated solvents in ultraviolet light). Metal fumes vary with the composition of the metal being cut. Fumes of beryllium, cadmium, cobalt, copper, lead, mercury, silver, vanadium, and several other elements may be hazardous to individuals in the PAC area. Various limits imposed on the levels of gases and fumes in the work area are listed in a handbook published by the Occupational Safety and Health Administration (OSHA) and in the American Welding Society document A6.3-69, "Recommended Safe Practices for Plasma Arc Cutting."

Gases and fumes created by the PAC process can be effectively controlled by properly installed ventilation systems in the work area. Water tables that are used either alone, for surface or underwater cutting, or in conjunction with water-shrouded systems can effectively reduce gases and fumes. Respirators can be used when ventilation systems and water tables are impractical. Chlorinated solvents and other sources of phosgene gas should be removed from the PAC work area.

Noise. The high level of noise associated with some PAC operations (usually, high power) can lead to hearing damage. Maximum exposure times to various noise levels are printed in the OSHA handbook. The operator and any other personnel within the vicinity of the PAC operation should wear proper ear protection. Underwater cutting and the use of water-shrouded systems are effective means for reducing noise levels.

Radiant Energy. The ultraviolet infrared and visible light from the plasma arc can lead to injury of the eyes and skin. Operators and anyone else in the vicinity of the PAC operation should be protected by proper clothing that covers all skin and by welding helmets or shields that contain the proper shaded lens. For high-powered operations, the use of a number 10 (or greater) shaded lens may be required by the operator. If the intensity of the PAC process causes eye discomfort to the operator, a lens with a darker shade should be utilized.

Electric Shock. Both the input power to and the output from a PAC system is sufficient to be hazardous if an individual receives a shock from the system. Output voltages in the PAC process usually range from 100 to 200 V dc; typical welding processes run at 20 to 40 V dc. All equipment should be installed and maintained according to the USA Standard National Electrical Code and any local standards. All components of a PAC system should be properly earth grounded. System power should be shut off at a wall disconnect before the torch or any other system component is serviced. Any cracked insulators, power leads, or exposed live parts should be corrected immediately. Operators of PAC systems should be insulated from the workpiece and ground, and those who work in wet or damp areas should take precautions to ensure adequate protection from electric shock.

Fire. The sparks and the hot molten metal that is blown out of the cut can cause fires. Sparks that result from piercing can travel a considerable distance. All combustibles should be removed from the work area, and a fire extinguisher should be located in the vicinity. Because the pilot arc from a PAC torch is very hot, extra care should be taken to prevent it from contacting clothing and other flammable materials.

Compressed Gas Cylinders. High-pressure gas cylinders, which are often used to supply PAC systems, can be hazardous if they are not treated properly. Proper handling requires that valve covers always be in place when transporting cylinders, and that cylinders be secured to stationary objects by chains or lashing straps to prevent them from falling over.

Explosions. When hydrogen is used as a plasma or secondary gas, in conjunction with argon, extra care should be taken, because it is highly explosive. In some instances, explosions of hydrogen gas can occur even if hydrogen is not supplied as a portion of the plasma or secondary gas. This is because hydrogen can form when some metals, particularly aluminum, are being cut over a water table, by a reaction between the metal and the water, and by the dissociation of water that is due to the plasma arc. During the cutting operation, the plasma arc can ignite this hydrogen, which will explode if it is confined. Adequate ventilation of these hydrogen pockets is necessary for the safe operation of PAC systems. The water in the water table should not be any deeper than 50.8 mm (2 in.) below the bottom of the metal workpiece support bars. A blower system should be used to flush out all hydrogen from beneath the workpiece.

Air-Carbon Arc Cutting

Robert L. Strohl, Tweco Arcair

Introduction

AIR-CARBON ARC CUTTING (CAC-A) removes metal physically, rather than chemically, as in the oxyfuel cutting process. Gouging, or cutting, occurs when the intense heat of the arc between the carbon electrode and the workpiece melts part of the workpiece. Air simultaneously passes through the arc quickly enough to blow the molten material away. Because this process does not require oxidation to maintain the cut, it can gouge metals that the oxyfuel cutting process cannot. The metal re- moval rate depends on the melting rate and efficiency of the air jet in removing the molten metal. The air must lift the molten metal clear of the arc before the metal solidifies.

Applications. Industry has enthusiastically adopted CAC-A gouging for numerous applications, such as metal fabrication and casting finishing, chemical and petroleum technology, construction, mining, and general repair and maintenance.

The process is used throughout the world to create consistent grooves requiring little or no additional cleaning, on square-butt plate seams to prepare them for welding. The process can then be used to backgouge the seam to sound metal to ensure 100% penetration of the welded joint. If a problem arises during the welding process and an area of the weld does not meet specifications, then the process can be used to remove the defective area without damaging or detrimentally affecting the base metal.

The CAC-A process is also used in foundries to remove fins and risers from castings. It can then be used to smooth areas that contact the surface to prepare the casting for shipment. The process is flexible, efficient, and cost effective to use on numerous metals, such as carbon steel, stainless steel, and other ferrous alloys; gray, malleable, and ductile iron; aluminum; nickel; copper alloys; and other nonferrous metals.

Air-Carbon Arc Cutting

Robert L. Strohl, Tweco Arcair

Principles of Operation

Like electric arc welding, the CAC-A process requires an arc of intense heat to develop a molten pool on the workpiece. Compressed air then blows away this molten metal. The process requires a welding power source, an air compressor, a carbon electrode, and a gouging torch. Figure 1 shows how the components are typically arranged.

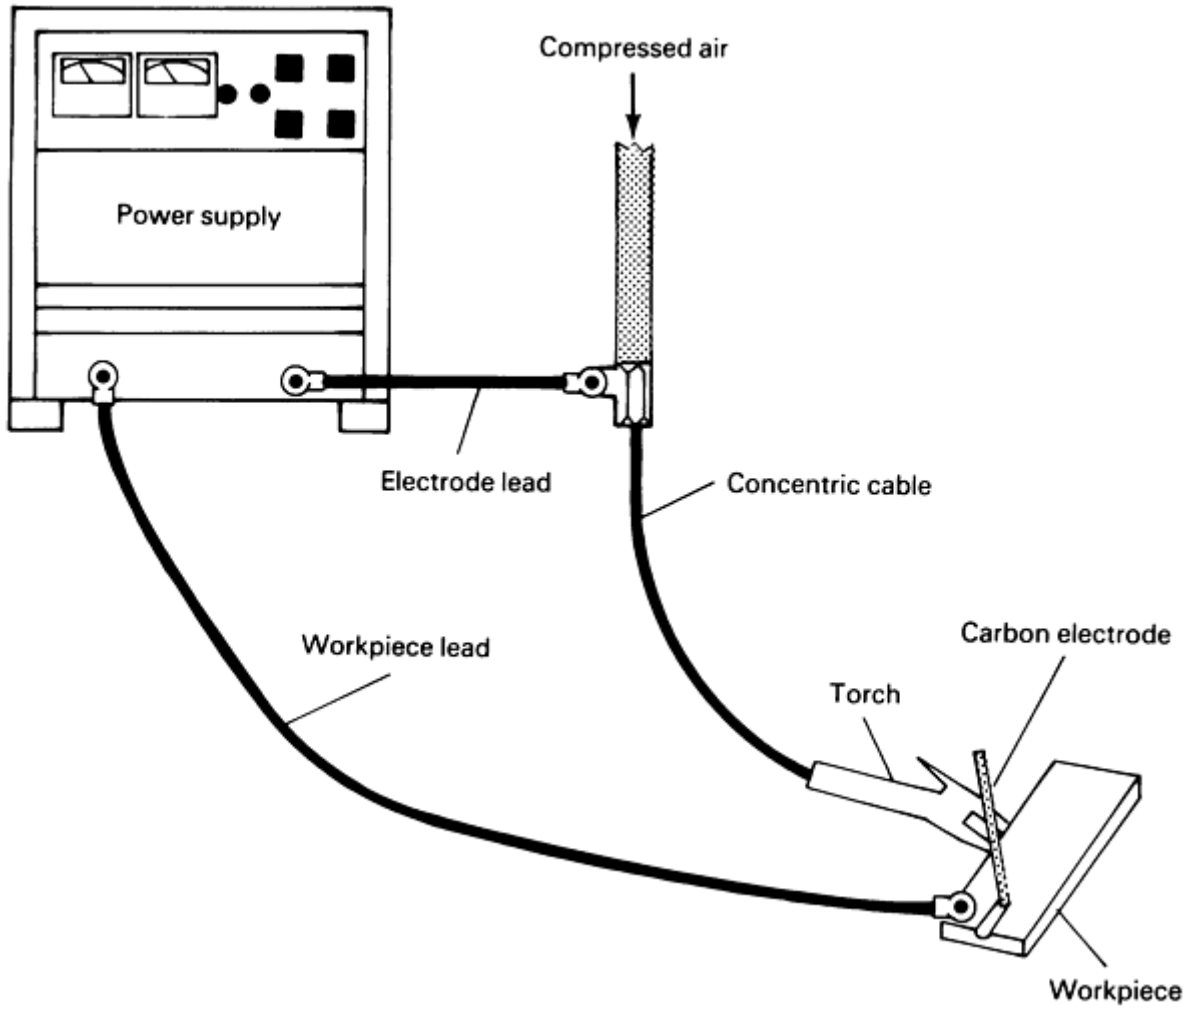

FIG. 1 ARRANGEMENT OF COMPONENTS USED IN THE CAC-A PROCESS

Cuts or gouges should be made only in the direction of the air flow. The electrode angle will vary, depending on the application. The cutter should maintain the correct arc length to enable air to remove molten metal (Fig. 2).

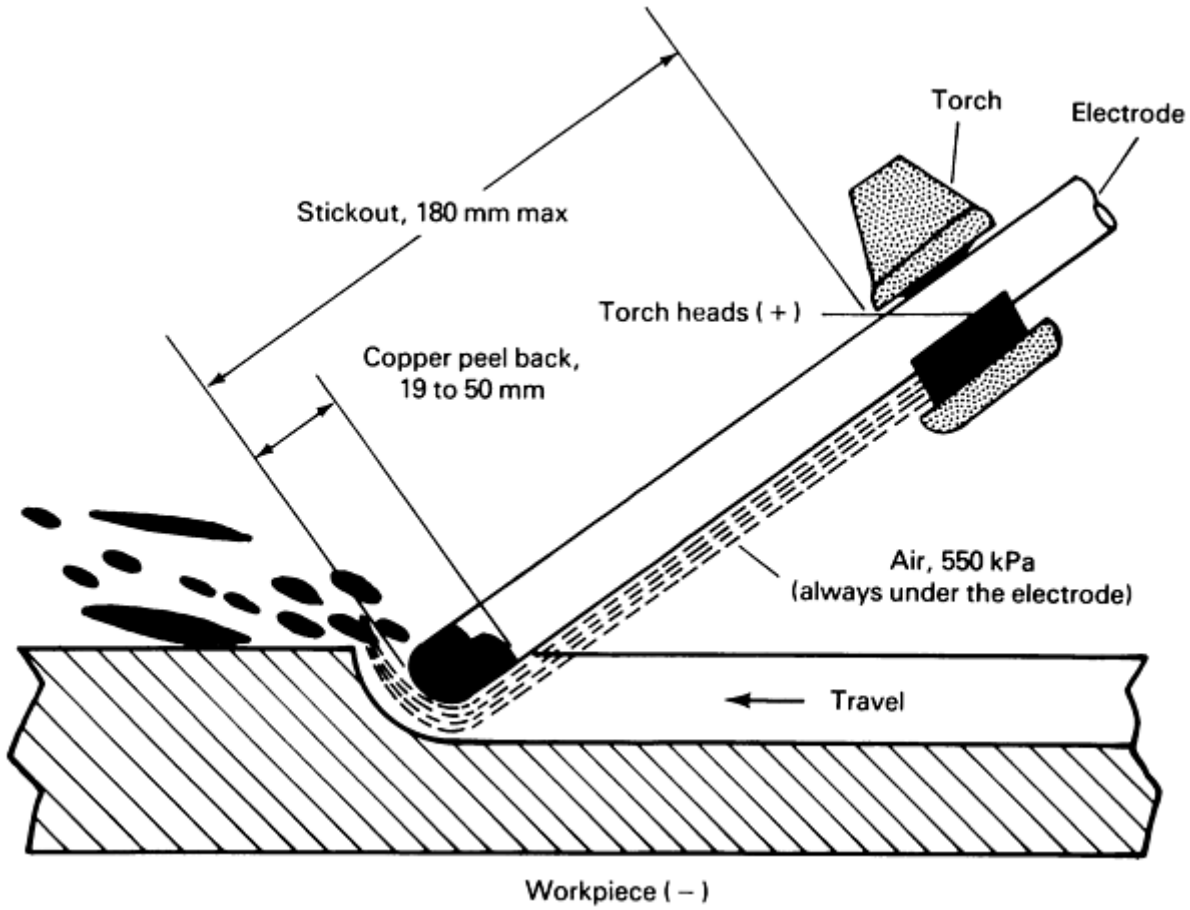

FIG. 2 PRINCIPLES OF CAC-A CUTTING

Power Sources. Single-phase machines with low open-circuit voltage may not work for CAC-A gouging. However, any three-phase welding power source of sufficient capacity can be used. The open-circuit voltage should be higher than the required arc voltage to allow for voltage drop in the circuit. Because the arc voltage typically ranges from a low of 35 to a high of 56 V, the open-circuit voltage should be at least 60 V. The actual arc voltage used in the process is governed by arc length and the type of gouging.

Direct current, electrode positive (reverse polarity, DCEP) is used with the process, except in special applications discussed later. The electrode should extend, at most, 178 mm (7 in.) from the gouging torch, with the air jet between the electrode and workpiece. A minimum extension of 50 mm (2 in.) should be used. Damage of the torch parts will occur if the electrode sticks out less than 50 mm (2 in.).

Compressed Air. Ordinary compressed air should be used for CAC-A gouging. Normal pressures range from 550 to 690 kPa (80 to 100 psi) at the torch. Higher pressures can be used, but they do not remove metal more efficiently. A pressure of 415 kPa (60 psi) should be used with the light-duty manual torch. This low level of pressure should not be used with general-duty torches.

Regardless of the pressure used with manual torches, the air hose supplying the cable assembly that is connected to the torch body should have an inside diameter (ID) of at least 6.4 mm ($\frac{3}{8}$ in.). Mechanized torches with automatic arc length control should have an air-supply hose with minimum ID of 12 mm ($\frac{1}{2}$ in.). Attention should be given to the field connections to ensure that this minimum is maintained without severely restricting the air-flow volume. Table 1 gives the consumption rates of compressed air for manual and mechanized torches, as well as compressor power rating for intermittent and continuous use. The compressor receiver tank must be large enough to accommodate the compressor rating.

TABLE 1 RECOMMENDED MINIMUM AIR SUPPLY REQUIREMENTS FOR AIR-CARBON ARC CUTTING

TYPE OF TORCH	AIR PRESSURE[A]		AIR CONSUMPTION		RECOMMENDED COMPRESSOR RATING				ASME RECEIVER SIZE	
					INTERMITTENT USE		CONTINUOUS USE			
	kpa	psi	l/min	ft^3/min	kw	hp	kw	hp	l	gal
LIGHT DUTY[B]	280	40	227	8	0.4	0.5	1.1	1.5	227	60

(B) ACCOMMODATES FLAT ELECTRODES.
(C) GENERALLY CONSIDERED TO BE A FOUNDRY TORCH.
(D) REQUIRES SOME KIND OF MECHANICAL MANIPULATION

Electrodes. The basic types of electrodes are described below.

Direct-current copper-coated electrodes are the most widely used type, because of their comparatively long electrode life, stable arc characteristics, and groove uniformity. These electrodes are made by mixing carbon and graphite with a binder. When this mixture is baked, it produces dense, homogeneous graphite electrodes of low electrical resistance. These electrodes are then coated with a controlled thickness of copper. The available diameters of these electrodes are 3.2 mm ($\frac{1}{8}$ in.), 4.0 mm ($\frac{5}{32}$ in.), 4.8 mm ($\frac{3}{16}$ in.), 6.4 mm ($\frac{1}{4}$ in.), 7.9 mm ($\frac{5}{16}$ in.), 9.5 mm ($\frac{3}{8}$ in.), 12.7 mm ($\frac{1}{2}$ in.), 15.9 mm ($\frac{5}{8}$ in.), and 19.1 mm ($\frac{3}{4}$ in.).

Jointed electrodes work without stub loss. They are furnished with a female socket and a matching male tang, and are available in diameters of 7.9 mm ($\frac{5}{16}$ in.), 9.5 mm ($\frac{3}{8}$ in.), 12.7 mm ($\frac{1}{2}$ in.), 15.9 mm ($\frac{5}{8}$ in.), 19.1 mm ($\frac{3}{4}$ in.), and 25.4 mm (1 in.). Jointed carbons are always used with the male tang pointing up (that is, away from the gouge). This ensures proper joint performance.

Flat, or rectangular, coated electrodes are available in dimensions of 4.0 × 9.5 mm ($\frac{5}{32} \times \frac{3}{8}$ in.) and 4.8 × 15.9 mm ($\frac{3}{16} \times \frac{5}{8}$ in.). These electrodes are used to make rectangular grooves and to remove weld reinforcements.

Direct-current electrodes are generally restricted to diameters of less than 9.5 mm ($\frac{3}{8}$ in.), and are therefore limited in use. During cutting, these electrodes erode more than the coated electrodes. They are manufactured in the same way as the coated electrodes, but without the copper coating. Plain electrodes are available in diameters of 4.0 mm ($\frac{5}{32}$ in.), 4.8 mm ($\frac{3}{16}$ in.), 6.4 mm ($\frac{1}{4}$ in.), 7.9 mm ($\frac{5}{16}$ in.), and 9.5 mm ($\frac{3}{8}$ in.).

Alternating-current (ac) coated electrodes are made from a mixture of carbon, graphite, and a special binder. Rare-earth materials are added to ensure arc stabilization when using alternating current. These electrodes, coated with copper, are available in diameters of 4.8 mm ($\frac{3}{16}$ in.), 6.4 mm ($\frac{1}{4}$ in.), and 9.5 mm ($\frac{3}{8}$ in.).

A manual gouging torch is shown in Fig. 3. The electrode is held in a swivel head that contains one or more air holes, so that the air jet stays aligned with the electrode, regardless of the angle of the electrode to the gouging torch. Torches

with two heads (that is, the air jet is on two sides of the electrode) or with a fixed angle between the electrode and the holder are better for certain applications, such as removing pads and risers from large castings (pad washing).

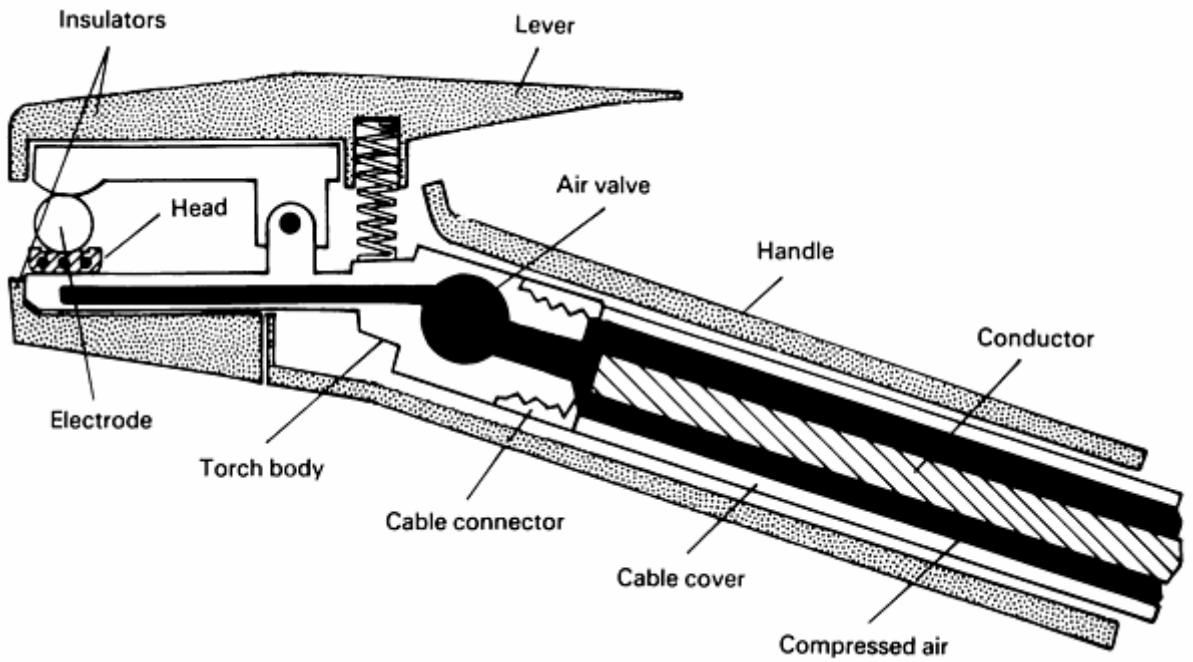

FIG. 3 CUTAWAY VIEW OF A MANUAL GOUGING TORCH WITH AIR FLOW ON BOTTOM OF ELECTRODE

Manual torches are usually air cooled. In high-current applications, water-cooled cable assemblies can be used with heavy-duty torches.

Control of Automatic Gouging Torches. There are two methods of controlling automatic CAC-A gouging torches. Either method can make grooves of consistent depth to a tolerance of ±0.64 mm (±0.025 in.). These automatic units are used to achieve high-quality gouges and to increase production (Fig. 4).

FIG. 4 AUTOMATIC GOUGING UNIT

The amperage-controlled method maintains the arc current by amperage signals through solid-state controls. This method controls the electrode feed speed, which maintains the preset amperage. It is run with constant-voltage power sources only.

A voltage-controlled method maintains arc length by voltage signals through solid-state electronic controls. This method controls the electrode feed speed, which maintains the preset voltage. It can run with constant-current power sources.

Robert L. Strohl, Tweco Arcair

Operating Techniques

Gouging with Manual Torches. As shown in Fig. 2, the electrode should be gripped so that a maximum of 178 mm (7 in.) extends from the torch. For aluminum, this extension should be 76.5 mm (3 in.). Table 2 shows suggested currents for the different electrode types and sizes.

TABLE 2 SUGGESTED CURRENT RANGES FOR VARIOUS ELECTRODE SIZES

ELECTRODE SIZE		MINIMUM AMPERAGE	MAXIMUM AMPERAGE
mm	in.		
3	$\frac{1}{8}$	60	90
4	$\frac{5}{32}$	90	150
5	$\frac{3}{16}$	200	250
6	$\frac{1}{4}$	300	400
8	$\frac{5}{16}$	350	450
10	$\frac{3}{8}$	450	600
13	$\frac{1}{2}$	800	1000
16	$\frac{5}{8}$	1000	1250
19	$\frac{3}{4}$	1250	1600
25	1	1600	2200

The air jet should be turned on before striking the arc, and the torch should be held as shown in Fig. 5. The electrode should slope back from the direction of travel, with the air jet behind the electrode. During gouging, the air jet sweeps beneath the electrode end and removes all molten metal. The arc can be struck by lightly touching the electrode to the workpiece. The electrode should not be drawn back once the arc is struck.

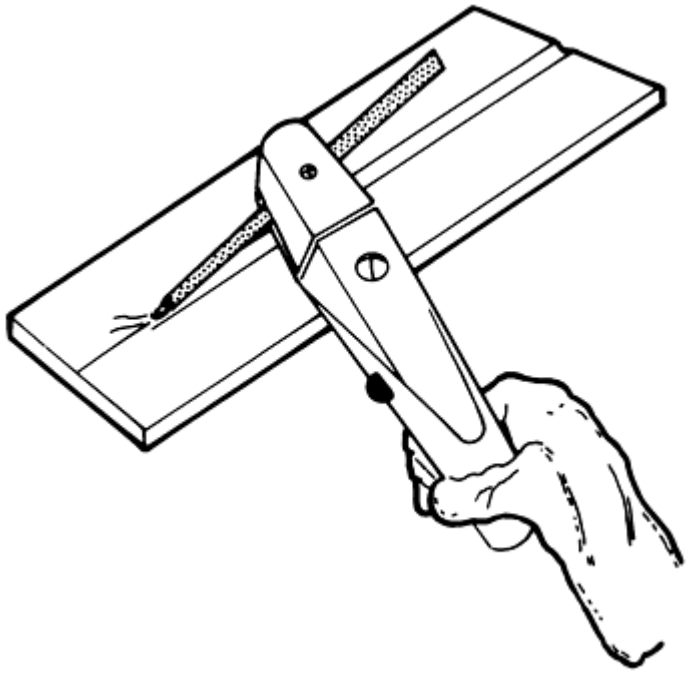

FIG. 5 FLAT GOUGING POSITION

Gouging is different from arc welding in that metal is removed, rather than deposited. A short arc should be maintained in the direction of cut by working fast enough to keep up with metal removal. Steadiness of movement controls the smoothness of the resulting cut.

Vertical gouging should be conducted downhill, permitting gravity to help remove the molten metal. Although vertical gouging can be accomplished uphill, it is difficult. Horizontal gouging can be done either to the right or to the left, but always with forehand gouging.

The air jet should always be positioned under the electrode. When gouging in the overhead position, the electrode and torch should be held to prevent molten metal from dripping on the glove of the operator. The depth of the groove is controlled by the travel speed. Grooves up to 25 mm (1 in.) deep can be made. However, the deeper the groove, the more experienced the operator needs to be. Slow travel speeds will produce a deep groove. Fast speeds will produce a shallow groove. The width of the groove is determined by the size of the electrode used. The groove is usually about 3.2 mm ($\frac{1}{8}$ in.) wider than the diameter of the electrode. A wider groove can be made with a small electrode that is oscillated in either a circular or weave motion. When gouging, a push angle that is 35° from the surface of the workpiece should be used for most applications. A steady rest will ensure a smoothly gouged surface, especially in the over-head position. Proper travel speed depends on electrode size, the base metal being used, amperage, and air pressure. The proper speed, which produces a smooth hissing sound, will result in a good gouge.

The severing technique is like gouging, except that the operator holds the electrode at a steeper angle that is between 70 and 80° to the workpiece surface. When cutting thick, nonferrousmetals, the electrode should be held perpendicular to the workpiece, with the air jet favoring the desired side. With the electrode in this position, the operator can sever the metal by moving the arc up and down using a sawing motion.

Washing. When using the CAC-A process to remove metal from large areas (for example, surfacing metal or riser pads on castings), the operator should position the electrode as shown in Fig. 6. The electrode should weave from side to side while it is being pushed forward at the depth desired. In the pad-washing operation, an angle that is 15 to 70° to the workpiece should be used. The 15° angle is used for light finishing passes, whereas steeper angles allow deeper rough gouging with greater ease.

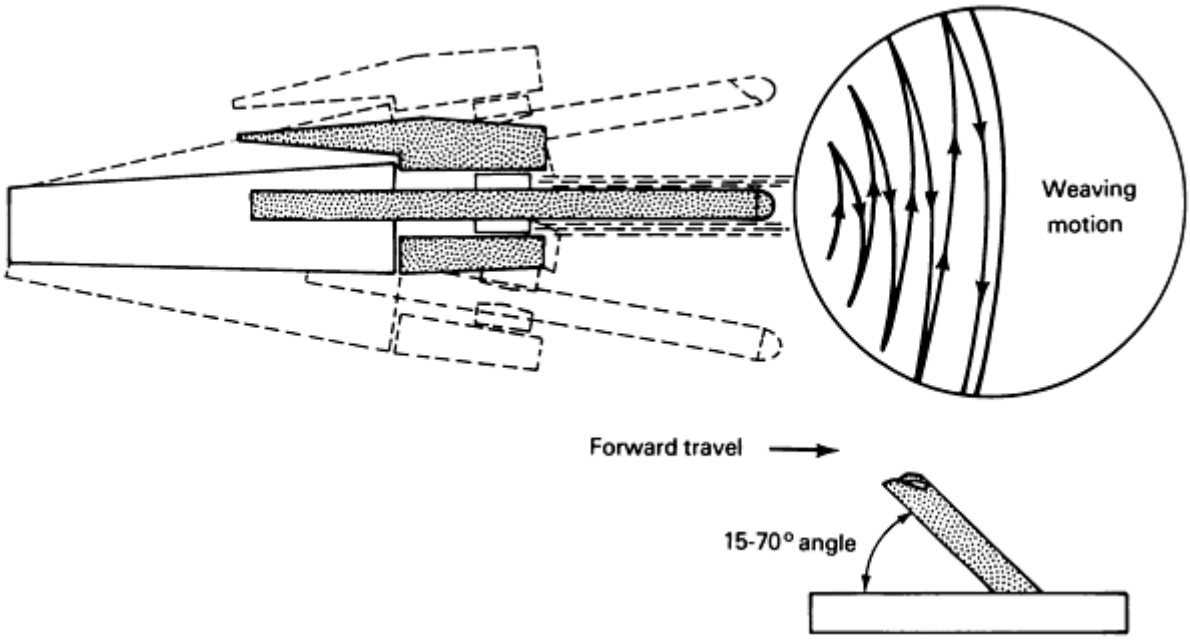

FIG. 6 PAD-WASHING TECHNIQUE. THE TORCH REMAINS PARALLEL TO THE WORKPIECE, AND A WEAVING MOTION IS USED FORWARD ACROSS THE WIDTH OF THE AREA BEING CLEANED. THE ELECTRODE-TO-WORKPIECE ANGLE SHOULD BE FROM 15 TO 70°. THE MORE SHALLOW THE ANGLE, THE SMOOTHER THE FINISH; THE 70° ANGLE IS USED MAINLY ON CAST IRON.

Gouging torches with fixed-angle heads that hold the electrode at the correct angle are well-suited for this application. When other types of torches are used, the air jet should be kept behind the electrode. Operator steadiness determines the smoothness of the surface produced.

Beveling. In one beveling method that is used for thick plates, the electrode should be held with a travel angle of 90° and a work angle that is equal to the bevel angle. The air jet should be positioned between the electrode and the workpiece. A second method, usually used for thin plates, requires that the torch be held parallel to the edge being beveled. Its position should equal the bevel angle. The air jet should be positioned between the electrode and the workpiece surface.

Air-Carbon Arc Cutting

Robert L. Strohl, Tweco Arcair

Equipment Selection

Gouging torches are selected for the specific application. They range from light-duty sizes appropriate for farm and body shop applications to extra-heavy-duty torches that are best suited to foundry applications.

General-purpose torches are available in four duty levels. Light-duty torches accept round electrodes that range from 3.2 to 6.5 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) and 9.5 mm ($\frac{3}{8}$ in.) flat electrodes. Their maximum current level is 450 A. Medium-duty torches accept round electrodes that range from 3.97 to 9.5 mm ($\frac{5}{32}$ to $\frac{3}{8}$ in.) and 9.5 mm ($\frac{3}{8}$ in.) flat electrodes. Their maximum current level is 600 A. Heavy-duty torches accept round electrodes that range from 3.97 to 12.7 mm ($\frac{5}{32}$ to $\frac{1}{2}$ in.) and flat electrodes of 9.5 or 15.9 mm ($\frac{3}{8}$ or $\frac{5}{8}$ in.). Their maximum current level is 1000 A. Extra-heavy-duty

torches accept round electrodes that range from 3.97 to 15.9 mm ($\frac{5}{32}$ to $\frac{5}{8}$ in.) and flat electrodes of 9.5 or 15.9 mm ($\frac{3}{8}$ or $\frac{5}{8}$ in.). Their maximum current level is 1250 A.

Foundry heavy-duty torches are appropriate for general foundry work and heavy-duty fabrication. They are limited to 1600 A when used with air-cooled cables and 2000 A when used with water-cooled cables.

Automated gouging torches are used for edge preparations and backgouging, as well as high-quality and high-productivity applications. Jointed carbon electrodes ranging from 7.9 to 19.1 mm ($\frac{5}{16}$ to $\frac{3}{4}$ in.) are accepted.

Power Sources. Any three-phase welding power source with enough capacity can be used for the CAC-A gouging process if the open-circuit voltage is high enough to allow for a voltage drop in the circuit. Some constant-voltage power sources with drooping characteristics require a very high open-circuit voltage to run CAC-A gouging equipment. Mechanized gouging and other applications that require maximum arc time should utilize a power source with a 100% duty cycle for the required amperage.

A dc constant-current power source motor generator, rectifier, or resistor grid unit is preferred for use with all electrode sizes. A dc constant-voltage power source motor generator or rectifier is usable only for 7.9 mm ($\frac{5}{16}$ in.) diameter and larger electrodes. It may cause carbon deposits when used with small electrodes, and it is not suitable for automatic torches with voltage control only. An ac constant-current power source (transformer) is recommended for ac electrodes only. With ac/dc transformer rectifiers, the direct current should be supplied by a three-phase source, because single-phase sources give unsatisfactory arc characteristics. Alternating current output from ac/dc units is satisfactory, if ac electrodes are used.

Automatic systems are often used in modern fabrication facilities. These systems offer a high-quality, high-productivity alternative to manual gouging. Two types of systems can be considered. Both operate on a signal from the arc to control the gouging.

Dual-Signal System. Either constant-current or constant-voltage power supplies can be used with this type of automatic system. When the system uses constant current, the arc length is maintained through a voltage-signal system. A predetermined voltage setting is set on the system controller, which then advances or retracts the electrode through a stepping motor to maintain the arc length. With a constant-voltage power source, amperage sensing controls the feeding or retracting of the electrode to maintain the right arc current.

The single-signal system, like the dual-signal system, maintains arc length through voltage signal. However, it will not operate with an amperage signal. This type of system only operates with a constant-current power source.

Advantages. Automatic CAC-A systems ensure better productivity and quality. The systems can perform out-of-position gouging. They perform well when making long gouges in flat workpieces using a moving gouging apparatus and when making circular gouges in pipes and tanks using stationary gouging apparatus. They produce an even U-shaped groove and can control the depth of the groove to within ±0.64 mm (±0.025 in.). Table 3 shows typical operating information for U-shaped grooves.

TABLE 3 AUTOMATIC AIR-CARBON ARC U-SHAPED GROOVE OPERATING DATA[(A)]

ELECTRODE DIAMETER		DESIRE DEPTH		DC CURRENT, A	TRAVEL SPEED	
mm	in.	mm	in.		mm/min	in./min
7.9	$\frac{5}{16}$	3.2	$\frac{1}{8}$	400	1651	65
7.9	$\frac{5}{16}$	4.8	$\frac{3}{16}$	400	1143	45

7.9	5/16	6.4	1/4	450	914	36
7.9	5/16	7.9	5/16	450	838	33
7.9	5/16	11.1	7/16	450	572	22.5
9.5	3/8	3.2	1/8	500	1778	70
9.5	3/8	4.8	3/16	500	1118	44
9.5	3/8	6.4	1/4	500	889	35
9.5	3/8	9.5	3/8	500	508	20
9.5	3/8	14.3	9/16	500	445	17.5
12.7	1/2	3.2	1/8	850	2438	96
12.7	1/2	6.4	1/4	850	1448	57
12.7	1/2	9.5	3/8	850	889	35
12.7	1/2	12.7	1/2	850	610	24
12.7	1/2	19.1	3/4	850	445	17.5
15.9	5/8	6.4	1/4	1250	1829	72
15.9	5/8	9.5	3/8	1250	1219	48
15.9	5/8	12.7	1/2	1250	940	37
15.9	5/8	15.9	5/8	1250	762	30
15.9	5/8	23.8	15/16	1250	495	19.5
19.1	3/4	6.4	1/4	1400	1829	72
19.1	3/4	9.5	3/8	1400	1068	42
19.1	3/4	12.7	1/2	1400	865	34
19.1	3/4	15.9	5/8	1400	687	27
19.1	3/4	19.1	3/4	1400	560	22
19.1	3/4	28.6	1 1/8	1400	330	13

Note: If a groove depth greater than 1.5 times the diameter of the electrode being used is desired, then the groove should be made in two or more passes.

(A) BASED ON LABORATORY CONDITIONS; INFORMATION SHOULD BE USED AS A GUIDE

AND ADJUSTED FOR FIELD VARIANCE AS REQUIRED.

Vacuum gouging represents a new variation of gouging that was developed in the late 1980s. This process replaces the air jet that is used to evacuate the molten slag from the groove area with a high-volume vacuum that not only captures the slag and fume associated with the gouging process, but also reduces the noise level created when performing the gouging process.

The vacuum gouging process utilizes a specially designed nozzle that attaches to an automatic gouging head. By water cooling the nozzle and the attached vacuum hose, the slag and fume from the gouging process are pulled by the vacuum into a capture dram. The slag is knocked into the bottom of the catch tank, which is partially filled with water, and the fume is caught in a filter before the air is exhausted from the vacuum. Currently, this new vacuum system is limited to automated gouging operations on flat plate or pressure vessel circumferential seams.

Air-Carbon Arc Cutting

Robert L. Strohl, Tweco Arcair

Important Process Variables

Like any thermal-cutting process, the CAC-A process is sensitive to variables in operation. These variables can cause changes in the finished gouge that range from being undetectable to being unacceptable.

Electrode diameter and type are variables that determine the groove size, as well as productivity, groove quality, and metal-removal rates. The width of the groove will be about 3.2 mm ($\frac{1}{8}$ in.) wider than the diameter of the electrode. The choice of a proper electrode can be based on the size of the desired groove. Available power will dictate the outer limit. For example, a 13 mm ($\frac{1}{2}$ in.) wide, 6.4 mm ($\frac{1}{4}$ in.) deep groove that is 254 mm (10 in.) long could be made manually in two passes using a 6.4 mm ($\frac{1}{4}$ in.) diameter electrode, or in one pass using a 9.5 mm ($\frac{3}{8}$ in.) diameter electrode. In the first case, the best gouging rate would be 254 mm/min (10 in./min), divided by 2, or 125 mm/min(5 in./min). The travel speed of the second case (one pass) is 430 mm/min (17 in./min).

The 9.5 mm ($\frac{3}{8}$ in.) diameter electrode increases the gouging rate by 200%, which could offset the additional cost of the electrode. Automatic systems increase the productivity rate even further, through finite control of the arc voltage.

