

ASM HANDBOOK[®]

VOLUME

8

*Mechanical
Testing and
Evaluation*

Publication Information and Contributors

Introduction

Mechanical Testing and Evaluation was published in 2000 as Volume 8 of the *ASM Handbook*. The Volume was prepared under the direction of the ASM Handbook Committee.

Volume Coordinator

The Volume Coordinators were Howard Kuhn, Concurrent Technologies Corporation and Dana Medlin, The Timkin Company.

Foreword

The new edition of *ASM Handbook, Volume 8, Mechanical Testing and Evaluation* is a substantial update and revision of the previous volume. This latest edition of Volume 8 contains over 50 new articles, and the scope of coverage has been broadened to include the mechanical testing of alloys, plastics, ceramics, composites, and common engineering components such as fasteners, gears, bearings, adhesive joints, and welds. This new scope is also complemented by substantial updates and additions in the coverage of traditional quasi-static testing, hardness testing, surface testing, creep deformation, high strain rate testing, fracture toughness, and fatigue testing.

The efforts of many people are to be commended for creating this useful, comprehensive reference on mechanical testing. The ASM Handbook Committee, the editors, the authors, the reviewers, and ASM staff

have collaborated to produce a book that meets high technical standards for the benefit of engineering communities everywhere. To all who contributed to the completion of this task, we extend our sincere thanks.

ASH Khare

President, ASM International

Michael J. DeHaemer

Managing Director, ASM International

Preface

At least three major trends have occurred since the last edition of Volume 8 in 1984. First, concurrent engineering is growing in importance in the industrial world, and mechanical testing plays a major role in concurrent engineering through the measurement of properties of product design, as well as for deformation processing. *ASM Handbook*, Volume 20, *Materials Selection and Design* (1997) reflects this focus in concurrent engineering and the broadening spectrum of involvement of materials engineers. Second, new methods of measurement have evolved such as strain measurement by vision systems and ultrasonic methods for measurement of elastic properties. This area will continue to grow as miniaturized sensors and computer vision technologies mature. Third, computer modeling capabilities, based on fundamental continuum principles and numerical methods, have entered the mainstream of everyday engineering. The validity of these computer models depends heavily on the availability of accurate material properties from mechanical testing.

Toward this end, this revision of *ASM Handbook*, Volume 8 is intended to provide up-to-date, practical information on mechanical testing for metals, plastics, ceramics, and composites. The first section, "Introduction to Mechanical Testing and Evaluation," covers the basics of mechanical behavior of engineering materials and general engineering aspects of mechanical testing including coverage on the accreditation of testing laboratories, mechanical tests in metalworking operations, and the general mechanical tests of plastics and ceramics. The next three sections are organized around the basic modes of loading of materials: tension, compression bending, shear, and contact loads. The first four modes (tension, compression, bending, and shear) are the basic simple loading types for determination of bulk properties of materials under quasi-static or dynamic conditions.

The third section, "Hardness Testing," describes the various methods for indentation testing, which is a relatively inexpensive test of great importance in manufacturing quality control and materials science. This section includes new coverage on instrumented (nano-indentation) hardness testing and the special issues of hardness testing of ceramics. Following the section on hardness testing, the fourth section addresses the mechanical evaluation of surfaces in terms of adhesion and wear characteristics from point loading and contact loading. These methods, often in conjunction with hardness tests, are used to determine the response of surfaces and coatings to mechanical loads.

The next four sections cover mechanical testing under important dynamic conditions of slow strain rates (i.e., creep deformation and stress relaxation), high strain rate testing, dynamic fracture, and fatigue. These four sections cover the nuances of testing materials under the basic loading types but with the added dimension of time as a factor. Very long-term, slow rate of loading (or unloading) in creep and stress relaxation is a key factor in many high-temperature applications and the testing of viscoelastic materials. On the opposite end of the spectrum, high strain rate testing characterizes material response during high-speed deformation processes and dynamic loading of products. Fracture toughness and fatigue testing are the remaining two sections covering engineering dynamic properties. These sections include coverage on the complex effects of temperature and environmental degradation on crack growth under cyclic or sustained loads.

Finally, the last section focuses on mechanical testing of some common types of engineering components such as gears, bearings, welds, adhesive joints, and mechanical fasteners. A detailed article on residual stress measurements is included, as residual stress from manufacturing operations can be a key factor in some forms of mechanical performance such as stress corrosion cracking and fatigue life analysis. Coverage of fiber-reinforced composites is also included as a special product form with many special and unique testing and evaluation requirements.

In this extensive revision, the end result is over 50 new articles and an all-new Volume 8 of the *ASM Handbook* series. As before, the key purpose of this Handbook volume is to explain test set-up, common testing problems and solutions, and data interpretations so that reasonably knowledgeable, but inexperienced, engineers can understand the factors that influence proper implementation and interpretation. Easily obtainable and

recognizable standards and research publications are referenced within each article, but every attempt is made to provide sufficient clarification so that inexperienced readers can understand the reasons and proper interpretation of published industrial test standards and research publications.

In this effort, we greatly appreciate the knowledgeable guidance and support of all the section editors in developing content requirements and author recommendations. This new content would not have been possible without their help: Peter Blau, Oak Ridge National Laboratory; James C. Earthman, University of California, Irvine; Brian Klotz, General Motors Corporation; Peter K. Liaw, University of Tennessee; Sia Nemat-Nasser, University of California, San Diego; Todd M. Osman, U.S. Steel Research; Gopal Revankar, Deere & Company; Robert Ritchie, University of California at Berkeley. Finally, we are all especially indebted to the volunteer spirit and devotion of all the authors, who have given us their time and effort in putting their expertise and knowledge on paper for the benefit of others. This work would not have been possible without them.

Staff

ASM International staff who contributed to the development of the Volume included Steven R. Lampman, Project Editor; Bonnie R. Sanders, Manager of Production; Nancy Hrivnak and Carol Terman, Copy Editors; Kathleen Dragolich, Production Supervisor; and Candace Mullet and Jill Kinson, Production Coordinators. Editorial Assistance was provided by Erika Baxter, Kelly Ferjutz, Heather Lampman, Pat Morse, and Mary Jane Riddlebaugh. The Volume was prepared under the direction of Scott D. Henry, Assistant Director of Reference Publications and William W. Scott, Jr., Director of Technical Publications.

Conversion to Electronic Files

ASM Handbook, Volume 8, *Mechanical Testing and Evaluation* was converted to electronic files in 2003. The conversion was based on the First printing (2000). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume to electronic files included Sally Fahrenholz-Mann, Sue Hess, Bonnie Sanders, and Scott Henry. The electronic version was prepared under the direction of Stanley Theobald, Managing Director.

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Introduction

THE SUCCESSFUL EMPLOYMENT OF METALS in engineering applications relies on the ability of the metal to meet design and service requirements and to be fabricated to the proper dimensions. The capability of a metal to meet these requirements is determined by the mechanical and physical properties of the metal. Physical properties are those typically measured by methods not requiring the application of an external mechanical force (or load). Typical examples of physical properties are density, magnetic properties (e.g., permeability), thermal conductivity and thermal diffusivity, electrical properties (e.g., resistivity), specific heat, and coefficient of thermal expansion. Mechanical properties, the primary focus of this Volume, are described as the relationship between forces (or stresses) acting on a material and the resistance of the material to deformation (i.e., strains) and fracture. This deformation, however, may or may not be evident in the metal after the applied load is removed. Different types of tests, which use an applied force, are employed to measure properties, such as elastic modulus, yield strength, elastic and plastic deformation (i.e., elongation), hardness, fatigue resistance, and fracture toughness. Typical specimens for these evaluations are shown in Fig. 1.

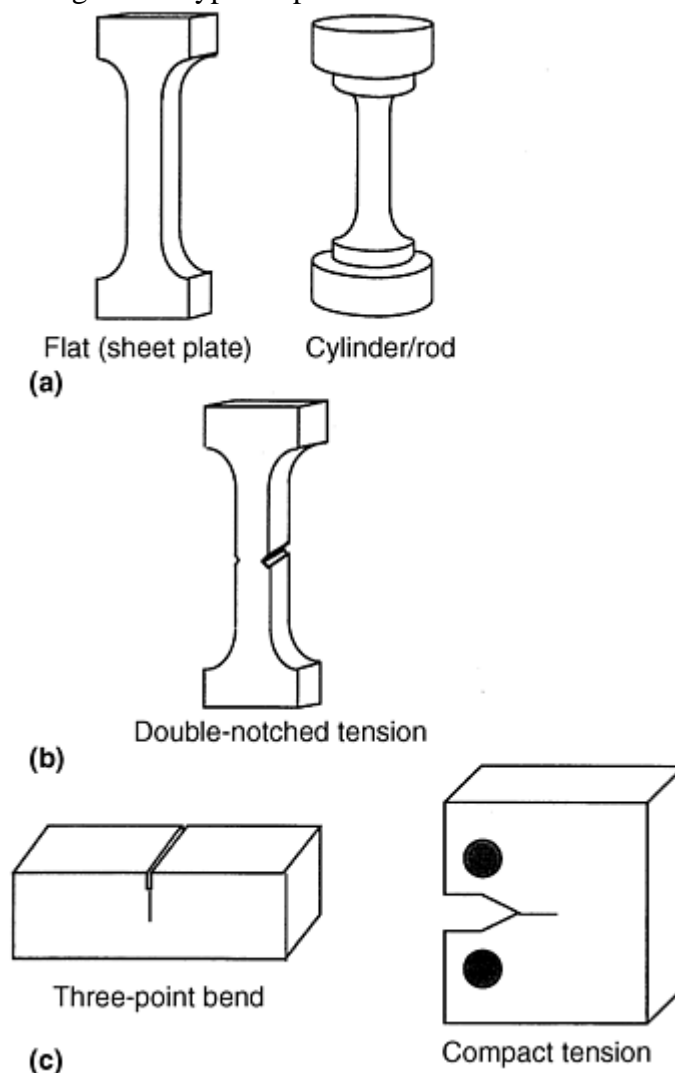

Fig. 1 Typical specimens for (a) tension testing, (b) notched tension testing, and (c) fracture toughness testing

As will be highlighted throughout the discussion below, mechanical properties are highly dependent on microstructure (e.g., grain size, phase distribution, second phase content), crystal structure type (i.e., the arrangement of atoms), and elemental composition (e.g., alloying element content, impurity level). A common illustration of the relationship between micro-structure and mechanical performance is the often observed increase in yield stress with a decrease in grain size. Relationships like these between metal structure and performance make mechanical property determination important for a wide variety of structural applications in metal working, in failure analysis and prevention, and in materials development for advanced applications. The following discussions are designed to briefly introduce typical relationships between metallurgical features (such as crystal structures and microstructures) and the mechanical behavior of metals. Using basic examples, deformation and fracture mechanisms are introduced. Typical properties measured during mechanical testing are then related to these deformation mechanisms and the microstructures of metals.

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Structure of Metals

At the most basic level, metallic materials (as well as many nonmetallic ones) are typically crystalline solids, although it is possible to produce amorphous metals (i.e., those with random atomic arrangement) in limited quantities. The basic building block of the crystal lattice is the unit cell, some examples of which are shown in Fig. 2(a) through (d). By repeating this arrangement in three dimensions, a crystal lattice is formed (see Fig 2.). Although the arrangement of atoms in space can be of fourteen different types (or Bravais lattices), most metals have face-centered cubic (fcc) (e.g., nickel, aluminum, copper, lead), body-centered cubic (bcc) (e.g., iron, niobium, tungsten, molybdenum), or hexagonal close-packed (hcp) (e.g., titanium, magnesium, zinc) structures as the unit cell structure. In very specific applications, materials can be used as single crystals where an entire component is fabricated with one spatial orientation repeating throughout. More often than not, however, engineering materials usually contain many crystals, or grains, as shown in Fig. 3. Depending on the composition and thermomechanical processing, these grains are typically approximately 1 to 1000 μm in size (although finer grain sizes can be produced via other techniques). While the crystal lattice within a grain is consistent, the crystalline orientations vary from one grain to another.

Fig. 2 Examples of crystal structures. Unit cells: (a) simple cubic, (b) face-centered cubic, (c) body-centered cubic, and (d) hexagonal close-packed. A crystal lattice: (e) three-dimensional simple cubic

Fig. 3 Examples of metallic microstructures: (a) Grains in an ultralow-carbon steel. Courtesy of U.S. Steel. (b) Grains in pure niobium. (c) Precipitates at grain boundaries in niobium. (d) Discontinuously reinforced metal matrix composite (silicon carbide particles in an aluminum matrix). Source:Ref 1. Note: the grains in a–c are highlighted through the use of a chemical etchant.

Although some nonstructural applications may require pure metals because of certain physical property advantages, additions of alloying elements are usually made for purposes of enhancing the mechanical properties or other material characteristics (e.g., corrosion resistance). Metal alloys may consist of over ten different elements in specific concentrations with the purpose to optimize a variety of properties. Minor alloying additions typically do not alter the basic crystal structure as long as the elements remain in solid solution. At sufficiently high concentrations, other phases (either with the same or different crystallographic forms) may precipitate within the base metal (at grain boundaries or in the grain interior) as shown in Fig. 3. Phase diagrams are used by metallurgists and materials engineers to understand equilibrium solubility limits in engineering alloys and predict the phases which may form during thermomechanical processing (Ref 2). As will be discussed later, solid solution elements and precipitates/particles are often used during alloy design to improve the strength of a metal.

Metal matrix composites can also be fabricated in which dissimilar constituents (e.g., ceramics and intermetallics) are incorporated into the metallic microstructure in order to enhance mechanical properties. The example microstructure in Fig. 3 shows the reinforcement material to be dispersed throughout a continuous metallic matrix with the metal representing 50% or greater of the total volume. Although the example shows particles as the reinforcement, these materials can be designed with whiskers, short fibers, or long fibers (e.g., rods or filaments). Processing of these composites typically entails the incorporation of the reinforcement material into the metal using ingot metallurgy or powder metallurgy techniques (Ref 3).

To the structural engineer, or in the macroscopic view ($1\times$), most metals appear to be continuous, homogeneous, and isotropic. Continuity assumes that structures do not contain voids; homogeneity assumes that the microstructure (in views at $\sim 100\text{--}1000\times$) and properties will be identical in all locations; isotropic behavior assumes that the properties are identical in all orientations. While these assumptions have been used in continuum mechanics to study the strength of materials and structures under load, engineering materials are often inhomogeneous and anisotropic. While it is desirable to minimize such inhomogeneities, it is often impossible to completely eliminate them. As discussed above, microstructural evaluation typically shows that

materials are comprised of an aggregate of grains of unique crystal structure and usually have second phases (with different properties) dispersed throughout the parent structure. Typically, materials will have variations in grain size, second phase size and distribution, and chemical composition, especially in binary and higher-order alloys. Fabrication route may also play a key role in affecting the preferred crystallographic orientation (or texture) of the grains, further contributing to the inhomogeneity and anisotropy of the microstructure. As will be shown later, all of these microstructural features can greatly influence the properties measured during mechanical testing.

