Obviously if the wear is to be accurately determined, all the debris must be completely removed. This can usually be achieved by ultrasonic cleaning. There have been chemical methods that involve the use of complex selenium compounds that remove the debris but do not attack the underlying material. Removal of the debris assists subsequent examination in the scanning microscope. Fretting wear is usually expressed, as are other types of wear, as a specific wear rate, that is, the volume of material lost per unit distance of sliding per unit of applied load.

A more sophisticated method of assessing fretting wear is to use thin-layer activation (TLA). It involves irradiation of one of the surfaces with protons from the cyclotron, which results in the formation of radionuclides, which in the case of steel is mainly cobalt-56. Measurement of the γ radiation from the debris or transferred material is claimed to give accurate results with a minute amount of debris (Ref 34).

Sliding Contact Damage Testing

Specimen Preparation

There are two factors that can influence the results in fretting wear tests. These are the surface roughness of the specimens and the existence of residual stresses in the specimen surface. Generally speaking, the more highly polished the surface the greater the wear. This is attributed to the fact that the oxide debris is an abrasive material and participates in the wear process. On a rough surface, contact is via well-defined asperities and the debris can drop into the adjacent grooves. Residual stress has an effect because one of the basic mechanisms is surface fatigue as exemplified in Suh's delamination theory (Ref 35). A residual tensile stress increases the amount of wear, whereas a compressive stress reduces it (Ref 36). This is an argument for the application of shot peening to prevent fretting wear since it roughens the surface and generates a compressive residual stress in the surface. In most experimental investigations, it is usual to give the specimens a light polish with 000

emery paper followed by degreasing in acetone or ultrasonic cleaning. The SEM is a very suitable piece of equipment for examining the surface damage. Figure 18 shows a typical example.

Fig. 18 SEM micrograph of fretting damage on a mild steel specimen showing compacted debris and delamination

Sliding Contact Damage Testing

Reducing Fretting Wear

The first approach to a fretting problem is to consider the basic design of the contacting components. This is particularly so if the fretting is the result of one of the members of the contact being subjected to a cyclic stress, that is, fatigued. In this case, it is important if possible to reduce stress concentrations in the region of the contact. In the case of a hub on a shaft, this is achieved by increasing the shaft diameter at the wheel seat with a generous fillet radius. A similar effect can be achieved by providing a stress-relieving groove. Such design changes are those customarily recommended in designing against fatigue. If the problem cannot be tackled in this way, then recourse has to be made to surface treatments. Increasing the hardness of the surface by work hardening, for example, by shot peening or surface rolling, or by diffusion treatments such as carburizing or nitriding in the case of steel can be effective. Beyond that there is now a wide variety of treatments

encompassed in the term “surface engineering.” Hard coatings such as titanium nitride (TiN) can be recommended if the substrate material is sufficiently strong to support them (Ref 37). However, if breakdown occurs the result can be disastrous because one then has a very abrasive material in the contact. Ion implantation has the advantage of surface alloying not possible by other means and also the development of residual compressive stress. More information on the control of fretting wear is given in Ref 31 and the article “Fretting Fatigue Testing” in this Volume.

Introduction to Creep and Stress-Relaxation Testing

James C. Earthman, University of California at Irvine

Introduction

THE FIELD of materials behavior at elevated temperatures has seen a formidable wealth of advancements over the last century. These accomplishments were made possible by the work of many scientists and engineers throughout the world who developed critical technologies necessary to make high-temperature materials stronger and more reliable (Ref 1, 2, 3). Applications for these materials include jet engines, power generation facilities, automobile engines, and electronic devices (Ref 4, 5). The potential efficiency of these systems typically increases with increasing operating temperature. This natural trend provides a strong demand for materials that can withstand higher temperatures. For aerospace applications, there is also a strong need for reducing weight, and it is often the high-temperature materials that have the highest densities in the aerospace structure. Reduced weight has been achieved by reducing component geometry, leading to greater stresses in high-temperature materials. Naturally, the importance of reliable creep and stress-rupture testing increases with increasing service stress. Introducing new high-temperature materials that have lower densities is another means by which weight reduction goals have been met for aerospace structures.

Introduction to Creep and Stress-Relaxation Testing

James C. Earthman, University of California at Irvine

Trends and New Technologies in Materials Testing

Considerable resources and effort have been spent over the last few decades on developing new methods of materials synthesis in order to satisfy the demand for better high-temperature materials. For example, mechanical alloying, sol gel processing, and various spray processing technologies have developed rapidly (Ref 6). These and other processing methods have successfully provided new materials systems that exhibit significantly higher creep strengths compared to those for conventional alloys. These new materials are typically tested extensively at elevated service temperatures before they can be approved for use (Ref 3). The demand for reliable data has led to the advancement of high-temperature testing methodologies that incorporate computer-based data acquisition and control.

Creep deformation and rupture experiments are used to determine the strength and lifetime of materials under quasi-static conditions at elevated temperatures. This testing typically involves imposing constant stress or displacement conditions as well as a constant elevated temperature. In addition to simulating service environments, these quasi-static conditions typically induce a physical behavior that is quite tractable from a theoretical perspective. Accordingly, there have been a considerable number of advancements in the theory of creep and creep rupture that can provide a physically based understanding of the microstructural mechanisms that govern the observed behavior. For the practicing engineer, an understanding of the physics of creep behavior can be quite useful for determining how a material might be altered microstructurally to perform better at elevated temperatures. This knowledge can also be used to improve methods of predicting high-temperature behavior from extrapolations of available laboratory data. With a good fundamental understanding, an engineer might also exercise more wisdom in selecting the best material for a given application. In light of these benefits, the following article in this Section, “Creep Deformation of Metals, Polymers, Ceramics, and Composites,” reviews the current theoretical underpinnings of creep deformation of engineering materials. This article provides the theoretical background for understanding many of the physical processes relevant to the testing methods, experimental results, and analytical approaches described in the subsequent articles.

Our best understanding of creep behavior has been developed for constant stress conditions. For relatively small strains (less than about 1%), constant load conditions suffice as a good approximation of constant stress in a creep experiment. For larger strains, constant stress conditions must be strictly imposed in order to obtain valid data. Accordingly, various approaches for imposing constant stress conditions in a creep test are presented in the article “Creep and Creep-Rupture Testing” in this Section. This article has been updated in the present volume to include two computer-aided approaches that are emerging as the preferred methods for creep laboratories.

Creep rupture often presents a severe risk in high-temperature applications when not addressed using appropriate testing and data interpretation methods. The article “Assessment and Use of Creep-Rupture Properties” covers methods for accurately assessing creep rupture properties. These methods include established interpolation and extrapolation procedures and properties-estimation schemes when data is sparse. The methods presented in this Section are primarily useful for testing under constant stress conditions.

Stress relaxation testing involves imposing a constant displacement under load at elevated temperatures. As mentioned above, this approach represents another quasi-static loading condition that can provide useful information about creep properties. The term *stress relaxation* refers to the time-dependent decrease in stress as creep deformation reduces elastic strain in the specimen under a fixed displacement. One of the primary advantages of this approach is that it can often provide an assessment of creep properties in a fraction of the time it takes using constant stress methods. It is also the most appropriate testing scheme when the target application, such as high-temperature bolting, undergoes a constant displacement condition. The article “Stress Relaxation Testing” gives an overview of methods that may be used to rapidly generate creep data over several orders of magnitude in strain rate.

Creep properties have for the most part been studied under uniaxial stress conditions in which the loading is applied parallel to the longitudinal axis of a cylindrical or plate specimen. Although uniaxial stress experiments have led to a good understanding of the physical processes involved, they often do not provide sufficient information to predict the behavior of high-temperature components. Load bearing parts at elevated temperatures are often subjected to multiaxial loading conditions that drive the deformation and rupture mechanisms in a manner that is different from uniaxial loads. Multiaxial conditions are particularly relevant for pressurized pipe and vessel components subjected to high temperatures. Hence, it is generally necessary to impose multiaxial stress conditions in creep and creep-rupture testing so that the effects of multiaxial stress states can be appropriately addressed. Accordingly, an article is also presented in this Section that describes the current state-of-the-art for testing tubular samples at elevated temperatures under multiaxial conditions.

Superplastic behavior refers to the ability of some fine-grained materials to achieve strains at elevated temperatures exceeding 300% and, in some cases, in excess of 2000%. From an industrial perspective, superplastic materials are of great interest because of the ability to produce complex shapes in a single inexpensive forming operation, eliminating labor-intensive machining costs. Naturally, exceptional testing methods are generally required for superplastic materials due to the large strains that are realized. A comprehensive overview entitled “Superplastic Deformation at Elevated Temperatures” is provided in this Section. Considerations for determining the optimum strain rate and impurity level are also discussed in this article.

Creep Deformation of Metals, Polymers, Ceramics, and Composites

Jeffery C. Gibeling, University of California, Davis

Introduction

CREEP DEFORMATION is any permanent inelastic strain that occurs when a material is subjected to a sustained stress. The rate at which this deformation occurs depends not only on the magnitude of the applied stress, but also on time and temperature. Thus, it is appropriate to consider creep to be a kinetic process and to write an appropriate rate law. In addition, the rate at which a material creeps depends on the size, spacing, and distribution of relevant microstructural features. As a consequence, it is also necessary to write equations that describe how the internal structure changes with respect to time or strain (Ref 1, 2).

Creep is considered to be a high-temperature phenomenon, although it is important to recognize that temperature is a relative quantity for any material. In crystalline solids such as metals and ceramics, creep is of concern when the service temperature is greater than or equal to approximately $0.5 T_m$, where T_m is the absolute melting temperature, commonly expressed on the Kelvin scale (Ref 3, 4). In the creep literature, it is common to refer to the ratio of T/T_m as the *homologous temperature*. Because homologous rather than absolute temperature is the relevant quantity, nickel-base superalloys undergo creep in gas turbine engine blades and vanes at 900 to 1400 K (1160–2060 °F), whereas the solder used to attach integrated circuits to their packages can deform at a service temperature of 400 K (260 °F). In both cases, the service temperature is high with respect to the melting point of the material. However, some crystalline materials exhibit measurable creep strains at temperatures as low as $0.25 T_m$. In noncrystalline materials such as polymers and glasses, the relevant reference is the glass transition temperature, T_g , above which creep occurs at measurable rates.

These observations suggest that a material with a sufficiently high melting temperature be chosen to achieve the creep resistance needed in a particular application. To do so, however, is rarely practical because of a variety of other design requirements including cost, density, and environmental stability. For this reason, the goal of materials engineers is to identify compositions and microstructures that will lead to improved creep strength at a given service temperature. To do so requires an understanding of the mechanisms by which creep deformation occurs.

Creep Testing

Creep deformation is normally studied by applying either a constant load (equivalent to a constant engineering stress) or a constant true stress to a material at a sufficiently high homologous temperature that a measurable amount of creep strain occurs in a reasonable time. Constant load testing is normally employed for engineering purposes, because this situation most accurately represents service loading conditions. In contrast, constant true stress testing is used to study deformation mechanisms. At small strains, the two methods give essentially the same results. However, since the focus of this article is on creep mechanisms, primary consideration is given to the outcome of constant true stress experiments. The basic record of such a test is a plot of creep strain, ϵ , versus time, t , as illustrated schematically in Fig. 1(a) for loading in tension. It is often useful to numerically differentiate these data to determine the creep rate, $d\epsilon/dt$, or $\dot{\epsilon}$, as shown in Fig. 1(b). Normally, a small permanent loading strain, ϵ_0 , is observed when the creep stress is first applied. This strain occurs so rapidly that it is generally treated as instantaneous. With increasing strain, the creep rate gradually decreases. This hardening transient is called *primary creep*. Eventually, however, the creep rate reaches a constant value, known as the *steady state creep rate*, $\dot{\epsilon}_{ss}$, or minimum creep rate in the secondary region. This value is commonly used to characterize the creep resistance of materials and to identify the mechanism that control the creep process. In addition, the steady state region often represents the largest fraction of time during the creep test because the strain rate is the lowest. As strain continues to occur, however, microstructural damage also begins to accumulate, and the creep rate increases. This final stage, known as *tertiary creep*, immediately precedes failure or creep rupture of the test specimen. The tertiary creep strains may be quite large in some materials, especially at high stresses.

Fig. 1 Schematic illustration of the dependence for pure materials of (a) creep strain on time and (b) creep rate on creep strain

A variety of empirical relations have been proposed to describe the shape of the creep curve shown in Fig. 1(a). At low temperatures ($T < 0.3T_m$), the primary creep transient is often logarithmic with time, and steady state may not be reached. The resulting creep response can be represented by a logarithmic dependence of strain on time. At higher temperatures, the transition from primary to secondary creep can be described by an equation of the form:

$$\epsilon = \epsilon_0 + \beta t^m + \dot{\epsilon}_{ss}t \quad (\text{Eq 1})$$

where m is typically equal to $\frac{1}{3}$ and β is a constant. A more recent approach is based on an empirical fitting procedure to describe all three regions given by:

$$\varepsilon = \theta_1(1 - e^{-\theta_2 t}) + \theta_3(e^{\theta_4 t} - 1) \quad (\text{Eq 2})$$

where the θ parameters include both the stress and temperature dependence of the creep process (Ref 5). It should be noted that this approach is based on the inherent assumption that the minimum creep rate represents a transition from primary to tertiary creep without the presence of any true steady state creep rate. This approach is especially relevant for many high-strength metals, intermetallic compounds, and ceramics for which the steady state region does not persist over large strains or long times.

As noted earlier, this discussion of creep mechanisms is based on data obtained primarily from constant true stress testing. However, the form of the creep curve is very similar under constant load testing. Since creep deformation occurs under conditions of constant volume (until internal voids begin to form during tertiary creep), the cross-sectional area must decrease as the sample length increases for deformation in tension. If the load is held constant, then the true stress must increase with increasing strain. As a consequence, a steady state is not expected under constant load conditions, and the tertiary region includes the effects of both microstructural and geometric softening. It is important to note, however, that this distinction between the two loading modes is only apparent at large strains.

While the characteristic creep response shown in Fig. 1 represents the behavior of a large number of materials, there are other important cases in which the creep response is quite different. For example, some solid solution strengthened alloys exhibit an inverted primary transient when the interaction between the solute atoms and the gliding dislocations is rate controlling. This observation is illustrated schematically in Fig. 2(a). Other materials may exhibit a behavior that combines a normal transient with an inverted transient, resulting in a sigmoidal primary region. This behavior is shown in Fig. 2(b).

Fig. 2 Schematic illustrations of the variation of creep strain with time. (a) Behavior exhibited by some solid solution strengthened materials characterized by an inverted primary transient. (b) Behavior of some other materials that combines a normal transient with an inverted transient

Creep Deformation of Metals, Polymers, Ceramics, and Composites

Jeffery C. Gibeling, University of California, Davis

Phenomenological Descriptions of Creep

Current knowledge of the mechanisms that control creep deformation is based on a combination of empirical correlations of results and micromechanical models (Ref 1, 2, 3, 4). Although a number of significant theoretical descriptions of creep have been presented, current understanding is based primarily on a correlation of the results from hundreds of independent investigations. In simplest form, creep of a variety of materials exhibiting a variety of mechanisms can be described by a phenomenological rate equation of the form:

$$\dot{\epsilon} = A \left(\frac{\sigma}{G} \right)^n \exp \left(\frac{-Q_c}{kT} \right) \quad (\text{Eq 3})$$

where A is approximately constant for a given material, n is the stress exponent, G is the elastic shear modulus, and Q_c is the activation energy for creep. This equation describes the dependence of the creep rate on the two key external variables, temperature and stress. Specific values of n and Q_c are associated with specific creep mechanisms. Thus, by characterizing the stress and temperature dependence of the creep rate, it is often possible to identify the rate-controlling mechanism for a particular material. Commonly, it is observed that the activation energy for creep is the same as that for diffusion; hence, the term $\exp -Q_c/kT$ is replaced by the relevant diffusivity, D (Ref 3, 4).

In the following sections, the creep behavior of crystalline and amorphous materials are considered separately. The emphasis in all cases is on correlating the macroscopic behavior with the underlying microscopic mechanisms. This requires that a variety of internal variables that describe the microstructural features that control the rate of deformation be considered.

Creep Deformation of Metals, Polymers, Ceramics, and Composites

Jeffery C. Gibeling, University of California, Davis

Creep Behavior of Crystalline Solids

The mechanisms of creep in crystalline solids primarily include dislocation motion and atomic diffusion. Each process dominates in certain regimes of stress and temperature for a given material. Accordingly, the stress and temperature dependencies of the creep rate can be used to identify the relevant creep mechanisms.

Diffusional Creep. Mechanistically, diffusional creep leads to deformation of grains when the transport of atomic vacancies (opposite to the direction of atom transport) is biased by an applied stress. As a consequence, it is necessary to include a grain-size dependence in the phenomenological creep equation, resulting in an expression of the form:

$$\dot{\epsilon} = A \frac{DGb}{kT} \left(\frac{\mathbf{b}}{d} \right)^2 \left(\frac{\sigma}{G} \right) \quad (\text{Eq 4})$$

where d is the grain size and \mathbf{b} is the Burgers vector. This grain size dependence is introduced because the grain boundaries serve as sources and sinks for the diffusing vacancies. Equation 4 reflects a linear dependence of creep rate on stress; hence, $n = 1$. When diffusion through the grain interiors provides the most rapid path, then the diffusivity, D , is equal to the lattice or bulk self-diffusion coefficient. This process is known as Nabarro-

Herring creep. Alternatively, diffusion may be more rapid through the grain boundaries, in which case D in Eq 4 is replaced by $\delta D_{gb}/d$, where δ is the grain boundary width and D_{gb} is the grain boundary diffusivity. As a consequence, the creep rate varies as d^{-3} when diffusion occurs via grain boundaries; this mechanism is known as Coble creep. Thus, the grain size exponent can be used to distinguish between mechanisms that exhibit the same stress exponent.

Diffusional creep is favored at high temperatures, low stresses, and fine grain sizes. As a consequence, this mechanism is especially important in ceramic materials, where dislocation motion may be restricted by the strong lattice friction associated with ionic and covalent bonding. Small, stable grains result from common processing methods. Conversely, resistance to diffusional creep can be improved by increasing the grain size or developing an elongated grain structure through directional solidification.

Dislocation Creep. When many crystalline metals and ceramics are tested at intermediate temperatures and stresses, the predominant deformation mechanism involves the motion of dislocations. Upon initial application of a stress to a well-annealed material, dislocations move rapidly, as there are few obstacles to their motion. However, they also multiply rapidly, and the subsequent strain hardening causes the creep rate to decrease dramatically during the primary transient as represented in Fig. 1. This strain hardening arises as the number of dislocations increases and they begin to serve as barriers to glide motion of other dislocations. During the primary creep transient, the dislocation structure gradually becomes organized into low-angle boundaries that define subgrains within the grains. This substructure becomes more stable as deformation approaches steady state. Through careful study of deformed materials, it is possible to demonstrate that the size of several key microstructural features scales with the applied stress in the steady state regime. Specifically, the subgrain size, the spacing of dislocations in the subgrain interiors, and the dislocation spacing within subgrain walls all vary as σ^{-1} . These microstructural features remain in dynamic equilibrium during steady state deformation as dislocations are continuously generated and annihilated (Ref 2, 6).

One of the most influential and compelling observations regarding creep of single-phase materials is that the temperature dependence is the same as that for lattice self-diffusion. This evidence supports the concept that power law creep is diffusion controlled. Diffusion is needed to enable dislocations to climb past obstacles to their continued glide. Thus, creep occurs by the sequential processes of dislocation glide and climb. As the climb step is slower than glide, it is rate controlling. A compilation of creep activation energy data (Q_c) for a wide variety of metals and ceramics shows that it is inevitably equal to the activation energy for self diffusion Q_L (Fig. 3). It should be noted that both species must diffuse to enable dislocation creep to occur in ceramics, but the creep rate is controlled by the rate of diffusion of the slower moving ions. While there are a few notable exceptions to the rule that $Q_c = Q_L$, the preponderance of evidence supports the concept that the rate of power law creep is controlled by lattice self-diffusion at homologous temperatures greater than 0.5. At lower temperatures, the activation energy falls to lower values, as shown in Fig. 4. The lower plateau (in the range $0.25 < T_H < 0.5$) generally corresponds to the activation energy for vacancy diffusion along dislocation cores. In this temperature range, the creep rate also depends on the density of dislocations to serve as diffusion paths. Since dislocation density varies inversely with stress, this leads to an effective diffusivity, D_{eff} , given by:

$$D_{eff} = D_L + \beta \left(\frac{\sigma}{G} \right)^2 D_c \quad (\text{Eq 5})$$

where D_c is the self-diffusion coefficient in the dislocation core and β is a constant about equal to 10. As a consequence of this additional stress dependence, the expected stress exponent is $n = 7$ in this temperature range.

Fig. 3 Comparison of activation energies and activation volumes for steady state creep and lattice self-diffusion for various materials above $0.5T_m$ (Ref 1)

Fig. 4 Activation energy for steady state creep of pure aluminum as a function of temperature. Source: Ref 1

The observation that high-temperature creep is controlled by lattice self-diffusion can be confirmed by measuring the hydrostatic pressure dependence of creep. The relevant measured quantity is the activation volume, ΔV . As shown in Fig. 3 for a limited set of available data, the activation volume for creep, ΔV_C , is equal to the activation volume for lattice self diffusion, ΔV_L .

Creep of single phase materials exhibits a power law stress dependence as given by Eq 3, where n is normally in the range of 4.5 to 5. Accordingly, this regime is often called power law creep. Although the observation of $n = 5$ in the power law region is well documented for a variety of materials, it is important to recognize that theoretical treatments can only rationalize a value of 3 or 4. This is often termed the *natural creep law*. Representative data for pure aluminum are plotted in Fig. 5. These data illustrate that power law creep is

observed over many orders of magnitude of strain rate. However, above a normalized stress of about $\sigma/E = 10^{-3}$ (or a normalized shear stress, $\tau/G = 10^{-3}$), the creep rate begins to increase more strongly with applied stress. From the perspective of power law creep, this region is described as power law breakdown and can be described mathematically by an exponential or hyperbolic sine function as indicated in the figure. Alternatively, this change in behavior may be considered a natural transition between high-temperature (power law) deformation and low-temperature flow (Ref 1, 2).

Fig. 5 Steady state creep properties of pure aluminum presented as normalized strain rate as a function of normalized stress. Source: Ref 1

Dislocation creep involves the interaction of the stress fields of moving dislocations with those of stationary dislocations. Since the stresses surrounding a dislocation depend on the elastic modulus of the solid, the creep rate is also expected to depend on elastic modulus. The most important contribution of modulus to understanding the mechanisms of creep is that it introduces an additional temperature dependence to the creep expression. For that reason, it is not important whether the elastic or shear modulus is considered, as long as the correct variation with temperature is taken into account. In particular, analysis of creep data to determine the activation energy must be based on a comparison of creep rates measured at constant values of stress normalized by modulus, not at constant values of stress.

When these factors are taken into account, the resulting empirical creep equation can be written as:

$$\dot{\epsilon} = A \frac{D G b}{k T} \left(\frac{\sigma}{G} \right)^n \quad (\text{Eq 6})$$

where A is essentially a fitting parameter that includes additional effects of microstructure such as stacking fault energy (Ref 3, 4). The parameter A must be determined from the data in order to calculate absolute values of the creep rate. As noted earlier, most pure materials and solid solution alloys that exhibit pure metal behavior are characterized by n values in the range of 4 to 8. Accordingly, measurement of values in this range can be taken as evidence that the creep mechanism involves climb-controlled dislocation motion.

In ceramics, the high lattice friction, or Peierls stresses, low dislocation densities, and lack of sufficient slip systems suggest that dislocation creep should be difficult. Nevertheless, at similar homologous temperatures and normalized stresses, the creep behavior of many ceramics is similar to that of metals (Ref 3, 7, 8). In particular, many ceramic materials also exhibit dislocation climb-controlled creep with $n \approx 5$, although in other cases a stress exponent closer to 3 is observed. Because subgrain structures are observed in these materials, dislocation climb from Bardeen-Herring sources has been identified as the principal mechanism of deformation

in the latter case. In general, the observation of $n = 3$ in essentially pure ceramics provides evidence that the material is not fully ductile, because it lacks the five independent slip systems required for general dislocation glide deformation. This situation may be attributed to both crystallographic orientation effects and the relatively high friction stresses associated with glide on some atomic planes in ceramics.

Creep in Alloys. As noted earlier, the creep curve for many solid solution strengthened alloys has a different form (Fig. 2a) than that observed for pure materials (Fig. 1) (Ref 3, 9). In these materials, solute atom clusters strongly interact with the stress fields of dislocations, and viscous glide of dislocations is the rate-controlling process. The principal interaction mechanisms that impede dislocation glide include segregation of solute atoms to dislocations, the destruction of short-range atomic order by gliding dislocations, and chemical interaction of solute atoms with dissociated (partial) dislocations. In addition to the characteristic shape of the creep curve, the behavior of these alloys differs from that of pure metals in that the stress exponent typically has a value of 3, and dislocations do not form extensive subgrain structures during deformation. Finally, the activation energy for creep generally equals that for self-diffusion of the solute atoms in the matrix. Together, these characteristics identify a material that exhibits class A (for alloy) behavior, which can be contrasted with the class M (for pure metal) response evidenced by alloys in which the dislocation/solute interactions are weaker and n is typically equal to 5. Similar viscous glide behavior has been observed in ceramic solid solutions. Here it is necessary to distinguish between glide-controlled creep and climb creep, described earlier. Both are characterized by $n = 3$, but subgrain structures do not form when creep is glide controlled.

An empirical analysis of the creep behavior of a number of solid solution alloys indicates that it is possible to predict whether an alloy will exhibit class M (climb-controlled) or class A (glide-controlled) behavior based on knowledge of fundamental physical quantities (Ref 9). In particular, deformation by viscous dislocation glide is expected when:

$$\left(\frac{kT}{ec^{1/2}Gb^3} \right)^2 < B \left(\frac{\gamma}{Gb} \right)^3 \left(\frac{\sigma}{G} \right)^2 \quad (\text{Eq 7})$$

where e is the solute-solvent atom size difference, c is the solute concentration, γ is the stacking fault energy of the alloy, and B is a constant, which is estimated from creep data for the Al-3%Mg alloy. This relationship correctly predicts the creep response of nearly all of the alloys to which it has been applied. As an example, data for a number of solid solution alloys are plotted in Fig. 6 along with the line representing the predictions of Eq 7. These data illustrate that the creep behavior of some alloys is controlled by the rate of dislocation glide while other alloys exhibit climb controlled deformation. In contrast, the data for some alloys, such as Al-3%Mg, reveal a transition from climb-controlled creep ($n = 5$) at low normalized stresses and normalized creep rates to glide-controlled deformation ($n = 3$) at high stresses.

Fig. 6 Criterion for viscous glide controlled creep and dislocation climb controlled creep in solid solution strengthened alloys. Source: Ref 9

Creep of Dispersion Strengthened Materials. One method to improve the creep resistance of materials for elevated temperature applications is to add a uniform distribution of fine particles that block the motion of dislocations. Creep tests of dispersion strengthened materials commonly reveal high stress exponents (on the order of 20–100) and activation energies that are up to twice those for lattice diffusion (Ref 10). An example of results for thoria-dispersed nickel-chromium alloys is illustrated in Fig. 7 (Ref 11). Phenomenologically, creep of dispersion strengthened metals can be rationalized by introducing a threshold stress denoted by σ_0 into Eq 3 to account for the effect of the particles on the moving dislocations. The modified creep equation then takes the form:

$$\dot{\epsilon} = A \left(\frac{\sigma - \sigma_0}{G} \right)^n \exp\left(\frac{-Q_c}{RT} \right) \quad (\text{Eq 8})$$

When a threshold stress is calculated from the creep data and included in the creep equation, the observed stress exponents are approximately equal to 5, and the calculated activation energies agree with those for lattice self-diffusion.

Fig. 7 Steady state creep results for a Ni-Cr alloy dispersion strengthened with ThO₂. Source: Ref 11

At high stresses, gliding dislocations can pass the dispersoid particles by the process of Orowan bowing. However, at the high temperatures and lower stresses that characterize creep deformation, it is more likely that dislocations climb out of their glide planes to overcome the particles. Theoretical treatments of climb are based on a mechanism in which only the segment of dislocation in the particle/matrix interface climbs (local climb) or one in which a significant length of dislocation line near the particle leaves the glide plane (general climb). While the climb process may introduce a threshold stress, its magnitude, as calculated from various models, is generally too low to explain the experimental observations. Further, the relatively strong temperature dependence of the threshold stress cannot be adequately explained by these theories. Thus, the threshold stress approach provides a powerful method to correlate creep data for dispersion strengthened materials, but cannot be fully justified on a theoretical basis.

A number of investigators have presented evidence from transmission electron microscopy (TEM) of creep tested dispersion strengthened metals showing dislocations that appear to be bound to particles (Ref 10). The distinctive feature of these micrographs is that the dislocations are stopped on the departure side of the particles after having climbed over them. These observations demonstrate that the line energy of the dislocations is reduced in the particle/matrix interface. Assuming that climb over the particles is relatively rapid, creep can then be modeled by considering the thermally activated release of dislocations from the departure side of the particles to be rate controlling. The resulting equation differs substantially from the usual form and contains several parameters that are difficult to evaluate from the creep data. A satisfactory fit has been obtained for creep data for a limited number of dispersion strengthened materials (Ref 10). Nevertheless, the TEM observations present compelling evidence that dislocations interact strongly with particles on a very local scale. Deformation Mechanism Maps. The mechanisms of dislocation glide, dislocation climb, and diffusional flow exhibit different stress and temperature dependencies. Thus, the relative contribution of each process will depend on the value of the applied stress, the temperature and microstructural features such as grain size. Ashby has developed a graphical method to represent the conditions under which the various creep mechanisms predominate (Ref 12).

An example of this graphical approach, known as a deformation mechanism map, is presented in Fig. 8 for creep of pure alumina (Al_2O_3) with a grain size of $100\ \mu\text{m}$. The axes of this map represent shear stress normalized by the shear modulus and homologous temperature. Each field of the map represents the range of stress and temperature over which a particular mechanism is expected to be the principal creep process. These maps are created using experimental data to determine the necessary material properties and constants in equations that describe each mechanism (such as Eq 4 and 6). Field boundaries are drawn where two mechanisms contribute equally to the overall creep rate. In addition, lines of constant total strain rate are superimposed as shown in Fig. 8.

Fig. 8 Deformation mechanism map for creep of pure alumina (Al_2O_3) with a grain size (d) of $100\ \mu\text{m}$. Source: Ref 12

Maps of this type have been constructed for a variety of metals and ceramics (Ref 12). Specific knowledge of the stress and temperature dependence of the various mechanisms provides a guide to material selection and component design and suggests equations that should be used in a particular design analysis. Perhaps most importantly, these maps can be used to identify an approach to designing materials for improved creep resistance.

Creep of Composites. Structural composite materials are generally created by adding a reinforcing phase to improve some aspect of the mechanical behavior of a matrix material. The primary goal in developing metal matrix composites (MMCs) is to improve the specific stiffness and/or strength. In contrast, the motivation for adding a reinforcing phase to a ceramic matrix composite (CMC) is usually to enhance fracture toughness. Nevertheless, both MMCs and CMCs have generated considerable attention as candidate materials for high-temperature applications where creep resistance is also of concern.

In most MMCs the reinforcement is a discontinuous ceramic phase (in the form of short fibers, whiskers, or particulates). Further, these reinforcements are assumed to remain elastic, even at elevated temperatures. As a consequence, the applied stress is shared by the matrix and reinforcement, resulting in a decreased stress in the matrix compared to an unreinforced material. This load sharing effectively increases the creep resistance of the composite. It is also important to recognize that the reinforcements are generally too large to interact with individual dislocations as do precipitates and dispersoids.

The results of numerous investigations of metal matrix composites suggest that their creep behavior is largely determined by the creep characteristics of the matrix in terms of the stress exponent and activation energy (Ref 13). When the effects of load sharing and redistribution are taken into account, the magnitude of the creep rate can also be predicted with reasonable accuracy. In many cases, MMCs appear to exhibit characteristics similar to dispersion-strengthened metals, including high stress exponents and activation energies as well as apparent threshold behavior. These characteristics generally reflect the fact that the material is prepared by powder processing methods that may also incorporate fine dispersoids in the matrix. These dispersoids control the matrix creep response, which dominates the response of the composite.

The creep response of multiphase ceramics depends on the relative volume fractions of the matrix and reinforcement phase (Ref 14). As with MMCs, it is usually assumed that the reinforcing phase is rigid and that deformation occurs in the matrix, although this idealization may not always hold true for CMCs. At low volume fractions of reinforcement, the particles behave independently of one another. In this case, creep is controlled by power law deformation in a crystalline matrix or (linear) viscous flow (if the matrix is amorphous). The results of creep studies of low volume fraction materials reveal little improvement in creep strength. As the volume fraction of reinforcement is increased, the creep resistance increases dramatically. For example, when the volume fraction of whiskers in a CMC exceeds 15%, the creep rate falls by 1 to 2 orders of magnitude from the rate observed in the unreinforced matrix. This improvement appears to be essentially independent of volume fraction of reinforcement in the range 15 to 50%. Finally, at high volume fractions, the creep behavior can be described as highly constrained flow of the matrix material coupled with cavitation. Often, this situation arises in liquid phase sintered materials with an amorphous grain boundary phase. Additional complications in describing creep arise if the reinforcements form a continuous network.

Creep Deformation of Metals, Polymers, Ceramics, and Composites

Jeffery C. Gibeling, University of California, Davis

Creep Response of Amorphous Solids

In contrast to the crystalline solids described in the previous section, glasses and many polymers have an amorphous atomic or molecular structure. Although these materials are not usually intended for structural applications in which resistance to creep deformation is a design consideration, their creep behavior is important in both processing and service. Many amorphous materials undergo viscoelastic deformation, which includes elastic, anelastic, and viscous plastic strain. Both anelastic and viscous deformation are commonly referred to as creep, although only the latter is permanent. To remain consistent with previous descriptions of creep, only the permanent, viscous deformation of amorphous solids is considered here.

A useful representation of the creep response of amorphous solids above the glass transition temperature is given by a simple expression for the rate of linear viscous flow:

$$\dot{\gamma} = \frac{\tau}{\eta} \quad (\text{Eq 9})$$

where τ is the shear stress, $\dot{\gamma}$ is the shear strain rate, and η is the structure- and temperature-dependent viscosity that is a function of the activation enthalpy (ΔH) as follows:

$$\eta = \eta_0 \exp \frac{\Delta H}{RT} \quad (\text{Eq 10})$$

Thus, creep in amorphous solids is a thermally activated process. In terms of tensile quantities, Eq 9 can be rewritten as:

$$\dot{\epsilon} = \frac{\sigma}{3\eta} \quad (\text{Eq 11})$$

While the preceding expressions adequately represent the behavior of both glasses and polymers, these two classes of materials differ significantly in their mechanisms of creep. These microstructural differences are reflected in the viscosities of the materials. In polymers, particularly those characterized as thermoplastics, the rate controlling creep mechanism involves cooperative motion of molecular chain segments with respect to one another. The rate and extent of creep strain decreases with increasing density of cross links between the molecular chains. Increasing molecular weight (resulting in longer molecular chains) also reduces the creep rate, but to a less significant extent. In glasses, the mobility of groups of atoms within the network of glass

forming oxides (such as SiO₂) determines the resistance to creep deformation. Network modifiers that break up the continuity of the network reduce the viscosity, thereby promoting higher creep rates (and easier formability).

Many engineering polymers also exhibit a phenomenon known as stress relaxation. In essence, stress relaxation is creep under conditions of constant total length, such that elastic strain is gradually converted to permanent plastic strain. This causes both the stress and the strain rate to decrease with time. However, the underlying mechanisms are essentially the same as for creep deformation.

Finally, we note that polymer matrix composites (PMCs) also exhibit creep deformation (Ref 15). In general, measurements of activation energy and activation volume reveal that the addition of stiff fibers does not alter the mechanism of deformation in the polymer matrix. However, an adequate description of the creep behavior of PMCs requires consideration of the volume replacement effect that gives rise to a stress redistribution and the role of constraint of deformation as the fibers essentially stiffen the matrix. Thus, the role of the reinforcements is similar in the case of crystalline matrix and amorphous matrix composites.

Creep and Creep-Rupture Testing*

Introduction

CREEP PROPERTIES are important in the design of components that are subjected to stresses at elevated temperatures for prolonged periods. In order to use materials for high-temperature components, it is essential to measure and evaluate the creep behavior of the material as a function of time. This may include creep tests and/or creep-rupture tests. Creep tests measure the amount of creep strain as a function of time, while creep-rupture tests measure the time to fracture for a given temperature and stress levels. Both tests have engineering application depending on design criteria. In some cases, the amount of creep strain is a design factor, while stress rupture is the design criterion in other cases. For example, Tables 1 and 2 list maximum-use temperatures in specific applications with different design criteria.

Table 1 Temperature limits of superheater tube materials covered in ASME Boiler Codes

Material	Maximum-use temperature			
	Oxidation/graphitization criteria, metal surface ^(a)		Strength criteria, metal midsection	
	°C	°F	°C	°F
SA-106 carbon steel	400–500	750–930	425	795
Ferritic alloy steels 0.5Cr-0.5Mo	550	1020	510	950
1.2Cr-0.5Mo	565	1050	560	1040
2.25Cr-1Mo	580	1075	595	1105
9Cr-1Mo	650	1200	650	1200
Austenitic stainless steel	760	1400	815	1500

Type 304H				
-----------	--	--	--	--

(a) In the fired section, tube surface temperatures are typically 20–30 °C (35–55 °F) higher than the tube midwall temperature. In a typical U.S. utility boiler, the maximum metal surface temperature is approximately 625 °C (1155 °F).

Table 2 Suggested maximum temperatures in petrochemical operations for continuous service based on creep or rupture data

Material	Maximum temperature based on creep rate		Maximum temperature based on rupture	
	°C	°F	°C	°F
Carbon steel	450	850	540	1000
C-0.5 Mo steel	510	950	595	1100
$\frac{1}{2}$ Cr-1Mo steel	540	1000	650	1200
Type 304 stainless steel	595	1100	815	1500
Alloy C-276 nickel-base alloy	650	1200	1040	1900

The purpose of this article is to review the basic equipment and methods for creep and creep-rupture testing. The article begins with a brief review of steady state creep behavior with subsequent sections on testing equipment, constant-load testing, and constant-stress testing. However, another engineering aspect of creep behavior is stress relaxation. Stress relaxation is the reduction of applied or residual stresses as a function of time when a stressed material is held at constant strain (i.e., held at a constant length without further deformation). Stress relaxation occurs over time, because the elastic strain within a stressed material is transformed into permanent (i.e., plastic) strain by creep deformation. This transformation, in effect, causes a reduction in elastic strain, which in turn, results in a reduction of the applied stress over time. For example, a common practical example of stress relaxation is when the tightness of high-temperature bolting undergoes progressive stress relaxation at a rate that depends on the creep strength of the material.

Stress relaxation testing principally has been used to measure and predict the relaxation of stress as a function of time and temperature. However, stress relaxation testing can also be considered as a type of creep test. Traditional creep-test methods involve the measurement of creep strain as a function of time with a fixed load (or stress) at constant temperature. Stress relaxation is a test of the same behavior but under the opposite set of test conditions, where the reduction of stress is measured with the total strain held constant at a given temperature. Stress relaxation testing is thus a complementary creep-test method that, in a short time, can generate creep-rate data as a function of stress covering five or more orders of magnitude in creep rate (see the section “Accelerated Testing” in the article “Stress Relaxation Testing” in this Volume).

Creep Properties

Creep properties are generally determined by means of a test in which a constant uniaxial load or stress is applied to the specimen and the resulting creep strain is recorded as a function of time. Typical shapes of creep curves are shown in Fig. 1. After the instantaneous strain, ϵ_0 , a decelerating strain-rate stage (primary creep) leads to a steady minimum creep rate (or secondary creep strain rate, $\dot{\epsilon}$), which is finally followed by an accelerating stage (tertiary creep) that ends in fracture at a rupture time, t_r . The strain at rupture, ϵ_r , represents the rupture ductility.

Fig. 1 Schematic illustration of creep-curve shapes. Source: Ref 1

The shape of the creep curve is determined by several competing reactions, including:

1. Strain hardening
2. Softening processes such as recovery, recrystallization, strain softening, and precipitate overaging
3. Damaging processes, such as cavitation and cracking, and specimen necking.

Of these factors, strain hardening tends to decrease the creep rate, whereas the other factors tend to increase the creep rate. The balance among these factors determines the shape of the creep curve. During primary creep, the decreasing slope of the creep curve is attributed to strain hardening. Secondary-stage creep is explained in terms of a balance between strain hardening and the softening and damaging processes, resulting in a nearly constant creep rate. The tertiary stage marks the onset of internal- or external-damage processes (item 3 in the preceding numbered list), which result in a decrease in the resistance to load or a significant increase in the net section stress. Coupled with the softening processes (item 2), the balance achieved in stage 2 is now offset, and a rapidly increasing tertiary stage of creep is reached.

Creep and Creep-Rupture Testing*

Stress and Temperature Dependence

Of all the parameters pertaining to the creep curve, the most important for engineering applications are the secondary creep, or minimum strain rate ($\dot{\epsilon}_{\min}$), and the time to rupture (t_r). Specifically, their dependence on temperature and applied stress are of utmost interest to the designer. This dependence varies with the applicable creep mechanism. A variety of mechanisms and equations have been proposed in the literature and have been reviewed elsewhere (Ref 2, 3, 4). Fortunately, all these mechanisms can be fitted into two basic categories: diffusional creep and dislocation creep.

In diffusional creep, diffusion of single atoms or ions either by bulk transport (Nabarro-Herring creep) or by grain-boundary transport (Coble creep) leads to a Newtonian viscous type of flow. The flow of atoms is envisaged to occur from regions of local compressive stress toward regions of local tensile stress, balanced by a counterflow of vacancies in the opposite direction. No motion of dislocations is envisaged. In this form of creep, the steady state creep rates are postulated to vary linearly with stress (i.e., $\dot{\epsilon} \propto \sigma$). At low stresses, diffusional creep is seen only at very high temperatures above $0.6 T_m$, where T_m is the melting point of the material. This high-temperature regime is not generally of engineering significance for design of components.

For structural applications and high-temperature components, the pertinent temperature regime is about 0.4 to $0.6 T_m$ (Ref 5). Most engineering applications for high-temperature components fall within this intermediate temperature regime of 0.4 to $0.6 T_m$.

Creep deformation in the “intermediate” temperature regime can be associated with a combination of mechanisms from the low-temperature regime ($T < 0.4 T_m$) and high-temperature regime ($T > 0.6 T_m$). At temperatures below $0.4 T_m$, deformation is primarily controlled by dislocation glide. Recovery processes within the low-temperature regime involve the cross slip of dislocations and are therefore considered as dynamic recovery processes. Within the low-temperature regime, diffusional processes are considered negligible and do not contribute to the deformation process. As temperatures are increased above $0.4 T_m$, dislocations move on their glide planes just as at low temperatures, although more systems may become operative due to the increased temperature. The most important difference, however, is that now dislocations acquire a new degree of freedom, the ability to climb from one slip system to another by diffusional processes, a static recovery process. This contribution of diffusion to creep deformation has been discussed extensively with much of our current understanding coming from the work of Sherby (Ref 5). Sherby and Miller (Ref 6) have also compiled a large body of data that clearly suggest a one-to-one relationship between the activation energy for lattice self-diffusion and the activation energy for creep deformation.

Power Law Model of Steady State Creep Rates. In the intermediate temperature regime ($0.4 T_m < T < 0.6 T_m$), the creep rate varies nonlinearly with stress, as either a power function or an exponential function of stress, in contrast to the linear stress dependence of diffusional creep. At stresses and temperatures of interest to the engineer, the following behavior proposed by Norton (Ref 7) and Bailey (Ref 8) is generally obeyed:

$$\dot{\epsilon} = A\sigma^n \quad (\text{Eq 1})$$

where A and n are stress-independent constants. In addition, because one contribution to creep is a thermally activated diffusion process, its temperature sensitivity would be expected to obey an Arrhenius-type expression, with a characteristic activation energy Q for the rate-controlling mechanism. Equation 1 can, therefore, be rewritten as (Ref 9):

$$\dot{\epsilon} = A\sigma^n \exp\left(\frac{-Q}{RT}\right) \quad (\text{Eq 2})$$

where A and n are constants (for a given condition), and R is the universal gas constant.

Equation 2 is a power-law relation that provides a basis for modeling creep rates as a function of temperature and stress. However, A , n , and Q are parameters that depend on the particular material condition, stress level, and temperature. The parameter A , for example, includes microstructural factors that influence the modes of creep deformation. Therefore, the parameter A must be determined from data in order to calculate absolute values of creep rates (see “Deformation-Mechanism Maps” in this article for a discussion on how the power-law regime may vary for a material).

Creep deformation results also indicate that the values for n and Q in Eq 2 are both variable with respect to stress and temperature. An example of the change in the value of n is shown in Fig. 2 for a normalized-and-tempered $\frac{1}{4}\text{Cr}-\frac{1}{2}\text{Mo}$ steel (Ref 10). A distinct break in the curve is evident, with $n = 4$ at low stresses and $n = 10$ at higher stresses. The breaks in the curves occurred at stresses at which the fracture mode changed from intergranular (I) to transgranular (T) at high stresses.

Fig. 2 Variation of minimum creep rate with stress for a normalized-and-tempered $\frac{1}{4}\text{Cr}-\frac{1}{2}\text{Mo}$ steel. T and I denote transgranular and intergranular failure, respectively. Source: Ref 10

Values of n ranging from $n = 1$ at low stresses to $n = 14$ at high stresses have been reported (Ref 10 11 12 13 14 15 16), and Table 3 is a sample of studies selected to illustrate this point. Although many investigators report a distinct break in the curve, others view the value of n as continuously changing with stress and temperature.

Table 3 Examples of reported values of stress exponent and activation energy for creep of steels

System	Temperature (T)		Coefficients in the low-stress region		Coefficients in the high-stress region		Interpretation of coefficients	Reference
	°C	°F	n	Q , kJ/mole	n	Q , kJ/mole		
$\frac{1}{4}\text{Cr}-\frac{1}{2}\text{Mo}$ steel	510–620	950–1150	4	400	10	625	Grain boundary sliding at low stresses and matrix deformation at high stresses	10

$\frac{1}{24}$ Cr-1Mo steel	565	1050	2.5	...	12	...	Deformation governed by matrix deformation	11
1Cr- $\frac{1}{2}$ Mo steel, heat-affected zone	550–605	1020–1120	3	300	6	300	Diffusive mechanism at low stresses and dislocation mechanism at high stresses	12
1Cr- $\frac{1}{2}$ Mo steel, base metal	550–605	1020–1120	5.6	...	5.6	13
Cr-Mo-V-steel	550–600	1020–1110	4.9	326	14.3	503	Dislocation climb over particles at low stresses and bowing between particles at high stresses	14 (p 230)
20Cr-25Ni-Nb steel	750	1380	3–4.7	465–532	8–12	440–494	Metallographic measurement showed that $\dot{\epsilon}_{gb} = A\sigma^m$, where $m = 3.4$. Transition from low- σ to high- σ behavior was attributed to change from grain-boundary sliding to matrix deformation.	14 (p 106)
20Cr-25Ni-Nb steel	750	1380	2–5	250–390; average, 320	$n \sim$ corresponds to boundary sliding; $n > 3$ corresponds to matrix deformation. From scratch displacements it was found that $\dot{\epsilon}_{gbs} = A^{3.7}$ and $Q_{gbs} = 385$ kJ/mole.	14 (p 122)
20Cr-25Ni-Nb steel	700–750	1290–1380	n varied from 6 to 8.4 with increasing T. Q varied with σ. At $\sigma = 79$ MPa, $Q = 678$ kJ/mole.		Values of n and Q are only “apparent” unless a back stress due to NbC precipitate is considered.	14 (p 86)

To account for these changes, it has been suggested (Ref 11, 13, 14, 17, 18) that the effective stress changes with test conditions due to changes in an “internal back stress σ_0 ” and that the stress term in Eq 2 should be modified to $(\sigma - \sigma_0)^n$. The internal back stress represents a resisting force and is postulated to arise from a variety of microstructural factors such as dislocation configurations, precipitate dispersion, and solid-solution effects.

While discussions continue regarding the natures of n and Q and the reasons for their variations, industrial practice has continued to ignore these controversies and to use a simple power law (Eq 2) with discretely chosen values of n and Q . Because variations in n and Q are generally interrelated and self-compensating, no major discrepancies in the end results have been noted in the low-stress region, as indicated in Table 3. At higher stress levels, the power-law model of creep strain rates begins to break down, as discussed later in the section “Power-Law Breakdown.”

Deformation-Mechanism Maps. With a knowledge of the stress and temperature dependence of the creep rate for each mechanism, it is possible to construct plots showing the regimes for the various mechanisms in the stress/temperature space. These plots, which are usually called deformation-mechanism maps or Ashby maps, are constructed by plotting the shear stress (σ_s) normalized by the shear modulus (G), against the homologous temperature. Ashby maps for a turbine-blade alloy (MAR-M 200) are shown in Fig. 3 (Ref 1). As discussed previously, the diffusional creep mechanism operates at low stresses and high temperatures, whereas at intermediate stresses, dislocation creep or power-law creep is operative. By comparing Fig. 3(a) and (b), it can

be seen that increasing the grain size from 100 μm (3.9 mils) to 1 cm (0.39 in.) expands the power-law creep regime and appreciably decreases the creep rate of the turbine-blade material. These maps are thus very useful in providing insight into the operative creep mechanisms.

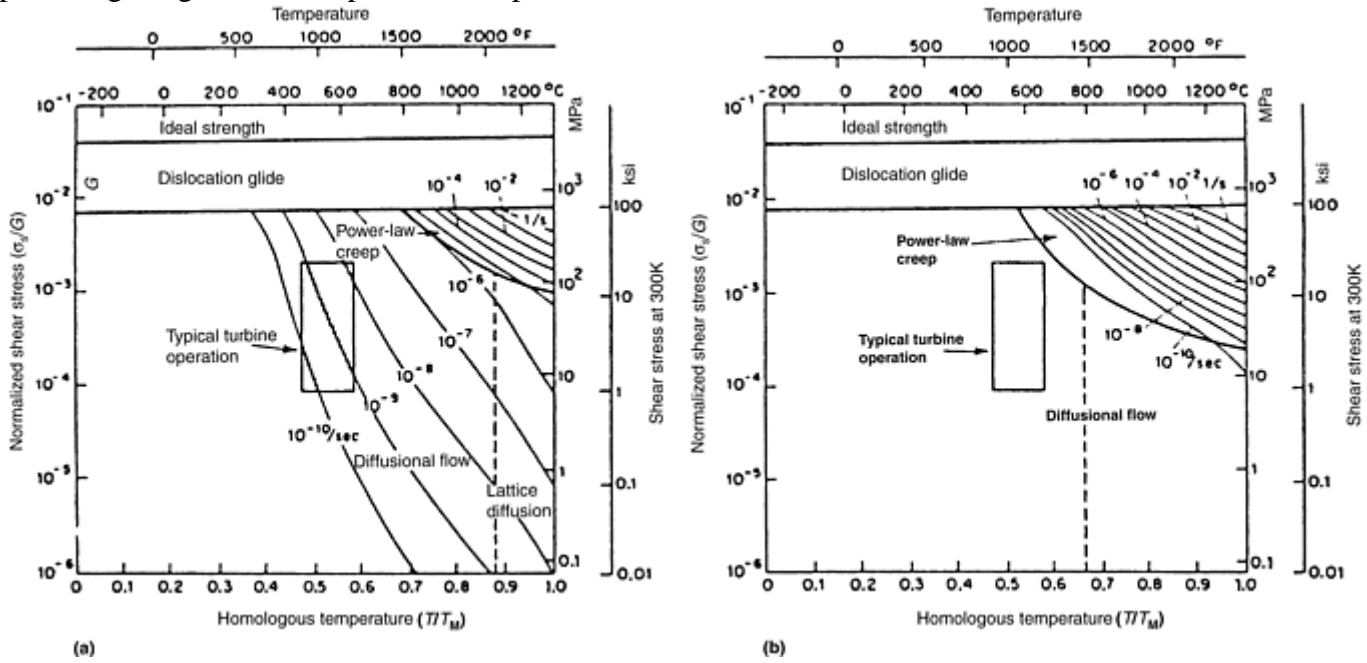

Fig. 3 Ashby deformation maps for MAR-M 200. A turbine blade will deform rapidly by boundary diffusion at a grain size of (a) 100 μm but not a grain size of (b) 1 cm

The two maps in Fig. 3 for the same material with different grain sizes also illustrate the wide variation in creep rates at a given combination of stress and temperature. This wide variation is reflected by the determination of parameter A (in Eq 2), which must be determined experimentally for calculation of creep rates.

Power-Law Breakdown. Steady state creep rate at high temperatures can be described well by a power law (Eq 2), where the stress exponent (n) ranges from 4 to 5 for face-centered cubic (fcc) metals (Fig. 4) and about 3 for body-centered cubic (bcc) metals (Fig. 5), and where the activation energy (Q) for creep is equal to that for lattice self-diffusion. The data presented in Fig. 4 and 5 (Ref 19) indicate that this holds for a wide variety of pure metals for normalized stress values below about $\sigma_s/G = 10^{-3}$.

Fig. 4 Creep data for several fcc metals plotted as a function of normalized shear stress (σ_s/G) compared with a power-law stress exponent of $n = 4$. Because the activation for creep (Q in Eq 2) is the same as that for diffusion, the term $\exp(-Q/RT)$ in Eq 2 is replaced here by the diffusion coefficient, D . b = Burgers vector. Source: Ref 5 with data largely from Ref 19

Fig. 5 Creep data for several bcc metals plotted as a function of normalized shear stress (σ_s/G) compared with a power-law stress exponent of $n = 3$. Source: Ref 5 with data largely from Ref 19

At normalized stresses above $(\sigma_s/G) = 10^{-3}$, creep rates begin to increase more strongly with stress, and the power-law model breaks down. This failure of the power law at higher stress levels is known in the literature as the *power-law breakdown*. In this high-stress region, an exponential or sink function appears to be more applicable. For example, an exponential relationship, although not generally used, has been proposed (Ref 9) to explain the behavior at very high stresses, as follows:

$$\dot{\epsilon} = A \exp(C_7\sigma) \quad (\text{Eq 3})$$

where A and C_7 are stress-independent constants. A sink function has also been used in the high-stress region (see Fig. 5 in the article “Creep Deformation of Metals, Polymers, Ceramics, and Composites” in this Volume). In addition to the increased effect of stress on steady state creep rates, the activation energies for creep within the high-stress regime also tend to decrease to values well below those for lattice self-diffusion. Robinson and Sherby (Ref 20) were among the first to suggest increasing stress exponents and decreasing activation energies at the stress levels associated with power-law breakdown. This has led to the concept of effective diffusivity. The effective diffusion coefficient is higher than the lattice diffusion coefficient, and strong evidence in favor of the effective diffusion concept can be found in the work of Luthy et al. (Ref 21). It was found that the steady state strain rates within the high stress-low temperature regime could be correlated with those obtained within the high-temperature regime by using an effective diffusivity to normalize the steady state strain rate. However, the concept of an effective diffusivity does not fully account for power-law breakdown. Spingarn et al. (Ref 22) have pointed out that the stress exponent and the activation energy should change together within the power-law breakdown regime. In analyzing the creep behavior of several metals within the intermediate regime, Spingarn et al. (Ref 22) found that for some metals, the activation energy decreased at lower temperatures, but the stress exponent remains constant. In other cases, the stress exponent is found to increase with decreasing temperature, but the activation energy remains constant. In the case of nickel, the activation energy decreases while the stress exponent increases as expected; however, the transition temperatures and stress levels are not in agreement with the predictions of the effective diffusivity. Perhaps the most limiting factor regarding the

effective diffusivity concept is that it does not provide a natural explanation of the increased effect of stress in the breakdown regime.

Composite Model and Constant-Structure Creep. At sufficiently high temperatures where creep is controlled by lattice self-diffusion steady state creep can be described quite well using a power-law approach. However, at higher stress levels (or lower temperatures), the power-law description begins to break down. As just described, an effective diffusion coefficient into the power-law equation provides an explanation for the increasing stress exponents and decreasing activation energies obtained within the high-stress/low-temperature region, but in many cases, it is not consistent with experiment.

A composite model of plastic flow, which involves diffusion-controlled recovery at high temperatures and cross-slip-controlled recovery at low temperatures, has been developed to unify the high- and low-temperature regimes (Ref 1, 23). In the framework of the composite model, power-law breakdown is considered as a natural transition from diffusion-controlled recovery at high temperatures (low stresses) to cross-slip-controlled recovery at lower temperatures (higher stresses).

The composite model is also the foundation upon which the concept of constant structure creep is derived. Constant structure creep, as it fits within the framework of the composite model, describes the kinetics of dislocation glide, multiplication, and annihilation within the cell interiors. Gibeling and coworkers (Ref 24, 25, 26, 27, 28) have argued that the power-law approach does not provide an adequate description of creep under constant structure condition.

Instead, it was suggested that the creep rate under constant structure conditions ($\dot{\epsilon}_{cs}$) can best be described by an exponential kinetic law of the form derived by Kocks et al. (Ref 25) for obstacle-controlled dislocation glide.

Stress and Temperature Dependence of Time to Rupture. The behavior of t_r with respect to σ and T is similar to that of $\dot{\epsilon}$, with the differences being that the signs are reversed for the stress exponent and the activation energy. The parameter A in Eq 2 also has slightly altered values. This behavior occurs when $\dot{\epsilon}$ and t_r are inversely related through Monkman-Grant-type relationships (i.e., $\dot{\epsilon}t_r \simeq \text{constant}$).

Extrapolation Techniques

Because many high-temperature components are designed to operate over long periods of time (sometimes in excess of 100,000 h), extrapolation of laboratory creep and rupture data to actual service conditions is unavoidable. Even if long-time data are available for selected heats of material, heat-to-heat variations in properties make it necessary to estimate the long-time behavior for other heats. Greater difficulty is encountered in estimating the remaining creep lives of in-service components, where decisions have to be made based on very short-time laboratory tests (usually less than 1000 h). The need for extrapolation techniques that permit estimation of the long-term creep and rupture strengths of materials based on short-duration tests is thus a very real and important one in design, quality control, and plant evaluation.

Basically, parametric techniques incorporate time stress and temperature test data into a single expression. When test data recorded over adequate times and at temperatures above the service temperature are incorporated into a single “master curve,” the stress for the service-temperature conditions can be read directly from the master curve.

Extensive reviews of parametric techniques have been given elsewhere (Ref 29 and 30). Their historical evolution up to the present time has been reviewed by Manson and Ensign (Ref 31). More detailed information on extrapolation is also provided in the article “Assessment and Use of Creep-Rupture Properties” in this Volume.

Methods and Equipment

Determination of creep characteristics of metals at high temperatures requires the use of a loading device or test stand, an electric furnace with suitable temperature control, and an extensometer. Equipment discussed in this section is for uniaxially loaded specimens in tension. More information on creep and stress-rupture testing equipment and methods can be found in the following standard:

Creep and Creep-Rupture Testing*

General Methods and Test Factors

Creep behavior is generally determined by uniaxial loading of test specimens heated to temperature in some environment. Creep-rupture experiments measure the deformation as a function of time to failure. If strain-time behavior is measured, but the test is stopped before failure, this is termed an *interrupted creep experiment*. Finally, if an inadequate strain-measuring system or no attempt to determine length is employed, and the test is run to fracture, a stress-rupture experiment results.

In terms of data that characterize creep, the stress-rupture test provides the least amount, because only the time-to-rupture and strain-at-rupture data are available for correlation with temperature and stress. These data and other information, however, can be obtained from creep-rupture experiments. Such additional measurements can include elastic strain on loading, amount of primary creep strain, time to onset of secondary, creep, steady state creep rate, amount of secondary creep, time to onset of tertiary creep, time to 0.5% strain, time to 1.0% strain, and so on. All of these data can be fitted to equations involving temperature and stress. An interrupted creep test provides much the same data as a creep-rupture experiment within the imposed strain-time limitations.

Direction of Loading. Most creep-rupture tests of metallic materials are conducted in uniaxial tension. Although this method is suitable for ductile metals, compressive testing is more appropriate for brittle, flaw-sensitive materials. In compression, cracks perpendicular to the applied stress do not propagate as they would in tension; thus, a better measure of the inherent plastic properties of a brittle material can be obtained.

In general, loading direction has little influence on many creep properties—for example, steady state creep rate in ductile materials (Ref 32). However, even in these materials, the onset of third-stage creep and fracture is usually delayed in compression compared with tension. This delay is due to the minimized effect of microstructural flaws and the inability to form a “neck-like” mechanical instability. For brittle materials, the difference in behavior between tension and compression can be extreme, primarily due to the response to flaws. Consequently, care must be exercised when using compressive creep properties of a brittle material to estimate tensile behavior.

Test specimens for uniaxial tensile creep-rupture tests are the same as those used in short-term tensile tests. Solid round bars with threaded or tapered grip ends or thin sheet specimens with pin and clevis grip ends are typical. However, many other types and sizes of specimens have been used successfully where the choice of geometry was dictated by the available materials. For example, small threaded round bars with a 12 mm (0.47 in.) overall length and a 1.52 mm (0.06 in.) diameter by 5 mm (0.2 in.) long reduced section have been used to

measure transverse stress-rupture properties of a 13 mm (0.51 in.) diameter directionally solidified eutectic alloy bar (Ref 33).

In the case of uniaxial compression testing, specimen design can be simple small-diameter right cylinders or parallelepipeds with length-to-diameter ratios ranging from approximately 2 to 4. Larger ratios tend to enhance elastic buckling, and smaller ratios magnify the effects of friction between the test specimen and the load-transmitting member. These specimen geometries are well suited for creep testing when only a small amount of material is available or when the material is difficult to machine.

Environment. The optimum conditions for a creep-rupture test are those in which the specimen is influenced only by the applied stress and temperature. This rarely occurs, particularly at elevated temperatures, and these conditions do not exist for real structures and equipment operating under creep conditions. For example, turbine blades are continuously exposed to hot, reactive gases that cause corrosion and oxidation.

Reactions between the test environment and material vary greatly, ranging from no visible effect to large-scale attack. For example, creep-rupture testing of aluminum, iron-chromium-aluminum, nickel-chromium, and nickel-base superalloys at elevated temperatures in air can generally be accomplished without problems because these materials form thin, stable, protective oxide films. This is not the case for refractory metals (molybdenum, niobium, tantalum, and tungsten) and their alloys, due to their strong reaction with oxygen, which leads to the formation of porous, nonprotective, and in some cases, volatile oxides. Environmental effects such as oxidation and corrosion reduce the load-bearing cross-sectional area and can also facilitate the formation and growth of cracks.

Reactions are also possible in inert atmospheres (such as vacuum) and in reducing gas environments. Elevated-temperature testing in vacuum can result in the loss of volatile alloying elements and subsequent loss of strength. Exposure to reducing gases can result in the absorption of interstitial atoms (carbon, hydrogen, and nitrogen), which may increase strength, but also induce brittleness.

A “perfect” environment does not exist for all creep testing. The appropriate choice depends on the material, its intended use, and the available environmental protection methods. If creep mechanisms are being determined, then the atmosphere should be as inert, or nonreactive, as possible. However, if the material is to be used in an unprotected state in a reactive atmosphere, then creep testing should reflect these conditions.

Creep data from inert atmosphere tests cannot be used for design purposes when the material will be exposed to conditions of severe oxidation. However, if environmental protection methods, such as oxidation- or corrosion-resistant coatings, are available, then testing in inert gas is acceptable, and the resulting data can be used for design.

If reactions occur between the test environment and the specimen, the resultant creep-rupture data will not reflect the true creep properties of the material. Rather, the measured data are indicative of a complex interaction between creep and environmental attack, where the effects of environmental attack become more important in long-term exposure.

On the specimen side of the machine, a balance beam leveling motor is recommended to compensate for elongation of the test specimen. If this is not available, the balance beam may become unlevel, thus changing the calibration of the weight system. However, properly designed creep testing machines will maintain load accuracy well within ASTM requirements, even when out of level by as much as $\pm 10^\circ$.

The procedure for calibration of weights is given in ASTM E 4, "Standard Practice for Force Verification of Testing Machines." The weights should be verified within a limit of 1% at least every 5 years. Additionally, the weight of the overall load train system should be verified within a limit of 1% at least once a year, except for test stands for long-term tests that last more than 1 year.

The test specimen is connected to the balance beam through the load train, a system of pull rods and couplings manufactured from high-temperature alloys that are capable of maintaining strength and corrosion resistance at the test temperatures encountered. The load train should be machined and assembled such that minimum bending moments are imposed on the test specimen. ASTM recommends a maximum of 10% bending strain, compared with the axial strain due to misalignment of the load train. To overcome this problem, alignment couplings (such as ball and socket or knife-edge systems) are used in the load train to facilitate self-alignment.

Vibration and shock loads can have a significant effect on the end results in creep and stress-rupture testing. Care must be taken in selecting the test site to ensure that vibration or shock is minimal. Additionally, the test stand should be isolated from the floor with a vibration-damping material such as cork or rubber. The leveling motor can introduce vibration that may affect long-term creep tests, or shorter tests if the vibration is significant.

A timer that automatically records the time to rupture is also included on most test stands. During creep tests, the time must be recorded with the creep values.

Creep and Creep-Rupture Testing*

Furnaces

Furnaces used in creep and stress-rupture testing generally are tubular, with an electrical-resistance winding that heats the test specimen through radiation in an air atmosphere. These furnaces can have single or multiple heating zones. The tube is located in a vertical position, with the pull rods connected to the specimen. Care must be taken to seal the opening of the furnace without interfering with the alignment of the load train or the action of the linkage for creep tests.

Temperature Control and Measurement. Materials properties frequently are affected by temperature. The requirement for temperature control of creep and stress-rupture tests is $\pm 1.7^\circ\text{C}$ ($\pm 3^\circ\text{F}$) when testing at 982°C (1800°F) and below, and $\pm 2.8^\circ\text{C}$ ($\pm 5^\circ\text{F}$) above that value. Maintaining control requires practice.

Temperature measurement systems require a transducer to convert a temperature differential to an electrical signal. The transducer typically is a thermocouple that is attached directly to the specimen. Specimens with gage length 25.4 mm (1.0 in.) or greater require two thermocouples; specimens with gage lengths 50.8 mm (2.0 in.) or greater require a third thermocouple.

The thermocouple should maintain in firm and close contact with the test specimen during the entire test. Inherent errors are associated with thermocouples, including calibration error, drift due to metallurgical changes to the thermocouple junction during the test, lead wire error, attachment gap error, radiation error, and conduction error.

Creep and Creep-Rupture Testing*

Extensometers

When creep data are required, the specimen strain must be measured as a function of time. With most metals this is difficult because use of strain-measuring transducers generally is not practical at the test temperatures encountered. A mechanical linkage must then be attached to the specimen to transmit the strain to the strain-measuring equipment outside the high-temperature environment.

The most commonly used strain transducer is the linear variable differential transformer, which consists of a movable metal core that changes the electrical characteristics with the small motion associated with strain measurements (Fig. 7). Linkages that attach to the specimen typically are made of alloys that can withstand the test temperatures encountered. The linkage can be attached either to the gage length or on the shoulders outside the gage length.

Fig. 7 Typical rod-and-tube-type extensometer for elevated-temperature creep testing. Extensometer is clamped to grooves machined in the shoulders of the test specimen.

Care must be taken to ensure that the measured deformation occurs only in the gage section. Thus, measurements based on the relative motion of parts of the gripping system above and below the test specimen are generally inaccurate because the site of deformation is unknown. Extensometry systems are currently available that attach directly to the specimen (shoulders, special ridges machined on the reduced section, or the gage section itself) and transmit the relative motion of the top and bottom of the gage section via tubes and rods

to a sensing device such as a linear variable differential transformer (LVDT). Figure 7 illustrates such a system. These systems are quite accurate and stable over long periods of time.

Typical problems encountered with the use of extensometers include:

- Error due to strain in the fillet of the test specimen when the extensometer linkage is attached to the shoulder (see Ref 34 for strain corrections)
- Fracture where the extensometer linkage attaches to the specimen gage length
- Error in strain measurement when the extensometer linkage is attached such that it measures the strain only on one side of the specimen
- Error due to slippage of extensometer linkage on the gage section of ductile specimens
- Damage to linkages and extensometers when the specimen fails
- Bending strain introduced to smaller test specimens, particularly strip specimens, due to the weight of the linkage and extensometer

Other methods of direct strain measurement exist and, under certain circumstances, are suitable. At low temperatures, strain gages can be directly bonded to the gage section and can be used to follow deformation over the range of extension for which the strain gage is valid. For specimens that will undergo reasonable deformations ($\epsilon > 1.0\%$), the distance between two gage marks can be optically tracked with a cathetometer as a function of time. While the location of strain is known, use of this technique is operator dependent and is generally limited to tests of less than 8 h or greater than 100 h in duration in order to permit sufficient readings to properly define the creep curve.

Creep and Creep-Rupture Testing*

Other Testing Considerations

Constant Load Versus Constant Stress Testing. Most uniaxial creep and stress-rupture tests are conducted under constant-load conditions. Although the method is simple, the stress in the gage section varies with strain (time). This can be seen by considering a bar of length L_0 and cross-sectional area A_0 subjected to a tensile load P . At time $t = 0$, the initial engineering stress on the bar is:

$$s_0 = \frac{P}{A_0} \quad (\text{Eq 4})$$

With the assumption of uniform deformation during creep, the bar lengthens to L and the cross-sectional area decreases to A , because volume must be conserved:

$$LA = L_0A_0 \quad (\text{Eq 5})$$

Therefore:

$$A = A_0 \left(\frac{L_0}{L} \right) \quad (\text{Eq 6})$$

and the true stress on the bar is:

$$\sigma = \left(\frac{P}{A} \right) = s_0 \left(\frac{L}{L_0} \right) \quad (\text{Eq 7})$$

Methods have been devised to account for the change in cross-sectional area during creep. These are based on a rearranged form of Eq 7, where:

$$\sigma = \frac{P}{A} = \frac{PL}{L_0 A_0} \quad (\text{Eq 8})$$

By maintaining PL at a fixed value, a constant stress test can be conducted. In general, the strain-time behavior under constant stress conditions follows the general forms of primary, secondary, and tertiary stages (Fig. 1). However, the period of time spent in primary and secondary creep under constant stress can be much longer than under an identical engineering stress (constant load). Hence, rupture life is longer under constant stress conditions.

Failure under constant stress conditions eventually occurs due to some microstructural and/or mechanical instability in the same manner as a constant load experiment. Once a local variation in cross-sectional area is formed, the actual stress is higher than the imposed constant stress, and further deformation concentrates at this location.

In reality, the basic assumptions of conservation of volume and/or uniform deformation have been violated; therefore, Eq 8 is no longer valid. When nonuniform deformation starts in either a constant load or constant stress test, the local strain and strain rate vary along the gage section in an unknown manner.

Engineering Strain Versus True Strain. In creep experiments, there is little difference between strains calculated by the engineering strain or true strain definitions when the length change is approximately 10% or less. For greater length changes, the calculated values of strain deviate greatly. Although this is of no consequence for tension, the limit of a maximum engineering strain of -1.00 in compression places an artificial barrier on the description of compressive creep. Hence, true strain is a much better indicator of compressive ductility and creep characteristics. In particular, creep behavior measured in tension and compression can be compared only when both are expressed as true strain due to the limiting engineering strain in compression.

Microstructure. During creep, significant microstructural changes occur on all levels. On the atomic scale, dislocations are created and forced to move through the material. This leads to work hardening as the dislocation density increases and the dislocations encounter barriers to their motion. At low temperatures, an ever-diminishing creep rate results; however, if the temperature is sufficiently high, dislocations rearrange and annihilate through recovery events.

The combined action of hardening and recovery processes during primary creep can lead to the formation of a stable distribution of subgrains or loose three-dimensional dislocation networks in some materials, or an approximately uniform dislocation distribution without subgrains in other materials. These stable dislocation configurations are maintained and are characteristic of second-stage creep.

Creep deformation also produces change in the light optical macro- and microstructures. Such changes include slip bands, grain-boundary sliding, cavity formation and growth, and cracking (grain-boundary, interphase boundary, and transgranular). The extent of these microstructural changes is generally increased near fracture sites compared with other regions.

The microstructure of an elevated-temperature creep or stress-rupture test specimen rarely resembles the initial microstructure. Most materials are not thermodynamically stable; hence, prolonged exposure under creep conditions can result in the precipitation of new phases, dissolution or growth of desired phases, grain growth, and so on. Although many of the structural changes can be duplicated through simple heat treatment, some changes will only occur under the combined influence of stress and temperature.

Microstructural changes due to the combined influence of temperature and stress are the most difficult to control. These changes enhance creep and therefore contribute to the observed strain. Even if the changes are essentially complete after primary creep, and the resultant microstructure is more creep resistant than the original structure, the creep strain from such changes may be so great that the material cannot be used. To circumvent these changes, simulation of creep exposure prior to actual use may be necessary.

Complete microstructural examination of tested and untested materials should be an essential part of any creep experiment. As a minimum, the as-received microstructure should be compared with those at and away from the fracture site for the shortest-lived and longest-lived test specimens at each temperature. Comparison of these specimens aids identification of the relevant deformation mechanism, indicates whether environment is affecting creep, and reveals any significant microstructural changes. Such information is vital for interpreting and understanding creep behavior.

Interrupted Tests. Power failure or some other problem may make it necessary to interrupt a test, during which time the specimen cools and must then be reheated. For many materials, this appears to have little effect on either creep properties or time to rupture if cooling and heating times are not too long. However, such treatment may affect the test material. Any interruption of a test should be reported.

Creep and Creep-Rupture Testing*

Constant-Load Testing

Most uniaxial creep and stress-rupture tests are conducted under constant-load conditions. The load is usually maintained constant throughout the test, and as the specimen elongates and decreases in cross-sectional area, the axial stress increases. The initial stress that was applied to the specimen is usually the reported value of stress. Methods of compensating for the change in dimensions of the specimen so as to carry out the creep test under constant-stress conditions have been developed (see the section “Constant-Stress Testing” in this article).

Creep and Creep-Rupture Testing*

Specimen Preparation

Test specimens for creep and stress-rupture tests in tension are similar to those used for short-time tensile tests. Notched specimens are discussed later in this article.

Specimens with round cross sections have threaded ends, except those used at very high temperatures or those of materials that are difficult to machine or display high sensitivity to notches. Specimens with shouldered ends (no threads), or “buttonhead” fittings, are used for tests conducted at very high temperatures, particularly those in vacuum. At high temperatures, threaded specimens tend to seize in the adapters after testing due to oxidation or diffusion. The method of gripping buttonhead specimens provides self-alignment, which is advantageous with brittle materials.

For sheet or plate specimens, the load is often applied via pins placed in through holes in the shoulder ends of the specimens. If the specimen is sufficiently large, it may have elongated shoulder ends extending outside the furnace. Extension tabs sometimes are welded or brazed to the specimen shoulder and extend outside the furnace. Specially designed grips that fit the fillets at the end of the gage length are also used to apply load.

The gage length of a specimen should be uniform. The diameter or width at the ends of the reduced section should not be less than the diameter or width at the center. It is sometimes desirable to have the diameter or width of the reduced section slightly smaller at its center. The difference should range from maximums of 0.5% for a 2.54 mm (0.100 in.) diameter or width specimen to 0.2% for a 12.8 mm (0.505 in.) diameter or width specimen. Specimens should be smooth and free from scratches or other stress raisers and should be machined to minimize cold working or surface distortion. In computing the stress or the load required to provide a certain stress, the smallest original cross-sectional area should be used.

Misalignment can cause high local stresses and premature failure. If threaded specimens are used, the threaded adapters that the specimens fit into should be inspected frequently to ensure proper alignment. These devices may creep during a test and, after several tests, may undergo appreciable misalignment.

Buttonhead specimens and adapters tend to be self-aligning and pose fewer alignment problems. With sheet specimens, it is important that any brazing or welding of extension tabs be done in an alignment fixture. For sheet specimens using a pin in each tab to apply the load, the pin holes must be centered on a line running through the center of the reduced section rather than centered on the tabs. Brittle materials are more sensitive to misalignment than ductile materials.

Creep and Creep-Rupture Testing*

Specimen Loading

Care is required to avoid straining the specimen when mounting it in the adapters and load train, particularly if the specimen is small or brittle. With the specimen in place, the load train (specimen adapters or grips, pull rods, etc.) should be examined carefully for any misalignment that may cause bending of the specimen under load.

The upper load train should be suspended from the lever arm and the compensating weight adjusted so that the lever arm balances. Strain-measuring clamps and an extensometer or platinum strips are attached to the specimen, and the load train is inserted into the furnace with the specimen centered. The specimen must be stabilized at temperature before loading. Also, the extensometer should be adjusted and zeroed.

Loading the weight pan should be done smoothly and without excessive shock. If the specimen is to be step-loaded, the weight is placed on the weight pan in measured increments, and the strain corresponding to each step of loading is recorded. The loading curve thus obtained is used in determining the elastic modulus and plastic strain from load application. If step-loading is not used, a method of smoothly applying the load must be used. This can be done by placing a support such as a scissors jack under the load pan during loading. When all weights are in place, the supporting jack is lowered smoothly from under the weight pan.

Relaxation Testing” in Volume 8 of the 9th Edition *Metals Handbook*. The section “Constant-Stress Testing” was updated by N.L. Carroll, Applied Test Systems Inc.

Creep and Creep-Rupture Testing*

Temperature Control

The specimen should not be overheated while brought to temperature. A common practice is first to bring the specimen to about 10 °C (18 °F) below the desired temperature in about 1 to 4 h. Then, over a longer period, the specimen is brought to the desired temperature.

A period of time above the desired temperature is not “cancelled out” by an equal period at a temperature the same amount below the desired temperature. If the temperature rises above the desired temperature by more than a small amount, the test should be rejected. Specified limits are ± 1.7 °C (± 3 °F) up to 982 °C (1800 °F) and ± 2.8 °C (± 5 °F) above 982 °C (1800 °F). At temperatures significantly above 1093 °C (2000 °F), the limits are broadened. Variations of temperature along the specimen from the nominal test temperature should vary no more than these limits at these temperatures. These limits refer to indicated variations in temperature according to the temperature recorder.

The indicated temperature must be as close to the true temperature as possible to prevent thermocouple error or instrument error. Thermocouples, particularly base-metal thermocouples, drift in calibration with use or when contaminated. Other sources of error are incorrect lead wires, lead wires that are connected incorrectly, and direct radiation on the thermocouple bead.

Representative thermocouples should be calibrated from each lot of wires used for base-metal thermocouples. At high temperatures, base-metal thermocouples should not be reused without first removing the wire exposed to high temperature and rewelding. Noble-metal thermocouples generally are more stable. However, they are also subject to error due to contamination and must be annealed periodically by connecting a variable transformer and passing sufficient current through the wires to make them incandescent.

When attaching the thermocouple to the specimen, the junction must be kept in intimate contact with the specimen. The bead at the junction should be as small as possible, and there must be no twisting of the thermocouple that could cause shorting. Any other metal contact across the two wires will cause shorting and erroneous readings. Shielding of the thermocouple junction from radiant heating is also recommended.

Most creep and stress-rupture machines are equipped with a switch that automatically shuts off a timer when the specimen breaks. In creep tests, the load usually is low enough that rupture does not occur. The microswitch that shuts off the timer often also shuts off or lowers the temperature of the furnace. In some furnaces, the life of the heating element is reduced significantly if the furnace is shut off after each test; instead, the temperature is merely lowered.

Creep and Creep-Rupture Testing*

Notched-Specimen Testing

Notched specimens are used principally as a qualitative alloy selection tool for comparing the suitability of materials for components that may contain deliberate or accidental stress concentrations. The rupture life of notched specimens is an indication of the ability of a material to deform locally without cracking under multiaxial stresses. Because this behavior is typical of superalloys, the majority of notched-specimen testing is performed on superalloys.

The most common practice is to use a circumferential 60° V-notch in round specimens, with a cross-sectional area at the base of the notch one-half that of the unnotched section. However, size and shape of test specimens should be based on requirements necessary for obtaining representative samples of the material being investigated.

In a notch test, the material being tested most severely is the small volume at the root of the notch. Therefore, surface effects and residual stresses can be very influential. The notch radius must be carefully machined or ground, because it can have a pronounced effect on test results. The root radius is generally 0.13 mm (0.005 in.) or less and should be measured using an optical comparator or other equally accurate means. Size effects, stress-concentration factors introduced by notches, notch preparation, grain size, and hardness are all known to affect notch-rupture life.

Notch-rupture properties can be obtained by using individual notched and unnotched specimens, or by using a specimen with a combined notched and unnotched test section. The ratio of rupture strength of notched specimens to that of unnotched specimens varies with notch shape and acuity, specimen size, rupture life (and therefore stress level), testing temperature, and heat treatment and processing history.

To avoid introducing large experimental errors, notched and unnotched specimens must be machined from adjacent sections of the same piece of material, and the gage sections must be machined to very accurate dimensions. For the combination specimen, the diameter of the unnotched section and the diameter at the root of the notch should be the same within ± 0.025 mm (± 0.001 in.).

Notch sensitivity in creep rupture is influenced by various factors, including material and test conditions. The presence of a notch may increase life, decrease life, or have no effect. When the presence of a notch increases life over the entire range of rupture time, the alloy is said to be notch strengthened; that is, the notched specimen can withstand higher nominal stresses than the unnotched specimen. Conversely, when the notch-rupture strength is consistently below the unnotched-rupture strength, the alloy is said to be notch sensitive, or notch weakened. Many investigators have defined a notch-sensitive condition as one for which the notch strength ratio is below unity. However, this ratio is unreliable and can vary according to class of alloy and rupture time.

Certain alloys and test conditions show notch strengthening at high nominal stresses and notch weakening at lower nominal stresses. Changes in heat treatment of some alloys may also alter notch sensitivity significantly. For example, single low-temperature aging of some alloys may produce very low rupture ductilities because the structure is not sufficiently stabilized. Consequently, exposure of such materials for prolonged rupture times will further reduce rupture ductility because of continued precipitation of particles that enhance notch sensitivity. On the other hand, multiple aging usually stabilizes the structure and thus reduces notch sensitivity. Generally, notch sensitivity increases as temperature is reduced.

Notch configuration can have a profound effect on test results, particularly in notch-sensitive alloys. Most studies on notch configuration present results in terms of the elastic stress-concentration factor. The design criterion for the weakening effect of notches at normal and low temperatures is that of complete elasticity. The design stress is the yield stress divided by the elastic stress-concentration factor K_t . The value of the peak axial (design) stress depends on the configuration of the notch.

There is no simple relationship for the effect of notches at elevated temperatures. For ductile metals, the ratio of rupture strength of notched specimens to that of unnotched specimens usually increases to some maximum as the stress-concentration factor is increased. For very insensitive alloys, there may be little further change. Metals that are more notch sensitive may undergo a reduction in ratio as the notch sharpness (stress-concentration factor) is increased beyond the maximum and may show notch weakening for even sharper notches. Very notch-sensitive alloys may undergo little or no notch strengthening, even for very blunt notches (low stress-concentration factor) and may undergo progressive weakening as notch sharpness increases.

Technology, Inc. The remaining sections of this article were adapted from “Creep, Stress-Rupture, and Stress-Relaxation Testing” in Volume 8 of the 9th Edition *Metals Handbook*. The section “Constant-Stress Testing” was updated by N.L. Carroll, Applied Test Systems Inc.

Creep and Creep-Rupture Testing*

Constant-Stress Testing

Norman L. Carroll, Applied Test Systems

Creep and stress-rupture data usually are obtained under constant-load test conditions. However, it is sometimes desirable or necessary to obtain test data under constant-stress conditions. In this case, the applied load is adjusted as the length of the specimen changes to maintain constant stress on the specimen.

Constant-stress testing is necessary to accurately determine differences between the temperature dependence and the stress dependence of a material. Early quantitative work on creep of materials demonstrated that the tensile creep of several pure metals and a selection of alloys under constant stress could best be represented by (Ref 35):

$$L = L_0(1 + \beta t^{1/3})e^{Kt}$$

where L is length of specimen after time, t , L_0 is the length immediately after loading, and β and K are material parameters. Typical creep curves and the effect of temperature and stress on the constants β and K in the Andrade creep equation (Ref 36) are shown in Fig. 8. The sensitivity to stress should be noted. In principle, a constant-stress test can be much more meaningful than a constant-load test. However, constant-stress tests are much more difficult to conduct because load reduction must be commensurate with the degree of straining. Furthermore, in reducing the load to keep the stress constant at a neck, the stress at other points along the gage length of the specimen is reduced. Under these conditions, the strain measured over the gage length of the specimen is no longer a representative strain. The constant-stress test, therefore, may be more meaningful when specimen elongation occurs uniformly rather than locally by necking (Ref 1) because the strain at the neck is also not simply related to the applied stress. Nonetheless, constant-stress creep tests are useful engineering tests that continue to be improved with computer-controlled test machines, as described later in this section.

Creep and Creep-Rupture Testing*

Test Methods

Hyperbolic-Weight Constant-Stress Apparatus. An early application of constant-stress methods in creep testing was the use of a hyperbolic weight by Andrade (Ref 36) in which load was reduced with extension of the specimen as the weight was lowered into a liquid (Fig. 9). The required shape of the weight is given by an equation of a hyperbola:

$$y = \sqrt{\frac{ML_0}{\rho\pi} \cdot \frac{1}{L+x}} \quad (\text{Eq 9})$$

where M is the mass of the load, L_0 is the initial length of the wire, and ρ is the density of the liquid, usually water. The coordinates of the hyperbola, x and y , are shown in Fig. 9. After selecting a particular M and L_0 , the exact size of the weight is given. A weight, once constructed, is exact for one particular initial load, but with reasonable approximation, the same weight can be used over a limited range of loads.

Fig. 9 Hyperbolic-weight constant-stress apparatus. Source: Ref 36

Andrade's tests on lead wire showed a significant difference between results on constant-load and constant-stress tests for the same initial length and the same initial load (Fig. 10). Under constant stress, the rate per unit length, once past the initial effect, is constant up to breaking.

Fig. 10 Results of tests on lead wire under constant-load and constant-stress conditions. Source: Ref 36

Balanced Beam with Cams. A more convenient and useful method uses a balanced beam with shaped cams (Ref 37). A beam (PH in Fig. 11) is supported by a knife edge B and carries two plates, F and C, one at each end. Plate C has a groove along its outer edge HK; the profile HK is an arc of a circle with center B. D is a thin steel wire resting in the groove that is fixed to the adjusting screw, E. The lower end of D is attached to the upper end of the wire to be stretched. F is the second plate, in the groove of which lies a thin steel wire supporting a weight W. The profile of the bottom of the groove PQR is made such that the moment of the weight W about the axis through B is inversely proportional to the length of the wire undergoing stretch, which (assuming that any change in density of the metal that may occur during stretch is negligible) will make the stretching force proportional to the cross section of the wire.

Fig. 11 Balanced beam with cams. See text for explanation of symbols. Source: Ref 37

A compact cam-lever apparatus for application of either constant stress or constant load in tension for large uniform deformations has been developed (Ref 38). Systems of this type have been used for constant-stress testing at loads up to 45 kN (10,000 lbf).

The profile of the constant-stress cam lever is similar to that of the balanced beam with cams (Ref 37), except that exact parametric equations for the cam profile have been determined. The load to the specimen is applied through a circular disk of radius R (Fig. 12). The initial mechanical advantage is r_0/R , but the ratio is reduced as the specimen elongates.

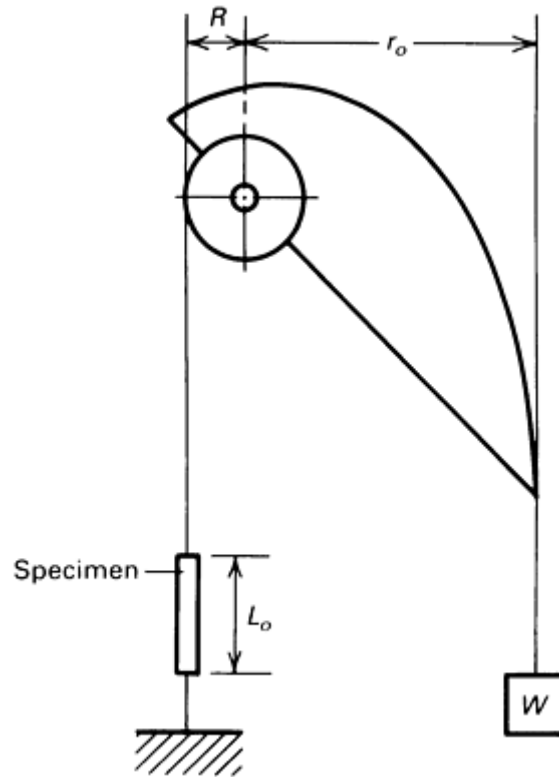

Fig. 12 Constant-stress cam-lever apparatus. Source: Ref 38

To maintain constant stress, the load P on the specimen must be reduced as the specimen elongates to compensate for the reduction in area A . Thus, the instantaneous stress P/A must remain constant. By assuming constant specimen volume and uniform strain, LA (where L is the specimen length) must remain constant. Therefore, it follows that PL also remains constant. In Fig. 12, under equilibrium conditions, $P = Wr/R$, where W is the applied weight and r is the instantaneous moment arm of the applied weight. Thus, to maintain a constant stress, the following condition must be satisfied:

$$rL = \text{constant} - r_0L_0 \quad (\text{Eq 10})$$

where L_0 is the initial specimen length and r_0 is the initial value of r .

As the length of the specimen increases, the arc of contact on the small wheel increases by an equivalent amount. Thus, the instantaneous specimen length may be written as:

$$L = L_0 + (\theta - \theta_0)R \quad (\text{Eq 11})$$

where θ_0 is the angle for the initial positioning of the constant-stress cam. Eliminating L from Eq 10 and 11 leads to:

$$r = \frac{r_0L_0}{L_0 + R(\theta - \theta_0)} \quad (\text{Eq 12})$$

This is the equation of the profile of a constant-stress cam. To design an actual cam profile, it is desirable to transform Eq 12 into a fixed Cartesian coordinate system (x, y) . These design considerations are discussed in Ref 37 and 38.

To provide balance and proper control of loading on the specimen, a balancing cam is added to the loading cam. As shown in Fig. 13, a circular disk or constant-load wheel also may be added to the cam for the purpose of performing constant-load testing. The load can be transmitted by a number of methods; steel bands or roller chain are used most frequently. The shaft of the cam assembly usually is supported by pillow block bearings. Another method of support is the use of hardened and ground knife edges and V-blocks (Fig. 14), although this method results in reduced cam rotation and specimen elongation.

Fig. 13 Constant-stress testing system with balancing cam and constant-load wheel

Fig. 14 Constant-stress testing system using V-block and knife-edge support

Typical systems of this type include a counterbalance cam, a pillow block bearing support, and a three-zone furnace for elevated temperature testing. A motorized automatic weight elevator with a platform usually provides gradual load application, reduces labor in handling weights, and minimizes shock upon specimen failure. The cams for these systems are programmed and machined on a computer numeric control (CNC) milling machine to provide optimum accuracy and minimum cost.

A constant-stress apparatus for use with low forces has been developed to eliminate frictional effects of hinges or bearings (Ref 39). Reference 40 describes a method of cam assembly support by means of steel tapes. Modifications of this method were designed to achieve the accurate maintenance of constant stress when forces as low as 0.1 N (0.022 lbf) are involved (Fig. 15).

Fig. 15 Constant-stress testing system for use with low forces. A, specimen; B, double cam; C, counterweight; D, pulley for counterweight; E, hollow cylinder from which specimen is suspended; F, force cell; G, tape displacement gage; H, loaded mass pan; I, hydraulic ram

To balance the mass of the cam about the point of suspension and thereby ensure that the only force on the specimen is the applied force due to the mass M , the counterweight C is necessary. With the modified suspension, the cam profile equation becomes:

$$r = \frac{(r_0 - R)L_0}{L_0 + 2R(\theta - \theta_0)} + R \quad (\text{Eq 13})$$

For actually determining the cam profile, Eq 13 usually is transformed into two profile equations that express the Cartesian coordinates x and y in terms of a single parameter.

In the absence of frictional forces, the lower limit on the applied force P is determined by the sensitivity with which the suspension system can be balanced. For the present apparatus, the lower limit was 0.1 N (0.022 lbf), which corresponds to 5.0 kPa (0.72 psi) if the specimen diameter is 5 mm (0.2 in.). Thus, the apparatus is suitable for use at small stresses, such as may be encountered in studies of plastic flow at temperatures close to the melting point. The system demonstrated accuracy within $\pm 0.50\%$.

High-Temperature Constant-Stress Compression Creep Apparatus. A constant-stress apparatus has been developed for high-temperature compression testing of ceramic materials in controlled atmospheres (Ref 41). The creep frame is based on the fundamental concepts developed in Ref 42 for the application of constant compressive stress loading using the Andrade fulcrum principle via a lever arm mechanism from a weight pan loaded system. The following equation ensures maintenance of constant stress:

$$L_3 = \frac{L_1 L_2}{L} \quad (\text{Eq 14})$$

where L_1 , L_2 , and L_3 are the distances between the various knife edges (Fig. 16 and 17) and L is the sample length.

Fig. 16 Knife-edge configuration for constant-stress compression testing. Source: Ref 41

Fig. 17 Alternate knife-edge construction providing a greater range of sample lengths. Source: Ref 41

Two knife edges provide the fulcrum for the lever arm, another supports the weight pan, and a fourth applies the force to the lower sample push rod. When the load pan support columns are vertical, the frame acts as a simple fulcrum to apply a force on the lower push rod that is greater than the force on the weight pan by a factor of L_2/L_1 . When the sample deforms, the frame tilts backward and the columns are no longer vertical.

This movement, which is proportional to the preset L_3 and the amount of deformation, increases the force applied to the push rod and also to the sample. The increase in force compensates for the increase in area of the sample as it is compressed, thus maintaining a constant stress. Shorter samples require a greater L_3 because the area of the sample becomes greater for the same amount of deformation than for a sample of greater height. Sample area is not important in making L_3 calculations because changes in area for a given amount of creep are of the same proportion for samples having either a large or a small area if both are of the same height. The system described also allows L_3 to be adjusted.

By increasing or decreasing the range of L_3 , the range of sample lengths can be changed. This is done by using longer or shorter weight pan support columns or by using an adjusting system that simultaneously changes L_3 and L_2 by moving the weight pan knife edge, as shown in Fig. 17. Two bars with weights are used to balance the frame.

The unit maintains constant stress to within 1%, as long as the total strain does not exceed 10% and the test is initiated with the weight pan columns in a vertical position. However, if an approximation of the total strain during the run can be predicted and if the unit is set such that it passes through the vertical position when approximately one-half of the total strain has occurred, the stress can be held to within 0.5% up to a total strain of 10%.

Creep and Creep-Rupture Testing*

Computer-Controlled Constant-Stress Testing

As previously noted, precision-machined cam-lever systems are designed to mechanically adjust the load with respect to the change in length of a specimen with a fixed initial gage length and overall length. Although the disadvantage of this type of testing system is the physical constraint on the initial geometry of the specimens to be tested, the lever arm lends a significant mechanical advantage to the testing machine. Moreover, by using the increased compliance, reduced force, and increased travel on the weight pan end of the lever system (e.g., with a ratio of 10:1 or 20:1), a significant increase in control parameters and sensitivity results in higher precision testing.

The use of a computer control system for constant-stress testing can overcome the constraints on specimen geometry imposed by the cam-lever and similar systems. The computer control system can be programmed to accommodate a wide variety of specimens as well as provide control over test parameters such as rate of load application and removal, step-loading, cyclic loading, test time, furnace or oven temperature, and so on. The computer control system can also be used for data acquisition and analysis and for emergency test situations.

Dynamically Adjusted Constant-Stress Creep Test Machine. A novel computer-controlled creep testing system, developed at the University of California, Davis, is called the dynamically adjusted constant-stress creep machine (DACSCM) (Ref 43). This system integrates the positive and beneficial aspects of the lever-arm test system with a computer-control system that modulates load control apparatus to perform constant-stress creep

experiments. The testing system, at the time of writing, accumulated well over 1200 experimental hours of usage by various investigators. The longest test lasted for more than 274 h at a single constant stress rate. The specific algorithm that relates load and tensile elongation to cross-sectional area is based on the assumption of volume constancy within the deforming gage length. The following expression can be written:

$$P_i = \sigma_0 \left(\frac{A_0 l_0}{l_0 + x_i} \right) \quad (\text{Eq 15})$$

where for the i_{th} data point, σ_0 is the desired stress, A_0 is the initial cross-sectional area, l_0 is the initial gage length, and x_i is the total accumulated specimen displacement. The expression will be assumed to be valid throughout the entire deformation process until the onset of necking (i.e., localized straining) within the specimen takes place. Also, since a significant amount of the experimental creep work is carried out at strain levels that are much less than those typically required to initiate necking, this assumption can be considered reasonable and acceptable.

Typical Computer-Controlled Constant-Stress Testing System. A typical constant-stress testing system with a lever arm and computer control and data acquisition is shown in Fig. 18. With proper programming and selection of lever arm ratios, a system of this type provides precision control and also data acquisition and analysis. The versatility of these systems makes it feasible to perform various test functions, such as creep/stress rupture testing, stress relaxation testing, constant-stress testing, and cyclic load or cyclic strain testing. This type of system can be easily converted from one test mode to any of the other modes. In addition, compression testing can be performed in any of the test modes by using an appropriate compression test fixture. Testing systems such as the one shown in Fig. 18, are available with dual ratio lever arms (e.g., 20:1 and 3:1), which extend the range and provide optimum control and sensitivity.

Fig. 18 Typical computer-controlled constant-stress test system with 90-kN (20,000 lbf) load capacity and furnace system.

In order to achieve precise test results, measurement is required on the specimen gage length and sometimes on the specimen diameter(s) as well. A typical extensometer is an averaging extensometer with dual high-precision capacitance transducers. Extensometers are also available to gage specimen diameter(s) change during testing, using similar transducers.

Creep and Creep-Rupture Testing*

Stress Relaxation

Traditional creep testing to develop descriptions of strain rate, stress, and temperature behavior can be time intensive and expensive, involving many creep test stands, specimens, and thousands of hours of testing. Stress relaxation offers the potential to eliminate this difficulty by producing strain rate/stress data over a wide range of rates from a single specimen (see the article “Stress Relaxation Testing” in this Volume). This information is developed when the elastic strain of a specimen extended (or compressed) to a certain constant length is converted to plastic strain. As the specimen slowly deforms, the load required to maintain the constant length is reduced, hence the term *stress relaxation* test. In addition, this type of experiment simulates the real engineering problem of the long-term loosening of tightened bolts and other fasteners.

In its simplest form, a stress relaxation test involves loading (straining) a specimen to some predetermined load (strain), fixing the position of the specimen (halting the crosshead motion in a universal test machine, for example), and measuring the load as a function of time. With knowledge of the elastic modulus of the specimen and the stiffness of the testing machine, the load-time data can be converted to stress/strain-rate data. This information can then be used to determine the stress components and activation energies of creep for deformation.

In stress relaxation testing, a material is loaded with an initial stress level (σ_0 , in the idealized graphic representation in Fig. 19). Depending on the application, the initial stress may be below, at, or above the yield stress on loading. Whether or not there is permanent plastic strain on loading, there is an elastic strain that, in linear elastic materials, is proportional to the stress through the appropriate temperature-dependent modulus. Most reported data concern stress relaxation in materials initially stressed below their yield strength. Conversely, if initial yielding occurs, an initial permanent or plastic strain develops (Fig. 20). The elastic strain remaining, EC, is directly proportional to the remaining stress, DC in Fig. 20, so that in effect, after the initial yielding, stress relaxation is a time-dependent conversion of elastic to plastic irrecoverable strain. As time progresses, line ED in Fig. 20 shifts to the right and the relaxation of stress ($\Delta\sigma$) is defined as equivalent to the stress required to produce an equal amount of elastic deformation, where (assuming that the modulus of elasticity is constant and that the change in cross-sectional area is negligible during the test):

$$\Delta\sigma = \sigma_0 - \sigma_t = E\varepsilon_p$$

where σ_t is the stress at time t , E is the elastic modulus, and ε_p is the plastic strain at time t . The quantity ε_p is equal to the residual strain after load removal.

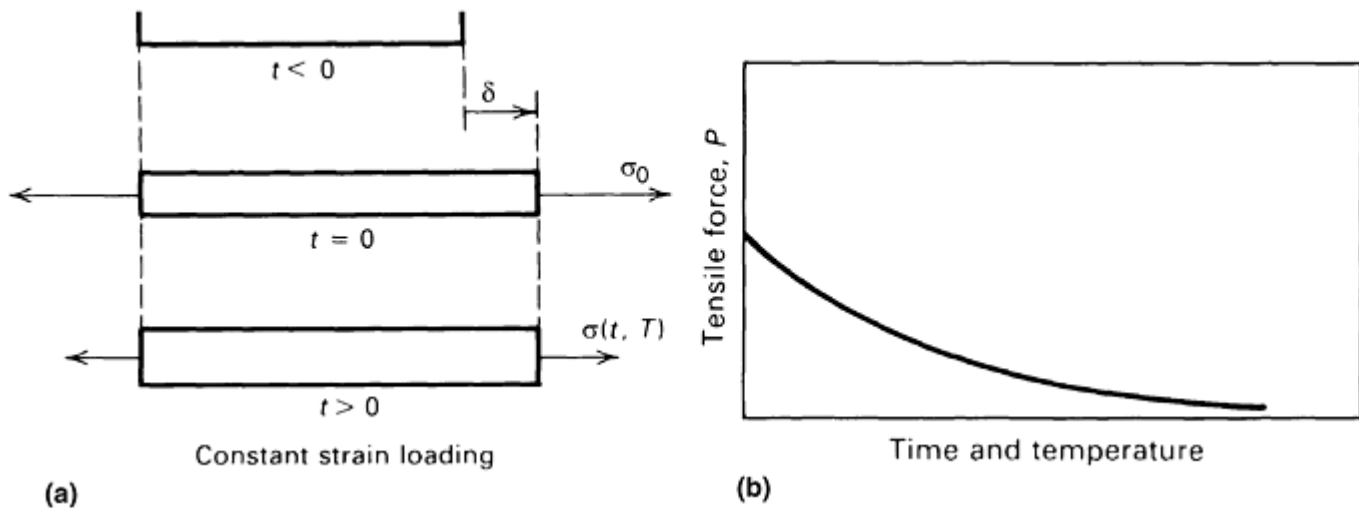

Fig. 19 Idealized concept of stress relaxation. (a) Constant strain loading in tension. (b) Stress-relaxation curves in tension

Fig. 20 Stress-strain diagram for determining relaxation in stress

One major drawback of many stress relaxation tests is the number of demands placed on the experimental equipment. The load-measuring system must be capable of making accurate measurements of very small changes as a function of time. The effect of the loading rate on the relaxation rate should be evident. In addition, room temperature, as well as specimen temperature, must be precisely controlled throughout the experiment. This is critical, because even small fluctuations in temperature will produce thermal expansion effects that can mask changes due to relaxation. Also, the calculated stress exponents and activation energies may not be the same as those determined from creep testing. The processes that produce plastic flow could be different for these two situations. Only comparison of the results from both types of testing can detect equivalent behavior.

Assessment and Use of Creep-Rupture Properties

Howard R. Voorhees, Materials Technology Corporation Martin Prager, Materials Properties Council

Introduction

USE OF CREEP-RUPTURE PROPERTIES to determine allowable stresses for service parts has evolved with experience, although guidelines for use differ among specifications.

Pioneering efforts by ASME (Ref 1 and earlier versions) to improve safety in use of metals for long-time operation at temperatures in the creep range set allowable stresses by considering the following criteria among others:

- 100% of the stress to produce a creep rate of 0.01%/1000 h, based on a conservative average of reported tests as evaluated by an ASME committee. In assessing data, greater weight is given to those tests run for longer times.
- 63% of the average stress or 80% of the minimum stress reported to produce rupture at the end of 100,000 h, as determined from available extrapolated data

These criteria continue to find wide acceptance.

For most commercial steels and alloys, available raw data come from tests with durations ranging from a few hundred to several thousand hours. Tests seldom run longer than 10,000 h, and durations of 100,000 h are rare. Measured secondary creep rates as low as 0.01%/1000 h are also unusual. Allowable stresses recommended in existing specifications usually are derived from extrapolations. Considerable scatter in test results may be observed even for a given heat of an alloy, so interpolated creep and rupture strengths are not precisely established.

Although measurement and application of creep-rupture properties is often imprecise, general trends are evident. Methods for assessing creep-rupture properties (including nonclassical creep behavior), common

interpolation and extrapolation procedures, and properties estimation based on insufficient data are discussed in this article.

Assessment and Use of Creep-Rupture Properties

Howard R. Voorhees, Materials Technology Corporation Martin Prager, Materials Properties Council

Scatter of Creep-Rupture Test Data

Reliable creep-rupture property measurements require that the test specimens be representative of the material to be used in service, preferably in the product form and condition of intended service. Testing results may vary significantly with sampling procedures. For example, heavy sections may exhibit variations in strength level with depth after normalizing or quenching and tempering treatments. A common practice is to take samples midway between the center and the surface of the specimen.

Similar variations in strength can occur for fully annealed plate or bar that has been cold straightened. Reannealing may be required before valid testing results can be obtained. For some materials (e.g., stainless steel castings several inches thick, or alloys subjected to elevated temperature after critical prior plastic deformation), the grains may become so coarse that a specimen cross section contains only one or several grains. Local creep rates may then vary considerably along the specimen gage length according to the orientation of the individual large grains with respect to the loading direction.

Sampling direction seldom affects creep and rupture properties for materials with uniform single-phase structures of small equiaxed grains. For such materials, specimen size also exhibits minimal influence, except for the greater relative importance of surface oxidation and similar effects in small specimens. Due to solidification and processing conditions, preferred orientation of secondary phases or grains can alter test results. In critical situations, the loading direction in the test specimen should parallel the major stress direction expected under service loading. For rolled materials, ASTM E 139 (Ref 2) recommends that specimens be taken in the direction of rolling, unless otherwise specified.

The presence of large discrete particles of lower ductility and strength (e.g., graphite flakes in gray cast iron, or large glassy inclusions in steel) may significantly lower the sound cross section of a small specimen, but have a lesser influence in a larger specimen. Specimen size may have the opposite effect if only a few scattered low-strength particles are present; consequently, a specimen small enough could be free of these large-scale areas of weakness. More subtle variations in local creep and rupture strengths arise at grain boundaries, precipitates, voids, composition gradients, and other regions of microscale nonuniformity.

Specimen Size. For many steels, the influence of specimen size is minimal compared to other variables. During testing of a low-alloy steel (ASTM A 193, grade B16) and a high-alloy steel (ASTM A 453, grade 660) using five different specimen diameters ranging from 5 to 84 mm (0.2–3.3 in.), rupture strength appeared to be independent of size for unnotched specimens (Ref 3). Variation in rupture time with size was erratic for notched specimens, but the largest size had about three quarters of the strength of the smallest geometrically similar specimen.

Scatter from Heterogeneities. Heterogeneities in a low-alloy steel of commercial quality have been found to cause much of the typical 30% scatter encountered in determining creep rates under strict testing conditions (Ref 4). Scatter for rupture times is approximately half that magnitude with materials that are specially prepared to be uniform.

Temperature and Other Testing Variables. Even with the use of precise temperature controllers and high-quality pyrometric practice, care is required to hold the average indicated specimen temperature within usual specifications of ± 2 °C (± 3.6 °F) (Ref 2) with time. Variation from one location to another along the specimen gage length typically approaches this magnitude, even in furnaces with independent adjustment of power input within zones.

These variations in indicated temperature do not include errors in initial thermocouple and pyrometer calibrations, leadwire mismatch, or drift in thermocouple output with time. Actual temperature can differ from the reported value by at least 5 °C (9 °F) during some portion of a representative creep or rupture test.

For steel at 450 °C (842 °F), a temperature disparity of 5 °C (9 °F) corresponds approximately to 20% variation in rupture time (Ref 4). A 10% change in creep rate results from a load change of 1.5%, or a temperature change of 2.5 °C (4.5 °F) (Ref 3). An error of more than 1% in the applied load is unlikely under typical conditions.

Equipment for creep-rupture testing commonly includes features to promote uniform axial loading. However, bending loads may still occur. The increase in secondary creep rates and reduction in rupture life with eccentricity of loading is analyzed in Ref 5, which reports that extreme cases of bending introduced by threaded ends on cylindrical specimens reduce rupture life by as much as 60%. The largest effects occur for short or notched specimens and for materials with low ductility to rupture.

Eccentric loading exerts maximum influence on creep measurements in the early stages of a test. With initially bowed specimens, which are common when specimens are as-cast or are strip-type machined from thin material, early creep indications may be erroneous if the extensometer fails to accurately average the strains at opposite sides of the specimen.

Typical Data Scatter. Rolled bars from a single heat of 2.25Cr-1Mo steel were tested by 21 laboratories in eight countries (Ref 6). The largest deviations in average results for one laboratory from the arithmetic mean of values from all laboratories for the stress to cause rupture in 1000, 3000, and 10,000 h were:

Temperature		Deviation
°C	°F	
550	1022	+14.3 and -16.6%
600	1112	+21.2 and -12.1%

Another group of 18 laboratories in seven countries cooperated in tests of Nimonic 105 alloy bars at 900 °C (1652 °F) (Ref 7). Mean rupture times adjusted to a common stress for individual laboratories (four tests each) ranged from a high of 1491.4 h to a low of 1090.2 h (15.5% deviation). Time to 0.5% total deformation varied from 75.4 to 182.3 h for 16 of these laboratories; deviation from the mean value thus increased to 41.5%.

Temperature control was found to be the most serious source of variation in rupture measurement. In particular, calibration drift of Chromel-Alumel thermocouples at this high test temperature was responsible for the long mean rupture times found by five of the laboratories. Not more than about 15% scatter generally can be attributed to testing variables, if a laboratory has followed standard procedures.

Multiple Heats and Product Forms. Scatter bands become much broader when data originate from tests on numerous heats, particularly when data include a broad range of product forms and sizes. Elevated-temperature properties for steel and superalloys are available (see, for example, Ref 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, and 18). Typically, data for each grade of steel include plots of the stress for rupture in 1000, 10,000, or 100,000 h versus the test temperature. Where appropriate, distinctive shapes of data points identify different product forms or heat treatments.

When data at a given temperature are extensive, the reported range of derived stresses to produce rupture in a given time typically consists of a two-fold ratio of the highest to the lowest stress level. The corresponding spread of rupture times for a given test stress is on the order of 100-fold.

If a new set of test results does not fall within the broad scatter bands, careful review and confirmation is required before the new data are accepted as valid. Bias of new data tends toward the upper half of the scatter bands compiled for older data because the increase of residual alloying elements from scrap recycling, higher nitrogen content, and improved alignment and temperature control in modern testers tend to raise indicated creep and rupture properties.

At a test temperature of 593 °C (1100 °F) and at a stress of 207 MPa (30 ksi), rupture life ranged from 84 to 2580 h and secondary creep rate ranged from 0.16 to 0.00077%/h for 20 heats of type 304 stainless steel in the reannealed condition (Ref 19). Corresponding large variations were observed at all test temperatures and for

tests on seven heats of type 316 stainless steel. Reannealing of as-received material lowered time to rupture in some cases, but the degree of variation persisted in properties among heats.

Good linear correlation was obtained when the logarithm of rupture strength was plotted against ultimate tensile strength at the same temperature for various types of austenitic stainless steels in the annealed and cold-worked conditions at temperatures ranging from 538 to 816 °C (1000–1500 °F) and for test times approaching 10,000 h. Tensile strength, in turn, was reported to be essentially proportional to $(C + N)d^{-1/2}$, where C and N represent the weight percentage of carbon and nitrogen content, respectively, and d is average grain diameter.

Although long-time performance generally cannot be accurately predicted from short-time data, the location of a particular set of rupture data within a published scatter band should agree with the relative tensile strength of the material being tested in the range of tensile strengths spanned by all heats and product forms. Tests to measure low rates of secondary creep frequently are terminated after the creep rate appears to have become reasonably constant. If the test duration had been prolonged substantially, a continued slow decline in creep rate may have been observed.

A “false” minimum rate may occur in some tests before the classical secondary creep period has been reached. Observations of many comparative creep and rupture strengths for steels has established the following general relationships:

$$\frac{0.0001\% / \text{h creep strength}}{10,000 \text{ h rupture strength}} = 0.7 \text{ to } 0.8$$

$$\frac{0.00001\% / \text{h creep strength}}{100,000 \text{ h rupture strength}} = 0.5 \text{ to } 0.6$$

If a new set of test results differs from these patterns, verification is suggested before the new results are accepted.

Assessment and Use of Creep-Rupture Properties

Howard R. Voorhees, Materials Technology Corporation Martin Prager, Materials Properties Council

Nonclassical Creep Behavior

The curve of creep deformation versus time traditionally displays three consecutive stages (Fig. 1). The longest period of substantially constant creep rate is preceded by a primary stage during which the rate declines from an initial high value and is followed by a tertiary stage of rising creep rate as rupture is approached (Fig. 2).

Fig. 1 Schematic tension-creep curve showing the three stages of creep

Fig. 2 Relationship of strain rate, or creep rate, and time during a constant-load creep test. The minimum creep rate is attained during second-stage creep.

Although this classical pattern can be made to fit many materials and test conditions, the relative duration of the three periods differs widely with materials and conditions. For example, in many superalloys and other materials in which a strengthening precipitate continues to age at creep temperatures, brief primary creep often shows transition to a long upward sweep of creep rate, with hardly more than a point of inflection for the secondary period.

Aging of normalized and tempered 0.5Cr-0.5Mo-0.25V steel during creep under 80 MPa (11.6 ksi) stress at 565 °C (1050 °F) has been reported to cause the creep curve to effectively exhibit only a continuously increasing creep rate to fracture (Ref 20). For twice the amount of stress, the creep curve in this case followed the classical trends. In other alloys, such as titanium alloys, with limited elongation before fracture, the tertiary stage may be brief and may show little increase in creep rate before rupture occurs.

A more obvious departure from classical behavior develops during the early portion of many tests when precise creep measurements are taken. When 34 ferritic steels were studied for as long as 100,000 h at temperatures ranging from 450 to 600 °C (842–1112 °F), step-form irregularities were observed, with an extended period of secondary creep preceded by a lower steady creep rate of shorter duration during primary creep (Ref 21).

Negative Creep. Because a variety of metallurgical processes can be involved and because the rates and direction of these processes can vary with time and temperature, departures from classical creep curves can take many forms and can be overlooked unless accurate creep readings are taken at sufficiently close intervals, particularly during early stages of the test. For 2.25Cr-1Mo, Cr-Ni-Mo, and Cr-Mo-V steels, some tests have demonstrated an abrupt drop to negative creep rate (contraction) after a brief beginning period of positive primary creep. Once this contraction ceased, the remaining portion of the test displayed the classical succession of declining, steady, and then rising creep rates. Figure 3 gives an example for normalized and tempered 2.25Cr-1Mo steel, tested at 275.8 MPa (40 ksi) at 482 °C (900 °F) (Ref 22).

Fig. 3 Creep curve of 2.25Cr-1Mo steel with nonclassical early stage. Normalized and tempered to 607 MPa (88 ksi) tensile strength at room temperature. Tested at 482 °C (900 °F) at 275.8 MPa (40 ksi)

Definite negative creep was noted in at least one test each at 482, 704, 816, and 871 °C (900, 1300, 1500, and 1600 °F) for cast CF8 austenitic stainless steel in tests of boiler and pressure-vessel materials (Ref 22). Rupture times for these tests ranged from 1000 h to longer than 30,000 h. For some combinations of material lots and test temperatures, nearly all creep curves of these tests showed an early “false” minimum rate during part of the primary stage. Structural changes responsible for the measured contraction were undetermined.

Short-term negative creep also was observed in tests on quenched and tempered 2.25Cr-1Mo steel at 482 °C (900 °F) and at 482 and 538 °C (900 and 1000 °F) for the same steel in the normalized and tempered condition. Two steady-state creep stages for annealed 2.25Cr-1Mo steel have been reported (Ref 23), which were due to the interaction of molybdenum and carbon atoms with dislocations and the subsequent decrease in the number of these atoms as Mo_2C precipitated. A volume decrease associated with the precipitation process also could account for the observed creep curve trends.

Interstitial diffusion of carbon and hydrogen into dislocations has been observed, and alloy strain-aging effects have been found to cause creep rate transitions noted for carbon steels and normalized 0.5% Mo steel (Ref 24). Negative creep in Nimonic 80A appears related to an ordering reaction in the Ni-Cr matrix and possible formation of Ni_3Cr (Ref 25).

Oxide and Nitride Strengthening. An entirely different source of variation from classical patterns occurs in creep tests at high temperature due to reaction with the air that forms the environment. Tests longer than 50 h with 80Ni-20Cr alloys at 816 and 982 °C (1500 and 1800 °F) showed a deceleration of creep after the normal tertiary stage was reached, resulting in a second period of steady-state creep and later another period of last-stage creep (Ref 26). Figure 4 illustrates a creep curve showing the effect of oxide strengthening.

Fig. 4 Creep curves of alloy 2V tested at 980 °C (1800 °F) and 17.2 MPa (2500 psi). (a) Tests in argon and air for same duration. (b) Entire curve of specimen tested in air is shown. Filled square on both graphs represents same point.

This behavior, which prolonged rupture life and caused a slope decrease in curves of log stress versus log rupture life, was due to oxide and nitride formation on surfaces of the intercrystalline cracks that form extensively during tertiary creep. Observed interconnection of the bulk of these cracks added substantially to strengthening against creep deformation in the late stages of the tests.

This effect also was observed in 99.8% Ni tested at 815 °C (1500 °F) under 20.7 MPa (3000 psi) stress (Ref 27). Fracture after a prolonged time occurred in a lower stressed section of the fillet. Fewer intergranular cracks in this region resulted in less oxidation strengthening than in the gage section.

Assessment and Use of Creep-Rupture Properties

Howard R. Voorhees, Materials Technology Corporation Martin Prager, Materials Properties Council

Extrapolation and Interpolation Procedures

The determination of creep-rupture behavior under the conditions of intended service requires extrapolation and/or interpolation of raw data. No single method for determination of properties exists; rather, various techniques have evolved for data handling of most materials and applications of engineering interest. These techniques include graphical methods, time-temperature parameters, and methods used for estimations when data are sparse or hard to obtain. Recent developments for predicting remaining life of components in creep service are described in this section.

Graphical Methods

Test results frequently are displayed as plots of log stress versus log rupture time and log stress versus log secondary creep rate, with a separate curve (isotherm) for each test temperature. For limited ranges of test variables, test points frequently fall in a straight line for each temperature. Nonlinearity of isotherms with broader ranges of test parameters has been treated variously, but common practice is to represent the data by two or more intersecting straight line segments. Figure 5 illustrates such treatment for an aluminum alloy.

Fig. 5 Logarithmic plot of stress versus rupture life for aluminum alloy 6061-T651

Isotherms for lower temperatures characteristically display a flatter slope than those for higher temperatures. At a given temperature, when the test stresses drop below a given level that varies with alloy composition and metallurgical condition, the slope of the isotherm usually steepens. This steeper slope often approximates the slope for early times at the next higher test temperature.

Early investigators of engineering creep behavior introduced a “conservative” practice of using the slope from the next higher temperature when an isotherm had to be extended to longer times. Use of this method is limited to the specific temperatures of the test runs. Even under these conditions, extrapolations should be only in the direction of longer times for the lower range of test temperatures.

Because the change in slope of log stress versus log time isotherms historically appeared to be associated with a gradual change in fracture mode from transgranular at lower temperatures and higher stress to intergranular at relatively high temperatures and low stress, the belief developed that once the slope of the longer time portion became established, further slope change would not occur. Experimental data available at that time provided no indication that these linear plots could not be extrapolated to long times with confidence. Subsequent long-time data demonstrate that such extrapolations may lead to erroneous results.

Upward Inflection of Log-Log Rupture Plots at Long Times

Review of 52 heats from 31 wrought and cast steels, each with test times longer than 50,000 h, indicated that some portion of the log stress versus log rupture time curves for all ferritic steels showed a decrease in slope when tests were of sufficiently long durations (Ref 28). The degree of this upward inflection depends on composition, heat treatment, and, particularly, test temperature.

A sharp inflection at one temperature (e.g., 500 °C, or 930 °F) was usually accompanied by a less distinct inflection covering a broader time range at a higher test temperature (e.g., 550 °C, or 1022 °F). Generally, these inflections shifted to shorter times and lower stresses with increasing test temperature. Existence of inflections appeared to be related to precipitation phenomena.

For the heat-treatable aluminum alloy 6061-T651, test stresses between about 20 and 50 MPa (2900 and 7250 psi) for temperatures ranging from 260 to 343 °C (500–650 °F) exhibited nearly the same slope on a plot of log stress versus log rupture time, which was steeper than for either higher or lower stress levels (Ref 29). The long-time rupture results obtained had been predicted (Ref 30) by separate graphical extrapolation of each of three regimes of rather constant slope (see Fig. 5).

In this instance, the curves that were actually extended were lines for fixed stress levels (isostress lines) on plots of log rupture time versus temperature, or the reciprocal of absolute temperature. However, extrapolation could have been carried out on the usual log stress versus log rupture time plot by treating the data as a family of curves, with different portions of each curve falling into different slope regimes. Direct graphical extension of isostress lines appeared to provide better extrapolation of rupture data than other common methods (Ref 31).

Curves of log stress versus log rupture life for two chromium-molybdenum steels (ASTM A 387, grades 22 and 11) typically show an increase followed by a decrease in steepness for tests at 538 to 566 °C (1000–1050 °F). Consequently, correct prediction of 100,000 h strengths requires that these changes in slope be incorporated into the analysis (Ref 32). This requirement applies to all evaluation methods. Unless the input data include results that encompass structural changes of the type expected under intended service conditions, accurate extrapolation cannot be expected.

Some metallurgists prefer a semilogarithmic plot of stress versus log rupture time. The sigmoidal shape of isotherms is thus more evident, but extrapolation difficulties remain. The double inflections (or sigmoidal shape) for rupture curves can be greatly accentuated when notched specimens are tested. In the intermediate stress regime, rupture life can actually decrease as the level of test stress is lowered.

Time-Temperature Parameters

Temperatures that are higher than those encountered in service have traditionally been used to shorten the time required to obtain creep-rupture results. One such approach incorporates time and temperature into an expression or parameter, such that a single master curve of stress or log stress can represent all data obtained for a given lot of material over a wide range of test conditions.

When the parameter calculated for a desired service time and temperature falls within the range of the master curve, the corresponding stress can be read directly from that curve. More than 30 parameters have been proposed; although not always developed that way, several can be derived from the following:

$$P = \frac{\frac{\log t}{\sigma^Q} - \log t_A}{(T - T_A)^R} \quad (\text{Eq 1})$$

where t is rupture time in hours; σ is stress in psi; T is test temperature in °F; and T_A , $\log t_A$, Q , and R are constants determined from the experimental test data. Geometric requirements for lines of constant stress for several parametric models are shown in Fig. 6 (Ref 23), a plot of logarithm of time versus either temperature or its reciprocal. Of these, the Larson-Miller and Manson-Haferd parameters represent early developments in time-temperature parameters that retain considerable application.

$$P = f\left(\sigma \text{ or } \frac{\sigma}{E}\right) = (T_A)(\log t + C)$$

Larson-Miller

(a)

$$P = f\left(\sigma \text{ or } \frac{\sigma}{E}\right) = \frac{\log t - \log t_A}{T - T_A}$$

Manson-Haferd

(b)

$$P = f\left(\sigma \text{ or } \frac{\sigma}{E}\right) = \frac{\log t - \log t_A}{1/T - 1/T_A}$$

Goldhoff-Sherby

(c)

$$P = f\left(\sigma \text{ or } \frac{\sigma}{E}\right) = \log t - BT$$

Manson-Succop

(d)

$$P = f\left(\sigma \text{ or } \frac{\sigma}{E}\right) = AT\theta^{-B/T}$$

Orr-Sherby-Dorn

(e)

Fig. 6 Schematic representation of several parametric models. In the equations given for each parameter, σ is applied stress, t is time, T is temperature in $^{\circ}\text{C}$ or $^{\circ}\text{F}$, T_A is absolute temperature in K or $^{\circ}\text{R}$, Q is the activation energy, R is the gas constant, and B and C are numerical constants characteristic of the material and its metallurgical condition.

The Larson-Miller Parameter. In 1953, Larson and Miller introduced the concept of time-temperature parameters to correlate and extrapolate creep-rupture data (Ref 34) for absolute temperature, T_A , and time to

rupture, t_r . Their parameter $P = f(\sigma) = T_A (\log t_r + C)$ is depicted on a graph of $\log t$ or $\log (t_r)$ versus $1/T_A$ by straight constant stress lines converging to a point at $1/T_A = 0$ (Fig. 6a). At that point, $\log t = C$ defines the optimum value of C for the data involved.

In Fig. 7(a), an actual set of stress-rupture data is shown for the nickel-base alloy Inconel 718 as log stress versus log time to rupture. The data are then replotted as constant-time curves on coordinates of stress versus temperature in Fig. 7(b). To that graph dashed horizontal lines have been added for stress levels of 550, 620, 760, and 830 MPa (80, 90, 110, and 120 ksi). Values for T at the intercepts of these dashed lines and the constant-time curves have been read off and plotted in Fig. 7(c) on coordinates of $\log t$ versus $10^4/T_A$. By extending the data in Fig. 7(c), a plausible set of converging isostress lines meeting on the ordinate at a value of $\log t = -25$ can be obtained. The Larson-Miller equation for this set of data is:

$$P = T_A (\log t_r + 25) \tag{Eq 2}$$

where absolute temperature, T_A , is in units of the Kelvin or Rankine temperature scales.

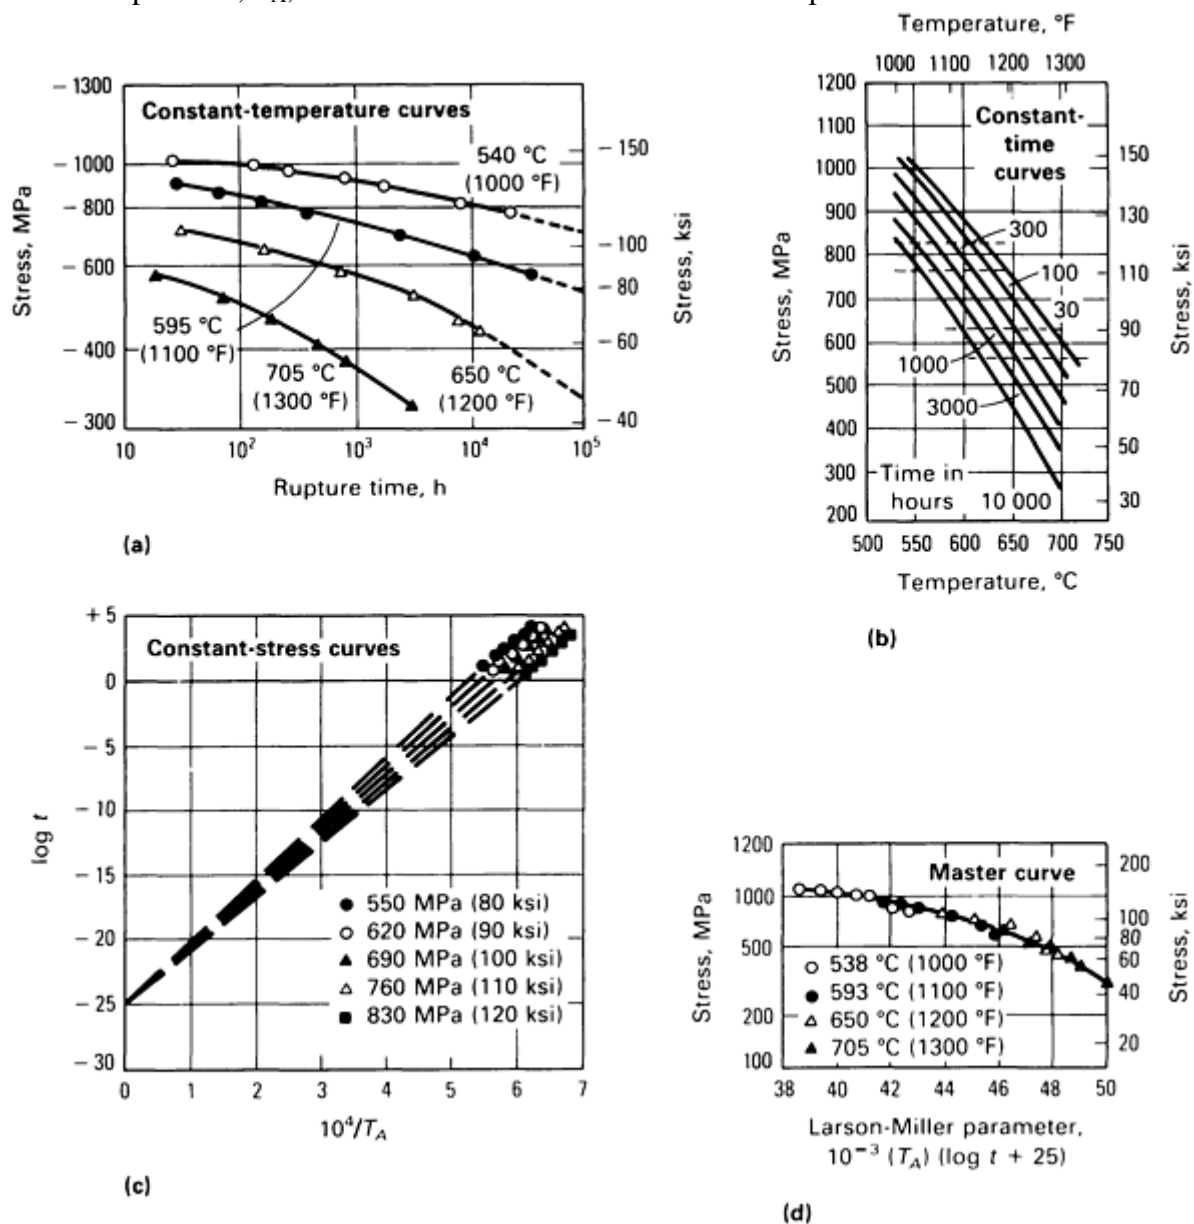

Fig. 7 Method of creating master Larson-Miller curve for Inconel 718 from experimental stress-rupture curves

For each data point in the original set of stress, time, and temperature data, the proper value can be substituted in Eq 2 and plotted as shown in Fig. 7(d). This is the compact parameter form of graphical representation known as the “master curve.” A common practice when input data are limited is to assume that $C = 20$, which has been found to be reasonably true for many materials.

Other Parameters. The Manson-Haferd parameter predicts a constant stress plot from log time, t , versus temperature, T (in °F, °C, or K), from the parametric relation:

$$P = f(\sigma) = \frac{(\log t - \log t_1)}{T - T_1}$$

This equation yields a family of straight lines converging to a point $t(T_A, t_A)$, which defines the optimum constants for that particular data set (Fig. 6b). On these same coordinates, the Manson-Succop parameter requires that isostress lines be straight and parallel (Fig. 6d). These conflicting patterns and still different patterns for the additional parameters cannot occur simultaneously over the entire range of data from a given set.

A frequent finding is that different parameters provide best fit to different portions of the same data. For example, using data obtained from tests on a 1Cr-1Mo-0.25V steel, the Larson-Miller parameter gave the best extrapolation at 482 °C (900 °F), and the Manson-Haferd parameter was preferable at 538 °F (1000 °F). However, the Orr-Sherby-Dorn parameter gave the best fit at 593 °C (1100 °F) (Ref 35, 36).

Although numerous studies have considered the relative merits of these and other proposed parameters, no one parameter has emerged as universally superior to all others. Five representative parameters were compared in terms of correlating and extrapolating extensive sets of data on the creep and rupture properties of seven steels and superalloys (Cr-Mo, Cr-Mo-V, 12%Cr, A 286, Astroloy, René 41, and Inconel 718) (Ref 37). The difference in fit among parameter methods was found to be relatively small and inconsistent from one alloy to another. The largest source of variation in the fitted values for time to rupture, time to 1% creep, and minimum creep rate was the difference between alloys, regardless of the parameter used.

Results were marginal to poor when extrapolation was beyond the range of the fitted master curve. When prediction of long-time data was confined to the master curve derived using only short-time data, no one parametric method gave consistently superior results.

For critical evaluation of the comparative ability to predict known long-time rupture lives (11,000–64,000 h) for the ferritic steels, data up to 10,000 h were applied to establish fit to the parametric model. For the superalloys, only data up to 1000 h were used to predict known rupture times between 1200 and 33,000 h. Table 1 lists ranges for the ratio (predicted life/actual life) extracted from Ref 37 for 46 extrapolations, including one in which slight extension was required beyond the fit of each master curve.

Table 1 Comparative extrapolation abilities of methods used to determine creep-rupture behavior

Parameter or method	Ratio: predicted life/actual life		
	Minimum	Average	Maximum
Larson-Miller	0.34	1.57	5.64
Manson-Haferd	0.44	1.51	6.30
Goldhoff-Sherby	0.36	1.64	8.85
Manson-Succop	0.39	1.53	4.96
Orr-Sherby-Dorn	0.11	1.09	4.01
Monkman-Grant	0.33	0.93	1.82

Studies on 0.5Cr-0.5Mo-0.25V steel pipe (Ref 38) found the Manson-Haferd parameter significantly superior to predict known rupture times (8712–20,664 h) from data points of less than 6000 h duration than either the Larson-Miller or Orr-Sherby-Dorn parameters. The latter two parameters generally provide optimistic prediction of behavior. According to Ref 38, very short-time data should be eliminated from the analysis if predictions beyond 10,000 h are desired, because their inclusion distorts the correlation at long times. As with graphical methods, the accuracy of parametric extrapolations is related to the interval of test variables on which the prediction is based.

Minimum Commitment Method. Experimental data may deviate from the requirement imposed by the form of each parameter for linearity of isostress curves or for parallelism or convergence of families of such curves. The minimum commitment method starts with a time-temperature-stress relationship sufficiently general to include all commonly used parameters. The pattern of the data is not forced in advance; instead, the actual experimental data naturally lead to the most appropriate functional relationship for the particular material.

Manson applied a “station-function” approach to $f(\log t) + p(T) = g(\sigma)$; all parametric formulations can reduce to this equation. Each of the functions f , p , and g were represented by their discrete numerical magnitudes at

specific values of the corresponding independent variable. Figure 8 illustrates treatment of Astroloy data given in Ref 37.

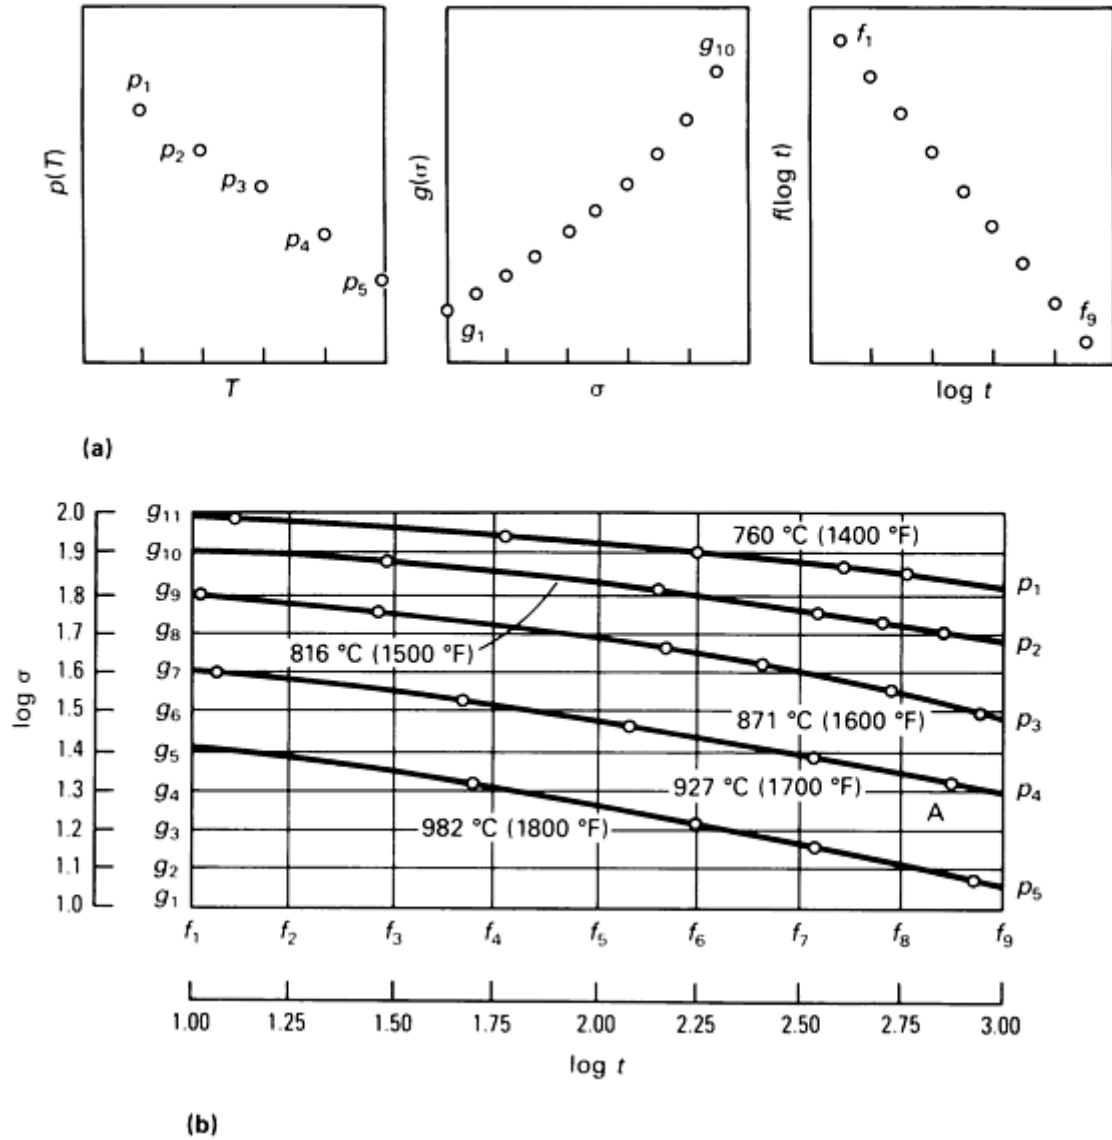

Fig. 8 Application of station function approach to Astroloy data. (a) Station-function representation of $p(T)$, $g(\sigma)$, and $f(\log t)$ at specific values of T , σ , and $\log t$. (b) Net point selections for solution. Source: Ref 39

Temperature stations were arbitrarily chosen at $T = 760, 816, 871, 927,$ and 982 °C (1400, 1500, 1600, 1700, and 1800 °F); the values of the p functions at these respective temperatures are designated $p_1, p_2, p_3, p_4,$ and p_5 . For times such that $\log t = 1.0, 1.25, 1.5, \dots, 3.0$, the respective corresponding f values are $f_1, f_2, f_3, \dots, f_9$. The g values are designated $g_1, g_2, g_3, \dots, g_{11}$ for levels of $\log \sigma = 1.0, 1.1, 1.2, \dots, 2.0$, with σ given in ksi. Consider the experimental point A ($T = 927$ °C, or 1700 °F); $\log t = 2.873$, $\log \sigma = 1.322$). At this point, p is directly p_4 , but values of f and g must be interpolated. Higher order interpolation can be easily accomplished, but simple linear interpolation was chosen for this illustration. For A between $\log t$ of $f_8 = 2.75$ and $f_9 = 3.00$:

$$\begin{aligned}
 f(2.873) &= \frac{3.0 - 2.873}{3.0 - 2.75} f_8 + \frac{2.873 - 2.75}{3.0 - 2.75} f_9 \\
 &= 0.508 f_8 + 0.492 f_9
 \end{aligned}
 \tag{Eq 3}$$

In a similar manner, the relation for stress at this point becomes:

$$g(1.322) = \frac{1.4 - 1.322}{1.4 - 1.3} g_4 + \frac{1.322 - 1.3}{1.4 - 1.3} g_5$$

$$= 0.78 g_4 + 0.22 g_5$$
(Eq 4)

Introducing these results into the original general equation yields:

$$0.508 f_8 + 0.492 f_9 + p_4 = 0.78 g_4 + 0.22 g_5$$
(Eq 5)

A similar equation can be written for each experimental point. By choosing a sufficient number of stations, the number of equations available will exceed the number of unknowns, so that a least-squares solution can be used to determine the unknowns. Once the equations have been solved, the function $f(\log t)$ may be extrapolated using graphical, polynomial, or recurrence relations.

Although a better fit to the data should result by the minimum commitment method than by forcing fit to an arbitrary parameter, extrapolations can still be imprecise. As with other methods, the degree of accuracy of predictions relies on having accurate and representative raw data from tests that reflect any structural changes expected to occur in the regime of the extrapolated conditions.

A specialized form of the general equation developed in 1971 (Ref 40) contains a characteristic material constant A :

$$\log t + AP(T) \log t + P(T) = G(\log \sigma)$$
(Eq 6)

The parameter A is a measure of structural stability, because the more unstable the material, the higher the negative value of A required to fit the data. On a plot of log stress versus log time, all isothermals converge at the extrapolated point $\log t = -(1/A)$ (Ref 41). For the parallel isotherms of the Orr-Sherby-Dorn parameter, $A = 0$; Miller-Larson requires $A = +0.5$. With data fitting the Manson-Haferd parameter, negative A values result; the Astroloy data discussed above converge at about $t = 6.36$, resulting in $A = -0.157$.

Establishing an accurate individualized value of A for a specific material is difficult from a short-life database. One acceptable approach is to use universalized values of $A = 0$ for aluminum alloys and pure metals, and $A = -0.05$ for most steels and superalloys (Ref 41). Highly unstable materials like Astroloy, as well as carbon steels, require higher negative values of A ; for these materials, $A = -0.15$ was found to be adequate in most instances. The minimum commitment method was initially developed for use with single-heat data. Application to multiple-heat analyses is discussed in Ref 42, including information on suitable computer programs.

Assessment and Use of Creep-Rupture Properties

Howard R. Voorhees, Materials Technology Corporation Martin Prager, Materials Properties Council

Estimation of Required Properties Based on Insufficient Data

Complete independent evaluation of creep-rupture properties for a new lot of material, whether by graphical, parametric, or minimum commitment methods, requires numerous test points covering an extensive range of test variables. Frequently, the amount of data available is too limited for full treatment by usual procedures. Experimental difficulties often limit obtaining accurate test results at conditions of interest, such as evaluation of creep-rupture properties near the low end of the temperature range in which time-dependent effects are significant.

Tests of short or moderate duration at these temperatures frequently require use of such high stress levels that the immediate high plastic strains at load application alter the nature of the material from that which exists during service under lower stresses. Testing at or near a stress of intended application often requires more time and/or expense than is feasible before the material is to be put into use. Approximate methods permit such difficulties to be treated in a generally satisfactory manner. Established correlations also permit estimation of some unmeasured properties from other types of available results.

The Monkman-Grant Relationship. Analysis of data for a variety of aluminum-, iron-, nickel-, titanium-, cobalt-, and copper-base alloys led Monkman and Grant to the following empirical relationship (Ref 43):

$$\log t_r + m \log (\text{mcr}) = C$$

(Eq 7)

where t_r is time to rupture; mcr is minimum creep rate; and m and C are constants that differ significantly among alloy groups, but exhibit nearly fixed values for a given heat of material, or for different lots within the same alloy group.

Equation 7 enables assessment of the reliability of each individual test by examining its fit within the scatter band for all tests. Once a minimum creep rate has been determined in a low-stress test, rupture life can be estimated without running the test to failure. Although Monkman and Grant stated that this relationship was not intended for extrapolation, it can be used for that purpose, particularly when only low-stress tests are acceptable to prevent large initial plastic strains.

Table 1 includes the results obtained when the Monkman-Grant relationship is applied to data obtained on these same seven materials (Ref 37). Overall prediction of rupture life for these 46 extrapolations using this technique was more accurate than that provided by any of the five time-temperature parameters.

For additional materials (Ref 44) where good fit is obtained to a single linear plot on the coordinates of log time versus log secondary creep rate, extrapolation of a known secondary creep rate to the corresponding rupture life appears to be as good or better than by other extrapolation methods. One advantage of Eq 7 is that it can be applied successfully to as few as four to six data points, in contrast to the approximately 30 tests needed to establish the entire Manson-Haferd master curve (Ref 45). For the minimum commitment method, even more data points are usually required.

One advantage of this correlation, particularly with materials that exhibit structural instability under testing, is that the specimens used to determine the input data for secondary creep rates experience the same history of structural change that exists during the corresponding period of a test carried to rupture. Best predictions result by concentrating on tests encompassing a limited range of stresses and temperatures.

Reduced scatter was noted (Ref 46) for eight nonferrous alloys and two superalloys when the term $\log t_r$ in Eq 7 was replaced by $\log (t_r/\epsilon_c)$, where ϵ_c is the total creep deformation at fracture. This trend was confirmed by Ref 47 in tests on a 2.25Cr-1Mo steel.

Although deformation-modified rupture time may improve correlation in some instances, other cases exist where use of the original relationship is sufficient or better. Data for 17 test points for 4% cold-worked type 304 stainless steel (Ref 48) exhibited a spread in creep elongation from 1.5 to 24%. Goodness of fit was identical (coefficient of determination $r_2 = 0.86$) for linear regression of the data treated by the original versus the modified log-log relationships.

Extrapolation is fast and direct when using the Monkman-Grant coordinates, but with the modified relationship, creep elongation at the given temperature and corresponding to the rupture time sought must first be estimated. This usually requires subjective extrapolation of only a few elongation values displaying wide scatter and with no evident single trend. Introduction of a creep elongation factor may have value when only correlation or interpolation of test results is desired, but it is not recommended for extrapolation.

One occasional problem in estimation of rupture life from creep data is uncertainty whether secondary creep has truly been established. Changes in creep rate with continuing test time are often sufficiently gradual and so close to the sensitivity of measurement that what appears to be a steady-rate condition may in fact still be a late portion of primary creep. Reference 49 illustrates successive apparent minimum creep rates of 2.05, 1.7, and 1.40%/10,000 h for respective test durations of 1000, 2000, and 5000 h.

A distinctive slope change in a plot of log creep rate versus time or log time often provides better assurance that the secondary creep period has been entered than study of the deformation-time curve itself. Although an equation expressing true strain in terms of elapsed time, secondary creep rate, and three constants deviates markedly from actual behavior during the early portion of primary creep, a statistical analysis such as that detailed in Ref 50 may predict acceptable values of secondary creep rate from transient data.

For type 316 stainless steel tested at 704 to 830 °C (1300–1525 °F), the initial transient rate at $t = 0$ was found to be almost equal to 3.3 times the secondary creep rate in the same test (Ref 51). A significantly different magnitude (near 1000) for this ratio of initial and secondary creep rates was found in Ref 52 for a high-temperature alloy. A simple proportionality of this type and the more general analysis cited above are tempting alternatives to permit shortened test durations, but both suffer from the need for creep measurements that are more precise than those commonly obtained. Currently, neither method is capable of replacing long-time testing.

The Gill-Goldhoff Method. Many designs for elevated-temperature service require that deformation not exceed some maximum value; in these cases, creep strain rather than rupture life becomes the focus. Although

published compilations and computer banks of data include rupture properties for most materials of engineering interest, corresponding information on the time-dependency of strain is frequently sparse or nonexistent. Many early studies did not include strain measurement during rupture tests. When creep data were obtained, accuracy was sometimes questionable due to inadequate control of temperature or low precision of strain measurements. Frequently, the only listed creep data are minimum creep rates. Most of these results were obtained from tests that were terminated after a few thousand hours, or even less, and true secondary creep rate may not have become established.

Studies by the Metal Properties Council (now the Materials Properties Council, or MPC) and similar groups attempt to report both the total strain on loading and the times to various levels of creep strain. Until such results are more universally available, creep strain to be expected in given design situations must still be estimated.

Gill and Goldhoff (Ref 49, 53) found a log-log correlation between stress to cause rupture and stress for a given creep strain for the same time and temperature. Figure 9 shows their composite plot for aluminum-base alloys and stainless steels, including several superalloys.

Fig. 9 Composite graph for the Gill-Goldhoff correlation. Source: Ref 53

To obtain this correlation, tests in which 0.1% creep occurred in less than 100 h were rejected to prevent intolerable data scatter. Despite this, the “universal” curves of Fig. 9 can be associated with fairly wide data scatter, particularly at low creep strains. Some deviations from the correlation were related to microstructural instabilities, which produce differing proportions of primary, secondary, and tertiary creep among alloys and for varying test conditions.

Despite occasional anomalies, the Gill-Goldhoff correlation meets some preliminary design needs, particularly if the technique is tailored to grades of alloys similar to those of immediate concern. In principle, this technique can also be used to predict rupture properties from early creep measurements from tests that are not continued to rupture. This use is limited by the short rupture times that are derived from tests terminated at creep strains of 1% or less. If these tests were continued to higher levels of creep, improved predictions of rupture should be obtained by determining the secondary creep rate and then applying the Monkman-Grant relationship.

Treatment of Isolated Test Points. Particularly at the start of a testing program, the need may arise to extract information from a single available test. The form of most parameters limits their use to situations in which multiple test results are available. The Larson-Miller parameter is an exception if the generalized constant $C = 20$ is used.

For the stress of the test, longer rupture times within a factor of ten from the test duration frequently can be estimated satisfactorily for temperatures below that of the test. If a master curve or graph of isothermals is available for another lot of like or similar alloy, a parallel curve passed through the coordinates of the test point for the new lot can serve as an approximate representation of expected behavior for limited ranges of variables from the test conditions.

Evaluating Remaining Creep-Rupture Life

Expected residual rupture life following a discrete change in service conditions may at times be estimated without further tests. The more usual practice is to test creep-exposed samples at increased stress and/or temperature than they had seen in service, to reduce testing duration. Results are then extrapolated back to nominal service conditions. In addition to parametric methods and isostress methods, at least three others procedures have found recent promotion:

- The MPC Omega Method
- Analysis on restricted-range Monkman-Grant coordinates
- Accelerated creep-test methodology of David Woodford

These methods are described in the section “Other Evaluation Methods” in this article.

Discrete Changes in Temperature or Stress. When a creep-rupture test is interrupted by cooling and reheating at a moderate rate at constant load, and if the time under changing temperature is brief compared to the original test duration, the effect of the interruption on either the creep curve or rupture life usually cannot be readily detected, unless thermal gradients cause gross plastic deformation or spalling of surface layers.

Similar results can be expected when temperature and stress rise and fall in unison, as during start-up and shutdown of a steam boiler. For the alternate situation in which unloading occurs while the creep temperature is maintained, significant recovery of primary creep can ensue; reapplying the load results in a period of primary creep.

Under step-wise alteration of load, temperature, or both during a test or service, performance often roughly follows the “life-fraction rule” or “linear cumulative damage rule” (Ref 54), in which the percentage of total life consumed for each period of fixed temperature and stress is represented as:

$$\% \text{ total life} = \frac{\text{actual time at the given conditions}}{\text{rupture life at those conditions without alteration}} \times 100$$

Accuracy of this rule ranges from excellent to rather poor, with best results for multiple small excursions (Ref 55). Although solid-state reactions, which can reverse at different exposure temperatures, may introduce complications under some conditions, investigators have found the life-fraction rule more appropriate for steels under temperature changes than under stress changes (Ref 56).

Life-fraction summations at failure as low as 0.36 and as high as 2.43 have been reported (Ref 57). The spread was only from 0.75 to 1.50 for the same tests using damage fractions defined by $K(t/t_r) + (1 - K)(\epsilon/\epsilon_r)$, where t and ϵ are the time and strain under a period of fixed conditions, for which the rupture time and fracture strain are t_r and ϵ_r . K is a material constant ranging from zero to 1; the zero limit applies to materials that develop cracks early in life, and K approaches 1 for materials that exhibit no cracking until rupture is imminent. Typical values of K (Ref 57) are as follows:

Material and test temperature	K
Copper at 250 °C (482 °F)	0.3
A 286 alloy at 649 °C (1200 °F), solution treated at 1204 °C (2200 °F)	0.47
A 286 alloy at 649 °C (1200 °F), solution treated at 982 °C (1800 °F)	0.43
Inconel X-750 at 732 °C (1350 °F)	0.625

When data are insufficient for determination of K , acceptable results frequently can be obtained with an empirical rule (Ref 58), by which the life-fractions added are defined by $\sqrt{(t/t_r)(\epsilon/\epsilon_r)}$. With any of these cumulative damage rules, comparison usually is against rupture life from constant-load tests—that is, with actual stress rising as creep reduces the cross section. When the same specimen undergoes load changes for

different periods, respective stress levels have been based on the initial cross section. This corresponds to using the same original load if an interrupted test must be restarted. The actual stress at the time of test restart is $(\sigma_n(A_o/A_c))$, where σ_n is the present nominal stress, A_o is the initial specimen cross section, and A_c is the specimen cross section after creep deformation up to the time of the test interruption.

When the specimen for a test in a later portion of creep has been machined from a part that has already undergone considerable reduction in cross section by prior creep, a corresponding area-modified stress must be employed for consistent interpretation of the results (Ref 59). The load applied to produce the desired nominal stress σ_n , related to the virgin material is calculated to make the actual stress $\sigma_a = \sigma_n(A_o/A_c)$, where the latter term relates cross-sectional areas of the original part before and after creep. Use of such an area-modified stress has been reported to improve prediction of remaining life from post-service rupture tests (Ref 59, 60).

An approximation of remaining rupture life for components that have undergone prolonged service can be calculated by introducing best estimates for operating temperatures and stresses into the above damage rules. More exact evaluation, however, can be obtained by testing representative samples removed from service.

Measurement of Creep-Rupture Properties After Service. Dependable application of techniques to estimate remaining life requires that the loading direction for the final test corresponds to the largest principal stress of service and that the specimen is representative of surface deterioration or other damage present in the part. Possible temperature and loading gradients in service must be kept in mind when selecting a sampling site and when applying test results to predictions of further serviceability. Despite these possible additional variables, assessments of post-service rupture properties require only about the same number and duration of tests as conventional evaluation of any new lot of familiar material.

Large specimens are recommended to limit relative loss in cross section from oxidation, unless surfaces are protected from the usual air environment of tests.

For samples from tubes or similar shapes subjected to internal-pressure service and consequent major service stress in the circumferential direction, uniaxial creep tests are preferred to have the test load act in that direction. Specimens from tube and pipe can have wedges of similar material welded to the outside-diameter face near the ends of a ring segment from the sample. Electron-beam welded attachments of imaginative design make possible the testing of many samples available only in small sizes or inconvenient shapes.

Isostress Tests. A typical study involves testing three or four specimens all at a single stress similar to, or slightly above, the stress of service, and each at a different temperature higher than that of service. Results are extrapolated to service temperature on coordinates of log rupture time versus either absolute temperature or its reciprocal.

The principal drawback of this procedure is that at least some tests must usually be conducted at a higher temperature than is needed in other evaluation methods.

Allowance for Data Scatter. In an effort to minimize uncertainties from extrapolation procedures, undue emphasis may be placed on a test with the longest affordable duration. Normal data scatter still limits evaluation of expected performance from isolated points. Indeed, a more reliable prediction may be obtained when the same total test time is devoted to performing a greater number of tests with intermediate duration rather than only a few with extended life. An exception is when instabilities occur only with very long testing.