The gouging amperage is the melting force of the process. It is affected by electrode size. If the amperage were set too low for the electrode size, then the melting rate of the base metal would be inadequate and free-carbon deposits would occur. Although the base metal would melt, a setting that is too high would rapidly deteriorate the electrode while reducing the metal removed per electrode. Too high a setting can also substantially reduce torch life.

Voltage is the pressure, or arc force, that enables the current to flow across the arc gap. The CAC-A process often requires a higher voltage than do most welding processes. To ensure proper operation, a power source with a high enough open-circuit voltage to maintain a 28 V operating minimum should be used. Inadequate voltage can create a sputtering arc or it can prevent arc establishment, resulting in uneven grooves and, probably, free-carbon deposits that would require excessive grinding to remove.

Adequate air pressure and flow rate are required for the adequate removal of molten metal by the air jet. Air volume is as important as air pressure. Pressure is the speed of the air that moves the molten metal from the groove. If there is an inadequate volume of air to lift the molten material out of the groove, then it cannot be removed by the pressure or velocity. The result is excessive slag adhesion and unnecessary grinding to clean up the groove.

Travel speed affects the depth of the gouge and the quality of the groove. The faster the travel speed of an electrode, the shallower the gouge. A smaller electrode can be used if the travel speed is too fast for the comfort of the operator, or automatic gouging can be used. A groove that is too deep for the diameter of the electrode results in a poor-quality groove that requires much grinding.

The electrode push angle can vary some-what. When gouging manually, a steeper angle tends to give a more V-shaped groove. When gouging automatically, a steeper angle gives a slightly deeper groove at the same travel speed.

Base Metals. The gouging procedures that are recommended for specific base metals are:

- FOR CARBON STEEL AND LOW-ALLOY STEEL, SUCH AS ASTM A 514 AND A 517, USE DC ELECTRODES WITH DCEP. ALTHOUGH AC ELECTRODES WITH AN AC TRANSFORMER CAN BE USED, THEIR EFFICIENCY IS HALF THAT OF DC ELECTRODES.
- FOR STAINLESS STEEL, THE SAME GUIDELINES APPLY AS FOR CARBON STEEL.
- FOR CAST IRON, INCLUDING MALLEABLE AND DUCTILE (NODULAR) FORMS, USE 13 MM ($\frac{1}{2}$ IN.) DIAMETER OR LARGER ELECTRODES AT THE HIGHEST RATED AMPERAGE. SPECIAL TECHNIQUES ARE NEEDED WHEN GOUGING THESE METALS. THE PUSH ANGLE SHOULD BE AT LEAST 70° OFF THE WORKPIECE, AND THE DEPTH OF THE CUT SHOULD NOT EXCEED 13 MM ($\frac{1}{2}$ IN.) PER PASS.
- FOR COPPER ALLOYS (COPPER CONTENT $\leq$60%), USE DC ELECTRODES WITH DIRECT CURRENT ELECTRODE NEGATIVE (DCEN) AT THE MAXIMUM AMPERAGE RATING OF THE ELECTRODE.
- FOR COPPER ALLOYS (COPPER CONTENT >60% OR LARGE WORKPIECE), USE DC ELECTRODES WITH DCEN AT THE MAXIMUM AMPERAGE RATING OF THE ELECTRODE, OR USE AC ELECTRODES WITH ALTERNATING CURRENT.
- FOR ALUMINUM BRONZE AND ALUMINUM-NICKEL-BRONZE (SPECIAL NAVAL PROPELLER ALLOYS), USE DC ELECTRODES WITH DCEN.
- FOR NICKEL ALLOYS (NICKEL CONTENT >80% OF MASS), USE AC ELECTRODES WITH ALTERNATING CURRENT.
- FOR NICKEL ALLOYS (NICKEL CONTENT <80% OF MASS), USE DC ELECTRODES WITH DCEP.
- FOR MAGNESIUM ALLOYS, USE DC ELECTRODES WITH DCEP AND WIRE-BRUSH THE GROOVE BEFORE WELDING.
- FOR ALUMINUM ALLOYS, USE DC ELECTRODES WITH DCEP AND WIRE-BRASH THE GROOVE WITH STAINLESS BRUSHES BEFORE WELDING. ELECTRODE EXTENSION (LENGTH OF ELECTRODE BETWEEN TORCH AND WORK) SHOULD NOT EXCEED 76.2 MM (3 IN.). DIRECT-CURRENT ELECTRODES WITH DCEN CAN ALSO BE USED.
- FOR TITANIUM, ZIRCONIUM, HAFNIUM, AND THEIR ALLOYS, THERE ARE NO CURRENT PROCEDURES. IF THESE METALS ARE PREPARED FOR WELDING USING THE CAC-A PROCESS, THEN THE GROOVE SHOULD BE CLEANED BEFORE WELDING. THESE METALS CAN BE CUT FOR REMELTING. IN CASES WHERE PREHEAT IS REQUIRED FOR WELDING, A SIMILAR PREHEAT SHOULD BE USED FOR GOUGING.

Effects of the Cutting Process on Base Metals. Metallurgically, the base metal is not affected by the carbon particles being carried toward it from the electrode, because it remains solid and the atoms are very tightly packed. However, because the material being removed is molten, the atoms are loosely spread. This material, usually referred to as slag, easily absorbs the carbon particles.

If the CAC-A process is properly used, no surface carburization will occur. Due to the rapid quenching effect of the air used to remove the metal, the heat-affected zone (HAZ) will undergo hardening. The heat-affected zone for CAC-A is typically 2.5 mm (0.10 in.) or less in thickness. This HAZ hardening must be considered when a finish machining operation follows the gouging process, especially when working on high-carbon steels. Some materials (for example, nickel) will undergo surface cracking when gouged. These conditions should be considered when choosing the parameters for any required machining operations.

When the CAC-A process is used under improper conditions, this molten carburized metal may be left on the workpiece surface. Its color is a dull gray-black, in contrast to the bright blue of the properly made groove. Inadequate air flow may

leave small pools of carburized metal in the bottom of the groove. Irregular electrode travel, especially in a manual operation, may cause ripples in the groove wall that trap the carburized metal. Finally, an improper electrode push angle may cause small beads of carburized metal to remain on the edge of the groove.

Copper from copper-coated electrodes does not transfer to the cut surface in base metal, unless the process is improperly used.

Carburized metal can be removed from a cut surface by grinding, but the necessity to do so can be prevented by gouging properly in the right condition.

When compared with oxyfuel cutting, the CAC-A process requires less heat input. Therefore, a workpiece that is gouged or cut by the CAC-A process is less distorted. The machining of low-carbon and nonhardenable steel is not affected by the CAC-A process. However, when used on cast iron and high-carbon steels, this process may cause enough hardening to make the cut surface tough to machine. Still, because the hardened zone is shallow (approximately 0.15 mm, or 0.006 in.), a cutting tool can penetrate it to remove the hardened surface.

Air-Carbon Arc Cutting

Robert L. Strohl, Tweco Arcair

Safety and Health

Safe practices in welding and cutting processes are described in ANSI Z49.1, "Safety in Welding and Cutting," and ANSI Z49.2, "Fire Prevention in Use of Welding and Cutting Processes." The operators of the CAC-A process and their supervisors should adhere to the practices discussed in these documents.

Electrodes. An electrode that carries electric current will arc if it touches the workpiece or any grounded metal object. Proper handling of the torch and electrode will prevent accidental arcing. Electrodes should always be used within their proper amperage range in order to effectively remove metal and to avoid damage to the torch. Carbon electrodes should be kept dry. Damp electrodes should be baked for 10 h at 176 °C (300 °F). Wet electrodes may shatter.

Torches. Oxygen should never be used in an air carbon-arc torch. Neither the torch nor the electrode should ever be immersed in water. All electrical connections should be wrench tight before the torches are used.

Electrical Power. The CAC-A process uses electric energy from a welding power source. The same safety precautions should be used as when welding. An operator should never stand in water while using CAC-A equipment, and the torches and electrodes should never be cooled by water. To prevent accidental arcing, partially used electrodes should be removed from torches when work is interrupted.

Personal Protective Equipment and Clothing. A No. 12 shade-filter lens should be used for eye protection against arc radiation. When conducting heavy metal-removal operations with large electrodes, a No. 14 shade-filter lens or an equivalent combination of filter lenses provides the best protection. Flash goggles should be used, especially when two or more welders are working in the same area. Proper protective clothing must be worn to provide enough protection from the infrared and ultraviolet radiations of the arc. Leather aprons, sleeves, leggings, and so on should be used for out-of-position gouging or for heavy metal-removal operations with large electrodes. Ear protection is recommended when noise exceeds permissible levels.

Fire and Burn Hazards. The CAC-A process may cause fire. All flammable materials should be removed from the work area. Booths, metal screens, and other deflectors should be placed to catch the hot metal and particle spray ejected by the compressed air stream. Protective clothing should be used to prevent burns caused by contact with hot metal or electrodes. Out-of-position or heavy metal-removal operations require that many precautions be taken.

Ventilation Hazards. The fumes from the CAC-A process can be harmful. Ventilation and/or an exhaust around the arc is necessary. When using gouging torches, the operator should keep his head away from the fumes. Protective-breathing or air-circulation gear may be needed.

Additional information is available in the article "Safe Practices" in this Volume.

Mechanical Cutting for Weld Preparation

ASM Committee on Mechanical Cutting for Welding Preparation*

Introduction

OXYFUEL AND PLASMA CUTTING are the processes most commonly associated with preparing metals for welding; however, mechanical cutting methods are also widely used by the metal fabrication industry. The purpose of this article is to introduce the welding fabricator to some of the mechanical equipment used to shape or prepare metals for welding. The most prevalent equipment used for mechanical cutting includes shears, iron workers, nibblers, and band saws. Each has specific applications for which it is efficient and cost effective.

Mechanical Cutting for Weld Preparation

ASM Committee on Mechanical Cutting for Welding Preparation*

Shears

Shears are normally used to prepare large, relatively thin materials (≤ 25 mm, or 1 in., thick) by cutting them to final dimensions. When maintained and adjusted properly, shears provide a clean, straight edge preparation. For thin sections, the square butt edge preparation provided by shearing may be all that is required for the welding operation. As a role, material with a thickness of 10 mm ($\frac{3}{8}$ in.) or more will require further preparation; the straightness of the sheared edge is an excellent reference point for setting up other equipment. The two principal shearing variations are straight-knife shearing and rotary shearing. Because straight-knife shearing is more widely used for welding preparation, it will be the focus of this section.

In straight-knife shearing, the work metal is placed between a stationary lower knife and a movable upper knife. As the upper knife is forced down, the work metal is penetrated to a specific portion of its thickness. The unpenetrated portion then fractures, and the work metal separates (Fig. 1). The amount of penetration depends largely on the ductility and thickness of the work metal. The knife will penetrate 30 to 60% of the work metal thickness for low-carbon steel, depending on thickness (see the section "Capacity" in this article). The penetration will be greater for a more ductile metal such as copper. Conversely, the penetration will be less for metals that are harder than low-carbon steel.

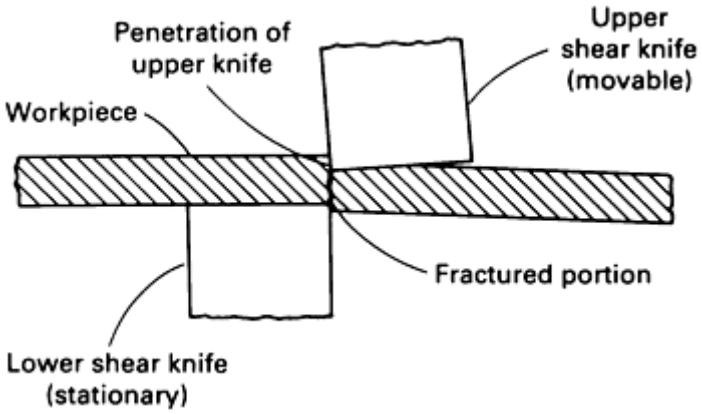

FIG. 1 SCHEMATIC SHOWING THE MECHANISM OF STRAIGHT-KNIFE SHEARING

A sheared edge is characterized by the smoothness of the penetrated portion and the relative roughness of the fractured portion. Sheared edges cannot compete with machined edges, but when knives are kept sharp and in proper adjustment, it is possible to obtain sheared edges that are acceptable for a wide range of applications. The quality of sheared edges generally improves as work metal thickness decreases.

Applicability. Straight-knife shearing is the most economical method of cutting straightsided blanks from stock no more than 50 mm (2 in.) thick. The process is also widely used for cutting sheet into blanks that will subsequently be formed or drawn. Because shear gaging can be set within ±0.13 mm (±0.005 in.), the shearing process is generally limited to ±0.4 mm ($\pm\frac{1}{64}$ in.) tolerances in 16 gage material. The tolerance range increases with thickness.

Straight-knife shearing is seldom used for shearing metal harder than about 30 HRC. When extremely soft, ductile metal (especially thin sheet) is sheared, the edges of the metal roll and large burrs result. As the hardness of the work metal increases, knife life decreases for shearing a given thickness of metal.

In general, it is practical to shear flat stock up to 38 mm ($1\frac{1}{2}$ in.) thick in a squaring shear. Squaring shears up to 9 m (30 ft) long are available (even longer shears have been built), and some types are equipped with a gap that permits shearing of work metal longer than the shear knife.

Machines for Straight-Knife Shearing

Punch presses and press brakes are sometimes used for shearing a few pieces or are used temporarily when more efficient equipment is not available. Production shearing, however, is usually done in machines that are designed for this operation.

Squaring shears are usually used for trimming and cutting sheet or plate to specific size (Fig. 2). Squaring shears (also called resquaring or guillotine shears) are available in a wide range of sizes and designs. Some types permit slitting by moving the work metal a predetermined amount in a direction parallel with the cutting edge of the knife after each stroke of the shear.

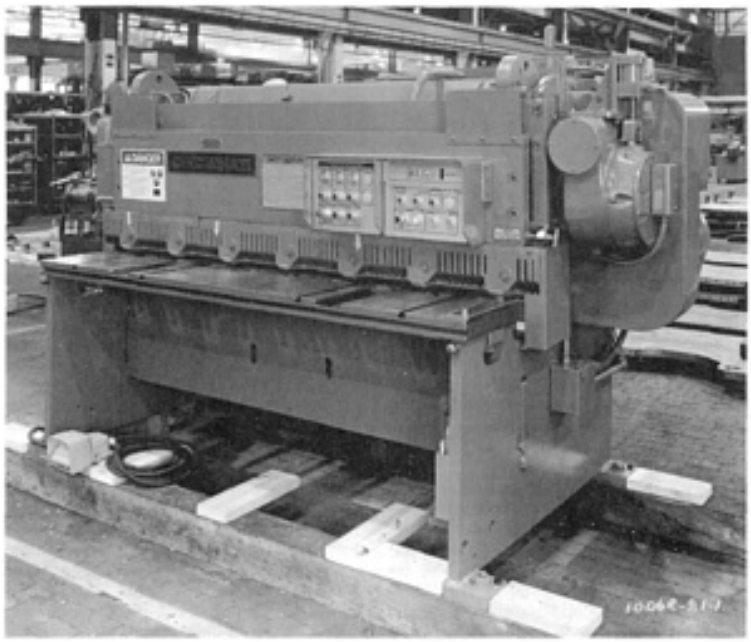

FIG. 2 TYPICAL SQUARING SHEAR. COURTESY OF CINCINNATI INC.

The sheet or plate is held rigid by hold-down devices while the upper knife moves down past the lower knife. Most sheet or plate is sheared by setting the upper knife at an angle. The position of one knife can be adjusted to maintain optimal clearance between the knives. Squaring shears can be actuated mechanically, hydraulically, or pneumatically.

Mechanical Shears. The power train of a mechanical shear consists of a motor, the flywheel, a worm shaft that is gear driven by a flywheel, a clutch that connects the worm gear drive to the driveshaft, and a ram actuated by the driveshaft through eccentrics and connecting links. Under most operating conditions, a mechanical shear can deliver more strokes per minute (spm) than a hydraulic shear. Some mechanical shears cycle as fast as 100 spm.

Another advantage of the mechanical shear is that, because of the energy stored in the flywheel, a smaller motor can be used for intermittent shearing. For example, a mechanical shear with a no-cutting or free-running speed of 65 spm can make approximately six full shearing strokes (maximum thickness and length of cut) per minute with a standard motor. However, when the same shear is cutting at full capacity in a rapid shear mode, a much larger motor is required. For such rapid cutting, there is not enough time between cuts for the smaller motor to restore the speed of the flywheel.

An additional advantage of the mechanical shear is that its moving knife travels faster than the moving knife of a hydraulic shear. In some cases, greater knife speed can decrease work metal twist, bow, and camber.

Hydraulic shears are actuated by a motordriven pump that forces oil into a cylinder against a piston; the movement of the piston energizes the ram holding the upper knife. A hydraulic shear can make longer strokes than a mechanical shear. In general, long shears and shears with low-carbon steel capacities above 12.7 mm ($\frac{1}{2}$ in.) are almost all hydraulic.

Hydraulic shears are designed with a fixed load capacity. This prevents the operator from shearing material that exceeds capacity and therefore saves costly damage to the machine structure. This is a basic advantage of hydraulic shears.

The total load that is experienced during the cut is related to the rake angle, sharpness of the knives, mechanical properties of the material, type of material, knife clearance, and the depth of the back piece. It is possible to stall the machine on a rated-capacity cut if the clearance is incorrect, the knife is dull, or the back piece is excessively deep. In this way, the hydraulic shear is protected from damage caused by overloading. A mechanical shear would not be constrained by an overload prevention system and would continue to cut under nearly all conditions.

Most mechanical shears are provided with enough horsepower to build up the flywheel speed after each cut, but not enough to allow the operator to run full-capacity cuts in a high-speed manner. Mechanical shears are rated in strokes per minute, not cuts per minute. Most shearing applications do not require high-speed cutting.

Hold-down pressure must be greater than the forces generated in cutting the work material. These forces depend on the knife clearance, rake angle, and depth of material back piece.

Greater knife clearance must be used to prevent the hydraulic shears from stalling when shearing large-area work, especially at or near maximum thickness capacity. For example, in cutting a 3 × 3 m (10 × 10 ft) plate into two equal parts, greater shearing force is required than for trimming a narrow strip from a 3 m (10 ft) long plate.

Capacity. Most shearing machines are rated according to the section size of low-carbon steel they can cut. The tensile strength of low-carbon steel sheet and plate is generally no higher than 520 MPa (75 ksi); the yield strength, no greater than 350 MPa (51 ksi). Shears frequently are rated in terms of their ability to cut low-carbon steel with a tensile strength of 414 MPa (60 ksi) and yield strength of 276 MPa (40 ksi). An allowance for normal over-tolerance material thickness is included in the capacity rating of the machine. The use of a machine for shearing other metals is primarily based on the relationship of the tensile strength and ductility of low-carbon steel to that of the metal to be sheared. Metals with a tensile strength greater than that of low-carbon steel almost always reduce the capacity of the machine. For example, the machine capacity for shearing high-strength low-alloy steels is reduced to about two-thirds to three-quarters of the rated capacity for low-carbon steel. Conversely, for shearing aluminum alloys, machine capacity can range from $1\frac{1}{4}$ to $1\frac{1}{2}$ times the rated capacity for low-carbon steel.

Table 1 compares the shearing capacities of various metals with those of low-carbon steel. The metal thicknesses given in Table 1 are based on the thickness of low-carbon steel that can be sheared with the same shearing capacity. For example, a specific force is required to shear 6.4 mm ($\frac{1}{4}$ in.) thick low-carbon steel. Table 1 shows that the same force can shear only a 4.8 mm ($\frac{3}{16}$ in.) thickness of type 302 stainless steel, but can shear a 9.5 mm ($\frac{3}{8}$ in.) thickness of aluminum.

TABLE 1 SHEARING CAPACITIES FOR VARIOUS METALS COMPARED TO THOSE FOR LOW-CARBON STEEL

THICKNESS OF LOW-CARBON STEEL[A]		THICKNESS THAN CAN SHEARED WITH SAME FORCE AS FOR LOW-CARBON STEEL					
		AISI TYPE 203 STAINLESS STEEL [B]		FULL-HARD STEEL STRIP		ALUMINUM ALLOYS

25.4	1	19.0	$\frac{3}{4}$	19.0	$\frac{3}{4}$	38.1	$1\frac{1}{2}$
31.8	$1\frac{1}{4}$	25.4	1	25.4	1	50.8	2

(A) ALSO APPLICABLE TO SOFT TO HALF-HARD STRIP STEEL, ALCLAD STEEL, AND COPPER AND COPPER ALLOYS.

(B) ALSO APPLIES TO MOST OTHER AUSTENITIC STAINLESS STEELS, NORMALIZED ALLOY STEELS SUCH AS 4130 OR 8630, ANNEALED HIGH-CARBON STEELS, AND ANNEALED TOOL STEELS

Ductility, measured by the elongation of the work metal, can also affect machine capacity. For example, annealed copper, because of its high elongation, requires as much shearing effort as low-carbon steel, even though copper has considerably lower tensile strength. Similarly, carbon steel with very low carbon (<0.1% C) and higher-than-normal elongation will reduce the capacity of a machine.

Accessory Equipment for Straight-Knife Shearing

Certain pieces of accessory equipment have been incorporated into most shear designs and are required for efficient and accurate straight-knife shearing.

Hold-downs (Fig. 2) are mechanical or hydraulic devices that hold the work metal firmly in position to prevent movement during shearing. The most efficient hold-down system is a series of independent units that securely clamps stock of varying thicknesses automatically and without adjustment.

The force on each hold-down foot must be substantial and can range from several hundred pounds on a machine for shearing sheet to several tons for shearing plate. Hold-downs must be timed automatically with the stroke of the ram so that they clamp the work metal securely before the knife makes contact and release their hold instantly after shearing is completed.

Back gages are adjustable stops that permit reproducibility of dimensions of sheared work-pieces in a production run. Most gages are controlled electrically. Push-button control provides a selection of fast traverse speeds and slow locating movements for accurate final positioning. The addition of a microcomputer (Fig. 3) permits gage positions to be quickly entered. An LED display enables the operator to confirm immediately the gage position entered, the current gage position, or the final gage location after positioning. Accurate gage screws, compensating nuts, precision slides and guides, and decimal indicators permit repeatable gage settings to an accuracy of 0.025 to 0.05 mm (0.001 to 0.002 in.).

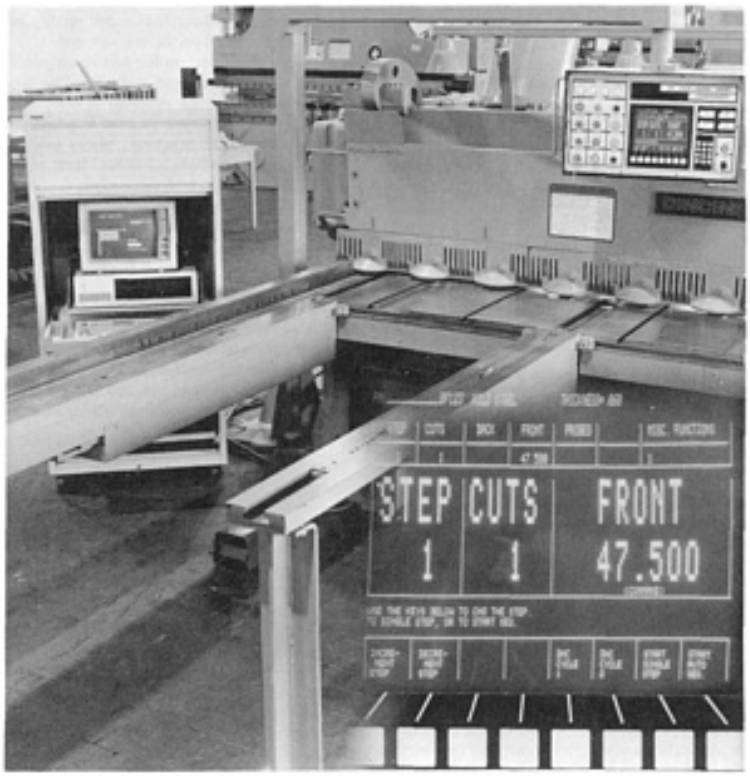

FIG. 3 MICROPROCESSOR-CONTROLLED SHEARING MACHINE WITH INSET (LOWER RIGHT) SHOWING LED DISPLAY. COURTESY OF CINCINNATI INC.

For thin sheet, magnetic overhead rollers eliminate sag and support the sheet for accurate gaging to a depth of 1.2 m (4 ft) into the shear. For rapid and accurate cutting, back gages are equipped with electronic sensors that automatically trip the shear only when the sheet is accurately positioned.

Pneumatic sheet supports are used to support ferrous and nonferrous thin sheet. Sheet support arms are designed to elevate into a horizontal position, flush with the shear table, permitting material to be supported in the correct position against the backgage stop. Blank inaccuracies due to unsupported and poorly positioned sheets are virtually eliminated.

Back gages are also equipped with retractable stops for shearing mill plate. With the stops out of the way, mill plate of almost any length can be fed into the shear and cut to the desired length. When stops are not used, the workpiece can be notched or scribed to indicate the cutoff position.

Front Gages. When gaging from the front of the machine, the operator locates the work metal by means of stops secured in the table or in the front support arms. Power operation of the front support arms allows the blank dimensions to be entered digitally using a microcomputer-based control. Front gaging is often done by means of a squaring arm.

Squaring arms (Fig. 4) are extensions attached to the entrance side of a shearing machine that are used to locate long sections of work metal in the proper position for shearing. Each arm is provided with a linear scale and with stops for accurate, consistent positioning of the work metal. Squaring arms are reversible to allow use of the shear at either end and to distribute the wear on the shear knives. Power operation can be added to the squaring arm for increasing blank accuracy and reducing setup time. This type of squaring arm prevents the arm from moving from side to side.

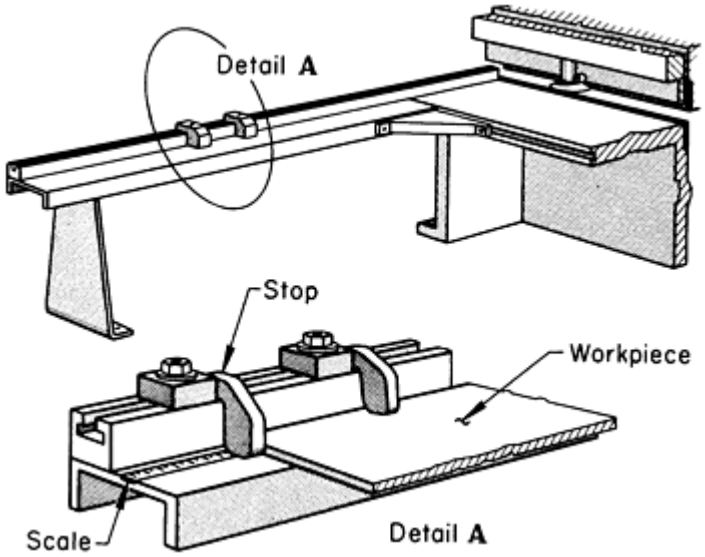

FIG. 4 SQUARING ARM ATTACHMENT FOR POSITIONING LONG PIECES IN A SHEARING MACHINE

Knife Rake

Rake is the slope of the angle formed by the cutting edges of the upper and lower knives (Fig. 2). It is usually expressed as the ratio of the amount of rise to a given linear measurement. For example, a rake of 21 mm/m ($\frac{1}{4}$ in./ft) means that the upper knife rises 21 mm for each meter ($\frac{1}{4}$ in. for each foot) of linear distance along the knives. Rakes below 21 mm/m ($\frac{1}{4}$ in./ft) are rarely used; a rake of 42 mm/m ($\frac{1}{2}$ in./ft) or higher is typical of many plate shears.

Rake is used to permit progressive shearing of the work metal along the length of the knife. This reduces the amount of force required and allows the use of a smaller machine than would be necessary if the cutting edges of the knives were parallel.

It is not possible, however, to calculate the required force for different work metal thicknesses based solely on change of rake, because knife penetration varies for different thicknesses. Even for low-carbon steel, the amount of knife penetration before fracture occurs can be as great as 60% of the work metal thickness for 3.43 mm (0.135 in.) thick stock and as little as 30% for 19 mm ($\frac{3}{4}$ in.) thick stock.

The primary disadvantage of using a high rake angle is that it increases the distortion of the work. Large rake angles can also cause slippage and therefore require high hold-down forces.

Knife Clearance

Excessive knife clearance causes the work metal to be wiped down between the knives during cutting and results in heavy burring or flanging of the work metal. The burrs and deformed metal are objectionable because of their interference with subsequent processing. A more serious consequence of excessive clearance is that it can cause the workpiece to be pulled between the knives, and this in turn causes overloading of the machine and may result in failure of machine components or shear knives.

When soft metals are sheared, insufficient clearance causes double (secondary) shearing, which appears as a burnished area at the top and bottom of a sheared edge with a rough area between the burnished edges. Because of the difference in action, greater tolerances are usually required when shearing plate than when shearing sheet--all other conditions being equal. Some mechanical shears are constructed to operate with a fixed clearance, and no adjustments are made for

variations in work metal composition or thickness. The knife clearance is set for the thinnest material to be sheared, and double shear is avoided if the range of thicknesses sheared is not too large.

Because of deflection, clearance at the center of the knife is usually set less than that at the ends. Knife clearance (except on machines using a fixed clearance) is generally increased as work metal thickness increases. For example, in one plant, a clearance of approximately 0.076 mm (0.003 in.) is used for squaring shears with a capacity of up to 6.4 mm ($\frac{1}{4}$ in.) thick low-carbon steel. To minimize knife deflection, clearance at the center of the knife is reduced to 0.051 mm (0.002 in.). Similarly, the clearance for shearing 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.) thick low-carbon steel is 0.36 mm (0.014 in.) at each end of the knives and 0.30 mm (0.012 in.) at the center of 3 to 3.7 m (10 to 12 ft) long knives used in a mechanical shear.

Ram Speed in Straight-Knife Shearing

The speed of the ram (and, in turn, that of the knife) has a slight effect on results in the shearing of flat stock. Low linear speed produces a rough sheared surface. As speed is increased, a cleaner sheared surface is obtained. In general, speeds to 21 to 24 m/min (70 to 80 ft/min) can be used without difficulty when shearing annealed metals. Regardless of the speed used, adequate hold-down force is mandatory.

Accuracy in Straight-Knife Shearing

The dimensional accuracy obtained in shearing is influenced by the capacity and condition of the machine, condition of the knives, knife clearance, work metal thickness, and work metal condition. Expressed as total tolerance, sheets no thicker than approximately 3.43 mm (0.135 in.) can be cut to size within 0.25 mm (0.010 in.) and strips can be sheared to width at the same total tolerance. These tolerances apply to stock up to 3.7 m (12 ft) long that is essentially free from stress and is flat within commercial limits. Sheets that are not flat or that have residual stress, or both, cannot be sheared with the same accuracy.

Greater tolerances are required in shearing plate. A total tolerance of 0.5 to 1.0 mm (0.020 to 0.040 in.) can be maintained when plate is sheared in squaring shears. Dimensions can be held to tolerance of about ±1.6 mm ($\pm\frac{1}{16}$ in.) when shearing in alligator shears.

Safety

Shearing machines must be equipped with devices for protecting personnel from the hazards of shear knives, flywheels, gears, and other moving parts. The guards and safety devices used must be rigid enough to withstand damage from operating personnel moving heavy material into position.

The squaring shears used for sheet metal should have guards on all moving parts, including flywheels, hold-downs, and knives. The treadle, whether mechanical or electrical, should have a lock for supervisory control. Knife and hold-down guard openings should be large enough to provide visibility but small enough to keep the operator's fingers out of the danger area. Proper opening dimensions are outlined in ANSI standard B11.4 (latest edition).

The shears used for shearing plate are more difficult to safeguard because of the greater clearances needed under the hold-downs and upper knife to permit entry of the plate (especially when it is bowed or buckled). Guards on shears for plate should be of the type that raises only when the plate is inserted and then rests on the surface of the plate. When there is no workpiece in the machine, the guards rest within 6.4 mm ($\frac{1}{4}$ in.) of the surface of the table.

Shears should comply with the construction requirements of the Occupational Safety & Health Act and National Safety Standards such as ANSI B11.4. Additional safety information can be obtained from the loss prevention group of major insurance carders for Workman's Compensation and the National Safety Council. Safety regulations also cover the maximum noise level permitted from a shearing operation to prevent permanent impairment of hearing.

Mechanical Cutting for Weld Preparation

ASM Committee on Mechanical Cutting for Welding Preparation*

Iron Workers

Iron workers (heavy-duty shears) are used primarily for preparing structural shapes such as bars, angles, and T-bars. Like the shears used for plate and flat sheet, iron workers leave a square butt edge that may require further preparation for heavier sections before welding. The production shearing of bars and bar sections is usually done in machines with a throat opening designed for large, bulky workpieces. Guillotine and multipurpose (combination) machines are widely used for welding preparation. The multipurpose machines feature interchangeable punches and dies for shearing, punching, and coping. Squaring shears, normally used for sheet and plate, can also be used for cutting bar stock to length. Punch presses and press brakes can be provided with appropriate tooling for cutting operations.

Combination Machines

Combination machines are multipurpose machines used primarily in metal-fabricating shops where there is a constant need for shearing small quantities (often two or three pieces) of a variety of shapes and sizes from bars or bar sections. Some combination machines can also be used for punching, slotting, and notching.

Many combination machines incorporate several devices within the frame for performing different operations; therefore, a new setup is not required for each. A holder for an interchangeable punch and die is located in an area with a deep throat. This facilitates the punching of holes, slots, or notches in plates and bars, and in webs or legs of structural members.

A slide moving at 45° from vertical carries a blade for shearing angles. The support bed is on a swivel so that the ends of the angle section can be varied as desired from 45 to 90°. In two strokes of the machine, angles can be sheared to produce miter joints for subsequent welding (see the section "Cutting of Angles" in this article).

Combination machines can be used for cutting square and rectangular notches in the leg of an angle. These machines can be set up to cut a 90° V-shaped notch in angles that subsequently will be bent into frames. Other shapes, such as beams and channels, can be notched in a similar manner if the machine can accommodate the vertical height between the upper and lower legs of the workpiece. Provision is also made for shearing bars with guillotine-type blades or special blades (see the section "Conforming Blades" in this article).

Combination machines are available in capacities ranging from 110 to 890 kN (12 to 100 tonf). The 110 kN (12 tonf) machine can punch a 14 mm ($\frac{9}{16}$ in.) diam hole through a 6.4 mm ($\frac{1}{4}$ in.) thick section and can shear 75 × 75 × 6.4 mm (3 × 3 × $\frac{1}{4}$ in.) angles, 22 mm ($\frac{7}{8}$ in.) diam rounds, 19 mm ($\frac{3}{4}$ in.) squares, and 102 × 6.4 mm (4 × $\frac{1}{4}$ in.) flats. The 890 kN (100 tonf) machine can shear 152 × 152 × 16 mm (6 × 6 × $\frac{5}{8}$ in.) rounds, 50 mm (2 in.) squares, and 203 × 19 mm (8 × $\frac{3}{4}$ in.) flats.

Guillotine Machines

Guillotine iron-working machines are designed for cutting bars and bar sections to desired lengths from mill stock. They are extensively used throughout the fabricating industry. Two general types are available: open end (Fig. 5) and closed end. The machine illustrated in Fig. 5 is termed an open-end machine because it has a C-frame construction with one end open and unsupported. Open-end machines are either single end, for one operator, or double end, for two operators. On double-end machines, both ends can be right-hand or left-hand, or one end can be right-hand and the other end left-hand, depending on the type of cutting to be done. A closed-end guillotine machine, on the other hand, is basically the same as the one shown in Fig. 5 except that it has frame supports on both sides.

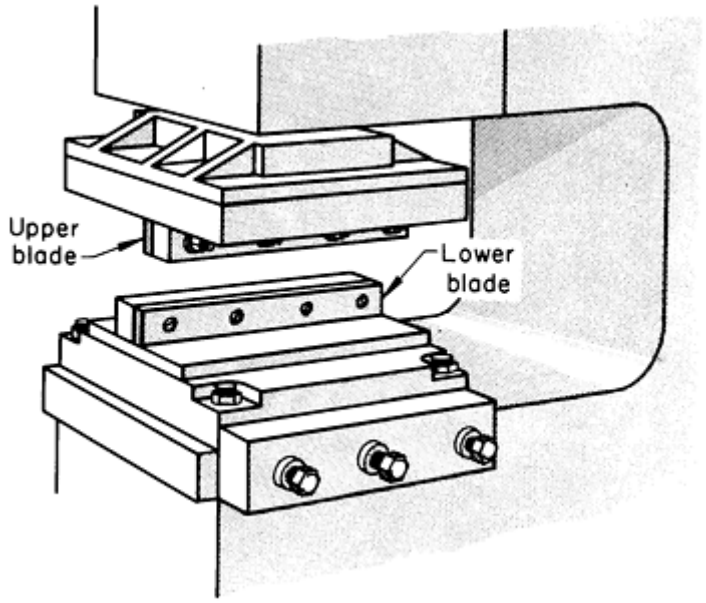

FIG. 5 OPEN-END GUILLOTINE IRON-WORKING MACHINE

An open-end machine has the advantage of giving the operator a clear view of the blades. However, because one end is open, a heavier frame and more floor space are required than for a closed-end machine of equal capacity.

Guillotine iron workers for bars and angles are available in capacities to 2700 kN (300 tonf). Either intermittent or continuous operation is possible. Guillotine iron workers can be equipped with simple straight blades (Fig. 5) or with two or more short blades having specific shapes.

Guillotine iron workers are actuated mechanically, hydraulically, or pneumatically. Hydraulic and pneumatic machines are lighter in weight for a specific shearing power, are more economical, and operate with less vibration than mechanical iron workers. Therefore, hydraulic or pneumatic machines up to 89 kN (10 tonf) capacity are completely portable, and units of 1800 to 2700 kN (200 to 300 tonf) capacity are semiportable (need not be solidly mounted in concrete).