When metals are subject to an external force, the response will depend on a number of factors. The type of loading (e.g., tension, compression, shear, or combinations thereof) is one key factor. The strain rate, temperature, nature of loading (monotonic versus alternating fatigue stresses), and presence of notches will also affect the deformation response of the metal. Chemical influences, such as those associated with stress-corrosion cracking (SCC) and hydrogen embrittlement, as well as physical alterations, such as those resulting from radiation damage, may affect the deformation behavior. Finally, the specimen size and surface preparation can influence the response observed during mechanical testing.

All of these factors are important and will be covered in various articles contained within this Volume. For simplicity, the remainder of this section focuses on basic examples to illustrate the relationship between the structure of a metal and the properties measured during mechanical testing.

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Deformation of Metals

The basic principles of deformation and fracture can be described through the use of a uniaxial tension (or tensile) test. A detailed review of tension testing is presented later in this Volume; therefore, only a brief description is presented for the purpose of introducing deformation and fracture mechanisms in metals. In general, tensile tests are performed on cylindrical specimens (e.g., rods) or parallel-piped specimens (e.g., sheet and plate) as shown in Fig. 1(a). The samples are loaded uniaxially, along the length of the specimen. The applied load and extension (or change in length) of the sample are simultaneously measured.

The load and displacement are used to calculate engineering stress (s) and engineering strain (e) using Eq 1 and Eq 2 :

$$S = P/A_0 \quad (\text{Eq 1})$$

$$e = \Delta L/L_0 = (L_i - L_0)/L_0 \quad (\text{Eq 2})$$

where P is the applied load, L_0 is the initial gage length, L_i is the instantaneous gage length, A_0 is the initial gage cross-sectional area, and ΔL is the change in length. This analysis facilitates the comparison of results obtained when testing samples that differ in thickness or geometry. (For validity, the samples need to conform to certain design specifications as detailed later in this Volume.) Although these engineering values are adequate, the best measures of the response of a material to loading are the true stress (σ) and true strain (ϵ) determined by the instantaneous dimensions of the tensile specimen in Eq 3 and Eq 4:

$$\sigma = P/A_i = S(1 + e) \quad (\text{Eq 3})$$

$$\varepsilon = \ln(L_i/L_0) = (1 + e)$$

(Eq 4)

Because the instantaneous dimensions of the specimen are not typically measured, the true stress and true strain may be estimated using the engineering stress and engineering strain (see Eq 1 and Eq 2). It is noted that these estimations are only valid during uniform elongation (see Fig. 4) and are not applicable throughout the entire deformation range.

Fig. 4 Typical engineering stress-versus-engineering strain curve

Figure 4 depicts a typical engineering stress-versus-engineering strain curve produced in a uniaxial tension test. In the initial stages of deformation, generally stress varies linearly with the strain. In this region, all deformation is considered to be elastic because the sample will return to its original shape (i.e., dimensions) when the applied stress is removed. If, however, the sample is not unloaded and deformation continues, the stress-versus-strain curve becomes nonlinear. At this point, plastic deformation begins, causing a permanent elongation that will not be recovered after unloading of the specimen. The stress at which a permanent deformation occurs is called the elastic (or proportional) limit; however, an offset yield strength (e.g., 0.2% offset) is typically used to quantify the onset of plastic deformation due to the ease and standardization of measurement. The tensile yield strength of most alloys is on the order of 10^2 to 10^3 MPa:

- 135 to 480 MPa (20–70 ksi) for low-carbon steels
- 200 to 480 MPa (30–70 ksi) for aluminum alloys
- 1200 to 1650 MPa (175–240 ksi) for high-strength steels

To understand the different deformation modes, the structure of a metal must be considered. Elastic deformation can be conceptualized by considering the bonds between individual atoms to be springs. As mentioned above, a metal will stretch under the application of a load, but will return to its original shape after the removal of that load if only elastic deformation occurs. Just as a spring constant relates the force to the applied displacement (i.e., $F = kx$), the elastic modulus (E) relates the tensile stress to the applied tensile strain (i.e., $\sigma = E\varepsilon$) and is simply the slope of the linear portion of the tensile stress-versus-tensile strain curve produced in the tension test. Differences in the measured elastic moduli for different metals can therefore be rationalized in part by the differences in the atomic bonds between the individual atoms within the crystal lattice.

Plastic deformation results in a permanent change of shape, meaning that after the load is removed, the metal will not return to its original dimensions. This implies a permanent displacement of atoms within the crystal lattice. If a perfect crystal is assumed, this deformation could only occur by breaking all of the bonds at once between two planes of atoms and then sliding one row (or plane) of atoms over another. Based on calculations using the theoretical bond strengths, this process would result in yield strengths on the order of 10^4 to 10^5 MPa. These strengths are much greater than those typically observed in actual metals (10^2 MPa); therefore, deformation must occur via a different method.

Even under the most ideal crystal growth conditions, metals are not crystallographically perfect, as shown in Fig. 2. Instead, the lattice may contain many imperfections. One such imperfection is an edge dislocation, which, for simple cubic structures, can be considered to be the extra half plane of atoms shown schematically in Fig. 5. Regions surrounding the dislocation may be a perfect array of atoms; however, the core of the dislocation is shown as a localized distortion of the crystal lattice. While it may appear that this structure is unfavorable, dislocations are necessary in metals. For example, at grain boundaries, dislocations are “geometrically necessary” to allow the individual grains of different orientations to match.

Fig. 5 Schematic of an edge dislocation

The nature and quantity of the dislocations become an integral aspect of plastic deformation. There are two generic types of dislocations, edge and screw, which are primarily differentiated by the manner in which each may traverse through the metallic crystal (Ref 4). It is noted that dislocations of mixed character (i.e., partially edge and partially screw) are most commonly observed. In general, both types of dislocations entail the stepwise movement of the dislocation across the crystal lattice as opposed to the displacement of an entire plane over another. This means that only one set of bonds is broken at a time as opposed to an entire plane. Motion now occurs on a distinct set of slip systems, which are combinations of planes—denoted as $\{uvw\}$ or (uvw) —and directions—denoted as $\langle hkl \rangle$ or $[hkl]$ —based on the closest packing of atoms within the crystal structure (see Fig. 6 for an example of crystallographic planes and directions) (Ref 5). For example, motion will predominantly occur on $\{111\} \langle 110 \rangle$ slip systems in fcc metals and on $\{110\} \langle 111 \rangle$, $\{112\} \langle 111 \rangle$, or $\{123\} \langle 111 \rangle$ slip systems in bcc metals. As a result, differences in the plastic behavior of a given type of metal (e.g., aluminum-killed versus fully stabilized steels) can in part be rationalized by which slip systems are active during deformation. Likewise, differences in the properties between different metal types (e.g., bcc iron versus fcc aluminum versus hcp titanium) can be related to the active slip systems in each metal and the relative ease with which dislocations can move within the slip systems.

Fig. 6 Examples of crystallographic planes and directions. (a) $(111)[\bar{1}\bar{1}0]$ and (b) $(110)(\bar{1}\bar{1}1)$

Motion within a slip system is governed by the critical resolved shear strength (τ_{CRSS}). As shown schematically in Fig. 7 for a single crystal, the attainment of τ_{CRSS} on a given slip system is related to the geometric relationship between the applied load and the slip system. This relationship is described mathematically by Schmid's law.

Fig. 7 Schmid's law. $\tau_R = (P/A) \text{COS } \phi \text{COS } \lambda$. Note: plastic flow on a given slip system will initiate when $\tau_R > \tau_{CRSS}$

In polycrystalline metals, plastic flow typically does not occur at a constant stress. In contrast, an increased stress must be applied to produce additional deformation, as shown in Fig 4. This trend can be rationalized by considering the motion, interaction, and multiplication of dislocations. As plastic flow continues, the number of dislocations increases, typically in a parabolic fashion (Ref 6). These dislocations begin to interact with each other and with interfaces such as grain boundaries. When a dislocation encounters a grain boundary, motion is usually halted. Although direct transmission to the neighboring grain may occur (Ref 7, 8, 9), more typically dislocations start to build up at the grain boundary and dislocation tangles may be created. As this buildup continues, a back stress develops that opposes the motion of additional dislocations, giving rise to work hardening (i.e., the increase in strength with straining shown in Fig. 4) (Ref 7).

Typically, the work hardening of a metal is calculated by assuming a parabolic fit to the true stress-versus-true strain data as suggested by Eq 5:

$$\sigma = K\varepsilon^n \quad (\text{Eq 5})$$

where K is the strength coefficient and n is the strain-hardening exponent. The true stress and true strain measured (or calculated from Eq 1 Eq 2 Eq 3 Eq 4) can be used to determine the strain-hardening exponent (n -value). This exponent is simply the slope calculated after plotting the logarithm of true stress versus the logarithm of true strain:

$$\log \sigma = n \log \varepsilon + \log K \quad (\text{Eq 6})$$

As will be discussed later in this Volume, the value of the strain-hardening exponent becomes important when predicting the response of metals to straining during primary metalworking as well as forming operations for final components.

As shown in Fig. 4, there is a point in the stress-versus-strain curve where the work hardening can no longer compensate for the increase in local stress arising from the reduced cross-sectional area. At this point, nonuniform plastic flow occurs in which deformation is concentrated in one region, called a neck. Necking in the tensile specimen usually coincides with the maximum stress (i.e., the ultimate tensile strength) in an engineering stress-versus-engineering strain curve.

Figure 7 introduces the influence of crystallographic orientation on the deformation of single crystals. Although this relationship becomes more complex in polycrystalline metals, the deformation will still depend on the orientation of the load with respect to the active slip systems. For example, the tensile properties of a highly oriented (i.e., textured anisotropic) metallic sheet product will be different when measured parallel (longitudinal), normal (transverse), or at 45° (diagonal) to the rolling direction. The variation in plastic deformation in different orientations can be defined in terms of Lankford values (Ref 10). The individual Lankford values in Eq 7 are calculated using strains measured in a tensile test:

$$r = \varepsilon_w / \varepsilon_t = -\varepsilon_w / (\varepsilon_l + \varepsilon_w) \quad (\text{Eq 7})$$

where ε_w , ε_t , and ε_l are width, thickness, and longitudinal true strains measured from a parallel-sided tensile specimen, respectively. The mean plastic anisotropy (r_m) and normal plastic anisotropy (Δr) can be calculated using Eq 8 and Eq 9, respectively:

$$r_m = \frac{(r_0 + 2r_{45} + r_{90})}{4} \quad (\text{Eq 8})$$

$$\Delta r = \frac{(r_0 - 2r_{45} + r_{90})}{2} \quad (\text{Eq 9})$$

where r_0 , r_{45} , and r_{90} are the r -values calculated from sheet tensile specimens oriented at 0° (parallel), 45° (diagonal), and 90° (normal) to the rolling direction, respectively. As may be expected, Lankford values depend on the crystal structure. Figure 8 relates the calculated Lankford values with crystallographic texture for a low-carbon steel as measured using X-ray diffraction techniques, further highlighting the influence of metallic structure on mechanical behavior.

Fig. 8 Relationship between average (mean) plastic strain ratio (r_m) and crystallographic texture.

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Strength of Metals

Thus far, the mechanical properties of crystalline metals have been discussed only in relationship to the crystal lattice. Because most metals are comprised of many grains (see Fig. 2), properties such as yield strength and ductility (i.e., elongation to fracture) are also highly dependent on the microstructure. Once again, the influence

of both of these factors can be rationalized by considering the motion of dislocations. The strength of a metal is related to the ease, or conversely the difficulty, of dislocation motion. If dislocation motion is uninhibited (i.e., motion is initiated easily and continues without hindrance), the strength will be low and relatively little work hardening will occur. In contrast, the presence of obstacles, or barriers, within the microstructure slow dislocation motion, resulting in an increase in strength.

Grain boundaries provide an obstacle to dislocation motion. As the grain size is decreased, the strength (σ) of the metal typically increases according to the Hall-Petch relationship given in Eq 10 and illustrated in Fig. 9 (Ref 12, 13):

$$\sigma = \sigma_0 + kd^{1/2} \quad (\text{Eq 10})$$

where σ_0 is the intrinsic strength of the metal, k is a coefficient, and d is the grain diameter. At small grain sizes, there is a larger probability of dislocation-dislocation interactions (e.g., dislocation “pile-up” at the grain boundaries), leading to a larger resistance to dislocation motion. As the grain size increases, the opposition to dislocation motion, due to back stresses associated with dislocation tangles at grain boundaries, lessens due to the larger distances between grain boundaries. Therefore, the lower strength of a large-grained metal when compared to a small-grained metal can be rationalized by a decrease in the resistance to dislocation motion.

Fig. 9 Influence of grain size diameter (d) on yield strength for α -iron alloys. Source: Ref 12

The strength of a metal will also be related to the impurity content. Sometimes elements are intentionally added to metals, such as adding nickel to copper or phosphorus to steel. Other times, the presence of impurities, such as inclusions (e.g., oxides) in copper or solute carbon in steel, may be undesired. In order to rationalize these statements, the effect of each on plastic flow in metals needs to be considered. Figure 10 schematically illustrates two scenarios for incorporating atoms into a metallic matrix. Substitutional atoms (see Fig. 10a) take the place of matrix atoms. Because of the mismatch in atomic size between the substitutional atom and the matrix atom, the lattice may become locally strained. This lattice strain may impede dislocation motion and is conventionally considered to be the source of solid solution strengthening in metals. In general, the strengthening increment varies proportionally with the mismatch in atomic size and properties (specifically modulus) between the solute and solvent atoms, as shown in Fig. 11 (Ref 14).