Some researchers study scatter by running multiple tests at one or more fixed combinations of stress and temperature. Again, a series of tests, each at different conditions, permits equally good statistical treatment to evaluate the scatter, while providing a broader indication of the material characteristics. Although emphasis has been placed on time to rupture, the extra expense of obtaining complete creep deformation data in all tests is often justified by the insight afforded into the effects of structural changes.

Evaluating Remaining Creep-Rupture Life

Expected residual rupture life following a discrete change in service conditions may at times be estimated without further tests. The more usual practice is to test creep-exposed samples at increased stress and/or temperature than they had seen in service, to reduce testing duration. Results are then extrapolated back to nominal service conditions. In addition to parametric methods and isostress methods, at least three others procedures have found recent promotion:

- The MPC Omega Method
- Analysis on restricted-range Monkman-Grant coordinates
- Accelerated creep-test methodology of David Woodford

These methods are described in the section “Other Evaluation Methods” in this article.

Discrete Changes in Temperature or Stress. When a creep-rupture test is interrupted by cooling and reheating at a moderate rate at constant load, and if the time under changing temperature is brief compared to the original test duration, the effect of the interruption on either the creep curve or rupture life usually cannot be readily detected, unless thermal gradients cause gross plastic deformation or spalling of surface layers.

Similar results can be expected when temperature and stress rise and fall in unison, as during start-up and shutdown of a steam boiler. For the alternate situation in which unloading occurs while the creep temperature is maintained, significant recovery of primary creep can ensue; reapplying the load results in a period of primary creep.

Under step-wise alteration of load, temperature, or both during a test or service, performance often roughly follows the “life-fraction rule” or “linear cumulative damage rule” (Ref 54), in which the percentage of total life consumed for each period of fixed temperature and stress is represented as:

$$\% \text{ total life} = \frac{\text{actual time at the given conditions}}{\text{rupture life at those conditions without alteration}} \times 100$$

Accuracy of this rule ranges from excellent to rather poor, with best results for multiple small excursions (Ref 55). Although solid-state reactions, which can reverse at different exposure temperatures, may introduce complications under some conditions, investigators have found the life-fraction rule more appropriate for steels under temperature changes than under stress changes (Ref 56).

Life-fraction summations at failure as low as 0.36 and as high as 2.43 have been reported (Ref 57). The spread was only from 0.75 to 1.50 for the same tests using damage fractions defined by $K(t/t_r) + (1 - K)(\epsilon/\epsilon_r)$, where t and ϵ are the time and strain under a period of fixed conditions, for which the rupture time and fracture strain are t_r and ϵ_r . K is a material constant ranging from zero to 1; the zero limit applies to materials that develop cracks early in life, and K approaches 1 for materials that exhibit no cracking until rupture is imminent. Typical values of K (Ref 57) are as follows:

Material and test temperature	K
Copper at 250 °C (482 °F)	0.3
A 286 alloy at 649 °C (1200 °F), solution treated at 1204 °C (2200 °F)	0.47
A 286 alloy at 649 °C (1200 °F), solution treated at 982 °C (1800 °F)	0.43
Inconel X-750 at 732 °C (1350 °F)	0.625

When data are insufficient for determination of K , acceptable results frequently can be obtained with an empirical rule (Ref 58), by which the life-fractions added are defined by $\sqrt{(t/t_r)(\epsilon/\epsilon_r)}$. With any of these cumulative damage rules, comparison usually is against rupture life from constant-load tests—that is, with actual stress rising as creep reduces the cross section. When the same specimen undergoes load changes for different periods, respective stress levels have been based on the initial cross section. This corresponds to using the same original load if an interrupted test must be restarted. The actual stress at the time of test restart is $(\sigma_n(A_o/A_c))$, where σ_n is the present nominal stress, A_o is the initial specimen cross section, and A_c is the specimen cross section after creep deformation up to the time of the test interruption.

When the specimen for a test in a later portion of creep has been machined from a part that has already undergone considerable reduction in cross section by prior creep, a corresponding area-modified stress must be employed for consistent interpretation of the results (Ref 59). The load applied to produce the desired nominal stress σ_n , related to the virgin material is calculated to make the actual stress $\sigma_a = \sigma_n(A_o/A_c)$, where the latter term relates cross-sectional areas of the original part before and after creep. Use of such an area-modified stress has been reported to improve prediction of remaining life from post-service rupture tests (Ref 59, 60).

An approximation of remaining rupture life for components that have undergone prolonged service can be calculated by introducing best estimates for operating temperatures and stresses into the above damage rules. More exact evaluation, however, can be obtained by testing representative samples removed from service.

Measurement of Creep-Rupture Properties After Service. Dependable application of techniques to estimate remaining life requires that the loading direction for the final test corresponds to the largest principal stress of service and that the specimen is representative of surface deterioration or other damage present in the part. Possible temperature and loading gradients in service must be kept in mind when selecting a sampling site and when applying test results to predictions of further serviceability. Despite these possible additional variables, assessments of post-service rupture properties require only about the same number and duration of tests as conventional evaluation of any new lot of familiar material.

Large specimens are recommended to limit relative loss in cross section from oxidation, unless surfaces are protected from the usual air environment of tests.

For samples from tubes or similar shapes subjected to internal-pressure service and consequent major service stress in the circumferential direction, uniaxial creep tests are preferred to have the test load act in that direction. Specimens from tube and pipe can have wedges of similar material welded to the outside-diameter face near the ends of a ring segment from the sample. Electron-beam welded attachments of imaginative design make possible the testing of many samples available only in small sizes or inconvenient shapes.

Isostress Tests. A typical study involves testing three or four specimens all at a single stress similar to, or slightly above, the stress of service, and each at a different temperature higher than that of service. Results are extrapolated to service temperature on coordinates of log rupture time versus either absolute temperature or its reciprocal.

The principal drawback of this procedure is that at least some tests must usually be conducted at a higher temperature than is needed in other evaluation methods.

Allowance for Data Scatter. In an effort to minimize uncertainties from extrapolation procedures, undue emphasis may be placed on a test with the longest affordable duration. Normal data scatter still limits evaluation of expected performance from isolated points. Indeed, a more reliable prediction may be obtained when the same total test time is devoted to performing a greater number of tests with intermediate duration rather than only a few with extended life. An exception is when instabilities occur only with very long testing.

Some researchers study scatter by running multiple tests at one or more fixed combinations of stress and temperature. Again, a series of tests, each at different conditions, permits equally good statistical treatment to evaluate the scatter, while providing a broader indication of the material characteristics. Although emphasis has been placed on time to rupture, the extra expense of obtaining complete creep deformation data in all tests is often justified by the insight afforded into the effects of structural changes.

Stress Relaxation Testing

D.A. Woodford, MPa, Inc.

Introduction

THE MAJORITY OF CREEP TESTING, as described in this Volume, uses a fixed load (or stress) at a constant temperature and measures the increase in strain as a function of time. However, materials may also creep under constraint with little or no dimensional change. This constraint then approximates a constant total strain, so a more appropriate test in such situations is one in which the material is deformed to a fixed strain, which is then held constant. Depending on the application, the corresponding initial stress may be below, at, or above the yield stress on loading. Whether or not there is permanent plastic strain on loading, there is an elastic strain that, in linear elastic materials, is proportional to the stress through the appropriate temperature sensitive modulus. If the temperature and stress are sufficiently high creep will occur, but since the total strain is held constant, this can only be achieved if the elastic strain decreases with a corresponding decrease in the stress. Creep at a fixed total strain, therefore, results in a time dependent stress relaxation.

A common practical example where stress relaxation is a major design issue is in high temperature bolting. After being initially torqued to ensure joint tightness the stress progressively relaxes at a rate that depends on the creep strength of the material. For major components such as steam turbine shell flanges, it is essential to avoid leakage by periodic bolt retightening. Alloys have to be used, which will ensure steam tight joints at least up to normal turbine overhaul periods that may now extend to 50,000 h (Ref 1).

In addition to many such mechanical fastener problems, stress relaxation is important in the wire of prestressed concrete (Ref 2), all types of springs (Ref 3), electrical contacts (Ref 4), soldered joints (Ref 5), and the relief of stress gradients induced by differential swelling in in-pile nuclear reactor tubes (Ref 6).

Stress relaxation is not limited to externally applied stresses. Residual stresses caused by metal working (Ref 7) or welding (Ref 8) may have to be reduced by stress relieving treatments prior to placing parts in service. Finally, parts such as gas turbine blades with internal cooling may develop severe stress and temperature gradients in service that will lead to stress redistribution under constraint, and temperature changes in cyclic operation may lead to residual stresses that relax at temperature. For repeated cycles the accumulated creep strain may eventually lead to cracking as a result of thermal fatigue (Ref 9).

From this discussion it is clear that stress relaxation and stress redistribution are major manifestations of creep deformation in practical applications. This is especially true for high-temperature cyclic operation. In many cases, however, suitable relaxation data does not exist, and analysis has to be made using existing constant load isothermal creep data. Thus there is much interest in predicting relaxation from creep data and vice versa. The problem is that most structural materials experience strong deformation path dependence. Thus, a material creeping under constant load and accumulating strain experiences a different deformation path from one subjected to a fixed total strain and decreasing stress. To convert one to the other requires a damage law such as time hardening or strain hardening or a mechanical equation of state, which incorporates one or more internal state variables (Ref 10). These approaches have varying degrees of success and will not be further considered.

This article concentrates on metallic materials as covered by ASTM E 328 (Ref 11), although stress relaxation is very important in plastics. For plastics a separate ASTM testing standard (Ref 12) is available that recognizes the viscoelastic behavior. This means that the creep strain may be mostly or fully recoverable upon removal of the load. Recent work on engineering ceramics suggests that these materials also show viscoelastic behavior (Ref 13). Composites of all types are expected to show internal stress redistribution between the components as well as complex macroscopic stress relaxation depending on the component phases.

Stress Relaxation Testing

D.A. Woodford, MPa, Inc.

Testing Considerations

Figures 1 and 2 illustrate load characteristics and data representation for stress relaxation testing for the most convenient and common uniaxial tensile test (Ref 2). The constraint is obtained by the application of the external load at either a constant strain rate or constant load rate. Figure 3 shows the response in each case for an initial stress, σ_0 , exceeding the proportional limit. If the stress and temperature are sufficiently high, the extent of nonelastic strain on loading will depend on the loading rate, which will in turn affect the initial relaxation rate. The loading rate should therefore be reasonably high. The stress relaxation test starts at $t = t_0$ when the desired level of constraint is obtained. The relaxation can be plotted in the form of remaining stress (Fig. 2a) or relaxed stress (Fig. 2b), which is the initial stress minus the remaining stress.

Fig. 3 Derivation of stress-relaxation curve for step-down creep test. (a) Constant extension approximated by a step-down creep test. (b) Stress-time relation

The components of strain can be considered to be elastic strain, ϵ_e , time-independent plastic strain (e.g., on loading), ϵ_p , and time-dependent creep strain, ϵ_c . The creep strain can further be designated as nonrecoverable and recoverable (or anelastic strain). For example, unloading after creep in plastics can lead to contraction at zero stress to the extent that the creep strain is fully recovered. In metals this recoverable strain is usually only a small fraction of the total creep strain (less than 10%). In ceramics the situation is intermediate with typically about 40 to 50% of the creep strain recovering (Ref 13). The total strain after loading is given as:

$$\epsilon_t = \epsilon_e + \epsilon_p + \epsilon_c = \text{constant} \quad (\text{Eq 1})$$

There is no need in Eq 2 to separate the creep strain into its two components of recoverable and nonrecoverable time-dependent strain. However, for ceramics and certainly for plastics, this does become a design consideration if deformation path dependence is important. Differentiating and remembering that the plastic strain on loading, by definition, is not time dependent, and that the total strain is constant:

$$0 = \dot{\epsilon}_e + 0 + \dot{\epsilon}_c \quad (\text{Eq 2})$$

Rearranging Eq 2:

$$\dot{\epsilon}_c = \frac{-\dot{\sigma}}{E} \quad (\text{Eq 3})$$

where E is the elastic modulus.

Equation 3 shows how the creep rate is equal in magnitude to the elastic strain rate and can be calculated at any time during relaxation from the stress rate divided by the elastic modulus. Thus the test is a self-programmed variable stress creep test and should be independent of the test machine characteristics.

Until recently the stress relaxation test has been used principally to measure and predict the relaxation of stress as a function of time and temperature. However, it is now recognized as a unique creep test, which in a short

time, can generate creep rate data as a function of stress covering five or more orders of magnitude in creep rate. This new application of the test is discussed in a subsequent section.

Stress Relaxation Testing

D.A. Woodford, MPA, Inc.

Stress Relaxation in Tension

There are now two types of stress relaxation tests performed in tension. They are distinguished by the test objectives and to a lesser extent by the type of equipment used and the stress levels covered. The long-term tests are designed to give specific data on the amount of stress relaxation that results in a particular time at a specific temperature. It assumes that predictions from traditional creep tests would be insufficiently accurate. The bolting problem is the most commonly cited example. In contrast, the accelerated tests are designed to give comprehensive information on the creep strength of the material, which can then be used in many ways. It provides an alternative to the traditional creep test as a basis for materials selection, design, and life prediction. Both types of test are described in the following.

Long-Term Tests

Because the objective in these tests is to measure quantitatively the amount of relaxation in very long times from a given stress, which is often below the yield stress, great precision and stability is required of the test equipment. Moreover, because the test will often be run for years to relate to actual service times, it is normal to use inexpensive load frames. Lever arm type creep machines with a means periodically to adjust the weight to maintain constant specimen constraint have been commonly used (Ref 14). The practicalities of testing have been discussed in detail recently (Ref 15) and emphasize the need for accurate control of strain and temperature and measurement of stress. For example, ASTM E 328-86 (Ref 11) requires strain control within $\pm 0.0025\%$ and temperature control that does not exceed $\pm 3^\circ\text{C}$ or $\pm 0.5\%$, whichever is greater. This must be true for the test duration, which can be several years. Moreover, the relaxation can be quite sensitive to the setup and loading procedure, including the loading rate, which can have a very significant effect on subsequent relaxation (Ref 15).

The use of a motor driven lever arm system for load adjustments offers a number of advantages: the force (torque) required on the motor drive is reduced by the lever arm ratio, which leads to less inertia, increased sensitivity, smoother action, and finer control. However, such systems generally are not designed for continuous control. Typically, the strain is held between limits, and one common procedure is shown schematically in Fig. 3 is taken from ASTM E 328-86. In this step-down test, when the upper limit of strain is reached, a small reduction in stress is made that leads to an instantaneous elastic contraction. The specimen then creeps under the reduced stress until the limit is reached when the stress is again reduced by the same

amount, and so on. An alternative approach is to allow a small amount of strain to occur beyond the set strain before reducing the load. Depending on the magnitude of the stress decrements the two results will differ slightly because the average strains will differ and the deformation paths will differ. There are also options as far as the choice of the appropriate stress to use in plotting the data from each cycle (i.e., the maximum, minimum, or average). Clearly the smaller imposed stress reduction is preferred in both cases.

Figure 4 shows a typical stress-relaxation system equipped for step-down tension testing. This has a three-zone furnace, a temperature-compensated extensometer system, an electronic control module, and a data recorder. It is constructed with a precision balanced lever arm supported on knife edges. The output from the load cell is used directly to construct a stress versus time relaxation curve.

Fig. 4 Schematic of stress-relaxation test system equipped for step-down tension testing

A useful measure of the precision expected for relaxation of a 1%Cr-Mo-V bolting steel at 500 °C is shown in Fig. 5. Results from nine British and six German laboratories are summarized on rolled, oil quenched, and tempered bars deformed to 0.2% strain (Ref 16). Both manual and mechanical load reduction techniques were used to maintain the strain nearly constant. The following mean values were found: initial stress, 319 MPa, residual stress at 2000 h, 107 MPa, and ratio of residual stress at 2000 h to initial stress, 0.34. Each of these mean values had a scatter of about $\pm 15\%$.

Fig. 5 Repeatability among fifteen laboratories for relaxation of Cr-Mo-V bolting steel from 0.2% strain at 500 °C

Accelerated Testing

As previously noted, the stress relaxation test is a self-programmed variable stress creep test that can reach extremely low creep rates in quite short times. Hart (Ref 17) was the first to recognize and exploit the comprehensive creep rate data that could be generated from the load relaxation test. Hart's objective was to express a plastic equation of state in terms of the stress versus creep rate relationship, and much of his work was confined to pure aluminum at room temperature. Hart used a screw-driven tensile machine and calculated the nonelastic extension rate of the specimen from the load record without the use of an extensometer. When the crosshead was stopped this nonelastic extension rate (\dot{L}) is given as:

$$\dot{L} = -C\dot{P} \quad (\text{Eq 4})$$

where \dot{P} is the rate of change of load and C is the elastic compliance of the entire load train including the load cell and specimen. To achieve the necessary accuracy with this method, a digital data acquisition and analysis technique was developed. It was necessary not only to control the specimen temperature accurately but also the ambient temperature for the machine to maintain constant system compliance. Considerable progress was made in developing a plastic equation of state for aluminum and identifying scaling laws for this and other pure metals and some alloys.

One of the early attempts to use this technique as a basis for creep strength evaluation in engineering materials was reported on Cr-Mo-V steel at temperatures up to 538 °C (Ref 18). Because the system compliance was not constant during the test at this temperature, an extensometer was used. Although this was a fixed crosshead test, the creep strain was able to be calculated directly. At any time during the test, it was the sum of the increase in overall strain, which was measured directly, plus the decrease in elastic strain on the specimen, which was calculated from the load record and specimen modulus.

In tests lasting two days, creep rates covering up to six decades in creep rate were obtained using the previously described method (Ref 18). However, in subsequent tests on all classes of materials, it was decided to use a fixed strain on the specimen rather than depending on the compliance of the machine. With suitable computer control for continuous strain adjustment, the tests could be conducted on any type of universal test machine (Ref 19). Because the specimen total strain was held constant, this was equivalent to using an infinitely stiff system so that, in principle, test results should be independent of the test equipment. This approach has been used on a wide range of steels (Ref 18, 20), superalloys (Ref 21), ceramics (Ref 13), and polymers (Ref 22). An example of this methodology is illustrated in Fig. 6 7 8 for Cr-Mo-V steel (Ref 20). Figure 6 gives the stress versus natural logarithm (ln) time curves at 500, 550, and 600 °C. The strain was held constant at 0.4%, which is just beyond the elastic limit ($\approx 0.3\%$) to minimize transient effects. These curves were fitted with polynomial expressions, which could then be differentiated to give stress versus creep rate curves directly using the elastic modulus as described previously (see Fig. 7). As with several other studies, it was found that the data could be superimposed by horizontal translation with good precision. This means that the curves can be parameterized using an exponential temperature function. This function was optimized and used to construct the creep rate/temperature parameter plot of Fig. 8. Also included in the figure are three minimum creep rate data points at the same three temperatures on the same heat. These were from tests lasting several thousand hours. The agreement is quite good despite the different deformation paths, especially at the highest temperature (or longest time) of 600 °C. The parameter plot can also be used as a basis for creep design. As an example, possible design points at different temperatures are identified on the figure at creep rates of $3 \times 10^{-11} \text{ s}^{-1}$. This is a rate corresponding to 1% in 100,000 h. The total test time for all the stress relaxation data shown in Fig. 6 was three days.

Stress Relaxation Testing

D.A. Woodford, MPa, Inc.

Other Stress States

For the operation of many devices and the relief of residual stresses, the stress state can be complex so that relaxation tests other than simple tension are more appropriate. The ASTM E 328 testing standard (Ref 11) covers some of these.

Compression Testing

Figure 9 shows a simple apparatus for conducting long-term compression stress relaxation tests. In this equipment, the specimen is subjected to an increasing compressive load using a hydraulic ram until the specified strain is attained. The nut on the load strut is adjusted to maintain a constant compressive strain on the test specimen. The force required to maintain a constant compressive strain drops as a function of time and temperature, and it is recorded by a pressure transducer, shown schematically as a pressure gage.

Fig. 9 Apparatus for conducting stress-relaxation compression test

As with tensile testing, the remaining stress can be measured continuously, periodically using step unloading, or by elastic springback at the end of the test period. In the latter method, the elastic strain calculated from the difference between the set total strain and the remaining plastic strain is proportional through the elastic modulus to the relaxed stress. If it is demonstrable that periodic reloading has no effect on the stress relaxation curve, the same specimen can be reloaded to the same compressed gage length to establish the stress relaxation curve as a function of time. This method is not accurate if significant anelastic recovery occurs.

In compression testing, the possibility of buckling and barreling must be minimized, and special consideration, thus, must be given to specimen alignment, precision of the bearing surfaces, and geometry of the test specimen. It is also possible to use a compression cage in a universal test machine and control directly on an extensometer positioned on the test specimen. This method would be more suitable for the accelerated testing method.

Bend Testing

Stress relaxation in bending is very common in flat springs, electronic connectors, and relay springs, and a number of extensive studies have been reported (Ref 4, 23, 24). In these methods, the outer fiber strain during bending is held constant.

The change in bending moment during relaxation is determined either by monitoring the applied force continuously using an apparatus such as that shown in Fig. 10 or by intermittently lifting the specimen just off its reaction point and measuring the force (or moment) required to accomplish this (see Fig. 11). Alternatively, the loss in moment can be determined either by using a mandrel (Fig. 12) or a tapered constant curvature specimen (Fig. 13) and measuring elastic springback upon unloading. A compressive study (Ref 25) at three different laboratories found that agreement was $\pm 5\%$ stress remaining (Fig. 14) for the following three methods:

- Continuously reading force indicator
- Force required to lift the specimen free of one or more constraints during the test period
- Elastic springback upon unloading at the end of the test period

Fig. 14 Percent stress remaining versus time for 70-30 brass (C26000) for test using three methods at three laboratories. Initial stress equals 80% of 0.2% yield strength.

Torsion Testing

In torsion testing, a cylindrical or tubular specimen is subjected to a constant torsional strain. The change in restraining torque associated with the stress relaxation can be determined by continuous monitoring with a torque transducer or by periodically applying a slight torque to transfer the remaining torque from the end grips to the transducer. Alternatively, the twist springback on unloading can be used to determine how much remanent twist angle remains, and consequently, how much torque would be required to twist the specimen back to its original angle of twist prior to relaxation.

Because of the increased complexity of testing and analysis of torsion stress relaxation, there is interest in predicting torsion stress relaxation based on tensile data. Using combined tension and torsion relaxation tests, it has been shown that in thin-walled copper tubes tested at 250 °C, the results of pure tensile stress relaxation tests can be used to predict complex stress relaxation behavior on the basis of octahedral shear stress equivalence (Ref 26).

Test on Springs

Designers need to be able to estimate how much force remains in a spring after a given service exposure. The experimental methods are similar to those for the other stress states and include:

- Monitoring the decrease in spring force at a constant temperature after deflection to a given displacement
- Determining the remaining spring load by transferring the load periodically from the deflecting member to a load measuring device
- Using the elastic springback on unloading to calculate the spring force remaining immediately prior to unloading using the spring constant

Figures 15 and 16 (Ref 27) illustrate the latter two methods.

Fig. 15 Setup for stress relaxation testing of a clamp spring

Fig. 16 Application of load during a stress-relaxation test of a helical compression spring at room temperature. Original free length, L_0 , compressed length, L_1 ; free length upon release from load at temperature, L_2 ; permanent set, ΔL

Figure 15 shows the apparatus used to determine the force remaining as a function of time and temperature in a complex relay pileup clamp spring. To measure the force of the spring on the pileup, the spring is clamped into a rigid steel fixture that is on a compression load cell. Force is applied using a universal testing machine by means of a plunger, which is depressed and then twisted to lock in place. Electrical contact is made between the plunger and a spring-loaded contact. The force required to break the electrical contact is measured as a function of time to give the relaxation curve.

In Fig. 16, a helical compression spring is deflected and held at the test temperature. The force remaining after time, t , is determined by measuring the permanent set, ΔL , on unloading by the relationship:

$$\frac{\Delta P}{P_0} = \frac{\Delta L}{L_0}$$

where P_0 is the initial load, ΔP is the change in load, L_0 is the initial length, and L is the permanent set.

Influence of Multiaxial Stresses on Creep and Creep Rupture of Tubular Components

R.C. Hurst and J.H. Rantala, European Commission, Joint Research Centre, Institute for Advanced Materials (The Netherlands)

Introduction

DESIGN OF PRESSURIZED COMPONENTS is normally based on uniaxial data because all the material data is generated using uniaxial tests. However, typical industrial piping components operate under a multiaxial state of stress as a result of the internal pressure, temperature gradients, and system stresses. Very general effective stress concepts have been used in component design codes to calculate the creep life of the material under triaxial state of stress. These concepts are based on the principle that the life of a component with a multiaxial effective stress corresponds to the rupture time at the same uniaxial stress according to the uniaxial design data.

Influence of Multiaxial Stresses on Creep and Creep Rupture of Tubular Components

R.C. Hurst and J.H. Rantala, European Commission, Joint Research Centre, Institute for Advanced Materials (The Netherlands)

Multiaxiality and Principal Stresses

Any complex stress combination with stresses in three directions and six different shear stresses can be reduced to just three stresses, the principal stresses $\sigma_1 > \sigma_2 > \sigma_3$. The highest of these is called the maximum principal stress (MPS). In the principal stress coordinate system there are no shear stresses.

The stress state is biaxial if $\sigma_3 = 0$, as is often assumed for thin-walled tubes. The stress system is reduced to uniaxial when $\sigma_1 = \sigma$ and $\sigma_2 = \sigma_3 = 0$. In thick-walled pipes and components the stress state is triaxial.

In the stress distribution figures in this article, a tube under internal pressure that has a ratio of inner radius to outer radius of 0.6 has been used as an example.

Effective Stress Equations

The basic idea of effective stresses is to calculate a stress for complex stress situations with a value that gives the correct failure time when applied to uniaxial data, which is often the basis for engineering design—and often the only data available in absence of representative multiaxial test data.

The effective stresses can be calculated for different cases, each of which will be described in detail in this article:

- Elastic stresses (see the section “Elastic Stress Distribution in a Tube”)
- Steady-state creep stresses (see the section “Steady-State Creep Stress Distribution in a Tube”)
- Stresses in a fully plastic case (see the section “Plastic Stresses in a Tube”)
- Thermal stresses (see the section “Thermal Stresses in a Tube”)

The thermal stresses are often superimposed with one of the former stress systems.

Von Mises Criterion. The most commonly used effective stress concept is the one presented in 1913 by von Mises, based on a concept of maximum energy of distortion:

$$\sigma_{VM} = \frac{1}{\sqrt{2}} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \quad (\text{Eq 1})$$

The von Mises effective stress is most widely used in engineering design, both in the low and high temperature ranges. It has been found to govern the deformation of materials under complex loading situations. It is also the controlling parameter for creep rupture at high stresses where the rupture is associated with large deformations and a ductile failure mechanism. However, in long-term service, the rupture is controlled either by MPS or a mixed MPS-von Mises criterion. Also in brittle materials, the rupture tends to be more MPS controlled.

Much work has been focused on whether or not creep rupture would occur under a complete tensile triaxiality when $\sigma_1 = \sigma_2 = \sigma_3 = \sigma$. Under these circumstances, von Mises would go to zero, which means that there is no deformation or rupture in the short term, but it is believed that creep rupture would occur under MPS control after a long exposure time with a constrained grain-boundary cavity nucleation and growth mechanism. Experimentally this is extremely difficult to verify because of the difficulty of triaxial loading using a cruciform specimen, for example.

For practical reasons, the von Mises equation is often used in engineering design in a different form where, instead of principal stresses, the engineering stresses are used, including torsion stress:

$$\sigma_{VM} = \frac{1}{\sqrt{2}} [(\sigma_h - \sigma_a)^2 + (\sigma_a - \sigma_r)^2 + (\sigma_r - \sigma_h)^2 + 3\tau^2]^{1/2} \quad (\text{Eq 2})$$

where σ_h is hoop stress (circumferential), σ_a is axial stress, σ_r is radial stress, and τ is torsion stress.

Often an effective stress concept has been used in the background when design rules have been determined, but it is not always apparent to the user from the design code itself. Similarly, plenty of detailed analyses have often been hidden behind the design safety factors.

Tresca Criterion. The yield criterion generally known as the Tresca criterion is based on the concept of maximum shear stress energy and is expressed simply as:

$$\sigma_{TR} = \sigma_1 - \sigma_3 \quad (\text{Eq 3})$$

Huddleston Criterion. This multiaxial effective stress concept is a modified version of the von Mises stress, and it is claimed to better take the multiaxiality into account (Ref 1, 2). Here the equation is shown in the simplified form.

$$\sigma_{\text{HUD}} = \sigma_{\text{VM}} \exp \left[0.24 \left(\frac{J_1}{S_S} - 1 \right) \right] \quad (\text{Eq 4})$$

$$J_1 = \sigma_1 + \sigma_2 + \sigma_3 \quad (\text{Eq 5})$$

$$S_S = \sqrt{\sigma_1^2 + \sigma_2^2 + \sigma_3^2} \quad (\text{Eq 6})$$

While under the steady-state creep conditions, the von Mises predicts highest stresses on the inner surface; the Huddleston distribution, on the other hand, is quite contrary and would probably provide a more reliable basis for damage and life predictions than von Mises, at least if only stress is considered in life prediction and not ductility. (See Fig. 1 in the section “Steady-State Creep Stress Distribution in a Tube” in this article.) This criterion was originally developed for stainless steels but has proved to be useful for ferritic high-temperature engineering materials as well. The Huddleston criterion was incorporated into ASME Code Case N-47-29.

Fig. 1 Distribution of normalized steady-state creep stresses in a pressurized tube with a ratio of inner radius, R_i , to outer radius, R_o , of 0.6. The principal facet stress values have been normalized by dividing by a factor of 2.24

Mixed Criteria. Often mixed criteria have been proposed because, in practical cases, none of the classical parameters describe the material behavior sufficiently in various stress cases. One of the most common criterion is the one developed at the former Central Electricity Generating Board in the United Kingdom, presented by Cane and Hayhurst (Ref 3, 4):

$$\sigma_{\text{eff}} = \alpha \sigma_1 + (1-\alpha) \bar{\sigma} \quad (\text{Eq 7})$$

where α is the coefficient of thermal expansion. A similar empirical effective stress concept for high-temperature materials has been proposed by the Russian research institute CKTI:

$$\sigma_{\text{CKTI}} = (\sigma_{\text{MPS}}^n + 0.47 \sigma_{\text{VM}}^n)^{1/n} \quad (\text{Eq 8})$$

where n is the Norton creep exponent.

The concept of principal facet stress σ_F has been developed (Ref 5) based on the observations that creep damage will first appear on grain boundaries transverse to the axis of MPS, and that on inclined boundaries there will be shear deformation, which is mainly controlled by von Mises effective stress:

$$\sigma_F = 2.24\sigma_1 - 0.62(\sigma_2 + \sigma_3) \quad (\text{Eq 9})$$

The principal facet stress has been found to bring uniaxial and multiaxial data together especially for ferritic and austenitic steels. However, this stress does not apply directly to engineering calculations because the stress values calculated by Eq 9 are high. Therefore, in Fig. 1, σ_F has been normalized by a factor of 2.24. The principal facet stress is then seen to coincide with the von Mises stress on the outer surface of the pressurized tube. Normalization by a factor of 2 would make σ_F coincide with the von Mises stress in the skeletal point and with the distribution of the Huddleston stress.

The Effect of Stress System on the Damage Processes. At least in the short term, the creep damage process of cavity nucleation seems to be von Mises controlled because cavity nucleation requires accumulation of shear strain. On the contrary, for brittle materials the number of cavities formed is a function of MPS and intergranular fracture is promoted by the increasing ratio of σ_1/σ_{VM} (Ref 3). Similarly, the effect of MPS becomes more pronounced under long service times, under which the uniaxial ductility is known to reduce remarkably and fracture becomes more brittle.

According to Cane (Ref 3), the growth of grain-boundary cavities is controlled by MPS at low effective stress levels and by von Mises at high stress levels. If component-integrity and life-assessment methods do not give proper consideration to the change of the damage mechanism, they are likely to be conservative at high stresses and short times when $\sigma_1/\sigma_{VM} < 1$ and not conservative at low stress levels in the long term when $\sigma_1/\sigma_{VM} > 1$.

Influence of Multiaxial Stresses on Creep and Creep Rupture of Tubular Components

R.C. Hurst and J.H. Rantala, European Commission, Joint Research Centre, Institute for Advanced Materials (The Netherlands)

Effective Strain

In a multiaxial stress system as well, strains occur in three different directions, which are assumed to coincide with the principal stress axes. It is assumed that failure will occur when the effective strain reaches the uniaxial rupture strain value. The effective strain equation is almost identical with the respective stress equation (Eq 2):

$$\bar{\varepsilon} = \frac{\sqrt{2}}{3} [(\varepsilon_1 - \varepsilon_2)^2 + (\varepsilon_2 - \varepsilon_3)^2 + (\varepsilon_3 - \varepsilon_1)^2]^{0.5} \quad (\text{Eq 10})$$

Similarly, the effective strain rate can be expressed as:

$$\dot{\bar{\varepsilon}} = \frac{\sqrt{2}}{3} [(\dot{\varepsilon}_1 - \dot{\varepsilon}_2)^2 + (\dot{\varepsilon}_2 - \dot{\varepsilon}_3)^2 + (\dot{\varepsilon}_3 - \dot{\varepsilon}_1)^2]^{0.5} \quad (\text{Eq 11})$$

The relationship between stress and strain rate can then be expressed:

$$\frac{\dot{\varepsilon}_1 - \dot{\varepsilon}_2}{\sigma_1 - \sigma_2} = \frac{\dot{\varepsilon}_2 - \dot{\varepsilon}_3}{\sigma_2 - \sigma_3} = \frac{\dot{\varepsilon}_3 - \dot{\varepsilon}_1}{\sigma_3 - \sigma_1} = \frac{3}{2} \frac{\dot{\varepsilon}}{\sigma} \quad (\text{Eq 12})$$

Further, a simple criterion comes from the fact that most engineering materials are considered to be incompressible. This rule applies for both strains and strain rates:

$$\dot{\varepsilon}_1 + \dot{\varepsilon}_2 + \dot{\varepsilon}_3 = 0 \quad (\text{Eq 13})$$

Elastic Stress Distribution in a Tube

The equations for the elastic stress distribution for hoop, axial, and radial stress (Ref 6) were first published by Lamé in 1852 and can be expressed as:

$$\sigma_h = \frac{p}{Y^2 - 1} \left[1 + \left(\frac{R_o}{r} \right)^2 \right] \quad (\text{Eq 14})$$

$$\sigma_a = \frac{p}{Y^2 - 1} \quad (\text{Eq 15})$$

$$\sigma_r = \frac{p}{Y^2 - 1} \left[1 - \left(\frac{R_o}{r} \right)^2 \right] \quad (\text{Eq 16})$$

where p is pressure, Y is the outer radius divided by the inner radius (R_o/R_i), and r is the radius. The elastic stress distribution is shown in Fig. 2 for an example tube ($R_i = 0.6R_o$) without any stress relaxation due to plasticity or creep.

Fig. 2 Distribution of normalized elastic stresses in a pressurized tube with a ratio of inner radius, R_i , to outer radius, R_o , of 0.6

The thicker the tube, the steeper the stress gradient becomes. The radial (compressive) stress on the inside is, by definition, equal to the inner pressure and gradually decreases to zero towards the outer surface. This radial stress has to be taken into account when calculating the effective stress. On the other hand, in a thin-walled tube, the radial stress is often considered negligible, and, therefore, the stress state is simplified to biaxial.

Steady-State Creep Stress Distribution in a Tube

The analytical solutions for a tube under steady-state creep (Ref 6, 7, 8) were published first in 1935 by Bailey, and therefore, the following equations for hoop, axial, and radial stresses are often referred to as the Bailey equations:

$$\sigma_h = \frac{p}{(Y)^{2/n} - 1} \left[1 + \frac{2-n}{n} \left(\frac{R_o}{r} \right)^{2/n} \right] \quad (\text{Eq 17})$$

$$\sigma_a = \frac{p}{(Y)^{2/n} - 1} \left[1 + \frac{1-n}{n} \left(\frac{R_o}{r} \right)^{2/n} \right] \quad (\text{Eq 18})$$

$$\sigma_r = \frac{p}{(Y)^{2/n} - 1} \left[1 - \left(\frac{R_o}{r} \right)^{2/n} \right] \quad (\text{Eq 19})$$

The stress distribution is shown in Fig. 1.

These stresses are related by a correlation, which can be used to check numerical calculations:

$$\sigma_a = 0.5(\sigma_h + \sigma_r) \quad (\text{Eq 20})$$

With creep, the initial elastic stresses are redistributed and the stresses are “reversed.” Under pressurization, the maximum elastic stresses appear on the inner surface of the tube, but, due to creep, these stresses relax and, under steady-state conditions, the maximum stresses move to the outer surface. The maximum initial elastic hoop stress of $2.13p$ on the inner surface is reduced to only $1.16p$ under steady-state creep. Meanwhile, on the outside, the initial elastic hoop stress of $1.13p$ increases to 1.76 under creep conditions. It should also be noted that the elastic stress distribution is a special case of creep stress distribution when $n = 1$.

Plastic Stresses in a Tube

These equations assume a completely plastic case:

$$\sigma_h = p \left[\frac{1 + \ln\left(\frac{r}{R_o}\right)}{\ln\left(\frac{R_o}{R_i}\right)} \right] \quad (\text{Eq 21})$$

$$\sigma_a = p \left[\frac{1 + 2 \ln\left(\frac{r}{R_o}\right)}{2 \ln\left(\frac{R_o}{R_i}\right)} \right] \quad (\text{Eq 22})$$

$$\sigma_r = p \left[\frac{\ln\left(\frac{r}{R_o}\right)}{\ln\left(\frac{R_o}{R_i}\right)} \right] \quad (\text{Eq 23})$$

A reference stress equal to the von Mises effective stress value can be calculated for the fully plastic case using Eq 24:

$$\sigma_M = \frac{p\sqrt{3}}{2 \ln\left(\frac{R_o}{R_i}\right)} \quad (\text{Eq 24})$$

The plastic stress distribution for the example tube is shown in Fig. 3. It should be noted that the plastic stress distribution in a cylindrical body is very similar to the creep stress distribution. This similarity has been used in the limit load analysis where plastic finite-element (FE) stress analysis is used to determine representative failure loads for various components. Second, both von Mises and Tresca distributions are constant through the wall thickness. Third, it should be noted that the Tresca value is equal to the maximum hoop stress value on the outer surface.

Thermal Stresses in a Tube

Often thermal stresses appear in plant components, which can have a significant influence on the stresses. In heat exchangers, tubes operate continuously under a thermal gradient, and, in many plants, thick-walled

components experience severe thermal gradients, especially during transition periods like start-up and shut-down of the plant. Often these thick-walled components set a limit to the start-up speed just because of the maximum allowable thermal stress in the wall.

During operation, thermal stresses are often superimposed on primary stresses originating from the pressure. The thermal stresses are called secondary because, in long-term operation, they may relax as a result of creep. In that case, after long-term operation (after complete stress redistribution), the stresses follow the steady state distribution; at shut-down, the initial elastic stresses and thermal stresses have to be subtracted. Then the remaining stress at zero pressure with zero temperature gradient becomes:

$$\text{Remaining stress} = \text{steady state stress} - \text{elastic stress}$$

from pressure - thermal stress

The thermal hoop, axial, and radial stresses can be calculated using the following equations. Here the temperature gradient has been defined as a result of external heating. For the cases of internal heating (applicable to the start-up of a cold component), the thermal gradient, ΔT , becomes negative and the stress distribution is reversed.

$$\sigma_h = \frac{E\alpha(\Delta T)}{2(1-\nu)\ln Y} \times \left[\ln(R_o/r) + \frac{(R_o/r)^2}{Y^2 - 1} \ln Y - 1 \right] \quad (\text{Eq 25})$$

$$\sigma_a = \frac{E\alpha(\Delta T)}{2(1-\nu)\ln Y} \times \left[2 \ln(R_o/r) + \frac{2 \ln Y}{Y^2 - 1} \ln Y - 1 \right] \quad (\text{Eq 26})$$

$$\sigma_r = \frac{E\alpha(\Delta T)}{2(1-\nu)\ln Y} \times \left[\ln(R_o/r) + \frac{1 - (R_o/r)^2}{Y^2 - 1} \ln Y \right] \quad (\text{Eq 27})$$

where E is the modulus of elasticity and ν is Poisson's ratio. An example of the distribution of multiaxial thermal stresses is shown in Fig. 4 for the example tube.

Fig. 4 Distribution of normalized thermal stresses in a pressurized tube with a ratio of inner radius, R_i , to outer radius, R_o , of 0.6 and with a temperature gradient of 50 °C (90 °F) under external heating

Influence of Multiaxial Stresses on Creep and Creep Rupture of Tubular Components

R.C. Hurst and J.H. Rantala, European Commission, Joint Research Centre, Institute for Advanced Materials (The Netherlands)

Comparison of Life Predictions By Different Effective Stress Criterion

Figure 5 contains data generated for P91 steel at 600 °C (1100 °F) using tubular specimens (outside diam 38×2 mm, thinner than the example tube in other figures) under internal pressure and axial end load with different ratios of hoop and axial stress. It should be noted that all the tests were started with the same initial von Mises stress. In the same figure, the continuum damage mechanics (CDM) model predictions are shown for three different multiaxial stress rupture criterion: von Mises, Tresca, and Huddleston.

Fig. 5 Multiaxial creep test results for a pressurized P91 tube with end load at 600 °C (1100 °F) under various ratios of hoop stress to axial stress and with constant initial von Mises stress

One would assume then that the von Mises prediction would be a flat curve, but the CDM model predicts always a slightly curved shape. Similarly, one would assume that at stress ratios of 2 and 0.5, the life would be the same, but it does not seem to be the case. The reason for this is that at a stress ratio of 2, the hoop stress is dominant and the hoop strain leads to an increase of the inner diameter, which will reduce the life in a pressurized test. On the other hand, at a stress ratio of 0.5 (hoop stress is half of the axial), the axial stress is dominant and the diameter actually remains constant (the necking as a result of the axial stress is balanced by the internal pressure). This leads to a slightly increased life.

When the initial von Mises stress is the same in all tests, the shape of the Tresca (or MPS) curve is explained by the hoop and axial stress components. Figure 6 clarifies this. The MPS in this figure consists of axial stress between stress ratios 0 to 1 and hoop stress when stress ratio is greater than unity. The MPS life curve in Fig. 5 is a “mirror image” of the MPS curve in Fig. 6.

Fig. 6 Hoop and axial strain components in an internally pressurized tube when the von Mises effective stress is kept constant

The plots like Fig. 5 can be used to tell whether the stress rupture criterion is von Mises or MPS. For many materials, the experimental points lie somewhere in the middle. It has been observed that the Huddleston stress, described by, Eq 4 correlates fairly well with this data. It should be noted, however, that plots like Fig. 5 are time dependent. This figure describes the short-term behavior where the failure is associated with large deformation. In long-term service, the damage mechanism is constrained grain-boundary cavitation, which is associated with very little deformation. Therefore, under the long-term service conditions, the creep behavior tends to become more MPS dominated.

Influence of Multiaxial Stresses on Creep and Creep Rupture of Tubular Components

R.C. Hurst and J.H. Rantala, European Commission, Joint Research Centre, Institute for Advanced Materials (The Netherlands)

Commonly Used Stress Equations for Design

Often, the design of pressurized components is based on simple and desirably conservative design rules, and, in many cases, a simple mean diameter hoop (MDH) stress equation is used only because experience has proved it to be conservative in most cases:

$$\text{MDH} = \frac{p(d_o - t)}{2t} \quad (\text{Eq 28})$$

where d_o is the outside diameter, and t is the tube thickness. According to Cane (Ref 4), the mean diameter hoop stress well describes the life at high pressures and underestimates it at low stresses; that is, MDH is conservative in design for long-term operation.

The axial stress component in a pressurized tube with axial loading can be calculated using the following equation:

$$\sigma_a = 0.5\text{MDH} + \frac{4F}{\pi (d_o^2 - d_i^2)} \quad (\text{Eq 29})$$

where F is the axial load and d_i is the inside diameter. These simple stress equations are insensitive to system (bending) stresses, which may appear, for example, in a piping as a result of thermal expansion between fixed points. This can result in severe secondary bending stresses, which should be taken into account in piping design. Omission of bending stresses can lead to premature failure in, for example, welds close to fixed points (type IV cracking).

For tubes, a skeletal stress has been found to correlate fairly well with the stress rupture data:

$$\sigma_{\text{skel}} = p \frac{\left(\frac{2-n}{n}\right) \left(\frac{R_o}{r}\right)^{2/n} + 1}{\left(\frac{R_o}{R_i}\right)^{2/n} - 1} \quad (\text{Eq 30})$$

The basis for this definition is the observation that in approximately the middle of the wall thickness there is a point where the stresses are not dependant on the Norton creep exponent, n , as demonstrated in Fig. 7. Calculation of the von Mises stress in the mid-wall using the steady-state creep stresses leads to Eq 30. The skeletal stress value for the tube used in the example of Fig. 7 becomes $1.71p$.

Fig. 7 Stress distributions in a creeping tube at different creep exponents showing the appearance of a skeletal stress in a point where the hoop stress value is practically independent of the Norton creep exponent (n). R_o , outside radius of tube

Multiaxial Creep Ductility

It is well known that triaxiality has a strong effect on the ductility of materials. Under high degrees of tensile triaxiality, ductility will decrease remarkably. Therefore, a constraint parameter, h , is introduced (Ref 9):

$$h = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3\sigma_{VM}} \tag{Eq 31}$$

Then the ratio of multiaxial and uniaxial ductility can be expressed by an exponential equation:

$$\frac{\epsilon_{fmx}}{\epsilon_f} = 1.65 \exp\left(\frac{-3h}{2}\right) \tag{Eq 32}$$

where ϵ_f is failure strain and ϵ_{fmx} is the failure strain under multiaxial conditions. An alternative solution is to define a triaxiality factor (TF), which is three times the h parameter:

$$TF = \frac{\sigma_1 + \sigma_2 + \sigma_3}{\sigma_{VM}} = 3h \tag{Eq 33}$$

Then multiaxial ductility (Ref 10) can then be calculated from a simple formula:

$$\frac{\epsilon_{fmx}}{\epsilon_f} = \frac{1}{TF} \tag{Eq 34}$$

These ductility equations give very different predictions of the multiaxial behavior at both extremes. The reciprocal Eq 34 gives very high values when TF approaches zero (equal tensile principal stresses) and does not work if TF is negative. The exponential Eq 32 gives lower multiaxial ductility values at small and negative values of h and is more conservative at high degrees of multiaxiality. Both curves go through the uniaxial point, which is $TF = 1$ and $h = 1/3$ (Fig. 8).

Fig. 8 Multiaxial ductility as a function of the triaxiality factor using Eq 32 and 34

High degrees of multiaxiality can be found especially at notch roots or in front of a crack tip. Also, in the soft zone of the heat-affected zone of a weld there is a strong element of tensile triaxiality, which will have an effect on the life.

The multiaxial ductility for our model tube ($R_i = 0.6R_o$) gives the values shown in Table 1 when calculated using the Eq 32 and 34. This result is extremely important because it explains the discrepancy between the two observations:

- Creep stress analysis for a cylindrical body gives always the maximum effective stress values on the *inner* surface of the tube.
- The service experience shows that the creep damage always appears on the *outer* surface of the tube—at least for materials other than the most brittle ones.

Table 1 Ratio of multiaxial and uniaxial ductility calculated at various locations in the wall of a tube

Location on tube wall	Ratio of multiaxial ductility to uniaxial ductility	
	$1/TF^{(a)}$	$1.65 \exp(-3h/2)^{(b)}$
Inner surface	7.60	1.54
Mid wall	1.01	1.00
Outer surface	0.58	0.69

Tube has a ratio of inner radius to outer radius of 0.6.

(a) See Eq 34.

(b) See Eq 32.

In a creeping tube, the strains are proportional to $1/\text{radius}$. Therefore, both the effective stress and the strain on the inner surface of the tube are the highest, but the multiaxial ductility is clearly higher than the uniaxial ductility, as shown in Table 1. This is why the damage does not initiate on the inside of the tube (except in materials where the uniaxial creep ductility is very low—then the relaxation of the high initial elastic stresses can cause failure on the inside). On the other hand, according to Eq 32 and 34, the ductility on the outer surface is much less than the uniaxial ductility, which leads to the initiation of the damage on the outer surface first.

Fortunately, the nature of creep rupture itself seems to simplify the problem of multiaxiality in plant components. In long-term service, creep rupture occurs with a constrained grain-boundary cavity nucleation and growth mechanism, it seems to be more MPS controlled, and damage appears predominantly on the outer surface (which is fortunate from an inspection point of view).

This finding could simplify the necessary engineering calculations of multiaxial stress systems to some extent. However, the present-day design codes for plant equipment do not necessarily reflect this idea, although design lives can be well above 100,000 h where MPS would become the controlling parameter. Further, it should be remembered that for components in the creep regime, the MPS should not be calculated according to the initial elastic distribution but according to the steady-state creep stress distribution.

Influence of Multiaxial Stresses on Creep and Creep Rupture of Tubular Components

R.C. Hurst and J.H. Rantala, European Commission, Joint Research Centre, Institute for Advanced Materials (The Netherlands)

Multiaxial Testing Methods

The vast majority of material creep tests have been performed using uniaxial tests and this will probably continue to be in the future. For modeling and validation purposes, multiaxial tests are indispensable due to their more representative stress state. The following multiaxial test methods have been used (Ref 11):

- Tubular specimen under tension and torsion
- Pressurized tube under internal pressure and end loading
- Notched uniaxial specimen (“Bridgman notch”)
- Fracture mechanic specimen (for example, compact tension or single-edge notched bend)
- Biaxial plate
- Triaxial cruciform specimen under triaxial tension (Ref 12)

A tubular specimen under combined tension and torsion provides a small and inexpensive specimen tested in machines that are commercially available. However, the stress state in the tension-plus-torsion test is such that the second principal stress, σ_2 , is negative, which is not representative of pressurized industrial components.

A tube under internal pressure and axial end load provides also a relatively small specimen, and test services are available from many laboratories. The loading is relatively well representative of the piping components, with axial loading giving the possibility to vary the stress ratio of σ_1/σ_2 . For thin-walled tubes with negligible radial stress, the stress state is close to biaxial, but the stress state becomes triaxial when thick-walled tubes or pipes are used with considerable (negative) radial stress. Pressurized tubes can be also tested with axial or circumferential notches or cracks. For safety reasons, pressure tests should be carried out only in dedicated concrete test cells.

A notched uniaxial specimen is certainly the cheapest multiaxial specimen and can be tested in a conventional creep testing machine. Axial and diametral extensometry will provide information about the deformation during the test. Recent work on notched bars provides detailed information about the stress distribution in the test specimen with various notch geometries (Ref 13).

In a fracture-mechanics specimen, there is a high degree of tensile triaxiality at the notch tip when the local deformation has been constrained by the surrounding material. This multiaxiality will probably enhance the creep damage process.

The biaxial plate and the three-dimensional cruciform specimen provide an ideal tool for the researcher with a possibility to vary the individual stress components, but they are extremely expensive to test in highly specialized test rigs and only very few laboratories in the world can offer these services.

Mechanical Behavior

Superplasticity is regarded as a creep phenomenon because it has been observed at temperatures at or above 50% of the melting point. Accordingly, in studying the mechanical behavior of superplastic alloys, it is essential to establish the following four relationships that define the basic deformation characteristics associated with a creep process: (a) the relationship between stress and strain rate, (b) the relationship between strain rate or stress and temperature, (c) the relationship between strain rate or stress and grain size, and (d) the relationship between strain contributed by boundary sliding and total strain.

The Relationship between Stress and Strain Rate

In general, the relationship between stress and strain rate is determined from two types of presentation. In the first type of presentation, the data are plotted as stress against strain rate on a logarithmic scale. The slope of this plot yields the value of the strain-rate sensitivity, m . In the second type of presentation, the data are plotted logarithmically as strain rate against stress. The slope of such a plot represents the stress exponent, n . Under steady-state conditions, n is equal to $1/m$.

In early work on the mechanical behavior of superplastic alloys, the plots of stress versus strain rate and the strain-rate sensitivity, m , were determined using several procedures in which specimens were tested in tension using a machine operated at a constant crosshead speed (a screw-driven type or a servohydraulic system) (Ref 7, 8, 9, 10, 11, 12). A summary of these procedures is given in Table 1. While the application of these procedures has provided useful information on the variation of m with strain rate during superplastic deformation, there are several problems that need attention when some of the procedures are used. Primary among these problems is the fact that true steady-state conditions cannot be achieved with a tensile machine operated at constant crosshead speed. As a result, the plot of stress against strain rate, using logarithmic scales, can produce erroneous results when used to determine the steady-state characteristics of superplastic flow, such as the activation energy for deformation or grain-size sensitivity. In addition, the stress-relaxation method can lead to inaccurate data if the procedure is not corrected for the effect of the stiffness of the testing machine. Furthermore, it is difficult to obtain very low strain-rate data on machines with constant crosshead speed or a constant strain rate. Due to this difficulty, it is not possible to unambiguously establish the characteristics of superplastic flow in this range of strain rates.

Table 1 Early procedures for calculating strain-rate sensitivity, m

Method	m	Representation	Procedure	Reference
A	$m = \frac{\log(P_b/P_a)}{\log(V_2/V_1)}$		The curve for V_1 is extrapolated to point a' such that the total strain at a' is equal to the strain at that of point b' (max load) on the curve for V_2	Ref 7

B	$m = \frac{\log(\sigma_b/\sigma_a)}{\log(V_2/V_1)}$		<p>The true stress and true strain rate at points <i>a</i> and <i>b</i> which represent the maximum loads on curves V_1 and V_2</p>	Ref 8
C	$m = \frac{\log(P_c/P_d)}{\log(V_2/V_1)}$		<p>The curve for V_2 is extrapolated to point <i>c</i> which is above point <i>d</i> at which the velocity change is made</p>	Ref 9
D	$m = \frac{\log(P_e/P_d)}{\log(V_2/V_1)}$		<p>The load values immediately before (point <i>d</i>) and after (point <i>e</i>) the velocity change are used</p>	Ref 10
E	$m = \frac{\partial \ln \sigma}{\partial \ln(d\varepsilon/dt)}$		<p>The values of true stress and true strain rate are calculated at various points along the load-time curve and $\log \sigma$ is then plotted against $d\varepsilon/dt$</p>	Ref 11
F	$m = \frac{\partial \ln \sigma}{\partial \ln(d\sigma/dt)}$		<p>The cross-head is stopped at <i>S</i> and the values of the true stresses are then estimated at different points along the relaxation curve. <i>m</i> is determined from the slope of the plot of $\log \sigma$ vs $\log d\sigma/dt$</p>	Ref 12

Recently, the stress dependence of strain rate, or, equivalently, the strain-rate dependence of stress in superplastic materials has been established under double-shear conditions (Ref 13, 14, 15). As indicated by experimental evidence, double shear specimens, shown in Fig. 2(a), have the following advantages over tensile specimens (Ref 16, 17, 18). First, a constant stress condition is maintained under constant load, and, as a result, it is not necessary to use a creep machine with a compact cam lever to maintain constant stress as is required in the case of a tensile specimen. Figure 2(b) schematically represents a simple creep machine that can be used in testing double shear specimens. Second, the problem of plastic instability can be avoided. Finally, shear deformation remains completely uniform over the gauge length of the specimen up to 120% strain. In conducting double-shear experiments, two different, but complimentary, procedures are used.

Fig. 2 Double shear testing. (a) Specimen configuration. $a = \frac{3}{8}$ in., $b = \frac{1}{8}$ in., $c = \frac{1}{16}$ in., $d_1 = \frac{3}{8}$ in., $d_0 = \frac{3}{4}$ in. (b) Creep machine for testing double shear specimens

In the first procedure, specimens are deformed under creep conditions of constant load (equivalent to true constant stress due to the use of double-shear specimen geometry). In this case, the steady-state strain rate is recorded for the imposed stress and the data are plotted logarithmically as strain rate against stress. Steady

strain rates are obtained by performing uninterrupted tests and/or stress-change tests. In uninterrupted tests, several identical specimens are tested at different stresses (constant temperature and constant grain size), and steady-state strain rates are calculated from creep curves that represent plots of strain against time. Typical examples of creep curves reported for commercial grade Zn-22Al at intermediate and low stresses are given in Fig. 3(a) and (b) respectively (Ref 14). Examination of these creep curves shows that the alloy exhibits a normal primary stage followed by a well-defined steady-state stage, and that the duration of the primary stage increases with decreasing applied stress. In stress-change tests, the steady-state strain rates are measured at several different stresses on a single specimen. In this procedure, a single specimen is crept at a constant stress to within steady-state creep, and then the initial stress is changed in successive steps to a final value. For each stress change, whether an increase or a decrease, sufficient strain is allowed to ascertain whether the new steady-state stage has been reached. Figures 4(a) and (b), in which the creep rate is plotted as a function of creep strain, provide typical examples of the application of this procedure to high purity Zn-22Al (Ref 14). The data presented in these figures reveal the following features: (a) After a stress increase, the creep rate decreases and reaches the new steady-state value (Fig. 4a), and by contrast, after a stress reduction, the creep rate increases and reaches the new steady-state value (Fig. 4a); (b) After a stress decrease or a stress increase, the amount of transient strain preceding steady-state creep is small, approximately 0.01 to 0.02.

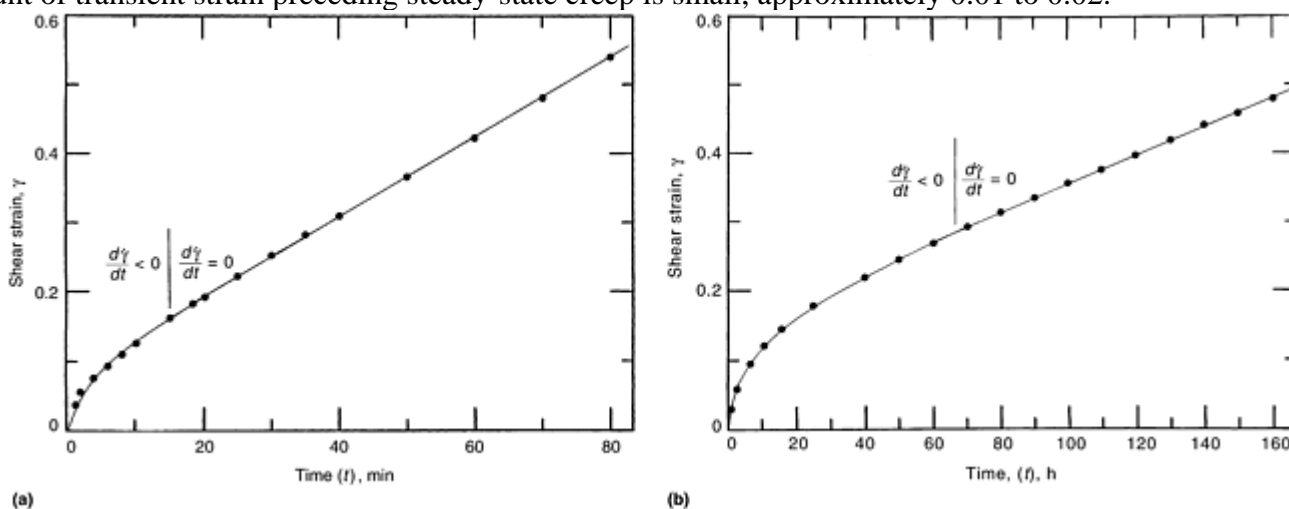

Fig. 3 Shear strain versus time (creep curve) for commercial purity Zn-22Al having a grain size of 3.5 μm . Temperature, 463 K. (a) $\tau = 4.14$ MPa. (b) $\tau = 0.825$ MPa. Source: Ref 14

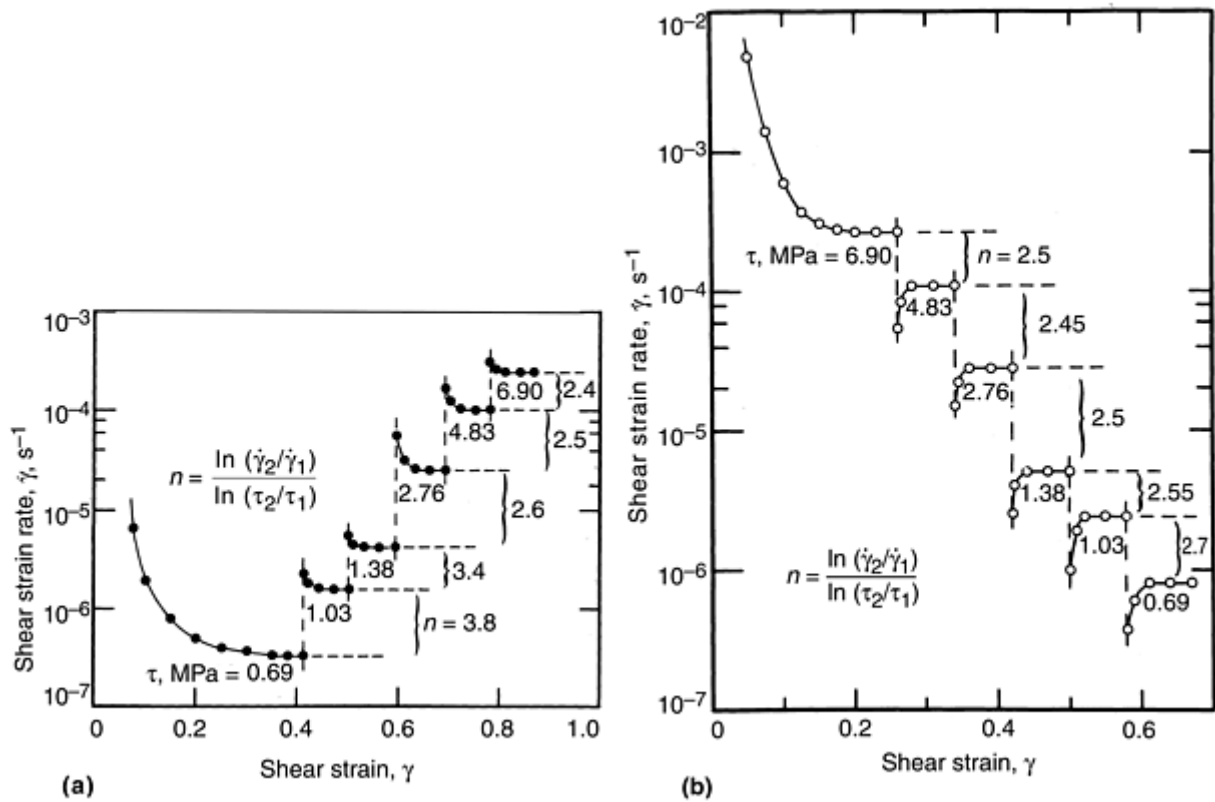

Fig. 4 The results of stress-change experiments for high-purity Zn-22Al having a grain size of 3.5 μm . Temperature, 463 K. (a) Stress is increased from $\tau = 0.69$ MPa in steps to $\tau = 6.0$ MPa. (b) Stress is decreased from $\tau = 6.9$ MPa in steps to $\tau = 0.69$ MPa. Source: Ref 14

In the second procedure, specimens are deformed using a testing machine that imposes a constant rate of crosshead displacement (equivalent to a true constant strain rate due to the double-shear configuration of the specimen). In this case, the steady-state flow stress is recorded for an imposed strain rate and the data are plotted as stress against strain rate on logarithmic scales. The steady-state stresses are obtained from tests conducted on several specimens at true strain rates (uninterrupted tests) or from cycling tests conducted on the same specimen (strain rate-change tests). Figure 5 illustrates both types of tests using double-shear specimens. In Fig. 5, the results on Zn-22Al are plotted as shear stress against shear strain up to strains of 125% (Ref 19). The solid lines show the individual stress-strain curves for the various specimens tested at different constant strain rates; the strain rates are indicated for each curve. The broken line shows the composite stress-strain curve obtained by cycling a single specimen through a number of constant strain rates.

Fig. 5 Shear stress plotted against shear strain for specimens of Zn-22Al at a temperature of 484 K, obtained either by testing each specimen at a single constant strain rate (solid line) or by cycling a single specimen through a number of constant strain rates (broken line). Source: Ref 19

Typical experimental results on the stress dependence of strain rate in commercial purity Zn-22Al (Ref 14) are shown in Fig. 6, in which shear strain rate, $\dot{\gamma}$, is plotted as a function of shear stress, τ , on a logarithmic scale. By identifying the individual datum points from the creep machine and universal testing machine (UTM) (a screw-driven machine operated at a constant cross-head speed), it is clear that there is excellent agreement between the two experimental procedures over intermediate stresses (and intermediate strain rates). In obtaining the data for Fig. 6, the creep machine (constant-stress and stress-change experiments) was primarily used to establish the deformation at low and intermediate stresses whereas the UTM (constant-strain-rate and strain-rate-cycling experiments) was used to establish behavior at intermediate and high stresses.

The Relationship between Strain Rate and Temperature

When the plastic deformation of a material is dictated by a thermally activated process, the strain rate for the i th deformation mechanism may be expressed in terms of rate reaction theory as:

$$\dot{\gamma}_i = A_i(\tau, T, d) \exp\left(-\frac{\Delta H_i}{RT}\right) \quad (\text{Eq 1})$$

where A_i is the frequency factor, τ is the applied stress, T is the absolute temperature, d is the grain size, ΔH_i is the activation enthalpy, and R is the gas constant. The activation enthalpy (ΔH_i) is an important component in the deformation equation, and its determination plays a key role in the process of identifying the rate-controlling mechanism. According to Eq 2, ΔH_i is uniquely defined by the expression:

$$\Delta H_i = R \left(\frac{\partial \ln \dot{\gamma}}{\partial (-1/T)} \right)_{\tau, d} \quad (\text{Eq 2})$$

Equation 2 suggests a simple and direct method of estimating ΔH_i , which is referred to as an activation enthalpy at constant stress and which, under creep conditions, is equivalent to the apparent activation energy, Q_a .

Superplasticity is a thermally activated process, and Eq 2 provides the basis of various methods adopted to determine the activation energy associated with the flow process. The following section outlines three methods for measuring the activation energy for super-plastic deformation.

Rapid Change in Temperature at Constant Stress. If the temperature is changed very rapidly during a test and the stress level remains constant, the apparent activation energy may be obtained from Eq 2 through the expression:

$$Q_a \approx \frac{R \ln(\dot{\gamma}_2 / \dot{\gamma}_1)}{(T_2 - T_1) / T_2 T_1} \quad (\text{Eq 3})$$

where $\dot{\gamma}_1$ and $\dot{\gamma}_2$ are the instantaneous creep rates immediately preceding and following a small increase in temperature from T_1 to T_2 (Ref 20, 21). Figure 7 provides an example of the application of this temperature change procedure to commercial purity Zn-22Al (Ref 14).

Fig. 7 Shear strain rate versus strain for commercial purity Zn-22Al having a grain size of 3.5 μm , showing the determination of the activation energy (Q) from the temperature change procedure. $\tau = 4.14$ MPa; $Q_{\text{ave}} = 84.2$ kJ/mole. Source: Ref 14

Variation of Strain Rate at Constant Stress. Under conditions of constant stress and grain size, Q_a is given by Eq 2. A plot of logarithmic $\dot{\gamma}$ versus $1/T$ at a constant stress has a slope of $-Q_a/2.3R$. The data of such a plot are obtained from a logarithmic plot of strain rate against stress at a constant grain size and with a range of temperatures (Fig. 6).

Variation of Stress at Constant Strain Rate. As mentioned earlier, tests on superplastic behavior are also conducted at constant strain rate. According to an analysis of the activation energy for superplastic flow, under conditions of constant strain rate, Q_a is given by:

$$Q_a = nR \left(\frac{\partial \ln \tau}{\partial (1/T)} \right)_{d, \dot{\gamma}} \quad (\text{Eq 4})$$

Therefore, a plot of logarithmic τ versus $1/T$ has a slope of $Q_a/2.3nR$ (Ref 21).

It is worth noting that due to the small values of the stress exponent for superplastic flow, the difference between the apparent activation energy and the true activation energy is not significant and falls in the range of the experimental error involved in measurement of Q_a , that is, the correction for the temperature dependence of the shear modulus may not be necessary (Ref 22).

The Relationship between Strain Rate or Stress and Grain Size

The relationship between strain rate and grain size can be established by conducting a series of tests at a constant temperature and with a range of grain sizes. The data obtained from these tests are then plotted as strain rate against stress on a logarithmic scale, as shown in Fig. 8. Finally, the grain-size exponent, s , is obtained from the logarithmic plot of strain rate against stress by logarithmically plotting strain rate against grain size at constant stress (Ref 14, 23).

Fig. 8 Shear strain rate versus shear stress (logarithmic scale) for high purity Zn-22Al for various grain sizes at 493 K. Source: Ref 14

The Relationship between Strain Contributed by Boundary Sliding and Total Strain

Grain-boundary sliding (GBS) is a process that occurs during the high-temperature creep of polycrystalline materials and in which one grain slides over another grain under the action of a shear stress. Sliding is shown schematically in Fig. 9. As a result of the sliding of the two grains offsets are produced at their common boundary; \mathbf{pr} is the sliding vector, u is the component of sliding resolved along the stress axis, v is the component measured perpendicular to both the stress axis and the specimen surface, and w is the component measured perpendicular to the stress axis but in the plane of the surface. Also, as shown in Fig. 9, the orientation of the grain boundary is defined by two angles θ and α : θ is the angle between the stress axis and the trace of the boundary in the plane of the surface, and α is the internal angle made by the boundary trace on a longitudinal section cut perpendicular to the surface.

Fig. 9 Schematic representation of grain-boundary sliding

In superplasticity experiments, the longitudinal offset, u , and/or the transverse offsets, w , are considered in calculating the strain contribution from boundary sliding to total strain. As described elsewhere (Ref 24, 25), the strain due to boundary sliding, ϵ_{gbs} , is obtained from \bar{u} and \bar{w} through the following expressions:

$$\epsilon_{\text{gbs}} = \Psi \bar{u} / \bar{L} \quad (\text{Eq 5a})$$

$$\epsilon_{\text{gbs}} = \phi \bar{w} / \bar{L} \quad (\text{Eq 5b})$$

where Ψ is a geometric constant equal to 0.8 (Ref 24) for the longitudinal offset, \bar{u} is the average offset, \bar{L} is the average linear intercept grain size, ϕ is a geometric constant equal to 1.5 for the transverse offset, and \bar{w} is the average transverse offset (Ref 24, 25). The method of calculating ε_{gbs} from u is applicable only when the grains are equiaxed, a condition that is satisfied during superplastic deformation. The contribution of boundary sliding to the total strain, ξ , is calculated from the equation:

$$\xi = \varepsilon_{\text{gbs}} / \varepsilon_t \quad (\text{Eq 6})$$

In taking measurements of GBS, several steps are carried out. First, prior to testing, one of the flat surfaces of each specimen is polished to a mirror-like scratch-free surface, and very fine lines (marker lines) are placed on the polished gage surface, either parallel or perpendicular to the specimen axis. One method of creating such lines is by drawing a lens tissue containing 1 μm diamond paste across the surface only once in either the longitudinal or the transverse direction. Longitudinal marker lines are used to measure the sliding offset perpendicular to the stress axis, w . Transverse marker lines are used to measure the sliding offset parallel to the stress axis, u . Figure 10 illustrates the two types of marker lines, longitudinal and transverse, and the two classes of offset, w and u . It is also possible to take measurements of sliding using a printed-grid technique. However, as reported elsewhere, the technique can be unsatisfactory due to the resolution difficulties in the scanning electron microscope (SEM) (Ref 24). Second, tensile specimens are deformed at a constant temperature on a testing machine operated at a constant crosshead speed. Tensile tests are conducted to a predetermined strain in the range of 20 to 100% at various initial strain rates. Third, after testing and cleaning in an ultrasonic cleaner, the specimens are examined in the SEM and a number of representative photomicrographs are taken within the gage length. These micrographs are enlarged, and individual sliding offsets are measured. In general, about 200 to 500 readings are taken on each one of the specimens.

Fig. 10 Schematic configuration of maker lines, longitudinal and transverse, and their offsets, w (perpendicular to stress axis) and u (parallel to the stress axis), respectively

Superplastic alloys such as Zn-22Al and Pb-62Sn have two phases, and in this case, there are two intercrystalline boundaries (e.g., Al-Al and Zn-Zn) and an interphase boundary (e.g., Al-Zn). To ensure that sampling of measurement for GBS does not favor a certain type of boundary, the number of each type of boundary counted experimentally should be selected according to an approach proposed by Gifkins (Ref 26). Such an approach, which was adopted in examining sliding behavior in high-purity Pb-62Sn (Ref 26, 27) and Zn-22Al (Ref 28), is extended here to describe the general case of a superplastic material consisting of two phases.

The approach by Gifkins (Ref 26) is based on the following assumptions: (a) the ratio of the volume fraction of the two phases of a micrograin superplastic alloy is equivalent to the ratio in the linear transverse intercept, and (b) grains make a single transverse array. If the ratio of the volume fraction of α and β phases in the alloy is f , then this ratio, on the basis of the above assumptions, may be expressed as:

$$X\bar{L}_\alpha / Y\bar{L}_\beta = f \quad (\text{Eq 7a})$$

where X and Y are the number of α and β grains respectively, and \bar{L}_α and \bar{L}_β are the linear sizes of α and β phases, respectively. This expression may be rewritten using the following consideration. If x (α - α) boundaries and y (α - β) boundaries are counted, there would be x (α) grains forming (α - α) boundaries and $y/2$ (α) grains forming α - β boundaries, that is, $X = x + y/2$. Then, the number of β grains, Y , and the number of (β - β) boundaries, z , are given, respectively, by:

$$Y = \frac{1}{f} \left(\frac{\bar{L}_\alpha}{\bar{L}_\beta} \right) \left(x + \frac{y}{2} \right) \quad (\text{Eq 7b})$$

and

$$z = Y - y/2 \quad (\text{Eq 7c})$$

The following example, based on the recent results reported for the superplastic Zn-22Al alloy (Ref 28), illustrates the application of Eq 7b(b) and (c) to boundary-sliding measurements. For this alloy, α is the aluminum-rich phase, β is the zinc-rich phase, and $f = 0.75$. Accordingly, Eq 7a(a) gives 100 zinc grains for every 88 aluminum grains when $\bar{L}_{\text{Zn}} = 303 \mu\text{m}$ and $\bar{L}_{\text{Al}} = 2.8 \mu\text{m}$. In performing sliding measurements, the number of Al-Al and Zn-Al boundaries sampled were close to 60 and 150, respectively. Using $x = 60$, $y/2 = 75$, $\bar{L}_{\text{Al}} = 2.8 \mu\text{m}$, and $\bar{L}_{\text{Zn}} = 3.3 \mu\text{m}$, Eq 7b(b) and (c) result in 78 Zn-Zn boundaries, a number used in the analysis reported in Ref 28.

Figures 11(a) and (b) show typical photographs of commercial purity Zn-22Al tested to an elongation of about 20% at $4 \times 10^{-5} \text{ s}^{-1}$ in the superplastic region (Ref 28). The photographs show several features associated with the occurrence of sliding in the alloy: (a) grain displacements are often large and sharp, as illustrated, for example, by Fig. 11(a); (b) striated bands (Fig. 11a) are usually observed at Zn-Al boundaries and Zn-Zn boundaries; and (c) grain rotation is observed to occur in both phases, the aluminum-rich phase (dark) and the zinc-rich phase (bright) (Fig. 11b).

Fig. 11 Typical area of the gage length for a Zn-22Al sample tested at $4 \times 10^{-5} \text{ s}^{-1}$ to an elongation of 20%. (a) A large offset at a Zn-Al boundary is shown at A and a striated band at a Zn-Zn boundary is marked at B and at C. (b) Grain rotation in a zinc-rich phase is shown at D. Source: Ref 28

To characterize the offset measurements, two types of histograms are normally constructed (Ref 24, 27, 28, 29). The first type is based on the relative frequency of various boundaries, whereas the second type is based on the relative sliding contribution of these boundaries. These two types of histograms are illustrated using some of the recent results reported for Zn-22Al (Ref 27). In Fig. 12(a), the histogram of the relative frequency of boundaries is shown. In this case, the relative frequency of the number of each boundary (Al-Al, Zn-Al, and Zn-Zn) is plotted against the offset w in increments of $0.1 \mu\text{m}$ at $\dot{\epsilon}_0 = 4 \times 10^{-5} \text{ s}^{-1}$, which corresponds to the super-plastic region. As noted in the figure, the largest displacements occur at Zn-Al interphase boundaries, the smallest displacements occur at Al-Al intercrystalline boundaries, and Zn-Zn intercrystalline boundaries exhibit slightly lower values than those at Zn-Al boundaries. In addition, the histogram shows the following features:

(a) all displacements are in the range of 0 to 0.8 μm ; (b) the maximum frequency occurs at the boundaries with the offset interval of 0.1 to 0.2 μm ; and (c) the largest sliding offsets at Al-Al intercrystalline boundaries are found in the interval of 0.4 to 0.5 μm .

(a)

(b)

Fig. 12 Histograms for commercial purity Zn-22Al with a grain size of 5.4 μm for offset increments of 0.1 μm at $\dot{\epsilon}_0 = 4 \times 10^{-5} \text{ s}^{-1}$ and 493 K. (a) Histogram showing the relative frequency of the number of boundaries. (b) Histogram showing the relative sliding contribution to the total sliding for each type of boundary

In Fig. 12(b), the histogram of relative sliding is presented. As shown in the figure, the percentage contributions to the total sliding for each type of boundary in Zn-22Al are plotted for the offset w in increments of 0.1 μm $\dot{\epsilon}_0 = 4 \times 10^{-5} \text{ s}^{-1}$. This histogram is more practical than that based on the frequency of the number of each type of boundary (Fig. 12a) because a small number of boundaries with a large amount of offsets can significantly contribute to the total sliding. According to the histogram, maximum contribution occurs at boundaries with displacement offsets in the interval of 0.2 to 0.3 μm .

Superplastic Deformation at Elevated Temperatures

Farghalli A. Mohamed, University of California, Irvine

Deformation Regions and Their Characteristics

Over the past three decades, the mechanical behavior of micrograin superplastic alloys has been extensively studied. As a result of these investigations, two findings are well documented. First, micrograin superplasticity is a diffusion-controlled process that can be represented by the following dimensionless equation (Ref 22):

$$\frac{\dot{\gamma}kT}{DG\mathbf{b}} = A \left(\frac{\mathbf{b}}{d} \right)^s \left(\frac{\tau}{G} \right)^n \quad (\text{Eq 8a})$$

with

$$D = D_0 \exp\left(-\frac{Q}{RT}\right) \quad (\text{Eq 8b})$$

where $\dot{\gamma}$ is the shear creep, k is Boltzmann's constant, T is the absolute temperature, D is the diffusion coefficient that characterizes the creep process, G is the shear modulus, \mathbf{b} is the Burgers vector, A is a dimensionless constant, d is the grain size, s is the grain-size sensitivity, τ is the applied shear stress, n is the stress exponent, Q is the activation energy for the diffusion process that controls the creep behavior, and D_0 is the frequency factor for diffusion.

Second, the relationship between stress (τ) and strain rate ($\dot{\gamma}$) is often sigmoidal (Ref 23, 30, 31, 32). Under creep-testing conditions, this sigmoidal relationship is manifested by the presence of three regions (Fig. 6): region I (low-stress region), region II (intermediate-stress region), and region III (high-stress region). The characterization of the sigmoidal trend in terms of these regions is mainly based on the value of the stress exponent, n ($n = (\partial \ln \dot{\gamma} / \partial \ln \tau)_{T,d}$) or strain rate sensitivity, m [$m = (\partial \ln \tau / \partial \ln \dot{\gamma})_{T,d}$] at constant temperature and grain size. Of these three regions, regions I and II have been the subject of many studies that have aimed at not only establishing the deformation characteristics of both regions but also providing interpretations of these characteristics in terms of deformation mechanisms. The characteristics of these three regions are briefly described below.

Region III. In this region (the high-stress region), the stress exponent is higher than 3, the apparent activation energy is higher than that for grain boundary diffusion, and the creep rates are sensitive to changes in grain size. **Region II** (the intermediate-stress region) covers several orders of magnitude of strain rate and is characterized by a stress exponent, n , of 1.5 to 2.5, an apparent activation energy, Q_a , that is close to that for boundary

diffusion, Q_{gb} , and a grain size sensitivity, s , of about 2. Contribution of GBS to the total strain is high and maximum ductility occurs. Because of these characteristics, region II is often referred to as the superplastic region. Experimental data show that superplastic behavior in this region is not sensitive to the presence of impurities. This finding is demonstrated in Fig. 13, where the experimental data of (a) Pb-62Sn and (b) Zn-22Al are plotted in terms of 8aEq 8b, as normalized creep rate versus normalized shear stress, τ/G , on a logarithmic scale. Normalized creep rate is given by $(\dot{\gamma}kT / D_{gb}Gb)(d/b)^s$, where $D_{gb} = D_0 \exp(-Q_{gb}/RT)$. In plotting the data on Pb-62Sn, the values of D_0 , Q_{gb} , b , and s were taken as $1 \text{ cm}^2/\text{s}$, 61 kJ/mol , $3.2 \times 10^{-8} \text{ cm}$, and 2.3 , respectively (Ref 17). In plotting the data on Zn-22Al, the values of D_0 , Q_{gb} , b , and s were taken as $1 \text{ cm}^2/\text{s}$, 78 kJ/mol , $2.7 \times 10^{-8} \text{ cm}$, and 2.4 , respectively (Ref 33). In addition to demonstrating that the creep rates of two grades of Pb-62Sn, having different impurity content, are identical in this region, Fig. 13(a) indicates that the same creep data cluster about a single straight line that extends over four orders of magnitude of strain rate. This result, which is similar to that shown for Zn-22Al in Fig. 13(b), confirms not only that region II behavior is insensitive to impurity atoms, but also that region II (the superplastic region) does not represent a transition region between region I (low-stress region) and region III (high-stress region), that is, region II is a consequence of the operation of a distinct deformation process.

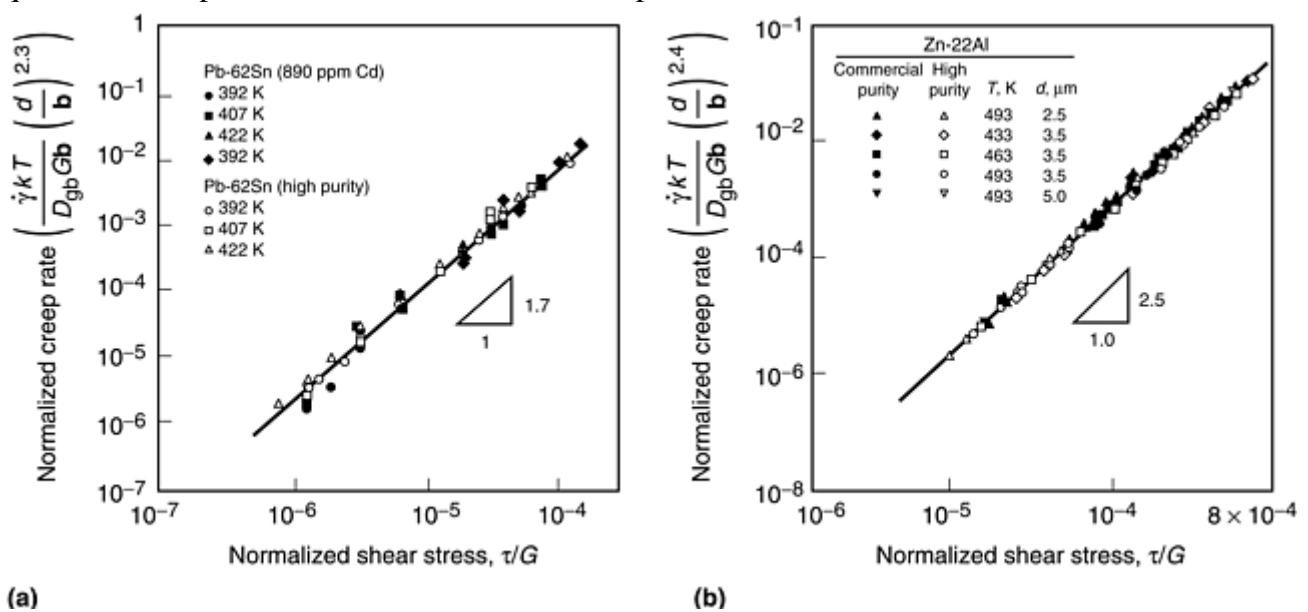

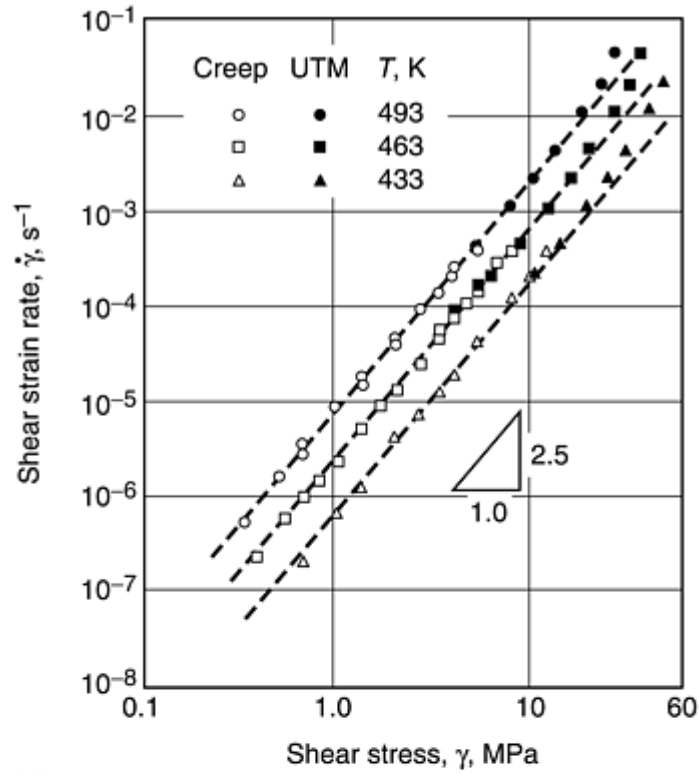

Fig. 13 Normalized creep rate versus normalized shear stress (logarithmic scale). (a) For Pb-62Sn doped with cadmium at intermediate stresses (region II) and for high-purity Pb-62Sn at both intermediate and low stresses. Source: Ref 15. (b) For commercial-purity Zn-22Al at intermediate stresses (region II) and for high-purity Zn-22Al at both intermediate and low stresses. Source: Ref 14

Region I (the low-stress region) is characterized by a stress exponent of 3 to 5 (Ref 23, 30, 31, 32), an apparent activation energy higher than that for grain-boundary diffusion, and a decrease in both ductility and contribution of GBS to total strain. However, the creep behavior in this region exhibits essentially the same grain-size sensitivity noted in region II. Recent experimental evidence (Ref 13, 14, 15, 33) has revealed that steady-state creep in region I, unlike that in region II, is influenced by impurities. This evidence has been demonstrated by two main experimental observations: (a) Zn-22Al (Ref 13, 14) and Pb-62Sn (Ref 15) do not exhibit region I when the impurity level in the alloy is reduced to about 6 ppm; and (b) the stress exponent, n , and the apparent activation energy for creep, Q_a , in region I, unlike those in region II, are sensitive to impurity content (Ref 13, 33). Observation (a) is demonstrated by Fig. 14(a) and (b), which show the absence of region I in high-purity Zn-22Al (Ref 13, 14) and high-purity Pb-62Sn (Ref 15), respectively. As indicated by Fig. 6, region I is present in commercial purity Zn-22Al that contains 100 ppm of impurities (Ref 14). Observation (b) is demonstrated by Fig. 15, in which the values of the apparent activation energy in regions I and II are plotted as a function of applied stress for three grades of Zn-22Al containing different impurity levels; grades 1, 2, and 3 contain 180, 100, and 6 ppm of impurities. As shown by the figure, Q_a in grade 3 (high-purity grade) is equal to 85 kJ/mol ($\sim Q_{gb}$), even at stresses typical of those used in investigating region I in grades 1 and 2; under the condition of constant stress, Q_a in region I for grade 2 (100 ppm of impurities) is smaller than that for grade 1 (180 ppm of impurities).

Superplastic Deformation at Elevated Temperatures

Farghalli A. Mohamed, University of California, Irvine

Deformation Mechanisms

Region III Deformation Mechanisms. The deformation mechanism responsible for this region is not well established. Early observations suggest that region III in superplastic alloys represents normal power-law creep, which controls the behavior of large-grained metals at elevated temperatures (Ref 22). These observations (Ref 3) include (a) measurements of high stress exponents in several superplastic alloys, (b) the presence of extensive dislocation activity in the interiors of grains, (c) the occurrence of changes in grain shape, (d) increases in the texture after deformation, and (e) the close correspondence between the transition stresses from region II (the superplastic region) to region III and those predicted from the equation that describes the dependence of the average subgrain size, λ , formed during the creep of metals on the applied stress (Ref 22, 34). This correspondence implies that region III occurs at higher stresses where a stable subgrain structure begins to develop (Ref 35). However, the above suggestion that the creep behavior of superplastic alloys in region III is controlled by the same type of dislocation process that is dominant in metals at high temperatures is not entirely satisfactory for two primary reasons. First, experimental results in a superplastic copper alloy have revealed an inverse dependence of creep rate on grain size in region III (Ref 36); this behavior contrasts with that of pure metals at high stresses where creep rates are essentially insensitive to changes in grain size. Second, experimental evidence indicates that at high stresses no well-developed subgrains are formed in the interiors of grains; only dislocation tangles are present (Ref 3). On the basis of these findings, it seems most likely that region III is the result of the operation of some form of an intragranular dislocation process, which is influenced by the presence of grain boundaries. It is worth mentioning that there are difficulties in establishing the mechanical characteristics of region III due to the fast creep rates associated with this region.

Region II Deformation Mechanisms. As a result of considerable efforts over the past three decades, a number of deformation mechanisms were proposed or speculated to explain the origin of superplastic flow, especially in region II. Of these mechanisms, the most commonly considered ones are based on grain-boundary sliding (GBS) (Ref 37, 38, 39, 40, 41, and 42-43). Depending on the nature of the accommodation process that is necessary to relieve stress concentration, the GBS models may be divided into two types: diffusional accommodation and dislocation accommodation.

GBS accommodated by diffusion flow is the basis of the model by Ashby and Verrall (Ref 37). This model, which involves a grain-switching event, predicts the presence of a sigmoidal relationship between stress and strain rate, the retention of an equiaxed grain structure, and the absence of a significant dislocation activity. While these predictions are in harmony with experimental evidence, there are several problems associated with the model. Of these problems, which are stated elsewhere in detail (Ref 14, 23, 30, and 31), the following two are worth mentioning. First, the nature of the sigmoidal relationship between stress and strain rate, as predicted by the model, is not consistent with experimental findings. According to the model, the stress exponent for creep in region II is not constant, but varies continuously with stress (Ref 37). This trend contrasts the results reported for superplastic alloys, in which region II exhibits a constant stress exponent over several orders of magnitude of strain rate. Second, the model predicts that the apparent activation energies in region I and II are the same. This prediction is in conflict with the finding that region I is associated with a higher apparent activation energy.

Models based on GBS accommodated by dislocation motion were developed by several investigators (Ref 38, 39, 40, 41, 42, and 43). While these models, in general, involve GBS and some form of dislocation motion, their details and assumptions are different (Table 2). However, despite their different details and assumptions, all of the models mentioned can be described by a rate-controlling equation:

$$\dot{\gamma} = C \frac{DGb}{kT} \left(\frac{b}{d} \right)^2 \left(\frac{\tau}{G} \right)^2 \quad (\text{Eq 9})$$

where C is a constant that can be estimated from the details of each mode; values of C for the models mentioned are given in Table 2. For all models, with the exception of that proposed by Gittus, $D = D_{gb}$; in the case of Gittus's model, $D = D_{IPB}$, where D_{IPB} is the interphase boundary diffusion (Ref 41). As indicated by 8aEq 8b, the models of GBS accommodated by dislocation motion predict the correct stress, temperature, and grain-size dependencies. In addition, the fact that for each model C does not depend on the impurity level of the superplastic alloy is in line with the experimental finding that region II behavior is insensitive to this parameter. Despite this excellent agreement, various objections were raised against the assumptions and details of some of the models mentioned. These objections are discussed in detail elsewhere (Ref 2, 45). In addition to these objections, the agreement between the values of the experimental creep rates in region II and those rates predicted from the models is not satisfactory (Ref 33); for example, in case of Pb-62Sn (Ref 15, 33), the experimental creep rates of Pb-62Sn at low stresses are two orders of magnitude faster than those estimated from the model by Ball and Hutchinson (Ref 38), which predicts the fastest rate among the GBS models listed in Table 2.

Table 2 Grain-boundary-sliding models accommodated by dislocation motion (Eq 9)

Model	Values for C (Eq 9)	Comments	Reference
Sliding of groups of grains	300	Sliding of group of grains. Dislocations are created at triple points and annihilated by the process of climb into grain boundaries.	38
Individual grain sliding	12	Grain slide individually. Dislocations are produced by ledges and protrusions. $D = D_{gb}$	39
Dislocation glide and climb	384	Dislocation movement by glide and climb in the mantle along the adjacent grains $D = D_{gb}$	40
Dislocation pile up	320	Pile-up of boundary dislocations at interphase boundaries $D = D_{IPB}$. τ_0 is ignored for region II.	41
Bardeen-Herring source	480	The creation of dislocations on a solute-free mantle by Bardeen-Herring multiplication $D = D_{gb}$	42
Grain rolling	30	Grain rolling. Grain-boundary sliding by the glide of grain-boundary dislocations on sliding grain facets. Accommodation by the climb of grain-boundary-sliding dislocations on facets with normal stresses $D = D_{gb}$ $\Omega = \text{atomic size} = 0.7b^3$ $\delta = \text{boundary thickness} \sim 2b$	43

Note: The table does not include a model (Ref 44) that predicts a grain-size exponent of 3 and is based on boundary sliding controlled by intragranular dislocation motion.

Region I Deformation Mechanisms. In earlier analyses of superplastic flow, region I behavior in superplastic materials was explained in terms of three possibilities: (a) the presence of threshold stress processes that are not sensitive to temperature, such as the interaction between boundary dislocations and ledges (Ref 41), and fluctuations in the grain boundary area (Ref 37); (b) the operation of a new deformation process related to pure boundary sliding (Ref 40), and for which $Q = 0.2 Q_L$, where Q_L is an activation energy for lattice diffusion; and (c) the occurrence of concurrent grain growth (Ref 46, 47). Possibilities (a) and (b) have been ruled out because they cannot account for the higher activation energy measured in region I (Ref 30, 31). Possibility (c) is not

supported by experimental evidence that has shown the presence of a well-defined region I under experimental conditions involving negligible grain growth (Ref 13, 14, 15, 23, 30, 31).

Recent experimental work shows that the characteristics of creep in region I are influenced by impurity level (Ref 13, 14, 15, 33). On the basis of this evidence, it is most likely that region I behavior is related to one of the following processes: (a) viscous glide (Ref 13, 48), (b) grain-boundary migration controlled by impurities (Ref 49), and (c) an impurity-dominated threshold stress (Ref 50). Consideration of the details of processes (a) and (b) suggests that they do not provide a satisfactory explanation for all the creep characteristics associated with region I for two reasons.

First, viscous glide creep, whether it is dominant in the interiors of grains or along the mantle in case of "mantle-and core" models, leads to an activation energy (equal to that for impurity diffusion) that is higher than Q_{gb} , in agreement with available experimental evidence; however, it fails to account for grain size and stress dependencies in region I. In addition, the observation of extensive primary creep in the creep curves at low stresses is not compatible with the characteristics of viscous glide creep as reported in solid-solution alloys of class I (Ref 51).

Second, grain boundary migration controlled by impurity drag, which was proposed by Gifkins (Ref 49) and represents a modification of his original grain-emergence model (Ref 52), is associated with two characteristics that are consistent with region I behavior: an activation energy higher than Q_{gb} and a high stress exponent. However, the occurrence of grain emergence, a feature on which the model is based, is debatable (Ref 53), and the exact value of the stress exponent is not predicted. In addition, the model has not been developed quantitatively, and, as a result, no comparison regarding the experimental values of creep rates in Zn-22Al can be made.

It has been suggested on the basis of an analysis of superplastic flow at low stresses (Ref 50), that region I behavior may be a consequence of the operation of a threshold-stress process whose origin is related to the segregation of impurity atoms at boundaries and their interaction with boundary dislocations; in this case, the threshold stress (τ_0) is equivalent to the stress that must be exceeded before boundary dislocations can break away from the impurity atmosphere and produce deformation. Recent creep data reported for several grades of Zn-22Al containing different levels of impurities, in particular iron, have revealed the presence of a threshold stress with characteristics consistent with various phenomena associated with boundary segregation, as summarized in the following paragraphs (Ref 54, 55, 56, 57, and 58).

No threshold stress is observed for super-plastic flow in high-purity Zn-22Al as shown by Fig. 16(a) (Ref 13, 14). A similar trend for high-purity Pb-62Sn is shown in Fig. 16(b). As reported elsewhere (Ref 13, 14, 15, 33, and 50) and illustrated by Fig. 16(a) and (b), τ_0 is determined from experimental creep data obtained for a superplastic alloy by plotting $\dot{\gamma}^{1/n}$ ($n = 2.5$) against τ at a single temperature on a double linear scale and extrapolating the resultant line to zero strain rate.

(a)

(b)

(c)

Fig. 16 Threshold stress behavior. (a) Determination of the threshold stress (τ_0) for superplastic flow in Zn-22Al at 433K. Source: Ref 14. (b) Determination of the threshold stress for superplastic flow in high-purity Pb-62Sn at 392 K. Source: Ref 15. (c) A plot of the logarithm of τ_0/G as a function of $1/T$ for grades 0, A, B, and C of Zn-22Al having a grain size of $2.5 \mu m$ and containing 1460 ppm, 423 ppm, 125 ppm, and 40 ppm of iron, respectively

According to the experimental data reported for superplastic alloys (Ref 13, 14, 15, 33) the temperature dependence of the threshold stress is described by the following (Ref 13, 14, 15, 33, and 54):

$$\frac{\tau_0}{G} = B_0 \exp(-Q_0 / RT) \quad (\text{Eq 10})$$

where B_0 is a constant and Q_0 is an activation energy term. The plot of Fig. 16(c), in which experimental data on the threshold-stress behavior of several grades of Zn-22Al doped with iron are plotted as τ_0/G versus $1/T$ on a logarithmic scale, provides a graphical presentation for this relation. Equation 10 resembles in form the following equation (Ref 55) that gives, to a first approximation, the concentration of impurity atoms segregated to boundaries, c , as a function of temperature:

$$c = c_0 \exp(-W / RT) \quad (\text{Eq 11})$$

where c_0 is the average concentration of impurity, and W is the interaction energy between a boundary and a solute atom.

As indicated by Fig. 13(a) and (b), the experimental data for two superplastic alloys, Pb-62Sn and Zn-22Al, in region II (the superplastic region) can be best described by the following:

$$\frac{\dot{\gamma}kT}{D_{gb}Gb} = A \left(\frac{b}{d} \right)^s \left(\frac{\tau}{G} \right)^n \quad (\text{Eq 12})$$

The concept of an impurity-dominated threshold stress signifies that the same deformation process controls both region II (the superplastic region) and region I (the low-stress region) and that the apparent difference in stress and temperature dependencies between the two regions are the result of the increasing importance of τ_0 with decreasing creep stress in grades containing sufficient impurity levels. On this basis, it is expected that the experimental data obtained for superplastic alloys in regions I and II at various temperatures can be described by a single deformation process that incorporates τ_0 and may be given by:

$$\frac{\dot{\gamma}kT}{D_{gb}Gb} = B \left(\frac{b}{d} \right)^s \left(\frac{\tau - \tau_0}{G} \right)^n \quad (\text{Eq 13})$$

The data for both Pb-62Sn and Zn-22Al are plotted as normalized creep rate, $(\dot{\gamma}kT / D_{gb}Gb) (d/b)^s$ versus $(\tau - \tau_0)/G$ on a logarithmic scale in Fig. 17(a) and (b), respectively (for high-purity Pb-62Sn and Zn-22Al, $(\tau - \tau_0)$ is equivalent to τ for all stresses, and $s = 2.3$ and 2.4 for Pb-62Sn and Zn-22Al, respectively). Examination of the figures demonstrates that the data of each alloy can be represented by a straight line that extends over several orders of magnitude of normalized creep rate.

Superplastic Deformation at Elevated Temperatures

Farghalli A. Mohamed, University of California, Irvine

Effect of Impurities on Superplastic Flow

The preceding discussion indicates that the creep characteristics, including the stress exponent and the activation energy for deformation, are influenced by the presence of impurities. In the following section, the effects of impurities on boundary sliding, cavitation, and ductility are presented.

Grain-Boundary Sliding. The occurrence of micrograin superplasticity in metallic systems requires a stable and equiaxed grain size of less than 10 μm . This requirement, along with the strong sensitivity of steady-state creep rates measured during superplastic flow to changes in grain size, d , has demonstrated the significant influence of boundaries on the superplastic behavior. Over the past three decades, considerable efforts have been made to characterize the nature and significance of their role. For example, as mentioned previously, the concept of boundary sliding accommodated by some form of dislocation activity was adopted in developing several deformation models that treated steady-state superplastic deformation in region II (Ref 38, 39, 40, 41, 42, and 43). In addition, many investigations have been performed in tension on several different superplastic alloys to evaluate the significance of grain-boundary sliding in the three regions of behavior previously mentioned.

In these investigations, measurements were taken of sliding offsets along prescribed marker lines on the surface of tensile specimens, and the contribution of boundary sliding to the total strain was estimated using appropriate equations. Despite minor differences in the procedures and equations used in boundary-sliding estimates, the results reported in the investigations are generally consistent and show that, at low elongations (typically of the order of 20–30%), the percentage contribution of boundary sliding to total strain generally ranges from 50 to 70% in region II, but it decreases sharply to approximately 20 to 30% in regions I and III (Ref 24, 29).

In a very recent study (Ref 28), the effect of impurity level on the contribution of boundary sliding to the total strain was examined in the superplastic Zn-22Al alloy. The results of that study follow.

Figure 18 shows a plot of the contribution from boundary sliding to the total strain, ξ , against initial strain rate, $\dot{\epsilon}_0$, for three grades of Zn-22Al (Ref 28). Grades 1 and 2 contain 180 and 100 ppm of impurities, respectively, whereas grade 3 is a high-purity grade containing 6 ppm of impurities. In this plot, the vertical lines *A* and *B* represent the transitions from region I to region II and from region II to region III, respectively. (As mentioned previously, these three regions characterize the sigmoidal relation between stress and strain rate.) An examination of such a plot reveals that the values of the contribution of boundary sliding to the total strain in Zn-22Al at low strain rates (region I) are affected by the presence of impurities, unlike those at intermediate and high strain rates (region II and region III, respectively). This finding is reflected in the following observations: (a) for all three grades, ξ exhibits the same value of 20% at high-strain rates, (b) for grade 3 (high-purity Zn-22Al), ξ at low strain rates is not only significant (61%) but also comparable to that at intermediate strain rates (~60%), (c) at the same strain rate in region I, the values of ξ in grades 1 and 2 are less than that in grade 3, and (d) at the same strain rate in region I, ξ in region I (180 ppm of impurities) is less than that in grade 2 (100 ppm of impurities).

Fig. 18 The contribution of boundary sliding to the total strain, ξ , as a function of strain rates for grades 1, 2, and 3 of Zn-22Al containing 180, 100, and 6 ppm of impurities, respectively. Grain size 5.4 μm ; temperature, 493 K. Source: Ref 59

As mentioned earlier, the sensitivity of region I to impurity level is most likely a reflection of the presence of a threshold stress for creep in Zn-22Al (Ref 13, 14, 33, 50), which is related to strong impurity segregation at boundaries and which strongly depends on temperature, according to Eq 9. The interpretation of the creep behavior of superplastic alloys, in terms of a threshold stress arising from impurity atom segregation, signifies that region I and II are controlled by the same deformation mechanism. However, it is not immediately clear why, as shown by the results on grades 1 and 2, ξ in region I is lower than that in region II if the rate-controlling mechanism is the same in the two regions. It is quite possible that the correlation between impurity level and the sliding contribution at low strain rates is a reflection of the influence of impurities on accommodation processes for boundary sliding such as boundary migration (Ref 49, 52) and lattice dislocation motion (Ref 59). This possibility is discussed in detail in Ref 28.

According to the preceding discussion, the effect of impurity level on the boundary-sliding contribution corresponds well with the effect of impurity level on steady-state creep characteristics reported for the present alloy (Ref 13, 14, and 33). This correspondence, the main aspects of which are summarized in Table 3, indicates that under the present experimental conditions, boundary sliding is an important feature of the deformation process that controls steady-state superplastic flow. Further studies are needed to investigate the effect of impurities on the contribution of boundary sliding to the total strain in Zn-22Al and other superplastic alloys at large strains (>30%). The data of such studies can be used to clarify whether the characteristics of boundary sliding reflect those of steady-state superplastic flow at all strains (small and large) (Ref 24, 60, 61, 62, and 63).

Table 3 Correspondence between effect of impurity level on the sliding contribution and that on steady-state superplastic flow

Strain rate region	Effect of impurity level on the sliding contribution	Effect of impurity level on steady-state superplastic flow
High-strain-rate region (region III)	Impurity level has no effect on the contribution of boundary sliding to the total strain, $\xi \cdot \xi \sim 24\%$.	Impurity level has no effect on the advent of region III.
Intermediate-strain-rate region (region II or the superplastic region)	Impurity level has no noticeable effect on the contribution of boundary sliding. Sliding contribution to the total strain is equal to $\sim 60\%$.	Impurity level has no effect on the values of the stress exponent and the activation energy for superplastic flow. $n = 2.5$ and $Q_c = Q_{gb}$
Low-strain-rate region (region I in grades 1 and 2)	For a high purity alloy, ξ is equal to that in the intermediate strain rates. The sliding contribution decreases with increasing impurity level.	For a high-purity alloy, the intermediate-stress region (region II) extends to the lowest strain rate with no evidence for region I. Both n and Q_c increase with increasing impurity level.

Cavitation. It is well-established that during superplastic deformation most materials develop internal cavities, which grow and coalesce, leading to cavitation damage. Such damage in turn gives rise to premature failure of the material, thereby imposing a serious limitation on the mechanical properties of components prepared by superplastic forming. A solution of this problem necessitates (a) a detailed understanding of the cavitation process in superplastic alloys over wide ranges of experimental conditions, and (b) an identification of various factors that may control the nucleation and growth of cavities. In recent years, the effect of impurities on cavitation during superplastic flow has received considerable attention.

As mentioned previously, segregation of impurities at boundaries has been suggested as a probable cause for occurrence of region I, which micrograin superplastic alloys often exhibit at low stresses. In support of the previously mentioned concept regarding impurity segregation, experimental results have revealed the following observations: (a) cavities are not observed in high-purity Zn-22Al (Ref 56, 64, 65, and 66), and (b) the extent of cavitation in Zn-22Al depends on the impurity content of the alloy (Ref 56, 60). Figure 19 illustrates these two observations. The observed correlation between the level of impurities and the extent of cavitation in Zn-22Al is most probably related to effects associated with the presence of excessive impurities at boundaries due to their segregation. As mentioned elsewhere (Ref 56, 59, 60, 61, and 67), impurity segregation may lead to accelerated cavitation rates through the following processes: (a) reduction of the surface energy, (b) formation of precipitates that serve as cavity nucleation sites, (c) reduction of grain-boundary diffusivity, (d) reduction of boundary cohesive strength, and (e) retardation of grain growth that involves boundary migration.

Fig. 19 Cavitation in Zn-22Al grades at 1.33×10^{-4} . (a) Grade 1 (180 ppm of impurities). (b) Grade 2 (100 ppm of impurities). (c) Grade 3 (6 ppm of impurities). Source: Ref 60

Ductility. The results of several analyses have demonstrated that ductility, defined as the percentage of elongation to fracture, is a sensitive function of the stress exponent n , which equals $1/m$ (Ref 68, 69, 70, 71). In general, ductility increases as the value of the stress exponent decreases (or as the value of the strain rate sensitivity increases), because, as suggested by several investigators, the lower the stress exponent, the larger the necking resistance (Ref 68, 69, 70, and 71). Mathematically, the dependence of ductility on the stress exponent can, for example, be expressed by the following equation, the development of which is based on consideration of plastic instabilities in a tensile specimen (Ref 68):

$$e\% = [\exp(c/n) - 1]\% \quad (\text{Eq 14})$$

where $c = \ln(400/n)$ and e represents elongation.

For a superplastic alloy, such as Zn-22Al, the stress exponent (n) exhibits a minimum at intermediate stresses or intermediate strain rates where the superplastic region dominates (Ref 13, 14, 23, and 30). Accordingly, it is expected that the ductility of the alloy, when plotted as the elongation to fracture versus stress or strain rate, would exhibit a maximum at intermediate stresses or intermediate strain rates. This behavior is presented in Fig. 20, where the average elongation for Zn-22Al is plotted as a function of initial strain rate (Ref 72).

Fig. 20 Tensile fracture strain as a function of initial strain rate for a testing temperature of 473 K and a grain size of $2.5 \mu\text{m}$ (upper); the corresponding plots of maximum flow stress versus initial strain rate (lower). Source: Ref 72

The effect of iron on the ductility of the superplastic Zn-22Al alloy was recently investigated (Ref 56). Some of the results of the investigation are shown in Fig. 21, where the average elongation to failure (e_f) estimated from several specimens that were pulled to failure at $1.33 \times 10^{-4} \text{ s}^{-1}$ in region II (the superplastic region), where $n = 2.5$, is plotted as a function of iron content. As shown by the figure, there are two regions of behavior: (a) e_f decreases slowly for iron concentrations less than 125 ppm, and (b) e_f decreases rapidly at higher iron levels. It has been suggested in Ref 56 that introducing high iron levels in Zn-22Al, while not changing the stress exponent for creep in region II, leads to a loss in the ductility of the alloy in this region for the following reason. Well documented experimental evidence has implied that during superplastic flow, segregation of impurities at

boundaries occurs. According to information previously mentioned, segregation of impurities at interfaces can lead to several different phenomena that involve a reduction in the value of the following materials parameters: surface energy, grain-boundary diffusivity, and boundary cohesive strength (Ref 56, 59, 60, 61, and 67). The occurrence of one or more of these phenomena would adversely influence ductility, either by resulting in nucleating cavities (the growth and interlinkage of which during deformation may cause premature failure) or by weakening boundaries.

Fig. 21 The average elongation to failure as a function of iron content for an initial grain size of 2.5 μm, testing temperature of 473 K, and an initial strain rate of $1.33 \times 10^{-4} \text{ s}^{-1}$. Source: Ref 56

Superplastic Deformation at Elevated Temperatures

Farghalli A. Mohamed, University of California, Irvine

Grain Growth during Testing

During superplastic flow, concurrent grain growth (deformation-enhanced grain growth or strain-induced grain growth) takes place. In some cases, the amount of concurrent grain growth is more significant than that arising from stress-free annealing or in the shoulder of a tensile specimen (static grain growth) (Ref 73). The occurrence of significant concurrent grain growth during superplastic flow can lead to the following effects: (a) the observation of a false region I (Ref 46, 47), (b) a loss of ductility in region II (Ref 56, 74), (c) erroneous values for creep rates measured in region II when the applied stress acting on a single specimen was changed during stress-increase experiments from a very low value (Ref 74), (d) the predominance of strain hardening in the stress-strain curves at high temperatures (Ref 75), and (e) an increase in the level of cavitation (Ref 76). (Excessive concurrent grain growth results in less accommodation of boundary sliding by boundary migration or boundary diffusion.)

Three comments are in order regarding concurrent grain growth. First, concurrent grain growth is very significant, and its associated effects, such as strain hardening, become noticeable when experiments are performed without an annealing treatment before testing (Ref 46, 75). Second, the results of a recent investigation on the superplastic flow of Zn-22Al doped with iron have shown that the effect of concurrent grain growth on cavitation is not as significant as that of the level of iron (Ref 56). Third, region I behavior is genuine and is not related to the occurrence of concurrent grain growth; a well-defined region I, with high values of the apparent stress exponent and the apparent activation energy, was observed in creep experiments involving negligible grain growth.

Introduction to High Strain Rate Testing

Sia Nemat-Nasser, University of California, San Diego

Introduction

HIGH STRAIN RATE TESTING is important for many engineering structural applications and metalworking operations. In structural applications, various components must be designed to function over a broad range of strain rates and temperatures. In metalworking operations, materials undergo large amounts of strains at various temperatures and strain rates. The constituent materials must, therefore, be characterized at the strain rates and temperatures of the intended application. Conventional servohydraulic machines are generally used for testing at quasi-static strain rates of 1 s^{-1} or less (Fig. 1). With special design, it is possible to attain greater strain rates, up to about 100 s^{-1} , with conventional load frames. For higher strain rates, other test methods are required. Table 1 summarizes various methods in terms of the ranges of the strain rates that they can achieve.

Table 1 Experimental methods for high strain rate testing

Applicable strain rate, s^{-1}	Testing technique
Compression tests	
<0.1	Conventional load frames
0.1–100	Special servohydraulic frames
0.1–500	Cam plastometer and drop test
200– 10^4	Hopkinson (Kolsky) bar in compression
10^3 – 10^5	Taylor impact test
Tension tests	
<0.1	Conventional load frames
0.1–100	Special servohydraulic frames
100– 10^3	Hopkinson (Kolsky) bar in tension
10^4	Expanding ring
$>10^5$	Flyer plate
Shear and multiaxial tests	
<0.1	Conventional shear tests
0.1–100	Special servohydraulic frames
10– 10^3	Torsional impact
100– 10^4	Hopkinson (Kolsky) bar in torsion
10^3 – 10^4	Double-notch shear and punch
10^4 – 10^7	Pressure-shear plate impact

Fig. 1 Strain rate regimes and associated instruments and experimental conditions

The articles in this Section describe various methods for high strain rate testing. Several methods have been developed, starting with the pioneering work of John Hopkinson (Ref 1) and his son, Bertram Hopkinson (Ref 2, 3). Based on these contributions and also on an important paper by Davies (Ref 4), Kolsky (Ref 5) invented the split-Hopkinson pressure bar, which allows the deformation of a sample of a ductile material at a high strain rate, *while maintaining a uniform uniaxial state of stress within the sample*. The basic concept of the Kolsky apparatus involves a test sample sandwiched between an input and output bar, as described in detail in the article “Classic Split-Hopkinson Pressure Bar Testing” in this section. This technique provides a capability to measure the stress-strain response of ductile materials at a high strain rate, usually between approximately 50 s^{-1} and 10^4 s^{-1} , depending on the sample size, over the entire stress-strain curve. Strains exceeding 100% can be achieved with the Hopkinson bar method. The maximum strain rate that can be attained in a Hopkinson bar varies inversely with the length of the test specimen. The maximum strain rate is also limited by the elastic limit of the Hopkinson bars that are used to transmit the stress pulse to the test sample. These basic factors of the Hopkinson bar method and some specialized compression and tension tests are discussed in the article “High Strain Rate Tension and Compression Tests” in this section. An overview of shear test methods (other than the torsional Kolsky bar method) is also provided in the article “High Strain Rate Shear Testing.”

The most important characteristic of Kolsky's split-Hopkinson compression apparatus is that it allows high strain rate deformation while the sample is, in fact, in *dynamic equilibrium*, that is, the stress gradient is essentially zero along the sample. It is thus possible to develop the uniaxial stress-strain response of many materials at a variety of strain rates. Because the response of most materials depends on both the strain rate and the temperature, the technique allows developing constitutive relations that express the uniaxial stress to the corresponding strain rate and temperature. From such results, one is able to produce experimentally based, three-dimensional constitutive models for numerous materials.

The series of articles on split-Hopkinson compression testing begins with the article “Classic Split-Hopkinson Pressure Bar Testing,” which is followed by the article “Recovery Hopkinson Bar Techniques.” One limitation of the classic split-Hopkinson bar technique had been the repeated loading of the sample by the stress pulses that travel back and forth along the bars. During the 1990s, techniques were developed to trap the reflected pulses at the free ends of the Hopkinson bars, making it possible to subject a sample to a single stress pulse and then recover the sample without it being subjected to any additional loading (Ref 6). Using this recovery

technique, it is possible to develop isothermal stress-strain curves for many materials at a desired temperature and strain rate (Ref 7). This technique is described in the article “Recovery Hopkinson Bar Techniques.”

Techniques Required for Split-Hopkinson Testing of Very Soft or Hard Materials

In order to render the split-Hopkinson technique useful and reliable for the testing of very soft and very hard materials, special techniques must be used. These techniques are described in the articles “Split-Hopkinson Pressure Bar Testing of Soft Materials” and “Split-Hopkinson Pressure Bar Testing of Ceramics,” respectively. The Hopkinson technique can also be used to study the strain rate dependence of the compressive failure stress of very hard materials. At room temperature, the strain in such a sample can be measured directly by attaching strain gages to the sample (see the articles “Recovery Hopkinson Bar Techniques” and “Split-Hopkinson Pressure Bar Testing of Ceramics”). For high-temperature tests new techniques are required, such as elevated-temperature testing discussed in the article “Recovery Hopkinson Bar Techniques.”

The split-Hopkinson technique has also been extended to include testing ductile materials in tension, in torsion (Ref 8, 9, 10, 11), and even in combined torsion and uniaxial stress (Ref 12). Torsional testing is described in detail in the article “Torsional Kolsky Bar Testing.” The Hopkinson technique can also be used for high strain rate indentation tests, as discussed in the article “Dynamic Indentation Testing.” another interesting development based on the split-hopkinson bar is the deformation of a sample at high strain rates while it is under a triaxial state of stress for both static and dynamic lateral confinement. (This is discussed in the article “Triaxial Hopkinson Techniques.”)

For yet higher strain rates beyond the range of Hopkinson techniques (Fig. 1) other special techniques are necessary. For very high strain rates, plate-impact experiments are used. The uniaxial Hopkinson experiments

provide a uniaxial stress in the sample (ideally speaking). The normal plate-impact experiment is designed to provide a uniaxial strain state in the central portion of the sample. In the oblique plate impact experiment, the uniaxial strain is accompanied by simple shearing. Strain rates of 10^5 and 10^6 s⁻¹, and even greater, have been achieved. This technique is discussed in the article “Low Velocity Impact Testing.” the strains that can be produced by the plate impact experiments are, however, limited. To obtain large strains at high strain rates, one may employ hat-shaped experiments and cylinder-collapse tests as described in the article “High Strain Rate Shear Testing.”

High Strain Rate Tension and Compression Tests

Introduction

MECHANICAL BEHAVIOR at high strain rates differs considerably from that observed at quasi-static or intermediate strain rates, and many engineering applications require characterization of mechanical behavior under dynamic conditions. For example, strain rates ranging from 100 s^{-1} to more than 10^4 s^{-1} occur in many processes or events of practical importance, such as foreign object damage, explosive forming, earthquakes, blast loading, structural impacts, terminal ballistics, and metalworking.

This introductory article briefly reviews the dynamic factors and experimental methods for high strain rate tension testing and compression testing methods listed in Table 1. Considerable data on the high strain rate behavior of many materials (including steels, aluminum and copper alloys, titanium, beryllium, magnesium, and zinc) are available in the literature (see the Selected References at the end of this article). Results indicate that for many metals a linear relation exists between flow stress and the logarithm of plastic strain rate in the range from quasi-static rates to about 10^3 s^{-1} . Above this range, however, the flow stress generally rises far more rapidly with strain rate. Thus, the linear relationship is no longer valid, and extrapolation from the lower strain rate regime becomes unreliable. Fewer data are available at the higher strain rates, particularly at very high strain rates above 10^3 or 10^4 s^{-1} , at which testing becomes more difficult. At strain rates in excess of 10^4 s^{-1} , the lower yield stress is often found to be directly proportional to strain rate, rather than to the logarithm of strain rate. This implies a new region of mechanical response controlled in part by a viscous damping mechanism in contrast to thermally activated processes at strain rates below 10^4 s^{-1} .

Table 1 Experimental methods for high strain rate testing

Mode	Applicable strain rate, s ⁻¹	Testing technique
Compression	<0.1	Conventional load frames
	0.1–100	Special servohydraulic frames
	0.1–500	Cam plastometer and drop test
	200–10 ⁴	Hopkinson pressure bar in compression
	10 ⁴ –10 ⁵	Taylor impact test
Tension	<0.1	Conventional load frames
	0.1–100	Special servohydraulic frames
	100–10 ⁴	Hopkinson pressure bar in tension
	10 ⁴	Expanding ring
	>10 ⁵	Flyer plate

High Strain Rate Tension and Compression Tests

Test Effects at High Strain Rates

Strain rate, $\dot{\epsilon}$, is the rate of change of strain, ϵ , with time, t :

$$\dot{\epsilon} = \frac{d\epsilon}{dt} \quad (\text{Eq 1})$$

where ϵ can be either the engineering or the true strain. Although compressive strain and strain rate are negative quantities, the negative sign is often omitted when it is understood that the test is a compression test. For a constant strain rate experiment, the strain rate is simply the total strain divided by the duration of the test:

$$\dot{\epsilon} = \frac{\epsilon}{t} \quad (\text{Eq 2})$$

When ϵ in Eq 1 is the engineering strain, then:

$$\frac{d\epsilon}{dt} = \frac{1}{L_0} \frac{dL}{dt} = \frac{V}{L_0} \quad (\text{Eq 3})$$

where L is the length of the specimen of original length, L_0 , and V is the velocity at which the specimen is being deformed. A constant crosshead speed in a mechanical testing machine yields a constant engineering strain rate defined by Eq 3.

A typical (quasi-static) mechanical test is performed at a strain rate of around 10^{-3} s^{-1} , which yields a strain of 0.5 in 500 seconds. The equipment and techniques generally can be extended to strain rates as high as 0.1 s^{-1} without difficulty. Tests at higher strain rates may necessitate other experimental techniques and additional dynamic considerations, such as inertia effects, wave propagation effects, and shock wave effects (Fig. 1). Thermal effects and the difficulties of strain measurement are additional factors in high strain rate testing.

Fig. 1 Dynamic aspects of materials testing. Source: Ref 1

Dynamic Factors

A fundamental difference between a high strain rate test and a quasi-static test is that inertia and wave propagation effects become more pronounced at higher strain rates (Fig. 1). These dynamic effects on test results become more pronounced at higher strain rates, as shown in Table 2, for low, medium, high, and very high strain rate regimes. When the strain rate is increased through the medium strain rate regime, the measurement of load is the first to be affected by stress wave propagation. As the strain rate is increased even further, uniform deformation within the specimen becomes more critical. At very high strain rates (beginning at about 10^4 or 10^5 s^{-1}), shock wave propagation becomes critical. Shock wave propagation is discussed in more detail in the article “Shock Wave Testing of Ductile Materials” in this Volume.

Table 2 Experimental techniques for various strain rate regimes in compression testing

Strain rate regime	Experimental techniques	Wave propagation
Low rate: $\dot{\epsilon} < 0.1 s^{-1}$	Standard mechanical testing procedures	Not significant
Medium rate: $0.1 s^{-1} \leq \dot{\epsilon} \leq 200 s^{-1}$	Servo-hydraulic frames, cam plastometer, drop test	Influences load measurement
High rate: $200 s^{-1} \leq \dot{\epsilon} \leq 10^5 s^{-1}$	Hopkinson pressure bar	Affects uniform stress approximation
	Rod impact (Taylor) test	Analysis required for interpretation of results
Very high rate: $\dot{\epsilon} > 10^5 s^{-1}$	Flyer plate impact	Critical

Source: Ref 2

Conventional Load Frames at Medium Strain Rates. Strain rate effects in uniaxial tension or compression are determined by tests with conventional load frames up to approximately 100 or 200 s^{-1} . Conventional test machines are available with increased ram velocities, as are high-speed pneumatic and hydraulic machines. The speed capability of a machine may be influenced by several factors. Speed may be a function of the load that

the ram is attempting to apply, and the no-load speed may be much higher than the full-load speed. The distance traveled may also affect the speed capability. A long-stroke machine may attain a given speed only after a significant amount of travel. Depending on the specimen length, considerable specimen strain could occur before final maximum velocity is obtained in a tension test. Finally, the ability to control speed is a function of the response capability of a servo-controlled machine working in a closed-loop mode. Open-loop machines provide speeds that can be influenced by specimen strength and cannot easily reproduce predetermined velocities or strain rates on materials with different yield strengths or strain hardening behaviors. Load cell ringing at intermediate or medium strain rates may be negligible. However, even if wave propagation effects in the test piece can be neglected, the characteristic response time of load cells must still be checked. At intermediate strain rates, “ringing” of a load cell can mask the desired measurement. Load cell ringing is frequently encountered in high-rate tensile testing. Generally, the load-cell response time (which is the reciprocal of its natural frequency in hertz) must be small compared to the total duration of the test. For example, if a load cell has a natural frequency of 1 kHz, its period of vibration is 10^{-3} s. This load cell could then be used only for experiments that lasted over ten times that amount, or over 10 μ s.

Another condition that must be satisfied is the distance of the load cell from the end of the specimen. If a sufficient distance exists between the specimen and load cell, the finite elastic wave transit time may result in load data that are not time-coincident with strain data. To prevent phase lags from obscuring the experimental data, the wave transit time from the specimen to load cell should be negligibly small compared to the test duration. Otherwise, the load data must be corrected for the delay, and such corrections seldom are precise.

Wave Propagation Effects. At high strain rates, uniform deformation within the test piece becomes a factor. Inertia initially opposes uniform deformation, and a stress wave is transmitted and reflected within the test piece at the speed of sound. If the deformation is purely elastic, then the longitudinal sound velocity, c_{EL} , is simply $c_{EL} = \sqrt{E/\rho}$, where E is the elastic modulus and ρ is density. If the material has deformed into the plastic region, the plastic-wave velocity is more appropriate and generally can be an order of magnitude smaller than the elastic wave velocity. One-dimensional strain-rate-independent theory predicts that the plastic wave propagates at a velocity, c_{PL} , determined by:

$$c_{PL} = \sqrt{\frac{d\sigma/d\varepsilon}{\rho}} \quad (\text{Eq 4})$$

where $d\sigma/d\varepsilon$ is the slope of the true stress/true strain curve. For many materials, the initial work-hardening rate $d\sigma/d\varepsilon$ is approximately 1% of E ; thus for these materials, the plastic wave velocity is approximately 10% of the elastic-wave velocity.

However, experimental evidence in a variety of metals suggests that the above estimate is too conservative. The stress waves generated by impacts at stress levels far in excess of the yield stress appear to travel, at least initially, closer to the elastic wave velocity rather than at the plastic wave velocity (Eq 4). This implies that the wave propagation behavior can be more complicated than described by Eq 4. The velocity of the plastic wave is

sometimes estimated as $\sqrt{B/\rho}$ where B is the bulk modulus.

The velocity of waves and the size of the test piece determine the upper limit of strain rate for accurate measurement of stress-strain curves. If many wave transits occur during a test, the use of average stresses and strains can be justified. However, if only a few wave reflections occur before the specimen fails, then individual wave propagation must be considered. In this case, average values alone cannot be considered, and the use of this test to determine dynamic stress-strain response is precluded. As a first approximation, Davies and Hunter (Ref 3): have estimated that three reverberations are required for stress equilibration in compression testing.

To illustrate the importance of stress wave propagation, consider compression testing of a 10 mm (0.4 in.) specimen, in which the elastic wave velocity is 5.0×10^3 m/s (16.4×10^3 ft/s) and the initial plastic wave velocity may be approximated as 5.0×10^2 m/s (16.4×10^2 ft/s). Assuming that three reverberations of the slower moving plastic wave are required for uniform stress within the deforming specimen, the time for these reverberations is computed to equal 60 μ s. At a strain rate of 10^3 s $^{-1}$, the specimen will have compressed to a strain of 6% during this interval. Thus, data at strains less than this may be invalid, because it cannot be assumed that the specimen was deforming uniformly. Even if the elastic wave velocity is used in the above example, the critical strain at which uniform stress within the specimen is achieved is computed to be equal to 0.6%. At a strain rate of 10^4 s $^{-1}$, this critical strain becomes 6%.

The above example illustrates that wave propagation becomes an important consideration affecting test validity in the high strain rate regime of Table 2. It also illustrates a major advantage of compression testing over tension testing at high strain rates; a compression test specimen can be fabricated to relatively small dimensions to minimize wave propagation times. Another way to determine whether or not wave propagation effects limit the validity of a test is the sample ring-up time, which is the time required for a sample to achieve a uniform state of stress. Generally, measurements are not valid for times such that $L \sim ct$, where c is the speed of stress wave propagation. This corresponds to a situation in which strain $\epsilon \gg \dot{\epsilon}L/c$. Consequently, small strain measurements are difficult to obtain at very high strain rates. Sample length can also be reduced, although there are limits in reducing specimen dimensions.

Another concern is that local failure may occur at the end to which the load is applied. The magnitude of the stress transient (σ_m) associated with the sudden application of velocity v_0 is $\sigma_m = \rho cv_0$ (where ρ is density of the material). Tension tests must be designed so that $\sigma_m < \sigma_{yy}$, the tensile yield stress. For example, consider a bar 25 mm (1 in.) in length that is accelerated at one end to 2.5 m/s (8.2 ft/s). For many engineering materials, including steels, aluminum alloys, and titanium alloys, the elastic wave velocity is about 5000 m/s (16,400 ft/s). The maximum stress generated at the accelerated end of the bar is ρcv , where v is the deformation speed ($v = \dot{\epsilon}L$). For a steel bar, the first stress pulse is 100 MPa (14.5 ksi) and the average strain rate is 100 s^{-1} . If a steel with a strength of 1 GPa (145 ksi) is being tension tested, the maximum allowable driving velocity is 25 m/s (82 ft/s). At that velocity, instantaneous failure would occur at the driven end.

Departure from Isothermal Test Conditions

It is well known that most of the work of deformation is expended as heat; only 5 to 10% of this work is actually stored in the defect structure of the deformed specimen. As the strain rate increases, there is insufficient time for the transport of this heat from the specimen to the grips, platens, or atmosphere. Thus, the specimen temperature can increase during deformation.

The work of deformation, W , is simply:

$$W = \int^{L_f} L P dL \quad (\text{Eq 5})$$

where P is the applied load, and L is the length of the specimen of final length, L_f , and original length, L_o . Equation 5 can be rewritten as:

$$W = A_o L_o \int^e s(e) de \quad (\text{Eq 6})$$

where A_o and L_o are the original specimen area and length, respectively, s is the engineering stress, and e is the engineering strain.

If it is assumed that this work is transformed to heat adiabatically (i.e., without heat flow), then the specimen temperature increase, ΔT , is defined by:

$$\Delta T = \frac{1}{\rho C_p} \int^{e_f} s(e) de \quad (\text{Eq 7})$$

where ρ is the density, and C_p is the heat capacity of the test piece material at constant pressure. As an example, consider the deformation of a stainless steel specimen to a strain of 0.5, and, for simplicity, also assume that the flow stress of the material is constant and equal to 750 MPa (109 ksi). With a density of 8 g/cm^3 (0.29 lb/in.^3) and a heat capacity of $500 \text{ J/kg} \cdot \text{K}$ ($0.120 \text{ cal/g} \cdot \text{°C}$), the temperature increase at a strain of 0.5 is estimated to be 94 K calculated from Eq 7. This is a significant increase and demonstrates that this is not an isothermal test.

The above estimate assumed adiabatic conditions, which are only the case in the high strain rate regime. However, at least under these conditions, the temperature increase can be estimated fairly accurately, and deformation within the specimen remains uniform. The medium strain rate regime is further complicated by heat flow, which in quiescent environments is dominated by conduction through the ends of the specimen. In this regime, there is the possibility of generating a substantial axial temperature gradient from the end to the midpoint of the specimen. This gradient can result in nonuniform deformation throughout the specimen, which complicates interpretation of the experimental results. In fact, if the temperature dependence of the flow stress is high enough, deformation may become highly localized at the center of the specimen; this situation is less likely in a compression specimen than it is in a tensile specimen, which has a much higher aspect ratio.

Measurement of Stress and Strain

Measurement of stress and strain and data acquisition becomes more difficult as the strain rate increases. For example, the frequency response of the load cell must be considered, as previously noted. The frequency response of other measurement devices, such as extensometers or strain gages, must also be considered, along with any signal conditioning and the sampling rates during digital data acquisition. Computer data acquisition systems with sampling at rates as fast as 100 kHz should be sufficient for tests at strain rates as high as 10^2 s^{-1} . For analog-to-digital processing, the sampling rate is inversely related to the desired accuracy or byte size of the digitized "word." For example, with a byte size of 10 bits, sampling rates with typical processors can be as fast as 20 MHz.

In some cases, the standard measurement techniques for stress or strain at low strain rates become unsuitable for testing at higher strain rates. For example, the use of fragile devices, such as extensometers, may not be appropriate for tests that involve large, rapid deformations. Specific procedures for each of the experimental techniques are discussed in more detail in the following sections, but a few general comments concerning strain measurement during tension tests with conventional load frames are summarized here. Additional information on compression testing at medium strain rates is also in the article "Uniaxial Compression Testing" in this Volume.

Measurement of strain is a major problem in high strain rate testing. In quasi-static tension testing, for example, the diameter of the minimum cross section in a cylindrical specimen is easily measured. In contrast, such measurements are virtually impossible or highly impractical in high-rate testing. Furthermore, although strains are easily measured over a uniform gage length section in quasi-static tension testing, the same measurements are considerably more difficult to obtain at high strain rates. Mechanical extensometers also are of little use at high strain rates due to the effects of inertia.

In high strain rate tests, strain measurements typically utilize strain gages, optical extensometers, and displacement measurements between loading fixtures to determine or infer the dynamic tensile in a test piece. At very high rates of strain, strains may be measured in some experimental configurations only through wave propagation analysis. This procedure generally requires that assumptions be made about the constitutive behavior, that wave propagation analysis be carried out, and that predictions and experimental observations be compared. Unique solutions cannot be guaranteed because some other constitutive model may conceivably provide similar results in a particular wave propagation problem.

Electrical resistance strain gages are the most direct, reliable method for strain measurement in high-speed testing. The frequency response capability of strain gages is considerably greater than the mechanical response of the combination of load train, specimen, and load cell. Another method of measuring strain involves the use of optical extensometers, in which displacement measurements across the loading fixtures are divided by an actual or effective gage length. When using crosshead displacement in tension test, caution must be exercised to ensure that these represent only specimen elongation and not machine, ram, or load train elongations. The same precautions that apply in quasi-static tests also apply in dynamic tests. If these precautions are observed, valid stress-strain data from tension testing in conventional load frames can be obtained up to maximum strain rates in the range of 10 to 100 s^{-1} . For higher strain rates, or for cases in which the above criteria are not met, more specialized testing techniques may have to be used, as discussed in this article and in the remaining articles in this Section.

Compression Tests at High Strain Rates

As listed in Tables 1 and 2, several methods are available for compression testing at strain rates up to about 10^4 to 10^5 s⁻¹. These high strain rate compression tests are briefly reviewed in this section with a focus on the general principles, advantages, and limitations of each test method.

Cam Plastometer

The cam plastometer is designed specifically for compression testing at strain rates from 0.5 to more than 200 s⁻¹. The axial load to compress the specimen is transferred from massive rotating flywheels through a cam; this provides the distinct advantage of being able to obtain a constant true strain rate experiment. The cam plastometer is used to obtain the resistance to compressive deformation of materials, principally metals, at constant strain rates over a useful and significant range of strain rates and a practical range of testing temperatures. Most plastometers have a capacity to compress cylindrical specimens homogeneously to a 50% reduction in height, assuming the material is tested at temperatures at which it is ductile enough to permit this reduction.

The development of the cam plastometer in the 1950s was significant because it allowed an extension of mechanical testing capability by three orders of magnitude in strain rate over that obtained in standard mechanical test machines. Furthermore, the cam plastometer mechanism lends itself to the generation of a constant true strain rate experiment, which is ideally suited for metal deformation studies. Most cam plastometer facilities have elevated-temperature testing capabilities. Some of these are equipped for testing in vacuum or in selected atmospheres. These require a vacuum chamber around the specimen-platen assembly and the use of O-ring or bellows grips. The elevated-temperature capability for some facilities is up to 1300 K through the use of in situ induction heating in a reducing atmosphere and the use of aluminum oxide platens. These platens appear to dampen some load cell ringing that occurs when using much denser tungsten carbide platens.

The cam plastometer was originally used to study the rolling characteristics of uranium plate and sheet by the classic Orowan method (Ref 4). This machine underwent several revisions in both mechanical design and instrumentation for compression testing of pure lead (Ref 5), commercial-purity aluminum (Ref 6), and steels (Ref 7). The first constant true strain rate cam plastometer was designed and built by Orowan at the British Iron and Steel Research Association (BISRA) in 1950. It was used to obtain true stress-strain curves for 12 steels at true strain rates of 0.05 to 100 s⁻¹ and temperatures from 1173 to 1473 K (Ref 7). Others have built cam plastometers to perform specific studies. Machines have been built to study the compressive deformation of aluminum and aluminum alloys (Ref 8, 9), depleted uranium (Ref 4, 10), zinc and zinc alloys (Ref 11, 12), and other ferrous and nonferrous metals (Ref 13). A modern version of the cam plastometer has also been designed and built at the Canadian Department of Mines, Energy, and Resources (Ref 14).

True strain rate compression tests are achieved in all cam plastometers by designing the load-applying mechanism in the form of a logarithmic cam (as true strain is, by definition, logarithmic strain). The true strain rate is constant only if the rotational speed of the cam is constant. This is achieved by storing large amounts of energy in flywheels and in the many rotating parts of transmissions, as well as in the cam. To maintain a constant strain rate, this stored energy must greatly exceed the energy required to compress the specimen. A typical cam plastometer setup is shown in Fig. 2, in which a 37 kW direct-current motor (behind the belt guard) and the 40 kV generator are depicted. The motor drives three flywheels distributed between and at both ends of the drive train, which consists of two large off-highway-type transmissions. Cam plastometers can be massive pieces of equipment. Size introduces problems in dynamically balancing the cam and in providing sufficient strength and minimum deflection of the loading frame and drive train. Some cam plastometers in Japan have been equipped with four-post loading frames to circumvent these problems.

Effects of Friction and Lubricants. As in all compression tests, deformation is homogeneous throughout the test only if frictional constraint is minimized at the interfaces between the platens and the specimen ends. That is, the specimen should start out as a cylinder and maintain this cylindrical geometry throughout the test. This requires the use of a suitable lubricant at the interfaces.

Minimizing the effects of friction in a compression test involves selection of a suitable length-to-diameter (L/D) ratio for the specimen and the selection of proper lubrication for the specimen/platen interfaces. An L/D ratio of 1.56 is generally considered optimum. Ratios much larger than this lead to buckling, whereas ratios much smaller than this yield higher stress-strain curves, indicating excessive specimen-platen frictional constraint. An L/D ratio of 1.56 is within the range specified in ASTM E 9, "Compression Testing of Metallic Materials at Room Temperature."

Many lubricants (e.g., viscous oils, powdered graphite, or powdered, liquid-based, and grease-based molybdenum disulfide) have been used for room-temperature testing. A satisfactory lubricant for room-temperature and lower-temperature (to 77 K) testing is "Motor-Mica," which is a mixture of finely ground powdered mica and a highly viscous commercial automotive oil.

At slightly elevated temperatures, powdered tungsten disulfide has been used successfully. At higher temperatures, various glass frits exhibiting viscosities in the range 4000 to 6000 Pa · s (400–600 poise) at temperature can be used. For a series of tests on a titanium alloy, the commercial glaze Deltaglaze 347m was used above 1283 K, and Deltaglaze 349m has been used between 900 and 1010 °C (1650 and 1850 °F).

Coefficient of friction measurements by the method proposed in Ref 15 may be helpful in the preliminary selection of lubricants. Concentric grooves in the ends of the specimen are necessary for most plastometer testing. Depth, spacing, and included angle of the grooves must be determined empirically.

Drop Tower Compression Test

The drop tower compression test, as the name implies, uses a falling weight to provide a compressive load to the specimen. The test technique has the capability to generate high loads at medium strain rates, which cannot be readily obtained by servohydraulic load frames or cam plastometers. Load capacities of 900 kN (100 tons) have been demonstrated for this technique, with test durations from 0.1 to 20 μ s resulting in loading rates as high as 1 GN/s (115×10^3 tons/s).

The drop tower compression test has been used to measure compressive fracture strengths, to determine the compressive stress-strain behavior of material at medium strain rates, and to evaluate the dimensional stability of components subjected to impact compressive loads. Two general approaches can be used for drop tower compression testing. Fracture or compressive stress-strain tests require that the strain rate does not vary significantly during the test. This is accomplished in the drop tower test by ensuring that the available energy of the crosshead (weight times height) is no less than three times (preferably an order of magnitude) greater than the energy absorbed by the specimen and the test system.

The second test approach is used to evaluate the effect of subcritical, or low blow, loadings on the test specimen or components. In this case, the available energy of the crosshead is selected to generate a specific load. During the test, the crosshead comes to a stop and then rebounds. To avoid secondary loadings, a device for removing the specimen or catching the crosshead on the rebound must be used.

Limitations. The drop tower compression test is neither a constant-displacement rate nor a constant-loading rate test. The rate and form of the compressive loading depend on the specimen and test system compliances, as well as the impact velocity and available energy of the falling weight. Test conditions must be determined by trial and error or from empirically derived parameters. The test velocities and, therefore, the loading and strain rates are limited by both the response time of the instrumentation and the inertia loading of the system. In many cases, it is the latter that limits the test velocity. In general, it is better to drop a larger weight from a lower height than the converse when energy requirements are a consideration. The lower velocity will reduce the inertia loading and still generate comparable maximum loads.

Specimen displacement and energy calculations, which are commonly made for instrumented impact (i.e., Charpy) tests, are based on measuring the momentum impulse acting on the falling weight and calculating the resultant temporal impact velocity. These calculated values can be highly inaccurate for the drop tower compression test because deformations in the systems can be greater than the specimen deflections.

Equipment. A typical drop tower compression system is shown in Fig. 3. The test system consists of a drop tower with a massive foundation, a dynamic compression fixture, and stop blocks. The 900 kN (100 ton) capacity system utilizes a commercially available drop tower with an adjustable crosshead weight of 225 to 1000 kg (500–2200 lb) and a maximum drop height of 1.5 m (5 ft). A 12,000 kg (26,500 lb) steel-reinforced concrete foundation is used to provide maximum rigidity to the drop tower.

Fig. 3 Drop tower with compression fixture and stop blocks in place

The dynamic compression fixture (Fig. 4) transfers the impact load from the crosshead to the specimen through a shaft. Proper alignment of the shaft with the specimen axis is maintained throughout the test by linear ball bearings. Small nonparallelisms in the specimen ends are accommodated by a spherical seat beneath the lower platen. The impact load is sensed by a load cell located directly below the spherical seat. Stop blocks arrest the falling crosshead to avoid continued loading of the dynamic compression fixture after the shaft has reached its maximum travel. The development of the dynamic compression fixture is described in Ref 16.

Fig. 4 Dynamic compression test fixture

A principal consideration in the design of the dynamic compression system is that the entire load train compliance must be kept quite low to achieve high loads. Gaps, mismatches, and foreign material at any of the interfaces in the load train adversely alter the rate and form of the impact loading. A second consideration is to minimize the mass of the fixture between the specimen and the centerline of the load cell. Acceleration of this mass to the test velocity causes inertia loads (Ref 17) that can obscure the actual mechanical loading of the specimen. The control of inertia effects is described in Ref 18.

Instrumentation. Equipment designed specifically for instrumented impact testing is used to acquire the load-versus-time data for the drop tower compression test. Minimum instrumentation requirements are a transducer to sense the specimen loading, the associated signal conditioning equipment, and recording instruments to provide a permanent record of the load-sensing transducer. The integrated system must be capable of sampling rates as fast as 35 kHz. The specific requirements for the load instrumentation, as well as the effect of limiting the frequency response, are described in Ref 17 and 19.

Specimen Requirements. Specific specimen requirements have not been developed for the drop tower compression test. However, several specimen configurations based on right-circular cylinders and lengths greater than two times their diameter have been used. As with all compression tests, the end constraint of the specimen due to friction is a primary concern. Hardened steel and modulus-matched inserts have been used between the platens and the specimen to minimize the constraint.

The Hopkinson Bar

Development of test techniques based on the Hopkinson bar has led to significant advances in high strain rate testing capabilities. These techniques yield the highest possible strain rates in a uniaxial compression test under uniform deformation conditions. In addition, the determination of stress within the deforming specimen is made without use of a load cell, and the measurement of strain is made without directly monitoring the specimen length.

The Hopkinson bar derives its name from its developer, who in 1914 used a long elastic bar to study the pressures produced by the impact of a bullet or by the detonation of an explosive (Ref 20). In designing this experiment, Hopkinson recognized that as long as the pressure bar remains elastic, the displacements in the pressure bar are directly related to the stresses and that the length of the wave in the bar is related to the duration of the impact through the velocity of sound in the bar, a quantity that is well known. A significant feature of this work is that the pressures were estimated by measuring the momentum (with a ballistic pendulum) acquired by a small section of the bar placed in contact with the bar at the far end. Further developments in the experimental techniques occurred a few decades after these original experiments, when Davies (Ref 21) and Kolsky (Ref 22) designed condensers to measure displacements in the pressure bars. Kolsky also introduced the split-Hopkinson pressure bar technique, in which the specimen is sandwiched between two pressure bars. He demonstrated how stress and strain within the deforming specimen are related to displacements in the pressure bars. Because of these contributions, the split-Hopkinson pressure bar is often referred as the Kolsky bar.

There are two basic configurations for Hopkinson pressure bar testing: the split-Hopkinson pressure bar (Fig. 5a) and the single pressure bar configuration (Fig. 5b). The basic principles of the two techniques are similar, and several investigators have used the single pressure bar configuration. The most widely used method is the split-Hopkinson pressure bar method, which consists of two elastic pressure bars that sandwich the specimen between them. Upon impact of a striker bar on an incident bar, an elastic compressive wave is generated within the incident bar, and the time-dependent strain in the pressure bar is measured at strain gage A at the midpoint of the incident bar (Fig. 5a). At the incident bar/specimen interface, the wave is partially reflected and partially transmitted into the specimen. A portion of the incident wave is reflected back along the incident bar as a tensile wave. This reflected strain is measured by strain gage A. Strain measurements are also taken on the output bar with strain gage B. These strain measurements on the pressure bars are used to determine the stress-strain behavior of the specimen if two basic conditions are met. First, the wave propagation within the pressure bars must be one-dimensional. Secondly, the specimen must deform uniformly. Under these two conditions, stress-strain behavior of the specimen can be determined as described below. More details are also in the article "Classic Split-Hopkinson Pressure Bar Testing" in this Volume.

Fig. 5 Typical configurations of the Hopkinson bar. (a) Split-Hopkinson pressure bar with specimen sandwiched between two long elastic pressure bars, each of which is instrumented at its midpoint with a strain gage. (b) Single pressure bar with striker bar impacting the specimen directly. With this configuration, the motion of the striker bar or displacement within the specimen must be monitored independently.

Relating Hopkinson Bar Strain Gage Measurements to Specimen Stress-Strain Behavior. The strain rate in the deforming specimen is:

$$\frac{d\varepsilon}{dt} = \frac{V_1 - V_2}{L} \quad (\text{Eq 8})$$

where V_1 and V_2 are the velocities at the incident bar/specimen and specimen/output bar interfaces, respectively. The velocity V_1 is the product of the longitudinal sound velocity, C_o , in the pressure bar and the total strain at the incident bar/specimen interface, which is $\varepsilon_I - \varepsilon_R$. Similarly, the velocity V_2 is equal to $C_o \varepsilon_T$. In this development the incident and transmitted strains (ε_I , ε_T) and ε are all compressive strains, but are considered positive, whereas the reflected strain (ε_R) represents a tensile strain and is negative. Replacing V_1 and V_2 in Eq 8 with these expressions yields:

$$\frac{d\varepsilon(t)}{dt} = \frac{C_o}{L} [\varepsilon_I(t) - \varepsilon_R(t) - \varepsilon_T(t)] \quad (\text{Eq 9})$$

The average stress on the specimen is:

$$\sigma(t) = \frac{P_1(t) + P_2(t)}{2A} \quad (\text{Eq 10})$$

where P_1 and P_2 are the forces at the incident bar/specimen and specimen/output bar interfaces, respectively, and A is the instantaneous cross-sectional area of the specimen. At the incident bar/specimen interface, the force is:

$$P_1(t) = E[\varepsilon_I(t) + \varepsilon_R(t)]A_o \quad (\text{Eq 11})$$

where E is Young's modulus and A_o is the cross-sectional area of the bar. Likewise, the force at the specimen/output bar interface is:

$$P_2(t) = E\varepsilon_T(t)A_o \quad (\text{Eq 12})$$

Combining Eq 11 and 12 with Eq 10 yields:

$$\sigma(t) = \frac{E}{2} \frac{A_o}{A} [\varepsilon_I(t) + \varepsilon_R(t) + \varepsilon_T(t)] \quad (\text{Eq 13})$$

When the specimen is deforming uniformly, the stress at the incident bar/specimen interface equals that at the specimen/output bar interface and from Eq 11 and 12.

$$\varepsilon_I(t) + \varepsilon_R(t) = \varepsilon_T(t) \quad (\text{Eq 14})$$

from which Eq 9 and 13 may be simplified:

$$\frac{d\varepsilon(t)}{dt} = \frac{-2C_o}{L} \varepsilon_R(t) \quad (\text{Eq 15})$$

$$\sigma(t) = E \frac{A_o}{A} \varepsilon_T(t) \quad (\text{Eq 16})$$

Thus, the stress-strain behavior of the specimen is determined simply by measurements made on the elastic pressure bars in a split-Hopkinson pressure bar test. The analysis applies as well to the single bar configuration shown in Fig. 5(b). However, because the striker bar impacts directly with the specimen in this test, the strain $\varepsilon_R(t)$, which now represents the wave generated in the striker bar, cannot be measured with a strain gage, and another measurement technique is required, such as with high-speed photography.

As previously noted, the above equations relating strain gage measurement to stress-strain behavior in the deforming specimen require that two important conditions be met. The first is that wave propagation within the pressure bars must be one-dimensional if surface displacement measurements are used to represent the axial displacement over the entire cross-sectional area of the pressure bar. The second condition is that the specimen must deform uniformly; this is opposed by both radial and longitudinal inertia and by frictional constraint at the specimen/pressure bar interfaces. These two conditions are discussed in more detail in the article "Classic Split-Hopkinson Pressure Bar Testing" in this Volume.

Rod Impact (Taylor) Testing

The rod impact test is based on the Taylor test for measuring the dynamic yield strength (Ref 23). The technique has been improved so that the entire stress-strain flow curve can be determined at high strain rates (around 10^4 or 10^5 s⁻¹) and large plastic strains (50–150%) for materials at ambient or elevated temperatures. The availability of this technique has been useful in determining constitutive behavior at high strain rates and the evaluation of dynamic compressive fracture.

The classic Taylor test (Ref 23, 24) involves a cylindrical specimen rod that impacts a “rigid” plate (Fig. 6a). The plastic deformation at the impact end shortens the rod, and the fractional change in rod length can, by one-dimensional rigid-plastic analysis, be related to the dynamic yield strength. This relationship was shown to be independent of both the rod aspect ratio and the impact velocity for a wide variety of materials, including copper, lead, paraffin wax, and various steels.

Fig. 6 Two-rod impact configurations. (a) Classic Taylor test. (b) Symmetric rod impact test

Although this method is appealing in its simplicity, the Taylor test received only moderate interest. Twenty-five years after the original Taylor tests, the use of two-dimensional wave propagation codes enabled a better understanding of and renewed interest in this technique. In 1972, Wilkins and Guinan (Ref 25), using a two-dimensional finite difference code and an elastic-plastic model with work hardening, were able to correctly simulate the final shapes and final lengths of Taylor test specimens of several metallic alloys at ambient temperatures. Their results showed good correlation between the dynamic yield strength and the fractional change in rod length for a wide range of impact velocities and rod aspect ratios, thus confirming many of the Taylor/Whiffin conclusions (Ref 23, 24).

Further improvements have led to two types of tests: symmetric rod impact tests and asymmetric rod impact tests. The advantage of the asymmetric rod impact test is that elevated temperature tests can be performed without heating a moving projectile, as required with the symmetric rod impact test. These types of tests are used in evaluation of constitutive models (Ref 26) and dynamic deformation and fracture behavior (Ref 27, 28). Determination of the dynamic flow curve of a material from a rod impact test is made by computationally simulating the experiment with a two-dimensional wave propagation computer code. The flow parameters are varied until the computed profiles agree with those determined experimentally at various times during the deformation history.

Symmetric Rod Impact Test. In the early 1980s, Erlich et al. (Ref 29) implemented two major modifications to the classic Taylor technique as a method for obtaining the entire stress-strain flow curve for materials undergoing high strain rate compressive and shear loading to large plastic strains. The first was to use ultrahigh-speed photography to monitor the deformation history of the specimen rod. This allows intermediate as well as final deformation states to be compared with two-dimensional computer simulations, thus improving the reliability of the flow curve determination.

The second modification was to replace the rigid plate with another rod of the same geometry and material as the impacting rod (Fig. 6b). This arrangement, referred to as the “symmetric rod impact” technique, allows the impacting ends of the two specimen rods to deform together symmetrically, thus eliminating boundary condition uncertainties in the analysis that arise from the unknown friction conditions at the rod/plate interface and from the deformation of the rigid plate adjacent to that interface. By using the symmetric rod impact

technique, dynamic flow curves at ambient temperature were obtained for 6061-T6 aluminum (Ref 29), a titanium alloy, and 4340 steel over a wide range of initial hardnesses (Ref 30).

A typical experimental arrangement for the symmetric rod impact test at ambient temperature is shown in Fig. 7. The specimen rods are identical right circular cylinders, the ends of which are machined flat and parallel to within about 0.01 mm (0.0004 in.). The impacting rod is mounted on the front end of a projectile, which is accelerated by expanding helium in a gas gun. Projectile velocity is recorded by a series of contact pins located near the end of the gun barrel. The stationary rod is held in place by six ceramic fingers attached to a target-mounting fixture, which in turn is affixed to an alignment plate at the muzzle of the gun. The position of the latter rod can be adjusted by rotating the threaded bars into which the ceramic fingers are inserted. Alignment of the two rods is critical to ensure that the impacting ends are parallel and coaxial.

Fig. 7 Symmetric rod impact tests at ambient temperature

The specimen rods are backlit by a quick-pulse, high-intensity light source (xenon flash tube or exploding bridge wires) triggered just before impact. The silhouettes of the deforming rods are recorded by a high-speed framing camera at framing rates between one half and one million frames per second. After deformation is complete (about 30–40 μ s after impact), the specimen rods fly into a recovery pipe filled with rags or other energy-absorbing materials that minimize additional deformation. The pipe is sufficiently narrow to prevent the projectile from entering the specimen and impacting it again. The recovered rods are then sectioned along the axis and examined metallographically to ascertain the extent of internal damage.