Punching and Shearing Machines

Punching and shearing machines are deep-throat C-frame machines for the punching, shearing, notching, or coping of plates, bars, and structural sections. Shoes, into which punches, dies, and shear blades can readily be inserted, are mounted on the bed and ram.

The shoes either rest on the bed or are overhung; the overhanging type is designed so that structural shapes can be punched in both web and flange. The plain type of shoe is primarily used for plate work; however, plates can be worked with the overhanging shoes. Both types of die blocks are fitted with die sockets that hold dies of different inside diameters. The punch holder is adjustable to suit the location of the dies.

Fixturing

Fixturing is an important consideration in the shearing of bars. For safety and the proper functioning of open-end machines (Fig. 5) and many other iron-working machines, hold-down fixtures are essential. Guide pins are also helpful, especially when cutting with conforming blades.

Blade Design and Production Practice

Straight-edge blades can cut almost any bar or shape that is within the capacity of the machine. However, unacceptable distortion may result in some shapes of workpieces when they are sheared with blades that are not designed for cutting specific edges.

Conforming Blades. One method of minimizing distortion in cut bars employs two hardened blades mounted face-to-face, with identical holes through each blade. The holes should conform to the shape of the work metal and should be large enough to allow easy passage through the blades (Fig. 6a). One blade is movable vertically and one is stationary. Relatively little movement of the machine is required when blades of this type are used. In addition, because the blades completely encircle the work metal, hold-downs are not needed. However, these blades are usually limited for use on specially built or combination machines.

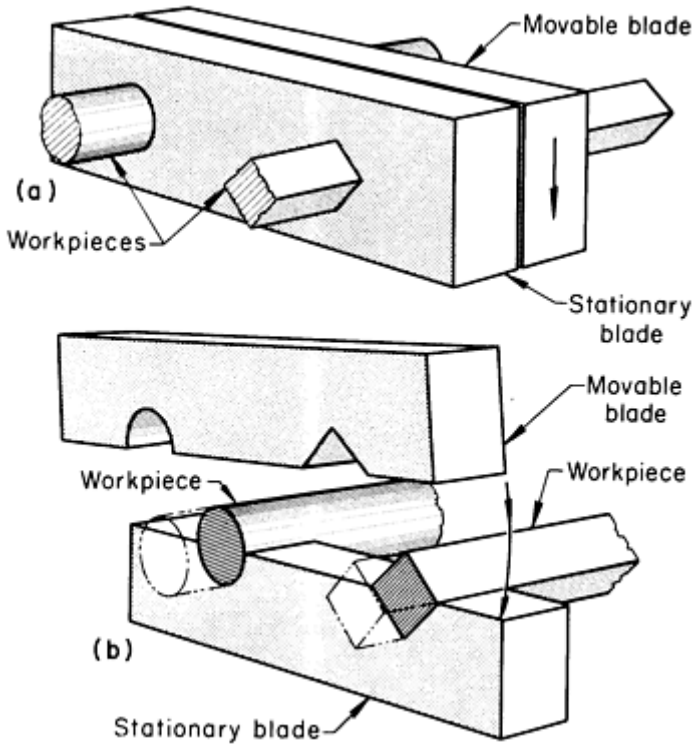

FIG. 6 TWO TYPES OF BLADES FOR THE CUTTING OF BARS

The cutting of round and square bars is more frequently done with the open-type blades illustrated in Fig. 6(b). Each blade is contoured to accommodate one-half the cross section of the work metal. The upper blade moves in a vertical direction, while the lower blade remains stationary. When using this technique, some type of hold-down is needed. Because of the stiffness of the work metal, the hold-down for bars should permit slight movement of the work metal in the axial direction to avoid double shearing. The hold-down can be a simple set screw (to permit adjustment) in a bracket or can be a more elaborate unit, such as a handwheel assembly utilizing an Acme thread.

For cutting square bars with any type of blade, the work metal should be placed so that the movement of the blade is across the diagonal of the square. With this technique the cutting force is applied to four sides instead of two, resulting in a smoother sheared surface. Cutting across the diagonal provides support on two sides of the square shape, which minimizes distortion and permits more than one size of bar stock to be cut in a given hole.

Best practice for cutting round bars is to use blades with holes for each size of stock to be cut. Blade holes appreciably larger than the stock size cause excessive distortion of the workpiece.

Cutting of angles is done either in a combination machine or by double cutting. In a combination machine--the more common method--two blades such as those shown in Fig. 7(a) are used. One blade, usually the one that is stationary, is L-shaped and is positioned as shown. The movable blade is square or rectangular and is mounted with its two cutting edges parallel to those of the stationary blade. Figure 7(a) also shows that the space between the blades in the loading position is the same shape as the workpiece.

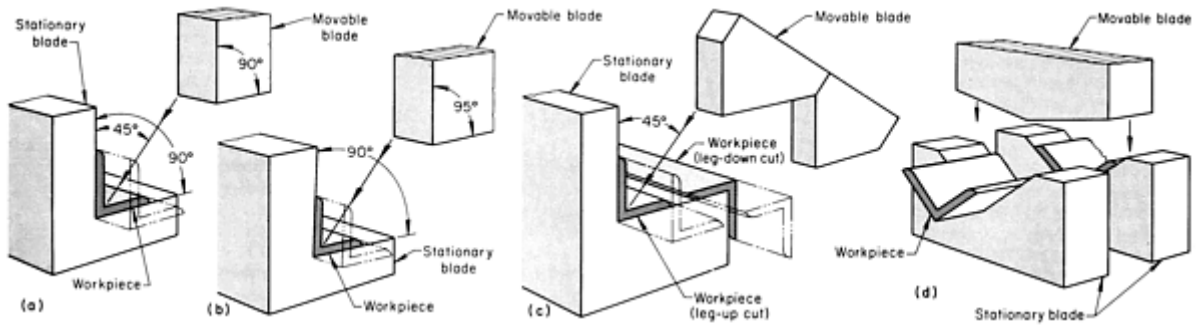

FIG. 7 FOUR TYPES OF BLADES FOR THE CUTTING OF ANGLE SECTIONS. (A) TO (C) CUTTING IN A COMBINATION MACHINE. (D) DOUBLE-CUTTING METHOD

The movable blade travels at 45° toward the stationary blade, and both blades contact the work metal uniformly. Shearing by this technique is essentially a blanking cut, and distortion of the workpiece is minimal. One disadvantage of the method is that all cutting occurs at once, resulting in a high shear load. This condition is not important when small angle sections are cut; however, for work metal larger than 102 × 102 × 13 mm (4 × 4 × $\frac{1}{2}$ in.), the movable blade should be provided with rake to prevent excessive loading.

To provide a rake angle between the movable and stationary blades, the included angle between the cutting edges of the upper or movable blade is increased to 95°, as shown in Fig. 7(b). Shearing begins at the extremity of each leg and progresses toward the root of the angle. The increase in the included angle of the movable blade results in some distortion of the drop-cut piece; the amount of distortion is about equal to the difference in angle between the movable and stationary blades (5° is normal). The part remaining on the table or stationary blade is not distorted.

Most combination cutting machines use a more versatile blade arrangement than those shown in Fig. 7(a) and 7(b). The setup shown in Fig. 7(c) is used to shear angle sections in both the leg-up and the leg-down positions. A swiveling table locates and holds the workpiece during shearing. With the swiveling table and two positions for the workpiece, the flanges can be easily mitered to any specific angle. For example, when cutting angle sections for a frame having the leg on the inside, the table would be set and locked at 45°. One end is mitered by placing the section in a leg-down position on the table and shearing off enough to make a clean cut. The other end is mitered by placing the section leg-up on the table and cutting to the proper length. The opposite positions are applicable when angle sections for a frame having the leg on the outside are being cut.

Cutting at a 45° angle reduces the capacity of the machine because a greater length of metal is cut at one time when a 90° cut is made. For example, a machine with a capacity of 203 × 203 × 32 mm (8 × 8 × $1\frac{1}{4}$ in.) when making a 90° cut has a capacity of only 203 × 203 × 25 mm (8 × 8 × 1 in.) when cutting at 45°.

Double cutting of angle sections, also called slugging, is used less frequently than cutting in a combination-type machine. This technique uses two stationary blades, spaced 13 mm ($\frac{1}{2}$ in.) apart, and one movable V-shaped blade arranged as shown in Fig. 7(d). The movable blade has a shallow V-shape that does not conform to the shape of the workpiece. Shearing starts at the extremity of each leg and progresses to the root of the angle, producing a 13 mm ($\frac{1}{2}$ in.) wide slug that is pushed out the bottom between the stationary blades.

In the double-cutting method, distortion occurs only in the slug, because the work metal is supported by the two stationary blades. There are two disadvantages of using the double-cutting method. First, increased power is required for making two cuts at the same time, and second, some metal is lost in the slug. The two stationary blades must be firmly supported to prevent their spreading during the cutting operation.

A similar tool can be used for cutting a channel section. The stationary blades should closely fit the contour of the channel section. Double cutting is adaptable to a guillotine machine, a combination machine, or a press.

Multiple Setups. Fabricating shops often must cut small quantities to a variety of shapes. To handle such work, many shops use a machine with a multiple setup. Without changing blades, the user can perform operations such as double cutting of angle sections, straight-blade cutting, cutting of round and square bars, and single cutting of L-sections. In this type of setup, all of the movable blades are attached to a single ram.

Mechanical Cutting for Weld Preparation

Iron Workers

Iron workers (heavy-duty shears) are used primarily for preparing structural shapes such as bars, angles, and T-bars. Like the shears used for plate and flat sheet, iron workers leave a square butt edge that may require further preparation for heavier sections before welding. The production shearing of bars and bar sections is usually done in machines with a throat opening designed for large, bulky workpieces. Guillotine and multipurpose (combination) machines are widely used for welding preparation. The multipurpose machines feature interchangeable punches and dies for shearing, punching, and coping. Squaring shears, normally used for sheet and plate, can also be used for cutting bar stock to length. Punch presses and press brakes can be provided with appropriate tooling for cutting operations.

Combination Machines

Combination machines are multipurpose machines used primarily in metal-fabricating shops where there is a constant need for shearing small quantities (often two or three pieces) of a variety of shapes and sizes from bars or bar sections. Some combination machines can also be used for punching, slotting, and notching.

Many combination machines incorporate several devices within the frame for performing different operations; therefore, a new setup is not required for each. A holder for an interchangeable punch and die is located in an area with a deep throat. This facilitates the punching of holes, slots, or notches in plates and bars, and in webs or legs of structural members.

A slide moving at 45° from vertical carries a blade for shearing angles. The support bed is on a swivel so that the ends of the angle section can be varied as desired from 45 to 90°. In two strokes of the machine, angles can be sheared to produce miter joints for subsequent welding (see the section "Cutting of Angles" in this article).

Combination machines can be used for cutting square and rectangular notches in the leg of an angle. These machines can be set up to cut a 90° V-shaped notch in angles that subsequently will be bent into frames. Other shapes, such as beams and channels, can be notched in a similar manner if the machine can accommodate the vertical height between the upper and lower legs of the workpiece. Provision is also made for shearing bars with guillotine-type blades or special blades (see the section "Conforming Blades" in this article).

Combination machines are available in capacities ranging from 110 to 890 kN (12 to 100 tonf). The 110 kN (12 tonf) machine can punch a 14 mm ($\frac{9}{16}$ in.) diam hole through a 6.4 mm ($\frac{1}{4}$ in.) thick section and can shear 75 × 75 × 6.4 mm (3 × 3 × $\frac{1}{4}$ in.) angles, 22 mm ($\frac{7}{8}$ in.) diam rounds, 19 mm ($\frac{3}{4}$ in.) squares, and 102 × 6.4 mm (4 × $\frac{1}{4}$ in.) flats. The 890 kN (100 tonf) machine can shear 152 × 152 × 16 mm (6 × 6 × $\frac{5}{8}$ in.) rounds, 50 mm (2 in.) squares, and 203 × 19 mm (8 × $\frac{3}{4}$ in.) flats.

Guillotine Machines

Guillotine iron-working machines are designed for cutting bars and bar sections to desired lengths from mill stock. They are extensively used throughout the fabricating industry. Two general types are available: open end (Fig. 5) and closed end. The machine illustrated in Fig. 5 is termed an open-end machine because it has a C-frame construction with one end open and unsupported. Open-end machines are either single end, for one operator, or double end, for two operators. On double-end machines, both ends can be right-hand or left-hand, or one end can be right-hand and the other end left-hand, depending on the type of cutting to be done. A closed-end guillotine machine, on the other hand, is basically the same as the one shown in Fig. 5 except that it has frame supports on both sides.

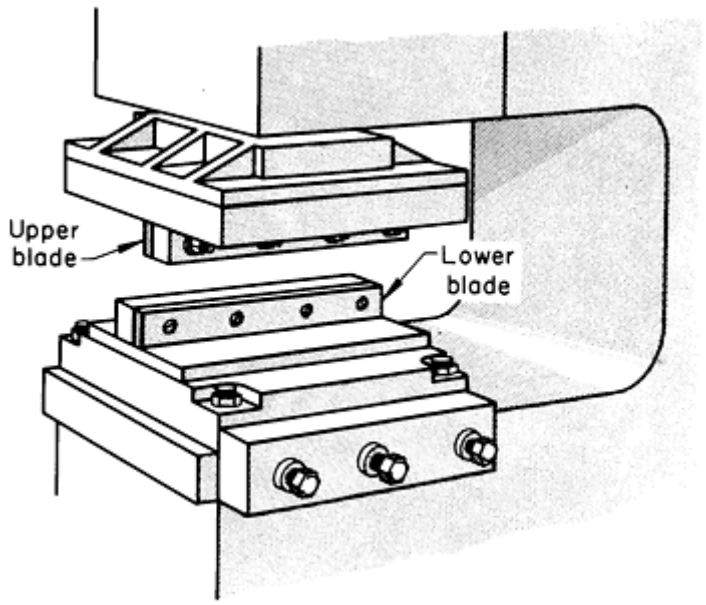

FIG. 5 OPEN-END GUILLOTINE IRON-WORKING MACHINE

An open-end machine has the advantage of giving the operator a clear view of the blades. However, because one end is open, a heavier frame and more floor space are required than for a closed-end machine of equal capacity.

Guillotine iron workers for bars and angles are available in capacities to 2700 kN (300 tonf). Either intermittent or continuous operation is possible. Guillotine iron workers can be equipped with simple straight blades (Fig. 5) or with two or more short blades having specific shapes.

Guillotine iron workers are actuated mechanically, hydraulically, or pneumatically. Hydraulic and pneumatic machines are lighter in weight for a specific shearing power, are more economical, and operate with less vibration than mechanical iron workers. Therefore, hydraulic or pneumatic machines up to 89 kN (10 tonf) capacity are completely portable, and units of 1800 to 2700 kN (200 to 300 tonf) capacity are semiportable (need not be solidly mounted in concrete).

Punching and Shearing Machines

Punching and shearing machines are deep-throat C-frame machines for the punching, shearing, notching, or coping of plates, bars, and structural sections. Shoes, into which punches, dies, and shear blades can readily be inserted, are mounted on the bed and ram.

The shoes either rest on the bed or are overhung; the overhanging type is designed so that structural shapes can be punched in both web and flange. The plain type of shoe is primarily used for plate work; however, plates can be worked with the overhanging shoes. Both types of die blocks are fitted with die sockets that hold dies of different inside diameters. The punch holder is adjustable to suit the location of the dies.

Fixturing

Fixturing is an important consideration in the shearing of bars. For safety and the proper functioning of open-end machines (Fig. 5) and many other iron-working machines, hold-down fixtures are essential. Guide pins are also helpful, especially when cutting with conforming blades.

Blade Design and Production Practice

Straight-edge blades can cut almost any bar or shape that is within the capacity of the machine. However, unacceptable distortion may result in some shapes of workpieces when they are sheared with blades that are not designed for cutting specific edges.

Conforming Blades. One method of minimizing distortion in cut bars employs two hardened blades mounted face-to-face, with identical holes through each blade. The holes should conform to the shape of the work metal and should be large enough to allow easy passage through the blades (Fig. 6a). One blade is movable vertically and one is stationary. Relatively little movement of the machine is required when blades of this type are used. In addition, because the blades completely encircle the work metal, hold-downs are not needed. However, these blades are usually limited for use on specially built or combination machines.

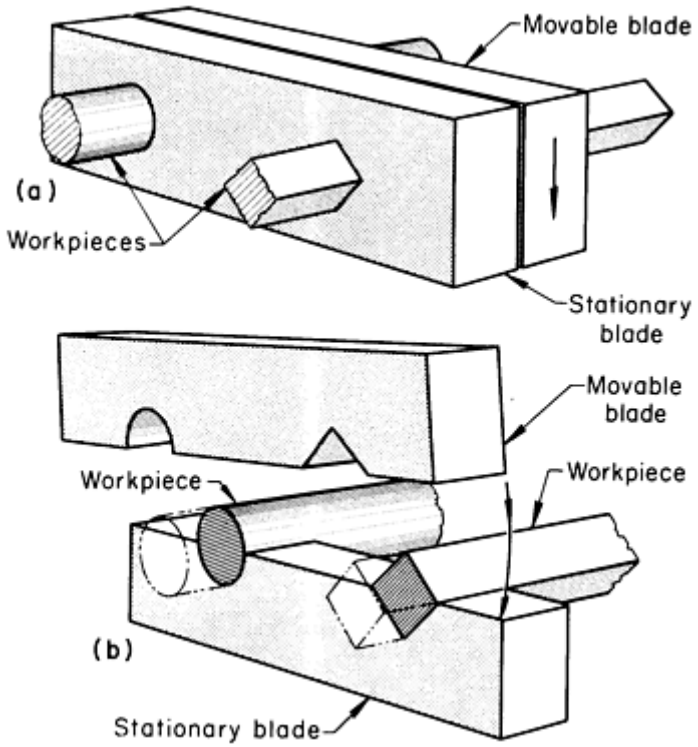

FIG. 6 TWO TYPES OF BLADES FOR THE CUTTING OF BARS

The cutting of round and square bars is more frequently done with the open-type blades illustrated in Fig. 6(b). Each blade is contoured to accommodate one-half the cross section of the work metal. The upper blade moves in a vertical direction, while the lower blade remains stationary. When using this technique, some type of hold-down is needed. Because of the stiffness of the work metal, the hold-down for bars should permit slight movement of the work metal in the axial direction to avoid double shearing. The hold-down can be a simple set screw (to permit adjustment) in a bracket or can be a more elaborate unit, such as a handwheel assembly utilizing an Acme thread.

For cutting square bars with any type of blade, the work metal should be placed so that the movement of the blade is across the diagonal of the square. With this technique the cutting force is applied to four sides instead of two, resulting in a smoother sheared surface. Cutting across the diagonal provides support on two sides of the square shape, which minimizes distortion and permits more than one size of bar stock to be cut in a given hole.

Best practice for cutting round bars is to use blades with holes for each size of stock to be cut. Blade holes appreciably larger than the stock size cause excessive distortion of the workpiece.

Cutting of angles is done either in a combination machine or by double cutting. In a combination machine--the more common method--two blades such as those shown in Fig. 7(a) are used. One blade, usually the one that is stationary, is L-shaped and is positioned as shown. The movable blade is square or rectangular and is mounted with its two cutting edges parallel to those of the stationary blade. Figure 7(a) also shows that the space between the blades in the loading position is the same shape as the workpiece.

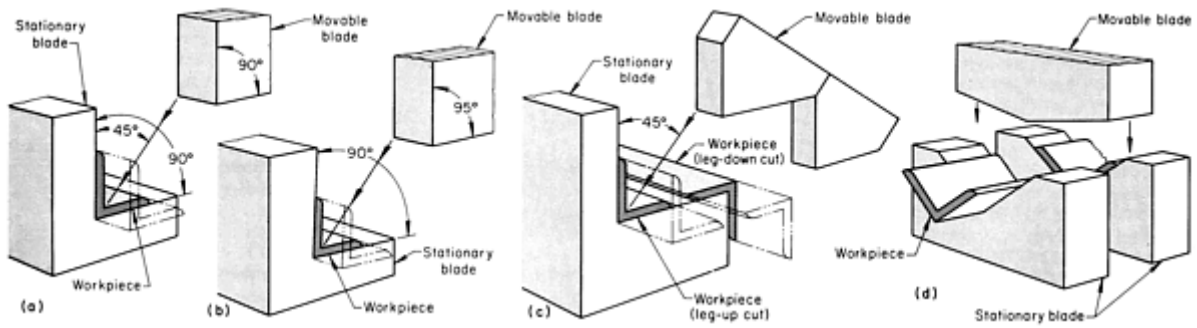

FIG. 7 FOUR TYPES OF BLADES FOR THE CUTTING OF ANGLE SECTIONS. (A) TO (C) CUTTING IN A COMBINATION MACHINE. (D) DOUBLE-CUTTING METHOD

The movable blade travels at 45° toward the stationary blade, and both blades contact the work metal uniformly. Shearing by this technique is essentially a blanking cut, and distortion of the workpiece is minimal. One disadvantage of the method is that all cutting occurs at once, resulting in a high shear load. This condition is not important when small angle sections are cut; however, for work metal larger than 102 × 102 × 13 mm (4 × 4 × $\frac{1}{2}$ in.), the movable blade should be provided with rake to prevent excessive loading.

To provide a rake angle between the movable and stationary blades, the included angle between the cutting edges of the upper or movable blade is increased to 95°, as shown in Fig. 7(b). Shearing begins at the extremity of each leg and progresses toward the root of the angle. The increase in the included angle of the movable blade results in some distortion of the drop-cut piece; the amount of distortion is about equal to the difference in angle between the movable and stationary blades (5° is normal). The part remaining on the table or stationary blade is not distorted.

Most combination cutting machines use a more versatile blade arrangement than those shown in Fig. 7(a) and 7(b). The setup shown in Fig. 7(c) is used to shear angle sections in both the leg-up and the leg-down positions. A swiveling table locates and holds the workpiece during shearing. With the swiveling table and two positions for the workpiece, the flanges can be easily mitered to any specific angle. For example, when cutting angle sections for a frame having the leg on the inside, the table would be set and locked at 45°. One end is mitered by placing the section in a leg-down position on the table and shearing off enough to make a clean cut. The other end is mitered by placing the section leg-up on the table and cutting to the proper length. The opposite positions are applicable when angle sections for a frame having the leg on the outside are being cut.

Cutting at a 45° angle reduces the capacity of the machine because a greater length of metal is cut at one time when a 90° cut is made. For example, a machine with a capacity of 203 × 203 × 32 mm (8 × 8 × $1\frac{1}{4}$ in.) when making a 90° cut has a capacity of only 203 × 203 × 25 mm (8 × 8 × 1 in.) when cutting at 45°.

Double cutting of angle sections, also called slugging, is used less frequently than cutting in a combination-type machine. This technique uses two stationary blades, spaced 13 mm ($\frac{1}{2}$ in.) apart, and one movable V-shaped blade arranged as shown in Fig. 7(d). The movable blade has a shallow V-shape that does not conform to the shape of the

workpiece. Shearing starts at the extremity of each leg and progresses to the root of the angle, producing a 13 mm ($\frac{1}{2}$ in.) wide slug that is pushed out the bottom between the stationary blades.

In the double-cutting method, distortion occurs only in the slug, because the work metal is supported by the two stationary blades. There are two disadvantages of using the double-cutting method. First, increased power is required for making two cuts at the same time, and second, some metal is lost in the slug. The two stationary blades must be firmly supported to prevent their spreading during the cutting operation.

A similar tool can be used for cutting a channel section. The stationary blades should closely fit the contour of the channel section. Double cutting is adaptable to a guillotine machine, a combination machine, or a press.

Multiple Setups. Fabricating shops often must cut small quantities to a variety of shapes. To handle such work, many shops use a machine with a multiple setup. Without changing blades, the user can perform operations such as double cutting of angle sections, straight-blade cutting, cutting of round and square bars, and single cutting of L-sections. In this type of setup, all of the movable blades are attached to a single ram.

Mechanical Cutting for Weld Preparation

ASM Committee on Mechanical Cutting for Welding Preparation*

Nibblers

Nibblers are power tools that "nibble" small pieces away from the material being worked. They range in size from hand-held machines to large floor-mounted equipment. Because the hand-held machines are portable, they are suitable for preparation of large parts on site, where thermal cutting may be impractical.

Nibblers can cut flat sheet of both ferrous and nonferrous metals, as well as of fiberglass and plastic. Corrugated and trapezoidal metal sheets can also be cut. Nibblers are frequently used to make edge preparations for welding of stainless steels and nonferrous metals. Unlike shears, which can curl or distort the separated pieces, nibblers remove material, creating a kerf or cutting slot; therefore, distortion of the sheet is eliminated.

Nibblers use a reciprocating punch and stationary die to accomplish the cutting process. During operation, the punch approaches and makes contact with the material being worked. The stroke of the punch compresses the material; the increased compression causes the material to deflect. As the shear point of the material is exceeded, the material is penetrated by the punch. The material then breaks (Fig. 8), and the break continues to widen until a cone-shaped chip is ejected. The punch is then withdrawn.

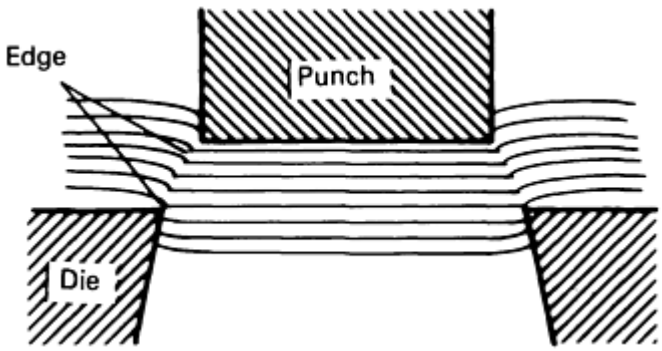

FIG. 8 SCHEMATIC OF NIBBLER CUTTING ACTION

The resulting edges are usually free of burrs. If burrs do occur, the gap between the punch and die is too wide (Fig. 9). On some equipment this gap can be varied.

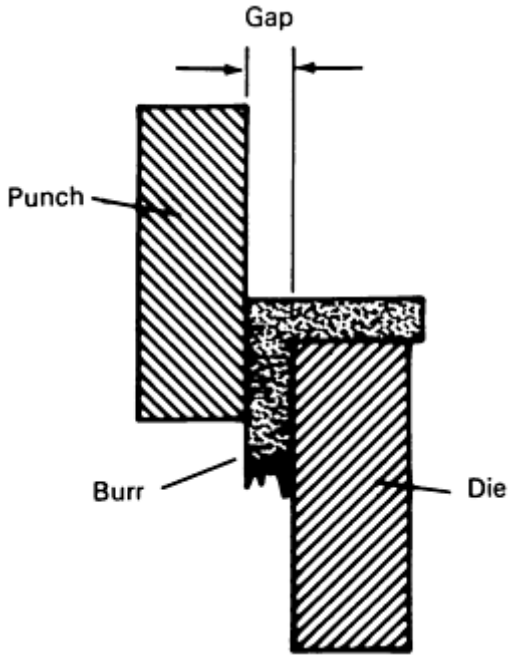

FIG. 9 SCHEMATIC OF NIBBLER SETUP WITH EXCESSIVE GAP BETWEEN THE PUNCH AND DIE, RESULTING IN THE FORMATION OF BURRS ON THE WORKPIECE

Because of their unique cutting action, nibblers do not need to be forced into the material. This so-called "natural feed" requires only light operator pressure. Also, the weight of the nibbler does not need to be supported solely by the operator: Once the nibbler has started cutting, the weight of the tool is supported by the sheet being worked. Nibblers are considered to be very safe to operate.

Some equipment is available with guide fences (similar to those used with circular saws), circle-cutting attachments, and template guides. Punches and dies on some nibblers can be resharpened; however, in many cases these parts are disposable. For optimum punch and die life, cutting oil should be used to lubricate the cutting process.

Mechanical Cutting for Weld Preparation

ASM Committee on Mechanical Cutting for Welding Preparation*

Band Saws

Band sawing is one method of cutting a workpiece to prepare it for further processing such as welding. The band saw machine, in its simplest form, consists of two wheels--one driven and one idle. The cutting tool is a welded continuous loop of flexible saw blade carried in one direction around the wheels and through the workpiece. This configuration permits full utilization of a cutting tool with hundreds of cutting edges, or teeth (Fig. 10). The band saw blade is thinner than other cutoff tools (typically 1.6 mm, or $\frac{1}{16}$ in. thick), which allows it to use less power and waste less material.

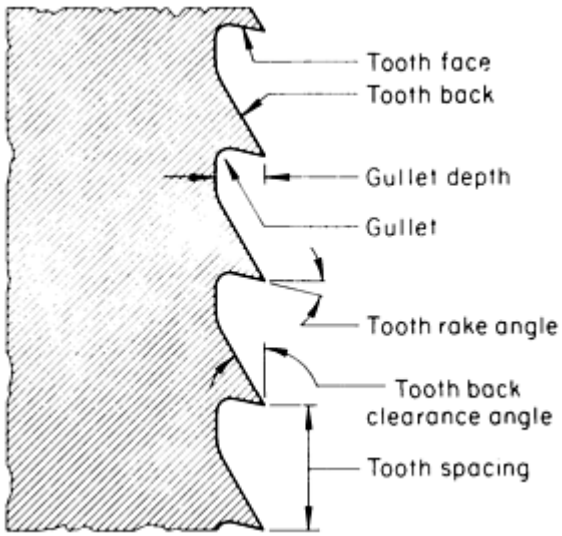

FIG. 10 SCHEMATIC SHOWING THE KEY ELEMENTS OF A BAND SAW BLADE CUTTING EDGE

Types of Machines

Band saw machines are either horizontal or vertical types; some are available as combination horizontal-vertical machines.

Contour band saws are vertical types that allow an operator to cut various contoured shapes by guiding the blade along a layout line. These machines can use very narrow bands for cutting small radii as well as wider bands for larger radii and straight cuts.

Cutoff band saws can be either horizontal or vertical. They cannot cut contours, but can make straight cuts very efficiently. Some machines can cut angles and compound miters in solids as well as structural shapes.

Band Saw Blade Selection

The two most widely used types of band saw blades available are carbon and bimetal.

Carbon steel blades are made from very high carbon tool steel and have either flexible backs or hard backs. The hard-back type has a heat-treated back for better strength and straighter cuts. Both types have hardened tooth tips for good wear resistance.

Carbon steel blades are most widely used for cutting of nonmetallic materials. However, they also do a satisfactory job when cutting low-carbon and low-alloy steels and perform well when cutting nonferrous alloys (for example, aluminum).

Bimetal blades are made with high-speed steel that is electron-beam welded to a lower-alloy backing steel. The result is a blade with the cutting properties of high-speed steel at the tooth tips and the flexibility and strength of a heat-treated alloy on the backing or carrier band. Bimetal blades should be used when cutting difficult-to-machine materials, and for high-production sawing. Bimetal blades will last longer than carbon blades, and they typically cut at ten times faster rates than those achieved with carbon blades.

Bimetal blades can be made with different grades of high-speed steels electron-beam welded to the tooth tips. The most popular grades used are M42 and Matrix II. Matrix II edges are best for cutting the lower-alloy materials and for cutting structural shapes or materials with varying cross sections. The higher hot hardness property of M42 is necessary when cutting difficult-to-machine alloys (for example, stainless steels and nickel alloys).

Table 2 gives the composition and physical properties of some welded-edge high-speed steel band saws.

TABLE 2 COMPOSITION AND PHYSICAL PROPERTIES OF SELECTED WELDED-EDGE HIGH-SPEED STEEL BAND SAW BLADES

PRODUCT	COMPOSITION, WT%								HEAT RESISTANCE		HARDNESS, HRC	
	C	Si	Mn	Cr	V	W	M	Co	°C	°F	TEETH	BODY
M2 HIGH-SPEED WELDED-EDGE BAND SAW	0.79-0.86	0.25	0.35	4.25	1.95	6.50	5.00	. . .	540	1000	64-66	40-47
MATRIX BAND SAW	0.70-0.78	0.30	0.25	4.25	1.00	1.00	5.00	8.00	590	1100	65-67	40-47
COBALT M42 BAND SAW	1.05-1.10	0.25	0.25	3.75	1.15	1.50	9.50	8.00	700	1300	67-69	40-47

Saw Width. The width of the saw blade along with its thickness determines the beam strength and thus its ability to cut straight and at high rates. Operators should always select the widest blade available in order to obtain the straightest cuts. For contour sawing, the widest blade that will cut the smallest radius should be selected.

The pitch of a saw blade is the number of teeth per 25 mm (1 in.). Selection of the correct pitch depends on the thickness of the material being cut. Thin materials require fine pitches, and thicker materials require coarser pitches. Blades are available in pitches as fine as 32 pitch and as coarse as 0.75 pitch. At least two teeth--and preferably three or more--should always be in contact with the piece being cut. It is especially important to observe this practice when cutting thin materials. A pitch that is too coarse will cause the teeth to rip out.

The selection of pitch often determines the success or failure of a particular cutting job. A pitch that is too coarse can cause the teeth to strip. A pitch that is too fine makes excessive feed pressure necessary, can cause binding in the cut, and will result in slow cutting or stripped teeth.

Variable-pitch blades are shapes designed to dampen resonance vibrations, especially when cutting structural shapes and workpieces with varying cross sections. The tooth spacing varies from tooth to tooth along an established length. This change in spacing cuts down on noise and vibration, resulting in quieter operation and smoother cuts.

Tooth Form. The choice of tooth form varies with each band saw blade manufacturer. Two basic forms are now most widely used: regular tooth and hook tooth (Fig. 11).

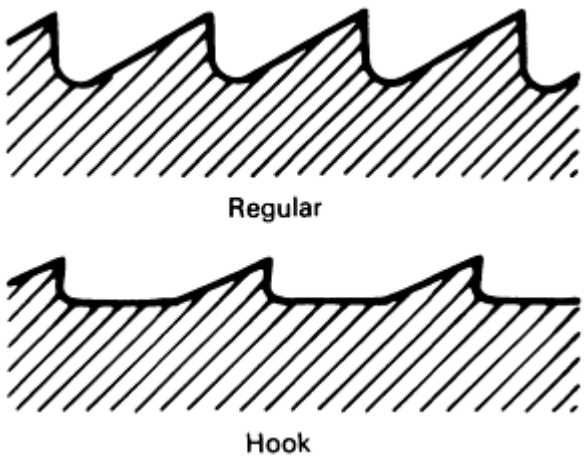

FIG. 11 BASIC TOOTH FORMS USED IN BAND SAW BLADES

The regular tooth form has deep gullets with smooth radii. The face angles vary from 0° rake to 15° positive rake. The neutral-rake blades work best for cutting structural shapes and thin materials, and for general-purpose low-volume cutting. The positive-rake blades use less feed pressure and cut more freely. This results in faster cutting rates and longer blade life, especially on heavy-duty band saws and at high production rates.

The hook tooth form is also a positive-rake blade, but the gullets are more shallow than those on the regular tooth form. The back angle is smaller than that on most regular tooth form blades. These factors combine to make a strong tooth that is capable of fast cutting speeds. The hook tooth form is especially suited for cutting of wide cross sections and for cutting of nonferrous materials such as aluminum.

Selection of Speeds and Cutting Rates

Table 3 lists the recommended speeds and cutting rates for many commonly sawed materials. The numbers are based on sawing of solid materials in the fully annealed condition. The data given should only be considered as a starting point; actual speeds and cutting rates will vary due to material variations and the type and condition of the saw that is used.

TABLE 3 SPEED AND CUTTING RATES FOR CUTOFF BAND SAWING WITH BIMETAL BLADES OF SELECTED FERROUS AND NONFERROUS METALS

WORK METAL	BAND SPEED[A]		CUTTING RATE[A]	
	m/min	sfm	$mm^2 \times 10^3$/min	$in.^2$/min
FERROUS METALS				
CARBON AND STEEL LOW-ALLOY STEELS				
1008-1013	100-84	325-275	9.0-6.4	14-10
1015-1035	106-90	350-300	9.7-7.1	15-11
1036-1064	68-58	225-190	5.8-4.5	9-7
1065-1095	52-44	170-145	5.2-3.9	8-6

(A) BASED ON THE USE OF A 25 MM (1 IN.) WIDE HIGH-SPEED STEEL BAND, REGULAR TOOTH FORM (EXCEPT HOOK TOOTH FORM FOR METAL THICKER THAN ABOUT 250 MM, OR 10 IN.), RAKER SET, TO CUT SCALE-FREE, SOLID BAR STOCK UP TO 460 MM (18 IN.) THICK; BASED ON THE USE OF A CUTTING FLUID, EXCEPT FOR D2, D3, AND D7 TOOL STEELS, WHICH ARE CUT DRY

Table 3 only applies when using bimetal blades. Carbon steel blades cannot be run at the band speeds shown because the heat generated at these speeds will cause them to soften and fail immediately.

When cutting pipes, tubes, or structural shapes, it is necessary to compute slower cutting rates than those given in Table 3. The cutting rates should be modified as follows:

PART SIZE		PERCENTAGE OF SPEED SHOWN IN TABLE 3
MM	IN.	
<4.8	$< \frac{3}{16}$	40
4.8-9.5	$\frac{3}{16} - \frac{3}{8}$	50
9.5-16	$\frac{3}{8} - \frac{5}{8}$	60
>16	$> \frac{5}{8}$	70

Proper break-in is important to ensure optimum blade performance. When using a new blade, cutting at the full rate will cause fracturing of the very sharp tooth edges. Breaking in a new blade removes the ultrasharp edges and allows the blade to retain its cutting ability longer. A new blade can be broken in by running at the recommended band speed, but reducing the feed pressure for the initial cuts. When cutting work-hardening materials (for example, nickel alloys), it is important to use enough feed pressure to generate a chip and to prevent work hardening of the cut surface.

Knowledge of chip formation is helpful in finding the optimum speeds and cutting rates to use when band sawing. When a blade cuts, each tooth tip penetrates the workpiece and shears off a chip of material. Parameters such as band speed, feed, lubrication, and blade tip design all affect chip formation.