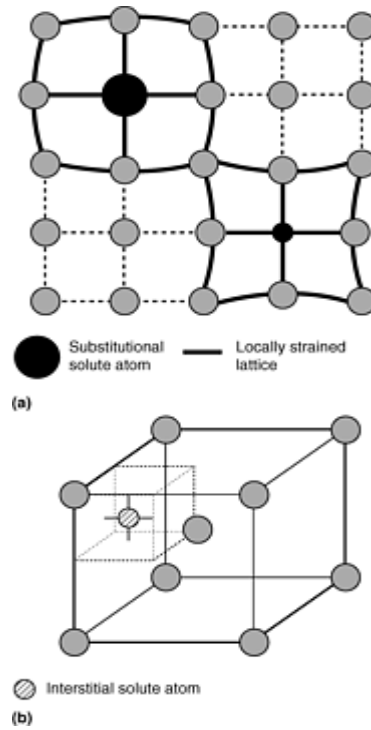

Fig. 10 Two scenarios of incorporating atoms into a metal matrix. (a) Substitutional atoms and (b) an interstitial atom in a body-centered cubic unit cell

Fig. 11 Relationship between mismatch factor and strengthening increment ($\Delta\tau_0/\Delta C$) for solute atoms in copper alloys. Source: Ref 14

Interstitial atoms can also be present within the metal (see Fig. 10b). In this case, the atom is much smaller than the matrix atoms and is located in the gaps (or interstices) in the crystal lattice. Most often, interstitial atoms can diffuse to the dislocation core (see Fig. 5) due to the more open structure and the local tensile stresses in this region of the crystal lattice. The presence of the interstitial can inhibit dislocation motion, leading to dislocation “locking.” This locking necessitates larger applied stresses to produce dislocation motion and further plastic deformation (Ref 15). In the classic example of carbon in iron, such a mechanism can result in discontinuous yielding as shown in Fig. 12. Deformation is not continuous, and a sharp upper yield point is typically observed followed by yielding at a constant stress. The serrations in the stress-versus-strain curve in

Fig. 12 are most often attributed to the breakaway of dislocations from the solute carbon atoms. If the physical appearance of the tensile specimen is considered, localized distortions, called Lüders fronts (local regions of yielded material), will traverse the length of the specimen during yield-point elongation, and continuous plastic flow under an increasing load will not commence until the entire gage section has yielded. The extent of the yield-point elongation will depend on the density of mobile dislocations (i.e., those which are not “locked”) and the ease with which these dislocations can move once initiated (Ref 16).

Fig. 12 Discontinuous yielding

Impurity atoms and interstitial alloy additions can often cause second phase particles or precipitates to be present in the structure. A fine dispersion of small particles generally produces a higher strength than a coarse dispersion of large particles, as suggested in Fig. 13. At each volume fraction, small particles (10 Å) produce a higher strength than large (100 Å) particles. The strengthening increase is related to two factors: (a) a higher probability of the mobile dislocation intersecting the particles due to the smaller interparticle spacing and (b) the higher fracture resistance of smaller particles. Conversely, as the size of the particles increases at a constant volume fraction, the interparticle spacing increases, causing the particles to become less effective strengtheners (i.e., barriers to dislocation motion) (Ref 18). This effect can be observed in hot-rolled, low-carbon steels. At low coiling temperatures, finer carbides (e.g., Fe₃C and NbC) are typically produced, resulting in increased strength. At higher coiling temperatures, the carbide particles coarsen at a constant volume fraction, which typically results in a lower strength.

Fig. 13 Influence of particle size on yield strength (NbC in an HSLA steel). Source: Ref 17

A similar scenario occurs with age-hardenable aluminum alloys. The strength of these alloys varies as a function of time at temperature as shown in Fig. 14. The yield strength initially increases proportionally with time, but eventually reaches a maximum. Longer aging times then result in decreased yield strength. These

trends are once again directly related to the mechanisms of particle hardening. At short aging times, small coherent precipitates form that are effective strengtheners. Overaging (i.e., soaking past the maximum yield strength) causes the particles to coarsen, and the interparticle spacing increases, resulting in the decreased strength.

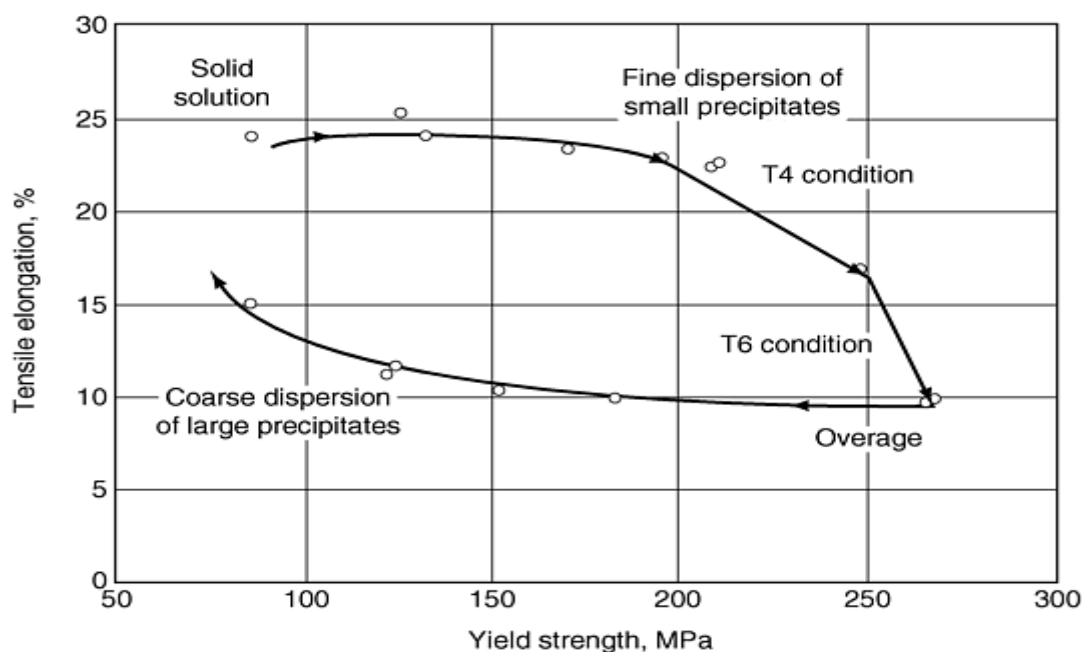

Fig. 14 Effect of aging heat treatment on ductility for a 2036 aluminum alloy. Source:Ref 19

Figure 14 also provides evidence that the ductility (i.e., the elongation prior to failure) of a metal will also be influenced by microstructural changes. Typically, there is an inverse relationship between strength and ductility. In order to rationalize this observation, the failure modes for metals need to be considered. In general, failure is classified as either ductile or brittle. There are many ways to differentiate the two types of failures, as illustrated in Table 1 and Fig. 15.

Table 1 Distinguishing characteristics of brittle versus ductile behavior depending on the scale of observation

Scale of observation	Brittle	Ductile
Structural engineer	Applied stress at failure is less than the yield stress	Applied stress at failure is greater than the yield stress
By eye (1×)	No necking, shiny facets, crystalline, granular	Necked, fibrous, woody
Macroscale (<50×)	“Low” RA or ductility	Medium to high RA
Microscale, scanning electron microscopy (100–10,000×)	Brittle microprocess, cleavage (see Fig. 15b), intergranular (see Fig. 15c)	Ductile microprocess, microvoid coalescence (see Fig. 15a)
Transmission electron microscopy (>10,000×)	May have a large level of local plasticity	High amount of plasticity globally

RA, reduction of area

Fig. 15 Examples of fracture surfaces of metals failing by (a) microvoid coalescence, (b) cleavage, and (c) intergranular fracture. Source: Ref 20

Ductile fracture is generally preceded by stresses that exceed the yield stress, and specimens failing with high reductions of area and by shear or microvoid coalescence. The process of ductile fracture by microvoid coalescence has been described by several authors (Ref 21, 22, and 23). Microvoids nucleate predominantly at particles (e.g., inclusions, precipitates) that are present in nearly all metals. The particle size and shape, the particle-matrix interfacial strength, and the matrix flow strength influence the mechanism of void formation. In general, void nucleation by particle cracking is favored by increasing particle size, higher interfacial strengths, and the presence of nonequiaxed particles. By contrast, void nucleation by interfacial decohesion is more likely with smaller particles, weaker interfaces, and lower matrix flow strength (Ref 23). After nucleation, the voids will grow in the direction of the applied tensile stress and secondary voids can also nucleate at smaller particles. During necking, expansion of the voids can occur, leading to coalescence by void impingement (resulting in higher uniform strain) or by void sheet formation (lower, more local strain). After failure, a “dimpled” fracture surface is typically observed, as shown in Fig. 15(a).

As a result, the ductility of a metal typically decreases with increasing particle content, as shown in Fig. 16. An increase in particle volume fraction results in a larger number of potential void nucleation sites. Furthermore, there is an increased probability for the linkage of neighboring voids (impingement).

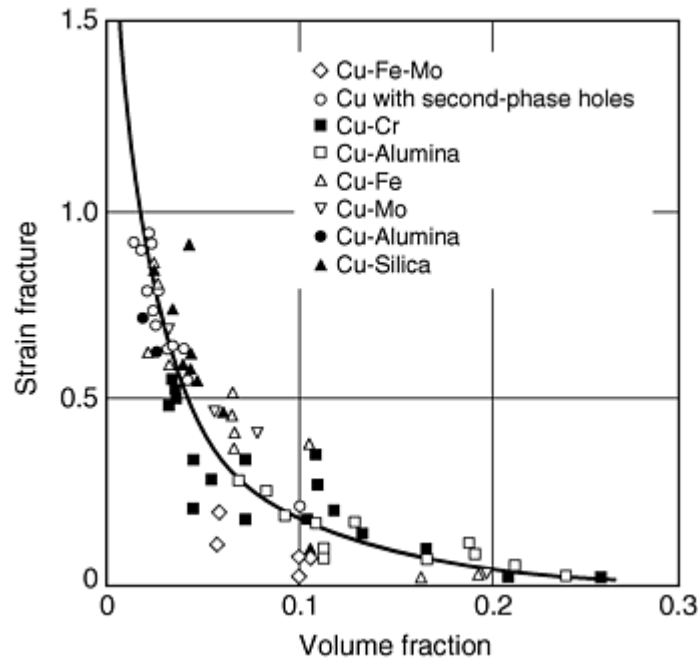

Fig. 16 Influence of particle content on ductility. Source: Ref 24

According to the descriptions in Table 1, brittle behavior is generally classified by failure at stresses below the yield strength and low reductions in area (little uniform strain) (Ref 25). Although this fracture process may be initiated by some dislocation activity, the levels generally detected are far below those found in a material exhibiting ductile behavior. Cleavage fracture, one of the brittle fracture modes, is distinguished by separation of individual grains along low index crystallographic planes in a transgranular manner—for example, iron cleaves along (100) planes. As shown in Fig. 15(b), lines on the cleavage facets, as seen in the scanning electron microscope (SEM), provide postmortem evidence of the direction of crack growth (i.e., the lines trace back to the origin of the failure origin). Each “line” is actually a step created between fractures propagating along parallel low index planes but separated by a small step. For pure cleavage, a step created on each side of the fracture surface should fit together except for some discrepancy that may occur due to some plasticity at the step. Another brittle fracture mode is intergranular fracture. In this case, a crack is initiated at grain boundaries and propagates along them. The grain-boundary facets appear to be “glassy smooth” as in Fig. 15(c). There may be evidence of local plasticity with tearing evident at the grain-boundary corners. It should be noted that intergranular microvoid coalescence, which is locally ductile fracture in grain boundary regions, can also occur.

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Special Conditions in Flow: Temperature and Strain Rate

Many of the most widely employed structural metals have bcc lattices (e.g., steels, refractory metals) or fcc lattices (e.g., aluminum, copper). The strength of fcc metals is relatively insensitive to test temperature; however, the properties of bcc metals are typically highly dependent on testing conditions. This dissimilar behavior is related to the nature of dislocation motion with the individual crystal lattices. Face-centered cubic metals are more closely “packed” (i.e., a shorter distance exists between atoms in the unit cell of Fig. 2) than body-centered cubic metals. A common slip system (i.e., $\{111\} \langle 110 \rangle$) prevails across temperature regimes for fcc metals; however, dislocations have been found to move on different slip systems in bcc metals (e.g., $\{110\} \langle 111 \rangle$, $\{112\} \langle 111 \rangle$, or $\{123\} \langle 111 \rangle$ for α -iron), depending on temperature (Ref 5, 25, and 26).

In bcc metals, a substantial increase in flow stress (or strength) can be observed at temperatures less than one-fifth the melting temperature of the metal. Under these conditions, the internal resistance to dislocation motion can greatly increase. If the barriers to dislocation motion are considered further, they can be separated into athermal (i.e., not influenced by temperature) and thermal (i.e., dependent upon temperature) components (Ref 5). Athermal barriers, such as long-range interaction of dislocations, are too large to be overcome by gliding dislocations utilizing only thermal fluctuations and the applied stress to move from one site to another. In contrast, thermal barriers, such as solute atoms and precipitates, are surmountable by dislocations with the assistance of this thermal energy and an applied stress.

At low temperatures, the thermal activation of dislocations is minimal; therefore, a large applied stress is required for deformation. At higher temperatures, thermal activation will assist in dislocation motion “around” the thermal barriers. The applied stress necessary for plastic flow is lowered, which reduces the measured strength. Above a critical temperature, thermal activation provides a substantial portion of the driving force for dislocation motion, such that the strength of the material will be primarily determined by athermal barriers.

The previous discussion assumes that plastic flow will take place and that there is a constancy of fracture mechanism. Such an assumption is not necessarily valid for bcc metals. These metals show a transition in fracture mode from ductile (microvoid coalescence or shear) to brittle (e.g., cleavage) with decreasing temperature. This transition can be conceptualized using a simple Orowan-type construction (Ref 27) such as the one shown in Fig. 17. The brittle fracture stress (the cleavage stress) varies weakly with temperature and may be considered to be approximately independent of temperature. The yield strength, however, will increase with decreasing temperatures as discussed previously. The temperature where the two curves intersect (T_1 in Fig. 17) is considered to be the ductile-to-brittle transition temperature (DBTT) for the metal. Above this temperature, the metal will yield prior to fracture, while below the DBTT, cleavage occurs without macroscopic yielding.