The impact velocity must be low enough to suppress the formation of tensile voids (which can occur at early times by the focusing of the radial release waves on the rod axis) or shear bands (which can occur at later times as a result of large plastic deformation near the impact end). Although a small amount of incipient damage can be tolerated, any significant amount of damage can affect the shape of the deforming rod profiles.

Asymmetric Rod Impact Test. As mentioned previously, one advantage of the asymmetric rod impact test is that elevated temperature tests can be performed without heating a moving projectile, as required with the symmetric rod impact test. In this variation, a rigid plate is launched into a stationary specimen rod that is preheated to the desired temperature. An elevated-temperature test with the asymmetric rod impact technique only requires that the target specimen be preheated to the desired test temperature. The specimen is preheated with three infrared line heaters. Radiation from each linear filament is focused onto the specimen by an elliptical reflector. In 1982, Gust (Ref 31) used a reverse ballistics variation of the classic Taylor test to measure fractional changes in the length of various metallic rods at initial temperatures up to about 1000 $^{\circ}$ C (1830 $^{\circ}$ F). If

frictional effects in the impact area are not a significant factor for a given specimen material and target, the asymmetric rod impact technique may be used to determine dynamic flow curves at ambient or elevated temperatures.

High Strain Rate Tension and Compression Tests

High Strain Rate Tension Testing

As previously noted, valid stress-strain data can be obtained in conventional load frames for strain rates in a range up to about 10 to 100 s⁻¹ if suitable precautions are observed with regard to wave propagation effects and instrument response times. For tension testing at higher strain rates, or for cases when wave propagation effects are important, then more specialized testing techniques may have to be used, as described subsequently.

Expanding Ring Test

The expanding ring test is a highly sophisticated technique for subjecting metals to tensile strain rates over 10^4 s^{-1} (Ref 32, 33, 34). Although the testing principle is simple, its performance requires specialized equipment available in only a few laboratories. The ring test can determine the high-rate stress-strain relationships, but a simplified, more widely used version can be employed to determine ultimate strain only (Ref 35, 36).

This test involves the sudden radial acceleration of a ring due to detonation of an explosive charge or electromagnetic loading. The ring rapidly becomes a free-flying body, expanding radially and decelerating due to its own internal circumferential stresses. A thin ring must be used for the analysis to be valid; the wall thickness should be less than one-tenth the ring diameter, which is typically 25 mm (1 in.). If R is the radius of the ring and σ is the hoop stress:

$$\sigma = -\rho R \frac{d^2 R}{dt^2} \quad (\text{Eq 17})$$

To obtain stress-strain data, radial displacement as a function of time must be calculated. Strain is proportional to change in radius (just as engineering strain in tension is $\Delta L/L_0$); thus:

$$\epsilon = \ln \frac{R}{R_0} \quad (\text{Eq 18})$$

where R_0 is the initial radius. Stress may be computed from Eq 17 by double differentiation of radial displacement data as a function of time. Ring displacement can be obtained through the use of high-speed photography, streak cameras, displacement interferometers, or other methods for measuring radius as a function of time.

It is difficult to determine stress accurately by double differentiation of displacement data. Several laboratories have used a laser velocity interferometer to measure ring velocity directly (Ref 37, 38). Thus, only a single differentiation is necessary to calculate stress, and precision is improved considerably.

Advantages of the Ring Test. The ring test has two principal advantages. The expanding ring test subjects the material to a state of dynamic uniaxial stress without the wave propagation complications that accompany other high strain rate tests. Also, the maximum strain rate available in the ring test is higher than in any other common tension tests involving large plastic strains.

Limitations of the Ring Test. Strain rate in the expanding ring test is not usually constant. The strain rate is computed from $(dR/dt)/R$, and both of these terms vary continually. Strain rate is usually greatest at the start of ring deceleration, when strain is smallest. Values in excess of 10^4 s^{-1} are readily obtained. If the ring does not rupture, the strain rate falls to zero at the end of the test.

Ring specimens also experience a compressive preload in the radial direction that often exceeds the yield stress during the acceleration phase. Because load history is known to affect the subsequent stress-strain behavior of many materials, data obtained from expanding ring tests do not always agree with results from other tests at slightly lower strain rates.

The difficulties, expenses, and limitations of the expanding ring test preclude its use as a standard test technique for generating high strain rate stress-strain data in tension. Only a few laboratories are capable of performing this test. However, if subjecting a material to high strain rates in tension without determining stress-strain data is of primary interest, the expanding ring test is much easier to conduct. A number of investigators have used this test to determine strain to failure under dynamic loading (Ref 35, 36). Here, the accurate determination of radial displacement versus time is not as critical because stresses are not calculated. Less precise displacement data provide reasonably accurate determinations of strain rate. The ambiguity arising from possible strain rate history effects still exists when the expanding ring test is used in this simpler manner.

The expanding cylinder test, a variation of the ring test, provides a dynamic stress state equivalent to that produced in a quasi-static tensile test on a wide sheet versus a thin strip of material. A difficulty encountered in this type of test is the need for an impulse to be generated simultaneously in time along the axis of the cylinder. Because explosive detonation along a wire, for example, propagates at a finite wave speed, uniform deformation along the length of the axis cannot be ensured. Dimensions, detonation wave speeds, and synchronization of multiple detonation all must be considered carefully to ensure that the cylinder is deformed as uniformly as possible and that axial stress waves are not generated (Ref 39).

Flyer Plate and Short Duration Pulse Loading

Traditionally, flat plate impact tests have been used to obtain high strain rate yield data, shock wave response data, and equation of state data for materials undergoing uniaxial strain. Uniaxial strain refers to a three-dimensional state of stress in which deformation or strain occurs in only one direction—the direction of loading. The uniaxial strain condition persists for only a short period of time until stress waves originating at lateral boundaries reach the specimen interior. In a typical experiment, this time period is on the order of several to tens of microseconds. Uniaxial strain is defined mathematically as:

$$u_x \neq 0, u_y = u_z = 0 \quad (\text{Eq 19})$$

where x is the direction of loading, u_x is the displacement in that direction, and y and z are orthogonal directions in a plane normal to x . The strains are obtained from the displacement derivatives, thus:

$$\varepsilon_x \neq 0, \varepsilon_y = \varepsilon_z = 0 \quad (\text{Eq 20})$$

The flat plate impact test is performed by launching a flat flyer plate against a second stationary target plate. Compressed gas guns, propellant guns, magnetic accelerators, and explosives have all been used to launch the flyer plate (Ref 40). Extreme precision must be achieved to eliminate relative tilt at the instant of impact. A typical experimental setup using a gas gun is shown in Fig. 8. The flyer plate is carried in the gas gun in a plastic sabot. Velocity of the flyer is determined from the transit time between the shorting pin in the gun barrel and time-of-arrival pins in the target. The target is supported by a spall ring that suppresses late-time radial tensile waves.

Fig. 8 Schematic of gas-gun-launched flyer plate impact test setup

The stress waves along the axis normal to the impact plane are shown in Fig. 9. A flyer plate of thickness d , moving left to right, strikes an initially stationary target of thickness T ; the impact occurs at the origin, O , of the (x, t) coordinates. Elastic-plastic behavior is assumed in Fig. 9. Elastic waves propagate at approximately c_{EL} , the longitudinal elastic sound speed. Plastic waves propagate at approximately $\sqrt{B/\rho}$ where B is the bulk modulus. The arrivals of the elastic and plastic waves at the target rear surface are denoted as E and P .

$$\sigma = \rho U v$$

(Eq 22)

where U is shock propagation speed and v is particle velocity. Peak particle velocity is half the impact velocity, v_0 , for a symmetric impact. For steel-on-steel impacts, Eq 22 becomes approximately $\sigma = 200 v_0$. For $\sigma > \sigma_{\text{HEL}} = 15$ kbar, a v_0 greater than 75 m/s (245 ft/s) is required. This presents no problem when a gas gun is used. Experiments with $v_0 < 100$ m/s (330 ft/s) are often difficult because of impact tilt, which becomes more critical at low velocities. Also, impact velocity must not be so high that the velocity of the P wave (Fig. 9) exceeds c_{EL} . That limit for steels usually is greater than 1 km/s (0.6 mile/s). The limit for other materials can be found by consulting the tables in Ref 43.

Given an appropriate impact velocity, to determine σ_{HEL} one of the following measurements must be made. The peak particle velocity behind the E wave can be measured. This can be accomplished at the free surface with capacitor gages, sloping mirrors, or a velocity interferometer. The velocity behind the wave is half the free surface velocity. The stress is related to the free surface velocity by Eq 22 with $v = c_{\text{EL}}$.

Direct measurement of σ_{HEL} can be obtained by embedded piezoresistive gages. Manganin and carbon gages frequently are used for this purpose. This technique requires sectioning the target or using a backing plate and correcting for partial transmission of the wave transmitted through the interface. Magnetic particle velocity gages can be used for nonconducting targets, such as plastics and rocks, but they are not suitable for metals.

Spall stress can be determined by two methods. The simplest, in terms of analysis, interpretation, and experimental technique, is to vary systematically the flyer plate thickness, d , and impact velocity, v_0 , to determine the critical values at which rupture occurs. As the flyer plate thickness is increased, the duration of the compressive and tensile load increases; the load duration is approximately $2d/c_{\text{EL}}$.

Eventually, for flyer plate thicknesses exceeding about 5 mm (0.2 in.), the spall stress reaches a load duration limit. In many metals, the limiting spall strength is several times the value of σ_{HEL} . Figure 10 illustrates typical spall stress data for low-carbon steel. The data illustrate that for pulse durations longer than a few microseconds, the greatest tensile stress that the material can sustain without rupture is 25 kbar.

Fig. 10 Spall data for low-carbon 1020 steel

Interpretation of experiments using thinner flyer plates is more complex because a computer code must be used to calculate the stress history on the spall plane. Finite difference codes (Ref 41) or method of characteristics codes (Ref 44) can be used. Finite difference codes are more accurate and more widely applicable than method of characteristics codes, but the user must be specially trained in this subject.

Another approach to spall characterization is to initiate impact above the spall threshold and to deduce the material behavior from the free surface velocity, Δv_s , data. Figure 11 illustrates a typical free surface velocity

history with spalling. E, P, R, and S refer to the same arrivals as explained in text for Fig. 9. The spall stress is given approximately by $\rho_{CEL} \Delta v_s/2$. However, a more exact determination requires code analysis.

Fig. 11 Free surface velocity data when spall occurs

Split-Hopkinson Bar in Tension

The principles of the split-Hopkinson bar in tension are similar to those in compression, as discussed in the article “Classic Split-Hopkinson Pressure Bar Testing” in this Volume. The primary differences are the methods of generating a tensile loading pulse, specimen geometry, and the method of attaching the specimen to the two bars (incident and transmitter).

Basically, three types of tension split-Hopkinson bars have been developed. The first (Ref 45) involves the use of compressive pulses in the input and transmitter bars, as in the compressive test. The input bar is solid, while the transmitter or output bar is a hollow tube of the same cross-sectional area as the input bar. The specimen is a complex “top-hat” type of geometry, as shown in Fig. 12. The specimen actually is comprised of four parallel tensile bars of equal cross-sectional area. Although specimen machining is somewhat complex, the test is conducted in the same manner as compressive testing.

Specimen configuration

Dimensions of test specimen

Fig. 12 Details of the split-Hopkinson tension specimen. Source: Ref 45

The second type of tension split-Hopkinson bar test involves the use of a smaller standard type of threaded tension specimen and generation of a tensile pulse directly on the end of the loading or input bar (Ref 46, 47). This can be accomplished in several ways, as shown in Fig. 13. In Fig. 13(a), a mass is impacted directly on an anvil attached to the end of the input bar. In Fig. 13(b), an anvil is loaded by a compressive wave transmitted through another loading bar that is a hollow tube. The compressive pulse in the loading tube is generated by the same techniques as the compression split-Hopkinson bar. In Fig. 13(c), a pulse is generated by the detonation of an explosive against the anvil. In Fig. 13(a) and (c), it is difficult to generate a pulse of constant amplitude, while in Fig. 13(b) a long time duration is accomplished in the same manner as in compressive testing.

Fig. 13 Schematic of three types of split-Hopkinson tension-loading techniques

The third type of tension test also uses a threaded specimen but uses the reflection of a compression pulse at a free end and a collar to protect the specimen from initial precompression (Ref 48). Figure 14(a) illustrates an experimental setup. Figure 14(b) is a Lagrangian $x-t$ diagram, which illustrates the details of wave propagation in the bars and the experimental procedures. When the striker bar is accelerated against bar No. 1, the impact generates a compression pulse, the amplitude of which depends on the striker velocity and the length of which is twice the elastic wave transit time in the striker bar. The pulse travels down the bar until it reaches the specimen. The threaded tensile specimen is attached to the two pressure bars, as shown in detail "A" of Fig. 14(a).

Fig. 14 Split-Hopkinson bar test using threaded tension specimen. (a) Schematic of tensile loading apparatus. Source: Ref 48. (b) Lagrangian diagram for tensile loading apparatus. CRO, cathode ray oscilloscope

After the specimen has been screwed into the bars, a split shoulder or collar is placed over the specimen, and it is screwed in until the pressure bars fit tightly against the shoulder. The shoulder is made of the same material as the pressure bars, has the same outer diameter, and has an inner diameter that just clears the specimen. The ratio of the cross-sectional area of the shoulder to that of the pressure bars is typically 3:4, while the ratio of the area of the shoulder to the net cross-sectional area of the specimen is typically 12:1.

The compression pulse travels through the composite cross section of the shoulder and specimen in an essentially undispersed manner. Tightening of the specimen by twisting the pressure bars, the relatively loose

fit of the threaded joint of the specimen into the bars, and the large area ratio of the shoulder to the specimen ensure that no compression beyond the elastic limit is transmitted to the specimen.

Ideally, the entire compression pulse passes through the supporting shoulder as if the specimen were not present, although in practice it is difficult to prevent prestraining of the specimen. The compression pulse continues to propagate until it reaches the free end of bar No. 2. There it reflects and propagates back as a tensile pulse, ϵ_i , and passes gage No. 2. Upon reaching the specimen at point A as shown in Fig. 14(b), the tensile pulse is partially transmitted through the specimen, ϵ_t , and partially reflected back into bar No. 2, ϵ_r . Note that the shoulder, which carried the entire compressive pulse around the specimen, is unable to support any tensile loads because it is not fastened to the bars.

Tight fitting of the shoulder against the bars is critical in transmitting the compression pulse down the bars without significant wave dispersion. Similarly, the tight fit of the threaded tensile specimen against the bars is essential to achieve smooth and rapid loading of the specimen as the tensile pulse arrives. Failure to remove all "play" from the threaded joint results in uneven loading of the specimen and spurious wave reflections.

Analysis of the tensile split-Hopkinson bar test is almost identical to that of the compression test. The major difference is the actual or effective gage length of the specimen. Contrary to the compression test, in which a right circular cylinder is used, the tensile test uses a cylindrical specimen with an attached shoulder and additional gripping, such as threads. Because the split-Hopkinson bar test can only provide data on the relative displacement between the ends of the incident and transmitter bars, an effective gage length generally must be used. This is equivalent to determining strain in a tensile test through crosshead displacement measurement. The use of strain gages on test samples to determine an effective gage length is strongly recommended. This calibration is accomplished easily at low strain rates, preferably in a conventional test machine in which the crosshead displacement is monitored separately.

As with any uniaxial tensile test, once localized necking occurs, it is no longer possible to simply convert load-displacement data to stress-strain data. The range of application of the Hopkinson bar test can be extended by high-speed photography of necking specimens. An analysis that allows estimation of effective stress and strain from the profile of the necking specimen is described in Ref 49. Photographs can be made with a suitable high-speed camera system through windows provided in the collar. The major technical difficulty is the precise synchronization of the exposures with the Hopkinson bar record (Ref 50).

High Strain Rate Tension and Compression Tests

Rotating Wheel

Another method for tension testing at high strain rates consists of a rotating wheel with claws or noses that quickly stroke a yoke containing test pieces. An early test machine was developed by Mann in 1936 (Ref 51), and in 1944 Fehr et al. (Ref 52) reached strain rates of nearly 10^3 s^{-1} with some bearable ringing. In the 1960s, Schopper produced and sold about 100 "rotating wheel machines," which also had a 200 kg (440 lb) wheel with a releasable claw and a specimen within a yoke fixed in front of the wheel (Fig. 15). By careful adjustments, velocities of about 40 m/s (130 ft/s) were reached without any bending moments. However, the overall frequency response of the fixture (despite the 50 kHz quartz transducer for force-time recording) was only 2.5 kHz, which is too low for high-rate testing.

Fig. 15 Principle of high-rate tensile testing with flywheel setup

The essential improvement has been to introduce load-measuring gages as close to the gage length as possible. This is realized by measuring elastic strains and converting to stresses by the elastic modulus. To assure low barriers for reflections of stress wave propagation, the strain gages for load measurement are positioned at cones of 8° on the smallest possible diameter. With this technique, stress-strain records are possible up to velocities of 30 m/s, which corresponds to strain rates of $\dot{\epsilon} = 2500 \text{ s}^{-1}$ with a gage length of 10.5 mm (0.41 in.) and a diameter of 3.5 mm (0.14 in.) ($L/D = 3$). Even with high strain hardening and highly deformable materials, there is practically no influence of the tested materials on the history of velocity or strain rate like in a Hopkinson bar setup because the energy content of the rotating wheel exceeds the fracture energy of the specimen more than 10 times (for striking velocities $v > 10 \text{ m/s}$, or 33 ft/s).

A similar setup, but based on a moving mass of a few kilograms guided along straight bars, has also been developed by Stelly and Dorneval at CEA, France with good results (Ref 53). Higher strain rates of $\dot{\epsilon} = 10^4 \text{ s}^{-1}$, for example, can be reached with short gage length. To provide easy strain recording for the complete loading up to fracture, electro-optical cameras or noncontact laser interferometers can be used. The advantage of this instrumentation is that the strain is measured, not calculated under certain assumptions.

In order to avoid more reflections of the stress wave from the upper end of the specimen, the length beside the gage length is extended to $2s > v_c \cdot t$ (where s is the rod length between gage length and fixture, v_c is the sound velocity, and t is the time to fracture at the used striking velocity). In the case of short lengths, a wave transmitter bar is connected to the specimen. This procedure requires the evaluation of impedance transfer between the sample and bar. Figure 16 shows stress-time diagrams of screwed, brazed, and welded joints tested under high strain rate conditions at about $\dot{\epsilon} = 1000 \text{ s}^{-1}$. These results reveal that screwing and brazing are insufficient methods to obtain stress-time diagrams of good quality. Therefore, in this test setup welded joints are most suitable to perform tensile tests at high and very high strain rates.

Fig. 16 Influence of joining method on stress-time curves for high strain rate tension test specimens

This procedure was successfully applied for high-rate, high-temperature tests (Fig. 17). Notice the occurrence of the upper and lower yielding and the following nearly undisturbed stress-time records. The wave transmitter bar was used for a stress measurement because the strain gages at the gage length were unsuitable at test temperature. Temperatures up to 600 °C (1100 °F) are reached with heated air; higher temperatures should be possible using small infrared ovens (Ref 54, 55) or induction heating.

Fig. 17 Stress-time diagrams from high rate tension testing of carbon steel (0.45% C) between room temperature and 600 °C (1100 °F)

High Strain Rate Shear Testing

Introduction

SHEAR DEFORMATION is encountered in several types of processing operations, such as punching, grinding, machining, forming, and events or processes that result in penetration. Using adequate models (like von Mises, Tresca, Nadai-Tresca, and Nadai-von Mises), one can convert mechanical properties from tension and compression testing to shear stress and shear strain; however, this conversion seldom extends into a high strain range. The limit is frequently about 20% strain, which is far less than the strains reached in the aforementioned applications. At higher plastic strains, the deviation between results can become quite significant, with axial tests invariably providing higher values on flow stress than shear tests provide (after conversion by either the von Mises or Tresca flow rule). Therefore, to accurately predict mechanical behavior at high strain (especially for nonisotropic materials), testing for shear behavior should be performed directly in shear at the appropriate level of strain, temperature, and strain rate for a given operation. In addition to immediate practical applications, high strain rate shear data are invaluable for the development of macroscopic constitutive models and for studies into possible deformation mechanisms for metals. Macroscopic results can be combined with microscopic observations to make fundamental contributions to the development of constitutive equations based on the micromechanisms that are dominant during deformation at a particular rate and temperature.

Shear and torsion testing also have some advantages over uniaxial testing in tension or compression testing. In particular, with the absence of a Poisson ratio effect, complications caused by radial expansion or contraction are eliminated during shear and torsion testing. The problems of necking, which occurs in tension tests, and barreling, which occurs in compression tests, thus, do not occur in shear and torsion testing. Furthermore, due to the Poisson ratio effect, radial expansion or contraction of stress waves during the initial phase of axial high-speed tests is opposed by a radial inertia that becomes greater with a shorter pulse and larger amplitude. This results in a short-pulse radial stress component in the specimen superposed on the axial stress component. Hence, in axial loading, the state of stress in the specimen is only at constant strain rates. In torsional testing, however, the inertial and frictional effects from radial expansion or contraction do not occur. The torsional inertia stresses still remain. Nevertheless, this is one consideration that originally led to the development of the torsional Kolsky bar, and it has since been shown that the strain rate sensitivities determined by torsion tests on a variety of materials compare more or less well with those determined by axial tests.

Another advantage of torsion testing at high strain rates is the absence of geometric dispersion. When an axial stress pulse (tension or compression) travels down a cylindrical bar, the pulse undergoes geometric dispersion; that is, the different frequency components in an axial pulse have different velocities. In contrast, there is no geometric dispersion when a torsional pulse travels along an elastic bar in its primary mode; that is, all frequency components of the torsional pulse have the same velocity. Hence, a torsional pulse initiated either by explosive detonation or by the release of a stored torque does not change its shape as it propagates toward the specimen.

On the other hand, with torsion testing, some disadvantages must be considered:

- All tube specimens imply a stress and strain gradient from the inner to the outer wall diameter that can be diminished by using a relative thin-wall thickness and a large diameter. The limit of “slenderness” is given by elastic buckling before yielding or plastic buckling while yielding.
- Upper and lower yield stresses, connected with Lüders bands, are flattened out because of the inability to local compliance.
- Flat products are often unsuited for torsion testing because of nonrotational texture distribution.

This article briefly reviews the dynamic factors and experimental methods for high strain rate shear testing by the methods listed in Table 1. As for axial loading, a variety of testing machines are available for shear loading. Selection usually depends on the rate of deformation required. A servo-hydraulic machine provides the most convenient testing method for rates up to about 10^2 s^{-1} , provided that precautions are observed for wave propagation effects within the loading column. Wave propagation effects place an upper theoretical limit on the attainable strain rates. Hence, other methods of testing become necessary. Torsional impact loading has been widely used to obtain strain rates up to about 10^2 s^{-1} . Between strain rates of 10^2 and 10^4 s^{-1} , the torsional Kolsky (or split-Hopkinson) bar has proven to be a very convenient method of testing. Other methods of high strain rate shear testing include double shear and punching, which provide somewhat higher rates than the torsional Kolsky bar. For rates above 10^4 up to approximately 10^7 s^{-1} , plate impact tests are used to subject thin specimens to combined pressure and shear.

Table 1 Shear tests for high strain rate conditions

Testing technique	Application strain rate, s^{-1}
Conventional shear	<0.1
Special servo-hydraulic frames	0.1 to 100
Torsional impact	10 to 10^3
Hopkinson (Kolsky) bar in torsion	10^2 to 10^4
Double-notch shear and punch	10^3 to 10^4
Pressure-shear plate impact	10^4 to 10^7

All of the techniques described in this article are capable of producing a complete stress-strain curve for a given material. Based on a combination of results obtained from tests using the methods already described, a complete analysis of material behavior in shear over a wide range of dynamic rates (10 to 10^7 s^{-1}) can be obtained. For penetration, punching, machining, etc., a strain rate range of 10^3 to 10^5 s^{-1} is of particular interest, but knowledge of material response over the entire range is very useful. For strain rates up to approximately 10^4 s^{-1} , the lower yield stress is often found to be proportional to the logarithm of strain rate. At strain rates in excess of 10^4 s^{-1} , the lower yield stress is often found to be directly proportional to strain rate, rather than to the logarithm of strain rate. This implies a new region of mechanical response controlled by a viscous damping mechanism, in contrast to thermally activated processes at strain rates below 10^4 s^{-1} .

High Strain Rate Shear Testing

High Strain Rate Torsion Testing

High strain rate torsion testing involves the use of high-speed hydraulic machines, torsional impact devices, or the Kolsky (split-Hopkinson) bar.

High-Speed Hydraulic Torsional Machines

Hydraulic torsion test machines can be used as an alternative to mechanically driven torsional devices to provide transient loading. High-speed hydraulic torsion machines are analogous to axial test machines, but a torsional actuator is used instead of a standard linear hydraulic actuator. A typical high-speed torsional system without the possibility of compensating axial loads is illustrated schematically in Fig. 1 (Ref 1). As in the torsional impact device discussed in the next section of this article, a stiff loading system and reaction frame are required, as well as low inertia in the moving parts. As illustrated in Fig. 1, these requirements are accomplished by enclosing the system, which features an integral actuator shaft, specimen, and load transducer, within a rigid housing. The vaned torsional actuator allows a rotation of about 3 rad.

Fig. 1 Dynamic hydraulic torsion test facility. Source: Ref 1

Hydraulic loading of the actuator is maintained by a servovalve and servo-control loop for operating at low rotational velocities, which provide shear strain rates to about 10 s^{-1} . For higher velocities, a solenoid-triggered quick-release valve conveys pressure from an accumulator directly to the actuator. In this open-loop mode, strain rates of up to 300 s^{-1} have been reported.

In contrast to mechanical impact devices, the rotary actuator shaft, specimen, and load transducer are initially attached (as in a standard test machine), and no transient mechanical engagement or impact is involved. This facilitates maintenance of coaxiality and alignment. However, the specimen still undergoes a rapid acceleration at the higher speeds, and inertial or resonance effects are still experienced by the load transducer.

Figure 2 illustrates a typical record of shear stress, τ , and shaft rotation, θ , as a function of time. The rotation is obtained from a rotary capacitance transducer that is attached to the bottom of the actuator shaft. The load transducer is a strain-gage element placed between the specimen and upper housing. Dynamic effects or “ringing” in the load signal are evident. Finite element analysis of the shaft, specimen, and load transducer

system can be used to ensure that the mean signal from the load transducer is an accurate representation of the shear stress in the specimen. The computed and measured stresses are compared in Fig. 2. Such dynamic analysis is often required for proper interpretation or verification of dynamic test procedures. The specimen geometry is similar to that used with torsional impact devices (thin-walled with a gage length of 3.2 mm, 6.4 mm inner radius $\theta_{\max} \approx 2.5$ radians).

Fig. 2 Comparison of computed response with experimental results for dynamic torsion test. Source: Ref 1

Such short specimens of $L/D = \frac{1}{4}$ are preferable for reading high strain at high-strain rates. In order to reach a stress and strain field as homogeneous as possible, longer gage lengths than the gage radius must be taken. An L/D ratio of 1 seems to be a minimum (Ref 2). An L/D ratio of 2 is better.

High Strain Rate Shear Testing

Torsional Impact Testing

Torsional impact loading methods have been used with a number of testing devices that were developed to test metals at strain rates up to about 10^3 s^{-1} (Ref 3, 4, 5, 6, 7). Early tests of this type used solid, round specimens. More recently, short, thin-walled tubular specimens in which nearly homogeneous stress and strain states can be achieved have been used.

The devices generally consist of a stationary supported specimen, initially uncoupled from the drive mechanism. The energy to deform the specimen is stored in a rotating flywheel and/or a drive shaft. The rotating system is brought to the desired angular velocity, and a release and engagement mechanism quickly couples the torsional load to the specimen.

Torsional impact systems require the following conditions:

- Alignment and concentricity of the specimen with the drive and engagement system
- Low inertia and high stiffness of the load train to minimize inertial effects and resonances during impact
- Adequate frequency response in the load-measuring and strain-measuring devices
- Sufficient energy in the drive system to maintain nearly constant strain rate in the test specimen during deformation

A typical torsional impact system is illustrated in Fig. 3. In this device, a commercial lathe bed and drive mechanism are utilized; however, the arrangement is typical of all torsional impact systems. The specimen is rotated in the chuck of the lathe, which has speeds from 500 to 2000 rpm. Other devices attach either the drive unit or the specimen to a flywheel, which is driven by a variable-speed motor. In either case, the drive unit is brought up to constant rotational speed before engagement of the specimen.

Fig. 3 Cross section of torsional impact machine. Source: Ref 4

When the rotational speed is established, a release mechanism (the trigger rod in Fig. 3) allows a compressed drive spring to engage the drive unit with the specimen by means of mated, tapered engagement beads. In the mechanical design of this type of device, alignment, coaxiality, and details of the engagement mechanism are important. An alternative to the arrangement in Fig. 3 consists of a stationary specimen and load cell and a rotating drive unit. Such an arrangement is described in Ref 4.

Torsional load is measured with a strain-gage elastic tubular element in the load train. The stiffness of this gage section should be as high as possible so that torsional resonances of the system induced by the impact on engagement do not produce excessive “ringing” in the load signal. These resonant frequencies are also governed by the total length of the load train between the rigid supports.

The mean shear strain rate, $\dot{\gamma}_m$, in the specimen is related to the angular velocity of the two ends of the specimen by:

$$\dot{\gamma}_m = \dot{\gamma}_a \frac{R_a + R_i}{2R_a}$$

where

$$\dot{\gamma}_a = \frac{Ra\dot{\theta}}{L} \quad (\text{Eq 1})$$

and where R_a and R_i are the outer and inner radii, respectively, and L is the length of the specimen gage section. Typical gage section dimensions are on the order of 3.2 mm (0.125 in.) in length, 6.4 mm (0.250 in.) in radius, and 0.76 mm (0.030 in.) in wall thickness. Thus, the shear strain rate is approximately twice the rotational speed of the drive mechanism.

Depending on the total angle of twist (θ) allowed, very large strains can be achieved, often in the range of $\gamma = 1$ to 5. Because such large strains generally are involved, the rotational velocity (either initial or transient) is used to determine strain rate (Eq 1) or strain. If the energy stored in the drive mechanism is large compared with the strain energy to deform the specimen, a nearly constant strain rate can be assumed to be proportional to the initial θ . Generally, direct strain measurements on the specimen are seldom made. Only Stiebler (Ref 2 and 3) has used strain gages; Meyer and Hahn have used strain gages as high-speed electro-optical devices. A photographic technique employing a drum camera to record the transient strain distribution in the specimen during deformation is described in Ref 4.

A significant aspect of dynamic torsion testing is the occurrence of plastic instabilities due to thermal feedback when the test conditions approach adiabatic deformation (Ref 2, 7, 8). For fully adiabatic conditions, the temperature rise, ΔT_a , in the specimen is given by:

$$\Delta T_a = \frac{k}{\rho C} \int_0^\gamma \tau d\gamma \quad (\text{Eq 2})$$

where τ and γ are the shear stress and strain, respectively; k is a proportionality constant (ratio of plastic work converted to thermal energy); ρ is density; and C is specific heat. Instability occurs when the thermal softening due to the adiabatic temperature rise overcomes the intrinsic strain-hardening capacity of the test material.

Observation of adiabatic shear instabilities in torsion test specimens are reported in Ref 2, 4, and 8. Depending on material properties and specimen geometry, such instabilities occur in the strain rate range from 10 to 10^3 s^{-1} . When instability occurs, sharp temperature and strain gradients may arise in the specimen. Transient measurement of these profiles is difficult, but post-test examination of the test specimen may reveal the existence of localized straining in the form of either deformation bands or, in some cases (e.g., steels), transformation bands (Ref 7, 8).

High Strain Rate Shear Testing

Torsional Kolsky (Split-Hopkinson) Bar

The torsional Kolsky bar is a reliable apparatus for testing materials in the 10^2 to 10^4 s⁻¹ strain rate regime (Ref 9). In general, the torsional Kolsky bar is well suited for conducting quasi-static and incremental strain rate tests, as well as dynamic strain rate tests. Thus, strain rate and strain rate history studies can be conducted using the same apparatus, thereby eliminating differences in test apparatus as a source of error in determining these effects. In the torsional Kolsky bar, a dynamic strain rate can be superposed on the quasi-static strain rate so that unloading does not occur, and the stress and strain rate increments can be measured directly for greater accuracy (Ref 10).

As previously noted, testing materials in torsion has some advantages over axial loading due to the absence of Poisson's ratio effects and geometric dispersion. When a torsional pulse travels along an elastic bar in its primary mode, all its frequency components have the same velocity. Hence, a torsional pulse initiated either by explosive detonation or by the release of a stored torque does not change its shape as it propagates toward the specimen. In Kolsky bar experiments, the absence of geometric dispersion in torsion means that a pulse initiated with a short rise time will maintain this rise time until it reaches the specimen, independent of the length of the Kolsky bar. Also, the torsional strain gage stations can be located as near or as far from the specimen as desired and still reveal the correct-shaped pulse incident on or reflected from the specimen. In an axial Kolsky bar, however, a gage placed too close to the specimen is subject to errors due to three-dimensional end effects, while a gage placed too far from the specimen produces unsatisfactory results because of geometric dispersion.

There is, however, a disadvantage in a non-dispersive pulse. If a torsional pulse is noisy when initiated (i.e., if some high-frequency components are superposed on the main pulse), this characteristic will be maintained, regardless of the length of the Kolsky bar. As a result, the strain rate imposed on the specimen will not be constant. In an axial Kolsky bar, such high-frequency components gradually disappear. Hence, an axial pulse tends to become flat—that is, tends to smooth out—as it travels along an elastic bar. A noisy torsional pulse such as that associated with explosive initiation of the pulse (Ref 11) will retain this characteristic; it will never become flat and, hence, will not provide deformation at a constant strain rate. As a result, for explosive initiation of a torsional pulse, a mechanical filter or pulse smoother is required to eliminate the high-frequency components. This type of device usually is not required when the torsional pulse is initiated by the stored-torque technique, because the amplitude is constant.

Torsional split-Hopkinson bar testing is described in more detail in the article “Torsional Kolsky Bar Testing” in this Volume. As in the case of pressure bar testing, values of torsional stress and strain in the specimen can be inferred from the measured records of the torsional strain in the incident and transmitter bars. These relations, which were first derived by Kolsky for the axial bar, can be transposed to shear values. In accordance with the analysis of Kolsky, the reflected pulse in a torsion bar provides a measure of the shear strain rate in the specimen $\dot{\gamma}(t)$ and, through a single integration, provides the shear strain in the specimen, $\gamma_s(t)$. The shear strain in the specimen is given by the difference in rotation between its two ends divided by its length:

$$\gamma_s = \frac{D_s\phi_1 - D_s\phi_2}{2L_s} \quad (\text{Eq 3})$$

where ϕ_1 and ϕ_2 are the angles of twist in the incident and transmitter bars, respectively; D_s is the mean diameter of the thin-walled specimen; and L_s is its length. The value of ϕ_2 can be determined from the shear strain measured at the surface of the transmitter bar through:

$$\gamma_T = \frac{D}{2} \frac{\partial \phi_2}{\partial x} = \frac{D}{2c} \frac{\partial \phi_2}{\partial t}$$

where D is the diameter of the Kolsky bar, and $c = \sqrt{G/\rho}$ is the torsional velocity in the Kolsky bar. As a result:

$$\phi_2 = \frac{2c}{D} \int_0^t \gamma_T(t) dt \quad (\text{Eq 4})$$

Similarly, ϕ_1 can be determined from the difference in strains due to the incident and reflected pulses:

$$\phi_1 = \frac{2c}{D} \int_0^t [\gamma_I(t) - \gamma_R(t)] dt \quad (\text{Eq 5})$$

where the negative sign is necessary because the reflected pulse travels in the $-x$ direction. If Eq 3 is differentiated and Eq 4 and 5 are utilized:

$$\dot{\gamma}_s(t) = \frac{c}{L_s} \frac{D_s}{D} [\dot{\gamma}_T(t) - \{\dot{\gamma}_I(t) - \dot{\gamma}_R(t)\}] \quad (\text{Eq 6})$$

where the strains are all functions of time. For a homogenous state of strain in the specimen, the transmitted pulse is the difference between the incident and reflected pulses, so that $\gamma_T = \gamma_I - (-\gamma_R)$ and hence:

$$\dot{\gamma}_s(t) = \frac{2cD_s}{L_s D} \dot{\gamma}_R(t) \quad (\text{Eq 7})$$

Because $\dot{\gamma}_R$ is determined from the output of the strain gages on the incident bar during passage of the reflected pulse and because all other quantities in Eq 7 are known, it provides a measure of the strain rate in the specimen as a function of time. The signal is integrated electronically to yield $\gamma_s(t)$, which is the strain in the specimen. Kolsky also showed that the transmitted pulse provides a direct measure of the average shear stress in the specimen, $\tau_s(t)$. For a thin-walled tube in torsion, the stress is given by:

$$\tau_s = \frac{2T_s}{(\pi D_s^2) t_s} \quad (\text{Eq 8})$$

where t_s is the wall thickness, and T_s is the average torque. The average torque in the specimen is also given by the average of the torques at each of its ends:

$$T_s = \frac{1}{2}(T_1 + T_2) \quad (\text{Eq 9})$$

where T_1 is the torque at the interface with the incident bar, and T_2 is the torque at the interface with the transmitter bar. The former is given in terms of the strain at the surface of the bar—that is, by the strain in the incident and reflected pulses—by $T_1 = G(\gamma_I + \gamma_R)\pi D^3/16$. For the homogeneous state of stress in the specimen, $\gamma_I + \gamma_R \approx \gamma_T$ so that:

$$\tau_s(t) = \frac{GD^3}{8} \frac{\dot{\gamma}_T(t)}{D_s^2 t_s} \quad (\text{Eq 10})$$

Thus, Eq 7 and 10 provide stress and strain in the specimen as functions of time. Eliminating time yields the stress-strain curve for the material at the strain rate provided through Eq 7.

High Strain Rate Shear Testing

Double-Notch Shear Testing and Punch Loading

Kolsky or split-Hopkinson bar testing in compression, tension, or torsion is governed by an upper limit (on the strain rate that can be achieved) of approximately 3000 s^{-1} . However, situations arise where strain rates of several orders of magnitude greater than this limit are expected, such as in high-speed metal forming operations or around rapidly propagating cracks. Attempts have thus been made to modify the Kolsky bar technique for use at strain rates in this range.

The most common method involves a drastic reduction in the effective gage length of the specimen, either by the use of a miniaturized version of the Kolsky bar, which is generally associated with an increase in the velocity of impact (Ref 12, 13, and 14), or by the use of specialized specimen designs. Two examples of specialized specimen designs are the double-notch shear test and the high-speed punching test. In both, the specimen material is subjected to a high rate of shear.

High Strain Rate Shear Testing

Double-Notch Shear Testing

In double-notch shear testing, the output bar is replaced by a tube into which the input bar can slide (Fig. 4). The lower end of the input bar and the upper end of the output tube are slotted to accommodate the thin plate specimen (see Fig. 5) into which two pairs of notches have been cut. With an effective gage length in this specimen of 0.84 mm (0.033 in.), a maximum shear strain rate of $40,000 \text{ s}^{-1}$, an order of magnitude greater than that reached in the standard Kolsky bar apparatus, has been achieved (Ref 15, 16).

Fig. 4 Kolsky bar apparatus for double-notch shear testing at very high strain rates

Fig. 5 Double-notch shear specimen

The principal disadvantage of this technique is that at shear strains greater than about 20%, the specimen ceases to deform in pure shear. Reliable results can only be obtained at relatively low values of shear strain (Ref 17). Because about 20 μ s are required for a constant strain rate to become established, results obtained at low strains can only be associated with an average value of strain rate.

High Strain Rate Shear Testing

Punch Loading

This version of the Kolsky bar is similar to the modification described above. In punch loading, however, the specimen is a flat plate in which a circular hole is punched. A typical setup is shown in Fig. 6. Although the clearance between the punch bar and the die tube is about 0.025 mm (0.001 in.) in Fig. 6, the effective gage length—that is, the width of the shear zone in an actual test specimen—was found to be considerably greater. The width of the shear zone is not very clearly defined, so in this case the quoted shear strains and strain rates are only approximate. Estimates of the effective gage width for the test may be made by optical microscopy with microhardness traverses across the shear zone or by comparing a derived shear stress/shear strain curve

based on an assumed gage width with the results of a conventional torsion test at a similar strain rates. Using this technique, shear strain rates in excess of 10^4 s^{-1} have been obtained (Ref 18).

High Strain Rate Shear Testing

Shear Testing with Hat-Shaped Specimen

L.W. Meyer and L. Krüger, Materials and Impact Engineering at Technical University Chemnitz and Nordmetall GbR, Germany

A special type of shear test configuration involves the use of a hat-shaped specimen to evaluate shear deformation and failure of metallic materials from high shear deformation at high strain rates (Ref 19, 20, 21, 22, 23, 24, 25, 26 27, 28, 29, 30). In this method, the material is forced to shear when a hat-shaped specimen is compressed in a Hopkinson bar or drop-weight machine. Depending on the material properties, broad or narrow shear areas develop, which may lead to a localization or concentrated adiabatic shear failure. The main advantage is that the shear tests can be stopped at any point of deformation, and the subsequent microstructures developed can be investigated in detail (Ref 21, 22, 23, 24, 25, 26, 27, and 28). Shear stress and work of deformation can also be estimated, because the force and displacement during shearing are measured (Ref 30, 31).

High Strain Rate Shear Testing

Test Setup and Operation

The test setup (Fig. 7a) (Ref 19, 30) is a specimen placed between the input and output bars. To reduce ringing effects during the shear test, a small lead or copper disc of 3 to 5 mm (0.12 to 0.20 in.) in diameter and 0.25 to 0.5 mm (0.01 to 0.02 in.) thickness is placed in between the striker bar and the input bar (Fig. 7b). This creates a trapezoidal or ramp-shaped input wave, which reduces the Pochhammer-Chree ringing (Ref 29, 30). The force applied to the sample is measured by strain gages on the output bar, and specimen displacement is measured with a precise high-speed electrooptical camera system. The force-time ($F-t$) and displacement-time ($s-t$) signals are recorded, and stress measurements are calculated from the transmitted and reflected elastic waves in the bars.

Fig. 7 Test setup for shear testing with hat-shaped specimen. (a) Specimen placed between input and output bar. (b) Detail of pulse shaper

Test Specimen. The specimen is machined from one piece in a cylindrical form and consists essentially of a tube on one side and a bar on the other side (Fig. 8). The region between the tube and bar section is the shear area (Fig. 8). To investigate the development of the shear-band formation and to stop the shear displacement at any desired stage, it is beneficial to use spacer rings of different thicknesses while testing (Fig. 9). This use of spacer rings allows the manufacturing of one fixed (or standard) specimen geometry for different test levels of shear displacement. Regarding the thickness of the spacer rings and the cut in width of the hat-shaped specimen

(E in Fig. 8), the possible shear displacement (Δs) is predetermined before the test. The advantage of this geometry and testing procedure is the symmetry in the left and right regions of the shear zone. Without the same properties of the material and the same geometry, the shear stresses inside and around the shear zone would have an asymmetrical distribution (Ref 32).

Fig. 8 Hat-shaped specimen to produce shear deformation under axial compression loading. All dimensions are in millimeters.

Fig. 9 Detail of loading with spacer ring for controlled shear displacement

The stress state in the plastic deformation region is fairly close to simple shear, and plastic strain is approximately equal to the ratio between the shear displacement and the thickness of the plastically deformed band. The stress pulse, produced by impacting the incident bar, generates controlled plastic shear deformation in the shear area (Fig. 9), while the rest of the specimen undergoes elastic deformation. The mean shear stress, τ , is estimated by the force, F , divided by the area of resisting shearing:

$$\tau = \frac{F}{\pi h \left(\frac{d_i + d_e}{2} \right)}$$

where d_i and d_e are the internal and external diameter, respectively, and h is the height of the area of the shear zone in the axial direction (Ref 27).

The shear strain γ can be determined from the ratio of the controlled displacement, δ , and the width of the shear band, x :

$$\gamma = \frac{\delta}{x}$$

and as shown by Andrade (Ref 25), the shear strain γ can be related to the uniaxial strain (Ref 33):

$$\varepsilon = \ln \left(\frac{\gamma^2}{2} + \gamma + 1 \right)^{1/2}$$

Using this test setup, it is possible to study microstructural changes just before and just after the initiation of the instability, even in the range of $\Delta s/h$ displacement ratios on the order of a hundred or more (Ref 19, 26, 27, 31). The onset of localized deformation is evident from the drop in the shear stress displacement diagram. This is shown schematically in the output graph in Fig. 10. Depending on the properties of materials, the drop may be very sharp (Fig. 10) or may be less sudden (Fig. 11). The influence of strain rate on strength and deformability under hat-shaped configurations is shown in Fig. 10. The statically loaded material exhibits a deformability of about 0.5 mm or 50% shear strain. Under dynamic loading in the same geometry, the deformability is reduced to low amounts (about 10% of the static values). In general, this can be interpreted as a velocity-induced “embrittlement,” expressed by the drastic reduction of energy absorption. Locally, very high shear strains are observed, and the shear strain rates are evaluated by means of micrographs of the measured thickness of the shear zones and the velocity of shear displacements. For the CrMoV steel, a strain rate $\dot{\varepsilon} = 10^5 - 10^6 \text{ s}^{-1}$ within shear band widths of approximately 5 to 10 μm is calculated.

Analysis of Shear Zones

The hat-shaped specimen is a suitable configuration to investigate the evolved microstructure and to compare materials under shear loading. For example, Pintat et al. (Ref 34, 35) analyzed the influence of predeformation and grain size on the work of deformation during shearing of two plain carbon steels (Ck 10, Ck 45) with 0.1 and 0.45 wt% C content. The energy consumption of the shear process was estimated by the integral of the force/displacement curve. With increasing predeformation or strain rate, the shear failure occurred at minor displacements, limiting the absorbed work of deformation. Furthermore, the work of deformation decreases with increasing shear rate.

Many investigators have also used this specimen to investigate the hardness, size, and shape of shear zones in different materials (e.g., Fig. 12) and the change in microstructure during shearing (Ref 21, 23, 31, 34, 36, and 37). For example, Beatty et al. (Ref 31) showed that 4340 steels with the same hardness but different distributions of carbon absorb varying amounts of energy. They analyzed adiabatic shear bands in 4340 steel, finding a structure of a large number of micrograins with grain sizes between 10 and 50 nm (Ref 31).

High Strain Rate Shear Testing

Drop-Weight Compression Shear Testing

L.W. Meyer and L. Krüger, Materials and Impact Engineering at Technical University Chemnitz and Nordmetall GbR, Germany

The distribution of stress and strains in materials is often inhomogeneous when materials are subjected to high strain rates and strains in various situations such as high-speed cutting, forging processes, ballistic impact, and crash behavior of structures. These very complex loading conditions at high strain rates may lead to localized regions of increased shear deformation (Fig. 13); when heat cannot be dissipated at high strain rates, adiabatic shear bands may develop, depending on the strain rate and the thermal properties of a material. For example, titanium alloys are very susceptible to adiabatic shear failure even under uniaxial dynamic compression loading. In contrast, sintered or sintered and swaged tungsten alloys are less sensitive to adiabatic shear failure (Ref 38), although shear localizations are observed in the tip of tungsten penetrators. Thus, conditions exist where even tungsten alloys may fail by adiabatic shear.

Fig. 13 Localized shear deformation band in tungsten alloy W90

The susceptibility to adiabatic shear failure under pure shear loads can be examined by dynamic torsion tests on tube specimens (Ref 39, 40, 41, 42) and shear tests using hat-shaped specimens (Ref 19, 21, 22, 23, 24, 25, 26, 27, 28, 31, 32, 33, 34, 35, 36, 43, 44, and 45). The torsion test allows the determination of stresses, shear strains, and strain rate conditions in a thin cross section at the initiation of adiabatic shear failure. The hat-shaped specimen method, as previously described in this article, has the advantage of applying very high strains and very high strain rates and, by geometry, can produce narrow shear bands, even in materials not susceptible to shear band formation. The disadvantage of the hat-shaped specimen method is that the stress concentration at both sides of the shear plane prevents a local stress determination.

It is also known that adiabatic shear failure occurs in uniaxial compression tests (Ref 46, 47, 48). This is observed mostly in high-strength materials like thermomechanically treated steels, titanium alloys, or ultrahigh-strength steels. Additionally, in most impact applications, pure shear or compression stress states are few. This leads to a necessity for biaxial dynamic loading systems that allow reproducible experiments under defined stress conditions of solid specimens instead of thin tubes (Ref 49, 50, and 51). This approach has been developed based on drop-weight testing with high strain rates as a way to evaluate the materials sensitivity or susceptibility for adiabatic shear failures. The advantage of the drop-weight testing (in contrast to typical Hopkinson setups) is that large amounts of stored energy can be applied, so that the strain-rate history is not influenced by the strain hardening of the test material under compressive and compression/shear loading. The drop-weight method also allows high strain testing of $\frac{3}{4}$ in. (20 mm) cross sections, even of high-strength materials. This may be of interest if there are geometry-dependent gradients in the hardness or stress-strain behavior.

High Strain Rate Shear Testing

Test Setup and Operation

A drop-weight tower consists essentially of a heavy weight that drops on a specimen placed on an anvil (Fig. 14). The frame (A) and all other parts of the test setup are of high stiffness, and the weight is guided in a special ball-bearing system in order to ensure a precise alignment of the hammer. Below the weight, a small tup is fixed to give a precise loading condition. To measure the load time history, calibrated strain gages are glued on

the top. The displacement can be measured with both a high-speed electro-optical camera and a light gate system from which the strain rate can be calculated. All measured data are amplified and stored in a fast oscilloscope. Special stopping devices and high-speed brakes allow evaluation of test results including recovery tests at any stage in the deformation history. The strain-rate limit is about 200 s^{-1} , compared to strain rates of about $2 \times 10^3 \text{ s}^{-1}$ for Hopkinson-bar methods (Ref 51).

High Strain Rate Shear Testing

Application and Analysis of Results

Drop-weight testing is a method for high strain rate compression testing that can produce combined compression-shear loading by using cylindrical specimens with a relatively small inclination angle along the loading axis of up to 10° (Fig. 14). This type of specimen configuration leads to nearly the same compressive stress distribution but applies additional shear stress. For example, an inclination of 3° to the loading axis gives an additional shear loading of 5.2% of the axial compression load (Fig. 15). Compared to the hat-shaped specimen with its shear forcing geometry, the inclined cylindrical specimen geometry just “offers” a dynamic biaxial stress state, and the material responds with its own specific behavior of sensitivity to adiabatic shear failure. Therefore, with this testing procedure, the tendency of failure under adiabatic shearing can be successfully evaluated under high-rate biaxial compression-shear loading. With the aid of stopping devices (Fig. 14), the history of the shear band development also can be explored thoroughly.

Fig. 15 Ratio of shear load to compressive load as a function of specimen inclination to the loading axis

The general effect of shear-band formation on uniaxial compression behavior is shown in Fig. 16 and 17. At low strains, the compressive stress-strain behavior is nearly the same for uniaxial and biaxial conditions. At high strains, however, biaxial loading leads to a turning point (point A in Fig. 17) and a stress maximum (B in Fig. 17). This behavior is explained by the development of shear bands (Ref 49). Depending on the material behavior, the subsequent adiabatic shear failure follows immediately or after few percent of strain (point C in Fig. 17). For example, Fig. 16 plots the dynamic compressive stress-strain behavior of a sintered and swaged tungsten alloy. Under (pure) compressive loading, the material can be compressed to high amounts of deformation without any shear bands or cracks. With the increase of an additional stress component in shear, the compressive strength and deformation behavior is changed beyond $\tau/\sigma = 7\%$. At a loading state of $\tau/\sigma = 10.5\%$, the adiabatic shear failure leads to a sharp reduction in axial deformation of about 30%. A further increase of additional shear stress causes a failure at 20% axial deformation.

Fig. 16 Engineering compression stress-strain behavior of a swaged tungsten (W-Ni-Co-Fe) alloy cylindrical specimen with inclination to the loading axis varying between 0 and 10°

Fig. 17 Typical behavior of engineering compression stress and axial deformation under a biaxial compression-shear load

In order to evaluate the influence of the biaxial compression-shear loading, data were developed for tungsten alloys and a high-strength, α - β titanium alloy, Ti-62222Si (Ti-6Al-2Sn-2Zr-2Mo-0.25Si). The titanium alloy was tested at room temperature under a wide range of strain rates. Under quasi-static loading, the material failed at about 32% compressive deformation with a nearly homogeneous distributed deformation around the 45° shear plane (Fig. 18). With increasing strain rates to 10^2 s^{-1} and 10^3 s^{-1} , the deformability is limited by adiabatic shear failure. The compressive deformation is reduced to about half of that under quasi-static loading. With increasing inclination of the specimen at $\dot{\epsilon} = 200 \text{ s}^{-1}$, the increase in the ratio of shear to compression stress leads additionally to both a strong reduction of the deformability and compressive strength (Fig. 19).

Fig. 18 Deformability behavior under pure compressive loading as function of strain rate for titanium alloy Ti-62222Si. Open circles, failure under stable plastic flow; solid circles, failure with adiabatic shear bands

Fig. 19 Effect of shear-compression stress ratio on the compressive strength and deformability of titanium alloy Ti-62222Si with initial strain rate of about $2 \times 10^2 \text{ s}^{-1}$

Figure 20 shows a comparison of the deformability of different materials as a function of induced stress state under dynamic loading of about 200 s^{-1} for titanium alloy Ti-6Al-4V and four tungsten-heavy alloys in different heat treatment and swaging conditions. The state of deformation just prior to failure is indicated by the symbols in the figure. The open symbols represent a nearly uniform broad strain distribution in the specimen without any additional cracks or strain concentrations. The diamonds with a cross inside represent the first occurrence of a crack in the specimen, such as small tensile or shear cracks or shear failure over a broad shear zone. Solid symbols indicate sharp and concentrated, nonuniform strain distribution where failure occurs by adiabatic shear. The size was 6 mm in diameter and 6 mm in height.

Fig. 20 Compressive deformation versus the biaxial shear-compression load ratio for titanium alloy Ti-6Al-4V and several tungsten alloys (see text). Open symbols: uniform deformation, no cracks, no failures; symbols with a cross inside: first tensile or shear cracks, (normal) shear failure (not concentrated); solid symbols: adiabatic shear failure

Tungsten alloy A (diamond symbol) is used in a sintered condition and reaches the highest deformation. Under uniaxial compression, this material can be compressed beyond 70% deformation without shear failure. First

shear cracks appear at 45° to the loading axis. Under a combined compression/shear loading with 15 ° inclination to the loading axis, only 23% axial strain is required for a broad (but not concentrated) shear failure. At 10° inclination and 34% axial strain, the test was stopped. Investigation of the deformed microstructure in the sample revealed that no cracks had appeared. The width of the shear band was about 0.5 mm in thickness. Response of tungsten alloy B (in the sintered and swaged condition and plotted with square symbols) shows a different failure behavior. Under pure uniaxial dynamic compression, the evolution of small cracks was detected on the surface. With the influence of combined shear stress, the compressive deformation to failure is reduced. At a loading of $\tau/\sigma = 5.2\%$ (3° inclination to the loading axis), one adiabatic shear failure at 34% axial deformation was measured in a group of three tests. At $\tau/\sigma = 10.5\%$ or 6 ° inclination, all three specimens failed by adiabatic shear at around 20% deformation. With further increase in additional amount of shear stress, the compressive deformation to failure decreases continuously without any change in failure mode. This diagram demonstrates that the method employed can distinguish between different materials as well as between materials within the same group.

Stopping devices also make it possible to arrest the dynamic test at any point of deformation. This possibility allows the recovery and subsequent analysis of the evolution of shear-band formation and shear-failure development by means of optical or transmission electron microscopy. For example, metallographic examination of Ti-6Al-4V (Ref 49) revealed that the beginning of the adiabatic shear formation leads to a decrease of the slope of the stress-strain curve. With the use of stopping devices, an intermediate stage of the developing shear band is shown (Fig. 13).

High Strain Rate Shear Testing

Thick-Walled Cylinder Testing

Vitali F. Nesterenko, Department of Mechanical and Aerospace Engineering, University of California, San Diego

The thick-walled cylinder (TWC) method is used for high strain rate testing of solid materials (Ref 52, 53, 54, 55, 56) and porous mixtures (Ref 57, 58). Figure 21 shows the basic experimental configuration used to produce the radial collapse of the metallic specimens. The system uses the controlled detonation of an explosive to generate the pressures required for the collapse of metallic samples. The specimens are placed within a copper jacket (copper-driver tube); the system extremities are composed of steel plugs. Annealed polycrystalline oxygen-free high-conductivity copper with grain size 100 μm or less was chosen as a driver because of the high resistance of this material to shear localization. Stopper tubes of copper can be used inside the hollow specimen to decrease strain. Driver and stopper tubes can also be constructed from tantalum, which can dissipate more energy during collapse.

Fig. 21 The basic experimental setup for explosion-driven collapse of a metallic sample

The TWC method is a valuable technique because it allows testing under conditions more complex than uniaxial conditions. Practically all applications under high strain rates involve either two-dimensional or three-dimensional deformation. With the exception of the before-mentioned shear-compression test, the Taylor impact test, the tensile/torsion tests of Stiebler (Ref 2, 3), other shear and torsional tests, and cavity expansion experiments by Klopp and Shockey et al. (Ref 59), most high strain rate testing is uniaxial.

Multiaxial testing is useful in the evaluation of localized regions of high deformation such as shear bands (Ref 60, 61, 62). The observations of shear bands under controlled strain conditions is very important for comparison of material behavior. The role of pressure is very important for localization in solid materials, and the strain-controlled TWC method is well suited for this application. An important feature of this method is that a relatively large amount of material is in the state of pure shear before the start of instability. This provides conditions for spontaneous shear localization, which is different, for example, than “forced” localization in the hat-shaped specimens method (Ref 63) discussed previously in this article.

Plastic flow of single crystals at high strains, and high strain rates is another example where the symmetry breakdown due to crystal structure can result in complex three-dimensional flow, which has been analyzed through numerical modeling and experiments (Ref 64). High strain rate flow of damaged ceramics also requires three-dimensional tests, because it involves localization of deformation on early stages of flow (Ref 65, 66) and, as a result, a broken symmetry of any initially symmetric one-dimensional or even two-dimensional configuration. The development of computational models for the flow of fragmented ceramics under armor penetration conditions, like the FRAGBED model by Curran, Seaman, Cooper and Shockey (Ref 67, 68) needs adequate support by three-dimensional experiments. Especially important are experiments that may allow separation of the volume distributed and the deformation localized inside shear bands (Ref 69, 70). The experimental validation of this type of modeling needs tests that subject prefractured ceramics to high strain, high strain rate compressive flow with controlled conditions and with the ability to recover the heavily damaged ceramics with very small postevent deformation. The last condition is very important because it allows the test to reveal the brittle fracture details of contacting ceramic particles and microstructural features of localized flow—such as shear-induced dynamic sintering of SiC within shear bands for fine particle size/granular material (Ref 71).

High Strain Rate Shear Testing

Test Setup

As previously noted, the basic setup is configured for radial collapse of metallic specimens. The system uses the controlled detonation of an explosive, which is placed coaxially along with the specimen. Detonation is initiated at the top, propagating along the cylinder axis. The explosive parameters in the TWC method (detonation velocity, density, and thickness) are carefully selected to provide a “smooth” pore collapse. The geometry of the experiment should be such that implosion should be practically stopped due to the dissipation processes inside the sample and driver tube. Wave reflection effects are minimized, and spalling of the internal cylinder surface is nonexistent. A low-detonation explosive (detonation speed, $D \approx 4000$ m/s, or 13,100 ft/s) with low initial density (0.9 to 1 g/cm³) is typically used. A description of the method can be found in Ref 69, 70, 71, and 52, 53, 54, 55, 56, 57, 58. The velocity of the inner wall of the tube is measured by an electromagnetic gage placed in the center of a cavity collapsing in external magnetic field (Ref 54, 55).

The collapse also can be driven by impulse magnetic field with detailed measurements of collapse geometry. The great advantage of this type of driver is the minimization of axial movement and very well-controlled boundary conditions represented by magnetic field (pressure) history on the outside surface of the driver tube. The results obtained with this method for thin aluminum alloy shells (Ref 72) as well as for thick-walled titanium and 304 stainless steel cylinders (Ref 73) are very encouraging. For example the dynamic of collapse of the titanium and stainless steel cylinders was apparently different, despite the domination of total mass of the assembly by the copper driver. That may be associated with damage induced by earlier shear localization in titanium.

A simple model to calculate the kinematics of implosion driven by explosion can be used with the assumption of instantaneous detonation. This assumption is applied because the velocity of the collapse is more than an order of magnitude less than the detonation speed. In this model, the initial conditions in the detonation products correspond to the uniform pressure, P_D ; density, ρ_D ; and sound speed, c_D , as follows:

$$P_D = \frac{\rho_o D^2}{k+1} \quad \rho_D = \frac{\rho_o (k+1)}{k} \quad c_D = \frac{k}{k+1} D$$

where ρ_0 is the initial density of explosive, D is the detonation speed, and k is the coefficient in the polytropic law for detonation products. The dependence of sound speed, c , on current density, ρ , in expanding detonation products has the following form:

$$c = c_D \left(\frac{\rho_D}{\rho} \right)^{1-k}$$

Material of the cylinder is considered to be incompressible and elastic-plastic with strain, strain rate, and temperature-dependent strength. This approach results in excellent agreement of calculations with measured time of collapse $8 \mu\text{s}$ for standard conditions of testing where the outside diameter of explosive was 60 mm (2.4 in.), the inside diameter was 30 mm (1.2 in.), $D = 4000 \text{ m/s}$ (13,100 ft/s), $\rho_0 = 1000 \text{ kg/m}^3$, and $k = 2.5$.

Test Factors

The implosion of relatively thin shell results in flow instability of geometrical nature (Ref 74, 75, 76, 77). In conditions of thick-walled cylinder experiments, the number of waves due to the growth of small perturbations on the inner wall caused by this geometric instability (any departures from circular form and uniform velocity grow during collapse) can be evaluated and is less than 1. The geometry of the TWC method is selected in such a way that material instability breaks the symmetry of the cylindrical collapse, resulting in shear localization.

The state of strain generated within the collapsing cylinder is one of pure shear before shear localization starts. This is shown in Fig. 22, in which the distortion of an elemental cube at radius r_o is followed as it moves toward the axis of the cylinder. There is no rotation of the elemental cube. The strain in the axial direction of the cylinder is zero, and the planes of maximum shear lie at 45° to a radius, as indicated at r_o in Fig. 22. In pressure insensitive materials, the planes are also inclined at 45° to the cylinder axis. The strains for material points being collapsed to different final radii r_f , are depicted on Fig. 23 for the initial inner and outer radii of a sample 7 and 10.5 mm (0.28 and 0.41 in.) respectively. Each line designates the strain of a material point as it converges inward. The extremity of the line designates the radius and strain of the inside surface of a sample with radius after collapse R_f equal to 3.1 and 4.3 mm (0.12 and 0.17 in.). As the tube collapses inward, the inner surfaces experience increasing strains as the final radius of the cavity (R_f) approaches zero.

Fig. 22 Geometry of pure shear in incompressible thick-walled cylinder under uniform plastic deformation. r_o and r_f are initial and final radii of element. Source: Ref 78

Fig. 23 Effective strain in titanium sample as a function of final radius of element r_f in partially collapsed geometry for two configurations with final inner sample radii R_f equal to 3.1 and 4.3 mm (0.12 and 0.17 in.)

Strain Rates. The main step in establishing strain rates is connected with determination of velocity field in the sample. The radial velocity of the cylindrical cavity $v(t)$ can be measured by an electromagnetic technique (Ref 54, 55). The insertion of samples from different materials inside a copper driver tube does not significantly change the time of collapse in comparison with the uniform copper cylinder having the same geometrical dimensions. This is because the replacement of the central part of copper by sample material does not essentially change the overall mass, which is dominated by the mass of outside copper (and initial velocity) of the assembly. That is why the velocity data obtained for a monolithic copper cylinder can be used as a first approximation to calculate the strain rate. Figure 24 shows the shear strain rates during the collapse process for two points corresponding to two values of final radii, which are the ends of shear bands in titanium. The strain rate is seen to fluctuate around corresponding mean values, and the variation ($\pm 15\%$) is not significant. That is why, to a first approximation, the strain rates for these material points can be considered as constant and equal to $3.5 \times 10^4 \text{ s}^{-1}$ and $6 \times 10^4 \text{ s}^{-1}$.

Fig. 24 Shear strain rate versus time in titanium sample as a function of final radii of element r_f . Source: Ref 78

Stresses in the TWC method are found experimentally or are based on the measured kinematics of implosion and corresponding constitutive equations. The situation is the same as in the impact rod (Taylor) test. The advantage of the TWC method is that it involves a very simple state of strain (pure shear during uniform flow and plane strain after instability starts). Also in the TWC method, stress gages can be used more effectively for

the same reason. Although the main dynamic input to stresses is from inertial effects due to the gradient of particle velocity in the cylinder, the effect of dynamic stresses on shear localization in solid materials can be neglected to a first approximation. In general, the distribution of stresses during implosion depends on material strength and cannot be controlled in this method. Therefore, numerical modeling should be used to extract the stress field during the collapse process. Two-dimensional models reflecting plane-strain conditions can be successfully applied, predicting the stress field and the relatively complex shape of the cavity (Ref 68, 79).

High Strain Rate Shear Testing

Advantages and Limitations

The TWC method allows investigation of the material instability during the high-strain flow. The use of a TWC (with a ratio of cylinder-wall thickness to hole diameter of approximately 1) is very important for reproducible tests involving instability phenomena. A thick wall stabilizes the symmetry of implosion and creates macroscopically uniform boundary conditions, even when instability breaks symmetry at the internal parts of the setup.

Internal patterning induced by deformation in this method can also be clarified, depending on the precise control of overall strain due to the developed, simple “soft” self-recovery setup. This allows comparative analysis of the stages of shear localization in solids, chemical reactions, and deformation localization in ceramics in high strain rate deformation. Also, it allows investigation of material instabilities from implosion phenomena.

The TWC method could benefit from several improvements in the technique, such as these:

- In situ measurements of stresses during the collapse process, at least during the stage of uniform flow before instability
- Development of driver systems (such as magnetically driven systems) with greater precision during implosion to reduce the axial component of strain
- Development of continuous measurements of the kinematics of inner and outer surfaces of the assembly
- Methods to investigate the influence of boundary conditions on shear instability
- Methods to investigate nucleation sites using high-quality interfaces between the sample and the stopper tube

High Strain Rate Shear Testing

Pressure-Shear Plate Impact Testing

Pressure-shear plate impact testing is a procedure that is used to obtain stress-strain curves at the highest strain rates attainable under well-characterized loading conditions (Ref 80). Shear strain rates on the order of 10^5 s^{-1} are obtained for specimens thinned to thicknesses of about 0.2 mm (0.008 in.). Even higher strain rates, up to 10^7 s^{-1} , can be obtained for very thin specimens (with thicknesses of 2.5 μm) prepared by vapor deposition. In addition to providing high strain rates, this type of testing provides simple shearing deformation and controllable levels of nearly hydrostatic pressure.

Pressure-shear plate impact testing is limited to fine-grained materials, because the grain size must be small compared to specimen thickness to ensure that a representative average polycrystalline response is measured. The specimen material should also be soft relative to the plate materials used to impose the deformation so that these plates will remain elastic under the impact loading conditions.

Pressure-shear experiments require a plate impact facility and instrumentation for measuring the shear waves that are generated by pressure-shear impact. Such experiments are lengthy because of the time required for specimen preparation. Although these limitations restrict the materials that can be studied and the facilities that can perform the testing, the scientific and technical importance of understanding the plastic response of metals at strain rates up to 10^5 s^{-1} and above necessitates further development of the technique. The method has been used successfully to obtain dynamic stress-strain curves of several face-centered cubic and body-centered cubic metals at strain rates of 10^5 s^{-1} and higher.

The method is based on concepts drawn from plate impact experiments and Kolsky bar experiments. From the former is taken the concept that plane waves should be used in experiments designed to measure dynamic material properties to simplify the interpretation of experimental results by making a one-dimensional wave theory applicable. Plate impact experiments also provide the methodology and instrumentation required for conducting such experiments. From Kolsky bar experiments is taken the concept of sandwiching a thin, soft specimen between two hard, elastic materials in order to sustain high strain rates in the specimen and to allow its response to be determined from measurements of wave profiles in the elastic materials. These measured profiles are related to the stresses and nominal strain rates in the specimen by one-dimensional elastic wave theory.

The pressure-shear loading configuration was introduced originally as a means of generating shear waves in symmetric plate impact experiments involving the impact of two plates of the same material. Shear waves are used, because shear wave profiles provide a more sensitive indication of the dynamic plastic response of materials than do longitudinal waves generated in conventional normal impact of plates. Shear waves have been

generated by the impact of parallel plates inclined relative to their direction of approach (Ref 81, 82) and by the normal impact of an anisotropic elastic plate of y -cut quartz (Ref 83, 84). Shear wave profiles have been monitored by means of a transverse displacement interferometer (Ref 83), two normal-velocity interferometers (Ref 85) with beams at nonnormal incidence (Ref 84), and, for nonmetallic targets, an embedded electromagnetic gage (Ref 82).

Pressure-shear waves have been used to study the plastic response of 6061-T6 aluminum (Ref 84, 86, 87, 88) and alpha-titanium (Ref 46). These studies are important because of the greater sensitivity of the shear wave profiles to the plastic flow characteristics of materials and because of the information they provide on the effects of nonproportional loading on the dynamic plastic response of materials. However, as with other wave propagation experiments, limitations include the fact that the constitutive relation between stress, strain, and strain rate is not obtained directly but must be inferred by comparison of the recorded wave profiles with those predicted for various assumed constitutive models.

Another limitation of plastic wave propagation experiments is that, although high shear strain rates are generated near the impact face, the recorded wave profiles are determined primarily by plastic response of the material at remote positions where the wave profiles have spread and strain rates have decreased. Both of these drawbacks to pressure-shear wave propagation experiments are overcome in the high strain rate pressure-shear plate experiment.

The following is a brief description of the basic concepts of plate impact tests. More detailed discussions are in the article "Low Velocity Impact Testing" in this Volume.

Basic Concepts

High strain rate pressure-shear impact testing is performed by impacting a thin, soft specimen plate with a hard, elastic flyer plate inclined at an angle, θ , as shown in Fig. 25. The thin specimen plate is backed by a thick elastic anvil plate, which creates a state of high pressure and high shear strain rate in the thin specimen. Because the flyer and anvil plate remain elastic during the experiment, the stresses in the elastic plates can be inferred by measuring the projectile velocity and the particle velocity at the rear surface of the anvil plate.

Fig. 25 Schematic representation of high strain rate pressure-shear impact configuration. u_0 is the initial velocity of the flyer plate in the normal direction, and v_0 is the initial velocity of the flyer plate in the transverse direction. V_0 is the projectile velocity and θ is the flyer plate angle.

During early stages of the test, before release waves reach the center of the plate from the periphery, one-dimensional wave theory applies. All states at the impact face of an elastic flyer plate must satisfy the following characteristic relations (Ref 89):

$$-\sigma + \rho c_1 u = \rho c_1 u_0 \quad (\text{Eq 11})$$

$$\tau + \rho c_2 v = \rho c_2 v_0 \quad (\text{Eq 12})$$

All states at the impact face of an elastic anvil plate must satisfy:

$$-\sigma - \rho c_1 u = 0 \quad (\text{Eq 13})$$

$$\tau - \rho c_2 v = 0 \quad (\text{Eq 14})$$

where σ is the normal stress in the x -direction, τ is the shear traction in the transverse direction, ρc_1 is the longitudinal acoustic impedance, ρc_2 is the shear impedance, u is the particle velocity in the normal direction, and v is the particle velocity in the transverse direction. The initial normal and transverse components of the velocity of the flyer plate are u_0 and v_0 , respectively.

The loci of stress and particle velocity states for the flyer and anvil plates are shown in Fig. 26 for the normal components and in Fig. 27 for the transverse components. At impact, shear waves and longitudinal waves are sent forward into the anvil and backward into the specimen, as shown in the $x-t$ diagram in Fig. 28. The flyer and anvil plates are selected to have impedances that are greater than or equal to that of the specimen so that unloading does not occur as the waves reflect back and forth.

Fig. 26 Loci of normal stress-particle velocity states for flyer, anvil, and specimen, ρc_1 is the longitudinal acoustic impedance; u_0 is the particle velocity state for the flyer and anvil plates in the normal direction.

Fig. 27 Loci of shear stress/transverse particle velocity states for flyer, anvil, and specimen. v_A is the anvil particle velocity and v_{fs} is the transverse particle velocity at the free surface of the anvil. v_F is the particle velocity; v_0 is the particle velocity state for the flyer and anvil plates in the transverse direction.

Fig. 28 $x-t$ diagram illustrating the shear waves and longitudinal waves at impact

Because the waves in the specimen are plastic, they are quickly attenuated, and the stress state in the specimen becomes nominally homogeneous. This has been verified computationally for aluminum specimens sandwiched between steel plates (Ref 89). It was also verified that after a few reflections, the hydrostatic pressure in the specimen becomes nearly equal to the value of the homogeneous normal stress (Ref 89). The homogeneous normal stress attained is the value at the point of intersection of the two lines given by Eq 3 and 5.

$$-p \approx \sigma = \frac{1}{2} \rho c_1 u_0 \quad (\text{Eq 15})$$

This point, which is the apex in Fig. 26, is attained because the elastic resistance of the specimen to volume change will not allow a finite normal velocity difference to be maintained across the thickness of the specimen, while flow in the radial direction is prohibited.

It is possible, however, to maintain a finite transverse velocity difference across the thin specimen for the duration of the experiment. If the specimen behaves viscoplastically and if the stress state is homogeneous, then the shear stress will equilibrate at a value τ in Fig. 27, and the flyer and anvil particle velocities will be v_F and v_A , respectively. The nominal shear strain rate is:

$$\dot{\gamma} = \frac{v_F - v_A}{h} \quad (\text{Eq 16})$$

where h is the specimen thickness. Note that:

$$v_F - v_A = v_0 - v_{fs} \quad (\text{Eq 17})$$

where v_{fs} is the transverse particle velocity at the free surface of the anvil. The shear strain rate can be integrated over time to give the shear strain. From Eq 14, the shear stress is:

$$\tau = \rho c_2 v_A = \frac{1}{2} \rho c_2 v_{fs} \quad (\text{Eq 18})$$

Thus, it is only necessary to measure the incident projectile velocity, the skew angle, and the particle velocity at the rear surface of the anvil to construct a shear stress versus shear strain curve at high strain rates and high hydrostatic pressures.

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Introduction

EXPERIMENTAL TECHNIQUES in characterizing the behavior of materials at high rates of strain are concerned with measuring the change in mechanical properties, such as yield strength, work hardening, and ductility, which can vary with strain rate. Strain rate, $\dot{\epsilon}$, is defined as the rate of change of strain (defined as the ratio of change in the length of a mechanical test sample) with respect to time, t . Minimal scientific or engineering attention was historically paid to the effects of high strain rates on material behavior until increased manufacturing production techniques (Ref 1, 2, 3, 4, 5), such as high-speed wire drawing and cold rolling, as well as studies supporting military technologies concerned with ballistics (Ref 6, 7), armor, and detonation physics, required further knowledge. Interest in the high-rate mechanical behavior of materials has continued to expand during the last 40 years, driven by demands for increased understanding of material response subjected to high-rate loading and impact events. High-rate-loading experiments provide the critically needed data required for the development of predictive constitutive model descriptions of materials.

Constitutive models strive to capture the fundamental relationships between how independent variables, such as stress, strain rate, strain, stress state, and temperature, independently affect the constitutive behavior of materials (Ref 8, 9, 10). Robust material models capturing the controlling physics of high-rate materials response are required for large-scale finite-element simulations of many complex engineering systems and processes, including the following:

- Automotive crashworthiness
- Aerospace impacts, including foreign-object damage, such as during bird ingestion in jet engines, blade containment in engines, and meteorite impact on satellites
- Dynamic structural loadings, such as those occurring during an earthquake
- High-rate manufacturing processes, including high-rate forging, machining, shot peening, shock welding, and laser surface processing
- Cavitation and particulate erosion in turbines and marine propulsion
- Defense applications, including projectile/armor and explosive or propellant/material interactions

Measurement of the mechanical properties of materials is normally conducted via loading test samples in compression, tension, or torsion. Conventional mechanical testing frames can be used to achieve nominally

constant loading rates for limited plastic strains and thereby a constant engineering strain rate. Typical screw-driven or servohydraulic testing machines are routinely used to measure the stress-strain response of materials up to strain rates as high as 1 s^{-1} . Specially designed testing machines, typically equipped with high-capacity servohydraulic valves and high-speed control and data acquisition instrumentation, can be used during compression and tensile testing to achieve strain rates as high as 200 s^{-1} . Above this strain rate regime, $\dot{\epsilon} > 200 \text{ s}^{-1}$, alternate techniques employing projectile driven impacts have been developed to directly or indirectly induce stress-wave propagation in a sample material.

Chief among these techniques is the split-Hopkinson pressure bar, which is capable of achieving the highest uniform uniaxial stress loading of a specimen in compression at nominally constant strain rates of the order of 10^3 s^{-1} . Hopkinson bar techniques have also been developed to probe the high-rate response of materials in tensile- and torsion-loading stress states. In each instance, stress is directly measured using elastic elements in series with the specimen of interest. Stress waves are generated via an impact event, and the elastic elements used are long bars such that the duration of the loading pulse is less than the wave transit time in the bar. In each of the Hopkinson bar techniques, the dynamic stress-strain response of materials at strain rates up to $2 \times 10^4 \text{ s}^{-1}$ in compression, and somewhat lower in tension or torsion, and true strains of 0.3 can be readily achieved in a single test.

Historical Background of the Hopkinson Bar Technique

The split-Hopkinson pressure bar technique is named for Bertram Hopkinson (Ref 7) who, in 1914, used the induced-wave propagation in a long elastic metallic bar to measure the pressures produced during dynamic events. Through the use of momentum traps of differing lengths, Hopkinson studied the shape and evolution of stress pulses as they propagated down long metallic rods as a function of time. Based on this pioneering work, the experimental apparatus using elastic stress-wave propagation in long rods to study dynamic processes in materials was named the Hopkinson pressure bar. Later work by Davies (Ref 11, 12) and Kolsky (Ref 13) used two Hopkinson pressure bars in series, with the sample sandwiched in between, to measure the dynamic stress-strain response of materials. This technique thereafter has been referred to as either the split-Hopkinson pressure bar (Ref 3, 14), Davies bar (Ref 15), or Kolsky bar (Ref 3, 13, 16, 17, 18). The generalized split-Hopkinson pressure bar technique in its current form owes a debt of gratitude to each of these innovative scientists, as well as to the engineers and scientists responsible for the development of high-precision strain gages, signal conditioners, and high-speed digital oscilloscopes, without which the sensitivity, accuracy, and reproducibility of this technique would not be possible.

Following the original split-Hopkinson pressure bar apparatus developed to measure the compressive mechanical behavior of a material, alternate Hopkinson bar schemes were designed for loading samples in uniaxial tension (Ref 14, 19, 20), torsion (Ref 21), simultaneous torsion compression (Ref 22), and simultaneous compression torsion (Ref 23). High-strain-rate testing in a Hopkinson bar under an imposed lateral confinement has also been demonstrated using shrink-fit metallic containment sleeves on a sample (Ref 24). Split-Hopkinson bars have also been used to load notched samples to measure either the shear strength (Ref 25, 26, 27, 28, 29) or the fracture toughness (Ref 30) of an impact-loaded material. The basic theory of how to reduce the pressure bar data based upon one-dimensional stress wave analysis, as presented in the theory of the split-Hopkinson pressure bar section, is common to all three loading stress states. Of the different Hopkinson bar techniques (i.e., compression, tension, and torsion) the compression bar remains the most readily analyzed and least complex method to achieve a uniform high-rate stress state. In addition, the compression bar uses simple right-regular solid samples. Details of the dynamic loading of materials in tension using either the tensile split-Hopkinson pressure bar or expanding ring test are compared and contrasted with the compression Hopkinson bar technique discussed in the section "Stress-State Equilibrium during Split-Hopkinson Pressure Bar Testing" in this article.

An alternate method of probing the mechanical behavior of materials at high strain rates, of the order of 10^3 s^{-1} , is the Taylor rod impact test. This technique, named after G.I. Taylor (Ref 31), who developed the test, entails firing a solid cylinder of the material of interest against a rigid target. The deformation induced in the rod due to the impact in the Taylor test shortens the rod as radial flow occurs at the impact surface. The fractional change in the rod length can then, by assuming one-dimensional rigid-plastic analysis, be related to the dynamic yield strength. By measuring the overall length of the impacted cylinder and the length of the undeformed (rear) section of the projectile, the dynamic yield stress of the material can be calculated (Ref 31). The Taylor test technique offers an apparently simplistic method to ascertain information concerning the dynamic strength properties of a material. However, this test represents an integrated test rather than a unique experiment with a uniform stress state or strain rate, as does the split-Hopkinson pressure bar. Accordingly, the Taylor test has been used most prevalently as a validation experiment in concert with two-dimensional finite-element calculations.

This article describes the techniques involved in measuring the high-strain-rate stress-strain response of materials using a split-Hopkinson pressure bar, hereafter abbreviated as SHPB (Ref 18). The focus of this article is on the generalized techniques applicable to all SHPBs, whether compressive, tensile, or torsion. Emphasis is given to the methods of collecting and analyzing compressive high-rate mechanical property data and a discussion of the critical experimental variables that must be controlled to yield valid and reproducible

high-strain-rate stress-strain data. Comparisons and contrasts to the differences invoked when using a tensile Hopkinson bar in terms of loading technique, sample design, and stress-state stability also are discussed.

Principles of the Split-Hopkinson Pressure Bar

While there is no universal standard design for SHPB test apparatus, all facilities share common design elements. A compression Hopkinson bar test apparatus consists of the following:

- Two long, symmetrical bars
- Bearing and alignment fixtures to allow the bars and striking projectile to move freely while retaining precise axial alignment
- Compressed gas launcher/gun tube or alternate propulsion device for accelerating a projectile, termed the striker bar, to produce a controlled compressive pulse in the incident bar
- Strain gages mounted on both bars to measure the stress-wave propagation in the bars
- Associated instrumentation and data acquisition system to control, record, and analyze the stress-wave data in the bars (Ref 18)

In a compression split-Hopkinson pressure bar, a sample is sandwiched between an elastic incident and a transmitted bar (Fig. 1). The terms *incident/input* and *transmitted/output* are used interchangeably throughout this article to describe the two pressure bars used in the SHPB. The elastic displacements measured in these bars are in turn used to determine the stress-strain conditions at each end of the sample.

Fig. 1 Schematic of a compression split-Hopkinson pressure bar

The bars used in a split-Hopkinson bar setup are traditionally constructed from a high-strength structural metal, AISI-SAE 4340 steel, maraging steel, or a nickel alloy such as Inconel. Such construction is used because the yield strength of the selected pressure bar material determines the maximum stress attainable within the deforming specimen given that the pressure bars must remain elastic. Inconel bars have been previously used for elevated-temperature Hopkinson bar testing because this alloy's elastic properties are essentially invariant up to 800 °C (Ref 3). Because a lower-modulus material increases the signal-to-noise level, the selection of a bar material with lower strength and lower elastic modulus material for the bars is sometimes desirable to facilitate high-resolution dynamic testing of low-strength materials such as polymers or foams. Researchers have selected bar materials possessing a range of elastic stiffnesses from maraging steel (210 GPa) to titanium (110 GPa) to aluminum (90 GPa) to magnesium (45 GPa) (Ref 5, 32), and finally, to polymer bars (<20 GPa) (Ref 17, 33, 34, 35). Alternately, the signal-to-noise of a Hopkinson bar used to test polymeric materials can be

increased using a hollow tubular transmitted pressure bar (Ref 36). While this technique can yield increased transmitted wave measurement sensitivity, the absolute resolution of the sample stress-strain data for polymeric materials must still address the elastic wave dispersion in the tubular-transmitted bar (Ref 37, 38).

The length, l , and diameter, d , of the pressure bars are chosen to meet a number of criteria for test validity as well as the maximum strain rate and strain level desired in the sample. The length of the pressure bars must first ensure one-dimensional wave propagation for a given pulse length; for experimental measurements on most engineering materials, this propagation requires approximately 10 bar diameters. To readily allow separation of the incident and reflected waves for data reduction, each bar should exceed a length-to-diameter (L/D) ratio of ~ 20 . In addition, the maximum strain rate desired will influence the selection of the bar diameter because the highest strain-rate tests require the smallest diameter pressure bars (this aspect of bar design is discussed in a later section). The third consideration affecting the selection of the bar length is the amount of total strain desired to be imparted into the specimen; the absolute magnitude of this strain is related to the length of the incident wave. The pressure bar must be at least twice as long as the incident wave if the incident and reflected waves are to be recorded without interference. In addition, because the bars must remain elastic during the test, the displacement and velocity of the bar interface between the sample and the bar can be accurately determined. Depending on the sample size, for strains $>30\%$ it may be necessary for the split-Hopkinson bars to have an L/D ratio of 100 or more (Ref 3). There are similar requirements for bar L/D ratios to allow wave separation for compression, tensile, and torsion Hopkinson bars.

For proper Hopkinson bar operation, the bars must be physically straight, free to move without binding, and carefully mounted to ensure optimal axial alignment. Precision bar alignment is required for both uniform and one-dimensional wave propagation within the pressure bars as well as for uniaxial compression within the specimen during loading. Bar alignment cannot be forced by overconstraining or forceful clamping of curved pressure bars in an attempt to straighten them because this clamping violates the boundary conditions for one-dimensional wave propagation in an infinite cylindrical solid. Lack of free movement of the bars will lead to additional noise on the wave forms measured on the pressure bars. Bar motion must not be impeded by the mounting bushings but rather must remain free to readily move along the bar axis. Accordingly, it is essential to apply precise dimensional specifications during construction and assembly. Pressure bars are often centerless ground along their length to achieve the uniform diameter and straightness required. In typical bar installations, as schematically shown in Fig. 1, the pressure bars are mounted to a common rigid base to provide a rigid and straight mounting platform. Construction of the Hopkinson pressure bar facility, compression, tension, or torsion, on an optical rail beam rigidly attached to an I-beam, can be used to facilitate reproducible alignment. Figure 2 shows one of the compression Hopkinson bar facilities at Los Alamos National Laboratory, where an optical rail is used to maintain accurate pressure bar alignment. Individual mounting brackets or stanchions with slip bearings through which the bars pass are typically spaced every 200 to 300 mm (8 to 12 in.), depending on the bar diameter and stiffness. Mounting brackets are generally designed so that they can be individually translated to adjust bar alignment within each stanchion.

Fig. 2 A compression split-Hopkinson pressure bar facility at Los Alamos National Laboratory

The most common method of generating an incident wave in the input bar is to propel a striker bar to impact the end of the incident bar. The striker bar is normally fabricated from the same material and is of the same diameter as the pressure bars. The length and velocity of the striker bar are chosen to produce the desired total strain and strain rate within the test specimen. While elastic waves can also be generated in an incident bar through the adjacent detonation of explosives at the free end of the incident bar, as Hopkinson did (Ref 7), it is more difficult to ensure a one-dimensional excitation within the incident bar by direct explosive loading.

The impact of a striker bar on the free end of the incident bar develops a longitudinal compressive incident wave in this bar, designated ϵ_i , as denoted in Fig. 3. Once this wave reaches the bar-specimen interface, a part of the pulse, designated ϵ_r , is reflected while the remainder of the stress pulse passes through the specimen and, upon entering the output bar, is termed the transmitted wave, ϵ_t . The time of passage and magnitude of these three elastic pulses through the incident and transmitted bars are recorded by strain gages normally cemented at the midpoint positions along the length of the two pressure bars. Figure 3 shows an illustration of the strain-gage data measured as a function of time for the three wave signals during the testing of a 304L stainless steel sample using maraging steel pressure bars. The incident and transmitted wave signals represent compressive loading pulses, while the reflected wave is a tensile wave.

Fig. 3 Strain-gage data, after signal conditioning and amplification, from a compression split-Hopkinson pressure bar test of a 304 stainless steel sample showing the three stress waves measured as a function of time. Note that the wave positions in time are arbitrarily superimposed due to the time delays used during data acquisitions.

Using the wave signals from the gages on the incident and transmitted bars as a function of time, the forces and velocities at the two interfaces between the pressure bars and the specimen can be determined. When the specimen is deforming uniformly, the strain rate within the specimen is directly proportional to the amplitude of the reflected wave. Similarly, the stress within the sample is directly proportional to the amplitude of the transmitted wave. (termed the 1-wave stress as discussed later). The reflected wave is also integrated to obtain strain and is plotted against stress to give the dynamic stress-strain curve for the specimen.

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Theory of the Split-Hopkinson Pressure Bar

The determination of the stress-strain behavior of a material being tested in a Hopkinson bar, whether it is loaded in compression as in the present illustration or in a tensile or torsion bar configuration, is based on the same principles of one-dimensional elastic-wave propagation within the pressure loading bars as previously reviewed (Ref 1, 3, 16, 18, 39).

As identified originally by Hopkinson (Ref 7) and later refined by Kolsky (Ref 13), the use of a long elastic bar to study high-strain-rate mechanical behavior of materials is feasible using remote elastic bar measures of sample response because the wave propagation behavior in such a geometry is well understood and mathematically predictable. Accordingly, the displacements or stresses generated at any point can be deduced by measuring the elastic wave at any point, x , as it propagates along the bar (Ref 3, 18, 40).

The subscripts 1 and 2 are used in this description to denote the incident and transmitted bar ends of the specimen, respectively. The strains in the bars are then designated as ϵ_i , ϵ_r , and ϵ_t (incident, reflected, and transmitted strains, respectively) and the displacements of the ends of the specimen as u_1 and u_2 at the incident bar-specimen and specimen-transmitted bar interfaces as given schematically in the enlarged view of the test specimen in Fig. 4.

Fig. 4 Expanded view of incident (input) bar/specimen/transmitted (output) bar region

From elementary wave theory, it is known that the solution to the wave equation:

$$\frac{\partial^2 u}{\partial x^2} = \frac{1}{c_b^2} \frac{\partial^2 u}{\partial t^2} \quad (\text{Eq 1})$$

can be written as:

$$u = f(x - c_b t) + g(x + c_b t) = u_i + u_r \quad (\text{Eq 2})$$

for the incident (input) bar, where f and g are functions describing the incident and reflected wave shapes, and c_b is the longitudinal wave speed in the pressure bars.

By definition, the 1-D strain is given by:

$$\epsilon = \frac{\partial u}{\partial x} \quad (\text{Eq 3})$$

Therefore, differentiating Eq 2 with respect to x , the strain in the incident rod is given by:

$$\epsilon = f' + g' = \epsilon_i + \epsilon_r \quad (\text{Eq 4})$$

Differentiating Eq 2 with respect to time and using Eq 4 gives:

$$\dot{u} = c_b (-f' + g') = c_b (-\epsilon_i + \epsilon_r) \quad (\text{Eq 5})$$

for the incident bar.

The time derivative of the displacement in the transmitted bar, $u = h(x - c_b t)$, yields:

$$\dot{u} = -c_b \epsilon_t \quad (\text{Eq 6})$$

in the transmitted bar. Equations 5 and 6 are true everywhere, including at the ends of the pressure bars. The strain rate in the test specimen is:

$$\dot{\epsilon} = \frac{(\dot{u}_1 - \dot{u}_2)}{l_s} \quad (\text{Eq 7})$$

where l_s is the instantaneous length of the specimen, and \dot{u}_1 and \dot{u}_2 are the velocities at the incident bar-specimen and specimen-transmitted bar interfaces, respectively.

Substituting Eq 5 and 6 into Eq 7 gives:

$$\dot{\epsilon} = \frac{c_b}{l_s} (-\epsilon_i + \epsilon_r + \epsilon_t) \quad (\text{Eq 8})$$

By definition, the forces in the two bars are:

$$F_1 = AE(\epsilon_i + \epsilon_r) \quad (\text{Eq 9})$$

and

$$F_2 = AE\epsilon_t \quad (\text{Eq 10})$$

where A is the cross-sectional area of the pressure bar, and E is the Young's elastic modulus of the bars (normally equal, given that identical material is used for both the incident and transmitted pressure bars).

After an initial "ringing-up" period, where the exact duration or period depends on the sample sound speed and sample geometry (in particular, its length), it is assumed that the specimen is in force equilibrium, and the

specimen is deforming uniformly. If these assumptions are valid, a simplification can be made equating the forces on each side of the specimen (i.e., $F_1 = F_2$). Comparing Eq 9 and 10, therefore, means that

$$\varepsilon_t = \varepsilon_i + \varepsilon_r \quad (\text{Eq 11})$$

Substituting this criterion into Eq 8 yields:

$$\dot{\varepsilon} = \frac{2 c_b \varepsilon_r}{l_s} \quad (\text{Eq 12})$$

The engineering stress, or conventional stress, in conventional mechanical testing of materials is calculated from the force divided by the sample original area, A_0 . Because of the constancy of volume in incompressible solids, $A_0 l_0 = A_s l_s$, (where l_0 is the original length of the specimen, A_0 is the original cross-sectional area, and A_s is the instantaneous cross-sectional area of the sample) (Ref 41). Expressions for the strain can therefore be written in terms of either the length or the area of the test sample. Accordingly, the true stress is calculated from the strain-gage-signal measure of the transmitted force divided by the instantaneous cross-sectional area, A_s , of the specimen over which it acts:

$$\sigma(t) = \frac{AE\varepsilon_t}{A_s} \quad (\text{Eq 13})$$

The importance of this requirement to all types of Hopkinson bar testing using the one-dimensional wave assumptions detailed is that true stress in a sample in the Hopkinson bar cannot be extracted for materials whose volumes are not conserved. The instantaneous sample area used in Eq 13 is deduced from the reflected strain signal in the incident bar assuming that the constancy of volume assumption is valid in the sample (i.e., there is a fixed relationship between sample cross-sectional area and its length). Without this assumption, there is no basis for using the transmitted signal to measure force and the reflected wave to extract strain in the sample. Materials for which this problem exists include metallic and polymeric foams, honeycomb structures, and porous compacts for which mechanical loading produces compaction, densification, or porosity during testing. Valid Hopkinson bar testing of materials for which the constant volume criterion is not valid, therefore, requires additional sample diagnostics during the duration of the test to calculate true stress. Simultaneous use of high-resolution high-speed photography can be used to monitor sample length and diameter during testing. The photographic data, once digitized, can then be used to measure the actual strain rate and true strain as a function of time in the sample. Such data, when combined with the transmitted wave-data measuring force, can provide the needed data to calculate true stress.

Given that the volume constancy requirement is satisfied in the sample, Eq 12 and 13 can be used to determine the dynamic stress-strain curve of the sample. This analysis is termed a 1-wave analysis because it uses only the reflected wave to calculate strain in the sample, and only the transmitted wave is used to calculate the stress in the sample. The 1-wave analysis assumes that stress equilibrium is ensured in the sample (i.e., as a function of time, the stress and strain in the sample are uniform along its length). Conversely, the stress in the sample at the incident bar-sample interface can be calculated using a momentum balance of the incident and reflected wave pulses, termed a 2-wave stress analysis because it is a summation of the two waves at this interface. However, it is known that such a condition cannot be correct at the early stages of any test because of the transient effect that occurs when loading starts at the incident bar-specimen interface while the other sample face remains at rest. Given finite stress-wave propagation through the sample, time is required for stress-state equilibrium to be achieved. Reduced sound speed and high radial inertia in the sample will increase this problem (Ref 32).

Previous researchers have additionally adopted a 3-wave stress analysis, which averages the forces on both ends of the specimen to track the ringup of the specimen to a state of stable stress (Ref 18, 40). The term *3-wave* indicates the use of all three waves to calculate an average stress in the sample, the transmitted wave to calculate the stress at the specimen-transmitted interface (back stress), and the combined incident and reflected pulses to calculate the stress at the incident bar-specimen interface (front stress). In the 3-wave case, the specimen stress is then simply the average of the two forces divided by the combined interface areas:

$$\sigma(t) = \frac{F_1(t) + F_2(t)}{2 A_s} \quad (\text{Eq 14})$$

Substituting Eq 9 and 10 into Eq 14 then gives:

$$\sigma(t) = \frac{AE}{2A_s}(\epsilon_i + \epsilon_r + \epsilon_t) \quad (\text{Eq 15})$$

From these equations, the average stress-strain curve of the specimen can be computed from the measured reflected and transmitted strain pulses as long as the volume of the specimen remains constant and the sample is free of barreling (i.e., friction effects are minimized).

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Practical Aspects of the Split-Hopkinson Pressure Bar

Calibration. To analyze the strain-gage data from a split-Hopkinson pressure bar test, the system must be calibrated prior to testing (Ref 3, 18). Calibration of the entire Hopkinson bar setup is obtained in situ by comparing the constant amplitude of a wave pulse with the impact velocity of the striker bar for each bar

separately, termed “bars apart.” Operationally, this calibration is accomplished by inputting a known velocity pulse into the input bar, and then, in turn, the transmitted bar, with no sample present. Thereafter, impact of the striker with the input bar in direct contact with the transmitted bar, with no specimen, gives the coefficient of transmission, termed “bars together.” Accurate measurement of the velocity, V , of the striker bar impact into a pressure bar is linearly related by:

$$\varepsilon_j = \frac{V}{2c_b} \quad (\text{Eq 16})$$

where ε_j is the strain in the incident or transmitted bar, depending on which is being calibrated, and c_b is the longitudinal wave speed in the bar if the impacting striker bar and the pressure bar are the same material and have the same cross-sectional area. Careful measurement of the striker velocity, using a laser interruption scheme or shorting pins, for example, in comparison with the elastic strain signal in a pressure bar, can then be used to calculate a calibration factor for the pressure bar being calibrated. Accurate measurement of the longitudinal-wave velocity in the pressure bars being used is critical. The use of textbook values is not advised. Variations in alloy chemistry, microstructure, and heat treatment from the manufacturer can all lead to measurable variations in the longitudinal wave speed in the pressure bars and should not be assumed to be a constant but rather measured for each set of bars used. Calibration values also include validation due to strain-gage response, including cement or epoxy interfaces, wiring, amplifiers, and so on. Calibrations should be verified periodically, especially when changes are made to either mechanical or electronic components.

Optimal data resolution also requires careful design of the sample size for a given material as well as the selection of an appropriate striker bar length and velocity to achieve test goals. The determination of the optimal sample length first requires consideration of the sample rise time, t , required for a uniform uniaxial stress state to be achieved within the sample. It has been estimated (Ref 42) that this rise time is the time required for three (actually π) reverberations of the stress pulse within the specimen (Ref 3). For a plastically deforming solid that obeys the Taylor-von Karman theory, time follows the relationship:

$$t^2 \geq \frac{\pi^2 \rho_s l_s^2}{\partial\sigma/\partial\varepsilon} \quad (\text{Eq 17})$$

Here, ρ_s is the density of the specimen, l_s is the specimen length, and $\partial\sigma/\partial\varepsilon$ is the stage 2 work-hardening rate of the true stress/true strain curve for the material to be tested. For rise times less than that given by Eq 17, the sample should not be assumed to be deforming uniformly, and stress-strain data will accordingly be in error. Materials possessing either high work-hardening rates, slow sound speeds, and/or high densities will require shorter sample lengths to facilitate rapid ringup and, therefore, rapid attainment of a uniaxial stress state in the sample.

One approach for achieving a uniform stress state during split-Hopkinson pressure bar testing is to decrease the sample length such that the rise time, t , from Eq 17 is as small as possible. Other considerations of scale, which are described in the sample design section, limit the range of L/D ratios appropriate for a given material; the specimen length may not be decreased without a concomitant decrease in the specimen and bar diameters. The use of small diameter bars (<6 mm) to achieve higher strain rates is a common practice in split-Hopkinson pressure bar testing (Ref 3).

Pulse Shaping. Because the value of t from Eq 17 has a practical minimum, an alternate method to facilitate stress-state equilibrium at low strains is to increase the rise time of the incident wave. Use of impedance-matched materials for the striker and incident bar (i.e., a symmetric impact) yields a short rise-time pulse, which approximates a square wave. The rise time of such a square-wave pulse is likely to be less than t in Eq 16 in most instances. Contrarily, if the rise time of the incident wave pulse is increased to a value more comparable with the time to ring up the specimen, then the data will be valid at an earlier strain. Furthermore, because the highly dispersive short wavelength components arise from the leading and trailing edges in the incident wave, a longer rise-time pulse will contain fewer of these components than will a sharply rising pulse (Ref 3, 43). The consequence of this solution is a lower applied strain rate.

Experimentally, the rise time of the incident wave can be increased by placing a soft, deformable metal shim between the striker and the incident bar during impact. The choice of material and thickness for this shim, or tip material (Ref 43), depends on the desired strain rate and the strength of the specimen. Typically, the tip material is selected to have the same strength as the specimen and is 0.1 to 2 mm (0.004 to 0.08 in.) in thickness. An additional benefit of this layer is that it can result in a more uniform strain rate throughout the experiment. However, for thick shims the strain rate will not be constant and will ramp up during the test. The exact

selection of the optimal tip material and thickness for a given test sample is not readily calculated and remains a matter of experience via trial and error. The use of tip materials to shape the incident pulse is particularly effective in attaining constant strain rates and stress-state equilibrium in modest- and high-strength materials exhibiting steep strain-hardening rates.

A recent proposed alternative to the use of tip material to increase the incident pulse rise time is to use a three-bar Hopkinson configuration (Ref 44, 45). In the three-bar configuration, an additional pressure bar and a dummy sample are positioned between the striker bar and the traditional incident bar. The pulse transmitted by the dummy specimen becomes the new incident pulse applied to the incident bar. With this method, the transmitted pulse sent into the incident pressure bar is ramp shaped, with only a minor amount of oscillations (Ref 45). The disadvantages of this method are the need for an additional pressure bar and an additional sample for each test. Alternately, a lower-strength preloading bar can be substituted, which damps many of the high-frequency oscillations and removes the need for a second sample (Ref 45).

Hopkinson Bar Test Setup. Once the Hopkinson bar system has been calibrated and the optimal specimen length, l_s , has been selected, preparations for testing can proceed (Ref 3). At a constant strain rate, the maximum strain that can be achieved in the specimen is directly proportional to the length of the striker bar utilized, L :

$$\epsilon = 2\dot{\epsilon} \frac{L}{c_b} \quad (\text{Eq 18})$$

The nominal strain rate in the specimen may be conservatively approximated by considering momentum conservation between the striker bar and incident bar. It can similarly be shown that (Ref 3):

$$\dot{\epsilon} = \frac{V}{l_s} \quad (\text{Eq 19})$$

where V is the striker bar velocity, and l_s is the length of the specimen. This equation overestimates the strain rate but can provide a useful value for test design. At higher striker-bar velocities, this relationship has been found to be a good first approximation for soft metals, such as annealed copper or aluminum. Equations 18 and 19 can be used to approximate the striker-bar length and striker-bar velocity required to achieve a desired strain and strain rate for a given sample size. These formulas provide a good starting point for selecting test parameters to achieve a valid SHPB test. However, samples possessing high initial yield strengths, yield drops such as those often seen in low-carbon steels or other refractory metals, and/or very high strain-hardening responses, will require increased striker-bar lengths and impact velocities to achieve the desired strain value.

Stress-State Equilibrium during Split-Hopkinson Pressure Bar Testing. The classic split-Hopkinson pressure bar equations relating strain-gage measurement to stress-strain behavior in the deforming specimen require that the specimen deform uniformly. This behavior is opposed by both radial and longitudinal inertia and by frictional constraint at the specimen-pressure bar interfaces. To understand the procedure to validate attainment of a uniform stress state in the sample in an SHPB test, it is instructive to review the different analyses discussed, which are used to calculate sample stress from the pressure bar strains and what they indicate. In the 1-wave analysis, the sample stress is directly proportional to the bar strain measured in the output bar as calculated using Eq 13. This waveform characteristically exhibits low oscillation amplitude because the deforming sample effectively damps much of the high-frequency oscillations inherent in the incident pulse as it propagates through the sample. More importantly, the 1-wave stress analysis reflects the conditions at the sample-transmitted bar interface and is often referred to as the sample back stress.

Alternatively, in a 2-wave analysis, the sum of the synchronized incident and reflected bar waveforms (which are opposite in sign) is proportional to the sample front stress and represents the conditions at the incident bar-sample interface. Unfortunately, both the incident and reflected waveforms contain substantial inherent oscillations which, compared to the transmitted waveform, cause uncertainty in the interpretation of stress, especially near the yield point. In addition, these harmonic oscillations are subject to dispersion due to the wavespeed dependence of different frequencies that causes asynchronization of the raw overlapped waveforms and, therefore, inaccuracy in the calculation of the front stress (Ref 18, 32).

A dispersion-correction analysis has been developed (Ref 3, 40, 43) to account for these changes in phase angle of the primary mode harmonic oscillation of all three strain signals. This analysis results in more accurate and smoother stress-strain curves, especially near the yield point. Finally, a third stress-calculation variation that

considers the complete set of three measured bar waveforms, the 3-wave analysis, is simply the average of the front and the back stress. The 3-wave average is calculated as described by Eq 15.

Sample equilibrium can be checked by comparing the 1-wave and 2-wave (or 3-wave) stress-strain response (Ref 18, 40, 46, 47, 48). Recent studies have demonstrated that both inertia and wave propagation effects can significantly affect the stress differences across the length of a specimen deformed in a compression SHPB (Ref 18, 32, 47, 49).

The validity of an SHPB test may be verified by examining the incident and transmitted pressure-bar data for stress-state equilibrium as well as a constant strain rate. When the stress state is uniform throughout the sample, the 2-wave stress oscillates equally above and below the 1-wave stress. Figure 5 shows the 1-wave, 2-wave, and strain-rate data as a function of strain for an SHPB test conducted on a 304L stainless steel sample. In this illustration, the front and back stress data reductions exhibit very similar response beyond ~ 0.02 strain, verifying that the sample attained a uniform stress state. Verification of attaining an essentially constant strain rate throughout an SHPB test will serve as validation of a careful balance of striker-bar length, striker-bar velocity, and the use of tip material. In addition to a check of the stress equilibrium in the specimen, a constant strain rate demonstrates a high-precision, valid material characterization measurement.

Fig. 5 Stress-strain response of a 304 stainless steel specimen showing the 1- and 2-wave stress curves and the strain rate

Contrarily, when the stress state is *not* uniform throughout the SHPB sample, the 2-wave stress diverges and exceeds the 1-wave stress values. Previous Hopkinson bar studies of ceramic materials using this 1-wave versus 2-wave comparison have shown quite dramatically that a sample is not in stress equilibrium when divergence is observed (Ref 50). In ceramic and cermet materials, this divergence correlates very well with the onset of nonuniform plastic flow and/or premature fracture events. Split-Hopkinson bar analysis for attenuating materials, such as in the case of testing soils, has shown that the time required to achieve stress uniformity can be considerable (Ref 51). Valid analysis of the dynamic stress-strain behavior of the soil samples during the course of testing required the use of a Lagrangian analysis coupled with a standard analysis.

Results have revealed that the slow longitudinal sound speeds typical for some polymeric materials make stress equilibrium during SHPB testing difficult to achieve (Ref 32, 34, 52, 53). The pronounced difference in the initial 1-wave and 2-wave signals for a 6.35 mm (0.25 in.) long, 1 to 1 aspect ratio, high-purity lead sample is shown in Fig. 6. This behavior can be viewed as an indication of a sluggish sample ringup to stress-state equilibrium, compared with the incident wave rise time and a marginally valid Hopkinson bar test at strains

>6%, even though a reasonably stable strain rate is indicated throughout the entire test. The data in Fig. 6 and recent studies on polymeric materials, therefore, assert the need to examine the technique of using thinner sample aspect ratios when studying the high strain rate constitutive response of low sound speed, dispersive materials (Ref 47, 49) and low-strength, high-density solids. Based on the data in Fig. 6, all subsequent testing for this sample material used 3.2 mm (0.12 in.) long samples with a length-to-diameter aspect ratio of 0.5 and lower striker-bar velocities to reduce the strain rate, thereby helping sample ringup. The combination of these measures proved successful in attaining stress equilibrium at lower strain levels in metallic lead samples.

Fig. 6 Room-temperature stress-strain response of a high-purity lead (6.35 mm long by 6.35 mm diam) sample showing the 1- and 2-wave stress curves in addition to strain rate

The finite time to achieve stress-state equilibrium demonstrates that the high-rate elastic modulus of a sample cannot be measured by any Hopkinson bar. Because the stress equilibrium does not occur until well over 1% plastic strain, it is impossible to accurately measure the compressive Young's modulus of materials at high strain rates using the SHPB. The compressive Young's modulus of a material is best measured using ultrasonic techniques.

Increased resolution of the ringup during SHPB testing of materials possessing high sound speeds and/or low fracture toughness values can be achieved by measuring the strain in the sample via strain gages bonded directly on the sample (Ref 54). Testing of ceramics, cermets, thermoset epoxies, and geological materials requires accurate measurement of the local strains. The difficulties with this technique are that reproducible gage application on small samples is challenging and labor intensive, and the specimens often deform to strains greater than the gages can survive (nominally, 5% strain) so they can only be used once.

Split-Hopkinson Bar Testing as a Function of Temperature. The development of robust constitutive material model descriptions of a material's mechanical behavior often requires quantitative knowledge of the coincident influence of temperature and strain rate variations. Accurate measurement of the high strain-rate mechanical response of a material using an SHPB at temperatures other than ambient, however, presents several technical and scientific challenges. Because the stress and strain as a function of time within the deforming specimen are determined by strain-gage measurements made using the elastic pressure bars, the longitudinal sound speed and elastic modulus of the pressure bars, both of which vary with temperature, are important parameters. The pronounced effect of temperature on the elastic properties of viscoelastic materials, which have been proposed as alternate bar materials to achieve increased stress resolution, has been a chief barrier to their adoption to measuring the high-rate response of polymers over a range of temperatures (Ref 32, 35). In this case, both a rate

and temperature-dependent constitutive model for elastomer pressure bars themselves would be required to reduce SHPB data for a sample of interest because an assumption of linear elasticity cannot be invoked for polymeric pressure bars over a range of strain rates and temperatures.

Various techniques have been developed to heat samples in an SHPB depending on whether it is a compression or tensile Hopkinson bar. The combined length of both pressure bars (which can easily exceed 2 m, or 6.5 ft) while simultaneously maintaining alignment within the supporting stanchions makes it operationally impossible to heat or cool the entire bar assembly, either tensile or compressive, with any uniformity of temperature. Even if heating or cooling were feasible, it would require a bar material capable of withstanding the high/low temperatures desired as well as the development of new temperature-calibrated strain gages and robust adhesives/epoxies to rigidly attach them to the bars. Operationally, therefore, the most common techniques for elevated-temperature testing include the following (Ref 3, 5):

- Heating only the sample and perhaps a short section of the pressure bars and then correcting for the temperature gradient effects on the properties of the pressure bars if they are significant (Ref 55)
- Correcting the temperature-dependent sound velocity and elastic modulus of the bars based on an assessment of the temperature gradient, either estimated or measured with a thermocouple. The strain-gage signals are then corrected for the temperature-dependent sound velocity and elastic modulus of the bars (Ref 14).
- Tapering the bars to maintain the mechanical impedance constant along the length of the bars (Ref 56). A disadvantage of this method is that a bar of a particular profile can only compensate for one particular temperature gradient and is, therefore, of minimal use.
- Using mechanical devices that bring the ambient temperature pressure bars into contact with the heated sample a fraction of a second before the stress pulse arrives at the end of the incident bar (Ref 57)

In the first method, heat input into the pressure bars can be minimized in the case of tensile Hopkinson bar testing by rapid heating of the sample gage section using either high-speed radiant (Ref 58) or induction heating (Ref 59, 60). This technique of sample heating will not avoid the altering of the elastic properties of the pressure bars in the case of compressive Hopkinson bar testing unless heating of the bars can be avoided. The second method has been used at temperatures up to 613 °C (Ref 14). Alternately, the selection of a bar material, such as Inconel, which exhibits only a small variability in its elastic properties up to ~600 °C, can alternately be used without the need for corrections up to modest temperatures. Heating/cooling to modest temperatures (-55 to +55 °C) of interest for polymer testing over which the elastic properties of Ti-6Al-4V or Mg bars are unaffected can also be achieved using heated/cooled helium (He) gas as a heat transfer medium (Ref 32, 49).

The last heating technique provides a solution that eliminates the need for corrections to the strain-gage data because heat is applied only to the specimen and not to any part of the bars. This method, however, is only practical in the case of a compression SHPB because in a tensile or a torsion bar the sample is mechanically coupled to the pressure bars. In the case of a compression SHPB, this heating method is accomplished by starting with the bars separated from the sample. The sample is heated independently in a specially designed resistance furnace (a vacuum furnace minimizes radiant heating), by direct radiant heating, or by an induction-heating coil. Just prior to firing the striker bar, the pressure bars are mechanically positioned into contact with the heated sample using bar movers (Ref 43). If the contact time between the sample and the bars is minimized to less than 200 milliseconds, the specimen temperature and the temperature at the ends of the bars remain approximately constant. This approach, while requiring careful attention to the timing between the movement of the pressure bars and the firing of the striker bar, has been used successfully at temperatures up to 1200 °C (Ref 61).

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Split-Hopkinson Pressure Bar in Tension

Tensile-Loading Techniques. The principles and the data analysis for the tensile split-Hopkinson pressure bar are similar to those discussed for the compression SHPB (Ref 62, 63, 64). The primary differences are the methods of generating a tensile-loading pulse, specimen geometry, and the method of attaching the specimen to the two bars (incident and transmitted). Three separate general types of tension split-Hopkinson pressure bar design have been developed (Ref 63). All three loading techniques use measures of the tensile pulses in the input and transmitter bars, as in the compressive SHPB, to study the dynamic tensile response of a material.

Method 1. In the first method, developed by Lindholm and Yeakley (Ref 14), the incident bar is solid, while the transmitted bar is a hollow tube of the same cross-sectional area as the input bar. A complex “top-hat” type of sample geometry, as shown in Fig. 7, is machined from the material of interest. The specimen essentially comprises four parallel tensile bars of equal cross-sectional area. Although specimen machining is somewhat complex in this method, the actual SHPB test is conducted in the identical manner because compressive testing

and the data analysis is identical to that outlined previously. The advantage of this tensile loading method is that, given a suitable hollow transmitted bar matched to the incident bar, tensile Hopkinson bar tests can be conducted using a standard compressive SHPB loading setup as shown in Fig. 1 and 2.

Fig. 7 “Top-hat” tensile split-Hopkinson bar sample design. Source: Ref 14

Method 2. The second type of tensile split-Hopkinson bar test, and the most commonly implemented mode of loading (Ref 5), involves direct tensile loading of the incident bar to subject a sample in a uniaxial tensile stress state. This loading mode can be accomplished using a standard type of axisymmetric circular tension specimen threaded directly into the ends of the incident and transmitted pressure bars, a dumbbell-shaped sample loaded through flanges attached to the incident and transmitted bars, or a flat tensile sample loaded using a small compression grip assembly designed into the ends of the incident and transmitted bars. A tensile pulse in each instance is generated in the incident bar either by loading the end of the incident bar through direct impact of a mass with a flange on the end of the incident bar (Ref 19) or by releasing a tensile pulse stored in the incident bar using a clamping fixture (Ref 20). Figure 8 shows a schematic of a tensile split-Hopkinson bar setup using the hollow-striker-bar loading method. In this loading method, a long tensile pulse, similarly stable as in a compressive bar, can be imparted using a hollow striker tube accelerated along the incident bar from a compressed gas breech or from a falling weight in a vertically configured tensile bar. In the second variation, tensile wave loading in the incident bar is generated through the release of a tensile load that is initially stored in a section of the incident bar.

Fig. 8 Schematic of a tensile split-Hopkinson pressure bar test setup

Method 3. The third type of Hopkinson bar loading in tension also uses a circular specimen threaded into the ends of the two pressure bars but uses the reflection of the compression pulse at the free end of the transmitted bar to load the sample in tension and a circular collar to protect the specimen from the initial compressive pulse

(Ref 62). After the specimen has been screwed into the incident and transmitted bars, a split shoulder or collar is placed over the specimen, and it is screwed in until the pressure bars fit tightly against the shoulder. The shoulder is made of the same material as the pressure bars, has the same outer diameter, and has an inner diameter that just clears the specimen. The ratio of the cross-sectional area of the shoulder to that of the pressure bars is typically 3 to 4, while the ratio of the area of the shoulder to the net cross-sectional area of the specimen is typically 12 to 1 (Ref 62, 63). When the striker bar impacts the incident bar, a compressive pulse travels down the incident bar until it reaches the specimen. The amplitude of the pulse, which is a function of the striker velocity and length, is twice the elastic wave transit time in the striker bar.

In this loading method, the compression pulse travels through the composite cross section of the loading collar and specimen in an essentially undisturbed manner. The relatively loose fit of the threaded joint of the specimen into the bars and the large area ratio of the collar to the specimen ensure that no compression beyond the elastic limit is transmitted through the specimen (Ref 63). Ideally, the entire compression pulse passes through the supporting circular collar as if the specimen were not present, although in practice it is operationally difficult to prevent prestraining of the specimen to some degree. The compression pulse continues to propagate until it reaches the free end of the transmitted bar where it reflects and propagates back as a tensile pulse. Upon reaching the specimen, the tensile pulse is partially transmitted through the specimen and partially reflected back into the bar, which is now acting as the incident bar. Because the shoulder, which carried the entire compressive pulse around the specimen, is not rigidly connected to the pressure bars, it will not support any tensile load. Tight fitting of the collar against the two pressure bars is critical in transmitting the compression pulse down the bars without significant wave dispersion or prestraining of the sample. Similarly, the fit of the threaded tensile specimen against the bars is essential to achieve smooth and rapid loading of the specimen as the tensile pulse arrives. Failure to remove all play from the threaded joint results in uneven loading of the specimen and spurious wave reflections because of the open gaps in the loading thread area.

Data analysis for a tensile split-Hopkinson bar test is essentially identical to that of the compression Hopkinson bar analysis detailed previously. The additional complications encountered in the tensile and torsional Hopkinson techniques are related to the following:

- Modification of the pressure bar ends to accommodate gripping of complex samples, which alter wave propagation in the sample and bars
- Potential need for additional diagnostics to calculate true stress
- Increased need to accurately incorporate inertial effects into data reduction to extract quantitative material constitutive behavior
- More complicated stress pulse generation systems required for tensile and torsion bars

Alteration of the bar ends to accommodate threaded or clamped samples leads to complex boundary conditions at the bar specimen interface and, therefore, introduces uncertainties in the wave mechanics description of the test (Ref 14).

When complex sample geometries are used, signals measured in the pressure bars record the structural response of the entire sample, not just the gage section, where plastic deformation is assumed to be occurring. When plastic strain occurs in the sections adjacent to the sample's uniform gage area, accurate determination of the stress-strain response of the material is more complicated. In these cases, additional diagnostics, such as high-speed photography, are mandatory to quantify the loaded section of the deforming sample. In the tensile bar case, an additional requirement is that exact quantification of the deforming sample cross-sectional area as a function of strain is necessary to achieve true-stress data. Contrary to a compressive SHPB test, in which a right-circular cylindrical sample is most often utilized, the tensile SHPB test uses a cylindrical specimen with an attached shoulder and additional gripping, including threads. Because the split-Hopkinson bar data analysis only provides data on the relative displacement between the ends of the incident and transmitter bars, an effective gage length generally must be used. This is equivalent to determining strain in a tensile test through cross-head displacement measurement. The use of strain gages on test samples to determine an effective gage length is strongly recommended. This calibration is accomplished easily at low strain rates, preferably in a conventional test machine in which the cross-head displacement is monitored separately.

As with any uniaxial tensile test, once localized necking occurs, it is no longer possible to simply convert load-displacement data to stress-strain data. This lack of valid stress-state analysis is related to both the lack of uniform plastic deformation in the sample and the attendant volumetric sample expansion, which damage-

evolution processes represent. The range of application of the Hopkinson bar test can be extended by high-speed photography of necking specimens, although an accurate measure of the deforming volume of the sample as necking proceeds is difficult at best, given a lack of knowledge of the damage processes evolving within the sample. An analysis that allows estimation of effective stress and strain from the profile of the necking specimen can be obtained. Using the apparatus described in method 3, photographs can be made with a suitable high-speed camera system through windows provided in the collar (Ref 65, 66).

The final complexity inherent to the tension Hopkinson loading configurations has to do with the increased sample dimensions required. Valid dynamic characterization of many material product forms, such as thin sheet materials and small-section bar stock, may be significantly complicated or completely impractical using either tensile or torsion Hopkinson bars because of an inability to fabricate test samples. Techniques have been developed, however, to address these concerns in the case of testing sheet materials in the Hopkinson bar (Ref 66).

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Data Reduction Measurement and Analysis Automation

Acquisition of split-Hopkinson bar data requires a high degree of automation because of the high-speed nature of the stress loading inherent to the Hopkinson bar and the need for signal measurement and storage equipment capable of these acquisition speeds (Ref 18, 67, 68, 69). The measurement instrumentation required for a split-

Hopkinson pressure bar test includes two strain-gage signal conditioners and a means of recording these signals. The strain-gage signal conditioners must have a frequency response of at least 1 MHz to achieve adequate data resolution. Units with sampling frequencies as high as 1 GHz are now available. In addition, modern signal conditioners possess variable gain amplification, up to 1000 times, while retaining high signal-to-noise levels. Gain settings in excess of 500 are critical to the high-resolution measurement of the very low flow stresses typical of many polymer and polymeric composites. Until recently, oscilloscopes were used almost exclusively to capture and record the strain-gage signal pulses. When using one oscilloscope to capture the strain-gage data, the transmitted wave and integrated reflected wave can be fed to an oscilloscope with x - y capability to directly yield the dynamic stress-strain curve for the specimen. The reflected wave may be fed through an operational amplifier to yield a signal directly proportional to the strain in the specimen but without dispersion correction.

The three wave signals are now often captured using high-speed analog-to-digital (A/D) recorders or high-speed A/D data-acquisition computer modules, which are directly interfaced with a personal computer. Using either platform, it is now possible to digitize the raw data directly and perform the integration numerically. With the improved availability of the digitized data, more robust Hopkinson bar data reduction software is now regularly used by research labs conducting split-Hopkinson bar testing. This software can be used to calibrate the bars and store the calibration information, adjust the timing between the transmitted and reflected waves to account for the transit time through the specimen, and calculate the elastic wave dispersion in the measured data.

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Wave Dispersion in the Split-Hopkinson Pressure Bar

Applying the equations given in the theory of the Hopkinson bar section, the stress-strain behavior of the specimen can be computed from the measured incident, reflected, and transmitted strain pulses made on the elastic bars (Ref 3, 18, 67). Knowing the timing required for the elastic wave signals to traverse from the specimen to the gages on the input and output bars based on the calibration procedure, the reflected and transmitted pulses can be synchronized to coincide at the specimen interface. By integrating Eq 13, and remembering that $\varepsilon = \ln(l_0/l_s)$ in compression, $\varepsilon(t)$ and $l_s(t)$ can be calculated in the specimen. Assuming constancy of volume of the specimen during the course of deforming the specimen, $A_s(t)$ and, therefore, $\sigma(t)$ can now be calculated from Eq 13. The average true stress-true strain curve is then produced by removing time as a variable between the stress and strain data.

The 1- and 2-wave analyses used to calculate average stress discussed in the theory section implicitly assume that the strain-time pulses measured at the strain gages are identical with those at the ends of the bars in contact with the specimen. This assumption, however, is not correct because the specimen is normally smaller in diameter than the bar such that the bar ends are not uniformly loaded across their diameter and, therefore, will indent elastically. In addition, as the bars are compressed longitudinally, albeit elastically, they expand radially in response to the applied force (i.e., the Poisson effect). While the exact mathematical descriptions of these effects on the propagation of an elastic pulse through a large elastic rod are very complex, the result is that different frequencies of pulses induced in the bars disperse with distance traveled in the bar. The result of this dispersion is such that the pulse induced in the input bar through the impact of the striker bar does not immediately rise into a steady square-wave impulse of fixed amplitude but rather “rings” up. These end effects quickly dampen after the wave has propagated about ten bar diameters (Ref 40, 67).

The wave propagation behavior thereafter becomes fully described by the equation of motion in an infinite cylindrical solid. The solution of the equation of motion for these boundary conditions was derived independently during the late 19th century by the mathematicians Pochhammer (Ref 70) and Chree (Ref 71). These relations were later specifically applied to address dispersion in the SHPB (Ref 12, 15, 40, 72, 73, 74). The pressure bars have been determined to vibrate predominantly in a fundamental mode (i.e., while there are an infinite number of potential solutions to the equation of motion according to the vibrational mode, only one frequency appears to dominate in long elastic bars).

This vibration of the bar leads to wave dispersion that can mask resolution of the fine details in the stress-strain data of interest, particularly at higher strain rates where the period of the oscillations can be a large fraction of the total strain measured. While this elastic dispersion cannot be eliminated, techniques have been adopted based on the Pochhammer-Chree equation of motion to correct for any additional dispersion that occurs during the wave propagation from the specimen/bar interfaces to the gage locations (Ref 40, 72, 74, 75, 76, 77).

At any position, z , along the pressure bar, the wave, $f(t)$, may be represented by an infinite cosine Fourier series:

$$f(t) = \frac{A_0}{2} + \sum_{n=1}^{\infty} D_n \cos(n\omega_0 t - \delta_n) \quad (\text{Eq 20})$$

where ω_0 is the frequency of the longest wavelength component ($n = 1$), and δ_n is the phase angle of component $n\omega_0$. The wave dispersion in the pressure bars occurs because higher-frequency components travel more slowly than lower-frequency components and thus lag behind the leading edge of the wave. The dispersion results in a change of relative position and amplitude of the oscillations, together with a gradual increase in the rise time of the pulse as it travels along the bar. Because the strains measured in the pressure bars are measured by strain gages located some distance from the specimen, the pulse shapes at the strain-gage positions will be modified because of the dispersion effects and therefore do not accurately represent the pulse shapes at the specimen location.

The dispersion of the waves alters the phase angle, δ , such that at a position, $z + \Delta z$, the new phase angle can be calculated:

$$\delta(z + \Delta z) = \delta(z) + \frac{n\omega_0 \Delta z}{C_0} \left(\frac{C_0}{C_n} - 1 \right) \quad (\text{Eq 21})$$

where C_0 is the longitudinal wave speed in the bar, and C_n is the velocity of component $n\omega_0$. The value of C_n depends on the wavelength and on the mode of vibration; in the SHPB case, this is dominated by the fundamental mode (Ref 12). The phase angle at any position along the bar can be calculated using Eq 21, and the wave reconstructed at that new position using Eq 20. Accordingly, the raw stress-versus-strain data calculated using either the 1- or 2-wave analysis can be dispersion corrected by mathematically moving the wave to a common point on the bar (e.g., the bar-sample interface). This correction removes a large amount of the inherent wave dispersion, thereby yielding smoother final stress-strain curves (Ref 40, 43, 55, 72, 73, 78, 79).

Direct-Impact Compression Hopkinson Pressure Bar. Several researchers have suggested that one way to avoid the dispersion problem in the incident bar is to dispense with the incident bar altogether and impact the sample directly with the striker bar (Ref 72, 80 81 82 83 84 85 86 87 88). The initial intent of the direct-impact bar was to be used as a means of increasing the maximum strain rate achievable. While maximum higher strain rates can, in principle, be achieved using this technique, direct Hopkinson bars pose several difficulties. The first difficulty is that, because there is no incident bar, there is no means to calculate the strain rate and thereby the strain. Direct strain measurement on the sample and/or high-speed photography must be used to track diametral

sample expansion and therefore the strain. Careful study has shown that this is problematic, but this limitation can be overcome (Ref 83, 89). The second problem is that it is more difficult to achieve a constant strain rate in the sample because the direct impact of the striker bar on the sample lacks the equilibrium pulse achieved during the ringup in the incident bar in the split-Hopkinson configuration.

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Sample Design and Preparation

The errors due to radial and longitudinal inertia as well as friction effects can be reduced by choosing a sample size that minimizes the areal mismatch between the sample and the bar diameter and maintains a sample L/D ratio of 0.5 to 1.0.

For a given bar diameter, the sample diameter is typically chosen to be ~80% of the bar diameter for a compression bar test. Such a ratio allows ~30% true strain to be imparted into the sample before the sample exceeds the bar diameter. Samples for compressive split-Hopkinson bar testing similar to conventional low-rate compression testing need to be machined such that the two loading faces are flat, parallel to a 0.001 in. (0.01

mm) tolerance or better, as well as having the sides of the sample orthogonal to the loading faces. For brittle materials, this tolerance must be an order of magnitude greater. Orthogonality, as well as precision machining of parallel flat loading faces, is crucial to attaining uniform elastic loading in a compressive Hopkinson bar test and thereafter achieving a uniform stress-state in the sample.

While most investigators using the split-Hopkinson bar routinely use right-regular cylindrical samples, cubes and other square-sided shapes can be used. Ease of machining on a lathe to achieve accurate and reproducible sample specifications also favors cylindrical samples. The selection of the optimal sample diameter and L/D ratio is dependent on the maximum strain rate desired as well as the sample size requirement necessary to have specimens sufficiently large to ensure measurement of bulk properties of the material of interest. Coarse-scaled microstructures or composite materials require larger sample sizes than fine-scaled ones. An approximate rule of thumb is that the specimen diameter needs to be at least ten times the representative microstructural unit size for polycrystalline metals and alloys. Coarse-scaled materials, particularly, engineering composites such as concrete (Ref 90) or polymeric layups, require careful sample-size selection as well as specifically designed split-Hopkinson bars to achieve valid high-strain-rate stress-strain data.

Sample designs for Hopkinson bar testing of materials exhibiting a low resistance to axial cracking, such as ceramics, and/or composite matrix/reinforcement debonding, require the use of specialized sample designs. The use of “dog-bone” samples, originally designed by Tracy (Ref 91), allow the achievement of stable uniaxial stress in ceramics during Hopkinson bar testing. By suppressing axial cracking and/or brittle fracture processes in ceramic or cermet samples, because of the larger diameter ends of the samples, valid Hopkinson bar tests can be achieved (Ref 92). Accurate measurement of the high-strain-rate mechanical behavior of fiber-reinforced composite samples also requires a specialized sample design. Uniaxial testing of composites can be achieved using tapered compression samples with end sections constrained with chamfered rings to suppress axial splitting (Ref 93).

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

High-Rate Uniaxial Stress-Loading Effects on Materials

High-rate testing is conducted on a large number of materials of scientific and engineering interest to support the development of materials constitutive models (Ref 46, 94, 95, 96, 97, 98). Figure 9 shows the stress-strain response of electrical-grade iron measured in compression at various strain rates and temperatures. The range of temperatures and strain rates is conducted to facilitate a robust constitutive modeling fit for this metal. The

lower strain-rate tests were performed on a standard screw-driven Instron testing machine using the same specimen geometry as the dynamic tests. All the stress-strain curves, as a function of temperature and strain rate, are true values. Although the SHPB data at strains below ~ 1 to 2% are not in stress-state equilibrium, the curves are plotted in their entirety from load inception. Increasing strain rate at ambient temperature, 298 K, is seen to increase the flow stress of iron (Fe) equivalent to a decrease in temperature at a constant strain rate.

Fig. 9 Stress-strain response of electrical iron as a function of strain rate and temperature

The response of the iron in Fig. 9 is similar to that of other body-centered-cubic (bcc) metals and alloys, such as tantalum (Ta), tungsten (W), molybdenum (Mo), and niobium (Nb) (Ref 94) and hexagonal-close-packed (hcp) metals and alloys, such as zirconium (Zr), beryllium (Be), zinc (Zn), and titanium (Ti) (Ref 99, 100). In this class of metals, strain-hardening responses after yielding are nearly invariant as a function of strain rate (i.e., the stress-strain curves are all nearly parallel in slope although offset in their initial yields). This response is typical of bcc, hcp, and lower-symmetry metals where the Peierls stress dominates low-temperature and high-strain-rate mechanical behavior (Ref 94).

Other materials, including high-purity, face-centered cubic metals in an annealed condition, such as copper (Cu), nickel (Ni), aluminum (Al), and silver (Ag), conversely exhibit nearly strain-rate independent yielding behavior while their post-yield strain hardening is strongly rate dependent. The stress-strain behavior of high-purity silver given in Fig. 10 is typical of this class of materials. In-depth knowledge of the simultaneous influence of temperature and strain rate is used as the basis for advanced materials model development to describe high-strain-rate material response.

Fig. 10 Stress-strain response of high-purity silver as a function of strain rate and temperature

In addition to the direct influence of strain rate on stress-strain behavior by modifying defect generation and storage processes, high-rate deformation also alters the measured mechanical response due to the adiabatic heating accompanying high-rate plastic deformation. While adiabatic heating can be neglected during quasistatic deformation, the effect of adiabatic heating on the measured high-rate stress-strain behavior of materials must be considered. To extract an isothermal curve of the material response at a high rate, a relationship between temperature and stress must be assumed, and the data corrected accordingly. The temperature increase, ΔT , for mechanical tests at strain rates above 500 s^{-1} can be calculated assuming a certain percentage, Ψ of the work of plastic deformation is converted into heat (Ref 101, 102):

$$\Delta T = \frac{\Psi}{\rho C_p} \int \sigma(\epsilon) \delta \epsilon \quad (\text{Eq 22})$$

where σ and ϵ are the true stress and strain, respectively; ρ is the density; and C_p is the heat capacity that can be written in the form (Ref 103):

$$C_p = A_0 + A_1 \cdot T + \frac{A_2}{T^2} \quad (\text{Eq 23})$$

Adiabatic heating may be significant in samples deformed at high strain rates, particularly at higher strains. Careful consideration of adiabatic effects on overall constitutive response is crucial to accurate material model development.

Classic Split-Hopkinson Pressure Bar Testing

George T. (Rusty) Gray III, Los Alamos National Laboratory

Limitations and Problem Areas

In addition to the care needed to ensure the achievement of stress equilibrium during SHPB testing, several other problems can be encountered during experimental investigations studying the mechanical behavior of materials at high rates of loading. These problems are associated with inertia effects in the test machine, sample constraint due to friction at the points of contact, and issues related to assuring accurate strain gage measurements on the pressure bars.

Inertia. Even when the specimen has been evaluated to be deforming uniformly, longitudinal and radial inertia caused by the rapid particle accelerations imposed during high strain-rate testing can influence the measured stress-strain behavior (Ref 3, 104). The errors due to both longitudinal and radial inertia have been analyzed, and corrections have been derived for these errors (Ref 42). This analysis states that:

$$\sigma(t) = \sigma_m(t) + \rho_s \left(\frac{l_s^2}{6} - \nu_s \frac{d^2}{8} \right) \frac{\delta^2 \epsilon(t)}{\delta t^2} \quad (\text{Eq 24})$$

where σ_m is the measured stress, ρ_s is the density of the specimen, ν is the Poisson's ratio, l_s is the specimen length, and d is the specimen diameter. This expression predicts that errors are minimized if the strain rate is held constant or if the term inside the brackets is set to zero by choosing specimen dimensions such that

$$\frac{l_s}{d} = \sqrt{\frac{3v_s}{4}} \quad (\text{Eq 25})$$

For a Poisson's ratio of 0.33, Eq 25 suggests that the optimum sample l_s/d ratio to minimize errors caused by inertia is 0.5. Further work by Bertholf and Karnes (Ref 105) using a full two-dimensional finite-difference, elastoplastic finite-element analysis confirmed these results. This l_s/d ratio is less than that determined to be the most favorable for the minimization of errors due to friction in ASTM E 9, which specifies that $1.5 < l_s/d < 2.0$ (Ref 3). However, because the total strain in a split-Hopkinson pressure bar test is typically limited to approximately 25% to reduce the area mismatch between the specimen and the pressure bar, samples with an l_s/d of 0.5 are not expected to introduce any serious errors.

Radial inertia considerations limit the strain rate for which the SHPB technique is valid to about 10^5 s^{-1} for a high sound-speed material. The reason for this limitation is that as the strain rate is increased, the specimen size must be decreased accordingly. The specimen required eventually becomes so small that it no longer represents bulk material response. Only very fine-grained materials, such as nanocrystalline-structured materials, with high sound speeds can be tested with valid results at the very highest strain rates using this technique.

Friction is an important consideration in determining the validity of all compression testing (Ref 106). Further, the assumption of uniaxial stress conditions in the specimen can be affected by the presence of frictional forces that can cause radial traction at the interfaces between the pressure bars and the specimen. Lubrication is therefore required at the specimen/pressure bar interfaces. The optimum l_s/d ratio to minimize friction for a split-Hopkinson pressure bar compression test specimen is approximately one-half that determined to be most favorable for minimizing errors caused by friction for low-rate tests.

Early workers studying the SHPB were concerned about longitudinal inertial effects (i.e., how long it takes the forces on the ends of the specimen to become equal, that is, the ringing up time). Accordingly, they tested thin wafers of material with a thickness-to-diameter ratio of 0.1. Such extreme sample aspect ratios are known to maximize the effect of friction as the measured yield pressure, p , is related to the material flow stress, σ_f , according to the relation (Ref 107):

$$p = \left(\frac{1 + mD}{3\sqrt{3}l_s} \right) \sigma_f \quad (\text{Eq 26})$$

where m is the ratio of the friction stress to the shear strength of the material, D is the specimen diameter, and l_s is the specimen thickness (or length). Bell (Ref 108) identified that the absence of proper lubrication at the pressure bar/sample interfaces can cause large discrepancies between the measured strain on the radial surface of the specimen and the average strain obtained from the relative displacement of its two faces in the compression split-Hopkinson bar test.

Care must be exercised, therefore, in lubricating samples prior to testing as well as to limiting the strain in a single test to strains less than ~20 to 25%. Repeated reloading of a sample, with intermediate remachining to ensure flat and parallel sample loading surfaces, can be utilized to achieve higher total strains. Repetitive reloading offers the added benefit of minimizing adiabatic heating effects on the measured stress-strain behavior. The size of the sample can also have a significant effect on the friction condition during an SHPB test. Gorham (Ref 104) showed that larger samples of copper deformed at the same strain rate involve longer radial displacement at higher velocities than in the case of smaller samples. Breakdown in the lubricant is more likely under large displacements, and loss of lubricant by jetting is enhanced at increased strain rates. Care must therefore be exercised to avoid velocity-dependent frictional constraints altering the stress-strain response if larger test samples are used.

The use of an oil-based molybdenum disulfide lubricant has been shown to be effective for room-temperature SHPB testing (Ref 3). For elevated-temperature tests, a thin layer of fine boron nitride powder can be used to lubricate the specimen/pressure bar interfaces. So far, no lubricant has been found that completely eliminates friction for metallic specimens in this geometry, although the frictional stresses can be reduced to about 4% of the metal's shear strength. Friction can, in principle, be measured using annular specimens, the idea being that the higher the friction, the smaller the ratio of the internal to external diameter for a given strain (Ref 107, 109). However, the presence of a layer of lubricant at these interfaces can influence the timing between the waves recorded on the incident and output pressure bars. Consequently, it is important to maintain as thin as possible the layer of lubricant on the bar ends. Routine examination of the surface finish and flatness of the pressure-bar-

loading faces, in addition to checking for any possible cracking or erosion of the bar ends, are also critical elements influencing valid SHPB data acquisition.

Strain-Gage Measurements. Because the stress-strain behavior of the material of interest is deduced from the elastic strain signals in the pressure bars, the details of the conditions controlling the accuracy and reproducibility of the strain gages are crucial. A number of considerations related to strain-gage installation and usage can affect the elastic strain measurements obtained. Two gages generally are mounted at diametrically opposite positions on each bar and connected so as to average out most bending strains in the bars and increase the magnitude of the strain signal measured by a factor of two. The use of four gages arranged equidistantly around the bar diameter, comprising a complete Wheatstone strain gage bridge, will totally eliminate any bending effects on the strain data. The four-gage arrangement additionally corrects for any magnetostriction effects (induced voltage in the strain gages due to stress wave propagation in a ferromagnetic bar material). Use of nonmagnetic pressure bar materials, such as Ti-6Al-4V or Mg, eliminates any potential magnetostriction errors in the strain-gage outputs. In addition to the elimination of bending forces through the use of multiple gage locations, shielding of the wire leads from the strain gages to the signal conditioners is important for minimizing external noise given the small magnitude of the absolute strain signals and the level of amplification required to boost the signals to the levels required by the data acquisition system.

Finally, bonded strain gages have a finite-time-response capability that is linked to the stiffness of the epoxy used to bond the gages to the bars as well as the thickness of the interface. Using an epoxy that is too compliant can dampen the signals transferred from the bar surface to the strain gages. Conversely, an epoxy that is too stiff and brittle will require frequent replacement. Careful selection, application, and maintenance of the gages bonded to the SHPB is required to ensure accurate bar operation. Periodic calibration is used to monitor the gage/epoxy bond degradation.

New Developments in Split-Hopkinson Bar Testing

The Hopkinson pressure bar, as a research and engineering tool for the quantitative measurement of the high-rate stress-strain behavior of materials, is a technique that is far from static. In recent years, a number of new improvements have been designed and their value proven to improve both the accuracy and timeliness of measurements. One-, two-, and three-dimensional finite-element models of the split-Hopkinson pressure bar have proven their ability to simulate test parameters and allow pretest setup validation checks as an aid to planning. Finite-element models additionally offer a means in the future to validate the data and dispersion analysis used in the Hopkinson bar to probe for the effects of inertia and friction, for example, and provide an opportunity to extend the use of the Hopkinson bar to the characterization of materials for which the SHPB technique was previously unable to achieve a valid uniaxial stress state. Previous research using this approach on the SHPB testing and analysis of soil samples has shown the utility of such a finite element method (FEM)/standard SHPB analysis (Ref 51). A current example of this promising line of research is applied to split-Hopkinson bar testing of viscoplastic materials (more information can be found in the article “Split-Hopkinson Pressure Bar Testing of Soft Materials” in this Volume).

Novel methods of characterizing sample diametrical strains are also being developed for the Hopkinson bar using optical diagnostic techniques (Ref 110, 111). This technique offers an alternate mechanism to measure the diametrical strain in a Hopkinson pressure bar sample as a function of time using a linear laser line-measuring diagnostic device. This technique offers a valuable additional way to accurately measure sample dimensional changes without the use of strain gages attached to the sample. This technique, however, must also be cautiously approached as a stand-alone technique where anisotropic plasticity in the sample could falsely portray the sample diametral strain unless multiple viewing points are surveyed. Additional optical techniques are emerging that may provide a quantitative means of measuring axial and radial strains in SHPB samples during testing. These techniques include monitoring strains on a cylindrical sample using Bragg grating sensors (Ref 112) and the measurement of tangential displacements on samples and/or the pressure bars themselves using speckle interferometry (Ref 113).

Finally, careful attention to controlling wave reflections in the SHPB has also opened new opportunities to study defect/damage evolution in brittle materials during high-rate loading histories (Ref 114). Careful momentum trapping of the transmitted and reflected wave pulses in the pressure bars can be utilized to facilitate single pulse loading of the sample. Researchers are also exploring exciting new methods for in situ dispersion measurements (Ref 47) on pressure bars, which offer opportunities for increased signal resolution in the future.

Recovery Hopkinson Bar Techniques

Sia Nemat-Nasser, University of California, San Diego

Introduction

THE CLASSICAL split-Hopkinson bar technique is described in separate articles in this Section for tension, compression, and torsion tests. For all three cases, the stress pulse travels along the incident bar and is partly transmitted to the transmission bar by the specimen sandwiched between the two bars. The remaining part of the stress pulse is reflected back in the incident bar as tension in the compression bars, as compression in the tension bars, and as reverse torsion in the torsion bars. Both the transmitted and reflected pulses travel along the corresponding bar and are then reflected back and eventually reload the sample. If the sample does not fail in the course of the first loading, it will then be subjected to repeated loading by these elastic waves traveling back and forth along the bars.

There are many applications where it is necessary to subject a sample to a single loading and then recover it, without the sample having been subjected to any additional loads. Such a capability allows, for example, to relate the microstructural changes to the loading history or, as is shown later, to produce isothermal stress-strain relations for certain metals, at high strain rates (Ref 1, 2, 3).

For compression tests, special fixtures, such as “stopper rings,” can be used to limit the total axial strain of the sample and to transmit the remaining compression pulse through the stopper ring once the sample length equals that of the ring (Ref 4, 5, 6). A similar technique, however, does not apply to the tension or torsion tests. Moreover, even in compression, such a technique works only if large axial permanent straining of the sample is involved, and even then, the sample with the stopper ring is repeatedly loaded elastically. For hard, brittle materials, such as ceramics and their composites, the total axial strain to failure is very small, and, therefore, a “stopper-ring approach” is difficult, if not impossible, to implement. For this class of materials, once the initial compressive pulse has produced microcracks in the brittle sample, the subsequent reflected compression pulses may shatter the specimen, making recovery essentially impossible by that technique. For tension tests, and in the absence of wave trapping, both the transmitted and reflected pulses load the sample repeatedly.

The stopper-ring approach fails also when recovery tests are to be performed at high temperatures. For high strain-rate tests at elevated temperatures, it is necessary to heat the sample to the required temperature, while keeping the incident and transmission bars at suitably low temperatures. If the bars are in contact with the specimen within the furnace, their temperature will increase, having a variable distribution along the bars. This affects the elastic properties of the bar and, hence, the stress pulses. Moreover, the bars being good heat conductors (usually of maraging steel), the considerable heat loss that occurs makes controlling the experiment difficult.

To remedy these major problems, techniques have been developed where, for compression and tension tests (Ref 7), both the reflected and transmitted pulses are trapped at the far end of the bars, once the sample is

subjected to the initial loading. Moreover, this can be done at elevated temperatures, where the sample is heated within an attached furnace, with the Hopkinson bars held outside the furnace. These bars are then brought into contact with the specimen microseconds before the stress pulse reaches the end of the incident bar. The method ensures that the sample is subjected to a single stress pulse with a time variation that is also fully controlled.

In addition to the compression and tension recovery Hopkinson bar techniques, a technique has been worked out that allows recovery of the sample after it has been subjected to a compression followed by a tension pulse (Ref 7). This technique permits the study of the Bauschinger effect and the strain-rate history effects on the mechanical properties and microstructural evolution of materials under various dynamic loading conditions (Ref 8, 9).

The dynamic tests of hard materials (e.g., ceramics) at elevated temperatures present a new challenge. At suitably low temperatures, the sample strain can be measured directly by placing a strain gage on the sample (Ref 10, 11, 12, 13). This, however, may not be possible at elevated temperatures. Even at low temperatures, indentation of the bars by the sample must be prevented in order to obtain reliable results and preclude damaging of the bars. This latter problem is solved by using properly confined tungsten carbide (WC) inserts, placed between the sample and the bars (Ref 12). The impedance of the inserts is carefully matched with that of the bars. For strain measurements at high temperatures, a new technique is *differential strain measurement* (DSM), which can be used to obtain accurate and reliable values of the strain in the dynamic test of very hard ceramics at elevated temperatures. This method is briefly discussed in the section “High-Temperature, High Strain Rate Testing of Hard, Brittle Materials” in this article.

Recovery Hopkinson Bar Techniques

Sia Nemat-Nasser, University of California, San Diego

Momentum Trapping for Hopkinson Bars

In a tension recovery Hopkinson bar, both the reflected compression and the transmitted tension pulses must be trapped once the loading of the sample is completed. In a compression bar, on the other hand, only the tension pulse, which reflects off the sample, must be trapped since the transmitted compression cannot reload the sample.

Figure 1(a) shows the momentum trapping scheme for a tension pulse. The free end of the bar terminates with a transfer flange F in contact with a momentum-trap tube MT, which has the same impedance as the bar (e.g., the tube has the same cross-sectional area and is made of the same material as the bar). The tensile pulse T in Fig. 1(a) reflects off the free end F of the transfer flange as compression. This compressive pulse is then fully transferred into the momentum-trap tube MT in contact with the flange because of the matched impedances. The compression then reflects off the free end of the tube as tension and is trapped in the tube, which begins to move away from the transfer flange once the reflected tension reaches the tube's end in contact with the flange. This process is similar to transferring compression pulses across contacting bars with fully matched impedances. As shown in Fig. 1(b), the compression pulse C will be completely transmitted from bar A to bar B across the contact surface S_c when the bars have the same impedance. This transmitted compressive pulse then reflects from the free end of the bar B as tension and is fully trapped in B.

Fig. 1 Momentum trapping in recovery Hopkinson bar testing. (a) Momentum-trap tube MT in contact with transfer flange F traps the tension pulse T upon reflection off the flange F. (b) Bar B in contact with bar A traps compression pulse C. Source: Ref 7

Tension Hopkinson Bar with Momentum Traps. In a tension Hopkinson bar, the momentum trapping scheme shown in Fig. 1(a) and (b) can be used to trap the compression pulse (Fig. 1b), which reflects off the sample, back into the incident bar, and the tension pulse (Fig. 1a), which is transmitted through the sample into the transmission bar, respectively.

Figures 2, 3, 4 show a complete system that includes at the loading end a tubular striker, an incident bar with a transfer flange at its free end, a gas gun through which the incident bar passes, and a momentum-trap bar. The far end of the transmission bar terminates in a momentum-trap tube (not shown), which is the mirror image of the one shown in Fig. 1(a).

Fig. 2 Recovery tension Hopkinson bar setup. Source: Ref 7

Fig. 3 Operation of the recovery tension Hopkinson bar. (a) Striker tube impacts transfer flange. (b) The resulting tensile pulse closes the preset precision gap. (c) The compression pulse, which reflects off the sample into the incident bar, reaches the transfer flange and is transmitted into the momentum-trap bar. (d) The momentum in the trapped pulse causes the bar to fly off. Source: Ref 7

Fig. 4 Photograph of tension Hopkinson bar momentum-trap construction. Source: Ref 7

A preset precision gap separates the momentum-trap bar and the transfer flange of the incident bar. The precision gap is set such that the end of the momentum-trap bar and the face of the transfer flange are brought into contact, once the entire tensile pulse, produced by the tubular striker, is transferred into the incident bar through the transfer flange. This tensile pulse then travels toward the sample, where it is partly transmitted into the transmission bar and is partly reflected as compression back into the incident bar. This reflected compression (often nearly the same as the incident pulse) is then transmitted into the momentum-trap bar and reflects off the other (free) end of this bar as a tensile pulse. This pulse is then trapped in the momentum-trap bar since the contact interface with the transfer flange cannot support tension. The momentum of the trapped pulse causes the bar to fly off. The incident bar then is everywhere at rest. The pulse, which is transmitted through the sample into the transmission bar, is also trapped at the free end of this bar by a momentum-trap tube. This free end of the transmission bar includes a transfer flange and a momentum-trap tube in contact with the flange, similar to those in Fig. 1(a).

At the striker end of the incident bar, the precision gap between the transfer flange and the momentum-trap bar must be calculated and set with some care to obtain satisfactory results, as illustrated in Fig. 5(a). If the gap is too large, the reflected compression pulse in the incident bar will not be transmitted to the momentum-trap bar. On the other hand, if the gap is too small, it will be closed during the loading of the incident bar by the striker. This affects the stress pulse, moves the momentum-trap bar into an improper position, and, hence, produces undesirable results. An example is shown in Fig. 5(b), where the gap was much too large.

Fig. 5 (a) A typical tensile stress pulse, its reflected compression pulse, and its residue after trapping. (b) A poorly trapped reflected compression; the gap between the momentum-trap and incident bars was too big. Source: Ref 7

The momentum-trap bar is correctly positioned when the gap is set such that when the initial collision between the striker and the incident bar is complete, the incident bar is fully in contact with the momentum-trap bar. While the necessary separation can be calculated, in practice this provides a starting point that then is optimized by trial and error. If the breech pressure of the gas gun and the striker velocity are kept constant while adjusting the gap, within a few trials the correct gap for a given striker bar and breech pressure will be obtained. With data of this kind, a calibration curve of breech pressure versus gap can be established for further use. Calibration curves of this kind are not universal and must be rechecked periodically for the same system and reestablished each time a change in the system is made.

Recovery Hopkinson Bar Techniques

Sia Nemat-Nasser, University of California, San Diego

Stress-Reversal and Strain Rate Jump Hopkinson Techniques

Using a flange and a momentum-trap tube, it is possible to produce a compression pulse followed by a tension pulse and to create a sudden jump (an increase or a decrease) in the strain rate. These techniques are discussed in this section.

Stress-Reversal Technique. Figure 6 shows the overall design of this stress-reversal Hopkinson bar. The loading end of the incident bar begins with a transfer flange, as shown in Fig. 6 and 7 (see also Fig. 8). In this setup, the incident tube, the striker bar, and the incident bar have the same impedance. The incident tube rests against the transfer flange at one end and against a reaction mass at the other, as shown in Fig. 6 and 7. The reaction mass is a large steel cylinder through which the incident bar passes.

Fig. 6 A stress-reversal Hopkinson bar setup. Source: Ref 7

Fig. 7 Operation of stress-reversal Hopkinson bar. (a) Striker bar impacts transfer flange. (b) Compressive pulse in the incident tube reflects from the reaction mass. (c) Striker bar bounces away. Source: Ref 7

Fig. 8 Photograph of a stress-reversal loading fixture. Source: Ref 7

When the striker bar impacts the transfer flange at velocity V_0 , it imparts a common axial strain to the incident tube and incident bar. The compression pulse in the incident bar travels along this bar toward the specimen. The compression pulse in the incident tube reflects from the reaction mass as compression and reaches the transfer flange at the same instant that the tension release pulse—which is reflected from the free end of the striker—reaches the end of the striker bar in contact with the transfer flange. Since the combined cross section of the incident bar and tube is twice that of the striker bar, having the same material properties, the striker bar begins to bounce back, away from the transfer flange, as the transfer flange is loaded by the compression pulse traveling along the incident tube. This compression pulse then imparts a tensile pulse to the incident bar, which follows the then-existing compression pulse in the incident bar, both pulses traveling toward the sample. Figure 9 illustrates a typical result.

Fig. 9 A typical stress pulse generated by the stress-reversal Hopkinson bar technique. Source: Ref 7

It is important to bear in mind the significance of the perfect impedance matching of the striker bar, incident bar, and incident tube, as well as the configuration of the transfer flange in the design of the loading fixture for proper functioning of the stress-reversal Hopkinson technique.

From the equality of particle velocities at contacting surfaces and the conservation of linear momentum, it follows that the particle velocity in the incident bar and incident tube at impact is $V_0/3$. The particle velocity of the compressed portion of the striker bar, relative to its unstressed part, then is $2V_0/3$. When the reflected release-wave front in the striker reaches the contact with the transfer flange, the striker bar begins to move at velocity $V_0/3$ away from the transfer flange. At the same instant, the compression wave in the incident tube imparts to the transfer flange exactly the same particle velocity (i.e., $V_0/3$) in exactly the same direction. Thus, the contact surfaces remain in contact for a short period, $t_0 = 2l_0/C_0$, until the striker separates at a third of its initial impact velocity, as the flange comes to rest; here, l_0 is the common length of the striker bar and the incident tube, and C_0 is their common longitudinal elastic-wave speed.