Visual examination of the chips can be used to determine proper speeds and cutting rates (Table 4). In general, the optimum conditions are present when the chips are curled and silver in color, indicating they were properly formed without excessive heat generation.

TABLE 4 VISUAL EXAMINATION OF CHIPS TO DETERMINE ADJUSTMENTS IN BAND SAW PARAMETERS THAT ARE REQUIRED TO OPTIMIZE MACHINABILITY

Safe Practices*

American Welding Society

Introduction

THIS ARTICLE covers the basic elements of safety general to all welding, cutting, and related processes. It includes safety procedures common to a variety of applications. However, it does not cover all safety aspects of every welding process; especially not those involving sophisticated technology. For this reason, those chapters in this Volume devoted to specific processes should also be referenced for additional important safety information.

Note

* THIS ARTICLE IS REPRINTED BY PERMISSION OF THE AMERICAN WELDING SOCIETY FROM THE *WELDING HANDBOOK*, 8TH EDITION, VOLUME 1, AMERICAN WELDING SOCIETY, 1987. IT WAS PREPARED BY THE AWS WELDING HANDBOOK SAFE PRACTICES CHAPTER COMMITTEE CONSISTING OF G.R. SPIES, *CHAIRMAN*, THE B.O.C. GROUP, LNC.; G.C. BARNES, ALLOY RODS COMPANY; K.L. BROWN, THE LINCOLN ELECTRIC COMPANY; W. BEISNER, HOBART BROTHERS COMPANY; O.J. FISHER, BABCOCK AND WILCOX COMPANY; W.S. HOWES, NEMA; C. PHILP, HANDY AND HARMAN COMPANY; UNDER THE DIRECTION OF AWS WELDING HANDBOOK COMMITTEE MEMBER A.F. MANZ, A.F. MANZ ASSOCIATES, AND AWS WELDING HANDBOOK COMMITTEE CHAIRMEN J.H. HANNAHS, MIDMARK CORPORATION, AND M.J. TOMSIC, PLASTRONICS INCORPORATED (AFFILIATIONS CIRCA 1987).

Safe Practices*

American Welding Society

General Welding Safety

Safety is an important consideration in all welding, cutting, and related work. No activity is satisfactorily completed if someone is injured. The hazards that may be encountered and the practices that will minimize personal injury and property damage are discussed here.

Management Support

The most important component of an effective safety and health program is management support and direction. Management must clearly state objectives and demonstrate its commitment to safety and health by consistent execution of safe practices.

Management must designate approved areas where welding and cutting operations may be carried on safely. When these operations must be done in other than designated areas, management must ensure that proper procedures to protect personnel and property are established and followed.

Management must be certain that only approved welding, cutting, and allied equipment is used. Such equipment includes torches, regulators, welding machines, electrode holders, and personal protective devices. Adequate supervision must be provided to ensure that all equipment is properly used and maintained.

Training

Thorough and effective training is a key aspect of a safety program. Adequate training is mandated under provisions of the U.S. Occupational Safety and Health Administration (OSHA), especially those of the Hazard Communication Standard (29 CFR 1910.1200). Welders and other equipment operators perform most safely when they are properly trained in the subject. (The term *welder* as used in this article is intended to include all welding and cutting personnel, brazers, and solderers.) Proper training includes instruction in the safe use of equipment and processes, and the safety rules that must be followed. Personnel need to know and understand the rules and the consequences of disobeying them. For example, welders must be trained to position themselves while welding or cutting so that their heads are not in the gases or fume plume. (Fume plume is the smokelike cloud containing minute solid particles arising directly from the area of melting metal. In distinction to a gas, fumes are metallic vapors that have condensed to solid and are often associated with a chemical reaction, such as oxidation.)

Before work begins, users must always read and understand the manufacturer's instructions on safe practices for the materials and equipment, and also the material safety data sheets.

Certain AWS specifications call for precautionary labels on consumables and equipment. These labels concerning the safe use of the products should be read and followed. A typical label is illustrated in Fig. 1.

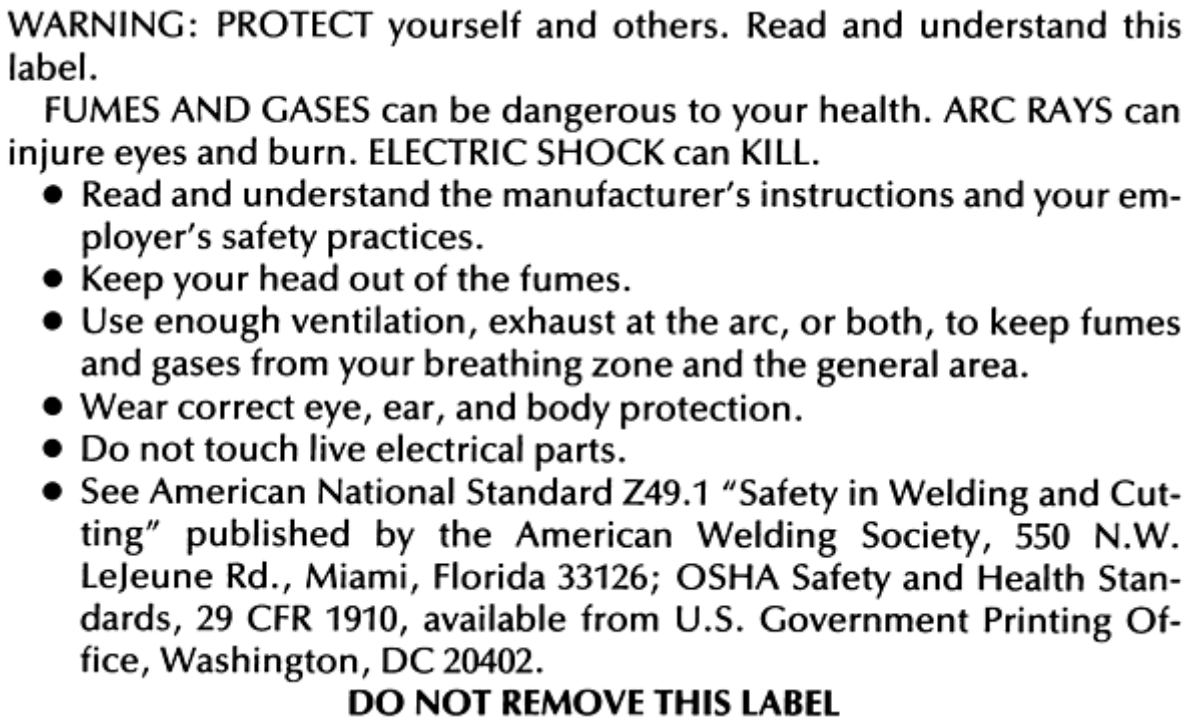

FIG. 1 MINIMUM WARNING FOR ARC WELDING PROCESSES AND EQUIPMENT

Manufacturers of welding consumables must provide on request a Material Safety Data Sheet (MSDS) that identifies those materials present in their products that have hazardous physical or health properties. The MSDS provides the OSHA permissible exposure limit, called the Threshold Limit Value (TLV), and any other exposure limit used or recommended by the manufacturer.

Employers that use consumables must make the applicable MSDS readily available to their employees, as well as train them to read and understand the contents. The MSDS contain important information about the ingredients contained in welding electrodes, rods, and fluxes, the composition of fumes that may be generated in their use, and means to be followed to protect the welder and others from hazards which might be involved.

Under OSHA Hazard Communication Standard 29 CFR 1910.1200, employers are responsible for the training of employees with respect to hazardous materials used in their workplace. Many welding consumables are included in the definition of hazardous materials according to this standard. Welding employers must comply with the communication and training requirements of this standard.

The proper use and maintenance of the equipment must also be taught. For example, defective or worn electrical insulation cannot be tolerated in arc welding or cutting, nor can defective or worn hoses be used in oxyfuel gas welding and cutting, brazing, or soldering. Proper training in equipment operation is fundamental to safe operation.

Persons must be trained to recognize safety hazards. If they are to work in an unfamiliar situation or environment, they must be thoroughly briefed on the potential hazards involved. For example, consider a person who must work in a confined space. If the ventilation is poor and an air-supplied helmet is required, the need and instructions for its proper use must be thoroughly explained to the employee. The consequences of improperly using the equipment must be covered. When employees believe that the safety precautions for a given task are not adequate, or not understood, they should question their supervisors before proceeding.

General Housekeeping

Good housekeeping is essential to avoid injuries. A welder's vision is often restricted by necessary eye protection. Persons passing a welding station must shield their eyes from the flame or arc radiation. The limited vision of the welder and passers-by make them vulnerable to tripping over objects on the floor. Therefore, welders and supervisors must always

make sure that the area is clear of tripping hazards. Management must lay out the production area so that gas hoses, cables, mechanical assemblies, and other equipment do not cross walkways or interfere with routine tasks.

When work is above ground or floor level, safety rails or lines must be provided to prevent falls as a result of restricted vision from eye protection devices. Safety lines and harnesses can be helpful to restrict workers to safe areas, and to catch them in case of a fall.

Unexpected events, such as fire and explosions, do occur in industrial environments. All escape routes must be identified and kept clear so that orderly, rapid, and safe evacuation of an area can take place. Storage of goods and equipment in evacuation routes should be avoided. If an evacuation route must be temporarily blocked, employees who would normally use that route must be trained to use an alternate route.

Protection in the General Area

Equipment, machines, cables, hoses, and other apparatus should always be placed so that they do not present a hazard to personnel in passageways, on ladders, or on stairways. Warning signs should be posted to designate welding areas and to specify that eye protection must be worn.

Protective Screens. Persons in areas adjacent to welding and cutting must be protected from radiant energy and hot spatter by (1) flame-resistant screens or shields, or (2) suitable eye and face protection and protective clothing. Appropriate radiation-protective, semitransparent materials are permissible.

Where operations permit, work stations should be separated by noncombustible screens or shields (Fig. 2). Booths and screens should permit circulation of air at floor level as well as above the screen.

FIG. 2 PROTECTIVE SCREENS BETWEEN WORK STATIONS

Wall Reflectivity. Where arc welding or cutting is regularly carried on adjacent to painted walls, the walls should be painted with a finish having a low reflectivity of ultraviolet radiation. Finishes formulated with certain pigments, such as titanium dioxide or zinc oxide, have low reflectivity to ultraviolet radiation. Color pigments may be added if they do not increase reflectivity. Pigments based on powdered or flaked metals are not recommended because they reflect ultraviolet radiation. Additional information is available in *Ultraviolet Reflectance of Paint,* published by the American Welding Society.

Public Demonstrations

Persons putting on public demonstrations involving observations of arc or oxyfuel gas welding or cutting processes are responsible for the safety of observers and the general public. Observers are not likely to have the necessary protective equipment to let them observe demonstrations safely. For exhibits involving observation of arc or oxyfuel gas welding and cutting processes, appropriate eye protection for both observers and passers-by is mandatory.

Fume exposure must be controlled by appropriate ventilation. Electric cables and hoses must be routed to avoid audience exposure to possible electric shock or tripping hazards. Protection must be provided against fires from fuels, combustibles, and overheated apparatus and wiring.

Fire extinguishers must be on hand in case of fire. Combustible materials must be removed from the area or shielded from flames, sparks, and molten metal.

Safety precautions at public events should be passive types, that is, they should not require the audience to take action to protect itself. For example, a protective, moveable transparent screen allows an audience to observe a welding operation with the screen in place. After welding is completed, the screen can be moved to allow the audience to observe the completed weld. Additional information is given in ANSI/AWS Z49.1, *Safety in Welding and Cutting.*

Fire

In most welding, cutting, and allied processes, a high-temperature heat source is present. Open flames, electric arcs, hot metal, sparks, and spatter are ready sources of ignition. Many fires are started by sparks, which can travel horizontally up to 10 m (35 ft) from their source and fall much greater distances. Sparks can pass through or lodge in cracks, holes, and other small openings in floors and walls.

The risk of fire is increased by combustibles in the work area, or by welding or cutting too close to combustibles that have not been shielded. Materials most commonly ignited are combustible floors, roofs, partitions, and building contents including trash, wood, paper, textiles, plastics, chemicals, and flammable liquids and gases. Outdoors, the most common combustibles are dry grass and brush.

The best protection against fire is to perform welding and cutting in specially designated areas or enclosures of noncombustible construction that are kept free of combustibles. Combustibles should always be removed from the work area or shielded from the operation.

Fuel for engine-driven equipment should be stored and used with care. Equipment manufacturer instructions should be followed because fuels and their vapors are combustible and can be explosive under some conditions.

Fuel gases, such as acetylene or propane, are other common flammables often found in cutting and welding areas. Special attention should be given to fuel gas cylinders, hoses, and apparatus to prevent gas leakage.

Combustibles that cannot be removed from the area should be covered with tight fitting, flame-resistant material. These include combustible walls and ceilings. Floors should be free of combustible materials for a radius of 10 m (35 ft) around the work area. All doorways, windows, cracks, and other openings should be covered with a flame-resistant material or, if possible, the work area should be enclosed with portable flame-resistant screens.

If welding or cutting is to be performed on or adjacent to a metal wall, ceiling, or partition, combustibles on the other side must be moved to a safe location. If this cannot be done, a fire watcher should be stationed where the combustibles are located. Heat from welding can be conducted through metal partitions and ignite combustibles on the opposite side. A thorough examination for evidence of fire should be made before leaving the work area. Fire inspection should be continued for at least 30 min after the operation is completed.

Welding or cutting should not be performed on material having a combustible coating or internal structure, as in walls or ceilings. Hot scrap or slag must not be placed in containers holding combustible materials. Suitable fire extinguishers should always be available nearby.

Welding, brazing, or cutting should not be performed on combustible floors or platforms that may readily be ignited by heat from the operation. Welders must be alert for traveling vapors of flammable liquids. Vapors are often heavier than air and can travel along floors and in depressions for distances of several hundred feet from where the flammable liquid is stored. Light vapors can travel along ceilings to adjacent rooms.

Hot Work Permit System

When welding, cutting, or similar hot working operations are to be performed in areas not normally assigned for such operations, a hot work permit system should be used. The purpose of the hot work permit system is to alert area supervisors to an extraordinary danger of fire that will exist at a particular time. The permit system should include a check list of safety precautions that includes an inspection for fire extinguishers, establishment of fire watches if necessary, search for flammable materials, and safety instructions for personnel in the area who are not involved in the hot work.

Explosion

Flammable gases, vapors, and dusts, when mixed with air or oxygen in certain proportions, present danger of explosion as well as fire. To prevent explosions, operators must avoid all sources of ignition. Welding, brazing, soldering, cutting, or operating equipment that can produce heat or sparks must not be done in atmospheres containing flammable gases, vapors, or dusts. Such flammables must be kept in leak-fight containers or be well removed from the work area. Heat or sparks may cause otherwise low-volatile materials to produce flammable vapors.

Hollow containers must be vented before applying heat. Heat must not be applied to a container that has held an unknown material, a combustible substance, or a substance that may form flammable vapors on heating. Additional information is given in AWS F4.1, *Recommended Safe Practices for the Preparation for Welding and Cutting of Containers and Piping That Have Held Hazardous Substances*, American Welding Society, latest edition. The container must first be thoroughly cleaned or filled with an inert gas. Heat should never be applied to a workpiece that is covered by an unknown substance, nor to a substance that may form flammable or toxic vapors on heating.

Adequate eye and body protection must be worn when operations involve a risk of explosion.

Burns

Burns of the eye or body are serious hazards of welding, brazing, soldering, and cutting. Eye, face, and body protection for the operator and others in the work area are required to prevent burns from ultraviolet and infrared radiation, sparks, and spatter.

Eye and Face Protection

Arc Welding and Cutting. Welding helmets or handshields containing appropriate filter lenses and cover plates must be used by welders and welding operators and nearby personnel when viewing an arc. Suggested shade numbers of filter plates for various welding, brazing, soldering, and thermal cutting operations are given in Table 1.

TABLE 1 SUGGESTED VIEWING FILTER PLATES

OPERATION	PLATE THICKNESS		WELDING CURRENT, A	LOWEST SHADE NO.	COMFORT SHADE NO.[A]

TORCH BRAZING	. . .	. . .	. . .	. . .	3, 4
TORCH SOLDERING	. . .	. . .	. . .	. . .	2

(A) TO SELECT THE BEST SHADE FOR THE APPLICATION, FIRST SELECT A DARK SHADE. IF IT IS DIFFICULT TO SEE THE OPERATION PROPERLY, SELECT SUCCESSFULLY LIGHTER SHADES UNTIL THE OPERATION IS SUFFICIENTLY VISIBLE FOR GOOD CONTROL. HOWEVER, DO NOT GO BELOW THE LOWEST RECOMMENDED NUMBER, WHERE GIVEN.

(B) WITH OXYFUEL GAS WELDING OR CUTTING, THE FLAME EMITS STRONG YELLOW LIGHT. A FILTER PLATE THAT ABSORBS YELLOW OR SODIUM WAVE LENGTHS OF VISIBLE LIGHT SHOULD BE USED FOR GOOD VISIBILITY.

(C) THE SUGGESTED FILTERS ARE FOR APPLICATIONS WHERE THE ARC IS CLEARLY VISIBLE. LIGHTER SHADES MAY BE USED WHERE THE ARC IS HIDDEN BY THE WORK OR SUBMERGED IN WATER.

Safety spectacles, goggles, or other suitable eye protection must also be worn during welding and cutting operations. Such devices must have full conforming side shields when there is danger of exposure to injurious rays or to flying particles from grinding or chipping operations. Spectacles or goggles may have clear or colored lenses, depending on the intensity of the radiation that may come from adjacent welding or cutting operations when the welding helmet is raised or removed. Number 2 filter lenses are recommended for general purpose protection.

Oxyfuel Gas Welding and Cutting, Submerged Arc Welding. Safety goggles with filter lenses (Table 1) and full conforming side shields must be worn while performing oxyfuel gas welding and cutting. During submerged arc welding, the arc is covered by flux and not readily visible; hence, an arc welding helmet is not needed. However, because the arc occasionally flashes through the flux burden, the operator should wear tinted safety glasses.

Torch Brazing and Soldering. Safety spectacles with or without side shields and with appropriate filter lenses are recommended for torch brazing and soldering. As with oxyfuel gas welding and cutting, a bright yellow flame may be visible during torch brazing. A filter similar to that used with those processes should be used for torch brazing.

Resistance, Induction, Salt-Bath, Dip, Infrared Welding, and Brazing. Operators and helpers engaged in these processes must wear safety spectacles, goggles, and a face shield to protect their eyes and face from spatter. Filter lenses are not necessary but may be used for comfort.

Standards for welding helmets, handshields, face shields, goggles, and spectacles are given in ANSI Z87.1, *Practices for Occupational and Educational Eye and Face Protection,* American National Standards Institute (latest edition).

Protective Clothing

Sturdy shoes or boots, and heavy clothing similar to that in Fig. 3 should be worn to protect the whole body from flying sparks, spatter, and radiation burns. Woolen clothing is preferable to cotton because it is not so readily ignited. Cotton clothing, if used, should be chemically treated to reduce its combustibility. Clothing treated with nondurable flame retardants must be retreated after each washing or cleaning. Clothing or shoes of synthetic or plastic materials which can melt and cause severe burns should not be worn. Outer clothing should be kept free of oil and grease, especially in an oxygen-rich atmosphere.

FIG. 3 TYPICAL PROTECTIVE CLOTHING FOR ARC WELDING

Cuffless pants and covered pockets are recommended to avoid spatter or spark entrapment. Pockets should be emptied of flammable or readily ignitable materials before welding because they may be ignited by sparks or weld spatter and result in severe burns. Pants should be worn outside of shoes. Protection of the hair with a cap is recommended, especially if a hair-piece is worn. Flammable hair preparations should not be used.

Durable gloves of leather or other suitable material should always be worn. Gloves not only protect the hands from burns and abrasion, but also provide insulation from electrical shock. A variety of special protective clothing is also available for welders. Aprons, leggings, suits, capes, sleeves, and caps, all of durable materials, should be worn when welding overhead or when special circumstances warrant additional protection of the body.

Sparks or hot spatter in the ears can be particularly painful and serious. Properly fitted, flame-resistant ear plugs should be worn whenever operations pose such risks.

Noise

Excessive noise, particularly continuous noise at high levels, can damage hearing. It may cause either temporary or permanent hearing loss. U.S. Department of Labor Occupational Safety and Health Administration regulations describe allowable noise exposure levels. Requirements of these regulations can be found in General Industry Standards, 29 CFR 1910.95.

In welding, cutting, and allied operations, noise may be generated by the process or the equipment, or both. Processes that tend to have high noise levels are air carbon arc and plasma arc cutting. Engine-driven generators sometimes emit a high noise level, as do some high-frequency and induction welding power sources.

Additional information is presented in *Arc Welding and Cutting Noise,* American Welding Society, 1979.

Machinery Guards

Welders and other workers must be protected from injury by machinery and equipment that they are operating or by other machinery operating in the work area. Moving components and drive belts must be covered by guards to prevent physical contact.

Because welding helmets and dark filter lenses restrict the visibility of welders, they may be even more susceptible than ordinary welders to injury from unseen, unguarded machinery. Therefore, special attention is required to this hazard.

When repairing machinery by welding or brazing, the power to the machinery must be disconnected, locked out, and tagged to prevent inadvertent operation and injury. Welders assigned to work on equipment with safety devices removed should fully understand the hazards involved and the steps to be taken to avoid injury. When the work is completed, the safety devices must be replaced. Rotating and automatic welding machines, fixtures, and welding robots must be equipped with appropriate guards or sensing devices to prevent operation when someone is in the danger area.

Pinch points on welding and other mechanical equipment can also result in serious injury. Examples of such equipment are resistance welding machines, robots, automatic arc welding machines, jigs, and fixtures. To avoid injury with such equipment, the machine should be equipped so that both of the operator's hands must be at safe locations when the machine is actuated. Otherwise, the pinch points must be suitably guarded mechanically. Metalworking equipment should not be located where a welder could accidently fall into or against it while welding. During maintenance of the equipment, pinch points should be blocked to prevent them from closing in case of equipment failure. In very hazardous situations, an observer should be stationed to prevent someone from turning the power on until the repair is completed.

Safe Practices*

American Welding Society

Fumes and Gases

Welders, welding operators, and other persons in the work area must be protected from overexposure to fumes and gases produced during welding, brazing, soldering, and cutting. Overexposure is exposure that is hazardous to health and exceeds the permissible limits specified by a government agency, such as the U.S. Department of Labor, Occupational Safety and Health Administration Regulations 29 CFR 1910.1000, or other recognized authority, such as the American Conference of Governmental Industrial Hygienists in its publications *Threshold Limit Values for Chemical Substances* and *Physical Agents in the Workroom Environment.* Persons with special health problems may have unusual sensitivity that requires even more stringent protection.

Fumes and gases are usually a greater concern in arc welding than in oxyfuel gas welding, cutting, or brazing because a welding arc may generate a larger volume of fume and gas, and greater varieties of materials are usually involved.

Protection from excess exposure is usually accomplished by ventilation. Where exposure would exceed permissible limits with available ventilation, respiratory protection must be used. Protection must be provided not only for the welding and cutting personnel but also for other persons in the area.

Arc Welding

Nature and Sources. Fumes and gases from arc welding and cutting cannot be classified simply. Their composition and quantity depend upon the base metal composition; the process and consumables used; coatings on the work, such as paint, galvanizing, or plating; contaminants in the atmosphere, such as halogenated hydrocarbon vapors from cleaning and degreasing activities; and other factors.

In welding and cutting, the composition of the fume usually differs from the composition of the electrode or consumables. Reasonably expected fume constituents from normal operations include products of volatilization, reaction, or oxidation of consumables, base metals, coatings, and atmospheric contaminants. Reasonably expected gaseous products include carbon monoxide, carbon dioxide, fluorides, nitrogen oxides, and ozone.

The quantity and chemical composition of air contaminants change substantially with the process and with a wide range of variables inherent in each process. During arc welding, the arc energy and temperature depend on the process as well as the welding variables. Therefore, fumes and gases are generated in varying degrees in different welding operations.

Welding fume is a product of vaporization, oxidation, and condensation of components in the consumable and, to some degree, the base metal. The electrode, rather than the base metal, is usually the major source of fume. However, significant fume constituents can originate from the base metal if it contains alloying elements or a coating that is volatile at elevated temperatures.

Various gases are generated during welding. Some are a product of the decomposition of fluxes and electrode coatings. Others are formed by the action of arc heat or ultraviolet radiation emitted by the arc on atmospheric constituents and contaminants. Potentially hazardous gases include carbon monoxide, oxides of nitrogen, ozone, and phosgene or other decomposition products of chlorinated hydrocarbons, such as phosgene.

Helium and argon, although chemically inert and nontoxic, are simple asphyxiants and could dilute the atmospheric oxygen concentration to potentially harmful low levels. Carbon dioxide (CO_2) and nitrogen can also cause asphyxiation.

Ozone may be generated by ultraviolet radiation from welding arcs. This is particularly true with gas shielded arcs, especially when argon is used. Photochemical reactions between ultraviolet radiation and chlorinated hydrocarbons result in the production of phosgene and other decomposition products.

The arc heat is responsible for the formation of oxides of nitrogen from atmospheric nitrogen. Hence, nitrogen oxides may be produced by a welding arc or other high-temperature heat sources. Thermal decomposition of carbon dioxide and inorganic carbonate compounds by an arc results in the formation of carbon monoxide. Levels can be significant when CO_2 is used as the shielding gas.

Reliable estimates of fume and gas composition cannot be made without considering the nature of the welding process and system being examined. For example, aluminum and titanium are normally welded in an atmosphere of argon or helium, or mixtures of the two gases. The arc creates relatively little fume but may emit an intense radiation that can produce ozone. Inert gas shielded arc welding of steels also creates a relatively low fume level.

Arc welding of steel in oxidizing environments, however, generates considerable fume and can produce carbon monoxide and oxides of nitrogen. The fumes generally consist of discrete particles of amorphous slags containing iron, manganese, silicon, and other metallic constituents, depending on the alloy system involved. Chromium and nickel compounds are found in fumes when stainless steels are arc welded.

Some covered and flux-cored electrodes are formulated with fluorides. The fumes associated with those electrodes can contain significantly more fluorides than oxides.

Factors Affecting Generation Rates. The rate of generation of fumes and gases during arc welding of steel depends on numerous variables. Among these are:

- WELDING CURRENT
- ARC VOLTAGE (ARC LENGTH)
- TYPE OF METAL TRANSFER OR WELDING PROCESS
- SHIELDING GAS

These variables are interdependent and can have a substantial effect on total fume generation.

Welding Current. In general, fume generation rate increases with increased welding current. The increase, however, varies with the process and electrode type. Certain covered, flux-cored, and solid-wire electrodes exhibit a nonproportional increase in fume generation rate with increasing current.

Studies have shown that fume generation rates with covered electrodes are proportional to the welding current raised to a power. The exponent is 2.24 for E6010 electrodes and 1.54 for E7018 electrodes. Similar trends were reported in other studies. Additional information is available in *Fumes and Gases in the Welding Environment,* American Welding Society, 1979.

Flux-cored and solid electrode fume generation rates are more complexly related to welding current. Welding current levels affect the type of metal droplet transfer. As a result, the fume generation rate can decrease with increasing current until some minimum is reached. Then, it will increase in a relatively proportional fashion.

An increase in current can increase ultraviolet radiation from the arc. Therefore, the generation of gases formed photochemically by this radiation, such as ozone, can be expected to increase as welding current is increased. Measurements of ozone concentration during gas-metal arc and gas-tungsten arc welding have shown such behavior.

Arc voltage and arc length are directly related. For a given arc length, there is a corresponding arc voltage, mostly dependent upon the type of electrode, welding process, and power supply. In general, increasing arc voltage (arc length) increases the fume generation rate for all open arc welding processes. The levels differ somewhat for each process or electrode type.

Type of Metal Transfer. When steel is joined with gas-metal arc welding using a solid-wire electrode, the mode of metal transfer depends upon the current and voltage. At low welding current and voltage, short-circuiting transfer takes

place; that is, droplets are deposited during short circuits between the electrode and molten weld pool. As the current or voltage is increased, metal transfer changes to globular type, where large globules of metal are projected across the arc into the weld pool. At high currents, transfer changes to a spray mode, where fine metal droplets are propelled rapidly across the arc. Fume generation rate appears to follow a transition also. It is relatively high during short-circuiting transfer because of arc turbulence. As the transition current is approached in an argon-rich shielding gas, the fume rate decreases and then increases again as spray transfer is achieved. In the spray region, the rate of fume generation is proportional to welding current.

For other welding processes, the type of metal transfer does not vary substantially with current or voltage. In these cases, fume generation follows the relationship for welding current changes.

Shielding Gas. When gas-metal arc welding or flux-cored arc welding with certain electrodes, shielding gas must be used. The type of shielding gas affects both the composition of the fume and its rate of generation. It also affects the kind of gases found in the welding environment. For example, the fume generation rate is higher with CO_2 shielding than with argon-rich shielding. The rate of fume formation with argon-oxygen or argon-CO_2 mixtures increases with the oxidizing potential of the mixture.

For welding processes where inert gas shielding is used, such as gas-tungsten arc or plasma arc welding, the fume generation rate varies with the type of gas or gas mixture. For example, there can be more fume with helium than with argon shielding.

By-product gases also vary with shielding gas composition. The rate of formation of ozone depends upon the wave lengths and intensity of the ultraviolet rays generated in the arc; ozone is more commonly found with argon-rich gases than with carbon dioxide. Oxides of nitrogen are present in the vicinity of any open arc process. Carbon monoxide is commonly found around CO_2 shielded arcs.

Welding Process. Studies of the relative fume generation rates of consumable electrode processes for welding on mild steel have shown definite trends. Considering the ratio of the weight of fumes generated per weight of metal deposited, covered electrodes and self-shielded fluxcored electrodes produce the most fume. Gas-shielded flux-cored electrodes produce less fume, and solid-wire electrodes produce an even smaller amount. The submerged arc welding process consistently produces the least fumes because the fume is captured in the flux and slag cover.

Consumables. With a specific process, the fume rate depends on the composition of the consumables. Some components of covered and flux-cored electrodes are designed to decompose and form protective gases during welding. Hence, they will generate relatively high fume levels.

Because the constituents of many covered and flux-cored electrodes are proprietary, the fume generation rates of electrodes of the same AWS classification produced by different manufacturers can differ substantially. The only reliable method for comparing filler metals is actual product testing to determine specific fume generation characteristics.

Oxyfuel Gas Welding and Cutting

The temperatures encountered in oxyfuel gas welding and cutting are lower than those found in electric arc processes. Consequently, the quantity of fumes generated is normally lower. The gases formed are reaction products of fuel gas combustion and of chemical reactions between the gases and the other materials present. The fumes generated are the reaction products of the base metals, coatings, filler metals, fluxes, and the gases being used. In oxyfuel gas cutting of steel, the fumes produced are largely oxides of iron.

Fume constituents of greater hazard may be expected when coatings such as galvanizing, paint primers, or cadmium plating are present. Gases of greatest concern include oxides of nitrogen, carbon monoxide, and carbon dioxide. Oxides of nitrogen may be present in especially large amounts when oxyfuel gas cutting stainless steels using either the chemical flux or the iron powder process.

Exposure Factors

Position of the Head. The single most important factor influencing exposure to fume is the position of the welder's head with respect to the fume plume. When the head is in such a position that the fume envelops the face or helmet,

exposure levels can be very high. Therefore, welders must be trained to keep their heads to one side of the fume plume. In some cases, the work can be positioned so the fume plume rises to one side.

Type of Ventilation. Ventilation has a significant influence on the amount of fumes in the work area and hence the welder's exposure. Ventilation may be local, where the fumes are extracted near the point of welding, or general, where the shop air is changed or filtered. The appropriate type will depend on the welding process, the material being welded, and other shop conditions. Adequate ventilation is necessary to keep the welder's exposure to fumes and gases within safe limits.

Shop Size. The size of the welding or cutting enclosure is important. It affects the background fume level. Fume exposure inside a tank, pressure vessel, or other confined space will certainly be higher than in a high-bay fabrication area.

The background fume level depends on the number and type of welding stations and the duty cycle for each station.

Design of Welding Helmet. The extent to which the helmet curves under the chin towards the chest affects the amount of fume exposure. Close-fitting helmets can be effective in reducing exposure.

Base Metal and Surface Condition. The type of base metal being welded influences both the constituents and the amount of fume generated. Surface contaminants or coatings may contribute significantly to the hazard potential of the fume. Paints containing lead and platings containing cadmium generate dangerous fumes during welding and cutting. Galvanized material evolves zinc fume.

Ventilation

The bulk of fume generated during welding and cutting consists of small particles that remain suspended in the atmosphere for a considerable time. As a result, fume concentration in a closed area can build up over time, as can the concentration of any gases evolved or used in the process. The particles eventually settle on the walls and floor, but the settling rate is low compared to the generation rate of the welding or cutting processes. Therefore, fume concentration must be controlled by ventilation.

Adequate ventilation is the key to control of fumes and gases in the welding environment. Natural, mechanical, or respirator ventilation must be provided for all welding, cutting, brazing, and related operations. The ventilation must ensure that concentrations of hazardous airborne contaminants are maintained below recommended levels. These levels must be no higher than the allowable levels specified by the U.S. Occupational Safety and Health Administration or other applicable authorities.

Many ventilation methods are available. They range from natural convection to localized devices, such as air-ventilated welding helmets. Examples of ventilation include:

- NATURAL VENTILATION
- GENERAL AREA MECHANICAL VENTILATION
- OVERHEAD EXHAUST HOODS
- PORTABLE LOCAL EXHAUST DEVICES
- DOWNDRAFT TABLES
- CROSSDRAFT TABLES
- EXTRACTORS BUILT INTO THE WELDING EQUIPMENT
- AIR-VENTILATED HELMETS

General Ventilation. In most cases, general ventilation is more effective in protecting personnel in adjacent areas than in protecting the welders themselves. Such ventilation may occur naturally outdoors, or when the shop doors and windows are open. It is acceptable when precautions are taken by the welder to keep his or her breathing zone away from the fume plume and when sampling of the atmosphere shows that concentrations of contaminants do not exceed permissible limits. Natural ventilation often meets these criteria when all of the following conditions are present:

- SPACE OF MORE THAN 283 M^3 (10,000 FT^3) PER WELDER IS PROVIDED.
- CEILING HEIGHT IS MORE THAN 5 M (16 FT).
- WELDING IS NOT DONE IN A CONFINED AREA.
- THE GENERAL WELDING AREA IS FREE OF PARTITIONS, BALCONIES, OR OTHER STRUCTURAL BARRIERS THAT SIGNIFICANTLY OBSTRUCT CROSS VENTILATION. (GENERAL AREA REFERS TO A BUILDING OR A ROOM IN A BUILDING, NOT A WELDING BOOTH OR SCREENED AREA THAT IS USED TO PROVIDE PROTECTION FROM WELDING RADIATION.)
- TOXIC MATERIALS WITH LOW PERMISSIBLE EXPOSURE LIMITS ARE NOT PRESENT AS DELIBERATE CONSTITUENTS. (THE EMPLOYER SHOULD REFER TO THE MATERIAL SAFETY DATA SHEET PROVIDED BY THE MATERIAL SUPPLIER.) WHEN NATURAL VENTILATION IS NOT SUFFICIENT, FANS MAY BE USED TO FORCE AND DIRECT THE REQUIRED AMOUNT OF AIR THROUGH A BUILDING OR WORK ROOM.

The effectiveness of general ventilation, natural or forced, depends on the design of the system. Work areas where fresh air is introduced and contaminated air is exhausted must be arranged so that the welding fumes and gases are carried away, not concentrated in dead zones. In some cases, the fresh air supply may be located so that incoming air provides the required protection for the welders as well as for personnel in the general area.

Air movement should always be from either side across the welder. This makes it easier for the welder to keep out of the plume and to keep fumes and gases from entering the welding helmet. Air should not blow toward the face or back of the welder because it may force the fume behind the helmet.

General mechanical ventilation may be a necessary supplement to local ventilation to maintain the background level of airborne contaminants within acceptable limits. Local ventilation is usually necessary to provide satisfactory health hazard control at the individual welding station.

Local Ventilation. General ventilation may control contamination levels in the broad area, but in many cases, it will not provide the local control needed to protect the welder. Local exhaust ventilation is usually the most effective way of providing protection at the local work station. It provides efficient and economical fume control and may be applied by one of the methods listed below.

A fixed open or enclosing hood consisting of a top and at least two sides can be placed to surround the welding or cutting operation. It must have sufficient air flow and velocity to keep contaminant levels at or below permissible limits. Additional information is available in *Industrial Ventilation: A Manual of Recommended Practice,* American Conference of Governmental Industrial Hygienists (latest edition).

A movable hood with a flexible duct can be positioned by the welder as close as practicable to the point of welding (Fig. 4). It should have sufficient air flow to produce a velocity of 30 m/min (100 ft/min) in the zone of welding.

FIG. 4 MOVABLE HOOD POSITIONED NEAR THE WELDING ARC

Air flow requirements range from 4 m^3/min (150 ft^3/min) when the hood is positioned at 100 to 150 mm (4 to 6 in.) from the weld, to 17 m^3/min (600 ft^3/min) at 250 to 300 mm (10 to 12 in.) from the weld. This is particularly applicable for bench work but may be used for any location, provided the hood is moved as required. An air velocity of 31 m/min (100 ft/min) will not disturb the torch gas shield during gas shielded arc welding, provided adequate gas flow rates are used. Higher air velocities may disturb the gas shield and render it less effective.

Crossdraft or Downdraft Table. A crossdraft table is a welding bench with the exhaust hood placed to draw air horizontally across the table. The welder should face in a direction perpendicular to the air flow so that the air flow is across his or her body. A downdraft table has a grill to support the work above an exhaust hood that draws the air downward and away from the welder's head.

Gun-mounted fume removal equipment extracts the fumes at the point of welding and results in an almost smokeless environment. The exhaust rate must be set so that it does not interfere with the shielding gas pattern provided by the welding process. The flux-cored arc welding process produces large quantities of fume, and virtually all of the fume can be collected using a gun-mounted fume removal device (Fig. 5).