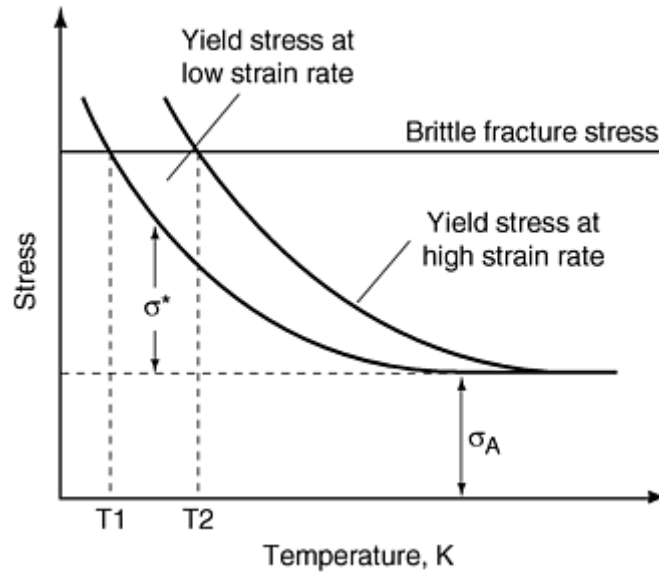

Fig. 17 Schematic illustration of the ductile-to-brittle transition in body-centered cubic metals

In addition to temperature, the rate of loading (i.e., strain rate) during testing will also greatly affect the measured mechanical properties of bcc metals. In general, an increase in strain rate is analogous to a decrease in temperature. The combined effect of strain rate ($\dot{\epsilon}$) and temperature (T) can be seen in Eq 11 (Ref 5):

$$\dot{\epsilon} = \dot{\epsilon}_0 \exp\left[\frac{-\Delta G^*(\tau^*)}{kT}\right] \quad (\text{Eq 11})$$

where ΔG^* is the Gibbs free energy associated with the shear stress (τ^*) required to overcome short-range obstacles and $\dot{\epsilon}_0$ is the product of the mobile dislocation density, the vibration frequency for the dislocation segment, and the Burgers vector for the dislocation, the distance that the dislocation may “jump.” This relationship illustrates that sufficiently high temperatures or low enough strain rates increase the probability for exciting dislocation motion through a thermal activation event in the presence of an applied load. On the other hand, low temperatures and high strain rates can lead to significant strengthening due to smaller contributions by thermal activation.

For bcc metals, which exhibit a ductile-to-brittle transition, increasing the strain rate can have an additional effect. As discussed previously and shown schematically in Fig. 17, the yield strength increases at a higher strain rate. This shifts the temperature dependence of yield strength, resulting in an intersection with the brittle fracture stress at a higher temperature (T_2 in Fig. 17). The end result is that the measured DBTT will be greater at a higher strain rate (T_2) than at a lower strain rate (T_1).

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Special Conditions in Fracture: Notches and Cracks

The deformations and processes governing fracture in metals are affected by both the stresses and strains experienced in the specimen. In a simple tension test, the stresses are designed to be uniform throughout the cross section of the sample. When stress is applied to a component with a notch, crack, or other stress concentration, regions in the vicinity of these features will always experience much higher stresses compared to unaffected regions, and the strains produced can be very different from what would be predicted by the stresses. The stress fields created around stress concentrations are controlled by three factors: (a) the extent of deformation prior to failure, (b) the mode of loading (i.e., the relative orientation of the applied load with respect to the plane of the crack), and (c) the constraints, if any, on the cracked body (Ref 25, 27).

As a result, the mechanical properties measured when testing specimens with notches (see Fig. 1b) or cracks (see Fig. 1c) will be much different than those observed in uniaxial tension tests. For the case of notched tensile specimens, the measured tensile yield strength often will be greater than that observed in a uniaxial tension test. However, the ductility and load-carrying capacity will be decreased. As the sample is loaded, the notched region will yield first due to the elevated local stresses and strains associated with the notches. The maximum stress ahead of the notch will be a function of the geometry of the notch and the applied loading (Ref 28, 29). Furthermore, the stresses are no longer purely uniaxial (such as is developed in a tensile test), but now become triaxial (i.e., tensile stresses in the three primary directions of space). If ductile fracture via microvoid coalescence is reconsidered, the elevated stress and strain fields may accelerate the nucleation of secondary voids. The void growth rate will also increase proportionally to the level of the triaxial stresses, resulting in reduced ductility for notched samples compared to smooth, uniaxial tensile specimens (Ref 30, 31).

A more severe stress concentration will occur in cracked specimens, such as those used to determine fracture toughness (see Fig. 1c). In the most limiting case (e.g., opening of a sharp crack or Mode I loading), the component is highly constrained (with the level of constraint dependent on mechanical properties and component size). Under these conditions and with the application of a sufficient load, the peak tensile stresses around the crack tip can reach levels as high as five times the yield strength of the metal. As in the case of notched specimens, this change in stress state reduces the measured fracture strains due to a local acceleration of the fracture process.

To understand effects of cracks in ductile metals, the interactions between microstructural features and the elevated stress fields around the crack tip need to be considered. Ahead of a sharp crack, a finite volume of material is subjected to deformations at high stress values. To a first-order approximation, this volume of material, or the “plastic zone” in plane strain, can be represented as the radius of a circle as described by Eq 12 (Ref 25, 27):

$$r_p = \frac{1}{6\pi} \left(\frac{K_I}{\sigma_{ys}} \right)^2 \quad (\text{Eq 12})$$

where r_p is the distance from the crack to the elastic-plastic boundary, K_I is the stress intensity calculated from the geometry and loading conditions, and σ_{ys} is the uniaxial yield strength of the material. The highly constrained regions experiencing the triaxial stress state are located within this volume. As a result, the size of this zone relative to the microstructural features becomes a key factor influencing the measured properties of cracked specimens.

In general, the stresses are highest in a plastically deforming material ahead of the crack tip. In contrast, the plastic strains are highest at the notch tip and decrease after a critical distance, which is approximately equivalent to the crack-opening displacement (i.e., the relative displacement of the “mouth” of the crack) (Ref 27). The extent of the strained region often becomes comparable to microstructural features (grain size, interparticle particle spacing, etc.) and can initiate failure. When large strains are required for fracture, the crack-opening displacement must reach a critical size as to envelop the microstructural features responsible for void nucleation. Depending on the intrinsic fracture resistance of the metal, void growth and failure will occur when this zone becomes 1.0 to 2.7 times the microstructural feature responsible for fracture (e.g., the grain size or the mean spacing of second-phase particles) (Ref 32, 33).

An example of this type of fracture process can be seen in the case of metal matrix composites (i.e., a ductile metal matrix with brittle reinforcement particles). Crack growth in such a material is schematically shown in Fig. 18. When a crack in the ductile matrix is loaded, the large stresses ahead of the notch promote void nucleation by particle fracture or interface decohesion. This void nucleation limits the straining capacity of the metal in the vicinity of the crack tip. The high strain field ahead of the tip then allows for continued growth of

the nucleated voids to the point of instability, as the blunted crack links with the microcrack. This process of microcracking, crack-tip blunting, and failure of the matrix (void formation) between the particles continues as the crack propagates. This mechanism gives cracks an easy path for failure and clearly shows that the presence of a stress raiser exacerbates the processes of fracture compared to the case of uniaxial tension.

Fig. 18 Rice and Johnson model for failure in ductile matrix composites. Top: sharp crack blunts. Middle: particle cracking occurs followed by ductile tearing. Bottom: crack propagation. λ is the interparticle spacing; δ_t is the crack opening displacement. Source: Ref 32

The interaction between the microstructure of a metal and the resulting properties measured during mechanical testing is further illustrated by Fig. 18. In this example, crack propagation from a notch or crack tip is related to the spacing of microstructural features. As a result, a metal with a reduced volume fraction of particles (and the assumed increased interparticle spacing) can exhibit a greater resistance to fracture than a metal with a larger amount of particles (in agreement with Fig. 16).

Introduction to the Mechanical Behavior of Metals

Todd M. Osman, U.S. Steel Research; Joseph D. Rigney, General Electric Aircraft Engines

Summary

The previous discussions were designed to provide a brief introduction to the influence of microstructure on the mechanical behavior of metals. The mechanisms of elastic and plastic flow have been highlighted along with the response of metals to stress raisers such as notches. The properties measured during mechanical testing can be rationalized by considering the effect of microstructural features, such as grain size and particle content, on deformation mechanisms. During quality-control testing, a larger-than-normal strength (or hardness) for a given metal during testing might be the result of grain refinement during processing. A lower strength observed for an age-hardenable metal might be the result of particle coarsening during overaging in heat treatment. Likewise, a dramatic drop in ductility might be the result of an increased inclusion content (or, in some cases, from embrittlement due to impurity segregation to the grain boundaries).

The relationship between microstructure and mechanical properties is also important when designing processing conditions, as well as in material selection for various applications. If increased strength in the final product is desired, solid-solution strengtheners may be added (e.g., adding nickel to copper), or the thermomechanical processing may be changed to produce a finer distribution of particles (e.g., lowering the coiling temperature for hot-rolled steel). If the final application has notches, it may be beneficial to use a metal with a lower inclusion content.

The remaining articles in this Volume will continue to build on this theme. In particular, the design of mechanical testing procedures and the analysis of resultant data will be highly dependent on the structure of the metal. Small variations in this structure may result in large changes in mechanical properties. As highlighted above, these changes are a direct consequence of the relationship between the metallurgical features and the mechanisms of deformation and fracture.

Introduction to the Mechanical Behavior of Nonmetallic Materials

M.L. Weaver and M.E. Stevenson, The University of Alabama, Tuscaloosa

Introduction

MANY DIFFERENT types of materials are used in applications where a resistance to mechanical loading is necessary. The type of material used depends strongly upon a number of factors including the type of loading that the material will experience and the environment in which the materials will be loaded. Collectively known as *engineering materials* (Ref 1), they can be pure elements, or they can be combinations of different elements (alloys and compounds), molecules (polymers), or phases and materials (composites). All solid materials are typified by the presence of definite bonds between component atoms or molecules. Ultimately, it is the type of bonding present that imparts each class of materials with distinct microstructural features and with unique mechanical and physical properties.

Crystalline solids exhibit atomic or molecular structures that repeat over large atomic distances (i.e., they exhibit long-range-ordered, LRO, structures) whereas noncrystalline solids exhibit no long-range periodicity. The atomic and molecular components of both crystalline and noncrystalline solids are held together by a series of strong *primary* (i.e., ionic, covalent, and metallic) and/or weak *secondary* (i.e., hydrogen and Van der Waals) bonds. Primary bonds are usually more than an order of magnitude stronger than secondary bonds. As a result, *ceramics* and *glasses*, which have strong ionic-covalent chemical bonds, are very strong and stiff (i.e., they have large elastic moduli). They are also resistant to high temperatures and corrosion, but are brittle and prone to failure at ambient temperatures. In contrast, thermoplastic *polymers* such as polyethylene, which have weak secondary bonds between long chain molecules, exhibit low strength, low stiffness, and a susceptibility to creep at ambient temperatures. These polymers, however, tend to be extremely ductile at ambient temperatures.

In this article, some of the fundamental relationships between microstructure and mechanical properties are reviewed for the major classes of nonmetallic engineering materials. The individual topics include chemical bonding, crystal structures, and their relative influences on mechanical properties. The present article has been derived in structure and content from the article “Fundamental Structure-Property Relationships in Engineering Materials,” in *Materials Selection and Design*, Volume 20 of *ASM Handbook* (Ref 2). In light of the bewildering number of different engineering materials within each class, discussions were limited to a number of general examples typifying the general features of the major classes of nonmetallic materials.

Introduction to the Mechanical Behavior of Nonmetallic Materials

M.L. Weaver and M.E. Stevenson, The University of Alabama, Tuscaloosa

General Characteristics of Solid Materials

Engineering materials can be conveniently grouped into five broad classes: metals, ceramics and glasses, intermetallic compounds, polymers, and composite materials. Metals, ceramics and glasses, polymers, and composites represent the most widely utilized classes of engineering materials, whereas intermetallic compounds (i.e., intermetallics), which are actually subcategories of metals and ceramics, are an emerging class of monolithic materials. The general features of five major classes of materials are summarized in Fig. 1 and are described in the following sections. Though this article deals with the properties of nonmetallic materials, a brief discussion of the general characteristics of metallic materials is included where pertinent.

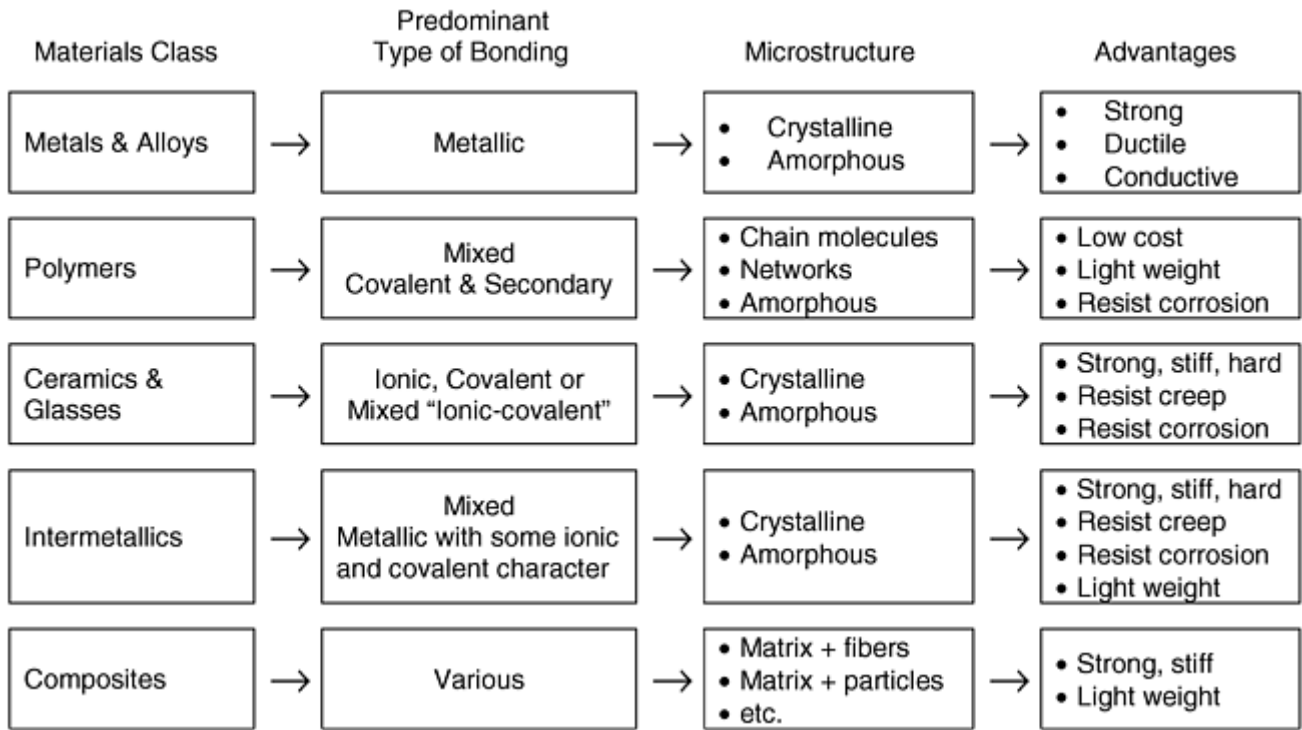

Fig. 1 General characteristics of major classes of engineering materials. Adapted from Ref 3

Metals

Metals represent the majority of the pure elements and form the basis for the majority of the structural materials. The mechanical behavior of metals depends on a combination of microstructural and macrostructural features, which ultimately depend upon bonding, chemical composition, and mode of manufacture. Metals are held together by metallic bonds. Metallic bonds arise because on an atomic scale, the outer electron shells in metals are less than half full. As a result, each atom donates its available outer shell (i.e., valence) electrons to an electron cloud that is collectively shared by all of the atoms in the solid. This is referred to as *metallic bonding* and is responsible for the high elastic moduli and the high thermal and electrical conductivity exhibited by metals. Many metals also exhibit a limited solid solubility for other atoms (i.e., one metal can dissolve into another). Consequently, engineers can often vary their properties by varying composition. In terms of atomic arrangements, metals also have large coordination numbers (CNs), typically 8 to 12, which account for their relatively high densities. Metals, by their nature, tend to be ductile in comparison to other engineering materials and exhibit a high tolerance for stress concentrations. As such, many metals can deform locally to redistribute load. Structurally, metals are generally crystalline, though amorphous structures (i.e., metallic glasses) are possible using special processing techniques. Further information concerning structure-property relationships in metals is provided in the article "Introduction to the Mechanical Behavior of Metals" in this volume.