Strain Rate Jump. The stress-reversal technique can be used to change the strain rate during the course of Hopkinson bar compression or tension experiments (Ref 14). Consider a recovery compression system first. The loading (striker) end of the incident bar includes a transfer flange, an incident tube, and a reaction mass, as sketched in Fig. 10(a). Suppose the transfer tube is in contact with the transfer flange. Then, as the striker bar impacts the incident bar over the transfer flange, elastic compressive stresses are induced in both the incident bar and the incident tube, as well as in the striker bar, in accordance with their impedances. To change (decrease) the stress (and, hence, the strain) in the incident bar in the course of the experiment, a predetermined gap is introduced between the transfer flange and the incident tube (Fig. 10b). As the striker bar now impacts the incident bar, a compressive stress pulse is imparted into this bar, resulting in the shortening of the bar. Once the incident bar is sufficiently shortened to come in contact with the incident tube over the transfer flange, a stress pulse is also imparted into the incident tube, reducing the compressive stress (and, hence, the compressive strain) in the incident bar. Since the sample strain rate is a linear function of the incident strain in the incident bar, the procedure allows implementation of a change in the sample strain rate during the course of the experiment. By proper choice of the gap and the involved impedances, a desired change in the sample strain rate can be achieved.

Fig. 10 Recovery Hopkinson bar compression testing. (a) Test configuration. (b) A gap between the incident tube and the transfer flange leads to a decrease in the strain rate, once the gap is closed. (c) A gap between the incident tube and the reaction mass leads to an increase in the strain rate. Source: Ref 8

It is also possible to increase the sample strain rate using the same construction. For this purpose, the incident tube first rests against the transfer flange, as the striker bar impacts the flange (Fig. 10c). If the length of the incident tube is suitably smaller than that of the striker, and if the other end of this tube (which is not in contact with the transfer flange) is free, the compressive pulse in the tube will be reflected off its free end as a tensile release pulse, reaching the transfer flange before the tensile release wave in the striker reaches there. The incident tube then separates from the transfer flange while the striker bar continues to impart a stress pulse into the incident bar. Upon separation of the tube from the flange, the stress (and, hence, the strain) in the incident bar is increased accordingly. Thus, the incident strain at the sample-incident bar interface is increased, resulting in a corresponding increase in the sample strain rate.

For numerical estimates, ρ , C , E , A , u , ϵ , and σ denote the mass density, longitudinal wave speed, Young's modulus, area, particle velocity, axial strain, and axial stress, respectively, and subscripts st, i, and tb represent the striker bar, incident bar, and the incident tube, respectively. Set $k = \rho CA$, and note that $C^2 = E/\rho$. Since the bar and the tube remain elastic throughout the experiment, in general:

$$\sigma = \rho Cu = \sqrt{\rho E} u = E\epsilon \quad (\text{Eq 1})$$

$$\epsilon = \frac{u}{C} = \frac{\sigma}{E}$$

While a gap separates the incident tube and the transfer flange (Fig. 4b):

$$k_i u_i = k_{st} u_{st} \quad (\text{Eq 2})$$

$$V_0 - u_{st} = u_i$$

where V_0 is the (constant) initial velocity of the striker bar. From Eq 1 and 2, it follows that:

$$\epsilon_i = \frac{k_{st}}{k_{st} + k_i} \frac{V_0}{C_i} \quad (\text{Eq 3})$$

This strain in the incident bar is the incident strain at the sample end of the incident bar. If the strain in the transmission bar is denoted by ϵ_t , then the strain rate in the sample, $\dot{\epsilon}_s$, is given by:

$$\begin{aligned}\dot{\epsilon}_s &= 2 \frac{C_i}{l_s} (\epsilon_i - \epsilon_t) \\ &= 2 \frac{C_i}{l_s} \left(\frac{k_{st}}{k_{st} + k_i} \frac{V_0}{C_i} - \epsilon_t \right)\end{aligned}\quad (\text{Eq 4})$$

where l_s is the sample length. Note that, in general, the incident and transmission bars have common area, wave speed, and so on.

When the gap between the transfer flange and the incident tube is closed (Fig. 10c), the incident strain is reduced to:

$$\epsilon_i = \frac{k_{st}}{k_{st} + k_i + k_{tb}} \frac{V_0}{C_i} \quad (\text{Eq 5})$$

resulting in the sample strain rate of:

$$\dot{\epsilon}_s = 2 \frac{C_i}{l_s} \left(\frac{k_{st}}{k_{st} + k_i + k_{tb}} \frac{V_0}{C_i} - \epsilon_t \right) \quad (\text{Eq 6})$$

If the sample material is rate independent, ϵ_t will be the same in Eq 4 and 6, and the change in the sample strain rate becomes:

$$\begin{aligned}\Delta \dot{\epsilon}_s &= 2 \frac{V_0}{l_s} \left(\frac{k_{st}}{k_{st} + k_i + k_{tb}} - \frac{k_{st}}{k_{st} + k_i} \right) \\ &= -2 \frac{V_0}{l_s} \left[\frac{k_{st} k_{tb}}{(k_{st} + k_i)(k_{st} + k_i + k_{tb})} \right]\end{aligned}\quad (\text{Eq 7})$$

When $k_{st} = k_i = k_{tb}$:

$$\Delta \dot{\epsilon}_s = -\frac{1}{3} \frac{V_0}{l_s} \quad (\text{Eq 8})$$

For example, with a striker velocity of 30 m/s (98 ft/s) and sample length of 5 mm (0.2 in.), $\Delta \dot{\epsilon}_s = 2 \times 10^3 \text{ s}^{-1}$. Note that these results apply to both reduction and increase in the sample strain rate.

For rate-dependent materials, the flow stress changes with the strain rate. Hence, the transmitted strain ϵ_t in the transmission bar is changed:

$$\epsilon_t = \frac{\sigma_s A_s}{E_t A_t}$$

where subscripts s and t refer to the sample and transmission bar, respectively. Hence, if the change in the sample flow stress is $\Delta \sigma_s$:

$$\begin{aligned}\Delta \dot{\epsilon}_s &= -2 \frac{V_0}{l_s} \left[\frac{k_{st} k_{tb}}{(k_{st} + k_i)(k_{st} + k_i + k_{tb})} \right] \\ &\quad - 2 \frac{C_i A_s}{l_s E_t A_t} \Delta \sigma_s\end{aligned}\quad (\text{Eq 9})$$

where $\Delta \dot{\epsilon}_s$ is negative when the strain rate (and, hence, the flow stress) is decreased.

Figure 11 illustrates the results of this method. Point A on the lower curve in this figure marks the strain in the sample, at which the strain rate is changed from about 1600 s^{-1} to about 850 s^{-1} ; the strain rate difference is about 750 s^{-1} . The impact velocity of the striker bar is 8 m/s (26 ft/s); the Young's modulus of the incident bar is 200 GPa (29×10^6 psi). The diameter of the transmission bar is 1.27 cm (0.5 in.). The length of the sample is 0.35 cm (0.14 in.). The stress difference in Fig. 11 due to the change of the strain rate is 350 MPa (50 ksi). From Eq 9 and these data, a strain rate difference of 757 s^{-1} is obtained (Ref 8). This calculated result is very close to the observed one.

Fig. 11 Illustration of strain rate jump. At point A the strain rate is changed from about 1600 s^{-1} to about 850 s^{-1} , leading to a stress difference of about 350 MPa (50 ksi). Source: Ref 8

Strain Rate Jump in Tension. The tension bar with a momentum trap can be used to change the strain rate during the course of tension Hopkinson tests. First, consider a case in which it is required to decrease the strain rate during a test. To accomplish this, a gap is provided between the momentum-trap bar and the transfer flange of the incident bar in Fig. 1(a) such that this gap is closed while the striker tube is transferring the load to the transfer flange. By suitable choices of the impedances of the incident bar, momentum-trap bar, and the striker tube, it is then possible to suddenly decrease the strain rate by a desired amount. The basic equations follow from those given in the previous section.

To increase the strain rate in a tension Hopkinson test, a suitably short momentum-trap bar in contact with the flange is used (Fig. 1a), *before* the striker tube impacts the transfer flange. Then, the striker bar imparts a tensile pulse into the incident bar and, simultaneously, a compression pulse into the momentum-trap bar. This compression pulse reflects off the other end of the momentum-trap bar as a tensile release wave, separating the bar from the flange, once it reaches the contact between the bar and the flange. For a suitably long striker tube, this can occur while the striker is continuing to load the transfer flange. Again, the necessary equations are similar to those given in the previous section. Note that the impedances must be properly selected in order to achieve a desired increase or decrease in the strain rate.

Recovery after Combined Compression-Tension Loading. In many high strain rate applications, materials may be subjected to dynamic compressive loads, followed by tension. An example is the examination of the dynamic Bauschinger effect and its relation to the microstructure of the material. Experimental investigations of this kind require techniques to recover the sample after it has been subjected to a cycle of compression followed by tension, or tension followed by compression.

The stress-reversal technique can be used to subject a specimen to a combined compression-tension pulse without interruption and then recover it for post-test characterization (Ref 7). The loading fixture is the same as shown in Fig. 6 7 8. The sample configuration and the manner by which it is attached to the incident and transmission bars are designed such that, after the specimen is subjected to the desired compression-tension pulse, it is detached from the incident bar without additional loading of its central gage portion. This process is accomplished as follows.

As shown in Fig. 12 (see also photograph in Fig. 13), in addition to the reaction mass R_0 , there are two other reaction masses, denoted by R_1 and R_2 . The sample construction (Fig. 14) includes two threaded ends and a reaction flange F_S , which, at the start of the experiment, rests against the reaction mass R_1 , with the sample end fully threaded into the incident bar.

Fig. 12 Combined compression-tension dynamic recovery experiment. Source: Ref 7

Fig. 13 Photograph of combined compression-tension setup showing the manner by which the sample is connected to the incident and transmission bars. Source: Ref 7

Fig. 14 Two samples of the same material (Al-Cu), one flanged for recovery test and the other unflanged for data acquisition. Source: Ref 7

The sample is threaded into the transmission bar through the reaction mass R_2 . The transmission bar rests against a thin flange F_2 , constructed in R_2 by reducing its opening diameter around the sample, as shown in Fig. 12. The other (output) end of the transmission bar is in contact with a bar of the same impedance, which can trap compression pulses transmitted through the sample into the transmission bar. When the striker hits the transfer flange of the incident bar, a compression pulse followed by a tension pulse is imparted into the incident bar, as discussed in the section “Stress-Reversal Technique” in this article. The compression-tension pulse travels toward the sample and subjects the sample to compression first (which shortens the sample), followed by tension (which almost restores the initial length of the sample). A part of the compression pulse is transmitted through the sample into the transmission bar and is trapped at the far end of this bar by the momentum-trap bar (hatched in Fig. 12). The remaining part of the compression pulse is reflected off the specimen into the incident bar as tension. This tension then reflects back from the striker end of the incident bar and returns to the sample as tension because of the presence of the transfer flange, incident tube, and the reaction mass R_0 .

When the tensile segment of the initial compression-tension pulse reaches the specimen, it is partly transmitted through the sample into the transmission bar and is partly reflected off the sample as compression, back into the incident bar. As the sample shortens during the compressive loading, prior to the arrival of the tension pulse, its flange, F_S , separates from the reaction mass R_1 . The subsequent tensile loading (almost) restores the sample's initial length, bringing the sample's flange (almost) in contact with the reaction mass R_1 . The tensile pulse, which reflects as compression from the far end of the transmission bar, returns to the sample, loading it (just slightly) until the transmission bar comes in contact with the flange F_2 of the reaction mass R_2 . At this instant, the sample flange F_S is in complete contact with the reaction mass R_1 . Shortly after, the tensile pulses, which are reflected from the loading end of the incident bar, reach the sample, pulling the incident bar away from the sample, while the sample flange F_S is engaged against the reaction mass R_1 . (As discussed previously, both compression and tension pulses are reflected as tension from the loading end back into the incident bar.) The threads that connect the sample to the incident bar are designed to strip off during this final tensile-loading process. Note that the threads are pulled against the flange F_S resting on R_1 . This prevents loading the sample over its gage length during this recovery stage. The sample is then recovered, having been subjected to a cycle of compression-tension loading over its gage length.

The flange F_S in combination with the threaded ends of the sample makes the impedance matching difficult and, hence, complicates the interpretation of the resulting data. This problem can be overcome to a great extent by performing two tests, one to recover the sample (which has a flange) for post-test analysis and the other (using a sample that does not have a flange) to collect the required data. Figure 12 shows the two samples. The corresponding data are given in Fig. 15. Even though the data obtained with the flanged sample are noisy, they agree quite well with those obtained with the unflanged sample. The unflanged sample, on the other hand, is subjected to additional tensile pulses, which may cause necking, or even tensile failure of the sample.

Fig. 15 Data at 3200 s^{-1} strain rate, using flanged (solid curve) and unflanged (dashed curve) specimens (compression is positive). Source: Ref 7

Recovery after Tension and Compression Loading. The recovery tension and compression Hopkinson techniques can be used to subject a sample to a tensile pulse, recover the sample, produce from it compression samples (Fig. 16), and then subject these samples to compression and recover them. This allows the studying of the response and microstructural changes when the material is subjected to a tension, recovered, and then subjected to a compression (Ref 8, 9). In this approach, the tensile loading is not followed immediately by a compression pulse. Hence, if there are any microstructural changes during the recovery and preparation of the compression samples from the original tension sample, these changes may affect the subsequent compression test results. Indeed, the effects of such changes on the response of the material can be studied by this method.

Recovery Dynamic Testing of Hard Materials

Most ceramics are extremely hard and undergo very little strain prior to failing. Their response is essentially linear, up to failure. Thus, special techniques are necessary in order to perform high strain rate recovery experiments on these materials.

In the classical compression split-Hopkinson bar, the yield stress of the sample must be considerably smaller than the yield stress of the bars. The ends of the incident and transmission bars, in contact with the specimen, therefore remain essentially flat as the sample deforms. Furthermore, the impedance of the sample generally is considerably smaller than that of the bars throughout the entire loading history. Therefore, the tensile pulse that reflects off the sample into the incident bar is a good measure of the velocity of the sample end of the incident bar relative to that of the transmission bar.

When very hard materials, such as ceramics and ceramic composites, are being tested in the compression split-Hopkinson bar, the reflected pulse, in general, no longer accurately measures the strain rate in the sample. Indeed, if the diameter of the sample is not considerably smaller than the diameter of the bar, the impedance of the sample may be close to, or, in certain cases, even greater than that of the incident bar, resulting in a very small reflected tensile pulse, or even a reflected compressive pulse. On the other hand, as is often required, when the diameter of the sample is considerably smaller than that of the bars, the hard sample indents the ends of the bars (Fig. 17). Furthermore, since the total strain to failure for hard ceramics and their composites is usually quite small (1 or 2%), the indentation, in general, introduces significant errors in the results if the reflected pulse is used to calculate the strain in the sample. The reflected wave in the incident bar no longer is an accurate measure of the strain rate in the sample of hard, brittle materials, although the transmitted pulse is still a good indication of the stress in the sample.

Fig. 17 Indentation of the bar by a hard (ceramic) specimen. Source: Ref 7

As can be seen from Eq 4, for the sample strain rate to be constant it is necessary that $\dot{\epsilon}_r = -(\dot{\epsilon}_i - \dot{\epsilon}_t)$ be constant. In the classical Hopkinson technique, this is accomplished by seeking to impart a constant stress pulse into the incident bar. A constant stress pulse, however, does not produce a constant strain rate in an elastic sample. Instead, such a pulse deforms the sample in three distinct regimes, namely, an initial regime of positive strain rate when the stress in the sample increases to a constant level, followed by a regime of zero strain rate, which is then followed by a regime of negative strain rate. Thus, for hard ceramics, it is necessary to render the strain differential, $\epsilon_i - \epsilon_t$, as nearly constant as possible. This can be achieved by using a ramp pulse.

These basic problems have been solved (Ref 10, 11, 12, 13) using the following techniques:

- The strain is measured directly by attaching strain gages to the sample. For samples with square cross sections, two strain gages are used, one to measure the axial strain and the other to measure the lateral strain (Ref 10, 11).
- A thin metal cushion is placed at the striker end of the incident bar to produce a ramp stress pulse in the incident bar. Figure 18 shows typical stress and strain pulses that can be obtained in this manner. In Ref 7, a detailed analysis of the finite deformation of the copper cushion is given, together with experimental verification of the results. It is shown that the pulse shape depends on the cushion

geometry and the length and velocity of the striker and that it can be reliably predicted using finite plasticity theory.

- The yielding of the bars by the hard ceramic samples can be prevented using an impedance-matched small platen of polished tungsten carbide. When necessary, a composite of the tungsten carbide, which is press fitted within a ring of, for example, Kovar, may be used. Figure 19(a) shows the construction used by Sharma et al. (Ref 12), and Fig. 19(b) shows a composite tungsten-carbide platen. It is important to attain a good impedance match between the inserts and the bars in such constructions.

Applications of Recovery Hopkinson Techniques

The recovery of the sample that has been subjected to a single stress pulse allows a number of interesting applications, a few of which are reviewed in this section.

Isothermal Flow Stress of Ductile Materials at High Strain Rates. Incremental straining can be used to measure the strain softening produced by the temperature rise associated with the high strain rate plastic deformation of ductile samples. The effect of any recovery on the flow stress that may occur during unloading and cooling to room temperature, and reloading of the sample, is assessed by overlapping the incremental straining of similar samples of the material. Figure 20 provides results for a tantalum-tungsten alloy (Ta-10%W). Curves 1 and 2 are obtained quasi-statically (Instron machine) at 10^{-3} and 1 s^{-1} strain rates. Curve 3 is the adiabatic stress-strain relation at a 5700 s^{-1} strain rate, starting with $25 \text{ }^\circ\text{C}$ ($77 \text{ }^\circ\text{F}$) initial temperature; different samples are used. To obtain the (quasi-) isothermal flow stress at a 5700 s^{-1} strain rate, a fourth sample is deformed incrementally in the recovery Hopkinson system, obtaining curves 4, 5, and 6. Then, curve 7 is constructed using these results.

Fig. 20 The true stress-true strain relations for Ta-10%W at $25 \text{ }^\circ\text{C}$ ($77 \text{ }^\circ\text{F}$). Curves 1, 2, and 7 are isothermal relations at strain rates of 10^{-3} , 1, and 5700 s^{-1} . Curve 5 is adiabatic at 5700 s^{-1} strain rate. Source: Ref 1

Before accepting curve 7 as the quasi-isothermal stress-strain relation of this material, it is necessary to establish whether a uniform stress state is attained in the sample prior to yielding in each straining increment. The sample in this experiment was 3.8 mm (0.15 in.) long. The duration of the elastic wave to travel the length of the sample is about 1.2 μs . Hence, the stress in the sample is essentially uniform after 5 μs . The time required to bring the sample to its yield point is greater than 10 μs . Hence, a uniform stress is attained in each incremental loading prior to yielding.

The results in Fig. 20 also show that the differences among curves 1, 2, and 7 are only due to the change in the strain rate because the effect of temperature is now removed. It is interesting to note that these three curves are essentially parallel, their common slope being a measure of the material's work hardening. Moreover, the thermal softening can be read off directly from the difference between curves 3 and 7.

It is also possible to check whether there have been any substantial changes in the microstructure of the material, when the sample is unloaded and cooled to room temperature, in each incremental loading. In addition, it is possible to evaluate the part of the plastic work, which is used to increase the sample temperature during its high strain rate deformation. This is illustrated by the results given in Fig. 21 for the same Ta-10% W alloy, tested at the same 5700 s^{-1} strain rate. The dashed curve in this figure is the adiabatic result. Curve 1 is obtained by an incremental deformation of a new sample of the same material, at the same strain rate, in the recovery Hopkinson system. It follows the dashed curve closely, indicating the repeatability of the experiment. The area under this solid curve can be used to calculate the total plastic work per unit mass. The change in the temperature of the sample can then be computed from:

$$\Delta T = \int_0^\epsilon \frac{\eta \sigma}{\rho C_v} d\epsilon \quad (\text{Eq 10})$$

where ϵ and σ are the axial strain and stress in the sample, respectively; ρ is the mass density of the sample; and C_v is the (temperature-dependent) heat capacity at constant volume. In Eq 10, η is the fraction of the energy used to increase the sample temperature. To obtain curve 2 in Fig. 21, it was necessary to assume that all the plastic work was used to increase the sample temperature, setting $\eta = 1$. The results show that, to within experimental errors, this is a good assumption for the present case (see Ref 15 for comments and comparison with infrared measurements using several different materials).

Fig. 21 The true stress-true strain relations for Ta-10%W at 5700 s^{-1} strain rate; all three curves are adiabatic, with an initial temperature of 25 °C (77 °F) for the dashed curve and for curve 1 and an initial temperature of 135 °C (275 °F) for curve 3. Source: Ref 1

Recovery Hopkinson Bar Techniques

Sia Nemat-Nasser, University of California, San Diego

High-Temperature Dynamic Recovery Tests

For high strain rate tests at elevated temperatures, it is necessary to heat the sample to the required temperature while keeping the incident and transmission bars at suitably low temperatures. If the bars are in contact with the specimen within the furnace, their temperature will increase, having a variable distribution along the bars. This affects the elastic properties of the bars and, hence, the stress pulses. Moreover, the bars being good heat conductors (usually of maraging steel), the considerable heat loss that occurs makes controlling the experiment difficult.

Different techniques are required in order to alleviate these difficulties when testing metals that are ductile and ceramics that are hard and brittle, as discussed subsequently.

High-Temperature, High Strain Rate Testing of Ductile Materials. In this case, the bars are kept outside the range of the heating unit in the furnace, while keeping the specimen at the center of the furnace. The bars are then brought into contact with the specimen microseconds before the stress pulse reaches the end of the incident bar. This is accomplished by two bar movers that are activated by the same gas gun that propels the striker bar toward the incident bar. Figure 22(a) illustrates the experimental setup just before the gun is fired, and Fig. 22(b) shows the configuration after the bar movers have brought the incident and transmission bars in contact with the sample. The motion of the bar movers is controlled by the area of its piston and the gas pressure in the breech of the gas gun. In a properly designed system of this kind (Ref 1), the bars are brought into contact with the specimen microseconds before the sample is loaded by the elastic pulse traveling in the incident bar. Once the sample is loaded, the bars move out, and the sample is recovered without having been subjected to any stresses other than the initial one.

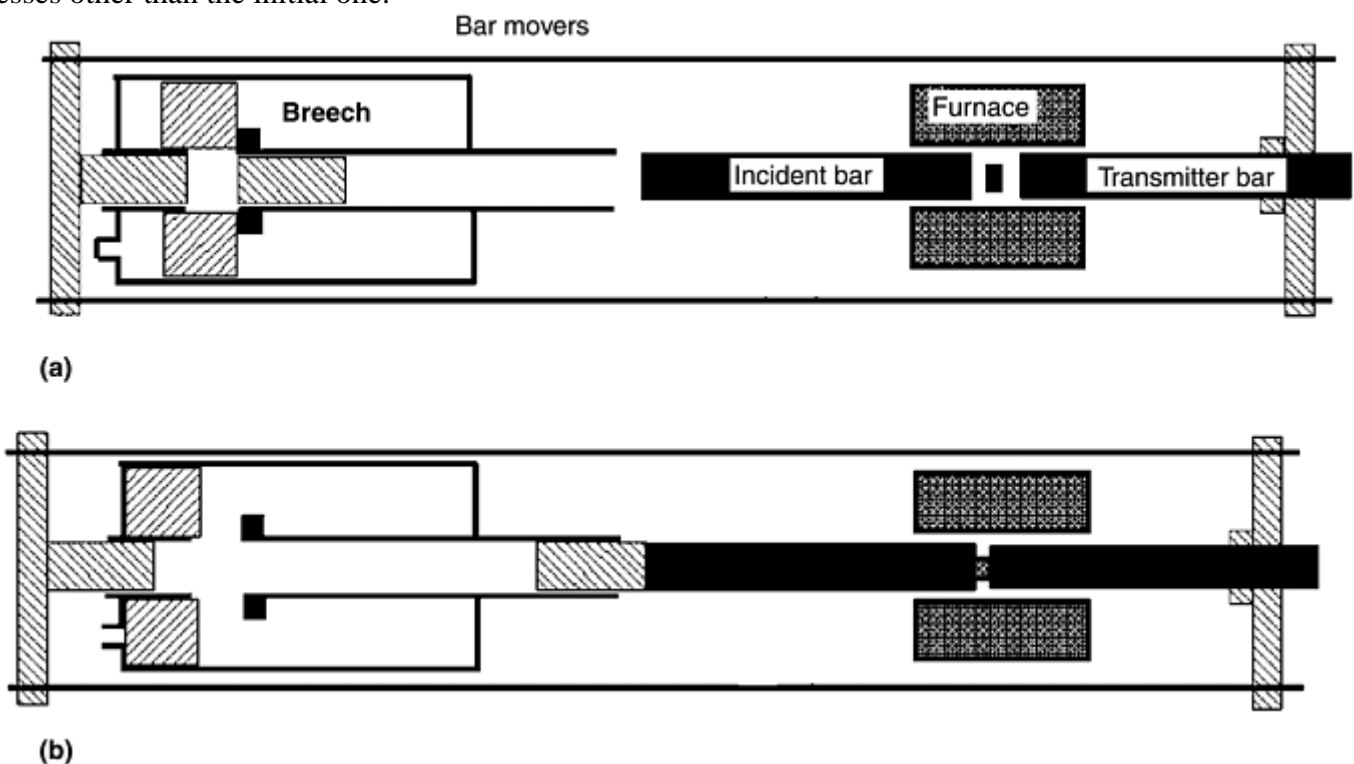

Fig. 22 Operation of the high-temperature recovery Hopkinson bar (a) before and (b) during the test. Source: Ref 1

Figure 23(a) shows the furnace and the ends of the incident and transmission bars. Figure 23(b) shows the relative position of the sample held by thermocouples, and the ends of the incident and transmission bars; this is the configuration maintained in the furnace just before firing the gas gun. The sample is attached by suitable wires to a sleeve, which is a thin tube. The bar movers then move the transmission bar, bring it into contact with the sample, and then the sample, the sleeve, and the transmission bar are brought into contact with the incident bar. Figure 23(c) shows the furnace and the sample attached to the sleeve outside of the furnace. Figure 23(d) shows the bar movers attached to the breech of the gas gun of the Hopkinson construction.

(c) Furnace and the sample attached to the sleeve. (d) Bar movers attached to the breech of the gas gun of the Hopkinson construction. Source: Ref 1

Isothermal Flow Stress of Ductile Materials at High Temperatures and High Strain Rates. To produce an isothermal flow stress at a high strain rate and high temperature, the sample is heated to the required temperature in the furnace attached to the recovery Hopkinson bar and then loaded incrementally. After the application of each load increment, the sample is unloaded without being subjected to any additional stress pulses. The sample is then allowed to return to room temperature, its dimensions are measured, and it is reheated in the furnace to its initial temperature before the application of the next strain increment.

Since the unloading, the cooling of the sample, the reheating to its initial temperature, and the reloading may affect the microstructure and, hence, the thermomechanical properties of the material, it is necessary to check this in each case. To this end, a sample that has been loaded, unloaded, and cooled to its initial temperature may then be reheated to the temperature it had reached just prior to its unloading. If there are no substantial changes in the microstructure that affect the flow-stress properties, then the flow stress, upon reloading, should follow the previous stress-strain curve. The procedure is similar to that described for Fig. 21. The only difference is the initial temperature.

As an application, consider measurement of the high strain-rate isothermal flow stress of the Ta-10%W alloy at 325 °C (615 °F); see Fig. 24. The room-temperature results are the same as in Fig. 20. Figure 24 includes the high strain rate, room-temperature results reported in Fig. 20; for example, curve 3 in Fig. 24 is the same as curve 7 of Fig. 20.

Fig. 24 True stress-true strain relations for Ta-10%W at 5700 s^{-1} strain rate. Curves 1, 2, 3, and 4 are for $25 \text{ }^{\circ}\text{C}$ ($77 \text{ }^{\circ}\text{F}$), and curves 5, 6, 7, and 8 are for $325 \text{ }^{\circ}\text{C}$ ($615 \text{ }^{\circ}\text{F}$) initial temperatures. The isothermal curves for $25 \text{ }^{\circ}\text{C}$ ($77 \text{ }^{\circ}\text{F}$) and $325 \text{ }^{\circ}\text{C}$ ($615 \text{ }^{\circ}\text{F}$) are essentially parallel.

With an approach similar to that for the room-temperature tests of Fig. 20, but now using an attached furnace, the results given in Fig. 24 for a $325 \text{ }^{\circ}\text{C}$ ($615 \text{ }^{\circ}\text{F}$) initial temperature have been obtained. As is seen, the quasi-isothermal curves for 25 and $325 \text{ }^{\circ}\text{C}$ (77 and $615 \text{ }^{\circ}\text{F}$) initial temperatures are almost parallel, showing essentially the same work hardening for the Ta-10%W alloy. Comparing these results with those of Fig. 24, it is seen that the isothermal work hardening seems to be independent of the temperature for this material, within the considered temperature and strain rate ranges. Hence, the work hardening due to plastic straining is not coupled with either temperature or strain rate. This is an important property since the flow stress then can be divided into an athermal part and a thermally activated part where the athermal part may be assumed to depend solely on the microstructure. The thermal part is due to the short-range barriers to the motion of dislocations (Ref 16). Note that here again it is necessary to establish whether a uniform stress state is attained in the sample, prior to yielding in each incremental straining, and whether the structure of the material is affected by the cycle of unloading, cooling, reheating, and reloading, as discussed in the section “Isothermal Flow Stress of Ductile Materials at High Strain Rates.”

High-temperature, high strain rate testing of hard, brittle materials poses the following challenges:

- It is necessary to prevent the indentation of the bars by the sample.
- It is necessary to heat the sample while keeping the bars outside the heating zone within the furnace.
- It is necessary to measure the strain of the sample at high temperatures within the furnace.

In compression, these qualifications can be met as follows. First, in addition to the techniques outlined in the section “Recovery Dynamic Testing of Hard Materials,” long inserts (e.g., 1 in.) are used for elevated-temperature tests. The use of longer inserts ensures that while the sample is heated to the required temperature, the bars remain at a suitably low temperature. Second, since strain gages have a limited temperature range of operation and cannot be used at elevated temperatures, differential strain measurement (DSM) has been developed to obtain accurate and reliable measurements of strains for dynamic tests of hard ceramics at elevated temperatures.

The DSM technique is based on the observation that an error is introduced due to the presence of the inserts and their interfaces with the sample and the bars. Hence, the displacement recorded by the strain gage on the

incident bar may be considerably greater than the actual sample displacement. For two tests, if the experimental conditions and the area of contact between the sample and the inserts and that between the inserts and the bars are kept the same, the error produced by the presence of the inserts will also be essentially the same in both tests.

To apply the DSM technique, two high strain rate tests are conducted on the Hopkinson bar, with two samples of different lengths. All other experimental conditions such as the striker bar length, the striker velocity, the pulse-shaper dimensions, and the sample temperature are maintained the same in both tests. After the two tests are conducted for the same stress, the difference in the strain can be attributed to the difference in the sample lengths. The displacement of the shorter sample is subtracted from that of the longer sample at several stress levels, and the differential displacement is obtained as a function of the stress. The displacement data thus obtained correspond to the displacement data for a sample with a length equaling the difference in the lengths of the two test samples. Thus, the stress-displacement data obtained now are the actual data that would correspond to a sample with a length equal to the difference in the lengths of the test samples.

Using a well-designed ramped loading, it is possible to measure the elastic modulus of ceramics at high temperatures and high strain rates by this procedure with considerable accuracy. Figure 25 shows the strain as a function of time for two samples of silicon nitride tested at 730 °C (1350 °F). The samples are of different lengths and are both tested in the elastic regime. It may be noted that the strain rate is nearly the same for the two tests.

Fig. 25 Strain-time data for two samples of different lengths tested at 730 °C (1350 °F)

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Introduction

THE HIGH-STRAIN-RATE, STRESS-STRAIN RESPONSE of polymers and polymeric-composite materials has received increased scientific and industrial attention in recent years. This interest is driven by the need for predictive constitutive model descriptions to support large-scale finite-element simulations of polymers subjected to high-strain-rate (impact) loading. Applications for which high-strain-rate loading represents an important service environment for polymers include:

- Automotive crashworthiness, where polymers, polymer foams, and polymeric composites have seen significantly increased structural usage
- Aerospace damage tolerance, including foreign-object damage such as during bird ingestion in jet engines equipped with polymeric composite blades and vanes
- Sporting goods applications where dynamic behavior and impact resistance of polymer composites is critical, such as tennis rackets, golf shafts, mountain bike frames, and so on
- Polymeric binder constituents used in polymer-bonded explosives (PBXs) and rocket propellants

The establishment of more physically based constitutive models to describe complex loading paths and to understand the effect of manufacturing processes on polymers and polymeric composites subjected to dynamic loading environments requires a detailed knowledge of the separate and synergistic effects of temperature and strain rate on their mechanical response. Split-Hopkinson pressure bar (SHPB), or Kolsky-bar, testing remains the main experimental method to characterize the high-strain-rate mechanical behavior of these materials. The specialized aspects required to accurately quantify the behavior of these “soft” materials using the SHPB is the subject of this article.

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Background

A significant number of previous studies have probed the high-rate constitutive response of a wide variety of polymers and polymer composites, starting with Kolsky in 1949 through the present (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11). Several in-depth reviews by Walley and others summarize the broad spectrum of polymers (Ref 12, 13, 14). Beginning with the high-rate pressure-bar studies of Kolsky (Ref 1) on polythene (polymerized ethylene) and rubber, it has been shown that:

- The effective elastic moduli of polymeric materials are strongly influenced by strain rate.
- The flow stress of a ductile polymer reaches a maximum strength at some moderate strain level under constant, high-strain-rate loading.
- Some polymers exhibit no permanent plastic flow after substantial high rate straining, the strain recovery effect being time dependent.
- Stress-wave propagation through some polymers, such as polythene, is so dispersive that over a certain sample length no transmitted Hopkinson bar signal is measured.

Experimental results for a large number of polymers over a wide range of strain rates have exhibited a linear relationship between the compressive yield stress of the polymer and log (strain rate) (Ref 13, 14).

The low inherent flow strength and low elastic impedance of polymers and polymeric composites pose additional challenges to the accurate measurement of their high-strain-rate uniaxial stress mechanical response using an SHPB (Ref 3). Resolution of the low flow strengths in polymers has prompted the adoption of alternate pressure-bar materials in deference to the high-strength steels classically used. Because lower modulus bar materials increase the signal-to-noise level of measurement strain gages, their selection is desirable to facilitate high-resolution dynamic testing of low-strength materials such as polymers, as long as the yield strength of the sample material remains well below that of the bar materials. Researchers have documented the use of bar materials possessing a range of elastic stiffnesses from maraging steel to titanium to aluminum to magnesium (Ref 15, 16) and, finally, to polymer bars (Ref 3, 17, 18, 19). Table 1 summarizes the elastic modulus and impedance values for a range of typical pressure-bar materials.

Table 1 Comparison of the impedance properties of bar materials for split-Hopkinson pressure bar testing

Bar material	Elastic modulus (E)		Wave impedance (ρ/C_0), $\text{km} \cdot \text{g/s} \cdot \text{cm}^3$	Impedance relative to steel, $(\rho/C_0)_x/(\rho/C_0)_{\text{steel}}$, %
	GPa	10^6 ksi		
Steel	212	31	40.8	100
Ti-6Al-4V	115	17	22.8	56
Aluminum	90	13	13.5	33
Magnesium	45	7	8.6	21
Polymethyl methacrylate (PMMA)	4	1	2.2	5

The ideal materials properties desired for pressure bars used in an SHPB are multifaceted and reflect a range of effects to control physical parameters that either improve measurement fidelity and robustness or are the chief sources of potential errors that can complicate data analysis and resolution and, thereby, test accuracy. The selection of an appropriate pressure-bar material represents a balance of the tradeoffs pursuant to a given material. The traditional use of metallic pressure bars reflects the fact that many metals and alloys exhibit a number of positive attributes in regard to their use as “load cells” in parallel with the sample and as wave guides for high-fidelity wave propagation. Ideal pressure bars should exhibit all of the following properties, and any deviations in practice constitute a compromise:

Good wave guide properties:

- Very low attenuation. Signal loss in perfectly elastic materials is essentially zeroed.
- Little or no time-dependent response, including frequency dependence, anelasticity, and dispersion

- Little radial wave attenuation. A low Poisson ratio is desirable.
- Large thermal range, both above and below ambient, over which the elastic properties are constant
- Low interference potential—low susceptibility to picking up stray signals during testing (high impedance mismatch with air, little coupling between bar and bar stanchions due to large impedance mismatch)
- Large input range before bars exhibit distortion—high strength/high elastic limit

Good load cell properties:

- High sensitivity for high-gage signal-to-noise, low-modulus bars
- Large input range—high-strength and high-elastic-limit bars
- High-wave-speed bar material resulting in good dynamic range (high bandwidth)
- Little signal interference from strain gages and glue joints—high modulus ratio between the pressure bar material and the glue and strain gages
- Minimal coupling of pressure bars with stanchions, strain-gage cables, and connections
- Low Poisson ratio of pressure bars to maximize one-dimensional strain conditions in pressure bars since longitudinal strain is measured (i.e., minimize two-dimensional strain effects on gage measurements)

The adoption of increasingly lower impedance pressure bar materials for Hopkinson bar testing over the past ten years is a direct result of the desire to increase the signal-to-noise gain to adequately resolve the low elastic strains produced in the pressure bars during testing of low-strength materials. Even with a high-gain, strain-gage signal conditioner using a 500× gain, it can be difficult or impossible to resolve the transmitted pressure pulse of a soft polymer using traditional steel pressure bars. In essence, if the wave impedance (ρC_0) of the sample material under investigation is much lower than that of the pressure bars, the magnitude of the transmitted pulse can become very weak. In addition, as described in the article “Classic Split-Hopkinson Pressure Bar Testing,” several different wave analyses should be used to calculate the sample stress from the incident, reflected, and transmitted bar time-resolved measured strains to validate stress-state equilibrium. Issues of stress-state equilibrium are addressed subsequently as pertains to polymer testing.

The additional complications inherent to testing viscoelastic materials and the care that must be exercised to accurately measure their mechanical behavior in an SHPB were introduced in the seminal work of Kolsky (Ref 1) on plastics and rubber. Kolsky (Ref 1, 20) discussed the difficulty in resolving the low-magnitude transmitted pulses for rubber or polythene and, thereafter, the importance of using thin sample thicknesses to reduce the time a sample takes to “ring up” to a state of uniform uniaxial stress. His studies demonstrated that thin samples were critical when studying the high-rate constitutive response of plastics and rubber or the “assumption that the pressure on both sides of the specimen are sensibly the same is no longer valid” (Ref 1). In this article, some of the specialized SHPB developments within the last ten years to facilitate testing soft materials are detailed. These techniques include the data-reduction techniques and assumptions required to use polymer pressure bars, the importance of sample-size considerations to polymer testing, and temperature-control methodologies germane to measuring the high-strain-rate uniaxial stress response of polymers and other soft materials.

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Split-Hopkinson Bar Testing of Polymers

The quantification of the uniaxial stress-strain compressive response of low mechanical impedance soft materials in the SHPB has been the subject of significant innovation since 1992. Higher-resolution measurement of the stress-strain responses of increasingly lower-flow-strength materials has led to the adoption of lower-impedance pressure bars, specifically titanium-alloy, aluminum-alloy, magnesium or magnesium-alloy, and, finally, polymer pressure bars. The technical advantages and disadvantages of each are discussed in this section.

Polymer Pressure Bars

Based on the low impedance of many structural plastics, such as polymethyl methacrylate (PMMA) and polycarbonate (PC), a number of researchers have explored the benefits of using polymers for the pressure bars in an SHPB to test low-impedance polymers and foams (Ref 17, 18, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, and 33). These researchers have pursued the use of polymer bars to access the significant signal-to-noise gains that polymeric bars promise, as summarized in Table 1. While the lower inherent impedance of polymers offers positive attributes to SHPB testing of soft materials, their use requires additional analysis for data reduction, temperature complications, and additional restrictions compared with traditional metallic pressure bars.

Polymeric materials, unlike metals and alloys loaded in their elastic regime, are not ideally linear elastic, nor do they exhibit undistorted wave propagation. Polymeric materials, on the contrary, exhibit significant stress-wave attenuation, wave dispersion due to time and frequency dependency, a strong temperature dependency between ± 50 °C (± 90 °F), and are susceptible to gradual degradation in their “elastic” properties during prolonged usage due to the effects of oxidation and ultraviolet radiation. Notwithstanding these shortcomings, numerous researchers have explored the opportunities that the lower impedance and low modulus of polymers offers to the field of SHPB testing.

Researchers exploring the high-strain-rate, stress-strain response of lower-impedance soft materials have worked to quantify how the nonlinear response of polymeric bars alters the classic SHPB data reduction. In metallic bars, the linear elastic response of the bars defines that the measured strain pulse describes not only the local strain wave but also the associated stress wave and the particle velocity at different positions along the pressure bar. On the contrary, a viscoelastic material, such as PMMA, exhibits both wave attenuation and wave dispersion. As a wave travels down a polymer pressure bar, the wave amplitude decreases due to attenuation, and the shape of the waveform becomes distorted. Accordingly, strains measured at a given position on a viscoelastic bar do *not* represent the strain pulse at another position along the pressure bar without complex manipulation and corrections. Therefore, the “classic” SHPB analysis based on the undistorted character of wave propagation must be modified when viscoelastic bars are used instead of linear-elastic metallic bars. The measured strain pulse on a viscoelastic bar represents the strain wave *only* at the measured point, but neither the stress nor the particle velocity can be directly deduced from a measured strain signal in a viscoelastic bar by simply using a proportional coefficient as in the case of metals where the elastic modulus is used. This fact has been demonstrated by a number of researchers (Ref 17, 21, 23, 24, and 25). Quantification of the stresses, strains, and strain rates in a sample to be tested in an SHPB equipped with polymeric pressure bars, therefore, requires a viscoelastic wave analysis of the pressure-bar responses. Use of a simple linear elastic data reduction

for polymeric bars is inappropriate and will lead to errors as large as 52% as quantified by Wang and others (Ref 23).

Use of polymeric bars in an SHPB, therefore, requires the derivation of an accurate predictive material constitutive model description of the dispersion and dissipation in the viscoelastic bars to deduce the stress-strain behavior of the sample being tested. Zhao and Gary (Ref 24) proposed using a stress-strain constitutive model derived by using the wave recorded at one point on the incident bar as input data. The model parameters are thereafter determined through comparison with the predicted wave and the wave recorded at another point on the incident bar. A similar model reduction can be conducted for the transmitted pressure bar. Once the model parameters have been identified, this data can also be used for the wave dispersion correction (Ref 34).

Quantification and comparison of the forces in the transmitted bar are conducted using a bars-together configuration, where no sample is present. Here, the stress in the incident and transmitted bars are ideally equal. Using this technique, Zhao and Gary (Ref 24) characterized the frequency and phase velocity of their viscoelastic bars. The complex modulus of the polymer pressure bars is then calculated from the phase velocity and attenuation. Both of these quantities are bar-diameter dependent, and the frequency characteristics become less and less accurate as the wave frequency and the bar diameter increase. The work of Zhao and Gary (Ref 24) showed that in the case of PMMA pressure bars, selection of bar with diameters less than 10 mm (0.4 in.) minimized errors.

Sawas, Brar, and Brockman (Ref 33) similarly proposed measurement of the strain or particle velocity at two different locations along a polymer pressure bar. The strain measurements for the two positions were then reduced analytically to derive the model parameters for a viscoelastic description of the pressure bars. Figure 1 presents an example of the similitude of stress-strain mechanical property for 1100 aluminum alloy using a conventional SHPB and what can be obtained using cast acrylic pressure bars. In the experimental setup described by Sawas, Brar, and Brockman (Ref 33), high-strength titanium anvils were placed between the aluminum alloy sample and the two polymeric pressure bars to prevent damage to the bars during testing and to minimize elastic deformation at the specimen bar interface.

Fig. 1 Comparison of the stress-strain data measured for 1100 aluminum alloy using a conventional metallic pressure bar and an acrylic pressure bar for split-Hopkinson pressure bar testing. Source: Ref 33

Zhao, Gary, and Klepaczko (Ref 29) have additionally analyzed the use and modeling of polymeric pressure bars in the SHPB. In this model, a Fourier stationary wave approach is presented. This modeling approach was proposed because the numerical efficiency and precision are independent of the distance between the bar/specimen interface and the gage location. Additionally, this approach addresses the need to deal with the three-dimensional effects, such as bar-diameter effects, without introducing additional computational penalties. Their analysis of the solution of the propagation of the harmonic waves in an elastic bar reduces to the Pochhammer-Chree frequency equation, which gives the relation between the wave number and the frequency of the wave. Further analysis by Bacon (Ref 35, 36) supports the accuracy of harmonic wave modeling and its applicability to any solid cylindrical cross-sectional linear viscoelastic-infinite pressure bar.

The constitutive behavior of the polymeric bars, independent of whether a transient wave analysis (Ref 23) or a Fourier stationary harmonic wave analysis (Ref 29) is employed, is modeled using a Maxwell element-based approach to describe linear viscoelastic behavior. Zhao, Gary, and Klepaczko (Ref 29) proposed using a 4 Voigt element and 1 spring in a series Maxwell element rather than a more classic 3-element Maxwell model (a mechanical analog composed of a spring in parallel with a dashpot in series with a spring). Due to the almost constant damping and phase velocity, they selected the more complex form rather than a 3-element Maxwell model to model the high frequencies. Upon implementation of this model, Zhao, Gary, and Klepaczko (Ref 29) demonstrated that analyses of an SHPB test cannot be performed by simply shifting the effects of elastic geometry dispersion and the effects of the one-dimensional viscoelastic wave propagation. This is because of the strong effect of bar geometry on wave attenuation in the polymeric pressure bars.

Researchers interested in implementing one of these constitutive modeling approaches should examine in detail the appropriate papers. The main problem with using polymeric pressure bars to quantify the constitutive response of soft materials is the dependency on a complex geometry-dependent viscoelastic model analysis of the pressure bar signals to deduce sample behavior. This is in contrast to the relatively simple “classic” linear elastic data reduction where metallic pressure bars are used. These papers have demonstrated that a detailed solution to the dissipation and dispersion behavior of polymeric pressure bars can be accurately obtained for constant ambient temperature testing. Accordingly, sufficiently accurate dynamic stress-strain behavior of soft materials can be measured using polymeric pressure bars.

However, modeling to date of the polymer pressure-bar constitutive response has only been successfully demonstrated for ambient-temperature testing. In the case of metallic bars, the elastic properties are essentially constant well above and below ambient temperature. This allows testing without modification of the analysis and without the extremely difficult task of controlling the entire bar system and sample temperature to within a few degrees. In the case of polymer bars, testing at temperatures below and above ambient temperature also requires a strain-rate- and temperature-dependent constitutive model and a thermal profile of each test if the temperature of the entire bar cannot be maintained at the same level for accurate modeling of the pressure-bar response and thereafter the data reduction of the sample mechanical behavior.

Lower-Impedance Metallic Pressure Bars

The use of increasingly lower impedance titanium (Ti) (Ref 3, 16), aluminum (Al) (Ref 13, 37, 38), and magnesium (Mg) (Ref 15, 16, 39) metallic pressure bars to achieve higher-resolution transmitted bar signals requires no additional data reduction assumptions or caveats. Analysis of the stresses and strains in test samples using any metallic pressure bar material maintained in their elastic regimes can be readily conducted per the linear-elastic bar analysis detailed in the article “Classic Split-Hopkinson Pressure Bar Testing.” Unlike the case of using polymeric pressure bars, the data reduction to determine the stress-strain response of a sample tested using metallic pressure bars benefits from not only the validity of a simple linear-elastic bar response but also the relatively undistorted character of wave propagation in metallic bars (wave dispersion must still be corrected for maximum fidelity, as discussed in the article “Classic Split-Hopkinson Pressure Bar Testing”).

The absolute resolution of metallic pressure bars can be additionally increased through the concurrent use of high-gain, wide bandwidth, strain-gage signal amplifiers. Low-noise signal conditioners capable of gains up to 1000× and 3 MHz bandwidths are now commercially available (Ref 15). The use of pressure bars of 6061-T6 aluminum alloy or AZ31B magnesium alloy have proved capable of accurately resolving the mechanical response of a number of polymeric materials. Figure 2 illustrates the measurement of the dynamic stress-strain behavior of a soft Estane (B.F. Goodrich, Richfield, OH)-based binder material using magnesium pressure bars (Ref 15). The resolution of the 1- and 2-wave stress-strain responses for this binder material at stress levels below 1 MPa (145 psi) demonstrates that a classic metallic SHPB using magnesium bars can accurately resolve low-amplitude transmitted strain pulses. The delay in equilibrium, which is evident in Fig. 2 by the difference between the 1- and 2-wave signals, is consistent with the pronounced dispersive damping of stress-wave propagation through low-strength viscoelastic specimens. The ramifications of this pronounced lag in stress-state stability is discussed in the next section of this article.

Fig. 2 Stress-strain response of a viscoelastic estane-based polymeric energetic binder tested at 0 °C (30 °F) measured with magnesium pressure bars and using an incident bar strain-gage gain of 200× and transmitted bar strain-gage gain of 500×. W1, one-wave signal; W2, two-wave signal. Source: Ref 15

An additional recent approach to increase the sensitivity of an SHPB to resolve the stress-strain behavior of polymers is the use of a hollow aluminum transmitted pressure bar. Chen and others (Ref 38) have demonstrated that using a hollow high-strength aluminum alloy transmitted pressure bar can significantly increase the signal to noise measured during the SHPB testing of RTV630 silicon rubber. A pulse shaper was used with the hollow aluminum alloy transmitted bar to simultaneously increase the rise time of the incident pulse as well as to filter out the high-frequency components of the incident waveform, thereby reducing the effect of the end cap of the hollow transmitted bar (Ref 38). While an end cap can be used to suppress damage to the ends of the bar and not interfere with the transmitted stress signal, the presence of an additional interface at the end cap/incident bar intersection will significantly complicate the reflected strain signal, which is needed to calculate the sample strain and strain rate. The influence of an end cap on a hollow pressure bar on stress-state equilibrium in a polymer sample should be evaluated by comparing the 1- and 2-wave analyses of the state of stress in the sample, as described subsequently.

While lower-impedance metallic bars can significantly increase the signal to noise to resolve the stress-strain response of low-strength solids, there remain classes of soft polymeric materials that cannot be analyzed using conventional split-Hopkinson bar data analysis. For all types of Hopkinson bar testing, the assumption of one-dimensional wave propagation in the bar and sample requires that true stress in a sample in the Hopkinson bar cannot be extracted for materials whose volumes are not conserved. The instantaneous sample area used in Eq 6 in the article “Classic Split-Hopkinson Pressure Bar Testing” is deduced from the reflected strain signal in the incident bar, assuming that the constancy of volume assumption is valid in the sample (i.e., there is a fixed relationship between sample cross-sectional area and its length). In addition, samples not possessing constant volumes by their very nature of compacting or exhibiting nonhomogeneous deformation processes prior to achieving a “bulk” response during testing will exhibit significant time delays before the sample attains a uniform state of uniaxial stress-state equilibrium (if at all) during testing. These materials include metallic and polymeric foams, honeycomb structures, and porous compacts, including types of wood, for which mechanical loading produces densification or porosity during testing.

Valid Hopkinson bar testing of materials for which the constant volume criterion is not valid, therefore, requires additional sample diagnostics during the duration of the test to calculate true stress; simultaneous use of high-

resolution, high-speed photography can be used to monitor sample strain during testing. The photographic data, once digitized, can then be used to measure the actual instantaneous sample area as a function of time in the sample for use in determining the true sample strain and strain rate. Finally, this data, when combined with the transmitted wave data, can provide the means to calculate true stress in the sample.

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Stress-State Equilibrium of Soft Materials

The stress-state equilibrium in a sample during testing in an SHPB can be checked by comparing the 1- and 2-wave (or 3-wave) stress-strain response of the sample as described in the article “Classic Split-Hopkinson Pressure Bar Testing” and illustrated in Fig. 2 (Ref 34, 40, 41, 42, and 43). Recent studies have documented that both inertia and wave propagation effects during testing of a compression SHPB sample can significantly affect the stress differences across the length of a specimen during loading (Ref 3, 15, 41, and 43). Experimental results have revealed that the slow longitudinal sound speeds typical of some polymeric materials make longitudinal stress equilibrium during SHPB testing difficult to achieve (Ref 13, 15, 18, and 44).

Assuming frictional effects on the stress state are insignificant, the validity of an SHPB test on polymeric materials can be evaluated by examining the incident and transmitted pressure-bar data for stress-state equilibrium in addition to assessing whether a constant strain-rate condition has been achieved during a test. When the stress state is uniform throughout an SHPB sample, the 2-wave stress oscillates equally above and below the 1-wave stress. In the 1-wave analysis, the sample stress is directly proportional to the bar strain measured from the transmitted bar. This waveform characteristically exhibits low oscillation amplitude because the deforming sample effectively damps much of the ringing inherent in the incident pulse as it propagates through the sample. This damping can be quite significant in low-sound-speed materials such as polymers.

The 1-wave stress analysis represents the conditions at the sample transmitted bar interface and is referred to as the sample “back stress.” In a 2-wave analysis, the sum of the synchronized incident and reflected bar waveforms is proportional to the sample “front stress” and represents the conditions at the incident bar sample interface. However, both the incident and reflected waveforms contain substantial inherent oscillations that give rise to large uncertainty in the stress level, especially near the yield point, compared with the stress calculated from the transmitted waveform. These harmonic oscillations are also subject to dispersion due to the wave-speed dependence of different frequencies propagating through the pressure bars. This causes asynchronization of the overlapped waveforms and, therefore, inaccuracy in the calculation of the front stress. Mathematical methods have been developed to correct the primary mode of wave dispersion, and this dispersion correction results in higher-accuracy calculations of the stress at low strains (Ref 34). Finally, a third stress-calculation variation that considers the complete set of three measured bar waveforms, the 3-wave analysis, is simply the average of the front and the back stress.

Figure 2 shows the 1-wave, 2-wave, and strain-rate data as a function of strain for an SHPB test conducted on an Estane-based polymer binder sample. In this illustration, the front and back stress data reductions exhibit substantially different responses up to moderate strain values, verifying that the sample did not attain a uniform stress state until after a strain of 0.06. Attempts to achieve higher strain rates ($>5000 \text{ s}^{-1}$) at $25 \text{ }^{\circ}\text{C}$ ($77 \text{ }^{\circ}\text{F}$) proved difficult to unsuccessful. For example, at a strain rate of 7000 s^{-1} , the 1- and 2-wave signals diverged for the entire test (invalidating the stress analysis as discussed previously). The data in Fig. 2 illustrate the difficulty in testing polymeric materials possessing low impedance independent of whether a conventional metallic SHPB or polymeric-pressure-bar SHPB setup is used. Achievement of stress-state equilibrium in the sample is dependent on both the viscoelastic nature of the sample material and on sample geometry, which is discussed subsequently.

Achievement of a constant strain rate in a polymer sample throughout an SHPB test serves as validation of the careful balance of striker-bar length, striker-bar velocity, and tip material and thickness. In addition, a constant strain rate is a further qualitative check of the attainment of stress equilibrium in the specimen.

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Sample-Size Effects

The sample thickness used in an SHPB test is constrained by the need to assure a uniform stress state for accurate and reproducible constitutive data (Ref 3, 4, 38, and 45). Given the documented influence of temperature on the elastic and plastic properties of ductile polymers, it is also important to evaluate sample geometry effects over a range of temperatures (Ref 3).

The pronounced difference in the initial 1-, 2-, and 3-wave signals for several polymers has demonstrated the importance of carefully assessing sample size to achieve a uniform uniaxial stress state in the sample (Ref 3, 15). Differences in the 1- and 2-wave stress levels for sample length/diameter (l/d) aspect ratio = 1 samples (6.35 mm, or 0.25 in., thick) of a polyurethane elastomer (Adiprene [Uniroyal Chemical Company Inc., Middlebury, CT] L100) (Ref 3), polyamide (nylon), or Teflon (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) (Ref 39) indicate a sluggish ringup to stress-state equilibrium and, therefore, a marginally valid Hopkinson bar test at strains <5%, even though a constant strain rate is indicated throughout the entire test. Similar to the early findings of Kolsky (Ref 1) and more recent studies of Diah and others (Ref 4, 45) and Chen and others (Ref 38), the high-rate stress-strain response of polymeric samples exhibits pronounced sample-size dependence. The 1-wave stress analysis for Adiprene L100 samples tested at ambient temperature were found to depend on sample thickness as shown in Fig. 3. While the maximum flow stress attained for each sample thickness was nominally the same for a strain of 10%, the details of the ringing up of the sample and the falloff in flow stress after the maximum stress level was reached is seen to be significantly different. The 1 to 1 aspect ratio sample exhibits the most dispersive oscillatory ringup, as well as the most rapid falloff in flow stress for the three sample thicknesses. The 3.2 mm (0.125 in.) thick sample ($l/d = 0.5$) exhibited a clear yield strength and the lowest ringing amplitude. Chen and others (Ref 38) similarly observed substantial wave attenuation in 6.34 mm (0.25 in.) thick RTV630 rubber samples compared with 1.54 mm (0.06 in.) thick samples, which exhibited significantly faster ringup during testing.

Fig. 3 Stress-strain response of 6.35 mm (0.25 in.) diam Adiprene L100 samples as a function of sample length at high strain rate (2500 s^{-1})

The ambient temperature data in Fig. 3 for Adiprene L100 illustrates the need to use lower sample aspect ratios when studying the entire high-strain-rate constitutive response of low-sound-speed dispersive materials such as polymers. The measurements on Adiprene L100 (Ref 3) and RTV630 rubber (Ref 38) suggest that, depending on the polymer and temperature range of testing, sample aspect ratios (l/d) of 0.5 or 0.25 can be effective in minimizing wave attenuation while also keeping frictional effects under control. Another interesting observation from Fig. 3 is the difference in the stress falloff as a function of sample thickness at strains over 10%. Taking into account that the lubrication conditions were the same for all samples, these results suggest that the dynamic stress relaxation of Adiprene L100 is also a function of sample size. The sample aspect ratio needed to achieve satisfactory uniaxial stress-state equilibrium also was found to be strongly dependent on the test temperature. While an $l/d = 0.5$ sample facilitated achieving equilibrium at $25 \text{ }^\circ\text{C}$ ($77 \text{ }^\circ\text{F}$) on Adiprene L100, samples with higher aspect ratios, such as $l/d = 1$, proved suitable at temperatures below approximately 240 K ($-28 \text{ }^\circ\text{F}$). These observations clearly demonstrate that achievement of stress equilibrium within polymeric samples is influenced by their initial elastic properties. Further experiments also are needed to quantify the stress-relaxation kinetics of viscoelastic materials as well as damage evolution processes in polymeric composites (Ref 43). A novel approach to studying these processes is to compare finite-element modeling (FEM) predictions for the bar outputs with actual bar outputs using proposed material models. This work is described in detail later.

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Split-Hopkinson Bar Testing as a Function of Temperature

While numerous studies have investigated the influence of strain rate on the constitutive response of a range of polymers, the influence of temperature at high strain rate on polymer mechanical behavior has been less extensively researched (Ref 14, 44). This lack of data is in contradiction to the fact that robust constitutive modeling descriptions of polymers used in structural applications must accurately describe polymer response as a function of service temperature. Polymer and polymer-composite responses for temperatures from -40 to +40 °C (-40 to 105 °F) are relevant for arctic to desert service environments. Testing at temperatures below 25 °C (77 °F) for a range of polymers has shown that both the measured “loading elastic” modulus and the measured peak flow stresses increase with decreasing temperature (Ref 14, 44). Based on these results, it is apparent that the construction of robust material models for polymeric constitutive behavior requires systematic knowledge of the independent effects of temperature and strain rate.

Constant temperature conditions between 200 and 350 K (-100 and 170 °F) on a split-Hopkinson bar have been achieved with the use of a specially designed gas manifold system developed at the Los Alamos National Laboratory. Here, samples can be cooled and heated using helium gas within a type 304 stainless steel containment chamber held at a partial vacuum, as shown in Fig. 4. Helium gas, due to its inertness and high thermal conductivity, was selected as the heat-transfer medium to heat/cool a range of materials including polymers, energetics, and propellant materials. The helium gas is cooled below ambient temperature by passing the helium through a copper coil positioned within a liquid nitrogen dewar, while elevated temperatures are achieved by heating the helium in a parallel coil within a glycerin-filled beaker warmed to approximately 450 K (350 °F) by a heating plate.

Fig. 4 Photograph of specialized split-Hopkinson pressure bar setup using either Ti-6Al-4V or magnesium pressure bars and a helium-gas manifold heating/cooling system to allow controlled temperature testing at high strain rates of polymers

Sample temperature in this heating/cooling scheme is monitored using a thermocouple positioned to lightly contact the outside of the sample. Regulating the helium gas flow rate to the manifold surrounding the sample allows fine temperature control. The heat transfer time required to heat or cool a 1 to 1 aspect ratio sample of Adiprene L-100 was determined using a thermocouple inserted into the middle of a dummy sample. A time duration of 5 min was determined to be necessary to equilibrate a polymer sample at temperature after attaining a stable helium gas temperature within the manifold surrounding the sample. A similar procedure is being used at Los Alamos National Laboratory for evaluating the temperature dependency of the high-strain-rate response of a range of engineering polymers and energetic materials (Ref 39, 43). An example of the type of data that can be measured for a polymer is shown in Fig. 5 for Teflon.

Fig. 5 Stress-strain response of Teflon at 2500 s^{-1} as a function of temperature

To yield the highest fidelity stress measurements while still testing below the yield strength of the pressure bars themselves using either Ti-6Al-4V or magnesium pressure bars and $l/d = 0.5$ aspect ratio samples, the high-strain-rate response of Teflon as a function of test temperature from -55 to $+55$ °C (-65 to 130 °F) was measured (Ref 39). The anelastic flow stress response (post-yield behavior) of Teflon is shown in Fig. 5 to exhibit nominally parallel stress-strain curves as a function of temperature. This nominally constant “hardening” behavior suggests that the deformation mechanisms controlling post-yield anelastic flow in Teflon is not substantially temperature dependent, while its yield strength varies with temperature for a fixed loading rate. Invariant strain hardening as a function of temperature is similar to the response of body-centered-cubic (bcc) metals where a Peierls stress dominates yielding behavior. This suggests that a thermally activated approach to modeling polymer constitutive behavior appears fruitful and demonstrates the importance of studying temperature effects on polymer constitutive behavior.

Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Test Sample Preparation

Due to the soft, viscoelastic nature of some polymers and polymeric composites at ambient temperatures, a special procedure has been adopted at Los Alamos National Laboratory and other facilities to machine SHPB specimens with parallel loading surfaces within a tolerance of 0.03 mm (0.001 in.). First, the rough-cut specimens are slowly cooled (<20 °C/min, or 36 °F/min) on a metal platen surrounded by liquid nitrogen. Then, during machining, the polymeric specimens are sprayed with cold nitrogen gas from the vaporization of liquid nitrogen to keep the sample in a hardened state well below the glass transition temperature. The increased stiffness of the cooled samples significantly increases the ease of single-point turning of samples. Similarly, the specimens must be slowly warmed back to ambient conditions to minimize thermal shock, residual stresses, and specimen distortion.

Finite-Element Modeling (FEM) of the Split-Hopkinson Bar

In recent years, a number of new innovations have been demonstrated for the SHPB, and their value has been demonstrated in improving both the accuracy and timeliness of high-rate testing measurements. One-, two-, and three-dimensional FEMs of the SHPB have proved their ability to simulate test parameters and allow pretest setup validation checks as an aid to planning. Finite-element models, therefore, offer a means to validate the data and dispersion analysis used in the Hopkinson bar to probe for the effects of inertia and friction and to provide an opportunity to extend the use of the Hopkinson bar. An example is the characterization of polymeric materials for which a uniaxial stress state cannot be achieved. Previous research using this approach on soil samples has shown the utility of a combined FEM/SHPB analysis (Ref 46).

Systematic FEM modeling of the SHPB with concurrent experimental SHPB measurements is a means to extend the use of the SHPB technique beyond that of a conventional measurement apparatus (Ref 47). It can afford the characterization of materials for which the SHPB technique was previously invalid using classic one-dimensional data analysis, serving as a validation tool for complex sample geometries, and facilitating data analysis and constitutive model development for sample materials exhibiting nonuniform and/or nonconservative behaviors such as compaction, shear band formation, and fracture.

In the first instance, a coupled experimental and FEM approach can facilitate the high rate characterization of materials for which the attainment of a stable uniaxial stress state during testing is problematic or impossible, such as polymer foams. In the second case, FEM can provide a valuable tool to verify and validate sample geometry design where equilibrium considerations are paramount, such as tensile SHPB specimens. Unlike the compressive Hopkinson bar where right-regular sample shapes are most often used, tensile Hopkinson bar testing uses complex sample geometries. During tensile Hopkinson bar testing, the signals measured in the pressure bars record the structural response of the entire tensile sample, not just the gage section, where plastic deformation is assumed to be occurring. Because the split-Hopkinson bar data analysis only provides data on the relative displacement between the ends of the incident and transmitter bars, an effective gage length generally must be used. Finite-element modeling coupled with high-speed photographic characterization of the sample gage section as a function of time also may provide a technique to extract quantitative stress-strain constitutive data from a tensile SHPB test, even in the presence of unavoidable strain gradients in the sample. The time-resolved local measurement of strain in the sample gage length is also important to validate modeling of the constitutive response of the sample material.

In the final instance, FEM can be used to examine the validity of constitutive and damage evolution models for sample materials for which conventional Hopkinson-bar analysis is limited. Examples include the high-rate deformation response of materials such as metallic and polymeric foams and honeycomb structures where nonuniform compaction occurs, materials that undergo nonuniform plasticity such as shear banding and kinking, and materials that undergo damage or fracture processes that invalidate the tacit SHPB data analysis assumption of homogeneous deformation in the calculation of sample stress. Local strain quantification using high-speed photographic techniques coupled with FEM modeling of “crush-up” densification could use SHPB test data to validate the accuracy of the densification modeling scheme for a metallic foam. In this approach, the stress-time histories for the incident and transmitted pressure bars are used as a validation check against FEM simulations of the metallic foam response for a range of applied strain rates, sample geometries, and temperatures.

The SHPB configuration can be modeled using a Lagrangian mesh as shown in Fig. 6 (Ref 47). In this example, solid cylindrical lengths of steel, titanium, aluminum, or magnesium alloy can represent the striker, incident, and transmitted bars. An axis of symmetry can be presumed about the longitudinal (length) axis of the pressure bars, and as such, modeling of the pressure bars is performed assuming two-dimensional axisymmetry and linear elasticity. The specimen, however, must be modeled using a three-dimensional Lagrangian mesh such that nonuniform deformation processes within the sample, such as compaction in the case of foams, shear banding, kinking, and so on, are to be physically described. Elemental and nodal quantities in the finite-element

model are then recorded at various positions along the longitudinal (length) axis of the SHPB model. Figure 6 presents an FEM simulation snapshot plotting sample strain rate for an SHPB test of a Teflon sample using Ti-6Al-4V pressure bars. The graphical data in Fig. 6 illustrate the nonuniformity in strain rate in a polymeric sample during the initial stages of ringup prior to the achievement of a uniform uniaxial stress state in the sample or a nominally constant strain rate of loading (Ref 47).

Fig. 6 Finite-element simulation of a Teflon. $l/d = 1$ sample in a split-Hopkinson pressure bar test. The early stages of the ringup of the Teflon sample toward achieving a uniform uniaxial stress state is reflected by the nonuniform strain rate as a function of position within the sample. Split-Hopkinson Pressure Bar Testing of Soft Materials

George T. (Rusty) Gray III and William R. Blumenthal, Los Alamos National Laboratory

Summary

The Hopkinson pressure bar, as a research and engineering tool for the quantitative measurement of the high-rate stress-strain behavior of soft materials, has undergone significant evolution in the past 5 years. Higher-resolution measurements of the constitutive responses of viscoelastic solids under ambient conditions have been developed using both polymeric and magnesium pressure bars compared with measurements with high-strength steel bars. Due to their time- and temperature-dependent dispersive and dissipative nature, viscoelastic solids pose unique challenges during Hopkinson bar testing. The most daunting of these challenges is the attainment of stress-state equilibrium. Careful selection of sample geometry and the use of 1- and 2-wave stress-wave analyses are crucial to verifying the attainment of a uniaxial stress state during Hopkinson bar testing. Finite-element modeling of SHPB measurements coupled with experimental SHPB measurements offers great promise as a means to extend the use of the SHPB technique beyond that of solely a measurement method. Finite-element modeling of the SHPB can support the quantification of the constitutive behavior of materials, which were previously invalid using only classic one-dimensional SHPB stress-wave analysis. These

simulations can serve as a validation and verification tool for complex sample geometries and facilitate data analysis and constitutive model development for materials exhibiting nonuniform and/or nonconservative behaviors such as compaction (foams), shear band formation, and fracture.

Split-Hopkinson Pressure Bar Testing of Ceramics

G. Subhash, Michigan Technological University G. Ravichandran, California Institute of Technology

Introduction

SPLIT-HOPKINSON PRESSURE BAR (SHPB) TESTING, described elsewhere in this Section, was originally developed by Kolsky (Ref 1) and has been traditionally used for determining the plastic properties of metals (which are softer than the pressure bar material) at high strain rates in the range of 10^2 to 10^4 s⁻¹. Ceramics, on the other hand, are hard and brittle and typically exhibit higher compressive strength than metals. Because most of the ceramics reveal only elastic strains to failure, accurate measurement of these strains using the traditional SHPB technique is often not a trivial task.

In this article, the inherent limitations of the traditional SHPB technique for testing ceramics and the modifications necessary in design and test procedures are discussed. Before describing the test method for ceramics, a brief discussion of the operational principle of the traditional SHPB technique and the relevant assumptions in the derivation of the stress-strain relationship are presented. This is followed by discussion of the inherent limitations on the validity of these assumptions while testing ceramics and the necessary modifications in SHPB design and test procedure for high-strength brittle ceramics. Other topics covered in this article include maximum strain rate that can be obtained in ceramics using an SHPB, the necessity of incident pulse shaping, specimen design considerations, interpretation of experimental results obtained from SHPB testing of ceramics, and the effectiveness of the proposed modifications.

Review of Traditional Split-Hopkinson Pressure Bar Operational Principles

A traditional SHPB configuration (Fig. 1) consists of a striker bar, an incident bar (AB), and a transmission bar (CD). A specimen of suitable dimensions is sandwiched between the incident and transmission bars. The striker bar is launched from a gas gun at a predetermined velocity towards the incident bar. Upon impact at A , a compressive pulse is generated in the incident bar and travels towards the specimen. The duration of the pulse is equal to the round trip travel time of the longitudinal wave in the striker bar. Upon reaching the specimen, a portion of the incident pulse is transmitted into the transmission bar as a compression pulse, and the remaining portion is reflected back into the incident bar traveling toward the impact end, A . Strain gages are mounted at midpoints along the length of the incident and transmission bars to capture the stress pulses as they pass by. In general, the specimen is chosen to have a lower impedance (product of density, wave velocity, and area of cross section) than the bar material, and, hence, the reflected pulse is rendered tensile in nature. Based on one-dimensional analysis, it can be shown that the equations for stress, strain, and strain rate in the specimen are given by (Ref 1, 2):

$$\sigma_s(t) = \frac{A_o E_o}{A_s} \varepsilon_T(t) \quad (\text{Eq 1})$$

$$\dot{\varepsilon}_s = -\frac{2c_o}{l_s} \varepsilon_R(t) \quad (\text{Eq 2})$$

$$\varepsilon_s(t) = \int_0^t \dot{\varepsilon}_s(t) dt \quad (\text{Eq 3})$$

where A is cross-sectional area, E is Young's modulus, l is length, σ is stress, ε is strain, $\dot{\varepsilon}$ is strain rate, and t is time. The subscripts o , s , T , and R correspond to the bar, specimen, transmitted pulse, and reflected pulse, respectively; and c_o is the longitudinal bar wave velocity, which is given by $\sqrt{E_o/\rho_o}$, where ρ_o is density. In deriving Eq 1 2 3, the following assumptions are made:

1. The specimen is under a uniform and uniaxial state of stress during deformation.
2. The incident and transmission bars remain elastic at all times during the experiment, and the end surfaces of the bars in contact with the specimen remain flat and parallel during the deformation of the specimen.
3. The incident, transmitted, and reflected pulses undergo minimal dispersion as they travel along the length of the bar.
4. The stress distribution across the cross section of the incident and transmission bars is fairly uniform (meaning that the measured strains on the surface of the bar using strain gages are representative of the stress in the elastic bars).
5. The accumulated strain in the specimen (determined from the reflected strain gage signal in Eq 3) is solely due to a single incident compression pulse reaching the specimen; in other words, the specimen is subjected to only a single incident stress pulse to cause the observed deformation.

Fig. 1 Schematic of the traditional split-Hopkinson pressure bar test configuration. AB, incident bar; CD, transmission bar; A, impact location

These assumptions (except the fifth one) are easily satisfied while testing metals where plastic deformation is desired. Ceramics, on the other hand, are hard, have high strength, and exhibit no more than 1 to 2% strains before fracture. Therefore, several of the above assumptions are violated while testing ceramics using the traditional SHPB procedure, and, thus, caution must be exercised while interpreting the experimental data. Proper modifications must also be made in the testing procedure to ensure the accuracy and reliability of the stress and strain measurements. Each of the five assumptions (and related issues in SHPB testing of ceramics) is discussed in the following section.

Split-Hopkinson Pressure Bar Testing of Ceramics

G. Subhash, Michigan Technological University G. Ravichandran, California Institute of Technology

Limitations of Testing Ceramics by Traditional Split-Hopkinson Pressure Bar Techniques

The first assumption (that the specimen is under a uniform and uniaxial state of stress) ensures that the stress within the specimen is in equilibrium before the required data (e.g., failure strength) about the ceramic behavior is extracted from the strain-gage signals. Stress equilibrium in the entire specimen is ensured by choosing the duration of the incident loading pulse to be sufficiently longer than the travel time of the longitudinal wave within the specimen. This allows for sufficient wave reflections to occur within the specimen, after which a state of uniaxial and uniform stress is expected to prevail. While testing metals where plastic properties are of interest, the specimen undergoes elastic deformation during the initial few reflections of the incident wave within the specimen, during which a nonuniform state of stress prevails. Therefore, the elastic deformation obtained for metals using a SHPB test is often neglected, and only plastic strains are plotted.

In the case of ceramics (where only elastic strains form a significant portion of the overall response), specimen failure can occur before sufficient reflections occur or before stress equilibrium within the specimen has been established. Thus, the failure strength data obtained under these conditions does not represent the true uniaxial compressive strength of a ceramic. Ravichandran and Subhash (Ref 3) demonstrated that if the impedance

mismatch between a ceramic specimen and the steel bars is taken into account, it is possible to derive the magnitude of the stress difference between the two end surfaces of the specimen at any given instant while the specimen is being loaded by an incident pulse in SHPB testing. Figure 2 illustrates the result of their analysis. On the y -axis is the normalized parameter $R(t)$ defined as the ratio of stress difference, $\Delta\sigma(t)$, between the two end surfaces of the specimen, B and C , at a given instant to the mean stress, $\sigma_m(t)$, in the specimen at that instant, that is:

$$R(t) = \left| \frac{\Delta\sigma(t)}{\sigma_m(t)} \right| \quad (\text{Eq 4})$$

On the x -axis is the normalized time, where t_s is the time required for one single transit of the longitudinal wave within the specimen, that is, $t_s = l_s/c_s$. The results are plotted as a function of impedance mismatch parameter, r , between the specimen and the steel bars, which is defined as:

$$r = \frac{\rho_o c_o A_o}{\rho_s c_s A_s} \quad (\text{Eq 5})$$

Fig. 2 A plot of normalized stress difference between the two ends of a ceramic specimen versus number of wave reflections within the specimen. See discussion in text. Source: Ref 3

The plot shown in Figure 2 indicates that several reflections are needed before complete stress equilibrium is achieved within a ceramic specimen. For practical purposes, a stress difference of 5% between the two end surfaces of the specimen with respect to the mean stress is assumed reasonable. It takes at least four transit times to reach this value, and, therefore, for the fracture strength data to be valid, the failure of the ceramic specimen should occur at least after this time has elapsed during loading of the incident pulse. These results were also confirmed by Chen et al. (Ref 4) using finite element simulations. A typical incident stress pulse containing equal loading and unloading portions should, therefore, have a total duration, T , of at least eight transit times (assuming failure occurs only during the loading phase) of the longitudinal wave within a ceramic specimen, that is:

$$T = 8t_s = \frac{8l_s}{c_s} \quad (\text{Eq 6})$$

The maximum length, l_s , of a ceramic specimen for a given incident pulse duration is now limited to:

$$l_s = \frac{Tc_s}{8} \quad (\text{Eq 7})$$

The equation clearly reflects the fact that the time required for stress equilibration increases with specimen length.

The second assumption (that the incident and transmission bars remain elastic at all times during the experiment, and the end surfaces of the bars in contact with the specimen remain flat and parallel during deformation of the specimen) is usually met by making the incident and transmission bars out of a high-strength material, for example, maraging steel. Notice that the equation for the stress (Eq 1) in the specimen contains the area of the bar in the numerator and the area of the specimen in the denominator. Therefore, by making the specimen diameter smaller (or the bar diameter bigger) one can impose a sufficiently high stress level to cause fracture in a high-strength ceramic specimen while keeping the stress level in the incident and transmission bars within the elastic limit of the bar material. Because ceramics are harder than steel, however, they can indent into the steel bars, as illustrated in Fig. 3(a), thus violating the later part of the second assumption (i.e., the end surfaces of the bars in contact with the specimen remain flat and parallel during the deformation). The indentation into the steel bars can also cause stress concentration along the circumference of the specimen end faces and lead to a nonuniform (or nonhomogeneous deformation) and nonuniaxial stress state within the specimen, thus also violating the first assumption. The stress concentration can lead to premature failure (e.g., chipping) of the ceramic by initiating microcracking at these locations. This problem can be reduced by sandwiching the ceramic specimen between two identical high-strength tungsten-carbide (WC) inserts and placing this whole assembly in the SHPB testing setup, as shown schematically in Fig. 3(b). The main requirement in this approach is that the tungsten-carbide inserts should not alter the incident, reflected, and transmitted stress-wave characteristics as the wave crosses the specimen-bar interfaces to avoid misinterpretation of strains measured by the strain gages on the bars. This requirement can be achieved by matching the impedance of the tungsten-carbide inserts to that of the bar material, that is:

$$(\rho c A)_{WC} = \rho_o c_o A_o \quad (\text{Eq 8})$$

This requirement can also be achieved by accordingly choosing the diameter of the inserts. The length of the inserts is typically chosen to be one fourth of the length of the specimen.

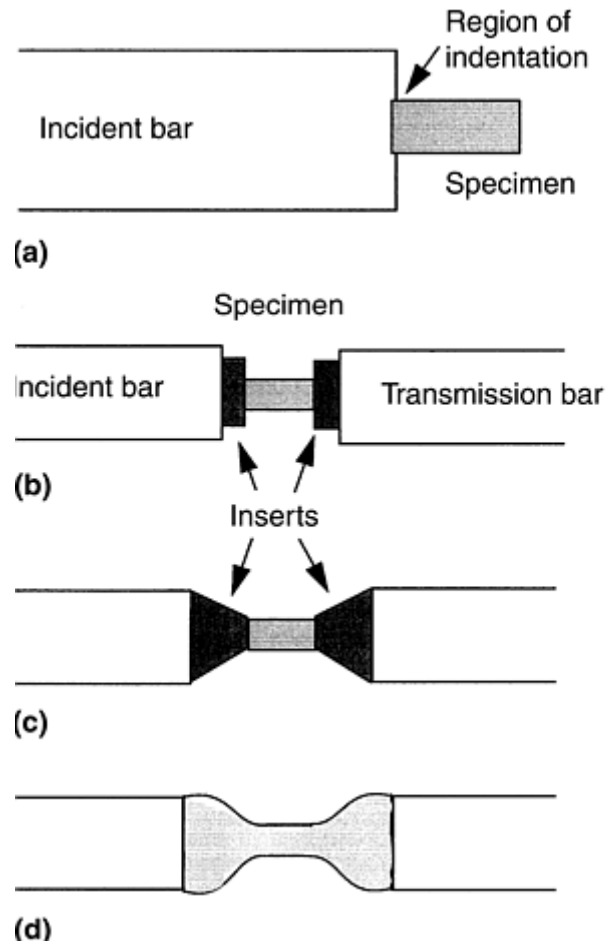

Fig. 3 Problem caused by the hardness of ceramic specimens and techniques developed to solve the problem. (a) Schematic illustration of indentation of hard ceramic into the bars. (b) Specimen-insert assembly with impedance matched tungsten carbide inserts. (c) Specimen-insert assembly with matching diameter conical inserts. (d) Dog-bone shaped specimen with end diameters sized to match the incident and transmission bars

Alternate insert geometry to reduce the indentation into the bars was proposed by Anderson et al. (Ref 5). In this design, conical ceramic inserts with matching diameters at both ends, as shown in Fig. 3(c), were used. Finite element analysis on various specimen-insert configurations (Ref 4) has confirmed that the magnitude of indentation into the steel bars, as well as the stress concentrations in the specimen, can be eliminated by using conical inserts. However, the analysis also revealed that conical inserts can alter the reflected and transmitted wave characteristics considerably due to the impedance mismatch with the steel bars. Other disadvantages of ceramic conical inserts compared to the constant-diameter impedance-matched tungsten-carbide inserts are higher manufacturing cost and need to customize the inner diameter of the cone whenever the specimen dimensions change. A dog-bone shaped ceramic specimen with an end diameter matched to that of the bar, shown in Fig. 3(d), has also been used in the literature to reduce the stress concentration and avoid indentation into the bars (Ref 6, 7). Again, this specimen geometry is prohibitively expensive to manufacture from a ceramic material.

While using inserts to avoid indentation into the bars, it is assumed that the strength of inserts is considerably greater than the ceramic being tested. However, smaller-diameter high-strength ceramic specimens can cause stress concentration on the inserts and cause fracture of the inserts before the ceramic specimen. Once the failure of insert occurs, the ceramic fractures invariably (due to stress concentration caused by the insert fragments on the ceramic), thus rendering the data on ceramic fracture strength invalid. To eliminate this possibility, it is recommended that the inserts be laterally confined using steel rings that can provide adjustable confining pressures, as shown in Fig. 4. To avoid impedance mismatch at the contact surface between the bar and the insert, the thickness of the steel ring is made slightly smaller than that of the inserts.

Fig. 4 Schematic of the adjustable lateral confinement ring to avoid premature fracture of inserts

The third assumption (that the incident, transmitted, and reflected pulses undergo minimal dispersion as they travel along the length of the bar) points to the fact that stress-strain response of a ceramic is not measured on the specimen during its deformation, but at distances farther away from the specimen (and at a time different from that of specimen deformation) using strain gages on the incident and transmission bar surfaces (Fig. 1). Under these circumstances, it is imperative that the reflected (which is a measure of strain) and transmitted (which is a measure of stress) strain-gage signals reflect the true response of the specimen. If dispersion is present in the propagating pulse, the amplitude and duration of the pulse changes by the time it reaches the strain gages and results in erroneous measurement of stress and strain within a ceramic. The extent of dispersion depends on the dominant frequency components present in (or the shape of) a propagating stress pulse (Ref 3). When the diameter of the bar is comparable to the wavelength of the dominant frequency component (or when the period of the pulse is comparable to the transit time of the bar wave across the diameter of the bar), dispersion effects become extremely severe, and the use of surface measurements at distances farther away from the specimen lead to erroneous measurement of the stress-strain response. It is suggested that the pulse duration should at least be 10 times larger than the transit time of the longitudinal wave across the diameter of the bar to minimize the dispersion in a propagating stress pulse (Ref 2, 8). Because the minimum pulse duration of the incident stress pulse and the maximum obtainable strain within a ceramic are limited, the maximum strain rate that can be imposed on to a ceramic specimen using SHPB testing is also limited. This concept is discussed in detail in the section “Limiting (Maximum) Strain Rate” in this article.

One way to avoid the problems associated with the dispersion is to eliminate the use of strain-gage signals from the bars. Instead, one can mount strain gages directly on the ceramic specimen and record the axial and transverse strains in situ during the deformation of the specimen. This procedure is also expected to give a more accurate measure of strain in a ceramic. Because the majority of ceramics undergo only linear elastic response until failure, the stress to fracture, σ_f , can be determined from the measured strain to fracture, ϵ_f , using Hooke's law ($\sigma_f = E\epsilon_f$). However, caution should be exercised while adopting this linear elastic approach on ceramics that exhibit significant inelastic strain before fracture. For example, zirconia ceramics, such as MgO-PSZ and Y-TZP, exhibit considerable inelastic strains due to stress-induced transformation and associated microcracking (Ref 9, 10), as discussed in the section “Pulse Shaping” in this article. In such cases, use of linear elastic response until fracture can overestimate the failure strength.

The fourth assumption (that the stress distribution across the cross section of the steel bars at a given instant is uniform) implies that the strain-gage measurements on the surface of the bars are representative of the stress at any interior point at that cross section of the bar. To further illustrate this concept, consider the stress distributions in the bar shown in Fig. 5. Obviously, for the stress distribution shown in Fig. 5(a), the measured strains on the surface of the bars will represent those at any interior point on the bar cross section. For the stress distributions shown in Fig. 5(b) the strain-gage measurements are not representative of the strains inside the bars, and, hence, the surface measurements will be meaningless. The nonuniform stress distribution can occur if either a planar impact is not ensured between the striker and the incident bars or when the duration of the incident stress pulse is comparable to that of the time required for transit of the longitudinal wave across the diameter of the bar, which can amplify the dispersion effects (Ref 3).

Fig. 5 Examples of (a) uniform stress and (b) nonuniform stress distribution in split-Hopkinson pressure bar testing

The fifth assumption (that the accumulated strain in the specimen is due solely to a single incident compression pulse reaching the specimen) emphasizes the fact that in traditional SHPB testing, a ceramic specimen is subjected to repeated loading (due to wave reflections within the incident bar) unless it is fractured during the first compression pulse loading. In the traditional design, shown in Fig. 1, the reflected pulse off the specimen is tensile in nature, and when it reaches the striker end of the incident bar, A, it reflects back as a compression pulse and travels once again toward the specimen, thus reloading the specimen. This process repeats several times causing multiple loadings on the specimen. Notice that the stress-strain response obtained from the initial transmitted (Eq 1) and reflected (Eq 3) strain-gage signals does not account for the accumulated damage in the specimen due to multiple loadings. Therefore, the microstructural changes (or the accumulated strain) in a specimen cannot be correlated to the macroscopic stress-strain response. For example, in the case of ceramics, suppose that the amplitude of the incident stress pulse is such that it is slightly below the stress level required for complete fracture but well above the stress level for initiating microcracking in a ceramic specimen (e.g., zirconia ceramics). The repeated loading due to reflected pulses can completely fracture the already weakened (or microcracked) specimen, but the stress-strain response may indicate otherwise because this is derived from the first transmitted and reflected pulses only.

The reloading of the specimen due to reflected pulses can be eliminated by using the modified SHPB technique shown in Fig. 6. In this design, the tensile pulse reflected off the specimen into the incident bar is captured by the “momentum-trap” assembly designed at the striker end of the incident bar. The technique is described in the article “Recovery Hopkinson Bar Techniques” in this Volume. Upon impact of the striker, the momentum-trap design also introduces a tensile pulse following the traditional compression pulse into the incident bar. Moreover, once a specimen is subjected to the initial compression pulse, all other pulses travelling towards the specimen end are rendered tensile and, therefore, cannot reload the specimen as the incident bar retracts away from the specimen. The trapping of the tensile pulse reflected off the specimen has overriding importance in recovery experiments on some ceramics (e.g., zirconia ceramics), where considerable microcracking and inelastic deformation can occur before complete fracture of the specimen (Ref 9, 10).

Split-Hopkinson Pressure Bar Testing of Ceramics

G. Subhash, Michigan Technological University G. Ravichandran, California Institute of Technology

Limiting (Maximum) Strain Rate

The concept of limiting strain rate for ceramics using a SHPB test originates from the fact that ceramics are hard and exhibit extremely small strains (<1%) before fracture. Consequently, several of the assumptions previously discussed are violated. For failure strength data obtained from SHPB experiments to be valid, the stress in a specimen must be made to reach equilibrium, which means that enough wave reflections must occur within the specimen before fracture is initiated. This condition imposes limits on either the pulse duration (Eq 6) or the specimen length (Eq 7). The following simple calculations further illustrate this concept (Ref 3). The time required for an incident wave to travel from one end of the specimen to the other is given by:

$$t_s = \frac{l_s}{c_s} \quad (\text{Eq 9})$$

Let τ be the time required for stress equilibration within the specimen and t_f be the time to fracture during loading by the incident pulse. For failure strength data to be valid, t_f should be greater than or equal to τ . Assume that the time required for stress to reach equilibrium is an integer multiple of transit time, t_s , that is:

$$\tau = \alpha t_s \quad (\text{Eq 10})$$

where α represents the number of wave reflections within the specimen. The nominal strain rate at the time of failure in a ceramic that exhibits only elastic strains is given by:

$$\dot{\epsilon} = \frac{\epsilon_f}{t_f} \quad (\text{Eq 11})$$

where ϵ_f is the failure strain. Because t_f has to be at least equal to τ for failure strength data to be valid, substituting Eq 9 and 10 in Eq 11 gives the maximum (or limiting) strain rate that can be achieved in a ceramic, that is:

$$\dot{\epsilon}_l = \frac{\epsilon_f c_s}{\alpha l_s} \quad (\text{Eq 12})$$

As illustrated in Fig. 2, at least four transit times in a ceramic specimen are required for stress equilibrium to be achieved ($\alpha = 4$). Typical ceramic specimen lengths used in SHPB testing are around 9.5 mm (0.375 in.), and assuming a wave speed of 10,000 m/s (32,800 ft/s) and a failure strain of around 1% in a ceramic, the maximum strain rate that can be achieved in a ceramic specimen using SHPB testing is around 2600/s. Because the failure strain and wave velocity are fixed for a given ceramic, acquiring failure strength data beyond this strain rate requires further reduction in specimen length (and a corresponding reduction in diameter to keep the length-to-diameter ratio of 2 to 1). For various structural ceramics, this limiting strain rate is found to be in the range of 2500 to 3000/s (Ref 3).

The concept of limiting (or maximum) strain rate in a ceramic using SHPB testing can also be approached from the dispersion effects of propagating stress pulses in a slender bar, discussed earlier under the third assumption. Let us assume that the incident pulse propagating in the bar has a fundamental frequency, ω_o , and a period, T , where:

$$\omega_o = \frac{2\pi}{T} \quad (\text{Eq 13})$$

Because a typical input pulse in SHPB testing is composed of multiple frequencies, all of which are assumed to be integer multiples of the fundamental frequency, a characteristic wave velocity is associated with each of the frequencies, ω , and the corresponding phase velocity, c_p , is given by:

$$c_p = \frac{\omega}{2\pi} \Lambda \quad (\text{Eq 14})$$

where Λ is the wave length associated with a particular frequency component. The phase velocity can be obtained from the approximate dispersion relation (Ref 2, 8) given by:

$$\frac{c_p}{c_o} = 1 - \nu^2 \pi^2 \left(\frac{a}{\Lambda} \right)^2 \quad (\text{Eq 15})$$

where ν is the Poisson's ratio and a is the radius of the bar. For propagating longitudinal stress pulses in a cylindrical bar, it has been shown that when $a/\Lambda > 0.1$, dispersion effects become dominant, and the stress and displacement fields become highly nonuniform across the cross section of the bar (e.g., Fig. 5b). Therefore, the data obtained from the surface measurements at distances farther away from the specimen lead to erroneous results (violation of assumptions 3 and 4). To minimize dispersion, the dominant frequency component in the frequency spectrum of the incident pulse should be such that $a/\Lambda < 0.1$ (Ref 2, 8). This condition can be rewritten using Eq 13 and 14 as:

$$\left(\frac{c_o}{c_p} \right) \left(\frac{\omega}{\omega_o} \right) < 0.1 \quad (\text{Eq 16})$$

where the fundamental frequency can be determined in terms of bar geometry and material properties as:

$$\omega_o = 2\pi \frac{c_o}{a} \quad (\text{Eq 17})$$

Using relevant numbers for a 9.5 mm (0.375 in.) diameter SHPB made of maraging steel ($a = 4.75$ mm, or 0.19 in., $\nu = 0.3$, and $c_o = 4970$ m/s), ω_o can be calculated from Eq 17 as 6.574×10^6 rad/s. For $a/\Lambda = 0.1$, c_p can be calculated from Eq 15 to obtain a limiting value of the fundamental frequency, ω , from Eq 16 as 6.516×10^5 rad/s. Finally, the corresponding period, T , of the pulse is calculated from Eq 13 to be $9.64 \mu\text{s}$. A given pulse typically consists of equal durations of loading and unloading phases. Assuming the failure of the specimen coincides with the peak input load (i.e., at $4.82 \mu\text{s}$) for a failure strain of 1% in a ceramic specimen, the maximum strain rate that can be achieved based on dispersion relation is calculated using Eq 11 to be 2074/s. This value should be deemed as a lower bound for the limiting strain rate because in $4.8 \mu\text{s}$ approximately 5 wave reflections can occur for a ceramic specimen of length 9.5 mm (0.375 in.).

From the preceding discussions, it is clear that the maximum strain rate that can be achieved in a ceramic specimen using SHPB testing can be derived from two approaches: one based on time required for stress to reach equilibrium in the specimen and the other based on dispersion effects in the propagating pulse. Both approaches yield the maximum strain rate limit between 2000 and 2600/s. However, this value can be further extended by reducing the specimen length, decreasing the bar diameter, or increasing the failure strain of the ceramic material (through microstructural control). However, decreasing the bar diameter will warrant further reductions in the specimen dimensions so as to obtain the required stress level to cause fracture in a ceramic specimen.

Split-Hopkinson Pressure Bar Testing of Ceramics

G. Subhash, Michigan Technological University G. Ravichandran, California Institute of Technology

Pulse Shaping

Traditionally, a rectangular shaped incident pulse is generated in the incident bar through a planar impact between the striker and the incident bars. For metallic specimens, this wave form is ideally suited because metals undergo large plastic strains and the rectangular shaped loading pulse imposes a nominally uniform strain rate throughout the plastic deformation (Fig. 7a). In the case of a ceramic specimen, use of rectangular incident pulse is not recommended because ceramics undergo only elastic strain before fracture, and the total energy contained in the rectangular pulse can be too large to cause excessive fragmentation of ceramics without any possibility for recovery of the intact but microcracked specimen for post-test quantification and analysis. Moreover, the rectangular pulse with its steep rise in stress level can impose a nonuniform strain rate during the elastic deformation of the ceramic due to the differences between the slopes of the imposed loading rate and the stress-strain response, as shown in Fig. 7(b). Therefore, modification in the incident pulse shape that matches the slope of the elastic response of the ceramic is recommended. Figure 7(c) illustrates the advantage of using a ramp pulse while testing ceramics. When incident stress amplitude of the ramp pulse is greater than the stress required for microcracking in a ceramic, the total energy contained in the ramp pulse beyond the fracture

strength is much smaller than the traditional rectangular pulse of similar duration. At the onset of inelasticity (such as microcracking or transformation plasticity in the case of zirconia ceramics), the remaining duration of the pulse with excess energy is considerably shorter, and, hence, the cracks have less available time and energy to propagate, coalesce, and cause catastrophic failure of the ceramic, which can occur if the traditional rectangular incident pulse of constant duration is imposed. By matching the slopes of the incident ramp pulse and the stress-strain response, one can also attain a constant strain rate throughout the elastic deformation of the ceramic.

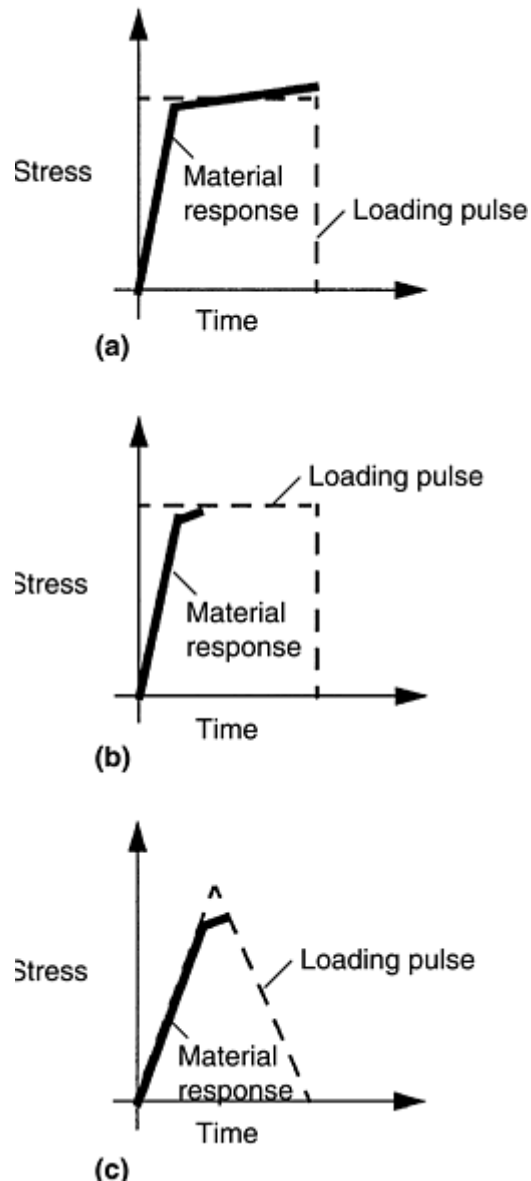

Fig. 7 Schematic illustration of the influence of incident pulse shaping on the stress-strain response of a ceramic specimen. (a) Rectangular-shaped pulse on a ductile specimen. (b) Rectangular pulse on a ceramic specimen. (c) Ramp-shaped pulse on a ceramic specimen

A ramp pulse can be produced by placing a thin ductile (e.g., copper, aluminum) metallic disk of 0.5 to 1 mm (0.02–0.04 in.) thick and 2 to 3 mm (0.08–0.12 in.) diameter on the impact end of the incident bar, as shown in Fig. 6. Upon impact by a striker, the plastic deformation of the disk generates a ramp pulse in the incident bar. The rise and fall times in the ramp pulse can be controlled by changing the material of the pulse shaper as well as the velocity and length of the striker bar. Figure 8(a) illustrates the traditional rectangular pulse; Fig. 8(b) shows the typical ramp stress pulse obtained using a copper disk. Note that, although both the pulses are obtained with the same striker bar, the ramp pulse duration is almost twice that of the rectangular pulse. In-depth discussions on pulse shaping can be found in Ref 11.

Fig. 8 Comparison of (a) rectangular-shaped pulse with (b) ramp-shaped pulse obtained from the same length striker bar

Although pulse shaping allows controlled damage in a ceramic specimen at a constant strain rate, use of traditional SHPB does not preclude the possibility for repeated reloading of the specimen due to wave reflections in the incident bar. Even if the amplitude of the incident stress pulse is carefully adjusted such that it is just enough to cause microcracking in the ceramic (but not complete fracture), the reloading of the specimen by reflected pulses in a traditional SHPB test will suffice to cause complete fracture of the already weakened (due to microcracking during the first loading) specimen, further emphasizing the need for momentum trapping discussed previously. With the above modifications, precise stress-strain curves can be obtained in microcracking ceramics, such as zirconia ceramics, even after significant inelastic strain (due to the stress-induced transformation) and extensive microcracking have accumulated in the specimen. A typical stress-strain curve revealing transformation and microcracking phases for magnesia partially stabilized zirconia (MgO-PSZ), obtained using a ramp loading pulse in a modified SHPB is shown in Fig. 9. In these experiments, strain gages were mounted on the specimen to obtain the axial and transverse strains during the deformation.

Specimen Design

The stress-strain response and failure strength data on ceramics obtained from SHPB is strongly influenced by the tolerances in the ceramic specimen dimensions, such as parallelism between the end faces, normality of the end faces with the axis of the specimen, and surface finish. Similar to uniaxial static compression testing of metals and ceramics, a length-to-diameter ratio of 2 to 1 is recommended for high-strain-rate testing. Because ceramics have a high elastic modulus (nearly 1.5 to 2 times that of steel) and small failure strains (<1%), small variations in the parallelism between the end surfaces can cause high stress concentrations at these locations leading to chipping or initiation of fracture during deformation. Therefore, it is extremely important to grind the end surfaces to a high degree of flatness (at least 0.01 mm, or 0.0004 in.) and parallelism (within 0.001 mm, or 0.00004 in.) to avoid premature failure of the specimen. Because ceramics are also flaw sensitive, it is recommended that all surfaces be polished to reduce the influence of machining induced surface flaws.

Interpretation of Test Results

High-strain-rate response of brittle materials, in particular ceramics, differs from quasi-static response in two ways. First, there is an increase in fracture strength at high strain rates. Figure 10 illustrates data on aluminum-nitride uniaxial compressive fracture strength as a function of strain rate. Similar trends were also observed in several other structural ceramics, such as alumina, silicon carbide, and rocks (Ref 13, 14, 15). Note that, beyond a critical strain rate, the fracture strength increases with strain rate dramatically. Second, there is an increased propensity for multiple microcrack initiation from several locations in the specimen. Both these effects are intimately connected to the inherent microstructure. A brief discussion on the mechanisms of brittle fracture and damage evolution follows. The discussion is expected to assist a nonspecialist in this field in proper interpretation of the experimental results obtained using an SHPB test.

Fig. 10 Plot of variation of fracture strength as a function of strain rate for aluminum nitride (AlN) ceramic. Source: Ref 12

Mechanisms of Brittle Failure Under High-Strain-Rate Loading. It has been well established that processing-induced microstructural inhomogeneities, such as inclusions, grain boundary impurities, second phases, triple junctions, and pores are mainly responsible for the nucleation of microcracks that lead to fracture in ceramics (Ref 14, 16, 17). However, the difference in the characteristics of crack growth from these inhomogeneities is mainly responsible for the rate-sensitive nature of fracture strength in brittle materials. At low strain rates, typically below 100/s, both sintered and hot-pressed ceramics, in general, do not exhibit rate-sensitive failure strength. This behavior has been attributed to unstable crack growth from inhomogeneities and their instantaneous coalescence, which inhibits any subcritical crack growth.

At high strain rates, beyond a critical strain rate, both sintered and hot-pressed ceramics exhibit a high rate-sensitive fracture stress due to inertia-dominated crack growth (Ref 14, 15, 17); that is, as the loading rate increases, the time available for a crack to initiate and grow reduces. The inertia associated with the crack-growth acceleration will inhibit early fracture initiation while the applied stress continues to rise rapidly, thus elevating the compressive failure strength under dynamic loads. The critical strain rate at which transition from the rate-insensitive (unstable) to rate-sensitive (inertia dominated) crack growth in microcracking solids has been found to depend on material properties. Grady and Lipkin (Ref 18) proposed the following relationship for the transitional strain rate:

$$\dot{\epsilon} = \frac{K_{Ic}}{\rho c r_o^{3/2}} \quad (\text{Eq 18})$$

where K_{Ic} is the fracture toughness, ρ is material density, c is wave velocity, and r_o is the average initial microcrack size, which is typically assumed to be the same as the grain size in ceramics. Ravichandran and Subhash (Ref 17) proposed this equation:

$$\dot{\epsilon} = \frac{\sigma_f \tilde{c}}{E l_s} \quad (\text{Eq 19})$$

where σ_f is the quasi-static compressive strength and \tilde{c} is the characteristic crack velocity which is taken as the speed at which inertia effects become significant, that is, when the crack velocity reaches approximately 0.2 of shear wave velocity. Equation 19 is a modified version of the equation proposed by Lankford (Ref 14) where the length is replaced by radius of the specimen and by shear wave speed. Both Eq 18 and 19 predict the transitional strain rate to be between 1200 and 1500/s.

In the inertia-dominated (high-strain-rate) regime, the relationship between the compressive fracture strength, σ_f , and strain rate at fracture for a variety of brittle ceramics has been found to follow a relationship (Ref 18):

$$\sigma_f \propto \dot{\epsilon}^{1/3} \quad (\text{Eq 20})$$

A micromechanical damage model for brittle materials developed by Ravichandran and Subhash (Ref 17) shows a similar relationship, $\sigma_f \propto \dot{\epsilon}^n$, where n ranges from $1/4$ to $1/3$. The value of n depends on the relationship describing the dynamic fracture toughness as a function of crack speed. Although the relationship discussed previously has been found to reasonably represent the failure behavior of coarse-grained ceramics, recent experimental results on fine-grained, high-purity ceramics revealed a complete absence of such a transitional strain rate (Ref 19, 20). In these ceramics, the uniaxial compressive fracture strength increased linearly with strain rate in the range between 10^{-3} and 10^5 /s. This behavior has been attributed to fine grain size, significant reduction in the process induced flaws, and elimination of inhomogeneities during processing, all of which resulted in enhanced dislocation activity and microshear banding similar to those observed in ductile metals.

Damage Evolution. One of the major characteristics of crack growth during uniaxial compressive loading of brittle materials is that crack growth occurs in a direction parallel to the loading axis. On a plane perpendicular to the loading axis, the cracks can be randomly oriented, thereby making the specimen transversely isotropic. The problem of tensile crack growth from preexisting microcracks has been analyzed in detail (Ref 21, 22). Under uniaxial compressive loading, tensile cracks nucleate from the preexisting flaws in the direction of maximum tensile stress. The major difference in crack growth under static and dynamic loading is that in static loading, a single crack typically dominates the fracture behavior. This is because once the stress required for crack initiation is reached, the weakest crack starts to grow first, and the stored elastic energy continues to provide the necessary driving force for unstable crack growth to continue and cause eventual failure of the specimen. Here the rate of loading is extremely slow compared to the crack growth rate, and, hence, once crack growth is initiated it cannot be controlled. In the case of dynamic loading, the inertia associated with the crack tip opening delays the crack growth while the applied stress rises much more rapidly beyond that required for

several cracks to grow; therefore, multiple cracks grow simultaneously. The difference in the crack growth phenomena between static and dynamic loading rates is illustrated schematically in Fig. 11. If the loading process continues during dynamic testing, the energy required for crack growth continues to be supplied to the crack tips, leading to complete fragmentation of the specimen. Through proper pulse shaping, the amount of input energy can be controlled (Fig. 7, 8), and microcrack growth can be limited, allowing for recovery of the intact but microcracked specimen.

Fig. 11 Schematic of crack growth from preexisting flaws under (a) static and (b) dynamic uniaxial compressive loads

In order to confirm multiple crack growth during dynamic loading, Subhash and Nemat-Nasser (Ref 9) conducted dynamic uniaxial compression experiments on a MgO-PSZ ceramic specimen in a modified SHPB with a ramp-shaped input pulse. They subjected the specimen to uniaxial compressive loads successively in two perpendicular directions. The first loading caused axial crack growth parallel to the first loading direction. The second loading (in a direction perpendicular to the first one) also induced axial crack growth parallel to this loading direction. The micrograph provided in Fig. 12 reveals the network of cracks developed parallel to the two loading directions. Notice that the microcracks developed during the first loading do not seem to influence the crack growth during the second loading, suggesting that in uniaxial compression, cracks always grow parallel to the loading axis even in the presence of some material anisotropy caused during the first loading. Complete recovery of the specimen after multiple microcrack growth was possible due to the controlled energy input through pulse shaping and ensuring a single loading through modified SHPB testing. With continued loading, one could expect the specimen to break into columnar fragments due to crack growth from several locations. Investigations by Kipp and Grady (Ref 23) and Lankford and Blanchard (Ref 16) have confirmed that fragment size is inversely proportional to the applied strain rate. Smaller fragment size and its narrow distribution in high-strain-rate experiments imply nucleation and rapid coalescence of numerous microcracks under dynamic loading, a conclusion that was also supported by the modeling studies on strain-rate effects on brittle fracture in compression by Nemat-Nasser and Deng (Ref 24).

Split-Hopkinson Pressure Bar Testing of Ceramics

G. Subhash, Michigan Technological University G. Ravichandran, California Institute of Technology

Conclusions

The inherent limitations of the traditional SHPB technique for testing of brittle materials necessitate modifications in the SHPB design and testing procedure. In order to obtain accurate and reliable data on the behavior of ceramics at high strain rates, modifications such as strain gaging the specimen, sandwiching the specimen between high-strength impedance matching inserts, momentum trapping, and incident pulse shaping should be employed. Because ceramics exhibit only elastic strains to failure, one should also be aware of the maximum strain rate that can be achieved using the SHPB technique. This limiting strain rate depends on specimen size, its elastic properties, incident pulse duration, and the bar diameter. For more accurate measurement of fracture strains and identification of true failure modes, it is emphasized that close tolerances should be maintained for flatness and parallelism of the loading surfaces, and the specimens should be carefully ground and polished to reduce machining-induced damage on the surfaces.

Torsional Kolsky Bar Testing

Amos Gilat, The Ohio State University

Introduction

THE TORSIONAL KOLSKY BAR TEST is a reliable technique for testing materials in the 10^2 to 10^4 s^{-1} strain-rate regime (Fig. 1). In this technique, shown schematically in Fig. 2, a short material specimen is placed between two bars. The specimen is loaded by a torsional wave that is generated in one of the bars. Once loaded, the wave is partially reflected back and partially transmitted to the other bar. The history of load and deformation in the specimen is determined by monitoring the waves in the bars, which remain elastic throughout the test. The technique is a variation of a technique proposed by Kolsky (Ref 2), in which the specimen is loaded in compression. It is described in the article “Classic Split-Hopkinson Pressure Bar Testing” in this Volume.

Historical Perspective

In 1949 Kolsky devised an experiment in which short specimens are placed between two long elastic cylindrical bars that act as wave guides for a loading pulse. The experiment was referred to as the split-Hopkinson bar, although the purpose of the test, the instrumentation, and the specimen were quite different from those in Hopkinson's original experiment (Ref 3).

In Kolsky's test, loading is accomplished by a compressive wave propagating along one of the bars and through the specimen. This wave is partially transmitted into the second bar and partially reflected by the specimen. The bars in this configuration are used for applying the load to the specimen and as transducers for measuring the displacements and loads at the specimen ends, which are in contact with the bars. Kolsky showed that the portion of the incident loading wave that is transmitted through the specimen provides a measure of the axial stress in the specimen, while the magnitude of the wave that is reflected back is proportional to its strain rate. It is assumed that the specimen is under a state of uniaxial stress and that the stress and strain are uniform along the specimen because the wave transit time through the specimen is very short compared to the duration of the loading wave.

The first torsional Kolsky bar was introduced in 1966 by Baker and Yew, who produced a torsional wave by a sudden release of a clamped pretwisted end section of an elastic bar (Ref 4). They showed that the stress-strain curves in shear for the specimen could be obtained by an analysis of the waves measured in the elastic bars on both sides of the specimen. Originally, a torsional version of the Kolsky bar was developed to eliminate radial inertia effect in the specimen and in the bars and the radial traction component that can be imposed (if friction is not eliminated) at the interfaces between the specimen and the bars in the compression test. Today these reasons no longer seem as important because the results from torsional tests have been found to be consistent with those of compression. However, torsional loading has other advantages, as described later in this article.

In the early 1970s, several configurations of torsional Kolsky bar were introduced by several investigators (Ref 5, 6, and 7). The various machines differ mainly in the method used for generating the torsional loading wave. Duffy et al. originally used explosive loading to initiate the loading pulse (Ref 5). Others used a sudden release of a stored torque. Explosive loading produces a short pulse with a short rise time. A stored-torque loading system provides a longer pulse, which produces larger strains in the specimen. The pulse, however, has a longer rise time that depends on the details of the clamp design.

The torsional Kolsky bar has also been modified for studying strain-rate history effects by conducting incremental and decremental strain-rate tests. In incremental strain-rate tests, the specimen is first twisted quasi-statically, and then a dynamic strain rate is imposed with no intermediate unloading (Ref 8, 9). In decremental strain rate tests an initial high strain rate deformation is suddenly reduced and continues at a lower strain rate (Ref 10, 11). Both strain rates are within the range of the torsional Kolsky bar.

The technique has also been adapted for testing materials at temperatures below and above the ambient (Ref 12, 13). For temperatures below the ambient and above the ambient up to about 150 °C, or 302 °F the technique is used without any modifications. In tests at higher temperatures (up to 1000 °C, or 1832 °F), the effect of heating the specimen on the adjacent elastic bars must be addressed.

The torsional Kolsky bar also provides means for studying localization of plastic deformation through the formation of adiabatic shear bands (Ref 14, 15, and 16). The evolution of the localization is recorded by high-speed photography and associated temperature increase is measured by detecting infrared radiation. Recently, a recovery experiment, in which the specimen was loaded up to a predetermined strain and then unloaded and recovered for microscopic examination, has also been introduced (Ref 17).

Torsional Kolsky Bar Testing

Amos Gilat, The Ohio State University

Comparison with Compression Kolsky Bar

The torsional Kolsky bar was originally introduced in order to verify strain-rate effects that were observed in tests with the compression Kolsky bar. Concerns have been raised with regard to the effects of inertia and friction on the experimental results when a compression load is used. Although the compressive and torsional Kolsky bar techniques are based on the same principles, there are significant differences between the two. In addition to the difference in the states of stress, the techniques use specimens that have different geometry, and the boundary conditions at the specimen ends are different. The two techniques are now compared in detail.

Inertia Effects in the Specimen. Due to the Poisson's ratio effect, loading in the compressional test is accompanied by radial expansion of the specimen. This radial expansion is opposed by a radial inertia that becomes greater with a shorter pulse and larger amplitude. This effect results in a radial stress component in the specimen superposed on the axial stress component. Hence, in axial loading, the state of stress in the specimen is not fully uniaxial. Furthermore, the radial component of stress is difficult to evaluate because it depends on dynamic material properties that have not yet been determined. In torsional testing, due to the absence of Poisson's ratio effect, radial expansion or contraction does not occur and inertial effects do not exist.

Friction Effects. In the compression Kolsky bar, radial deformation accompanies the axial motion. Radial traction is imposed at the interfaces between the specimen and the bars because the Poisson's ratio of the specimen is not necessarily the same as of the bars, and because the specimen undergoes plastic deformation. The radial traction causes unknown stresses and barreling in the specimen. Although friction can be minimized by proper lubrication, it cannot be completely eliminated. In torsional testing, friction does not exist.

Wave Dispersion in the Bars. In the compression Kolsky bar, the elastic waves that travel in the bars undergo geometric dispersion because different frequency components in the compressive pulse have different velocities. In particular, the higher frequency components travel at a lower velocity than the main pulse. In contrast, there is no geometric dispersion when a torsional pulse travels along an elastic bar in its primary mode; that is, all frequency components of the torsional pulse have the same velocity. Hence, a torsional pulse does not change its shape as it propagates toward the specimen.

The absence of geometric dispersion in torsion means that a pulse initiated with a short rise time will maintain this rise time until it reaches the specimen, independent of the length of the Kolsky bar. Also, the torsional strain gage stations can be located as near or as far from the specimen as desired and still reveal the correct shape pulse incident on, or reflected from, the specimen. In an axial Kolsky bar, however, a gage placed too close to the specimen is subject to errors due to three-dimensional end effects, while a gage placed too far from the specimen may produce unsatisfactory results due to geometric dispersion.

If a torsional pulse is noisy when initiated (i.e., if some high-frequency components are superposed on the main pulse), this characteristic will be maintained, regardless of the length of the Kolsky bar. As a result, the strain rate imposed on the specimen will not be constant. In axial Kolsky bar, such high-frequency components gradually disappear. Hence, an axial pulse tends to become flat—that is, tends to smooth out—as it travels along an elastic bar. A noisy torsional pulse will retain this characteristic; it will never become flat and, hence, will not provide deformation at a constant strain rate.

Specimens. Polycrystalline specimens tested in a torsional Kolsky bar experiment are shaped as short, thin-wall tubes. These specimens require substantially more material and are more expensive to machine than the specimens used in a compression Kolsky bar, which are shaped as short cylinders. In addition, gripping tubular specimen is more difficult, and special care must be taken that the specimens are attached firmly to the bars and that there are no wave reflections due to the gripping method.

Torsional Kolsky Bar Testing

Amos Gilat, The Ohio State University

Description

The torsional Kolsky (split-Hopkinson) bar apparatus is made up of two collinear bars that face each other and are supported by bearings that allow them to rotate freely. The specimen, which is usually a short, thin-wall tube, is attached between the two bars. To conduct a test, a torsional wave is generated in one of the bars

(incident bar). The wave propagates toward the specimen, and, when it arrives, the specimen is loaded and the wave is partially reflected back to the incident bar and partially transmitted to the other bar (transmitter bar). The apparatus and the specimen are designed such that the amplitude of the incident wave is much larger than the torque required for deforming the specimen or causing the specimen to fail. Consequently, most of the wave is reflected back to the incident bar and only a small portion is transmitted to the transmitter bar. As a result, the end of the incident bar where the specimen is attached rotates with an angular velocity that is much larger than the angular velocity of the other end of the specimen that is connected to the transmitter bar. The difference in the angular velocity between the specimen ends causes the specimen, which is very short, to deform at a high rate. In addition, because the specimen is short, and hence, the time it takes for the wave to propagate through is very short, the deformation is uniform. The history of load and deformation of the specimen is determined by monitoring the waves in the bars, which remain elastic throughout the test.

The Bars

The bars typically have a diameter of about 25 mm (1 in.) and are made of aluminum. Steel and titanium have also been used. The bars must be aligned properly and supported along the length by a series of bearings that allow free rotation. Aluminum bars are easy to use and are suitable for most applications. For an elastic torsional wave that propagates in a bar, the relationship between the torque, T , and the angular velocity, $\dot{\theta}$, is given by:

$$\dot{\theta} = \frac{T}{\rho J c} \quad (\text{Eq 1})$$

where ρ is the density, J is the polar moment of inertia, and c is the torsional wave speed. The maximum torque that can propagate in an elastic bar is limited by the yield stress of the material, τ_Y , which is related to the torque by:

$$T = \frac{\tau_Y J}{r} \quad (\text{Eq 2})$$

where r is the radius of the bar. Substituting T from Eq 2, and $c = \sqrt{G/\rho}$, where G is the shear modulus, in Eq 1 gives:

$$\dot{\theta} = \frac{\tau_Y}{r \sqrt{\rho G}} \quad (\text{Eq 3})$$

Equation 3 shows that, theoretically, a higher angular velocity can be achieved with bars made of a material that has high yield stress and low density and shear modulus. Titanium is a material that has a high value of $\tau_Y/\sqrt{\rho G}$. Practically, however, it is difficult to produce a torsion pulse in the incident bar with an amplitude high enough for the shearing stress to approach the yield stress of alloyed titanium. With this limitation, an aluminum bar has an advantage because, for the same torque, it will have a higher angular velocity than titanium.

Generating the Incident Wave

To conduct a test, a torsional wave has to be generated in the incident bar. The wave is characterized by its rise time, shape, amplitude, and duration. The most common method for generating the wave is a sudden release of a stored torque. The torsional wave can also be initiated by explosives. Descriptions of both methods follow.

Stored-Torque Torsional Kolsky Bar. A stored-torque Kolsky bar is shown schematically in Fig. 3. The loading wave in the incident bar is produced by the release of a torque that is initially stored at the section of the bar between the clamp and the loading end. The stored torque is generated by first tightening the clamp and then turning the end of the bar. It is important that the section of the bar with the stored torque will be loaded with pure torque without bending moment or axial force. This can be done by rotating a wheel, attached at the end of incident bar, with a hydraulic system of a cable and pulleys that applies a pure couple to the wheel. The design of the clamp is crucial for good results. The clamp must be able to hold the desired torque without slipping and release the torque rapidly enough to produce a sharp-fronted stress pulse traveling toward the specimen.

Fig. 3 Schematic of a stored-torque torsional Kolsky bar and its wave characteristic diagram. Torsional wave speed is denoted by c .

Clamping Techniques. The design of the quick-release clamp has a direct influence on the quality of the incident loading wave. Ideally, the incident pulse should rise instantly to a constant amplitude and then drop off immediately to zero at the end of the pulse, thus forming a square loading pulse. In practice, a finite time (rise time) is required to achieve maximum torque in the loading pulse.

A clamp designed by Duffy (Ref 18) is shown in Fig. 4. It consists of two arms that are held together at the top by a notched pin and are hinged at the bottom to a fixed peg on one side and to a sliding peg on the other. The clamp is tightened by a hydraulic ram that pushes the lower ends of the clamp arms together. After the desired torque is loaded between the loading end and the clamp, the hydraulic pressure is increased until the notched pin at the top fractures, releasing the stored torque.

Fig. 4 Clamp designed by Duffy for the torsional Kolsky bar. Source: Ref 18

A variation of this design introduced by Gilat is illustrated in Fig. 5. In this design, both arms can slide at the bottom. The clamp is tightened by a hydraulic C-clamp that pushes the lower ends of the clamp arms against each other. The hydraulic C-clamp is attached to the frame by means of a cable, a pulley, and a soft spring. In this way the C-clamp is “floating,” adjusting itself to the location of the bar. In this design, the clamp arms are shaped to match the circumference of the loading bar. Between tests, the bare surfaces of the bar and the arms that are in contact are cleaned with acetone to ensure good gripping.

Fig. 5 Clamp designed by Gilat for the torsional Kolsky bar

The amount of torque required to achieve the desired strain rate is a determining factor in selecting the notched-pin material and the depth of the notch. Pulse rise time is also affected by the choice of material for the notched pin. The pin material must exhibit minimal ductility, but must not be brittle enough to fracture before the clamp

is tight enough to hold the desired stored torque. Functional pin materials include 6061-T6 and 7075-T6 aluminum alloys. The desired clamping force and fracture point are achieved by varying the depth of the notch. Steel pins can also be used, but even brittle steels produce a longer rise time than aluminum alloys. It might be expected that the mass of the clamp would affect the rise time of the pulse, but this appears not to be the case. The rise time of the pulse can be decreased much more significantly by proper selection of pin material.

Misalignment of the various components of the Kolsky bar can result in a small unloading pulse immediately preceding the incident loading pulse, particularly if misalignment is caused by the action of the clamp. The entire clamp mechanism must be allowed to slide relative to the bar. This is achieved with the movable carriage and the floating hydraulic C-clamp in the designs shown in Fig. 4 and 5, respectively. Care should be taken to prevent bending of the incident bar when the clamp is tightened.

Explosively Loaded Torsional Kolsky Bar. An explosively loaded torsional Kolsky bar is shown schematically in Fig. 6. The torsional pulse is generated by the simultaneous detonation of two small charges at the loading end (Fig. 7). To obtain a pure torque with no bending, each charge must provide an equal impulse, and they must be detonated at the same instant. The first requirement is met by using equal weights of explosive and the second by using a single detonator connected to the explosive charge by means of "leaders" that are also made of the explosive. These leaders are of equal length, and tests have shown that the explosive charges are detonated less than 0.1 μs apart. Although the pulse that is initiated is almost entirely torsional, some low-amplitude axial and bending stress pulses are also initiated. The amplitude of these undesirable pulses can be decreased by inserting a mechanical filter in the bar. The filter, resembling a rather stiff bellows, is shown at the top of Fig. 8. It is made of an aluminum alloy, such as 6061-T6, with relatively high yield stress.

Fig. 6 Schematic of explosively loaded torsional Kolsky bar

Fig. 7 Loading end of explosively loaded torsional Kolsky bar

Fig. 8 Cross section of pulse filter showing the axial pulse attenuator (top) and the torsional pulse smoother (bottom)

The advantage of explosive loading is the short rise time in the loading pulse compared to a stored-torque system. A typical rise time is only 7 to 10 μs , compared with 20 to 40 μs with the stored-torque system, depending on pulse amplitude. The pulse produced by the explosion at the loading end, however, is neither “square” nor “smooth.” The amplitude of the pulse varies considerably with time. Because no geometric dispersion occurs for a torsional pulse in its first mode, the pulse profile remains unchanged as the pulse propagates toward the specimen. The variation in amplitude is undesirable because it results in loading the specimen at a variable strain rate. The pulse profile can be smoothed by a second mechanical filter (pulse smoother). The pulse smoother is a short length of tubing with a narrow neck made of 1100-O aluminum so that it deforms plastically during the passage of the pulse. It reduces the magnitude of the higher-frequency

components, smoothing the pulse. As shown in Fig. 8, the two filters are placed next to each other in the incident bar.

The explosive charges produce a relatively short pulse so that the total strain is generally small. With a stored-torque bar, the distance between the loading end and the clamp can be increased to produce as long a pulse as the available laboratory space will allow.

Test Specimens

Polycrystalline specimens used in the torsional Kolsky bar experiments usually are short, thin-wall tubes with integral flanges machined from bar stock (Fig. 9). The specimen is held in position by either cementing its flanges to the Kolsky bars with epoxy cement, shown in Fig. 9(a), or by mechanical means, shown in Fig. 9(b).

Fig. 9 Details of the polycrystalline specimen used in the torsional Kolsky bar experiment. (a) Tubular specimen with cylindrical flanges for cementing. (b) Tubular specimen with hexagonal flanges

Cemented connections where the faces of the flanges are glued directly to the bar ends are rigid and provide sufficient strength for specimens that have relatively low flow stress (e.g., 1100-O aluminum, OFHC copper, or zinc). Specimens made of materials with higher flow stress can still be cemented by using an adapter that increases the surface area of the glue. Cemented connections are less convenient to use because it takes a long time for the epoxy to cure and the bar ends have to be cleaned after each test. In addition, cemented connections cannot be used in tests at elevated temperatures.

Mechanical connections must be as rigid as possible to prevent loss of motion between the specimen and the bars as the stress pulses pass. Threaded connections do not meet this requirement. However, success has been achieved using hexagonal flanges on the specimen with matching sockets in the ends of the Kolsky bars. To prevent lost motion between the socket and the flanges, small set screws are used to hold the specimen flanges against the driving faces of the hexagonal sockets. For specimen materials with high flow stress, such as alloy steel, the set screws may not grip the specimen tightly enough to prevent relative rotation. To enhance rigidity, the hexagonal socket can be filled with warm glycol phthalate, the specimen inserted, and the set screws tightened.

The dimensions of the flanges and the design of any adapter or mechanical connection device must be such that the torsional mechanical impedance matches that of the bar so that the stress pulses do not undergo reflection when propagating through. This condition requires that the product ρcJ is constant along the bar. The use of short specimens in the torsional Kolsky bar implies that a nearly homogenous state of strain is obtained after a few reflections of the loading pulse from the ends of the specimen. To examine the development of the elastic-plastic boundary within the wall thickness of the tubular specimen, a finite-element analysis of the strain distribution is performed (Ref 19). In this analysis, a bilinear elastic-plastic stress-strain relation is used with an elastic modulus and a plastic-hardening rate approximately equal to those of commercially pure aluminum. Figure 10 illustrates the growth of the plastic zone (the dark areas) at various stages of deformation.

Fig. 10 Results of a finite-element analysis showing the growth of the plastic zone within the tubular specimen used in the torsional Kolsky bar. Each diagram shows a cross section through half the length of the tube wall, plus the adjacent flange. The plastic zone is represented by the dark area and the applied torque is T . Source: Ref 19

The plastic zone begins at the reentrant corner between the thin-wall tube and the flange, and from there spreads gradually throughout the thickness of the wall. Each diagram in Fig. 10 represents one quarter of the cross section of the tube and the adjacent part of the flange; thus, the central axis of the specimen lies below in each diagram. The values of the applied torque are given.

The plastic zone proceeds radially toward the inside wall surface and then across the gage length along the outside surface of the specimen. The plastic zone is contained until almost the entire specimen begins to flow. These results are based on a static analysis, but because the wavelength of the pulse is much longer than the specimen, these data can be applied to the dynamic deformation and appear to agree well with experimental results.

With continued loading into the plastic range, the strain distribution in the thin-wall tube may not remain homogeneous. For example, depending on the material, shear bands may form that completely encircle the thin-wall tube. Whenever the strain is not homogeneous, interpretation of the strain gage records is significantly altered because the strain rate and, hence, the strain that are calculated from the strain-gage records are average values based on the assumption that the deformation is homogeneous. If shear bands develop, they are not encountered until some plastic deformation has accumulated. For instance, Costin et al. observed shear bands in 1018 cold-rolled steel at plastic strain of 8 to 10% (Ref 14). The presence of shear bands in a thin-wall tubular specimen is easy to detect by scribing fine axial lines on the inside-wall surface of the specimen before loading. If the strain remains homogeneous throughout the deformation process, after testing, each of these lines appears tilted at the shear angle within the gage length of the specimen, but remains straight and axial in the flange area (Fig. 11b). Any departure from a straight line within the gage length is evidence of nonhomogeneous strain. When nonuniform strain is present, as in the case of a shear band, the lines depart drastically from straight lines (Fig. 11a).

Fig. 11 Section of specimen showing scribe line after testing. (a) Specimen with nonhomogenous strain distribution due to the formation of a shear band. (b) Specimen with homogenous strain distribution

Single-crystal specimens can be tested in the torsional Kolsky bar using a small rectangular parallelepiped. A matched set of four single-crystal specimens with the same crystallographic orientation are tested together. The specimens are arranged circumferentially at 90° intervals (Fig. 12).

Fig. 12 Aluminum single-crystal specimens showing the arrangement relative to the Kolsky bar

The specimens are secured with an epoxy cement. These cements are sufficiently strong to test pure metals, which generally have a low flow stress. With strong metals, the epoxy might break before any significant amount of strain accumulates. Each test yields the average stress-strain properties of the four specimens (Ref 20).

Measuring the Waves in the Bars

The torsional waves in the Kolsky bars are detected by electrical-resistance strain gages. At each measuring station, four strain gages, equally spaced around the circumference, are placed on the bar. Two gages on opposite sides are at $+45^\circ$ to the axis of the bar, and the other two gages, also on opposite sides but rotated 90° relative to the first two, are at -45° to the axis of the bar. The four gages are connected in a four-arm Wheatstone bridge.

Location of Measuring Stations. A wave-characteristic diagram for a stored-torque Kolsky bar that shows the positions of the wave fronts with time is shown in Fig. 3. Upon release of the clamp, the torsional pulse, with a torque of amplitude equal to half that of the stored torque, propagates down the bar toward the specimen. Simultaneously, an unloading pulse of equal magnitude propagates from the clamp toward the loading pulley. The torsional mechanical impedance of the pulley is sufficiently large so that the reflected unloading wave reduces the torque in the incident bar to zero as it propagates back along the bar. The duration of the loading pulse is the time required for the pulse to travel twice the distance along the bar between the clamp and the loading end.

The waves are measured on the incident and transmitter bars. On the transmitter bar, the wave is measured in one location. On the incident bar, the wave can be measured at either one or two locations.

When the pulse on the incident bar is measured at one location, as shown in Fig. 3, the location must be at a sufficient distance from the specimen so that a clear record of both the incident and the reflected pulses is obtained without overlap or interference. For example, if the distance between the clamp and the loading end is 760 mm (30 in.), the pulse length would be $490 \mu\text{s}$ for an aluminum bar with a shear wave speed of 3100 m/s

(10,200 ft/s). To ensure that the reflected pulse does not overlap with the incident pulse at the gage station and thus cause interference, the gage station must be placed at least 760 mm (30 in.) from the specimen. Furthermore, to ensure that the stress in the bar returns to zero after the pulse has passed, the station should be located at an even greater distance from the specimen. For example, for the bar shown in Fig. 3, the gage station is located 915 mm (36 in.) from the specimen. A gage station for monitoring the transmitted pulse is located at the same distance from the specimen (915 mm, or 36 in.). Figure 13 shows an oscilloscope record from a test with the stored-torque Kolsky bar in which the pulse on the incident bar was recorded at one location.

Fig. 13 Oscilloscope record from a test with a stored-torque Kolsky bar in which the pulse in the incident bar is recorded at one gage station. Each horizontal division equals 200 μs. Transmitted output magnified 2×. Fracture of the specimen causes transmitted pulse magnitude to drop to zero.

When the pulse in the incident bar is measured at two locations, one station is located near the clamp and the other near the specimen (Fig. 14). The angular velocity and torque at the interface between the incident bar and the specimen can be determined from the recorded pulses in the two stations. The duration of the experiment that can be analyzed depends on the location of the gage stations. A longer duration is obtained if stations *A* and *B* are placed close to the clamp and the specimen, respectively. To have a uniform wave in the gage station *A*, it should not be located too close to the clamp (a distance of 3–4 bar diameters appears to be appropriate). The length of the clamped section of the incident bar should be designed such that the reflected wave from the loading wheel reaches gage station *A* just after the reflected wave from the specimen arrives there. When processing the data it is also convenient (though not necessary) to place gage stations *B* and *C* at the same distance from the specimen. Figure 15 shows oscilloscope records from a test with the stored-torque Kolsky bar in which the pulse on the incident bar was recorded at two locations (Ref 21).

Calculating Stress, Strain, and Strain Rate. The average shear strain rate in the specimen as a function of time, $\dot{\gamma}_s(t)$, is determined from the difference in the angular velocity between its two ends by:

$$\dot{\gamma}_s(t) = \frac{r_s}{L_s} [\dot{\theta}_1(t) - \dot{\theta}_2(t)] \quad (\text{Eq 4})$$

where $\dot{\theta}_1(t)$ and $\dot{\theta}_2(t)$ are the angular velocities of the specimen ends where it attaches to the incident and transmitter bars, respectively; r_s is the mean radius of the thin-wall specimen; and L_s is the length of the specimen.

When one gage station is used to measure the waves on the incident bar $[\dot{\theta}_1(t) - \dot{\theta}_2(t)]$ is determined from the reflected pulse by:

$$[\dot{\theta}_1(t) - \dot{\theta}_2(t)] = \frac{2[-T_R(t)]}{\rho J c} \quad (\text{Eq 5})$$

where $T_R(t)$ is the amplitude of the torque of the reflected pulse. Equation 5 is derived by assuming that the specimen is under a uniform state of stress such that the torque at both ends is equal. The torque, T , at a gage station is related to the measured shear strain on the surface of the bar, γ , by:

$$T = \frac{GJ}{r_b} \gamma \quad (\text{Eq 6})$$

where r_b is the radius of the bar. Using Eq 6 to replace T_R with γ_R in Eq 5 and substituting in Eq 4 gives the strain rate in the specimen as a function of strain of the reflected pulse:

$$\dot{\gamma}_s(t) = \frac{r_s}{L_s} \frac{2c}{r_b} [-\gamma_R(t)] \quad (\text{Eq 7})$$

When two strain gage stations are used to measure the waves on the incident bar, $[\dot{\theta}_1(t) - \dot{\theta}_2(t)]$ is determined by:

$$\begin{aligned} [\dot{\theta}_1(t) - \dot{\theta}_2(t)] = & \frac{1}{\rho J c} [T_A(t - t_A) + T_A(t - t_A + 2t_B) \\ & - T_B(t + t_B) - T_C(t + t_C)] \end{aligned} \quad (\text{Eq 8})$$

where T_A , T_B , and T_C are the torques in the bars at gage stations A , B , and C , respectively; and $t_A = L_A/c$, $t_B = L_B/c$, and $t_C = L_C/c$ are the times required for the elastic waves in the bars to propagate the distance from the specimen to gage stations A , B , and C , respectively. The strain rate in the specimen at time t is obtained by using Eq 6 and substituting Eq 8 in Eq 4:

$$\begin{aligned} \dot{\gamma}_s(t) = & \frac{c}{r_b} \frac{r_s}{L_s} [\gamma_A(t - t_A) + \gamma_A(t - t_A + 2t_B) \\ & - \gamma_B(t + t_B) - \gamma_C(t + t_C)] \end{aligned} \quad (\text{Eq 9})$$

where γ_A , γ_B , and γ_C are the strains measured at gage stations A , B , and C , respectively. The shear strain in the specimen γ_s is obtained by integrating the strain rate (given by Eq 7 or 9, depending on the configuration of gage stations on the incident bar):

$$\gamma_s(t) = \int_0^t \dot{\gamma}_s(t) dt \quad (\text{Eq 10})$$

Figure 16 shows the strain rate and strain versus time calculated from the pulse records shown in Fig. 15.

Fig. 16 Strain rate in the A533B steel specimen as calculated from the pulses in Fig. 15

The shear stress in the specimen, τ_s , is determined from the torque in the specimen, T_s . For a thin-wall tube the stress is given by:

$$\tau_s = \frac{T_s}{2 \pi r_s^2 t_s} \quad (\text{Eq 11})$$

where t_s is the wall thickness. Because the stress in the specimen is assumed to be uniform, the torque at each end of the specimen is the same, and the torque of the pulse transmitted to the output bar is the torque in the specimen. In terms of the strain measured by the strain gage station on the output bar, the shear stress in the specimen at time t is given by:

$$\tau_s(t) = \frac{Gr_b^3}{4r_s^2 t_s} \gamma_C(t + t_C) \quad (\text{Eq 12})$$

Figure 17 shows the stress-strain curve that is obtained from the records in Fig. 15 and 16.

Fig. 17 Stress-strain curve for A533B steel obtained from the records in Fig. 15 and 16. Test temperature, 25 °C (77 °F); strain rate, 5000 s⁻¹

Data Recording. The signals from the Wheatstone bridges are typically recorded by a digital oscilloscope with a frequency response of at least 1 MHz. The signals can then be processed with the oscilloscope to determine the strain rate, strain, and strain in the specimen. Alternatively, the digitized signals can be transferred for processing and plotting to a computer. With the availability of fast data-acquisition boards for personal computers, recording and processing can be also done by a computer directly.

Application Areas

Limitations on Strain Rate. The practical upper limit on the strain rate that can be achieved in tests with the torsional Kolsky bar is about 10^4 s^{-1} . This can be observed by combining Eq 4 and 5 to write the strain rate as a function of the reflected torque, and substituting $T_I - T_T$ for $-T_R$, which gives:

$$\dot{\gamma}_s = \frac{r_s}{L_s} \frac{2}{\rho J c} (T_I - T_T) \quad (\text{Eq 13})$$

where T_I is the incident torque and T_T is the transmitted torque. For a solid circular cylinder, the incident torque is related to the shear stress in the incident bar (τ_b) by:

$$T_I = \frac{J}{r_b} \tau_b \quad (\text{Eq 14})$$

Using Eq 11 and 14, the strain rate in the specimen can be obtained as:

$$\dot{\gamma}_s = \frac{2}{L_s \rho c} \left[\tau_I \left(\frac{r_s}{r_b} \right) - 4 \left(\frac{r_s}{r_b} \right)^3 \left(\frac{r_s}{r_b} \right) \tau_s \right] \quad (\text{Eq 15})$$

Where τ_I is the incident shear stress. From Eq 15, it is evident that the maximum strain rate is attained when the quantity on the right side is maximized. One means is to make the specimen shorter, that is, to decrease L_s . However, with very short specimens, the end effects can become important; that is, the strain in the specimen may never be uniform.

Because the second term in Eq 15 generally is small, another method of increasing the strain rate is to increase the ratio r_s/r_b by decreasing the radius of the bar, or by increasing the mean radius of the specimen. The limiting ratio of r_s/r_b that can be used is 1 because r_s cannot be greater than r_b without a significant change in the impedance.

Yet another method of increasing the strain rate is to select a bar material with a high yield stress in order to maximize τ_I in Eq 15. This would appear to have an advantage because a much greater torque can be stored in the bar. However, two other factors affect the selection of the bar material. First, the mass density, ρ , of the bar material has to be considered. For example, the mass density of steel is about three times that of aluminum. Thus, unless the steel has a yield stress that is more than three times that of aluminum, there will be no increase in strain rate when using a steel bar. With this regard, a material with a high ratio of yield stress to density, such as a titanium alloy, will theoretically maximize the strain rate. Secondly, the ability to clamp a high torque has to be considered. As discussed earlier, it is difficult, if not impossible, to clamp a torque such that the shear stress in the bar approaches the yield stress. High clamping pressures may also produce an axial pulse upon the release of the clamp.

It is evident from Eq 15 that an increase in the diameter of the Kolsky bar will not increase strain rate significantly. Increased diameter alters only the second term in Eq 15, which is considerably smaller than the first term. From Eq 14, it is evident that, although optimum bar dimensions and material exist to achieve a maximum strain rate, there is a physical limit of strain rate of about 10^4 s^{-1} that is attainable.

The practical lower limit on strain rate in the Kolsky bar is about 10^2 s^{-1} because a lower strain rate cannot be held constant throughout the test. A constant value of strain rate requires that the magnitude of the reflected pulse be held constant, and this in turn requires that the input pulse be considerably larger than that of the transmitted pulse. Depending on the rate of work hardening of the specimen material, this imposes a lower limit on the strain rate that can be attained with the Kolsky bar.

In practice, it is easiest to design a torsional Kolsky bar to reach a strain rate of about 10^3 s^{-1} . This value is easily doubled by shortening the specimen, or can be reduced by imposing less torque. Tests outside the range of 500 to 2000 s^{-1} require special consideration.

Low- and High-Temperature Testing. Theoretically, the torsional Kolsky bar technique can be used for testing at any temperature without further modifications (other than heating or cooling) if either the whole apparatus is at the same temperature, or only the specimen is at the testing temperature and the rest of the system is at constant (room) temperature. Practically, it is very difficult, if not impossible, to conduct tests in either manner. Changing the temperature of the specimen introduces a temperature gradient in the incident and transmitter bars. Such gradients produce a variation in the shear modulus of the bars and, hence, variations in the impedance. An impedance that is not constant along the bars causes reflections of the elastic waves that make interpretation of the recorded wave data very difficult.

In tests below room temperature, or at mildly elevated temperatures of up to about 200 °C (392 °F), a possible change in the elastic constants along the bars, due to temperature gradient caused by the heating or cooling of the specimen, is small and can be neglected.

For testing at higher temperatures, various methods have been introduced. They can be divided into two categories. One approach is to allow and monitor temperature gradients in the bars and correct for their effects. Using this approach, Chiddister and Malvern corrected for this effect, in tests with a compression Kolsky bar, through a calculation of the repeated partial reflections as the pulse propagated along the bar in the heat-affected zone (Ref 22). Although this approach is acceptable, the calculations can be cumbersome. This method can be adapted to the torsional configuration. A different solution was proposed by Eleiche and Duffy, who tapered the Kolsky bars to counteract the effect of the thermal gradients (Ref 12). In this approach, the taper in the Kolsky bar, which provides a variable impedance, is determined by calculation to counteract the change in the impedance due to the temperature gradient, resulting in a constant impedance. An example of a tapered bar used for tests conducted at 250 °C (482 °F) is shown in Fig. 18. The disadvantage of this method is that it requires a temperature survey before testing so that the Kolsky bar can be machined to the right taper. Furthermore, a bar tapered for testing at one temperature cannot be used for testing at a different temperature. The advantage of this method is that the data recorded at the strain gage stations requires no further interpretation beyond the usual treatment for room-temperature tests. Results for 1020 steel, obtained at a variety of temperatures at a dynamic strain rate of 10^3 s^{-1} , are shown in Fig. 19.

Fig. 18 Tapered steel torsional Kolsky bar for test at 250 °C (482 °F). Source: Ref 12

Fig. 19 Static and dynamic shear stress-strain curves at various temperatures for 1020 hot-rolled steel

Another approach is to heat the specimen and minimize the temperature increase and the length of the affected regions of the bars. This approach was used by Gilat and Wu for tests at temperatures up to 1060 °C (1940 °F) (Ref 13). They used a rapid-heating device and a connection between the specimen and the bars that allows transmission of the torsional wave with constant impedance and minimizes heat conduction to the bars. The heat-affected zone was only 20 mm (0.79 in.) long and did not have a noticeable effect on the propagating pulses. This allows recording and processing of the data in the same manner as in room-temperature tests. In a similar method, inserts, made of a material with elastic constants that are not affected significantly by temperature of the magnitude used in the test, are placed between the specimen and the bars (Ref 23). The specimen and the adjacent ends of the inserts are heated to the testing temperature while the temperature gradient is confined to the inserts.

Quasi-Static and Incremental Strain-Rate Testing. Specimens can also be tested in torsion quasi-statically using a stored-torque Kolsky bar, as shown schematically in Fig. 20. In this case, the incident bar is clamped against rotation as in the dynamic test, but quasi-static loading is applied by a pulley system at the far end of the transmitter bar by means of a variable-drive low-speed electric motor.

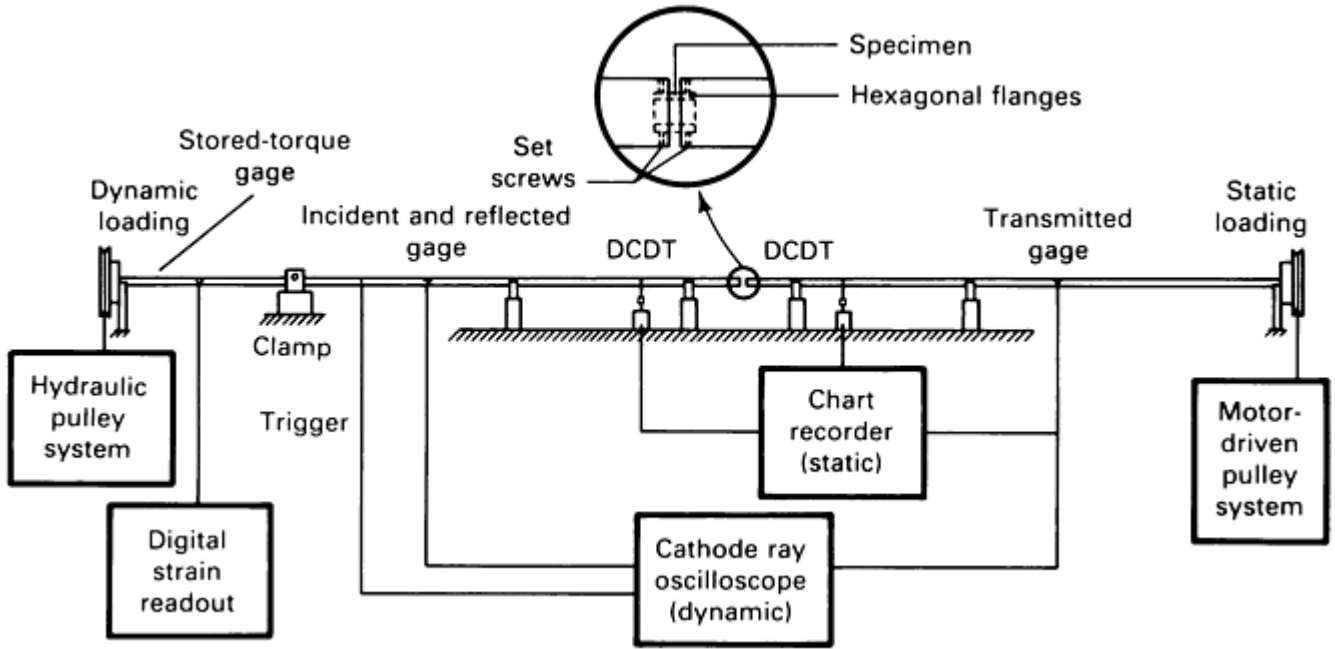

Fig. 20 Schematic of a stored-torque torsional Kolsky bar modified for quasi-static and incremental strain rate tests. DCDT, direct current differential transformer

The stress during the quasi-static loading is measured, as in the dynamic test, by a four-arm bridge on the transmitter bar. To determine the strain in the specimen, two linear direct-current differential transformers are placed equidistant from the specimen. Extremely fine wires attached to the cores of the differential transformers are wound around the bars. As the bars rotate, the cores are pulled vertically out of the transformer coils. The difference between the output signals from the direct-current differential transformers is directly proportional to the amount of twist undergone by the specimen plus the elastic twist of the portion of the Kolsky bar between the differential transformers. To obtain the shear strain in the specimen, the elastic rotation of the bar between the two differential transformers is subtracted from the total rotation. The elastic rotation is measured by cementing the bars together without a specimen and loading them quasi-statically. Results for 1020 steel obtained at a variety of temperatures at a quasi-static strain rate of $5 \times 10^{-4} \text{ s}^{-1}$ are included in Fig. 19.

In incremental strain-rate testing, the incident bar is clamped and a torque for the dynamic test is stored. Then, a quasi-static loading is applied by a pulley system at the far end of the transmitter bar. When the strain in the specimen reaches the predetermined value, the clamp is released and the specimen is dynamically loaded (Ref 8, 9).

Constant strain-rate tests and incremental strain-rate tests can be used for determining the apparent and true strain-rate sensitivity. The apparent strain-rate sensitivity, μ_a , is defined by:

$$\mu_a = \frac{\partial \tau_a}{\partial \ln \dot{\gamma}} \approx \frac{\Delta \tau}{\ln \left(\frac{\dot{\gamma}_r}{\dot{\gamma}_i} \right)} \quad (\text{Eq 16})$$

where $\Delta \tau$, as shown in Fig. 21, is the difference in flow stress between two constant strain-rate curves at $\dot{\gamma}_i$ and $\dot{\gamma}_r$. Experiments are performed at various constant strain rates, and the stress (at a given value of strain) is plotted as a function of strain rate on a logarithmic scale. The slope of this line provides the value of the derivative in Eq 16.

Fig. 21 Schematic representation of the effect of rapid changes in strain rate on flow stress for face-centered-cubic metals

The true strain-rate sensitivity, $\bar{\mu}_T$, is defined by:

$$\bar{\mu}_T = \frac{\partial \tau_a}{\partial \ln \dot{\gamma}} \approx \frac{\Delta \tau_s}{\ln \left(\frac{\dot{\gamma}_r}{\dot{\gamma}_i} \right)} \quad (\text{Eq 17})$$

where $\Delta \tau_s$ is the difference in flow stress due to an increment in strain rate from $\dot{\gamma}_i$ to $\dot{\gamma}_r$. The true strain-rate sensitivity is determined from the incremental strain-rate test. Figure 21 illustrates a typical stress-strain curve obtained in such a test. As shown, the flow stress after the strain-rate increment is different from the flow stress at the same value of strain in a specimen strained entirely at the dynamic strain rate. This leads to a difference between the apparent and true strain-rate sensitivities. For face-centered-cubic (fcc) and hexagonal-close-packed (hcp) metals, the all-dynamic flow stress is greater than the flow stress immediately after the increment in strain rate. This difference is commonly referred to as the strain-rate history effect because in both cases the strain is the same, but the history of strain rate is different (Ref 8, 9, and 24).

Frequently, with further deformation, the difference between the two values of flow stress diminishes, and eventually the two dynamic curves merge. In this case, the material is said to have a “fading memory” (Ref 25). Body-centered cubic metals, under certain conditions and particularly at very low temperatures, may exhibit a negative strain-rate history effect; that is, the flow stress after an increment in strain rate is greater than the flow stress for the material strained entirely at the dynamic rate (Ref 26). At room temperature, bcc metals generally show only a small history effect, although the influence of strain rate on flow stress usually is considerably greater than that for fcc metals.

In incremental strain rate tests, the Kolsky bar provides an important advantage: the transmitted signal furnishes a measure not of the total stress in the specimen, but of the excess stress, $\Delta \tau_s$, imposed by the stress pulse above the existing stress as a result of loading at the quasi-static strain rate (Fig. 22). Thus, rather than evaluation of a small difference between two large numbers, measurement of the stress increment, $\Delta \tau_s$, can be made directly from oscilloscope records. Results of incremental strain-rate tests on aluminum are shown in Fig. 23.

Fig. 22 Oscilloscope record of dynamic portion of incremental strain-rate test. Vertical deflection represents excess stress over τ_s , the maximum static stress. Horizontal deflection represents excess strain over γ_s .

Fig. 23 Behavior of 1100-O aluminum under static, dynamic, and incremental strain-rate loading in shear. Strain rate changes from 5×10^{-5} to 850 s^{-1} in incremental rate test. Source: Ref 8

Localization and Shear-Banding Experiments. The torsional Kolsky bar has been used for studying localization of plastic deformation and the formation of adiabatic shear bands (Ref 14, 15, and 16). As already mentioned, the existence of localized deformation is evident when a scribed line along the gage length of the specimen appears to be discontinuous after the test (Fig. 11). A detailed study of the evolution of the localization is done by taking high-speed photographs of deforming grid lines on the specimen (Ref 15, 16). Strain profiles, obtained by analyzing the deformed grid at different times along the specimen gage length, are shown in Fig. 24. Attempts have also been made to measure the increase in temperature at the shear band during the deformation process (Ref 15). This was done by measuring the infrared radiation emitted from the surface of the specimen.

Fig. 24 Shear strain profiles across the specimen width during the formation of adiabatic shear band. Source: Ref 16

Recently, a recovery experiment, in which the specimen is loaded up to a predetermined strain and then unloaded and recovered for microscopic examination, has also been introduced (Ref 17). In a standard test, the actual material testing takes place during loading by the first wave that arrives to the specimen. The transmitted and reflected waves, however, are reflected back toward the specimen from the far ends of the bars and continue to reverberate in the system. If the specimen does not break during the first loading, it is subjected to further loading as the waves reflect back and forth. Consequently, when the specimen is removed after the test, its microstructure cannot be related to the deformation that took place during the initial loading.

In a recovery experiment, the specimen is loaded only once, which means that after the test the specimen can be removed and examined. In Ref 17, reloading of the specimen by the reflected transmitted pulse is eliminated by trapping the wave. Reloading by a reflection of the incident wave is avoided by designing the test so that the amplitude of the reflected wave is reduced to a level below the elastic limit. Recovery experiments are simpler to conduct with the compression version of the Kolsky bar.

Triaxial Hopkinson Techniques

Sia Nemat-Nasser, Jon Isaacs, and Jacob Rome, University of California, San Diego

Introduction

COMPRESSIVE PROPERTIES AND FAILURE MODES of many materials, particularly brittle materials, are dramatically affected by stress triaxiality. This has been demonstrated through various laboratory experiments, since the early work of Bridgman (Ref 1), who demonstrated several failure modes peculiar to high pressures, leading to paradoxical results. The common feature of these paradoxes is that failure always occurs by the formation of *tension* cracks in specimens subjected to *pure compression*. While all these paradoxes have been fully understood (Ref 2), they do emphasize the importance of controlled triaxial experiments in materials characterization. Indeed, in axial compression, brittle materials such as rocks or ceramics fail by axial splitting, faulting, or plastic deformation (barreling), depending on the relative magnitude of the confining pressure that may accompany the axial compression (Ref 3, 4, 5, and 6). Model studies show that similar results emerge at high strain rate.

Triaxial Hopkinson techniques can be used to simultaneously subject a sample to axial and lateral compressions. The lateral compression may be applied through a pneumatic pressure vessel (Ref 7, 8, and 9) or dynamically using a special Hopkinson technique. These two techniques are reviewed in this article.

Pneumatic Pressure Vessel

Figures 1 and 2 are a photograph and a schematic, respectively, of a 75 mm (3 in.) Hopkinson system, particularly designed to test large samples of concrete, rock, polymeric composites, and other materials with relatively coarse microstructures. Except for a 6 ft brake bar to absorb the momentum and dissipate the energy, the system is similar to the classical Hopkinson bar discussed in the article “Classic Split-Hopkinson Pressure Bar Testing” in this section. The brake bar acts as a simple friction brake. Two clamps are secured around the brake bar, and the tightness is adjusted to ensure that the brake bar absorbs the energy efficiently.