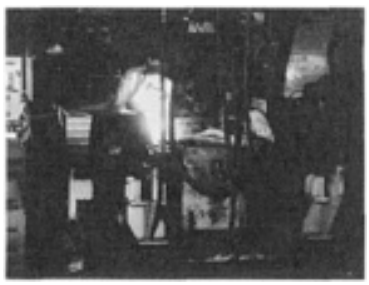

FIG. 5 REMOVAL OF FUME WITH A GUN-MOUNTED DEVICE

Where permissible, air cleaners that have high efficiencies in the collection of submicron particles may be used to recirculate a portion of ventilated air that would otherwise be exhausted. Some air cleaners do not remove gases. Therefore, the filtered air must be monitored to ensure that harmful gas concentrations do not exceed safe limits.

Water Table Used for Oxyfuel Gas and Plasma Arc Cutting Operations. This is a cutting table filled with water near or in contact with the bottom surface of the work. Much fume emerging from the cut is captured in the water.

Respiratory Protective Equipment. Where natural or mechanical ventilation is not adequate or where very toxic materials require a supplement to ventilation, respiratory protective equipment must be used. Airline respirators or face masks that give protection against all contaminants are generally preferred. Air-supplied welding helmets are also available commercially. Filter-type respirators, approved by the U.S. Bureau of Mines for metal fume, give adequate protection against particulate contaminants that are less toxic than lead, provided they are used and maintained correctly. Their general use is not recommended, however, because of the difficulty in ensuring proper use and maintenance. They will not protect against mercury vapor, carbon monoxide, or nitrogen dioxide. For these hazards an airline respirator, hose mask, or gas mask is required.

For additional information, refer to ANSI Z88.2, *Practices for Respiratory Protection,* American National Standards Institute (latest edition).

Special Ventilation Situations

Welding in Confined Spaces. Special consideration must be given to the safety and health of the welders and other workers in confined spaces. Gas cylinders must be located outside of the confined space to avoid possible contamination

of the space with leaking gases or volatiles. Welding power sources should also be located outside to reduce danger of engine exhaust and electric shock.

A means for removing persons quickly in case of emergency must be provided. Safety belts and lifelines, when used, should be attached to the worker's body in a manner that avoids the possibility of the person becoming jammed in the exit. A trained helper should be stationed outside the confined space with a preplanned rescue procedure to be put into effect in case of emergency.

In addition to keeping airborne contaminants in breathing atmospheres at or below recommended limits, ventilation in confined spaces must also (1) ensure adequate oxygen for life support (at least 19.5% by volume), (2) prevent accumulation of an oxygen-enriched atmosphere (i.e., not over 23.5% by volume), and (3) prevent accumulation of flammable mixtures. Asphyxiation can quickly result in unconsciousness and death without warning if oxygen is not present in sufficient concentration to support life. Air contains approximately 21% O by volume. A confined space must not be entered unless it is well ventilated, or the welder is properly trained to work in such spaces and is wearing an approved air-supplied breathing apparatus. (Approved air-supplied respirators or hose masks are those accepted by the U.S. Bureau of Mines or other recognized agency.) A similarly equipped second person must be present.

Confined spaces should be tested before entering for (1) toxic or flammable gases and vapors and (2) adequate or excess oxygen. The tests should be made with instruments approved by the U.S. Bureau of Mines. Heavier-than-air gases, such as argon, methylacetylene-propadiene, propane, and carbon dioxide, may accumulate in pits, tank bottoms, low areas, and near floors. Lighter-than-air gases, such as helium and hydrogen, may accumulate in tank tops, high areas, and near ceilings. The precautions for confined spaces also apply to those areas. If practical, a continuous monitoring system with audible alarms should be used for work in a confined space.

Oxygen-enriched atmospheres pose great danger to occupants of confined areas. They are especially hazardous at oxygen concentrations above 25%. Materials that burn normally in air may flare up violently in an oxygen-enriched atmosphere. Clothing may burn fiercely; oil or grease-soaked clothing or rags may catch fire spontaneously; paper may flare into flame. Very severe and fatal burns can result.

Protection in confined spaces must be provided not only for welders but also for other persons in the enclosure. Only clean, respirable air must be used for ventilation. Oxygen, other gases, or mixtures of gases must never be used for ventilation.

When welding, cutting, or related processes are performed in confined areas where adequate and proper ventilation cannot be provided and there is immediate danger to life and health, positive pressure self-contained breathing apparatus must be used. It must have an emergency air supply of at least five minutes duration in the event that the main source fails.

For further precautions, see ANSI Z117.1, *Safety Requirements for Working in Tanks and Other Confined Spaces* (latest edition).

Welding of Containers. Welding or cutting on the outside or inside of containers or vessels that have held dangerous substances presents special hazards. Flammable or toxic vapors may be present, or may be generated by the applied heat. The immediate area outside and inside the container should be cleared of all obstacles and hazardous materials. For more complete procedures, refer to AWS F4.1, *Recommended Safe Practices for the Preparation for Welding and Cutting of Containers and Piping That Have Held Hazardous Substances*, American Welding Society, latest edition. When repairing a container in place, entry of hazardous substances released from the floor or the soil beneath the container must be prevented. The required personal and fire protection equipment must be available, serviceable, and in position for immediate use.

When welding or cutting inside of vessels that have held dangerous materials, the precautions for confined spaces must also be observed.

Gases generated during welding should be discharged in a safe and environmentally acceptable manner in accordance with Government rules and regulations. Provisions must be made to prevent pressure buildup inside containers. Testing for gases, fumes, and vapors should be conducted periodically to ensure that recommended limits are maintained during welding.

An alternative method of providing safe welding of containers is to fill them with an inert medium such as water, inert gas, or sand. When using water, the level should be kept to within a few inches of the point where the welding is to be done. The space above the water should be vented to allow the heated air to escape. With inert gas, the responsible individual needs to know the percentage of inert gas that must be present in the tank to prevent fire or explosion, and how to safely produce and maintain a safe atmosphere during welding.

Highly Toxic Materials. Certain materials, which are sometimes present in consumables, base metals, coatings, or atmospheres for welding or cutting operations, have permissible exposure limits of 1.0 mg/m^3 (4.4×10^{-4} gr/ft^3) or less. Among such materials are the following metals and their compounds:

- ANTIMONY
- ARSENIC
- BARIUM
- BERYLLIUM
- CADMIUM
- CHROMIUM
- COBALT
- COPPER
- LEAD
- MANGANESE
- MERCURY
- NICKEL
- SELENIUM
- SILVER
- VANADIUM

Base metals and filler metals that may release some of these materials as fume during welding or cutting are given in Table 2.

TABLE 2 POSSIBLE TOXIC MATERIALS EVOLVED DURING WELDING OR THERMAL CUTTING

BASE OR FILLER METAL	**EVOLVED METALS OR THEIR COMPOUNDS**
CARBON AND LOW-ALLOY STEELS	CHROMIUM, MANGANESE, VANADIUM
STAINLESS STEELS	CHROMIUM, MANGANESE, NICKEL
MANGANESE STEELS AND HARDFACING MATERIALS	CHROMIUM, COBALT, MANGANESE, NICKEL, VANADIUM
HIGH-COPPER ALLOYS	BERYLLIUM, CHROMIUM, COPPER, LEAD, NICKEL
COATED OR PLATED STEEL OR COPPER	CADMIUM(A), CHROMIUM, COPPER, LEAD, NICKEL, SILVER

(A) WHEN CADMIUM IS A CONSTITUENT IN A FILLER METAL, A WARNING LABEL MUST BE AFFIXED TO THE CONTAINER OR COIL. REFER TO ANSI/ASC Z49.1, *SAFETY IN WELDING AND CUTTING,* AMERICAN NATIONAL STANDARDS INSTITUTE (LATEST EDITION).

Manufacturer's material safety data sheets should be consulted to determine if any of these highly toxic materials are present in welding filler metals and fluxes being used. Material safety data sheets should be requested from suppliers. However, welding filler metals and fluxes are not the only source of these materials. They may also be present in base metals, coatings, or other sources in the work area. Radioactive materials under Nuclear Regulatory Commission jurisdiction require special considerations.

When toxic materials are encountered as designated constituents in welding, brazing, or cutting operations, special ventilation precautions must be taken to ensure that the levels of these contaminants in the atmosphere are at or below the limits allowed for human exposure. All persons in the immediate vicinity of welding or cutting operations involving toxic materials must be similarly protected. Unless atmospheric tests under the most adverse conditions establish that exposure is within acceptable concentrations, the following precautions must be observed.

Confined Spaces. Whenever any toxic materials are encountered in confined space operations, local exhaust ventilation and respiratory protection must be used.

Indoors. When any toxic materials are encountered in indoor operations, local exhaust mechanical ventilation must be used. When beryllium is encountered, respiratory protection in addition to local exhaust ventilation is essential.

Outdoors. Whenever any toxic materials are encountered in outdoor operations, respiratory protection approved by the Mine Safety and Health Association (MSHA), the National Institute of Occupational Safety and Health (NIOSH), or other approving authority may be required.

Persons should not consume food in areas where fumes that contain materials with very low allowable exposure limits may be generated. They should also practice good personal hygiene, such as washing hands before touching food, to prevent ingestion of toxic contaminants.

Fluorine Compounds. Fumes and gases from fluorine compounds can be dangerous to health and can burn the eyes and skin on contact. Local mechanical ventilation or respiratory protection must be provided when welding, brazing, cutting, or soldering in confined spaces involving fluxes, coatings, or other material containing fluorine compounds.

When such processes are employed in open spaces, the need for local exhaust ventilation or respiratory protection will depend upon the circumstances. Such protection is not necessary when air samples taken in breathing zones indicate that all fluorides are within allowable limits. However, local exhaust ventilation is always desirable for fixed-location production welding and for all production welding of stainless steels when filler metals or fluxes containing fluorides are used.

Zinc. Fumes containing zinc compounds may produce symptoms of nausea, dizziness, or fever (sometimes called metal fume fever). Welding or cutting where zinc may be present in consumables, base metals, or coatings should be done as described for fluorine compounds.

Cleaning compounds often require special ventilation precautions because of their possible toxic or flammable properties. Manufacturers' instructions should be followed before welding or cutting is done with cleaned consumables or on cleaned base metal.

Chlorinated Hydrocarbons. Degreasing or cleaning operations involving chlorinated hydrocarbons must be so located that vapors from such operations do not enter the atmosphere surrounding molten weld metal or the welding arc. A reaction product having an objectionable, irritating odor, and containing highly toxic phosgene gas is produced when such vapors enter the atmosphere of arc welding operations. Low levels of exposure can produce feelings of nausea, dizziness, and weakness. High exposures may produce serious health impairment.

Cutting of stainless steel by oxyfuel gas, gas shielded arc, or plasma arc cutting should be done using local mechanical ventilation to remove the fumes generated. Fume from plasma arc cutting done under water is mostly captured in the water.

Measurement of Exposure

The American Conference of Governmental Industrial Hygienists (ACGIH) and the U.S. Department of Labor, Occupational Safety and Health Administration (OSHA) have established allowable limits of airborne contaminants. They are called threshold limit values (TLV) or permissible exposure limits (PEL).

The TLV is the concentration of an airborne substance to which most workers may be repeatedly exposed day after day, without adverse effect. In adapting these to the working environment, a threshold limit value-time weighted average (TLV-TWA) quantity is defined. TLV-TWA is the time-weighted average concentration for a normal 8 h workday or 40 h workweek to which nearly all workers may be repeatedly exposed without adverse effect. TLV-TWA values should be

used as guides in the control of health hazards and should not be interpreted as sharp lines between safe and dangerous concentrations.

TLVs are revised annually as necessary. They may or may not correspond to OSHA permissible limits (PEL) for the same materials. In many cases, current ACGIH values for welding materials are more stringent than OSHA levels.

The only way to ensure that airborne contaminant levels are within the allowable limits is to take air samples at the breathing zones of the personnel involved. An operator's actual on-the-job exposure to welding fume should be measured following the guidelines provided in ANSI/AWS F1.1, *Method for Sampling Airborne Particulates Generated by Welding and Allied Processes.* This document describes how to obtain an accurate breathing zone sample of welding fume for a particular welding operation. Both the amount of fume and the composition of the fume can be determined in a single test using this method. Multiple samples are recommended for increased accuracy. When a helmet is worn, the sample should be collected inside the helmet in the welder's breathing zone.

Safe Practices*

American Welding Society

Handling of Compressed Gases

Gas Cylinders and Containers

Gases used in welding and cutting operations are packaged in containers called cylinders. Only cylinders designed and maintained in accordance with U.S. Department of Transportation (DOT) specifications may be used in the United States. The use of other cylinders may be extremely dangerous and is illegal. Cylinders requiring periodic retest under DOT regulations may not be filled unless the retest is current.

Filling. Cylinders may be filled only with the permission of the owner. They should only be filled by recognized gas suppliers or those with the proper training and facilities to do so. Filling one cylinder from another is dangerous and should not be attempted by anyone not qualified to do so. Combustible or incompatible combinations of gases must never be mixed in cylinders.

Usage and Storage. Welding must not be performed on gas cylinders. Cylinders must not be allowed to become part of an electrical circuit because arcing may result. Cylinders containing shielding gases used in conjunction with arc welding must not be grounded. Electrode holders, welding torches, cables, hoses, and tools should not be stored on gas cylinders, which might cause arcing or interference with valve operation. Are-damaged gas cylinders may rupture and result in injury or death.

Cylinders must not be used as work rests or rollers. They should be protected from bumps, falls, falling objects, and weather, and they should not be dropped. Cylinders should not be kept in passageways where they might be struck by vehicles. They should be kept in areas where temperatures do not fall below -30 °C (-20 °F) nor exceed 55 °C (130 °F). Any of these exposures, misuses, or abuses could damage them to the extent that they might fail, with serious consequences.

Cylinders must not be hoisted using ordinary slings or chains. A proper cradle or cradle sling that securely retains the cylinder should be used. Electromagnets should not be used to handle cylinders.

Cylinders must always be secured by the user against falling during either use or storage. Acetylene and liquefied gas cylinders should always be stored and used in the upright position. Other cylinders are preferably stored and used in the upright position, but this is not essential in all circumstances.

Before using gas from a cylinder, the contents should be identified by the label thereon. Contents must never be identified by any other means such as cylinder color, banding, or shape. These may vary among manufacturers, geographical areas, or product lines and could be completely misleading. The label on the cylinder is the only proper notice of the contents. If a label is not on a cylinder, the contents should not be used and the cylinder should be returned to the supplier.

A valve protection cap is provided on many cylinders to protect the safety device and the cylinder valve. This cap should always be in place except when the cylinder is in use. The cylinder should never be lifted manually or by hoist by the valve protection cap. The threads that secure these valve protection caps are intended only for that purpose and may not be capable of supporting full cylinder weight. The caps should always be threaded completely onto the cylinders and hand tightened.

Gas cylinders and other containers must be stored in accordance with all state and local regulations and the appropriate standards of OSHA and the National Fire Protection Association (NFPA). Safe handling and storage procedures are discussed in the Compressed Gas Association's *Handbook of Compressed Gases.*

Withdrawal of Gas. Many gases in high-pressure cylinders are filled to pressures of 14 MPa (2000 psig) or more. Unless the equipment to be used with a gas is designed to operate at full cylinder pressure, an approved pressure-reducing regulator must be used to withdraw gas from a cylinder or manifold. Simple needle valves should never be used. A pressure-relief or safety valve, rated to function at less than the maximum allowable pressure of the welding equipment, should also be employed. The valve function is to prevent failure of the equipment at pressures in excess of working limits if the regulator should fail in service.

Valves on cylinders containing high-pressure gas, particularly oxygen, should always be opened slowly to avoid the high temperature of adiabatic recompression, which can occur if the valves are opened rapidly. In the case of oxygen, the heat can ignite the valve seat, which, in turn, may cause the metal to melt or burn. The cylinder valve outlet should point away from the operator and other persons when the valve is being opened to avoid injury should a fire occur.

Prior to the connection of a gas cylinder to a pressure regulator or a manifold, the valve outlet should be cleaned of dirt, moisture, and other foreign matter by first being wiped with a clean, oil-free cloth. Then the valve should be opened momentarily and closed immediately. This is known as "cracking the cylinder valve." Fuel gas cylinders must never be cracked near sources of ignition (i.e., sparks and flames), while the operator is smoking, or in confined spaces.

A regulator should be drained of gas pressure prior to being connected to a cylinder and also after the cylinder valve is closed upon shutdown of operation. The outlet threads on cylinder valves are standardized for specific gases so that only regulators or manifolds with similar threads can be attached. (Refer to ANSI/CGA V-l, *Compressed Gas Cylinder Valve Outlet and Inlet Connections,* Compressed Gas Association.) Standard valve thread connections for gases normally used for welding, brazing, and allied processes are given in Table 3.

TABLE 3 COMPRESSED GAS ASSOCIATION STANDARD AND ALTERNATE VALVE THREAD CONNECTIONS FOR COMPRESSED GAS CYLINDERS

GAS	CONNECTION NO.
ACETYLENE	510 OR 300
ARGON	580
BUTANE	510
CARBON DIOXIDE (CO_2)	320
HELIUM	580
HYDROGEN	350
METHYLACETYLENE-PROPADIENE (MPS)	510
NITROGEN	580 OR 555
OXYGEN	540
PROPANE	510
PROPYLENE	510

It is preferable not to open valves on low-pressure fuel gas cylinders more than one turn. This usually provides adequate flow and permits rapid closure of the cylinder valve in an emergency. High-pressure cylinder valves, on the other hand, usually must be opened fully to backseat the packing and prevent packing leaks during use.

The cylinder valve should be closed after each use of a cylinder and when an empty cylinder is to be returned to the supplier. This prevents loss of product through leaks that might develop and go undetected while the cylinder is

unattended and also avoids hazards that might be caused by leaks. It also prevents backflow of contaminants into the cylinder. It is advisable to return cylinders to the supplier with about 172 kPa (25 psi) of contents remaining. This prevents possible contamination by the atmosphere during shipment.

Pressure-Relief Devices. Only trained personnel should be allowed to adjust pressure-relief devices on cylinders. These devices are intended to provide protection in the event the cylinder is subjected to a hostile environment, usually fire or other source of heat. Such environments may raise the pressure within cylinders. To prevent cylinder pressures from exceeding safe limits, the safety devices are designed to relieve the contents.

Cryogenic Cylinders and Tanks

Cryogenic cylinders and tanks are used to store at very low temperatures those liquids that change to gases at normal conditions of temperature and pressure. So-called cryogenic liquids for commercial purposes include oxygen, nitrogen, and argon, although other gases may be handled as cryogenic liquids.

Cylinders and tanks for storing cryogenic liquids are usually double-walled vessels that are evacuated and insulated between the walls. They are designed to contain liquids at very low temperatures with a minimum of heat gain. Heat gain from the atmosphere causes evaporation of the product. Liquid containers hold a greater amount of product for a given volume than high-pressure gas cylinders. For safety, containers of liquid must be handled carefully. They must always be maintained in an upright position. Whenever they are moved, a cylinder handling truck designed for this purpose must be used. They should not be rolled on a bottom edge, as is often done with high-pressure cylinders.

Failure to properly handle these cylinders can result in rupture of either the inner or outer cylinder wall with consequent loss of vacuum and rapid rise of internal pressure. This will result in activation of the cylinder's protective devices and loss of the cylinder contents. The cylinder protection devices must never be tampered with nor deactivated. Overpressurization could result in explosive failure.

Damage to the internal walls or fittings of a cryogenic-liquid container is often evidenced by visible frosting on the exterior of the container. Whenever frosting appears on the exterior of a cryogenic-liquid container, personnel should be kept clear and the gas supplier notified. In general, people should stay clear of the container until the frost disappears. When the frost disappears it means that the contents have evaporated and any dangerous internal pressure has been relieved.

Although the contents of cryogenic-liquid containers are predominantly in liquid form at very low temperatures, the product withdrawn from these containers should be a gas at room temperature. The conversion takes place within a vaporizer system that evaporates the liquid and warms the gas to atmospheric temperature.

In some cases, the user may want to withdraw liquid from the container. When liquid is withdrawn, protective clothing should be worn to prevent bodily contact with the cold product. Loose-fitting insulated gloves and an adequate face shield are essential. Contact of liquid with the skin will cause burns similar to heat burns, and prolonged contact will cause severe frostbite. Injuries of this nature should be treated in the same manner as injuries from exposure to *low* temperatures.

Compared to their normal properties, the properties of many materials are drastically different at cryogenic liquid temperatures. Many metals, including carbon steel, and most elastomers, such as rubber, become extremely brittle. When cryogenic liquids are to be withdrawn from cylinders, all materials in the transfer line must have satisfactory properties at the low temperatures.

Liquid oxygen may react with explosive violence on contact with asphalt or similar bituminous materials. Therefore, liquid oxygen tanks must never be mounted on such surfaces and liquid oxygen must not be allowed to contact them. Liquid oxygen tanks must always be installed on concrete pads.

Regulators

A pressure-reducing regulator should always be used when withdrawing gas from gas cylinders for welding or cutting operations. Gas regulators should meet the requirements of E-4, *Standard for Gas Regulators for Welding and Cutting,* Compressed Gas Association, and other code regulations.

Pressure-reducing regulators must be used only for the gas and pressure given on the label. They should not be used with other gases, or at other pressures even though the cylinder valve outlet threads may be the same. The threaded connections to the regulator must not be forced. Improper fit of threads between a gas cylinder and regulator or between the regulator and hose indicates that an improper combination of devices is being used.

Use of adapters to change the cylinder connection thread is not recommended because of the danger of using an incorrect regulator or of contaminating the regulator. For example, gases that are oil-contaminated can deposit an oily film on the internal parts of the regulator. This film can contaminate oil-free gas or result in fire or explosion in the case of oxygen.

The threads and connection glands of regulators should be inspected before use for dirt or damage. If a hose or cylinder connection leaks, it should not be forced with excessive torque. Damaged regulators and components should be repaired by properly trained mechanics or returned to the manufacturer for repair.

A suitable valve or flowmeter should be used to control gas flow from a regulator. The internal pressure in a regulator should be drained before it is connected to or removed from a gas cylinder or manifold.

Manifolds

A manifold is used when gas is needed without interruption or at a higher delivery rate than can be supplied from a single cylinder. A manifold must be designed for the specific gas and operating pressure, and be leak tight. The manifold components should be approved for such purpose and used only for the gas and pressure for which they are approved. Oxygen and fuel gas manifolds must meet specific design and safety requirements. (Refer to ANSI/NFPA 51, *Oxygen-Fuel Gas Systems for Welding, Cutting, and Allied Processes,* National Fire Protection Association, latest edition, for information on manifold and piping systems.)

Piping and fittings for acetylene and methyl-acetylene-propadiene (MPS) manifolds must not be unalloyed copper or alloys containing 70% or more copper. These fuel gases react with copper under certain conditions to form unstable copper acetylide. This compound may detonate under shock or heat.

Manifolded piping systems must contain an appropriate over-pressure relief valve. Each fuel gas cylinder lead should incorporate a backflow check valve and a flash arrester. Backflow check valves must also be installed in each line at each station outlet where both fuel gas and oxygen are provided for a welding, cutting, or preheating torch.

Piping Systems. Unless it is known that a piping system is specifically designed and constructed to withstand the full cylinder pressure or tank pressure of the compressed gas source supplying it, the piping system must always be protected with safety pressure-relief devices sufficient to prevent development of pressure in the system beyond the capacity of the weakest element.

Such pressure-relief devices may be relief valves or bursting disks. A pressure-reducing regulator must never be solely relied upon to prevent overpressurization of the system. A pressure-relief device must be located in every section of the system which could be exposed to the full source supply pressure while isolated from other protective relief devices (such as by a closed valve).

Some pressure regulators have integral safety relief valves. These valves are designed for the protection of the regulator only and should not be relied upon to protect the downstream system.

In cryogenic piping systems, relief devices should be located in every section of the system where liquified gas may become trapped. Upon warming, such liquids vaporize to gas, and in a confined space, the gas pressure can increase dramatically.

Pressure-relief devices protecting fuel gas piping systems or other hazardous gas systems should be vented to safe locations.

Oxygen

Oxygen is nonflammable, but it supports the combustion of flammable materials. It can initiate combustion and vigorously accelerate it. Therefore, oxygen cylinders and liquid oxygen containers should not be stored in the vicinity of combustibles nor with cylinders of fuel gas. Oxygen should never be used as a substitute for compressed air. Pure oxygen

supports combustion more vigorously than air, which contains only 20% O. Therefore, the identification of oxygen and air should be differentiated.

Oil, grease, and combustible dusts may spontaneously ignite on contact with oxygen. Hence, all systems and apparatus for oxygen service must be kept free of any combustibles. Valves, piping, or system components that have not been expressly manufactured for oxygen service must be cleaned and approved for this service before use. (Refer to G4.1, *Cleaning Equipment for Oxygen Service,* Compressed Gas Association.)

Apparatus that has been manufactured expressly for oxygen service, and is usually so labeled, must be kept in the clean condition as originally received. Oxygen valves, regulators, and apparatus should never be lubricated with oil. If lubrication is required, the type of lubricant and the method of applying the lubricant should be specified in the manufacturer's literature. If it is not, then the device should be returned to the manufacturer or authorized representative for service.

Oxygen must never be used to power compressed air tools. These are almost always lubricated with oil. Similarly, oxygen must not be used to blow dirt from work and clothing because they are often contaminated with oil, or grease, or combustible dust.

Only clean clothing should be worn when working with oxygen systems. Oxygen must not be used to ventilate confined spaces. Severe bums may result from ignition of clothing or the hair in an oxygen-rich atmosphere.

Fuel Gases

Fuel gases commonly used in oxyfuel gas welding (OFW) and cutting (OFC) are acetylene, methylacetylene-propadiene (MPS), natural gas, propane, and propylene. Hydrogen is used in a few applications. Gasoline is sometimes used as a fuel for oxygen cutting. It vaporizes in the torch. These gases should always be referred to by name.

Acetylene in cylinders is dissolved in a solvent so that it can be safely stored under pressure. In the free state, acetylene should never be used at pressures over 15 psig (100 kPa) because it can dissociate with explosive violence at higher pressures.

Acetylene and MPS should never be used in contact with silver, mercury, or alloys containing 70% or more copper. These gases react with these metals to form unstable compounds that may detonate under shock or heat. Valves on fuel gas cylinders should never be opened to clean the valve outlet, especially not near possible sources of flame ignition or in confined spaces.

When fuel gases are used for a brazing furnace atmosphere, they must be burned or vented to a safe location. Prior to filling a furnace or retort with fuel gas, the equipment must first be purged with a nonflammable gas, such as nitrogen or argon, to prevent formation of an explosive air-fuel mixture.

Special attention must be given when using hydrogen. Flames of hydrogen may be difficult to see and parts of the body, clothes, or combustibles may come in contact with hydrogen flames.

Fuel Gas Fires. The best procedures for avoiding fire from a fuel gas or liquid is to keep it contained within the system, that is, to prevent leaks. All fuel systems should be checked carefully for leaks upon assembly and at frequent intervals thereafter. Fuel gas cylinders should be examined for leaks, especially at fuse plugs, safety devices, and valve packing. One common source of fire in welding and cutting is ignition of leaking fuel by flying sparks or spatter.

In the event of a fuel fire, one of the most effective means for controlling the fire is to shut off the fuel valve, if accessible. A fuel gas valve should not be opened beyond the point necessary to provide adequate flow. In this way it can be shut off quickly in an emergency. In most cases, this is less than one turn of the handle. If the immediate valve controlling the burning gas is inaccessible, another upstream valve may cut off the flow of gas.

Most fuel gases in cylinders are in liquid form or dissolved in liquids. Therefore, the cylinders should always be used in the upright position to prevent liquid surges into the system.

A fuel gas cylinder can develop a leak and sometimes result in a fire. In case of fire, the fire alarm should be sounded, and trained fire personnel should be summoned immediately. A small fire in the vicinity of a cylinder valve or a safety device

should be extinguished, if possible, by closing the valve or by the use of water, wet cloths, or fire extinguishers. If the leak cannot be stopped, the cylinder should be removed by trained fire personnel to a safe outdoor location, and the supplier notified. A warning sign should be posted, and no smoking or other ignition sources should be permitted in the area.

In the case of a large fire at a fuel gas cylinder, the fire alarm should be actuated, and all personnel should be evacuated from the area. The cylinder should be kept wet by fire personnel with a heavy stream of water to keep it cool. It is usually better to allow the fire to continue to burn and consume the issuing gas rather than attempt to extinguish the flame. If the fire is extinguished, there is danger that the escaping gas may reignite with explosive violence.

Shielding Gases

Argon, helium, nitrogen, and carbon dioxide (CO_2) are used for shielding with some welding processes. All, except carbon dioxide, are used as brazing atmospheres. They are odorless and colorless and can displace air needed for breathing.

Confined spaces filled with these gases must be well ventilated before personnel enter them. If there is any question, the space should be checked first for adequate oxygen concentration with an oxygen analyzer. If an analyzer is not available, an air-supplied respirator should be worn by anyone entering the space. Containers of these gases should not be placed in confined spaces, as discussed previously.

Safe Practices*

American Welding Society

Electrical Safety

Electric Shock

Electric shock can cause sudden death. Injuries and fatalities from electric shock in welding and cutting operations can occur if proper precautionary measures are not followed. Most welding and cutting operations employ some type of electrical equipment. For example, automatic oxyfuel gas cutting machines use electric motor drives, controls, and systems.

Some electrical accidents may not be avoidable, such as those caused by lightning. However, the majority are avoidable, including those caused by lack of proper training.

Shock Mechanism. Electric shock occurs when an electric current of sufficient magnitude to create an adverse effect passes through the body. The severity of the shock depends mainly on the amount of current, the duration of flow, the path of flow, and the state of health of the person. The current is caused to flow by the applied voltage. The amount of current depends upon the applied voltage and the resistance of the body path. The frequency of the current may also be a factor when alternating current is involved.

Shock currents greater than about 6 milliamperes (mA) are considered primary because they are capable of causing direct physiological harm. Steady state currents between 0.5 and 6 mA are considered secondary shock currents. Secondary shock currents are defined as those capable of causing involuntary muscular reactions without normally causing direct physiological harm. The 0.5 mA level is called the perception threshold because it is the point at which most people just begin to feel the tingle from the current. The level of current sensation varies with the weight of the individual and to some extent between men and women.

Shock Sources. Most electrical equipment can be shock hazards if improperly installed, used, or maintained. Shock can occur from lightning-induced voltage surges in power distribution systems. Even earth grounds can attain high potential relative to true ground during severe transient phenomena. Such circumstances, however, are rare.

In welding and cutting work, most electrical equipment is powered from ac sources of between 115 and 575 V, or by engine-driven generators. Most welding is done with less than 100 arc volts. (Fatalities have resulted with equipment

operating at less than 80 volts.) Some arc cutting methods operate at over 400 V, and electron-beam welding machines at up to about 150 kV. Most electric shock in the welding industry occurs as the result of accidental contact with bare or poorly insulated conductors operating at such voltages. Therefore, welders must take precautions against contacting bare elements in the welding circuit, as well as those in the primary circuits.

Electrical resistance is usually reduced in the presence of water or moisture. Electrical hazards are often more severe under such circumstances. When arc welding or cutting is to be done under damp or wet conditions including heavy perspiration, the welder must wear dry gloves and clothing in good condition to prevent electric shock. The welder should be protected from electrically conductive surfaces, including the earth, by rubber-soled shoes as a minimum and preferably by an insulating layer such as a rubber mat or dry wooden board. Similar precautions against accidental contact with bare conducting surfaces must be taken when the welder is required to work in a cramped kneeling, sitting, or lying position. Rings and jewelry should be removed before welding to decrease the possibility of electric shock.

Wearers of Pacemakers

The technology of heart pacemakers and the extent to which they are influenced by other electrical devices is constantly changing. It is impossible to make a general statement concerning the possible effects of welding operations on such devices. Wearers of pacemakers or other electronic equipment vital to life should check with the device manufacturer or their doctor to determine whether any hazard exists.

Equipment Selection

Electric shock hazards are minimized by proper equipment installation and maintenance, good operator practice, proper operator clothing and body protection, and the use of equipment designed for the job and situation. Equipment should meet applicable NEMA or ANSI standards, such as American National Standards Institute's ANSI/UL 551, *Safety Standard for Transformer Type Arc Welding Machines,* latest edition.

If a significant amount of welding and cutting work is to be done under electrically hazardous conditions, automatic machine controls that reduce the no-load (open circuit) voltage to a safe level are recommended. When special welding and cutting processes require open-circuit voltages higher than those specified in ANSI/NEMA publication EW-1, *Electrical Arc Welding Apparatus,* insulation and operating procedures that are adequate to protect the welder from these higher voltages must be provided.

Personnel Training

A good safety training program is essential. Employees must be fully instructed in electrical safety by a competent person before being allowed to commence operations. As a minimum, this training should include the points covered in ANSI/ASC Z49.1, *Safety in Welding and Cutting* (published by the American Welding Society). Persons should not be allowed to operate electrical equipment until they have been properly trained.

Equipment Installation

Equipment should be installed in a clean, dry area. When this is not possible, it should be adequately guarded from dirt and moisture. Installation must be done to the requirements of ANSI/NFPA 70, *National Electric Code,* and local codes. This includes necessary disconnects, fusing, and type of incoming power lines.

Terminals for welding leads and power cables must be shielded from accidental contact by personnel or by metal objects, such as vehicles and cranes. Connections between welding leads and power supplies may be guarded using (1) dead front construction and receptacles for plug connections, (2) terminals located in a recessed opening or under a non-removable hinged cover, (3) insulating sleeves, or (4) other equivalent mechanical means.

Grounding

The workpiece being welded and the frame or chassis of all electrically powered machines must be connected to a good electrical ground. Grounding can be done by locating the workpiece or machine on a grounded metal floor or platen, or by connecting it to a properly grounded building frame or other satisfactory ground. Chains, wire ropes, cranes, hoists, and elevators must not be used as grounding connectors nor to carry welding current.

The work lead is not the grounding lead. The work lead connects the work terminal on the power source to the workpiece. A separate lead is required to ground the workpiece or power source work terminal.

Care should be taken when connecting the grounding circuit. Otherwise, the welding current may flow through a connection intended only for grounding and may be of higher magnitude than the grounding conductor can safely carry. Special radio-frequency grounding may be necessary for arc welding machines equipped with high-frequency arc initiating devices. (See EW-1, *Electric Arc Welding Power Sources,* Section 10.5.6, National Electrical Manufacturers Association.)

Connections for portable control devices, such as push buttons to be carried by the operator, must not be connected to circuits with operating voltages above about 120 V. Exposed metal parts of portable control devices operating on circuits above 50 V must be grounded by a grounding conductor in the control cable. Controls using intrinsically safe voltages below 30 V are recommended.

Cables and Connections

Electrical connections must be tight and checked periodically for tightness. Magnetic work clamps must be free of adherent metal particles and spatter on contact surfaces. Coiled welding leads should be spread out before use to avoid overheating and damage to the insulation. Jobs alternately requiring long and short leads should be equipped with insulated cable connectors so that idle lengths can be disconnected when not needed.

Equipment, cables, fuses, plugs, and receptacles must be used within their current carrying and duty cycle capacities. Operation of apparatus above the current rating or the duty cycle results in overheating and rapid deterioration of insulation and other parts. Actual welding current may be higher than that shown by indicators on the welding machine if welding is done with short leads or low voltage, or both. High currents are likely with general-purpose welding machines when they are used with processes that use low arc voltage, such as gas-tungsten arc welding.

Welding leads should be the flexible type of cable designed especially for the rigors of welding service. Insulation on cables used with high voltages or high-frequency oscillators must provide adequate protection. The recommendations and precautions of the cable manufacturer should always be followed. Cable insulation must be kept in good condition, and cables repaired or replaced promptly when necessary.

Operations

Welders should not allow the metal parts of electrodes, electrode holders, or torches to touch their bare skin or any wet covering of the body. Dry gloves in good condition must always be worn. The insulation on electrode holders must be kept in good repair. Electrode holders should not be cooled by immersion in water. If water-cooled welding guns or holders are used, they should be free of water leaks and condensation that would adversely affect the welder's safety. Welders should not drape nor coil the welding leads around their bodies.

A welding circuit must be de-energized to avoid electric shock while the electrode, torch, or gun is being changed or adjusted. One exception concerns covered electrodes with shielded metal arc welding. When the circuit is energized, covered electrodes must be changed with dry welding gloves, not with bare hands. In any case, de-energization of the circuit is desirable for optimum safety even with covered electrodes.

When a welder has completed the work or has occasion to leave the work station for an appreciable time, the welding machine should be turned off. Similarly, when the machine is to be moved, the input power supply should be electrically disconnected at the source. When equipment is not in use, exposed electrodes should be removed from the holder to eliminate the danger of accidental electrical contact with persons or conducting objects. Also, welding guns of semi-automatic welding equipment should be placed so that the gun switch cannot be operated accidently.

Multiple Arc Welding Operations

There can be increased danger of electrical shock when several welders are welding on a large metal structure, such as a building frame or ship, and the structure is part of the return welding circuits. Proper electrical contact must exist at all joints in the structure. Sparking or heating at any point in the structure makes it unsuitable as a return circuit.

Where two or more welders are working on the same structure and one is likely to touch simultaneously the exposed parts of more than one electrode holder, the welding machines must be connected to minimize shock hazard. It is preferable that all dc welding machines be connected with the same polarity. A test lamp or voltmeter can be used to determine whether the polarities are matched. It is preferable to connect all single-phase ac welding machines to the same phase of the supply circuit with the same instantaneous polarity. These precautions minimize the potential difference between electrode holders.

In some cases, the preferable connections may not be possible. Welding may require the use of both dc polarities, or supply circuit limitations may require distribution of ac welding machines among the phases of the supply circuit. In such cases, the no-load voltage between electrode holders or welding guns may be twice the normal voltage. Because of the increased voltage, the welders and other area personnel must be instructed to avoid simultaneous contact with more than one electrode holder, welding gun, or installed electrode.