Ceramics and Glasses

Ceramics and glasses include a broad range of inorganic materials containing nonmetallic and metallic elements. Like metals, these materials can be formed directly from the melt or via powder processing techniques (e.g., sintering or hot isostatic pressing) and their mechanical properties depend on structural (i.e., microstructural and macrostructural) features and chemical composition. They differ from metals in that strong ionic, covalent, or intermediate bonds, which often result in higher hardness, stiffness, and melting temperatures compared with metals, hold them together.

Ionic bonding occurs in compounds containing electropositive (i.e., metals, atoms on the left side of the periodic table) and electronegative (i.e., nonmetals, atoms on the right side of the periodic table) elements. This type of bonding involves the transfer of electrons whereby electropositive elements readily donate their valence electrons to the electronegative elements, allowing the establishment of stable outer shell configurations in each element. Figure 2 depicts ordinary table salt, NaCl, which is a perfect example of an ionically bonded solid. In

ionic solids, the coordination number (CN), which is defined as the number of cation/anion (i.e., positive ion/negative ion) nearest neighbors, are typically lower than those in metals, which accounts for their slightly lower densities compared with metals. Ionic solids are typically hard and brittle, and electrically and thermally insulative (i.e., with lower electrical and thermal conductivity than metals). The insulative properties are a direct result of the electron configurations within the ionic bond. Ionic solids usually form only in stoichiometric proportions (e.g., NaCl and Al_2O_3), which cause them to have little tolerance for alloying.

Fig. 2 Schematic representation of ionic bonding in NaCl. Note that this structure consists of Na^+ and Cl^- ions sitting on interpenetrating fcc Bravais lattices.

Covalent bonding occurs in compounds containing electronegative elements. Covalent bonding involves the sharing of valence electrons with specific neighboring atoms. This is schematically illustrated for methane (CH_4) in Fig. 3. For a covalent bond to occur between C and H, for example, each atom must contribute at least one electron to the bond. These electrons are shared by both atoms, resulting in a strong directional bond between atoms. The number of covalent bonds that form depends on the number of valence atoms that are available in each atom. In methane, carbon has four valence electrons, while each hydrogen atom has only one. Thus, each hydrogen atom can acquire one valence electron to fill its outer orbital shell. Similarly, each carbon atom can accommodate four valence electrons to fill its outer shell. This type of bonding makes covalent solids strong, brittle, and highly insulative because electrons are incapable of detaching themselves from their parent and moving freely through the solid. Covalent solids also have lower CNs due to this localized electron sharing resulting in lower densities. For example, diamond, which is an elemental covalent compound, has a CN of 4 (Fig. 4). Like ionic solids, covalent solids tend to exhibit very narrow composition ranges and exhibit little tolerance for alloying additions. Examples of covalent molecules, elements, and compounds include H_2O , HNO_3 , H_2 , diamond, silicon, GaAs, and SiC.

Fig. 3 Schematic representation of covalent bonding in methane (CH_4)

Fig. 4 An example of perfect covalent bonding in diamond

In general, most ceramic compounds exhibit a mixture of ionic and covalent bonding, the degree of which depends on the positions of the constituent elements on the periodic table. For elements exhibiting a greater difference in electronegativity, bonding tends to be more ionic, while for elements with smaller differences, bonding tends to be more covalent. Solids that exhibit mixed bonding, which are termed polar covalent solids, often exhibit high melting points and elastic moduli. Silica (SiO_2) is a good example of a polar covalent solid. Ceramics and glasses have higher elastic moduli than most metals and exhibit extremely high strengths when deformed in compression. The presence of strong ionic and covalent bonds allows these materials to retain their strength to high temperature and makes them extremely resistant to corrosion. However, these same bonds render ceramics and glasses brittle at ambient temperatures, resulting in little tolerance for stress concentrations (e.g., holes, cracks, and flaws) and usually in catastrophic failure during tensile or shear loading.

Intermetallic Compounds

In some cases, intermetallic compounds can form within alloys. These materials are composed of two or more metallic or metalloid constituents and exhibit crystal structures that are distinctly different from its constituents. Unlike solid solution alloys, these mixtures form stoichiometric compounds (e.g., NiAl , Ni_3Al , TiAl , and Ti_3Al), and their bonding is typically a combination of metallic, ionic, and/or covalent types. In terms of mechanical and physical properties, intermetallics occupy a position between metals and ceramics. As in the case of ionic and covalent solids, extremely strong bonds exist between unlike constituents, which imparts intermetallics with lower CNs and densities than metals, highly directional properties, higher stiffness and strength, and good resistance to temperatures or chemical attack. These materials, which have intrinsically high strengths and elastic moduli, are often used in precipitate form to strengthen commercial alloys (e.g., Ni_3Al in Ni-base superalloys), and their low densities and high microstructural stability makes them attractive for use in high-temperature structural applications such as turbine blades, exhaust nozzles, and automotive valves. Examples of some typical intermetallic compounds are illustrated in Fig. 5. Of the more than 25,000 known intermetallic compounds, recent emphasis has focused on the development of NiAl , FeAl , Ni_3Al , TiAl , and MoSi_2 base alloys for use as monolithic alloys in structural applications (Ref 4). As in the cases of ceramics and glasses, the same bonds that impart intermetallics with high strengths render most of them with low ductility and fracture toughness at ambient temperatures.

Fig. 5 Some simple intermetallic crystal structures

Fig. 7 Schematic representation of secondary bonding between two molecular dipoles

Fig. 8 Schematic representation of secondary bonding between two polymer chains

In comparison to metals, intermetallics, and ceramics and glasses, polymers have very low CNs, which is part of the cause for their low densities; however, they also consist primarily of light atoms such as C and H, which tends to result in lower density. The localized nature of electrons in polymers renders them good electrical insulators and poor thermal conductors.

There are three categories of polymers: thermoplastics, thermosetting plastics, and elastomers. Thermoplastics have linear chain configurations where chains are joined by weak secondary bonds as described above. These materials often melt upon heating but return to their original solid condition when cooled. In thermosetting polymers, covalent cross-links or strong hydrogen bonds occur between polymer chains resulting in three-dimensional networks of cross-linked molecular chains. Phenol formaldehyde, or Bakelite, is a good example. Thermosettings change chemically during processing and will not melt upon reheating. Instead, they will remain strong until they break down chemically via charring or burning. Elastomers differ from thermoplastics and thermosetting polymers in that they are capable of rubbery behavior and are capable of very large amounts of recoverable deformation (often in excess of 200%). Structurally, these materials consist of networks of heavily coiled and heavily cross-linked polymer chains, which impacts higher strengths than thermoplastics by inhibiting the sliding of polymer chains past each other. Elastomers are typified by natural rubber and by a series of synthetic polymers exhibiting similar mechanical behavior (e.g., polyisoprene).

Composites

Composites are relatively macroscopic arrangements of phases or materials designed to take advantage of the most desirable aspects of each. As a result, the strengths and/or physical properties of composites are usually an average of the strengths and/or properties of the individual constituents/phases. Most composites are composed of a compliant, damage-tolerant matrix and a strong reinforcing phase/constituent, usually filaments, fibers, or whiskers, that are too brittle for use in a monolithic form. In composites with brittle matrices (e.g., ceramic matrix composites), the reinforcing constituent may toughen the material more than strengthen it.

Introduction to the Mechanical Behavior of Nonmetallic Materials

M.L. Weaver and M.E. Stevenson, The University of Alabama, Tuscaloosa

Structures of Materials

Depending upon the application, engineering materials can be pure elements such as silicon, compounds such as aluminum oxide (Al_2O_3) or gamma titanium aluminide ($\gamma\text{-TiAl}$), or combinations of different molecules (polymers) or materials (composites). All materials are composed of a three-dimensional arrangement of atoms, the general details of which are described subsequently.

Inorganic Crystalline Solids

The basic building blocks of crystalline solids are unit cells, which represent the smallest repeating unit within a crystal. When stacked together, these repeating unit cells form a *space lattice*, which is a repeating three-dimensional array of atoms. Due to geometrical considerations, atoms can only have one of 14 possible arrangements, known as Bravais lattices (Fig. 9). Most metals and metallic alloys crystallize with face-centered cubic (fcc), hexagonal close-packed (hcp), or body-centered cubic (bcc) crystal structures. However, the structures in nonmetallic solids tend to be more complicated.

Fig. 9 The 14 Bravais lattices illustrated by a unit cell of each: 1, triclinic, primitive; 2, monoclinic, primitive; 3, monoclinic, base centered; 4, orthorhombic, primitive; 5, orthorhombic, base centered; 6, orthorhombic, body centered; 7, orthorhombic, face centered; 8, tetragonal, primitive; 9, tetragonal, body centered; 10, hexagonal, primitive; 11, rhombohedral, primitive; 12, cubic, primitive; 13, cubic, body centered; 14, cubic, face centered. Source: Ref 6

Crystalline ceramics and intermetallics have crystal structures consisting of multiple interpenetrating Bravais lattices, each of which is occupied by a specific atomic constituent. For example, common table salt (NaCl) consists of two fcc (cubic F) Bravais lattices, slightly offset and overlaid on top of each other. One Bravais lattice contains Cl⁻ ions and is centered at origin, 0 0 0, while the second Bravais lattice contains Na⁺ ions and is centered at 0 ½ 0 (Fig. 10). The structure of the intermetallic compound β-NiAl, which is often called an ordered

bcc structure, actually consists of two simple cubic (primitive) Bravais lattices, one containing Ni atoms centered at 0 0 0 and the second containing Al atoms centered at $\frac{111}{222}$.

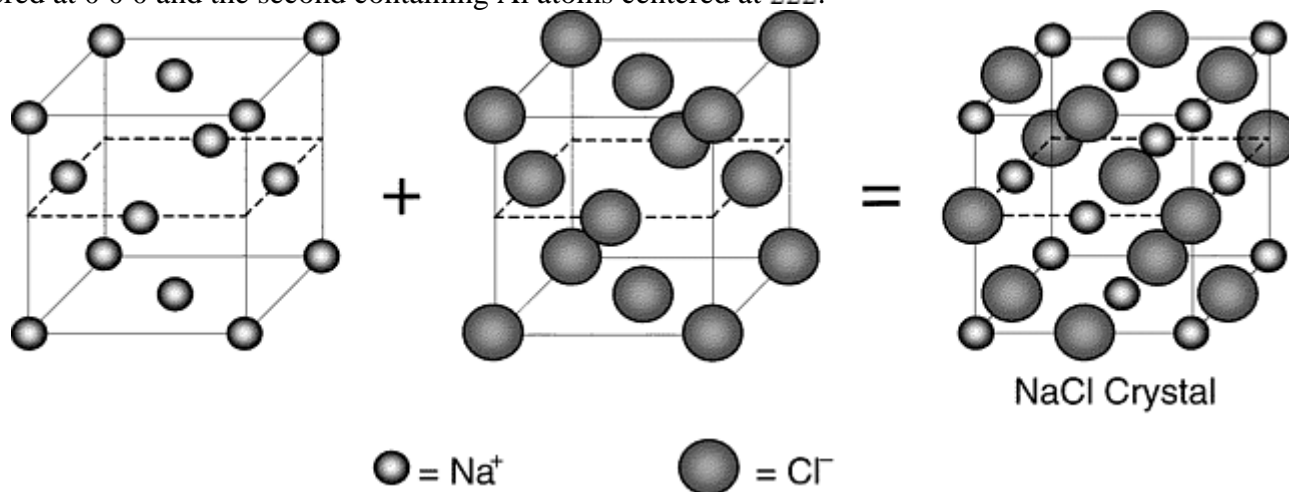

Fig. 10 Schematic illustration of the construction of NaCl from two interpenetrating fcc Bravais lattices

Inorganic Noncrystalline Solids

Not all solids are crystalline. Unlike their crystalline counterparts, noncrystalline materials do not display long-range order. Instead, these solids exhibit some local order (i.e., short-range order) where atomic or molecular subunits repeat over short distances. This group of materials, often collectively referred to as glasses, includes many high molecular weight polymers, some polar-covalent ceramics, and some metallic alloys. Amorphous structures arise because the mobility of atoms within these materials is restricted such that low energy configurations (crystalline) cannot be reached.

To fully describe the nature of glassy materials, it is useful to consider the structure and properties of commercial inorganic glasses. When cooling from the liquid state, materials may solidify in two different ways. If the cooling rate is sufficiently slow, the liquid may freeze in the form of a crystalline solid. If the cooling rate is extremely high, the liquid may pass through the freezing range without crystallizing so that it becomes a supercooled liquid, which transforms to glass at lower temperatures. The critical cooling rate required for glass formation in common inorganic glass is very low ($\leq 10^{-1}$ K/s), which means that it is very easy to form inorganic glasses with these compositions. In metallic alloys, glass formation is more difficult and requires cooling rates in excess of 10^5 K/s (Ref 7).