Fig. 1 Photograph of a 75 mm (3 in.) diam Hopkinson bar test system

Fig. 2 Schematic of a 75 mm (3 in.) diam Hopkinson bar test system

A large diameter pressure vessel provides the pneumatic confinement (Fig. 3, 4). A steel cylinder of 150 mm (6 in.) outside diameter (OD) and 13 mm ($\frac{1}{2}$ in.) wall thickness surrounds the sample. The aluminum end plates are each 25 mm (1 in.) thick and are held together by four 9.5 mm ($\frac{3}{8}$ in.) bolts. A rubber sleeve, secured by hose clamps, is placed over the sample to prevent direct contact between the sample and the high-pressure gas. O-rings are used to seal the pressurized chamber. A band clamp and the brake bar restrain the incident and transmission bars, respectively, to prevent them from moving apart. This pressure vessel provides a constant radial confinement of up to 7 MPa (1000 psi).

Dynamic Confinement

The classical Hopkinson Bar can be modified to allow dynamic triaxial compressive loading of a sample. This technique simultaneously loads the sample in the axial and radial directions. Figures 5 and 6 are a photograph and schematic, respectively, of this system. The striker (A) impacts the first incident bar (B), generating the incident pulse. The wave is transmitted to the second incident bar (C) and the incident tube (F). (Note: With this design, the reflected pulse cannot be measured directly, so it is calculated as the difference between the transmitted pulse and the incident pulse.) The sample (D) is inside a Teflon (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) tube (G), which in turn is inside an aluminum sleeve (H).

Fig. 5 Close-up photograph of dynamic triaxial load cell on a 19 mm ($\frac{3}{4}$ in.) Hopkinson bar

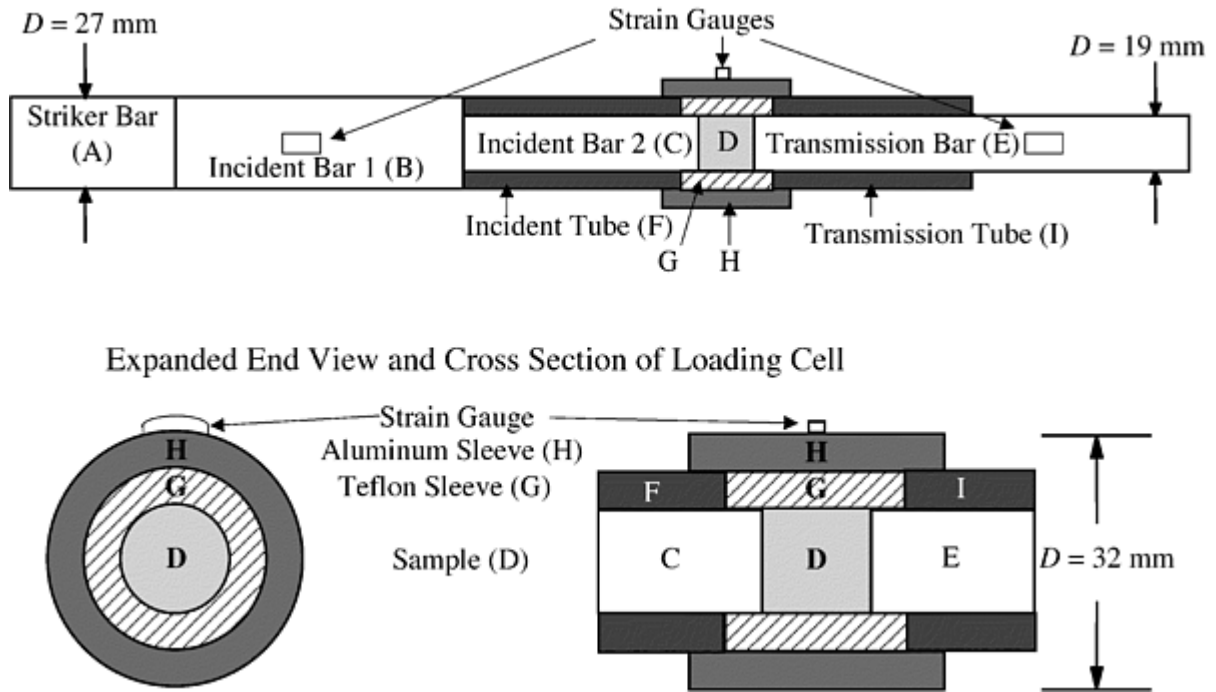

Fig. 6 Schematic of a 19 mm ($\frac{3}{4}$ in.) Hopkinson bar featuring the dynamic triaxial load cell

The confinement is provided by the Teflon, which is dynamically compressed between the incident tube (F) and the transmission tube (I). Restrained laterally by the aluminum sleeve, a large hydrostatic stress is produced in the Teflon. This pressure creates a large radial stress on the sample. The hoop strain in the aluminum sleeve is measured, and the radial confining stress is calculated. The radial stress can be controlled independently from the axial stress and strain to a limited extent by, for example, altering the thickness of the aluminum sleeve to control when the sleeve yields.

The simultaneous loading in the radial and axial directions is ensured by the design of the bar. The stress waves in the incident bar and the incident tube are generated at the same time. The bar and the tube are made of the same material and they have nearly the same length. Thus, the stress wave in the incident bar reaches the sample (loading it axially) at the same time as the stress wave in the incident tube reaches the Teflon (loading the sample radially).

This method has been used to test several samples. In Fig. 7, the response of a mortar sample tested in uniaxial compression is compared with another mortar sample tested in triaxial compression. These results demonstrate both the effect radial confinement can have on a brittle material and the simultaneous loading of the sample in the axial and radial directions.

Dynamic Indentation Testing

G. Subhash, Michigan Technological University

Introduction

STATIC INDENTATION TESTING is one of the oldest and most widely used methods for characterizing materials properties. Its immense popularity stems from the simplicity of the testing procedure and its ability to

characterize material response in a wide range of engineering applications. The technique has been used extensively for determining hardness, which has been related to mechanical properties of materials (e.g., yield stress, tensile strength, work-hardening rate, wear resistance, and fracture toughness of brittle materials), for evaluating the effectiveness of heat treatment processes and surface modification techniques, and for measuring the adhesive strength of thick films and surface coatings. A comprehensive review on static hardness testing and its applications is available in Ref 1, 2, 3 and in the section "Hardness Testing" in this Volume.

Indentation hardness is defined as the intensity of the indentation load (i.e., indentation load over the projected area of the indentation imprint). Depending upon its intended application, indentation hardness has been interpreted broadly. For a machinist, hardness is a measure of resistance to cutting, for a metallurgist, it is resistance to penetration, and for a tribologist, it is resistance to wear. All these definitions relate to a material's resistance to permanent deformation (i.e., a measure of yield stress in metals and fracture strength in brittle ceramics). Therefore, static hardness basically refers to plastic properties that are indirectly derived (or related) through this method without laborious specimen preparation. However, it is well established in high-strain-rate literature (e.g., Ref 4) that plastic properties of materials are strongly a function of strain rate for a vast majority of materials.

The use of static hardness as a measure of yield stress, for example, in a high-speed machining process or under high-velocity impact applications, may not be appropriate. This is because in a static indentation hardness test, a predetermined indentation load is applied over 5 to 15 s, causing an imprint of the indenter on a given material. The rate of deformation (or strain rate) during this test is typically of the order of $10^{-5}/s$. A machinist may use this hardness data for selecting suitable process parameters, such as speed, feed, tooling, and so on, to effectively perform a desired machining operation on a workpiece. Note that the selection of process parameters is based on a static measure, whereas in a high-speed machining operation, material removal occurs in less than several hundred microseconds, resulting in a strain rate in excess of $10^3/s$. This strain rate is at least 5 to 6 orders of magnitude greater than that achieved in a static indentation test. At such high strain rates, it is well established that the inelastic properties of materials are considerably different from their quasi-static counterparts. For example, metals exhibit an increase in yield strength (Ref 4, 5), and ceramics exhibit an increase in fracture strength (e.g., Ref 6, 7, 8, 9) and fracture toughness (Ref 10, 11).

Similar situations also may arise while characterizing impact and dynamic wear behavior of materials where the deformation rates are several orders of magnitude greater than that achieved in a typical static indentation or uniaxial tension test. In addition, high-strain-rate deformation also results in a significant rise in temperature due to the adiabatic nature of deformation and strongly influences the plastic response, which also is not captured in a static indentation test where isothermal conditions prevail during the deformation. Under such circumstances, use of dynamic hardness where the indentation load is applied in microsecond duration may lead to a more accurate assessment of material behavior and process parameter selection.

Recently, there has been an increased interest in dynamic indentation technique because of its ability to predict dynamic plastic properties of materials at high strain rates ($>10^3/s$). Such studies have considerable relevance in the analysis of structures subjected to impact, high-velocity sliding wear, crash, and so on. For example, in the field of wear of materials, Meng and Ludema (Ref 12) pointed out that 28 generic erosion models have been used to predict the wear properties of materials. Several inelastic properties such as hardness, yield strength, and fracture toughness appear in a majority of these equations. However, the exponent of the velocity term in these models has been observed to range between 2 and 5. Based on the momentum considerations, these authors argue that the velocity exponent should be around 2. One of the reasons for the observed variability is rationalized in terms of inappropriate use of static properties. Since wear is a dynamic process, they suggest the use of dynamic materials properties, such as dynamic hardness, dynamic strength, and dynamic fracture toughness, which they speculate could make a difference by a factor of 10 in estimating the wear rates. Although several established techniques, such as split Hopkinson pressure bar and plate-impact experiments, exist to evaluate the properties of materials at high strain rates, none of these techniques offer the ease and simplicity that parallel a typical hardness test. Therefore, several approaches have been adopted to evaluate indentation hardness in time scales much shorter than a few seconds. This article describes a method (based on split Hopkinson pressure bar testing) for determining the dynamic indentation response of metals and ceramics. This method of dynamic indentation testing can determine rate-dependent characteristics of metals and ceramics at moderate strain rates. For example, dynamic indentation testing reveals a significant effect of loading rates on the hardness and the induced plastic zone size in metals and the hardness and induced crack sizes of brittle materials.

Dynamic Indentation Testing

G. Subhash, Michigan Technological University

Dynamic Hardness Testing: A Review

Rebound Method. To determine dynamic hardness, several methods based on rigid body dynamics have been used previously (Ref 1, 13, 14, 15). The majority of these techniques use gravity to accelerate an indenter from a predetermined height onto a specimen and measure the rebound height to determine the hardness of a specimen. A similar principle is adopted in projectiles shot from a gas gun where both the incident and rebound velocities are measured. Based on the kinetic energy of the impacting projectile and the energy required to form the resulting crater, an expression for dynamic hardness is derived. However, unlike a static hardness test,

where the load is directly measured, these methods warrant measurement of incident velocity, V_i , of the indenter for determining the dynamic hardness, H_d , as per the following equation (Ref 15, 16):

$$H_d = \frac{MV_i^2}{2U} \quad (\text{Eq 1})$$

where M is the mass of the indenter and U is the unrelaxed volume of the indentation imprint on the specimen. This relationship assumes that the ratio of decrease in indentation volume due to the elastic recovery to unrelaxed volume is the same as the ratio of rebound velocity to incident velocity of a spherical ball. Another assumption is that the resistance to indentation is constant throughout the deformation, but this assumption has been questioned by several authors (Ref 16, 17). Moreover, it is difficult to control the loading duration in this approach because it depends on the frictional properties and coefficient of restitution (which itself varies with indenter velocity) between the specimen and the indenter. The loading duration and the strain rate during the deformation are estimated (not directly measured) based on the energy absorbed to create the crater and the rebound height of the indenter. Therefore, these rebound methods do not parallel the simplicity of the static indentation test method where the indentation load and the contact time are directly measured to determine the static indentation hardness.

Commercial devices, such as Equotip hardness testers, based on rebound techniques also have emerged in the market (Ref 18). In this method, the hardness of a material is not determined, but a numerical measure called an "Equotip hardness number," which is proportional to the ratio of rebound velocity to impact velocity, is used to represent the hardness. However, this number has not been correlated to the established hardness measures such as Rockwell, Brinell, or Vickers hardness numbers.

Pendulum Method. Nobre and others (Ref 16) used a pendulum machine to investigate the surface resistance of a ductile steel to impact by hard ceramic balls. The pendulum is equipped with a piezoelectric transducer that enables the history of impact as well as the velocity of pendulum before and after the impact to be obtained. Obviously, the impact force or indentation load can be controlled by the amplitude of displacement from the mean position where the specimen is situated. Similar to the rebound method, the duration of contact with the specimen cannot be controlled in this technique because it depends on the resistance offered by the specimen material, which is a function of the geometry and materials properties. Therefore, assumptions similar to those in the rebound technique also should be made in this method to determine the dynamic hardness, and all these factors render this technique different from the method for static hardness determination.

The basic disadvantage of these methods is that neither the indentation load nor the duration of the indentation are precisely controlled a priori. This makes the determination of dynamic hardness nontrivial compared with the static hardness testing where the hardness is determined by a simple relationship based on the measured load and the size of the indentation imprint. Therefore, a technique that parallels the method for static indentation hardness determination, where the indentation load and the size of indentation are directly measured, can be of significant practical value for comparison of the static and dynamic hardness measurements and for determination of strain-rate-sensitive properties of materials.

Dynamic Indentation Testing

G. Subhash, Michigan Technological University

Dynamic Indentation Hardness Testing

One of the basic requirements for conducting indentation testing is the ability to deliver a single indentation load. Methods based on the split Hopkinson pressure bar (SHPB) were adopted by Mok and Duffy (Ref 17), where repeated loading due to wave reflections that occur in an incident bar were avoided by using a rigid stopper. Again, the load was not directly measured but calculated based on several assumptions. Although this method offers an ad hoc, or temporary, solution to create a single dynamic indentation, none of the methods offer the elegance and simplicity of the recovery bar momentum-trapping device developed for SHPB (see Ref 19 and the article “Recovery Hopkinson Bar Testing” in this Volume). With proper instrumentation, this technique can be effectively used (Ref 20, 21, 22) to determine the dynamic indentation hardness of metals and ceramics. The method does not use any of the theoretical formulations developed in previously described methods to determine either the load or the duration of impact. The hardness is determined by directly measuring the load and the size of indentation, exactly similar to the procedure used for static-hardness determination. The velocity of the indenter during the penetration of the indenter into the specimen is also measured directly to obtain a more accurate picture of the resistance of the specimen and the velocity of the indenter during the impact. This information is later used to calculate the strain rate of deformation and to verify the hardness measurements with the yield stress values obtained from uniaxial stress-strain response at similar strain rates.

Test Setup. The test setup comprises four major parts: a gas gun to propel a short striker rod; a long, slender rod with a strain gage mounted at the center; a high-frequency load cell; and a cantilever beam with a strain gage. The long, slender rod (length-to-diameter ratio >20) is designed with an integral “flange-sleeve-rigid mass” assembly, called the momentum trap (MT), at one end and an indenter mounted in a housing at the other end. The long, slender rod is the same as the incident bar in the modified SHPB (Ref 19) described in the article “Recovery Hopkinson Bar Techniques” in this Volume. The assembly is made of heat treated high-strength maraging steel. The inner diameter of the sleeve and the rigid mass is designed to slide smoothly over the incident bar. The outer diameter of the sleeve is designed to match the impedance of the incident rod, where impedance is defined as the product of the area of cross section, density, and wave velocity. Since both the sleeve and the incident rod are made of the same material, the outer diameter of the sleeve is calculated based on the cross-sectional area of the rod. The outer diameter and the length of the rigid mass are arbitrary but typically range between 8 and 10 times the diameter of the incident bar. The flange diameter is the same as the outer diameter of the sleeve. All the contact surfaces between the flange, sleeve, and rigid mass are carefully polished to a high degree of flatness for effective transfer of wave energy during the operation. More details of the momentum-trap design can be found in Ref 19 and the article “Recovery Hopkinson Bar Techniques” in this Volume.

A high-frequency (200 kHz) load cell is mounted on a separate rigid base at the indenter end of the incident bar. The load-cell signal is passed through a charge amplifier into a digital oscilloscope. A specimen material of suitable dimensions, preferably the same diameter and length of the load cell (6 mm), is sandwiched between

the indenter and the load cell. A thin metallic strip mounted with a $350\ \Omega$ strain gage in the center is held fixed at one end with its free end resting against the indenter base in the housing. This metallic strip acts as a cantilever beam with its free end moving in unison with the indenter during the hardness testing. The configuration of the dynamic indentation testing device is shown in Fig. 1. A short striker bar is launched from a gas gun to make a planar impact on the sleeve end of the incident bar. The diameter of the striker bar is the same as that of the incident bar, and the length is typically kept the same as the sleeve length. The impacting surfaces are made flat and perpendicular to the bar axis so that a planar impact is ensured during the operation.

Fig. 1 Experimental setup for dynamic indentation hardness measurements

An alternate design (Ref 21) places the load cell between the indenter and the incident bar. This configuration is suitable when indentation hardness measurements are to be performed on large specimens. Although the hardness measurements were statistically the same in both configurations, the signal generated by the load cell in the later configuration was extremely noisy due to the stress-wave interactions at the interface between the load cell and the incident bar.

Operation. Before describing the operation of the dynamic hardness tester or the incident bar with a momentum trap, it is imperative to understand the elastic stress-wave-propagation phenomena in a slender rod *without* the momentum trap. Assume an incident bar with a strain gage mounted at the center of the rod *without* the momentum trap. A short striker bar is propelled from a gas gun to cause an impact at one end of the incident bar. Figure 2(a) illustrates the strain-gage signal obtained from an incident bar without the momentum trap. Upon impact of the striker bar onto an incident bar, a single compression pulse (C_{impact}) is generated in the incident bar whose amplitude is proportional to the velocity of the impacting striker bar, and the duration is equal to the round-trip travel time of the longitudinal wave in the striker bar. If an indenter is attached to the other end of the incident bar (illustrated on the top of the strain-gage signals), the compression wave will reach the indenter end and cause the indenter to penetrate the specimen. Since the indenter tip has a negligible area, it acts as a free end, and the compression pulse will reflect as a tensile pulse (T_{impact}) traveling back toward the impact end. Upon reaching this end, this tensile pulse reflects back again as a compression pulse and travels toward the indenter to cause another indentation. This process will repeat several times, causing multiple indentations, thus making the incident bar without the momentum trap unsuitable for indentation investigations and hardness determination where a single indentation imprint is desired.

(a)

(b)

Fig. 2 Strain-gage signals revealing the stress pulses in the incident bar (a) in the absence of the momentum trap and (b) with the momentum trap. The illustrations on top of the strain signals indicate the physical position of these pulses in the bar.

To avoid multiple indentations, a momentum-trap assembly is designed at the impact end of the incident bar, as shown in Fig. 1. Upon impact of the striker onto the flange end of the incident bar, compressive stress pulses are generated in both the incident bar and the sleeve. The pulse in the sleeve travels toward the rigid mass and reflects back as a compressive pulse at the rigid mass. Since the particle velocity in a compression wave is in the direction of wave travel, upon reaching the flange end, the materials particles within the wave push against the flange, thus loading a tensile pulse into the incident bar. Therefore, the strain gage mounted at the center of the incident bar will record a compressive pulse (C_{impact}) followed by a tensile pulse (T_{mt})—as indicated in the strain-gage signal shown in Fig. 2(b)—both traveling toward the indenter. The compression pulse causes the desired indentation upon reaching the indenter and reflects back as a tension pulse (T_{impact}) similar to the situation in the incident bar without the momentum trap described previously. The original tensile pulse (T_{mt}),

upon reaching the indenter, retracts the indenter away from the specimen and reflects back as a compression pulse (C_{mt}) into the incident bar.

Both these reflected pulses (T_{impact} and C_{mt}) now travel toward the flange end (shown in the illustrations with arrows on top of the strain-gage signals). Upon reaching the sleeve end, the T_{impact} is captured by the momentum-trap assembly and separates the contact between the flange and the sleeve. Therefore, the strain gage on the incident bar will not sense this pulse in its subsequent readings. A circle indicating the position of the trapped pulse is illustrated in Fig. 2(b). The C_{mt} will reflect back as a tensile pulse, T_{mt} (due to the free-boundary condition at the flange end), and travel toward the indenter. This pulse will travel back and forth in the incident bar as a tensile pulse while traveling toward the indenter and as a compressive pulse while traveling toward the flange, until it is eventually dissipated. In both situations, the incident bar moves farther away from the specimen, thus avoiding repeated indentations. *Thus, by designing the momentum trap suitably, it can be ensured that only a single compression pulse reaches the indenter end, thus allowing dynamic indentation tests to be performed at high strain rates.*

In this method, the incident pulse impact duration and amplitude are independent of the indenter-specimen interactions, and hence, the impact duration is maintained irrespective of the specimen properties. The reflected pulse (i.e., T_{impact}) contains information on the specimen and, therefore, can provide some estimate of the indentation load. However, any effort to obtain the load estimate from the reflected signal will warrant a prior knowledge of the specimen properties and some assumptions on the energy absorbed in the specimen, thus making this method different from that of static indentation testing, where the load is directly measured. To accomplish this objective, a high-frequency load cell is mounted rigidly on a separate base. The specimen is sandwiched between the indenter and the load cell and is held by a small compression force.

Similar to static testing, the indenter is placed in contact with the specimen before the striker is impacted onto the incident bar. By choosing a long incident bar, normal impact is ensured in the experiment without causing any rotation of the indenter. After the dynamic indentation, the load experienced by the specimen during the indentation is captured by the load cell and recorded on a digital oscilloscope. Figure 3 is a typical load-cell signature during indentation of a metallic specimen. The peak indentation load is measured from this pulse. The size of the indentation imprint on the specimen is measured after the experiment to calculate the dynamic hardness according to ASTM E 92-82 (Ref 23):

$$\text{Vickers hardness} = 1.8544 P/d^2 \quad (\text{Eq 2})$$

where d is the average indentation diagonal, and P is the peak load measured by the load cell. For comparison purposes, static hardness measurements were made using a hardness tester at suitable loads of 15 s duration. In both static and dynamic cases, a diamond Vickers indenter with a 136° apex angle is used.

Fig. 3 Typical load-cell signal during indentation on a metal

Measurement of Time of Contact. The displacement of the indenter is fully controlled by the duration and amplitude of the initial compression pulse (C_{impact}), and hence, the time of contact between the indenter and the specimen is the same as the duration of the initial compression pulse. Note that in a rebound method the time of contact is controlled by specimen and indenter properties (e.g., coefficient of restitution, frictional characteristics, and so on). In the current method, the velocity of the indenter is measured using a steel strip as a cantilever beam with its free end resting against the indenter base as shown in Fig. 1. A strain gage mounted on

the steel strip monitors the displacements of the free end as the indenter penetrates into the specimen. The voltage generated by the strain gage is converted to the deflection at the free end using simple beam theory. Figure 4 illustrates a typical profile of the movement of the tip of the cantilever beam during the indentation on a steel specimen.

Fig. 4 Profile of strain-gage signal mounted on the cantilever beam, indicating the depth of indentation as a function of time

Dynamic Indentation Testing

G. Subhash, Michigan Technological University

Test Results

A range of commercially available metals and ceramics have been tested by this method. Dynamic indentation hardness measurements on metals, when compared with the yield stress obtained at similar strain rates, verify the validity of the Tabor's relationship $H = 3 \times Y$, where H is the hardness and Y is the yield strength at 8% strain. To further validate the dynamic indentation results, the plastic zone size beneath the indentation in

metals also has been measured as a function of the rate of indentation. Indentation hardness measurements on brittle materials also have been done. The extent of cracks generated from the corners of the indentation can be correlated to the strain-rate effects in these ceramics.

Dynamic indentation hardness of metals has been tested on several commercial aluminum, copper, steel, and titanium alloys with specimens of 4 to 6 mm diameter and 8 to 10 mm length. The diameter of the specimens was limited by the size of the load cell used in the experimental setup. The loading surfaces of each specimen were metallographically prepared and polished down to 6 μm surface finish. Figure 5 presents the load versus the square of the average indentation diagonal for both static and dynamic indentations on the test materials. A regression line is plotted through each set of data. The slope of this line multiplied by 1.8544 (Eq 2) gives the hardness. Note that the slope of the dynamic Vickers hardness (DHV) data is consistently greater than the static Vickers hardness (HV) data. The straight-line nature of the data indicates that the hardness is relatively constant in the range of loads used in these experiments. The hardness measurements obtained from these plots, as well as the percent increase in dynamic hardness over the static hardness, that is, $([\text{DHV}-\text{HV}]/\text{HV}) \times 100$, are summarized in Fig. 6. For aluminum and copper alloys, which have a face-centered cubic (fcc) structure, the percentage increase in hardness at higher rates varies between 2 and 10%. For steels (most of the commercial steels have complex crystal structure), this increase is between 10 and 20%, and for titanium and its alloys (hexagonal closed-pack structures), it is well above 20%.

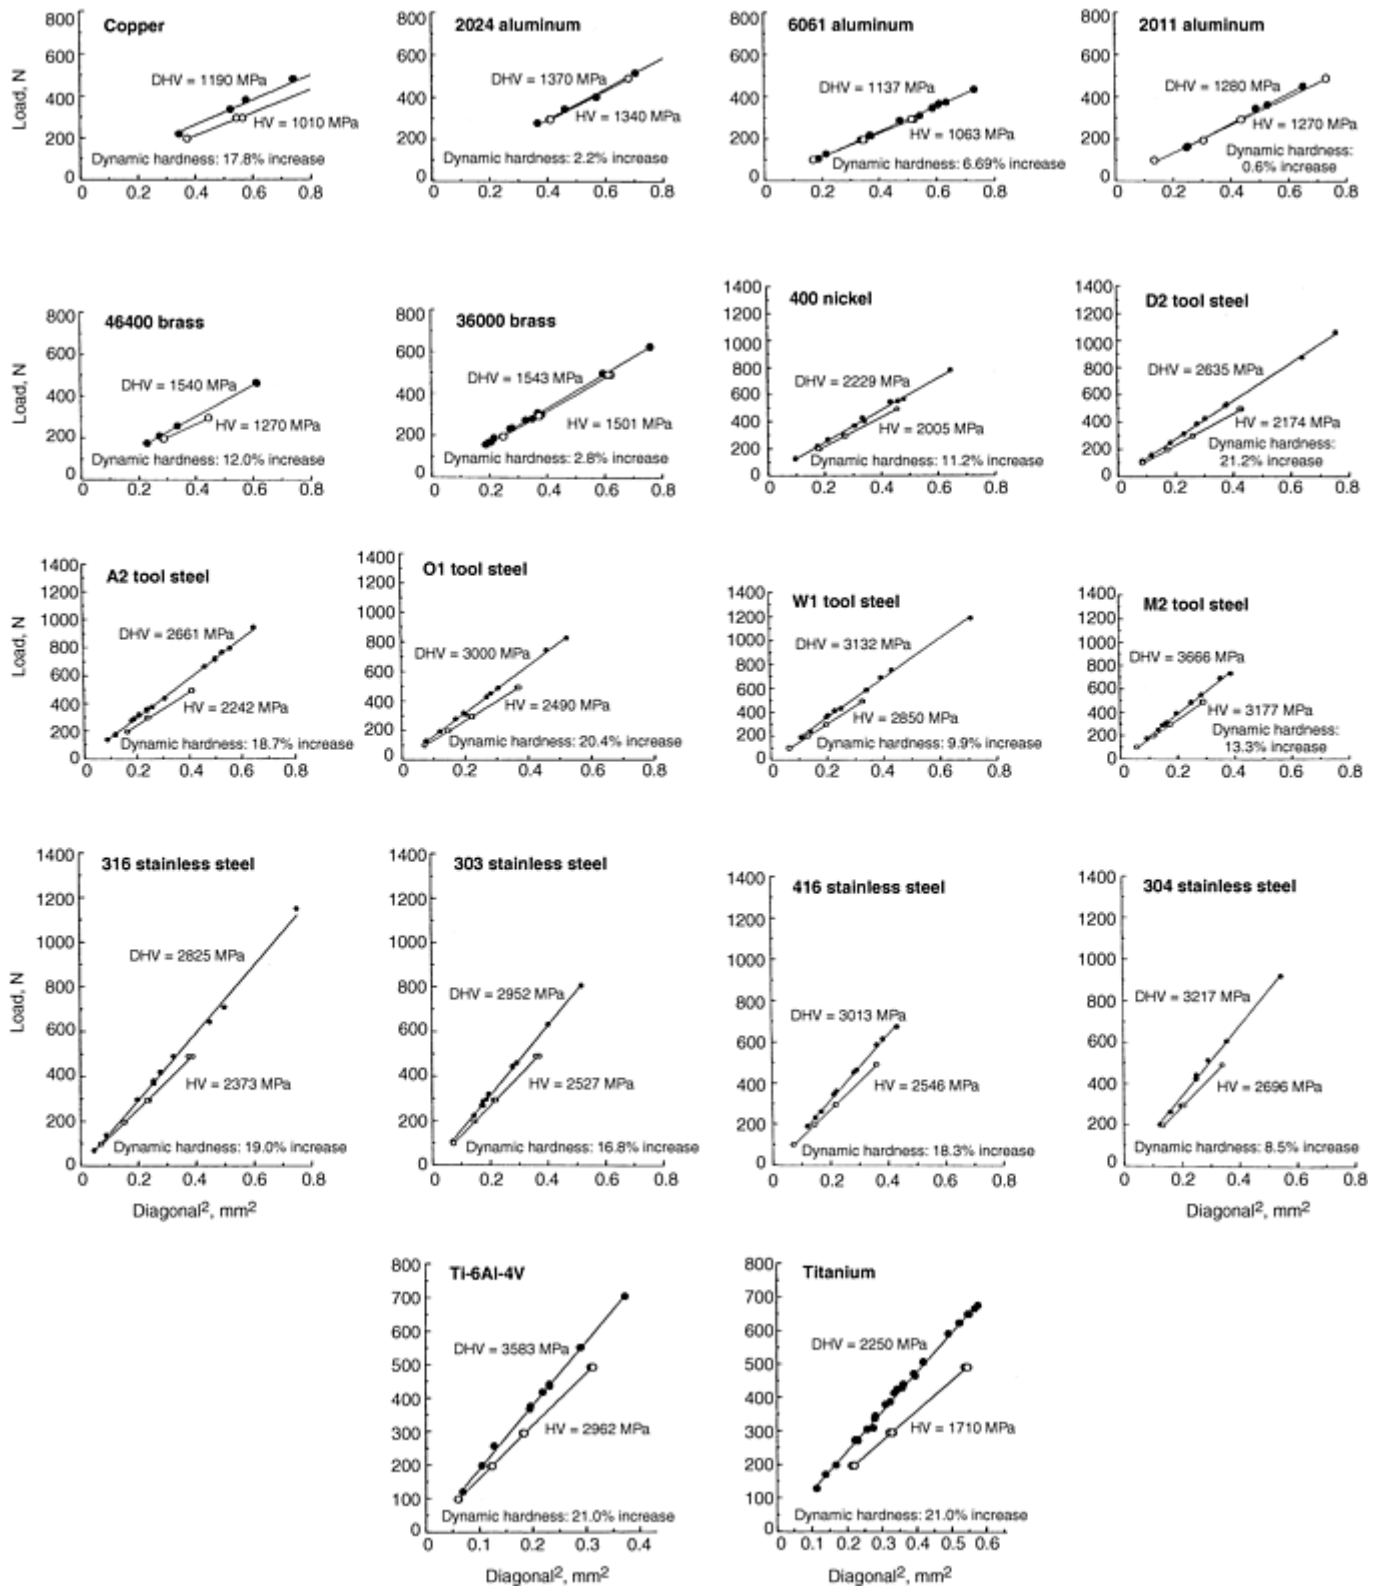

Fig. 5 Plots of load versus square of the mean indentation diagonal for selected metals and alloys

Fig. 6 Summary of static and dynamic Vickers hardness data for the metals and alloys included in Fig. 5. The numbers on the right indicate the percentage increase in dynamic hardness over the static hardness.

Velocity of the Indenter and Deformation Strain Rate. The velocity of the indenter during the penetration is calculated from the recorded strain (Fig. 4) from a gage (mounted on the cantilever beam) signal. The strain signal is converted to the displacement at the free end of the cantilever beam using basic beam-theory equations. The slope of this curve gives an estimate of the velocity of indenter during penetration. Note that the profile of this curve is considerably different from the incident compression (C_{impact}) pulse shown in Fig. 2(b), but the duration of both curves is close to 100 μs . The plot indicates that the indenter penetrates with a higher velocity close to 7.25 m/s during the early stages and then slows down to 1.5 m/s before unloading. The initial high velocity is due to the low resistance encountered by the indenter sharp-tip as it penetrates the specimen. With continued penetration, the area resisting the indenter increases due to the pyramidal shape of the indenter, and the velocity decreases. It is cautioned here that the velocity of the indenter in the current method is measured while the indenter is in contact with the specimen and should not be confused with the free velocity of the indenter in air used in the rebound method.

Hardness has been related to yield stress of metallic materials through Tabor's relationship ($H = 3 \times Y$), where H is the indentation hardness and Y is the yield stress at 8% strain (Ref 1, 2). However, this equation has been verified only for static indentations. To verify the current results on dynamic hardness and to establish the validity of Tabor's relationship in the dynamic regime, it is necessary to estimate the strain rate of deformation during the dynamic indentation process. However, in an indentation experiment, the accumulated plastic strain varies considerably within the plastic zone. The residual strain is maximum in a region closer to the tip of the indentation and decreases rapidly at distances farther away. The nonhomogeneity of plastic strain results in a

nonuniform strain rate within the plastic zone. Therefore, an average measure of strain rate will be defined from global velocity measurements as follows:

$$\text{Average strain rate} = \frac{\text{velocity of the indenter}}{\text{size of the indentation}} \quad (\text{Eq 3})$$

Any measure of the size of indentation, such as the diagonal or the depth of indentation, could be used because the order of strain rate does not vary significantly with either of the measurements. Based on the loading range employed in this investigation, the size of the diagonal of the indentation was measured to be approximately 0.6 to 0.7 mm. The velocity of the indenter was chosen as the lesser of the two velocities (1.5 m/s) in Fig. 4. This is because the deformation volume is greater during the later stages of the penetration process. Accordingly, the average strain rate was determined to be around 2200/s. This value of strain rate is in reasonable agreement with the dynamic spherical indentation experiments by Mok and Duffy (Ref 17), who used a split Hopkinson pressure bar and determined the strain rate to be around 1500/s. Finite element simulations of the dynamic indentation process also confirmed that a large portion of the plastic volume experiences a strain rate in the range of 1000 to 2000/s (Ref 24).

Validation of Tabor's Relationship in Dynamic Indentation Experiments. To verify the validity of Tabor's equation in the dynamic regime, uniaxial compressive stress-strain response was obtained at a quasi-static strain rate of around 0.001/s and a dynamic strain rate of around 2000/s for all the materials. The quasi-static experiments were performed on a servohydraulic machine, and the high-strain-rate experiments were performed using a compression split Hopkinson pressure bar. Specimen sizes of 4 to 6 mm diameter and 8 to 12 mm length were used in these experiments. The stress-strain curves at these two strain rates are given in Fig. 7 for the same materials included in Fig. 5 and 6. For rate-sensitive materials, significant increase in yield strength can be observed. From the given stress-strain curves, yield stress at 8% strain was obtained and plotted against the corresponding hardness in Fig. 8. For static data, the regression line yields a slope of 3, thus validating the Tabor relationship. Similar analysis of the dynamic data yields a slope slightly less than 3. This slight variation may be expected because the strain rate in the indentation test determined according to Eq 3 is an average measure. Moreover, the stress-strain data generated from the Hopkinson pressure bar experiment was not exactly at one constant strain rate but varied between 1800 and 2200/s for different materials. Nevertheless, the data validate the Tabor's relationship under dynamic conditions also (i.e., $DHV=3Y_d$, where Y_d is the yield stress at 8% strain).

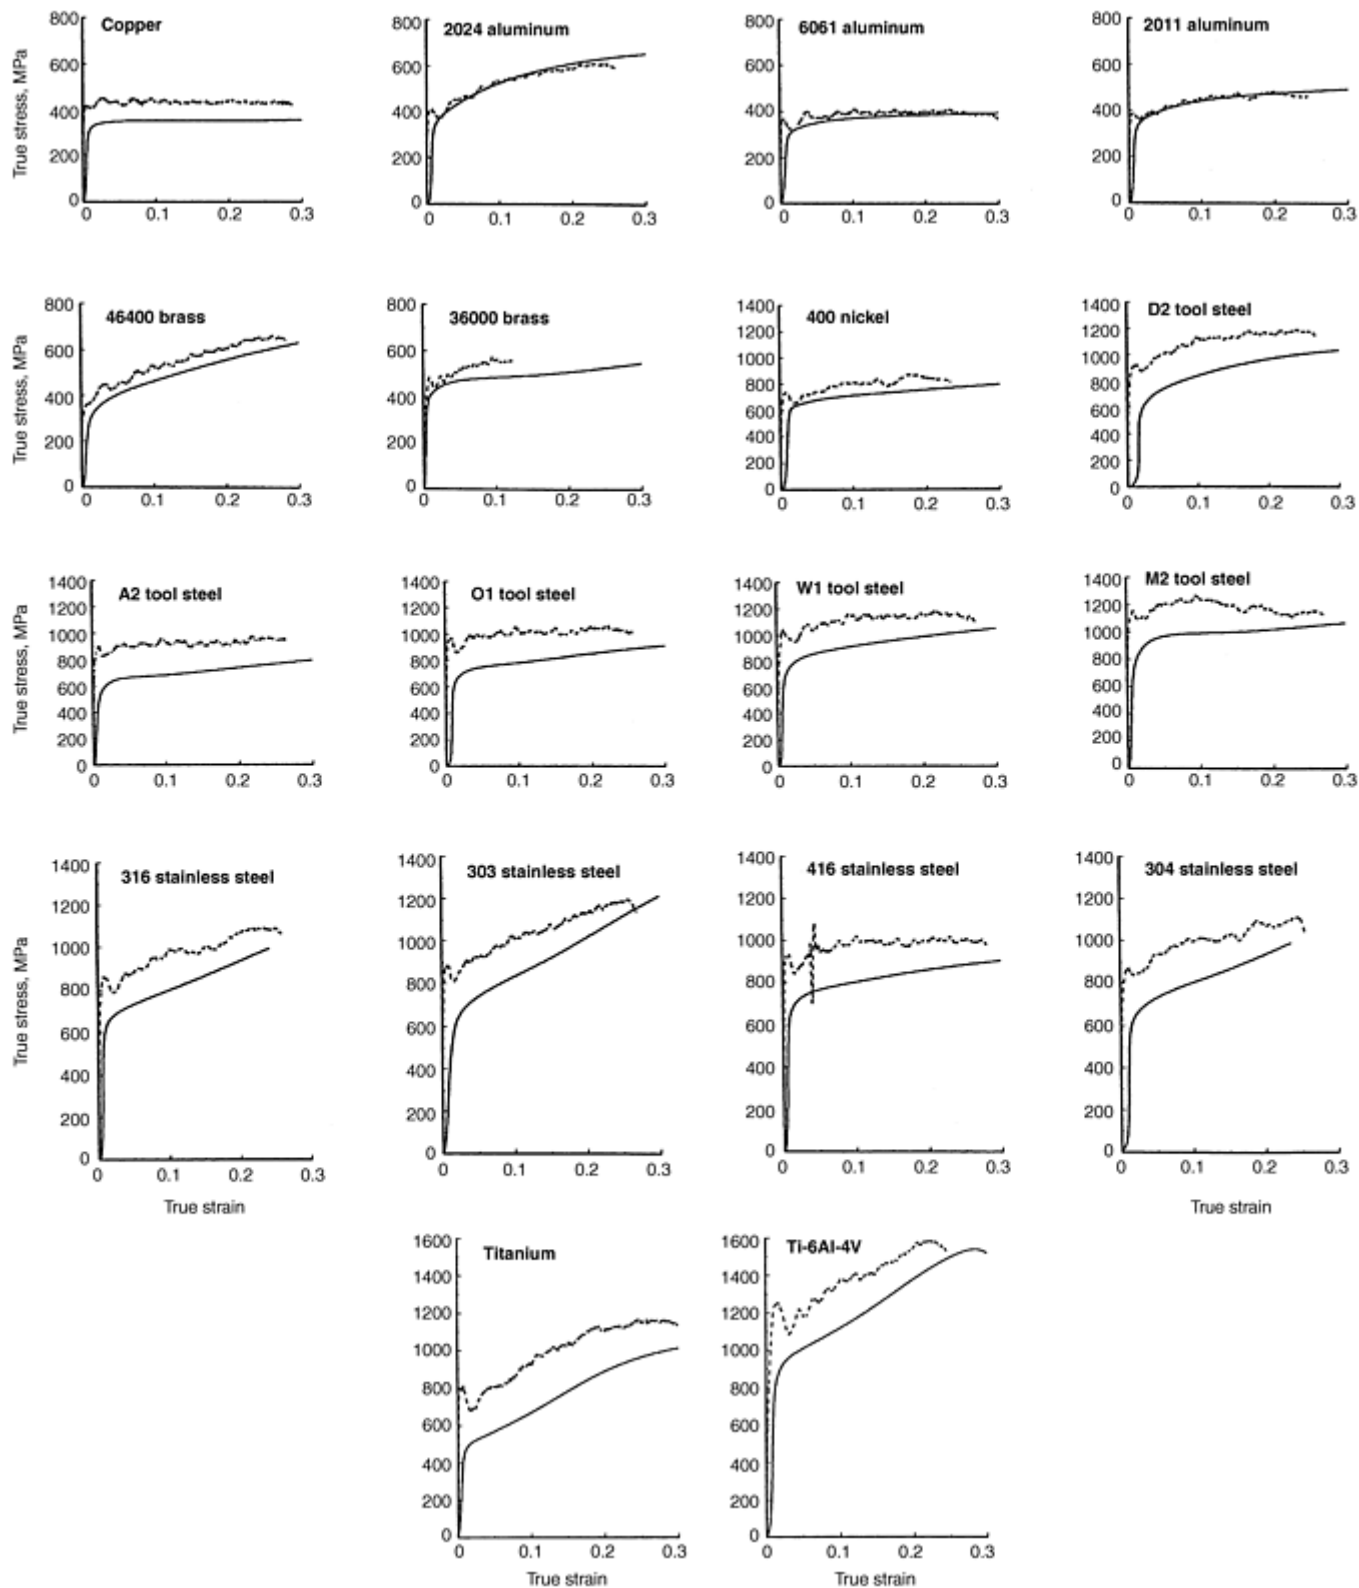

Fig. 7 Stress-strain response for metals at quasi-static and high strain rates

Fig. 8 Hardness versus yield stress at 8% strain for metals under (a) static loading and (b) dynamic loading. The numbers next to the data points refer to metals and alloys listed in Fig. 6.

Characteristics of the Indentation Plastic Zone. To estimate the differences in plastic zone size with respect to the loading rate, microhardness measurements have been performed within the indentation zones of two materials that exhibited a strain-rate-sensitive and a strain-rate-insensitive stress-strain response. Static and dynamic indentations were performed at similar load levels (approximately 490 N) on 2024 aluminum (rate insensitive) and 316 stainless steel (rate sensitive) (Fig. 7). The specimens were then sectioned just outside of the indentation zone using a low-speed diamond saw and then carefully ground and polished such that the final polished surface passed through the midsection of the indentation as shown in Fig. 9 (Ref 20). In the region surrounding the indentation, static microhardness measurements (which are basically hardness measurements at much lower load levels) were performed as per ASTM E 384-89 (Ref 25), and the data were contoured to give an indication of the accumulated plastic strains as a function of depth beneath the indentation. For the present work, loads of 100 g for aluminum and 200 g for stainless steel were used with microindentation spacing of 0.12 mm and 0.16 mm, respectively.

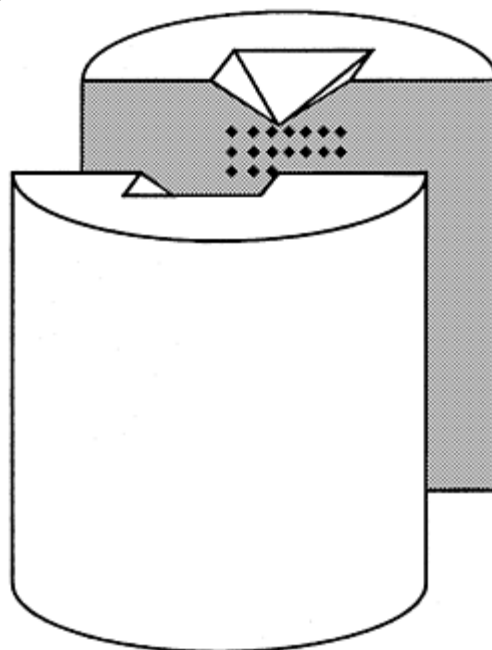

Fig. 9 Schematic of the plane illustrating the grid of microhardness measurements surrounding the macroindentation

Contours of microhardness for static and dynamic indentations on aluminum and steel are shown in Fig. 10. The exact magnitude of the accumulated plastic strains closest to the surface or the tip of indentation could not be obtained with this procedure due to the constraint imposed by the ASTM standard (Ref 25) (i.e., hardness measurements should be performed at a distance at least 2.5 times the diagonal of indentation from a free surface). The position of the free surface of the specimen is denoted by a solid line in the figure. For comparison purposes, all the contours are plotted on the same scale, with shaded regions representing the area where the microindentations were performed.

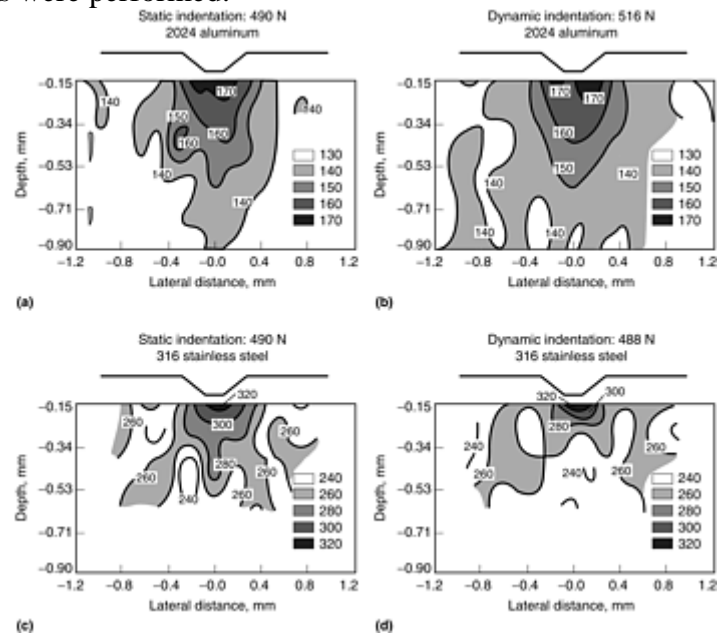

Fig. 10 Contours of microhardness measurements revealing the plastic zone size beneath static and dynamic indentations. (a) 2024 aluminum, static indentation. (b) 2024 aluminum, dynamic indentation. (c) 316 stainless steel, static indentation. (d) 316 stainless steel, dynamic indentation

Two major observations can be made from these plots. The first observation is that the size of the plastic zone for 2024 aluminum is almost the same under static and dynamic loads. The contours of microhardness are also approximately similar in terms of their depth, width, and magnitude of microhardness. This is expected since this material exhibits no rate sensitivity in both its hardness (Fig. 6) and constitutive response (Fig. 7). The minor scatter seen in the microhardness contours may be a result of the natural scatter in microhardness measurements and minor compositional and microstructural variations between the two specimens. In contrast, the contours of microhardness for 316 stainless steel reveal that the plastic zone size is considerably smaller under dynamic indentation compared with the static indentation for similar loads. This is consistent with the rate-sensitive nature of steel—that is, a higher yield stress at higher strain rates (Fig. 7).

The second observation is that the static yield stress at 8% strain for 316 stainless steel is around 750 MPa and that of aluminum is close to 500 MPa. Correspondingly, the plastic volume size in steel under static indentation is significantly smaller compared with that of aluminum. A similar result also is seen for dynamic loads where the effect is further enhanced due to an increase in yield strength in steel and relatively no change in aluminum.

To avoid single crystal effects associated with individual grains, this analysis should be used only when the grain size is considerably smaller than the size of microindentation. For large-grained materials one can take advantage of the micromechanisms of deformation (other than dislocation plasticity) to identify the extent of residual plastic zone. For example, in the case of titanium, which undergoes mechanical twinning during plastic deformation, the extent of twinned region beneath the indentation can be used to estimate the plastic zone size (Ref 20). However, caution should be used in interpreting the results based on such microstructural features because twinning is a preferred mode of plastic deformation at high strain rates in body-centered cubic (bcc) and hexagonal close-packed (hcp) materials (Ref 26). Moreover, the orientation of individual grains with respect to the local stress axis may also play a major role in inducing twins in a specific grain irrespective of its distance from the indentation within the plastic zone. It also is important to be aware of the fact that plastic strain also is accommodated by the dislocation activity and should be considered before any definite conclusions can be drawn.

Dynamic Indentation Testing

G. Subhash, Michigan Technological University

Dynamic Indentation of Brittle Materials

Static indentation investigations were used extensively to analyze the fracture characteristics of brittle materials (Ref 27, 28, 29, and 30). The approach also has been extended to model material-removal mechanisms during grinding and sliding wear of ceramics (Ref 31, 32). In order to develop a representative model of material removal during machining of brittle materials, the interaction of an abrasive grit with the workpiece has been viewed as an indentation event where the indenter is attempting to penetrate the workpiece surface in the normal direction, while being dragged in the lateral direction. Such a premise forms the basis for the “indentation fracture” models for machining of brittle materials. During static Vickers indentation studies, it was noted that penny-shaped median cracks develop during loading of the indenter, and lateral cracks parallel to the surface develop during unloading of the indenter. In a surface-grinding operation, the lateral cracks assist in chip formation and material removal, whereas median cracks leave residual damage in a workpiece. The role of these cracks is reversed in a dicing operation (i.e., median cracks assist material separation and lateral cracks induce surface damage). These model studies were typically performed using static indentations where the rate effects are not sufficiently captured as described previously. Therefore, a technique for performing dynamic Vickers indentations is of significant practical value for better characterizing the indentation fracture behavior of brittle materials at similar strain rates.

Static and dynamic Vickers indentation hardness have been compared for six commercially available brittle materials: Pyrex (Corning, Inc., Corning, NY) (borosilicate) glass, sintered alumina (Al_2O_3), hot pressed pure aluminum nitride (AlN), 3% yttria-doped AlN (Y_2O_3 -AlN), maximum-strength-grade magnesia, partially stabilized zirconia (MgO-PSZ), and yttria tetragonal zirconia polycrystal (Y_2O_3 -TZP or Y-TZP) (as described further in Ref 22). A plot of indentation load (P) versus the square of the mean indentation diagonal (d^2) is plotted for all the brittle materials in Fig. 11. A regression line was fit through the static and dynamic data

separately. Note that, similar to metals, the dynamic indentation hardness measurements on brittle materials were consistently greater than the static hardness measurements, and there seems to be no apparent dependence of hardness on the indentation load in the range of loads used in this investigation. In the case of AlN, notice that both the pure and doped AlN had essentially the same static hardness of 11.45 GPa. However, the pure AlN revealed a 19% increase in the dynamic hardness over the static hardness compared with 8% in the doped AlN. This may suggest that the addition of the yttria dopant in AlN decreased the rate sensitivity by half. The commercially sintered alumina exhibited a 12% increase in the dynamic hardness over its static hardness. The static Vickers hardness for this commercial-grade alumina is around 9.54 GPa, which is considerably lower than that for a dense and pure alumina, which typically has hardness in the range of 19 to 26 GPa (Ref 33). The lower hardness of the commercial alumina is attributed to extensive porosity and impurities present in the material. Similarly, data for zirconia ceramics revealed that there is an increase of 9.0% for MgO-PSZ and a 12% increase for Y-TZP in their dynamic hardness.

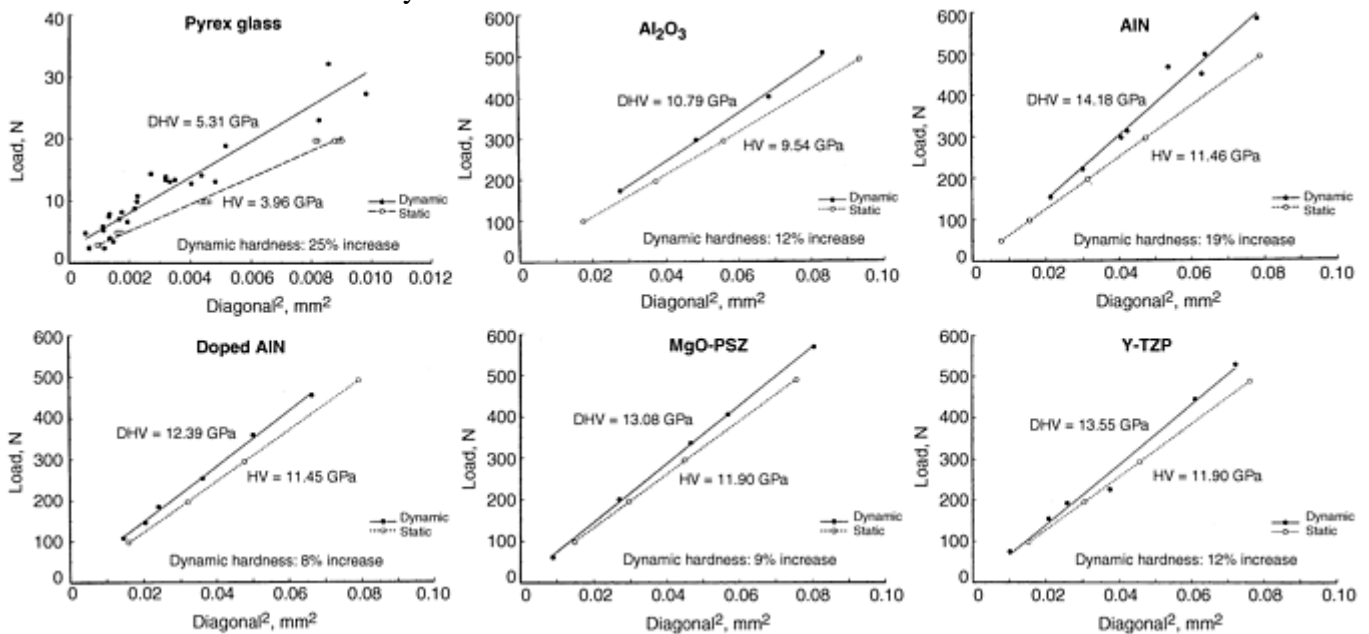

Fig. 11 Plots of load versus square of the mean indentation diagonal for brittle materials

The current results on brittle materials (i.e., increase in hardness under dynamic loading compared with that of static loading) is consistent with the previous results on glass by Fairbanks and others (Ref 34). The hardness results also are supported by the observed rate-dependent uniaxial strength of structural ceramics where an increase in fracture strength with increase in loading rate has been observed in Pyrex glass (Ref 35), alumina (Ref 36), zirconia ceramics (Ref 37, 38), and aluminum nitride ceramics (Ref 9). However, for ceramics, the Tabor relationship between hardness and fracture strength cannot be established because of absence of significant plastic strain and the resulting early onset of unstable fracture. Lankford and others (Ref 36) rationalized the reasons for the nonexistence of Tabor's relationship in ceramics and concluded that, even if plasticity initiates in ceramics at high confining stresses, the accompanying stress concentration will initiate microcracking simultaneously and cause catastrophic fracture well before a stress magnitude of $H/3$ is reached. Induced Crack Morphology. Typical crack systems induced in brittle materials due to an indentation by a rigid indenter have been summarized by Cook and Pharr (Ref 27). Of specific interest are radial and median cracks because these crack systems leave a surface trace on the specimen and can be easily measured for quantification of damage and fracture toughness calculations. Figure 12 illustrates the effect of loading rate on static and dynamic indentations in zirconia ceramics. It is clear from the micrographs that the median crack lengths are considerably larger during static indentations compared with the dynamic indentations at similar load levels.

Fig. 12 Micrographs revealing the extent of induced median cracks in MgO-PSZ under (a) static and (b) dynamic indentations

A plot of half median crack length, c , versus the half indentation diagonal, a , is presented in Fig. 13 for Pyrex glass and MgO-PSZ. The inset in this figure gives a pictorial representation of c and a . Similar plots for AlN and Al₂O₃ revealed no significant differences in the induced crack sizes between the static and dynamic indentations (Ref 22). This is because only a limited number of specimens for each ceramic were tested, and the data did not exhibit any specific trends in the extent of damage with loading rate. From Fig. 13, it can be noticed that in the case of Pyrex glass, the median crack size induced under dynamic loading is consistently greater than in the static loading. This is contrary to the observed behavior in zirconia ceramics where the median crack sizes are significantly smaller under dynamic loads compared with the static loads. This difference has been attributed to transformation toughening in these ceramics (Ref 39). Under dynamic loading, the zirconia ceramics exhibit higher yield strength and large inelastic strains close to 2% (Ref 37, 38). Such large inelastic strains can effectively absorb the imposed dynamic loads and result in the reduced cracking and enhanced fracture toughness.

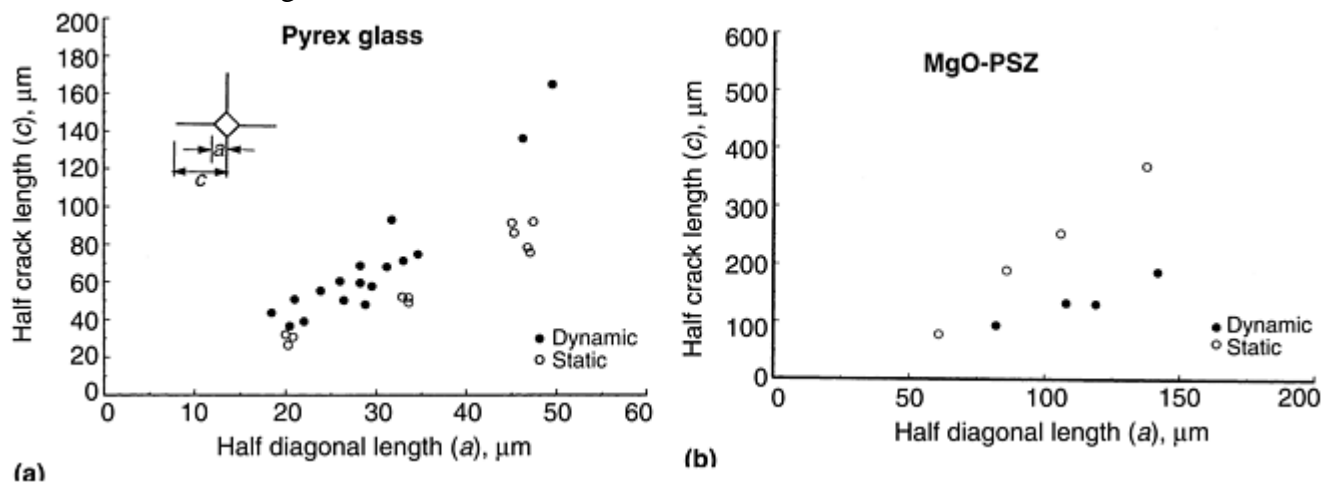

Fig. 13 Plots of half median crack length versus half indentation diagonal for (a) Pyrex glass and (b) MgO-PSZ under static and dynamic indentations

It is interesting to see that the trends in hardness are similar for Pyrex glass and structural ceramics, but the extent of induced damage in Pyrex glass is contrary to that observed in zirconia ceramics. The fracture behavior of glasses has been viewed as a representative behavior in brittle ceramics (Ref 27, 29, 30, and 32). Although the fracture patterns may be similar in glasses and ceramics under static loading, the current study reveals that the rate effects are significantly different in glasses compared with those in structural ceramics. Similar studies in glasslike materials (such as ZnS) also confirm these observations (i.e., an increase in hardness as well as induced damage—or decrease in fracture toughness—under impact loading compared with static loading) (Ref 13). This implies that the use of static models based on the observations on static fracture behavior of glasses may not be appropriate when modeling the material-removal rates of structural ceramics under high-velocity

grinding and sliding conditions. These results also support the observations of Meng and Ludema (Ref 12) on erosion model predictions discussed previously. One of the reasons for such contrasting behavior in glasses and structural ceramics under static and dynamic loads is that glasses are amorphous in structure whereas ceramics are polycrystalline materials with microstructural features such as grain boundaries, second phases, impurities, voids, and triple junction, which can promote crack deflection and contribute to radically different crack growth characteristics and fracture toughness. These inhomogeneities that form during processing have also been found to be responsible for early fracture as well as the rate-sensitive nature of failure in brittle materials (Ref 6, 40). Several empirical models for fracture-toughness estimation based on the indentation hardness and the induced crack sizes have been proposed in the literature. Recently, Ponton and Rawlings (Ref 41, 42) have summarized these equations and provided standardized indentation toughness equations for several classes of ceramics.

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Introduction

THE STUDY of the physical properties of ductile solids subjected to shock wave loading is undertaken to understand how the thermodynamic conditions and strain rate affect material response. Much of the development of the field of shock wave physics and metal plasticity has taken place since World War II and stems from the engineering importance and scientific interest in this technical area related to conventional and nuclear weapons. In contrast to quasi-static loading, the stress applied during shock loading is the result of the inertial response of the sample to a rapidly applied external load. As with quasi-static loading, the behavior of a material during shock loading is uniquely controlled by its stress-volume response or equation of state (EOS) (Ref 1, 2). The Rankine-Hugoniot or “Hugoniot” of a material is the locus of end states obtained through a shock process defining the pressure-volume relationship of a solid (Ref 3). Contrary to quasi-static loading, in the case of shock loading, conservation of mass and momentum applied to the shock transition give extra constraints allowing exact information on the stress, density, and material energy behind the shock. Numerous review papers chronicle the EOS of materials during shock loading (Ref 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12). The focus of this review is an introduction to the experimental techniques used to study the effects of shock wave loading on ductile materials (primarily metals, although the techniques apply equally to polymeric solid), and the scientific and engineering applications motivating these studies.

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Development of Shock Wave Studies

The earliest study of the relation between the propagation of elastic pulses and the formation of brittle fracture was documented in the work of John Hopkinson in 1872 (Ref 13). Hopkinson studied the strength of steel wires subjected to impulsive tensile loading. He explained the observed phenomena in terms of one-dimensional elastic wave propagation. Studies concerned with the response of ductile metals subjected to shock wave loading date to the seminal work of Bertram Hopkinson, John Hopkinson's son, in 1921. Hopkinson described how shock wave loading influenced mechanical behavior and fracture response of iron and steel samples subjected to an impulse load generated from exploding “gun cotton” placed in contact with a metal sample (Ref 14).

Hopkinson was the first to document how shock-induced fracture in a ductile metal could be initiated due to the interaction of the reflected wave from the rear surface of a sample assembly with the tail of the release wave from the impactor. Bertram Hopkinson documented in his paper “The Pressure of a Blow” (Ref 14) that when gun cotton was exploded on a 12.7 mm (0.5 in.) thick steel plate it punched out a hole of its own diameter through the plate. When the same explosive charge was detonated on a 19 mm (0.75 in.) thick plate, a scab of steel was formed. Experimenting with a still thicker plate revealed the formation of an internal crack parallel to the surface of the plate. This formation of internal damage and cracking, but not complete separation of the target plate to form a scab, is now called *incipient spall* (Ref 15). Rinehart (Ref 16) in 1952 referred to this process as *scabbing* following the terminology previously used by Hopkinson. This impulse-driven fracture

process, previously termed *Hopkinson fracture* (Ref 17, 18), or scabbing (Ref 16), is today more generically called *spallation* (Ref 15). Spallation is known to be strongly influenced not only by bulk mechanical properties but also by microstructure in materials as summarized in several reviews (Ref 15, 19, 20, 21, 22, and 23).

Work on the EOS, strength effects, and development of shock recovery techniques on ductile metals has its origins with the research of Walsh, McQueen, Marsh, and Rice (Ref 3, 5, and 6). The beginning of studies of metallurgical substructure and postmortem strengthening effects of shock wave loading on metals began with the pioneering article of Cyril Stanley Smith (Ref 24) in 1958. In this article Smith describes how the uniaxial strain, high-strain-rate loading, characteristic of shock wave loading, affects the generation and storage of defect structures in metals and alloys. His article further describes the genesis of the method of shock recovery first developed at Los Alamos National Laboratory during the Manhattan Project era. Through the use of shock recovery experiments, samples can be subjected to high-pressure shock through impact and subsequently recovered for the purpose of allowing postmortem metallurgical evaluation of the effects of the shock straining on the microstructure of a material. This technique, which introduced the use of impedance-matched radial momentum trapping rings, as well as a backing plate to prevent radial release and spallation, respectively, within the sample, when coupled with water deceleration of the sample, lead to recovery of intact shocked samples.

Studying the physical properties of materials during the very rapid loading rate and short time interval during the actual passage of a shock wave through a material is difficult. Shock recovery experiments provide insights into the processes occurring during shock wave loading through the analysis of carefully recovered samples. Characterization and quantification of “soft” recovered samples provides a mechanism to quantify the defect generation and storage mechanisms operative in materials subjected to impulse loading histories (Ref 25).

Smith (Ref 24) in his study using optical metallography first described how substructural studies of shock-recovered samples can provide valuable insight into the hydrodynamic effects of shock loading on materials. Since 1958, a number of in-depth reviews have summarized the systematic changes in structure and the commensurate property changes produced by the passage of shock waves through metals and alloys (Ref 26, 27, 28, 29, 30, 31, 32, 33, 34, and 35). In each of these reviews, the microstructure/mechanical property changes observed in shock-recovered samples have been correlated with the shock compression characteristics imposed (e.g., peak pressure, duration, rarefaction rate, and temperature) and the specific shock-induced defects produced. In addition, for a variety of metals and alloys, the defects produced during shock prestraining have been compared and contrasted with those typically observed following quasi-static deformation.

Applications of Shock Wave Tests. Interest in studying the effects of shock wave loading on materials has two components. The first gives knowledge of its pressure-volume (EOS) behavior during the actual time interval of the shock process. These studies include “real-time” shock physics diagnostic experimental methods, which quantify the response of a material during the passage of the shock wave through it as registered in the shock wave profile and other measurements, such as temperature, resistivity, and x-ray diffraction (Ref 36). The second experimental aspect of shock wave research includes analysis of samples subjected to an impact excursion to examine the postmortem signature of the shock prestraining and/or Hopkinson fracture process as described above. Postmortem studies are a type of Sherlock Holmes exercise in which scientific quantification of the structure/property manifestations in a material, due to exposure to a shock wave, is utilized to provide insight into the physical processes during shock wave loading. Experimental programs that couple both real-time and postmortem aspects offer the most promising opportunities to the understanding of shock processes in ductile materials and to the support of the development of physically based theoretical models describing shock loading (Ref 37, 38, and 39).

Types of Shock Waves. In typical shock-loading experiments, there are up to three distinct waves (Ref 40, 41, and 42):

- Elastic wave
- Plastic wave (termed the plastic I wave)
- Phase transformation wave (termed the plastic II wave)

The magnitude of the imposed shock on a material determines whether a “purely” elastic wave or an elastic plus a plastic wave traverses a sample. In the case of materials that undergo a pressure-induced change of phase, such as iron, tin, bismuth, titanium, zirconium, and hafnium, a third wave that we call the second plastic wave traverses the sample (Ref 40, 42, 43, and 44). Figure 1 is the wave profile for a sample configured to

study the spallation of tin. This profile illustrates the fundamental aspects of elastic-plastic behavior in a ductile metal, which are observed during shock loading of a ductile material. Relative scales are given in Fig. 1 to illustrate the high velocities and short times typical for shock wave profiles. The range of possible experimental techniques to quantify the structure/property effects of planar shock waves on ductile materials (specifically metals and alloys) due to the manifestations of wave propagation through a material are presented in this article.

Fig. 1 Shock wave profile for tin illustrating various shock processes. Source: Ref 45

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Techniques for Shock-Loading Materials

Samples are most frequently shock loaded under laboratory or controlled firing-point conditions using either high-exposure (HE) explosives, gun-launched impactors (also referred to as flyer or driver plates), exploding foils, or direct radiation impingement, including lasers and electron beams (Ref 3, 7, 8, 12, 25, 34, 36, 46, 47, 48, 49, and 50). Given sufficient lateral extent of the load and sufficiently thin sample thickness, a sample is shocked in a one-dimensional plane strain manner; the sample experiences uniaxial strain loading and uniaxial unloading. Each of these techniques offers advantages and disadvantages as summarized below.

Explosive-Driven Shock-Loading Methods. A controlled shock history can be imparted to a sample of interest using several different explosive-driven system designs. A review of HE-driven shock assemblies used for shock experimentation is detailed in several reviews including Dieter (Ref 46), Zukas (Ref 40), Duvall (Ref

51), Graham (Ref 36), Fowles (Ref 47), and McQueen (Ref 49). Explosive-driven shock-loading systems offer the advantage of shock loading very large sample assemblies and components. Impact velocities up to approximately $6 \text{ mm}/\mu\text{s}$ ($\frac{15}{64} \text{ in.}/\mu\text{s}$) and a large range in shock pressures up to approximately 5 Mbar in ductile metals can be readily obtained. HE-driven experiments can be relatively low cost. The disadvantages of using HE-driven shock-loading methods are that they provide less control over flyer-plate velocity than other methods and they cause tilt and bow of the driver plate.

Figure 2 shows several common HE-driven shock assembly designs. A driver plate is positioned either parallel or inclined and displaced at the necessary standoff distance from the target. An explosive is detonated by a line wave or plane wave generator that then either directly drives a driver plate or serves to uniformly ignite a main HE charge that accelerates a driver plate into a sample assembly.

Fig. 2 Explosive-driven shock-loading assemblies. (a) Inclined-plate system. (b) Parallel-plate glass system. (c) Plane wave generator lens

The inclined-plate assembly, sometimes termed a “mouse-trap plane wave initiator” (Ref 47), as seen in Fig. 2(a), has been used for low-velocity ($<15 \text{ GPa}$, or $2.2 \times 10^6 \text{ psi}$), peak shock pressure shock experiments. A line wave generator is comprised of a perforated triangle of HE sheet that is initiated at one end of the generator with a blasting cap and a small starter charge. Passage of the detonation front between the series of carefully spaced holes in the line generator results in an essentially linear wave front arrival at the base of the generator. The “mouse-trap” loading technique is used only when a rough approximation to planar impact is required due to limitations imposed by edge effects and the requirement for high precision during assembly manufacture (Ref 47).

Parallel Plate Glass Assembly. At higher pressures a parallel-plate-driven or plane wave lens-driven assembly design is used (Ref 40, 46). Parallel plate-driven shock assemblies offer the opportunity to shock load large assemblies to high peak pressures while still retaining plane wave loading. In a parallel-plate design (Fig. 2b), point detonation of a line wave generator is used to produce line detonation of a starter charge of HE sheet, such as plastic explosive with a pentaerythritol tetranitrate (PETN) base, placed on top of a thin sheet of steel or of glass. In the first case, a thin steel sheet positioned at a preset angle above the main charge is made to impact uniformly across the main charge to provide plane wave loading of the driver plate (Ref 52). In the second instance, shown in Fig. 2(b), two overlapping sheets of plastic explosive fracture a glass sheet upon which they are resting. The preset angle of the glass sheet above the main charge provides a planar shower of high-speed glass fragments resulting in simultaneous detonation over the entire main charge surface.

Plane-Wave Generator Lens Assembly. As shown in Fig. 2(c), a driver plate in a parallel-plate configuration can be driven using a plane wave generator lens placed directly above the main explosive charge (Ref 6, 7). In a plane wave lens, a pyramidal construct of HE is fabricated using an outer layer of higher-detonation explosive surrounding a lower-detonation inner explosive. Careful design of the lens geometry and explosives used will produce planar shock arrival at the base of the lens. Plane wave lenses offer the highest degree of planar shock wave drive. The disadvantage of using a plane wave generator lens is the substantially increased cost associated with the fabrication, casting, and machining of HE lenses.

Diagnostic Techniques. For real-time shock-physics experiments the assembly designs shown in Fig. 2 can be modified to allow placement of diagnostics immediately behind or adjacent to the shock assembly. The range of diagnostic techniques applied to quantifying the physical property changes occurring during the passage of a shock wave through a sample is diverse, including:

- Shorting pins to measure the impactor velocity and tilt
- Free surface velocity using capacitors (Ref 53), interferometric techniques (Ref 45, 54), or magnetic technique (Ref 53) to record the particle-velocity time history at the rear of the specimen
- High-speed or streak photography to record shock wave breakout at the rear of the specimen (Ref 55, 56)
- Electrical conductivity or piezoelectric or piezoresistance response
- X-ray diffraction to quantify sample structural changes (currently a developmental technique)

Wave profile measurements, manganin pressure gages, or interferometry (specifically velocity interferometer system for any reflector, or VISAR), can be used to quantify the broad range of phenomena illustrated in Fig. 1 for shock-loaded tin. For experimental configurations where the intent is to recover the shock-prestrained sample, the HE-driven sample assembly is placed above a deceleration medium, such as a water tank or soft wet sand (Ref 52). Deceleration and simultaneous cooling of the sample by firing the sample into water has been shown to be effective in minimizing the microstructural and substructural changes that slow cooling can allow (Ref 46, 52). The water effectively minimizes these changes by removing the residual heat induced in the sample due to the dissipative shock compression process.

Gas/Powder Launcher-Driven Shock Loading. Based on the reproducibility of projectile launch velocity and impact planarity, convenience of use in a laboratory setting, and ability to perform controlled oblique impact (such as for combined pressure-shear studies, described in Ref 57), guns or launchers have become the method of choice for many ductile material EOS, shock recovery, and spallation studies. For impacts at peak shock stresses below approximately 700 GPa (100×10^6 psi) the precise control afforded by launchers is unequaled. Gas- and propellant-driven launchers additionally offer unequaled control of impactor-target alignment and impact planarity through the use of long-axis projectiles to minimize tilt (Ref 58, 59). Angular misorientations between the projectile and target assembly of a few tenths of a milliradian are routinely achieved. Higher velocities (up to 2 km/s, or 1.2 miles/s) can be achieved using propellant-driven launchers. Projectile velocities up to 8 km/s (5.0 miles/s) are routinely achieved using a two-stage light-gas gun (Ref 60). Launchers and/or guns of various designs usually possess smooth-bore launch tubes with barrel lengths from 3 to 30 m (10–100 ft). Acceleration of the projectile is accomplished using a compressed light gas (air, nitrogen, helium), hydrogen, a propellant, or a combination of these. While hydrogen can result in substantially increased launcher performance, the environmental and safety hazards commensurate with the use of hydrogen have reduced its use except in the case of two-stage launchers. The disadvantages of fixed launchers are their high initial cost, limited sample sizes (typically <100 mm, or 4 in., in diameter), and their significant facility sizes, making them

less portable than explosive-driven systems. Figure 3 illustrates many of the key design features of a launcher, including its breech, launch tube, experimental chamber, and catch tank. As in the case of HE-driven shock experiments, a broad range of diagnostics can be positioned directly adjacent to the sample during loading to facilitate real-time measurements. Deceleration of samples for post mortem evaluation following shock prestraining or Hopkinson fracture (spallation) testing can be achieved using a water-filled catch assembly or soft rags positioned immediately behind the shock assembly in the catch tank (Ref 61, 62). Details of the parameters used to design either real-time or recovery fixtures for postmortem studies using either HE- or launcher-driven shock loading are discussed below.

Fig. 3 Schematic of 80 mm (3.1 in.) launcher at Los Alamos designed to facilitate soft recovery shock wave testing

Shock-Loading Methods Using Exploding Foil and Laser-Driven Impactors. Shock loading of samples can also be accomplished using impactors accelerated with an exploding foil (Ref 47) or a laser-driven flyer plate (Ref 63).

In the exploding-foil technique, shock loading is accomplished by discharging a high-energy capacitor bank through a metallic foil, causing it to explode (Ref 64, 65). A flyer plate positioned adjacent to the exploding foil is thereby accelerated. The impact velocity of the flyer plate is controlled by the energy of the discharge, the mass per unit area of the foil, and the standoff distance between the flyer plate and the specimen. The electrical energy transferred into the flyer can be augmented by placing a sheet of explosive between the foil and flyer plate. An intermediate layer of explosive positioned in this manner is used to generate higher-amplitude, longer-duration pulses. The principal advantage of this technique is its ability to generate very-short-duration pulses facilitating attenuation shock studies and the ability to do many experiments in a short time. Disadvantages of the exploding-foil technique include the fact that flyer-plate planarity is lower than achievable with gas and propellant launchers, and tilt is generally not measured. Additionally, small flyer-plate dimensions impose restrictions on the pulse durations and sample thicknesses that can be loaded in one dimension, and the electrical fields commensurate with the capacitance-bank loading technique yield a high electrical field.

Laser-driven impactors are also used to shock load materials. In this technique a high-power laser is directed through a quartz substrate to a metal-substrate interface (Ref 66). The metal layer, made from aluminum or copper, is physically vapor deposited to a thickness of 0.5 to 50 μm thick on the quartz substrate. The laser energy is deposited into the ablative layer, thus accelerating the metal layer (Ref 66). The high-temperature and high-pressure ablative layer serves to accelerate the remaining tamped solid metal as a miniature flyer plate. The flyer plate launched is the same diameter as the laser beam, which is typically 0.4 to 1 mm (0.016–0.04 in.) in diameter. Miniature flyer plates using this technique can be accelerated to velocities ranging from 0.5 to more than 6 mm/ μs (0.02–0.24 in.). The advantage of this loading technique is its compact size scale, ability to produce very-short-duration shock pulses, and potential as a means to interrogate interfaces in bicrystals (Ref 67). The disadvantages of this technique include the fact that the very thin flyer plate limits the shock pulse duration to short times (e.g., <100 ns), and the short pulse duration and the rapid attenuation of the short pulse lengths produced by the thin flyer plates will not support steady shocks in thicker samples (>0.5 mm, or 0.02 in., thick), thereby limiting the usefulness of this technique to studying bulk phenomena, such as spallation, in polycrystals.

Radiation-Driven Shock-Loading Methods. Shock loading of materials can also be achieved through direct application of a penetrating radiation impulse to a ductile material (Ref 47). This can be achieved using electron beam impulse loading (Ref 68), direct laser impingement (Ref 69), or exposure to an underground near-nuclear weapon (Ref 12).

Pulsed electron beam machines can produce electron energies of more than 5 MeV, fluences of several hundred calories per square centimeter, and pulse durations of a few tens of nanoseconds (Ref 68). Electron beams can be used to produce beams of essentially uniform power over areas of a few square centimeters. The stress pulse in the sample is generated by the extremely rapid heating of the sample at depths in the material, which cannot be relaxed by a rarefaction wave during the deposition time of the pulse.

Direct laser impingement on the surface of a sample can similarly be used to induce a shock wave in a material (Ref 69, 70, 71, 72, and 73). In this type of shock-loading experiment a high-power laser is focused on a thin sample. Testing is conducted in a vacuum to avoid air ionization. The irradiated metallic surface is vaporized producing a plasma, which induces a compressive shock wave in the target. The duration of the pressure pulse in the target is of the same order of magnitude as that of the laser pulse, typically 0.5 to approximately 30 ns. The amplitude of the stress pulses induced by laser heating can induce strong shocks up to 200 GPa (29×10^6 psi) depending on the irradiation intensity. Uniaxial strain can be achieved in a central portion of thin samples as long as the diameter of the irradiated spot is larger than the sample thickness. The advantages and disadvantages of this technique are analogous to the miniature flyer discussed above. The principal disadvantage to direct laser irradiation for shock wave studies is the attainment of a steady shock wave through a polycrystalline material. The short pulse duration and the attenuation of these pulses restricts testing to samples typically less than 1 mm (0.04 in.) thick.

Exposure to Nuclear Explosion. The final direct radiation-driven shock wave technique results from the placement of samples in the near zone of an underground nuclear explosion. Such experiments proved capable of supporting studies of the compressibility of metals such as iron, lead, copper, and uranium in the pressure range up to 20 TPa (29×10^{12} psi) (Ref 12, 74, 75, and 76). Experimental tests of this type have yielded extremely high-pressure compressibility and EOS information on a range of ductile metals, as summarized in the references, but has not produced absolute EOS information.

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Design of Shock Recovery and Spallation Fixtures

The structure/property relationships in materials subjected to shock wave deformation are very difficult to conduct and complex to interpret due to the dynamic nature of the shock process and the very short time of the test. Due to these imposed constraints, the majority of real-time shock process measurements are limited to studying the interactions of the transmitted wave arrival at the free surface or at target-window interfaces. To augment these in situ wave profile measurements, shock recovery techniques were developed in the late 1950s to experimentally assess the residual effects of shock wave compression, release, and shock-induced fracture events on materials. The object of soft recovery experiments is to examine the terminal structure-property relationships of a material that has been subjected to a known uniaxial shock history then returned to ambient conditions without experiencing radial release tensile wave loading or collateral recovery strains. Tensile wave interactions may be mostly mitigated by surrounding the sample with tightly fitting material of the same (or nearly the same) shock impedance, both laterally and axially around the sample. This technique, termed *momentum trapping*, has continued to evolve to prevent large radial release waves from entering the sample and to prevent Hopkinson fracture (spallation) for a variety of sample configurations and shock-loading methods. When ideally trapped, the residual strain, ϵ_{res} , in the recovered sample (defined here as the final sample thickness divided by the initial sample thickness) should be on the order of only a few percent. Since the inception of shock recovery studies, the use of momentum trapping techniques has been successfully applied to a large number of metallic systems and a more limited number of brittle solids.

Several review papers chronicle the development and design of shock recovery techniques (Ref 25, 26, 34, 40, 48, 77, and 78). To correctly assess the influence of shock wave deformation on ductile material structure and properties, it is crucial to systematically control the experimental loading parameters and design the shock fixtures to recover the test sample with minimum residual strain. With higher peak pressures (from 10 GPa, or 1.5×10^6 psi, upward) however, recovery of shock-loaded samples becomes increasingly difficult. For low-pressure shocks, for example, a few times the Hugoniot elastic limit of the material, shock recovery is straightforward independent of whether the shock is generated via HE, launcher impact, or radiation impingement. At pressures in excess of 50 to 60 GPa (7.3×10^6 to 8.7×10^6 psi) recovery of bulk metallic samples that have not been seriously compromised by significant shock heating and/or radial release strains is nearly impossible. At shock pressures greater than 100 GPa (14.5×10^6 psi) recovery of samples is essentially impossible. The techniques described below have been used for both HE- and launcher-driven shock recovery experiments.

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Design Parameters for Flyer-Plate Experiments

The variation of the shock parameters (peak pressure and pulse duration) for recovery experiments can be calculated using several simple formulations. Equations have been developed by Orava and Wittman (Ref 77) for the design of recovery assemblies to achieve a given peak pressure and pulse duration and to protect the sample from significant radial release and possible subsequent spallation. Design of the target-flyer variables to achieve a given set of shock parameters in a shock recovery experiment is typically started by fixing the desired peak shock pressure or true transient strain. This is linked to the fact that changes in peak shock pressure are known to produce the most significant variation in post shock material structure-property relations (Ref 24, 25, 26, 28, 29, 30, 40, 42, 44, and 46). When the flyer plate and target assembly are the same material, called symmetric impact, the material velocity behind the shock is exactly one half of the projectile velocity (Ref 77, 79):

$$V_p = \frac{U_P^D}{2} + \frac{U_P^T}{2} = U_p \quad (\text{Eq 1})$$

where V_p is the projectile velocity and U_p is the particle velocity partitioned between the driver plate, $\frac{U_P^D}{2}$, and the target, $\frac{U_P^T}{2}$. Symmetric impact is generally preferred because it is most easily analyzed. In the case of dissimilar materials, the particle velocity is divided according to the Hugoniot equations of each by the impedance matching method (Ref 6). In this situation, complex release behavior is typical. Hugoniot data for a wide range of materials can be found tabulated in Ref 79. The total equivalent or effective transient strain induced in the sample due to this impact (encompassed as a sum of both the elastic and plastic compression and elastic and plastic release portions of the shock process), ϵ_t , is determined from the measured Hugoniot data, which is the dynamic compressibility of the material as a function of pressure where V_0 and V are the initial and final volumes of the material during the peak of the shock. Assuming that the residual strain remaining in the sample after the shock release is zero (Ref 80), the transient or equivalent total strain imparted to the sample due to the shock-loading impulse and release is given by:

$$\epsilon_t = \frac{4}{3} \ln \left(\frac{V}{V_0} \right) \quad (\text{Eq 2})$$

In Fig. 4, a time-distance diagram of a symmetric impact by a driver plate with the target backed by a spall plate is presented that ignores strength in the sample. The symmetry of impact is reflected in the similar slope

of the shock velocity, labeled U_s , into the driver and target starting at time zero. The length of time the sample remains at pressure is determined by combining the shock wave and release wave transit times through the flyer. When the rarefaction wave reaches the flyer-target interface the pressure in the sample is released. The release process is stretched in time in the form of a “rarefaction fan” due to the variation in longitudinal and bulk wave speeds as a function of pressure. The pulse duration time, t_p , at the front of the sample is approximated by (Ref 77):

$$t_p = d^D \left(\frac{1}{U_s^D} + \frac{\rho_0^D}{\rho_s^D C^D} \right) \quad (\text{Eq 3})$$

where d^D is the driver plate thickness, U_s^D is the shock velocity in the driver in shock, ρ_0^D and ρ_s^D are density of driver at ambient pressure and under shock, respectively, and C^D is the bulk sound speed in the compressed (shocked-state) driver.

Fig. 4 Time-distance diagram of a symmetric shock wave impact

To assure the recovery specimen experiences uniaxial strain, that is, one-dimensional strain, in nature during both loading and unloading it is necessary to protect the sample from radial release prior to uniaxial release. Figure 4 schematically represents the time distance for a symmetric impact and the commensurate particle-velocity time history, which would be visible to an interferometer, such as a VISAR, looking at the rear surface of the sample assembly. If the driver plate and target assembly have the same dimension, then immediately after the target assembly is impacted by the driver, radial release waves will be directed toward the interior of the target assembly from the driver edges. In order to mitigate these lateral release waves, the sample within the target assembly is surrounded by momentum traps comprised of rings or rails of material similar to the sample. The width of the momentum trapping necessary must be sufficient to contain the total shock event in the flyer and target of time, t_s (Ref 77).

Given simple centered flow conditions where the driver, target, and momentum trapping materials are the same, the minimum trapping width w is given by (Ref 77):

$$w \geq \frac{C}{C_0} \left[\left(\frac{U_s + C_0}{U_s} \right) d^D + d^T \right] \quad (\text{Eq 4})$$

After the shock has traversed the sample, if it is not obstructed, it will reflect off the back surface of the specimen as a release wave. This further complicates the loading history of the sample, indeed, if the rear surface release wave is allowed to interact with the forward-moving release wave propagating in from the driver that releases the sample to ambient pressure. In this case the two tensile release fans will meet and cause spall fracture when the amplitude is above the dynamic tensile strength of the material. To prevent this from occurring in the sample intended for postshock characterization, a spall plate is placed behind the sample to isolate the release wave interactions in the spall plate, thereby protecting the sample spallation (Fig. 4). The release time, t_R , must be greater than or equal to the shock time. To protect the sample from spall interactions, the spall plate thickness must equal or exceed the dimension (Ref 77):

$$h \geq \frac{C}{C_0} \left[\left(\frac{U_s + C_0}{U_s + C} \right) d^D + \left(\frac{U_s - C_0}{U_s + C} \right) d^T \right] \quad (\text{Eq 5})$$

As an example, a 10 GPa (1.5×10^6 psi), 1 μ s pulse shock in a 5 mm (0.2 in.) thick high-purity copper sample (symmetric impact, $C_0 = 3.94$ mm/ μ s, $C = 4.425$ mm/ μ s, $U_s = 4.326$ mm/ μ s, and $V/V_0 = 0.94$) requires an impactor traveling at 0.518 mm/ μ s ($U_p = 0.259$ mm/ μ s) using a 2.25 mm (0.09 in.) thick copper impactor or driver plate. The minimum momentum trapping and spall plate requirements are then calculated to be 10.45 mm (0.41 in.) and 10.56 mm (0.42 in.), respectively. While Eq 4 and 5 pertaining to the momentum trapping and spallation requirements can be corrected for nonsymmetrical impact, this is not usually done. Internal impedance mismatching within the assembly will cause additional wave reflections that compromise the simple compression loading history of the sample. In instances where symmetric assembly design is impossible, as is typically the case for most brittle solids, other techniques are necessary.

Figure 5 illustrates an example of a soft shock recovery fixture positioned on a shock support or impact assembly for conducting shock recovery experiments on a gas- and/or propellant-driven launcher. Following release of the shock through the sample, the two opposing release waves are designed to interact within the spall plate, thereby isolating the sample from the high tensile stresses resulting from the overlap of the two release fans. The central opening in the impact is thereafter utilized to facilitate the escape of the sample assembly into the recovery catch tank area for deceleration. This central passageway additionally serves as a mechanism to separate the sample assembly from the continued forward momentum on the projectile. Inadequate assembly design to ensure a one-dimensional shock loading and release sequence has been shown to alter the sample shock history and subsequent structure-property response due to the additional plastic work imposed on the sample due to late-time radial release effects (Ref 80, 81). Careful attention to momentum trapping of samples during shock recovery experimentation is therefore required if the structure-property effects quantified in postmortem recovered samples are to be correlated to processes occurring during shock loading.

Fig. 5 Schematic of a soft shock recovery fixture used on a gas/powder launcher assembly

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Shock Recovery and Spallation Studies of Ductile Materials

As described previously, shock wave research includes analysis of samples subjected to an impact excursion to examine the postmortem signature of the shock prestraining on the substructure and mechanical behavior of a material in addition to damage evolution of a ductile material when subjected to a spallation uniaxial strain loading history. A few examples of the types of experimental data and post mortem characterization results typically quantified for both shock recovery and spallation research are introduced below.

Defect Generation during Shock Loading as Quantified Using Shock Recovery Experiments. In an ideal isotropic homogeneous material, the passage of an elastic shock through a bulk material should leave behind no lattice defects or imperfections. In practice, the severe loading path conditions imposed during a shock induce a high density of defects in most materials (i.e., dislocations, point defects, and/or deformation twins). In addition, during the shock process some materials may undergo a pressure-induced phase transition that affects

the material response. If the high-pressure phase persists upon release of pressure to ambient conditions (although metastable) the postmortem substructure and mechanical response will also reflect the high-pressure excursion. Interpretation of the results of shock wave effects on materials must therefore address all of the details of the shock-induced deformation substructure in light of the operative metallurgical strengthening mechanisms in the material under investigation and the experimental conditions under which the material was deformed and recovered.

Microstructural examinations of shock-recovered samples have characterized the differing types of lattice defects (dislocations, point defects, stacking faults, deformation twins, and, in some instances, high-pressure phase products) generated during shock loading. The specific type of defect or defects activated and their density and morphology within the shock-recovered material have, in turn, been correlated to the details of the starting material chemistry, microstructure, and initial mechanical behavior or hardness, and the postmortem mechanical behavior of the shock-prestrained material. Several in-depth reviews have summarized the microstructural and mechanical response of shock-recovered metals and alloys (Ref 24, 25, 26, 28, 29, 30, 40, 42, 44, and 46). In general, the deformation substructures resulting from modest shock loading (up to 40 GPa, or 6×10^6 psi) in metals are observed to be very uniformly distributed on a grain-to-grain scale.

The specific type of substructure developed in the shock in a given metal (e.g., dislocation cells, twins, or faults) has been shown to critically depend on a number of factors. These include the crystal structure of the metal or alloy, the relevant strengthening and deformation mechanisms in the material (such as alloying, grain size, second phases, and interstitial content), temperature, stacking fault energy, and the shock-loading parameters and experimental conditions. The overall substructure, while macroscopically uniform, can vary within single grains. The substructure can consist of homogeneously distributed dislocation tangles or cells, coarse planar slip, stacking faults, or twins (i.e., be locally heterogeneous). The type of substructure formed depends on the deformation mechanisms operative in the specific material under the specific shock conditions. These shock-induced microstructural changes in metallic systems in turn correlate with variations in the postmortem mechanical properties. For example, the formation of deformation twins is facilitated in many materials due to the very high strain rate during shock loading (Ref 61).

Shock loading in most metals and alloys has been shown to manifest greater hardening than quasi-static deformation for the same total strain, particularly if the metal undergoes a polymorphic phase transition, such as is observed in pure iron (Ref 42). Figure 6 compares the stress-strain response of annealed copper and annealed tantalum samples that have been quasi-statically loaded with the quasi-static reloading responses of the samples that have been shock prestrained. The shock-loaded stress-strain curves are plotted offset at the approximate total transient shock strains, calculated as $\frac{1}{3} \ln(V/V_0)$ for the shock (where V and V_0 are the compressed volumes during the shock and the initial volumes, respectively). The offset curve for copper shows that the reload behavior of the shock-prestrained sample (compared at an equivalent strain level) exhibits a reload flow stress considerably higher than the unshocked copper. Other face-centered cubic metals and alloys (e.g., copper, nickel, and aluminum) have been seen to exhibit similar behavior (Ref 24, 25, 26, 28, 29, 30, 40, 42, 44, and 46). On the contrary, the reload stress-strain response of tantalum shock prestrained to 7 and 20 GPa (1 and 3×10^6 psi) is observed to display essentially no enhanced shock hardening in comparison to quasi-static loading to an equivalent plastic strain.

Fig. 6 Stress-strain response of tantalum and copper illustrating the varied effect of shock prestraining on postshock mechanical behavior

Spallation “Hopkinson Fracture” Studies of Ductile Materials. Spallation is the failure in a material due to the action of tensile stresses developed in the interior of a sample or component through the overlap of two release waves. Since the early work of Hopkinson (Ref 14), numerous researchers have studied this phenomena (Ref 15, 16, 20, 22, and 82). Early work by Rinehart (Ref 16), through systematic studies on a range of engineering metals and alloys, demonstrated that a critical shock stress is needed to produce scabbing in a material. The characteristic nature of this material quantity, as well as its importance to understanding interactions between shock and the structure, continues to make spallation research of primary scientific and engineering interest. A systematic representation of the idealized process of release wave overlap driving a material into a dynamic tension, uniaxial strain, loading state is shown in Fig. 4. The elastic wave in this figure is assumed to be negligible compared to the plastic I wave; no additional waves, such as a phase transition plastic II wave, are present.

Measurements of the spall strength are based on analysis of the one-dimensional motion of compressible, contiguous, condensed matter following the reflection of the shock pulse from the surface of the sample or component. Figure 4 shows the shock trajectory that a sample undergoes during the path in a spallation experiment. The shock that is imparted into the target through the jump in particle velocity upon impact with the driver plate (or impactor) is thereafter unloaded through the release wave originating (in one dimension) from the rear surface of the driver plate that diminishes the free surface velocity. If the impactor is sufficiently thin, the rarefaction will overtake the shock because the release wave is traveling into the precompressed solid and, therefore, its wave speed is higher than the shock velocity. In this case, the rarefaction will attenuate the shock. This unloading wave is actually a fan of characteristics, which erodes the shock down toward ambient pressure. This reduces the particle velocity from the peak Hugoniot State achieved by the imposed shock. For thicker impactors, as in Fig. 4, the release fan arrives at the rear surface of the target well after the arrival of the main shock. At the free rear surface of the target, the shock wave is reflected as an unloading wave that travels

back toward the interior of the target. Overlap of the release fans causes the material in the overlap region to be loaded in tension. The maximum tensile stress is reached in the central area of the overlap of the two release fans, termed the spall plane.

If the maximum tensile stress achieved exceeds the local fracture strength, damage is initiated in the target. Fracture of the material at the spall plane causes the tensile stress to decrease rapidly to zero. As a result, a compression wave forms in the matter adjacent to the spall plane region. These waves propagate in each direction away from the spall plane. At the rear surface of the target, as in Fig. 4 where the particle velocity is monitored, this compression wave is manifested as a jump in velocity. When the target spalls, a stress wave is trapped between the spall plane and the rear of the target. Later reverberations of this stress wave lead to a damped oscillation in the particle velocity record. This “ringing,” or period of oscillations, can be used to determine the thickness of the spalled layer or scab produced.

Monitoring of the rear surface velocity of the sample or of the sample-window interface using a manganin pressure gage or VISAR quantifies the sample particle velocity history. A representation of the correlation between the spallation process within a sample and its manifestation on the sample rear surface or sample-window surface is shown on the right side of Fig. 4. Measurements of the wave profile of a sample driven to spall provides information on the time-dependent wave propagation and intersection processes leading to damage evolution in a material if the tensile stresses are sufficiently high. Shock studies designed to study spallation in a material therefore use the wave profile and, specifically, the details of the magnitude of the “pull-back” signal to quantify the energy necessary to nucleate and propagate damage. Figure 7 presents a VISAR wave profile of high-purity zirconium subjected to spall loading (Ref 83). The arrow A identifies the Hugoniot elastic limit for this material and the pull-back signal documents that this shock amplitude is sufficient to cause damage evolution in this material; in this case, however, no scab was formed but rather only incipient spall.

Fig. 7 Rear surface velocity shock wave profile (developed using VISAR interferometry) showing spallation in zirconium. Source: Ref 83

Profiles such as Fig. 7 provide quantitative data to compare with one-dimensional wave propagation finite-difference and finite-volume code calculations that model dynamic fracture. Additional insight into the physics and materials science controlling the process of spallation can be provided through examining the postshocked and damaged samples, just as Hopkinson did in his first steel studies. Figure 8 shows a metallographic cross section through an incipiently spalled high-purity tantalum sample following impact loading. In this example, nearly spherical ductile voids are observed to have nucleated and grown, as a function of position from the central fracture plane, and begun to coalesce under the imposed tensile stress history. Given sufficient tensile stress amplitude and appropriate geometry, damage can lead to scab formation and, therefore, complete separation of the sample into multiple pieces. Identification of the final fracture modes manifesting complete separation can be obtained by soft recovering the scab formed and then examining its fracture surface. Figure 9 presents an example of a fracture surface of a spalled Ta-10W sample illustrating cleavage fracture behavior.

Fig. 8 Metallographic cross section of soft-recovered tantalum sample following spallation

Fig. 9 Scanning-electron microscopy (SEM) image of transgranular cleavage fracture in Ta-10W spallation sample. Source: Ref 84

Quantification of the damage nucleation and evolution processes leading to dynamic failure provide the critical physical insight into the micromechanisms governing this complex dynamic fracture process (Ref 22). Documentation of the time- and stress-dependent loading parameters, specific damage mechanisms controlling nucleation and growth, and the microstructural factors influencing these processes is needed to develop physically based models describing the spallation of ductile materials.

Shock Wave Testing of Ductile Materials

George T. (Rusty) Gray III, Los Alamos National Laboratory

Summary

Systematic shock-loading studies of materials, in which microstructural “real-time” shock physics processes, mechanical property, and dynamic fracture effects are characterized quantitatively, provide important diagnostic tools to understand the constitutive behavior of materials. A variety of loading techniques can be used to shock load materials including HE-driven gas/powder launchers, exploding foils, laser-driven flyer plates, and direct radiation impingement (including lasers and electron beams). Shock recovery experiments provide a post mortem snapshot of the structure-property response of a material to the extreme conditions of strain rate, triaxial stress, and temperature imposed by the shock for comparison with in situ wave profile and shock-reload data. Postmortem characterization of shock-loaded materials will continue to contribute valuable data to the understanding of real-time wave profile and shock wave data.

Shock Wave Testing of Ductile Materials

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

Introduction

IMPACT TESTS are used to study dynamic deformation and failure modes of materials. Low-velocity impact techniques can be classified as plate-on-plate, rod-on-plate, plate-on-rod, or rod-on-rod experiments. Two types of plate-on-plate impact tests have been developed: wave propagation experiments and thin-layer high-strain-rate experiments. The plate-on-plate experiments are further classified as nonrecovery or recovery experiments. The focus of this article is on plate-on-plate experimental techniques. At the end of this article, rod-on-plate and plate-on-rod experiments are briefly examined.

Observation of plane waves in materials provides a powerful method for understanding and quantifying their dynamic response (Ref 1, 2, 3, 4, 5, 6, 7, 8, and 9) and failure modes (Ref 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, and 29). Plate impact experiments are used to generate such plane waves (Ref 30, 31, and 32). These experiments provide controlled extreme stress-state loading conditions, involving one-dimensional stress-pulse propagation. The recovery configurations in plate-on-plate impact experiments are performed with the objective of examining the microstructural changes in the specimen after it is subjected to loading under a uniaxial strain condition. The experiments are designed to achieve a controlled plane-wave loading of the specimens. In practice, this is limited by the finite size of the plates employed, which generate radial release waves. This has the potential for significant contribution to the damage processes by introducing causes other than the uniaxial straining of the material. Hence, this aspect of the plate impact experiment has been a subject of considerable research in the past (Ref 11, 13, 33, 34, 35, 36, 37, 38, and 39).

The plate impact experiments are performed in two main modes: *normal impact* and *pressure-shear*, or *oblique impact*. Both modes have been specialized to several new configurations to achieve different aspects of control over the imposed loading. In these experiments, the time histories of the stress waves are recorded and used to infer the response of the specimen with the goal of constitutive modeling. To enable the formulation of correct constitutive behavior for the considered material, knowledge of the micromechanisms of deformation that occur during the passage of the stress waves is necessary. Such knowledge is also necessary for damage-evolution studies. Hence, it is important that the specimen is recovered after it is subjected to a well-characterized loading pulse so that it can be analyzed for any changes in its microstructure. This is achieved in the normal plate impact mode by using an impedance-matched momentum trap behind the specimen (Ref 1, 7, and 11). Ideally, the momentum-trap plate captures the momentum of the loading pulse and flies away, leaving the specimen at rest.

Initially, the recovery technique was developed for the normal plate experiments (Ref 1, 38, and 39), and it has been implemented in the pressure-shear mode to study shear stress-sensitive, high-rate deformation mechanisms. The difficulty in conducting pressure-shear recovery experiments stems from the fact that both the shear and longitudinal momenta must be trapped and that there is a large difference in the longitudinal and shear wave velocities for any given material. To overcome this problem, one idea that had been proposed was to use a composite flyer made of two plates of the same material that are separated by a thin layer of a low shear resistance film, such as a lubricant (Ref 40, 41). This design would enable the shear pulse to be unloaded at the interface, while the pressure pulse would be transmitted to the next plate. The pressure pulse would return to the specimen momentum-trap interface as an unloading wave after the unloading of the shear wave has taken place. The thickness of the momentum-trap plate is chosen such that the normal unloading wave from its rear surface arrives at this interface much later, and hence, the momentum trap would separate just as in the normal recovery experiment, but after trapping both the shear and normal momenta.

The plate impact experiments can be performed at different temperatures by providing temperature-control facilities in the test chamber. This may consist of a high-frequency (0.5 MHz) induction heating system, for high-temperature tests, or a cooling ring with liquid nitrogen circulating through an inner channel, for low-temperature experiments (Ref 42, 43, and 44).

Confined and unconfined rod experiments have been performed (Ref 45, 46) with the aim of extending the uniaxial strain deformation states imposed in the plate impact experiments. The bar impact and pressure-shear experiments provide a measurement of yield stress at rates of 10^3 to $10^5/s^{-1}$. They also allow the experimental verification and validation of constitutive models and numerical solution schemes under two-dimensional states of deformation. In-material stress measurements, with embedded manganin gages, are used to obtain axial and lateral stress histories. Stress decay, pulse duration, release structure, and wave dispersion are well defined in these plate and rod experiments.

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

Plate Impact Facility

Gas Gun. The low-velocity impact experiments are generally performed in single-stage gas guns that are capable of firing projectiles of complex shapes as well as various materials and weights at limited velocities. Plate impact experiments discussed in this section were carried out on single-stage light-gas guns capable of projectile velocities from a few tens of meters per second to 1200 m/s (3940 ft/s).

A light gas gun facility generally has four interconnected parts: a pressure chamber or breech, a gun barrel, a target chamber, and a catcher tank (Fig. 1). Different types of breeches have been used. The most common is a wraparound breech, which employs no moving parts under pressure except the projectile itself as a fast-opening valve. The projectile back piston, which closes the breech, is designed to withstand the gas pressure. The breech holds gas at pressures between 1.4 and 20.7 MPa (200 and 3000 psi) to accelerate the projectile through the gun barrel and into the target chamber. The gun barrel diameter and length may be different, depending on the design. Examples include:

- 76.2 mm (3 in.) diameter and 6.09 m (20 ft) long gun with velocities in the range of 50 to 1000 m/s (165 to 3280 ft/s)
- 60 mm (2.4 in.) diameter and 1.2 m (3.9 ft) long gun with moderate velocities up to 200 m/s (660 ft/s)
- 56 mm (2.2 in.) diameter and 10 m (33 ft) long high-velocity gun with velocities up to 1200 m/s (3940 ft/s)
- 152 mm (6 in.) diameter and 5 m (16.4 ft) long gun with moderate velocities up to 400 m/s (1300 ft/s)
- 25 mm (1 in.) diameter and 5 m (16.4 ft) long gun with velocities up to 1200 m/s (3940 ft/s)

The inner surface of the barrel is honed to an almost mirror polish to reduce friction. To prevent projectile rotation, either a keyway is machined along the barrel, or the barrel is lightly broached. The target chamber is equipped with a special mounting system to hold the target assembly at normal or oblique angles. This system may allow remote rotation of the target, in any direction, to preserve the alignment upon target heating/cooling or simply prior to firing. The chamber and gun barrel are evacuated using a vacuum pump to a pressure of approximately 50 mtorr. Among other things, this prevents the formation of an air cushion between the target and flyer at impact. To avoid overpressure in the target chamber, after gas expansion, an exhaust system to ambient air may have to be implemented if the volume of the target chamber and the catcher tank is not adequate. The target and specimen leave the vacuum chamber through a rear port. A catcher tank filled with cotton rugs is used to decelerate and recover the projectile and target.

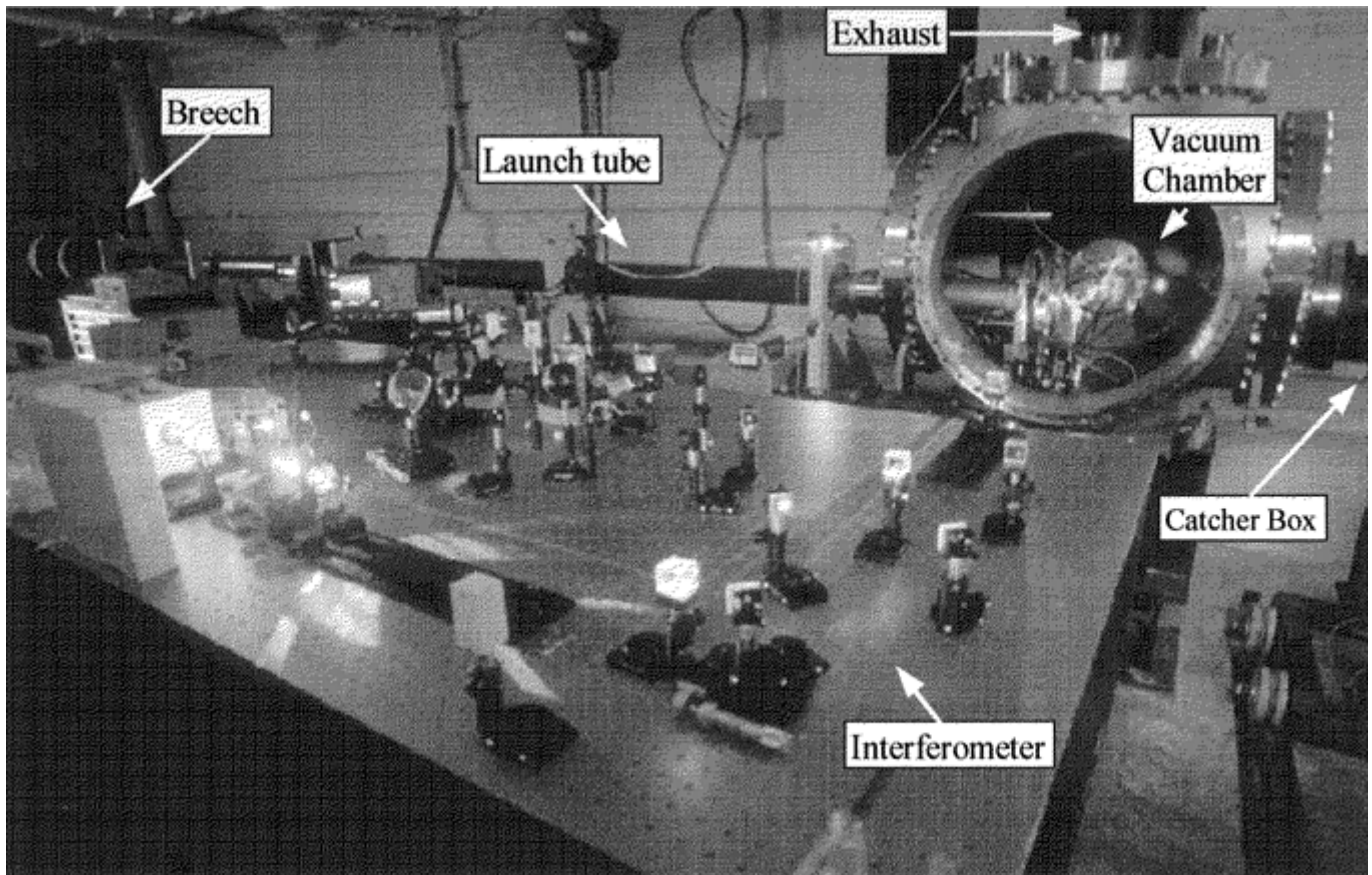

Fig. 1 Gas gun facility for low-velocity impact testing

Projectile. The projectile used for these experiments consists of a fiberglass tube, usually about 25 cm (10 in.) in length, with an aluminum back piston on the rear end and a polyvinyl chloride (PVC) holder on the front. The flyer plate or rod is glued to the PVC holder, which has a machined cavity. The fiberglass tube is centerless ground so that it slides smoothly in the gun barrel. A set of two holes in the fiberglass tube ensures that the pressure inside the projectile remains essentially the same as that on the outside. This prevents unwanted deformation of the projectile when the system is under vacuum. The aluminum back piston is screwed or glued to the fiberglass tube for high and low velocities, respectively. It holds a sealing set of two O-rings to withstand the breech pressure. A plastic key fitting the barrel keyway is placed in a slot machined on the wall of the fiberglass tube. The PVC holder carries the flyer backed by foam material to achieve wave release. All the pieces are glued together with five min epoxy.

Velocity Measurements. The velocity of the projectile just prior to impact is measured by means of a method that is similar to the one described in Ref 47. Ten pins of constantan wire, less than 0.1 mm (0.004 in.) in diameter, are positioned in pairs at the exit of the gun barrel. The pins are connected to an electronic box in which output, recorded in an oscilloscope, consists of steps every time a pair of pins closes the circuit. The PVC holder is coated with a silver paint to achieve conductivity between pins. The distance between the positive pins is measured with a traveling microscope with a resolution of 1 μm or better. When this distance is divided by the time between steps, as recorded in the oscilloscope, an average velocity is obtained. The accuracy of the system is better than 1%.

The motion of the target or anvil velocity is measured by interferometric techniques (Ref 48, 49, 50, and 51). In the case of low-velocity experiments, the variable sensitivity displacement interferometer (VSDI) is employed (Ref 52). Alternatively, for high- and low-temperature planar impact tests, an air-delay-leg normal velocity interferometer for any reflecting surface (ADL-VISAR) is used. In both cases, disposable mirrors are positioned at a certain distance from the rear surface of the specimen to allow illumination and interrogation of the target back surface. A side window on the target chamber provides access to the laser beam of the interferometer. Two digital oscilloscopes record the interferometer traces and velocity/tilt signals. Maximum sample rate, up to 4 million samples per second, 1 GHz bandwidth and 8 MB of memory may be used. The oscilloscopes are employed at full bandwidth and with a sample rate of 1 million samples per second or higher.

Tilt Measurement. The tilt during impact is measured by means of four contact pins placed on the surface of the target (Ref 1). When the target or the anvil plate can be drilled, four self-insulated metallic pins lapped flush with the front surface of the target/anvil plate are positioned in the periphery. When these pins are grounded by the flyer, a staircase signal is recorded on the oscilloscope at a ratio of 1 to 2 to 4 to 8. The tilt can be estimated by fitting a plane through the tilt pins by a least-square analysis. When the previous technique cannot be used, a special shape-conductive coating can be applied, using a mask, to the target impact surface and the same principle applied (Ref 7, 11). In some cases, such as in high-temperature testing, neither of the previous approaches is feasible, and tilt cannot be measured without major modifications.

High-and Low-Temperature Facilities. A high-temperature facility consists of an induction heating system and a heat exchanger for cooling the device and the coil around the specimen. A schematic of the high-temperature target assembly is shown in Fig. 2. This type of system is capable of delivering 25 kW of constant power at high frequency (0.5 MHz). Temperatures up to 1200 °C (2200 °F) in metallic and ceramic materials have been achieved in calibration tests. A photograph of the target chamber and high-temperature setup is shown in Fig. 3. The temperature is externally monitored by a K-type thermocouple glued close to the back face of the sample. An electronic control is employed to regulate the temperature. The system adjusts the heating ramp to minimize thermal shock and deformation in the specimen.

Fig. 2 Target assembly for high-temperature, low-velocity impact tests. Dimensions in inches. Source: Ref 44

Fig. 3 Gas gun vacuum chamber with high-temperature setup. Source: Ref 44

The induction copper coil is mounted in the mentioned target holder and connected to the heating system by means of a specially designed feedthrough. The coil is made from copper tubing. The copper section conducts the high-frequency electrical energy, whereas the inner core carries refrigeration water. The intense electromagnetic field inside the coil induces parasite currents in the magnetic target. A graphite susceptor holder is employed to position the target and heat nonconductive materials. Ceramic foam is placed between the sample and the copper coil to confine heat to the sample. A copper tube is connected to a water line to keep its temperature low and shield electromagnetic radiation. This shield is attached to the alignment rings, which support the whole target assembly.

For low-temperature testing, a cooling ring with liquid nitrogen circulating through an inner channel is used to reduce the temperature of the samples down to $-150\text{ }^{\circ}\text{C}$ ($-238\text{ }^{\circ}\text{F}$). The ring consists of two pieces of aluminum machined to fit together with special seals for low temperature to make the holder leak proof. Appropriated stainless steel hoses are used to drive liquid nitrogen from an external reservoir tank. The sample is kept in place inside the cooling ring by means of a disposable aluminum ring and polymethyl methacrylate (PMMA) pins. The liquid nitrogen is provided by a 175 kPa (25 psi) external tank. Once the heat exchange has taken place, the nitrogen in gaseous state is bled from the vacuum chamber. The temperature is monitored by means of a type J thermocouple glued to the rear surface of the specimen (Ref 27).

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

Specimen Preparation and Alignment

To generate plane waves at impact and upon reflection off interfaces, the faces of the flyer and specimen plates must be flat. The flyer plate and specimen are lapped flat (using, e.g., 15 μm alumina abrasive first, and then 6 μm diamond abrasive). The accepted flatness of these surfaces is around 1.5 to 2 wavelengths of green light ($\lambda = 550 \text{ nm}$). This is measured by counting the number of interference fringes (Newton's rings) formed between the polished surface and an optical flat. The procedure is continued until only two fringes are visible over the whole surface. The rear surface of the target plate is polished using 1 μm and $\frac{1}{4}\mu\text{m}$ diamond abrasive to obtain a reflective surface for interferometric purposes. For a pressure-shear recovery experiment, the surfaces corresponding to the solid or liquid lubricant interface are highly polished. All other surfaces are roughened by lapping with 15 μm diamond paste. This is to ensure sufficient surface roughness to transfer the shear loading by dry friction. The specimen is cleaned ultrasonically in ethyl alcohol. The polished surface is wiped clean with acetone and ethyl alcohol, in that order, and stored. The final surface is often scanned using a profilometer.

When certain materials are tested at high temperatures, oxide thin films may form, which can reduce reflectivity significantly. For instance, Ti-6Al-4V surfaces oxidize very fast. Thin layers of oxide form at temperatures between 315 and 650 °C (600 and 1200 °F). The film is barely perceptible, but with increasing temperature and time, it becomes thicker and darker, acquiring a straw-yellow color at about 370 °C (700 °F) and dark blue at 480 °C (900 °F). Temperatures high enough to produce oxidation may be reached even under a vacuum of less than 50 mtorr. This oxide layer reduces the reflectivity of the titanium surface, making it difficult to obtain a good interferometric signal. To overcome this difficulty in Ti-6Al-4V, a platinum coating (0.1 μm thick) has been applied to the back surface of the specimen. A pre-etching of the surface guarantees a good adhesion of the coating. Platinum is stable at high temperature; however, due to mismatch in coefficients of thermal expansion, debonding may occur if the surface temperature of the specimen is increased too fast. Therefore, the induction heating power must be controlled at all times with a feedback loop and coating materials selected to match the target thermal properties.

The plate dimensions are selected such that at the center of the specimen, a unidimensional strain state is kept for a few microseconds before release waves from the periphery arrive to the observation point(s). These dimensions are a function of the type of experiment and configuration and are therefore discussed separately.

The plates are optically aligned at room temperature using the technique described in Ref 1. For this technique, the projectile is advanced to a position near the target, and a specially coated precision prism is placed between the two surfaces to be impacted. An autocollimator is used to first align the prism to the flyer and then the specimen to the prism. In this way, the surfaces of the flyer and the specimen are aligned with an accuracy of 0.02 milliradians. After alignment, the projectile is pulled back to the other end of the launch tube. To preserve target alignment, especially in the case of high- and low-temperature experiments, the position of a collimated laser beam, reflected from the rear surface of the target plate, is monitored on a stationary screen roughly 12 m (40 ft) away. A target plate tilt of 1 milliradian results in a beam translation of 1.2 cm (0.47 in.) on this screen. This remote beam system allows monitoring of the tilt along the vacuum process and during the heating or cooling of the sample. Remote mechanical controls attached to the target holder screws are employed to drive the target back to its original position, thereby ensuring that the target and the flyer plates maintain their original room-temperature alignment. The quality of the interferometric signals is usually an indication of the parallelism at impact.

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

Surface Velocity Measurements with Laser Interferometric Techniques

Barker and Hollenbach (Ref 48) developed a normal velocity interferometer (NVI), where normally reflected laser light from a target plate was collected and split into two separate beams, which are subsequently interfered after traveling through different path lengths. The sensitivity of the interferometer is a function of the delay time between the interfering beams. The resulting fringe signal is related directly to changes in the normal particle velocity. Barker and Hollenbach (Ref 49) then introduced a significantly improved NVI system termed a velocity interferometer for any reflecting surface (VISAR), developed based on the wide-angle Michelson interferometer (WAM) concept, resulting in an interferometer capable of velocity measurements from either a spectrally or diffusely reflecting specimen surface. Another improvement incorporated into the VISAR was the simultaneous monitoring of two fringe signals 90° out of phase. In most VISAR systems, three signals are recorded—the two quadrature optical signals obtained from horizontally and vertically polarized components of

light that differ in phase because of the retardation plate and the intensity-monitoring signal used in data reduction. However, higher signal-to-noise ratios can be obtained by subtracting the two s-polarized beams and the two p-polarized beams, both pairs 180° out of phase (Ref 53). This feature, known as *push-pull*, significantly reduces the noise introduced by incoherent light entering the interferometer.

Another laser interferometer to emerge in the 1970s was the laser Doppler velocimeter (LDV) developed by Sullivan and Ezekiel (Ref 54). The LDV can be used to monitor in-plane motion but does not lend itself to the simultaneous monitoring of normal motion. The need to measure both normal and in-plane displacements prompted the development of the transverse displacement interferometer (TDI) by Kim et al. (Ref 50). The TDI takes advantage of diffracted laser beams generated by a grating deposited or etched onto the specimen rear surface. In this technique, the 0th order reflected beam is used to monitor longitudinal motion in a conventional way, for example, by means of an NVI or normal displacement interferometer (NDI), while any pair of n th order symmetrically diffracted beams is interfered to obtain a direct measure of the transverse particle displacement history. The sensitivity of the TDI is given by $\frac{1}{2\sigma} n$ (mm/fringe) where σ is the grating frequency and n represents the order of the interfering diffracted beams.

Chhabildas et al. (Ref 55) presented an alternative interferometric technique particularly suited for monitoring in-plane particle velocities in shock wave experiments. The technique employs two VISARs that monitor specific diffracted laser beams from a target surface.

Both techniques, the two-VISAR and the NDI-TDI, have advantages and disadvantages. The combined NDI-TDI system has a much better resolution at low velocities but requires the deposition of grids on the free surface of the target plate. On the other hand, the two-VISAR technique provides velocity profiles directly without the need to differentiate displacement profiles. Although the two-VISAR technique is simpler to use when optical window plates are needed, it was shown that a combined NVI-TDI with window interferometer is feasible (Ref 56).

The relatively small range of velocities that can be measured by the NDI motivated the development of the NVI. The sensitivity of the NDI is given by $\lambda/2$ (mm/fringe) where λ represents the laser light wavelength. The extreme sensitivity of this interferometer severely limits its application in wave propagation experiments due to the inordinately high signal frequencies that may be generated. An NVI or a VISAR, on the other hand, has a variable sensitivity given by $\lambda/[2\tau + (1 + \delta)]$ (mm/ μ s/fringe), where τ represents a time delay between the interfering light beams introduced by an air-delay leg or etalon in the interferometer. The factor $(1 + \delta)$ is a correction term to account for the refractive index of the etalon. An appealing feature of this interferometer is that the fringe record is a direct measure of particle velocity, thereby alleviating the need for differentiation of the reduced signal. Moreover, signal frequencies generated by an NVI are proportional to particle acceleration and are, therefore, lower than equivalent signal frequencies generated by an NDI. However, during an initial time period τ , an NVI is functioning as an NDI since the delayed light arriving at the detector from the delay leg or etalon is reflected from a stationary target (Ref 57). Ironically, it is the interpretation of the NVI in the interval where it operates as an NDI that limits the usefulness of the NVI in the low-velocity range (0.1–0.25 mm/ μ s). In this velocity range, values of τ in the neighborhood of 5 ns or more are required to obtain records with at least three or four fringes. This in turn leads to a greater averaging of the velocity measurements. Furthermore, elastic precursors causing velocity jumps of more than 0.1 mm/ μ s in a time less than τ cannot be detected because the early time NDI signal frequency may exceed the frequency response of the light-detection system. This feature is described as *lost fringes* in Ref 58.

Clearly, the NDI and VISAR principles described here indicate that there is a velocity range between 0.1 and 0.25 mm/ μ s over which particle velocities may not be measured with the desired accuracy. Barker and Hollenbach (Ref 49) investigated the accuracy of the VISAR experimentally. They found that measurements with 2% accuracy could be obtained when a delay time of approximately 1 ns corresponding to a velocity per fringe constant equal to 0.2 mm/ μ s is used. Certainly, velocities below 0.2 mm/ μ s can be measured, but the uncertainty of the measurement increases because only a fraction of a fringe is recorded. In this case, signals in quadrature have to be recorded immediately before the experiment and assume the amplitude remains the same during the experiment (Ref 59). It should be pointed out that the VISAR data reduction is very sensitive to the position and shape of the Lissajous (Ref 59). Despite these minor subtleties, the VISAR is currently the more versatile and easy-to-set-up interferometer. Many laboratories around the world have adopted the VISAR as a routine tool for particle velocity measurement in normal impact experiments. Typically, delay times between 1 and 1.5 ns are employed. In this working range, the VISAR possesses a very high accuracy and sensitivity.

A common feature of all interferometers discussed in this section is that successful signal acquisition requires good fringe contrast during the time of the experiment. Contrast losses arise from two main causes, interferometer imperfections and target motion (displacement and tilt). These losses can be, in general, time varying. For instance, a beam splitter that does not split light equally will produce a constant loss of contrast, while unevenly curved surfaces will produce a variable contrast change as a function of the light path in the interferometer. Target rotations that change the light path can be very detrimental to most interferometers. In this respect, interferometers that use scatter light from the target and fiber optics to transfer the laser light will minimize the loss in fringe contrast because the light path in the interferometer is fixed. Furthermore, even target rotations of a few milliradians will not result in signal loss in such systems. By contrast, standard interferometer setups, without fiber optics, require tilts smaller than 1 milliradian to avoid a change in the light path that can offset the beam from the optical components of the interferometer. This feature is particularly relevant in two- and three-dimensional wave propagation problems (e.g., penetration experiments, in which significant surface rotations are expected at diagnostic points). In the early 1990s, Barker developed a VISAR with these features (Ref 58). In 1998, the same company introduced a multipoint fiber optics VISAR to the market.

Espinosa et al. (Ref 52) introduced a variable sensitivity displacement interferometer (VSDI) to provide an alternative to the NDI, as well as to VISAR interferometers as applied to plate impact experiments, particularly when normal and in-plane velocity measurements need to be recorded simultaneously in the range of 50 to 250 m/s (165 to 820 ft/s). The sensitivity of such an interferometer is variable, and thus, it can operate over a wide range of particle velocities without exceeding the frequency response of the light-detection system. The VSDI interferometer is discussed in more detail subsequently.

Variable Sensitivity Displacement Interferometer (VSDI) Theory. To examine the results of this method, consider the effect of interfering a normally reflected beam with a beam diffracted at an angle θ with respect to the specimen normal as shown in Fig. 4. The normally reflected beam is split at beam splitter BS1. Each half of the normal beam is then made to interfere with one of the diffracted beams via beam splitters BS2 and BS3. The resulting signals generated by each interfering beam pair are monitored by photodetectors. The combined field for either pair of interfering plane waves leads to a classical interference expression, from which the following result is deduced (Ref 52).

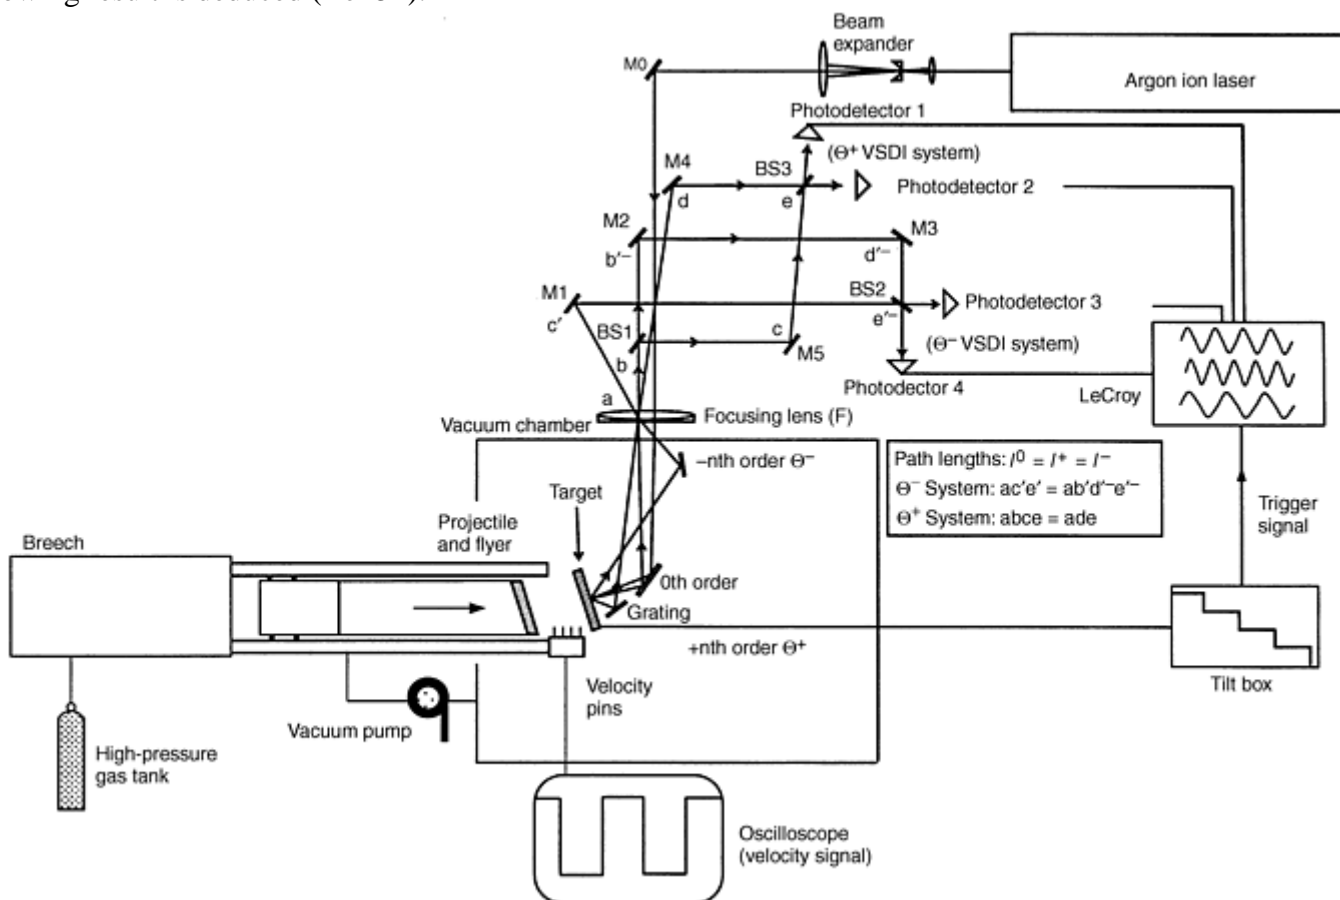

Fig. 4 Optical layout of a variable sensitivity displacement interferometer (VSDI) system. The Θ^\pm system is obtained by combining a normally reflected beam and a diffracted beam at an angle Θ^\pm . In this figure, mirrors M0-M5 and beam splitters BS1-BS3 are used to obtain the VSDI systems. The lens with focal length F is used to focus the beam at the grating plane in the anvil back surface. Source: Ref 52

For *purely normal motion* (desensitized normal displacement interferometer, DNDI):

$$\frac{\text{normal displacement}}{\text{fringe}} = \frac{\lambda}{1 - \cos \theta} = \frac{\lambda}{1 - \sqrt{1 - (n\lambda\sigma)^2}}$$

where $\sigma = 1/d$ represents the frequency of a diffraction grating with pitch d . The fringe constant varies from infinity at $\theta = 0^\circ$ to λ (mm/fringe) at $\theta = 90^\circ$. Therefore, a VSDI is obtained that is particularly well suited for normal plate impact experiments with particle velocities in excess of 100 m/s (330 ft/s). Clearly, the selection of the appropriate angle θ should be based on deductive knowledge of the frequency range that will be spanned. For *purely in-plane motion* (desensitized transverse displacement interferometer, DTDI):

$$\frac{\text{transverse displacement}}{\text{fringe}} = \frac{\lambda}{\sin \theta} = \frac{1}{\sigma n}$$

The DTDI sensitivity ranges from a complete loss of sensitivity at $\theta = 0^\circ$ to a theoretical sensitivity limit of λ (mm/fringe) at $\theta = 90^\circ$. The interferometer is “desensitized” in the sense that, for the same diffraction orders, it exhibits one-half the sensitivity of the transverse displacement interferometer (TDI) (Ref 50).

For *combined normal and in-plane motions* (VSDI system):

$$\frac{\text{normal displacement}}{\text{fringe}} = \frac{\lambda}{2(1 - \cos \theta)}$$

$$\frac{\text{transverse displacement}}{\text{fringe}} = \frac{\lambda}{2 \sin \theta}$$

This last sensitivity is the same as the one exhibited by the TDI (Ref 50). It should also be noted that the normal displacement sensitivity is twice the sensitivity obtained by a single VSDI system in the case of pure normal motion principally because the signal obtained by the addition of two VSDI systems exhibits a double recording of the normal displacement.

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

Plate Impact Soft-Recovery Experiments

Normal and pressure-shear plate impact soft-recovery experiments (Ref 16, 17, and 18) offer attractive possibilities for identifying the principal mechanisms of inelasticity under dynamic tension and compression, with and without an accompanying shearing. The samples are recovered, allowing their study by means of microscopic characterization. This feature, together with the real-time stress histories, may be used to assess the validity of constitutive models (Ref 8, 14, 20, 21, 22, 29, and 60). This kind of experiment on brittle materials provides information on the onset of elastic precursor decay, spall strength, and material softening due to microcracking.

A plate impact experiment involves the impact of a moving flat plate, called a *flyer*, with another stationary plate, called the *target*, which may be the specimen. In the normal plate impact experiment, the specimen is subjected to a compression pulse, and the material at the center of the specimen is under a strictly uniaxial strain condition. In the pressure-shear experiment, the specimen undergoes a combined compression and shearing. Thus, the material undergoes a transverse shearing while it is in a compressed condition. The wave propagation is one dimensional, since both the pressure and shear pulses travel along the same axis.

The recovery configuration in the normal impact mode employs a backing plate for the target to capture the longitudinal momentum. In the pressure-shear recovery mode (Ref 16, 17, 18, 19, and 52) two flyer plates that are separated by a thin lubricant layer (which is a thin film of minimal shearing resistance and very high bulk modulus) are used along with the backing plate to capture the longitudinal and shear momenta. A liquid lubricant was used by Machcha and Nemat-Nasser (Ref 16), while a solid lubricant (photoresist AZ 1350J-from Hoechst Celanese) was used by Espinosa and coworkers (Ref 17, 18, 19, and 52). In practice, the amount of the trapped shear momentum depends on the shear properties of the lubricant thin film. All plates have to be reasonably impedance matched to obtain good results. Good discussions of the requirements for normal recovery can be found in Ref 7, 11, and 38. Figure 5 shows the configuration of the plates and the time-distance, t - X , diagram for the normal impact recovery experiment (Ref 1, 7, 11). Figures 6 and 7 show the experimental layouts and t - X diagrams for the high-strain-rate (Ref 17, 18, and 19) and wave propagation (Ref 16, 18, and 19) pressure-shear recovery experiments, respectively.

To reduce the boundary release wave effects, guard rings and confining fixtures have been used around the circumference of the sample (Ref 33, 36, and 37). This requires close tolerances in machining, making the specimen preparation and assembly difficult. A better approach was proposed by Kumar and Clifton (Ref 38), who made use of a star geometry for the flyer to redirect the release waves and decrease their damaging effect at the center. This approach was implemented in experimental studies by a number of researchers (Ref 11, 13, 14, 35, 37, 61, and 62). Three-dimensional simulations on different configurations have also been conducted by many authors (Ref 13, 36, 63, and 64) for the normal impact configuration, leading to several recommendations to improve this configuration. Experimental evidence shows that it is difficult to recover brittle specimens intact, even at moderate stresses of about 2.0 GPa (290 ksi). Results from numerical simulations suggest that thin flyer plates must be used, which lead to short loading duration. This is difficult to implement in the pressure-shear recovery experiments since very thin plates produce negligible shear pulse duration. Investigation of the release effects in the pressure-shear and normal plate impact recovery experiments on brittle materials shows that the geometry of the plates may be used to mitigate release effects (Ref 16, 17, 18, and 19). Independently of the geometry of the pressure-shear configuration, some fraction of the energy always

remains in the sample as shear momentum and may affect the radial release waves before they are trapped. The question of the residual shear pulse, which arises because of the shear strength of the lubricant layer, must always be addressed.

Normal Plate Impact

Experimental facilities, projectile characteristics, measurement techniques, and specimen preparation and alignment are discussed in the preceding sections of this article. To illustrate the basic procedure and the corresponding results, consider first the normal configuration shown in Fig. 5(a), with the t - X diagram of Fig. 5b, in the context of the investigation of inelasticity in a ceramic composite (Ref 7). The fiberglass tube projectile carries steel and star-shaped Ti-6Al-4V flyer plates that are separated by a low-impedance foam to prevent reloading of the specimen by reflected waves. The Ti-6Al-4V flyer has sufficiently high yield strength and acoustic impedance lower than the tested ceramic composite sample. The target assembly consists of an inner cylinder for supporting the specimen and an outer anvil for stopping the projectile. The anvil has a disposable brass nose, which absorbs part of the impact energy. The 22 by 22 mm² (0.87 by 0.87 in.²) specimen is a thin plate of AlN/AlN/Al composite, backed up by the same size plate, which, ideally, has matching impedance. This plate flies off the back of the specimen after the main compressive pulse reflects from the rear surface and returns to the interface.

Experimental Procedure. A 63 mm (2.5 in.) gas gun was used (Ref 7). The specimen characteristics and relevant test data are reported in Tables 1 and 2. For the purpose of aligning and triggering the oscilloscopes, a multilayer thin film mask was sputtered onto the impact face of the specimen. Since the AlN/AlN/Al composite is conductive, a 1 μm thick insulating layer of Al₂O₃ was first sputtered. Then, by using a mask, a 0.1 μm thick layer of aluminum was sputtered in the form of four diagonal strip pins at the corners and two ground strips crossing at the center. Tilt and impactor velocity were measured using the techniques discussed in the section “Plate Impact Facility” in this article. The normal motion at four points on the rear surface of the momentum-trap plate was monitored by means of a normal displacement interferometer (NDI) to identify nonplanar motions that can be correlated with the microcracking process and the unloading waves from the star-shaped flyer.

Table 1 Properties of materials used in normal impact recovery experiments

Material	Density, g/cm ³	Longitudinal wave speed, mm/μs	Transverse wave speed, mm/μs	Acoustic impedance, GPa · μs/mm	Shear impedance, GPa · μs/mm
Hampden steel	7.86	5.983	3.264	47.03	25.66
Ti-6Al-4V	4.43	6.255	3.151	27.71	13.96
AlN/AlN/Al	3.165	9.50	5.5	30.07	17.41

Wave Propagation Analysis. At impact, plane compression waves are produced in both the thin star-shaped flyer and the specimen. The reflection from the foam-flyer interface unloads the compressive wave, resulting in a compressive pulse of duration equal to the round-trip travel time through the thickness of the star flyer. When the compressive pulse reaches the rear surface of the specimen, the gap between the specimen and the momentum-trap plate produces a reflected wave, which unloads the compressive pulse. Tensile stresses are generated after crossing the compressed region. By the time this pulse reaches the flyer-specimen interface,

separation between the flyer and specimen has taken place, and the pulse reflection causes compressive stresses. The initial compressive pulse, minus the pulse reflected at the gap, propagates into the momentum trap and reflects back. When this tensile pulse reaches the interface between the specimen and the momentum trap, the momentum trap separates because this interface cannot withstand tension. At this time, the specimen is left unstressed and without momentum. Because of the impedance mismatch between the specimen and the momentum trap, an additional compressive wave is reflected at the interface and makes a round trip through the specimen. This relatively small compressive reloading occurs later than the principal loading of interest and is expected to have minor influence on the observed damage.

This one-dimensional analysis is valid in the central region of the specimen (Ref 38), where the effects of diffracted waves from the corners and the edges of the flyer are minimized. The only cylindrical wave, which passes through the central octagonal region, is a shear wave diffracted from the boundary upon the arrival of a cylindrical unloading wave at 45° . To fully assess the role of the cylindrical waves diffracted from the edges of the star and the spherically diffracted waves from the corners of the flyer and the specimen, three-dimensional elastic computations have been performed (Ref 13). The principal unloading waves that travel in the central octagonal region are diffracted spherical waves emanating from the corners of the flyer. These waves produce tensile stresses within the sample. The maximum amplitudes of such stresses occur for transverse tensile stresses at the rear surface of the specimen. These amplitudes are of the order of 15% of the longitudinal compressive stress in the incident plane wave. It should be pointed out that this amplitude represents an upper bound for such stresses. First, in real experiments there is a lack of simultaneity for the time of contact of the eight corners due to the tilt between the flyer and the specimen. Second, the divergence of the unloading waves from the corners will induce microcracking near these corners and thereby reduce the level of tensile stresses that propagate into the central octagonal region to a value below a fracture stress threshold. These features have been observed systematically in Al_2O_3 and $\text{AlN}/\text{AlN}/\text{Al}$ composite tested samples.

Experimental Results. A summary of the experiments is given in Tables 1 and 2. The velocity-time histories of two typical results are given in Fig. 8(a) and (b). The reported stresses are at the interface between the specimen and the momentum trap. The maximum shear stress is given. The stress-time histories at the front surface of the momentum trap can be read from the secondary vertical axis. Dashed lines in the plot are the elastic solution results, which are used as a reference to discuss several observed inelastic effects. The main compressive pulse, with duration between 240 and 195 ns, is followed by a second compressive pulse corresponding to the tensile pulse generated by an intentional gap of 30 and 85 ns in Fig. 8(a) and (b), respectively. The third pulse results from the reflection of the main pulse at the interface between the specimen and the momentum trap. Its close resemblance to the main pulse is an indication of the dominance of plane waves in the central region of the sample. In the experiment at lower impact velocity (Fig. 8a), the compressive pulse has the full amplitude of the elastic prediction. This implies that, initially, the material did not undergo inelastic processes at this level of stresses. The small reduction in amplitude at the end of the pulse can be interpreted from the analysis of release waves from the star-shaped flyer corners (Ref 13). The tail at the end of the first compressive pulse appears to be the result of the inelastic strain rate produced by the nucleation and propagation of microcracks (Fig. 8a). If so, the duration of the tail can be associated with the time required for the stress, at the wave front, to relax to the threshold value required for initiating crack propagation. Strong evidence of microcracking is found in the attenuation and spreading of the second compressive pulse. In Fig. 8(b), some indication of inelasticity in compression appears toward the end of the pulse. This feature is consistent with the increase in dislocation density, within the AlN filler particles, the AlN reaction product, and the Al phase, observed in transmission electron microscopy (TEM) samples made from the recovered specimens (details can be found in Ref 7).

Fig. 8 Velocity-time profiles for normal impact recovery experiments. (a) Profile for shot No. 91-01 in Table 2. Second compressive pulse is attenuated due to material dynamic failure in tension. (b) Profile for shot No. 91-02 in Table 2. A strong spall signal and attenuation of the first compressive pulse are observed. Source: Ref 7

Pressure-Shear Plate Impact

Inclining the flyer, specimen, and target plates with respect to the axis of the projectile produces compression-shear loading. By varying the inclination angle, a variety of loading states may be achieved. For small angles of inclination, small shear stresses are produced, which can be used to probe the damage induced by the accompanying pressure. This pressure-shear plate impact experiment was modified by Ramesh and Clifton (Ref 6) to study the elastohydrodynamic lubricant response at very high strain rates. The idea of recovery pressure-shear plate impact experiment was presented by Nemat-Nasser et al. (Ref 40), Espinosa (Ref 41), and Yadav et al. (Ref 65) and was first successfully implemented to study the response and failure modes of alumina ceramics by Machcha and Nemat-Nasser (Ref 16) and later by Espinosa et al. (Ref 17, 18, 19, and 52) in their studies of dynamic friction and failure of brittle materials.

Wave Propagation Analysis. The Lagrangian time-distance (t - X) diagrams for pressure-shear high-strain-rate and wave propagation configurations, designed for specimen recovery, are shown in Fig. 6(b) and 7(b). In the case of pressure-shear high-strain-rate experiments, the specimen is a thin wafer, 100 to 500 μm thick, sandwiched between two anvil plates. At impact, plane compression waves and shear waves are produced in both the impactor and the target. Since the shear wave velocity is approximately half the longitudinal wave velocity, a thin film with very low shear resistance needs to be added to the flyer plate such that the arrival of the unloading shear wave, to the impact surface, precedes the arrival of the unloading longitudinal wave generated at the back surface of the second flyer plate. The longitudinal and shear wave fronts arriving to the anvil-free surface are shown in Fig. 6(b). These wave fronts determine the longitudinal and shear windows measured interferometrically. These velocity histories contain information on the sample stress history as discussed in the next paragraph. A similar wave analysis applies to the wave propagation pressure-shear configuration (Fig. 7b).

According to one-dimensional elastic wave theory (Ref 5), the normal stress is given by $\sigma = \rho c_1 u_0/2$, in which ρc_1 is the flyer and anvil longitudinal impedance, and u_0 is the normal component of the impact velocity V (i.e., $u_0 = V \cos \theta$). The strain rate is given by the velocity difference between the two faces of the sample divided by its thickness (i.e., $\dot{\lambda} = (v_f - v_a)/h = (v_0 - v_{fs})/h$), where v_f and v_a are the flyer and anvil transverse velocities, respectively, at their interfaces with the specimen, and $v_0 = V \sin \theta$ and v_{fs} are, respectively, the transverse components of the impact velocity and the velocity of the free surface of the anvil plate. The integration of the strain rate over time gives the shear strain $\gamma(t)$. One-dimensional elastic wave theory can be used again to express the shear stress in terms of the measured free surface transverse velocity (i.e., $\tau = \rho c_2 v_{fs}/2$), where ρc_2 is the anvil shear impedance. These equations can be used to construct $\tau - \gamma$ curves at strain rates as high as $1 \times 10^5 \text{ s}^{-1}$ and pressures in the range of 2 to 5 GPa (290 to 725 ksi). It must be emphasized that this analysis is based on the assumption that inelasticity takes place only in the specimen. An investigation of this requirement at high strain rate and temperatures can be found in Ref 42.

Numerical simulations have been performed by Machcha and Nemat-Nasser (Ref 23) for the pressure-shear recovery experiments. The results confirm the advantages of the star-shaped geometry. Machcha and Nemat-Nasser positioned the star-shaped flyer as a second flyer plate, which does not fully mitigate lateral release waves, in the central portion of the sample. Espinosa and coworkers (Ref 18, 19) positioned the star-shaped flyer plate as the first plate of the multiplate flyer assembly. The selection of materials for the manufacturing of flyer plates depends on the application for which experiments are conducted. In the characterization of hard materials, demanding requirements are placed on the manufacturing of flyer and momentum-trap plates. These plates must be hard enough in compression and shear to remain elastic at the high stress levels required for the inelastic deformation of the specimen. The momentum trap must be strong enough in tension to prevent failure at 45° when the shear wave propagates through the unloaded region adjacent to the rear surface of the momentum trap. These requirements are met by using Speed Star (Carpenter Technology Corp.—Specialty Alloys, Reading, PA) steel plates with a 0.2% offset yield stress greater than 2200 MPa (320 ksi) in shear and a tensile strength in excess of 1500 MPa (220 ksi). Another important feature in the selection of the flyer material is that its longitudinal and shear impedances must be smaller or equal to those of the specimen. In this way, a

single compression-shear pulse is introduced in the sample. Moreover, the longitudinal and shear impedances of the momentum-trap plate must match the impedances of the sample to avoid wave reflections at the specimen momentum-trap interface. Density, wave speeds, and impedances for the materials used in this investigation are reported in Table 3.

Table 3 Properties of materials used in pressure-shear impact recovery experiments

Material	Density kg/m ³	Wave speed, mm/μs		Impedance, GPa · mm/μs	
		<i>c</i> ₁	<i>c</i> ₂	ρc ₁	ρc ₂
Speed-Star Steel	8138	5.852	3.128	47.62	25.46
TiB ₂	4452	10.93	7.3	48.66	32.5
Al ₂ O ₃ /SiC	3890	10.56	6.24	41.08	24.27

Source: Ref 19

Experimental Procedure. The 76 mm (3.0 in.) gas gun described in the section “Plate Impact Facility” was used. The multiplate flyer and target plates were made of Speed Star steel. The specimens were made with two types of ceramics. In the high-strain-rate pressure-shear experiment, an Al₂O₃/SiC nanocomposite wafer was used. TiB₂ plates were employed in the wave propagation pressure-shear experiments. In the latter case, two specimen configurations were investigated. The first one consisted of a square specimen with the same dimensions as the star-shaped flyer. The second configuration consisted of a hollow square steel plate in which a TiB₂ ceramic rod 12.7 mm (0.5 in.) in diameter was shrunk fitted.

The target rear surface was polished, and then a thin layer of positive photoresist was deposited using a spinning machine. A holographic phase grating was constructed by interference of two laser beams. The angle between the beams was selected such that a sinusoidal profile with 1000 lines/mm was obtained. This grating was used to measure the normal and transverse displacements by means of a variable sensitivity displacement interferometer (VSDI) (Ref 52). The signals generated by each interfering beam pair were monitored by silicon photodetectors.

Experimental Results. A summary of these experiments is presented in Table 4. The normal velocity-time profile obtained from the high-strain-rate pressure-shear recovery configuration is shown in Fig. 9(a). The normal particle velocity shows a velocity reduction after an initial jump indicating the presence of a small gap between the Al₂O₃/SiC nanocomposite and the multiplate flyer. Upon reverberation of waves within the specimen, the normal velocity rises to a value of about 140 m/s (460 ft/s) at approximately 0.4 μs and remains almost constant until release waves from the boundary reach the observation point. The peak normal stress in this shot, computed according to $\sigma = \rho c_1 u_{fs}/2$, reaches 3.45 GPa (500 ksi). The transverse particle velocity history for this experiment is shown in Fig. 9(b). The velocity rises progressively and then drops for a few nanoseconds. Since in this experiment, shear motion is transferred by friction, a reduction in normal traction at the specimen-steel plate interface results in a drop of the transmitted shear motion. When the gap closes, the transverse velocity increases until it reaches a maximum value of 22 m/s (72 ft/s) at about 500 ns. It then decays continuously while the normal velocity remains constant (Fig. 9a). The maximum shear stress, given by $\tau = \rho c_2 v_{fs}/2$, is 280 MPa (41 ksi). This value is well below the expected shear stress of 575 MPa (83 ksi), assuming elastic material response. The progressive reduction in anvil-free surface transverse velocity implies a variable strain rate and absence of a homogeneous stress state in the sample. In this experiment, round plates were used and the sample was precracked through a sequence of microindentations in a diameter of 38 mm (1.5 in.) Lateral trapping of release waves was attempted by forming a circular crack with the unloaded sample in the central region. Despite these efforts, the degree of damage was severe enough that the ceramic sample was reduced to fine powder upon unloading. This feature of material pulverization upon unloading was investigated by Zavattieri et al. (Ref 22) by simulating compression-shear loading on representative volume elements at the grain level. These investigators show that a ceramic microstructure containing a dilute set of microcracks may pulverize in unloading due to the stored elastic energy within the grains.

Table 4 Summary of parameters for pressure-shear recovery experiments

Shot No.	Specimen	Specimen thickness	Impactor thickness	Target thickness	Projectile velocity	Tilt, mrad	Configuration
----------	----------	--------------------	--------------------	------------------	---------------------	------------	---------------

		mm	in.	mm	in.	mm	in.	m/s	ft/s		
7-1025	Al ₂ O ₃ /SiC	0.54	0.021	2.42–3.65	0.095–0.144	7.99	0.31	148	486	1.3	High strain-rate recovery
7-1115	TiB ₂	4.15	0.163	1.04–2.55	0.041–0.100	4.53	0.18	130	427	20.3	Wave propagation recovery
8-0131	TiB ₂	8.9	0.35	0.92–3.0	0.036–0.12	4.05	0.16	133	436	1.32	Wave propagation recovery

The time scale starts with the arrival of the shear wave to the anvil-free surface. Source: Ref 18, 19

In the case of the wave propagation pressure-shear recovery configuration, round and square-shaped TiB₂ plate specimens were used. The longitudinal and shear waves recorded in the case of the square-shaped TiB₂ specimen are shown in Fig. 10(a) and 10(b), respectively. The velocity profile in the first microsecond is shown in solid lines, while the remaining part of the signal is shown in dashed lines. Figure 10(a) shows the normal velocity rises to a value predicted by one-dimensional elastic wave theory. After approximately 200 ns, the longitudinal particle velocity progressively decays and then rises again at approximately 500 ns. This longitudinal velocity history is very close to the one-dimensional elastic wave propagation prediction if the effect of spherical waves emanating from the star-shaped flyer corners is taken into account (Ref 13). Another source of stress decay is the presence of a thin polymer layer in the multiplate flyer. As previously discussed, longitudinal stress decay occurs until a homogeneous deformation state is reached in the polymer film. The transverse particle velocity shown in Fig. 10(b) also presents clear features. Upon wave arrival to the back surface of the momentum-trap plate, an in-plane velocity of about 10 m/s (33 ft/s) is measured interferometrically. After shear wave arrival, according to the *t-X* diagram discussed previously, the transverse velocity rises to a maximum of 38 m/s (125 ft/s). This value is below the shear wave velocity predicted by one-dimensional wave propagation theory. Hence, the material clearly exhibits an inelastic behavior in shear. At approximately 800 ns, the transverse velocity decays progressively.

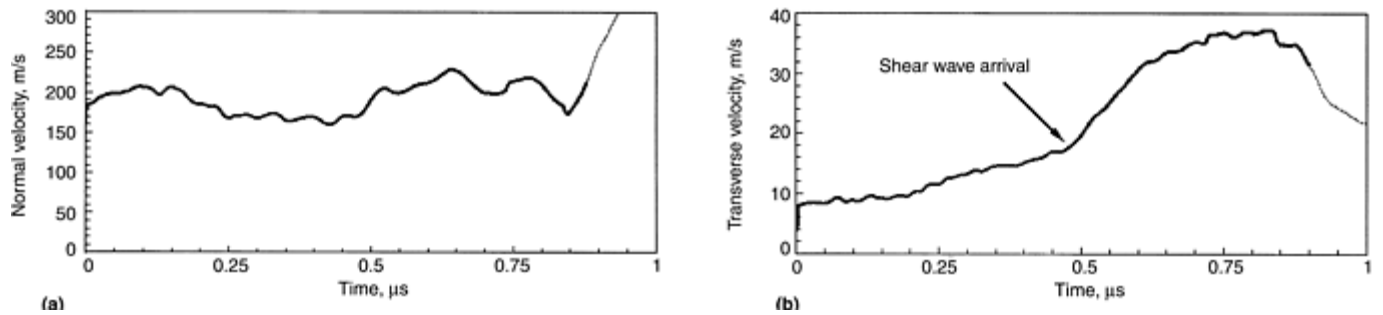

Fig. 10 Velocity histories from a pressure-shear wave propagation experiment (shot No. 8-0131 in Table 4). (a) Normal velocity history. The time scale starts with the arrival of the longitudinal wave to the momentum-trap-free surface. (b) Transverse velocity history. The time scale starts with the arrival of the shear wave to the momentum-trap-free surface. Source: Ref 19

Understanding these complex velocity histories requires complete three-dimensional simulations of the compression-shear experiment including damage and tilt effects. In this experiment, the steel plates are fully recovered. In contrast to the shrink-fitted specimen, the ceramic specimen is fragmented with varying fragment sizes (Fig. 11). The larger fragment is several millimeters in size, but its location in the square plate could not be identified unambiguously. In this case, the star-shaped flyer also is fragmented in the central region. In addition, long cracks are observed running parallel to the edges. Severe indentation is observed in the second flyer plate, although its hardness was measured to be 55 HRC. In this configuration, the momentum-trap plate remains intact with no cracks observable to the naked eye. Additional details can be found in Ref 18 and 19.

Low-Velocity Impact Testing

Pressure-Shear Friction Experiments

This technique was originally introduced by Prakash and Clifton (Ref 66). Its main objective was to investigate time-resolved friction at slipping speeds (5 to 30 m/s, or 16 to 98 ft/s) and pressures (1 to 3 GPa, or 145 to 435 ksi) typical of high-speed machining processes. As discussed in Ref 66, the technique can be easily interpreted within the one-dimensional wave propagation theory. By using characteristic equations it can be shown that the shear and normal stresses at the sliding interface are given by:

$$\tau(t) = 0.5(\rho c_2)_t v_{fs}(t)$$

$$\sigma(t) = 0.5(\rho c_1)_t u_{fs}(t)$$

in which $(\rho)_t$ is the target material density, $(c_1)_t$ and $(c_2)_t$ are the longitudinal and shear wave velocities of the target material, and v_{fs} and u_{fs} are the shear and longitudinal free-surface velocities interferometrically measured. Furthermore, the slipping velocity is given by:

$$V_{\text{slip}} = V \sin \theta - \left[\frac{(\rho c_2)_t + (\rho c_2)_f}{2(\rho c_2)_f} \right] v_{fs}$$

The friction coefficient is obtained by the ratio $\tau(t)/\sigma(t)$. More details about the derivation of these formulas can be found in Ref 67.