Modification and Maintenance

Only qualified personnel should perform equipment modification and maintenance. Commutators on rotating welding machines should be kept clean to prevent excessive arcing. Rectifier-type welding machines should be inspected frequently for accumulations of dust or lint that interfere with ventilation. Louvers and internal electrical coil ventilating ducts should be similarly inspected. It is good practice to occasionally blow out the welding machine with clean, dry compressed air at low pressure. Adequate safety precautions such as proper eye protection should be taken. Air filters in the ventilating systems of electrical components are not recommended unless provided by the manufacturer of the welding machine. The filters should be inspected as recommended by the manufacturer. The reduction of air flow resulting from the accumulation of dust on the air filter can subject internal components to an overheating condition and subsequent failure. Machines that have become wet should be thoroughly dried and properly retested before being used.

Prevention of Fires

Fires resulting from electric welding equipment are generally caused by overheating of electrical components, flying sparks or spatter from the welding or cutting operation, or mishandling of fuel in engine-driven equipment. Most precautions against electrical shock are also applicable to the prevention of fires caused by overheating of the equipment. Avoidance of fire from sparks and spatter was covered previously in this article.

The fuel systems of engine-driven equipment must be in good condition. Leaks must be repaired promptly. Engine-driven machines must be turned off before refueling, and any fuel spills should be wiped up and fumes allowed to dissipate before the engine is restarted. Otherwise, the ignition system, electrical controls, spark producing components, or engine heat may start a fire.

Safe Practices*

American Welding Society

Processes

The broad areas of welding safety that are applicable to most welding, cutting, brazing, or soldering processes have been addressed previously in this article. The precautions and procedures that are unique to the particular processes are discussed here. All applicable information must be considered to provide complete safety precautions and procedures for each process.

Oxyfuel Gas Welding and Cutting

Torches. Only approved welding and cutting torches should be used. Oxyfuel gas torches should meet the requirements of E-5, *Torch Standard for Welding and Cutting,* Compressed Gas Association, and appropriate government regulations. They should be kept in good working order and should be serviced at regular intervals by the manufacturer or qualified technicians. A torch must be used only with the fuel gas for which it is designed. The fuel gas and oxygen pressures should be those recommended by the torch manufacturer.

The procedures recommended by the manufacturer should be followed when lighting and extinguishing the torch. The torch should be lighted only with a friction lighter, pilot light, or similar ignition source. Matches or cigarette lighters should not be used.

Hoses. Hoses used should be only those specified for oxyfuel gas welding and cutting systems. Generally, these hoses are manufactured in accordance with *Specification 1P-7 for Rubber Welding Hose,* published by the Compressed Gas Association and the Rubber Manufacturer's Association. Fuel gas hose is usually red with left-hand threaded fittings. Green hose with right-hand threaded fittings is generally used for oxygen. Hose connections must comply with E-l, *Standard Connections for Regulators, Torches and Fitted Hose for Welding and Cutting Equipment*, Compressed Gas Association. Hoses should be free of oil and grease, and in good condition. When parallel lengths are strapped together for convenience, no more than 100 mm (4 in.) of any 300 mm (12 in.) section of hose should be covered.

Only proper ferrules and clamps should be used to secure hose to fittings. Long runs of hose should be avoided. Excess hose should be coiled to prevent kinks and tangles, but it should not be wrapped around cylinders or cylinder carts while in use.

Backfire and Flashback. A backfire during welding and cutting is a momentary retrogression of the flame back into the tip. It usually results in a momentary flame-out followed by reignition of the normal tip flame and is accompanied by a pop or bang, depending upon the size of the tip. In severe cases, the hot combustion products within the tip may be forced back into the torch and even the hoses. Occasionally (but especially with oxygen), such backfires ignite the inner liner of the hose and result in burn-through of the hose wall. Such backfires can cause injury. Furthermore, when the hose ruptures, the flow of gases into the area is continuous until the valve at the tank is closed.

A flashback is an occurrence initiated by a backfire where the flame continues to burn inside the equipment instead of being re-established at the tip. Flashbacks result in very rapid internal heating of the equipment and can quickly destroy it. A flashback is usually recognized by a whistling or squealing sound. The equipment will heat up rapidly and sparks may issue from the tip. The flashback should be extinguished by turning off the torch valves as quickly as possible. Different manufacturers may recommend shutting off either the fuel or oxygen first, but the most important concern is to get both valves closed quickly.

Backfires and flashbacks are not ordinarily a concern if the apparatus is operated in accordance with the manufacturer's instructions. Generally, they occur from allowing a tip to become overheated by flame backwash, forcing the tip into the work, or providing insufficient gas flow for the size of the tip. If frequent backfiring or flashbacks are experienced, the cause should be investigated. There is probably something wrong with the equipment or operation.

To prevent backfires and flashbacks, hose lines should be purged before lighting oxyfuel gas equipment. Purging flushes out any combustible oxygen-fuel or air-fuel gas mixtures in the hoses. It is done by first opening either the fuel or oxygen valve on the torch and allowing that gas to flow for several seconds to clear that hose of any possible gas mixtures. That valve is then closed, and the other valve is opened to allow the other gas to flow for a similar period of time. Purging should always be done before any welding or cutting tip is lighted. The purge stream must not be directed toward any flame or source of ignition. Torches should not be purged in confined spaces because of possible explosion of accumulated gases.

Hose Line Safety Devices. Reverse-flow check valves and flashback arresters for hose line service are available. These devices can prevent backflow of gases and flashbacks into hoses provided they are operating properly. They must be used strictly in accordance with the manufacturer's instructions and maintained regularly in accordance with the manufacturer's recommendations.

Shutdown Procedures. When oxyfuel gas operations are completed, the equipment should always be completely shut down and the gas pressures drained from the system. Cylinder supply valves must be closed. The equipment should not be left unattended until the shutdown has been completed.

Ventilated Storage. Oxyfuel gas cylinders or equipment connected to cylinders must always be stored in well-ventilated spaces and should not be stored in confined areas or unventilated cabinets. Even small gas leaks in confined spaces can result in explosive mixtures that might be ignited with disastrous results. For the same reason, oxygen gas cylinders should never be transported in enclosed vehicles, particularly not in closed vans or the trunks of automobiles.

Arc Welding and Cutting

The potential hazards of arc welding are fumes and gases, electric shock, infrared and ultraviolet radiation, burns, fire, explosion, and sometimes noise. These hazards have been described previously. Precautions to avoid injury or death from these hazards must be followed. The safety precautions for arc welding also apply to arc cutting.

Noise during arc cutting operations can be high. Prolonged exposure to high noise levels can lead to hearing damage. Where necessary, ear protection must be provided for the operator and others in the area.

Plasma arc cutting is a particularly noisy and a high fume generating process. Two common accessories are available for mechanized plasma arc cutting of plate to aid in fume and noise control. One accessory is a water table, which is simply a cutting table filled with water to the bottom surface of the plate or above the plate. In the latter case, cutting is done under water using a special torch to minimize noise and reduce radiation. The high-speed gases emerging from the plasma jet produce turbulence in the water. This action traps almost all of the fume particles in the water.

Another accessory is a water muffler to reduce noise. The muffler is a nozzle attached to a special torch body that produces a curtain of water around the front of the torch. It is always used in conjunction with a water table. The combination of a water curtain at the top of the plate and a water table contacting the bottom of the plate encloses the arc in a noise-reducing shield. The noise output is reduced by roughly 20 dB. This equipment should not be confused with cutting variations using water injection or water shielding.

Resistance Welding

The main hazards of resistance welding processes and equipment are:

- ELECTRIC SHOCK FROM CONTACT WITH HIGH-VOLTAGE TERMINALS OR COMPONENTS
- EJECTION OF SMALL PARTICLES OF MOLTEN METAL FROM THE WELD
- CRUSHING OF SOME PART OF THE BODY BETWEEN THE ELECTRODES OR OTHER MOVING COMPONENTS OF THE MACHINE

Guarding. Initiating devices on resistance welding equipment, such as push buttons and switches, must be positioned or guarded to prevent the operator from inadvertently activating them.

With some machines, the operator's hands can be expected to pass under the point of operation during loading and unloading. These machines must be effectively guarded by proximity-sensing devices, latches, blocks, barriers, dual hand controls, or similar accessories that prevent (1) the hands from passing under the point of operations or (2) the ram from moving while the hands are under the point of operation.

Static Safety Devices. Press, flash, and upset welding machines should have static safety devices to prevent movement of the platen or head during maintenance or setup for welding. Pins, blocks, and latches are examples of such devices.

Portable Welding Machines. The support system of suspended portable welding gun equipment, with the exception of the gun assembly, must be capable of withstanding the total mechanical shock load in the event of failure of any component of the system. Devices such as cables, chains, or clamps are considered satisfactory.

Guarding should be provided around the mounting and actuating mechanism of the movable arm of a portable welding gun if it can cause injury to the operator's hands. If suitable guarding cannot be achieved, the gun should have two handles and two operating switches that must be actuated to energize the machine.

Stop Buttons. One or more emergency stop buttons should be provided on all welding machines, with a minimum of one at each operator position.

Guards. Eye protection against expelled metal particles must be provided by a guard of suitable fire-resistant material or by the use of approved personal protective eye wear. For flash welding equipment, flash guards of suitable fire-resistant material must be provided to control flying sparks and molten metal.

Electrical Considerations. All external welds initiating control circuits should operate at a maximum of about 120 V for stationary equipment and about 36 V for portable equipment.

Resistance welding equipment containing high-voltage capacitors must have adequate electrical insulation and must be completely enclosed. All enclosure doors must be provided with suitable interlocks that are wired into the control circuit. The interlocks must effectively interrupt power and discharge all high-voltage capacitors when the door or panel is open. In addition, a manually operated switch or suitable positive device should be provided to ensure complete discharge of all high-voltage capacitors. The doors or panels must be kept locked except during maintenance.

The welding transformer secondary should be grounded by one of the following methods:

- PERMANENT GROUNDING OF THE WELDING SECONDARY CIRCUIT
- CONNECTION OF A GROUNDING REACTOR ACROSS THE SECONDARY WINDING WITH A REACTOR TAP TO GROUND

As an alternative on stationary machines, an isolation contactor may be used to open all of the primary lines.

The grounding of one side of the secondary windings on multiple spot welding machines can cause undesirable transient currents to flow between the transformers when they are connected to different primary phases or have different secondary voltages, or both. A similar condition can also exist with portable spot welding guns when several units are used to weld the same assembly or another one that is nearby. Such situations require use of a grounding reactor or isolation contactor.

Installation. All equipment should be installed in conformance with the ANSI/NFPA 70, *National Electric Code* (latest edition). The equipment should be installed by qualified personnel under the direction of a competent technical supervisor. Prior to production use, the equipment should be inspected by competent safety personnel to ensure that it is safe to operate.

Brazing and Soldering

Hazards encountered with brazing and soldering operations are similar to those associated with welding and cutting processes. Brazing and soldering operations may be done at temperatures where some elements in the filler metal will vaporize. Personnel and property must be protected against hot materials, gases, fumes, electrical shock, radiation, and chemicals.

It is essential that adequate ventilation be provided so that personnel do not inhale gases and fumes generated during brazing or soldering. Some filler metals and base metals contain toxic materials such as cadmium, beryllium, zinc, mercury, or lead that vaporize during brazing. Fluxes contain chemical compounds of fluorine, chlorine, and boron that are harmful if they are inhaled or contact the eyes or skin. Suitable ventilation to avoid these hazards was described previously.

Brazing Atmospheres. Flammable gases are sometimes used as atmospheres for furnace brazing operations. These include combusted fuel gas, hydrogen, and dissociated ammonia. Prior to introducing such atmospheres, the furnace or retort must be purged of air by safe procedures recommended by the furnace manufacturer.

Adequate area ventilation must be provided to exhaust and discharge to a safe place explosive or toxic gases that may emanate from furnace purging and brazing operations. Local environmental regulations should be consulted when designing the exhaust system.

Dip Brazing and Soldering. In dip brazing and soldering, the parts to be immersed in the bath must be completely dry. The presence of moisture on the parts will cause an instantaneous generation of steam that may expel the contents of the dip pot with explosive force and create a serious burn hazard. Predrying of the parts will prevent this problem. If supplementary flux is necessary, it must be adequately dried to remove not only moisture but also water of hydration to avoid explosion hazards.

Solder Flux. Some fluxes, such as the rosin, petrolatum, and reaction types, give off considerable smoke, the amount depending on the soldering temperature and the duration of heating. The American Conference of Governmental Industrial Hygienists has established a safe threshold limit value for decomposition products of rosin core solder of 0.1

mg/m^3 (4×10^{-5} gr/ft^3) aliphatic aldehydes, measured as formaldehyde. Suitable ventilation must be provided for soldering operations to meet this requirement.

Other fluxes give off fumes that are harmful if breathed in any but small quantities. Prolonged inhalation of halides and some of the newer organic fluxes should be avoided. The aniline type fluxes and some of the amines also evolve fumes that are harmful and can cause dermatitis. Fluorine in flux can be dangerous to health, cause burns, and be fatal if ingested. Thus, proper ventilation must be provided in the work area to remove fume from soldering operations.

High-Frequency Welding

High-frequency generators are electrical devices and require all usual safety precautions in handling and repairing such equipment. Voltages are in the range from 400 to 20,000 V and are lethal. These voltages may be either low or high frequency. Proper care and safety precautions should be taken while working on high-frequency generators and their control systems. Units must be equipped with safety interlocks on access doors and with automatic safety grounding devices to prevent operation of the equipment when access doors are open. The equipment should not be operated with panels or high-voltage covers removed nor with interlocks and grounding devices blocked. This equipment should not be confused with high-frequency arc stabilization equipment used in GTAW.

The output high-frequency primary leads should be encased in metal ducting and should not be operated in the open. Induction coils and contact systems should always be properly grounded for operator protection. High-frequency currents are more difficult to ground than low-frequency currents, and grounding lines must be kept short and direct to minimize inductive impedance. The magnetic field from the output system must not induce heat in adjacent metallic sections and cause fires or burns.

The injuries from high-frequency power, especially at the upper range of welding frequencies, tend to produce severe local surface tissue damage. However, they are not likely to be fatal because current flow is shallow.

High-frequency welding stations often emit a loud steady whine that can cause permanent hearing loss. Ear protection is essential under these circumstances.

Electron-Beam Welding

The primary hazards associated with electron-beam welding equipment are electric shock, x-radiation, fumes and gases, and damaging visible radiation. Precautionary measures must be taken at all times to ensure that proper protective procedures are always observed. AWS F2.1, *Recommended Safe Practices for Electron Beam Welding and Cutting* and ANSI/ASC Z49.1, *Safety in Welding and Cutting* (latest edition) give the general safety requirements that should be strictly adhered to at all times.

Electric Shock. Every electron-beam welding machine operates at voltages above 20 kV. These voltages can cause fatal injury, regardless of whether the machine is referred to as a low-voltage or a high-voltage machine. The manufacturers of electron-beam welding equipment, in meeting various regulatory requirements, produce machines that are well-insulated against high voltage. However, precautions should be exercised with all systems when high voltage is present. The manufacturer's instructions should be followed for operation and maintenance of the equipment.

X-rays. The x-rays generated by an electron-beam welding machine are produced when electrons, traveling at high velocity, collide with matter. The majority of x-rays are produced when the electron beam impinges upon the workpiece. Substantial amounts are also produced when the beam strikes gas molecules or metal vapor in the gun column and work chamber. Underwriters Laboratories and OSHA regulations have established firm rules for permissible x-ray exposure levels, and producers and users of equipment must observe these rules.

Generally, the steel walls of the chamber are adequate protection in systems up to 60 kV, assuming proper design. High-voltage machines utilize lead lining to block x-ray emission beyond the chamber walls. Leaded glass windows are employed in both high- and low-voltage electron-beam systems. Generally, the shielded vacuum chamber walls provide adequate protection for the operator.

In the case of nonvacuum systems, a radiation enclosure must be provided to ensure the safety of the operator and other persons in the area. Thick walls of high-density concrete or other similar material may be employed in place of lead, especially for large radiation enclosures on nonvacuum installations. In addition, special safety precautions should be

imposed to prevent personnel from accidently entering or being trapped inside the enclosure when equipment is in operation.

A complete x-ray radiation survey of the electron-beam equipment should always be made at the time of installation and at regular intervals thereafter. This should be done by personnel trained to make a proper radiation survey to ensure initial and continued compliance with all radiation regulations and standards applicable to the site where the equipment is installed.

Fumes and Gases. It is unlikely that the very small amount of air in a high-vacuum electron-beam chamber would be sufficient to produce ozone and oxides of nitrogen in harmful concentrations. However, nonvacuum and medium-vacuum electron-beam systems are capable of producing these by-products, as well as other types of airborne contaminants in concentrations above acceptable levels.

Adequate area ventilation must be employed to reduce concentrations of airborne contaminants around the equipment within permissible exposure limits. Proper exhausting techniques should be employed to maintain residual concentrations in the enclosure within those limits.

Visible Radiation. Direct viewing of intense radiation emitted by molten weld metal can be harmful to eyesight. Viewing of the welding operation should be done through a filter lens commonly used for arc welding.

Laser-Beam Welding and Cutting

The basic hazards associated with laser operation are:

- EYE DAMAGE FROM THE BEAM INCLUDING BURNS OF THE CORNEA OR RETINA, OR BOTH
- SKIN BURNS FROM THE BEAM
- RESPIRATORY SYSTEM DAMAGE FROM HAZARDOUS MATERIALS EVOLVED DURING OPERATION
- ELECTRICAL SHOCK
- CHEMICAL HAZARDS
- CONTACT WITH CRYOGENIC COOLANTS

Laser manufacturers are required to qualify their equipment with the U.S. Bureau of Radiological Health (BRH). Electrical components should be in compliance with NEMA standards. User action is governed by OSHA requirements. In all cases, American National Standard Z136.1, *Safe Use of Lasers* (latest edition), should be followed.

Eye Protection. Eye injury is readily caused by laser beams. With laser beams operating at visible or near infrared wavelengths, even a 5 mW beam can inflict retinal damage. Safety glasses are available that are substantially transparent to visible light but are opaque to specific laser beam outputs. Selective filters for ruby, Nd:YAG, and other laser systems are available. Glasses appropriate to the specific laser system must be used. At longer infrared wavelengths (such as that of a CO_2 laser), ordinarily transparent materials such as glass are opaque. Clear safety glasses with side shields may be used with these systems, and the only light reaching the eye will be from incandescence of the workpiece. Nevertheless, extreme brilliance can result if a plasma is generated at high power and, filter lenses should then be used for viewing the operation.

Burns. Laser burns can be deep and very slow to heal. Exposure must be avoided by appropriate enclosure of the beam or by methods that prevent beam operation unless the beam path is unobstructed. This is particularly important for nonvisible beams that provide no external evidence of their existence unless intercepted by a solid.

Electric Shock. High voltages as well as large capacitor storage devices are associated with lasers. Therefore, the possibility for lethal electrical shock is always present. Electrical system enclosures should have appropriate interlocks on all access doors and provisions for discharging capacitor banks before entry. The equipment should be appropriately grounded.

Fumes and Gases. Hazardous products may be generated from interaction of the beam and the workpiece. For example, plastic materials used for "burn patterns" to identify beam shape and distribution in high-power CO_2 laser systems can generate highly toxic vapors if irradiated in an oxygen-lean atmosphere.

In deep-penetration welding, fine metal fume can arise from the joint. Also, intense plasma generation can produce ozone. Consequently, adequate ventilation and exhaust provisions for laser work areas are necessary.

Friction Welding

Friction welding machines are similar to machine tool lathes in that one workpiece is rotated by a drive system. They are also similar to hydraulic presses in that one workpiece is forced against the other. Therefore, safe practices for lathes and power presses should be used as guides for the design and operation of friction welding machines.

Machines should be equipped with appropriate mechanical guards and shields as well as two-hand operating switches and electrical interlocks. These devices should be designed to prevent operation of the machine when the work area, rotating drive, and force system are accessible to the operator or others.

Operating personnel should wear appropriate eye protection and safety apparel commonly used with machine tool operations. In any case, applicable Occupational Safety and Health Administration (OSHA) standards should be strictly observed.

Explosion Welding

Explosives and explosive devices are a part of explosion welding. Such materials and devices are inherently dangerous, but there are safe methods for handling them. However, if the materials are misused, they can kill or injure, and destroy or damage property.

Explosive materials should be handled and used only by trained personnel who are experienced in that field. Handling and safety procedures must comply with all applicable federal, state, and local regulations. Federal jurisdiction on the sale, transport, storage, and use of explosives is through the U.S. Bureau of Alcohol, Tobacco, and Firearms; the Hazardous Materials Regulation Board of the U.S. Department of Transportation; the Occupational Safety and Health Administration; and the Environmental Protection Agency. Many states and local governments require a blasting license or permit, and some cities have special explosive requirements.

The Institute of Makers of Explosives provides educational publications to promote the safe handling, storage, and use of explosives. The National Fire Protection Association provides recommendations for safe manufacture, storage, handling, and use of explosives. (See ANSI/NFPA 495, *Manufacture, Transportation, Storage, and Use of Explosive Materials,* American National Standards Institute, latest edition.)

Ultrasonic Welding

With high-power ultrasonic equipment, high voltages are present in the frequency converter, the welding head, and the coaxial cable connecting these components. Consequently, the equipment should not be operated with the panel doors open or housing covers removed. Door interlocks are usually installed to prevent introduction of power to the equipment when the high-voltage circuitry is exposed. The cables are shielded fully and present no hazard when properly connected and maintained.

Because of hazards associated with application of clamping force, the operator should not place hands or arms in the vicinity of the welding tip when the equipment is energized. For manual operation, the equipment should be activated by dual palm buttons that meet the requirements of OSHA. Both buttons must be pressed simultaneously to actuate a weld cycle, and both must be released before the next cycle is initiated. For automated systems in which the weld cycle is sequenced with other operations, guards should be installed for operator protection. Such hazards can be further minimized by setting the welding stroke to the minimum that is compatible with workpiece clearance.

Thermite Welding

Thermite mix, in the crucible or on the workpieces, can lead to rapid formation of steam when the chemical reaction for thermite welding takes place. This may cause ejection of molten metal from the crucible. Therefore, the thermite mix

should be stored in a dry place, the crucible should be dry, and moisture should not be allowed to enter the system before or during welding.

The work area should be free of combustible materials that may be ignited by sparks or small particles of molten metal. The area should be well ventilated to avoid the buildup of fumes and gases from the reaction. Starting powders and rods should be protected against accidental ignition.

Personnel should wear appropriate protection against hot particles or sparks. This includes full face shields with filter lenses for eye protection and headgear. Safety boots are recommended to protect the feet from hot sparks. Clothing should not have pockets or cuffs that might catch hot particles.

Preheating should be done using the safety precautions applicable to oxyfuel gas equipment and operations.

Thermal Spraying

The potential hazards to the health and safety of personnel involved in thermal spraying operations and to persons in the immediate vicinity are:

- ELECTRICAL SHOCK
- FIRE
- FUMES AND GASES
- DUST
- ARC RADIATION
- NOISE

These hazards are not unique to thermal spraying methods. For example, flame spraying has hazards similar to those associated with the oxyfuel gas welding and cutting processes. Likewise, arc spraying and plasma spraying are similar in many respects to gas metal arc and plasma arc welding, respectively. Safe practices for these processes should be followed when thermal spraying with similar equipment. However, thermal spraying does generate dust and fumes to a greater degree. Additional information may be found in *Thermal Spraying: Practice, Theory, and Application,* American Welding Society, 1985.

Fire Prevention. Airborne finely divided solids, especially metal dusts, must be treated as explosives. To minimize danger from dust explosions, spray booths must have adequate ventilation.

A wet collector of the water-wash type is recommended to collect the spray dust. Bag or filter-type collectors are not recommended. Good housekeeping in the work area should be maintained to avoid accumulation of metal dusts, particularly on rafters, tops of booths, and in floor cracks.

Paper, wood, oily rags, and other combustibles in the spraying area can cause a fire and should be removed before the equipment is operated.

Protection of Personnel. The general requirements for the protection of thermal spray operators are the same as for welders.

Eye Protection. Helmets, hand shields, face shields, or goggles should be used to protect the eyes, face, and neck during all thermal spraying operations. Safety goggles should be worn at all times. Table 4 is a guide for the selection of the proper filter shade number for viewing a specific spraying operation.

TABLE 4 RECOMMENDED EYE FILTER PLATES FOR THERMAL SPRAYING OPERATIONS

OPERATION	FILTER SHADE NUMBERS
WIRE FLAME SPRAYING (EXCEPT MOLYBDENUM)	2 TO 4

WIRE FLAME SPRAYING OF MOLYBDENUM	3 TO 6
FLAME SPRAYING OF METAL POWDER	3 TO 6
FLAME SPRAYING OF EXOTHERMICS OR CERAMICS	4 TO 8
PLASMA AND ARC SPRAYING	9 TO 12
FUSING OPERATIONS	4 TO 6

Respiratory Protection. Most thermal spraying operations require that respiratory protective devices be used by the operator. The nature, type, and magnitude of the fume and gas exposure determine which respiratory protective device should be used. All devices selected for use should be of a type approved by the U.S. Bureau of Mines, National Institute for Occupational Safety and Health, or other approving authority for the purpose intended.

Ear Protection. Ear protectors or properly fitted soft rubber ear plugs should be worn to protect the operator from the high-intensity noise from the process. Federal, state, and local codes should be checked for noise protection requirements.

Protective Clothing. Appropriate protective clothing required for a thermal spraying operation will vary with the size, nature, and location of the work to be performed. When working in confined spaces, flame-resistant clothing and gauntlets should be worn. Clothing should be fastened tightly around the wrists and ankles to keep dusts from contacting the skin.

The intense ultraviolet radiation of plasma and electric arc spraying can cause skin burns through normal clothing. Protection against radiation during arc spraying is practically the same as that for normal arc welding at equivalent current levels.

Adhesive Bonding

Adequate safety precautions must be observed with adhesives. Corrosive materials, flammable liquids, and toxic substances are commonly used in adhesive bonding. Therefore, manufacturing operations should be carefully supervised to ensure that proper safety procedures, protective devices, and protective clothing are being used. All federal, state, and local regulations should be complied with, including OSHA Regulation 29CRF 1900.1000, *Air Contaminants.*

Flammable Materials. All flammable materials, such as solvents, should be stored in tightly sealed drums and issued in suitably labeled safety cans to prevent fires during storage and use. Solvents and flammable liquids should not be used in poorly ventilated, confined areas. When solvents are used in trays, safety lids should be provided. Flames, sparks, or spark-producing equipment must not be permitted in the area where flammable materials are being handled. Fire extinguishers should be readily available.

Toxic Materials. Severe allergic reactions can result from direct contact, inhalation, or ingestion of phenolics and epoxies as well as most catalysts and accelerators. The eyes or skin may become sensitized over a long period of time even though no signs of irritation are visible. Once workers are sensitized to a particular type of adhesive, they may no longer be able to work near it because of allergic reactions. Careless handling of adhesives by production workers may expose others to toxic materials if proper safety rules are not observed. For example, co-workers may touch tools, door knobs, light switches, or other objects contaminated by careless workers.

For the normal individual, proper handling methods that eliminate skin contact with an adhesive should be sufficient. It is mandatory that protective equipment, barrier creams, or both be used to avoid skin contact with certain types of formulations.

Factors to be considered in determining the extent of precautionary measures to be taken include:

- THE FREQUENCY AND DURATION OF EXPOSURE
- THE DEGREE OF HAZARD ASSOCIATED WITH A SPECIFIC ADHESIVE
- THE SOLVENT OR CURING AGENT USED
- THE TEMPERATURE AT WHICH THE OPERATIONS ARE PERFORMED
- THE POTENTIAL EVAPORATION SURFACE AREA EXPOSED AT THE WORK STATION

All these elements should be evaluated in terms of the individual operation.

Precautionary Procedures. A number of measures are recommended in the handling and use of adhesives and auxiliary materials.

Personal Hygiene. Personnel should be instructed in proper procedures to prevent skin contact with solvents, curing agents, and uncured base adhesives. Showers, wash bowls, mild soaps, clean towels, refatting creams, and protective equipment should be provided.

Curing agents should be removed from the hands with soap and water. Resins should be removed with soap and water, alcohol, or a suitable solvent. Any solvent should be used sparingly and be followed by washing with soap and water. In case of allergic reaction or burning, prompt medical aid should be obtained.

Work Area. Areas in which adhesives are handled should be separated from other operations. These areas should contain the following facilities in addition to the proper fire equipment:

- SINK WITH RUNNING WATER
- EYE SHOWER OR RINSE FOUNTAIN
- FIRST AID KIT
- VENTILATING FACILITIES

Ovens, presses, and other curing equipment should be individually vented to remove fume. Vent hoods should be provided at mixing and application stations.

Protective Devices. Plastic or rubber gloves should be worn at all times when working with potentially toxic adhesives. Contaminated gloves must not contact objects that others may touch with their bare hands. Those gloves should be discarded or cleaned using procedures that remove the particular adhesive. Cleaning may require solvents, soap and water, or both. Hands, arms, face, and neck should be coated with a commercial barrier ointment or cream. This type of material may provide short-term protection and facilitate removal of adhesive components by washing.

Full face shields should be worn for eye protection whenever the possibility of splashing exists, otherwise glasses or goggles should be worn. In case of irritation, the eyes should be immediately flushed with water and then promptly treated by a physician.

Protective clothing should be worn at all times by those who work with the adhesives. Shop coats, aprons, or coveralls may be suitable, and they should be cleaned before reuse.

Glossary of Terms*

American Welding Society Committee on Definitions and Symbols

THE COMMITTEE on Definitions and Symbols was formed by the American Welding Society to establish standard terms and symbols to aid in the communication of welding information. *Standard Welding Terms and Definitions,* ANSI/AWS A3.0, is the major product of work done by the Subcommittee on Definitions in support of this purpose. This glossary is a selection of terms and definitions from ANSI/AWS A3.0; the reader is referred to the latest edition of ANSI/AWS A3.0 for the most current and complete welding vocabulary, including illustrations and commentary.

The standard terms and definitions published here are those that should be used in both the oral and the written language of welding; however, their use is particularly important in the writing of standards (codes, specifications, recommended practices, methods, classifications, and guides) and all other documents concerning welding. Because ANSI/AWS A3.0, from which this glossary is extracted, is intended to be a comprehensive compilation of welding terminology, nonstandard terms used in the welding industry are also included. All terms are either standard or nonstandard, and nonstandard terms are labeled as such.

To make this glossary most useful, the terms are arranged in the conventional dictionary letter-by-letter alphabetical sequence. It is the policy of the American Welding Society to use only generic terms and definitions in this glossary. The numerous proprietary brand and trademark names commonly used to describe welding processes, equipment, and filler metals are not included.

It should be noted that the *ASM Handbook* editorial style for the hyphenation of certain terms deviates from that dictated by ANSI/AWS A3.0. The style shown in this glossary is the standard AWS usage.

- A
- ACTIVATED ROSIN FLUX
- A rosin-base flux containing an additive that increases wetting by the solder.
- ACTUAL THROAT
- The shortest distance between the weld root and the face of a fillet weld.
- ADHESIVE BONDING
- A materials joining process in which an adhesive is placed between the faying surfaces. The adhesive solidifies to produce an adhesive bond.
- AIR CARBON ARC CUTTING (AC-A)
- An arc cutting process that melts base metals by the heat of a carbon arc and removes the molten metal by a blast of air.
- ARC BLOW
- The deflection of an electric arc from its normal path because of magnetic forces.
- ARC BRAZING (AB)
- A brazing process that uses an arc to provide the heat. See carbon arc brazing .
- ARC CUTTING (AC)
- A group of cutting processes that melt the base metal with the heat of an arc between an electrode and the base metal.
- AIR CUTTING GUN (GAS METAL ARC CUTTING)
- A device used in semiautomatic, machine, and automatic arc cutting to transfer current, guide the consumable electrode, and direct the shielding gas.
- ARC FORCE
- The axial force developed by an arc plasma.
- ARC GOUGING
- An arc cutting process variation used to form a bevel or groove.
- ARC OXYGEN CUTTING
- A nonstandard term for oxygen arc cutting .
- ARC SEAM WELD
- A seam weld made by an arc welding process.
- ARC SPOT WELD
- A spot weld made by an arc welding process.
- ARC SPRAYING (ASP)
- A thermal spraying process using an arc between two consumable electrodes of surfacing materials as a heat source and a compressed gas to atomize and propel the surfacing material to the substrate.
- ARC STRIKE
- A discontinuity consisting of any localized remelted metal, heat-affected metal, or change in the surface profile of any part of a weld or base metal resulting from an arc.
- ARC WELDING (AW)
- A group of welding processes that produces coalescence of metals by heating them with an arc, with or without the application of pressure, and with or without the use of filler metal.
- ARC WELDING ELECTRODE
- A component of the welding circuit through which current is conducted and which terminates at the arc.
- ARC WELDING GUN
- A device used in semiautomatic, machine, and automatic arc welding to transfer current, guide the consumable electrode, and direct the shielding gas.
- AS-WELDED
- The condition of weld metal, welded joints, and weldments after welding, but prior to any subsequent thermal, mechanical, or chemical treatments.
- AUTOGENOUS WELD
- A fusion weld made without the addition of filler metal.
- AUTOMATIC WELDING
- Welding with equipment that performs the welding operation without adjustment of the controls by a welding operator. The equipment may or may not load and unload the workpieces. See also machine welding .

- B
- BACK BEAD
- A weld bead resulting from a back weld pass.
- BACKFIRE
- The momentary recession of the flame into the welding tip or cutting tip followed by immediate reappearance or complete extinction of the flame.
- BACK GOUGING
- The removal of weld metal and base metal from the other side of a partially welded joint to facilitate complete fusion and complete joint penetration upon subsequent welding from that side.
- BACKHAND WELDING
- A welding technique in which the welding torch or gun is directed opposite to the progress of welding.
- BACKING
- A material or device placed against the back side of the joint, or at both sides of a weld in electroslag and electrogas welding, to support and retain molten weld metal. The material may be partially fused or remain unfused during welding and may be either metal or nonmetal.
- BACKING BEAD
- A weld bead resulting from a backing pass.
- BACKING FILLER METAL
- A nonstandard term for consumable insert .
- BACKING PASS
- A weld pass made for a backing weld.
- BACKING RING
- Backing in the form of a ring, generally used in the welding of pipe.
- BACKING SHOE
- A nonconsumable backing device used in electroslag and electrogas welding.
- BACKING WELD
- Backing in the form of a weld.
- BACKSTEP SEQUENCE
- A longitudinal sequence in which weld passes are made in the direction opposite to the progress of welding.
- BACK WELD
- A weld made at the back of a single-groove weld.
- BALLING UP
- The formation of globules of molten brazing filler metal or flux due to lack of wetting of the base metal.
- BASE MATERIAL
- The material to be welded, brazed, soldered, or cut. See also base metal and substrate .
- BASE METAL
- The metal to be welded, brazed, soldered, or cut. See also base material and substrate .
- BEAD WELD
- A nonstandard term for surfacing weld .
- BEVEL
- An angular edge preparation.
- BEVEL ANGLE
- The angle formed between the prepared edge of a member and a plane perpendicular to the surface of the member.
- BEVEL GROOVE WELD
- A type of groove weld.
- BIT
- That part of the soldering iron, usually made of copper, that actually transfers heat (and sometimes solder) to the joint.
- BLACKSMITH WELDING
- A nonstandard term for forge welding .
- BLOCK SEQUENCE
- A combined longitudinal and cross-sectional sequence for a continuous multiple-pass weld in which separated increments are completely or partially welded before intervening increments are welded.
- BLOWHOLE
- A nonstandard term for porosity .