The supercooled liquid transforms to glass at the glass transition point, T_g in Fig. 11(a). At this point, the temperature dependence of the specific volume of the liquid changes. In glassy materials, there is little or no change in volume upon cooling below the melting point, T_{mp} . In contrast, crystallization is accompanied by a sharp decrease in volume below T_{mp} . At temperatures below T_g , the slopes of both the glass and crystallized solid curves are the same; however, the volume of glass is greater than the crystalline solid at all temperatures where both forms can exist. The volume difference and the glass transition temperature depend on the cooling rate, as illustrated in Fig. 11(b). The volume difference is related to the more open structure in the glass. The difference is usually very small, in the range of a few percent for silicate glasses. In metallic glasses, it is usually less than one percent (Ref 7).

Fig. 11 Schematic representation of (a) the specific volume of liquid, glass, and crystal versus temperature, and (b) the effect of cooling rate

The transition from supercooled liquid to glass during cooling is believed to be caused by a rapid rise in the viscosity of the supercooled liquid during cooling. Empirical relationships have been derived to describe the viscosity of glass as a function of temperature. The simplest relationship is (Ref 8):

$$\eta = \eta_0 \exp\left(\frac{B}{T - T_0}\right) \quad (\text{Eq 1})$$

where η is the viscosity, T is the absolute temperature, and η_0 , B , and T_0 are constants.

Below the glass transition point, viscous flow of the supercooled liquid becomes so slow that the liquid begins to behave as though it was elastic. In other words, the supercooled liquid structure existing at the glass transition temperature becomes frozen in place below T_g .

Most common inorganic glasses are based on the silicate tetrahedron shown in Fig. 12(a). A three-dimensional solid forms when the corner oxygen atoms join with the adjacent tetrahedra. In the glassy state (Fig. 12b), the tetrahedra join randomly, whereas in the crystalline state the tetrahedra take on long-range order, as illustrated in Fig. 12(c). Pure silica glass exhibits a high glass transition temperature, making it suitable for elevated temperature applications but also making it viscous and difficult to work. To overcome this problem, network modifiers, such as CaO or Na₂O, are usually added to commercial glasses. The network modifiers introduce positive ions to the structure, which are accommodated by breaking up the three-dimensional network (Fig. 12d).

Metallic glasses exhibit many unique physical and mechanical properties. Some of these materials exhibit high strength coupled with high ductility, and high corrosion resistance. Metallic glasses deform by homogeneous shear above their glass transition temperatures. In this type of flow, every atom or molecule responds to the applied shear stress and participates in deformation. Homogeneous shear flow is a common deformation mechanism in liquids. Above T_g , metallic glasses behave like liquids. Below T_g , the deformation is inhomogeneous and occurs via the formation of localized shear bands. Each band is accompanied by extensive local offsets. The formation of multiple shear bands can produce extensive ductility.

Polymers

As noted previously, polymers are composed of covalently bonded long-chain molecules, which are joined together by secondary bonds or covalent cross links. Under applied stresses, polymer chains slide over each other, and failure occurs by separation of chains rather than by breaking of interchain bonds. This type of motion is relatively easy where secondary bonds join molecules. However, most polymers have side branches or bulky side groups on their chains and are not strictly linear. Side branches alter the properties of polymers by

inhibiting interchain sliding. Cross-linking also influences the properties of polymers. Cross-linking can occur, for example, when unsaturated carbon bonds (e.g., double bonds) exist between the atoms making up the backbone of the polymer chain that can be broken, allowing individual atoms or molecules to link to adjacent chains. Heavily cross-linked polymers can develop rigid three-dimensional network structures that inhibit interchain sliding, resulting in increased strength and decreased ductility.

Structurally, most polymers are amorphous and consist of a random arrangement of molecules, as illustrated in Fig. 13. Examples of amorphous polymers include polyvinyl chloride (PVC), polymethyl methacrylate (PMMA), and polycarbonate (PC).

Fig. 13 Schematic representation of a polymer. The spheres represent the repeating units of the polymer chain, not individual atoms. Source: Ref 9

Some polymers can exhibit limited crystallinity. This occurs when the polymer chains arrange themselves in a regular manner. Crystalline polymers are characterized by a degree of crystallinity, which is a measure of the extent of long-range three-dimensional order. In general, simple polymers, such as polyethylene with little or no side branching crystallize very easily whereas in heavily cross-linked polymers, such as polyisoprene, and in polymers containing bulky side groups, crystallization is inhibited. As such, thermoset polymers are seldom crystalline. In polymers containing side groups, the degree of crystallinity is often to the location of the side group. Polystyrene (PS), for example, is amorphous in its *atactic* form where benzene ring substitution is random within each repeating unit of the molecule. However, PS is crystalline in the *isotactic* form where substitution occurs at the same location within each repeating unit. The regular structure of the isotactic form promotes crystallinity. Crystalline structures are also likely in polymers that are *syndiotactic*, where the side groups alternate positions in a regular manner. Examples of atactic, isotactic, and syndiotactic arrangements are schematically illustrated in 14 14Fig. 14.

Fig. 14 Schematic representation of the possible side group arrangements in a simple vinyl polymer: (a) atactic (random), (b) isotactic (all on same side), and (c) syndiotactic (regularly alternating). Source: Ref 10

Amorphous polymers are normally used near or below their glass transition temperatures. Above this temperature, the elastic modulus decreases rapidly, and creep effects become pronounced. Below this temperature, they tend to be glassy and brittle with elastic moduli on the order of 3 GPa. Crystalline polymers are, in general, less brittle than amorphous polymers. In addition, they retain their strength and stiffness more effectively than amorphous polymers at elevated temperatures.

Some polymers, known as *network polymers* or *cross-linked thermosets*, form three-dimensional structures via *cross-linking* between chains. Common examples include Bakelite, polyester resins, and epoxy adhesives. In Bakelite, cross-links form by means of phenol rings, which are integral parts of each chain. The structure of Bakelite is schematically illustrated in Fig. 15. Unlike thermoplastic polymers, thermosets do not have real glass-transition temperatures and thus will not melt during heating. Instead, they tend to degrade (depolymerize) at elevated temperatures.

Fig. 15 Schematic representation of the structure of a phenol formaldehyde. (a) Two phenol rings join with a formaldehyde molecule to form a linear chain polymer and molecular by-product. (b) Excess formaldehyde results in the formation of a network, thermosetting polymer due to cross-linking.

Elastomers are another class of polymers that include natural rubber and a variety of other synthetic polymers exhibiting similar mechanical properties. Elastomers also form via cross linking between chains, and most behave like thermosets. Polyisoprene, for example, is a synthetic polymer with the same basic structure as natural rubber, but without the impurities found in natural rubber. The addition of sulfur along with heat (~140 °C) and pressure causes sulfur cross-links to form. As the degree of cross-linking increases, the polymer becomes harder. This particular process is known as *vulcanization*. A schematic representation of these cross-linking arrangements is shown in Fig. 16. Sometimes curved polymer chains can also evolve due to the arrangement of bonds between the atoms forming the backbone of each chain. This is schematically represented in Fig. 17. In this example, the molecule or atom, R, is placed on an unsaturated carbon chain in either a cis or trans position. In the cis position, the unsaturated bonds lie on the same side of the chain. In the trans position, they lie on opposite sides of the chain. The cis structure makes the molecule tend to coil rather than remain

linear. This coiling is believed to be responsible for the extensive elasticity observed in elastomers (e.g., rubber).

Introduction to the Mechanical Behavior of Nonmetallic Materials

M.L. Weaver and M.E. Stevenson, The University of Alabama, Tuscaloosa

Deformation/Strengthening Mechanisms

Crystalline Solids

As noted in the previous article, metals generally deform via slip and/or twinning. Slip occurs via the motion of dislocations on close-packed planes and in close-packed directions, whereas twinning occurs via the cooperative movement of atoms producing a macroscopic shear. In slip, the combination of slip planes and directions are known as slip systems. The most common slip systems for disordered metals and alloys are schematically illustrated in Fig. 18. According to the von Mises criteria, at least five independent slip systems must be available in polycrystalline materials for the material to be capable of plastic deformation. Thus, the greater the number of independent slip systems, the greater is the possibility for plastic deformation. Most technically significant metals and alloys with cubic structures have five or more independent slip systems and thus exhibit substantial plasticity. For example, Ni and Cu, which are fcc metals, each have five independent slip systems and are extremely ductile at ambient temperatures. However, Co, which is an hcp metal, has less than five independent slip systems and is brittle at ambient temperatures. Metals with less than five slip systems can exhibit plasticity at ambient temperatures provided other deformation modes are available. A good example of this is Zn, which exhibits only three systems but also exhibits twinning.

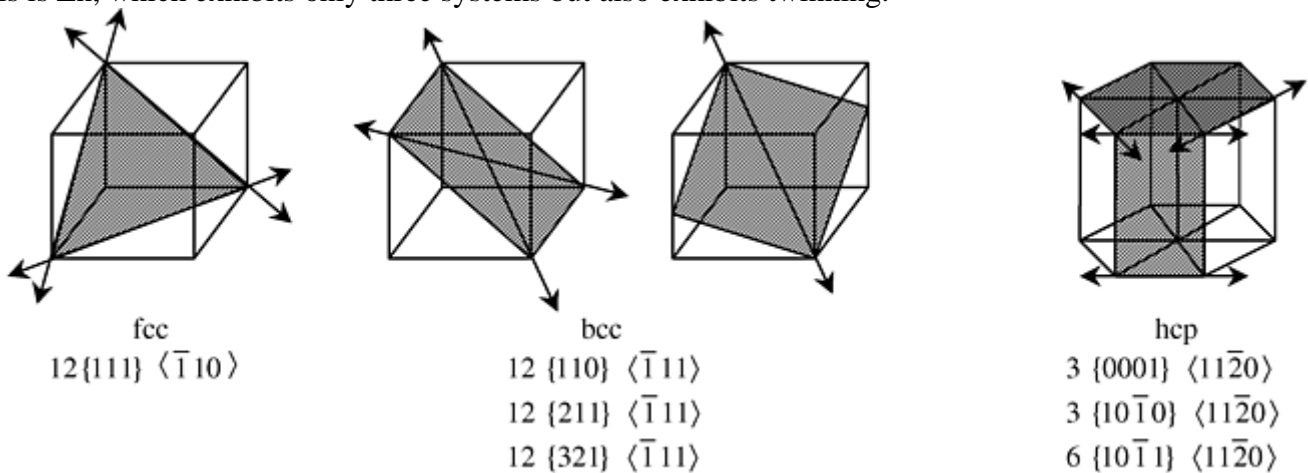

Fig. 18 Common slip systems observed for fcc, bcc, and hcp crystal structures

Twinning is a particularly important deformation mode in materials where slip is restricted. A schematic diagram of twinning is provided in Fig. 19. Twinning produces a reorientation of the lattice resulting in a region that is a mirror image of the parent lattice. The actual amount of strain that is gained from twinning is very small (typically less than 5%). The true benefit of twinning is that the lattice inside the twin is frequently

reoriented such that the slip systems are more favorably aligned with respect to the applied stress, which can allow some limited plastic deformation to occur.

Fig. 19 Schematic of twinning as it occurs in an fcc lattice. Source: Ref 11

Plastic deformation in ceramic and intermetallics also occurs via slip and/or twinning. However, plastic deformation is typically more difficult in ceramics and intermetallics compared with metals, due, in part, to the strong and directional atomic bonds, ordered atomic distributions, and less symmetric lattice structures present in these materials. These features combine to restrict the motion of dislocations. In comparison with metals, ceramics are considered to be intrinsically hard and brittle. Intermetallics cannot be described as being intrinsically hard or soft; however, they are typically brittle. The different mechanical properties of these materials are related to bonding. The metallic bonds in metals make dislocation motion relatively easy, whereas the highly directional ionic, covalent, and mixed bonds observed in ceramics and intermetallics present large lattice resistance to dislocation motion.

In their polycrystalline form, most ceramics and intermetallics exhibit limited plasticity at ambient temperatures because they do not have enough independent slip systems for general deformation to occur. In many of these materials the lack of slip systems can be traced to the crystal structure, which is often so complex that the stress required to move a dislocation (the Peierls stress) becomes larger than the fracture stress. In NaCl, for example, slip occurs on $\{111\} \langle 1\bar{1}0 \rangle$ slip systems at ambient temperatures. This only yields two independent slip systems, which is not enough for polycrystalline ductility. In isostructural AgCl, slip occurs on both $\{111\}$ and $\{100\}$ planes, which provide enough independent slip systems for polycrystalline deformation.

In ionically bonded polycrystalline ceramics such as NaCl, deformation is further complicated because local charge neutrality must be maintained during deformation. In ionic ceramics, proper charge balance on either side of the slip plane is accomplished by introducing two extra half planes of atoms. The lines of ions at the bottoms of these half planes consist of alternating positive and negative ions. Dislocations can become charged, which can influence their mobility. The formation of a jog in a dislocation (20) can cause a localized charge imbalance, which must be compensated for by the formation of defects or the accumulation of atmospheres of oppositely charged impurities.

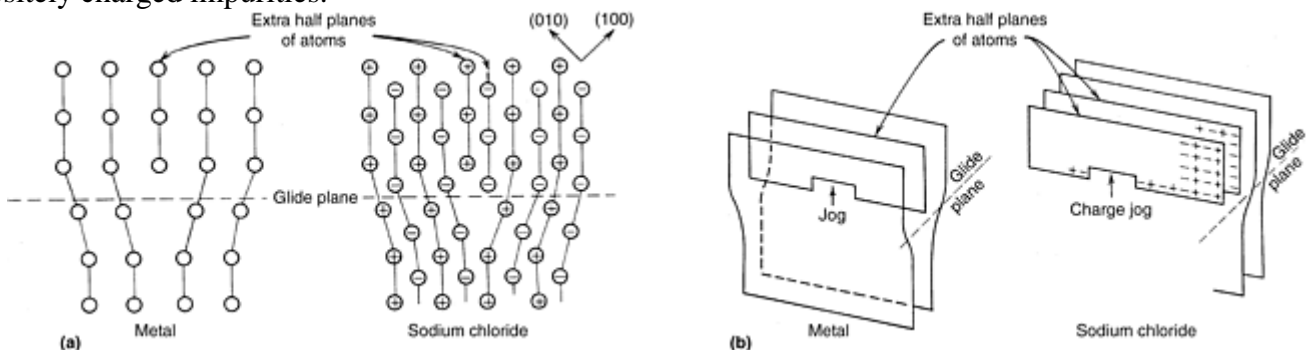

Fig. 20 (a) Schematic representation of an edge dislocation in NaCl. (b) Demonstration of how dislocation jogs in ionic crystals can have effective charges. Source: Ref 12

In more covalent ceramics and intermetallics, slip is complicated by the requirement that atomic order must be maintained. Perfect single dislocations, which do not influence the order of atoms, have longer Burgers vectors than dislocations in disordered alloys. Thus, these dislocations have higher strain energy. Such dislocations can assume lower energy configurations by dissociating into shorter dislocation segments, partial dislocations, which are separated by stacking faults and/or antiphase boundaries. These combinations of partial dislocations, stacking faults, and antiphase boundaries are known as superdislocations. When superdislocations move, the atomic order that is destroyed by passage of the leading partial dislocation is restored by passage of the trailing partial dislocation. Additional reasons for the lack of ductility in intermetallics include: difficulty transmitting slip across grain boundaries, intrinsic grain boundary weakness, segregation of deleterious solutes to grain boundaries, covalent bonding and high Peierls stress, and environmental susceptibility. Increased ductility can be obtained in some intermetallics by microalloying (e.g., NiAl with Fe, Mo, or Ga; Ni₃Al with B; or Ti₃Al with Nb). At higher temperatures, however, thermal activation permits additional slip activity to occur in all of these materials, which may allow them to be ductile.