The pressure-shear friction experimental technique discussed in this section is an extension of the technique introduced by Prakash and Clifton (Ref 66) in the sense that the experiment is designed for specimen recovery. Here, the specimen is the interface formed after impact by the flyer and target plates rather than the thin specimen shown in Fig. 6. Certainly, a coating may be deposited on the flyer and/or the target plates to examine its frictional properties under pressure and sliding velocities typical of manufacturing processes or ballistic penetration events. The preparation of the plates, assembly of the target, and alignment follow the procedures outlined in the section ‘‘Specimen Preparation and Alignment’’ in this article.

In an experiment reported in Ref 52, 4340 steel tribopair was used. Typical VSDI signals obtained in these experiments are shown in Fig. 12(a) and (b). In Fig. 12(a), the normal free-surface velocity history is plotted together with the Θ VSDI amplitude corrected signal. Upon arrival of the longitudinal wave to the target-free surface, the normal velocity exhibits an increase in velocity to a level of approximately 80 m/s (260 ft/s) followed by a reduction and increase in velocity due to wave reverberations in the thin polymer layer used in the multiplate flyer. A few bumps are observed in the first 900 ns of the normal velocity history. These variations in normal velocity are likely the result of the low signal-to-noise ratio in the early part of the record (Fig. 12a). They are also due in part to errors in data reduction arising from the insensitivity of the displacement interferometer at the peaks and valleys of the trace (Ref 7). Experience suggests that signals with higher frequencies are less sensitive to errors caused by signal noise. The noise level can be observed in the part of the record preceding the longitudinal wave arrival. In later experiments, the angle θ used in the Θ VSDI has been increased with good results. An approximately constant velocity of 115 m/s (377 ft/s) is monitored in the next 1.8 μ s, which is in agreement with the elastic prediction. It should be noted that this normal velocity would lead to a frequency of 450 MHz in an NDI, while in the VSDI system, a much smaller frequency is recorded.

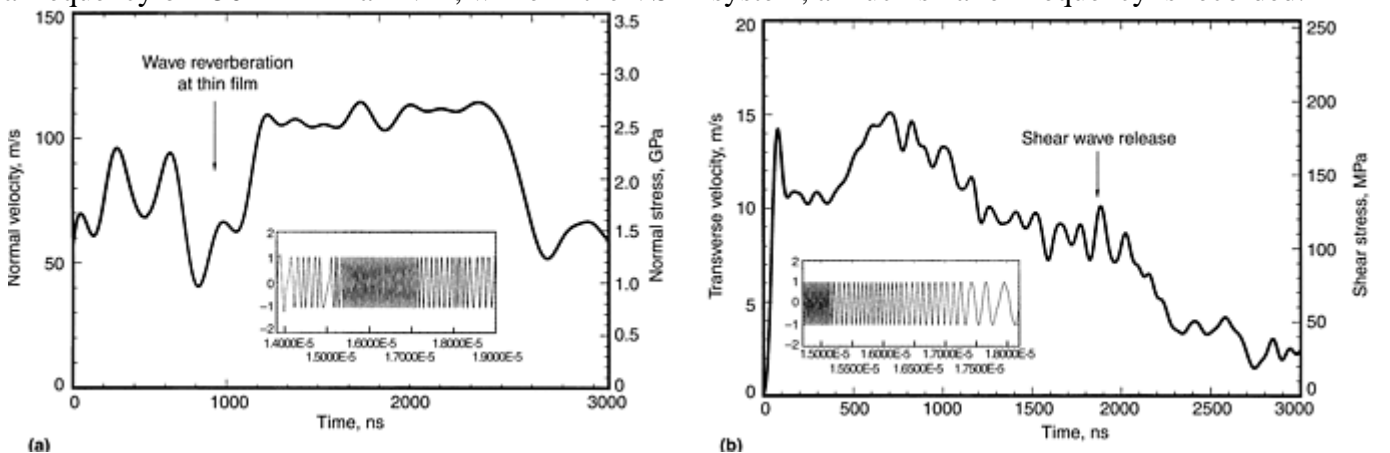

Fig. 12 Particle velocity-time profiles for a dynamic friction recovery experiment. (a) Normal profile; impact velocity, 125 m/s (410 ft/s). The inset shows the Θ VSDI trace after amplitude correction. (b) Transverse profile; impact shear velocity, 38.62 m/s (126.7 ft/s). The inset shows the TDI trace after amplitude correction. Source: Ref 52

In Fig. 12(b) the transverse velocity history and the TDI amplitude corrected signal are shown. A transverse velocity well below the impact shear velocity is measured, indicating interface sliding. Small fluctuations in the transverse velocity are due in part to errors in data reduction arising from the insensitivity of the TDI at the peaks and valleys of the trace (Ref 7). An in-plane wave release is observed at approximately 2 μ s. This wave release is in agreement with the wave release predicted by one-dimensional elastic wave theory. It should be noted that the reduction in in-plane motion is progressive. A residual transverse velocity of 5 m/s (16 ft/s) is recorded, likely due to the shear resistance of the thin polymer film used in the multiplate flyer. Modeling of the experiment, including the frictional behavior of the steel interface and the nonlinear behavior of the polymer thin film, is required to fully interpret the transverse velocity history. Further evidence on the shear wave duration can be observed in Fig. 13 in which an optical micrograph shows sliding marks, approximately 50 μ m in length. From the transverse velocity history, an average sliding velocity of 26 m/s (85 ft/s) is computed. This velocity during 2 μ s leads to a sliding length of 52 μ m, which correlates very well with the sliding marks observed on the micrographs.

Fig. 13 Optical micrograph of impact surface from recovered flyer plate. Sliding marks approximately 50 μ m in length are observed. Source: Ref 52

Prakash and Clifton (Ref 66) and Prakash (Ref 67) reported dynamic friction coefficients for various tribopairs, namely, WC/4340 steel and WC/Ti-6Al-4V. This work was later extended by Rajagopalan et al. (Ref 68) concerning the estimate of temperature histories in the two plates. Pressure-shear friction experiments on preheated target plates were conducted by Frutsky and Clifton (Ref 69). In their work, the friction phenomenon is investigated at high temperatures. Additional insight into the dynamic friction experimental technique can be found in these references.

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

High-Temperature Plate Impact Testing

Understanding materials response at high temperatures and high strain rates is essential to the development of constitutive models describing dynamic failure of advanced materials. Such models are of crucial importance to many applications, for example, crack arrest in engineering structures, failure of turbine engine blades, foreign object impact on satellites, automotive crashworthiness, and military applications such as projectile deformation and armor penetration. Current understanding of basic properties such as plastic flow and dynamic fracture strength in the high-temperature and high-strain-rate regime is very limited. This is due to the scarcity of experimental studies with the needed spatial and temporal resolution to identify damage and failure mechanisms.

It has been shown that high strain rates increase the yield stress in metals (Ref 70, 71, 72, and 73), whereas it is generally accepted that a rise in temperature tends to reduce the resistance to flow by lowering activation barriers associated with the atomic mechanisms of deformation (Ref 74, 75, 76, and 77). When a metallic material is subjected to dynamic and high-temperature loading, a competition process between work hardening (resulting from the production, motion, and interaction of dislocations and other defects) and thermal softening occurs. Extensive research on the stress-strain temperature-dependent behavior in many body-centered cubic and face-centered cubic metals has been carried out (Ref 78, 79, 80, and 81). These results show that temperature has a much greater effect on material strength than strain rate if the deformation is performed under both high-strain-rate and high-temperature conditions.

Even though inelastic mechanisms at high strain rates are not completely understood, researchers agree on the definition of the Hugoniot elastic limit (HEL) as the axial stress, under one-dimensional strain, leading to the onset of material inelasticity. Hence, the evolution of the HEL or its equivalent, the dynamic yield stress, with temperature can be identified by means of normal impact high-temperature experiments. Frutschy and Clifton (Ref 42) carried out pioneer work on the temperature and rate dependence of the dynamic yield stress in oxygen-free high-conductivity copper. Instead of the normal impact experiment described, they performed pressure-shear high-temperature experiments.

Simultaneous nucleation, growth, and coalescence of microvoids or microcracks govern the spall process in advanced materials. Thermal energy plays an important role in the deformation mechanisms leading to strain inhomogeneities that drive the failure process. Limited experimental work exists to define the role of thermal

activation on spall behavior of materials. Recently, studies from Kanel et al. (Ref 82) and Golubev and Sobolev (Ref 83) on aluminum and magnesium have been published. It has been found that spall strength drops with temperature, but no further investigations have been carried out to establish the role of the microstructure in the spallation process.

This section describes the experimental technique developed for shock impact testing at high temperature and reports the variation of HEL and spallation with temperature in Ti-6Al-4V. Microstructural analyses that provide insight into the deformation mechanisms of high-temperature-shocked materials are reported in Ref 44 and 84.

Wave Propagation Analysis for HEL and Spallation Identification. The Dynamic Inelasticity Laboratory described in the section “Plate Impact Facility” in this article possesses the instrumentation to perform planar impact experiments at different temperatures. The setup is similar to the one developed by Frutsky and Clifton (Ref 42, 43) for pressure-shear impact experiments.

The selected experimental configuration is a symmetric planar impact or spall configuration (Fig. 14a). The elastic wave fronts and their interaction can be understood by examining the Lagrangian (t - X) diagram shown in Fig. 14(b). At impact, plane compression waves are produced in both the flyer and the specimen (state 1). Reflection from the foam-flyer interface unloads almost completely the compressive wave, resulting in a compressive pulse duration equal to the round-trip travel time through the flyer thickness. When the compressive pulse reaches the rear surface of the specimen, a reflected wave is generated. This wave unloads the compressive pulse (state 2). Tensile stresses are generated when the two unloading waves, one from the flyer and the other from the specimen back surface, meet in the central part of the specimen (state 3). By the time this pulse reaches the flyer-specimen interface, separation takes place and the pulse reflection causes further compressive stresses (state 4).

Fig. 14 High-temperature spall experiments. (a) Impact configuration. (b) Lagrangian t - X diagram of spall configuration. Source: Ref 44

For the experiments reported in this subsection, the thickness of the targets was close to 8 mm (0.3 in.) for all specimens with a corresponding half thickness for the flyers. Hence, the spall plane was located near the middle of the target plate. The impact velocity range was selected such that the lowest velocity was enough to induce dynamic yield in Ti-6Al-4V (about 900 MPa, or 130 ksi, according to Ref 85), whereas the highest velocity would induce spallation.

Experimental Procedure. The experimental procedure follows the technique discussed in the section “Specimen Preparation and Alignment.” Something unique to the high-temperature target setup is the assembly of the target plate to the target holder. The Ti-6Al-4V sample is placed hand tight inside a graphite susceptor and glued using high-temperature epoxy. The two pieces together are slipped into a ceramic-foam sleeve that fits inside the coil shown in Fig. 2 and 3. The sleeve is firmly attached by high-temperature epoxy and four ceramic pins to the surrounding copper coil.

The induction heating process generates a temperature gradient in the sample. In fact, the induced currents tend to stay on the surface of the specimen, generating more heat at the surface than in the bulk of the material (Ref 86). Titanium alloys have low thermal conductivity; therefore, the heating gradient can be important. A reduction in the coil diameter generates a denser electromagnetic field that can penetrate the shield generated by the induced currents, achieving a more homogeneous heating (Ref 86). A more practical approach is to employ a material with high electrical conductivity and heat thermal capacity to hold the target and minimize transient time. The graphite susceptor shown in Fig. 2 is introduced in the developed setup with this aim. Temperature is measured by a thermocouple attached to the rear face of the specimen, as close as possible to the center point.

The high velocities required in this study generated a strong shock wave within the target chamber upon the exit of the projectile from the launch tube. To protect the high-temperature assembly, an extension was added to the gun barrel. Following aerodynamic considerations, the extension was designed to keep the high-temperature target assembly outside of the gas-flow cone emanating from the end of the gun barrel. An exploded view of the described experimental assembly is presented in Fig. 15. The assembly and alignment of the plates and the measurement of projectile velocity follow the techniques described in the section “Specimen Preparation and Alignment.”

Fig. 15 Exploded view of gas gun extension. Source: Ref 44

A disposable mirror is suspended at a certain distance from the rear face of the specimen to allow the laser beam to monitor the motion of the rear surface of the specimen. The target chamber has a side window to

provide access for the laser beam that is used in the air-delay-leg normal velocity interferometer for any reflecting surface (ADL-VISAR) (Ref 44) depicted in Fig. 16. To avoid overheating of the mirror employed to collect light for the interferometer, a ceramic foam is used to close the ceramic sleeve that contains the target (Fig. 2). A small hole is drilled on the center of the cup, and the laser light is sent in and collected back through it.

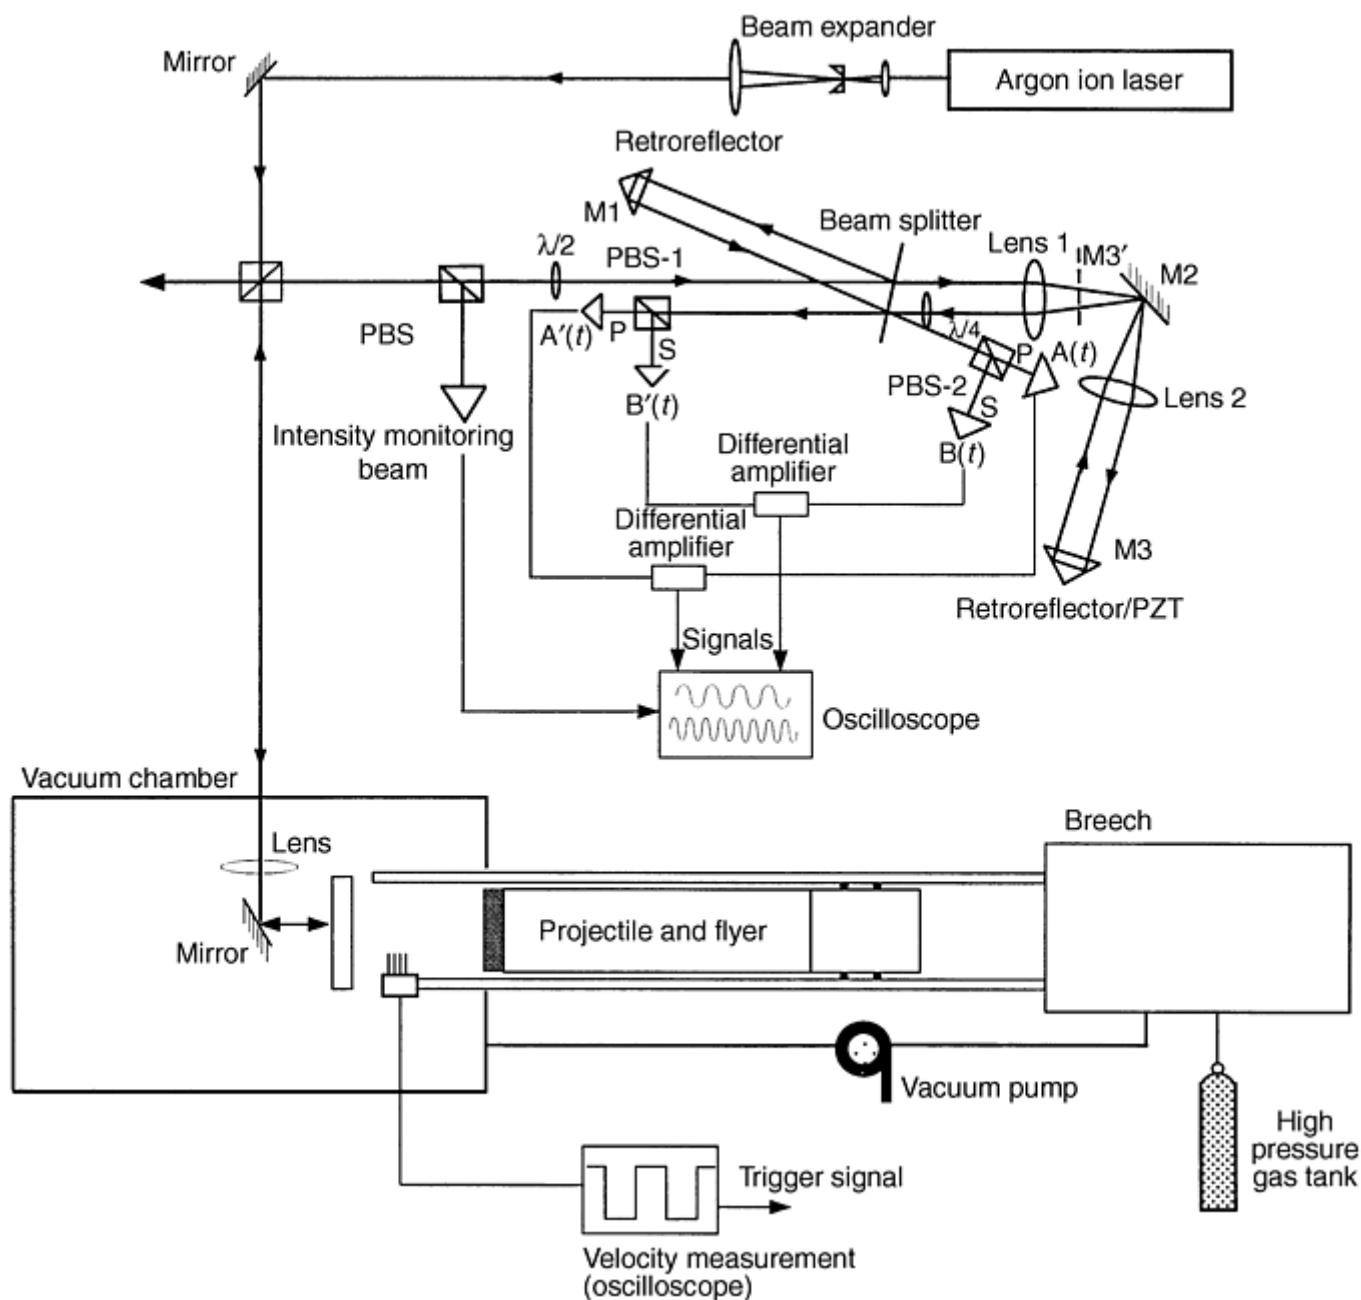

Fig. 16 Schematic of ADL-VISAR interferometer. Source: Ref 87

Tested Material. Details on the hot-rolled commercial grade plates Ti-6Al-4V, its chemical composition, and metallographic examination of the as-received plates can be found in Ref 44. It is interesting to point out the high interstitial oxygen content (0.18%) and grain elongation in the rolling direction. The target and flyer plates were all machined from the as-received plates in such a way that the impact axis was perpendicular to the rolling direction. The hardness was measured to be 35.6 HRC. At room temperature, the longitudinal wave speed, ultrasonically measured, is $c_L = 6232$ m/s (20,446 ft/s), and the material density is 4430 kg/m³; therefore, the acoustic impedance is 27.608 GPa/mm/ μ s.

Experimental Results. A summary of performed high-temperature impact experiments is presented in Tables 5 and 6. A first experiment, 98-0924, was performed to have a reference of the material behavior at room temperature. Its time-velocity history is shown in Fig. 17. As can be observed in this figure, the elastic precursor in this experiment was lost due to the low velocity per fringe (18.75 m/s, or 62 ft/s) employed in the

interferometer. Twelve fringes were added to the fringe count to match the boundary conditions (Ref 49). The velocity jump corresponding to the HEL is 200.5 m/s (657.8 ft/s) in good agreement with the 201 m/s (659 ft/s) reported in Ref 88.

Table 5 Summary of parameters for high-temperature impact experiments

(a) Reported in the literature

Fig. 17 Velocity histories of normal high-temperature impact experiments. Source: Ref 44, 84

The transition between elastic-plastic behavior is clearly captured; there is a sharp elastic unloading followed by a dispersive unloading tail. The dispersion in the unloading tail is due to the severe plastic deformation the material underwent in the loading phase. The reloading pulse that is generated by the reflection at the flyer-specimen interface is greatly reduced with respect to the expected elastic behavior. Even though some hardening is expected due to the passage of the first loading pulse, the hardening must appear as a change in the slope of the second loading pulse instead of the observed attenuation. The attenuation indicates that part of the energy is dissipated in the form of shock-induced damage at the applied stress level. Note that no spall signal is observed in the free-surface velocity record. Hence, the stress-pulse attenuation is indicative of damage initiation without the formation of a spall region within the sample. This was confirmed by scanning electron microscopy (SEM) studies performed on the recovered samples. Microvoids at the α - β interface were observed through the thickness of the target plate. Details can be found in Ref 44.

An interesting feature of experiment 98-0924 is the oscillation of the velocity profile close to the end of the first unloading. Mescheryakov et al. (Ref 89) reported that oscillations in their VISAR signal appeared to indicate a shock-induced phase transformation in Ti-6Al-4V. Their post-test SEM studies performed over samples recovered right after the experiment in a water chamber presented evidence of an ω residual phase in the microstructure. The setup for this experiment did not allow for cooling the samples right after impact, but the similarity with Mescheryakov et al. (Ref 89) in the interferometric records indicates the presence of a shock-induced phase transformation in Ti-6Al-4V. The stress level for the transformation is 2.17 GPa (315 ksi), close to ω -start pressure reported by Vohra et al. (Ref 90) but lower than the phase transition reported by Mescheryako, 2.95 GPa (428 ksi). The direct transformation is not observed because it is overcome by the elastic wave.

A second experiment, 98-1210, performed at 298 °C (568 °F) shows the effect of temperature on damage kinetics at similar stress and strain rate levels. The elastic precursor is also lost in this experiment; several fringes were added to match boundary conditions. A higher plastic deformation expected at high temperature makes the slope of the plastic wave more pronounced, as can be observed in Fig. 17. The smoothness of the velocity profile shows a progressive deformation of the free surface, which is a clear indication of high plastic deformation within the target plate. The velocity jump corresponding to the HEL is lower, 166 m/s (545 ft/s), showing a decrease in the dynamic yield stress with temperature. The so-called precursor decay is also more pronounced due to the increased rate of plastic deformation. In this experiment, the temperature rise was estimated to be 17 °C (31 °F), giving a final temperature of 315 °C (600 °F) well below the β -transus temperature range for Ti-6Al-4V (570–650 °C, or 1060 to 1200 °F). No evidence of shock-induced phase transition appears in this experiment (see first unloading in Fig. 17).

Experiment 99-0602 was carried out at 315 °C (600 °F). This temperature is close to the temperature in experiment 98-1210, but the impact velocity is higher. For this experiment the interferometer was modified to a higher velocity per fringe, 95.1 m/s (312 ft/s). Even though a shorter delay leg was used, part of the elastic precursor overcame the recording system, and one fringe needed to be added to match the boundary conditions. According to the velocity profile shown in Fig. 17, the velocity jump corresponding to the HEL coincides with the one in experiment 98-1210 (same temperature). The plastic wave slope is higher, indicating a stronger hardening due to the higher inelastic strain rate. The unloading is dispersive and shows again the reverse-phase transformation. Between the first and second loading pulse, a clear spall signal appears. Spallation occurs at a lower stress than the one reported by other investigators (e.g., Ref 91). Some researchers attribute this to an incomplete fracture at the spall plane. There are several approaches to calculate spall strength. For consistency with results reported in the literature, for other metallic materials, the approach stated by Kanel et al. (Ref 82) is employed. Such an approach establishes the spall strength for a symmetric impact, according to $0.5 \rho C_0 \Delta V$, where ΔV is the velocity drop from the peak velocity to the spall signal. According to this equation, experiment 99-0602 presents spall strength of 4.47 GPa (648 ksi). This value represents a reduction of ~10% from the value of 5.1 GPa (740 ksi) at room temperature, reported in Ref 88 and 91. The reduction in spall strength with temperature was previously reported by Kanel et al. (Ref 82) in magnesium and aluminum. Oscillations in the free-surface velocity profile during unloading again indicate the phase transition $\omega \rightarrow \alpha$. This phase transition happens at a compressive stress level of approximately 2.25 GPa (434 ksi), slightly higher than the phase transition at room temperature. The temperature rise was estimated to be 40 °C (72 °F), giving a final temperature of 351 °C (664 °F). As in the previous case, the final temperature is well below the β -transus; hence, allotropic transformations were not likely to occur.

To further explore the spall behavior, experiment 99-1008 was carried out at a temperature close to the limit of applicability of Ti-6Al-4V, that is, ~500 °C (930 °F). The impact velocity was set to about 590 m/s (1935 ft/s) to ensure a clear spallation process. The velocity per fringe in the interferometer was 97.2 m/s (318.9 ft/s), resulting in a partial loss of the elastic precursor as in experiment 98-1210. The free-surface velocity profile for this last experiment is shown in Fig. 17. A consistent reduction of the HEL with temperature can be observed. The plastic wave slope is steeper than in the other discussed experiments, indicating an even stronger hardening. A Hugoniot state is clearly achieved followed by a dispersive unloading pulse as in previous experiments. The overall wave profile is smooth, indicating a progressive deformation when the wave travels through the target. Between the expected first and second loading pulses, a fast-rising pull-back signal and clear spallation signal appear, which indicates the formation of a well-defined spall fracture plane. The higher rate of velocity increase during spallation is evidence that the fracture process is more violent than the one in experiment 99-0602. In fact, the recovered target was split into two pieces (Ref 44). Using the approach developed by Kanel et al. (Ref 82), the spall strength was estimated at 4.30 GPa (624 ksi). This indicates a reduction of 5% in the spall strength with an increment of ~200 °C (360 °F). The decrease in spall strength is in agreement with the results reported in Ref 82 for magnesium and aluminum. The inverse shock phase transformation $\alpha - \omega$ was not present in this experiment. The spall signal rings at a higher stress than the level corresponding to the inverse shock transformation previously observed. Therefore, it is not possible to conclude whether the increase of the peak shock stress can trigger the inverse shock transformation despite the increase in temperature. The temperature rise for this experiment was estimated to be 81 °C (146 °F), resulting in a final temperature of 593 °C (1100 °F). The final value is close to the β -transus temperature. Thermomechanical properties change with allotropic transformations in Ti-6Al-4V (Ref 92).

A comprehensive microscopy study on the failure and damage modes of Ti-6Al-4V as a function of temperature can be found in Ref 44 and 84.

Low-Velocity Impact Testing

Horacio Dante Espinosa, Northwestern University, Sia Nemat-Nasser, University of California, San Diego

Impact Techniques with In-Material Stress and Velocity Measurements

Several research efforts have been made for in-material measurements of longitudinal and shear waves in dynamically loaded solids. Successful experiments where velocity histories have been obtained at interior surfaces by inserting metallic gages in a magnetic field and measuring the current generated by their motion have been reported (Ref 93, 94, and 95); these gages are called electromagnetic particle velocity (EMV) gages. This technique can be applied only to nonmetallic materials.

Another technique developed for in-material measurements employs manganin gages placed between the specimen and a back plate to measure the time history of the longitudinal stress, or by placing a manganin gage at an interface made in the direction of wave propagation to measure lateral stresses (Ref 96, 97). In this

configuration, the dynamic shear resistance of the material can be obtained by simultaneously measuring the axial and lateral stresses.

An alternative technique for the in-material measurement of the dynamic shear resistance of materials is the use of oblique impact with the specimen backed by a window plate (Ref 56). In this technique, longitudinal and shear wave motions are recorded by a combined normal displacement interferometer (NDI) or a normal velocity interferometer (NVI) (Ref 48) and a transverse displacement interferometer (TDI) (Ref 50). Alternatively, the VSDI interferometer previously discussed can be used. The velocity measurements are accomplished by manufacturing a high-pitch diffraction grating at the specimen-window interface (Ref 56).

In-Material Stress Measurements with Embedded Piezoresistant Gages. Many materials exhibit a change in electrical resistivity as a function of both pressure and temperature. Manganin, an alloy with 24 wt% Cu, 12 wt% Mn, and 4 wt% Ni, was first used as a pressure transducer in a hydrostatic apparatus by Bridgman in 1911 (Ref 98). Manganin is a good pressure transducer because it is much more sensitive to pressure than it is to temperature changes. Impact experiments performed by Bernstein and Keough (Ref 99) and DeCarli et al. (Ref 100) showed a linear relationship between axial stress σ_1 , in the direction of wave propagation, and resistance change; namely, $\sigma_1 = \Delta R / kR_0$ in which R_0 is the initial resistance and k is the piezoresistance coefficient. For manganin, DeCarli et al. (Ref 100) found $k = 2.5 \times 10^{-2} \text{ GPa}^{-1}$. The value of this coefficient is a function of the gage alloy composition; therefore, a calibration is required. Manganin gages are well suited for stress measurements above 4 GPa (580 ksi) and up to 100 GPa (15×10^6 psi). At lower stresses, carbon and ytterbium have a higher-pressure sensitivity (Ref 101), resulting in larger resistance changes and, hence, more accurate measurements. Carbon gages can be accurately used up to pressures of 2 GPa (290 ksi), while ytterbium can be used up to pressures of 4 GPa (580 ksi).

In plate impact experiments, the gage element is usually embedded between plates to measure either longitudinal or transverse axial stresses. A schematic of the experimental configuration is shown in Fig. 18. If the gage is placed between conductive materials, it needs to be electrically insulated by packaging the gage using polyester film, mica, or polytetrafluoroethylene. Another reason for using a gage package is to provide additional protection in the case of brittle materials undergoing fracture.

Fig. 18 Manganin gage experiment configuration. Gages G1 and G2 record transverse stress at two locations. Gage G3 records the longitudinal stress at the specimen back plate interface. Source: Ref 87

Through the use of metallic leads, the gage is connected to a power supply that energizes the gage prior to the test. The power supply comprises a capacitor that is charged to a selected voltage and discharged upon command into a bridge network by the action of a timer and a power transistor. The current pulse that is delivered to the bridge is quasi-rectangular with duration between 100 and 800 μs . The bridge network is

basically a Wheatstone bridge that is externally completed by the gage. The gage, which is nominally $50\ \Omega$, is connected to the bridge with a $50\ \Omega$ coaxial cable. The reason for using a pulse excitation of the bridge, rather than a continuous excitation, is that such an approach permits high outputs without the need for signal amplification and avoids excessive Joule heating effects that can result in gage failure. The bridge output is connected to an oscilloscope for the recording of voltage changes resulting from changes in resistance. The relation between voltage and resistance change is obtained by means of a calibration with a variable resistor.

A concern with this technique is the perturbation of the one dimensionality of the wave propagation due to the presence of a thin layer, perpendicular to the wave front, filled with a material having a different impedance and mechanical response. Calculations by Wong and Gupta (Ref 102) show that the inelastic response of the material being studied affects the gage calibration. In 1994, Rosenberg and Brar (Ref 103) reported that in the elastic range of the gage material, its resistance change is a function of the specimen elastic moduli. In a general sense, this is a disadvantage in the lateral stress-gage concept. Nonetheless, their analysis shows that in the plastic range of the lateral gage response, a single calibration curve for all specimen materials exists. These findings provide a methodology for the appropriate interpretation of lateral gage signals and increase the reliability of the lateral stress-measuring technique.

Example: Identification of Failure Waves in Glass. In-material axial and transverse stress measurements have been successfully used in the interpretation of so-called failure waves in glass (Ref 24, 25, and 45). By using the configuration shown in Fig. 18 with the longitudinal gage backed by a PMMA plate, the dynamic tensile strength of the material was determined (Ref 45). In these experiments, manganin gages were used. Soda-lime and aluminosilicate glass plates were tested. The density and longitudinal wave velocity for the soda-lime glass were $2.5\ \text{g/cm}^3$ and $5.84\ \text{mm}/\mu\text{s}$, respectively. The aluminosilicate glass properties were density = $2.64\ \text{g/cm}^3$, Young's modulus = $86\ \text{GPa}$ ($12 \times 10^6\ \text{psi}$), and Poisson's ratio = 0.24.

By appropriate selection of the flyer-plate thickness, the plane at which tension occurs for the first time within the sample was located close to the impact surface or close to the specimen-PMMA interface. In experiment 7-0889, a 5.7 mm (0.22 in.) thick soda-lime glass target was impacted with a 3.9 mm (0.15 in.) aluminum flyer at a velocity of 906 m/s (2972 ft/s). The manganin gage profile is shown in Fig. 19. The spall plane in this experiment happened to be behind the failure wave. The profile shows the arrival of the compressive wave with a duration of approximately $1.5\ \mu\text{s}$, followed by a release to a stress of about 3 GPa (435 ksi) and a subsequent increase to a constant stress level of 3.4 GPa (493 ksi). The stress increase after release is the result of reflection of the tensile wave from material that is being damaged under dynamic tension and represents the dynamic tensile strength of the material (spall strength). From this trace, it was concluded that soda-lime glass shocked to a stress of 7.5 GPa (1088 ksi) has a spall strength of about 0.4 GPa (58 ksi) behind the so-called failure wave. The experiment was repeated with a 2.4 mm (0.09 in.) thick aluminum flyer (7-1533); the result was complete release from the back of the aluminum impactor (Fig. 19). A pull-back signal was observed after approximately $0.45\ \mu\text{s}$ with a rise in stress of about 2.6 GPa (377 ksi). It should be noted that the spall plane in this experiment was in front of the failure wave. These two experiments clearly show that the spall strength of glass depends on the location of the spall plane with respect to the propagating failure wave. For soda-lime glass, a dynamic tensile strength of 2.6 and 0.4 GPa (377 and 58 ksi) was measured with manganin gages in front of and behind the failure wave, respectively. Dandekar and Beaulieu (Ref 104) obtained similar results using a VISAR.

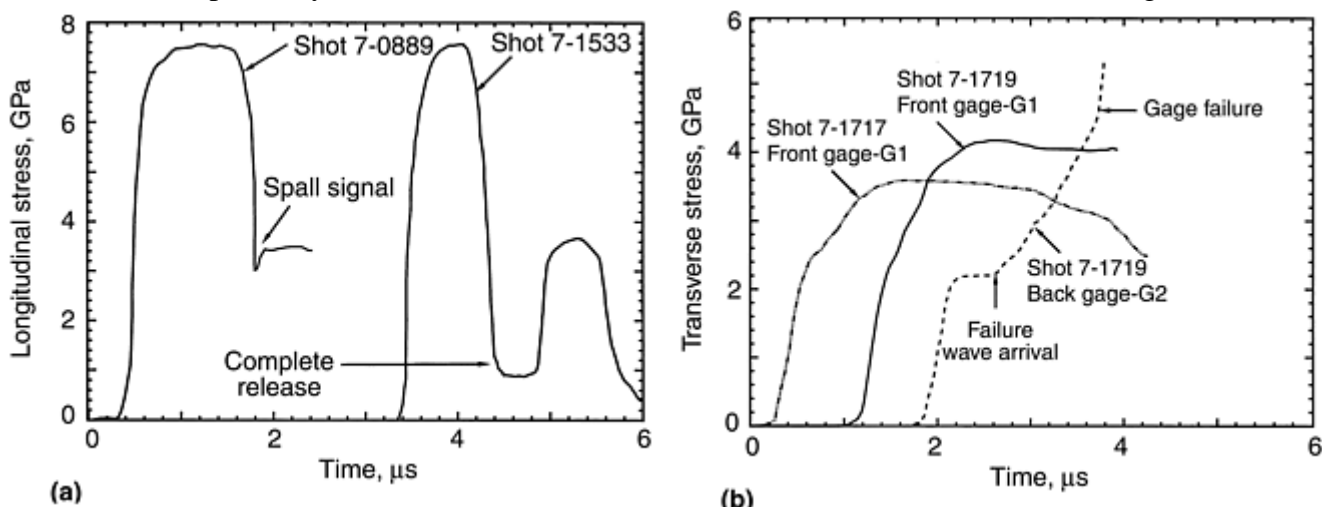

Fig. 19 In-material gage profiles from spall experiments. (a) Longitudinal profiles. Gage profile on the left shows a strong reduction in spall strength (measurement behind the so-called failure wave front). (b) Transverse profiles showing transverse stress histories at two locations within the glass specimen. Source: Ref 87

Additional features of the failure-wave phenomenon were obtained from transverse gage experiments performed on soda-lime and aluminosilicate glasses (Ref 24). In these experiments, one or two narrow 2 mm (0.08 in.) wide manganin gages (type C-8801113-B) were embedded in the glass target plates in the direction transverse to the shock direction as shown in Fig. 18. A thick back plate of the same glass was used in the target assembly. Aluminum or glass impactor plates were used to induce failure waves. The transverse stress, σ_2 , was obtained from the transverse gage record. Figure 19 shows measured transverse gage profile at two locations (shot 7-1719) in the aluminosilicate glass. The two-wave structure that results from the failure wave following the longitudinal elastic wave can clearly be seen. The first gage, at the impact surface, shows an increase in lateral stress to the value predicted by one-dimensional wave theory, 2.2 GPa (319 ksi) in Fig. 19, immediately followed by a continuous increase to a stress level of 4.2 GPa (609 ksi). The second gage, at 3 mm (0.12 in.) from the impact surface, initially measures a constant lateral stress of 2.2 GPa (319 ksi) followed by an increase in stress level on arrival and passage of the failure wave. It should be noted that the initial slope was measured by lateral gage G2. This can only be the case if the failure wave does not have an incubation time so the increase in lateral stress with the sweeping of the failure wave through the gage increases the initial slope in gage G1. By contrast, gage G2 sees the arrival of the failure wave about 700 ns after the arrival of the elastic wave (see step at 2.2 GPa). Furthermore, these traces also confirm that the failure wave initiates at the impact surface and propagates to the interior of the sample. This interpretation is in agreement with the impossibility of monitoring impact surface velocity with a VISAR system (Ref 104) when failure waves are present. The impact parameters used in these experiments are summarized in Table 7. Measured profiles of manganin gages were converted to stress-time profiles following the calibrations of longitudinal and transverse manganin gages under shock loading given in Ref 105 and 103, respectively.

Table 7 Summary of parameters and results for manganin gage experiments

Shot No.	Material	Thickness of aluminum impactor		Target thickness		Impact velocity		Normal stress	
		mm	in.	mm	in.	m/s	ft/s	GPa	ksi
7-0889	Soda-lime glass	3.9	0.15	5.7	0.22	906	2972	7.5	1088
7-1533	Soda-lime glass	2.4	0.09	5.7	0.22	917	3009	7.6	1102
7-1717	Aluminosilicate glass	12.7	0.50	19.4	0.76	770	2526	6.1	885
7-1719	Aluminosilicate glass	14.5	0.57	19.4	0.76	878	2881	6.97	1011

Low-Velocity Impact Testing

Low-Velocity Penetration Experiments

In many ballistic impact tests, often only the incident and residual velocities are recorded. To understand how targets defeat projectiles, the complete velocity history of the projectile must be recorded. Moreover, multiple instrumentation systems are highly desirable because they provide enough measurements for the identification of failure through modeling and analysis. In this section, a new experimental configuration that can record tail-velocity histories of penetrators and target back surface out-of-plane motion in penetration experiments is presented. The technique provides multiple real-time diagnostics that can be used in model development. Laser interferometry is used to measure the surface motion of both projectile tail and target plate with nanosecond resolution. The investigation of penetration in woven glass fiber reinforced polyester (GRP) composite plates also is discussed.

Experimental Setup. Penetration experiments were conducted with a 75 mm (3 in.) light gas gun with keyway. The experiments were designed to avoid complete destruction of the target plate so that microscopy studies could be performed in the samples. Impactor tail velocity and back surface target plate velocity histories were successfully measured by using the setups shown in Fig. 20(a) and (b), direct and reverse penetration experiments, respectively.

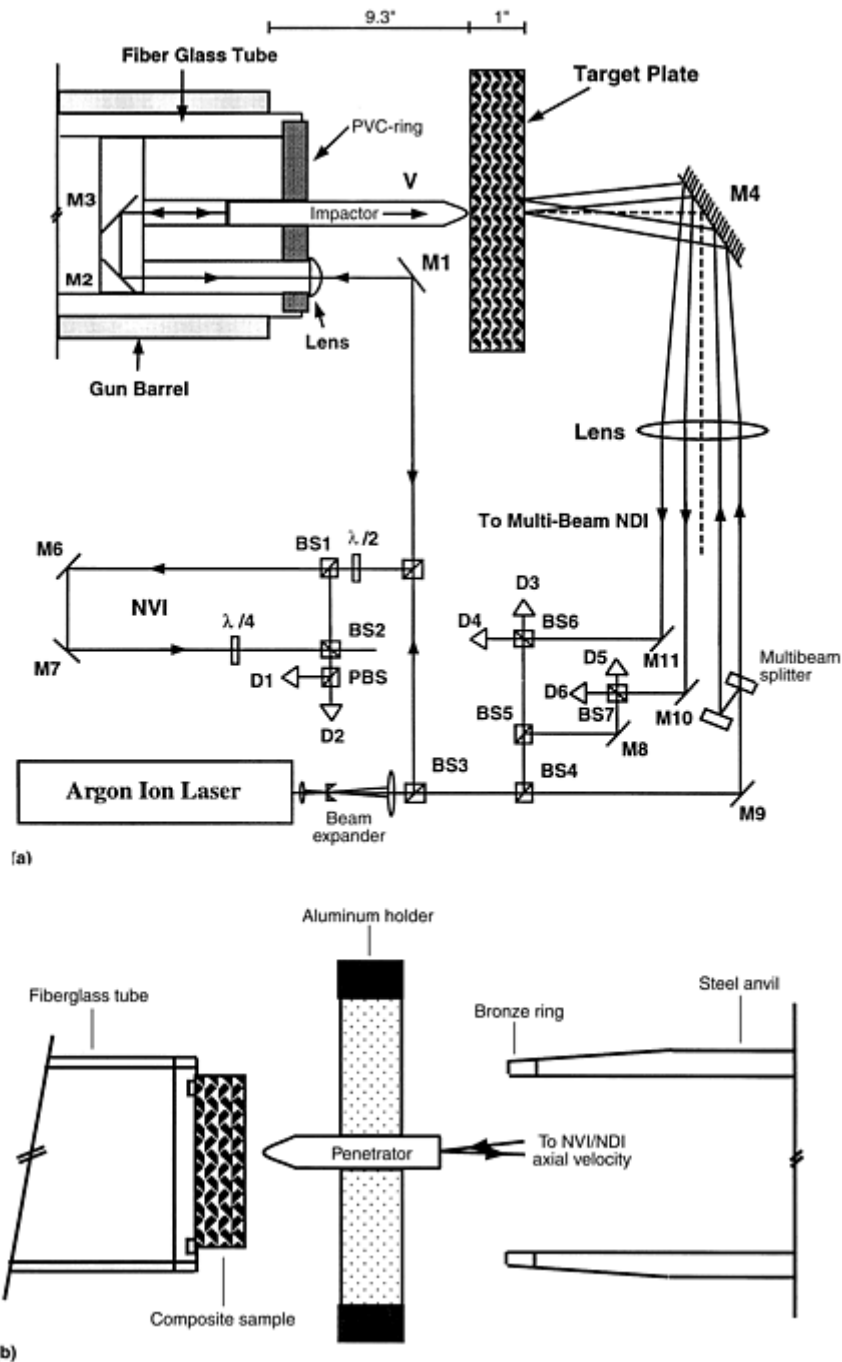

Fig. 20 Low-velocity penetration experiments. (a) Setup for direct penetration experiment (rod-on-plate). (b) Setup for reverse penetration experiment (plate-on-rod). Source: Ref 107

In the case of direct penetration experiments (Fig. 20a), the projectile holder was designed such that a normal velocity interferometer could be obtained on a laser beam reflected from the back surface of the projectile. In addition to this measurement, a multipoint interferometer was used to continuously record the motion of the target back surface. It should be noted that the NVI system used in this configuration has variable sensitivity so its resolution can be adjusted to capture initiation and evolution of failure. The NVI records contain information on interply delamination, fiber breakage and kinking, and matrix inelasticity as these events start and progress in time.

A cylindrical target plate 100 mm (4 in.) in diameter and 25 mm (1 in.) thick was positioned in a target holder with alignment capabilities. The target was oriented so that impact at normal incidence was obtained. A steel penetrator with a 30° conical tip was mounted in a fiberglass tube by means of a PVC holder. This holder contained two mirrors and a plano-convex lens along the laser beam path. The focal distance of the plano-convex lens was selected to focus the beam at the penetrator back surface. Penetrator tail velocities were measured by means of the normal velocity interferometer (NVI), with signals in quadrature (Fig. 20a). The

interferometer beams were aligned while the penetrator was at the end of the gun barrel (i.e., on conditions similar to the conditions occurring at the time of impact). The alignment consisted of adjusting mirrors M1, M2, and M3 such that the laser beam, reflected from the penetrator tail, coincided with the incident laser beam. Through motion of the fiberglass tube along the gun barrel, it was observed that the present arrangement preserves beam alignment independently of the position of the penetrator in the proximity of the target. Therefore, a considerable recording time could be expected before the offset of the interferometer. A few precautions were taken to avoid errors in the measurement. First, the PVC holder was designed such that the penetrator could move freely along a cylindrical cavity (i.e., no interaction between the steel penetrator and PVC holder was allowed and, therefore, true deceleration was recorded). The penetrator was held in place during firing by means of epoxy deposited at the penetrator periphery on the front face of the PVC holder. Second, in order to avoid projectile rotation that could offset the interferometer alignment, a polytetrafluoroethylene key was placed in the middle of the fiberglass tube. Target back surface velocities were measured with a multipoint normal displacement interferometer (NDI). Since woven composites are difficult to polish, the reflectivity of the back surface was enhanced by gluing a 0.025 mm (0.001 in.) mylar sheet, and then a thin layer of aluminum was vapor deposited.

In the case of reverse-penetration experiments (Fig. 20b), composite flyer plates were cut with a diameter of 57 mm (2.25 in.) and a thickness of 25 mm (1 in.). The composite plates were lapped flat using 15 μ m silicon carbide powder slurry. These plates were mounted on a fiberglass tube by means of a backing aluminum plate. The penetrator, a steel rod with a 30° conical tip, was mounted on a target holder and aligned for impact at normal incidence. In these experiments, the penetrator back-surface velocity was simultaneously measured by means of NDI and NVI systems. A steel anvil was used to stop the fiberglass tube and allow the recovery of the sample.

Experimental Results: Velocity Measurements. A summary of experiments is given in Table 8. The NVI signals in quadrature were analyzed following the procedure described in Ref 106. The NDI signals were converted to particle velocities according to the procedure described in Ref 52. The impactor velocity during the penetration event, in experiments 5-1122 and 6-1117, is given in Fig. 21. A velocity reduction of approximately 32 m/s (105 ft/s) in shot 5-1122 and about 20 m/s (66 ft/s) in shot 6-1117 are observed after 100 μ s of the recorded impact. A progressive decrease in velocity is observed in the first 30 μ s followed by an almost constant velocity and a sudden velocity increase of 7 m/s (23 ft/s) at approximately 60 μ s. Further reduction in velocity is measured in the next 40 μ s. In the case of shot 6-1117, the tail velocity shows a profile with features similar to the one recorded in shot 5-1122. These velocity histories present a structure that should be indicative of the contact forces that develop between penetrator and target, as well as the effect of damage in the penetration resistance of GRP target plates. It should be noted that a projectile traveling at 200 m/s (656 ft/s) moves a distance of 20 mm (0.8 in.) in 100 μ s.

Table 8 Summary of parameters for rod-on-plate and plate-on-rod impact experiments

Experiment No.	Impact velocity		Specimen diameter		Type of experiment
	m/s	ft/s	mm	in.	
5-1122	200 ^(a)	656 ^(a)	102	4	Direct penetration
6-0308	200 ^(a)	656 ^(a)	57	2.25	Reverse penetration
6-0314	500 ^(a)	1640 ^(a)	57	2.25	Reverse penetration
6-0531	181.6	596	102	4	Direct penetration
6-1117	180.6	593	102	4	Direct penetration

Note: For all experiments, specimen thickness was 24 mm (1 in.); impactor dimensions were 14 mm (0.56 in.) diam; 30° conical, 64 mm (2.5 in.) length.

(a) Velocity estimated from gas gun calibration curve based on breech pressure.

Source: Ref 107

Fig. 21 Penetrator tail velocity histories recorded with normal velocity interferometer (NVI) using the direct penetration configuration. V , velocity. Source: Ref 107

Back-surface velocity histories at the specimen center measured by means of a normal displacement interferometer (NDI) are shown in Fig. 22 for shot 5-1122, 6-0531, and 6-1117. A velocity increase to a value of 22 m/s (72 ft/s), followed by a decrease and increase to a maximum velocity of about 50 m/s (164 ft/s), after 20 μ s, is measured in shot 5-1122. The trace from shot 6-0531 and 6-1117 shows features similar to the features present in the velocity history recorded in experiment 5-1122. However, significant differences in amplitude are observed. A maximum particle velocity of 18 m/s (59 ft/s) is observed at about 37.5 μ s. These velocity histories present variations such as small humps with some apparent periodicity. Numerical simulation of the experiments, incorporating the observed failure modes, is required to interpret the various features observed in the velocity traces.

Fig. 22 Back surface normal velocity histories at the center of glass fiber-reinforced epoxy composite target. V , velocity. Source: Ref 107

To confirm the velocities measured in the direct penetration experiment, two reverse penetration experiments were conducted at impact velocities of 200 and 500 m/s (656 and 1640 ft/s), experiments 6-0308 and 6-0314, respectively. Another objective of these experiments was to examine rate effects in the penetration resistance of woven-fiber composites. The interferometrically measured penetrator tail velocities are plotted in Fig. 23. The steel penetrator velocity shows a progressive increase and a decrease to almost zero velocity upon arrival of an unloading wave generated at the penetrator-free surface. The arrival time of approximately 14 μ s coincides with

the round-trip time of the wave through the penetrator nose back to the penetrator tail. This feature is observed in both experiments. A continuous increase in velocity is recorded with velocities of 20 m/s and 32 m/s (66 and 105 ft/s) after 42 μ s, respectively. A maximum velocity of 50 m/s (164 ft/s) is recorded in experiment 6-0314 after 65 μ s. A comparison of the velocity histories in these two experiments clearly reveals that composite failure presents moderate rate sensitivity. Moreover, velocities recorded in experiment 6-0308 appear to confirm the velocity reduction interferometrically recorded in experiment 5-1122 (direct-penetration experiment).

Fig. 23 Penetrator tail velocity histories recorded with normal displacement interferometer (NDI) in reverse penetration configuration. Source: Ref 107

Microscopy studies were performed in recovered samples to assess the amount of delamination and fiber fracture and kinking. The details of this study can be found in Ref 107.

Fracture Toughness and Fracture Mechanics

Introduction

FRACTURE may be defined as the mechanical separation of a solid owing to the application of stress. Fractures of engineering materials are broadly categorized as ductile or brittle, and fracture toughness is related to the amount of energy required to create fracture surfaces. In ideally brittle materials such as glass, the energy required for fracture is simply the intrinsic surface energy of the material, as demonstrated by Griffith (Ref 1). For structural alloys at room temperature, considerably more energy is required for fracture because plastic deformation accompanies the fracture process.

Fracture-mechanics technology has significantly improved the ability to design safe and reliable structures. The application of fracture-mechanics concepts has identified and quantified the primary parameters that affect structural integrity. These parameters include the magnitude and range of the applied stresses; the size, shape orientation, and rate of propagation of the existing crack; and the fracture toughness of the material.

Two categories of fracture mechanics are linear-elastic fracture mechanics (LEFM) and elastic-plastic fracture mechanics (EPFM). Linear-elastic fracture mechanics is used if the crack tip in a body is sharp and there is only a small amount of plastic deformation at or near the crack tip. Some materials that are designed using LEFM concepts are high-strength steels, titanium, and aluminum alloys. Elastic-plastic fracture mechanics is used when the crack tip is not sharp and there is some crack-tip plasticity (blunting). Elastic-plastic fracture mechanics is used to design materials such as lower-strength, higher-toughness steels. Elastic-plastic fracture mechanics is also used in the evaluation of ceramic matrix composites (see the article “Fracture Toughness of Ceramics and Ceramic Matrix Composites” in this Volume).

The LEFM approach to fracture analysis assumes a part or specimen contains a crack or other flaw, the crack is a flat surface in a linear-elastic stress field, and the energy released during rapid crack propagation is a basic material property and is not influenced by part size.

Linear-elastic fracture-mechanics technology is based on an analytical procedure that relates the stress-field magnitude and distribution in the vicinity of a crack tip to the nominal stress applied to the structure: to the size, shape, and orientation of the crack or cracklike imperfection; and to the material properties.

A crack in a loaded part or specimen generates its own stress field ahead of a sharp crack, which can be characterized by a single parameter called stress intensity (K). Relations between the stress-intensity factors and various body configurations; crack sizes, shapes, and orientations; and loading conditions are available in the published literature (e.g., Ref 2).

K represents a single parameter that includes both the effect of the stress applied to a sample and the effect of a crack of given size in the sample. It can have a simple relation to applied stress and crack length, or the relation can involve complex geometry factors for complex loading, various configurations of real structural components, and variations in crack shapes.

Rapid crack propagation is controlled solely by a material constant, called the critical stress-intensity factor (K_c) where crack propagation becomes rapid. The greater the value of K_c , the higher the stress required to produce rapid propagation and the greater the resistance of the material to brittle fracture. The critical stress-intensity factor is determined using relatively simple laboratory specimens.

Figure 1 defines three modes of loading: mode I, opening, or tensile, mode; mode II, sliding, or shear, mode; and mode III, tearing mode. Fracture-mechanics concepts are essentially the same for each mode. However, the great majority of all actual cracking and fracture cases are mode I problems. A crack in the very early stage of development will turn into a direction in which it experiences only mode I loading, unless it is prevented from doing so by geometrical confinement. For this reason, fracture mechanics is generally confined to mode I.

Fig. 1 Modes of loading. Mode I (opening mode): tension stress in the y direction, or perpendicular to crack surfaces. **Mode II (edge-sliding mode):** shear stress in the x direction, or perpendicular to crack tip. **Mode III (tearing mode):** shear stress in z direction, or parallel to crack tip

The nomenclature for K_c is modified to include the loading mode. For example, K_{Ic} is the critical stress-intensity factor or fracture toughness under mode I loading. The vast majority of testing to determine fracture toughness is performed in mode I; therefore, most of the published fracture-toughness values are K_{Ic} .

The stress-intensity factor, K_I , for a crack tip in any body that is subjected to tensile stresses, σ , perpendicular to the plane of the crack (mode I deformation) is given by the relationship:

$$K_I = \sigma \sqrt{\pi a} f(g) \quad (\text{Eq 1})$$

where a is crack length and $f(g)$ is a function that accounts for crack geometry and structural configuration. This general relationship makes it possible to translate laboratory results into practical design information without the need for extensive service experience or correlations.

Fracture Toughness and Fracture Mechanics

Fracture Toughness

Toughness is defined as the ability of a material to absorb energy. It is usually characterized by the area under a stress-strain curve for a smooth (unnotched) tension specimen loaded slowly to fracture. Notch toughness represents the ability of a material to absorb energy usually determined under impact loading in the presence of a notch. Notch toughness is measured by using a variety of specimens such as the Charpy V-notch impact specimen, the dynamic-tear specimen, and plane-strain fracture-toughness specimens under static loading (K_{Ic}) and under impact loading (K_{Id}).

Ductile-to-Brittle Fracture Transition. Traditionally, the notch-toughness characteristics of low- and intermediate-strength steels have been described in terms of the transition from ductile to brittle behavior as test temperature increases. Most structural steels can fail in either a ductile or a brittle manner depending on several conditions such as temperature, loading rate, and constraint.

The most widely used specimen for characterizing the ductile-to-brittle transition behavior of steels has been the Charpy V-notch impact specimen, which is described in ASTM E 23 (Ref 3). These specimens may be tested at different temperatures and the impact notch toughness at each test temperature may be determined from the energy absorbed during fracture, the percent shear (fibrous) fracture on the fracture surface, or the

change in the width of the specimen (lateral expansion). An example of the ductile-to-brittle transition with temperature for each of these parameters is presented in Fig. 2. The actual values for each parameter and the locations of the curves along the temperature axis are usually different for different steels and even for a given steel composition.

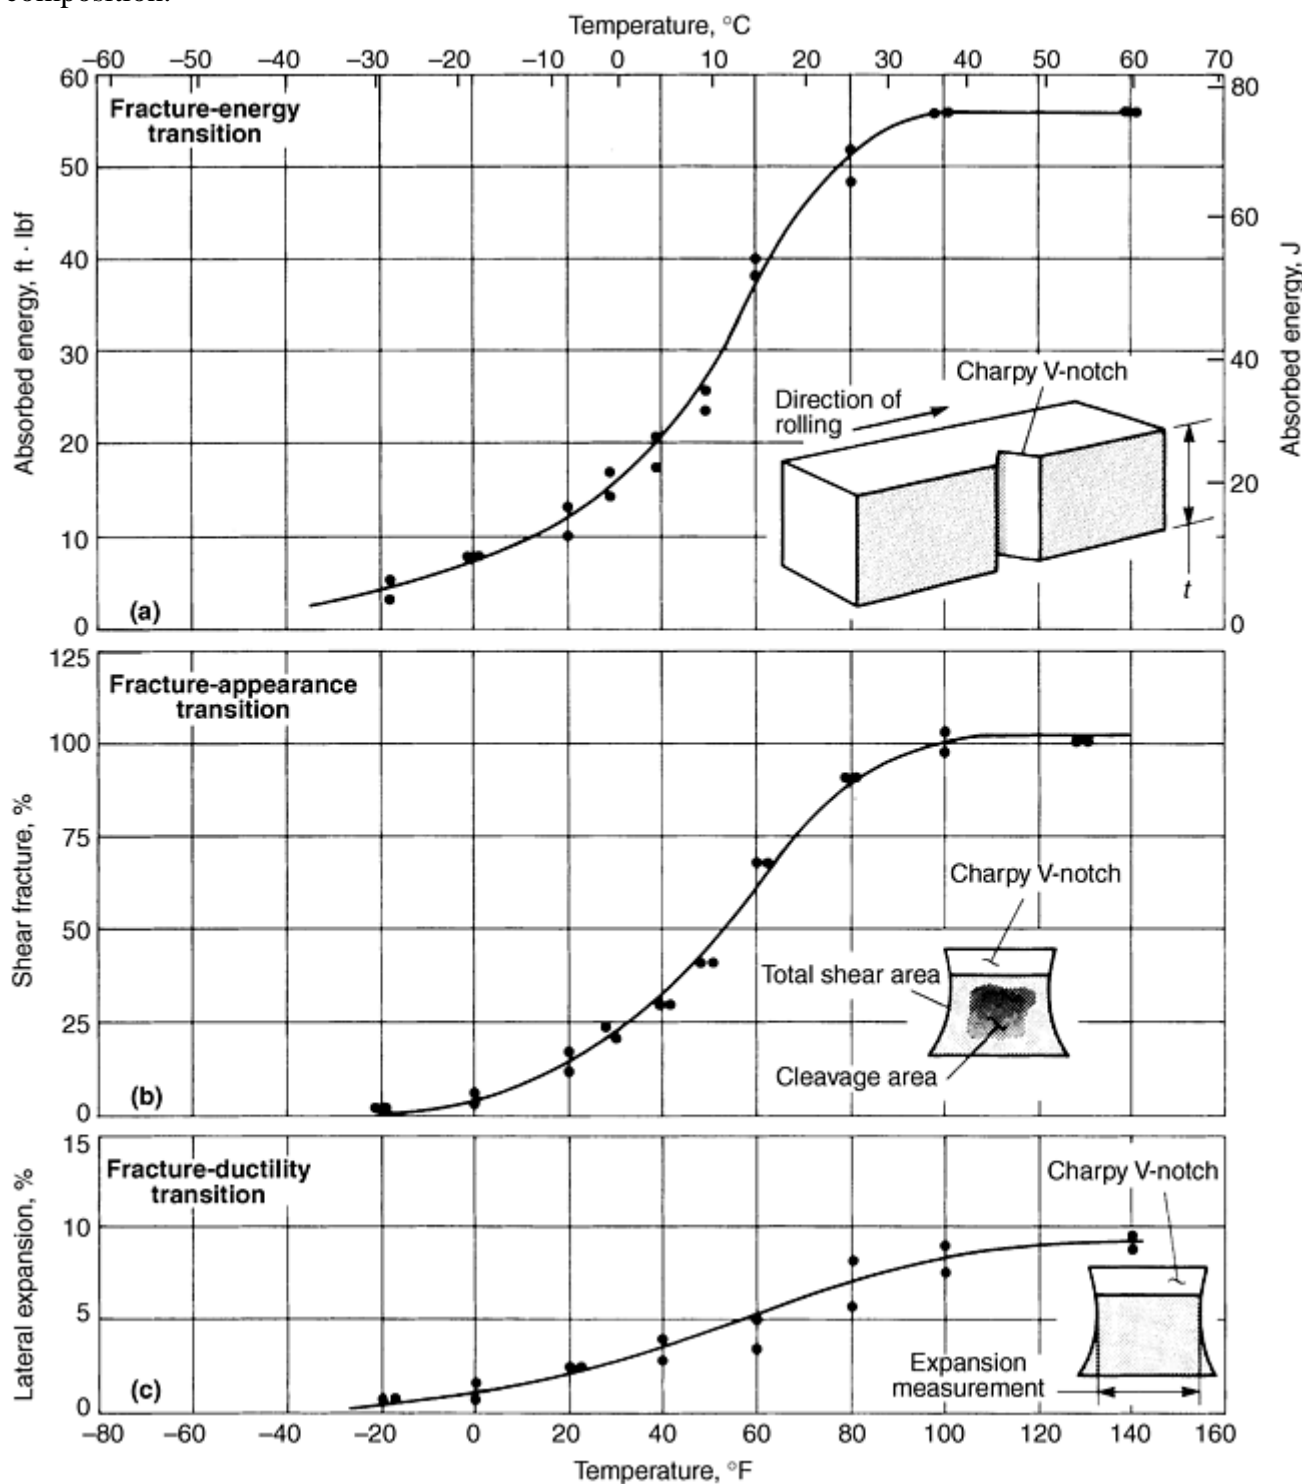

Fig. 2 Characteristics of the transition-temperature range for Charpy V-notch testing of low-carbon steel plate, as determined by (a) fracture energy, (b) fracture appearance, and (c) fracture ductility. The drawings at lower right in the graphs indicate: (a) orientation of the specimen notch with plate thickness, t , and direction of rolling; (b) location of the total shear area on the fracture surface; and (c) location of the expansion measurement in this series of tests—all illustrated for a Charpy V-notch specimen. Percentage of shear fracture and lateral expansion were based on the original dimensions of the specimen. Material is semikilled low-carbon steel plate (0.18% C, 0.54% Mn, 0.07% Si)

The rate of change from ductile to brittle behavior depends on many parameters, including strength and composition of the material. Because the transition occurs over a range of temperatures, it has been customary to define a single temperature within the transition range that reflects the behavior of the steel under consideration. Several equally useful definitions are in use, including the 20 J (15 ft · lbf) temperature, the 380 μm (15 mil) temperature, and the 50% shear temperature.

Fracture Mechanics. Fracture-toughness behavior, or the ability of a material to withstand fracture in the presence of cracks, can be established best by using fracture-mechanics concepts. The stress-intensity value for a given applied stress increases with increasing crack length, and for a given crack length increases with increasing applied stress. One of the underlying principles of fracture mechanics is that unstable fracture occurs when the stress-intensity factor at the crack tip reaches a critical value, K_c . For mode I loading (opening, or tensile mode) and for small crack-tip plastic deformation (plane-strain conditions), the critical stress-intensity factor for fracture instability, K_{Ic} , represents the inherent ability of a material to resist progressive tensile crack extension. However, this fracture-toughness property varies with constraint, and like other material properties such as yield strength, varies with temperature and loading rate as follows:

K_c	Critical stress-intensity factor for static loading and plane-stress conditions of variable constraint. Thus, this value depends on specimen thickness and geometry, as well as on crack size.
K_{Ic}	Critical stress-intensity factor for static loading and plane-strain conditions of maximum constraint. Thus, this value is a minimum value for thick plates.
K_{Id}	Critical stress-intensity factor for dynamic (impact) loading and plane-strain conditions of maximum constraint
$K_c, K_{Ic},$ or K_{Id}	$C\sigma\sqrt{a}$

where C is a constant that is a function of specimen and crack geometry, σ is nominal stress in MPa or ksi, and a is flaw size in millimeters or inches.

Each of these values (K_c , K_{Ic} , and K_{Id}) is also a function of temperature, particularly for those structural materials exhibiting a transition from brittle to ductile behavior.

By knowing the critical value of K_I at failure (K_c , K_{Ic} , or K_{Id}) for a given material of a particular thickness and at a specific temperature and loading rate, the designer can determine flaw sizes that can be tolerated in structural members for a given design stress level. Conversely, the designer can determine the design stress level that can be safely used for an existing crack that may be present in a structure. In general, the relationship among fracture toughness (K_c), stress (σ), and crack size (a) is shown schematically in Fig. 3 (Ref 4) for a through-thickness crack in a plate. The figure shows that there are many combinations of stress and crack size (e.g., σ_f and a_f) that may cause fracture, and many combinations (e.g., σ_0 and a_0) that will not cause fracture, of the particular material under slow loading and at test temperature.

Fig. 3 Relationship among stress, flaw size, and material toughness. CTOD, crack tip opening displacement

Fracture toughness properties are obtained by testing standard specimens at a given test temperature and loading rate. These are discussed in more detail in the article “Fracture Toughness Testing” in this Volume.

Effects of Constraint, Temperature, and Loading Rate. Fracture toughness, K_c , varies with the degree of localized constraint to plastic flow along the tip of the fatigue crack. Thus, cracks in very thick members are subjected to higher constraints than are cracks in thinner members. The maximum constraint, as defined in ASTM E 399 (Ref 5), occurs under plane-strain conditions and results in the lowest value of fracture toughness, K_{Ic} . Under identical test conditions, the K_c values for thinner plates are usually higher than those observed under plane-strain conditions (i.e., $K_c > K_{Ic}$).

Fracture toughness, K_{Ic} , of constructional steels under a constant rate of loading increases with increasing temperature (Ref 2, 4). The rate of increase of K_{Ic} with temperature does not remain constant, but increases markedly above a given test temperature. An example of this behavior is shown in Fig. 4 (Ref 2, 6) for A36 steel plate tested at three different loading rates. This transition in plane-strain fracture toughness is related to a change in the microscopic mode of crack initiation at the crack tip from cleavage to increasing amounts of ductile tearing.

Fig. 4 Effect of temperature and strain rate on plane-strain fracture-toughness behavior of ASTM type A36 steel

An analysis of plane-strain fracture-toughness data that were obtained for constructional steels and that were valid according to ASTM standard procedures shows that the fracture-toughness transition curve is translated (shifted) to higher temperature values as the loading rate is increased. Thus, at a given temperature, fracture toughness values measured at high loading rates are generally lower than those measured at lower loading rates. Also, the fracture-toughness values for constructional steels decrease with decreasing test temperature to a minimum K_{Ic} value that is equal to about $27.5 \text{ MPa} \sqrt{m}$ ($25 \text{ ksi} \sqrt{11\text{in.}}$). This minimum fracture-toughness value is independent of the loading rate used to obtain the fracture-toughness transition curve.

Data for steels having yield strengths between 36 and 250 ksi, such as those presented in Fig. 5 (Ref 2, 6), show that the shift between static and impact plane-strain fracture-toughness curves is given (Ref 2) by:

$$T_{\text{shift}} = 215 - 1.5 \sigma_{ys} \quad (\text{Eq 2a})$$

$$\text{for } 28 \text{ ksi} < \sigma_{ys} \leq 130 \text{ ksi}$$

and

$$T_{\text{shift}} = 0 \text{ for } \sigma_{ys} > 130 \text{ ksi} \quad (\text{Eq 2b})$$

where T is temperature in °F and σ_{ys} is room-temperature yield strength. The temperature shift between static and any intermediate or impact plane-strain fracture-toughness curves is given (Ref 7) by:

$$T_{\text{shift}} = (150 - \sigma_{ys}) \dot{\epsilon}^{0.17} \quad (\text{Eq 3})$$

where T is temperature in °F, σ_{ys} is room-temperature yield strength in ksi, and $\dot{\epsilon}$ is strain rate in s^{-1} . The strain rate is calculated for a point on the elastic-plastic boundary (Ref 8) according to:

$$\dot{\epsilon} = \frac{2 \sigma_{ys}}{tE} \quad (\text{Eq 4})$$

where t is the loading time for the test and E is the elastic modulus for the material.

Fig. 5 Effect of yield strength on shift in transition temperature between impact and static plane-strain fracture-toughness curves

A proper use of fracture-mechanics methodology for fracture control of structures necessitates the determination of fracture toughness for the material at the temperature and loading rate representative of the intended application.

The morphology of fracture surfaces for steel can be understood by considering the fracture-toughness transition behavior under static and impact loading (Fig. 6). The static fracture-toughness transition curve depicts the mode of crack initiation at the crack tip. The dynamic fracture-toughness transition curve depicts the mode of crack propagation.

Fig. 6 Fracture-toughness transition behavior of steel under static and impact loading

The fracture-toughness curve for either static or dynamic loading can be divided into three regions as shown in Fig. 6. In region I_s for the static curve, the crack initiates in a cleavage mode from the tip of the fatigue crack. In region II_s, the fracture toughness to initiate unstable crack propagation increases with increasing temperature. This increase in crack-initiation toughness corresponds to an increase in the size of the plastic zone and in the zone of ductile tearing (shear) at the tip of the crack prior to unstable crack extension. In this region, the ductile-tearing zone is usually very small and is difficult to delineate by visual examination. In region III_s, the static fracture toughness is quite large and somewhat difficult to define, but the fracture initiates by ductile tearing (shear).

Once a crack has initiated under a static load, the morphology (cleavage or shear) of the fracture surface for the propagating crack is determined by the dynamic behavior and degree of plane strain at the temperature. Regions I_d, II_d, and III_d in Fig. 6 correspond to cleavage, increasing ductile tearing (shear), and full-shear crack propagation, respectively. Thus, at temperature A, the crack initiates and propagates in cleavage. At temperatures B and C, the crack exhibits ductile initiation, but propagates in cleavage. The only difference between the behaviors at temperatures B and C is that the ductile-tearing zone for crack initiation is larger at temperature C than at temperature B. At temperatures D, cracks initiate and propagate in full shear. Consequently, full-shear fracture initiation and propagation occur only at temperatures for which the static and dynamic (impact) fracture behaviors are on the upper shelf.

Correlations of K_{I_d} , K_{I_c} , and Charpy V-Notch Impact Energy Absorption. The Charpy V-notch impact specimen is the most widely used specimen for material development, specifications, and quality control. Moreover, because the Charpy V-notch impact energy absorption curve for constructional steels undergoes a transition in the same temperature zone as the impact plane-strain fracture toughness (K_{I_d}), a correlation among these test results has been developed for the transition region and is given (Ref 2, 6) by:

$$\frac{(K_{I_d})^2}{E} = 5(\text{CVN}) \quad (\text{Eq 5})$$

where K_{I_d} is in $\text{ksi} \sqrt{\text{in}}$, E is in ksi , and CVN is in $\text{ft} \cdot \text{lb}$. The validity of this correlation is apparent from the data presented in Fig. 7 for various grades of steel ranging in yield strength from about 36 to about 140 ksi and in Fig. 8 for eight heats of SA 533B, class 1, steel. Consequently, a given value of CVN impact energy absorption corresponds to a given K_{I_d} value (Eq 5), which in turn corresponds to a given toughness behavior at lower rates of loading. The behavior for loading rates less than impact are established by shifting the K_{I_d} value to lower temperatures by using Eq 2a, 2b, or 3. Conversely, for a desired behavior at the minimum operating temperature and maximum in-service loading rate, the corresponding behavior under impact loading can be established by using Eq 2a, 2b, or 3, and the equivalent CVN impact value can be established by using Eq 5.

Fig. 7 Correlation of plane-strain impact fracture toughness and impact Charpy V-notch energy absorption for various grades of steel

Fig. 8 Correlation of plane-strain impact fracture toughness and impact Charpy V-notch energy absorption for SA 533B, class 1, steel

Barsom and Rolfe (Ref 2) suggested a relationship between K_{Ic} and upper-shelf Charpy V-notch impact energy absorption. This upper-shelf correlation, shown in Fig. 9, was developed empirically for steels having room-temperature yield strength, σ_{ys} , higher than about 110 ksi and is given by:

$$\left(\frac{K_{Ic}}{\sigma_{ys}}\right)^2 = \frac{5}{\sigma_{ys}} \left(CVN - \frac{\sigma_{ys}}{20} \right) \quad (\text{Eq 6})$$

where K_{Ic} is in ksi $\sqrt{\text{in}}$, σ_{ys} is in ksi, and CVN is energy absorption in ft · lbf for a Charpy V-notch impact specimen tested in the upper-shelf (100% shear fracture) region.

Fig. 9 Relation between plane-strain fracture toughness (K_{Ic}) and Charpy V-notch (CVN) impact energy. Tests conducted at 27 °C (80 °F). VM, vacuum melted; AM, air melted

At the upper shelf, the effects of loading rate and notch acuity are not as critical as in the transition region. The effect of loading rate is to elevate the yield strength by about 25 ksi. Thus, Eq 6 may be used to calculate K_{Ic} values by replacing σ_{ys} with the dynamic yield strength, σ_{yd} , where $\sigma_{yd} \approx \sigma_{ys} + 25$ ksi. This use of Eq 6 to calculate K_{Ic} is consistent with the observation that, in the upper-shelf region, the dynamic fracture toughness of steels is higher than the static fracture toughness.

Fracture Toughness and Fracture Mechanics

Fracture Mechanics

Fracture mechanics is the study of the influence of loading, crack size, and structural geometry on the fracture resistance of materials containing natural flaws and cracks. When applied to design, the objective of the fracture-mechanics analysis is to limit operating stresses so that a preexisting flaw of assumed initial size will not grow to critical size during the desired service life of the structure. Service life is calculated on the basis of probable initial flaw sizes limited by inspection, a stress analysis of the structure, and experimental data relating crack growth and fracture to fracture-mechanics parameters.

Linear Elastic Fracture Mechanics

The fundamental ideas underlying the foundation of fracture mechanics stem from the work of Griffith (Ref 1), who demonstrated that the strain energy released upon crack extension is the driving force for fracture in a cracked material under linear-elastic conditions. The elastic strain energy, U , is the work done by a load, P , causing a displacement, Δ :

$$U = P\Delta/2 = CP^2/2 \quad (\text{Eq 7})$$

where $C = \Delta/P$, the elastic compliance.

The loss of elastic potential energy with crack extension of unit area, A , is defined as the strain-energy release rate, G . For a crack extending at constant deflection or at constant load:

$$G = dU/dA = (P^2/2)dC/dA \quad (\text{Eq 8})$$

This relationship characterizes the fracture resistance of structural materials by defining a critical strain-energy release rate, G_c , at the critical load, P_c , when fracture occurs in a specimen with a known compliance function, dC/dA .

Stress-Intensity Factor. Fracture mechanics is based on a stress analysis of the stress distribution near the tip of a crack located in a linear-elastic body. The magnitude of the crack-tip stress field, σ_{ij} , is proportional to a single parameter, K , the stress-intensity factor:

$$\sigma_{ij} = K(2\pi r)^{-1/2} f_{ij}(\theta) = K \cdot f(\text{position}) \quad (\text{Eq 9})$$

where r and θ are cylindrical position coordinates, $r = 0$ at the crack tip, and $\theta = 0$ in the crack plane. K is a function of the applied stress, σ , a is the crack length, and $Y(a)$ is a factor dependent on structural geometry:

$$K = Y(a)\sigma(\pi a)^{1/2} \quad (\text{Eq 10})$$

The strain-energy release rate and stress-intensity approaches are related:

$$K^2 = E'G \quad (\text{Eq 11})$$

where for plane stress, $E' = E$, the elastic modulus; for plane strain, $E' = E/(1 - \nu^2)$, where ν is Poisson's ratio. Thus, it is equivalent to attribute the driving force for fracture to the crack-tip stress field, which is proportional to K or to the elastic strain-energy release rate, G . The stress intensity, K , is used more commonly than G , because K can be computed for different structural geometries using stress-analysis techniques.

Fracture occurs when the crack-tip stress field reaches a critical magnitude, that is, when K reaches K_c , the fracture toughness of the material. K_c is a mechanical property that is a function of temperature, loading rate, and microstructure, much the same as yield strength is; K_c is also a function of the extent of plastic strain at the crack tip relative to the other specimen or structure dimensions. If the plastic zone is small compared with the specimen dimensions and the crack size, then K_c approaches a constant minimum value defined as the plane-strain fracture toughness, K_{Ic} .

Crack Tip Plasticity. Applicability of the linear-elastic analysis has been extended to conditions approaching net section yielding by correcting for the zone of plasticity that exists at the crack tip (Ref 9). The assumption is that the plastic material at the crack tip strains without carrying the incremental load; therefore, the crack behaves as if it were a slightly longer crack in a linear-elastic material. The adjustment is made by adding the radius of the plastic zone, r_y , to the crack length, a , such that the expression for the stress-intensity factor becomes:

$$K = Y(a + r_y) \sigma [\pi(a + r_y)]^{1/2} \quad (\text{Eq 12})$$

where

$$r_y = 1/2\pi (K/\sigma_y)^2 \quad (\text{Eq 13})$$

where σ_y is the yield strength at the crack tip. The r_y correction modifies the crack-tip stress field to account for the elastic stress redistribution that is due to the localized plasticity.

Size Effect. A two-dimensional stress state is assumed in a bulk material when one of the dimensions of the body is small relative to the others. A two-dimensional stress state called plane strain develops when plastic deformation at the crack tip is severely limited. This is promoted by thick sections, high strength and limited ductility. In contrast, a two-dimensional stress state called plane stress develops when much more plastic deformation occurs around the crack tip. This is promoted by low-strength ductile materials and very thin sections of high-strength materials. The difference between plane strain and plane stress is based on the presence or absence, respectively, of transverse constraint in material deformation in the vicinity of the crack tip.

As specimen thickness, B , increases, σ_y increases from σ_{ys} (the engineering yield stress of the material at 0.2% strain) to $(3\sigma_{ys})^{1/2}$ because of a geometric constraint to plastic deformation associated with a transition from plane-stress to plane-strain conditions. The maximum value of σ_y is reached when the plastic zone size is limited to about 5% of the thickness. Thus, in a given material, the plastic zone size as computed by Eq 13 may vary with thickness by a factor of 3, leading to a strong dependence of K_c on thickness, as shown in Fig. 10. The inflection point of the curve in Fig. 10 occurs at approximately $(K_{Ic}/\sigma_{ys})^2$. Therefore, for maximum toughness:

$$B < (K_{Ic}/\sigma_{ys})^2 \text{ or } K_{Ic} > \sigma_{ys}(B)^{1/2} \quad (\text{Eq 14})$$

Equation 14 is useful in material selection.

Fig. 10 Fracture toughness transition in structural alloys

Of great importance is the fact that the curve in Fig. 10 approaches an asymptote at a thickness of $B \geq 2.5 \left(\frac{K_{Ic}}{\sigma_{ys}}\right)^2$. At this point the fracture toughness value, K_{Ic} , is a material constant, independent of further increase of thickness.

Elastic-Plastic Fracture Mechanics

High-toughness structural materials undergo extensive plastic deformation prior to fracture. Therefore, the concepts of linear-elastic fracture mechanics need to account for elastic-plastic behavior. The general concepts of EPFM, as they relate to metallic materials and ceramic composites, are described in more detail in the article “Feature Toughness of Ceramics and Ceramic Matrix Composites” in this Volume.

Three basic methods of EPFM include the crack-tip opening displacement (CTOD), the J -integral, and the R -curve methods. These tests are intended to provide specialized measurements of fracture properties as follows:

- CTOD: full range of fracture toughness; for slow loading rates
- J -integral: elastic-plastic fracture toughness; for slow loading rates
- R -curve: resistance to fracture extension; for elastic-plastic fracture and slow loading rates

Crack-Tip Opening Displacement. The concept of the CTOD and crack-mouth opening displacement (CMOD) is shown schematically in Fig. 11, which shows a sample specimen before and after (hidden lines) deformation (Ref 10). Note that the CMOD is evaluated at the load line (centerline of the loading) and the CTOD is evaluated at the crack tip. Some test methods used for evaluating the CTOD are British Standard 7448, Part 1 and ASTM E 1290 (Ref 11, 12).

Fig. 11 Sample specimen showing the definition of crack-mouth opening displacement (CMOD) and crack-tip opening displacement (CTOD). CTOD is the diameter of the circular arc at the blunted crack tip and should not be confused with the plastic zone. Source: Ref 10

The CTOD concept is a crack tip strain criterion for fracture. For a crack in an elastic body, the crack-opening displacement, v , at a distance r from the crack tip is given by the displacement equation:

$$v = 2K/\pi E' (2\pi r)^{1/2} \quad (\text{Eq 15})$$

Under conditions of small-scale yielding, the displacement at the crack tip, δ , can be calculated by assuming the effective crack tip ($a_{\text{eff}} = a + r_y$) is at a distance, r_y , from the actual crack tip:

$$\delta = 2v = 4K/\pi E' (2\pi r_y)^{1/2} = 4K^2/\pi E' \sigma_y \quad (\text{Eq 16})$$

Theoretically, fracture occurs when $\delta = \delta_c$, the critical CTOD. In practice, a characteristic value for δ exists only for the crack initiation event; significantly more scatter exists for δ measured at maximum load or final fracture. The CTOD approach is limited by the analytical and experimental uncertainties of the crack-tip region. Analytically, δ is defined as the CTOD at the interface of the elastic-plastic boundary and the crack surface. Experimentally, δ is calculated from displacement measurements taken remotely from the crack tip because direct physical measurements are not precise. Further uncertainty is introduced by the term σ_y in Eq 16, which may vary by 75%, depending on the degree of elastic constraint—a crack-tip characteristic that cannot be measured directly.

The CTOD approach offers a significant improvement over linear-elastic methods in the plastic range. An empirical correlation, known as a design curve, relates CTOD, crack size, and applied strain for a wide range of structural and material combinations.

For many years, only the CTOD test measured toughness for a brittle, unstable fracture event using a nonlinear-fracture parameter. In addition, the method allows the measurement of toughness after a “pop-in,” which is described as a discontinuity in the load-versus-displacement record usually caused by a sudden, unstable advance of the crack that is subsequently arrested.

The J -integral (Ref 13) characterizes the elastic-plastic field in the vicinity of the crack tip. J is defined as the line integral:

$$J = \int_{\Gamma} [w dy - \bar{T}(\partial \bar{u} / \partial x) ds] \quad (\text{Eq 17})$$

where Γ is any contour surrounding the crack tip, w is the strain-energy density, \bar{T} is the force vector normal to Γ , \bar{u} is the displacement vector, and s is the arc length along Γ . The J -integral is path independent for linear and nonlinear elastic materials and nearly so for most structural materials (elastic-plastic) under monotonic loading conditions (Ref 14). Thus, J can be computed using numerical methods by analyzing loads and displacements

along a contour away from the crack tip, that is, in a region where the analysis methods are quite accurate. This eliminates the uncertainties of the crack-tip region—a problem that seriously limits the usefulness of the CTOD method.

An equivalent interpretation is that J is equal to the change of the pseudopotential energy (the area under the load-displacement curve), U , upon an increment of crack extension of unit area, A ;

$$J = dU/dA \quad (\text{Eq 18})$$

For the linear-elastic case, the potential energy equals the strain energy ($U = V$), and therefore, Eq 18 is the same as Eq 8 and $J = G$. Thus, J appears to be a logical extension of LEFM into the elastic-plastic range.

Because of the irreversibility of plastic deformation, the energy interpretation of the J -integral does not apply to the process of crack extension, and J is not equal to the energy available for crack extension in elastic-plastic materials as G is for elastic materials. J is simply an analytically convenient, measurable parameter that is a characteristic of the elastic-plastic field at the crack tip.

Crack initiation under elastic-plastic conditions occurs at a characteristic value of J , called J_{Ic} ; J_{Ic} is related to the linear-elastic plane-strain toughness, K_{Ic} , in the same way G is related to K in Eq 11. Thus, J -integral methods can be used to determine K_{Ic} in specimens significantly smaller than the size requirements for linear-elastic response.

The J -integral concept is not only applicable to crack initiation, but also is applicable to crack propagation. For most materials that fail in the elastic-plastic range, significant fracture resistance exists after crack initiation. Therefore, in some cases the J -integral may be unduly conservative as a fracture criterion.

J -integral analysis must properly account for the stress-strain characteristics of the material. Thus, for a given structural configuration, J -integral solutions are required for each distinct material instead of the single solution needed for K analyses.

The R -curve concept, introduced by Krafft, Sullivan, and Boyle (Ref 15), is a characterization of the increase in fracture resistance accompanying the slow crack extension that precedes unstable fracture. ASTM E 561 covers the standard practice for R -curve determination. The R -curve is constructed by plotting crack extension, Δa , as a function of the driving force for fracture expressed in terms of G , K , J , or δ . The level of driving force required to extend the crack is defined as the resistance, R , of the material. An R -curve is shown in Fig. 12, where R is expressed in terms of K and is denoted by K_R . The R -curve may be used as a fracture criterion when crack-driving-force curves expressed in terms of K versus a at constant load in Fig. 12 are shown on the same plot. Fracture is predicted when the following conditions are met:

$$K = K_R \text{ and } \partial K/\partial a = \partial K_R/\partial a \quad (\text{Eq 19})$$

Fig. 12 Crack growth resistance curve and crack driving force curves in R -curve format. Source: Ref 16

K_R and K are computed for the test specimen and structure, respectively, using the appropriate value of $Y(a + r_y)$ in Eq 12.

In applying the R -curve concept as a fracture criterion, it is assumed that the R -curve is a property of the material for a given thickness and temperature, and the influence of planar geometry on the predicted instability point is considered in the calculation of K for the driving-force curves.

The conditions for tearing instability are shown in Fig. 13. The dashed line segment, tangent to the R -curve, shows the magnitude and slope of K versus a , calculated for a structural application at a loading condition where the application values of K and dK/da match the values of K_R and dK_R/da . As with R -curve K -values, an r_Y -type plastic zone adjustment is used for calculation of application K values. The values of K_R and of dK_R/da must be calculated for the applications crack using r_Y -corrected estimates of K_R .

Fig. 13 Schematic R -curve. Dashed line shows a segment of the driving K -value, for which dK/da and K match the slope of the K -value of the R curve.

There is a close relationship between basic concepts used in R -curve testing and in J - R testing. However, with R -curve testing, the main emphasis is on the crack front conditions of plane stress; with J - R testing, emphasis is on crack front conditions of plane strain.

The R -curve approach is used as a measure of fracture toughness for plate thicknesses where valid K_{Ic} data cannot be obtained because of the size requirements for linear elasticity. For example, nickel steels have been evaluated at temperatures down to 76 K using the R -curve approach (Ref 17). The results can be misleading if one compares materials on the basis of fracture toughness; that is, an initiation criterion, such as K_{Ic} , indicates a substantially lower toughness than an instability criterion, such as the R -curve.

Fracture Toughness Testing

Fracture toughness is a single-parameter characterization of the fracture resistance of a material containing a crack. The single parameter depends on the fracture criterion chosen and varies as a function of temperature, loading rate, and microstructure. In this section, K_{Ic} is used as the linear-elastic fracture criterion and J_{Ic} is used as the fracture criterion for the elastic-plastic and fully plastic cases. Load-displacement records representing the three fracture cases are shown in Fig. 14.

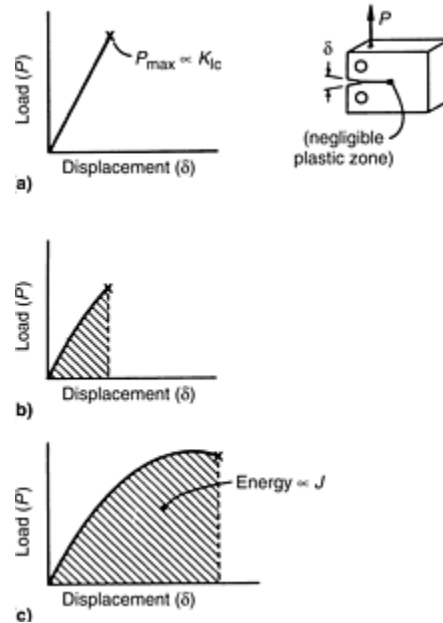

Fig. 14 Load-displacement behavior observed in fracture toughness tests. (a) Linear-elastic. (b) Elastic-plastic (failure before limit load). (c) Fully plastic (exhibits a limit load). (a) shows brittle behavior (K_{Ic} is measured). (b) and (c) show ductile behavior (J_{Ic} is measured).

Although the J_{Ic} value can be used to obtain an estimate of K_{Ic} , denoted $K_{Ic}(J)$, it should be understood that K_{Ic} and $K_{Ic}(J)$ may represent significantly different fracture behavior. K_{Ic} is the critical K level for the linear-elastic case, at which significant measurable extension of the crack occurs, often triggering unstable fracture. For valid measurements of K_{Ic} , the critical K level must be reached prior to significant plastic deformation; that is, the plastic zone size is negligible, less than 2% of the crack length and the thickness. In contrast, $K_{Ic}(J)$ for elastic-plastic or fully plastic fracture indicates an estimate K_{Ic} calculated from J_{Ic} , the J -integral value at which the first measurable extension of the crack occurs. Since plastic deformation prior to the onset of cracking does not invalidate the J_{Ic} measurement, smaller specimens can be used. Either: (a) significant amount of stable crack extension under rising load is displayed before final fracture occurs or (b) the elastic-plastic behavior culminates in plastic instability (Ref 18). The differences in K_{Ic} and $K_{Ic}(J)$ may be clarified by consideration of their test methods.

Linear-Elastic Fracture Toughness. Standard test method ASTM E 399 (Ref 5) is used to measure plane-strain fracture toughness, K_{Ic} . The standard is designed to ensure that linear-elastic conditions prevail throughout the test. This is achieved by requiring a sufficiently large specimen for the particular toughness and yield strength of the material being tested. Planar dimensions are sized to ensure elastic response of the specimen, and the thickness is sized to ensure sufficient through-thickness constraint. The dimensional criteria in ASTM E 399 are:

$$B, a \geq 2.5(K_{Ic}/\sigma_{ys})^2 \quad (\text{Eq 20})$$

where B and a are defined in Fig. 15 for the compact specimen.

Fig. 15 ASTM E 399 compact specimen for fracture toughness testing

The specimens are precracked by fatigue cycling to an initial relative crack length of $a/W \simeq 0.5$. Precracking loads are limited to low values to keep the plastic zone size at the crack tip small; the fatigue loads must be such that the maximum K level during fatigue is less than $0.6 K_{Ic}$. (Changes in yield strength must be taken into account if precracking is performed at room temperature and testing at cryogenic temperatures.) Subsequently, the specimens are monotonically loaded to failure. During loading, load, P , and displacement, Δ , are measured and a P - Δ curve is recorded. The critical load, P_Q , as defined in ASTM E 399, is either the maximum load or the load at a 5% secant offset from the linear part of the P - Δ test record. If the maximum load in the test exceeds $1.10 P_Q$, the test is invalid. A trial value of fracture toughness, K_Q , is calculated from the critical load, the measured crack length, the specimen dimensions, and the specimen calibration function $Y(a/W)$, as follows:

$$K_Q = P_Q Y(a/W) / B W^{1/2} \quad (\text{Eq 21})$$

If all the conditions of ASTM E 399 are met, such as precracking procedures, load-displacement record, and specimen dimensions, then $K_Q = K_{Ic}$.

The K_{Ic} test method was standardized by ASTM in 1970. Uncertainties in K_{Ic} measurements obtained by this method lie between 4 and 10% (Ref 19). Three tests per material per temperature are considered sufficient to demonstrate reproducibility.

J-integral fracture toughness. J_{Ic} measurement is based largely on the method proposed in 1974 (Ref 20, 21), as shown schematically in Fig. 16. Typically, a series of deeply notched compact specimens are precracked to $a/W \simeq 0.6$, and each specimen is loaded to a J -level in the region where crack extension is anticipated. The load-displacement curve is recorded on an X - Y recorder, with displacement being measured at the load line. Then the specimen is unloaded and heated to tint the region of crack extension. The specimen is fractured, and the crack extension, Δa , is measured from the exposed fracture surface. J is calculated from the load-displacement record and specimen dimensions using:

$$J = (A/Bb)f(a_0/W) \quad (\text{Eq 22})$$

where A is the area under the load-displacement curve, $b = (W - a)$ is the uncracked ligament, and $f(a_0/W)$ is a function of crack length.

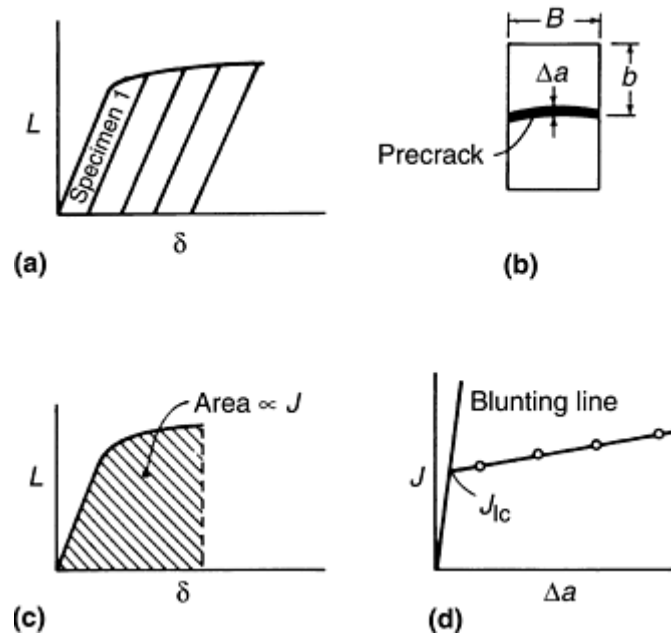

Fig. 16 J -resistance curve test method for J_{Ic} determination. (a) Test records. (b) Heat-tinted fracture surface. (c) J calculation. (d) Resistance curve

The results of a test series are plotted as J versus Δa . On the same graph, the line defined by Eq 23 is drawn:

$$J = 2\bar{\sigma}\Delta a \quad (\text{Eq 23})$$

where $\bar{\sigma}$ is the flow stress (the average of the yield and ultimate strengths). The intersection of the J - Δa plot and the $J/2\bar{\sigma}$ line is defined as J_{Ic} , the value of J at the onset of crack extension. Apparent crack extension at Δa values of less than $J/2\bar{\sigma}$ is attributed to deformation at the crack tip instead of material separation. The linear-elastic plane-strain fracture toughness can be estimated from J_{Ic} as follows:

$$K_{Ic}(J) = [J_{Ic}E/(1 - \nu^2)]^{1/2} \quad (\text{Eq 24})$$

where E is Young's modulus and ν is Poisson's ratio.

The J -integral method has been combined into ASTM E 1820 (Ref 22), and the individual standard E 813 was withdrawn from the *Annual Book of ASTM Standards* in 1998.

Other Test Methods. Fracture toughness data can be obtained using test methods other than the currently favored K_{Ic} and J_{Ic} methods. Care must be taken in comparing these data with K_{Ic} and J_{Ic} values and in applying the data to materials selection or design. Difficulties arise owing to differences in measurement criteria and fracture criteria.

In both K_{Ic} and J_{Ic} testing, the measurement point (i.e., P_Q for K_{Ic} and the $J/2\bar{\sigma}$ intersection for J_{Ic}) is near the onset of crack extension. Fracture toughness data are frequently reported where the maximum load values are used to calculate fracture toughness, and the results are reported in terms of K or J values—often with a change of subscript (e.g., K_{max} , K_{IE} , K_C , J_C).

Significant differences in toughness also may be attributed to differences in the fracture criteria. Data obtained by the CTOD or R -curve methods evaluate the fracture toughness of ductile materials after significant crack extension and plasticity have occurred. Consequently, the toughness values for the same material are higher than those obtained by the K_{Ic} or J_{Ic} methods. Advantages and disadvantages of various fracture toughness tests are shown in Table 1.

Table 1 Fracture toughness tests

Method	Advantages	Disadvantages
K_{Ic} , ASTM E 399	This method is the most reliable to get fracture toughness values at lower temperatures. The success of all other methods is based on their ability to give data comparable to this method.	The high cost of testing the large specimens required for higher temperature tends to reduce the number of data points. Linear extrapolation from valid K_{Ic} at lower temperature to higher temperature

		produces conservatism. No valid K_{Ic} values at higher temperature.
<i>J</i> -integral, ASTM E 813	Provides fracture toughness values that agree with K_{Ic} method. Yields realistic fracture toughness data at higher temperature. Has the advantage (over CTOD) of a sound theoretical basis, which permits evaluation of stable crack growth. Determination of dJ/da is a measure of the resistance to continued crack propagation. Testing many small <i>J</i> specimens provides an indication of material toughness variation.	Not able to evaluate irregular crack propagation due to residual stress or at HAZ near welds. Not accurate enough at low temperatures. Measurements are inaccurate due to irregular crack fronts. Not valid for thin materials where K_J is 2.5 K_{Ic} . When heat tinting is used, the additional number of specimens adds to testing costs.
CTOD, BS 7448, ASK-AAN 220	Provides fracture toughness values that agree with ASTM K_{Ic} method. Yields realistic fracture toughness data at higher temperatures. CTOD results have shown good consistency and comparability with toughness values using other methods. Simultaneous measurement of CTOD and <i>J</i> -integral is possible for a minor extra cost.	Variations in the measurement of δ results in variations of K_{Ic} of up to a factor of 2. This method restricted to temperatures above -60 °C.
Simple equal energy	Provides fracture toughness values that agree with ASTM K_{Ic} method. Yields realistic fracture toughness data at higher temperatures. Toughness data are identical or closely similar to <i>J</i> -integral data.	Limitations similar to those of the <i>J</i> -integral method. This method is more empirical in nature, so <i>J</i> -integral testing is preferred.
Instrumented Charpy testing	Requires small specimens. Practically suited for determination of toughness variations in small regions of complex parts, in HAZ of welds, and in other locally embrittled zones. Error in K_{Ic} is small (in comparison to ASTM K_{Ic} method) for predominantly brittle failure.	Can provide very pessimistic values, particularly at higher temperatures. K_{Ic} is slightly underestimated at low temperatures, but considerable scatter of measurements exists above the brittle-transition temperature within a factor of 3 due to small size of specimens. Difficulty in separating the crack-initiation and crack propagation components of fracture.
Empirical methods per Begley and Logsdon	Requires small specimens. Offers a rapid and inexpensive technique to estimate K_{Ic} for wrought ferritic steels. This method indicates that Charpy K_{Ic} values are scattered and lie entirely below ASTM K_{Ic} data. Conservative by a factor of up to 3. K_{Ic} by this method provides narrow scatter band with the results below ASTM K_{Ic} by a factor of 2.	Can provide very pessimistic values, particularly at higher temperatures. Cannot give information relevant to small regions such as HAZ at welds, castings, or materials other than the ferritic steels.

CTOD, crack-tip opening displacement; HAZ, heat-affected zones.

Source: Ref 10

Specimens. There are many fracture-specimen types and sizes, each offering specific advantages and disadvantages. Some of these are listed in Table 2. The choice of a particular specimen geometry depends on technical purposes and test requirements. The three-point bend and compact specimens (standard specimens of the ASTM E 399 and E 813 methods) are often preferred for general laboratory materials evaluation, because *K* and *J* calibrations for these specimens are accurately known and relatively low loads are required during testing. Data obtained with nonstandard specimens must be evaluated carefully to ensure that the same fracture criteria are used, such as the onset of cracking.

Table 2 Advantages and disadvantages of selected fracture toughness test specimens

Specimen type	Advantages	Disadvantages
Compact specimen	High K_{Ic} measurement capability for size Standard specimen (ASTM E 399) Low loads required	Expense of machining
Three-point bend	Standard specimen (ASTM E 399) Low loads required Suitable for wide range of orientations	A long span transverse to loading direction, which may be a disadvantage for some cryostats
Center-cracked tension	Pure tensile loading	High loads and large material requirements
Double-edge notched	Pure tensile loading	High loads and large material requirements
Single-edge notched	Easy notch preparation	High loads and material requirements
Double cantilever beam	Tapered specimens, can be designed such that the value of K is independent of crack length	Long span transverse to loading direction Side grooving may be necessary to guide cracking direction Machining expenses
Surface-flawed specimen (part-through crack)	Simulates a flaw type commonly found in service	Size requirements are difficult to establish K solution not precisely known High loads are required
C-shaped specimen	Special geometry suitable for bar stock	Limited applicability
Wedge-opening-load specimen	Larger width than compact specimen May be bolt loaded at one end	Expense of machining

For K_{Ic} measurements, ASTM E 399 describes procedures using test specimens such as those shown in Fig. 17. The crack-tip plastic region is small compared with crack length and to the specimen dimension in the constraint direction. A compact-type (CT) specimen, shown in Fig. 17(d), often is used to experimentally determine fracture toughness and other fracture properties. From a record of load versus crack opening and from previously determined relations of crack configuration to stress intensity, plane-strain fracture toughness can be accurately measured if all the criteria for a valid test are met.

Fig. 17 Specimen types used in plane-strain fracture-toughness (K_{Ic} testing (ASTM E 399)

Compliance-based fracture testing uses a CMOD gage. Direct-current signals are amplified and conditioned to control and monitor the test. Generally, the load is monitored using a load cell mounted within the test frame in the load train.

Specimen Orientation. Most structural alloys are anisotropic—their fracture toughness varies with direction. Fracture anisotropy is caused by microstructural inhomogeneities, such as irregular grain structure, chemical segregation, crystallographic texturing, or inclusion morphology. Specimen orientation is important since it determines the direction of crack propagation through the microstructure.

In some alloys, nearly equiaxial microstructures are achieved. Then, fracture properties may be nearly isotropic. The fracture resistance of most alloys, however, is quite dependent on orientation, more so than some tensile properties. Rolled plates having elongated grains may exhibit J_{Ic} variations of up to 2 to 1. Knowledge of anisotropy can be used to advantage by orienting components judiciously in relation to the maximum service stress.

Loading Rate. Plastic deformation is a time-dependent process that can be suppressed at high loading rates. High loading rates produce higher yield strengths and reduce the toughness of some alloys, particularly the body-centered cubic (bcc) alloys. Dynamic tests are typically performed at high rates between 10^4 and 10^6 $\text{MPa}\sqrt{\text{m}} \cdot \text{s}^{-1}$, whereas static K_{Ic} tests are conducted at stress-intensity-factor rates of about $1 \text{ MPa}\sqrt{\text{m}} \cdot \text{s}^{-1}$. As a rule, alloys that show rate-sensitive tensile behavior also show rate-sensitive fracture behavior. If the tensile yield strength of an alloy is raised significantly while its ductility is lowered at high strain rates, reduced fracture toughness values may be expected for dynamic loading. This is typically the case for low-strength ferritic steels.

Thermal and Metallurgical Effects on Toughness

As shown in Fig. 18, fracture toughness may increase or decrease as temperature is lowered, depending on metallurgical factors.

Fig. 18 Temperature dependence of fracture toughness for alloys, illustrating characteristic behavior for three different crystal structures

To be suitable for cryogenic applications, structural alloys should fracture in a ductile manner at all service temperatures. Ductile fracture is caused by the formation and growth of the voids that eventually comprise the fracture surface. Thus, the toughness of ductile metals is related to the factors that influence the nucleation and growth of voids. Voids nucleate most readily at second-phase particles, such as inclusions and precipitates (1 to 10 μm in size), as a result of interfacial separation, fracture of the particle, or matrix separation caused by strain concentration near the particle. Voids grow and coalesce by ductile tearing of the matrix. Ductile tearing resistance is a function of the strength and ductility of the matrix. As matrix strength increases, less energy is dissipated by plastic deformation during tearing, and toughness is reduced. Increased matrix strength also tends to activate additional void nucleation sites. Consequently, yield strength is inversely proportional to fracture toughness, as shown in Fig. 19.

Fig. 19 Fracture toughness versus yield strength for some structural steels, TRIP, transformation-induced plasticity

Brittle fracture requires less energy for surface formation than ductile fracture. Lower energy fracture modes include cleavage and intercrystalline (grain-boundary) fracture. Cleavage is a fracture mode in which material separation proceeds along preferred crystallographic planes without sizable plastic deformation prior to fracture. Metals subject to cleavage usually have a large increase in yield strength as temperature is decreased. Cleavage occurs when the cleavage fracture stress is reached before the energy required for void formation is exceeded. Intercrystalline fracture occurs when the cohesive strength of the grain boundary is exceeded before cleavage or ductile fracture occurs. As matrix strength increases with decreasing temperature, intergranular failure may occur more readily in a susceptible alloy.

The influence of selected metallurgical factors on toughness at low temperatures is discussed in the following sections.

Crystal Structure. Figure 18 indicates that crystal structure is a reliable guide for qualitative prediction of temperature dependence: face-centered cubic (fcc) alloys typically exhibit high toughness throughout the ambient-to-cryogenic range; body-centered cubic (bcc) alloys exhibit precipitous decreases in fracture toughness at critical transition temperatures; and hexagonal close-packed (hcp) alloys are noted for comparatively low toughness at all temperatures. Metallurgical factors (composition, purity, and processing) can strongly modify the fracture behavior, and in every crystal structure class there are exceptional alloys.

Face-Centered Cubic Alloys. Annealed fcc alloys have low strength and high fracture toughness. Included in this group are copper alloys, aluminum alloys, austenitic stainless steels, and nickel-base superalloys. Ductile tearing is typical, even in thick sections. Fracture toughness values for these alloys usually increase between 295 and 4 K, often showing a broad maximum at temperatures near 77 K.

Body-Centered Cubic Alloys. Because of their ductile-to-brittle transitions, alloys having bcc structure are of limited use at cryogenic temperatures. The transitions are associated with a change in fracture mode from void coalescence to cleavage as temperature is reduced. The transition temperature range is a function of the metallurgical and mechanical variables that alter matrix strength. Factors tending to raise the transition temperature for a given alloy and heat treatment combination include increasing grain sizes, thicker sections, and higher loading rates. Nickel alloying decreases the transition temperatures of ferritic steels.

Hexagonal Close-Packed Alloys. The fracture toughness of hcp metals and alloys is usually quite low, and many exhibit transitional behavior such as that observed in bcc alloys. Beryllium, for example, exhibits room temperature, K_{Ic} values of about 7 to 23 $\text{MPa}\sqrt{m}$, and a 30% decrease occurs as temperature is reduced to 77

K. Low-temperature ductile-to-brittle transitions have been observed in zinc, beryllium, and magnesium, but not in cadmium. Under certain conditions, titanium alloys have exhibited abrupt toughness reductions. The chemical composition of an alloy determines its crystal structure, phase balance, and potential strengthening and deformation mechanisms. Thus, composition has the primary influence on material behavior, including fracture toughness. Chemical composition includes impurities dissolved in the matrix or present as precipitates and inclusions.

Alloy additions increase the stability of the fcc phase in austenitic stainless steels. For example, toughness of nitrogen-strengthened Fe-Cr-Ni-Mn stainless steels at 76 and 4 K may increase with increasing austenite stability. However, the influence of austenite stability on low-temperature toughness is not clear in the Fe-Cr-Ni stainless steels such as AISI 304, 310, and 316.

Phase balance can have a marked effect on toughness at cryogenic temperatures. For example, 308L and 316L stainless steel weld metals are formulated to provide 5 to 10% ferrite, a bcc phase, and the balance austenite. The ferrite is needed to prevent hot cracking, but at cryogenic temperatures the ferrite is brittle and lowers the toughness of the weld metal. Other examples of phase balance are the 5, 6, and 9% Ni steels, where the nickel content results in a 5 to 10% retained austenite after the alloys have been properly heat treated. Retained austenite contributes to improved toughness of these alloys at temperatures from 300 to 76 K.

Potential strengthened mechanisms are a function of alloy content. Solid-solution strengthening of austenitic stainless steels by interstitial nitrogen provides a large increase in yield strength at cryogenic temperatures and a corresponding decrease in fracture toughness. By comparison, solid-solution strengthening by substitutional elements, such as magnesium in aluminum, has a relatively small effect on the temperature dependence of strength and toughness. For precipitation-hardened alloys having an fcc matrix, changes in strength and toughness at low temperatures are also small.

In addition to intentional alloying elements, commercial alloys inevitably contain impurity elements that cannot be economically removed during processing. In most cases, impurities either dissolve interstitially, thereby reducing matrix toughness, or precipitate in the solidifying metal because they are less soluble upon cooling. Precipitates formed in this way increase the ease of void formation and reduce toughness. Occasionally impurities segregate to grain boundaries, causing severe toughness losses that are due to intergranular embrittlement. A classic example is temper brittleness in steels where small concentrations of impurities segregate to the grain boundaries and form a continuous intergranular fracture path.

Processing includes producing, refining, and casting of the alloy; working the ingot into a suitable product form; and heat treating the final product. Within the limits imposed by chemical composition, processing controls the alloy microstructure and, consequently, the properties. Production, refining, and casting operations determine the cleanliness and homogeneity of the alloy. Working the ingot into a suitable product form influences anisotropy, grain size, homogeneity, and cold working. Heat treatment provides the final microstructural control. All of these processes influence toughness at all temperatures. Table 3 summarizes the effects of microstructure on toughness.

Table 3 Effects of microstructural variables on fracture toughness of steels

Microstructural parameter	Effect on toughness
Grain size	Increase in grain size increases K_{Ic} in austenite and ferritic steels
Unalloyed retained austenite	Marginal increase in K_{Ic} by crack burning
Alloyed retained austenite	Significant increase in K_{Ic} by transformation-induced toughening
Interlath and intralath carbides	Decrease K_{Ic} by increasing the tendency to cleave
Impurities (P, S, As, Sn)	Decrease K_{Ic} by temper embrittlement
Sulfide inclusions and coarse carbides	Decrease K_{Ic} by promoting crack or void nucleation
High carbon content (>0.25%)	Decrease K_{Ic} by easily nucleating cleavage
Twinned martensite	Decrease K_{Ic} due to brittleness
Martensite content in quenched steels	Increase K_{Ic}
Ferrite and pearlite in quenched steels	Decrease K_{Ic} of martensitic steels

Processing to minimize grain size is desirable because matrix strength is increased with a minimum change in toughness. Grain refinement is particularly beneficial to alloys that undergo a ductile-to-brittle transition, such as the ferritic steels, because it lowers the transition temperature.

Processing treatments that cause grain-boundary precipitation of intermetallic compounds, usually carbides, can reduce toughness at cryogenic temperatures. Embrittlement due to grain-boundary precipitates only occurs when the matrix strength exceeds the grain-boundary strength; that is, it may occur at cryogenic temperatures but not necessarily at room temperature.

Fatigue Crack Growth

Fatigue progresses in three stages: crack initiation, crack growth, and fracture on the final cycle. Therefore, the fatigue lifetime of a component is determined by the number of cycles required to initiate and propagate a crack to critical proportions. In complex structures, cracks already exist as a result of manufacturing or fabrication or are assumed to exist because inspection methods are not sensitive enough to verify their absence. In low-cycle fatigue applications, crack initiation occurs quickly and may account for little of the total fatigue life.

In reviews of extensive crack propagation data, Paris (Ref 23) observed that a log-log plot of the crack growth rate, da/dN , versus the stress-intensity range, ΔK , is a straight line, obeying an equation of the form:

$$da/dN = c(\Delta K)^n \quad (\text{Eq 25})$$

where c and n are empirical constants and $\Delta K = K_{\max} - K_{\min}$ (K_{\max} and K_{\min} are the maximum and minimum stress-intensity factors of the fatigue cycle). This relation, known as the Paris equation, implies that the cyclic crack-tip stress field described by ΔK is the driving force for fatigue crack extension. Cyclic profile, frequency, mean load, and stress state are of secondary importance. The principal limitation of Eq 25 is the failure to account for environmentally enhanced fatigue crack growth, but Eq 25 still provides a useful basis for the empirical analysis of crack growth data. Accordingly, most data are presented as log-log plots of da/dN versus ΔK . When fatigue crack growth rates are measured over a more complete range (10^{-8} to 1 mm/cycle), the curve has three distinct regions, as shown in Fig. 20. At low growth rates, the curve approaches a threshold value of ΔK , denoted ΔK_{th} , below which fatigue crack growth does not occur. At intermediate growth rates, the curve is linear on a log-log-scale and conforms to Eq 25. Finally, accelerated crack growth occurs when K_{\max} approaches K_c .

Fig. 20 Fatigue crack growth rate data trends, illustrating the sigmoidal curve of da/dN versus ΔK

Test Methods. Fatigue crack growth rate measurements are generally conducted in fatigue test machines capable of applying a constant load amplitude cycle at frequencies on the order of 10 Hz. The standard method for constant amplitude fatigue crack growth rate measurements above 10^8 m/cycle is designated ASTM E 647 (Ref 24). Specimens are precracked by fatigue cycling at a load amplitude equal to or less than the test-load amplitude. During the test, crack length is measured as a function of number of cycles and the data are plotted and reduced in terms of da/dN versus ΔK , as shown in Fig. 20. The growth rate, da/dN , is the slope of the a versus N curve at a given value of a , and the stress intensity range is the ΔK level at that value of a calculated for the specific specimen configuration. For the case of the compact specimens:

$$\Delta K = (P_{\max} - P_{\min})Y(a/W)/B(W)^{1/2} \quad (\text{Eq 26})$$

where P_{\max} and P_{\min} are the maximum and minimum values of the constant-amplitude load cycle.

The basic data in fatigue crack propagation tests are the cycle number and crack length. The cycle number is readily monitored by electronic or mechanical counters. Several methods of crack length determination have been successfully used in room-temperature studies: direct visual measurement, ultrasonic sensing, electrical potential measurements, and the compliance method.

The compliance method is an indirect technique, applicable at all temperatures. It is based on the correlation between specimen compliance (displacement per unit load) and crack length: compliance increases as crack length increases.

The basic procedures for calibrating the compliance method are illustrated schematically in Fig. 21. Crack-front striations (beach marks) on specimen fracture surfaces are created by changes in the minimum fatigue load. The crack lengths are then measured, averaged, and plotted against their compliance values. The resultant curve is then fit using a polynomial expression that is used to infer crack lengths from compliance data recorded during fatigue crack growth tests.

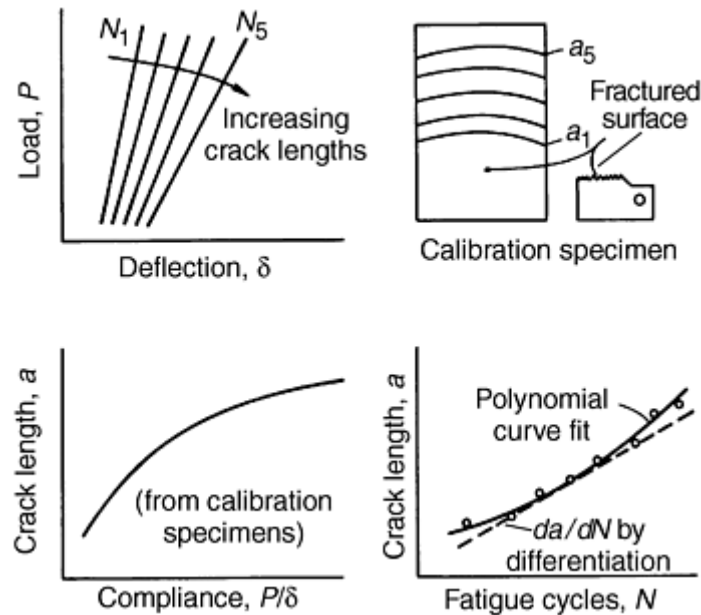

Fig. 21 Compliance method for fatigue crack growth rate measurements

The compliance method offers advantages for testing thick specimens, because the crack-front curvature is accounted for in the average crack length derived from the compliance value. In contrast, the visual method measures the crack length at the specimen surface. Otherwise, the accuracies of the visual and compliance methods are comparable.

Today, laboratory testing for fracture toughness relies more on servohydraulic equipment, which consists of mechanical test apparatus with sophisticated computer data acquisition and controls. In compliance-based fracture testing, the displacement usually is measured across the crack mouth opening using cantilever beam clip gages, optical (laser and white light) extensometry, or back face strain gages. Each of these techniques has its own advantages and may be used to continuously monitor crack length. An additional benefit of compliance techniques is that the same signal can be used for determining crack closure.

Mechanical Test Variables. The data trends illustrated in Fig. 20 should hold as long as ΔK is a valid descriptive parameter for the crack-tip stress field. In cases of extreme plasticity, ΔJ is a better parameter for correlating fatigue crack growth.

Mean stress is proportional to the stress-intensity ratio, $R = K_{\min}/K_{\max}$, and can significantly influence fatigue crack growth rates. In general, for constant ΔK values, da/dN often increases as R increases.

The stress-intensity ratio is usually held constant at a value between 0 and 0.1 for laboratory tests. However, in service applications, R may be higher or variable, and this must be considered in fatigue crack growth predictions.

Cyclic frequency and waveform are important variables for tests at elevated temperatures and in corrosive environments because creep and corrosion are time-dependent processes. However, at cryogenic temperatures, cyclic frequency and waveform have little influence on fatigue crack growth rates.

Test Environment. The room temperature fatigue properties of some alloys are more sensitive to the chemical environment than static tensile properties or fracture toughness. Most cryogenic environments are inert or their chemical reactivity is abated, so that few problems with structural alloys are encountered. Some room-temperature environments, normally considered benign, may actually cause accelerated cracking. For example, unconditioned room-temperature air contains enough moisture to accelerate the fatigue crack growth rates of a wide variety of steel and aluminum alloys. This moisture effect must be recognized when comparing data for inert cryogenic environments with data for unconditioned laboratory air at room temperature. Unless data for dehumidified air are available, it may be difficult to differentiate between temperature effects and chemical reaction.

Specimen Orientation. Crack growth rates in the intermediate range are relatively insensitive to specimen orientation. At high ΔK values, however, orientation effects become obvious and are usually associated with inhomogeneities due to grain structure, second-phase particles, or inclusion distribution and morphology. Some wrought alloys having elongated grain structures also exhibit nearly isotropic fatigue crack growth resistance.

Fatigue Life Calculations. Equation 25 is frequently used to estimate the life of a cracked structure subject to fatigue. For a crack assumed to exist at a selected location in a structure, the relationship between K_c , respectively. Life is calculated by integrating Eq 25 between the limits set by the initial flaw size and the final size, based on fracture toughness data:

$$N = \int_{a_i}^{a_c} da / [c(\Delta K)^n]$$

$$= 1/[c(\Delta \sigma)^n] \int_{a_i}^{a_c} da / [f(a)]^n \quad (\text{Eq 27})$$

For complex load histories, $\Delta\sigma$ takes on many values as a function of time, and Eq 27 must be integrated sequentially using numerical methods. Several computerized techniques have been developed to evaluate Eq 27, including some to account for load interaction effects. A load interaction effect is the beneficial effect of peak loads on subsequent low-load growth rates. For example, da/dN is frequently reduced below expected values during the low-stress amplitude cycles that follow high-stress amplitude cycles.

Fatigue Life Calculations for Brittle Materials. For safety-critical applications involving most metallic materials, integration of crack growth data is frequently done according to Eq 27. This approach is more difficult with brittle materials like ceramics and intermetallics, which have fatigue crack growth rates that are more sensitive to the applied stress intensities than are rates for metallic materials (e.g., Fig. 22). This higher sensitivity results in a higher exponent, n , in the Paris equation and makes life projection from integration more difficult for brittle materials. Accordingly, a more appropriate approach for brittle materials may be to design on the basis of threshold levels below which fatigue failure cannot occur.

Fig. 22 Schematic variation of fatigue-crack propagation rate (da/dN) with applied stress intensity range (ΔK), for metals, intermetallics, and ceramics. Source: Ref 25

Fracture Toughness Testing

John D. Landes, University of Tennessee, Knoxville

Introduction

FRACTURE TOUGHNESS is defined as a “generic term for measures of resistance to extension of a crack” (Ref 1). The term fracture toughness is usually associated with the fracture mechanics methods that deal with the effect of defects on the load-bearing capacity of structural components. Fracture toughness is an empirical material property that is determined by one or more of a number of standard fracture toughness test methods. In the United States, the standard test methods for fracture toughness testing are developed by ASTM (formerly the American Society for Testing and Materials). These standards are developed by volunteer committees and are subjected to consensus balloting. This means that all objecting points of view to any part of the standard must be accounted for. Other industrial countries have equivalent standards writing organizations that develop fracture toughness test standards. In addition, international bodies such as the International Organization for Standardization (ISO) develop fracture toughness test standards that have an influence on products intended for the international market. In this review of fracture toughness testing, the ASTM approach is emphasized to provide a consistent point of view.

The standard fracture toughness test methods were written primarily for the testing of metallic materials. Toughness testing of nonmetals is also important. For many nonmetals, standards are developed based on procedures, analyses, and methods used for metallic fracture toughness tests with some possible modification to account for special needs of the nonmetal material behavior. Fracture toughness test methods written specifically for a particular nonmetal are relatively new. Therefore, this review emphasizes those standards written for metals without intent to make them apply exclusively to metals. A short discussion of fracture toughness testing for ceramics and polymers is included at the end of this article.

General Fracture Toughness Behavior. As a general background before discussing the details of fracture toughness testing and analysis, fracture toughness behavior and the parameters used to describe it are discussed. Fracture toughness is defined as resistance to the propagation of a crack. This propagation is often thought to be unstable, resulting in a complete separation of the component into two or more pieces. Actually, the fracture event can be stable or unstable. With unstable crack extension, often associated with a brittle fracture event, the fracture occurs at a well-defined point, and the fracture characterization can be given by a single value of the fracture parameter. With stable crack extension, often associated with a ductile fracture process, the fracture is an ongoing process that cannot be readily described by a point (Ref 2). This fracture process is characterized by a crack growth resistance curve, or *R*-curve. This is a plot of a fracture parameter versus the ductile crack extension, Δa . An example *K*-based *R*-curve is shown in Fig. 1. Sometimes a single point is chosen on the *R*-curve to describe the entire process; this is mostly done for convenience and does not give a complete quantitative description of the fracture behavior.

Fig. 1 Schematic of K -based crack resistance, R , curve with definition of K_{Ic}

Whether the fracture is ductile or brittle does not directly influence the deformation process that a component or specimen might undergo during the measurement of toughness (Ref 2). The deformation process is generally described as being linear-elastic or nonlinear. This determines which parameter is used in the fracture toughness test characterization. All loading begins as linear-elastic. For this, the primary fracture parameter is the well-known crack-tip stress-intensity factor, K (Ref 3). If the toughness is relatively high, the loading may progress from linear-elastic to nonlinear during the toughness measurement, and a nonlinear parameter is needed. The nonlinear parameters that are most often used in toughness testing are the J -integral (Ref 4), labeled J , and the crack tip opening displacement (CTOD), labeled δ (Ref 5). Because all loading starts as linear-elastic, the nonlinear parameters are all written as a sum of a linear component and a nonlinear component. This is illustrated with the individual descriptions of the various methods in this article.

Test Methods Covered. The test methods covered include linear-elastic and nonlinear loading, slow and rapid loading, crack initiation, and crack arrest. The development of the test methods followed a chronological pattern; that is, a standard was written for a particular technology soon after that technology was developed. Standards written in this manner tend to become exclusive to a particular procedure or parameter. Because most fracture toughness tests use the same specimens and procedures, this exclusive nature of each new standard did not allow much flexibility in the determination of a fracture toughness value. The newer approach is to write standards to encompass all parameters and measures of toughness into a single test procedure. This approach is labeled the common fracture toughness test method approach and has resulted in a new standard developed by ASTM as well as similar standards from organizations in other countries. The test standards for fracture toughness testing are not completed; revision and expansion of existing standards are in progress at this time. It is a requirement of ASTM that standards be reevaluated every five years and be updated if necessary. Therefore, work on revising and updating standards is continually in progress.

The fracture toughness test is generally conducted on a test specimen containing a preexisting defect; usually the defect is a sharp crack introduced by fatigue loading and called the precrack. The test is conducted on a machine that loads the specimen at a prescribed rate. Measurements of load and a displacement value are taken during the test. The data resulting from these measurements are subjected to an analysis procedure to evaluate the desired toughness parameters. These toughness results are then subjected to qualification procedures (or validity criteria) to see if they meet the conditions for which the toughness parameters can be accepted. Values meeting these qualification conditions are labeled as acceptable standard measures of fracture toughness. The

standard fracture toughness test, thus, has these ingredients: test specimens, types, and preparation; loading machine, test fixture, and instrumentation requirements; measurement taking; data analysis; and qualification of results. The following sections discuss the various standard fracture toughness test methods following this format. The fracture toughness test methods written as ASTM standards follow a prescribed format. It is not always easy to determine the step-by-step procedure required to conduct the test from the standard. The sections below, which describe the various methods, follow a format of a step-by-step procedure rather than the format of the actual standards. The application of the fracture toughness result to the evaluation of structural components containing defects is not explicitly covered in the ASTM standard test methods, nor is it covered in this article. The description of the fracture toughness test methods follows a somewhat chronological outline, beginning with the methods that use the linear-elastic parameter K . After this, the methods that use the nonlinear parameters J and δ are discussed. Next, some of the work in progress to update the standards and the newest standards is discussed. Finally, a brief overview of fracture toughness testing for ceramic and polymer materials is given (see the articles “Fracture Resistance Testing of Plastics” and “Fracture Toughness of Ceramics and Ceramic Matrix Composites” in this Volume for additional information about testing of these materials).

Fracture Toughness Testing

John D. Landes, University of Tennessee, Knoxville

Linear-Elastic Fracture Toughness Testing

Fracture mechanics and fracture toughness testing began with a strictly linear-elastic methodology using the crack-tip stress-intensity factor, K . Later, nonlinear parameters were developed. However, the first test methods developed used the linear-elastic parameters and were based on K . These methods are described first in this article.

The linear-elastic methods of fracture toughness testing are used to measure a single-point fracture toughness value. For fracture by a brittle mechanism, this is no problem. Fracture occurs at a distinct point, and the fracture toughness measurement is taken as a value of the fracture parameter at that point. For fracture by a ductile mechanism, the fracture is a process, and the fracture toughness measurement is an R -curve. To get a single value for this fracture toughness, a point on the R -curve must be chosen. This usually involves a construction procedure. The ASTM E 399 K_{Ic} standard fracture toughness test method, which is described next,

gives an example of a construction procedure that is used to get a single-point measurement of fracture toughness on the R -curve.

Plane-Strain Fracture Toughness (K_{Ic}) Test (ASTM E 399)

The first fracture toughness test that was written as a standard was the K_{Ic} test method, ASTM E 399. This test measures fracture toughness that develops under predominantly linear-elastic loading with the crack-tip region subjected to near-plane-strain constraint conditions through the thickness. The test was developed for essentially ductile fracture conditions, but can also be used for brittle fracture. As a ductile fracture test, a single point to define the fracture toughness is desired. To accomplish this, a point where the ductile crack extension equals 2% of the original crack length is identified. This criterion is illustrated schematically with a K - R curve in Fig. 1. This criterion gives a somewhat size-dependent measurement, and so validity criteria are chosen to minimize the size effects as well as to restrict the loading to essentially the linear-elastic regime. The various elements of the K_{Ic} test are discussed in a little more detail than are some of the other tests for fracture toughness measurement. In this way, the K_{Ic} test can serve as a model for the other discussions. The details of this test can be found in Ref 6.

Test Specimen Selection. The first element of the test is the selection of a test specimen. Five different specimen geometries are allowed (Fig. 2). These are the single edge-notched bend specimen, SE(B), compact specimen, C(T), arc-shaped tension specimen, A(T), disk-shaped compact specimen, DC(T), and the arc-shaped bend specimen, A(B). Many of these specimen geometries are used in the other standards as well. The acronyms are standard ASTM nomenclature given in Ref 1. The bend and compact specimens (Fig. 2a and b, respectively) are traditional fracture toughness specimens used in nearly every fracture toughness test method. The other three are special geometries that represent structural component forms. Therefore, most fracture toughness tests are conducted with either the edge-notched bend or compact specimens. The choice between the bend and compact specimen is based on the following:

- The amount of material available (the bend takes more)
- Machining capabilities (the compact has more detail and costs more to machine)
- The loading equipment available for testing (discussed next)

All of the specimens for the K_{Ic} test must be precracked in fatigue before testing. This means that a sharp crack is developed at the end of a notch by repeated loading and unloading of the specimen, that is, fatigue loading. Refer to ASTM E 399 (Ref 6) for details on precracking.

Fig. 2 Specimen types used in the K_{Ic} test (ASTM E 399). (a) Single edge-notched bend, SE(B). (b) Compact specimen, C(T). (c) Arc-shaped tension specimen, A(T). (d) Disk-shaped compact specimen, DC(T). (e) Arc-shaped bend specimen, A(B)

The choice of the specimen also requires a choice of the size. Because the validity criteria depend on the size of the specimen, it is important to select a sufficient specimen size before conducting the test. However, the validity criteria cannot be evaluated until the test is completed; therefore, choosing the correct size is a guess that may turn out to be wrong. There are guidelines (Ref 6) for choosing a correct size, but no guarantee that the chosen size will pass the validity requirement. The test specimens must also be chosen so that the proper material is sampled. This means that the location in the material source and the orientation of the sample must

be correct and accounted for. The ASTM standards have a letter system to specify orientation (Ref 1). As the specimens are being prepared, requirements for tolerances on such things as locations of surfaces, size and location of the notch and pin holes, and surface finishes must be followed.

Loading Machines and Instrumentation. The next step in the test procedure is the choice of a loading machine and the preparation of loading fixtures and instrumentation for recording the test data. Most tests are conducted on either closed-loop servo-hydraulic machines or constant-rate crosshead drive machines. The first machines allow load, displacement, or other transducer control but are more expensive. They are preferred for precracking, which is usually done at a constant load range so load control is desired. The second type of loading machine is less expensive and may give more stability but allows only crosshead control. Because this is required in most of the fracture toughness tests, this type of machine is quite satisfactory for the actual fracture toughness testing but is not so good for precracking.

Loading fixtures must be designed for the test. Two types can be used (3); choice of loading fixture depends on the test specimen chosen. The bend specimens SE(B) and A(B) use a bend fixture. The tension specimens C(T), DC(T), and A(T) require a pin-and-clevis loading. Note in Fig. 3(a) that the bend loading is three point; this is the case for all bend- loaded specimens. Also note in Fig. 3(b) that the clevis has a loading flat at the bottom of the pin hole. This allows free rotation of the specimen arms during the test and is essential for getting good results.

For the K_{Ic} test, a continuous measurement of load and displacement is required during testing. The load is measured by a load cell, which should be on all loading machines. The measurement of displacement is usually done with a strain-gaged clip gage that is positioned over the mouth of the crack in the specimen. An example of a clip gage is shown in Fig. 4. Figure 3(a) shows the bend specimen with a clip gage in place. The standards give guidelines for the accuracies and working requirements of the load and displacement gages used in the tests.

Fig. 4 An example clip gage for displacement measurement (all dimensions in mm)

The loading of the specimen is done at a prescribed rate. It must be done fast enough so that any environmental or temperature interactions are not a problem. On the other hand, it must be done slowly enough so that it is not considered a dynamically loaded test. For the K_{Ic} test, the load must be applied at a rate so that the increase in K is given by the range 0.55 to $2.75 \text{ MPA} \sqrt{m/s}$. The loading is done in displacement control, which usually means test machine crosshead control. During the loading, the load and displacement are measured continuously. This can be done autographically or digitally.

Test Data and Analysis. The load-and-displacement record provides the basic data of the test. The data are then analyzed to determine a provisional K_{Ic} value, labeled K_Q . This provisional value is determined from a

provisional load, P_Q , and the crack length. The P_Q value is determined with a secant line of reduced slope on the load-and-displacement record (Fig. 5). The construction for P_Q involves drawing the original loading slope of the load-versus-displacement record. A slope of 5% less than the original (secant slope) is then drawn. For a monotonically increasing load, the P_Q is taken where the 5% secant slope intersects the load-versus-displacement curve; this is illustrated as type I in Fig. 5. For other records in which an instability or other maximum load is reached before the 5% secant, the maximum load reached up to and including the possible intersection of the 5% secant is the P_Q . Type II illustrated in Fig. 5 is an example of one of the other types of load-versus-displacement records. The 5% secant corresponds to about 2% ductile crack extension; this may be physical crack extension or effective crack extension related to plastic zone development. Unstable failure before reaching the 5% offset also marks a measurement point for P_Q at the maximum load reached at the point of instability.

Fig. 5 Typical load-versus-displacement record for the two types of K_{Ic} testing

The P_Q value is used to determine the corresponding K_Q value. This is calculated from the equation:

$$K = P f(a/W) / \sqrt{W} \quad (\text{Eq 1})$$

where P is load, B and W are specimen thickness and width, and $f(a/W)$ is a calibration function that depends on the ratio of crack length to specimen width, a/W , and is given in the standard. For the calculation of K , a crack length value, a , is required. This comes from a physical measurement on the fracture surface of a broken specimen half. The specimen must be fractured into halves if it is not already that way from the test. The crack length is measured to the tip of the precrack using an averaging formula given in the test standard. This value of crack length normalized with width, W , is used in the calibration function $f(a/W)$ to determine the K_Q value.

The K_Q is a provisional K value that may be the K_{Ic} if it passes the validity requirements. The first of the two major validity requirements is quantified as:

$$\frac{P_{\max}}{P_Q} \leq 1.10 \quad (\text{Eq 2})$$

which limits the R -curve behavior to an essentially flat trend and ensures some physical crack extension. The second requirement is:

$$a, B \geq 2.5 \left(\frac{K_Q}{\sigma_{ys}} \right) \quad (\text{Eq 3})$$

which guarantees linear-elastic loading and plane-strain thickness. P_{\max} is the maximum value of load reached during the test. An example of P_{\max} is shown in Fig. 5; σ_{ys} is the 0.2% offset yield strength. Other validity requirements relating to specimen preparation, precracking, and crack front straightness must also be met.

Values of K_Q that pass all validity requirements are labeled as valid K_{Ic} and are reported as such. The ASTM E 399 standard lists all of the information required for the test report.

Rapid-Load $K_{Ic}(t)$ Test

A value of fracture toughness labeled $K_{Ic}(t)$ can be determined for a rapid-load test. Details of this method are given in a special annex to ASTM E 399 (Ref 6). For the static loading rate K_{Ic} value, the maximum loading rate is $2.75 \text{ MPA } \sqrt{\text{m}}/\text{s}$. Anything faster than that is labeled as a rapid-load fracture toughness. The specimens, apparatus, and procedure are much the same as for the regular K_{Ic} test. Special instructions are given to ensure that the instrumentation can handle the rapidly changing signals. The interpretation of results must be based on a dynamic value of the yield stress, σ_{YD} . An equation for σ_{YD} is given in the Annex to ASTM E 399. Results are reported as $K_{Ic}(t)$, where the loading time of the test, t , is written in parentheses after the measured toughness value.

K-R Curve Test (ASTM E 561)

Ductile fracture toughness behavior is measured by a crack growth resistance curve, or R -curve, which is defined as “a plot of crack-extension resistance as a function of slow-stable crack extension” (Ref 1). Although many ductile fracture processes can be measured as a single-point, such as with K_{Ic} , the R -curve is a more complete description of the fracture toughness. When the R -curve increases significantly with increased loading, a single-point measurement is even less descriptive of the actual fracture toughness. Steeply rising R -curves occur in many metallic materials but especially in thin plate or sheet materials. The steeply rising R -curve makes the single-point definition of fracture toughness more size-dependent and geometry-dependent and does not lend itself to correct structural evaluation.

The K - R curve is a good method for fracture toughness characterization in cases where the R curve is steeply rising but the fracture behavior occurs under predominantly linear-elastic loading conditions. The K - R curve procedure is given by ASTM E 561 (Ref 7). The objective of the method is to develop a plot of K , the resistance parameter, versus effective crack extension, Δa_e . The method allows three different test specimens, the compact, C(T), the center-cracked tension panel, M(T), and the crack-line-wedge-loaded specimen, C(W). The compact specimen is shown in Fig. 2(b). The center-cracked tension panel and the crack-line-wedge-loaded specimens are shown in Fig. 6(a) and (b), respectively. The first two specimens use a conventional loading machine with fixtures that are specified in the test method. The C(W) specimen is wedge loaded to provide a stiff, displacement-controlled loading system (Fig. 6b). This can prevent rapid, unstable failure of the specimen under conditions where the R -curve toughness is low so that the R curve can be measured to larger values of Δa_e . All specimens must be precracked in fatigue.

Fig. 6 Specimens for the K - R curve test (ASTM E 561). (a) Center-cracked tension specimen, M(T). (b) Crack-line-wedge-loaded compact specimen, C(W), in loading fixture

The instrumentation required on the specimens is similar to that for the K_{Ic} test, except for the case of the C(W) specimen. The basic test result is a plot of load versus a displacement measured across the specimen mouth. From this, an effective crack length is determined from secant slopes on the load-versus-displacement record (Fig. 7). An effective crack extension is the difference between the original and effective crack lengths. Effective crack length is determined from the slope of the secant offset using the appropriate compliance function, which relates this slope to crack length. The K is determined as a function of the applied load, P , and corresponding effective crack length. This is given by:

$$K = P f(a_c / W) / \sqrt{W} \quad (\text{Eq 4})$$

The resulting plot of K versus effective crack length is the desired K - R curve fracture toughness. The result is subjected to a validity requirement that limits the amount of plasticity. For the C(T) and C(W) specimens

$$b = (W - a) \geq (4/\pi)/(K_{\max}\sigma_{ys})^2 \quad (\text{Eq 5})$$

where b is the uncracked ligament length, σ_{ys} is the 0.2% offset yield strength, and K_{\max} is the maximum level of K reached in the test. For the M(T) specimen, the net section stress based on the physical crack size must be less than the yield strength.

Fig. 7 Secant measurement of effective crack length

For the C(W) specimen, a load is not measured. The data collected are a series of displacement values taken at two different points along the crack line, one near the crack mouth and one nearer the crack tip. From the two different displacement values, an effective crack length can be determined from the ratio of the two displacement values and from calibration values given in ASTM E 561. From the crack length and displacement a K value can be determined and the K - R curve constructed. The toughness result is then a curve of K versus Δa_e , somewhat similar to the one in Fig. 1. The K - R curve fracture toughness is a function of the material thickness; all results are given for a specified thickness. There is no validity requirement relating to a thickness level as with the K_{Ic} standard.

Crack Arrest, (K_{Ia}) Test (ASTM E 1221)

This procedure allows a toughness value to be determined based on the arrest of a rapidly growing crack. The specimen and procedure are somewhat different from those for the previously discussed toughness test methods, which determine initiation toughness values only. The specimen for crack arrest testing is called the compact crack-arrest specimen (Fig. 8). It is similar to the crack-line-wedge-loaded specimen, C(W), of the K - R curve method and requires wedge loading in order to provide a very stiff loading system to arrest the crack. The specimen also requires side grooves—machined notches on the specimen planar face (Fig. 8)—to aid in getting a straight-running crack during the test. The notch preparation is different from that used in the other standards in that the specimen has a notch with no precrack. A brittle weld bead is placed at the notch tip to start the running crack. The running crack advances rapidly into the test material and must be arrested by the test material to produce a K_{Ia} result. The only instrumentation on the specimen is a displacement gage. A load cell is placed on the loading wedge, but it does measure the load on the specimen. The displacements at the beginning of the unstable crack extension and at the crack arrest position are measured and converted to K values. To eliminate effects of nonlinear deformation, which cannot be directly measured with only a displacement gage, a series of loads and unloads are conducted on the specimen until the unstable cracking occurs.

Fig. 8 Crack-line-wedge-loaded compact crack-arrest specimen

The value of K_{Ia} is determined from a displacement value and the crack length at the arrest point. Validity is determined from the size criterion:

$$W - a \geq 1.25 (K/\sigma_{YD})^2 \quad (\text{Eq 6})$$

where σ_{YD} is a dynamic yield strength. To complete a successful K_{Ia} test, careful attention must be paid to the instructions in ASTM E 1221 (Ref 8).

Fracture Toughness Testing

John D. Landes, University of Tennessee, Knoxville

Nonlinear Fracture Toughness Testing

Linear-elastic parameters are used to measure fracture toughness for relatively low toughness materials, which fracture under or near the linear-loading portion of the test. For many materials used in structures, it is desirable to have high toughness, a value at least high enough so that the structure would not reach fracture toughness before significant yielding occurs. For these materials, it is necessary to use the nonlinear fracture parameters to measure fracture toughness properties. The two leading nonlinear fracture parameters are J and δ .

For many of the nonlinear fracture toughness measurements, the fracture mode is a ductile one. In this case the fracture toughness is measured by an R -curve, that is, a plot of the fracture-characterizing parameter as a function of the ductile crack advance. The evaluation of the R -curve toughness requires three measurements during the test: load, displacement, and crack length. The load and displacement are standard measurements. The crack length requires a special monitoring system. In the standards, the crack length has been measured visually on the fracture surface and by an elastic unloading compliance method that uses the elastic properties of the specimen geometry to evaluate crack length. Methods that have also been used are an electrical potential drop method and a key curve, or normalization, method. The electrical potential method uses the electrical resistance of the material to evaluate crack length. The method of normalization uses the plastic deformation properties of the material to evaluate crack length.

The visual method was the first and longest used of the methods. It has a disadvantage in that it requires a number of specimens to evaluate one R -curve. Each specimen generates only one point on the R -curve. It is often called the multiple-specimen method. The other methods require only one specimen to generate an R -curve and are often called single-specimen methods. The elastic unloading compliance method is the most often used of the single-specimen methods and is used in many of the standards to measure fracture toughness during nonlinear loading. It cannot be used under rapid loading conditions or for materials that do not have a linear-elastic loading character. This would include polymer materials. The electrical potential drop method requires a material that has a measurable electrical resistance. It is mostly used for metallic materials. In the past it has been in some standard test methods, but presently it is withdrawn from all existing standards because it has not always given accurate crack length measurement during a fracture toughness test. The method of normalization has not been standardized. It is advantageous in that it can be used for any material that generates nonlinear loading that is similar to plastic deformation in metals. It can be used to measure crack length both for polymers and for rapid loading test conditions.

J_{Ic} Testing (ASTM E 813)

The first standard test developed using the J parameter is the J_{Ic} test, originally standardized as ASTM E 813 (Ref 9). (Changes to this standard will be discussed later.) In this test an R -curve is developed using J versus Δa pairs. A point near the beginning of the R -curve is defined as J_{Ic} , “a value of J near the onset of stable crack extension” (Ref 9). The specimens for the J_{Ic} test are the bend, SE(B), and compact, C(T). These are similar to the ones used for K_{Ic} testing (Fig. 2a and b); however, the compact specimen for J testing allows for a load line displacement measurement in the line of the applied loads. Therefore, a cutout is machined in the front of the specimen to accommodate the placement of a clip gage on the load line (Fig. 9). Also, side grooving is recommended on this specimen to assist in maintaining a straight crack front during the stable crack growth. The loading fixtures required are the bend fixture for the bend specimen (Fig. 3a) and the pin and clevis for the compact specimen (Fig. 3b). As with the K_{Ic} test, the clevis has a loading flat at the bottom of the pinhole, which is essential for free rotation of the specimen. The instrumentation required is the load cell and a displacement measuring clip gage. The clip gage for the J_{Ic} test requires more resolution than that for the K_{Ic} test if a single-specimen test method is used. For the bend specimen, a loadline clip gage is needed to measure J . Additionally, a second clip gage can be used over the crack mouth if a single-specimen method is used.

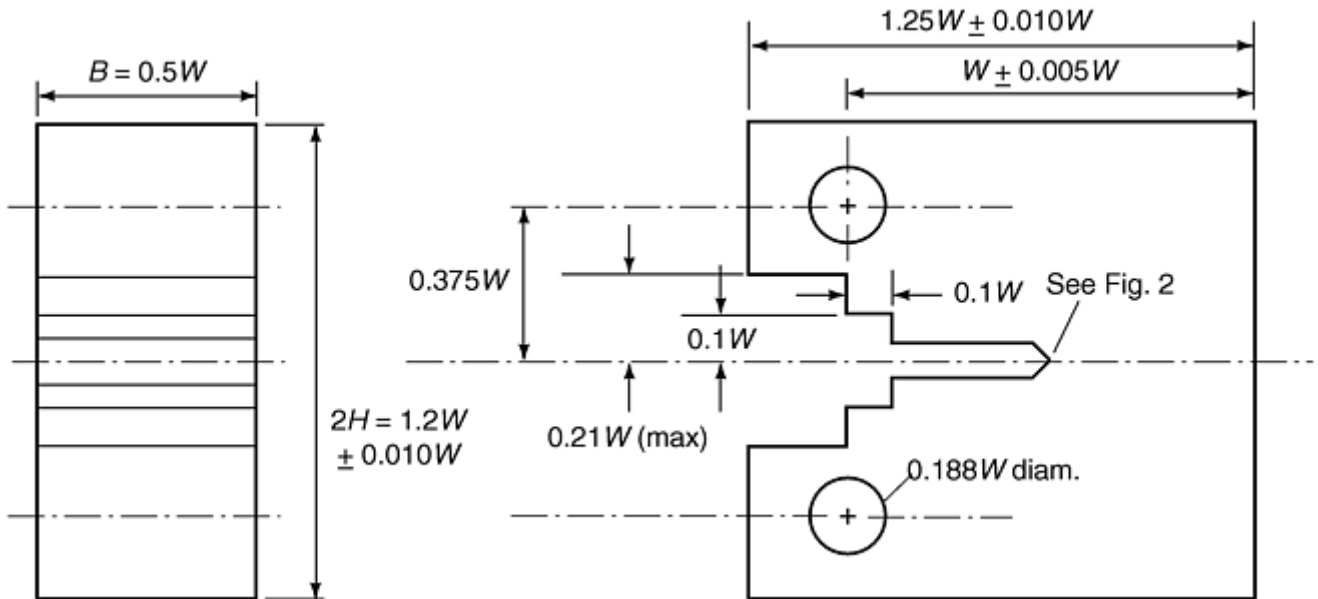

Fig. 9 J_{Ic} compact specimen with load line cutout

J_{Ic} Test Procedures. The basic output of the test is a plot of J versus physical crack extension (Δa). (Unlike the $K-R$ curve method, which uses effective crack extension, the J_{Ic} test uses physical crack extension.) To obtain the required J versus Δa data, measurements of load, displacement, and physical crack length are required during the test. Two techniques are used to develop these data. The first is the multiple-specimen test method, in which each specimen develops a single value of J and Δa , but no special crack monitoring equipment is needed during the test. Crack extension is measured on the fracture surface at the conclusion of the test. However, for this technique a number of specimens (usually five or more) are required to develop the plot of J versus Δa from which the J_{Ic} is evaluated. The other test method is the elastic unloading compliance method, a single-specimen test from which all of the J and Δa values needed for the result are developed from one test specimen.

The test procedure depends on the method of crack length monitoring. For the multiple-specimen test, five or more identical specimens are loaded to prescribed displacement values that are expected to give some physical crack extension without complete separation of the specimen. This results in a number of individual load-versus-displacement records as shown in Fig. 10. When the prescribed displacement is reached, the specimen is unloaded, and the crack tip is marked by a procedure called heat tinting. Heat tinting consists of marking the physical crack extension by heating the specimen until oxidation occurs on the crack. The specimen is then broken open, and the crack extension is measured on the fracture surface.

Fig. 10 Load versus displacement for multiple-specimen tests

The single-specimen method using elastic compliance is initially loaded in the same way; however, during the test, partial unloadings are taken to develop elastic slopes from which crack length can be evaluated using compliance relationships (Fig. 11). The compliance relationships are given in ASTM E 813 (Ref 9).

Fig. 11 Load versus displacement with unloading slopes

Data Evaluation. From these test results, J is evaluated from the load-versus-loadline displacement record. The J is calculated from a linear combination of an elastic term and a plastic term given as:

$$J = J_{el} + J_{pl} \frac{K^2(1-\nu^2)}{E} + \frac{\eta_{pl}}{Bb} \int_0^{v_{pl}} P dv_{pl} \quad (\text{Eq 7})$$

where K is the stress-intensity factor, E is elastic modulus, ν is Poisson's ratio, P is load, v_{pl} is plastic displacement, B is specimen thickness, b is specimen uncracked ligament ($W - a$, where W is specimen width) and η_{pl} is a coefficient that has values of $\eta_{pl} = 2$ for the SE(B) specimen of Fig. 2(a) and $\eta_{pl} = 2 + 0.522b/W$ for the compact specimen of Fig. 9.

The crack length is used to determine $\Delta a = a - a_0$, where a_0 is the original crack length at the beginning of the test. For the multiple-specimen method, all Δa values are determined from measurements taken from the fracture surface of the test specimen. For some metals, heat tinting does not oxidize the crack surfaces, and another method of marking the crack extension, for example posttest fatiguing, can be used. The specimen is broken in two after the heat-tint procedure, usually at a low temperature to induce brittle fracture for easy reading of the ductile crack extension and to otherwise minimize plastic deformation during this procedure. Typically, this is done by cooling the specimen to the temperature of liquid nitrogen before breaking it in two. Crack lengths a_0 and a_f , original and final, are measured on the fracture surface. A nine-point measurement and averaging method is used because the crack front is usually neither straight or regular. This procedure is described in ASTM E 813 (Ref 9). For the single-specimen methods for which crack length monitoring systems are used, the crack length is evaluated at prescribed points during the test. In the elastic unloading compliance method, a crack length can be determined at each unload. Typically, about 20 of 50 unloading data pairs, P , v , and a are evaluated for each test. For single-specimen tests, a physical measurement of the final crack length is made at the end of the test using the same procedure that is followed for the multiple-specimen test, so that this measured crack length can be compared with the final crack length evaluated by the crack monitoring system.

The J versus Δa results form a part of the J - R curve and are the basic data of the J_{Ic} method. The objective is to get J versus Δa values in a certain restricted range. These data are then subjected to a prescribed evaluation scheme to choose a point on the J - R curve that is near the initiation of stable cracking. The method for developing the J_{Ic} is somewhat complicated, and the details are given in ASTM E 813 (Ref 9). Basically, the J versus Δa pairs are evaluated to see which fall in a prescribed range. The pairs falling in the correct range are fitted with a power-law equation:

$$J = C_1(\Delta a)^{C_2} \quad (\text{Eq 8})$$

where C_1 and C_2 are constants. A construction line is drawn, and the intersection of this with the fitted line, Eq 8, is the evaluation point for a candidate J_{Ic} value. This candidate value is labeled J_Q . A schematic of the process of J_{Ic} evaluation is shown in Fig. 12.

Fig. 12 J_{Ic} evaluation scheme

The candidate J_Q value is subjected to qualification criteria to see if it constitutes an acceptable value. The basic one is to guarantee a sufficient specimen size:

$$b, B \geq 25(J_Q / \sigma_Y) \quad (\text{Eq 9})$$

where σ_Y is an effective yield strength and

$$\sigma_Y = (\sigma_{ys} + \sigma_{uts})/2 \quad (\text{Eq 10})$$

where σ_{ys} and σ_{uts} are the yield strength and ultimate tensile strength, respectively.

If the qualification requirements are met, the J_Q is J_{Ic} and the results are reported following the prescribed format in ASTM E 813 (Ref 9).

J-R Curve Evaluation (ASTM E 1152)

A more complete evaluation of fracture toughness for ductile fracture based on J is the J - R curve. The test procedure was originally standardized as ASTM E 1152 (Ref 10). This standard uses the same specimens, instrumentation, and test procedures as the J_{Ic} test. The J - R curve test cannot be conducted with the multiple-specimen test procedure; it must use a single-specimen procedure. The purpose of the J - R curve is to develop points of J versus Δa ; these comprise the fracture toughness evaluation. A single value of J is not specifically measured as it is for the J_{Ic} procedure. The single-specimen method used is again primarily the elastic unloading compliance method. Equation 7 is the basic J formula for the case of a nongrowing crack. It is based on a K equivalence for the elastic component of J and an area term for the plastic component of J . Alternate J formulas are given in ASTM E 1152 (Ref 10) for the growing crack. Qualification criteria are also given in the standard (Ref 10). The J_{Ic} and J - R curve methods are very similar; hence the two have recently been combined into one standard, ASTM E 1820 (Ref 11). The individual standard ASTM E 813 and E 1152 were withdrawn from the *Annual Book of ASTM Standards* beginning in 1998.

Crack Tip Opening Displacement (CTOD) Test (ASTM E 1290)

The crack tip opening displacement method of fracture toughness measurement was the first one that used a nonlinear fracture parameter to evaluate toughness (Ref 5). The first CTOD standard was written by the British Standards Institution (Ref 12). Subsequently, ASTM E 1290 was written as the U.S. version of this test method (Ref 13). The basic idea of the test method is to evaluate a fracture toughness point for brittle fracture or to evaluate a safe point for the case of ductile fracture. The primary measurements of toughness are at unstable fracture before significant ductile crack extension, labeled δ_c , unstable fracture after significant crack extension, δ_u , or the point of maximum load in the test, δ_m . The method originally had a point near the beginning of stable crack extension, δ_i , that was measured as a point on an R -curve in a similar manner to J_{Ic} . This point was subsequently removed from the test method.

The CTOD standard uses the same bend and compact specimens that are used in the J_{Ic} test; thus the same loading fixtures are used. The method requires measurement of load and displacement during the test. As for J , the formulas for δ calculation use a combination of an elastic and a plastic component:

$$\delta = \frac{K^2(1-\nu^2)}{2\sigma_{ys}E} + \frac{r_p(W-a_0)v_p}{r_p(W-a_0) + a_0 + z} \quad (\text{Eq 11})$$

In this equation, the elastic component of δ is based on a K equivalence, and the plastic component is based on a rigid plastic rotation of the specimen about a neutral stress point at $r_p(W-a_0)$ from the crack tip. In Eq 11, ν is Poisson's ratio, σ_{ys} is the yield strength, r_p is a rotation factor, v_p is a plastic component of displacement, $W-a_0$ is the uncracked ligament length, and z is the distance from the clip gage measurement position to the front face for an SE(B) specimen or to the load line for a C(T) specimen (Fig. 13). The rotation factor, r_p , is 0.44 for the bend specimen and a variable ranging from 0.46 to 0.47 for the compact specimen.

Fig. 13 Definitions of length parameters used in plastic CTOD

For many years the CTOD test was the only one that measured toughness for a brittle, unstable fracture event using a nonlinear fracture parameter. Now fracture toughness can be measured for unstable fracture using J in ASTM E 1820. The ASTM E 1290 method also allows the measurement of toughness after a pop-in, which is described as a discontinuity in the load-versus-displacement record usually caused by a sudden, unstable advance of the crack that is subsequently arrested.

Fracture Toughness Testing

John D. Landes, University of Tennessee, Knoxville

New Standards for Metallic Materials

The development of standard fracture toughness test methods is not completed. In the past five years, two new standards have been developed, successfully balloted, and placed in the *Annual Book of ASTM Standards*. They are the common test method, a new fracture toughness standard that combines most of the standard test methods discussed above into a single standard, and the transition fracture toughness standard. A standard for testing of weldments is still being developed.