- BOND
- See bonding force , covalent bond , mechanical bond , and metallic bond .
- BOND COAT (THERMAL SPRAYING)
- A preliminary (or prime) coat of material that improves adherence of the subsequent spray deposit.
- BONDING FORCE
- The force that holds two atoms together. It results from a decrease in energy as two atoms are brought closer to one another.
- BOND LINE
- The cross section of the interface between thermal spray deposits and substrate, or between adhesive and adherend in an adhesive bonded joint.
- BOTTLE
- A nonstandard term for gas cylinder .
- BOXING
- The continuation of a fillet weld around a corner of a member as an extension of the principal weld.
- BRAZE
- A weld produced by heating an assembly to the brazing temperature using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metal. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.
- BRAZE INTERFACE
- The interface between filler metal and base metal in a brazed joint.
- BRAZEMENT
- An assembly whose component parts are joined by brazing.
- BRAZER
- One who performs a manual or semiautomatic brazing operation.
- BRAZE WELDING
- A welding process variation in which a filler metal, having a liquidus above 450 °C (840 °F) and below the solidus of the base metal, is used. Unlike brazing, in braze welding the filler metal is not distributed in the joint by capillary action.
- BRAZING (B)
- A group of welding processes that produce coalescence of materials by heating them to the brazing temperature in the presence of a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metal. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.
- BRAZING ALLOY
- A nonstandard term for brazing filler metal .
- BRAZING FILLER METAL
- The metal that fills the capillary joint clearance and has a liquidus above 450 °C (840 °F) but below the solidus of the base metals.
- BRAZING OPERATOR
- One who operates machine or automatic brazing equipment.
- BRITTLE NUGGET
- A nonstandard term used to describe a faying plane failure in a resistance weld peel test.
- BRONZE WELDING
- A nonstandard term for braze welding .
- BUILDUP
- A surfacing variation in which surfacing metal is deposited to achieve the required dimensions. See also buttering .
- BURNER
- A nonstandard term for oxygen cutter .
- BURNING
- A nonstandard term for oxygen cutting .
- BURN THROUGH
- A nonstandard term for excessive melt through or a hole.
- BURN THROUGH WELD
- A nonstandard term for a seam weld or spot weld .
- BUTTERING

- A surfacing variation that deposits surfacing metal on one or more surfaces to provide metallurgically compatible weld metal for the subsequent completion of the weld. See also buildup .
- BUTT JOINT
- A joint between two members aligned approximately in the same plane.
- BUTTON
- That part of a weld, including all or part of the nugget, that tears out in the destructive testing of spot, seam, or projection welded specimens.
- BUTT WELD
- A nonstandard term for a weld in a butt joint.
- C
- CARBON ARC BRAZING (CAB)
- A brazing process that produces coalescence of metals by heating them with an electric arc between two carbon electrodes. The filler metal is distributed in the joint by capillary action.
- CARBON ARC CUTTING (CAC)
- An arc cutting process that severs base metals by melting them with the heat of an arc between a carbon electrode and the base metal.
- CARBON ARC WELDING (CAW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a carbon electrode and the base metal. No shielding is used. Pressure and filler metal may or may not be used.
- CARBONIZING FLAME
- A nonstandard term for reducing flame .
- CAULK WELD
- A nonstandard term for seal weld .
- CHAIN INTERMITTENT WELD
- An intermittent weld on both sides of a joint in which the weld increments on one side are approximately opposite those on the other side.
- CHAMFER
- A nonstandard term for bevel .
- CHEMICAL FLUX CUTTING (FOC)
- An oxygen cutting process that severs base metals using a chemical flux to facilitate cutting.
- CHILL RING
- A nonstandard term for backing ring .
- CLAD BRAZING SHEET
- A metal sheet on which one or both sides are clad with brazing filler metal.
- COALESCENCE
- The growing together or growth into one body of the materials being welded.
- COATED ELECTRODE
- A nonstandard term for covered electrode .
- COATING DENSITY
- A nonstandard term for spray deposit density ratio .
- COEXTRUSION WELDING (CEW)
- A solid-state welding process that produces coalescence of the faying surfaces by heating and forcing base metals through an extrusion die.
- COLD CRACK
- A crack that develops after solidification is complete.
- COLD SOLDERED JOINT
- A joint with incomplete coalescence caused by insufficient application of heat to the base metal during soldering.
- COLD WELDING (CW)
- A solid-state welding process in which pressure is used at room temperature to produce coalescence of metals with substantial deformation at the weld. See also diffusion welding , forge welding , and hot pressure welding .
- COMPLETE FUSION
- Fusion which has occurred over the entire base metal surface intended for welding and between all adjoining weld beads.
- COMPLETE JOINT PENETRATION

- A penetration by weld metal for the full thickness of the base metal in a joint with a groove weld.
- COMPLETE PENETRATION
- A nonstandard term for complete joint penetration .
- CONCAVITY
- The maximum distance from the face of a concave fillet weld perpendicular to a line joining the weld toes.
- CONE
- The conical part of an oxyfuel gas flame next to the orifice of the tip.
- CONSTRICTED ARC (PLASMA ARC WELDING AND CUTTING)
- A plasma arc column that is shaped by a constricting nozzle orifice.
- CONSUMABLE INSERT
- Preplaced filler metal that is completely fused into the joint root and becomes part of the weld.
- CONTACT RESISTANCE (RESISTANCE WELDING)
- Resistance to the flow of electric current between two workpieces or an electrode and a workpiece.
- CONTACT TUBE
- A device that transfers current to a continuous electrode.
- CONVEXITY
- The maximum distance from the face of a convex fillet weld perpendicular to a line joining the weld toes.
- COPPER BRAZING
- A nonstandard term for brazing with a copper filler metal.
- CORED SOLDER
- A solder wire or bar containing flux as a core.
- CORNER-FLANGE WELD
- A flange weld with only one member flanged at the joint.
- CORNER JOINT
- A joint between two members located approximately at right angles to each other.
- CORONA (RESISTANCE WELDING)
- The area sometimes surrounding the nugget of a spot weld at the faying surface which provides a degree of solid-state welding.
- CO_2 WELDING
- A nonstandard term for gas metal arc welding .
- COVALENT BOND
- A primary bond arising from the reduction in energy associated with overlapping half-filled orbitals of two atoms.
- COVERED ELECTRODE
- A composite filler metal electrode consisting of a core of a bare electrode or metal-cored electrode to which a covering sufficient to provide a slag layer on the weld metal has been applied. The covering may contain materials providing such functions as shielding from the atmosphere, deoxidation, and arc stabilization and can serve as a source of metallic additions to the weld.
- CRACK
- A fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement.
- CRATER
- A depression at the termination of a weld bead.
- CUTTING ATTACHMENT
- A device for converting an oxyfuel gas welding torch into an oxygen cutting torch.
- CUTTING BLOWPIPE
- A nonstandard term for cutting torch.
- CUTTING NOZZLE
- A nonstandard term for cutting tip .
- CUTTING TIP
- The part of an oxygen cutting torch from which the gases issue.
- CUTTING TORCH (ARC)
- A device used in air carbon arc cutting, gas tungsten arc cutting, and plasma arc cutting to control the position of the electrode, to transfer current, and to control the flow of gases.
- CUTTING TORCH (OXYFUEL GAS)

- A device used for directing the preheating flame produced by the controlled combustion of fuel gases and to direct and control the cutting oxygen.
- CYLINDER MANIFOLD
- A multiple header for interconnection of gas or fluid sources with distribution points.
- D
- DEFECT
- A discontinuity or discontinuities that by nature or accumulated effect (for example, total crack length) render a part or product unable to meet minimum applicable acceptance standards or specifications. This term designates rejectability. See also discontinuity and flaw .
- DEPOSIT (THERMAL SPRAYING)
- A nonstandard term for spray deposit .
- DEPOSITED METAL
- Filler metal that has been added during welding.
- DEPOSITION EFFICIENCY (ARC WELDING)
- The ratio of the weight of deposited metal to the net weight of filler metal consumed, exclusive of stubs.
- DEPOSITION EFFICIENCY (THERMAL SPRAYING)
- The ratio of the weight of spray deposit to the weight of the surfacing material sprayed, usually expressed in percent.
- DEPOSITION SEQUENCE
- A nonstandard term for weld pass sequence .
- DEPTH OF FUSION
- The distance that fusion extends into the base metal or previous pass from the surface melted during welding.
- DIFFUSION BONDING
- A nonstandard term for diffusion brazing and diffusion welding .
- DIFFUSION BRAZING (DFB)
- A brazing process that produces coalescence of metals by heating them to brazing temperature and by using a filler metal or an *in situ* liquid phase. The filler metal may be distributed by capillary action or may be placed or formed at the faying surfaces. The filler metal is diffused with the base metal to the extent that the joint properties have been changed to approach those of the base metal. Pressure may or may not be applied.
- DIFFUSION WELDING (DFW)
- A solid-state welding process that produces coalescence of the faying surfaces by the application of pressure at elevated temperature. The process does not involve macroscopic deformation, melting, or relative motion of the workpieces. A solid filler metal may or may not be inserted between the faying surfaces. See also cold welding , forge welding , and hot pressure welding .
- DILUTION
- The change in chemical composition of a welding filler metal caused by the admixture of the base metal or previous weld metal in the weld bead. It is measured by the percentage of base metal or previous weld metal in the weld bead.
- DIP BRAZING (DB)
- A brazing process using the heat furnished by a molten chemical or metal bath. When a molten chemical bath is used, the bath may act as a flux. When a molten metal bath is used, the bath provides the filler metal.
- DIP SOLDERING (DS)
- A soldering process using the heat furnished by a molten metal bath which provides the solder filler metal.
- DIRECT CURRENT ELECTRODE NEGATIVE (DCEN)
- The arrangement of direct current arc welding leads in which the workpiece is the positive pole and the electrode is the negative pole of the welding arc.
- DIRECT CURRENT ELECTRODE POSITIVE (DCEP)
- The arrangement of direct current arc welding leads in which the workpiece is the negative pole and the electrode is the positive pole of the welding arc.
- DIRECT CURRENT REVERSE POLARITY
- A nonstandard term for direct current electrode positive .
- DIRECT CURRENT STRAIGHT POLARITY
- A nonstandard term for direct current electrode negative .
- DISCONTINUITY

- An interruption of the typical structure of a weldment, such as a lack of homogeneity in the mechanical, metallurgical, or physical characteristics of the material or weldment. A discontinuity is not necessarily a defect. See also defect and flaw .
- DOUBLE-BEVEL-GROOVE WELD
- A type of groove weld.
- DOUBLE-FLARE-BEVEL-GROOVE WELD
- A weld in grooves formed by a member with a curved surface in contact with a planar member.
- DOUBLE-FLARE-V-GROOVE WELD
- A weld in grooves formed by two members with curved surfaces.
- DOUBLE-J-GROOVE WELD
- A type of groove weld.
- DOUBLE-SQUARE-GROOVE WELD
- A type of groove weld.
- DOUBLE-U-GROOVE WELD
- A type of groove weld.
- DOUBLE-V-GROOVE WELD
- A type of groove weld.
- DOUBLE-WELDED JOINT
- A fusion-welded joint that is welded from both sides.
- DOWNHAND
- A nonstandard term for flat position .
- DRAG (THERMAL CUTTING)
- The offset distance between the actual and straight line exit points of the gas stream or cutting beam measured on the exit surface of the material.
- E
- EDGE-FLANGE WELD
- A flange weld with two members flanged at the location of welding.
- EDGE JOINT
- A joint between the edges of two or more parallel or nearly parallel members.
- EDGE WELD
- A weld in an edge joint.
- EDGE WELD SIZE
- The weld metal thickness measured at the weld root.
- EFFECTIVE THROAT
- The minimum distance minus any convexity between the weld root and the face of a fillet weld.
- ELECTRIC ARC SPRAYING
- A nonstandard term for arc spraying .
- ELECTRIC BONDING
- A nonstandard term for surfacing by thermal spraying.
- ELECTRIC BRAZING
- A nonstandard term for arc brazing and resistance brazing .
- ELECTRODE
- See welding electrode .
- ELECTRODE EXTENSION
- For gas metal arc welding, flux cored arc welding, and submerged arc welding, the length of unmelted electrode extending beyond the end of the contact tube.
- ELECTRODE FORCE
- The force between the electrodes in making spot, seam, or projection welds by resistance welding.
- ELECTRODE HOLDER
- A device used for mechanically holding the electrode while conducting current to it.
- ELECTRODE INDENTATION (RESISTANCE WELDING)
- The depression formed on the surface of workpieces by electrodes.
- ELECTRODE LEAD
- The electrical conductor between the source of arc welding current and the electrode holder.
- ELECTROGAS WELDING (EGW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the work. Molding shoes are used to confine the molten weld metal

for vertical position welding. The electrodes may be either flux cored or solid. Shielding may or may not be obtained from an externally supplied gas or mixture.

- ELECTRON BEAM CUTTING (EBC)
- A cutting process that uses the heat obtained from a concentrated beam composed primarily of high-velocity electrons which impinge upon the workpieces; it may or may not use an externally supplied gas.
- ELECTRON BEAM GUN
- A device for producing and accelerating electrons. Typical components include the emitter (also called the filament or cathode), which is heated to produce electrons via thermionic emission; a cup (also called the grid or grid cup); and the anode.
- ELECTRON BEAM WELDING (EBW)
- A welding process that produces coalescence of metals with the heat obtained from a concentrated beam composed primarily of high-velocity electrons impinging on the joint.
- ELECTROSLAG WELDING (ESW)
- A welding process that produces coalescence of metals with molten slag that melts the filler metal and the surfaces of the workpieces. The weld pool is shielded by this slag, which moves along the full cross section of the joint as welding progresses. The process is initiated by an arc that heats the slag. The arc is then extinguished by the conductive slag, which is kept molten by its resistance to electric current passing between the electrode and the workpieces.
- END RETURN
- A nonstandard term for boxing .
- EROSION (BRAZING)
- A condition caused by dissolution of the base metal by molten filler metal resulting in a reduction in the thickness of the base metal.
- EXPLOSION WELDING (EXW)
- A solid-state welding process that affects coalescence by high-velocity movement together with the workpieces produced by a controlled detonation.
- F
- FACE REINFORCEMENT
- Weld reinforcement at the side of the joint from which welding was done. See also root reinforcement .
- FAYING SURFACE
- That mating surface of a member that is in contact with or in close proximity to another member to which it is to be joined.
- FERRITE NUMBER
- An arbitrary, standardized value designating the ferrite content of an austenitic stainless steel weld metal. It should be used in place of percent ferrite or volume percent ferrite on a direct replacement basis.
- FILLER METAL
- The metal to be added in making a welded, brazed, or soldered joint. See also brazing filler metal , consumable insert , solder , welding electrode , welding rod , and welding wire .
- FILLER WIRE
- A nonstandard term for welding wire .
- FILLET WELD
- A weld of approximately triangular cross section joining two surfaces approximately at right angles to each other in a lap joint, T-joint, or corner joint.
- FILLET WELD BREAK TEST
- A test in which the specimen is loaded so that the weld root is in tension.
- FILLET WELD LEG
- The distance from the joint root to the toe of the fillet weld.
- FILLET WELD SIZE
- For equal leg fillet welds, the leg lengths of the largest isosceles right triangle that can be inscribed within the fillet weld cross section. For unequal leg fillets, the leg lengths of the largest right triangle that can be inscribed within the fillet weld cross section.
- FILLET WELD THROAT
- See actual throat , effective throat , and theoretical throat .
- FIRECRACKER WELDING
- A variation of the shielded metal arc welding process in which a length of covered electrode is placed along the joint in contact with the workpieces. During the welding operation, the stationary electrode is consumed as the arc travels the length of the electrode.
- FISHEYE

- A discontinuity found on the fracture surface of a weld in steel that consists of a small pore or inclusion surrounded by an approximately round, bright area.
- FLAME CUTTING
- A nonstandard term for oxygen cutting .
- FLAME PROPAGATION RATE
- The speed at which a flame travels through a mixture of gases.
- FLAME SPRAYING (FLSP)
- A thermal spraying process in which an oxyfuel gas flame is the source of heat for melting the surfacing material. Compressed gas may or may not be used for atomizing and propelling the surfacing material to the substrate.
- FLANGE WELD
- A weld made on the edges of two or more members to be joined, usually light gage metal, at least one of the members being flanged.
- FLANGE WELD SIZE
- The weld metal thickness measured at the weld root.
- FLARE-BEVEL-GROOVE WELD
- A weld in a groove formed by a member with a curved surface in contact with a planar member.
- FLARE-V-GROOVE WELD
- A weld in a groove formed by two members with curved surfaces.
- FLASH
- Material that is expelled from a flash weld prior to the upset portion of the welding cycle.
- FLASH BUTT WELDING
- A nonstandard term for flash welding .
- FLASH COAT
- A thin coating usually less than 0.05 mm (0.002 in.) in thickness.
- FLASH WELDING (FW)
- A resistance welding process that produces coalescence at the faying surfaces of a butt joint by a flashing action and by the application of pressure after heating is substantially completed. The flashing action, caused by the very high current densities at small contacts between the parts, forcibly expels the material from the joint as the parts are slowly moved together. The weld is completed by a rapid upsetting of the workpieces.
- FLAT POSITION
- The welding position used to weld from the upper side of the joint; the face of the weld is approximately horizontal.
- FLAW
- A near synonym for discontinuity but with an undesirable connotation. See also defect and discontinuity .
- FLOW BRIGHTENING (SOLDERING)
- Fusion of a metallic coating on a base metal.
- FLUX
- Material used to prevent, dissolve, or facilitate removal of oxides and other undesirable surface substances.
- FLUX CORED ARC WELDING (FCAW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the work. Shielding is provided by a flux contained within the tubular electrode. Additional shielding may or may not be obtained from an externally supplied gas or gas mixture. See also flux cored electrode .
- FLUX CORED ELECTRODE
- A composite filler metal electrode consisting of a metal tube or other hollow configuration containing ingredients to provide such functions as shielding atmosphere, deoxidation, arc stabilization, and slag formation. Minor amounts of alloying materials may be included in the core. External shielding may or may not be used.
- FLUX COVER (METAL BATH DIP BRAZING AND DIP SOLDERING)
- A layer of molten flux over the molten filler metal bath.
- FLUX OXYGEN CUTTING
- A nonstandard term for chemical flux cutting .
- FOREHAND WELDING
- A welding technique in which the welding torch or gun is directed toward the progress of welding.

- FORGE WELDING (FOW)
- A solid-state welding process that produces coalescence of metals by heating them in air in a forge and by applying pressure or blows sufficient to cause permanent deformation at the interface. See also cold welding , diffusion welding , hot pressure welding , and roll welding .
- FRICTION WELDING (FRW)
- A solid-state welding process that produces coalescence of materials under compressive force contact of workpieces rotating or moving relative to one another to produce heat and plastically displace material from the faying surfaces.
- FURNACE BRAZING (FB)
- A brazing process in which the workpieces are placed in a furnace and heated to the brazing temperature.
- FURNACE SOLDERING (FS)
- A soldering process in which the workpieces are placed in a furnace and heated to the soldering temperature.
- FUSED SPRAY DEPOSIT (THERMAL SPRAYING)
- A self-fluxing spray deposit that is subsequently heated to coalescence within itself and with the substrate.
- FUSION
- The melting together of filler metal and base metal (substrate), or of base metal only, which results in coalescence. See also depth of fusion .
- FUSION FACE
- A surface of the base metal that will be melted during welding.
- FUSION WELDING
- Any welding process that uses fusion of the base metal to make the weld.
- FUSION ZONE
- The area of base metal melted as determined on the cross section of a weld.
- G
- GAP
- A nonstandard term for joint clearance and root opening .
- GAS BRAZING
- A nonstandard term for torch brazing .
- GAS CUTTER
- A nonstandard term for oxygen cutter .
- GAS CUTTING
- A nonstandard term for oxygen cutting .
- GAS CYLINDER
- A portable container used for transportation and storage of a compressed gas.
- GAS GOUGING
- A nonstandard term for oxygen gouging .
- GAS LASER
- A laser in which the lasing medium is a gas.
- GAS METAL ARC CUTTING (GMAC)
- An arc cutting process in which metals are severed by melting them with the heat of an arc between a continuous filler metal electrode and the workpiece. Shielding is obtained entirely from an externally supplied gas.
- GAS METAL ARC WELDING (GMAW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the workpieces. Shielding is obtained entirely from an externally supplied gas.
- GAS POCKET
- A nonstandard term for porosity .
- GAS REGULATOR
- A device for controlling the delivery of gas at some substantially constant pressure.
- GAS SHIELDED ARC WELDING
- A general term used to describe flux cored arc welding (when gas shielding is employed), gas metal arc welding , and gas tungsten arc welding .
- GAS TORCH
- A nonstandard term for cutting torch and welding torch.

- GAS TUNGSTEN ARC CUTTING (GTAC)
- An arc cutting process in which metals are severed by melting them with an arc between a single tungsten electrode and the workpiece. Shielding is obtained from a gas.
- GAS TUNGSTEN ARC WELDING (GTAW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a tungsten electrode (nonconsumable) and the workpieces. Shielding is obtained from a gas. Pressure may or may not be used, and filler metal may or may not be used.
- GAS WELDING
- A nonstandard term for oxyfuel gas welding .
- GLOBULAR TRANSFER (ARC WELDING)
- The transfer of molten metal in large drops from a consumable electrode across the arc. See also short circuiting transfer and spray transfer .
- GOUGING
- The forming of a bevel or groove by material removal. See also arc gouging , back gouging , and oxygen gouging .
- GROOVE ANGLE
- The total included angle of the groove between the workpieces.
- GROOVE FACE
- That surface of a joint member included in the groove.
- GROOVE RADIUS
- The radius used to form the shape of a J- or U-groove weld.
- GROOVE WELD
- A weld made in a groove between the workpieces.
- GROOVE WELD SIZE
- The joint penetration of a groove weld.
- GROOVE WELD THROAT
- A nonstandard term for groove weld size .
- GROUND CONNECTION
- An electrical connection of the welding machine frame to the earth for safety. See also workpiece connection and workpiece lead .
- GROUND LEAD
- A nonstandard term for workpiece lead .
- GUN
- See air cutting gun , arc welding gun , electron beam gun , resistance welding gun , soldering gun , and thermal spraying gun .
- H
- HAMMER WELDING
- A nonstandard term for cold welding and forge welding .
- HARD SOLDER
- A nonstandard term for silver-base brazing filler metals.
- HEAT AFFECTED ZONE
- That portion of the base metal that has not been melted, but whose mechanical properties or microstructure have been altered by the heat of welding, brazing, soldering, or cutting.
- HIGH FREQUENCY RESISTANCE WELDING
- A group of resistance welding process variations that uses high frequency welding current to concentrate the welding heat at the desired location.
- HORIZONTAL FIXED POSITION (PIPE WELDING)
- The position of a pipe joint in which the axis of the pipe is approximately horizontal, and the pipe is not rotated during welding.
- HORIZONTAL POSITION (FILLET WELD)
- The position in which welding is performed on the upper side of an approximately horizontal surface and against an approximately vertical surface.
- HORIZONTAL POSITION (GROOVE WELD)
- The position of welding in which the weld axis lies in an approximately horizontal plane and the weld face lies in an approximately vertical plane.
- HORIZONTAL ROLLED POSITION (PIPE WELDING)

- The position of a pipe joint in which the axis of the pipe is approximately horizontal, and welding is performed in the flat position by rotating the pipe.
- HOT CRACK
- A crack that develops during solidification.
- HOT PRESSURE WELDING (HPW)
- A solid-state welding process that produces coalescence of metals with heat and application of pressure sufficient to produce macrodeformation of the base metal. Vacuum or other shielding media may be used. See also diffusion welding and forge welding .
- HYDROGEN BRAZING
- A nonstandard term for any brazing process that takes place in a hydrogen atmosphere.
- I
- IMPULSE (RESISTANCE WELDING)
- A group of pulses occurring on a regular frequency separated only by an interpulse time.
- INCLINED POSITION
- The position of a pipe joint in which the axis of the pipe is at an angle of approximately 45° to the horizontal, and the pipe is not rotated during welding.
- INCLINED POSITION (WITH RESTRICTION RING)
- The position of a pipe joint in which the axis of the pipe is at an angle of approximately 45° to the horizontal, and a restriction ring is located near the joint. The pipe is not rotated during welding.
- INCLUDED ANGLE
- A nonstandard term for groove angle .
- INDUCTION BRAZING (IB)
- A brazing process in which the heat required is obtained from the resistance of the workpieces to induced electric current.
- INDUCTION SOLDERING (IS)
- A soldering process in which the heat required is obtained from the resistance of the workpieces to induced electric current.
- INDUCTION WELDING (IW)
- A welding process that produces coalescence of metals by the heat obtained from the resistance of the workpieces to the flow of induced high frequency welding current with or without the application of pressure. The effect of the high frequency welding current is to concentrate the welding heat at the desired location.
- INERT GAS
- A gas that normally does not combine chemically with the base metal or filler metal. See also protective atmosphere .
- INERT GAS METAL ARC WELDING
- A nonstandard term for gas metal arc welding .
- INERT GAS TUNGSTEN ARC WELDING
- A nonstandard term for gas tungsten arc welding .
- INFRARED BRAZING (IRB)
- A brazing process in which the heat required is furnished by infrared radiation.
- INFRARED SOLDERING (IRS)
- A soldering process in which the heat required is furnished by infrared radiation.
- INTERGRANULAR PENETRATION
- The penetration of a filler metal along the grain boundaries of a base metal.
- INTERPASS TEMPERATURE
- In a multipass weld, the temperature of the weld metal before the next pass is started.
- IRON SOLDERING (INS)
- A soldering process in which the heat required is obtained from a soldering iron.
- J
- J-GROOVE WELD
- A type of groove weld.
- JOINT
- The junction of members or the edges of members which are to be joined or have been joined.
- JOINT CLEARANCE
- The distance between the faying surfaces of a joint. In brazing, this distance is referred to as that which is present before brazing, at the brazing temperature, or after brazing is completed.

- JOINT EFFICIENCY
- The ratio of the strength of a joint to the strength of the base metal, expressed in percent.
- JOINT PENETRATION
- The depth a weld extends from its face into a joint, exclusive of reinforcement.
- JOINT ROOT
- That portion of a joint to be welded where the members approach closest to each other. In cross section, the joint root may be either a point, a line, or an area.
- JOINT TYPE
- A weld joint classification based on the five basic arrangements of the component parts such as butt joint, corner joint, edge joint, lap joint, and T-joint.
- K
- KERF
- The width of the cut produced during a cutting process.
- L
- LAMELLAR TEAR
- A terracelike fracture in the base metal with a basic orientation parallel to the wrought surface. It is caused by the high stress in the thickness direction that results from welding.
- LAND
- A nonstandard term for root face .
- LAP JOINT
- A joint between two overlapping members in parallel planes.
- LASER
- A device that produces a concentrated coherent light beam by stimulating electronic or molecular transitions to lower energy levels. Laser is an acronym for light amplification by stimulated emission of radiation.
- LASER BEAM CUTTING (LBC)
- A thermal cutting process that severs materials by melting or vaporizing them with the heat obtained from a laser beam, with or without the application of gas jets to augment the removal of material.
- LASER BEAM WELDING (LBW)
- A welding process that produces coalescence of materials with the heat obtained from the application of a concentrated coherent light beam impinging upon the joint.
- LEAD BURNING
- A nonstandard term for the welding of lead.
- LIQUATION
- The separation of a low melting constituent of an alloy from the remaining constituents, usually apparent in alloys having a wide melting range.
- LOCKED-UP STRESS
- A nonstandard term for residual stress .
- LONGITUDINAL CRACK
- A crack with its major axis orientation approximately parallel to the weld axis.
- M
- MACHINE WELDING
- Welding with equipment that performs the welding operation under the constant observation and control of a welding operator. The equipment may or may not load and unload the workpieces. See also automatic welding .
- MACROETCH TEST
- A test in which the specimen is prepared with a fine finish and etched to give a clear definition of the weld.
- MANUAL WELDING
- A welding operation performed and controlled completely by hand. See also automatic welding , machine welding , and semiautomatic welding .
- MASK (THERMAL SPRAYING)
- A device for protecting a substrate surface from the effects of blasting or adherence of a spray deposit.
- MECHANICAL BOND (THERMAL SPRAYING)
- The adherence of a spray deposit to a roughened surface by the mechanism of particle interlocking.
- MELT-THROUGH
- Visible root reinforcement produced in a joint welded from one side.

- METAL ARC CUTTING (MAC)
- Any of a group of arc cutting processes that serves metals by melting them with the heat of an arc between a metal electrode and the base metal. See also gas metal arc cutting and shielded metal arc cutting .
- METAL CORED ELECTRODE
- A composite filler metal electrode consisting of a metal tube or other hollow configuration containing alloying materials. Minor amounts of ingredients and fluxing of oxides may be included. External shielding gas may or may not be used.
- METAL ELECTRODE
- A filler or nonfiller metal electrode used in arc welding or cutting that consists of a metal wire or rod that has been manufactured by any method and that is either bare or covered.
- METALLIC BOND
- The principal bond that holds metals together and is formed between base metals and filler metals in all welding processes. This is a primary bond arising from the increased spatial extension of the valence electron wave functions when an aggregate of metal atoms is brought close together. See also bonding force and covalent bond .
- METALLIZING
- A nonstandard term for thermal spraying .
- METALLURGICAL BOND
- A nonstandard term for metallic bond .
- METAL POWDER CUTTING (POC)
- An oxygen cutting process that severs metals through the use of powder, such as iron, to facilitate cutting.
- MIG WELDING
- A nonstandard term for flux cored arc welding and gas metal arc welding .
- MIXING CHAMBER
- That part of a welding or cutting torch in which a fuel gas and oxygen are mixed.
- MOLTEN WELD POOL
- A nonstandard term for weld pool .
- MULTIPORT NOZZLE (PLASMA ARC WELDING AND CUTTING)
- A constricting nozzle containing two or more orifices located in a configuration to achieve a degree of control over the arc shape.
- N
- NEUTRAL FLAME
- An oxyfuel gas flame in which the portion used is neither oxidizing nor reducing. See also oxidizing flame and reducing flame .
- NONTRANSFERRED ARC (PLASMA ARC WELDING AND CUTTING, AND PLASMA SPRAYING)
- An arc established between the electrode and the constricting nozzle. The workpiece is not in the electrical circuit. See also transferred arc .
- NOZZLE
- A device that directs shielding media.
- NUGGET
- The weld metal joining the workpieces in spot, roll spot, seam, or projection welds.
- NUGGET SIZE (RESISTANCE WELDING)
- The diameter of a spot or projection weld or width of a seam weld measured in the plane of the faying surfaces.
- O
- ORIFICE GAS (PLASMA ARC WELDING AND CUTTING)
- The gas that is directed into the torch to surround the electrode. It becomes ionized in the arc to form the plasma and issues from the orifice in the torch nozzle as the plasma jet.
- OVEN SOLDERING
- A nonstandard term for furnace soldering .
- OVERHEAD POSITION
- The position in which welding is performed from the underside of the joint.
- OVERLAP
- The protrusion of weld metal beyond the weld toes or weld root.
- OVERLAP (RESISTANCE SEAM WELDING)

- The portion of the preceding weld nugget remelted by the succeeding weld.
- OVERLAYING
- A nonstandard term for surfacing
- OXIDIZING FLAME
- An oxyfuel gas flame having an oxidizing effect due to excess oxygen. See also neutral flame and reducing flame .
- OXYACETYLENE WELDING (OAW)
- An oxyfuel gas welding process that produces coalescence of metals by heating them with a gas flame or flames obtained from the combustion of acetylene with oxygen. The process may be used with or without the application of pressure and with or without the use of filler metal.
- OXYFUEL GAS CUTTING (OFC)
- A group of cutting processes used to sever metals by means of the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by means of gas flames obtained from the combustion of a specified fuel gas and oxygen. See also oxygen cutting .
- OXYFUEL GAS SPRAYING
- A nonstandard term for flame spraying .
- OXYFUEL GAS WELDING (OFW)
- A group of welding processes that produces coalescence by heating materials with an oxyfuel gas flame or flames, with or without the application of pressure, and with or without the use of filler metal.
- OXYGAS CUTTING
- A nonstandard term for oxygen cutting .
- OXYGEN ARC CUTTING (AOC)
- An oxygen cutting process used to sever metals by means of the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by an arc between a consumable tubular electrode and the base metal.
- OXYGEN CUTTER
- One who performs a manual oxygen cutting operation.
- OXYGEN CUTTING (OC)
- A group of cutting processes used to sever or remove metals by means of the chemical reaction between oxygen and the base metal at elevated temperatures. In the case of oxidation-resistant metals, the reaction is facilitated by the use of a chemical flux or metal powder. See also chemical flux cutting , metal powder cutting , oxyfuel gas cutting , oxygen arc cutting and oxygen lance cutting .
- OXYGEN CUTTING OPERATOR
- One who operates machine or automatic oxygen cutting equipment.
- OXYGEN GOUGING
- An application of oxygen cutting in which a bevel or groove is formed.
- OXYGEN GROOVING
- A nonstandard term for oxygen gouging .
- OXYGEN LANCE
- A length of pipe used to convey oxygen to the point of cutting in oxygen lance cutting.
- OXYGEN LANCE CUTTING (LOC)
- An oxygen cutting process used to sever metals with oxygen supplied through a consumable lance. The preheat to start the cutting is obtained by other means.
- OXYGEN LANCING
- A nonstandard term for oxygen lance cutting .
- OXYHYDROGEN WELDING (OHW)
- An oxyfuel gas welding process that produces coalescence of materials by heating them with a gas flame or flames obtained from the combustion of hydrogen with oxygen, without the application of pressure and with or without the use of filler metal.
- P
- PARALLEL WELDING
- A resistance welding secondary circuit variation in which the secondary current is divided and conducted through the workpieces and electrodes in parallel electrical paths to simultaneously form multiple resistance spot, seam, or projection welds.
- PARENT METAL
- A nonstandard term for base metal .
- PARTIAL JOINT PENETRATION

- Joint penetration that is intentionally less than complete.
- PENETRATION
- A nonstandard term for joint penetration and root penetration .
- PERCUSSION WELDING (PEW)
- A welding process that produces coalescence at the faying surface using the heat from an arc produced by a rapid discharge of electrical energy. Pressure is applied percussively during or immediately following the electrical discharge.
- PILOT ARC (PLASMA ARC WELDING)
- A low current continuous arc between the electrode and the constricting nozzle to ionize the gas and facilitate the start of the welding arc.
- PLASMA ARC CUTTING (PAC)
- An arc cutting process that severs metal by melting a localized area with a constricted arc and removing the molten material with a high velocity jet of hot, ionized gas issuing from the constricting orifice.
- PLASMA ARC WELDING (PAW)
- An arc welding process that produces coalescence of metals by heating them with a constricted arc between an electrode and the workpiece (transferred arc) or the electrode and the constricting nozzle (nontransferred arc). Shielding is obtained from the hot, ionized gas issuing from the torch which may be supplemented by an auxiliary source of shielding gas. Shielding gas may be an inert gas or a mixture of gases. Pressure may or may not be used, and filler metal may or may not be supplied.
- PLASMA METALLIZING
- A nonstandard term for plasma spraying .
- PLASMA SPRAYING (PSP)
- A thermal spraying process in which a nontransferred arc of a plasma torch is utilized to create a gas plasma that acts as the source of heat for melting and propelling the surfacing material to the substrate.
- PLENUM CHAMBER (PLASMA ARC WELDING AND CUTTING, AND PLASMA SPRAYING)
- The space between the inside wall of the constricting nozzle and the electrode.
- PLUG WELD
- A weld made in a circular hole in one member of a joint, fusing that member to another member. A fillet-welded hole is not to be construed as conforming to this definition.
- POLARITY
- See direct current electrode negative and direct current electrode positive .
- POROSITY
- Cavity type discontinuities formed by gas entrapment during solidification.
- POSTHEATING
- The application of heat to an assembly after welding, brazing, soldering, thermal spraying, or thermal cutting. See also postweld heat treatment .
- POSTWELD HEAT TREATMENT
- Any heat treatment after welding.
- POWDER CUTTING
- A nonstandard term for chemical flux cutting and metal powder cutting .
- PRECOATING
- Coating the base metal in the joint by dipping, electroplating, or other applicable means prior to soldering or brazing.
- PREFORM
- Brazing or soldering filler metal fabricated in a shape or form for a specific application.
- PREHEAT
- A nonstandard term for preheat temperature .
- PREHEAT CURRENT (RESISTANCE WELDING)
- An impulse or series of impulses that occur prior to and are separated from the welding current.
- PREHEAT TEMPERATURE
- A specified temperature that the base metal must attain in the welding, brazing, soldering, thermal spraying, or cutting area immediately before these operations are performed.
- PRESSURE-CONTROLLED WELDING
- A resistance welding process variation in which a number of spot or projection welds are made with several electrodes functioning progressively under the control of a pressure-sequencing device.
- PRESSURE GAS WELDING (PGW)

- An oxyfuel gas-welding process that produces coalescence simultaneously over the entire area of faying surfaces by heating them with gas flames obtained from the combustion of a fuel gas and oxygen and by the application of pressure, without the use of filler metal.
- PRETINNING
- A nonstandard term for precoating .
- PROCEDURE QUALIFICATION
- The demonstration that welds made by a specific procedure can meet prescribed standards.
- PROCEDURE QUALIFICATION RECORD (PQR)
- A document providing the actual welding variables used to produce an acceptable test weld and the results of tests conducted on the weld to qualify a welding procedure specification.
- PROCESS
- A grouping of basic operational elements used in welding, cutting, adhesive bonding, or thermal spraying.
- PROJECTION WELDING (PW)
- A resistance welding process that produces coalescence by the heat obtained from the resistance to the flow of the welding current. The resulting welds are localized at predetermined points by projections, embossments, or intersections.
- PROTECTIVE ATMOSPHERE
- A gas or vacuum envelope surrounding the workpieces used to prevent or facilitate removal of oxides and other detrimental surface substances.
- PUDDLE
- A nonstandard term for weld pool .
- PULL GUN TECHNIQUE
- A nonstandard term for backhand welding .
- PULSE (RESISTANCE WELDING)
- A current of controlled duration of either polarity through the welding circuit.
- R
- RANDOM INTERMITTENT WELDS
- Intermittent welds on one or both sides of a joint in which the weld increments are made without regard to spacing.
- REACTION FLUX (SOLDERING)
- A flux composition in which one or more of the ingredients reacts with a base metal upon heating to deposit one or more metals.
- REACTION STRESS
- A stress that cannot exist in a member if the member is isolated as a free body without connection to other parts of the structure.
- REDUCING ATMOSPHERE
- A chemically active protective atmosphere which at elevated temperature will reduce metal oxides to their metallic state.
- REDUCING FLAME
- A gas flame having a reducing effect due to excess fuel gas. See also neutral flame and oxidizing flame .
- REFLOWING
- A nonstandard term for flow brightening .
- REFLOW SOLDERING
- A nonstandard term for a soldering process variation in which preplaced solder is melted to produce a soldered joint or coated surface.
- RESIDUAL STRESS
- Stress present in a member that is free of external forces or thermal gradients.
- RESISTANCE BRAZING (RB)
- A brazing process in which the heat required is obtained from the resistance to electric current flow in a circuit of which the workpiece is a part.
- RESISTANCE BUTT WELDING
- A nonstandard term for flash welding and upset welding .
- RESISTANCE SEAM WELDING (RSW)
- A resistance welding process that produces coalescence at the faying surfaces of overlapped parts progressively along a length of a joint. The weld may be made with overlapping weld nuggets, a

continuous weld nugget, or by forging the joint as it is heated to the welding temperature by resistance to the flow of the welding current.