Strengthening Mechanisms in Crystalline Solids (Ref 13, 14, 15)

As just discussed, ceramics and intermetallics generally deform via slip and/or twinning. As a result, anything that reduces the mobility of dislocations (i.e., anything that inhibits slip) will cause an increase in strength. The most common strengthening mechanisms, work hardening, solid-solution hardening, particle/precipitation hardening, and grain size hardening are described here.

Solid Solution Strengthening. Pure metals generally have low yield stresses compared with impure metals or single-phase alloys and compounds. The addition of substitutional or interstitial solute atoms to the lattice of a pure metal gives rise to local stress fields around each impurity atom. These local stress fields interact with those surrounding dislocations, which reduces the mobility of dislocations leading to increased strength. The amount of strengthening is related to the binding energy between the solute atoms and the dislocation, the concentration of the solute atoms, and the locations of the solute atoms within the lattice. For example, the magnitude of strengthening can be greater when solute atoms assume specific locations within the lattice (i.e., they order) as opposed to when they assume random positions. The same general principles apply in ceramics and intermetallics; however, the presence of long-range ordered crystal structures and charged ions within these materials makes it difficult to apply conventional models for solid solution hardening.

Solid solution strengthening can be considered by assuming that each foreign atom produces a restraining force, F , on the dislocation line. The magnitude of the restraining force (and thus the amount of strengthening obtained) depends on the nature of the interactions between foreign atoms and dislocations. The two most common interactions are elastic interactions and chemical interactions. Assuming that the atoms are spaced at an average distance, d , along the dislocation line, and that the dislocation glides a distance b on the slip plane, the ratio F/d gives the force per unit length of dislocation that must be overcome by the applied shear stress, τ . The increment in applied stress needed to overcome the restraining force per unit line length is $\Delta\tau b$ such that:

$$\Delta\tau = \frac{F}{bd} \quad (\text{Eq 2})$$

When the solute atoms have different sizes than the host atoms or different elastic moduli, they tend to alter the crystal lattice locally in the vicinity of the solute atom. This causes the moving dislocation to be either attracted to or repelled away from the solute. When the dislocation is attracted toward the solute, strengthening is caused because more force is required to pull the dislocation away from the solute. When the dislocation is repelled by the solute, strengthening is caused because more force is required to push the dislocation past the solute atom.

Solid solution strengthening can occur in ceramics and intermetallics just as it does in metals. Both substitutional and interstitial types are possible. In ceramics, interstitial solid-solution strengthening will occur if the ionic radius of the solute is small in comparison with the solvent (anion). In the case of substitutional solid-solution strengthening, because both anions and cations are present, a substitutional impurity will substitute for the host ion to which it is most similar in the electrical sense (i.e., if the impurity atom normally forms a cation in a ceramic material, then it will likely substitute for the host cation). In NaCl, for example,

Ca^{2+} and O^{2-} would probably substitute for Na^+ and Cl^- ions, respectively. To achieve appreciable solid solubility, the ionic size and charge of the substituting atoms must be nearly the same as those of the host ions. If impurity ions have different charges than the host ions, the crystal must compensate structurally such that charge neutrality is maintained. This can be accomplished by the formation of lattice defects, such as vacancies or interstitials (Schottky, Frenkel defects).

In ionic crystals, the presence of charged dislocations also plays a role. Solutes exhibiting different valence than the host atoms (i.e., aliovalent) are more effective in increasing the yield stress than ions with the same valence (isovalent). Aliovalent ions are more effective because they produce an asymmetric elastic distortion, which interacts strongly with dislocations. The stress increment caused by solid solution strengthening in ceramics is described by the equation:

$$\left(\frac{\Delta\tau}{\tau_0}\right)^{1/2} = 1 - \left(\frac{T}{T_0}\right)^{1/2} \quad (\text{Eq 3})$$

where T is the absolute temperature, $T_0 = G\Delta\epsilon b^3/(3.86\alpha k)$, $\tau_0 = G\Delta\epsilon c^{1/2}/(3.3)$, c is the concentration of defects, $\Delta\epsilon$ is the misfit strain, b is the Burgers vector, α is a constant, and k is Boltzmann's constant (Ref 14).

Work hardening, also known as strain hardening, is an important industrial process that is used to harden metals or alloys. The hardening or strengthening is a direct result of dislocation multiplication and dislocation-dislocation interactions. Work hardening is also an important phenomenon in some intermetallic systems but is not a viable process for ceramics and glasses. Polymers do not work harden; however, an analogous phenomenon, cold drawing, occurs in thermoplastics. Cold drawing is addressed in a subsequent section of this article.

When dislocations moving on intersecting slip systems collide some of them will become pinned. The more the material is plastically deformed, the higher the dislocation density becomes, resulting in more restricted dislocation motion. A high work hardening rate implies the obstruction of dislocations gliding on intersecting systems. Thus, techniques that increase dislocation density also increase strength. For a given dislocation distribution, the shear flow stress, τ , is related to the dislocation density, ρ , by an equation of the form:

$$\tau = \tau_0 + \alpha G b \rho^{1/2} \quad (\text{Eq 4})$$

where α is a materials specific constant that varies from 0.2 to 0.4 for different fcc and bcc metals, G is the material shear modulus, b is the Burgers vector, and τ_0 is the flow strength in absence of work hardening (Ref 6). At high strains, dislocations will tangle and form cell structures. The hardening then becomes more a function of cell size than of dislocation length.

Grain Size Strengthening. Internal boundaries also act as obstacles to dislocation motion. Boundaries impede dislocations over a large length, which often makes boundary strengthening a more potent strengthening mechanism than solid-solution strengthening or work hardening. At grain boundaries, there is a change in crystallographic orientation, which prevents or inhibits the passage of dislocations. For slip to continue across a grain boundary, yielding must occur within the adjacent grain. If the orientation of the adjacent grain is unfavorable, dislocations will pile up against the boundary leading to a stress concentration at the boundary. Under action of a stress concentration, slip can be initiated within the adjacent grain. The increase in stress associated with grain size can be represented by the Hall-Petch relation from which the stress increment can be written as:

$$\Delta\tau = \frac{k_y}{\sqrt{D}} \quad (\text{Eq 5})$$

where D is the grain diameter and k_y is a locking parameter that describes the relative strength of the boundary. This relationship shows that as the grain size increases, the stress concentration at the boundary decreases, resulting in reduced strengthening compared with fine-grained materials. Other boundaries such as subgrain boundaries and stacking faults can also form obstacles to dislocation motion; however, they are less potent strengtheners than grain boundaries.

Precipitation/Particle Hardening. Substantial strengthening can also be obtained by adding precipitates or dispersoids to the material. The extent of strengthening is determined by a number of factors including volume fraction, particle size, particle shape, and strength of the particle-matrix interface (Ref 14, 15). This is directly related to interactions between moving dislocations and the particles as the presence of particles inhibits dislocations by providing additional barriers to their motion.

To overcome the presence of particles, dislocations will either cut through (i.e., shear) them or will bow around them. If the particles are small and coherent, they are more likely to be shearable. Whether or not shearing occurs depends on a number of factors including particle misfit, particle modulus, and particle structure. In shearable particles, the presence of coherent particles with lattice parameters that are either larger or smaller than the matrix leads to internal stress fields that interact with dislocations. Similarly, particles exhibiting different shear moduli than the matrix will also alter or inhibit dislocation motion. Additional strengthening can also be achieved if the particles have low stacking fault energies or exhibit ordered crystal structures. An additional form of strengthening, chemical strengthening, is related to the energy required to create an additional area of particle-matrix *interface* when the particle is sheared. If the particles are large or incoherent, dislocations will bow around the particles until the bowing segments join. The dislocation can then proceed, leaving a dislocation loop around the particles. This is known as *Orowan looping*. As particle size increases, the bowing stress decreases. In precipitation-hardened systems, maximum strengthening (at a fixed volume) is achieved when the shearing stresses and the bowing stresses are equal.

The above descriptions refer to materials with a relatively low volume-fraction of particles. However, in metal-matrix composites, higher concentrations of particles have been used to strengthen materials. Usually in these dispersion-strengthened systems, high strength, high-modulus particles or fibers are artificially added to a low modulus substrate. The strengthening is believed to result in part from the modulus difference between the matrix and the dispersed particles. The high-modulus particles or fibers carry most of the stress, while the relatively ductile matrix accommodates most of the strain. There is also usually enhanced work hardening within the matrix near the particles, which leads to strengthening.

Deformation and Strengthening of Polymers (Ref 16, 17)

Mechanical properties of polymers are influenced by a variety of the structural parameters introduced previously. The strength of many polymers is directly related to the molecular weight and to the degree of crystallinity. Properties related to tension are often expressed in the form:

$$\text{Property} = a - \frac{b}{M_n} \quad (\text{Eq 6})$$

where \overline{M}_n is the number average molecular weight and a and b are experimental constants. The number average molecular weight is defined as:

$$\overline{M}_n = \frac{\sum[x_i M_i]}{\sum x_i} \quad (\text{Eq 7})$$

where x_i is the number of molecules in each size fraction and M_i is the molecular weight in each size fraction. Increased crystallinity can lead to increased tensile strength, stiffness, and yield strength. When polymers exhibit some crystallinity, stiffness and elastic modulus can change by more than an order of magnitude. Copolymerization of multiple monomers also can modify mechanical properties by decreasing crystallinity and, thus, lowering stiffness and yield point.

Many polymers exhibit viscoelastic behavior. When viscoelastic polymers are stressed, there is an immediate elastic response as indicated in Fig. 21 (Ref 17), followed by viscous flow, which decreases with increasing time until a steady state is achieved. If the material is then unloaded, the elastic strain is recovered followed by time dependent (delayed) recovery. Some permanent strain, denoted as permanent recovery in Fig. 21, remains.

Fig. 21 Schematic representation of viscoelastic behavior of a polymer. Loading produces an immediate elastic strain followed by viscous flow. Unloading produces an immediate elastic recovery followed by additional recovery over a period of time. Source: Ref 17

In thermoplastic polymers, permanent deformation occurs via interchain sliding. Strengthening is accomplished by impeding chain sliding. One way to accomplish this is by adding “bulky” side groups to each polymer chain. This results in a geometric (steric) hindrance to chain sliding. For example, for a polymeric series based on the monomer C_2H_3R , where R represents a specific atom or side group, strength increases proportionally with the size of the side group. For example, polypropylene ($R = CH_3$) is stronger than polyethylene ($R = H$).

In general, crystalline polymers are much stronger than noncrystalline ones. Higher density in crystalline polymers can be correlated with the fact that the polymer chains are aligned closer together, which makes chain displacement more difficult. One good example of this is polyethylene where strengthening can be achieved by drawing, which effectively increases the amount of crystalline material. Most thermoplastic polymers are difficult to crystallize, however, due to their bulky side groups and greater viscosity (Ref 18).

Drawing is a technique used to strengthen thermoplastics. During drawing, the long axes of the polymer chains align along the drawing direction. In filament form, the strength of drawn polymers is related directly to the strength of the covalent bonds in the polymer backbone rather than the resistance to interchain sliding. This type of strengthening, which is truly realized only in filaments, forms the backbone of the textile industry.

Though different polymers can exhibit limited solubility between each other, polymers cannot really be solid-solution strengthened as metals, ceramics, and intermetallics can be. Exceptions occur when rigid rod molecules with very stiff backbones are added. These molecules reinforce the polymer when dispersed in it in the same way that fibers reinforce composite materials.

Deformation and Strengthening of Composite Materials

Composites are classified either by the type of matrix or the type of reinforcement. Common matrix classifications include polymer-matrix composite (PMC), metal-matrix composite (MMC), ceramic-matrix composite (CMC) and intermetallic-matrix composite (IMC). Reinforcement classification schemes include particulate-reinforced composite, fiber-reinforced composite, and laminate composite. Composites are designed to take advantage of the best characteristics of each component.

Microstructurally, composites consist of a matrix and a reinforcing phase. In fiber-reinforced composites, the matrix holds the fibers together, protects them from damage, and transmits load to the fibers. The reinforcing phases, which can be fibers, filaments, laminates, and so on, usually involves high strength, high modulus materials that are too fragile for use in a monolithic form. Ductile reinforcements can also be used to toughen brittle matrix materials.

Polymer-matrix composites are the commercially important composites. The polymer matrix is typically a thermoset, as opposed to a thermoplastic. Unlike thermoplastics, thermosets are relatively stable over a wide range of temperatures and are resistant to plastic deformation. Many common PMCs contain glass fibers embedded in epoxy resins. Stronger fiber, such as graphite fiber, is used as well.

Thermoset composites are made by adding a reinforcement to the thermoset during or prior to setting. The thermoset bonds the reinforcement together. The polymer matrix also protects glass-fiber interfaces from degradation. Glass is prone to react with water vapor in air, which induces corrosive surface flaws (crack initiation sites).