Common Fracture Toughness Test Method

Because the J_{Ic} and J - R curve test standards are similar in many respects, they have been combined into a single test standard, ASTM E 1820 (Ref 11). This standard method also allows a measurement of fracture toughness using the linear elastic parameter, K , and the nonlinear parameters, J and δ . The idea of a common method is that most of the fracture toughness tests use the same specimens, instrumentation, and test procedures. However, the analysis part of the standard gives each an exclusive quality that was derived from the historical development of the fracture mechanics methodology. The way individual methods were written in the past allows for the likelihood that a test can produce an invalid or unqualified result with no way to use the analysis procedure of another test method to try to obtain an acceptable result. The common method combines all measurements of fracture toughness into a single standard instead of many specialized standards. Therefore, after the test has been completed, the behavior of the material can dictate the nature of the analysis used, and a satisfactory fracture toughness result can be achieved for most tests. The analysis can use a linear elastic or an elastic-plastic parameter; it can use a single point fracture measurement or an R -curve toughness measurement. The way that each test is evaluated depends on the nature of the deformation and fracture behavior during the test. Therefore, the actual test result has a major influence on how the data are analyzed.

An additional feature of the new common method is an initialization procedure to assure that the initial portion of the J - R curve is aligned properly with the initial measured crack length. The ASTM E 813 method of J_{Ic} measurement did not specifically align the initial portion of the curve and could give artificially raised or lowered values of J_{Ic} reflecting the misalignment in the initial J - R curve. The ASTM E 1820 method includes

all of the fracture toughness methods discussed in the previous section except for the K - R curve method and the crack arrest test method.

Transition Fracture Toughness Testing

The measurement of transition fracture toughness for ferritic steels has long been a problem. The fracture behavior is usually brittle sometimes after an initial period of ductile crack extension. The toughness values show extensive scatter and size dependency that cause difficulty in the characterization of toughness for the evaluation of structures. The scatter and size dependency has been attributed to statistical influences and constraint differences (Ref 14). Characterization of the toughness relies mainly on the statistical handling of the data.

Test method ASTM E 1921 has been developed recently to handle the problems of transition fracture toughness testing (Ref 15). The specimens, fixtures, instrumentation, test procedures, and calculation of toughness parameters follow existing standards, for example, ASTM E 1820. The evaluation of the statistical aspects are handled with a weakest-link Weibull statistical distribution (Ref 15). Six or more fracture toughness test results are required at a given temperature. If the specimen size is not the unit size prescribed in the standard, a statistical size adjustment is made to the fracture toughness values. From the toughness results and using a statistical evaluation, a median value of toughness is identified. All median values of the distribution are aligned on a master curve (Fig. 14). The assumption is made that in the standard, the master curve of median toughness values is reproducible for the range of steel alloys with yield strengths between 275 and 825 MPa. The master curve is positioned with a reference temperature, T_0 , which is the temperature where a median toughness has a value of $100 \text{ MPa}\sqrt{m}$. All of the equations relating to the application of the Weibull statistics and the determination of T_0 for the placement of the master curve are given in the ASTM E 1921 (Ref 15). From the master curve and Weibull statistics, the toughness distribution at other temperatures can be determined. Also, from the statistical distribution, a percentage lower bound confidence level of toughness can be identified. For example, a 95% lower bound confidence level can be determined from the statistical distribution as a function of temperature.

Fig. 14 Master curve of transition fracture toughness, K_{Jc} , critical stress intensity based on the J integral

Fracture Testing of Weldments

Preparation of a test method for the fracture toughness testing of weldments is ongoing. Weldments do not require a different set of parameters, specimens, or equipment for toughness testing; however, special problems exist for the testing of weldments. Solutions to these problems are not covered in the other standards.

Weldments have a composite of materials containing base metal, heat-affected zone, and weld metal regions. Such things as the placement of the notch for the sampling of the correct material, the precracking procedure to get the crack to grow into the correct area, and the handling of such thing as distortion and residual stresses present problems. These will be covered in the weldment standard. The parts that are common with the other standards are not covered in this method, but the tester is referred to the other standards to complete the testing and analysis after the special problems inherent to the testing of weldments have been addressed. In its first version, this standard will be annexed to the existing ASTM E 1290 method on CTOD testing, and the test result will be analyzed primarily with the δ parameter.

Fracture Toughness Testing

John D. Landes, University of Tennessee, Knoxville

Fracture Toughness Test for Nonmetals

The standardization of fracture toughness test methods for nonmetals is relatively new compared to standardization for metallic materials. However, in the past ten years, several new standards have been written for ceramic and polymer materials. These are usually patterned after similar standards for metallic materials. The requirements to use the fracture mechanics approach for fracture toughness determination are that the materials are homogeneous, isotropic, and have a macroscopic defect. Because no material meets this requirement at all levels, it is required that it fits this criterion at some scale. Usually, this could be a scale of the same approximate size as the defect length.

To develop the correct test procedure, the deformation behavior of the material must be considered to determine the fracture parameter to be used to characterize the fracture toughness results. To determine whether the fracture is characterized by a single point or by an R -curve, the fracture behavior of the material must be considered. Brief discussion of fracture toughness testing of ceramics and polymer materials follows. A more complete description is given in other articles in this Section specifically written for these materials. Some fracture toughness standards have been developed for other nonmetallic materials including glass, rock, and polymer matrix composites. These standards are not discussed in this article.

Fracture Toughness Testing for Ceramics

Discussion of the fracture toughness testing of ceramics considers two different groups, monolithic ceramics and ceramic matrix composites.

Monolithic ceramics are brittle and fracture in a linear-elastic manner. The toughness, therefore, can be characterized by the K parameter. A fracture toughness test procedure could be similar to the K_{Ic} test procedure given in ASTM E 399 or ASTM E1820 following the methods used for metallic materials. A major problem for the fracture toughness testing of ceramics is the introduction of the defect. Because the toughness is so low, failure can occur during a fatigue precracking procedure. One fracture toughness method that has been used for

brittle materials including ceramics is the chevron-notch fracture toughness test, ASTM E 1304 (Ref 16). This is one of the test methods that do not require a fatigue precrack. The ASTM E 1304 method was developed for metallic materials but can often be used for brittle ceramic materials. Because the fracture behavior of ceramics is brittle, the toughness can be measured as a single point value. A new and provisional standard, PS 70 (Ref 17), has been developed for the fracture toughness testing of advanced ceramics at ambient temperatures. In this standard, a defect may be introduced as a precrack, or a hardness indentation or a chevron notch can be used to start the defect, as in ASTM E 1304. The precrack is popped in using a compression loading fixture; fatigue loading is not used for precracking advanced ceramics.

Ceramic-matrix composites have a more ductile looking toughness character. These materials exhibit more of an *R*-curve behavior. In some cases the deformation has a nonlinear characteristic. Although the nonlinear behavior may not be the same as plasticity in metallic materials, the nonlinear fracture parameters may still apply. Fracture toughness testing for these materials is largely in the experimental stages, and testing information is available in a variety of articles on the subject. The article “Fracture Toughness of Ceramics and Ceramic Matrix Composites” includes a good set of references relative to the fracture testing of ceramic matrix materials.

Fracture Toughness Testing for Polymers

The fracture toughness behavior for polymers usually falls into two classes, below the glass transition temperature T_g , and above T_g . Below T_g , the deformation is nearly linear elastic, and fracture is unstable. Therefore, a single-point toughness value, characterized by K , can be used. Above T_g , the deformation is nonlinear, and the fracture behavior is stable cracking. A *J*-based *R*-curve approach can be used. Two problems that must be addressed in developing test standards for polymers that make them different from metals are the viscoelastic nature of the polymer deformation behavior and the problem of introducing a defect by fatigue loading. The viscoelastic deformation character makes the fracture toughness result dependent on the loading rate, and that must always be specified in the test report. Comparison of toughness results for polymers should always be made with awareness of the effect of loading rate. Also, due to the viscoelastic nature of polymers, introduction of the defect is not easily accomplished with fatigue loading, and the crack is usually introduced with a razor blade cut.

Fracture toughness testing of polymer materials has been standardized in the past few years. The ASTM D 5045 method, standardized in 1996 (Ref 18), is used for determining fracture toughness of plastic materials that fail under essentially plane-strain and linear-elastic conditions. It has a basis in the ASTM E 399 method and follows a lot of the same methods. For more ductile polymers, the ASTM D 6068 method, also standardized in 1996 (Ref 19), develops the *J*-*R* curve fracture toughness for plastic materials. It follows the ASTM E 813 method in that it is a multiple specimen technique used where each test generates a single point on the *J*-*R* curve. It does not have a J_{Ic} analysis as ASTM E 813 does, but it uses the entire *R*-curve as the fracture toughness characterization. Both of these standard test methods for plastics require a reporting of the loading rate during the test and an introduction of the defect with a razor blade cut. A single specimen method for developing the *J*-*R* curve has not been standardized for polymers; however, the normalization method for developing the *J*-*R* curve has been shown to work well as a single-specimen method for several of the more ductile polymers (Ref 20).

More detailed information is provided in the article “Fracture Resistance Testing of Plastics” in this Volume.

Creep Crack Growth Testing

B.E. Gore, Northwestern University, W. Ren, Air Force Materials Laboratory, P.K. Liaw, The University of Tennessee

Introduction

HIGH-TEMPERATURE APPLICATIONS in the chemical processing, aerospace, nuclear and fossil power-generation industries, and waste incineration industries are realizing a need for materials that can withstand increasingly more strenuous working environments for longer periods of time. While many of the methods used to predict the service life of a structural component involve tests based on the behavior of a material under pure creep conditions, many applications require an understanding of how creep-fatigue conditions affect the life of a component.

Using the fossil energy industry as an example, their systems are rarely operated under steady-state conditions. Due to factors such as shutdowns for safety inspections and changing demands, there is often a thermal-mechanical fatigue process introduced during service (Ref 1). These processes can affect the service life of a material by inducing a redistribution of crack-tip stresses and by affecting the creep zone growth behavior (Ref 2) or by changing the creep crack propagation mechanisms (Ref 3). Therefore, the interaction of creep and fatigue damage is an important concern in structural life assessments. There is also an increasing demand to develop methods of increasing the service life of existing systems, as well as to develop more accurate techniques of predicting the initial life span of a material (Ref 4). These demands are a result of not only economic concerns but safety considerations as well (Ref 5).

Test methods for the evaluation of creep-fatigue interactions include fatigue-life testing with hold times and creep crack growth testing with hold times. Fatigue-life testing involves stress-controlled ($S-N$) or strain-controlled ($\epsilon-N$) cyclic loading, where hold times and waveform patterns are used to evaluate the time-dependent effects of creep conditions on fatigue life. These fatigue-life test methods are used to evaluate materials for safe-life designs by either infinite life ($S-N$) or finite life ($\epsilon-N$) criteria. Test methods for this approach are discussed in more detail in the article “Fatigue, Creep-Fatigue, and Thermomechanical Fatigue-Life Testing” in this Volume.

Creep crack growth testing is based on the concepts of fracture mechanics where subcritical crack growths are evaluated from a preexisting flaw or crack. Although careful measures are taken to ensure that materials, especially those designed for high-temperature applications, do not contain potentially damaging internal errors, it is true that small defects, such as those due to machining or inclusions in the material, may elude inspections

(Ref 5, 6). Unintended defects typically serve as the point of origin of a crack, which can ultimately lead to the failure of the material. For these reasons, it is important to understand not only the mechanisms by which a crack propagates in a particular material, but also to be able to predict the rate of crack growth and to use experimental data in order to develop a model for the behavior of a material prior to its application in real-world situations. This article focuses on a description of the experimental method that should be followed in conducting tests of creep-fatigue crack growth (CFCG) with various hold times and also provides an overview of some suitable life-prediction models.

Creep and Creep Fatigue

Static Loading (Creep Conditions). Testing involving a static load could also be characterized as a crack growth test conducted with an infinite hold time. In such a case, there is little or no fatigue effect to be accounted for; however, depending on the environment, there can be significant and sometimes fatal damage due to creep (permanent deformation resulting from a steady load). A final failure would either occur due to widespread or localized creep damage (Ref 5, 7). Creep damage is liable to be widespread if the material is in a uniform stress and temperature environment. In this case, failure is likely to occur due to creep rupture. Failure of this kind is most commonly observed in a component, such as a steam pipe or an inlet casing, where the material is thin (Ref 8). Correspondingly, in a structural component, such as a turbine blade, one is apt to observe failure due to creep crack propagation as opposed to creep rupture. In this case, the creep is localized as a result of nonuniform stresses and temperatures (Ref 5).

Cyclic Loading (Creep-Fatigue Conditions). In a test run under cyclic loading conditions, the constant load is periodically interrupted by unloading and reloading. In this case, the effects of creep-fatigue interactions during transitory load periods play a major role in the initiation and growth of cracks along with the effects of creep during the intervals of steady-state loads. This type of scenario might occur in a fossil energy system, for example, when there are pressure and temperature fluctuations due to changes in output energy demands (Ref

1). Creep-fatigue damage might also be of foremost concern in turbine casings where it is often the primary cause of crack initiation and propagation (Ref 8). It remains that creep contributes to crack growth in regions where temperatures exceed 427 °C (800 °F), while thermal stresses are considered responsible for fatigue and creep-fatigue crack growth in the lower temperature regions (Ref 5, 6).

Material Characterization

Creep-Ductile Materials. Materials that are classified as being creep-ductile have the ability to sustain significant amounts of crack growth before failure. Examples of these materials would include Cr-Mo steels, stainless steels, and Cr-Mo-V steels (Ref 5). Crack growth in this type of material is normally accompanied by substantial creep deformation at the crack tip. As a result, in order to be able to make accurate predictions for the lives of high-temperature components made from such materials, a complete understanding of the crack growth mechanics and damage mechanisms is necessary. An example of the characteristic flow of this methodology is shown in Fig. 1.

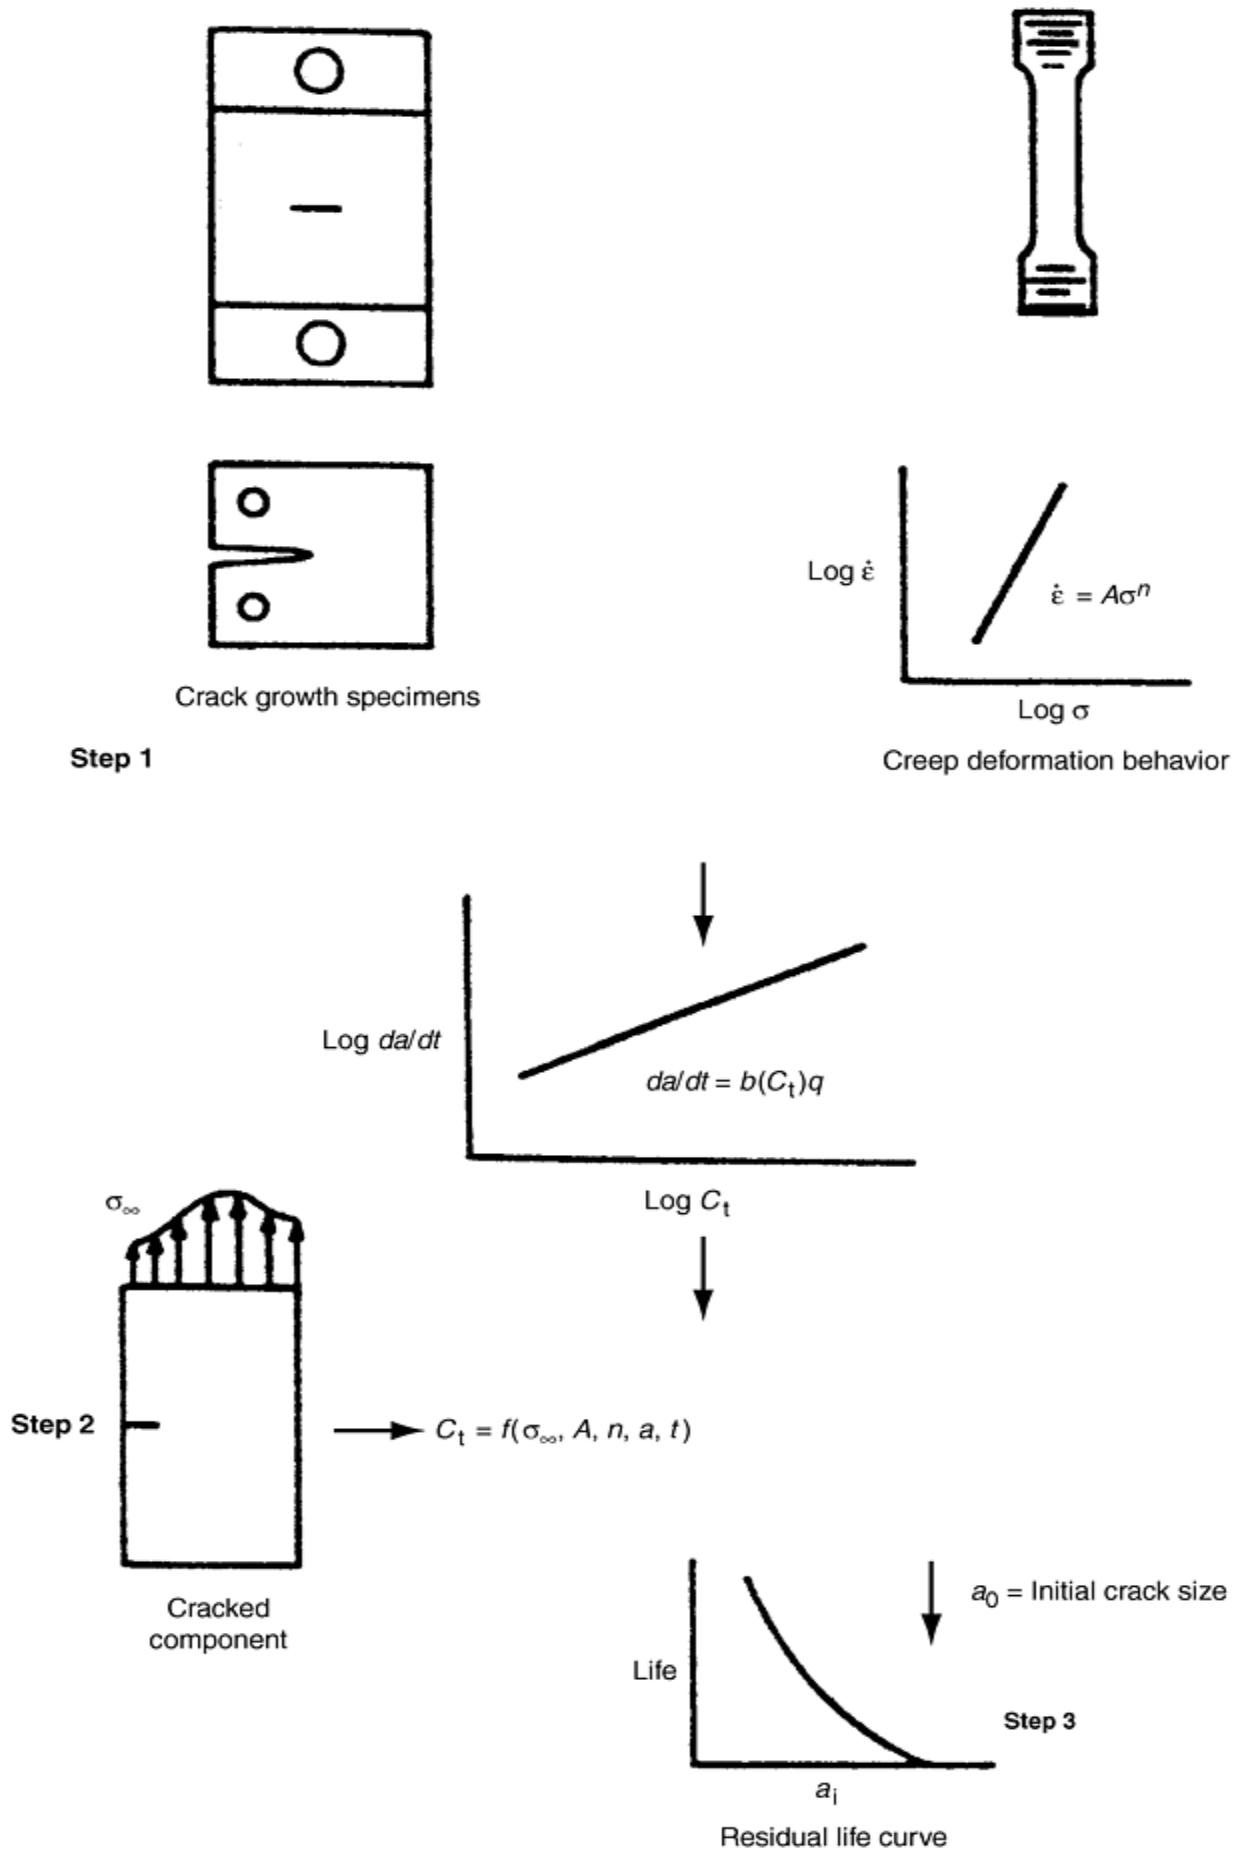

Fig. 1 The methodology for predicting crack propagation life using time-dependent fracture mechanics concepts. Source: Ref 9

Typically, crack growth in this type of material is due to grain boundary cavitation. The cavitation is commonly seen to initiate at second-phase particles or at defects along the grain boundaries (Ref 10). As the cavities nucleate and grow larger, a coalescence of the cavities is observed that will eventually lead to crack propagation and, ultimately, failure (Ref 11). This mechanism is considered to be characteristic of creep crack growth. Other mechanisms for fatigue crack growth with hold times include an alternating slip mechanism (a crack-tip blunt mechanism) and the influence of corrosive environment (Ref 5).

Creep-Brittle Materials. A second type of material is the creep-brittle material. These materials are typified by the fact that creep crack growth is normally accompanied by small-scale creep deformation and by crack growth rates that are comparable to the rates at which creep deformation spreads in the cracked body (Ref 5). This can substantially influence the crack-tip parameters that characterize their crack propagation rates. Examples of this type of material include nickel-base superalloys, titanium alloys, high-temperature aluminum alloys, intermetallics, and ceramic materials.

Time-Dependent Fracture Mechanics

Parameters for Static Loading

In time-dependent fracture mechanics, parameters have been defined for static loading and cyclic loading. There are six crack-tip parameters considered to be applicable for cases of static loading. Each parameter is specific to a particular set of testing conditions. These conditions are outlined below along with the definitions and calculations that correspond to each parameter. All of the following information on parameters is found in Ref 1.

In order to be able to characterize the creep crack behavior of a cracked body, the creep deformation and the relationship among the creep strain, stress, and strain rate must first be considered. For cracks in creeping solids under conditions of static loading, the following equation is most frequently used to describe this relationship (Ref 12):

$$\dot{\epsilon} = \frac{\dot{s}}{E} + A_1 e^{-P_2 n_1 (1+P)} + A_2 s^n \quad (\text{Eq 1})$$

where $\dot{\epsilon}$ is the engineering creep strain rate, \dot{s} is the applied engineering stress rate, e is the engineering strain, s is the engineering (nominal) stress, E is Young's modulus, A_1 is the primary creep coefficient, p and n_1 are the primary creep exponents, A_2 is the secondary creep coefficient, and n is the secondary creep exponent. Under extensive creep conditions, the first term in Eq 1 can be neglected. This term is due to the elastic strain rate, which is only of importance during small-scale creep. The second term is due to primary creep, and thus, under extensive primary creep conditions, Eq 1 can be reduced to:

$$\dot{\epsilon} = A_1 e^{-p} s^{n_1(1+p)} \quad (\text{Eq 2})$$

Similarly, the third term is due to secondary creep, and so under extensive secondary creep conditions, Eq 1 reduces to:

$$\dot{\epsilon} = A_2 s^n \quad (\text{Eq 3})$$

All of the coefficients and exponents in the above equations may be obtained from creep deformation test results.

C^* Parameter. The conditions for the application of C^* can be described as extensive secondary creep conditions (Ref 1). In cases where the pure secondary creep condition is emphasized, one might see the use of the notation C_s^* instead of C^* . The level of load and, accordingly, the characterization of the loading have a negligible effect on the material behavior because, under extensive creep conditions, the creep strain rate dominates the elastic or plastic strain rate throughout the cracked specimen (Ref 1). The C^* parameter is analogous to the path-independent J -integral discussed previously. The basic definition of the integral, as given by Landes and Begley (Ref 13), Nikbin et al. (Ref 14), and Taira et al. (Ref 15) is as follows:

$$C^* = \int_{\Gamma} \left(W_s^* dy - T_i \frac{\partial \dot{u}_i}{\partial x} ds \right) \quad (\text{Eq 4})$$

where Γ is a counter-clockwise contour of the integral that encloses the crack tip (Fig. 2), T_i is the outward stress vector acting on the contour around the crack, \dot{u}_i is the displacement rate vector, and ds is an increment of the contour path. W_s^* is the strain energy rate density defined by the equation:

$$W_s^* = \int \dot{\epsilon}^{mn} \sigma_{ij} d\dot{\epsilon}_{ij}$$

Overall, C^* is a calculation of the energy input rate in the crack-tip area, similar to the J -integral. It could also be referred to as the stress-power dissipation rate in the cracked body (Ref 13).

Fig. 2 Schematic of the contour integral in terms of crack-tip coordinate system used to define C^* . n is the unit normal vector. Source: Ref 5

An approximation for estimating C^* can be found in the Electric Power Research Institute (EPRI) Handbook solution (Ref 1). In this case, C^* is indirectly calculated from the material power-law creep constants, A_2 and n , from Eq 3. When under plane strain conditions, the equation for a compact-type (CT) specimen is given by:

$$C^* = \frac{A_2}{(W-a)^n} h_1 \left(\frac{a}{W}, n \right) \left(\frac{P}{1.445 \zeta_B} \right)^{n+1} \quad (\text{Eq 5})$$

with

$$\xi = \left[\left(\frac{2a}{W-a} \right)^2 + 2 \left(\frac{2a}{W-a} \right) + 2 \right]^{1/2} - \left(\frac{2a}{W-a} \right) - 1 \quad (\text{Eq 6})$$

where W is the compact tension specimen width, a is the crack length, P is the applied load, B is the thickness of the cracked body, and h_1 is a function of a/W and the strain-hardening exponent (the numerical values of h_1 can be found in Ref 16).

In addition, C^* can also be described as the energy input rate difference between two identically loaded bodies with incrementally differing crack lengths, da :

$$C^* = - \frac{1}{B} \frac{dU^*}{da} \quad (\text{Eq 7})$$

where U^* is the power input in the cracked body. From this last equation, an expression has been derived for experimentally determining C^* :

$$C^* = \frac{P\dot{V}_c}{B_N W} \eta \left(n, \frac{a}{W} \right) \quad (\text{Eq 8})$$

where \dot{V}_c is the load-line deflection due to creep, B_N is the net specimen thickness (in side-grooved specimens, B_N is equal to the distance between the roots of the grooves), and η is a function of crack length, the exponent on stress in Norton's creep equation, and specimen geometry (Ref 1).

Because as the cracked body is under extensive secondary creep conditions and the stress and strain rates are related by Eq 3, the crack-tip stress and strain rate fields can be described in terms of C^* as follows (Ref 17, 18):

$$\sigma_{ij} = \left[\frac{C^*}{I_n A_2 r} \right]^{1/(n+1)} \tilde{\sigma}_{ij}(\theta; n) \quad (\text{Eq 9})$$

$$\epsilon_{ij} = \left[\frac{C^*}{I_n A_2 r} \right]^{n/(n+1)} \dot{\epsilon}_{ij}(\theta; n) \quad (\text{Eq 10})$$

where I_n is a dimensionless factor (Ref 19), $\tilde{\sigma}_{ij}(\theta; n)$ is the dimensionless stress angular distribution (Ref 19), $\dot{\epsilon}_{ij}$ is the strain rate tensor, and $\dot{\epsilon}_{ij}(\theta; n)$ is the dimensionless strain rate angular distribution.

$C^*(t)$ Parameter. For the $C^*(t)$ parameter, the conditions are extensive primary and/or secondary creep conditions (Ref 1). Again, the level of the load has little effect on the material behavior. The $C^*(t)$ parameter is essentially the extension of C^* from extensive secondary creep conditions into extensive primary creep conditions. This parameter can be defined as:

$$C^*(t) = \int_{\Gamma} \left[W^*(t) dy - T_i \frac{\partial u_i}{\partial x} ds \right] \quad (\text{Eq 11})$$

where $W^*(t)$ is the instantaneous stress-power or energy rate per unit volume.

One can see in Eq 11 that when the specimen is under pure secondary creep conditions, $W^*(t)$ is replaced by W_s^* , and thus, $C^*(t)$ is equal to C^* (as shown in Eq 4).

Conditions of extensive creep are not always associated with pure secondary or pure primary creep. Often, a mixture of primary and secondary creep is found. Under such conditions, the $C^*(t)$ integral is no longer path independent. However, an approximation of $C^*(t)$ can still be calculated path-independently with an error of 2% (Ref 20).

Under extensive primary-secondary creep conditions, the value of $C^*(t)$ can also be approximated by the sum of $C^*(t)$ under extensive primary creep conditions and $C^*(t)$ or C^* under extensive secondary creep conditions. This approximation is given by:

$$C^*(t) \approx \frac{C_h^*}{(1+p)t^{p/(1+p)}} + C_s^* \quad (\text{Eq 12})$$

where C_h^* is the stress-dependent part of the path-independent integral $C^*(t)$ under extensive primary creep conditions. In Eq 12, the first term on the right-hand side is the value of $C^*(t)$ under extensive pure primary creep conditions, while the second term is the $C^*(t)$ or C^* value under extensive pure secondary creep conditions. Another expression of Eq 12 would be:

$$C^*(t) \approx [1 + (t_2/t)^{p/(1+p)}] C_s^* \quad (\text{Eq 13})$$

where t_2 is the time of the transition from extensive primary creep to extensive secondary creep. Here t_2 can be determined by:

$$t_2 = \left[\frac{C_h^*}{(1+p)C_s^*} \right]^{(1+p)/p} \quad (\text{Eq 14})$$

Knowing that C^* can be estimated experimentally from Eq 8, $C^*(t)$ can similarly be measured in test specimens under extensive secondary creep conditions using this equation:

$$C^*(t) = \frac{P\dot{V}_c}{B_N W} \eta \left(n_1, n, \frac{a}{W} \right) \quad (\text{Eq 15})$$

Equation 15 differs from Eq 8 in that the function, η , is a function of the primary creep exponent, n_1 , in addition to the secondary creep exponent, n , and the ratio of crack size to specimen width, a/W . The expression for η is given by (Ref 21):

$$\eta = \left[\frac{n}{n+1} \frac{t}{t_2} + \frac{n_1}{n_1+1} \left(1 - \frac{t}{t_2} \right) \right] \times \left(\frac{2}{1-a/W} + 0.522 \right) \quad (\text{Eq 16})$$

For CT specimens, it has been shown that there is little dependence of η on n and n_1 . For this reason, it is recommended that for these specimens, η can be approximated using the following equation (Ref 22):

$$\eta = \frac{n}{n+1} \left(\frac{2}{1-a/W} + 0.522 \right) \quad (\text{Eq 17})$$

This equation has been adopted by ASTM E 1457, "Standard Test Method for Measurement of Creep Crack Growth Rates in Metals" (Ref 23).

C_h^* Parameter. The conditions for C_h^* can be expressed as extensive primary creep conditions (Ref 1). This parameter was defined as a path-independent integral by Riedel (Ref 24). As such, C_h^* is the stress-dependent part of $C^*(t)$ under extensive primary creep conditions shown as:

$$C^*(t) = \frac{C_h^*}{(1+p)t^{p/(1+p)}} \quad (\text{Eq 18})$$

C_h^* can be determined by the equation:

$$C_h^* = \frac{[A_1(1+p)]^{1/(1+p)}}{(W-a)^{n_1}} h_1 \left(\frac{a}{W}, n_1 \right) \times \left(\frac{P}{1.445\zeta B} \right)^{n_1} \quad (\text{Eq 19})$$

$C(t)$ Parameter. The conditions for the $C(t)$ parameter are frequently found at the crack tip. These conditions can be described as small-scale, elastic, primary and/or secondary creep conditions (Ref 1). Ohji et al. (Ref 25), Bassani and McClintock (Ref 26), and Ehlers and Riedel (Ref 27) studied the crack-tip stress fields under these conditions, and the $C(t)$ integral was defined as follows:

$$C(t) = \int_{\Gamma_s} \left(W_s^* dy - T_i \frac{\partial \dot{u}_i}{\partial x} ds \right) \quad (\text{Eq 20})$$

where Γ_s is a counter-clockwise contour of the integral that encloses the crack within the crack-tip creep zone. This differs from the counter-clockwise contour of the C^* integral because, in that case, the contour of the integral was not limited to the crack-tip creep zone. The reason for this limitation is that it is only in the creep zone that the creep strain rate may dominate the elastic strain rate. The loading is confined to elastic loading for this parameter due to the fact that the creep strain rate may not be able to dominate the plastic strain rate under small-scale creep zone conditions. This is because the plastic zone size may be larger than the creep zone size. Just from the definition of the $C(t)$ parameter, it is evident that when the creep zone scale transitions from small to extensive conditions, the definition of the parameter becomes indistinguishable from that of the $C^*(t)$ parameter.

When experiencing small-scale, elastic, secondary creep conditions in the case of plane strain, the value of $C(t)$ can be approximated by this equation (Ref 25, 26, and 27):

$$C(t) \approx \frac{K^2(1-\nu^2)}{(n+1)Et} \quad (\text{Eq 21})$$

where K is the stress intensity factor, and ν is Poisson's ratio.

Another approximation for $C(t)$ under the same conditions is given as (Ref 27):

$$C(t) = [1 + t_T / t] C_s^* \quad (\text{Eq 22})$$

where t_T is the transition time from small-scale to extensive creep given by the equation:

$$t_T = \frac{K^2(1-\nu^2)}{E(n+1)C_s^*} \quad (\text{Eq 23})$$

The approximations from Eq 22 have been confirmed in several numerical studies and have been determined to be reasonably accurate (Ref 20, 28).

When under small-scale, elastic conditions with primary and/or secondary creep conditions, the $C(t)$ parameter can be approximated as follows (Ref 20, 29):

$$C(t) = [1 + t_{TP}/t + (t_2/t)^{p/(1+p)}] C_s^* \quad (\text{Eq 24})$$

where t_{TP} is the transition time from the small-scale primary creep to extensive primary creep conditions as determined by:

$$t_{TP} = \left[\frac{K^2(1-\nu^2)}{EC_s^*} \right]^{1+p} \frac{1}{1+n_1} \quad (\text{Eq 25})$$

For creep deformation ranging from small-scale to extensive creep, Ehlers and Riedel (Ref 27) proposed that $C(t)$ can be determined from the sum of the small-scale and extensive creep solutions as follows:

$$C(t) = \frac{K^2(1-\nu^2)}{(n+1)Et} + C^* \quad (\text{Eq 26})$$

Their analytical work, along with that of Ohji et al. (Ref 25), shows that similar to C^* for the extensive, secondary creep conditions, $C(t)$ may be used to describe the crack-tip stress and strain fields under the small-scale, elastic creep conditions:

$$\sigma_{ij} = \left[\frac{C(t)}{I_n A_2 r} \right]^{1/(n+1)} \tilde{\sigma}_{ij}(\theta; n) \quad (\text{Eq 27})$$

$$\epsilon_{ij} = \left[\frac{C(t)}{I_n A_2 r} \right]^{n/n+1} \dot{\epsilon}_{ij}(\theta; n) \quad (\text{Eq 28})$$

Even though $C(t)$ can be applied to both small-scale and extensive creep conditions, this parameter has a severe drawback. The values of $C(t)$ can only be calculated with the given equations and cannot be experimentally measured, as was the case with C^* and $C^*(t)$. In addition, the accuracy of its calculated values depends heavily on the accuracy of the constitutive equations employed for the calculation (Ref 1).

$C_{st}(t)$ Parameter. The conditions for the $C_{st}(t)$ parameter can be described as small-scale, elastic, primary and/or secondary creep conditions during the time shortly after t_1 is reached and long before t_2 is reached (Ref 1). In

this case, t_1 is the transition time from small-scale primary creep in the elastic field to extensive primary creep conditions. McDowell et al. (Ref 30) have shown that in a compact tension (CT) specimen during this time, $C(t)$ becomes essentially path independent because a stationary stress field is achieved across the remaining ligament. Under such conditions, $C(t)$ is defined as $C_{st}(t)$, and can be determined from the following equation:

$$C_{st}(t) = [1 + (t_2/t)^{p/(1+p)}] C_s^* \quad (\text{Eq 29})$$

C_t Parameter. For C_t , the conditions can best be described as small-scale or transition, elastic, and primary and/or secondary creep conditions (Ref 1). The C_t parameter was originally proposed by Saxena (Ref 31) in order to avert the disadvantage of $C(t)$, which cannot be experimentally measured. This parameter can be thought of as an extension of the C^* integral into the small-scale and transition creep regions, and, under extensive creep conditions, the C_t parameter approaches the value of $C^*(t)$ in much the same way as the $C(t)$ parameter does (Ref 1). Under small-scale conditions, however, the C_t parameter behaves differently from $C(t)$. Whereas $C(t)$ is the amplitude of the crack-tip stress field, C_t , as defined by Saxena, is uniquely related to the rate of expansion of the creep zone size under small-scale creep conditions (Ref 28):

$$(C_t)_{SSC} = \frac{2}{3} (1 - \nu^2) \frac{K^2}{EW} (F'/F) \beta \dot{\gamma}_c \quad (\text{Eq 30})$$

where $(C_t)_{SSC}$ is the value of C_t when the small-scale creep condition is emphasized, F is the K -calibration factor [$F = (K/P)BW/2$], F' is the a/W derivative of F [$F' = dF/da(a/W)$], and $\dot{\gamma}_c$ is the rate of expansion of the creep zone size.

For the rate of expansion of the creep zone size, $\dot{\gamma}_c$, expressions have been derived for elastic, primary creep and elastic, secondary creep conditions (Ref 21, 28). An analytical estimation of $(C_t)_{SSC}$ may be found by substituting the corresponding $\dot{\gamma}_c$ expressions into Eq 30 (Ref 1).

When the specimen is under small-scale, elastic primary creep conditions, the rate of expansion of the creep zone is given by the following equation:

$$\begin{aligned} \dot{\gamma}_c &= \frac{K^2}{2\pi} \left[\frac{I_{n_1} E}{2\pi(1-\nu^2)} \right]^{2/(n_1-1)} \\ &\times [(1+n_1)(1+p)A_1]^{2/(1+p)(n_1-1)} \\ &\times \left[\frac{\tilde{\gamma}_c(\theta)}{1+p} \right] \times \left[\frac{2}{n_1+1} \right]^{[2/(1+p)(n_1-1)-1]} \end{aligned} \quad (\text{Eq 31})$$

where I_{n_1} is a nondimensional factor dependent upon n_1 , and $\tilde{\gamma}_c(\theta)$ is the dimensionless function defining the creep zone shape (Ref 1).

Under small-scale, elastic secondary creep conditions, the rate of expansion of the creep zone size is given by:

$$\dot{\gamma}_c = \frac{2\alpha}{n-1} K^2 t^{-(n-3)/(n-1)} (EA)^{2/(n-1)} \tilde{\gamma}_c(\theta) \quad (\text{Eq 32})$$

where α is a dimensionless constant dependent on n .

C_t may also be estimated over a range, from small-scale to extensive creep conditions, using the following:

$$C_t = (C_t)_{SSC} + C^*(t) \quad (\text{Eq 33})$$

where $(C_t)_{SSC}$ and $C^*(t)$ are both calculated rather than experimentally measured values. Again, it is important to note that C_t changes from $(C_t)_{SSC}$ to $C^*(t)$ as conditions progress from small-scale to extensive creep (Ref 1).

An equation has been included in the ASTM handbook (Ref 23) that allows the experimental measure of C_t under small-scale creep conditions. This equation is included as follows:

$$(C_t)_{SSC} = \frac{P\dot{V}_c}{\sqrt{B_N B W}} \left(\frac{F'}{F} \right) \quad (\text{Eq 34})$$

Parameters for Cyclic Loading

For cyclic loading, there are two parameters considered to be applicable for tests involving cyclic loading. Again, the testing conditions, definitions, and necessary calculations for each parameter are outlined below.

ΔJ_c Parameter. The ΔJ_c parameter is simply a time integral of C^* or J^* over the hold time, t_h , involved in trapezoidal waveform loading (Ref 1). The parameter was first introduced by Jaske and Begley (Ref 32) and Taira et al. (Ref 33) in order to correlate with the time-dependent creep crack growth during a trapezoidal waveform loading at elevated temperatures. Its definition is:

$$\Delta J_c = \int_0^{t_h} C^* (dt) \quad (\text{Eq 35})$$

where t_h is the hold time at the maximum load of a trapezoidal load form.

When a material is subjected to trapezoidal waveform loading, its response can be divided into two parts: the loading portion and the hold time portion. Creep deformation may occur at the crack tip during both portions. When integrated over the hold time, the ΔJ_c parameter gives the total energy input in the crack-tip area due to creep deformation that occurs during the hold time (Ref 1). During the loading portion, the amount of creep deformation generally depends on the rate of loading. If the loading is conducted quickly, the creep deformation is small compared to the elastic and plastic deformation. Thus, it is usually a negligible effect, and, therefore, no time-dependent fracture-mechanics parameter has been defined for such instances. However, in the case of slow loading, creep deformation can dominate the elastic and plastic deformation. In this instance, Ohtani et al. (Ref 34) and other researchers (Ref 35, 36, and 37) have proposed a method to use for estimation of ΔJ_c . This method functions on the assumption that creep deformation occurs under extensive creep conditions.

Because trapezoidal waveform loading involves both elastic and plastic deformations, the total energy output for the entire cycle should be described by the sum of the cycle-dependent and time-dependent parts (Ref 1). Therefore, the ΔJ_c parameter can be integrated into the total J -integral (ΔJ_T) defined as:

$$\Delta J_T = \Delta J_f + \Delta J_c \quad (\text{Eq 36})$$

where ΔJ_f is the cycle-dependent integral associated with time-independent plasticity (Ref 1).

$(C_t)_{\text{avg}}$ Parameter. The $(C_t)_{\text{avg}}$ parameter is, as the notation denotes, the average value of the C_t parameter during the hold time periods of a trapezoidal waveform (Ref 1). The parameter was first defined by Saxena as the following (Ref 38, 39, and 40):

$$(C_t)_{\text{avg}} = \frac{1}{t_h} \int_0^{t_h} C_t dt \quad (\text{Eq 37})$$

The definition of the $(C_t)_{\text{avg}}$ parameter given in Eq 37 is applicable only for creep deformation encountered during the hold time, t_h . In general, along with the creep deformation during this time, there is elastic deformation as a result of stress relaxation. With longer hold times, the creep zone expands from small-scale to extensive creep, so eventually the elastic deformation will become insignificant. As can be seen through Eq 37, as C_t approaches C^* , $(C_t)_{\text{avg}} \cdot t_h$ becomes equal to ΔJ_c (Ref 1). It is important to note, however, that under small-scale creep conditions, the $(C_t)_{\text{avg}} \cdot t_h$ and ΔJ_c parameters will not be equal. This is especially true when the values are calculated as opposed to being experimentally obtained (Ref 1).

According to which method is used to estimate the deflection rate of the cracked body, there are two ways to determine the value of $(C_t)_{\text{avg}}$. For a CT specimen test, where the load and load-line deflection as functions of time can be determined experimentally, the value of $(C_t)_{\text{avg}}$ is experimentally measured. However, for the case of a cracked component, where the deflection rate can only be predicted analytically, $(C_t)_{\text{avg}}$ is found by calculation.

When measured experimentally, $(C_t)_{\text{avg}}$ can be obtained from the following:

$$(C_t)_{\text{avg}} = \frac{\Delta P \Delta V_c}{B W_{t_h}} \frac{F'}{F} - C^* \left(\frac{F'}{F} \frac{1}{\eta} - 1 \right) \quad (\text{Eq 38})$$

where ΔP is the applied load range and ΔV_c is the load-line deflection due to creep during the hold period. The value of $(C_t)_{\text{avg}}$, when determined analytically, is found through the employment of equations that depend on material conditions. If a material has low resistance to cyclic plasticity, where the cyclic plastic zone is larger than the creep zone during the first hold time, $(C_t)_{\text{avg}}$ may be determined from the following equation (Ref 39) as elastic-cyclic plastic-secondary creep conditions:

$$(C_1)_{\text{avg}} = \frac{2\alpha\beta\tilde{\gamma}_c(\theta)}{E} (1 - \nu^2) \frac{\Delta K^4}{W} \frac{F'}{F} (EA_2)^{2/n-1} \times \left[\frac{(t_h + t_{\text{pl}})^{2/n-1} - (t_{\text{pl}})^{2/n-1}}{t_h} \right] + C^* \quad (\text{Eq 39})$$

where ΔK is the range of the stress intensity factor, t_{pl} is the factor added to account for retardation in the creep zone expansion rate due to cyclic plasticity, and α and β are constants. In order to estimate t_{pl} , the following may be used:

$$t_{\text{pl}} = \frac{1}{EA_2} \left[\xi \left(\frac{m' - 1}{m' + 1} \right) \left(\frac{1}{2\sigma_{\text{YS}}^c} \right)^2 \times \frac{1}{\alpha\tilde{\gamma}_c(90^\circ)} \right]^{(n-1)/2} \quad (\text{Eq 40})$$

where m' is the cyclic strain-hardening exponent, σ_{YS}^c is the cyclic yield strength determined as the stress amplitude ($\Delta\sigma/2$) corresponding to a plastic strain amplitude ($\Delta\varepsilon_p/2$) of 0.2%, and ξ is a constant.

On the other hand, for materials having high resistance to cyclic deformations, where creep rates are high and the creep zone size quickly exceeds the cyclic plastic zone size, the value of $(C_1)_{\text{avg}}$ may be calculated from a different equation (Ref 41):

$$(C_1)_{\text{avg}} = \frac{4\alpha n\beta\tilde{\gamma}_c(\theta)}{EW} (1 - \nu^2) \times \Delta K^4 \frac{F'}{F} \times (EA_2)^{2/(n-1)} (N_{t_h})^{-(n-1)/(n-3)} + C^* \quad (\text{Eq 41})$$

where N is the number of fatigue cycles. For more detail concerning these last few equations, consult Ref 39 and 41.

Creep Crack Growth Testing

B.E. Gore, Northwestern University, W. Ren, Air Force Materials Laboratory, P.K. Liaw, The University of Tennessee

Creep-Fatigue Crack Growth Testing

The following description of the experimental test method for creep crack growth tests using a compact specimen geometry, under cyclic or static loading, is in agreement with the ASTM E 1457 "Standard Test Method for Measurement of Creep Crack Growth Rates in Metals" (Ref 23). The aforementioned technique entails applying a constant load to a heated, precracked specimen until significant crack extension or failure occurs. During the test, the crack length, load, and load-line deflections must be monitored and recorded, and upon test completion, the final crack length must be measured. Analysis of the test data involves an examination of the crack growth rate with respect to time, da/dt , in terms of the magnitude of an appropriate elevated-temperature crack growth parameter (Ref 5, 23). The various crack growth parameters are presented earlier in this article.

Specimen Configuration and Dimensions. The recommended specimen for creep crack growth testing is the CT specimen. Figure 3 illustrates the specimen geometry, including details of the design specifications. Although other configurations have also been used, such as the center-cracked tensile (CCT) panel and the single-edge notch (SEN) specimen, the CT specimen is considered to be more suitable for creep and creep-fatigue crack growth testing (Ref 5) and remains most convenient. In terms of suitability, the transition time for extensive creep conditions to develop is longer in CT than in CCT specimens for the same K and a/W for samples of

identical width (Ref 42). Due to the extended transition time, during creep-fatigue testing, the necessary condition that $t_c/t_1 \ll 1$, with t_c representing cyclic time, and t_1 being the aforementioned transition time, is more easily met. In terms of convenience, an advantage of the CT specimen is that a clip gage can be easily attached for the measurement of load-line deflection, which is one of the components required in the calculation of crack-tip parameters. In addition, one of the most important advantages is that the magnitude of the applied load needed to obtain a particular value of K is significantly lower for CT than for CCT specimens. Hence, machines with smaller load capacities and small fixtures can be used for testing (Ref 5).

Fig. 3 Drawing of standard CT specimen. Source: Ref 22

Testing Machines. Three different types of machines can be used to run crack growth tests: dead-weight, servomechanical, and servohydraulic machines. Regardless of the choice of machine, it is necessary to be able to maintain a constant load over an extended period of time (variations are not to exceed $\pm 1.0\%$ of the nominal load value at any time). Note that to fulfill this requirement, if lever-type, dead-weight creep machines are used, care must be taken to ensure that the lever arm remains in a horizontal position. More detailed specifications of the testing machine may be found in ASTM E 4, "Practices for Load Verification of Testing Machines" (Ref 43). Additionally, it is recommended that precautions be taken to ensure that the load is applied as nearly axial as possible.

Control Parameter. For those tests run under creep-fatigue conditions where a trapezoidal waveform is employed, a choice between testing conducted under a load-controlled or displacement-controlled conditions must be made. Figure 4(a) shows a schematic representation of the displacement versus time and crack size versus time for a load-controlled case. Displacement-controlled testing schematics of the load versus time and crack size versus time are shown in Fig. 4(b) for comparison (Ref 5).

Fig. 4 Schematic comparison of (a) load-controlled and (b) displacement-controlled testing under trapezoidal loading. Source: Ref 5

Due to matters of convenience, tests are most frequently conducted under load-controlled conditions. However, there are a few advantages of displacement-controlled testing that should be considered. For instance, due to a continuous rise in the net section stress ahead of the crack in load-controlled tests during crack growth, K continually increases as the size of the remaining ligament decreases. Consequently, this means that the scale of creep in the specimen increases as the test progresses, which causes ratcheting in the specimen as the inelastic deflection accumulates with the completion of each cycle (Ref 5). Comparatively, as can be seen in Fig. 4(b), the applied load decreases with crack extension in displacement-controlled tests, so ratcheting is avoided (Ref

44). Also, data can be collected for greater crack extensions in displacement-controlled tests than in load-controlled tests. Overall, load-controlled tests are more suitable for low crack growth rates, and displacement-controlled tests are suited for higher crack growth rates (greater than 4×10^{-6} mm/cycle) and tests with extensive hold times (Ref 5).

Grips and Fixtures. For the CT specimen, a pin and clevis assembly should be used at both the top and bottom of the specimen. This assembly will allow in-plane rotation as the specimen is loaded. Materials for the grips and pull rods should be creep resistant and able to withstand the temperature environment to which they will be exposed during the test. Examples of current elevated-temperature materials being used include AISI grade 304 and 316 stainless steels, grade A 286 steel, Inconel 718, and Inconel X750. The loading pins should be machined from temperature-resistant steels, such as A 286, and should be heat treated to ensure that they acquire a high resistance to creep deformation and rupture.

Heating Devices. Samples are generally heated by means of either an electric resistance furnace or a laboratory convection oven. Before the application of load and for the duration of the test, the difference between the temperature indicated by the device and the nominal test temperature is not to exceed ± 2 °C (± 3 °F) for temperatures at or below 1000 °C (1800 °F). It is to remain within ± 3 °C (± 5 °F) for temperatures above 1000 °C (1800 °F). In the initial heating of the specimen, it is important to avoid temperature overshoots that could potentially affect test results. In order to measure the specimen temperature, a thermocouple must be attached to the specimen. The thermocouple should be placed in the uncracked ligament region of the sample 2 to 5 mm (0.08–0.2 in.) above or below the crack plane. If the width of the specimen exceeds 50 mm (2 in.), it is advisable to attach multiple thermocouples at evenly spaced intervals in the uncracked ligament region around the crack plane, as stated previously. Thermocouples must be kept in intimate contact with the specimen. In order to avoid short circuiting, ceramic insulators should cover the individual wires of the temperature circuit.

Fatigue Precracking. In order to eliminate the effects of the machined notch and to provide a sharp crack tip for crack initiation, it is necessary to precrack creep and/or creep-fatigue test specimens. An extensively detailed method for the process can be found in ASTM E 399, “Test Method for Plane-Strain Fracture Toughness of Metallic Materials” (Ref 45). Specimen precracking must be conducted in the same condition as it is going to be tested. The temperature is to be at or above room temperature and must not exceed the designed test temperature. For the process of precracking, equipment must be used that is capable of applying a symmetric load with respect to the machined notch and must be able to control the maximum stress intensity factor, K_{max} , to within $\pm 5\%$. The fatigue load used during the process must remain below the following maximum value (Ref 23):

$$P_f = \frac{0.4B_N(W - a_0)^2 \sigma_{ys}}{(2W + a_0)} \quad (\text{Eq 42})$$

where B_N is the corrected specimen thickness, W is the specimen width, a_0 is the initial crack length measured from the load line, and σ_{ys} is the yield strength. While the fatigue precrack is in the final 0.64 mm (0.025 in.) of extension, the maximum load shall not exceed P_f or a load such that the ratio of the stress intensity factor range to Young's modulus ($\Delta K/E$) is equal to or less than 0.0025 mm^{1/2} (0.0005 in.^{1/2}), whichever is less (Ref 23). In this manner, it is ensured that the final precrack loading will not exceed that of the initial creep or creep-fatigue crack growth test.

The crack length for the fatigue precrack can be measured using the same methods described in the next section, “Test Procedure,” for monitoring crack length during crack growth testing. Measurements of the fatigue precrack must be accurate to within 0.1 mm (0.004 in.). Measurements must be taken on both surfaces, and their values must not differ by more than 1.25 mm (0.05 in.). If surface cracks are allowed to exceed this limit, further extension will be required until the aforementioned criteria are met (Ref 5). The total initial crack length (the starter notch plus fatigue precrack) must be at least 0.45 times the width, but no longer than 0.55 times the width.

Creep Crack Growth Testing

B.E. Gore, Northwestern University, W. Ren, Air Force Materials Laboratory, P.K. Liaw, The University of Tennessee

Test Procedure

Number of Tests. Data collected during creep crack growth rate testing will inherently exhibit scatter. Values of da/dt at a given value of $C^*(t)$ can vary by as much as a factor of two (Ref 23, 46). This inherent scatter can be further augmented by variables, such as microstructural differences, load precision, environmental control, and data processing techniques (Ref 23). It is thus advised that replicate tests be conducted; when this is impractical, multiple specimens must be tested in order to obtain regions of overlapping da/dt versus $C^*(t)$ data. Assurance of the inferences drawn from the data is augmented by increasing the number of tests conducted.

Test Setup. Prior to testing, it is necessary to take measures to prepare for the measurements of the crack length, load-line displacement, temperature, and number of completed cycles. As discussed in subsequent sections, the electric potential drop method, in which fluctuations in potential in a constructed voltage loop are monitored, is often used to calculate the crack length during testing. In order to prepare for this method, the specimen must be fitted with current input and voltage leads to the current source and potentiometer, respectively. The fitting can be conducted either prior to or just after specimen installation according to preference. In order to avoid contact with other components in the test setup that could potentially skew results, the leads can be covered with protective ceramic insulators. In order to begin installation of the specimen, both clevis pins must be inserted, after which a small load of approximately 10% of the intended test load should be applied in order to bolster the axial stability of the load train. At this point, the extensometer must be placed along the load line of the specimen in order to monitor load-line displacements. Care must be taken to make sure that the device is in secure contact with the knife edges. Subsequently, the thermocouples must be attached to the specimen by being placed in contact with the crack plane in the uncracked ligament region. Lastly, the furnace must be brought into position, and heating of the specimen should begin. The initialization of the current for the electric potential system must be in concordance with the point of turning on the furnace. This is because resistance heating of the specimen will occur as a result of the applied current.

In order to avoid overshoots in temperature exceeding the limits set forth previously, it is recommended that the heating of the specimen be slow and steady. It may even be desirable to stabilize the temperature at an increment of 5 to 30 °C (10–50 °F) below the final testing temperature and then make adjustments as necessary. Once the appropriate test temperature is achieved and stabilized, it should be held for a given amount of time

necessary to ensure that the temperature will be able to be maintained within the aforementioned limits. This time is to be, at minimum, 1 hour per 25 mm (1 in.) of specimen thickness. After these requirements have been met, a set of measurements must be recorded while in the initial no-load state for reference. It follows that the next step is the application of the load. The load must be applied carefully in order that shock loads or inertial loads can be avoided, and the length of time for the application of the load should remain as short as possible. The load or K -level chosen depends on the required crack growth rates during the test. For effective testing, the crack growth rates must be selected to mimic those encountered during the service life of a material. Without delay, upon the completion of loading the sample, another set of measurements of electric potentials and displacements must be taken to be used as the initial loading condition (time = 0).

Data Acquisition during Testing. The electric potential voltage, load, load-line displacement, test temperature, and number of cycles must be monitored and recorded continuously throughout the test if autographic strip chart recorders or voltmeters are used. If digital data acquisition systems are employed, a full set of readings must be taken no less frequently than once every fifteen minutes. The resolution of these data acquisition systems must be at least one order of magnitude better than the measuring instrument (Ref 5).

Crack Length Measurement. When monitoring creep crack propagation, the chosen technique should be able to resolve crack extensions of at least 0.1 mm (0.004 in.). Surface crack length measurements by optical means, such as a travelling microscope, are not considered reliable as a primary method due to the fact that crack extension across the thickness of the specimen is not always uniform. However, optical observation may be used as an auxiliary measurement method. For the aforementioned reason, the selected crack length measurement technique must be capable of measuring the average crack length across the specimen thickness. The most commonly used method for the determination of crack length in creep-fatigue crack growth testing is the electric potential drop method. This method involves applying a fixed electric current and monitoring any changes in the output voltage across the output locations. Because any increase in crack length (corresponding to a decrease in the uncracked ligament) would result in an increase in the electric resistance, the final result is an increase in the output voltage (Ref 5). The electric potential drop method is considered to be the most compatible with elevated-temperature creep crack growth testing.

The input current and voltage lead locations for a typical CT specimen are shown in Fig. 5. The leads may be attached either by welding them to the material or by connecting them to the material with screws. The choice of the method essentially depends on the material and test conditions. For a soft material tested at relatively low temperatures, threaded connections are fine, but for harder materials, it is recommended that the leads be welded, especially for tests conducted at elevated temperatures (Ref 5). The leads must be long enough to allow current input devices and output voltage measuring instruments to be far enough away from the furnace so as to avoid excessive heating. In addition, leads should be about the same length to minimize lead resistance, which contributes to the thermal voltage, V_{th} , as described below. Concerning material choice for the leads, 2 mm (0.08 in.) diameter stainless steel wires have been shown to work very well due to excellent oxidation resistance at elevated temperatures. Nonetheless, any material that is resistant to oxidation and is capable of carrying a current that is stable at the test temperature should be suitable. In the past, nickel and copper wires have been effectively used as a lead material for tests conducted at lower temperatures (Ref 5).

Fig. 5 Input current and voltage lead locations for which Eq 43 applies. Source: Ref 22

In order to calculate the crack size for the setup shown in Fig. 5 from the measured output voltage and initial voltage values, V and V_0 , the following closed-form equation should be used (Ref 47, 48):

$$a_i = \frac{2W}{\pi} \cos^{-1} \left(\frac{\cosh(\pi Y_0 / 2W)}{\cosh \left[\frac{V}{V_0} \cosh^{-1} \left(\frac{\cosh(\pi Y_0 / 2W)}{\cos(\pi a_0 / 2W)} \right) \right]} \right) \quad (\text{Eq 43})$$

where a_i is the instantaneous crack length, W is the specimen width, Y_0 is the half distance between the output voltage leads, V is the instantaneous output voltage, and a_0 is the reference crack size with respect to the reference voltage, V_0 . Usually a_0 is the initial crack size after precracking, and V_0 is the initial voltage. Often the voltages, V and V_0 , used for determining the crack size in the equation differ from their respective indicated readings when using a direct current technique. This is due to V_{th} , which can be caused by many factors, including differences in the junction properties of the connectors, differences in the resistance of the output leads, varying output lead lengths, and temperature fluctuations in output leads themselves (Ref 5). Measured values of V_{th} should be recorded before the load application and periodically throughout testing. To make these measurements, the current source must be turned off; then the output voltage should be recorded. Before calculations are made, the V_{th} value must be subtracted from the respective V and V_0 so that the actual crack extension length can be established.

When testing materials that have high electrical conductivity, fluctuations in V_{th} are often seen. This type of fluctuation can be of the same magnitude as the fluctuation in voltage that accompanies crack growth and could, therefore, veil this information. Because of this potential variation, it is recommended that the direct current electric potential drop method not be the only nonvisual method for crack length measurements chosen. Other more sophisticated techniques, such as the reversing current potential method, are recommended for use. The reversing direct current electrical potential drop (RDCEPD) method is simply a variation of the electrical potential drop method described by Johnson (Ref 47). This method is more sensitive to crack growth near the specimen surface. In the RDCEPD method, a direct current is used, but the polarity is reversed at a fairly low frequency (Ref 49). This step compensates for zero drift errors. Refer to Caitlin, et al. (Ref 50) for a more detailed description of this crack length monitoring method.

It is imperative to keep in mind, while performing creep crack propagation tests, the importance of maintaining a nearly straight crack front. The initial and final crack lengths must fluctuate no more than 5% across the specimen thickness. Often the maintenance of a straight crack front depends on the material and the sample thickness. It has been noted before that thicker specimens sometimes experience crack tunneling, or nonstraight crack extension. Crack tunneling (thumbnail-shaped crack fronts) is common in specimen configurations that are not side grooved (parallel-sided) (Ref 5, 7). Side-grooving the specimens can minimize the occurrence of crack tunneling. Side grooves of 20% reduction have been found to work well in several materials, although reductions of up to 25% are considered to be acceptable. The included angle of the grooves is usually less than 90° with a root radius less than or equal to 0.4 ± 0.2 mm (0.016 ± 0.008 in.). It is important to perform the precracking of the specimen before the side grooving, as it is difficult to detect the precrack when located in the grooves.

Load-Line Displacement Measurements. Load-line displacements can be described as those that occur at the loading pins due to the crack associated with the accumulation of creep strains. In order to be able to ultimately determine the crack-tip parameters, it is necessary to continually record the displacement measurements. These displacement measurements must be taken as close to the load line as possible. The measuring device must be attached on the knife edges of a CT specimen. Alternatively, for CCT specimens, the displacement should be measured on the load line at points ±35 mm (±1.40 in.) from the crack centerline (Ref 5). In order to directly measure the displacement, an elevated-temperature clip gage may be attached to the specimen (strain gages for up to approximately 150 °C, or 300 °F, or capacitance gages for higher temperatures), and then the entire assembly should be placed in the furnace. Instead, if the devices mentioned previously are not available, the displacements can be transferred outside the furnace using a rod and tube assembly. In this case, the transducer—a direct current displacement transducer (DCDT), linear variable displacement transducer (LVDT), or capacitance gage—is placed outside the furnace. It is important that the rod and tube be made of materials

that are thermally stable and be fabricated of the same material to avoid any adverse effects caused by differences in thermal expansion coefficients (Ref 23). The deflection measurement devices should have a resolution of at least 0.01 mm (0.0004 in.) (Ref 5).

Post-Test Measurements. When the test has been completed, whether due to specimen failure or to the acquisition of sufficient crack growth data, the load should be removed, and the furnace be turned off. Once the specimen has cooled down adequately, it should be removed from the machine. The initial crack length (due to precracking) and the final crack length (resulting from creep crack growth) should be measured at nine points equidistant from each other along the face of the crack. The collected data can be processed using a computer program that uses either the secant method or the seven-point polynomial method to calculate the deflection rates, dV/dt , crack growth rates, da/dt , and the crack-tip parameters. For a more detailed description of these methods refer to ASTM E 1457 (Ref 23).

Life-Prediction Methodology

In recent years, the subject of remaining-life prediction has drawn considerable attention. The interest in the issue of remaining-life prediction stems from the necessity to avoid costly forced outages, from the need to

extend the component life beyond the original design life for economic reasons, and from safety considerations (Ref 7, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, and 62). A closer look at the method of predicting the life of materials can be found in Ref 61. Here, high-temperature structural components in power plants are analyzed. Steam pipes, for example, are generally subject to elevated-temperature operating conditions. Because of the high-temperature exposure and the simultaneous internal-pressure loading, the pipes are prone to creep damage. Thus, material properties including creep data of in-service or ex-service steels are critical input parameters for accurate life assessment of steam-pipe systems.

Figure 1, again, shows a schematic of the general remaining-life-prediction methodology for high-temperature components (Ref 52). The life-prediction methodology can be separated into three steps. In step 1, two kinds of pertinent material testing are performed (i.e., creep crack growth and creep deformation and rupture experiments). By combining the results of these two tests and tensile tests, the rates of creep crack propagation, da/dt , can be characterized by the creep crack growth rate correlating parameter (C_t) (Ref 9, 31, 51, 52, and 63). In step 2, the value of C_t for a structural component containing a defect is calculated and used to estimate the creep crack growth rate. In step 3, the creep crack propagation rate equation— da/dt versus C_t —and the calculated value of C_t for the structural component are combined to develop residual life curves, such as a plot of initial crack size versus remaining life. The final life of the structural component can be determined based on certain failure criteria (e.g., fracture toughness).

Impact Toughness Testing

Introduction

DYNAMIC FRACTURE occurs under a rapidly applied load, such as that produced by impact or by explosive detonation. In contrast to quasi-static loading, dynamic conditions involve loading rates that are greater than those encountered in conventional tensile tests or fracture mechanics tests. Dynamic fracture includes the case of a stationary crack subjected to a rapidly applied load, as well as the case of a rapidly propagating crack under a quasi-stationary load. In both cases the material at the crack tip is strained rapidly and, if rate sensitive, may offer less resistance to fracture than at quasi-static strain rates. For example, values for dynamic fracture toughness are lower than those for static toughness (K_{Ic}) in the comparison shown in Fig. 1.

Fig. 1 Comparison of static (K_{Ic}), dynamic (K_{Id}), and dynamic-instrumented (K_{Idi}) impact fracture toughness of precracked specimens of ASTM A 533 grade B steel, as a function of test temperature. The stress-intensity rate was about $1.098 \times 10^4 \text{ MPa}\sqrt{\text{m}} \cdot \text{s}^{-1}$ ($10^4 \text{ ksi}\sqrt{\text{in.}} \cdot \text{s}^{-1}$) for the dynamic tests and about $1.098 \times 10^6 \text{ MPa}\sqrt{\text{m}} \cdot \text{s}^{-1}$ ($10^6 \text{ ksi}\sqrt{\text{in.}} \cdot \text{s}^{-1}$) for the dynamic-instrumented tests. Source: Ref 1

Because many structural components are subjected to high loading rates in service, or must survive high loading rates during accident conditions, high strain rate fracture testing is of interest and components must be designed against crack initiation under high loading rates or designed to arrest a rapidly running crack.

Furthermore, because dynamic fracture toughness is generally lower than static toughness, more conservative analysis may require consideration of dynamic toughness.

Measurement and analysis of fracture behavior under high loading rates is more complex than under quasi-static conditions. There are also many different test methods used in the evaluation of dynamic fracture resistance. Test methods based on fracture mechanics, as discussed extensively in other articles of this Section, produce quantitative values of fracture toughness parameters that are useful in design. However, many qualitative methods have also been used in the evaluation of impact energy to break a notched bar, percent of cleavage area on fracture surfaces, or the temperature for nil ductility or crack arrest. These qualitative tests include methods such as the Charpy impact test, the Izod impact test, and the drop-weight test. Other less common tests are the explosive bulge test, the Robertson test, the Esso test, and the Navy tear test (described in the 8th Edition *Metals Handbook*, Volume 10, p 38–40).

This article focuses exclusively on notch-toughness tests with emphasis on the Charpy impact test. The Charpy impact test has been used extensively to test a wide variety of materials. Because of the simplicity of the Charpy test and the existence of a large database, attempts also have been made to modify the specimen, loading arrangement, and instrumentation to extract quantitative fracture mechanics information from the Charpy test. Other miscellaneous notch-toughness test methods are also discussed in this article.

Impact Toughness Testing

History of Impact Testing

Before fracture mechanics became a scientific discipline, notched-bar impact tests were performed on laboratory specimens to simulate structural failures, eliminating the need to destructively test large engineering components. The simulation of structural component failure by notched-bar impact tests is based on severe conditions of high loading rate, stress concentration, and triaxial stress state. These tests have been extensively used in the evaluation of ductile-to-brittle transition temperature of low- and medium-strength ferritic steels used in structural applications such as ships, pressure vessels, tanks, pipelines, and bridges.

The initial development of impact testing began around 1904 when Considère discovered and noted in a published document that increasing strain rate raises the temperature at which brittle fracture occurs. In 1905 another Frenchman, George Charpy, developed a pendulum-type impact testing machine based on an idea by S.B. Russell. This machine continues to be the most widely used machine for impact testing. In 1908 an Englishman by the name of Izod developed a similar machine that gained considerable popularity for a period of time but then waned in popularity because of inherent difficulties in testing at temperatures other than room temperature.

Impact testing was not widely used, and its significance not fully understood, until World War II when many all-welded ships were first built (approximately 3000 of them). Of these 3000 ships, approximately 1200 suffered hull fractures, 250 of which were considered hazardous. In fact, 19 or 20 of them broke completely in two. These failures did not necessarily occur under unusual conditions; several occurred while the ships were at anchor in calm waters. In addition to ship failures, other large, rigid structures, such as pipelines and storage tanks, failed in a similar manner. All failures had similar characteristics. They were sudden, had a brittle appearance, and occurred at stresses well below the yield strength of the material. It was noted that they originated at notches or other areas of stress concentration, such as sharp corners and weld defects. These failures were often of considerable magnitude: in one case a pipeline rupture ran for 20 miles.

The Naval Research Laboratory, along with others, launched a study of the cause of these fractures. It was noted that often, but not always, failures occurred at low temperatures. More detailed historical research

revealed that similar failures had been recorded since the 1800s but had been largely ignored. The results of this study renewed interest, and further investigation revealed that materials undergo a transition from ductile behavior to brittle behavior as the temperature is lowered. In the presence of a stress concentrator such as a notch, it takes little loading to initiate a fracture below this transition temperature, and even less to cause such a fracture to propagate. These transitions were not predictable by such tests as hardness testing, tensile testing, or, for the most part, chemical analysis, which were common tests of the times. It was then discovered that a ductile-to-brittle transition temperature could be determined by impact testing using test specimens of uniform configuration and standardized notches. Such specimens were tested at a series of decreasing temperatures, and the energy absorbed in producing the fracture was noted. The Charpy pendulum impact testing machine was used. At first, test results were difficult to reproduce. The problem was partly resolved by producing more uniformly accurate test equipment. The notch most often used was of a keyhole type created by drilling a small hole and then cutting through the test bar to the hole by sawing or abrasive cutting. It was soon found that by using specimens with sharper notches, better-defined transition temperatures that were more reproducible could be determined. A well-defined notch with a V configuration became the standard. Steels in particular could then be tested and the ductile-to-brittle transition temperature obtained.

Two problems remained. First, testing machines had to be standardized very carefully or the results were not reproducible from one machine to another. The other problem was that the transition temperature found by testing small bars was not necessarily the same as that for full-size parts.

Fortunately, the problem with standardization was resolved by the Army. They learned that impact testing was a necessity for producing successful armor plate and gun tubes. Research at the Watertown Arsenal resulted in the development of standard test specimens of various impact levels. The Army made these available to their various vendors so that the vendors could standardize their own testing machines. This program was so successful that such specimens were made available to the public, at a nominal charge, starting in the 1960s. Next, the manufacturers of testing equipment were pressured into making equipment available that would meet these exacting standards.

The problem of differing transition temperatures for full-size parts and test specimens was discovered when a series of full-size parts was tested using a giant pendulum-type impact machine and these results were compared with those determined using small standard test bars made from the same material. A partial solution to this problem was the development of the drop-weight test (DWT) and the drop-weight tear test (DWTT). These tests produced transition temperatures similar to those found when testing full-size parts. Unfortunately, such tests are adaptable only for plate specimens of limited sizes and have not become widely used.

The Charpy V-notch test continues to be the most used and accepted impact test in use in the industry. However, the restricted applicability of the Charpy V-notch impact test has been recognized for many years (Ref 2). Charpy test results are not directly applicable for designs, and the observed ductile-to-brittle transition depends on specimen size. Nonetheless, the Charpy V-notch test is useful in determining the temperature range of ductile-to-brittle transition.

Impact Toughness Testing

Types of Notch-Toughness Tests

In general, notch toughness is measured in terms of the absorbed impact energy needed to cause fracturing of the specimen. The change in potential energy of the impacting head (from before impact to after fracture) is determined with a calibrated dial that measures the total energy absorbed in breaking the specimen. Other quantitative parameters, such as fracture appearance (percent fibrous fracture) and degree of ductility/deformation (lateral expansion or notch root contraction), are also often measured in addition to the

fracture energy. Impact tests may also be instrumented to obtain load data as a function of time during the fracture event. In its simplest form, instrumented impact testing involves the placement of a strain gage on the tip (the striker).

Many types of impact tests have been used to evaluate the notch toughness of metals, plastics, and ceramics. In general, the categories of impact tests can be classified in terms of loading method (pendulum stroke or drop-weight loading) and the type of notched specimen (e.g., Charpy V-notch, Charpy U-notch, or Izod). The following descriptions briefly describe the key types of impact tests that are used commonly in the evaluation of steels or structural alloys.

The Charpy and Izod impact tests are both pendulum-type, single-blow impact tests. The principal difference, aside from specimen and notch dimensions, is in the configuration of the test setup (Fig. 2). The Charpy test involves three-point loading, where the test piece is supported at both ends as a simple beam. In contrast, the Izod specimen is set up as a cantilever beam with the falling pendulum striking the specimen above the notch (Fig. 2b).

(a)

(b)

Fig. 2 Specimen types and test configurations for pendulum impact toughness tests. (a) Charpy method. (b) Izod method

The Charpy V-notch test continues to be the most utilized and accepted impact test in use in the industry. It is written into many specifications. While this test may not reveal exact ductile-to-brittle transition temperatures for large full-size parts, it is easily adaptable as an acceptability standard on whether or not parts are apt to behave in a brittle manner in the temperature range in which they are likely to be used.

The drop-weight test is conducted by subjecting a series (generally four to eight) of specimens to a single impact load at a sequence of selected temperatures to determine the maximum temperature at which a specimen breaks. The impact load is provided by a guided, free-falling weight with an energy of 340 to 1630 J (250 to 1200 ft · lbf) depending on the yield strength of the steel to be tested. The specimens are prevented by a stop from deflecting more than a few tenths of an inch.

This is a “go, no-go” test in that the specimen will either break or fail to break. It is surprisingly reproducible. For example, Pellini made 82 tests of specimens from one plate of semikilled low-carbon steel. At -1 °C (30 °F) and 4 °C (40 °F), all specimens remained unbroken. At -7 °C (20 °F), only one of 14 specimens broke; however, at -12 °C (10 °F), 13 of the 14 specimens broke. At temperatures below -12 °C (10 °F), all specimens broke.

The drop-weight tear test (DWTT) uses a test specimen that resembles a large Charpy test specimen. The test specimen is 76 mm (3 in.) wide by 305 mm (12 in.) long, supported on a 254 mm (10 in.) span. The thickness of the specimen is the full thickness of the material being examined. The specimens are broken by either a falling weight or a pendulum machine. The notch in the specimen is pressed to a depth of 5 mm (0.20 in.) with a sharp tool-steel chisel having an angle of 45°. The resulting notch root radius is approximately 0.025 mm (0.001 in.). One result of the test is the determination of the fracture appearance transition curve. The “average” percent shear area of the broken specimens is determined for the fracture area neglecting a region “one thickness” in length from the root of the notch and “one thickness” from the opposite side of the specimen. These regions are ignored because it is believed that the pressing of the notch introduces a region of plastically deformed material which is not representative of the base material. Similarly the opposite side of the specimen is plastically deformed by the hammer tup during impact. The fracture appearance plotted versus temperature defines an abrupt transition in fracture appearance. This transition has been shown to correlate with the transition in fracture propagation behavior in cylindrical pressure vessels and piping.

Impact Toughness Testing

Charpy Impact Testing

As previously noted, the specimen in the Charpy test is supported on both ends and is broken by a single blow from a pendulum that strikes the middle of the specimen on the unnotched side. The specimen breaks at the notch, the two halves fly away, and the pendulum passes between the two parts of the anvil. The height of fall minus the height of rise gives the amount of energy absorption involved in deforming and breaking the specimen. To this is added frictional and other losses amounting to 1.5 or 3J (1 or 2 ft · lbf). The instrument is calibrated to record directly the energy absorbed by the test specimen.

Methods for Charpy testing of steels are specified in several standards including:

Designation	Title
ASTM E 23	Standard Test Methods for Notched Bar Impact Testing of Metallic Materials
BS 131-2	The Charpy V-Notch Impact Test on Metals
BS 131-3	The Charpy U-Notch Impact Test on Metals
BS 131-6	Method for Precision Determinations of Charpy V-Notch Impact Energies for Metals
ISO 148	Steel—Charpy Impact Test (V-Notch)
ISO 83	Steel—Charpy Impact Test (U-Notch)
DIN-EN 10045	Charpy Impact Test of Metallic Materials

These standards provide requirements of test specimens, anvil supports and striker dimensions and tolerances, the pendulum action of the test machine, the actual testing procedure and machine verification, and the determination of fracture appearance and lateral expansion.

The general configuration of the Charpy test, as shown in Fig. 3 for a V-notch specimen, is common to the requirements of most standards for the Charpy test. Differences between ASTM E 23 and other standards include differences in machining tolerances, dimensions of the striker tip (Fig. 4), and the ASTM E 23 requirements for testing of reference specimens. The most pronounced difference between standards is the different geometry for the tip of the striker, or tup. The tup in the ASTM specification (Fig. 4a) is slightly flatter than in many other specifications (Fig. 4b). From a comparison of results from Charpy tests with the two different tup geometries, differences appeared more pronounced for several steels at impact energies above 100 J (74 ft · lbf) (Ref 3). From this evaluation, a recommendation was also made to use the sharper and smoother tup (Fig. 4b) if the national standards are unified further.

There are also three basic types of standard Charpy specimens (Fig. 5): the Charpy V-notch, the Charpy U-Notch, and the Charpy keyhole specimen. These dimensions are based on specifications in ASTM E 23, ISO 148, and ISO 83. The primary specimen and test procedure involves the Charpy V-notch test. Other Charpy-type specimens are not used as extensively because their degree of constraint and triaxiality is considerably less than the V-notch specimen.

(a)

(b)

(c)

Fig. 5 Dimensional details of Charpy test specimens most commonly used for evaluation of notch toughness. (a) V-notch specimen (ASTM E 23 and ISO 148). (b) Keyhole specimen (ASTM E 23). (c) U-notch specimen (ASTM E 23 and ISO 83)

The Charpy V-notch impact test has limitations due to its blunt notch, small size, and total energy measurement (i.e., no separation of initiation and propagation components of energy). However, this test is used widely because it is inexpensive and simple to perform. Thus, the Charpy V-notch test commonly is used as a screening test in procurement and quality assurance for assessing different heats of the same type of steel. Also, correlation with actual fracture toughness data is often devised for a class of steels so that fracture mechanics analyses can be applied directly. Historically, extensive correlation with service performance has indicated its usefulness.

The keyhole and U-notches were early recognized (1945) as giving inadequate transition temperatures because of notch bluntness. Even the V-notch does not necessarily produce a transition temperature that duplicates that of a full-size part. Under current testing procedures, the Charpy V-notch test is reproducible and produces close approximations of transition temperatures found in full-size parts. It is widely used in specifications to ensure that materials are not likely to initiate or propagate fractures at specific temperature levels when subjected to impact loads.

Equipment

Charpy testing requires good calibration methods. Machine belting should be examined regularly for looseness, and broken specimens should be examined for unusual side markings. Anvils should also be examined for wear. Testing Machines. Charpy impact testing machines are available in a variety of types. Some are single-purpose machines for testing Charpy specimens only. Others are adaptable to testing Izod and tension impact specimens also. They are offered in a range of loading capacities. The most common of these capacities are 325 and 160 J (240 and 120 ft · lbf). Some machines have variable load capabilities, but most are of a single-fixed-load type. When purchasing or using a machine, be sure that the available loading is such that specimens to be tested will break with a single blow, within 80° of the machine capacity (as shown by the scale on the machine).

While loading capacity depends on the anticipated strength of specimens to be tested, the maximum value of such specimens is the principal consideration. Very tough specimens may stop the hammer abruptly without breaking. A number of such load applications have been known to cause breakage of the pendulum arm. On the other hand, lower-capacity machines may be more accurate and more likely to meet standardization requirements. For most ordinary steel testing applications, the machine with a capacity of 160 J (120 ft · lbf) makes a good compromise choice. Testing of a large number of very tough specimens may require a machine with a capacity of 325 to 400 J (240–300 ft · lbf).

Charpy impact machines are of a pendulum type. They must be very rigid in construction to withstand the repeated hammering effect of breaking specimens without affecting the operation of the pendulum mechanism. The machine must be rigidly mounted. Special concrete foundations are sometimes used, but at least the machine must be bolted down to an existing concrete foundation, which should be a minimum of 150 mm (6 in.) thick. The pendulum should swing freely with a minimum of friction. Any restriction in movement of the pendulum will increase the energy required to fracture the specimen. This produces a test value that is higher than normal. There will always be small effects of this type, and they are usually compensated for, along with windage friction effects, by scale-reading adjustments built into the equipment.

While the pendulum must be loose enough to swing freely with little friction, it must not be loose enough to produce inaccuracies, such as nonuniform striking of the specimen. The components must be sturdy enough to resist deformation at impact. This is particularly true of the anvil and pendulum. It is important that the instrument be level. Some machines have a built-in bubble-type level. Others have machined surfaces where a level can be used. In operation, the pendulum is raised to the proper height and held by a cocking mechanism that can be instantly released.

ASTM E 23 specifies that tests should be made at velocities between 3 and 6 m/s (10 and 20 ft/s) and that this is defined as “the maximum tangential velocity of the striking member at the center of strike.” When hanging freely, the striking tip of the pendulum should be within 2.5 mm (0.10 in.) of touching the area of the specimen where first contact will be made. The anvil that retains the test specimen must be made such that the specimen can be squarely seated. The notch must be centered so that the pendulum tip hits directly behind it.

Most impact testing machines have scales that read directly in foot-pounds (scales also may read in degrees). As noted, the scale can be adjusted to compensate for windage, pendulum friction, and other variations. The scale should read zero when the pendulum is released without a specimen being present. Pendulum and anvil design, configuration, and dimensions are important. It is also important that the broken specimens be able to fly freely without being trapped in the anvil by the pendulum. Proper anvil design, such as that shown in Fig. 6, can minimize jamming.

Fig. 6 Typical anvil arrangement with modification that reduces the possibility of jamming

Specimens. As previously noted, there are three commonly used standard Charpy impact test specimens, which are similar except for the notch (Fig. 5). The V-notch bar is the most frequently used specimen, although some specific industries still use the other types of test bars. The steel casting industry, for instance, uses the keyhole-notch specimen more frequently. There are also many varieties of subsized specimens that should be used only when insufficient material is available for a full-size specimen, or when the shape of the material will not allow removal of a standard specimen.

It is important that specimens be machined carefully and that all dimensional tolerances be followed. Care must be exercised to ensure that specimens are square. It is easy to grind opposite sides parallel, but this does not ensure squareness. The machining of the notch is the most critical factor. The designated shape and size of the notch must be strictly followed, and the notch must have a smooth (not polished) finish. Special notch-broaching machines are available for V-notching. A milling machine with a fly cutter can also be used.

In preparing keyhole-notch specimens, the hole should be drilled at a low speed to avoid heat generation and work hardening. Use of a jig with a drill bushing ensures accuracy. After the hole has been drilled, slotting can be done by almost any method that meets specifications, but care should be exerted to prevent the slotting tool from striking the back of the hole. In all cases it is desirable to examine the notch at some magnification. A stereoscopic microscope or optical comparator is suitable for this examination. In fact, a V-notch template for use with the optical comparator can be used to ensure proper dimensions.

Specimens must generally be provided with identification markings. This is best done on the ends of the specimen. In preparing specimens where structural orientation is a factor (e.g., rolling direction of wrought materials), such orientation should be taken into consideration and noted, because orientation can cause wide variations in test results. If not otherwise noted, the specimen should be oriented in the rolling direction of the plate (forming direction of any formed part) and the notch should be perpendicular to that surface (orientation A in Fig. 7). This produces maximum impact values. All notching must be done after any heat treatment that might be performed.

Fig. 7 Effect of specimen orientation on impact test results

While correlation exists between full-size specimens and subsize specimens, such correlation is not direct. Many specifications (ASTM and ASME, for example) specify differing acceptable values for various specimen sizes (Table 1).

Table 1 Conversion table for subsize Charpy impact-test specimens

Size of specimens ^(a) , mm	Minimum average impact strength for three specimens		Minimum impact strength for one specimen or for set of three specimens	
	J	ft · lbf	J	ft · lbf
10 × 10 (full size)	20.3	15.0	13.6	10.0
10 × 7.5	16.9	12.5	11.5	8.5
10 × 5	13.6	10.0	9.5	7.0
10 × 2.5	6.8	5.0	4.7	3.5

(a) Insofar as possible, full-size Charpy keyhole specimens should be used. However, where absolutely necessary, it is permissible to use specimens with width (in direction of the length of the notch; see ASME Section VIII, U-84, Unfired Pressure Vessels) reduced in accordance with the above tabulation.

Calibration. ASTM E 23 goes into considerable detail to ensure proper calibration of testing machines. Other relevant standards for qualification or calibration of the test machines are:

ASTM E 1236	Standard Practice for Qualifying Charpy Impact Machines as Reference Machines
BS 131-7	Verification of the Test Machine Used for Precision Determination of Charpy V-Notch Impact
BS-EN 10045-2	Charpy Impact Test on Metallic Materials Part 2: Method for the Verification of Impact Testing Machines
ISO 148-2	Metallic Materials—Charpy Pendulum Impact Test Part 2: Verification of Test Machines

These publications should be consulted for a basic understanding of machine calibration. Calibration and test variables are also reviewed in Ref 4 and 5. These publications help identify causes of improper results.

Standard test bars for calibration can be purchased from: Director, Army Materials and Mechanics Research Center, Attention AMXMR-MQ, Watertown, MA 02172 (formerly known as the Watertown Arsenal). Standard specimens are tested as per instructions, and the results, along with a filled-out questionnaire and the broken specimens, are returned. A report is then sent stating if the machine meets calibration standards and, if not, what should be done to ensure qualification.

Test Method

Once the equipment has been properly set up and calibrated and the specimens have been correctly prepared, testing can be done. Prior to each testing session, the pendulum should be allowed at least one free fall with no test specimen present, to confirm that zero energy is indicated. Specimen identification and measurements are then recorded along with test temperature. The pendulum is cocked, and the specimen is carefully positioned in the anvil using special tongs (Fig. 8) that ensure centering of the notch. The quick-release mechanism is actuated, and the pendulum falls and strikes the specimen, generally causing it to break. The amount of energy absorbed is recorded (normally in foot-pounds), and this data is noted adjacent to the specimen identification on the data sheet. The broken specimens are retained for additional evaluation of the fracture appearance and for measurement of lateral expansion where required. The broken halves are often placed side by side, taped together, and labeled for identification.

Fig. 8 Use of tongs to place a specimen in a Charpy impact testing machine for testing

The release mechanism must be consistent and smooth. Test specimens must leave the impact machine freely, without jamming or rebounding into the pendulum; requirements on clearances and containment shrouds are specific to individual machine types. The test specimen must be accurately positioned on the anvil support within 5 s of removal from the heating (or cooling) medium; requirements for heating time depend on the heating medium. Identification marks on test specimens must not interfere with the test; also, any heat treatment of specimens should be performed prior to final machining.

A daily check procedure of the apparatus must be conducted to ensure proper performance. Verification of the testing system is required using Army Materials and Mechanics Research Center (AMMRC) standardized specimens; verification should be completed at least once a year or after any parts are replaced or any repairs or adjustments are made to the machine. An operational testing sequence is recommended, as well as specifics on dial energy reading, lateral expansion measurement (technique and measuring fixture), and fracture appearance estimation.

Test Temperature. Specimen temperature can drastically affect the results of impact testing. If not otherwise stated, testing should be done at temperatures from 21 to 32 °C (70–90 °F). Much Charpy impact testing is done at temperatures lower than those commonly designated as room temperature. Of these low-temperature tests, the majority are made between room temperature and -46 °C (-50 °F), because it is within this range that most ductile-to-brittle transition temperatures occur. A certain amount of testing is also done down to -196 °C (-320 °F) for those materials that may be used in cryogenic service. Some additional testing (mainly research) is done at the liquid helium and liquid hydrogen temperatures (-269 and -251 °C, or -452 and -420 °F). Such testing requires special techniques and will not be discussed here. For testing at temperatures down to or slightly below -59 °C (-75 °F), ethyl alcohol and dry ice are most commonly used. This combination solidifies at around -68 °C (-90 °F). A suitable insulated container should be used to cool the test specimens (a container insulated with a layer of styrofoam works fine). A screen-type grid raised at least 25 mm (1 in.) above the bottom of the container allows cooling liquid to circulate beneath the specimens. A calibrated temperature-measuring device,

such as a low-temperature glass or metal thermometer or a thermocouple device, should be placed so as to read the temperature near the center of a group of specimens being cooled. The solution should be agitated sufficiently to ensure uniformity of bath temperature. The cooling liquid should cover the specimen by at least 25 mm (1 in.). The specimen-handling tongs should be placed in the same cooling bath as the specimens. When the specimens have been placed in the alcohol bath along with the tongs, chips of solid CO₂ (dry ice) can be added and the solution agitated. Experience will dictate the amount of dry ice required to reach a certain temperature. Once the temperature is reached, it seems to hold steady with only an occasional addition of a small chip of dry ice. The specimens in a liquid bath should be held within +0 and -1.5 °C (+0 and -3 °F) of test temperature for at least 5 min prior to testing. The specimens should then be removed one at a time with the cooled tongs and tested within 5 s of removal from the bath. Watch the temperature between tests because the tongs can raise the bath temperature if left out of the bath too long. The commercial cooling baths that are available range from insulated stainless steel containers to containers with self-contained refrigeration units. Also available are thermocouple devices that can be placed in the cooling bath and will give a digital temperature readout. Dry ice cannot be stored for any length of time, but there is a device that produces “instant” dry ice from a CO₂ compressed gas bottle. Testing between -59 and -196 °C (-75 and -320 °F) requires a liquid medium that will not solidify at these temperatures. Various liquids are available. One that has been successfully used is isohexane (adequate ventilation should be provided and care exercised to avoid inhalation of the volatile organic fumes). Liquid nitrogen replaces the dry ice as a coolant material, and the procedure is then similar to that for dry ice and alcohol. It is wise to keep handy a large, easy-to-handle piece of metal to serve as a temperature moderator in case the temperature becomes lower than desired. It can be plunged into the bath and, acting as a heat sink, can cause the temperature to rise quickly.

High-Temperature Testing. Occasionally, high-temperature impact testing is performed. This can be done using an agitated, high-flashpoint oil (heat treating quenching oils may work) or other liquid medium that is stable at the desired test temperature. The bath and specimens are then held at temperature in a furnace or oven for at least 10 min prior to testing.

Test Results

Results of impact testing are determined in three ways. In the first method, already discussed, they can be read directly from the testing machine (in joules or foot-pounds). This is the most commonly specified test result. It is desirable to test three specimens at each test temperature; the average value of the three is the test result used. If a minimum test value is specified for material acceptance, not more than one test result of the three should fall below that value. If the value of one of the three specimens is about 6 J (5 ft · lbf) lower than the average, or lower than the average value by greater than $\frac{2}{3}$ of the specified acceptance value, the material should be either rejected or retested. In retesting, three additional specimens must be tested, and all must equal or exceed the specified acceptance value. Since it is often required or important to determine the ductile-to-brittle transition temperature, impact test results are plotted against test temperature. Somewhere in that transition zone between the high-energy and low-energy values is an energy value that can be defined as the transition temperature. When the transition is very pronounced, this value is easily determined. However, because the more common case is a less sharply defined transition, an energy value may be specified below which the material is considered to be brittle (below the ductile-to-brittle transition temperature). Such a value may vary with material type and requirements, but the value of 20 J (15 ft · lbf) is often used as a specified value.

Fracture Appearance Method. Other methods of specifying ductile-to-brittle transition temperature are sometimes presented along with the energy values obtained. The first of these auxiliary tests is the *fracture-appearance method*. The fractured impact bars are examined and the fractures compared with a series of standard fractures or overlays of such fractures. By this method the percentage of shear fracture is determined. The amount of shear fracture can also be determined in another way. This is done by carefully measuring the dimensions of the brittle cleavage exhibited on the specimen fracture surface (Fig. 9), and then referring to Table 2. These methods are described in detail in ASTM A 370. The percentage of shear can be plotted against test temperature and the transition temperature can be ascertained using the shear percentage value specified.

Table 2 Tables of percent shear for measurements made in both inches and millimeters for impact-test specimens

Because these tables are set up for finite measurements or dimensions *A* and *B* (see Fig. 9), 100% shear is to be reported when either *A* or *B* is zero.

Fig. 9 Sketch of a fractured impact test bar. The method used in calculating percent shear involves measuring average dimensions A and B to the nearest 0.5 mm (0.02 in.) and then consulting a chart (Table 2) to determine the percent shear fracture. (Courtesy of ASTM)

Unlike Charpy energy, fracture appearance is indicative of how a specimen failed. It is therefore useful when attempting to correlate results of Charpy testing with other toughness test methods that use different specimen geometries and loading rates. However, the fracture-appearance method can also be subjective. In one round-robin test survey of 20 specimens (Ref 6), results showed that agreement was best when operators are experienced, samples are close to the fracture-appearance transition, and when simple, two-dimensional figures are used for assessment.

Lateral-Expansion Method. The other auxiliary method of determining transition temperature is the *lateral-expansion method*. This procedure is based on the fact that protruding shear lips are produced (perpendicular to the notch) on both sides of each broken specimen. The greater the ductility, the larger the protrusions. This lateral expansion can be expressed as a measure of acceptable ductility at a given test temperature. The broken halves from each end of each specimen are measured. The higher values from each side are added together, and this total is the lateral-expansion value. A minimum value of lateral expansion must be specified as a transition value. These test results are then plotted against test temperature and a curve interpolated. The impact energy (in joules or foot-pounds) is also reported. These methods are described in detail in ASTM A 370 and E 23.

Applications

Test criteria for Charpy V-notch impact testing usually involve:

- A minimum impact energy value
- Shear appearance of fractured test bars expressed in percent
- Lateral expansion

For steels, the minimum acceptable values most commonly specified for these three evaluation methods are, respectively: 20 J (15 ft · lbf), 50% shear, and 1.3 mm (50 mil). As a general rule of thumb, Charpy V-notch impact strengths of 14 J (10 ft · lbf) and lower are likely to initiate fractures. An impact strength of 27 J (20 ft · lbf) is likely to propagate brittle fracture once initiated, and values well above 27 J (20 ft · lbf) are necessary to arrest fracturing once it has been initiated.

Charpy impact testing does not produce numbers that can be used for design purposes, but is widely used in specifications such as ASTM A 593, “Specification for Charpy V-Notch Testing Requirements for Steel Plates for Pressure Vessel.” Other applications are briefly described below.

Nuclear Pressure Vessel Design Code. For nuclear pressure vessels, the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (Ref 7) and the Code of Federal Regulations (Ref 8) currently use fracture mechanics principles that dictate toughness requirements for pressure vessel steels and weldments. The specified toughness requirements are obtained using Charpy V-notch test specimens coupled with the nil-ductility transition temperature (NDTT) per ASTM E 208. The actual approach involves a reference temperature, designated RT_{NDT} , and the reference fracture toughness curve, K_{IR} . The reference fracture toughness curve defined in Appendix G, Section III, of the ASME Code uses an experimentally

determined relationship between toughness and temperature that is adjusted along the temperature axis according to an index reference temperature.

The reference toughness curve, K_{IR} , is assumed to describe the minimum (lower bound) fracture toughness for all ferritic materials approved for nuclear pressure boundary applications having a minimum specified yield strength of 345 MPa (50 ksi) or less. The value of RT_{NDT} is obtained by measuring the drop-weight nil-ductility transition temperature and performing standard Charpy V-notch tests. The nil-ductility transition temperature is determined initially, and then a set of three Charpy V-notch specimens is tested at a temperature that is 33 °C (60 °F) higher than the nil-ductility transition temperature to measure the temperature, T_{CV} , which ensures an increase in toughness with temperature. Charpy energies of 68 J (50 ft · lbf) and lateral expansion of 0.89 mm (35 mil) are used to ensure this condition.

The nil-ductility transition temperature becomes the RT_{NDT} temperature if the Charpy results equal or exceed the above limits. If the Charpy values at T_{CV} or the nil-ductility transition temperature plus 33 °C (60 °F) are lower than required, additional Charpy tests should be performed at higher test temperatures, usually in increments of 5.6 °C (10 °F), until the requirements are satisfied and T_{CV} is measured. The RT_{NDT} temperature then becomes the temperature (T_{CV}) at which the criteria are met minus 33 °C (60 °F). Thus, the reference temperature is always either greater than or equal to the nil-ductility transition temperature.

Steel Bridge Toughness Criteria. The American Association of State Highway and Transportation Officials (AASHTO) has adopted Charpy impact toughness requirements for primary tension members in bridge steels based on section thickness, yield strength, and expected service temperature. They are based on the fracture toughness corresponding to the maximum loading rate expected in service (Ref 9).

Correlations with Fracture Toughness. Empirical attempts have been made to correlate the Charpy impact energy with K_{Ic} to allow a quantitative assessment of critical flaw size and permissible stress levels. Most of these correlations are dimensionally incompatible, ignore differences between the two measures of toughness (in particular, loading rate and notch acuity), and are valid only for limited types of materials and ranges of data. Additionally, these correlations can be widely scattered. However, some correlations can provide a useful guide to estimating fracture toughness; in fact, the preceding design criteria for nuclear pressure vessel and bridge steels are partially based on such correlative procedures.

Some of the more common correlations are listed in Table 3 (Ref 9, 10, 11, 12, 13, 14, 15, and 16) with appropriate units. Note that some of the correlations attempt to eliminate the effects of loading rate; the dynamic fracture toughness, K_{Id} , is correlated with Charpy energy. Other attempts have been made to improve and explain some of the correlations (see, for example, Ref 17). A study has also been conducted using a portion of the Charpy energy to separate initiation and propagation components in the Charpy test (Ref 18). The results from this study for an upper-shelf J_{Ic} correlation for pressure vessel steels were not significantly better than the Rolfe-Novak correlation listed in Table 3. A statistically based correlation for lower-bound toughness has also been developed for pressure vessel steels (Ref 19, 20). Thus, simple and empirical correlations can be used as general guidelines for estimating K_{Ic} or K_{Id} within the limits of the specific correlation.

Table 3 Typical Charpy/ K_{Ic} correlation for steels

Correlation	Transition temperature regime
Barsom (Ref 9)	
$K_{Id}^2/E = 5$ (CVN)	$K_{Ic} K_{Id} = \text{psi} \sqrt{\text{in.}}$ $E = \text{psi}$ $\text{CVN} = \text{ft} \cdot \text{lbf}$
Barsom-Rolfe (Ref 10) $K_{Ic}^2/E = 2(\text{CVN})^{3/2}$	
Sailors-Corten (Ref 11)	
$K_{Ic}^2/E = 8$ (CVN)	$K_{Id} = \text{ksi} \sqrt{\text{in.}}$ $\text{CVN} = \text{ft} \cdot \text{lbf}$
$K_{Id}^2 = 15.873(\text{CVN})^{3/8}$	
Begley-Logsdon—three points (Ref 12)	
$(K_{Ic})_1 = 0.45 \sigma_y$ at 0% shear fracture temperature	$K_{Ic} = \text{ksi} \sqrt{\text{in.}}$ $\sigma_y = \text{ksi}$
$(K_{Ic})_2$ From Rolfe-Novak Correlation at 100% shear fracture temperature	
$(K_{Ic})_3 = \frac{1}{2}[(K_{Ic})_1 + (K_{Ic})_2]$ at 50% shear fracture temperature	

Marandet-Sanz—three steps (Ref 13)	
$T_{100} = 9 + 1.37 T_{28J}$	$T_{100} = \text{°C, for which } K_{Ic} = 100 \text{ MPa}\sqrt{m}$ $T_{28} = \text{°C, for which CVN} = 28J$ $K_{Ic} = \text{MPa}\sqrt{m}$ $\text{CVN} = J$
$K_{Ic} = 19 \text{ (CVN)}^{1/2}$ Shift K_{Ic} curve through T_{100} point	
Wullaert-Server (Ref 14)	
$K_{Ic,d} = 2.1 (\sigma_y \text{ CVN})^{1/2}$	$K_{Ic,d} = \text{ksi}\sqrt{\text{in.}}$ $\text{CVN} = \text{ft} \cdot \text{lbf}$ $\sigma_y = \text{ksi corresponding to approximate loading rate}$
Upper-shelf region	
Rolfe-Novak— $\sigma_y > 100 \text{ ksi}$ (Ref 15)	
$(K_{Ic}/\sigma_y)^2 = 5 \text{ (CVN}/\sigma_y - 0.05)$	$K_{Ic} = \text{ksi}\sqrt{\text{in.}}$ $\text{CVN} = \text{ft} \cdot \text{lbf}$ $\sigma_y = \text{ksi}$
Ault-Wald-Bertolo—ultrahigh-strength steels (Ref 16)	
$(K_{Ic}/\sigma_y)^2 = 1.37 \text{ (CVN}/\sigma_y) - 0.045$	$K_{Ic} = \text{ksi}\sqrt{\text{in.}}$ $\text{CVN} = \text{ft} \cdot \text{lbf}$ $\sigma_y = \text{ksi}$

1.0 ksi = 6.8948 MPa; $1.0 \text{ ksi}\sqrt{\text{in.}} = 1.099 \text{ MPa}\sqrt{m}$; $1.0 \text{ ft} \cdot \text{lbf} = 1.356 \text{ J}$; CVN is the designation for Charpy impact energy; σ_y is the yield stress; and E is the Young's modulus.

As previously described, a lower-bound K_{IR} toughness curve is shifted relative to a reference temperature, RT_{NDT} , and used to define the ductile-to-brittle transition. The RT_{NDT} is a critical value and is defined very conservatively in terms of Charpy and dynamic tear specimen results. Continued application of these requirements is now a principal limitation to continued operation of several commercial nuclear power plants (Ref 21). Recent work by ASTM Committee E-8 has proposed a method to obtain a new reference temperature and a method to define, using a probabilistic approach, a median ductile-to-brittle transition curve from a set of six properly tested small samples that would, in many cases, be precracked Charpy specimens. Statistical confidence bounds would then be available for this median transition “master curve,” which would be specific to the particular nuclear plant of interest and could be used to assure that the pressure vessel had adequate toughness for continued operation.

A generalized prediction method to predict K_{Ic} transition curves has also been developed with data from various steels including 2.25Cr-1Mo, 1.25Cr-0.50Mo, 1Cr and 0.50Mo chemical pressure vessel steels, and ASTM A 508 C1.1, A 508 C1.2, A 508 C1.3 and A 533 Gr.B C1.1 nuclear pressure vessel steels (Ref 22). This method consists of a master curve of K_{Ic} and a temperature shift, ΔT , between fracture toughness and Charpy V-notch impact transition curves versus yield strength relationship for T_0 , where T_0 is the temperature showing 50% of the upper-shelf K_{Ic} value. The K_{Ic} transition curves predicted using both methods showed a good agreement with the lower bound of measured K_{Ic} values obtained from elastic-plastic, J_c , tests.

Instrumented Charpy Impact Test

The use of additional instrumentation (typically an instrumented tup) allows a standard Charpy impact machine to monitor the analog load-time response of Charpy V-notch specimen deformation and fracturing. The primary advantage of instrumenting the Charpy test is the additional information obtained while maintaining low cost, small specimens, and simple operation. The most commonly used approach is application of strain gages to the striker to sense the load-time behavior of the test specimen. In some cases, gages are placed on the specimen as well, such as for the example shown in Fig. 10 (Ref 23).

Fig. 10 Charpy specimen with additional instrumentation at the supports

General Description

Instrumentation of the tup provides valuable data in terms of the load-time, $P-t$, history during impact. Extensive efforts have been made to help determine the dynamic fracture toughness, K_{Id} , over a range of behavior in linear-elastic, elastic-plastic, and fully plastic regimes. An overview of these efforts is given in Ref 24.

Figure 11 schematically illustrates the change in Charpy behavior as a function of temperature for a medium-strength steel. As shown, instrumentation clearly allows the various stages in the fracture process to be identified. The energy value, W_M , is associated with the area under the load-time ($P-t$) curve up to maximum load, P_M . This impulse value is converted to energy by using Newton's second law, which accounts for the pendulum velocity decrease during the deformation-fracture process. This velocity decrease is proportional to the instantaneous load on the specimen at any particular time, t_i ; the actual energy absorbed, ΔE_i , simplifies to (Ref 25):

$$\Delta E = E_a \left[1 - \left(\frac{E_a}{4E_o} \right) \right] \tag{Eq 1}$$

where E_0 is the total available kinetic energy of the pendulum ($\frac{1}{2}m \cdot V_0^2$) and:

$$E_a = V_0 \int_0^{t_i} P \cdot dt \quad (\text{Eq 2})$$

where V_0 is the initial impact velocity, and m is the effective mass of the pendulum. The ability to separate the total absorbed energy into components greatly augments the information gained by instrumentation. Load-time diagrams can be constructed to illustrate the various fracture process stages indicative of the fracture mode transition from brittle to ductile behavior (Ref 26).

Fig. 11 Load-time response for a medium-strength steel. P_M , maximum load; P_{GY} , general yield load; P_F , fast fracture load (generally cleavage); P_A , arrest load after fast fracture propagation; t_M , time to maximum load; t_{GY} , time to general yield; W_M , energy absorbed up to maximum load

One of the primary reasons for the development of the instrumented Charpy test was to apply existing notch bend theories (slow bend) to the dynamic three-point bend Charpy impact test. Obtaining load information during the standard Charpy V-notch impact test establishes a relationship between metallurgical fracture parameters and the transition temperature approach for assessing fracture behavior (Ref 27). Initial studies concentrated on the full range of mechanical behavior from fully elastic in the lower Charpy shelf region to elastic-plastic in the transition region to fully plastic in the upper shelf region (see Fig. 11).

Most studies have been performed on structural steels, with primary emphasis on the effect of composition, strain rate, and radiation on the notch bend properties. Interest in instrumented impact testing has expanded to include testing of different types of specimens (e.g., precracked, large bend), variations in test techniques (e.g., low blow, full-size components), and testing of many different materials (e.g., plastics, composites, aerospace materials, ceramics). The many variations in test methods is a motivation for standardized test methods, although standardization for instrumented Charpy testing has been slow (see the section "Standards and Requirements" in this article).

Instrumentation

Instrumentation for a typical Charpy impact testing system includes an instrumented striker, a dynamic transducer amplifier, a signal-recording and display system, and a velocity-measuring device. The instrumented striker is the dynamic load cell, which is securely attached to the falling weight assembly. The striker has cemented strain gages to sense the compression loading of the tup while it is in contact with the test specimen. The dynamic transducer amplifier provides direct-current power to the strain gages and typically amplifies the strain gage output after passing through a selectable upper-frequency cutoff.

The impact signal is recorded and stored either on a storage oscilloscope or through the use of a transient signal recorder. Digital data from a transient recorder can be reconverted back to analog form and plotted on an x - y recorder, or the digital data can be transferred to a computer for direct analysis.

Triggering is best accomplished through an internal trigger that has the ability to capture the signal preceding the trigger; external triggering from the velocity-sensing device is often used instead of an appropriate internal trigger. The velocity-measuring system should be a noncontacting, optical system that clocks a flag on the impacting mass immediately before impact so that initial velocity measurements can be made. Velocities must be determined for all impact drop heights used.

The impact machine and the instrumentation package must be calibrated to ensure reliable data. Calibration of the Charpy pendulum impact machine is performed in accordance with ASTM E 23, as discussed previously in this article in terms of periodic proof testing of AMMRC calibration specimens to ensure reliable dial energy values.

Instrumentation calibration consists of a time base and load-cell calibration with a system frequency response measurement. The time base calibration consists of passing a known time mark pulse through the system and calibrating accordingly. The load-cell calibration is typically accomplished by testing notched specimens of 6061-T651 aluminum that are only slightly loading-rate sensitive over the range used (Ref 28). The load cell is calibrated when the measured dynamic limit load is only slightly higher than the predetermined quasi-static limit load (measured using the same loading arrangement and anvil dimensions) and when the dial energy (or velocity-determined energy measurement) matches the integrated total energy. The relationship used for obtaining total absorbed energy, ΔE_o , from the area under the load-time record follows the approach in Eq 1 and 2.

The calculated ΔE_o value will match the dial energy reading when the system is calibrated (in addition to the limit load check). Because the aluminum limit load is fairly low (around 7.1 kN, or 1600 lbf), a check on load-cell linearity at higher loads is also needed. To accomplish this, the integrated energy/dial energy requirement for a quenched and tempered 4340 specimen (52 HRC) that has a higher fracture load (near 27 kN, or 6000 lbf) is checked.

Low-energy AMMRC calibration specimens can be used for this procedure. If the energies match for the 4340 test at the same amplifier gain as for the aluminum calibration, the load-cell calibration is usually linear throughout the usable load range. Static linearity checks can also be made if the static loading system exactly duplicates the dynamic loading conditions. Daily test checks using the aluminum calibration specimens are suggested to verify load-cell calibration.

The system frequency response is determined experimentally by superimposing a constant-amplitude sine wave signal on the output of the strain gage bridge circuit (Ref 29). The peak-to-peak amplitude of the signal should be equivalent to approximately half the full-scale capacity of the load transducer at a frequency low enough to ensure no signal attenuation. The frequency of the sine wave is then increased until the amplitude is attenuated 10% (0.915 dB), and the response time, t_R , is calculated as:

$$t_R = \frac{0.35}{f_{0.915}} \quad (\text{Eq 3})$$

where $f_{0.915}$ is the frequency at 0.915 dB (10%) attenuation.

Standards and Requirements

Instrumented impact tests that generate P - t plots from instrumented tups require careful attention to test procedures and analytical methods in order to determine dynamic fracture toughness values with the accuracy and reliability required for engineering purposes. Extensive efforts have been made to standardize instrumented impact tests, but many inherent difficulties in analysis and interpretation have impeded the formal development of standard methods. Nonetheless, instrumented impact testing is an accepted method in the evaluation of

irradiation embrittlement of nuclear pressure vessel steels (Ref 30). Several instrumented impact tests have also been developed for plastics (Ref 31) with the ISO standard 179-2 on instrumented Charpy testing of plastics (Ref 32). The following discussions focus on requirements for steels, while more information on impact testing of plastics and ceramics are addressed in the article “Mechanical Testing of Polymers and Ceramics” in this Volume. For nonmetallic materials, such as plastics and ceramics, the application of available models involving energy considerations may be necessary for arriving at the true toughness values (Ref 24).

Standard Methods. Extensive efforts in the development of instrumented Charpy tests began in the 1960s and 1970s with the advent of fracture mechanics and precracked Charpy V-notch specimens, when a series of seminars and conferences in the 1970s (Ref 33, 34, 35, and 36) examined the role of instrumented impact testing in the evaluation of dynamic fracture toughness (Ref 24). The International Institute of Welding first attempted to standardize the instrumented Charpy test, but concluded that the test was not sufficiently documented, and the effort was discontinued (Ref 37). A few years later, two significant events prompted serious consideration of standardization. The development of the K_{IR} curve by the Pressure Vessel Research Committee and its inclusion in the ASME Code, Section III, created the need for dynamic initiation toughness, K_{Id} , data. Simultaneously, two other related groups began formulating procedures and conducting interlaboratory round robins. The Pressure Vessel Research Committee/Metals Property Council Task Group on Fracture Toughness Properties for Nuclear Components developed procedures for measuring K_{Id} values from precracked Charpy specimens (Ref 38).

The Electric Power Research Institute (EPRI) funded work to develop procedures known as the “EPRI Procedures” (Ref 28, 39). This procedure is summarized in the following section, “General Test Requirements.” Since that time, important theoretical and technical developments have occurred, as outlined in Ref 24. Efforts have also been made in the development of standards. In 1992, the European Structural Integrity Society (ESIS) formed a working party (formed within ESIS Technical Subcommittee 5) devoted to instrumented impact testing on subsize Charpy-V specimens of metallic materials. In 1994, ESIS issued a draft of a standard method for the instrumented Charpy V-notch test on metallic materials (Ref 40). This method allows one to estimate an approximate value of the proportion of ductile fracture surface by one of the following formulas:

$$\% \text{ shear} = [1 - (P_{IU} - P_A) / P_M] \times 100\%$$

$$\% \text{ shear} = [1 - (P_{IU} - P_A) / (P_M - P_{GY})] \times 100\%$$

$$\% \text{ shear} = \{1 - (P_{IU} - P_A) / [P_M + 0.5(P_M - P_{GY})]\} \times 100\%$$

$$\% \text{ shear} = \left(1 - \sqrt{[(P_{GY} / P_M) + 2]} / 3 \right)$$

$$\times \left[\left(\sqrt{P_{IU} - P_M} \right) - \left(\sqrt{P_A / P_M} \right) \right] \times 100\%$$

where P_{GY} , P_M , P_{IU} , and P_A are characteristic points on the load-time diagram shown in Fig. 12.

Fig. 12 Load vs. time record showing the definitions of the various load points used in various models to estimate the percent shear fracture; P_{GY} , characteristic value for onset of plastic deformation; P_M , maximum load; P_{IU} , load at the initiation of unstable crack propagation; P_A , load at the end of unstable crack propagation.

The working group also performed round-robin testing to help develop the state of knowledge on the dynamic behavior of miniaturized impact specimens (Ref 41). In 1992, a formal committee also was formed for development of a possible JIS standard for evaluation of dynamic fracture toughness by the instrumented Charpy impact testing method. Problems to be resolved before the standardization of the instrumented Charpy impact test method are pointed out in Ref 42.

General Test Requirements. Only subtle differences exist between the “EPRI Procedures” (Ref 28) and the Pressure Vessel Research Committee procedures for measuring K_{Id} values from precracked Charpy specimens (Ref 38, 43). The following test requirements are taken from the EPRI procedures.

The load signal obtained from an instrumented striker during an impact test oscillates about the actual load required to deform the specimen. Therefore, the signal analysis procedure employed should minimize the deviation of the apparent load from the actual specimen deformation load. A simplistic view of the impact event allows three major areas for test specification to be identified: initial loading, limited frequency response, and electronic curve fitting.

The impact loading of a specimen will create inertial oscillations in the contact load between striker and specimen, and a time interval between 2τ and 3τ is required for the load to be dissipated, where τ is related to the period of the apparent specimen oscillations and can be predicted empirically for a span-to-width ratio of 4 by:

$$\tau = 3.36 \left(\frac{W}{S_o} \right) (EBC_s)^{1/2} \quad (\text{Eq 4})$$

where W is the specimen width, B is the specimen thickness, C_s is the specimen compliance, E is the Young's modulus, S_o is the speed of sound in the specimen, and τ is typically $30 \mu\text{s}$ for standard Charpy steel specimens. When any time, t , is less than 2τ , it is not possible to use the striker signal to measure the portion of the specimen load caused by inertial effects. An empirical specification for reliable load and time evaluation is:

$$t \geq 3\tau \quad (\text{Eq 5})$$

Control of t is obtained by control of the initial impact velocity. The constant 3 in Eq 5 may be as low as 2.3 without adversely affecting the test results, if the curve-fitting technique described below is followed. A value of 3 was chosen for the case of “unlimited” frequency response. The original EPRI procedures corresponded to the 2.3 factor and included the selective filtering for curve fitting (Ref 28). Computer simulations of the Charpy test have approximately verified the value of τ and the 3τ criterion (Ref 44).

The potential problem of limited frequency response of the transducer amplifier is avoided by specifying:

$$t \geq 1.1t_R \quad (\text{Eq 6})$$

where t_R is defined as the 0.915 dB response time of the instrumentation, as indicated in Eq 3. Inadequate response results in a distorted signal response. It is important to note that the electronic attenuation must be representative of a resistance-capacitance circuit for Eq 6 to apply.

The curve fitting of the oscillations is achieved by specifying a minimum t_R . The amplitude of the observed oscillations is therefore reduced such that the disparity between tup contact load and effective deformation load is minimal. For the best test, it has been empirically found for resistance-capacitance circuit systems that:

$$t_R \geq 1.4t \quad (\text{Eq 7})$$

is adequate for the electronic curve fitting without altering the overall curve, when $t \geq 2.3\tau$. When $t \geq 3\tau$, it is not necessary to electronically curve fit because the disparity between the contact load and the specimen deformation load is less than approximately 5%.

The requirements for obtaining acceptable load-time records (in particular, Eq 5) result in the need to control V_o . By controlling the impact velocity, a corresponding control of kinetic energy (E_o) is inherent. The reduction in striker velocity during the impact loading of the specimen should therefore be minimized. A conservative requirement is:

$$E_o \geq 3W_M \quad (\text{Eq 8})$$

where W_M is the system energy dissipated to maximum load P_M . This requirement ensures that the tup velocity is not reduced by more than 20% up to maximum load. This requirement is seldom a problem for full-impact Charpy V-notch tests; Eq 8 may not be met, however, when precracked Charpy tests are conducted for very tough materials. The test requirements for reliable load measurement are summarized as follows:

Inertial effects	$t \geq 3\tau$
Limited frequency response	$t \geq 1.1t_R$, required only if $2.3\tau \leq t < 3\tau$
Electronic curve fitting	$t_R \geq 1.4\tau$
Energy criterion	$E_o \geq 3W_M$

The time t corresponds to the shortest time required for measurement after the specimen has been impacted; that is, t is the time to maximum load t_M for the elastic fracture, and t is the time to general yield, t_{GY} , in the postgeneral yield fracture (See Fig. 11). The specification for electronic curve fitting is only required if $2.3\tau \leq t < 3\tau$. Because it is often difficult to ensure that $t \geq 3\tau$ and because the filtering has no adverse effect when $t \geq 2.3\tau$ filtering at $t_R \geq 1.4\tau$ is always possible, assuming that $t \geq 1.1t_R$.

Limitations on Testing. Violation of any of the general test requirements presented above will invalidate the data obtained from instrumented Charpy V-notch tests. Limitations of this testing technique are the same as those for standard Charpy testing. The effects of small size relative to typical component size, the rounded machine notch, and shallow notch depth restrict general applicability and usefulness of the Charpy test. Note that the notch depth for the Charpy V-notch specimen is too shallow to prevent yielding across the gross section of the specimen.

Instrumentation has allowed separation of energy components and measurement of applied loads throughout the fracture event, but direct determination of the initiation component is not directly possible for ductile (microvoid coalescence) initiation from the instrumented test record. Some of these limitations have been addressed by fatigue precracking the Charpy specimen, which eliminates the notch effects and makes it a small fracture-mechanics-type specimen.

Impact Toughness Testing

Precracked Charpy Test

By inducing a fatigue precrack in the Charpy specimen, the notch acuity and depth restrictions are eliminated. Early work concentrated on correlations with fracture toughness using only the total absorbed energy (i.e., uninstrumented testing). These energy values usually are normalized per unit area (A) below the fatigue crack; the normalized energy values are designated as W/A .

Most of the correlations of W/A with fracture toughness have been conducted using slow-bend specimens. The basic problem in reaching an impact correlation is the difference in loading rates between the Charpy impact

and the static K_{Ic} tests, particularly for loading-rate sensitive materials (Ref 45). A general trend exists for a correlation between K_{Ic}^2/E and W/A , but the limited data and scatter make this difficult to utilize (Ref 16). A better correlation with K_{Id} may be possible. The reason for using K_{Ic}^2/E as the basis is the approximate proportionality between K_{Ic}^2/E and W/A , based on a presumed fracture mechanics relationship (Ref 45). The precracked Charpy W/A values can also be used to estimate the nil-ductility transition temperature. The typical technique defines an inflation point between lower shelf and transition region behavior as the estimated nil-ductility transition temperature (Ref 46). Some exceptions have been noted to this approach (Ref 47).

Instrumented Data

The types of data and test techniques used for instrumented precracked Charpy testing are the same as those discussed earlier for instrumented Charpy impact testing. The 3τ criterion, which limits the impact velocity, becomes more important for deeply cracked, brittle materials. The greatest advantage of precracking is the transformation of the Charpy V-notch specimen into a dynamic fracture mechanics test piece. The direct calculation of fracture toughness (within certain limitations) is now possible using the instrumented load-time information. The following discussion presents the calculational aspects of these fracture toughness parameters. If fracture is known to initiate at maximum load (as it usually does for cleavage initiation), the energy value of W_M (see Fig. 11) can be considered an initiation energy. However, W_M includes contributions other than that caused by the deflection of the specimen. Therefore, a compliance energy correction is needed to determine the true specimen energy, E_M (Ref 48). When the fracture is linear elastic (fracture before general yield; see the first two load-time records in Fig. 11), the value of E_M can be calculated directly:

$$E_M = \frac{C_{ND}(P_M^2)}{2EB} \quad (\text{Eq 9})$$

where C_{ND} is the nondimensional specimen compliance (Ref 49). For a fracture occurring after general yield (see Fig. 11), E_M is obtained by correcting W_M :

$$E_M = W_M - \left\{ \left[\frac{P_M^2}{2} \right] \left[C_T - \left(\frac{C_{ND}}{EB} \right) \right] \right\} \quad (\text{Eq 10})$$

where C_T is the total system compliance calculated at general yield and corrected for the decrease in velocity through general yield:

$$C_T = \left(\frac{V_o t_{GY}}{P_{GY}} \right) - \left(\frac{V_o^2 t_{GY}^2}{8E_o} \right) \quad (\text{Eq 11})$$

This compliance correction is assumed to be linear with load, but the actual correction is not so simple. However, the error in assuming a linear relationship results in a slightly smaller (conservative) value of E_M (Ref 43).

It is often desirable to partition the total fracture energy into initiation and postinitiation (propagation) components. Assuming initiation occurs at maximum load, the propagation energy, E_P , is:

$$E_P = E_T - E_M \quad (\text{Eq 12})$$

where E_T is the total fracture energy, as determined from a dial indicator, kinetic energy change (initial and final velocity measurements), or ΔE_o .

Linear Elastic Fracture Toughness. When the fracture is elastic (fracture occurs before general yield), the stress-intensity factor, K_{Ic} , can be calculated by applying linear elastic fracture mechanics:

$$\begin{aligned}
K_{Ic} &= \frac{4P_M}{BW^{1/2}} \\
&\times \left\{ 3 \left(\frac{a}{W} \right)^{1/2} \left[1.99 - \left(\frac{a}{W} \right) \left(1 - \frac{a}{W} \right) \right] \right. \\
&\times \left(2.15 - 3.93 \frac{a}{W} + 2.7 \frac{a^2}{W^2} \right) \left. \right\} \\
&+ \left[2 \left(1 + \frac{2a}{W} \right) \left(1 - \frac{a}{W} \right)^{3/2} \right]
\end{aligned} \tag{Eq 13}$$

where a is the crack length.

The ASTM size requirements for a valid K_{Ic} are quite limiting, even if a dynamic yield strength is used. However, the general specimen size requirements of ASTM E 399 may be too conservative for dynamic testing of ferritic medium-strength steels (Ref 50). Therefore, if general yielding has not occurred, a linear-elastic value of fracture toughness, K_{Ic} , generally is calculated. The stress intensification rate \dot{K} is calculated as:

$$\dot{K} = \frac{K_{Ic}}{t_M} \tag{Eq 14}$$

This loading rate reflects the dynamic aspect of the loading, because the lowest \dot{K} for impact loading of precracked Charpy specimens is on the order of $11 \times 10^4 \text{ MPa}\sqrt{\text{m}} \cdot \text{s}^{-1} \times (1 \times 10^5 \text{ ksi}\sqrt{\text{in.}} \cdot \text{s}^{-1})$.

Postgeneral Yield Fracture Toughness. When general yielding occurs, an energy-based value of the J -integral can be used to obtain a measure of fracture toughness. The calculation of ductile fracture toughness, J_{Ic} , is contingent upon knowing the initiation point of fracture on the load-time record. For cleavage-initiated fracture, this point generally corresponds to maximum load. However, for fibrous (ductile) initiation, maximum load is generally a nonconservative assumption. When the initiation point is known or has been determined experimentally (Ref 51) and when $a/W \geq 0.5$ (Ref 52), then:

$$J_{Ic} = \frac{2E_M}{Bb} \tag{Eq 15}$$

where b is the remaining ligament depth ($W - a$). A stress-intensity factor K_{Ic} can be obtained from the J_{Ic} value as:

$$K_{Ic} = (EJ_{Ic})^{1/2} \tag{Eq 16}$$

An average K can also be computed, as in Eq 16, by using a K_{Ic} value. Validity criteria related to specimen dimensions appear to be (Ref 43):

$$a, b, B \geq 25 \left(\frac{J_{Ic}}{\sigma_f} \right) \text{ (fibrous initiation)} \tag{Eq 17}$$

and

$$a, b, B \geq 50 \left(\frac{J_{Ic}}{\sigma_f} \right) \text{ (cleavage initiation)} \tag{Eq 18}$$

where σ_f is the flow stress, defined as the average of the yield stress and the ultimate stress. For dynamic loading, the yield stress, σ_y , and flow stress, σ_f , of standard Charpy V-notch specimens can be estimated for postgeneral yield behavior as:

$$\sigma_y = 2.99 P_{GY} \frac{W}{Bb^2} \tag{Eq 19}$$

and

$$\sigma_f = \frac{[2.99(P_{GY} + P_M)W]}{2Bb^2} \quad (\text{Eq 20})$$

The general form of the equation results from slip-line field solutions for blunt-notch specimens, and the constant 2.99 has been obtained from extrapolation of results from a slip-line field solution that included the tup indentation at the center loading point (Ref 53). The constant of 2.99 reduces to 2.85 for sharp-notch specimens with a fatigue precrack. The stress values obtained using this approach agree favorably with high rate tensile test results (Ref 54).

Limitations. The test requirements and data analysis procedures described in this article were developed for ferritic pressure vessel steels. A review of instrumented precracked Charpy testing can be found in Ref 55, which discusses the theory and applicability of instrumented precracked Charpy testing. Not all of the relationships and approaches presented in Ref 55 are universally accepted because standards or recommended practices do not currently exist.

Related Test Techniques

Several attempts have been made to use the precracked Charpy specimen at loading rates beyond the limits applicable to quasi-static analysis. The procedures described above assume a quasi-static situation for times greater than the limiting values near 3τ . One such attempt for larger than Charpy-size specimens is described in Ref 56, in which strain gages were mounted near the crack tip to avoid many of the spurious wave effects. Other studies have been conducted using Hopkinson bar techniques (Ref 57) and the shadow optic method of caustics (Ref 58). These studies indicate the need for dynamic analysis when using the instrumented Charpy striker approach at high loading rates.

Impact Toughness Testing

Drop Weight Testing

Because Charpy V-notch testing does not necessarily reveal the same transition temperature as that observed for full-size parts, many other tests have been devised. Two such tests have achieved some degree of popularity. These are the drop-weight test (DWT) and the drop-weight tear test (DWTT). Both of these tests were developed at the United States Naval Research Laboratory. Both tests yield a transition temperature that more nearly coincides with that of full-size parts. This has been described as the nil-ductility temperature (NDT). Both tests have limited usage because of the required specimen sizes. There are three types of DWT specimens, as shown in Table 4. The smallest of these measures $16 \times 51 \times 127 \text{ mm}$ ($\frac{5}{8} \times 2 \times 5 \text{ in.}$), and thus, when four to eight specimens are required, a considerable amount of material is expended. Often parts are not of sufficient size or are not shaped in such a manner to allow preparation of such specimens. A provision is made for remelting and casting material to specimen size. Most DWT tests are made on plate that is 9.5 mm ($\frac{3}{8} \text{ in.}$) thick or thicker. The DWTT is also a plate testing specification. This test requires a specimen $76 \times 305 \text{ mm}$ ($3 \times 12 \text{ in.}$) by full plate size.

Table 4 Standard drop-weight test (DWT) conditions

Type of specimen	Specimen size, mm (in.)	Span, mm (in.)	Deflection stop, mm (in.)	Yield strength level, MPa (ksi)	Drop-weight energy for given yield strength level ^(a)	
					J	ft · lbf
P-1	25.4 × 89 × 356 (1 × 3½ × 14)	305 (12.0)	7.6 (0.3)	210–340 (30–50)	800	600
				340–480 (50–70)	1100	800
				480–620 (70–90)	1350	1000
				620–760 (90–)	1650	1200

				110)		
P-2	19 × 51 × 127 ($\frac{3}{4}$ × 2 × 5)	102 (4.0)	1.5 (0.06)	210–410 (30–60)	350	250
				410–620 (60–90)	400	300
				620–830 (90–120)	450	350
				830–1030 (120–150)	550	400
P-3	15.9 × 51 × 127 ($\frac{5}{8}$ × 2 × 5)	102 (4.0)	1.9 (0.075)	210–410 (30–60)	350	250
				410–620 (60–90)	400	300
				620–830 (90–120)	450	350
				830–1030 (120–150)	550	400

(a) Initial test of a steel with a given strength level should be conducted with the drop-weight energy stated in this column. In the event that insufficient deflection is developed (no-test performance), an increased drop-weight energy should be employed for other specimens of the given steel.

The same piece of test equipment is used for both the drop-weight test and the drop-weight tear test. The difference lies in the anvil that holds the specimen. The principal requirement is that sufficient impact can be generated to produce cracking. This is commonly provided by a vertical structure on which weights can be attached using guides. The weights are raised to a measured height, quickly released, and guided to strike the specimen properly.

The Drop-Weight Test

The DWT specimen and procedure are shown in Fig. 13 and are described in ASTM E 208. The crack inducer is a bead of hard-facing metal approximately 76 mm (3 in.) long. The specimen, 89 × 356 × 19 mm ($3\frac{1}{2}$ × 14 × $\frac{3}{4}$ in.), is placed, weld down, on rounded end supports and is struck by a 27 kg (60 lb) falling weight with sufficient energy to bend the specimen about 5°. A cleavage crack forms in the bead as soon as incipient yield occurs (at about 3° deflection), thus forming the sharpest possible notch, a cleavage crack in the test specimen. A series of specimens is tested over a range of temperatures to find the nil-ductility transition temperature.

Fig. 13 Drop-weight test method

The weld bead is deposited on one side of the specimen at the center using a copper template. The weld bead is purposely a hard, brittle deposit (the Murex-Hardex N electrode is recommended). A notch is made in the weld bead, but not in the specimen itself. The specimen, after being cooled to the desired temperature, is placed in the anvil with the notched weld deposit facing downward. The weight is dropped, striking the back side of the specimen (the amounts of weight and height depend on the strength of the material being tested; see Table 4). The specimen is allowed to deflect slightly under the impact load, controlled by deflection stops. This initiates a crack at the notch in the weld bead. When the crack reaches the specimen material it will be either propagated or arrested. The specimen is then examined to see whether or not it has fractured. A specimen is considered to

be broken if the crack extends to one or both sides of the specimen surface with the weld bead. If the crack does not propagate to the edge it is considered a “no break.” If the weld notch is not visibly cracked, or if complete deflection does not occur (determined by mark transfer on the deflection stops), it is considered a “no test.” The nil-ductility transition temperature (NDTT) is the maximum temperature at which the specimen breaks. When minimum temperatures are set in material specifications, at least two specimens must be tested at the specified temperature. All specimens tested shall show a “no-break” performance.

Drop-Weight Tear Test Procedure

The drop-weight tear test (ASTM E 436) is similar in some ways to the drop-weight test. The transition fracture appearance occurs at the same temperature as for full-size parts. It has the same sudden change from shear to cleavage as that observed in full-scale pieces of equipment. The test is relatively simple in terms of both specimen preparation and lack of sensitivity to specimen-preparation techniques. The results vary with specimen thickness in the same manner as actual parts do. The principal short coming, as in the drop-weight test, is that testing is confined to plate material between 3 and 19 mm (0.125 and 0.750 in.) thick. The test specimen is even larger than the DWT specimen: it is 76 mm (3 in.) wide by 305 mm (12 in.) long. Tests are made with the same apparatus used for the drop-weight test, but the test fixture for holding the specimen is altogether different. A large pendulum-type machine can also be used, but the vertical weight-dropping apparatus is more commonly used. Up to 2700 J (2000 ft · lbf) of energy may be required.

Test-Specimen Anvil. The holder for the test specimen must support the specimen on edge (305 mm, or 12 in., long edge) in such a manner that rotation will not occur when the specimen is struck. This usually requires adjustable supports for differing specimen thicknesses. Hardened supports at each end suspend the specimen, and a centering guide at one end centers the specimen. A slot in the center of the anvil allows downward clearance for the breaking specimen (Fig. 14).

Fig. 14 Drop-weight tear test specimen and support dimensions

Specimen Preparation. Test specimens can be removed by sawing, shearing, or flame cutting. Specimen dimensions and tolerances are shown in Fig. 14. A notch is impressed at the center of one of the 305 mm (12 in.) edges. This is accomplished by using a sharp tool-steel chisel that is hardened. The sharp edge should have an angle of 45 ± 1 or 2° . The depth of the notch is 0.5 ± 0.05 mm (0.020 ± 0.002 in.). The combination of the sharpness of the notch (radius of about 0.013 mm, or 0.0005 in.) and the cold working that occurs as the result of impressing it produces cleavage fractures under the notch.

Test Procedure. Specimens are tested at various temperatures. They are brought to the desired temperature by immersing them in a cooled solution and holding for at least 15 min at temperature. The bath should be agitated, and if several specimens are cooled simultaneously they should be separated by several specimen thicknesses. Specimens should be broken within 10 s after they are removed from the bath. The cooled specimen is inserted in the anvil so that the notch is directly beneath the point of load application, and the test load, which must be only of sufficient magnitude to produce a fracture, is suddenly applied. If the specimen buckles under the test load, the test is considered to be invalid. Otherwise, the specimen fractures and separates as it moves into the slotted anvil without the two pieces being jammed against one another.

Test Results. The test is evaluated by examining the broken pieces. The idea is to determine the percentages of the fracture surface that exhibit ductile shear and brittle cleavage. The two regions are very different in appearance, and the transition from one to the other is abrupt. There are two methods of making this evaluation. One is for percentages of shear from 45 to 100% (Fig. 15), and the other for percentages from 0 to 45% (Fig. 16). The acceptance criterion is percentage of shear at a specific temperature. The temperature at which 50% shear occurs is sometimes considered the ductile-to-brittle transition temperature. Such tests have often been used for evaluation of line-pipe material for natural-gas transmission lines. The specimens from the curved pipe may be flattened prior to testing.

Fig. 15 Method of calculating percent shear for drop-weight tear testing by examination and measurements made of the fractures. This method applies when the percent shear is between 45% and 100%. %SA is percent shear area; A is the width of the cleavage fracture at the one “ t ” line beneath the notch, in.; and B is the length of the cleavage fracture in between the two “ t ” lines, in.

Fig. 16 Method of shear calculation for drop-weight tear testing when the percent shear is less than 45%

Impact Toughness Testing

Other Impact Tests

Izod impact testing uses a specimen with a V-notch (Fig. 17) that is similar to the Charpy V-notch specimen. The principal difference is that the specimen is gripped at one end only, allowing the cantilevered end to be struck by the pendulum (Fig. 18). An advantage of this method is that several notches can be made in a single specimen and the ends broken off one at a time. The disadvantage that has caused it to lose popularity is that the required time for and method of clamping the specimen in an anvil preclude low-temperature testing. Izod specimens can also be round. Many testing machines can be used for both Charpy and Izod testing.

Fig. 17 Izod specimen

Fig. 18 Cross section depicting clamped specimen and contact point for testing. All dimensional tolerances are ± 0.05 mm (0.002 in.) unless otherwise specified. The clamping surfaces of A and B are flat and parallel within 0.025 mm (0.001 in.). Finish on unmarked parts is 2 μ m (63 μ in.). Striker width must be greater than that of the specimen being tested.

Impact toughness values from the British Standard Izod test are compared with various other methods of testing in Fig. 19. These graphs, derived from a large number of test results on carbon and low-alloy steels, are only intended to show comparative trends. The curves in Fig. 19 should not be used for comparing or compiling specifications (Ref 59).

Fig. 19 Impact values obtained with the British Standard Izod test and other test methods. The inner dotted band represents the area within which 50% of the results may be expected to fall, while the wider full band covers approximately 80% of results. Source: Ref 59

The one-point bend test uses a single-edge cracked specimen and the same testing arrangement as a conventional three-point bend test, except that the end supports are removed (Fig. 20). The specimen holder used in a Charpy or Izod test is replaced by a simple frame that supports the specimen, while allowing it to move freely in the horizontal plane. Depending on the design of the original pendulum and hammer, the impact tester may require retrofitting with a new hammer and striker that will not interfere with the specimen edges or the support frame. When the hammer strikes the specimen, the center portion of the specimen is accelerated away from the hammer; the end portions of the specimen lag behind because of inertia. This causes the specimen to bend and to load the crack tip.

Fig. 20 Experimental setup used to perform the one-point bend test

The primary advantage of the one-point bend test is that the measured stress-intensity history incorporates dynamic effects completely. Therefore, no limits need to be imposed on the impact velocity and the test duration to fracture. Use of the one-point bend test currently is restricted to small-scale yielding conditions (Ref 60).

Dynamic Notched Round Bar Testing. The dynamic notched round bar specimen is a long cylindrical bar with a fatigue precrack (Fig. 21). During the test, the specimen is loaded in tension at one end by an impact of sufficiently large magnitude that the resulting stress pulse produces a fracture at the notch. In principle, therefore, the dynamic notched round bar test is more amenable to analysis than the Charpy test because the fracture process is completed before the stress pulse has sufficient time to be reflected from the farthest end of the bar.

Fig. 21 Typical apparatus for dynamic fracture initiation experiment. Source: Ref 61

The Charpy test is a simple, low-cost test that rapidly detects changes in ductility. However, the Charpy test does have certain disadvantages for quantitative assessments. Fracture in the Charpy specimen does not occur under plane-strain conditions. Furthermore, the state of stress at the fracture site is unknown and quite complex due to multiple pulse reflections from its various surfaces. For these reasons, it is difficult to interpret Charpy results in terms of elastic or elastic-plastic fracture toughness parameters, although, as previously described, instrumented impact testing of precracked Charpy V-notch specimens provides useful results for evaluations of dynamic fracture toughness, as described in more detail in Ref 62.

Dynamic notched round bar testing yields data from which a reliable value of the dynamic critical stress-intensity factor K_{Id} can be calculated easily. Hence, results are immediately related on a quantitative basis to fracture mechanics parameters. However, the test setup is rather elaborate, and more material is required for each specimen compared to Charpy testing. As a result, the technique is not suitable for routine testing. It may be used, however, when a precise evaluation of the fracture initiation properties of a particular material is required, perhaps as a function of temperature as well as of loading rate.

In this test, measurements of the average stress across the fracture plane and of crack-opening displacement, both as functions of time, are easily obtained. Various methods can be used to measure crack-opening displacement, but the stress across the fracture plane is most easily determined by using electric resistance strain gages applied to the surface of the bar downstream from the fracture site. In this respect, and several others, the dynamic notched round bar test resembles the Kolsky (or split-Hopkinson) bar used in dynamic plasticity. Another example of using a notched round bar in evaluation of dynamic fracture toughness is given in Ref 63, where the K_{Id} toughness of A533-B reactor-grade steel was determined over the temperature range from 3 to 50 °C (37–122 °F), by dynamic loading of notched round bar specimens with axial precompression of the notch.

The Schnadt specimen, details of which are shown in Fig. 22, has been used primarily in Europe for testing ship plate. In the Schnadt test, five test pieces are used with different notch radii, ranging from no notch to a severe notch made by pressing a sharp knife into the bottom of a milled groove. A hardened steel pin is inserted in a

hole parallel to and behind the notch, replacing the material normally under compression in the Charpy or Izod tests. The specimen is broken by impact as a three-point-loaded beam.

Fig. 22 Details of the Schnadt notched-bar impact-test specimen

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Introduction

ENVIRONMENTALLY ASSISTED CRACK GROWTH is a special form of mechanical degradation that occurs when the combined effect (or interaction) of environment and applied or residual stresses causes subcritical crack growth or fracture. Materials ranging from metals and alloys to glasses, plastics, composites, and ceramics can be susceptible. Even materials such as very pure metals, which were once considered not susceptible to environmentally assisted cracking, have usually, on more detailed investigation, proven to be so. Relevant crack propagation rates from environmentally assisted cracking can range from more than 10 to less than 10^{-10} mm/s depending on the environment, load condition, and material.

In broad terms, environmentally assisted cracking includes stress-corrosion cracking, hydrogen embrittlement, and corrosion fatigue. Although these phenomena represent distinct forms of cracking, they also overlap to some degree, as the interaction of mechanical loads and environmental conditions has common mechanisms of degradation across a spectrum of loading conditions and materials. Thus, the choice between the term stress-corrosion cracking and corrosion fatigue may be somewhat arbitrary, as they may both refer to the same underlying degradation phenomenon. However, not all aspects of environmentally assisted crack advance are identical in all cracking systems. Therefore, phenomenological categories are still useful divisions in the evaluation of environmentally assisted crack growth.

This article briefly describes the typical test methods for the evaluation of hydrogen embrittlement, stress-corrosion cracking, and corrosion fatigue with an emphasis on fracture mechanics methodologies for metals. A brief overview on the environmentally assisted crack growth of nonmetallic materials is also included. In general, the test results of environmentally assisted cracking can be influenced by a wide range of variables, such as those listed in Table 1. In addition, because of the large contribution of environment to crack advance, attention to experimental detail is often critical. Unless the multidisciplinary nature of these studies is recognized, most efforts will produce seriously misleading results or outright confusion, which is perhaps most responsible for the slow progress in quantifying and understanding environmental cracking. Familiarity with chemical and physical metallurgy, mechanics, chemistry, electrochemistry, and corrosion also is generally considered essential.

Table 1 Material, environmental, and mechanical variables of environmentally assisted cracking

Metallurgical variables

- **Alloy composition**
- **Distribution of alloying elements and impurities**
- **Microstructure and crystal structure**
- **Heat treatment**
- **Mechanical working**
- **Preferred orientation of grains and grain boundaries (texture)**
- **Mechanical properties (strength, fracture toughness, etc.)**

Environmental variables

- **Temperature**
- **Types of environments: gaseous, liquid, liquid metal, etc.**
- **Partial pressure of damaging species in gaseous environments**

- Concentration of damaging species in aqueous or other liquid environments
- Electrical potential
- pH
- Viscosity of the environment
- Coatings, inhibitors, etc.

Mechanical variables

- Maximum stress or stress-intensity factor, σ_{\max} or K_{\max}
- Cyclic stress or stress-intensity range, $\Delta\sigma$ or ΔK
- Stress ratio (R)
- Cyclic loading frequency
- Cyclic load waveform (constant-amplitude loading)
- Load interactions in variable-amplitude loading
- State of stress
- Residual stress
- Crack size and shape, and their relation to component size and geometry

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Evaluation of Hydrogen Embrittlement

Hydrogen embrittlement is a time-dependent fracture process caused by the absorption and diffusion of atomic hydrogen into a metal, which results in a loss in ductility and tensile strength. Hydrogen embrittlement is distinguished from stress-corrosion cracking generally by the interactions of the specimens with applied currents (Ref 1). Cases where the applied current makes the specimen more anodic and accelerates cracking are considered to be stress-corrosion cracking, with the anodic-dissolution process contributing to the progress of cracking. On the other hand, when cracking is accentuated by current in the opposite direction, the hydrogen-evolution reactions are accelerated, and the cracking process is considered to be dominated by hydrogen embrittlement. These two basic types of environmental conditions have different phenomenological effects on cracking mechanisms, as briefly summarized in Table 2 for anodic and cathodic reactions.

Table 2 Corrosion/deformation cracking mechanisms including hydrogen embrittlement

Mechanism	Phenomenological implications
Anodic dissolution	Crack-tip blunting
Anodic-dissolution-formed film (oxide or dealloyed)	Film fracture or film-induced cleavage
Passivating film removal or breakdown	Promotion of plasticity (e.g., slip reversal in fatigue)
Cathodic reaction	Hydrogen enhanced crack-tip decohesion, or HEDE (brittle fracture)
	Hydrogen enhanced localized plasticity, or HELP (ductile fracture)
	Hydrogen phase forms and fractures

In a broad sense, the key phenomenological consequence of hydrogen embrittlement is subcritical crack growth that often produces a time-delayed fracture in production parts, sometimes even with no externally applied stress. However, the mechanisms of hydrogen embrittlement are not entirely understood, even though hydrogen

embrittlement of metals is an old, frequently encountered, phenomenon. There are many different sources of hydrogen, several types of embrittlement, and various theories for explaining the observed effects. These factors make evaluation more difficult. Hydrogen embrittlement is also a complex phenomenon that probably cannot be described by a single dominant mechanism.

Types of Hydrogen Embrittlement (Ref 2 and 3)

The metals processing, chemical, and petroleum industries have experienced various types of hydrogen-induced cracking for many years. Examples include hydrogen-induced failures of parts that have been forged, heat treated, welded, chemically milled, pickled, or exposed to paint removers. Hydrogen embrittlement is a problem in welding, due to the complex nature of welds and the various sources of hydrogen. Hydrogen sulfide stress cracking is also a major concern in the petroleum industry, and the aerospace industry has experienced unexpected hydrogen embrittlement problems, principally in dealing with high-strength steels. Other examples include hydrogen embrittlement of parts installed in boilers, pressurized-water reactors, high-pressure hydrogenation units, and parts with cathodic protection. Hydrogen cracking has also been a serious concern when hydrogen is used as the liquid fuel in engines.

There are three basic types of hydrogen embrittlement observed in metals:

- Internal reversible hydrogen embrittlement
- Hydrogen environment embrittlement
- Hydrogen reaction embrittlement

If specimens have been precharged with hydrogen from any source or in any manner and embrittlement is observed during mechanical testing, then embrittlement is caused by either internal reversible embrittlement or hydrogen reaction embrittlement. If hydrides or other new phases containing hydrogen form during testing in gaseous hydrogen, then embrittlement is attributed to hydrogen reaction embrittlement. For all embrittlement determined during mechanical testing in gaseous hydrogen other than internal reversible and hydrogen reaction embrittlement, hydrogen environment embrittlement is assumed to be responsible.

Internal reversible hydrogen embrittlement has also been termed slow-strain-rate embrittlement and delayed failure. This is the classical type of hydrogen embrittlement that has been studied quite extensively. Widespread attention has been focused on the problem resulting from electroplating, particularly of cadmium in high-strength steel components. Other sources of hydrogen are processing treatments, such as melting and pickling. More recently, the embrittling effects of many stress-corrosion processes have been attributed to corrosion-produced hydrogen. Hydrogen that is absorbed from any source is diffusible within the metal lattice. To be fully reversible, embrittlement must occur without the hydrogen undergoing any type of chemical reaction after it has been absorbed within the lattice.

Internal reversible hydrogen embrittlement can occur after a very small average concentration of hydrogen has been absorbed from the environment. However, local concentrations of hydrogen are substantially greater than average bulk values. For steels, embrittlement is usually most severe at room temperature during either delayed failure or slow-strain-rate tension testing. This time-dependent nature (incubation period) of embrittlement suggests that diffusion of hydrogen within the lattice controls this type of embrittlement. Cracks initiate internally, usually below the root of a notch at the region of maximum triaxiality. Embrittlement in steel is

reversible (ductility can be stored) by relieving the applied stress and aging at room temperature, provided microscopic cracks have not yet initiated. Internal reversible hydrogen embrittlement has also been observed in a wide variety of other materials, including nickel-base alloys and austenitic stainless steels, provided they are severely charged with hydrogen.

Hydrogen environment embrittlement was recognized as a serious problem in the mid-1960s when the National Aeronautics and Space Administration (NASA) and its contractors experienced failure of ground-based hydrogen storage tanks. These tanks were rated for hydrogen at pressures of 35 to 70 MPa (5–10 ksi). Consequently, the failures were attributed to high-pressure hydrogen embrittlement. Because of these failures and the anticipated use of hydrogen in advanced rocket and gas turbine engines and auxiliary power units, NASA initiated both in-house and contractual research. The contractual effort generally has been to define the relative susceptibility of structural alloys to hydrogen environment embrittlement. A substantial amount of research has concerned the mechanism of the embrittlement process. There is marked disagreement as to whether hydrogen environment embrittlement is a form of internal reversible hydrogen embrittlement or is truly a distinct type of embrittlement.

Hydrogen Reaction Embrittlement. Although the sources of hydrogen may be any of those mentioned previously, this type of embrittlement is quite distinct from hydrogen environment embrittlement. Once hydrogen is absorbed, it may react near the surface of diffuse substantial distances before it reacts. Hydrogen can react with itself, with the matrix, or with a foreign element in the matrix. The chemical reactions that comprise this type of embrittlement or attack are well known and are encountered frequently. The new phases formed by these reactions are usually quite stable, and embrittlement is not reversible during room-temperature aging treatments.

Atomic hydrogen (H) can react with the matrix or with an alloying element to form a hydride (MH_x). Hydride phase formation can be either spontaneous or strain induced. Atomic hydrogen can react with itself to form molecular hydrogen (H_2). This problem is frequently encountered after steel processing and welding; it has been termed flaking or “fisheyes.” Atomic hydrogen can also react with a foreign element in the matrix to form a gas. A principal example is the reaction with carbon in low-alloy steels to form methane (CH_4) bubbles. Another example is the reaction of atomic hydrogen with oxygen in copper to form steam (H_2O), resulting in blistering and a porous metal component.

Although hydrogen reaction embrittlement is not a major topic in this article, its definition is included for the sake of completeness and in the hope of establishing a single definition for each of the various hydrogen embrittlement phenomena to avoid problems with semantics.

Further confusion results from the relation of stress-corrosion cracking (SCC) to hydrogen embrittlement, because the crack growth mechanism is often found to be the same. On the surface, the active corrosion process produces the hydrogen that is the cause of the failure. In SCC, the pits or crevices (polarized anodically) are initiation sites, and, therefore, although the growth mechanisms are the same, the method of prevention based on initiation can be different.

Mechanisms and Models

Although the micromechanisms of hydrogen-related fracture have been the subject of intense interest and review in the literature (Ref 4, 5, 6, 7, and 8), many facets of hydrogen embrittlement are still not entirely understood. This is due, in part, to the ad hoc nature of many test methods and the large number of variables (Fig. 1) that influence test results. Several different types of mechanisms, rather than just one dominant mechanism, may also occur.

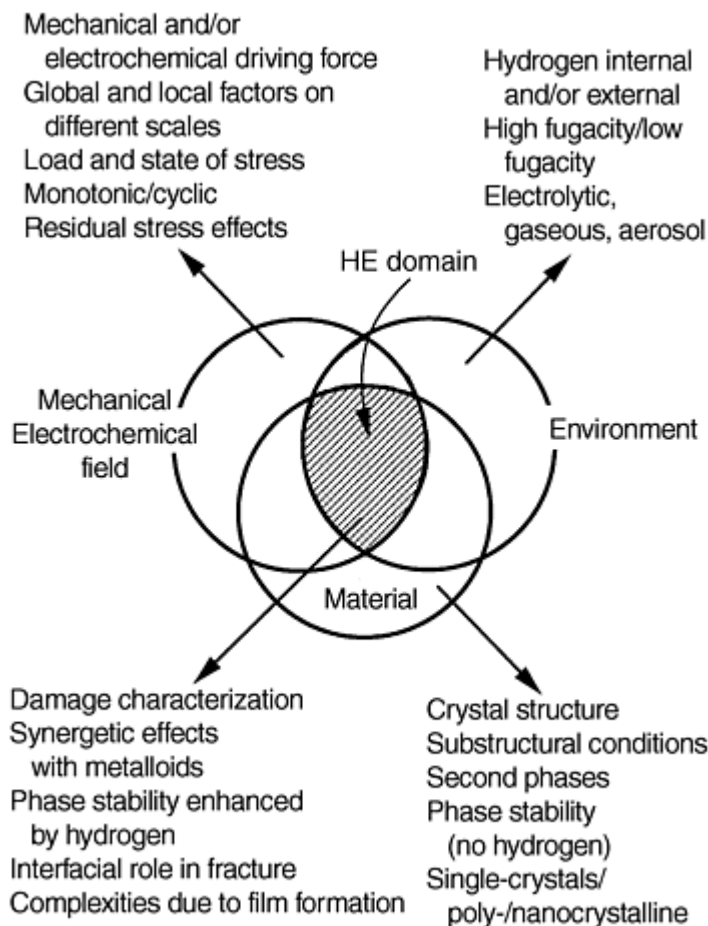

Fig. 1 Interaction variables in hydrogen embrittlement

Although numerous mechanisms have been proposed, there appear to be at least three distinct mechanisms of hydrogen embrittlement in metals (Table 2):

- Hydrogen-enhanced decohesion (HEDE) mechanism, which is characterized by hydrogen decreasing either grain boundary or cleavage plane cohesion (Ref 6, 9, 10, 11, 12, and 13)
- Hydrogen-enhanced local plasticity (HELP) mechanism, which proposes that solid-solution free hydrogen causes dislocation unpinning, which may increase dislocation mobility and allow highly localized deformation (Ref 7 and 8)
- Hydride formation (as previously noted, included here only for the sake of completeness)

In terms of mechanical testing and the use of fracture mechanics, the following sections describe the HEDE and HELP mechanisms in more detail. These damage models are conceptually related to the fracture-mechanics concepts of failure by brittle fracture or plastic collapse. In general, fracture occurs under one of three

conditions: plastic collapse, brittle fracture, or elastic-plastic fracture. These three fracture criteria are roughly defined in the failure assessment diagram (Fig. 2) of the R-6 Method (Ref 14), where the envelope of safe operation in the elastic-plastic region converges to either a brittle fracture condition ($K/K_c = 1$) or plastic collapse ($\sigma/\sigma_c = 1$). The HEDE and HELP mechanisms are conceptually related to these basic concepts of fracture mechanics, as illustrated in Fig. 2.

Fig. 2 Failure assessment diagram showing operative region of HEDE and HELP hydrogen degradation

Hydrogen-enhanced decohesion (HEDE) is based on brittle fracture associated with “embrittlement.” The HEDE model has allowed considerable progress to be achieved particularly regarding fracture criteria, including subcritical crack growth, threshold values, damage dependency on the hydrogen partial pressure, temperature, kinetic considerations, and delayed fracture analysis.

The HEDE model actually goes back to the original hydrogen embrittlement study by Troiano (Ref 15 and 16), which later developed in different stages. Following a comprehensive series of research activities (Ref 11 and 12), as related to brittle fracture concepts in general, further developments resulted also in the HEDE hydrogen embrittlement model (Ref 9 and 17). Basically the initial considerations are:

- Can the near-crack-tip mechanical field be better established?
- How can far-field stresses from fracture mechanics be related to theoretical calculations that established that hydrogen does decrease the cohesive strength of cleavage planes and grain boundaries?

The latter finding emerged from embedded-atom (Ref 18 and 19) and full-energy (Ref 20) calculations.

Following these developments, the connection between the local stress intensity, k_{tip} , and the far field, K_I , has been found (Ref 17 and 21). This was then coupled to the decrease in resistance associated with localized hydrogen concentrations. Moreover, this approach turned out to be very consistent experimentally with the ability to accommodate the principal common features related to the decrease of the threshold value, K_{Ith} , and the substantial increase of the crack growth rate with increasing K_I . Note that the high sensitivity of high-strength materials to hydrogen embrittlement becomes the dominant process in the more general framework of SCC.