- RESISTANCE SOLDERING (RS)
- A soldering process in which the heat required is obtained from the resistance to electric current flow in a circuit of which the workpiece is a part.
- RESISTANCE SPOT WELDING (RSW)
- A resistance welding process that produces coalescence at the faying surfaces of a joint by the heat obtained from resistance to the flow of welding current through the workpieces from electrodes that serve to concentrate the welding current and pressure at the weld area.
- RESISTANCE WELDING (RW)
- A group of welding processes that produces coalescence of the faying surfaces with the heat obtained from resistance of the work to the flow of the welding current in a circuit of which the work is a part, and by the application of pressure.
- RESISTANCE WELDING ELECTRODE
- The part(s) of a resistance welding machine through which the welding current and, in most cases, force are applied directly to the work. The electrode may be in the form of a rotating wheel, rotating bar, cylinder, plate, clamp, chuck, or modification thereof.
- RESISTANCE WELDING GUN
- A manipulatable device to transfer current and provide electrode force to the weld area (usually in reference to a portable gun).
- REVERSE POLARITY
- A nonstandard term for direct current electrode positive .
- ROLL WELDING (ROW)
- A solid-state welding process that produces coalescence of metals by heating and by applying sufficient pressure with rolls to cause deformation at the faying surfaces. See also forge welding .
- ROOT
- A nonstandard term for joint root and weld root .
- ROOT BEAD
- A weld that extends into or includes part or all of the joint root.
- ROOT EDGE
- A root face of zero width. See also root face .
- ROOT FACE
- That portion of the groove face adjacent to the joint root.
- ROOT GAP
- A nonstandard term for root opening .
- ROOT OPENING
- The separation at the joint root between the workpieces.
- ROOT PENETRATION
- The depth that a weld extends into the joint root.
- ROOT RADIUS
- A nonstandard term for groove radius .
- ROOT REINFORCEMENT
- Weld reinforcement opposite the side from which welding was done.
- ROOT SURFACE
- The exposed surface of a weld opposite the side from which welding was done.
- S
- SCARF JOINT
- A form of butt joint.
- SEAL COAT
- Material applied to infiltrate the pores of a thermal spray deposit.
- SEAL WELD
- Any weld designed primarily to provide a specific degree of tightness against leakage.
- SEAM WELD
- A continuous weld made between or upon overlapping members, in which coalescence may start and occur on the faying surfaces, or may have proceeded from the outer surface of one member. The continuous weld may consist of a single weld bead or a series of overlapping spot welds. See also arc seam weld and resistance seam welding .

- SECONDARY CIRCUIT
- That portion of a welding machine that conducts the secondary current between the secondary terminals of the welding transformer and the electrodes, or electrode and workpiece.
- SELF-FLUXING ALLOYS (THERMAL SPRAYING)
- Surfacing materials that wet the substrate and coalesce when heated to their melting point, without the addition of a flux.
- SEMIAUTOMATIC ARC WELDING
- Arc welding with equipment that controls only the filler metal feed. The advance of the welding is manually controlled.
- SERIES WELDING
- A resistance welding secondary circuit variation in which the secondary current is conducted through the workpieces and electrodes or wheels in a series electrical path to simultaneously form multiple resistance spot, seam, or projection welds.
- SET DOWN
- A nonstandard term for upset .
- SHADOW MASK
- A thermal spraying process variation in which an area is partially shielded during thermal spraying, thus permitting some overspray to produce a feathering at the coating edge.
- SHEET SEPARATION (RESISTANCE WELDING)
- The gap surrounding the weld between faying surfaces, after the joint has been welded in spot, seam, or projection welding.
- SHIELDED METAL ARC CUTTING (SMAC)
- A metal arc cutting process in which metals are severed by melting them with the heat of an arc between a covered metal electrode and the base metal.
- SHIELDED METAL ARC WELDING (SMAW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a covered metal electrode and the workpieces. Shielding is obtained from decomposition of the electrode covering. Pressure is not used, and filler metal is obtained from the electrode.
- SHIELDING GAS
- Protective gas used to prevent atmospheric contamination.
- SHORT CIRCUITING TRANSFER (ARC WELDING)
- Metal transfer in which molten metal from a consumable electrode is deposited during repeated short circuits. See also globular transfer and spray transfer .
- SHOULDER
- A nonstandard term for root face .
- SHRINKAGE STRESS
- A nonstandard term for residual stress .
- SHRINKAGE VOID
- A cavity type discontinuity normally formed by shrinkage during solidification.
- SILVER ALLOY BRAZING
- A nonstandard term for brazing with a silver-base filler metal.
- SILVER SOLDERING
- A nonstandard term for brazing with a silver-base filler metal.
- SINGLE-BEVEL-GROOVE WELD
- A type of groove weld.
- SINGLE-FLARE-BEVEL-GROOVE WELD
- A weld in a groove formed by a member with a curved surface in contact with a planar member.
- SINGLE-FLARE-V-GROOVE WELD
- A weld in a groove formed by two members with curved surfaces.
- SINGLE IMPULSE WELDING
- A resistance welding process variation in which spot, projection, or upset welds are made with a single impulse.
- SINGLE-J-GROOVE WELD
- A type of groove weld.
- SINGLE-PORT NOZZLE
- A constricting nozzle containing one orifice, located below and concentric with the electrode.
- SINGLE-SQUARE-GROOVE WELD

- A type of groove weld.
- SINGLE-U-GROOVE WELD
- A type of groove weld.
- SINGLE-V-GROOVE WELD
- A type of groove weld.
- SINGLE-WELDED JOINT
- A fusion welded joint that is welded from one side only.
- SKULL
- The unmelted residue from a liquated filler metal.
- SLAG INCLUSION
- Nonmetallic solid material entrapped in weld metal or between weld metal and base metal.
- SLOT WELD
- A weld made in an elongated hole in one member of a joint fusing that member to another member. The hole may be open at one end. A fillet weld slot is not to be construed as conforming to this definition.
- SLUGGING
- The act of adding a separate piece or pieces of material in a joint before or during welding that results in a welded joint not complying with design, drawing, or specification requirements.
- SOFT SOLDER
- A nonstandard term for solder .
- SOLDER
- A filler metal used in soldering that has a liquidus not exceeding 450 °C (840 °F).
- SOLDERING (S)
- A group of welding processes that produces coalescence of materials by heating them to the soldering temperature and by using a filler metal having a liquidus not exceeding 450 °C (840 °F) and below the solidus of the base metals. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.
- SOLDERING GUN
- An electrical soldering iron with a pistol grip and a quick heating, relatively small bit.
- SOLDERING IRON
- A soldering tool having an internally or externally heated metal bit usually made of copper.
- SOLDER INTERFACE
- The interface between filler metal and base metal in a soldered joint.
- SOLID-STATE WELDING (SSW)
- A group of welding processes that produces coalescence at temperatures essentially below the melting point of the base metal without the addition of a brazing filler metal. Pressure may or may not be used.
- SPACER STRIP
- A metal strip or bar prepared for a groove weld and inserted in the joint root to serve as a backing and to maintain the root opening during welding. It can also bridge an exceptionally wide root opening due to poor fit.
- SPIT
- A nonstandard term for flash .
- SPLIT PIPE BACKING
- Backing in the form of a pipe segment used for welding round bars.
- SPOOL
- A filler metal package consisting of a continuous length of welding wire in coil form wound on a cylinder (called a barrel) which is flanged at both ends. The flange contains a spindle hole of smaller diameter than the inside diameter of the barrel.
- SPOT WELD
- A weld made between or upon overlapping members in which coalescence may start and occur on the faying surfaces or may proceed from the outer surface of one member. The weld cross section (plan view) is approximately circular. See also arc spot weld and resistance spot welding .
- SPRAY DEPOSIT
- The coating or layer of surfacing material applied by a thermal spraying process.
- SPRAY DEPOSIT DENSITY RATIO (THERMAL SPRAYING)
- The ratio of the density of the spray deposit to the theoretical density of a surfacing material, usually expressed as a percent of theoretical density.
- SPRAY TRANSFER (ARC WELDING)

- Metal transfer in which molten metal from a consumable electrode is propelled axially across the arc in small droplets. See also globular transfer and short circuiting transfer .
- SQUARE-GROOVE WELD
- A type of groove weld.
- STACK CUTTING
- Thermal cutting of stacked metal plates arranged so that all the plates are severed by a single cut.
- STAGGERED INTERMITTENT WELD
- An intermittent weld on both sides of a joint in which the weld increments on one side are alternated with respect to those on the other side.
- STANDOFF DISTANCE
- The distance between a nozzle and the workpiece.
- STICK ELECTRODE
- A nonstandard term for covered electrode .
- STICK ELECTRODE WELDING
- A nonstandard term for shielded metal arc welding .
- STICKOUT
- A nonstandard term for electrode extension .
- STOPOFF
- A material used on the surfaces adjacent to the joint to limit the spread of soldering or brazing filler metal.
- STRAIGHT POLARITY
- A nonstandard term for direct current electrode negative .
- STRANDED ELECTRODE
- A composite filler metal electrode consisting of stranded wires that may mechanically enclose materials to improve properties, stabilize the arc, or provide shielding.
- STRESS RELIEF CRACKING
- Intergranular cracking in the heat affected zone or weld metal that occurs during the exposure of weldments to elevated temperatures during postweld heat treatment or high temperature service.
- STRESS RELIEF HEAT TREATMENT
- Uniform heating of a structure or a portion thereof to a sufficient temperature to relieve the major portion of the residual stresses, followed by uniform cooling.
- STRINGER BEAD
- A type of weld bead made without appreciable weaving motion. See also weave bead .
- STUB
- The short length of welding rod or consumable electrode that remains after its use for welding.
- STUD ARC WELDING (SW)
- An arc welding process that produces coalescence of metals by heating them with an arc between a metal stud, or similar part, and the other workpiece. When the surfaces to be joined are properly heated, they are brought together under pressure. Partial shielding may be obtained by the use of a ceramic ferrule surrounding the stud. Shielding gas or flux may or may not be used.
- STUD WELDING
- A general term for joining a metal stud or similar part to a workpiece. Welding may be accommodated by arc, resistance, friction, or other processes with or without external gas shielding.
- SUBMERGED ARC WELDING (SAW)
- An arc welding process that produces coalescence of metals by heating them with an arc or arcs between a bare metal electrode or electrodes and the workpieces. The arc and molten metal are shielded by a blanket of granular, fusible material on the workpieces. Pressure is not used, and filler metal is obtained from the electrode and sometimes from a supplemental source (welding rod, flux, or metal granules).
- SUBSTRATE
- Any material to which a thermal spray deposit is applied.
- SURFACE EXPULSION
- Expulsion occurring at an electrode-to-workpiece contact rather than at the faying surface.
- SURFACING
- The application by welding, brazing, or thermal spraying of a layer or layers of material to a surface to obtain desired properties or dimensions, as opposed to making a joint.
- SURFACING MATERIAL
- The material that is applied to a base metal or substrate during surfacing.

- SURFACING METAL
- The metal that is applied to a base metal or substrate during surfacing. See also surfacing material .
- SURFACING WELD
- A weld applied to a surface, as opposed to making a joint, to obtain desired properties or dimensions.
- SWEAT SOLDERING
- A soldering process variation in which two or more parts that have been precoated with solder are reheated and assembled into a joint without the use of additional solder.
- SYNCHRONOUS TIMING (RESISTANCE WELDING)
- The initiation of each half cycle of welding transformer primary current on an accurately timed delay with respect to the polarity reversal of the power supply.
- T
- TACKER
- A nonstandard term for a tack welder.
- TACK WELD
- A weld made to hold parts of a weldment in proper alignment until the final welds are made.
- THEORETICAL THROAT
- The distance from the beginning of the joint root perpendicular to the hypotenuse of the largest right triangle that can be inscribed within the cross section of a fillet weld. This dimension is based on the assumption that the root opening is equal to zero.
- THERMAL CUTTING (TC)
- A group of cutting processes that melts the base metal. See also arc cutting , electron beam cutting , laser beam cutting , and oxygen cutting .
- THERMAL SPRAYING (THSP)
- A group of processes in which finely divided metallic or non-metallic surfacing materials are deposited in a molten or semimolten condition on a substrate to form a spray deposit. The surfacing material may be in the form of powder, rod, or wire. See also arc spraying , flame spraying , and plasma spraying .
- THERMAL SPRAYING GUN
- A device for heating, feeding, and directing the flow of a surfacing material.
- THERMAL STRESS
- Stress resulting from nonuniform temperature distribution.
- THERMIT CRUCIBLE
- The vessel in which the thermit reaction takes place.
- THERMIT MIXTURE
- A mixture of metal oxide and finely divided aluminum with the addition of alloying metals as required.
- THERMIT MOLD
- A mold formed around the workpieces to receive the molten metal.
- THERMIT REACTION
- The chemical reaction between metal oxide and aluminum that produces superheated molten metal and a slag containing aluminum oxide.
- THERMIT WELDING (TW)
- A welding process that produces coalescence of metals by heating them with superheated liquid metal from a chemical reaction between a metal oxide and aluminum, with or without the application of pressure. Filler metal is obtained from the liquid metal. (*Note*: The *ASM Handbook* uses the spelling "thermit*e* welding.")
- THERMOCOMPRESSION BONDING
- A nonstandard term for hot pressure welding .
- THROAT OF A FILLET WELD
- See actual throat , effective throat , and theoretical throat .
- THROAT OF A GROOVE WELD
- A nonstandard term for groove weld size .
- TIG WELDING
- A nonstandard term for gas tungsten arc welding .
- TINNING
- A nonstandard term for precoating .
- T-JOINT
- A joint between two members located approximately at right angles to each other in the form of a T.
- TOE CRACK

- A crack in the base metal at the toe of a weld.
- TORCH BRAZING (TB)
- A brazing process in which the heat required is furnished by a fuel gas flame.
- TORCH SOLDERING (TS)
- A soldering process in which the heat required is furnished by a fuel gas flame.
- TORCH TIP
- See cutting tip and welding tip .
- TRANSFERRED ARC (PLASMA ARC WELDING)
- A plasma arc established between the electrode and the workpiece.
- TRANSVERSE CRACK
- A crack with its major axis oriented approximately perpendicular to the weld axis.
- TWIN CARBON ARC BRAZING
- A nonstandard term for carbon arc brazing .
- U
- U-GROOVE WELD
- A type of groove weld.
- ULTRASONIC COUPLER (ULTRASONIC SOLDERING AND ULTRASONIC WELDING)
- Elements through which ultrasonic vibration is transmitted from the transducer to the tip.
- ULTRASONIC SOLDERING
- A soldering process variation in which high frequency vibratory energy is transmitted through molten solder to remove undesirable surface films and thereby promote wetting of the base metal. This operation is usually accomplished without a flux.
- ULTRASONIC WELDING (USW)
- A solid-state welding process that produces coalescence of materials by the local application of high frequency vibratory energy as the workpieces are held together under pressure.
- UNDERBEAD CRACK
- A crack in the heat affected zone generally not extending to the surface of the base metal.
- UNDERCUT
- A groove melted into the base metal adjacent to the weld toe or weld root and left unfilled by weld metal.
- UNDERFILL
- A depression on the weld face or root surface extending below the adjacent surface of the base metal.
- UPSET
- Bulk deformation resulting from the application of pressure in welding. The upset may be measured as a percent increase in interface area, a reduction in length, a percent reduction in lap joint thickness, or a reduction in cross wire weld stack height.
- UPSET BUTT WELDING
- A nonstandard term for upset welding .
- UPSET DISTANCE
- The total loss of axial length of the workpieces from the initial contact to the completion of the weld. In flash welding, the upset distance is equal to the platen movement from the end of flash time to the end of upset.
- UPSET WELDING (UW)
- A resistance welding process that produces coalescence over the entire area of faying surfaces or progressively along a butt joint by the heat obtained from the resistance to the flow of welding current through the area where those surfaces are in contact. Pressure is used to complete the weld.
- V
- VACUUM BRAZING
- A nonstandard term for various brazing processes that take place in a chamber or retort below atmospheric pressure.
- VERTICAL POSITION
- The position of welding in which the weld axis is approximately vertical.
- VERTICAL POSITION (PIPE WELDING)
- The position of a pipe joint in which welding is performed in the horizontal position and the pipe may or may not be rotated.
- V-GROOVE WELD
- A type of groove weld.
- W

- WAVE SOLDERING (WS)
- An automatic soldering process where workpieces are passed through a wave of molten solder. See also dip soldering .
- WAX PATTERN (THERMIT WELDING)
- Wax molded around the workpieces to the form desired for the completed weld.
- WEAVE BEAD
- A type of weld bead made with transverse oscillation.
- WELD
- A localized coalescence of metals or non-metals produced either by heating the materials to the welding temperature, with or without the application of pressure, or by the application of pressure alone, with or without the use of filler metal.
- WELDABILITY
- The capacity of a material to be welded under the imposed fabrication conditions into a specific, suitably designed structure and to perform satisfactorily in the intended service.
- WELD AXIS
- A line through the length of the weld, perpendicular to and at the geometric center of its cross section.
- WELD BEAD
- A weld resulting from a pass. See also stringer bead and weave bead .
- WELD BONDING
- A resistance spot welding process variation in which the spot weld strength is augmented by adhesive at the faying surfaces.
- WELD BRAZING
- A joining method that combines resistance welding with brazing.
- WELD CRACK
- A crack located in the weld metal or heat affected zone.
- WELDER
- One who performs manual or semiautomatic welding operation.
- WELDER PERFORMANCE QUALIFICATION
- The demonstration of a welder's ability to produce welds meeting prescribed standards.
- WELD FACE
- The exposed surface of a weld on the side from which welding was done.
- WELDING
- A materials joining process used in making welds.
- WELDING BLOWPIPE
- A nonstandard term for welding torch.
- WELDING CURRENT
- The current in the welding circuit during the making of a weld.
- WELDING CYCLE
- The complete series of events involved in the making of a weld.
- WELDING ELECTRODE
- A component of the welding circuit through which current is conducted and that terminates at the arc, molten conductive slag, or base metal. See also arc welding electrode , flux cored electrode , metal cored electrode , metal electrode , resistance welding electrode , and stranded electrode .
- WELDING GROUND
- A nonstandard term for workpiece connection .
- WELDING LEADS
- The workpiece lead and electrode lead of an arc welding circuit.
- WELDING MACHINE
- Equipment used to perform the welding operation; for example, spot welding machine, arc welding machine, and seam welding machine.
- WELDING OPERATOR
- One who operates machine or automatic welding equipment.
- WELDING POSITION
- See flat position , horizontal fixed position , horizontal position, horizontal rolled position , inclined position , overhead position , and vertical position .
- WELDING PROCEDURE

- The detailed methods and practices involved in the production of a weldment. See also welding procedure specification .
- WELDING PROCEDURE SPECIFICATION (WPS)
- A document providing in detail the required variables for a specific application to ensure repeatability by properly trained welders and welding operators.
- WELDING ROD
- A form of welding filler metal, normally packaged in straight lengths, that does not conduct electrical current.
- WELDING SEQUENCE
- The order of making the welds in a weldment.
- WELDING TIP
- That part of an oxyfuel gas welding torch from which the gases issue.
- WELDING TORCH (ARC)
- A device used in the gas tungsten and plasma arc welding processes to control the position of the electrode, to transfer current to the arc, and to direct the flow of shielding and plasma gas.
- WELDING TORCH (OXYFUEL GAS)
- A device used in oxyfuel gas welding, torch brazing, and torch soldering for directing the heating flame produced by the controlled combustion of fuel gases.
- WELDING WHEEL
- A nonstandard term for resistance welding electrode .
- WELDING WIRE
- A form of welding filler metal, normally packaged as coils or spools, that may or may not conduct electrical current depending upon the welding process with which it is used. See also welding electrode and welding rod .
- WELD INTERFACE
- The interface between weld metal and base metal in a fusion weld, between base metals in a solid-state weld without filler metal or between filler metal and base metal in a solid-state weld with filler metal, and in a braze.
- WELD LINE
- A nonstandard term for weld interface .
- WELDMENT
- An assembly whose component parts are joined by welding.
- WELD METAL
- That portion of a weld that has been melted during welding.
- WELDOR
- A nonstandard term for welder .
- WELD PASS
- A single progression of welding or surfacing along a joint or substrate. The result of a pass is a weld bead, layer, or spray deposit.
- WELD PASS SEQUENCE
- The order in which the weld passes are made.
- WELD PENETRATION
- A nonstandard term for joint penetration and root penetration .
- WELD POOL
- The localized volume of molten metal in a weld prior to its solidification as weld metal.
- WELD PUDDLE
- A nonstandard term for weld pool .
- WELD REINFORCEMENT
- Weld metal in excess of the quantity required to fill a joint. See also face reinforcement and root reinforcement .
- WELD ROOT
- The points, as shown in cross section, at which the back of the weld intersects the base metal surfaces.
- WELD SIZE
- See edge weld size , fillet weld size , flange weld size , and groove weld size .
- WELD TAB
- Additional material on which the weld may be initiated or terminated.
- WELD THROAT

- See actual throat , effective throat , and theoretical throat .
- WELD TOE
- The junction of the weld face and the base metal.
- WETTING
- The phenomenon whereby a liquid filler metal or flux spreads and adheres in a thin continuous layer on a solid base metal.
- WIPED JOINT
- A joint made with solder having a wide melting range and with the heat supplied by the molten solder poured onto the joint. The solder is manipulated with a hand-held cloth or paddle so as to obtain the required size and contour.
- WORK CONNECTION
- A nonstandard term for workpiece connection .
- WORK LEAD
- A nonstandard term for workpiece lead .
- WORKPIECE
- The part being welded, brazed, soldered, or cut.
- WORKPIECE CONNECTION
- The connection of the workpiece lead to the workpiece.
- WORKPIECE LEAD
- The electrical conductor between the arc welding current source and the workpiece connection.

Note

* THIS GLOSSARY IS REPRINTED BY PERMISSION OF THE AMERICAN WELDING SOCIETY FROM THE *WELDING HANDBOOK*, 8TH EDITION, VOLUME 1, AMERICAN WELDING SOCIETY, 1987. IT WAS PREPARED BY THE AWS COMMITTEE ON DEFINITIONS AND SYMBOLS CONSISTING OF G.E. METGER, *CHAIRMAN*, AFWAL/MLLS; J.T. BISKUP, CANADIAN WELDING BUREAU; W.F. BROWN, WESTINGHOUSE HANFORD; C.D. BURNHAM, CONSULTANT; R.J. CHRISTOFFEL, GENERAL ELECTRIC COMPANY; G.B. COATES, GENERAL ELECTRIC COMPANY; MICHAEL D. COOPER, HOBART SCHOOL OF WELDING TECHNOLOGY; W.L. GREEN, OHIO STATE UNIVERSITY; J.E. GREER, GENERAL ELECTRIC RAILROAD; M.J. GRYCO, PACKER ENGINEERING ASSOCIATES; D.E. HAMILTON, TRINITY ENGINEERING TESTING CORPORATION; E.A. HARWART, CONSULTANT; A. RAY HOLLINS, JR., DUKE POWER COMPANY; M.J. HOULE, NATIONAL BOARD OF BOILER AND PRESSURE VESSEL INSPECTORS; STEPHEN R. MORSE, DEERE AND COMPANY; L.C. NORTHARD, TENNESSEE VALLEY AUTHORITY; D.H. ORTS, ARMCO, INCORPORATED; E.J. SEEL, AMERICAN WELDING SOCIETY; J.J. STANCZAK, STEEL DETAILERS & DESIGNERS; J.J. VAGI, BABCOCK AND WILCOX; J.L. WILK, COAST TO COAST CONSTRUCTION COMPANY; UNDER THE DIRECTION OF AWS WELDING HANDBOOK COMMITTEE CHAIRMEN J.H. HANNAHS, MIDMARK CORPORATION, AND M.J. TOMSIC, PLASTRONICS INCORPORATED (AFFILIATIONS CIRCA 1987).

Abbreviations, Symbols, and Tradenames

- ABBREVIATIONS AND SYMBOLS
- A
- austenite; ampere
- Å
- angstrom
- AA
- Aluminum Association
- AAR

- Association of American Railroads
- AASHTO
- American Association of State Highway and Transportation Officials
- ABS
- American Bureau of Shipping
- AC
- alternating current
- AC
- air cool; aligned carbide
- AC_{CM}
- in hypereutectoid steel, temperature at which cementite completes solution in austenite
- AC_1
- temperature at which austenite begins to form during heating
- AC_3
- temperature at which transformation of ferrite to austenite is completed during heating
- AE_{CM}, AE_1, AE_3
- equilibrium transformation temperatures in steel
- AES
- Auger electron spectroscopy; acoustic emission spectroscopy
- AF
- acicular ferrite
- AFM
- atomic force microscopy
- AI
- artificial intelligence
- AISC
- American Institute of Steel Construction
- AISI
- American Iron and Steel Institute
- AMS
- Aerospace Material Specification
- ANSI
- American National Standards Institute
- AOD
- argon-oxygen decarburization
- API
- American Petroleum Institute
- AR_{CM}
- temperature at which cementite begins to precipitate from austenite upon cooling
- AR_1
- temperature at which transformation to ferrite or to ferrite plus cementite is completed on cooling
- AR_3
- temperature at which transformation of austenite to ferrite begins on cooling
- AREA
- American Railway Engineers Association
- ASM
- American Society for Metals (now ASM International)
- ASME
- American Society of Mechanical Engineers
- ASTM
- American Society for Testing and Materials
- AT.%
- atomic percent
- ATM
- atmospheres (pressure)
- AWS
- American Welding Society

- B
- bainite
- BAL
- balance
- BCC
- body-centered cubic
- BCT
- body-centered tetragonal
- C
- edge length in crystal structure; speed of light; specific heat; constant
- C
- cementite; coulomb; heat capacity
- CAC
- carbon arc cutting
- CAC-A
- air carbon arc cutting
- CAD/CAM
- computer-aided design/computer-aided manufacturing
- CAFE
- Corporate Average Fuel Economy (standard)
- CAW
- carbon arc welding
- CAW-G
- gas carbon arc welding
- CAW-S
- shielded carbon arc welding
- CBN
- cubic boron nitride
- CCD
- charge-coupled device
- CCT
- continuous-cooling transformation
- CD
- candela
- CE
- carbon equivalent
- CGS
- centimeter-gram-second (system of units)
- CM
- centimeter
- CMC
- ceramic-matrix composite
- CNC
- computer numerical control
- COD
- crack-opening displacement
- C_P
- specific heat at constant pressure
- CP
- centipoise
- CP
- commercially pure
- CPT
- critical pitting temperature
- CR
- corrosion resistant
- CRT

- cathode-ray tube
- CST
- centistokes
- CTE
- coefficient of thermal expansion
- CTOD
- crack tip opening displacement
- CVD
- chemical vapor deposition
- CVN
- Charpy V-notch (impact test or specimen)
- *D*
- diameter
- *DA*/*DN*
- fatigue crack growth rate
- DARPA
- Defense Advanced Research Projects Agency
- DB
- decibel
- DB
- diffusion bonding; dip brazing
- DBTT
- ductile-to-brittle transition temperature
- DC
- direct current
- DCEN
- direct current, electrode negative
- DCEP
- direct current, electrode positive
- DFB
- diffusion brazing
- DFW
- diffusion welding
- DHC
- delayed hydride cracking
- DIAM
- diameter
- DIN
- Deutsche Industrie-Normen (German Industrial Standards)
- DPH
- diamond pyramid hardness
- DRA
- discontinuously reinforced aluminum
- DS
- dip soldering
- DTA
- differential thermal analysis
- *E*
- natural log base, 2.71828; charge of an electron
- EB
- electron beam
- EBC
- electron-beam cutting
- EBW
- electron-beam welding
- EDM
- electrical discharge machining

- EDXA
- energy-dispersive x-ray analysis
- EELS
- electron energy loss spectroscopy
- EERC
- Earthquake Engineering Research Center
- EGW
- electrogas welding
- ELI
- extra-low interstitial
- EMF
- electromotive force
- EPA
- Environmental Protection Agency
- EPFM
- elastic plastic fracture mechanics
- EPRI
- Electric Power Research Institute
- EQ
- equation
- ESW
- electroslag welding
- ***ET AL.***
- and others
- ETP
- electrolytic tough pitch
- EV
- electron volt
- EXB
- exothermic brazing
- EXP
- base of the natural logarithm
- EXW
- explosion welding
- ***F***
- frequency
- F
- ferrite
- FAA
- Federal Aviation Administration
- FAD
- failure-assessment diagram; fracture-assessment diagram
- FB
- furnace brazing
- FCAW
- flux-cored arc welding
- FCC
- face-centered cubic
- FCM
- fracture critical tension member
- FCT
- face-centered tetragonal
- FEA
- finite-element analysis
- FEM
- finite-element method
- FHA

- Federal Highway Administration
- FIG.
- figure
- FM
- frequency modulation
- FMVSS
- Federal Motor Vehicle Safety Standards
- FN
- ferrite number
- FRW
- friction welding
- FS
- furnace soldering
- FT
- foot
- FW
- flash welding
- G
- gram; acceleration due to gravity
- G
- graphite; gauss
- GAL
- gallon
- GBF
- grain-boundary ferrite
- GF
- gram force
- GMA
- gas-metal arc
- GMAC
- gas-metal arc cutting
- GMAW
- gas-metal arc welding
- GPA
- gigapascal
- GTA
- gas-tungsten arc
- GTAC
- gas-tungsten arc cutting
- GTAW
- gas-tungsten arc welding
- H
- hour; Planck's constant (6.626×10^{-27} erg · s)
- H
- Henry
- *H*
- enthalpy; hardness; magnetic field
- HAZ
- heat-affected zone
- HB
- Brinell hardness
- HCP
- hexagonal close-packed
- HHC
- hot-hollow cathode
- HIC
- hydrogen-induced cracking

- HIP
- hot isostatic pressing
- HK
- Knoop hardness
- HP
- horsepower
- HR
- Rockwell hardness (requires scale designation, such as HRC for Rockwell C hardness)
- HREM
- high-resolution electron microscopy
- HSLA
- high-strength low-alloy (steel)
- HSS
- high-speed steel(s)
- HTLA
- heat-treatable low-alloy (steel)
- HV
- Vickers hardness
- HZ
- hertz
- *I*
- intensity; electrical current
- IA
- inorganic acid
- ID
- inside diameter
- IGA
- intergranular attack
- IGSCC
- intergranular stress-corrosion cracking
- IIW
- International Institute of Welding
- I/M
- ingot metallurgy
- IMO
- International Maritime Organization
- IN.
- inch
- IPTS
- International Practical Temperature Scale
- IR
- infrared
- IRS
- infrared soldering
- IS
- induction soldering
- ISCC
- intergranular stress-corrosion cracking
- ISO
- International Organization for Standardization
- J
- joule
- K
- equilibrium distribution coefficient; thermal conductivity; Boltzmann constant
- K
- Kelvin
- KG

- kilogram
- KGF
- kilogram force
- K_{IC}
- plane-strain fracture toughness
- K_{ISCC}
- threshold stress intensity to produce stress-corrosion cracking
- KM
- kilometer
- KN
- kilonewton
- KPA
- kilopascal
- KSI
- kips (1000 lbf) per square inch
- KV
- kilovolt
- KW
- kilowatt
- L
- longitudinal, liter
- LB
- pound
- LBF
- pound force
- LBW
- laser-beam welding
- LCL
- lower control limit
- LEED
- low-energy electron diffraction
- LEFM
- linear elastic fracture mechanics
- LME
- liquid-metal embrittlement
- LMP
- Larson-Miller parameter
- IN
- natural logarithm (base *e*)
- LNG
- liquefied natural gas
- LOG
- common logarithm (base 10)
- LPG
- liquefied petroleum gas
- LSI
- large-scale integrated (circuit)
- LT
- long transverse (direction)
- LTE
- local thermodynamic equilibrium
- LTS
- low-temperature sensitization
- LVDT
- linear variable differential transformer
- M
- meter

- MA
- milliampere
- MC
- metal carbide
- MCL
- maximum crack length
- MEV
- megaelectronvolt
- M_F
- temperature at which martensite formation finishes during cooling
- MG
- milligram
- MG
- megagram (metric tonne, or kg × 10^3)
- MIC
- microbiologically influenced corrosion
- MIN
- minute; minimum
- ML
- milliliter
- MM
- millimeter
- MO
- multiple operator
- MPA
- millipascal
- MPA
- megapascal
- MPG
- miles per gallon
- MPH
- miles per hour
- MRDA
- man-rated demonstration vehicle
- MRR
- material removal rate
- MS
- millisecond
- M_S
- temperature at which martensite starts to form from austenite on cooling
- MS
- megasiemens
- MT
- millitesla
- MV
- millivolt
- MV
- megavolt
- MVC
- most vulnerable component
- N
- newton
- N
- number of cycles; normal solution; normal force
- NACE
- National Association of Corrosion Engineers
- NASA

- National Aeronautics and Space Administration
- NBS
- National Bureau of Standards (former name of NIST)
- NDE
- nondestructive examination
- NDE
- nondestructive evaluation
- NEC
- National Electric Code
- NEMA
- National Electrical Manufacturers Association
- NIST
- National Institute of Standards and Technology
- NM
- nanometer
- NMMA
- National Marine Manufacturers Association
- NNS
- neural network system
- NO.
- number
- NS
- nanosecond
- OA
- organic acid
- OAW
- oxyacetylene welding
- OCV
- open-circuit voltage
- OE
- oersted
- OFG
- oxyfuel gas
- OFW
- oxyfuel gas welding
- ORNL
- Oak Ridge National Laboratory
- OSHA
- Occupational Safety and Health Administration
- OZ
- ounce
- P
- page
- P
- pearlite
- PA
- pascal
- PAW
- plasma arc welding
- PEEM
- photoemission electron microscopy
- PH
- negative logarithm of hydrogen-ion activity
- PH
- precipitation hardenable; precipitation hardening
- PID
- proportional-integral-differential

- PM
- planar-magnetron
- PPB
- parts per billion
- PPM
- parts per million
- PPT
- parts per trillion
- PRE
- pitting resistance equivalent
- PRR
- pulse repetition rates
- PSI
- pounds per square inch
- PSIA
- pounds per square inch absolute
- PSIG
- gage pressure (pressure relative to ambient pressure) in pounds per square inch
- PSTM
- photon scanning tunneling microscopy
- PW
- projection welding
- PWAA
- postweld artificial aging
- PWB
- printed wiring board
- PWHT
- postweld heat treatment
- PWM
- pulse width modulation
- Q&T
- quenched and tempered
- R
- roentgen
- R_A
- surface roughness in terms of arithmetic average
- RA
- rosin fully activated; roughness average
- *RA*
- reduction in area
- RE
- rare earth
- REF
- reference
- REF
- relative erosion factor
- RF
- radio frequency
- RH
- relative humidity
- RMA
- rosin mildly activated
- RMS
- root mean square
- RPF
- relative potency factor
- RPM

- revolutions per minute
- R_Q
- rms (root mean square) roughness
- RS
- resistance soldering
- RSA
- rosin superactivated
- RSEW
- seam welding
- RSW
- resistance spot welding
- RT
- room temperature
- RW
- resistance welding
- RWMA
- Resistance Welder Manufacturers Association
- R_Y
- maximum peak-to-valley height
- R_Z
- ten-point height
- S
- second
- S
- siemens
- SA
- synthetic activated
- SACP
- selected-area channeling patterns
- SAE
- Society of Automotive Engineers
- SAM
- scanning acoustic microscope/microscopy
- SAW
- submerged arc welding
- SCC
- stress-corrosion cracking
- SCPM
- scanning chemical potential microscopy
- SCR
- silicon-controlled rectifier
- SEM
- scanning electron microscope/microscopy
- SFM
- surface feet per minute
- SHE
- standard hydrogen electrode
- SI
- Système International d'Unités
- SIR
- surface insulation resistance
- SLAM
- scanning laser acoustic microscope/microscopy
- SLEEM
- scanning low-energy electron microscopy
- SMA
- shielded metal arc

- SMAW
- shielded metal arc welding
- SPA-LEED
- spot profile analysis-low-energy electron diffraction
- SPC
- statistical process control
- SPF
- sideplate ferrite
- SQC
- statistical quality control
- SRA
- stress-relief annealing
- SSW
- solid-state welding
- STA
- solution-treated and aged
- STEM
- scanning transmission electron microscope/microscopy
- STM/S
- scanning tunneling microscopy/spectroscopy
- SUS
- Saybolt Universal Seconds (viscosity)
- SV
- sievert
- SW
- stud arc welding
- T
- thickness; time
- T
- tesla
- *T*
- temperature
- TB
- torch brazing
- TCP
- topologically close packed
- TEM
- transmission electron microscope/microscopy
- TGA
- thermogravimetric analysis
- TGSCC
- transgranular stress-corrosion cracking
- TIG
- tungsten inert gas (welding)
- TMCP
- thermomechanically controlled process
- TS
- torch soldering
- TTT
- time-temperature transformation
- TW
- thermit welding; thermite welding
- TZP
- tetragonal zirconia polycrystals
- UCL
- upper control limit
- UNS

- Unified Numbering System
- USW
- ultrasonic welding
- UTS
- ultimate tensile strength
- UW
- upset welding
- V
- velocity
- V
- volt
- VIM-VAR
- vacuum induction melted-vacuum arc remelted
- VOL
- volume
- VOL%
- volume percent
- VPPA
- variable polarity plasma arc
- W
- watt
- WI
- wettability index
- WRC
- Welding Research Council
- WS
- wave soldering
- WSN
- weld set number
- WT%
- weight percent
- XPS
- x-ray photoelectron spectroscopy
- YR
- year
- Z
- atomic number
- °
- angular measure; degree
- °C
- degree Celsius (centigrade)
- °F
- degree Fahrenheit
- €
- direction of reaction
- ÷
- divided by
- =
- equals
- ≅
- approximately equals
- ≠
- not equal to
- ≡
- identical with
- >
- greater than

- ?
- much greater than
- [GES]
- greater than or equal to
- ∞
- infinity
- ∝
- is proportional to; varies as
- ∫
- integral of
- <
- less than
- =
- much less than
- ≤
- less than or equal to
- ±
- maximum deviation
- -
- minus; negative ion charge
- ×
- diameters (magnification); multiplied by
- ·
- multiplied by
- /
- per
- %
- percent
- +
- plus; positive ion charge
- √
- square root of
- ~
- approximately; similar to
- ∂
- partial derivative
- α
- Stefan-Boltzmann constant
- γ
- shear strain rate
- γ_E
- elastic strain
- γ_T
- total strain
- Δ
- change in quantity; an increment; a range
- ε
- strain
- $\dot{e}$
- strain rate
- θ
- angle
- λ
- wavelength
- μ
- friction coefficient; magnetic permeability

- μ_S
- static coefficient of friction
- μ F
- microfarads
- μ IN.
- microinch
- μ M
- micrometer (micron)
- μS
- microsecond
- *n*
- Poisson's ratio
- π
- pi (3.141592)
-
- density
- σ
- stress; standard deviation
- Σ
- summation of
- *t*
- applied stress
- Ω
- angular velocity; frequency
- Ω
- ohm