Hydrogen-enhanced local plasticity (HELP) is based on the localized loss of load-bearing capacity from “shear” decohesion. The HELP model proposes the notion that solid-solution free hydrogen in metals causes dislocation underpinning, which increases dislocation mobility and allows highly localized deformation. Moreover, such enhanced plasticity has been claimed to result in localized softening, which enhances plastic failure in contrast to the usual sense of embrittlement. Enhanced ductile processes due to hydrogen interaction had first been suggested by Beachem (Ref 22), later joined by others (Ref 7 and 23). In fact, the direct relation between H solute causing enhanced dislocation mobility and fracture has been shown using in situ environmental cell transmission electron microscopy (TEM) measurements (Ref 24, 25, and 26). Nevertheless, observations of

deformation behavior and fracture under such plane-stress conditions leave significant issues unresolved. At least two major questions still remain:

- What is the exact sequence of events causing fracture in the bulk?
- Even observed, how do hydrogen solutes result in slip localization? Is this related to hydrogen-induced slip localization or to low-energy dislocation structures? Can local internal strains be separated from the role of any concurrent internal stress field?

Thus, in contrast to the HEDE model, the localized plasticity part of the HELP mechanism suggests alternatively that hydrogen promotes “shear” decohesion along slip planes. The HELP model still has limited predictive capability that needs to be developed.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Hydrogen Embrittlement Tests

Hydrogen embrittlement testing includes a wide variety of industrial and research methods. Industrial methods are often directed toward the prevention and control of hydrogen embrittlement from processing operations (such as plating) process and maintenance chemicals. These procedures are covered in ASTM F 519, “Standard Method for Mechanical Hydrogen Embrittlement Testing of Plating Processes and Aircraft Maintenance Chemicals.” Other industrial methods include sustained or step-load stress tests to evaluate the effectiveness of the hydrogen embrittlement relief treatments on hardware such as springs or structural fasteners.

With the development of fracture mechanics, conventional test methods have been modified for measurements in terms of crack nucleation, crack growth rate, and threshold stress-intensity values. Many research techniques have also been developed in order to obtain a more fundamental understanding of hydrogen embrittlement. Examples of research methods include:

- Measurement of threshold values under monotonic/cyclic loads (Ref 6, 27, 28, 29, 30, and 31)

- Electron microscopy, x-ray, and Mössbauer methods (Ref 6, 9, 27, 28, 32, 33, and 34)
- Fracture mechanics methodology (Ref 5, 6, 9, 31, and 35) with sustained loads or overloads
- Subcritical crack kinetics (Ref 9 and 35)
- Interfacial strength (Ref 36)
- Slow-strain-rate tests (Ref 5, 9, 10, 37, 38 and 39)
- Time-dependent tests (Ref 40)
- Internal friction, acoustic emission, and phonon dispersion (Ref 5, 9, 41, and 42)
- Elastic moduli measurements (Ref 43)
- Microautoradiography (Ref 44, 45, and 46)
- Infrared spectroscopy (Ref 47)

Research methods are directed toward improved understanding of the hydrogen embrittlement process and its fundamental characterization in terms of atomistic models (Ref 18 and 19), cohesive energy (Ref 15 and 48), discretized dislocation model (Ref 5, 6, 9 and 49), thermodynamically based computations (Ref 50 and 51), hydrogen/metal interaction (Ref 20 and 52), critical-concentration sites (Ref 17, 21, 53, and 54), and strain-energy models (Ref 8).

The main focus of this section is on accelerated small-specimen test methods for failure analysis and production control of hydrogen embrittlement. Because hydrogen embrittlement is a time-dependent process, accelerated testing has economic benefit for testing.

Standardized Tests

The evaluation of hydrogen embrittlement for particular materials and products forms are published in several standards that include:

Designation	Title
ASTM A 143	Practice for Safeguarding against Embrittlement of Hot-Dip Galvanized Steel Products and Procedure for Detecting Embrittlement
ASTM B 577	Standard Test for Detection of Cuprous Oxide (Hydrogen Embrittlement Susceptibility) in Copper
ASTM F 326	Standard Test for Electronic Hydrogen Embrittlement Test for Cadmium-Electroplating Processes
ASTM F 519	Mechanical Hydrogen Embrittlement Evaluation of Plating Processes and Service Environments
ASTM F 1459	Determination of the Susceptibility of Metallic Materials to Gaseous Hydrogen Embrittlement
ASTM F 1624	Standard Test Method for Measurement of Hydrogen Embrittlement Threshold in Steel by the Incremental Step Loading Technique
ASTM G 142	Determination of Susceptibility of Metals to Embrittlement in Hydrogen-Containing Environments
ASTM G 129	Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environments
BS 5899	Method for Hydrogen Embrittlement Test for Copper
BS-EN 2831	Hydrogen Embrittlement of Steels, Test by Slow Bending
BS-EN 2832	Hydrogen Embrittlement of Steels, Notched Specimen Test
BS-EN-ISO 2626	Copper—Hydrogen Embrittlement Test
ISO 2626	Copper—Hydrogen Embrittlement Test
ISO 15330	Fasteners—Preloading Test for the Detection of Hydrogen Embrittlement Parallel Bearing

The major application area for some of these standard tests are briefly described in this section, followed by descriptions of test methods and specimen types.

There are also numerous standards related to the prevention of hydrogen embrittlement, such as:

Designation	Title
AMS 2759/9	Hydrogen Embrittlement Relief (Baking) of Steel Parts
ASTM B 839	Residual Embrittlement in Metallic Coated, Externally Threaded Articles, Fasteners, and Rod
ASTM B 850	Standard Guide for Post-Coating Treatments of Steel for Reducing Risk of Hydrogen Embrittlement
ASTM B 849	Standard Spec Pre-Treatments of Iron or Steel for Reducing Risk of Hydrogen Embrittlement
ASTM F 1940	Process Control Verification to Prevent Hydrogen Embrittlement in Plated or Coated Fasteners
IFI 142	Hydrogen Embrittlement Risk Assessment

From a prevention standpoint, hydrogen embrittlement failures are reduced or eliminated by controlling the amount of hydrogen introduced during manufacture, processing, and in-service environment (including the use of cleaners and paint strippers) of materials. Test methods and the necessary prevention controls are covered in standards such as ASTM F 519 and ASTM F 326, as described below.

Another concern in the evaluation of hydrogen embrittlement appears to involve the identification of residual stresses that result from manufacturing operations such as heat treatment and, especially, welding. Much more attention must be given to evaluating the potential for hydrogen embrittlement failures in the presence of residual stresses. The occurrence and measurement of residual stresses are discussed in more detail in the article “Residual Stress Measurements” in this Volume.

ASTM F 519 and ASTM F 326. As previously noted, ASTM F 519 and ASTM F 326 describe the testing, evaluation, and prevention of hydrogen embrittlement. These standards are based on (1) not putting hydrogen into the steel by keeping the hydrogen in the plating bath at acceptably low levels (ASTM F 326) and (2) using mechanical tests to ensure that the amount of residual hydrogen after baking is under acceptably low levels (ASTM F 519).

ASTM F 326. This standard method covers an electronic hydrogen detection instrument procedure for the measurement of plating permeability to hydrogen, a variable that is related to hydrogen absorbed by steel during plating and to the hydrogen permeability of the plate during post-plate baking. A specific application of this method involves controlling cadmium-plating processes in which the plate porosity relative to hydrogen is critical, such as with cadmium plating of high-strength steel.

This method uses a metal-shelled vacuum probe as an ion gage. A section of the probe shell is cadmium plated at the lowest current density encountered during the electroplating process. During subsequent baking, the probe ion current that is proportional to hydrogen pressure is recorded as a function of time. The slope of this curve has an empirical relationship to failure data, such as those discussed in ASTM F 519.

ASTM F 519. This method covers the evaluation of the hydrogen-generating potential of fluids (aircraft maintenance chemicals) and the hydrogen embrittlement control of electroplating processes. Test specimens are installed into the plating bath during the plating of hardware to monitor indirectly the amount of hydrogen in the plating bath. The acceptable level of hydrogen is determined by a go/no-go situation established by the failure of a sustained loaded, stressed specimen that has been baked at 190 ± 14 °C (375 ± 25 °F) for a minimum of 23 h. The procedures and requirements are specified for the following five types of AISI 4340 steel test specimens:

- Type 1a: notched round bars, stressed in tension, under constant load
- Type 1b: notched round bars loaded in tension with stressed O-rings
- Type 1c: notched round bars loaded in bending with loading bars
- Type 1d: notched C-rings loaded in bending with loading bolt
- Type 2a: unnotched ring specimens loaded in bending with displacement bars

For platings, no stress is applied until the parts have been baked; baking is specified to occur within 1 h after plating. For maintenance chemicals and cleaners, stress is applied before the test specimens are exposed to the environment. The latter condition is obviously much more severe and discriminates against much lower levels of hydrogen but is more representative of their end use.

Hydrogen Embrittlement of Copper and Copper Alloys. Hydrogen embrittlement is observed when tough pitch coppers, which are alloys containing cuprous oxide, are exposed to a reducing atmosphere. Most copper alloys

are deoxidized and thus are not subject to hydrogen embrittlement. Nonetheless, several standards test methods for copper include:

Designation	Title
ASTM B 577	Standard Test for Detection of Cuprous Oxide (Hydrogen Embrittlement Susceptibility) in Copper
BS 5899	Method for Hydrogen Embrittlement Test for Copper
BS-EN-ISO 2626	Copper—Hydrogen Embrittlement Test
ISO 2626	Copper—Hydrogen Embrittlement Test

Hydrogen can be involved in copper-zinc or copper-aluminum alloys where hydrogen is more likely to be produced during cathodic reactions. For copper, minor bulk effects in terms of hydrogen embrittlement may relate to the limited range of hydrogen solubility in pure copper. This is not the case in the many copper alloys, such as β brass, that have the ordered *B2* crystal structure.

Fasteners and Bolts. ASTM F 1940 is a test method for process control verification to prevent hydrogen embrittlement in plated or coated fasteners. The test method uses a notched square bar specimen that conforms to ASTM F 519. ASTM F 1940 is a production-control method for the evaluation and control of the potential for hydrogen embrittlement that may arise from various sources of hydrogen in a plating or coating process. It does not address hydrogen embrittlement from environmental exposure (as in the case of ASTM F 1624, “Standard Test Method for Measurement of Hydrogen Embrittlement Threshold in Steel by the Incremental Step Loading Technique”). It is also not intended to measure the relative susceptibility of steels to either process-induced or environmentally induced hydrogen embrittlement.

ASTM F 606, “Standard Method for Conducting Tests to Determine the Mechanical Properties of Externally and Internally Threaded Fasteners, Washers, and Rivets” also describes a hydrogen embrittlement test for a metallic-coated externally threaded fastener. This test requires the use of a wedge to produce a sustained combined tension and bending load. The tension load is specified as 75% of the minimum ultimate tensile strength. The time specified is 48 h, after which the test fastener is visually and microscopically examined for hydrogen-embrittlement-induced failure. The torque is then reapplied to attain at least 90% of the initial tightening torque. The fastener should show no evidence of hydrogen-induced cracking when visually examined, and the retightening torque should not be less than 90% of the initial tightening torque to indicate successful testing.

In addition to standard ASTM tests, there are also other examples of nonstandardized tests for special product forms or evaluation of susceptibility to hydrogen embrittlement. Two examples are described below.

Hydrogen Embrittlement Testing of Steel Screws. Testing for hydrogen embrittlement of steel self-drilling tapping screws consists of inserting the self-drilling tapping screw against a type B standard plane washer and tightening to a prescribed torque. This stress is maintained for 24 h; the prescribed torque is then reapplied, and the screw is removed by the application of a removal torque. The fastener has failed the test if the reapplication of the torque cannot be obtained, or if the screw cannot be removed without shearing the fastener.

Modified Charpy V-Notch Testing of Bolts. Plated fasteners have been evaluated using a modified Charpy specimen configuration. Fixture adapters are screwed onto the shank of the fastener and tightened to a total length of 55 mm (2.16 in.), which is the length of a standard Charpy V-notch specimen. The assembly is inserted in a four-point bend test fixture meeting ASTM F 519 requirements. The rising-step-load test technique is used, and the specimen is loaded directly to failure. Overload fracture is measured and observed with scanning electron microscopy (SEM), and the maximum fracture load is thus established.

A second sample is then step loaded at 1 h intervals at each step until crack initiation begins, usually within 8 h. Crack extension continues, and the decreasing load is recorded. Scanning electron microscopy can be used to verify the presence of brittle cracking typical of hydrogen-embrittlement-type failures (i.e., flat facets instead of dimpled rupture).

Test Configurations

Conventional test methods include the cantilever beam, wedge-opening load, contoured double-cantilever beam tests, three-point and four-point bending, disk-pressure tests, and slow-strain-rate tension tests. Disk-pressure tests are used for testing in hydrogen atmosphere. The cantilever beam, wedge-opening load, and contoured

double-cantilever beam tests have also been adapted for testing in high-pressure gaseous hydrogen environments.

The cantilever beam test is a constant-load test in which a V-notched specimen is inserted along a portion of the beam and enclosed by an environmental chamber (Fig. 3). A crack at the root of the V-notch is initiated and extended by fatigue before testing. The notch-root thickness is prescribed by the requirement of $K_{\max}^2 < 0.4 B/YS^2$ (where B is the thickness and YS is the yield strength of the specimen), although this is often excessive for high-toughness steels. The specimen is subjected to a constant load over a predetermined time period. As the crack grows, the stress intensity increases. Time to failure is plotted versus applied stress intensity. The lower limit of the resultant curve is a threshold stress intensity for hydrogen embrittlement, K_{IHE} , as shown in Fig. 4.

Fig. 3 Fatigue-cracked cantilever beam test specimen and fixtures. Source: Ref 55

Fig. 4 Procedure to obtain K_{IHE} with precracked cantilever beam test specimen. Source: Ref 55

The K_{IHE} results of a cantilever beam test depend on how much time elapses before the test is terminated. Recommended test periods for establishing the true stress-intensity threshold range from 200 h, which is typical for hydrogen embrittlement testing, to as long as 5000 h (Ref 56). Another limitation of this test method is that it can be expensive in terms of materials and machining. As many as 12 specimens, placed under different loads in separate test machines, are needed for each test in order to obtain valid K_{IHE} values.

The wedge-opening load test applies a constant wedge- or crack-opening displacement; as the crack extends, stress intensity decreases until crack arrest occurs (Fig. 5). The initial load is assumed to be slightly above K_{IHE} . The specimen is maintained under these conditions for about 5000 h to establish the threshold. The crack grows

to a point after which further growth is not measured (K_{IHE}). However, it is difficult to determine precisely when the no-growth criterion is met. Crack-tip opening displacement should also be monitored.

Fig. 5 Schematic showing basic principle of modified wedge-opening load test specimen

The wedge-opening load test and the cantilever beam test both require costly and time-consuming steps and result in a parameter, K_{IHE} , whose design significance is questionable. However, the parameter does provide a relative ranking of susceptibility to hydrogen embrittlement or, more generally, SCC. The advantage of the wedge-opening load test is that only one specimen is required to measure K_{IHE} .

Generally, the threshold stress intensity measured with the wedge-opening load test is lower than that measured with the cantilever beam test. For example, Fig. 6 shows the results of wedge-opening load and cantilever beam tests on 25.4 mm (1 in.) thick iron-nickel-cobalt alloy steel specimens. The data imply that the crack arrest K_{IHE} values from the wedge-opening load test is the lower than the limit for the cantilever beam K_{IHE} threshold.

Fig. 6 Comparison of single-edge-notched cantilever beam and wedge-opening load (WOL) test results for hydrogen embrittlement cracking of iron-nickel-cobalt steels. The open circles represent “no fracture” at various exposure times for an overaged Fe-10Ni-8Co alloy in a cantilever beam test. The open squares indicate failure at increased stress intensities, following step loading at various exposure times at the lower stress intensity. Source: Ref 57

Corrosion reactions, accompanied by expansion in volume, may occur at the crack tip. This changes the opening displacement and increases the load, thus altering the desired testing conditions. In long-term tests, it is essential to ensure that the concentration and the composition of the environmental solution do not change over time. For example, evaporation may cause the solution level to drop the crack line of the specimen; this would render the test invalid. The data plots in Fig. 6 also suggest that load increases during the test produce more aggressive hydrogen embrittlement conditions. This may be due to the possible formation of an oxide film on the surface. When the load is increased, the oxide film is broken, exposing fresh metal, and more hydrogen is produced at the crack tip. For this reason, the test should use a rising load, because the constant-load cantilever-beam test does not provide worst-case (fresh metal exposed) loading conditions.

The data also suggest that the cantilever beam test can generate an artificially high K_{IHE} threshold, depending on the time limit selected. If the test had been terminated at 200 h rather than at 5000 h, the reported K_{IHE} values from the cantilever beam test (Fig. 6) would have been four times higher than those measured after the longer time period. Similarly, if insufficient time is allowed in the wedge-opening load test, the incubation period may not be exceeded, and no crack growth will result.

The contoured double-cantilever beam test is used to measure crack growth rate at a constant stress-intensity factor. This test simplifies the calculation of stress intensity by using a contoured specimen so that stress intensity is proportional to the applied load and is independent of the crack length. Under a constant load, stress intensity also remains constant with crack extension. For the test geometry shown in Fig. 7, the stress-intensity factor equals 20 times the load ($K = 20P$).

Fig. 7 Dimensions and configuration for double-cantilever beam test specimen. Specimen contoured to $3a^2/h^3 + 1/h = C$, where C is a constant. All values given in inches

Data on hydrogen embrittlement can be obtained with specimens below the thickness requirement of $K_{\max}^2 < 0.4 B/Y_S^2$ by using side grooves (Ref 58). Side grooves provide additional constraint on the material being tested. They also enable the maintenance of a plane-strain condition in a thin specimen by enhancing stress triaxiality. This method has been extensively used to study the effect of heat treatment (hardness) and environment on the hydrogen stress cracking of AISI 4340 steels (Fig. 8). The contoured double-cantilever beam test has also been used to study the stress history effect that produces an incubation time before hydrogen stress cracking (Ref 59).

Fig. 8 Hydrogen embrittlement crack growth rate as a function of applied stress intensity for two different hardnesses and environments for an AISI 4340 steel contoured double-cantilever beam test specimen

A new method for accelerating the collection of near-threshold corrosion fatigue crack propagation data, using local hydrogen embrittlement in the crack-tip region, has been investigated for ASTM A 710 HSLA steel with the “constant- K ” contoured double-cantilever beam (CDCB) specimens (Ref 60). Near-threshold fatigue crack growth rates were found to be 100 times faster in the locally hydrogen-charged specimens than in the uncharged material. Fatigue thresholds, ΔK_{th} , were also defined in less than one-fifth the time required for load shedding tests in air at 0.2 Hz. Although demonstrated for HSLA steels, the technique is applicable to any material that can be embrittled by hydrogen.

Three-Point and Four-Point Bend Tests. The contoured double-cantilever beam test uses a constant load to maintain a constant stress-intensity factor with crack extension. The same effect can be produced by using a three- or four-point bend test under displacement control. These tests use heavily side-grooved Charpy V-notch specimens (Fig. 9). Because crack-opening displacement is constant as the crack extends, the load decreases; therefore, there is a slight initial increase in stress intensity to a maximum value that drops slightly as the ratio of crack depth to specimen width exceeds 0.5. Typically, stress intensity is constant within a small range. Figure 10 compares the change in stress-intensity factor with crack extension as a function of load control to that of displacement control for a three-point bend specimen.

Fig. 9 Side-grooved Charpy V-notch test specimen used for three- and four-point bend tests

Fig. 10 Change in stress-intensity factor with crack extension as a function of load control and displacement control for a three-point bend specimen

The constraint effect and thickening action of the side-groove on a Charpy-size specimen in three-point bending are discussed in Ref 61. Evaluation of hydrogen embrittlement under three-point or four-point bending is also tested with other types of besides side-grooved Charpy specimens. For example, fracture tests using blunt-notched specimens tested in four-point bending have been used in the investigation of hydrogen damage mechanisms in a commercially produced 9Cr1Mo (Ref 62) and AISI 1080 steel (Ref 63). A nonstandard double-beam (DB) specimen in four-point bending was also used in the evaluation of cracking in wet H₂S environments for two commonly used pressure vessel steels (ASTM A 516-70 and A 285C) (Ref 64). The four-point test on these two pressure vessel steels was done in conjunction with several other test methods including:

- NACE TM0177-90A tensile tests
- NACE TM0177-90A tensile test with one-side (OS) exposure
- NACE TMO284
- NACE TM0284 with TM0177 solution
- TM0184 with OS exposure
- Nonstandard DB specimen in four-point bending with both immersion (IMM) and OS exposure

All the test methods showed a higher susceptibility to hydrogen-induced cracking in the A516-70 steel than in the A285C steel (Ref 64).

The rising-step-load test provides a stress intensity that is different at each load but that remains constant with crack extension as each load level is sustained. Crack initiation is signaled by a drop in load (Fig. 11). The rising step-load test was developed as an accelerated low-cost test for measuring the resistance of steels (particularly weldments) to hydrogen embrittlement (Ref 57, 66). The threshold obtained by this method could be slightly higher if the test duration of each load is too short, but the test duration can be extended near the initiation loads in duplicate tests in order to obtain a more accurate measurement.

Fig. 11 Typical load-time record for four-point rising step-load test. Source: Ref 65

To index susceptibility to hydrogen-assisted cracking, the test should last no longer than 24 h, and the hydrogen source should reflect the most aggressive environment (Ref 3). In one experiment, a 3.5% sodium chloride solution was selected to simulate seawater, and a cathodic potential of -1.2 V versus saturated calomel electrode (SCE) was used to generate hydrogen in order to reproduce the extreme conditions of sacrificial anodic protection generally found on a ship hull.

A Charpy specimen is used because such specimens are small and easy to machine and handle. Instead of using fatigue precrack, a machined notch-root is sometimes done to lower the cost and to give less ambiguous environmental conditions at the crack tip. A common practice used in crack growth rate tests to prevent the crack from branching is to use specimens with deep side grooves. Side grooves are also used in crack-opening displacement or J -integral testing in order to cause load displacement curves to increase monotonically to fracture by inducing a highly triaxial stress field at the crack tip. Because a Charpy specimen is small, deep side grooves produce a triaxial stress field at the notch and thus promote crack initiation. The extent of the side grooving is such that the remaining ligament is only 40% of the original thickness. The modified Charpy specimen dimensions are shown in Fig. 9.

Specimen loading under four-point bending can be accomplished by means of beams and an instrumented bolt as shown in Fig. 12. Bending is done under constant displacement control and stress intensity to produce crack growth. The specimen is enclosed in an environmental chamber with a potentiostat to produce hydrogen while under stress.

Fig. 12 Loading frame used for rising step-load test

The rising step-load test was used to evaluate high-strength HY ship steels and weldments in an environment simulating seawater under conditions of cathodic protection commonly used to protect ship hulls (Ref 66). Samples from the heat-affected zone (HAZ) and other locations in the weld metal were tested. Interlayer gas tungsten arc heating was evaluated as a means of providing a refined, homogeneous, tempered microstructure with improved resistance to hydrogen stress cracking. Test results showed that HY-180 is more susceptible to hydrogen stress cracking than HY-130 and that the resistance to hydrogen embrittlement of specimens taken from the HAZ and the fusion line is consistently higher than that of weld metal specimens (Ref 66).

Another application example of the rising step-load bend technique is the evaluation of potential-step polarization and hydrogen over-potential on crack propagation and crack arrest of T-250 maraging steel and PH-13-8Mo (UNS S13800) steel (Ref 67). In this case, the critical stress-intensity threshold for hydrogen-assisted cracking was measured as a function of potential. A fractographic examination of specimens tested at different potentials revealed distinct changes in the fracture mechanism as a function of potential. These changes are explained in terms of the decohesion model for hydrogen-assisted cracking. The crack arrest and propagation results reveal that the crack tip responds instantly to changes in the hydrogen activity from step polarization. The ability to arrest and restart crack propagation by stepping the applied potential at a constant applied stress intensity is demonstrated, proving that stress-intensity threshold is a direct function of hydrogen.

The disk-pressure test method measures the susceptibility to hydrogen embrittlement of metallic materials under a high-pressure gaseous environment (Ref 68). In this test, a thin disk of the metallic material to be tested is placed as a membrane in a test cell and subjected to helium pressure until it bursts. Because helium is inert, the fracture is caused by mechanical overload; no secondary physical or chemical action is involved. An identical disk is placed in the same test cell and subjected to hydrogen pressure until it bursts. Metallic materials that are susceptible to environmental hydrogen embrittlement fracture under a pressure that is lower than the helium-burst pressure; materials that are not susceptible fracture under the same pressure for both hydrogen and helium.

The test is used for the selection and quality control of materials, protective coatings, surface finishes, and other processing variables. The ratio, S_{H_2} , between the helium-burst pressure, P_{He} , and the hydrogen-burst pressure, P_{H_2} , indicates the susceptibility of the material to environmental hydrogen embrittlement. If S_{H_2} is equal to or less than 1, the material is not susceptible to environmental hydrogen embrittlement. When S_{H_2} is greater than 2, the material is considered to be highly susceptible. At values between 1 and 2, the material is moderately

susceptible, with failure expected after long exposure to hydrogen; therefore, the material must be protected against exposure.

A compilation of test results (Ref 3 and 68) indicate:

- Alloys having little or no sensitivity: 7075-T6 aluminum; Haynes 188 (cobalt base); beryllium copper (copper base); types 304, 316, and 310 austenitic stainless steel; type 430 ferritic steel; and age-hardened austenitic A 286 steel
- Alloys with high sensitivity: Cobalt- and iron-base alloys, including Haynes 25 and medium- and high-strength steels

Finite element models of the specimen have also been used for interpreting experimental results and to achieve a more general understanding of the capabilities of the disk pressure test for the characterization of hydrogen embrittlement effects (Ref 69).

Slow-strain-rate tensile tests can be used to evaluate many product forms, including plate, rod, wire, sheet, and tubing, as well as welded parts. Smooth, notched, or precracked specimens can be used. The principal advantage of this standardized test is that the susceptibility to hydrogen stress cracking for a particular metal/environment combination can be rapidly assessed. A variety of specimen shapes and sizes can be used; the most common is a smooth bar tensile coupon, as described in ASTM E 8. The specimen is exposed to the environment and is stressed under displacement control. For stainless steel in chloride solution, the strain rate is 10^{-6} s^{-1} . One or more of the following parameters are applied to the tensile test at the same initial strain rate:

- Time to failure
- Ductility, as assessed, for example, by reduction of area or elongation to fracture
- Maximum load achieved or reduction in ultimate and yield tensile stress
- Area bounded by a nominal stress-elongation curve or a true-stress/true-strain curve
- Presence of secondary cracking on the specimen gage section
- Appearance of the fracture surface

Slow-strain-rate tension testing is used extensively in the evaluation of environmentally assisted crack growth, and several standards have been published including:

Designation	Title
ISO 7539 (Part 7)	Slow Strain Rate Testing
ASTM G 129	Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environment

Slow-strain-rate testing is used extensively in materials research, as described in more detail in Ref 70. The decreasing of fracture ductility from testing at a lowered strain rate in tension has been useful in establishing the threshold stress-intensity factor K_{th} of high-strength steel (Ref 71) consistent with the model of K_{th} behavior of high-strength steel suggested by Gerberich (Ref 72). The slow-strain-rate tension test has also confirmed that initiation of cracks with low concentration of hydrogen is a mainly strain-controlled process in steels (Ref 73).

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Evaluation of Stress-Corrosion Cracking

Stress-corrosion cracking (SCC) can be influenced by a combination of anodic and/or cathodic reactions that influence crack growth mechanisms, as briefly summarized in Table 2. Thus, SCC can be a more complex process than hydrogen embrittlement, although many of the test methods are similar. Nonetheless, this section briefly describes the key features of SCC testing, as recently published in Ref 74. More detailed information on SCC testing is also contained in Ref 75 and 76.

Detailed information on SCC mechanisms and models is also beyond the scope of this article. Alloy design against SCC is an ongoing mission coupled with environmental control efforts. Generalized statements concerning interactive problems are not recommended, as they can be misleading. Table 3 summarizes typical SCC behavior for various alloy systems. In most cases, the scope of a comprehensive analysis must be designed to fit a given application.

Table 3 Stress-corrosion cracking of selected material systems

Material	Environment ^(a)	Applications	Remarks
Ferrous alloys			
Carbon steels, ferritic, pearlitic, or tempered martensitic (normally low carbon)	NaOH and nitrate solution H ₂ S, ammonia, carbonate/bicarbonate, aqueous solutions chlorides, seawater	Oil/gas production and transmission, oil refining, pulp and paper processing, power generation, marine and general application, wire products, strands, and wire ropes	Alloying has significant effects on SCC Crack propagation rate increases with water vapor lowering chloride concentration is beneficial.
High-strength steels (low or high alloy) normally tempered	Water and water vapor, aqueous electrolytes including phosphate ions, NaCl solutions, H ₂ S, strong acids, various organic	Aerospace, construction tools, dies, fasteners, landing gears, and general applications	Mutual considerations and compromises regarding alloying elements Trade-offs in mechanical

martensite	compounds		properties like yield strength, toughness, and SCC are controlled by alloying.
Ferritic stainless steels	Chloride ions aqueous solutions	Housewares, food industry (vessels, pipeline transmission, and general applications)	Highly sensitive to alloying elements with synergistic effects
Austenitic stainless steels	Chloride ion in solutions or steam, NaOH solutions, NaCl + H ₂ O ₂ solutions, seawater	Food industry (e.g., transmission) houseware, nuclear and chemical industry, biomedical instruments	Phase-stability aspects Attention also to carbon concentration and elements affecting sensitization
Duplex structure (combination of austenite and ferrite phases) stainless steels	Chloride ions (higher resistance than other stainless steel in some situations) aqueous solutions	Chemical and nuclear industry or more specific applications	Duplex stainless steel is picked to preserve a specific microstructure, thereby requiring particular attention to welding.
Martensitic and precipitation-hardening stainless steels	NaCl + H ₂ O ₂ , seawater, NaOH + H ₂ S, NaOH solutions, other sulfur compounds, marine environments	Aerospace, aeronautical, houseware, surgical tools	Used for applications that require high strength. This material group allows yield strength values to exceed 1100 MPa, calling for stress-intensity threshold evaluation.
Nonferrous alloys			
Low- and high-strength aluminum alloys	NaCl solutions, seawater, water vapor, aqueous solutions, halide ions, Cl, Br, and I solutions (synergistic effects)	General building construction elements, aerospace, aeronautic transportation, naval vessels	Attention to material selection in terms of alloy composition and strength Commercial aluminum alloys are well specified in material groups (composition and processing parameters). Combined environment and material group interaction differ regarding severity.
Nickel alloys	Pure steam, NaOH or KOH solutions, fused caustic sulfur compounds, various aqueous halide solutions, aqueous solutions, and cupric acid	Heat exchangers, higher-temperature applications in nuclear and chemical industry. Superalloys for jet engine components	Sensitive to microstructure and phases like γ, γ', and carbides
Copper alloys (including α or β brass)	Ammonia solutions, amines, water, mercury salt solutions, distilled water	General applications, munitions, marine components	...
Nickel-copper alloy (Monel)	HF or H ₂ SiFe ₆ solutions Mercury salt solutions	Specific corrosion-resistant applications	...
Titanium alloys	Seawater, organic liquids, N ₂ O ₄ , aqueous Cl, B, and I solutions, HCl + methanol solutions, HNO ₃ ,	Space, aircraft, biomedical prostheses, deep sea, and other specific applications	Microstructure and phase optimization for specific environment. Normally alloy types consider the α

	chlorinated hydrocarbons		(hexagonal closed packed) and the β (body-centered phase volume fraction). β at ambient temperatures is stabilized by alloying with Cr, Mo, V, Ta, and W.
Magnesium alloys	NaCl + K ₂ CrO ₄ solutions, marine atmosphere, distilled water, and other Cl ⁻ solutions	Specific applications relating to transportation	Highly reactive material group with intensive efforts for development in alloy design, i.e., ratio of strength to weight with acceptable properties
Zr alloys	Organic liquids Cl ⁻ solution I ² at elevated temperature	Nuclear applications for cladding and others based on beneficial nuclear properties	Attention to SCC susceptibility to iodine embrittlement
α -uranium alloys or stabilized γ -uranium	Cl solutions Water and wafer vapor Oxygen and hydrogen gas	Nuclear industry application for heavy metal specific applications	...
Thin-film aluminum and copper metallization	Hydrogen produced by thin-film processing or chemomechanical polishing; relative humidity attack of galvanic couples	Conductors, interconnects for microelectronics, optoelectronics, microelectromechanical systems, flexible circuits	Small volume effects on adhesion, strength, environmental susceptibility

(a) Environment here is used in the context of those known to produce SCC or hydrogen embrittlement, but those listed are not meant to be all-inclusive.

Besides common structural materials, there are special applications involving small-volume devices and multilayer or composite systems. To evaluate such materials, all the microstructural aspects and processing history must be provided (e.g., specific heat treatments and textures for structural components or sputtering temperatures and pressures for thin films).

Similar attention to detail applies to the environmental conditions where synergism is one of the major considerations. For example, in nuclear power stations, neutron or gamma radiation affects materials in terms of enhanced precipitation kinetics or reduced fracture resistance. Additionally, radiation affects the environment, for example, through radiolytic decay products. Informative background on such complexities has been published (Ref 38, 77, and 78). On the conceptual level, it is emphasized to the designer that design criteria can be established only when combined with experimental SCC evaluations.

Additional considerations include:

- High resistance to general corrosion is frequently a cause of major confusion when considering localized processes. General corrosion resistance of aluminum alloys, titanium alloys, or even nickel alloys does not imply resistance to local SCC under specific conditions.
- Attention should be given to processing variables. In many cases, alloy design is aimed at achieving some optimized conditions. This might necessitate sacrificing mechanical properties to minimize time-dependent damaging effects.
- Many applications, such as those associated with the power industry and others, follow restricted codes related to detrimental combinations of alloy concentration and impurities. Familiarity with the physical/chemical bases of such codes or standards for analogous applications are always beneficial.
- Although in many cases SCC arises from an ill-advised material selection, many also stem from poor assessment of the local mechanical/chemical loading factors.
- The distinction between long and small crack behavior is also a factor. Observations have confirmed that higher crack growth rates occur for small cracks compared to long cracks under identical applied stress-intensity conditions.

Considering the last point, the issue of crack size becomes particularly apparent regarding the initiation stage. During slow-strain-rate testing on smooth specimens, multicracking phenomena can also occur with different damage characteristics. At least intuitively, such behavior calls for a statistical approach, which potentially implies insight as to how one might approach design. Questions that might be included are:

- Is the attention only to the longest crack justified and at what stage of damage evolution?
- What about small crack coalescence that might evolve into a long-crack situation?

The latter is even more understandable in initiation-controlled processes. Critical crack growth does not necessarily involve a very long crack. Small cracks increasing by a factor of 2 to 3 can consume 80% of the total life (Ref 79).

Accordingly, other approaches, such as the one addressed by Parkins (Ref 80), have incorporated the aforementioned aspects. As indicated in Ref 80, the crack propagation rate is related to the crack density. Along with this, statistical models can be established for crack density and size with particular implication to the initiation stage and small crack growth. Interrupted tests as a function of time can establish crack-distribution functions incorporated in engineering models. Activities along such phenomenological lines have been conducted without using any mechanistic hypothesis (Ref 81). At this stage, a well-established methodology for design is not yet available, but the practical potential is self-evident. Although such a phenomenological approach is essential, the combination with mechanistic analysis would be more comprehensive. For such an analysis to be successful, a crack-distribution assessment should be assisted by high-resolution direct observation and not only by indirect methods such as acoustic emission.

SCC Testing

In order to determine the susceptibility of alloys to SCC, several types of testing are available that are covered in ASTM standards:

ASTM No.	Title
G 30	Standard Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
G 35	Standard Practice for Determining the Susceptibility of Stainless Steels and Related Nickel-Chromium-Iron Alloys to Stress-Corrosion Cracking in Polythionic Acids
G 36	Standard Practice for Evaluating Stress-Corrosion-Cracking Resistance of Metals and Alloys in a Boiling Magnesium Chloride Solution
G 37	Standard Practice for Use of Mattsson's Solution of pH 7.2 to Evaluate the Stress-Corrosion Cracking Susceptibility of Copper-Zinc Alloys
G 38	Standard Practice for Making and Using C-Ring Stress-Corrosion Test Specimens
G 39	Standard Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
G 41	Standard Practice for Determining Cracking Susceptibility of Metals Exposed under Stress to a Hot Salt Environment
G 44	Standard Practice for Exposure of Metals and Alloys by Alternate Immersion in Neutral 3.5% Sodium Chloride Solution
G 47	Standard Test Method for Determining Susceptibility to Stress-Corrosion Cracking of 2xxx and 7xxx Aluminum Alloy Products
G 58	Standard Practice for Preparation of Stress-Corrosion Test Specimens for Weldments
G 64	Standard Classification of Resistance to Stress-Corrosion Cracking of Heat Treatable Aluminum Alloys
G 103	Standard Test Method for Performing a Stress-Corrosion Cracking Resistance of Low Copper 7xxx Series Al-Zn-Mg-Cu Alloys in Boiling 6% Sodium Chloride Solution

In addition, other standards include:

Designation	Title
ISO 7539	Metals and Alloys—Stress-Corrosion Testing
DIN 50915	Testing the Resistance of Unalloyed and Low-Alloy Steels to Intergranular Stress-Corrosion Cracking
NACE TM0284	Evaluation of Pipeline Steels for Resistance to Stepwise Cracking
NACE TM0177	Laboratory Testing of Metals for Resistance to Specific Forms of Environmental Cracking

The general test methods and the type of information derived from testing are illustrated in Fig. 13. These test concepts apply to both SCC and hydrogen embrittlement. Tests for corrosion fatigue tests are also illustrated.

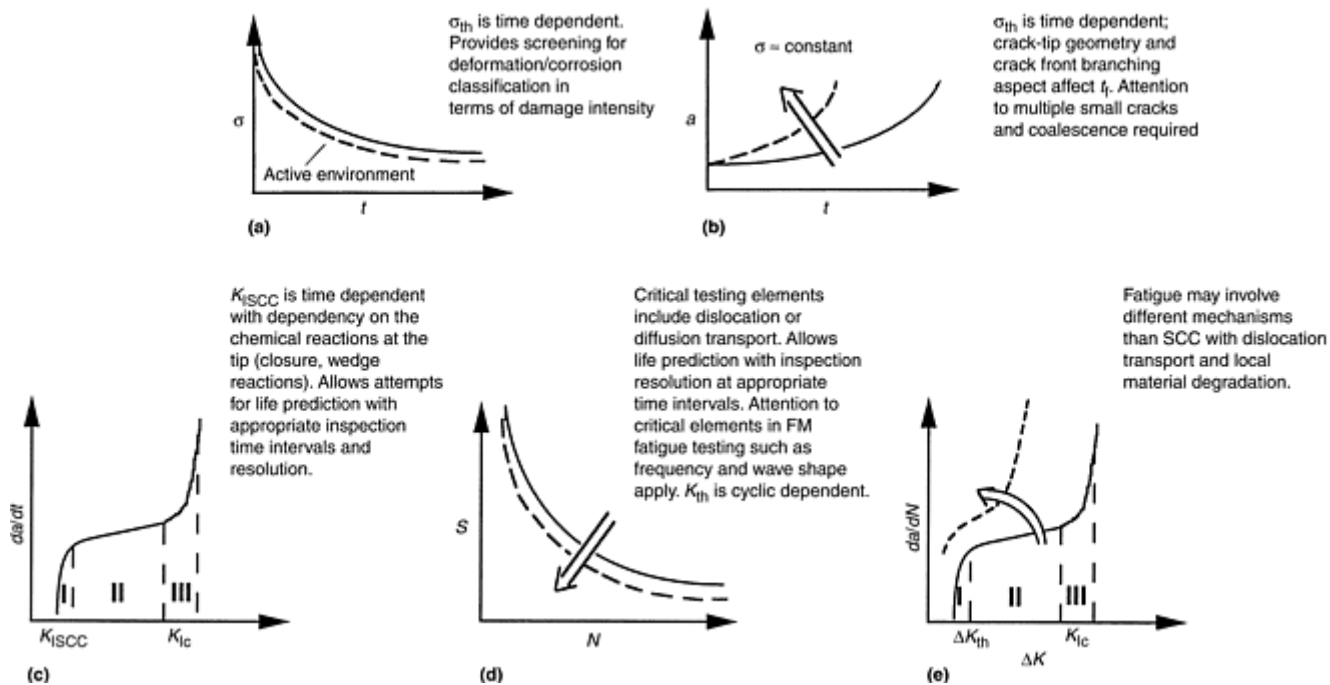

Fig. 13 General types of tests related to stress-corrosion cracking (SCC), hydrogen embrittlement, and corrosion fatigue. (a) Smooth specimen SCC testing for determination of a stress threshold, σ_{th} . (b) Slow-strain-rate (SSR) testing for strain-rate controlled evaluation of σ_{th} and time to failure, t_f . (c) Fracture mechanics evaluation with a notched or precracked specimen for determination of crack growth rate (da/dt) or crack growth threshold (K_{ISCC}). (d) Corrosion fatigue life ($S-N$) testing. (e) Corrosion fatigue crack growth testing for determination of crack growth rates of fatigue cracking threshold (ΔK_{th})

If the objective of testing is to predict the service behavior or to screen alloys for service in a specific environment, it is often necessary to obtain SCC information in a relatively short time. This requires acceleration of testing by increasing the severity of the environment or the critical test parameters. The former can be accomplished by increasing the test temperature or the concentration of corrosive species in the test solution and by electrochemical stimulation. Test parameters that can be changed to reduce the testing time include the application of higher stresses, continuous straining, and precracking, which allows bypassing the crack nucleation phase of the SCC process.

Stress-corrosion specimens can be divided into two main categories, namely smooth, and precracked or notched specimens. Further distinction can be made in the loading mode, such as constant deflection, constant load, and constant extension or strain rate. These different loading modes are briefly reviewed in the following sections. More detailed information is in Ref 76.

Important parameters during SCC testing include the orientation grain flow direction relative to stressing direction, surface condition, and residual stress. The nucleation of stress-corrosion cracks strongly depends on initial surface reactions, and thus the surface condition of the test specimens, particularly smooth specimens, has a significant effect on the test results. Smooth test specimens are often tested with a mechanically (machined or abraded) or (electro) chemically treated surface. It is very important to avoid or to remove machining marks or scratches perpendicular to the loading direction (per ASTM G 1, "Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens").

Smooth Specimen SCC Testing

Smooth SCC specimens allow for the evaluation of the total SCC life, which includes crack nucleation and propagation. Testing can be conducted under constant extension or strain, constant load, and constant extension or strain rate. The selection of a specific test method for SCC strongly depends on the particular service application and the time allowed for testing.

Constant Extension Testing

Constant extension or constant strain tests on smooth specimens are widely used and do not require elaborate testing fixtures. Depending on the specific configuration of the test articles, different types of constant extension tests are being used, the most common being bent-beam, U-bend, C-ring, and tensile type specimens. The simplest method of providing a constant load consists of a deadweight hung on one end of the specimen. This method is particularly useful for wire specimens. For specimens of larger cross section, however, lever systems such as those used in creep-testing machines are more practical. The primary advantage of any deadweight loading device is the constancy of the applied load.

Constant-strain SCC tests are performed in low-compliance tension-testing machines. The specimen is loaded to the required stress level, and the moving beam is then locked in position. Other laboratory stressing frames have been used, generally for testing specimens of smaller cross section.

Bent-Beam Specimens. The different types of bent-beam specimens are illustrated in Fig. 14. These specimens may be used to test sheet plate and flat extruded material, or wires and extrusions with a circular cross section. The figure shows that bending can be accomplished in several ways depending on the dimensions of the specimen. Stressing of the specimen is accomplished by bending the specimen in a stressing device, while restraining the ends. During stress-corrosion testing, both specimen and stressing device are exposed to the test environment. The most simple loading arrangement is the two-point loaded bent beam, which can only be used on relatively thin sheet or wire material. The elastic stress at the mid-point of the specimen can be estimated from the following equation:

$$L = (ktE/\sigma) \sin^{-1} (H/HktE)$$

where L is the specimen length, σ is the maximum stress, E is the elastic modulus, H is the length of holder, t is the specimen thickness, and k is the empirical constant (1.280).

Fig. 14 Schematic specimen and holder configurations for bent-beam specimens. (a) Two-point loaded specimen. (b) Three-point loaded specimen. (c) Four-point loaded specimen. (d) Welded double-beam specimen. Source: ASTM G 9

Three-Point Bend Specimens. Three-point bend tests are commonly used because of the ease of load application and the ability to use the same loading rigs for different stresses. The load is applied by turning a bolt in the rig, deflecting the specimen. The elastic stress at the mid-point of the specimen is calculated from the following equation:

$$\sigma = 6Et y / H^2$$

where σ is the maximum tensile stress, E is the elastic modulus, t is the specimen thickness, y is the maximum deflection, and H is the length of holder.

This test has a number of disadvantages. First, dissimilar metal corrosion and/or crevice corrosion can occur under the bolt. Secondly, once the crack has formed, the stress condition changes such that the outer layer of the specimen is not subject to a tensile stress only, but to a complex combination at tensile and bending stresses. The propagating crack will then deviate from the centerline. Thus, the three-point bend test can only be used as

a qualitative test to assess the susceptibility to stress-corrosion cracking. With the four-point bend test, described in the next paragraph, tensile stresses can be maintained during the growth of the crack.

Four-Point Bend Specimens. Four-point bend testing provides a uniform tensile stress over a relatively large area of the specimen. The elastic stress in the outer layer of the specimen between the two inner supports can be calculated from the following equation:

$$\sigma = 12Ety/(3H^2 - 4A^2)$$

where σ is the maximum tensile stress, E is the elastic modulus, t is the specimen thickness, y is the maximum deflection, H is the distance between outer supports, and A is the distance between outer and inner supports.

U-bend specimens are prepared by bending a strip 180° around a mandrel with a predetermined radius (Fig. 15). The figure shows that bends less than 180° degrees are also used. Standardized test methods are described in ASTM G 30. Because of the ease of fabrication, a large amount of specimens can be fabricated, and this test is therefore widely used to qualitatively evaluate the susceptibility of alloy and heat treatment to stress-corrosion cracking.

Fig. 15 Schematic two-stage stressing of a U-bend specimen. Source: ASTM G 30

A good approximation of the strain at the apex of the U-bend is:

$$\varepsilon = t/2R, \text{ when } t < R$$

where t is the specimen thickness and R is the radius of the bend. Then, an appropriate value for the maximum stress can be obtained from the stress-strain curve of the test material.

C-ring specimens are commonly used to determine the susceptibility to stress-corrosion cracking of alloys in different product forms. This test is particularly useful for testing of tubing, rod, and bar in the short-transverse direction, as illustrated in Fig. 16. The specimens are typically bolt loaded to a constant strain or constant load per ASTM G 338. If the stresses in the outer layers of the apex of the C-rings are in the elastic region, the stresses can be accurately calculated using the following equations:

$$D_f = D - \Delta$$

where

$$\Delta = \sigma d^2 / 4EtZ$$

and where D is the outer diameter of the C-ring before stressing, D_f is the outer diameter of stressed C-ring, σ is the elastic stress, Δ is the change of D at the desired stress, d is the mean diameter ($D - t$), t is the wall thickness, E is the elastic modulus, and Z is the correction factor for curved beam.

Fig. 16 Sampling procedure for testing various products with C-rings. (a) Tube. (b) Rod and bar. (c) Plate. Source: ASTM G 338

The stress on C-ring specimens can be more accurately determined by attaching circumferential and transverse strain gages to the stressed surface. The circumferential (σ_C) and transverse (σ_T) elastic stresses can be calculated with (Ref 82 and 83):

$$\sigma_C = E / (1 - \mu^2) \times (\varepsilon_C + \mu \varepsilon_T)$$

$$\sigma_T = E / (1 - \mu^2) \times (\varepsilon_T + \mu \varepsilon_C)$$

where E is the elastic modulus, μ is the Poisson's ratio, ε_C is the circumferential strain, and ε_T is the transverse strain.

Tensile Specimens. For specific purposes, such as alloy development, a large number of stress-corrosion specimens need to be evaluated. Tensile specimens have been used for this purpose where specimens used to determine tensile properties in air are adapted to SCC, as discussed in ASTM G 49. When uniaxially loaded in tension, the stress pattern is simple and uniform, and the magnitude of the applied stress can be accurately determined. Specimens can be quantitatively stressed by using equipment for application of either a constant load, a constant strain, or an increasing load or strain.

This type of test is one of the most versatile methods of SCC testing because of the flexibility permitted in the type and size of the test specimen, the stressing procedures, and the range of stress level. It allows the simultaneous exposure of unstressed specimens (no applied load) with stressed specimens and subsequent tension testing to distinguish between the effects of true SCC and mechanical overload.

A wide range of test specimen sizes can be used, depending primarily on the dimensions of the product to be tested. Stress-corrosion test results can be significantly influenced by the cross section of the test specimen. Although large specimens may be more representative of most structures, they often cannot be prepared from the available product forms being evaluated. They also present more difficulties in stressing and handling in laboratory testing.

Smaller cross-sectional specimens are widely used. They have a greater sensitivity to SCC initiation, usually yield test results rapidly, and permit greater convenience in testing. However, the smaller specimens are more difficult to machine, and test results are more likely to be influenced by extraneous stress concentrations resulting from nonaxial loading, corrosion pits, and so on. Therefore, use of specimens less than about 10 mm (0.4 in.) in gage length and 3 mm (0.12 in.) in diameter is not recommended, except when testing wire specimens.

Tension specimens containing machined notches can be used to study SCC and hydrogen embrittlement. The presence of a notch induces a triaxial stress state at the root of the notch, in which the actual stress will be greater by a concentration factor that is dependent on the notch geometry. The advantages of such specimens include the localization of cracking to the notch region and acceleration of failure. However, unless directly related to practical service conditions, the results may not be relevant.

Tension specimens can be subjected to a wide range of stress levels associated with either elastic or plastic strain. Because the stress system is intended to be essentially uniaxial (except in the case of notched specimens), great care must be exercised in the construction of stressing frames to prevent or minimize bending or torsional stresses.

Constant Load Testing

Although the constant extension tests are widely used for evaluating the susceptibility of alloys to stress-corrosion cracking because of the ease of specimen preparation and the ability to test a large number of specimens at one time, there is one major drawback. Once stress-corrosion cracks have formed, the gross cross section stress decreases, which will eventually cause the crack to stop. Application of a constant or a static load provides an alternative test method that represents some actual field conditions that can provide threshold values. It should be cautioned, however, that such threshold values are strongly dependent on the method of loading (i.e., deadweight or spring) and the specimen size and cannot be considered a material property. Moreover, Fig. 17 and (Ref 84) shows that as a crack develops, the stress at the crack tip increases, possibly decreasing the time to failure.

Constant Strain Rate Testing

Constant or slow-strain-rate testing is a very useful technique to evaluate the susceptibility of materials to SCC in a relatively short period of time (Ref 84 and 85). Typical strain rates range between 10^{-5} s^{-1} and 10^{-7} s^{-1} , but for most materials the typical strain rate is at 10^{-6} s^{-1} . The strain sensitivity to SCC can change for different alloys, even of the same metal. Figure 18 (Ref 85) shows that for the 2000 series aluminum alloys, the critical strain rate for the highest susceptibility to cracking is 10^{-6} s^{-1} , whereas no such critical strain rate exists for the

7000 series aluminum alloys. This difference in slow-strain-rate behavior of the two alloys may indicate different mechanisms for SCC. The slow-strain-rate behavior indicates that the principal mechanism for cracking of the 2000 series alloys is film rupture—anodic dissolution model, while the predominant mechanism for cracking of the 7000 series alloys is hydrogen embrittlement.

Fig. 18 Strain rate regimes for SCC of 2000, 5000, and 7000 series aluminum alloys in a 3% aqueous NaCl solution plus 0.3% H₂O₂. Source: Ref 85

The parameters that are typically measured in slow-strain-rate testing to determine the susceptibility to SCC are:

- Time to failure
- Percent elongation
- Percent reduction in cross-sectional area at the fracture surface
- Reduction in ultimate and yield tensile stress
- Presence of secondary cracking on the specimen gage section
- Appearance of the fracture surface

In order to assess the susceptibility of a material to SCC, the results of the slow-strain-rate test in a particular environment must be compared with those in an inert environment, such as dry nitrogen gas.

Precracked Specimen Testing

The use of precracked specimens in the evaluation of SCC is based on the engineering concept that all structures contain cracklike flaws. Moreover, precracking can contribute to the susceptibility to SCC of alloys such as titanium alloys, and this susceptibility may not always be evident from smooth specimens.

Precracking eliminates the uncertainties that are associated with crack nucleation and can provide a flaw geometry for which a stress analysis is available through fracture mechanics. Expressing stress-corrosion characteristics in terms of fracture mechanics provides a relationship between applied stress, crack length, and crack growth in a corrosive environment. When the plasticity can be ignored, or in other words, when the plastic zone ahead of the propagating crack is below a certain value and a triaxial or plane strain stress state exists at the crack tip, linear elastic fracture mechanics (LEFM) can be applied to describe the relationship between crack length (a) and the applied stress (σ) by the stress-intensity factor K :

$$K = F\sigma \cdot \sqrt{a}$$

where F is a polynomial factor that accounts for the specimen geometry. Linear elastic fracture mechanics, and thus the K factor, cannot be used to describe the relationship between applied stress and the crack length when there is significant plasticity or when the stress state at the crack tip is plane stress. Then, a more fundamental parameter, the J integral, is used.

Almost all standard plane strain fracture mechanics test specimens can be adapted to SCC testing. Several examples are illustrated schematically in Fig. 19 (Ref 76). ASTM E 399 describes the allowable specimen dimensions and test procedures for precracked specimens.

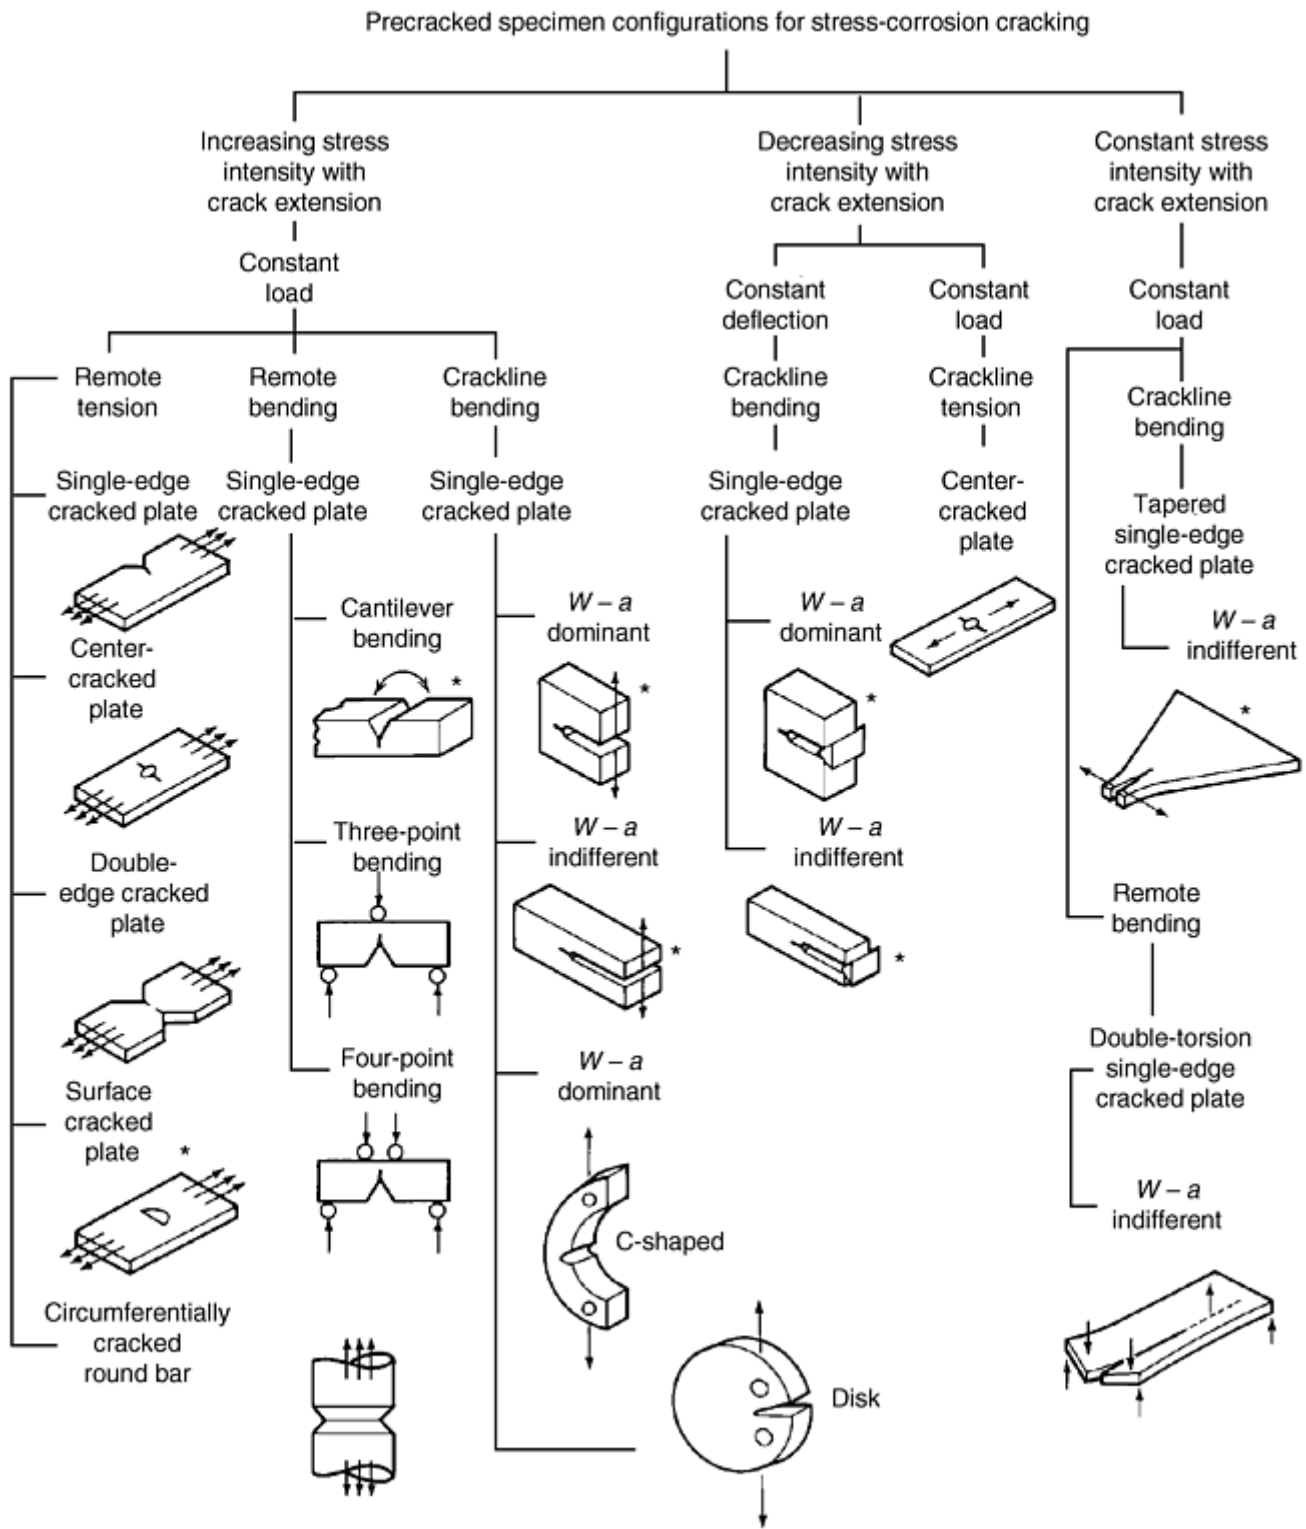

Fig. 19 Classification of precracked specimens for SCC testing. Source: Ref 76

Specimen Preparation. When using precracked fracture mechanics specimens, specific dimensional requirements need to be considered, as well as crack configuration and orientation. The basic dimensional requirement for application of LEFM is that dimensions are such that plane strain condition can be maintained. In general, for a valid K measurement, neither that crack length nor the specimen thickness should be less than $2.5 (K_{Ic}/\sigma_Y)^2$.

Several designs of initial crack configuration are available. ASTM E 399 recommends that the notch root radius is not greater than 0.127 mm (0.005 in.), unless a chevron notch is used, in which case it may be 0.25 mm (0.01 in.). In order to start out with a crack as sharp as possible, ASTM E 399 describes procedures for precracking.

The K level used for precracking should not exceed about two-thirds of the intended initial K value. This procedure prevents the forming of compressive stresses at the crack tip, which may alter the SCC behavior of the alloys.

Aluminum alloys can also be precracked by the pop-in method, where the wedge-opening method is used to the point of tensile overload. This method cannot be used for steels and titanium alloys, because of the strength of these alloys.

Loading Procedures. Stress-corrosion crack growth in precracked specimens can be studied in K -increasing and K -decreasing tests (Ref 84). In constant load or K -increasing tests, crack growth results in increased crack opening, which keeps the environment at the crack tip and corrosion products from interfering with crack growth. One of the problems with this mode of loading is that with increasing K , the plastic zone ahead of the crack tip may increase and at some point interfere with crack propagation. Moreover, for this type of testing bulky and relatively expensive equipment is required.

Constant displacement (K -decreasing) tests do not have the problems of the K -increasing tests indicated above. The plastic zone ahead of the crack tip does not increase with increasing crack size, so that the stress condition always remains in the plane strain mode. Also, the constant displacement tests can be self-loaded, and thus external testing equipment is not needed. Because in these tests the stress-intensity factor decreases with increasing crack growth, the stress-corrosion threshold stress-intensity factor (K_{Isc}) can be easily determined by exposing a number of specimens loaded to different initial K_I values. This can even be accomplished by crack arrest in one specimen.

A major problem with this test method occurs when corrosion products form in the crack, blocking the crack mouth and interfering with the environment at this crack tip. Moreover, the oxide can wedge open the crack and change the originally applied displacement and load.

Measurement of Crack Growth. In order to quantify the crack growth behavior in precracked stress-corrosion specimens, the crack length needs to be monitored, so that the crack velocity (da/dt) can be calculated, and the relationship between the increasing K and the crack velocity can be determined. There are basically three methods to monitor the growth of stress-corrosion cracks:

- Visual/optical measurements
- Measurement of the crack-opening displacement using clip gages
- The potential drop measurement, which monitors the increase in resistance across two points on either side of the propagating crack

These methods are described further in ASTM E 647, “Standard Test Method for Measurement of Fatigue Crack Growth Rates.”

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Corrosion Fatigue

Similar to SCC and/or hydrogen embrittlement under monotonic loads, environmentally assisted crack growth occurs under fatigue conditions as well. Several mechanistic aspects are similar for these forms of

environmentally assisted crack growth, although several areas of corrosion fatigue are not fully clarified, particularly with respect to the numerous variables and complex interactions that may cause crack initiation. However, very useful information is available in the literature regarding computational mechanics and advanced experimental techniques for corrosion fatigue (e.g., Ref 86 and 87). General reviews on SCC and corrosion fatigue are also contained in Ref 88 and 89. This section is a brief overview on the key variables and test methods of corrosion fatigue testing from Ref 90.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Key Test Variables (Ref 90)

The specific types and influence rankings of experimental variables in corrosion fatigue can vary markedly with specific alloy/environment systems. However, the following factors are crucial in most investigations of corrosion fatigue:

- Stress-intensity amplitude (ΔK) or stress amplitude ($\Delta\sigma$)
- Loading frequency (ν)
- Load ratio ($R = P_{\min}/P_{\max}$ or K_{\min}/K_{\max})
- Chemical concentration and contaminants (e.g., for aqueous environments: ionic species, pH, and dissolved species/gases, such as oxygen, hydrogen, and copper ion, that influence the corrosion potential)
- Alloy microstructure, yield strength, and often inhomogeneities, such as MnS and other inclusions and second phases, grain-boundary enrichment or depletion, and so forth

Other variables, such as load waveform, load history, and test temperature may also contribute, but they vary substantially in importance from system to system. Electrode potential should be monitored and, if appropriate, maintained constant during corrosion fatigue experimentation. Often, apparent effects of variables such as solution dissolved oxygen content, flow rate, ion concentration, and alloy composition on corrosion fatigue are traceable to changing electrode potential.

Stress-Intensity Amplitude (ΔK). While environmental crack growth rates increase with increasing ΔK , the specific dependency varies greatly. In some environments, the effect of environment is merely to offset the observed crack growth rate by some fixed factor above the inert rate. However, there is often a profound shift in the dependence of ΔK , typically producing a reduced ΔK dependence in aggressive environments, at least in the

intermediate region where power-law behavior is observed. It is always important to examine the entire relevant ΔK regime, not assuming the observed enhancement at a specific ΔK .

Environments do not always enhance the crack growth rate. The most common origins of crack retardation are associated with increased crack closure and crack blunting. Crack closure is most often increased by thicker oxides and perhaps the rougher (i.e., intergranular, with secondary cracks) fracture surface (Ref 91 and 92). Crack blunting results from aggressive environments that result in inadequate passivity. If the flanks of the crack are not adequately passive, then the crack tip will not remain sharp. This has been observed in low-alloy and carbon steels in hot water (Ref 93) and in other systems.

Shifts in ΔK , K_{max} , or load ratio during testing should be made very gradually, preferably continuously (e.g., under computer control). Changes in K should be limited to less than 10%, preferably much less. Any large change in growth rate should be confirmed using increments of <1%. Data may differ for rising K versus K -shedding conditions. Crack increments should be sufficient to provide statistically significant crack growth rates (e.g., >10 times above the crack length resolution) and should account for effects of plastic zone size under prior conditions during K -shedding. Shifts in frequency and hold time are not as restrictive, although changes greater than 3 to 10 times can lead to anomalous results.

The presence of an environment can also shift the dependence on stress amplitude ($\Delta\sigma$) or plastic strain amplitude ($\Delta\varepsilon$), not only by decreasing the stress at which a certain cyclic life can be attained, but also by eliminating the stress amplitude threshold altogether (Fig. 20). This, and increased scatter in the data, can lead to differences in estimating environmental effects at different stress amplitudes (Fig. 21). Note also that there is a consistent trend versus time in which the “bounding” curves are periodically shifted lower and to the left in Fig. 21.

Fig. 20 Stress amplitude versus cycle to failure for corrosion fatigue of 0.18% C steel in 3% NaCl at 25 °C, showing the strong effect of dissolved oxygen in accelerating cracking and eliminating the stress threshold. Source: Ref 94

Fig. 21 Empirically derived design codes for corrosion fatigue of offshore welded tube structures, illustrating their invalidity under specific test conditions and their constantly changing formulation. Hot spot stress range refers to local peak stress amplitudes at specific locations of the structure. Source: Ref 95

Loading Frequency (ν). Because the environment induces a significant time-dependent response, environment enhancement can vary markedly with loading frequency. At high frequency, it is common for the environmental enhancement to be substantially eliminated because of inadequate time available for associated chemical reaction and mass transport kinetics. Transitions in significant environmental enhancement are often apparent when plotting crack growth rate versus frequency or hold time. Predictive modeling has been quite successful in accounting for the transition between cycle- and time-dependent behavior as a function of corrosion potential, water purity, and degree of sensitization of the stainless steel (Ref 96 and 97).

Load Ratio (R). At higher load ratios (P_{\min}/P_{\max}), corrosion fatigue crack growth rates are usually higher than in inert environments. This can be viewed as a mean stress effect, and the greater environmental enhancement can be considered to result from the expected increase in contribution of time-dependent crack advance that would occur even under static load conditions.

Test Environment and Chemical Contaminants. Besides the obvious concern of primary species (such as NaCl concentration for salt water) in corrosion fatigue, small amounts of contaminants are also a key variable. A striking example (Ref 98) of an environmental-purity effect is illustrated in Fig. 22 for gaseous hydrogen embrittlement of a low-strength carbon steel. Relative to vacuum, crack growth is accelerated by factors of 3 and 25 for moist air and highly purified low-pressure hydrogen gas, respectively. Small additions of oxygen to the hydrogen environment essentially eliminate the brittle corrosion fatigue component to crack growth, consistent with a trend first reported by Johnson (Ref 99). Similar effects have been reported for carbon monoxide and unsaturated hydrocarbon contamination of otherwise pure hydrogen environments. In aqueous environments, the effects of bulk ionic concentration and pH are often quite pronounced (especially in unbuffered systems), although dissolved oxidants are often of greater consequence (e.g., dissolved oxygen, hydrogen peroxide, and copper and iron ions), as are contaminants (e.g., dissolved sulfur, chloride, lead, mercury).

Fig. 22 Effect of oxygen (O₂) contamination on gaseous hydrogen embrittlement of a low-strength AISI/SAE 1020 carbon steel. Frequency: 1 Hz. Source: Ref 98

The primary role of oxidizing and reducing species, especially dissolved oxygen and hydrogen, is in shifting the corrosion potential. Some species, such as nitrate, may also directly influence crack chemistry and, if reduced to ammonia, can be directly responsible for environmental enhancement (e.g., of brasses). In many cracking systems, the role of oxidants (elevated corrosion potential) is an indirect one, because inside the crack the oxidants are generally fully consumed and the corrosion potential is low. In such systems, the role of oxidants is to create a potential gradient, usually near the crack mouth, that causes anions (e.g., Cl⁻) to concentrate in the crack and causes the pH to shift.

Oxidants increase the corrosion potential in aqueous environments, which can have very pronounced effects on environmental enhancement. This can occur at exceedingly low concentrations; in high-temperature water, crack growth rates can increase by orders of magnitude merely from the presence of parts-per-billion levels of dissolved oxygen in water. Similar enhancements are observed for small concentrations of aqueous impurities (e.g., <10 ppb of sulfate or chloride) or MnS inclusions in low-alloy and carbon steels, which dissolve within the crack to form sulfides. This usually is associated with the formation of a differential aeration cell by complete oxygen consumption within the crack (Fig. 23). Thus, even very small cracks usually advance under deaerated conditions, and the gradient in corrosion potential that is formed from crack mouth to crack tip causes an increase in anion concentration and a shift in pH in the crack. The shift is often acidic, but not necessarily so, because it requires the presence of non-OH⁻ anions to balance the acidity (H⁺). Thus, if only OH⁻ is present (e.g., from NaOH), the pH shift can only be in the alkaline direction.

Fig. 23 Schematic of crack showing the differential aeration macrocell that establishes the crack-tip chemistry and the local microcell that is associated with metal dissolution and crack advance. Because the differential aeration macrocell is not essential to elevated crack growth rates, some coupling of the currents associated with these two cells may occur, but this is unnecessary. Source: Ref 100

Potentiostats can be used to control the specimen potential, although their use (which rarely directly simulates the real situation) can provide misleading data. Primary concerns are associated with:

- *Voltage drop in solution:* The reference electrode reading may be biased by the potential distribution in the solution associated with passage of ionic current.
- *Failure to polarize the crack tip:* Even in highly conductive solutions, the crack-tip potential is rarely significantly affected by external polarization, and therefore crack advance does not occur at the potential that is controlled on the specimen surface.
- *A reversal of surface reactions and shifts in local pH:* In solutions containing oxygen, the reaction on the external surface is cathodic, and inside the crack, anodic reactions occur. With a potentiostat, as the specimen is polarized to more positive potentials, it becomes more anodic and causes oxidation reactions to take place predominantly on the metal surface, which can alter the local pH. Cathodic reactions occur predominantly on the relatively remote counterelectrode.

To accurately measure potentials, commercial or custom-built reference electrodes are used. Both to measure potentials accurately and to prevent galvanic coupling, it is desirable to electrically isolate the specimen from the linkage and surrounding metal surfaces. If the environment is not very conducting or the potentials of surrounding metal surfaces are not too different from the specimen, electrical isolation may not be critical. However, it is then necessary to place the reference electrode much closer to the test specimen than to other (electrically connected) metal surfaces.

Other concerns for the environment include:

- Specimen and grip design (e.g., to avoid failure at crevices by minimizing stress in creviced regions)

- Proper design of environmental cells (e.g., to avoid contamination from leachants from or diffusion of oxygen through plastics)
- Maintenance of proper chemistry, which often requires refreshed/flowing systems for controlling the chemistry in gases or liquids
- Proper stability and measurement of temperature (near the specimen)
- Proper and thorough monitoring/recording of all relevant chemical and electrochemical parameters

Metallurgical Variables. Microstructure and alloy strength influence fatigue crack propagation in embrittling gases and liquids. In general, brittle corrosion fatigue cracking is accentuated by:

- Impurity (e.g., phosphorus or sulfur) segregation at grain boundaries
- Solute depletion or sensitization (e.g., chromium) about grain boundaries
- Planar deformation associated with ordering or peak-aged coherent precipitates
- Increased yield strength or hardness
- Large inclusions (e.g., MnS)

The effects of alloy composition, grain size, and microstructure (e.g., bainitic versus martensitic steel) vary with environment and brittle cracking mechanism. Laboratory experiments are necessary to establish specific trends. Yield strength plays a large role in environmental cracking, which has been attributed both to enhanced crack-tip strain rate as well as to complete shifts in the crack advance mechanism. The importance of hydrogen embrittlement in higher-strength materials has been confirmed by experiments in gaseous hydrogen. Its direct role in environmental crack advance is considered to be limited to about 150 °C (300 °F) in iron- and nickel-base alloys, although it may have an indirect role at higher temperatures.

Similar effects have been observed for bulk or surface cold work, which raises the yield strength. Thus, machining and surface treatments such as shot peening can significantly affect cracking. Shot peening and related treatments that produce surface compressive stresses can be very beneficial, provided that cracks do not exist (or form) and that tensile stresses do not exceed them. If sufficient strain occurs, transgranular cracks often nucleate in the surface-hardened region.

Other important microstructure factors include γ' or δ phases on grain boundaries of nickel alloys, martensite formation in steels, carbide formation (sensitization) in stainless steel and nickel alloys, and inhomogeneities (e.g., MnS and nonmetallic inclusions). These often have an even larger role in corrosion fatigue than under inert conditions, and a uniform microstructure or distribution of inhomogeneities can rarely be assumed.

Crack Closure Effects. Premature crack surface contact during unloading, or “crack closure,” can greatly reduce rates of fatigue crack propagation. The true (or effective) crack-tip driving force is reduced below the applied ΔK because of the reduced crack-tip displacement range. Closure phenomena are produced by a variety of mechanisms and are particularly relevant to fatigue crack propagation in the near-threshold regime, after large load excursions, or for corrosive environments.

Two mechanisms of crack closure are relevant to corrosion fatigue. Rough intergranular crack surfaces (typical of environmental embrittlement) promote crack closure, because uniaxially loaded cracks open in a complex three-dimensional mode, thus allowing for surface interactions and load transfer. Roughness-induced closure is most relevant to corrosion fatigue at low ΔK and at stress-ratio levels where absolute crack opening displacements (0.5–3 mm, or 0.02–0.12 in.) are less than fractured grain heights (5–50 mm, or 0.20–2 in.).

Alternately, crack closure is impeded by dense corrosion products within the fatigue crack. For mildly oxidizing environments, such as moist air, this closure mechanism is relevant at low stress-intensity levels and contributes to the formation of a “threshold,” as described in Ref 101.

For corrosive bulk environments or localized crack solutions, cracking at high ΔK values may be retarded below the growth rates observed for air or vacuum due to corrosion product formation within the crack. The engineering significance of beneficial crack closure influences depends on the stability of the corrosion product during complex tension-compression loading and fluid conditions.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Corrosion Fatigue Crack Growth Test Methods (Ref 90)

Standard methods of fatigue crack growth (as defined in ASTM E 647 and described in the article “Fatigue Crack Growth Testing” in this Volume) are generally applicable to corrosion fatigue crack growth tests. ASTM E 647 also contains an appendix specific to crack growth in marine environments. Procedures for other corrosion fatigue environments are not standardized, but various methods have evolved. Some general aspects of corrosion fatigue crack growth are described below, and additional background is provided in Ref 102.

Three problem areas are relevant to corrosion fatigue experimentation. First, the environment must be contained about the cracked specimen without affecting loading, crack monitoring, or specimen-environment composition. Parameters such as environmental purity, composition, temperature, and electrode potential must be monitored and controlled frequently.

Second, the deleterious effect of low cyclic frequency dictates that crack growth rates must be measured at low (often <0.2 Hz) frequencies, which lead to long test times, often from several days to weeks. Load-control and crack-monitoring electronics and environment composition must be stable throughout long-term testing.

Third, crack length must also be measured for calculations of stress intensity and crack growth rate. Optical methods are often precluded by the environment and test chamber. Indirect methods, based on specimen compliance or electrical potential difference, have been applied successfully to monitor crack growth in a wide variety of hostile environments and are described in more detail below. Experimental and analytical requirements, however, are complex for indirect crack monitoring.

Finally, specimen thickness, as it influences the degree of plane-strain constraint, and crack size, as it influences the chemical driving force, may affect corrosion fatigue crack speeds. Currently, such effects are unpredictable; specimen thickness and crack geometry must be treated as variables. In corrosion fatigue, the electrochemistry within the crack is mass transport dependent and can vary with crack depth, and possibly also with specimen geometry and with accessibility of solution in the through-thickness direction via the crack sides. These factors can influence crack growth rates despite the constancy of the range of the stress-intensity factor.

Because corrosion fatigue testing is often performed at low cyclic frequencies, multiple test stations are desirable. For this reason and for general economy, compact tension specimens are frequently used. Such specimens minimize the applied load required to achieve a given crack-tip stress intensity, thus permitting the use of low-load capacity and less expensive test machines. In applying load to specimens in a test cell, cell friction must not affect load in sealed systems. This is generally not a significant factor in most ambient-temperature applications, however. Insulation between specimens and grips, pin assemblies, and so forth is essential to avoid galvanic effects, but greases should not be used.

Electrode Potential

Monitoring and reporting the electrode potential during corrosion fatigue experiments is important. The potential should be measured using a reference electrode located in the bulk solution adjacent to the specimen. When impressed currents are applied to the specimen, measurement should be made adjacent to the surface using a Luggin capillary to minimize the potential drop between the reference electrode and the metal surface, the magnitude of which will depend on the solution conductivity and flow of current.

Selection of a reference electrode depends on the particular application, but those most commonly used in laboratory room-temperature tests are the SCE and the silver/silver chloride electrode. For some solutions in which contamination with chloride is undesirable, use of a mercury/mercurous sulfate reference electrode is an option. Contamination can be reduced by using commercially available double-junction electrodes, in which the outer jacket is filled with test solution.

In quoting measured potentials, the potential should be referred to a standard scale such as the standard hydrogen electrode (SHE) or the SCE at $25\text{ }^{\circ}\text{C}$ ($75\text{ }^{\circ}\text{F}$). In tests remote from $25\text{ }^{\circ}\text{C}$ ($75\text{ }^{\circ}\text{F}$), allowance must be made for the fact that the half-cell potential of the reference electrode varies with temperature. A high-impedance meter ($>10^{12}$ W), such as an electrometer or a pH meter, should be used for monitoring potential, although periodic (short-term) measurements can usually be successfully performed using digital voltmeters whose input impedance is $\geq 10^9\ \Omega$ (usually limited ≤ 2 V full-scale direct-current, dc, ranges).

Near room temperature, it generally is possible to use commercial reference electrodes such as calomel and silver chloride electrodes; some electrode designs permit use near boiling. Designs that place the reference electrode in a separate chamber at a different temperature than the test solution are complicated by formation of a thermal junction potential in the electrolyte, the magnitude of which may be large (above 0.1 V).

At temperatures above boiling, a custom reference electrode generally is necessary. Most investigators use internal or external silver/silver chloride reference electrodes. For internal electrodes, the silver chloride reaction occurs at the test temperature. For external electrodes, the silver chloride reaction occurs at room temperature, but system pressure is applied (so no streaming potentials form), with a temperature gradient occurring in the potassium chloride electrolyte as it enters the autoclave. A porous junction in the autoclave

isolates the potassium chloride electrolyte from the autoclave solution. This thermal junction potential has been well characterized over a range of temperatures and potassium chloride concentrations (Ref 103).

Potentials should be reported on the SHE scale, particularly for elevated-temperature tests, for which the conversion factors to V(SHE) are not widely known. However, when comparing results as a function of temperature, it may be helpful to eliminate the contribution of the standard hydrogen cell, because as in other reactions, it has a potential that varies with temperature. It is by convention that the standard hydrogen cell is 0 V at any temperature; relative to the standard hydrogen reaction at 25 °C (75 °F), the potential of the standard hydrogen reaction is about 0.021 V at 50 °C (120 °F), 0.057 V at 100 °C (212 °F), 0.086 V at 150 °C (300 °F), and about 0.105 V between 210 and 300 °C (410 and 570 °F).

Application of imposed potential using a potentiostat requires electrical isolation of the specimen. In some cases, it may be difficult to insulate the specimen from the loading linkage; instead, the linkage must be insulated from the autoclave, and the measured current flow cannot be attributed only to reactions at the specimen. Ground loops present perpetual problems, because most potentiostats are designed to hold the specimen at ground (or virtual ground). With necessary mechanical and plumbing connections, the autoclave is usually connected to ground; thus, the specimen is effectively connected to the autoclave. The problem is compounded if the autoclave is used as the counterelectrode, because the ground loop shorts out the potentiostat. Options include thorough electrical isolation of the autoclave from ground and use of a fully floating potentiostat.

Attachment of a lead to the specimen to permit measurement or application of potential can be a challenge in aggressive environments. Recommendations include use of wire that is either identical to the specimen or a very noble metal, such as platinum. Attachment using a weld bead (e.g., by gas-tungsten arc welding) usually is superior to spot welding. Covering the lead wire with heat-shrink Teflon and, at low test temperatures, covering the weld with an organic “stop-off” coating helps maintain a good connection and minimizes the effects of the wire (via galvanic coupling or its contribution to the measured current). Another technique involves the use of a commercially available plasma sprayed insulating coating, which can also be used in high-temperature water.

Errors in the potential applied by a potentiostat can occur in solutions of low conductivity. These iR drops, which result from current flow between the counterelectrode and working electrode in the high-resistance solution, are detected by the reference electrode and summed with the electrode potential of the specimen. Electronic compensation is possible, but not straightforward in most high-resistivity media. Partial compensation is possible by placing the reference electrode near the specimen, although for small specimens the measured potential becomes very sensitive to electrode positioning. A rough estimate of the possible error can be made by multiplying the resistivity of the solution (preferably determined by measuring the alternating current, ac, flowing between the counterelectrode and working electrode when a known 1000 Hz ac voltage is applied) by the potentiostat current that flows during a test.

Monitoring Crack Length

The electrical potential technique and the compliance method are frequently used to monitor fatigue crack growth in solution and in gaseous environments. Visual methods generally are not practical; often, the crack and the test specimen are obscured by the test chamber, or a microscope with a long focal length is needed.

The electrical potential technique is preferred over the compliance method for use inside an environmental test chamber, because the compliance gage may outgas and is a potential source of test environment contamination. Its use in a corrosive environment is also unsuitable. The electric potential technique, however, is noncontaminating and can be used in most environments.

Use of the compliance method is generally limited to compact tension (CT, or compact type) and wedge-opening load specimens. It is not used for center-cracked tension specimens because of limitations in sensitivity and accuracy. The electrical potential technique can be readily applied to all three specimen types. The principal drawback of the electrical potential technique is that the specimen must be electrically conductive; thus, it cannot be applied directly to specimens made of nonelectrically conducting materials, such as polymer-based composites and ceramics. In addition, electrical shorting across the crack surfaces may affect its measurement accuracy, particularly for tests in vacuum. Both the electrical potential and compliance techniques can be readily interfaced with a computer for real-time control of the experiment and for online data acquisition and reduction.

Potential Drop Method. The most common and sensitive in situ crack monitoring technique is reversing dc potential drop, which typically applies a constant current to a specimen and measures the changes in potential across the specimen as the crack grows. High-quality implementations of dc potential drop are consistently able to achieve a crack length resolution on 1T compact-type specimens of about 1 mm (0.04 in.), and an overall accuracy of <5% on the overall increment in crack advance. Current and potential leads can be insulated using Teflon tubing for test temperatures up to 300 °C (570 °F); above 300 °C, zirconia is generally used.

During environmental testing, there are several special considerations. Solution conductivity can be a major issue; an extreme example is the inability to use potential drop in liquid metal environments. Some deviations in crack length versus measured potential response can also occur in highly conducting environments (e.g., aqueous solutions), and it must be recognized that the crack chemistry can be substantially more conductive and at different pH than the bulk solution. However, despite the small distance between the upper and lower crack flanks, the role of ionic (e.g., aqueous) conductivity is not large compared to that of metal conductivity, because aqueous conductivities are typically measured in 10^{-1} to 10^{-6} S/cm (S, or Siemen, is W^{-1}), whereas metal conductivities are typically between 10^5 and 10^6 S/cm. Thus, errors associated with aqueous environments are relatively small, although not always ignorable.

Another concern relates to inaccuracies in indicated crack length because of a nonuniform crack front or because of metal contact along the crack flank during the fatigue cycle. In both cases, an abnormal fraction of the dc current “shorts” through the uncracked metal ligament in the wake of the nominal crack front, and the measured potential and indicated crack length is strongly affected. For example, if the crack front moves forward in a 25 mm (1 in.) compact-type specimen by 3 mm (0.12 in.) in all locations except along one narrow, rectangular ligament that is only 1 mm (0.04 in.) wide, the indicated crack advance by potential drop can be very small (i.e., dramatically less than the area average of crack advance). Nonuniform crack fronts are much more common when the environmental contribution to crack advance is high, and static loading (stress-corrosion cracking) is generally much worse than dynamic loading (e.g., corrosion fatigue). Certain microstructures, such as weld metal, can be quite susceptible to accelerated or retarded crack advance in localized regions (i.e., along certain weld dendrites). The “unzipping” of the final metal ligament can lead to anomalously high “apparent” crack growth rates over certain testing periods.

Other concerns for dc potential drop include electrochemical effects, particularly polarization. If a well-designed, ground isolated power supply is used, then all of the dc current that leaves the “+” terminal must return on the “-” terminal, and direct polarization of the specimen is not possible. In most cases, there is little basis for concern for the electrochemical effects of using dc potential drop, although, for example, the small potential difference between the crack flanks could have some influence in tight cracks in conductive solutions. This potential difference is very small near the crack tip, so it is more likely to influence, for example, dissolution of MnS inclusions at some distance toward the crack mouth, where the potential difference across the crack flanks is higher. While the potential difference between the upper and lower surfaces of the crack is small (typically 100 mV in many potential drop implementations), the gradient can be relatively large because of the small separation of the crack faces. The importance of this issue can be quantified by establishing a steady-state crack growth rate and disconnecting the potential drop system for a period of time, then reconnecting it to evaluate its effect (or by comparing a duplicate experiment using an extensometer to monitor the crack growth rate).

Electrochemical effects can also result from improperly insulated dc current leads. Because significant current is passed through leads that are often relatively small, the potential drop in the current leads can be large (e.g., >1 V). If the current leads are not continuously insulated through the entire solution right up to the location where they are spot welded onto the specimen, there is an opportunity for crosstalk with closely adjacent potential leads (where the signal is typically 100 mV). Additionally, biasing of the specimen can occur if the current leads are not continuously insulated through the system seals. Any ionic communication in the tight-fitting seal area permits leakage to the metal (e.g., autoclave), and a circuit is established. The current leads act like a 1 V battery that is shared across two resistors, one representing the water resistivity in the seal and one representing the water resistivity between the specimen and the autoclave. This can cause some polarization of the specimen in conductive solutions, or voltage (iR) drop in low-conductivity solutions. In the latter case, even though no substantial polarization occurs, reference electrodes that are located between the specimen and the autoclave “see” the voltage drop, and the apparent (measured) corrosion potential can be observed to fluctuate as the direction of the dc current is reversed. This represents a good check of the integrity of the dc potential drop system and wire insulation.

Finally, there is a potential concern for self-heating of the specimen by the applied dc current. While this is not a problem in aqueous environments or at common current densities, there have been cases where high current densities coupled with air or vacuum exposure resulted in significant self-heating.

Compliance Method and Other Cracking Monitoring Methods. The next most common crack monitoring technique is mechanical compliance, which relies on the relationship between crack mouth opening displacement and load during an unload/reload cycle). Resolution is typically limited by the strain gage or proximity sensors (e.g., eddy current or capacitance) that must monitor crack opening displacement in the (high-temperature water) environment. See the article “Fatigue Crack Growth Testing” in this Volume.

Another method is the ac potential drop technique, which relies on the “skin” (surface) effect of high-frequency current in metals. The advantage of the skin effect for detecting crack nucleation is generally more than offset by the higher noise (poorer noise rejection) of the ac measurement, even with sophisticated lock-in amplifiers, although improved instrumentation is closing the gap. Other crack-following techniques include burst detection by monitoring pressurized tubes, periodic ultrasonic or eddy current scans to detect small cracks, and periodic interruption and inspection.

In aqueous environments, electrochemical noise can be used as a semiquantitative crack monitoring technique. This technique measures the small variations in corrosion potential and/or corrosion current as cracks (or other corrosion phenomena, such as pitting) nucleate and grow. This technique is good at discriminating the early stages of crack initiation. However, the correlation between crack depth (or number of cracks) and the electrochemical noise signal is at best semiquantitative, because: (a) the noise signal intensity decreases with increasing crack depth, increasing distance between sensors, and the location of cracking on the specimen surface (especially in low-conductivity solutions); and (b) noise from multiple small cracks cannot be distinguished from noise from longer cracks.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Vacuum and Gases at Room Temperature (Ref 90)

One of the most critical considerations for fatigue tests in vacuum and gaseous environments is the maintenance of the purity of (and the reduction and measurement of the impurity level in) the test environment. As mentioned above, small amounts of contaminants (impurities) in the test environment can lead to fatigue crack growth rates that are not representative of the resistance of the material to fatigue crack growth in that environment.

A clean environmental test chamber that provides a very low background pressure and quantifiable impurity levels (below 10^{-7} to 10^{-6} Pa, or 7.5×10^{-10} to 7.5×10^{-9} torr) is essential, even if the tests are to be carried out in gaseous environments at relatively high pressures (i.e., above the background).

Environment Containment. An all-metal environmental test chamber with mechanical-force feedthroughs is preferred for the study of environmentally assisted fatigue crack growth in vacuum and gaseous environments. Stainless steels are suitable materials for the environmental test chamber, with copper used as the gasketing

material. The test chamber usually is equipped with a glass viewport that enables the operator to visually monitor the progress of the experiment.

With adequate pumping, the background pressure in the clean test chamber is usually below 10^{-6} Pa (7.5×10^{-9} torr). Maintaining an ultraclean test system is important, because a small amount of impurities can either significantly reduce or accelerate the fatigue crack growth rate, depending on the material and the types of impurities.

To achieve a low background pressure, the test chamber frequently is baked out (with the test specimen in place) at a temperature above ambient (60–400 °C, or 140–750 °F) to remove adsorbed and absorbed gases on the chamber wall. The bakeout temperature should be considerably below the tempering or aging temperature of the test material to ensure that the microstructure and the mechanical properties of the test material are not altered by the bakeout process. For example, the first-step artificial aging temperature for high-strength 7050-T7451 aluminum alloy is 121 °C (250 °F). The bakeout temperature for the test chamber is thus normally kept below 80 °C (175 °F).

Environment. Only high-purity, laboratory-grade gases should be used. Additional purification and dehumidification of the gas is recommended by passing it through a molecular-sieve purifier and a cold trap (-196 °C, or -320 °F) before allowing the gas to enter the test chamber. Gas pressure in the environmental test chamber is usually controlled by admitting the gas through a variable-leak valve.

If the test environment contains a toxic gas (such as hydrogen sulfide) or a combustible gas (such as hydrogen or methane), a protective hood with negative suction pressure should be used to enclose the test chamber or the entire test system. The test chamber should be purged thoroughly with an inert gas, such as argon or nitrogen, before it is reopened to the atmosphere.

If water vapor is used as the test environment, it can be drawn through the variable-leak valve from a high-purity reservoir that is attached to the test chamber. Deionized distilled water in the reservoir should be purified further by subjecting it to repeated freezing/pumping/thawing cycles to remove residual dissolved gases in the water (Ref 104).

Certain gases can decompose or react with containment vessels over time. For example, hydrogen sulfide can react with a stainless steel container to produce hydrogen. Provision must be made to remove the product gases before the test gas is admitted into the test chamber.

Finally, if the environment consists of mixed gases, the gas at the lowest partial pressure should be admitted first. If premixed gases are used, they must be thoroughly mixed in the supply reservoir to minimize stratification.

If test conditions such as gas pressure, test frequency, or applied load are changed during fatigue testing, a transient period may occur before the material assumes the steady-state fatigue crack growth rate that corresponds to the new test condition. The duration of this transient period depends on several variables, including the type of material, the test environment, and the magnitude of the change in test conditions.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

High-Temperature Vacuum and Oxidizing Gases

Fatigue testing in elevated-temperature vacuum and oxidizing environments requires a carefully designed vacuum test chamber. The chamber must keep the test specimen in a vacuum or oxidizing gas environment, allowing forces to be applied to the specimen, a means to measure crack length, and a method of applying and controlling the specimen temperature.

Variables that can affect fatigue crack growth rate at high temperature are time and rate dependent or structure dependent. Examples of time- and rate-dependent variables are oxidation and creep. Structure-dependent variables include phase transformations, nucleation and growth of new and existing phases, and grain growth. When fatigue crack growth rate test data are reported for these environments, test temperature, vacuum pressure, partial pressure of oxidizing gas, waveform type, waveform frequency, and stress ratio must be reported. Additional information on high-temperature fatigue crack growth testing is given in the article "Fatigue Crack Growth Testing" in this Volume.

Environment Chambers. Materials used in the test chamber should be selected to minimize outgassing in vacuum. For example, many plastic materials contain plasticizers, which slowly outgas in vacuum. These types of materials limit the ultimate vacuum obtainable. Stainless steel is suitable for the manufacture of the main test chamber. Components in the chamber should be designed for fast outgassing. When threaded components are used in the test chamber, channels should be machined in the threads to allow paths for fast outgassing.

For vacuum levels of 6.5×10^{-5} Pa (5×10^{-7} torr), O-rings provide sufficient sealing; for higher vacuum levels, copper gaskets should be used. Electricity, water, radiofrequency, and the thermocouple can be input into the chamber using standard vacuum feedthroughs.

Specimen Heating and Temperature Control. Induction heating is the only suitable method to heat test specimens in vacuum and oxidizing environments. Radiofrequency generators with frequencies of 200 to 500 kHz are used for induction heating of test specimens. The induction coils should be made of copper and have no insulating coating. When oxidizing gases are introduced into the test chamber, a certain pressure range exists at which the gases will be ionized between the specimen and induction coils. In this pressure range, it is impossible to heat the specimen, because the radiofrequency field arcs and shuts off the radiofrequency generator. To continue testing, the gas pressure must be either increased or decreased.

Two types of temperature controllers that are suitable for induction heating are thermocouple and infrared controllers. Each controller type has advantages and disadvantages. Infrared temperature controllers measure and control temperature from the spectral energy density emitted from the test specimen over a certain wavelength range. These measurements are noncontacting, but require a clear optical path from the sensor head to the test specimen. Infrared temperature controllers have a minimum temperature measurement capability of approximately 350 °C (660 °F). Two-color infrared controllers eliminate errors due to transmission loss and emissivity changes, but they have a minimum temperature measuring capability of 700 °C (1290 °F).

Thermocouple temperature controllers are also used in vacuum test chambers. A variety of thermocouple types can be used, depending on the temperature range and the required durability of the thermocouple. For example, American National Standards Institute type S and type K thermocouple temperature ranges overlap, but for long-term tests of more than one week, type S thermocouples are preferred because they are more oxidation resistant. This would not be a consideration in a high-vacuum environment. Thin thermocouple wire less than 0.25 mm (0.01 in.) in diameter must be used to eliminate inductive heating of the thermocouple wire. With some temperature controllers, it is necessary to filter out radiofrequency noise in the thermocouple with a passive inductor/capacitor-type filter.

Test Specimens. Because high-temperature vacuum requires specimen heating by induction, many of the standard fracture mechanics test specimens cannot be used. Center-cracked tension and single-edge notched specimens are commonly used, because it is relatively easy to maintain the specimen gage section at uniform temperature with induction heating. When tests are conducted at high vacuum levels or low oxidizing gas partial pressures, specimen thickness may affect crack growth rate, because transport of the oxidizing gas to the crack tip may be the rate-limiting factor.

Aqueous Solutions at Ambient Temperature (Ref 90)

Fatigue studies in aqueous solutions at ambient temperatures present fewer problems experimentally than many of the other environments considered in this article. Nevertheless, it is often the case that the most frequent problem in determining the validity of corrosion fatigue data lies with the control and monitoring of the bulk water chemistry and the monitoring and recording of the electrochemical potential.

Environment Containment. Glass and plastics are suitable materials for environmental test chambers and ancillary pipework for aqueous solutions at ambient temperatures. At elevated temperatures (>60 °C, or 140 °F), however, dissolution of silicates from glassware can inhibit corrosion. Dissolution of plasticizers from certain plastics (e.g., polypropylene) is also a concern. Flexible plastics, such as twin-pack casting silicone rubber, have proved to be useful in the vicinity of the fatigue specimen.

A corrosion fatigue test cell that avoids the need for a water-tight seal at the specimen is shown in Fig. 24. Normal specimen movement and any sudden fracture event can be accommodated without catastrophic consequences. Highly effective seals between plastic and metal surfaces can be made with silicone rubber caulking compounds, if necessary, although sufficient time must be allowed for escape of the acetic acid solvent base.

Fig. 24 Typical corrosion fatigue test cell. Maintenance of the equilibrium oxygen concentration is ensured by cascading the solution in the circulation rig.

Fatigue specimens of passive metals such as aluminum, titanium, and stainless steel may be subject to crevice corrosion under the caulking compound unless a primer and epoxy paint coat are applied initially to the metal surface. Gasket seals using O-rings, for example, can also form a satisfactory seal, but generally are more expensive to engineer and can also be subject to crevice corrosion in some configurations. The decision to circulate the environment depends on the application and the extent of any problems in controlling water chemistry.

Water Chemistry. The prevailing water chemistry and the electrode potential of the material in its environment in the field are essential factors in any simulation experiment. Accelerated fatigue cracking can occur in a number of environments, including seawater, salt water/salt spray, and body fluids. These must be reproduced as closely as possible in the laboratory, although limitations are necessarily imposed in simulating aspects of complex environments, such as the biological activity of seawater.

The importance of reproducing the service environment as closely as possible is illustrated by comparing the behavior of metals in sodium chloride and in seawater. The buffering action of seawater associated with dissolved bicarbonate/carbonate can result in the formation of calcareous scale under cathodic protection, which

can precipitate in cracks and influence the cyclic crack opening and closing, thus affecting crack growth rates. Substitute ocean water, as described in ASTM D 1141, usually is a satisfactory substitute for seawater, but some differences have been observed in relation to the rate of calcareous scale formation and the rate of corrosion fatigue growth.

Laboratory solutions should be prepared using the purest chemicals available in distilled or deionized water. Concentrations at the level of parts per million can have profound effects on electrochemistry and corrosion. Several variables must be measured and controlled when simulating an aqueous environment: solution purity, composition, temperature, pH, dissolved oxygen content, and the flow (circulation) rate of the solution.

Acidified Chloride (Ref 90)

Investigations performed in acidified chloride, particularly at high temperature, pose unique problems. These include not only experimental barriers, such as suitable containment and seal materials and sensitivity to low-level oxidizing species, but also interpretational complexities, such as the effects of pitting and crevice processes on enhancement or retardation (by blunting) of crack initiation and growth. Care must be exercised in designing and conducting experiments to ensure personnel and equipment safety and to ensure proper simulation, control, and monitoring of environmental parameters.

Below 100 °C (212 °F). Materials and techniques for solution containment depend on the test-temperature regime. Below the boiling point in solutions containing dissolved oxygen, a primary design concern is to prevent leaks that can damage equipment. A horizontal loading frame helps ensure that sensitive components are not readily damaged by leaks. Additionally, some specimen configurations (such as compact tension) permit the loading linkage to be placed above the solution, simplifying the choice of materials and seal designs.

Testing in deaerated solutions may require careful selection of materials, depending on the sensitivity of the test to low oxygen concentration. For example, the clear, flexible tubing often used in laboratories is very permeable to oxygen. Additionally, some plastics degrade in acidic environments.

Above 100 °C (212 °F), the propensity for pitting and crevice attack increases, the internal pressure rises, the design strength of some materials (e.g., titanium) begins to decrease, and good seal design (particularly for sliding seals) is crucial. Pitting and crevice potential studies show that the resistance of iron- and nickel-base alloys in environments containing chloride decrease from room temperature to about 200 °C (390 °F).

The best approach for selecting pressure boundary materials is to combine published data with recommendations from autoclave manufacturers and metals producers. No assumptions should be made regarding the performance of materials with varying environment. For example, commercial-purity titanium, which is often used in neutral and acidified chloride environments, performs very poorly in acidified chloride under reducing conditions, in acidified environments containing sulfate, and in caustic environments at high temperature. Addition of a small amount (0.2%) of palladium (grade 7) greatly improves resistance in acidified environments that contain sulfate.

Above 200 °C (390 °F), materials selection is particularly difficult. In general, for acidified chlorides, commercial-purity titanium is favored under oxidizing conditions (containing oxygen, iron ion, or copper ion), while zirconium (for example, UNS R60702) is favored for reducing environments. Zirconium alloys are highly intolerant of fluoride. In some cases, high-strength materials, such as Ti-6Al-4V or the Hastelloy C series

alloys, are required, although there is generally a loss in corrosion resistance. Liners of Teflon or tantalum are options in some instances.

Because of its effect on the autoclave and test results, control of the oxidizing nature of the environment is often critical. In addition to oxidizing species, such as oxygen, iron ions, and copper ions, care in the use of externally applied potential is required. The autoclave may be polarized into a harmful regime if ground loops exist, or if it is used as the counterelectrode. A similar result can occur if the autoclave contacts a dissimilar metal.

Because of the rate and extent of expansion on leakage, hot pressurized water poses a serious safety hazard. Each autoclave must have a pressure-relief device attached to it, preferably in a fashion that does not permit bypassing or isolation. Selection of the pressure-relief device must account for the pressure, environment (often gold-coated elements are used in rupture disks), and temperature at which the device actually operates. Additionally, autoclaves, particularly when used in aggressive environments, must be examined regularly for damage resulting from pitting, crevice attack, general corrosion, hydriding, and so forth.

Pressure testing coupled with dimensional checks must also be performed. Manufacturers offer this service and will usually provide the test details. Test pressure and dimensional tolerances are a function of autoclave design, material, and temperature of use. Leaks may also occur in tubing and in valves, which are often difficult to inspect or test. Leaks almost always develop slowly. Nevertheless, a relatively rapid, controlled method for depressurizing the system should be included in the system design.

For some applications, inexpensive miniature autoclaves can be custom fabricated. The small internal volume of these devices is an advantage if a leak occurs in the system.

Liquid Metal Environments (Ref 90)

Liquid metals (sodium, potassium, and lithium, for example) are frequently used in heat-transport applications at elevated temperatures. Such applications include liquid-metal-cooled nuclear reactors, first-wall coolant for fusion devices, and heat-transport systems in solar collectors. These applications often involve cyclic temperature and/or pressure fluctuations, as well as other sources of cyclic stresses. For this reason, knowledge of the fatigue crack propagation behavior of structural alloys in the liquid metal environments is sometimes necessary.

Generally, liquid metals react (in some cases, quite violently) with air and/or water vapor; therefore, testing systems must be designed to exclude both air and water. Three basic designs have been developed to expose the specimen (or crack region of a specimen) to the liquid metal environment, while excluding air, water, and other contaminants.

The simplest method uses a sealed environmental chamber attached to the specimen that completely surrounds the notch and crack extension plane in a compact-type specimen. The small environmental chamber contains the liquid metal, but does not extend to the region of the loading holes; hence, the loading pins, clevis grips, and remainder of the load train are not subjected to the liquid metal environment.

Relative motion across the notch and crack area is accommodated by bellows. This type of system has the advantages of simplicity and low cost. The main disadvantage is that the liquid metal is static; hence, the characteristics of large heat transport systems (e.g., mass transport due to nonisothermal operation) cannot be studied.

The second type of system, a circulating loop, is much more costly to build and operate, but it can be used to study potential effects on fatigue crack propagation such as mass transport, which occurs during carburizing, decarburizing, and dissolution of alloying elements. A third type of system consists of an open crucible (containing the test specimen immersed in static liquid metal) that is located within an inert gas cell or glovebox. This type of system is relatively inexpensive to build and operate, but it has the greatest potential for exposure to air and other contaminants.

Austenitic stainless steels generally have been used in the construction of current systems, and their use has been satisfactory. System designers should consider, however, that under some conditions mechanical properties (tensile, stress rupture, etc.) can be influenced by long-term exposure to liquid metals.

In most cases, fatigue crack propagation rates are lower in sodium environments than in elevated-temperature air environments. The relatively benign nature of sodium environments also leaves the fracture faces in excellent condition for viewing with optical microscopes, scanning electron microscopes, or transmission electron microscopes.

Steam or Boiling Water with Contaminants (Ref 90)

Corrosive environments, such as steam or boiling water with contaminants, come in contact with many structural components. To assess the structural integrity of machine hardware, testing in the environments of concern is essential. Fatigue crack growth testing in corrosive environments requires special care because of the presence of corrosive media and testing complexity.

Environment Containment. Special designs are required to accommodate fatigue crack growth testing in steam or boiling water with contaminants. If the environmental pressure and temperature are moderate, for example at a pressure of 500 kPa (72.5 psi) and a temperature of 100 °C (212 °F), simple stainless steel O-ring sealed chambers can be clamped to each side of the specimen in which cracking will occur. If necessary, the test environment can be circulated through the chamber at a controlled flow rate.

If the environmental pressure and temperature are high, for example in steam at a pressure of 7.2 MPa (1040 psi) and a temperature of 288 °C (550 °F), a chamber that encloses the test specimens must be constructed. Composition of the test environment must be carefully analyzed before and after the experiment, given the variety of possible chemical effects on crack growth rates.

Dissolved Oxygen. Control and measurement of dissolved oxygen levels in the steam environment are of prime importance, because oxygen can affect fatigue crack propagation rate properties. Oxygen content can be controlled by bubbling argon or nitrogen through the water reservoir, or by maintaining a hydrogen overpressure. Oxygen content can be measured by using a colorimetric technique or by using oxygen analyzers that continuously monitor oxygen in the parts per billion range.

Environmentally Assisted Cracking of Nonmetallic Materials

This section briefly reviews the evaluation of environmentally assisted crack growth in ceramics and plastics. However, another important manifestation of environmentally assisted cracking is the interfacial failures between two materials such as metal-polymer (Ref 105 and 106), ceramic-polymer (Ref 107), or metal-ceramic (Ref 108 and 109) interfaces. Evaluating interfacial failures from environmental degradation requires an understanding of adhesion; and further information on this topic is contained in the article “Adhesion Testing” in this Volume.

Environmentally Assisted Cracking in Ceramics

Ceramics are increasingly being used as either dielectrics or protective barriers where stress and environment interact to pose severe conditions. Being very brittle, ceramics in general exhibit very limited toughness compared to materials capable of substantial plastic deformation such as metals and polymers. Moreover, some classes of ceramic materials are extremely susceptible to environmental stress cracking. In glasses, this is manifested by stable slow crack growth at stress intensities substantially lower than fracture toughness determined from fast fracture or in an inert media. This phenomenon, frequently referred to as static fatigue, SCC, or subcritical crack growth, may be observed in almost every ceramic material providing an appropriate environment. Crack-growth kinetics curves for ceramics generally exhibit three distinctive regions as shown in Fig. 25. Region I is controlled by environment crack-tip reactions and may be described with a power-law relationship:

$$v = AK^N \quad (\text{Eq 1})$$

where v is crack velocity and A and N are constants. Equation 1 may be rewritten in a slightly different form:

$$v = v^* \left(\frac{K}{K_c} \right)^N \quad (\text{Eq 2})$$

where v^* is an empirical constant; the smaller N is, the higher the susceptibility to a static fatigue. Region I is of primary importance for design considerations. A linear region II is governed by transport of reactive species toward a crack tip. Finally, region III is determined by an “inert” fracture toughness with possible effects of electrostatic interactions (Ref 110). Controlling mechanisms of crack growth processes in these regions in different ceramic/environment systems are discussed here followed by a review of testing methods and a summary of crack growth data for selected systems.

Fig. 25 Crack growth kinetics curve showing three characteristic regions

Environment/Ceramic Interactions with No Stress

Although frequently regarded as inert, most ceramic materials are reactive when exposed to appropriate environment/temperature combination. Several examples are discussed here with the consideration for governing mechanisms.

Glasses. Glass dissolves slowly in aqueous solutions under ambient temperature. Here, different mechanisms dominate at different pH levels. In acidic solutions, ion exchange between the alkali ions in the glass and hydrogen atoms in the solution occurs (Ref 111). Generally, the exchange rate increases with increasing concentration of alkali ions in the glass composition. An exchange process produces more basic solution near the glass surface. Similarly, the presence of alkaline earth elements such as calcium and magnesium would also result in increase of a local pH. In contrast, for a pure silica glass, hydrolysis of silanol groups adds hydrogen ions to produce a slight acidification (Ref 112).

In basic environments, hydroxyl ions react with the bonds of the network (Ref 113). In general, dissolution rates increase with increasing pH. The increase is particularly steep for $\text{pH} > 9$, where a direct attack on the

silicate network becomes possible (Ref 114). With the network dissolution, atoms of modifiers such as phosphorus and boron may enter the solution, producing a more acidic local environment.

Depending on the exchange rates between a restricted volume such as a crack and a bulk solution, local environment composition inside this volume will be determined by an external environment (sufficient exchange), glass composition (insufficient exchange), or both.

Crystalline Ceramics. It should be noted that environmental reactions for single crystals may depend on the crystallographic orientation of an exposed surface. For the same environment/ceramic system, interaction may be strongly dependent on the structure of a material. A situation is even more complicated for composites where presence of second-phase particles may change susceptibility to an environmental attack.

Oxides. Environmental degradation of metal oxides such as alumina and titania has been observed in some aqueous solutions (Ref 115).

Nonoxide Ceramics. Susceptibility to SCC for a variety of ceramics may be attributed to oxide removal by an active environment. For example, silicon exhibits SCC when exposed to HF acid as revealed by indentation induced cracking (Ref 116). For silicon-base ceramics, integrity and protective properties of silicon oxide may also be critical in determining their environmental susceptibility. For example, SiC is sensitive to environmental attack under a combination of elevated temperatures and vapors containing metal halides (Ref 117) or Na₂SO₄ in oxidizing atmospheres (Ref 118). With the Na₂SO₄ environment, corrosion was attributed to chemical alteration of the normally protective SiO₂. In aqueous acid solutions at ambient temperatures, susceptibility to environmental attack may also depend critically on the formation of silica layers as demonstrated, for example, by Cook et al. (Ref 119) in their study on sintered and reaction-bonded SiC. Here, both materials were passive in aqueous solutions of HCl, HNO₃, and H₂SO₄, but reactive in HF solution. Here, reaction-bonded SiC exhibited a higher degree of degradation. With the above, structural differences may be very important in determining reactivity of a polycrystalline material. Grain-boundary chemistry would be very important notably for nanocrystalline materials where the fraction of grain-boundary material increases substantially.

Environment/Fracture Zone Interactions

The crack-tip environment interactions may be divided into four categories that were originally suggested for glasses (Ref 120), but may be extended to a broader range of ceramic materials.

Bond rupture reactions involve environmental assistance in breaking strained bonds at a near-tip region. With all the complexity of mechanisms that may be involved in subcritical crack growth in ceramics (diffusion, Ref 121, surface relaxation, Ref 122, or plasticity, Ref 123), molecular reactions at the crack tip appear to be a major driving force for subcritical crack growth. Michalske et al. (Ref 124) proposed a model of a reaction between water and highly strained silica bonds in the near-tip region. Here, the ability of water to donate both electrons and protons appears to be critical as shown in Fig. 26 (Ref 125). In excellent agreement with the above model, similar crack velocity versus stress intensity (v/K) curves result from testing in water and other species with the same structure and bonding characteristics as shown in Fig. 27 (Ref 125). Note that with the nearly equal molecular sizes of water and ammonia, kinetic diagrams for these liquids are indistinguishable.

Fig. 27 Crack velocity versus stress-intensity diagram for vitreous silica at room temperature, showing that water, hydrazine, ammonia, methanol, and formamide all have the effect of increasing the rate of slow crack growth. Source: Ref 125

With crack growth rates dependent on the relative humidity rather than concentration of water in an environment (Ref 126), it is implicit that there cannot be an absolutely inert liquid given even a small quantity of water present. The above may be evident from comparison of kinetic curves for water and “dry” nitrogen as shown in Fig. 27. Nearly equal initial slopes indicate similar mechanisms, while a difference between intercepts comes from a difference in activities of water in different environments. In acidic aqueous solutions, the water molecule is also suggested to be the key participant with the resulting mechanisms the same as in water. Analogous mechanisms of water-assisted bond rupture may occur for crystalline materials such as alumina having an ionic/covalent interatomic bond structure similar to silica (Ref 124). In basic solutions, the attack of the OH ion appears to control crack growth rates.

Surface layer formation involves reactions changing the chemical composition and physical properties of a ceramic surface. Surface layers with tensile (Ref 127) stresses may develop facilitating crack growth. Tensile surface stresses may be responsible for a horizontal v/K dependence in the low K region for soda silica glass as shown in Fig. 28. Note that absence of a static fatigue limit in this case may be quite disadvantageous for some practical applications.

Fig. 28 Crack velocity versus stress-intensity diagram showing the stress-corrosion behavior of three different silicate glasses in water. Source: Ref 127

Surface deposition involves preferential deposition of a reaction product in the crack-tip vicinity. For silica-aqueous systems, dissolution-precipitation processes may lead to silica deposits at the crack tip resulting in crack-tip blunting (Ref 127). On the other hand, in some cases, wedging associated with the reaction product inside of a crack may add to the driving force for crack extension (Ref 128).

Intermolecular or Interatomic Surface Forces. Environmental effects may decrease interatomic forces or produce surface bonds. Formation of hydrogen-bond linkages of surface adsorbed water molecules and electrostatic bonds between anionic surface groups (Ref 127) may oppose crack propagation. In contrast, an environment acting as a dielectric would decrease van der Waals dispersion forces (Ref 129). For highly ionic solids such as MgF_2 , ion solvation, a mechanism involving neutralization of the electrostatic attraction between ions may be a dominant mechanism (Ref 130) of static fatigue. Here, media with the high dielectric constants such as water or methanol would be effective in facilitating subcritical crack growth.

Crack Growth Kinetics

Thresholds. In an ideal system with no additional shielding mechanisms, threshold corresponds to an equilibrium where $G = 2\gamma$ and frequencies of bond fracture and bond healing events are equal resulting in zero crack velocity (Ref 131). Local processes in the crack-tip vicinity may affect local crack-tip stress, thus changing local strain-energy release rates. For example, crack blunting due to selective silica deposition would lower the local stress intensity. In contrast, tensile stresses in the near-surface region would increase the local stress intensity. This mechanism results in the absence of a threshold for soda silica glass in water, as mentioned earlier.

Reaction-Controlled Region. This part of the kinetic diagram is determined by environment, material composition, and temperature.

Environment and Material Composition. In general, increasing pH results in decreasing the exponent N of Eq 1, indicating greater susceptibility to SCC as shown in Fig. 29 for a pure silica glass (Ref 132). In this case, the glass did not contain elements that might have affected local crack-tip environment via dissolution reactions.

With the more complex glass composition, the effect is more intricate since crack-tip environment could be strongly affected by the glass composition. This effect may become prevalent at high crack velocities where there is insufficient exchange with an external environment (Ref 133).

Fig. 29 Crack velocity as a function of pH for silica glass. Source: Ref 132

With moisture-containing “inert” media, the activity of water in a given medium will determine a horizontal shift of the v/K curve with respect to that for water as shown in Fig. 27. As already mentioned in the previous section and shown in Fig. 27, bonding and structure of the environmental molecule are very important in determining SCC. Here, identical slopes of v/K curves for reactive media such as water, ammonia, hydrazine, methanol, and formamide indicate similar mechanisms. It should be noted that intercepts of kinetic curves increase with the increasing molecule sizes. The latter effect may possibly be related to crack-tip opening limitations (Ref 125).

Temperature. With the thermally activated governing reaction, there is a strong temperature dependence on crack growth rates as shown in Fig. 30 (Ref 131 and 134). Crack growth kinetics in the reaction controlled region may be described with a recently developed reaction rate model (Ref 131).

$$v = (a \, dc/dA) v_0 \sinh[(G - 2\gamma)/\eta] \quad (\text{Eq 3})$$

Here, a is a characteristic length in the bond rupture process, G is strain-energy release rate, γ is surface energy as affected by an environment, $\eta = 2kT/a^2$, and v_0 is a parameter determined by material properties. This parameter is crack-geometry independent and increases with increasing temperature. It is assumed that a crack may be characterized by a single geometrical crack length parameter c , and this crack length parameter is related to crack area by an expression: $A \propto c^\alpha$. Here, a parameter $\alpha = 1, 2, \text{ or } 3$ depends on the number of dimensions for crack growth. For example, $A = \pi c^2$ for a circular crack geometry. As follows from Eq 3, a parameter 2γ determines the horizontal position of the v/G curve, and $1/\eta$ characterizes the slope and v_0 , its vertical position. For a given material/environment combination, increasing temperature would cause an upward vertical displacement and decrease of the slope of the v/G curve. These trends correspond to experimentally observed temperature effects as shown in Fig. 30. A horizontal shift of the v/G curves increasing with increasing molecule size would also be predicted by Eq 3. Here, increasing molecule size would require higher crack opening displacement and, consequently, an increasing G value.

Fig. 30 Crack growth rates for soda lime glass. Experimental data (Ref 134) are presented with the best fit with the theoretical dependence given in Eq 3 (Ref 131)

Transport-Controlled Region. This region may depend on the activity of reactive species, for example, on a relative humidity as shown in Fig. 31 (Ref 135). Crack geometry and pressure gradients along a crack may also be important in determining transport towards a crack tip.

Fig. 31 Crack velocity curves for sapphire in moist air at different relative humidities. Double-cantilever beam data (constant load) at 25 °C (77 °F). Solid curves are theoretical fits to experimental data. Source: Ref 135

A transport model (Ref 131) describes crack velocity during stage II with the following expression:

$$v = \frac{(p_A^0 - p_A)kG}{(2\pi mkT)^{1/2} E} \quad (\text{Eq 4})$$

where p_A^0 and p_A are the partial pressures of the reactive species in the external environment and at the crack tip, respectively, m is the mass of the reactive species, and k is a dimensionless attenuation coefficient. This parameter characterizes the constraining profile of the crack over which the pressure gradient acts.

Polycrystalline Materials. In addition to structure effects affecting ceramic/environment reactions, as discussed earlier, presence of grain boundaries increase the level of complexity. Variation of grain-boundary chemistry was correlated to the change of crack growth exponents for polycrystalline alumina as determined with dynamic fatigue testing (Ref 136). Occurrence of transgranular versus intergranular fracture would depend on variety of factors. These include crack velocity and chemical composition of grains and grain boundaries (Ref 137).

Testing Methods

Linear elastic fracture mechanics developed for metallic systems are generally applicable to ceramics, as described in more detail in the article "Fracture Toughness of Ceramics and Ceramic Matrix Composites" in this Volume. Classical fracture mechanics techniques for brittle materials are also discussed in Ref 138. Based on the crack extension data, A and N can be determined by curve fitting Eq 1 to a power-law dependence. Among disadvantages in the above method would be a large amount of material necessary to produce a specimen of proper dimensions. A high scatter in experimental data, especially for polycrystalline ceramics, is a disadvantage here.

Dynamic fatigue techniques involve measurement of strength as a function of stressing rate. Both of these methods may be correlated with the following expression (Ref 139):

$$\sigma^{N+1} = [2(N+1)\sigma_{Ic}^N / AY^2 K_{Ic}^N (N-2)\dot{\sigma}] \quad (\text{Eq 5})$$

Here A and N correspond to the same coefficient and exponent in Eq 1, Y is a constant, σ_{Ic} is inert fracture strength, $\dot{\sigma}$ is stressing rate, K_{Ic} is critical stress-intensity factor. Alternatively, Eq 3 may be applied for the analysis of dynamic fatigue results as described in (Ref 127). With this approach, parameters γ , η , and v_0 determined from the best fit to experimental data may be used to predict crack growth kinetics for a specific geometry of interest.

In general, there is a satisfactory correlation between crack growth parameters determined with classical fracture mechanics and dynamic fatigue approaches. However, the role of surface state should be carefully evaluated when interpreting experimental results obtained with the dynamic fatigue data (Ref 140). Also, for reliable results, strength should be measured over at least three orders of magnitude in stressing rates (Ref 141). Introducing a controlled-size flaw for dynamic fatigue testing would be advantageous especially with the flaw size/geometry similar to those expected in service.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Environmental Stress Cracking and Crazeing in Polymers

Environmental stability of a polymer or an interface involving a polymeric material is of critical importance for a variety of applications. Ranging from nanoscale films to pipelines, these include biomedical and microelectronic devices, vessels, cladding, and composite materials. A variety of environments interacting with polymers during processing/service conditions include organic and inorganic liquids, pressurized gases, living tissues, and soils as well as irradiation exposure. In many cases, polymers are utilized to decrease the severity of environmental attack on metallic components. For example, polymer films, coatings, and finishes are designed to prevent environmental degradation of metallic surfaces. Polymer washers are frequently utilized in pipelines in order to eliminate galvanic contacts. Similarly, polymer fillers serve to reduce crevice corrosion effects at joint sites. For any of the above, the preventive effect is determined by the structural integrity of a polymeric component under exposure to an aggressive environment (with or without mechanical stresses). Design considerations for a polymer as a prospective material for a given application should account for:

- How interaction with a given environment affects the polymer microstructure on the molecular scale
- How stress-strain conditions particular to a given application influence these interactions
- How resulting microstructural changes affect plasticity and fracture behavior of a polymer

Note that consideration should be given to the highly time-dependent and temperature-dependent mechanical behavior of polymers as viscoelastic-plastic solids. This introduces an additional challenge if combined with the time-dependent nature of deformation/environment interactions.

Deformation and Fracture with No Environment

Factors determining mechanical behavior of polymers include structure, applied stress-state, testing time, and temperature with respect to T_g , the glass-transition temperature. With an increasing degree of crystallinity and a temperature sufficiently below a glass transition, polymers experience a ductile-brittle transition. Plastic deformation in polymers occurs either via shear yielding, crazing, or plastic instability (necking). Conditions essential for craze formation are temperature above T_g and a dilatational hydrostatic stress-state component. Dilatational stress results in formation of highly voided regions with so-called fibrils. These are fiberlike semicohesive structures capable of sustaining significant stress levels. In many cases, craze zone evolution at the vicinity of a nucleating or advancing crack plays an essential role in the fracture process in amorphous (Ref 142) and crystalline (Ref 143) polymers.

Polymer/Environment Interactions with No Stress

The main issues dealing with solid polymer/environment interactions are the penetration mechanism (diffusion) and change in polymer properties determining its mechanical behavior. Possible environmentally related changes include change in degree of crystallinity, polymer surface energy reduction (Ref 144), decrease of T_g (plasticizing), and dimensional change of a polymer (swelling). The latter change can be expressed in terms of the coefficient of hydroelasticity. This parameter is sensitive to both the chemical composition and the physical structure of a polymer (Ref 145). Finally, dissolution of a polymer may occur.

Environmentally Assisted Cracking and Crazing

Several important points need to be emphasized here, as shown in Fig. 32. First of all, environmentally enhanced cracking and/or crazing may occur even in “inert” media that does not affect a given polymer under no applied stress (Ref 146). Moreover, with the absence of environmental effects under simple tension, environmental stress crazing and/or cracking may occur under more complex stress states (Ref 147). For active media, stress may enhance environmental effects such as plasticization and swelling. This may become critically important at the highly stressed crack-tip region. In addition, for fast-moving cracks (200–650 m/s, or 650–2130 ft/s), a crack-tip temperature increase up to 500 K is possible (Ref 148). Thus, even for medium growth rates with a small environmentally induced decrease in T_g and/or a small temperature increase, local effects at the crack tip may be significant. Organic plasticizers or even inorganic salt solutions (Ref 149) are known to affect tensile properties of some polymers, for example, nylon. Local stress-enhanced crack-tip environmental interactions may induce a substantial decrease in the Young's modulus, thus easing local deformation. With the above examples, it becomes evident that predictions for environmental crazing or cracking for a given polymer/environment system may not be based exclusively on the interactions with no stress applied. Also, local crack-tip conditions need to be accounted for. It should also be noted that both cracking and crazing kinetics must be considered in assessing environmental effects. For example, high craze rates but more stable craze structure may result in longer time to complete failure. A brief consideration of the mechanisms of environmental stress crazing and cracking is given here as well as references for most commonly used experimental procedures. Examples for selected polymer/environment systems are included with consideration for dominating mechanisms and critical parameters.

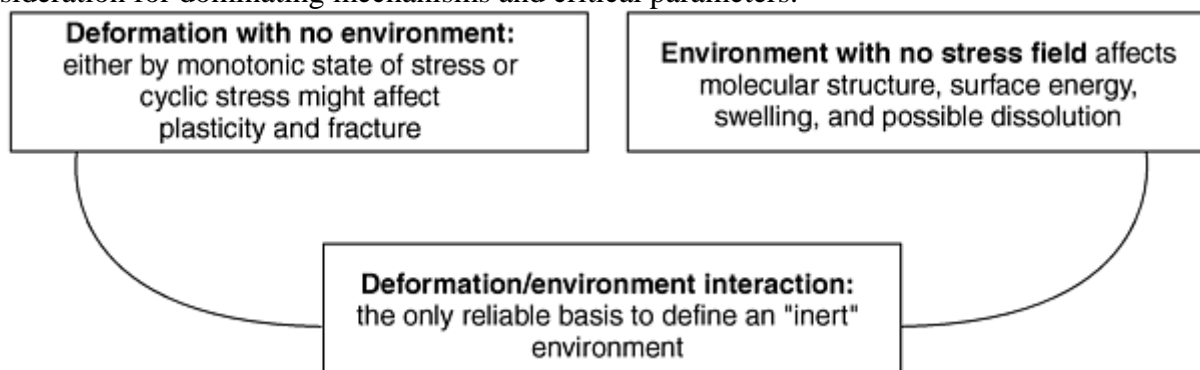

Fig. 32 Polymer/environment/stress interactions

Mechanisms in Liquid Media

Liquid Transport through a Porous Craze Zone or a Crack. Suggested driving forces are: (a) atmospheric pressure as the craze voids are under a vacuum, (b) capillary pressure in the craze or a crack, and (c) superimposed hydrostatic pressure (Ref 150). Viscosity of the liquid and a spreading coefficient with respect to a polymer are critical parameters controlling liquid transport through a crack and/or a craze zone. Specific liquid/polymer interactions may also be involved here.

Liquid Fracture Zone Interactions. An active media absorption at the fracture zone surface is followed by local changes in polymer properties. For some polymers, for example, polyethylene, stress enhances liquid absorption. Thus, under exposure to a solvent, enhanced swelling is expected in the highly stressed near-tip regions. It seems that solvent swells and plasticizes both the craze fibrils and the layer of bulk polymer contiguous to the craze surface. One of the consequences is believed to be a stress relaxation in a fibril. As the stress relaxes in a fibril, new fibrils need to be generated to balance the stress concentration at the crack tip. Thus, the craze tip advances. There is some evidence that inorganic media such as metal salt solutions can also diffuse into polymer and cause stress relaxation in a fibril (Ref 149). It is suggested that for media resistant to swelling, local plasticization may increase the effective radius of curvature at the crack tip, thus reducing the stress concentration (Ref 151).

Craze and/or Crack Growth Kinetics. For a variety of glassy polymer/liquid systems, crack growth rate versus stress-intensity dependencies exhibit three characteristic regions (Ref 147). In region I, crack growth rate increases rapidly with the stress-intensity factor once a threshold value is exceeded. This region is believed to be controlled by environment/polymer interactions. In region II, crack growth rate is controlled either by hydrodynamic flow properties of the environment (Ref 152), or by velocity of adsorption at the fracture process zone (Ref 153). For some systems, a region III exists where the fracture process is controlled by the mechanical properties of a material in air (Ref 154). However, in some cases, K_{Ic} in the presence of an environment may be either decreased or increased. For example, environmentally enhanced crazing results in an increased K_{Ic} for polymethylmethacrylate (PMMA) exposed to organic solvents (Ref 147). In this case, K_{Ic} may also depend on crosshead speed since the amount of crazing formed at the tip can vary with crack velocity (Ref 155). At the same time, the reader is cautioned to be aware that such solvents could enhance crack growth kinetics well below K_{Ic} . If a solvent causes dissolution and not crazing, K_{Ic} can be reduced (Ref 147). In some cases, crack deceleration due to crack-tip blunting is observed following region II (Ref 156). It should become clear that different solvent/polymer interactions may produce enhanced or decreased crack growth rates or final fracture, requiring case-by-case evaluation. A level of complexity increases substantially if a polymer is subjected to a cyclic rather than monotonic load. Here, crack growth may be highly dependent on the test frequency and loading amplitude as well as the stress-intensity factor range (Ref 157).

Mechanisms in Gaseous Media

Gas Fracture Zone Interactions. In general, hydrostatic pressure will increase T_g . However, if the pressurizing environment is soluble in the polymer, one might expect an initial decrease in T_g as a polymer is plasticized by an environment (Ref 158). An effect of gases such as argon, oxygen, and carbon dioxide close to their condensation point (high thermodynamic activity) is to reduce the surface energy of a crystalline polymer, facilitating the creation of a new surface in the holes and voids of the craze (Ref 159). On the other hand, high dilatational stress at the tip of an incidental flaw or an existing craze promotes enhanced absorption of a gas.

Craze Growth. The locally absorbed gas acts as a plasticizer, easing the flow involved in the craze nucleation and growth. The above effects are suggested to explain the ductile behavior of crystalline polymers between liquid nitrogen and room temperature. In the absence of a gas or at temperatures sufficiently above a gas condensation point, the crystalline material is rather brittle with a very limited extent of crazing. Craze velocity is directly related to the diffusion coefficient of a gas in a polymer (Ref 160).

Testing

Smooth specimens are commonly used when craze initiation and growth are investigated (Ref 150). If diffusivity of an environment is high, a constant strain rate tensile test may be utilized (Ref 150, 156). For low-diffusivity liquids, a creep test may be a better option (Ref 156). Note that for some inert liquids, no crazing

occurs under tensile load. However, for the same polymer/environment, crazing may occur readily under torsion (Ref 161) or tension with superimposed hydrostatic compression (Ref 162). Thus, evaluation of a polymer for a given application requires testing under loading conditions corresponding to those expected during service. An apparatus for tension or compression superimposed with the hydrostatic pressure and an environmental chamber may be obtained from Ref 163 and 164.

Environmentally assisted crack/craze propagation can be evaluated with double-edge (Ref 149) or single-edge notched (Ref 153) specimens. Razor-blade cutting is a common precracking technique. A procedure for obtaining sharp reproducible cracks of controlled length is detailed in Ref 165. Good results may also be accomplished with fatigue (Ref 166) or controlled impact (Ref 167). With a sustained load apparatus and an environmental chamber, as described in Ref 168, environmentally assisted craze and crack growth kinetics may be evaluated under constant load conditions (Ref 149, 153, and 169).

To summarize this section on environmentally induced degradation of polymeric systems, a number of the important chemomechanical factors are given in Table 4, and few examples of environmental interactions are summarized in Table 5.

Table 4 Summary of chemomechanical factors influencing environmental cracking and crazing in polymers

Factor	Considerations
Polymer	Degree of crystallinity
	Molecular weight
	Glass transition temperature
	Coefficient of hydroelasticity
	Solubility
Medium	Viscosity
	Spreading coefficient on a polymer
	Type: active or inert
	For active media: solubility as compared to that for a polymer; frequently, crack growth rates increase with the decreasing difference between solubility of a polymer and that of a liquid ($\delta_1 - \delta_P$) (Ref 149). Also, how much does it change T_g of a polymer; Q/R, a ratio of ionic charge to the ionic radius, is a critical parameter for several salt solutions (Ref 149).
Temperature	Testing temperature and a local crack-tip temperature (as increased locally at a tip of a rapidly growing crack of a) with respect to T_g (as decreased by an environment)
Loading Stress state	Dilatational component (necessary for crazing)
	Hydrostatic compression (suppresses crazing; facilitates liquid flow towards a tip of a moving crack) (Ref 150)
Strain rate	Affects craze and crack growth rate
Crack growth rate	Influences craze growth
	For high crack-growth rates: local temperature elevation at the crack tip (Ref 148), liquid transport (Ref 152), or absorption-controlled mechanisms (Ref 153)

Table 5 Examples of environmental interactions for selected systems

Material	Environment	Sample geometry	Loading	Environmental effects measured in terms of:	Suggested mechanism	Critical parameters
Low-density polyethylene (Ref 153)	Methanol, ethanol, ethyleneglycol, diethylene triamine DETA-NaOH	Single notched (sharp crack)	Sustained load 0.13 MPa applied stress (yield stress 11.3 MPa)	Crack velocity versus applied stress intensity	Micelles absorption on the fibril surface with the subsequent	Highest crack-growth rates with the lowest ($\delta_1 - \delta_P$) crack-growth rates

	(detergent)				fibril fracture	increasing with the increasing detergent concentration
Nylon (Ref 149)	Aqueous salt solutions: CaCl, LiCl, MgCl	Precracked tensile bars	Constant applied stress intensity	Craze growth velocity	Environment-induced decrease in T_g . Relaxation-controlled craze growth	The higher Q/R ratio, the more significant T_g reduction, the more enhanced craze growth
Polystyrene (Ref 150)	Silicon oil	Smooth cylindrical	Tension or tension with superimposed hydrostatic compression	Change in crazing behavior	Liquid flow controlled as affected by a stress-state hydrostatic compression facilitates liquid flow toward a crack tip	Type of a stress state

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Nanomechanical Testing

Nanomechanical techniques such as nanoindentation and nanoscratch methods have emerged from conventional hardness testing as described in more detail in the article “Instrumented Indentation Testing” in this Volume. Nanoscaled depth and load resolution available with the commercial nanoindenters allows probing of material properties at very shallow penetration depth. During a typical indentation test, an indenter is driven in and out of a surface under investigation. Resulting load-displacement curves serve as a basis for the mechanical behavior evaluation (Ref 170). Indentation curve discontinuities may be indicative of plasticity onset or various fracture events. Additional insight can be gained by examining a residual indentation cavity (Ref 171, 172, and 173). Here, features of plastic deformation and fracture would be of primary interest. One instrument, the Hysitron Triboscope, attached to an atomic force microscope (AFM), combines nanoindentation with the imaging of an indented area. This becomes especially advantageous for the evaluation of time-dependent phenomena. With nanoindentation, basic elastic-plastic properties such as Young's modulus (Ref 170) and yield stress (Ref 173) can be determined. Indentation-induced cracks allow evaluation of fracture behavior for bulk materials and thin films (Ref 174, 175, and 176).

During a continuous microscratch test, controlled vertical displacement alongside with the normal and tangential loads are recorded while an indenter is being moved across a surface under applied load. Examination of a residual scratch groove provides insight into evolution of plastic deformation and fracture with increasing load.

Note that for the systems where controlling flaws have a contact origin, nanoindentation and nanoscratch appear to be the most appropriate evaluation techniques. That is, they account for a specific stress-strain state around cracks initiated with normal or sliding contact such as environmentally enhanced fretting fatigue.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Evaluation of Nanoscale Environmental Effects

Here, indentation curve analysis may be combined with the imaging of a residual indentation cavity or a scratch groove. While both AFM and scanning electron microscopy (SEM) may provide high resolution images, AFM gives the advantage of quantitative evaluation of nanoscale fracture and plasticity features as discussed in detail in the section “Scanning Probe Microscopy.”

Environmentally Affected Plastic Deformation. For indentation into dislocation-free single-crystal materials, a characteristic discontinuity of a load-displacement curve may be indicative of plasticity initiation. Similar effects may be observed for coarse-grained polycrystalline materials where indentation size is small compared with the grain size.

With the *ex situ* testing of sapphire surfaces aged in different environments, clear evidence of chemomechanical effects was obtained by Hainsworth et al. (Ref 177). Here, presence of a damaged surface layer was suggested to explain decreased plasticity initiation loads after environmental exposure.

Several researchers have investigated the role of chemical or electrochemical oxide film removal on crystal plasticity (Ref 178, 179, and 180). With the potentiostatic control (Ref 178 and 180), it is possible to promote either oxide dissolution or growth by application of appropriate potential steps. It was discovered that electrochemical oxide film removal resulted in a dramatic decrease of the materials strength. With the electrochemical repassivation, an ability to support near theoretical strength was returned to the material. An example is shown in Fig. 33 (Ref 181), where indentation curves correspond to tests under different surface conditions controlled via applied potential. The yield point is influenced strongly by the presence of a passive film on titanium (Ref 181). A grade II titanium was vacuum annealed producing alpha grains of approximately 50 μm in diameter. Using the Hysitron Triboscope in conjunction with a Park Scientific Autoprobe CP scanning probe microscope, individual grains were imaged in a 0.01 *N* sulfuric acid solution, and a grain large enough to perform multiple indentations with no overlap was selected for indentation. This sample was then electrochemically polarized using a three-electrode system, with the titanium acting as the working electrode, a Ag/AgCl reference electrode, and a platinum counterelectrode. After identifying an appropriate grain, indentations were made using a Berkovich indenter tip after stepping the potential to 0.68 V above open circuit, showing reproducible yield points. The tip was then withdrawn 100 μm from the surface, and the passive film was removed by holding the specimen at 0.03 V above open circuit until the current began to increase (signifying the removal of the passive film). Indentations at this point show no significant yield point. However, after stepping the voltage back to the passive regime (0.77 V above open circuit) the yield point is recovered, and after 5 min the initial and newly passivated surface show almost identical indentation curves.

Fig. 33 Four indentations into grade II titanium in 0.01 N sulfuric acid during electrochemical polarization. The first indentation was made in the passive regime, at 0.63 V above open circuit (OC) by stepping to that potential from open circuit. The second was after removing the passive film by holding at potential 0.03 V above open circuit for about 10 min. The potential was then stepped to 0.77 V above open circuit, and indentations were made immediately after stepping and after 5 min at that potential. Source: Ref 181

To investigate hydrogen effects on yield initiation in 316 stainless steel, hydrogen charged and noncharged samples have been evaluated under indentation load (Ref 182). Reproducible load excursions at an average load of 200 μN were observed for noncharged samples as shown in Fig. 34(a) (Ref 182). These were attributed to the plasticity initiation as unloading just prior to an excursion load yielded no residual deformation. For comparison, indentation testing was carried immediately after hydrogen charging. Here, two samples charged at different conditions have been evaluated. Sample C1 was charged at 500 mA/m^2 for 6 h, and sample C2 was exposed to charging at 10 mA for 6 h. Figure 34(b) (Ref 182) shows indentation testing results for sample C1. As shown in this figure, yield initiation occurred at 650 to 700 μN immediately after charging. With increasing time, the load for plasticity initiation decreased down to 300 μN . For sample C2, yield initiation was observed at 350 μN instantly after charging. Then, the excursion load decreased approaching 200 μN . It became evident that the yield initiation load increases with increasing initial hydrogen concentrations. Hydrogen outgasses with time, causing the yield points to decrease back to its initial value. The above would agree with the notion that hydrogen suppresses dislocation nucleation and/or kinetics.

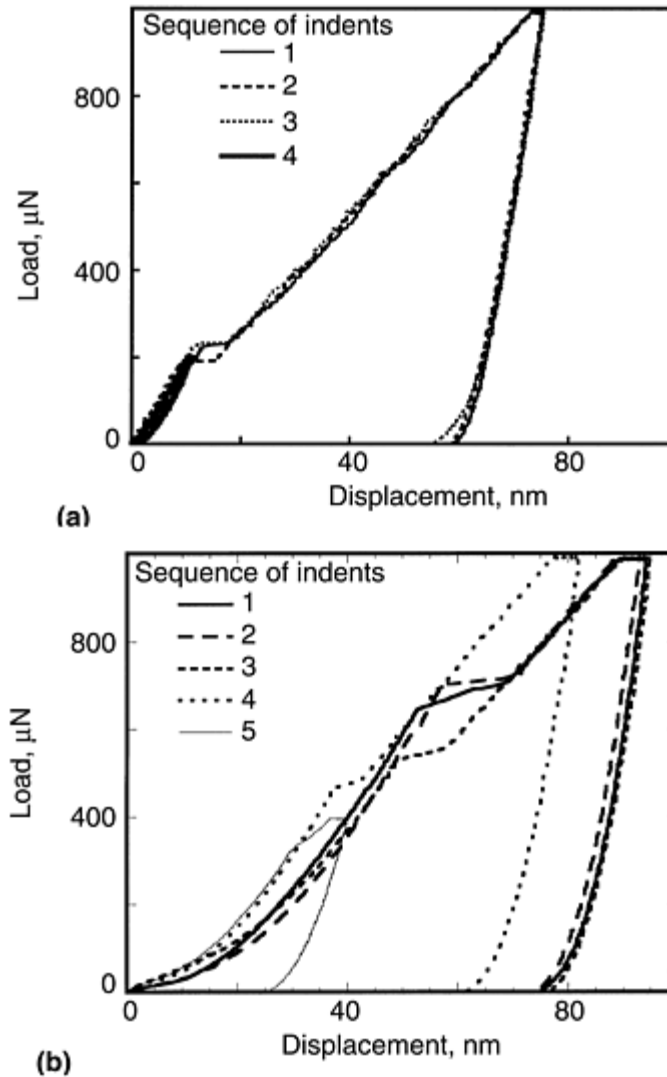

Fig. 34 Hydrogen effects on yield initiation in 316 stainless steel. (a) Noncharged sample. Curves 1 to 4 represent a sequence of indents over a 35 min time frame. (b) Indentation immediately after charging. Sample C1 at high hydrogen concentration. Time increases for curves 1 to 5 over a 35 min time frame. Source: Ref 182

Hydrogen/plasticity interactions were further explored with continuous scratch testing (Ref 181 and 183). Evaluation in a low-load regime allowed probing of near-surface hydrogen-saturated regions. A marked difference in both localized plastic deformation and microfracture has been observed as shown in Fig. 35 and 36. Here, both scratch grooves correspond to the same level of applied load. Atomic force microscopy enabled a quantitative analysis of environmental effects on plasticity and fracture. A comparison of plastic deformation characteristics for hydrogen-charged and noncharged surfaces as obtained from AFM measurements is shown in Table 6 (Ref 182 and 183).

Table 6 Hydrogen-charging effects on plastic deformation characteristics

Surface features	Noncharged	Charged
Along the pileup		
Slip-step spacing (s), nm	100	290
Slip-step height (h), nm	15	95
Perpendicular to the pileup		
Slip-step spacing (s), nm	105	260
Slip-step height (h), nm	13	16

Crack Initiation. Examples where nanomechanical testing in conjunction with the imaging techniques has been applied for crack initiation studies in different types of materials are provided in this section.

Metals. With the continuous microscratch under increasing load, crack initiation onset can be determined by analyzing a cracking pattern along a scratch groove. Location of the first crack is correlated to the magnitude of the applied load as determined based on the known loading and horizontal indenter motion rates. For the same load level, microcracking was evident for a hydrogen-charged sample, while there no cracks were seen for a noncharged sample, as shown in Fig. 35 and 36 (Ref 182). This suggests decreased stress for crack initiation in hydrogen-charged material.

Ceramics. The initiation of radial cracking in Vickers indentation of soda-lime glass was found to be strongly rate and environment dependent (Ref 184). With sufficiently long contact times, radial cracking initiated during unloading. For short contacts, crack initiation occurred after a complete load removal with significant scatter in delay times. These decreased with increasing peak load and increasing water content in an environment. Observed phenomena were interpreted in terms of incubation times necessary to develop a critical nucleus for crack initiation. With SEM, constrained shear fault were identified as possible crack precursors. A proposed theoretical model considers a two-step process with precursor faulting followed by crack growth to an instability. Moisture may influence both of these steps: first by enhancing the initiation of decohesion and second by slow crack growth. A stress-intensity factor analysis for the microcrack extension in residual-contact and applied-stress fields was used in conjunction with appropriate fracture conditions to determine critical instability configurations (Ref 185).

Polymers. Indentation-induced cracking in polystyrene (Ref 186) originated at the tip of a yielded zone where a characteristic shear band pattern has been observed. Based on a slip-line field analysis for the stress distribution within a plastic zone and elastic analysis for a surrounding material, the principal stresses corresponding to crack initiation were estimated. These were found to be similar to crazing initiation stresses for this material.

An approach may possibly be extended to evaluate environmental effects on cracking and crazing initiation in polymers.

Evaluation of Environmentally Assisted Crack Growth

Y. Katz, N. Tymiak, and W.W. Gerberich, University of Minnesota

Methods for Small-Volume Testing

Indentation and Continuous Scratch-Induced Cracking. Both cohesive and adhesive fracture are considered here.

Indentation-Induced Cohesive Cracking. Different systems of cracks may form during loading and unloading parts of an indentation process. These systems include cone, median, radial, half-penny, and lateral as discussed in a recent review (Ref 187). Sequential occurrence of different cracking patterns is determined by combination

of the evaluated material and an indenter geometry (Ref 188). With the blunt indenters, such as large radii spheres, cracking initiation would normally precede plasticity onset (Ref 187). In contrast, sharp pyramidal or conical indenters would initiate plastic deformation prior to cracking (Ref 187). Once yielding takes place during an indentation test, residual plastic deformation exists after load removal. Accommodation of this plastically deformed volume by surrounding elastic material results in a residual stress field. These stresses act to open an indentation crack in a similar way as a center-loaded point force. The stress intensity in this case can be approximated with (Ref 189, 190):

$$K_{\text{residual}} = \chi P/c^{3/2} \quad (\text{Eq 6})$$

where P is an indentation load, c is crack length, and χ is a characteristic constant for a given combination of material and indenter. It should be noted that with the absence of an additional external load, an indentation-induced crack is stable as the stress intensity decreases with increasing crack length. With the applied external load, the total stress intensity becomes (Ref 189, 191):

$$K_{\text{tot}} = K_{\text{app}} + K_{\text{res}} = \psi \sigma_{\text{app}} \sqrt{c} + \chi \frac{P}{c^{3/2}} \quad (\text{Eq 7})$$

where ψ is a geometrical factor, and σ_{ap} is applied stress.

Indentation-Induced Adhesive Fracture. For ductile films on brittle substrates, indentation-induced plastic deformation in a film provides a driving force for delamination (Ref 192, 193, and 194). With brittle films on ductile substrates, the delamination driving force more often comes from plastic deformation of the substrate (Ref 195, 196).

Continuous Scratch. Scratches are produced by traversing a surface at constant or continuously increasing vertical displacement. While the pattern of indentation cracking is defined by elastic-plastic properties of an indented material, indenter geometry, and load range, scratch-induced cracking depends on all of the above parameters plus several others. These factors include scratch velocity, indenter/surface adhesion, and a friction coefficient. With much more complicated stress/strain state and possible involvement of material time-dependent behavior, mechanisms of scratch-induced deformation and cracking are not well understood yet. Given the complexity of the problem, quantitative information gained from a scratch test should be interpreted very cautiously. To compare two materials, it is preferable to test them both using the same loading conditions. These would include indenter geometry, loading, and horizontal drive velocity. Similarly, such evaluations would require testing of both environmentally exposed and nonexposed samples under the same loading conditions. Theoretical analyses for scratch-induced cohesive and adhesive fracture may be obtained from Ref 197, 198, 199, 200, and 201, respectively.

Indentation or scratch “precracking” followed by application of an external load under exposure to an environment may be used. Possible geometries include a disk (Ref 202, 203) or cantilever beam specimen (Ref 204). Most commonly used is four-point bending test (Ref 205). Attention should be paid to possible effects of elastic anisotropy and asymmetry of indentation-induced plastic deformation and fracture (Ref 190). Crack extension can be monitored with optical microscopy (Ref 206). Crack arrest marking can be generated on the fracture surfaces by temporary unloading during subcritical crack growth (Ref 207).

Crack extension is driven by a combined action of applied load and residual indentation induced tensile stresses as given by Eq 7. Analysis of this equation implies stable crack growth providing $K \geq K_c$ and $dK/dc < 0$. Instability will occur as $dK/dc = 0$ and $K = K_c$. From these instability conditions, fracture strength, and critical crack length under inert conditions may be obtained:

$$\sigma_m = \frac{3K_{\text{Ic}}}{4\psi c_m^{1/2}} \quad (\text{Eq 8})$$

$$c_m = \left(\frac{4\chi P}{K_{\text{Ic}}} \right) \quad (\text{Eq 9})$$

Fatigue strength of an indented specimen may be expressed by the following function of stressing rate (Ref 208):

$$\sigma_f = (\beta' \dot{\sigma}_a)^{1/(n'+1)} \quad (\text{Eq 10})$$

where $n' = 0.75N + 0.5$ and

$$\beta = \frac{(2\pi n')^{1/2} \sigma_m^{n'}}{v^*}$$

with N and v^* being parameters used in Eq 2.

Values of n' and β' may be determined from the slope and the intercept of the dynamic fatigue curve, respectively. Examples of dynamic curves for soda-lime glass in various environments are shown in Fig. 37 (Ref 209). Here, low susceptibility to environmental crack growth in silicon and motor oils is evident from large values of n' exponents.

Fig. 37 Dynamic fatigue results of indented soda-lime glass specimens. Indent load, 19.6 N. Error bars represent ± 1.0 standard deviation. Source: Ref 209

Annealing or surface layer removal may be utilized to remove residual stresses prior to testing. Neglecting residual stress would result in a significant strength underestimate as shown in Fig. 38 (Ref 210). This in turn would give an overestimate of environmental susceptibility as determined via crack growth kinetics parameters from Eq 10.

Fig. 38 Dynamic fatigue response for indented soda-lime glass disks broken in water. Vickers indent load, 5 N. Source: Ref 210

It should also be stressed that in general, parameters χ and ψ are not constant but may be affected by changing crack geometry and interference between different crack systems (Ref 211). An example of changes in these parameters during different crack evolution stages is shown in Fig. 39.

Fig. 39 Complete trends of the shape factor (ψ) and of the residual stress factor (χ) as a function of the crack size (c). Source: Ref 211

Contact Mechanics Testing under or Following Exposure to an Environment. Environmental effects may be assessed by measuring an extent of indentation or scratch-induced cracking with and without an environment. A driving force here would be indentation-induced residual stresses as given by Eq 6. Based on the dynamic fatigue data, an analytical expression for a time dependent crack extent, $c(t)$ may be obtained (Ref 210). Fatigue parameters may be determined from plotting c versus t in double-log coordinates. However, values of crack growth exponents obtained from residual indentation stress driven slow crack growth were significantly different from these obtained in the same environments with dynamic fatigue (Ref 210). Moreover, postindentation crack growth in motor oil exhibited a significant environmental susceptibility in contrast to static fatigue testing. It was suggested that presence of the limited amount of water present in the oil would only be effective in the small crack regime corresponding to a residual stress driven crack extension. Whatever the reason, for the observed discrepancy design considerations would require using testing conditions most closely approximating service conditions. Special considerations required for cohesive and adhesive fracture in thin films are mentioned below.

Environmentally Assisted Crack Growth in Thin Films. Sensitivity to environmentally assisted cracking for small volumes often differs from that for bulk materials. Possible reasons include microstructural differences, one of the most important being nanoscale grain sizes for submicron thick films. With a nanoscale grain size, the fraction of grain-boundary material increases dramatically. With grain boundaries being the preferred pathway for diffusion, diffusivity increases with the grain size reduced to the nanoscale. Also, with the grain boundaries being more prone to preferential dissolution, susceptibility to environmental attack is enhanced for nanocrystalline materials. In addition, increasing fraction of grain boundaries results in elevated internal stresses in a film. These stresses combined with the ones produced by substrate constraint may affect resistance to crack propagation. Similarly, when indentation depth scales with the depth of any surface affected layer, stresses in this layer may affect indentation-induced crack growth. Tensile stresses would favor indentation crack propagation as opposed to compressive ones. In addition, stress relaxation could be promoted by either sign residual stress at higher temperatures. While the initial residual stress would tend to promote slow crack growth, any relaxation with time would diminish the driving force.

Environmentally Affected Thin-Film Adhesion. Contact mechanics methods provide the following advantages for thin-film adhesion testing:

- There is no possibility for interfacial property changes.
- Very small amount of material is required for testing.
- Testing can be carried under temperature, potentiostatic, or environmental control.
- Very simple sample preparation and testing procedure.

Indentation-induced blister for charged and noncharged samples are shown in Fig. 40 (Ref 182). Here, the larger size of an indentation-induced delamination for hydrogen-charged sample indicates hydrogen charging induced adhesion degradation.

Scanning Probe Microscopy

Scanning probe microscopes (SPM) such as the scanning tunneling microscope (STM) (Ref 212), AFM (Ref 213, 214, 215), and their modifications provide imaging and *quantitative* evaluation of atomic level surface features. One important feature is that atomic-scale resolution can be gained without an extensive sample modification such as thinning and/or polishing. Thus, small-scale aspects of plastic deformation and fracture can be observed without influence of sample preparation. Also, quantitative information can be obtained from *direct* three-dimensional topography measurements. An advantage of SPM is evident when three-dimensional strain (Ref 216) and stress (Ref 217) fields near a tip of a brittle crack can be obtained directly as compared to a rather complicated procedure based on digitizing of SEM images (Ref 218). Another example could be resolving nanoscale plasticity features associated with a brittle crack (Ref 216). Both STM and AFM can be easily operated in a variety of environments (Ref 219, 220). While the STM cannot be utilized for insulators, AFM works equally well on conducting, semiconducting, or insulating surfaces such as polymers and ceramics. With the controlled potential applied to the metallic (Ref 221) or semiconductor (Ref 222) surface, various solid/electrolyte interactions such as metal dissolution/electrodeposition or passive film evolution can be visualized and evaluated quantitatively. Here, surface topography mapping provides an accurate spatial distribution of material removal or deposition rates. Examples include localized dissolution enhanced by indentation-induced plastic deformation (Ref 223) and grain-boundary sensitization (Ref 224, 225). In the latter, selectively placed indents have been utilized to reveal preferential dissolution along chromium-depleted near-boundary regions (Ref 225). With the alternating periods of loading and SPM observations, an insight into crack initiation and growth can be gained. The above approach has been successively applied to initial stages of environmentally assisted fatigue (Ref 226, 227). In the latter, number of cycles for crack initiation was correlated to a damage parameter accounting for *global* plastic strain alongside with the corresponding *local* plasticity characteristics. These include persistent slip band (PSB) spacings and heights as measured with the SPM. Environmental effects on the fracture onset under increasing monotonic load can be evaluated from nanoscratch testing combined with the AFM imaging as described in more detail in the preceding section. Invention of loading devices operated in conjunction with the SPM (Ref 224, 228) enabled a continuous monitoring of crack initiation and propagation. In situ observations of loaded cracks in vacuo and laboratory air (Ref 224) show a clear environmental effect apparent from the sharpness of an air-exposed crack as opposed to blunting occurring at a crack tip in vacuo. Additional advantages come from indentation combined with the AFM pretest and posttest imaging of an indented area as detailed in the previous section.