Basic composite mechanics can be addressed by considering Fig. 22. Consider a two-phase material consisting of N lamellae of α and β phases with thickness of l_α and l_β , respectively. The volume fractions of each phase are:

$$V_\alpha = \frac{l_\alpha}{(l_\alpha + l_\beta)} \quad \text{and} \quad V_\beta = \frac{l_\beta}{(l_\alpha + l_\beta)} \quad (\text{Eq 8})$$

The application of a force along the y -axis and the stresses experienced by each lamellae are equal (i.e., $\sigma_\alpha = \sigma_\beta = \sigma_c = F/L^2$); however, the strains differ from lamellae to lamellae. The composite strain is, thus, the weighted average of the individual strains or:

$$\epsilon_c = V_\alpha \epsilon_\alpha + V_\beta \epsilon_\beta \quad (\text{Eq 9})$$

From Hooke's Law, the composite modulus thus becomes:

$$E_c = \frac{E_\alpha E_\beta}{(V_\alpha E_\beta + V_\beta E_\alpha)} \quad (\text{Eq 10})$$

Fig. 22 Schematic representation of lamellar arrangement in a two-phase composite material. Source: Ref 19

When a force is applied along the z-direction, each lamellae experiences equal strains (i.e., $\epsilon_\alpha = \epsilon = \epsilon_\beta = \epsilon_c$); however, the stresses experienced differ. For example, the force carried by each α lamella can be approximated by assuming that the sum of the forces borne by the individual phases equals the total external force:

$$F = (F_\alpha + F_\beta) \quad (\text{Eq 11})$$

Because each lamellar carries a stress, the forces experienced by the respective α and β lamellae are:

$$F_\alpha = \sigma_\alpha N l_\alpha L \text{ and } F_\beta = \sigma_\beta N l_\beta L \quad (\text{Eq 12})$$

Substitution of these relationships into Eq 11 allows the respective volume fraction rules for composite stress and modulus to be calculated as:

$$\sigma_c = V_\alpha \sigma_\alpha + V_\beta \sigma_\beta \text{ and } E_c = V_\alpha E_\alpha + V_\beta E_\beta \quad (\text{Eq 13})$$

This volume fraction rule is the one most commonly followed by composites since the phase distributions in most composites are close to that for which the equal strain approximation is valid.

Using these relationships, it is useful to plot the influence of volume fraction upon the load carried by the reinforcement in the elastic regime. Such a plot is shown in Fig. 23 assuming that the α -phase is stronger than the β -phase. This plot effectively shows that the strengthening phase is much more effective in carrying load when forces are applied parallel to the axis of the reinforcing phase. Reinforcements can be dispersed in a variety of ways in composite materials.

Fig. 23 Ratio of the force carried by the strong phase to that carried by the weak phase for deformation parallel and perpendicular to the lamellae. Source: Ref 19

Most composites are not as ideally arranged as those just described. Thus, variants of Eq 10 and 13 are used to describe the properties of materials possessing different types of reinforcements. For particle-reinforced materials, the composite stress and modulus can be expressed by:

$$\sigma_c = V_m \sigma_m + K_s V_p \sigma_p \text{ and} \quad (\text{Eq 14})$$

$$E_c = V_m E_m + K_c V_p E_p$$

where E_p and E_m represent the particle and matrix moduli, V_p and V_m represent the particle and matrix volume fractions, σ_m and σ_p represent the matrix and particle tensile strengths, and K_s and K_c represent constants.

One of the most common ways is to use reinforcements in the form of continuous fibers. A similar expression is valid for continuous fiber-reinforced composites; the volume fraction rule is similarly expressed as:

$$\sigma_c = V_f \sigma_f + V_m \sigma_m = V_f \sigma_f + (1 - V_f) \sigma_m \quad (\text{Eq 15})$$

where σ_c , σ_f , and σ_m represent the tensile strengths of the composite, fibers, and matrix, respectively, and V_f and V_m represent the respective fiber and matrix volume fractions in the composite. This equation applies when the long axis of the fibers is aligned parallel to the stress axis. Table 2 lists the properties of a number of continuous fibers. Nonmetallic fibers demonstrate high strengths and higher strength-to-density ratios, which make them attractive in applications such as aerospace where low weight is a premium. The volume fraction rule applies provided the long axis of the fibers remains aligned with the stress axis. Random distributions of fibers result in lower strengthening. In addition, strengthening is lower for particulates or when the fibers are not parallel to the stress axis. Expressions similar to the volume fraction rule derived here are used to estimate other composite properties like elastic modulus. Not all properties can be calculated using such a simple rule.

Table 2 Properties of selected fibers

Materials class	Material	Density mg/m ³ (ρ)	Tensile strength (TS)		TS/ρ, MNm/kg
			GPa	ksi	
Metals	Pearlitic steel (piano wire)	7.9	4.2	610	0.53
	Be	1.8	1.3	190	0.72
	Mo	10.3	2.1	310	0.2
	W	19.3	3.9	570	0.20
Ceramics and glasses	Al ₂ O ₃	3.96	2.0	290	0.51
	Graphite (Kevlar)	1.5	2.8	410	1.87

	Copolyhydrazide	1.47	2.7	390	1.84
	Poly(P-phenylene) terephthalamide	1.44	2.8	410	1.94

Source: Ref 19

The use of metals to reinforce ceramics (or intermetallics) usually increases toughness but decreases strength. Increased toughness is the result of the blunting and/or arrest of cracks by the ductile reinforcement. Reinforcement geometry is also important. Fibers and laminates tend to improve toughness more than equiaxed particles. When cracks approach fibers or lamellae (plates), they are often deflected along the reinforcement-matrix interface. This increase in crack tortuosity provides additional work to fracture and, thus, an increase in fracture toughness. Additional information on structure-property relationships for composite materials can be found in Ref 20 and 21.

Deformation and Strengthening of Glasses

The mechanical behavior of glasses is similar to that of crystalline materials, in that increases in strain rate and decreases in temperature result in increased strength. The actual mechanisms that are responsible for deformation, however, differ from those exhibited by crystalline materials.

At low temperatures and low stresses, all glasses deform in a linear elastic manner. Linear elastic strains result from stretching of the chemical bonds making up the glass structure. Linear elastic deformation is followed by viscoelastic deformation at intermediate temperature, which is followed by Newtonian viscous flow at elevated temperatures (i.e., $T_g \leq T \leq T_{mp}$). Viscoelastic strains, which are time dependent and recoverable, result from conformal rearrangements of the basic structural units making up the glass structure (i.e., SiO₄ tetrahedra in silica-base glasses, individual atoms in metallic glasses, and long chain molecules in organic glasses). Newtonian viscous flow, which can be correlated with a linear dependence of the applied stress on the applied strain rate, results from localized slip processes, which result in the permanent displacement of basic structural units of the material with respect to each other. In glassy polymers, the units are long chain molecules whereas for metallic or inorganic glasses the basic units are single atoms or SiO₄ tetrahedra, respectively. Elevated temperature deformation of noncrystalline materials is distributed uniformly throughout the volume of the material. These facts are often exploited to form glassy materials into useful geometry. As temperature is decreased, the material becomes stronger, and an alteration in flow behavior occurs. In inorganic glasses, permanent deformation does not occur at low temperatures. On the other hand, in metallic and organic glasses, permanent deformation occurs in a heterogeneous fashion involving the cooperative displacement of atoms or molecules. This process is known as *shear banding*.

Metallic glasses become softer after shear band formation because the stress required to propagate the band is lower than the stress required to initiate it. Fracture usually occurs after the propagation of a single shear band. Conversely, in organic glasses, shear band formation is not followed by instability and fracture. More shear bands form until the density of bands is so high that they coalesce, resulting in a neck containing highly oriented molecules. Once the neck forms, it propagates up and down the gage length, leading to an increase in strength.

Introduction to the Mechanical Behavior of Nonmetallic Materials

M.L. Weaver and M.E. Stevenson, The University of Alabama, Tuscaloosa

Fatigue and Fracture of Nonmetallic Materials (Ref 22, 23, 24)

Two important aspects of the mechanical behavior of any class of engineering material are the fatigue response and fracture resistance. Most engineering structures are subject, in some form, to fatigue. Therefore, the ability of a material to withstand the accumulation of damage from fatigue is very important in terms of the life span of the component. Additionally, the fracture behavior of a material is important in terms of preventing premature failure. Considering the importance of these properties, a brief overview of the response of ceramics and polymers is discussed here and comparison is made to many typical metallic materials.

Fatigue Response of Ceramics and Polymers

When discussing fatigue in terms of brittle solids, it is not necessarily assumed that the term *fatigue* refers to cyclic loading conditions. In most cases, fatigue in ceramics is limited to static loading conditions where the loss of strength with time is the underlying phenomenon. Until recently, it was a common misconception that cyclic fatigue damage was not observed in ceramics. More recently, the cyclic fatigue lives have been proven to be shorter than the static fatigue lives, which indicates that there is some effect, albeit an unclear one, that causes cyclic loading to vary from static loading.

In conventional metals, fatigue is commonly associated with some amount of plastic strain, which is not prevalent in ceramics and glasses. Since there is no dominance by plastic strains, application of the popular strain-life method is not possible for ceramic and glass materials at room temperature. For ceramics, the assumptions of linear elastic fracture mechanics (LEFM) are satisfied, and analysis using this method is more suitable.

In polymers, traditional fatigue analysis methods, such as those used in metals, can be applied. Polymers, however, involve a significant complication in the body of hysteresis heating and subsequent softening. This phenomenon significantly lowers the fatigue life and additionally induces the dominance of plastic flow as a deformation mechanism, whereas under isothermal conditions fatigue crack propagation dominates. In light of the additional heating and softening problem, polymers still exhibit a traditional fatigue limit, below which no cyclic deformation or resultant heating occurs significantly. Additionally, for polymer crystals, fatigue resistance increases as crystallinity increases (Ref 22, 23, 24).

Fracture Behavior of Ceramics and Polymers

The fracture behavior of materials is important in engineering design because of the high probability of flaws being present. As such, it is important to understand how a material will tolerate the presence under a flaw under operating conditions and how a material will resist the propagation of cracks from these flaws.

In ceramics, loading results in deformation in the elastic regime with little or no plastic deformation at fracture. Conversely, plastics exhibit little or no elastic deformation and a great degree of plastic deformation at final fracture. While the two materials do not share similar stress-strain curves, they do share low values for fracture toughness. The fracture toughness of a material is a measure of its ability to resist fracture propagation. Defined another way, it is the critical stress intensity at which final fracture occurs. In either case, both ceramics and polymers share low values of this parameter. Table 3 compares the approximate values of several classes of engineering materials in terms of their fracture toughness.

Table 3 Fracture toughness values for a variety of engineering materials

Material	Fracture toughness (K_{Ic}), MPa \sqrt{m}
Glasses	0.5–1
Most polymers	1–3
Ceramics	3–7
Intermetallics	1–20
Cast irons	10–40
Aluminum alloys	20–50
Titanium alloys	30–90
Steels (all types)	30–200

While polymers and ceramics do exhibit fracture toughness values that are of the same order of magnitude, the respective modes of fracture are not necessarily the same. In polymers, the fracture process is dominated in many cases by crazing, or the nucleation of small cracks and their subsequent growth. In ceramics and other ionic solids, cleavage on electrically neutral planes is often the dominant fracture mode. These two modes are distinctly different, even though the resistance to fracture for both classes of materials is similar. This brings up the point that, for most materials, no single parameter can quantify the behavior under a given set of conditions. In the example of fracture, K_{Ic} alone will not always provide sufficient data to understand the fracture process. Only an intimate knowledge of the materials structure and the fracture toughness will provide a completely accurate indicator. Besides the material aspects, the fracture process is also statistical in nature (weakest link theory). While fracture statistics can be complicated to understand fully, a good introduction can be found in Ref 24. A more detailed description of the fracture process of these classes of materials can be found by referring to the Selected References.

Mechanical Testing of Polymers and Ceramics

Introduction

THE MECHANICAL BEHAVIOR of polymers and ceramics differs from that of metallic materials due to some basic relationships between microstructure and mechanical properties, as described in the preceding article “Introduction to the Mechanical Behavior of Nonmetallic Materials” in this Volume. This article briefly reviews the general mechanical properties and test methods for polymers and ceramics. Additional coverage is also provided in other Sections of this Volume on hardness testing, high-strain-rate testing, fatigue testing, and fracture toughness. This article does not address the mechanical properties and testing of fiber-reinforced metal-matrix or polymer-matrix composites, which are a distinct product from that involves more specialized method for the testing and analysis of mechanical properties (see the article “Mechanical Testing of Fiber-Reinforced Composites” in this Volume).

Mechanical Testing of Polymers and Ceramics

Mechanical Testing of Polymers

Polymers are high-molecular-weight materials that may exhibit the mechanical behavior of a fiber, plastic, or elastomer (Fig. 1). The use of a polymer as an elastomer (rubber), a plastic, or a fiber depends on the relative strength of its intermolecular bonds and structural geometry. Noncrystalline polymers with weak intermolecular forces are usually elastomers or rubbers at temperatures above the glass transition temperature, T_g . In contrast, polymers with strong hydrogen bonds and the possibility of high crystallinity can be made into fibers. Polymers with moderate intermolecular forces are plastic at temperatures below T_g . Some polymers, such as nylon, can function both as a fiber and as a plastic. Other polymers, such as isotactic polypropylene, lack hydrogen bonds, but because of their good structural geometry, they can serve both as a plastic and as a fiber.

Fig. 1 Typical stress-strain curves for a fiber, a plastic, and an elastomer. Source: Ref 1

This section briefly reviews the mechanical properties and test methods commonly used for these three general categories of polymers, although most of the emphasis is placed on the mechanical properties of structural plastics. In terms of general structure, most polymers are amorphous (noncrystalline) materials with a hard glassy structure below the glass transition temperature (T_g), and either a viscous or rubbery structure above the glass transition temperature (Fig. 2a). This is in contrast to low-molecular-weight materials (such as metals) that typically have crystalline structures. However, the structure of some polymers is regular enough to promote some crystallization, which may result in a flexible crystalline structure above the glass transition temperature (Fig. 2b). For example, isotactic and syndiotactic polypropylenes can crystallize, but atactic polypropylene does

not (see the discussion with Fig. 14 in the preceding article “Introduction to the Mechanical Behavior of Nonmetallic Materials”). Generally, bulky side groups (as in polystyrene) hinder crystallization, while hydrogen bonding (as in nylons) promotes crystallization (Ref 2).

Fig. 2 Influence of molecular weight and temperature on the physical state of polymers. (a) Amorphous polymer. (b) Crystalline polymer. Source: Ref 2

Because of the partial or complete noncrystalline structure of polymers, they undergo a change in mechanical behavior that is not seen in fully crystalline materials. At temperatures well below T_g , plastics exhibit a high modulus and are only weakly viscoelastic. At temperatures above T_g , there is drastic reduction of modulus (Fig. 3), which may be as large as three orders of magnitude. Therefore, the glass transition temperature is the most important temperature that can be specified for most polymers because in all but highly crystalline polymers, it represents the temperature above which the polymer loses most of its stiffness and thus its dimensional stability.

Fig. 3 Shear modulus versus temperature for crystalline isotactic polystyrene (PS), two linear atactic PS materials (A and B) with different molecular weights, and lightly cross-linked atactic PS

A typical modulus-temperature curve is shown in Fig. 3. At temperatures below T_g , most plastic materials have a tensile modulus of about 2 GPa (0.3×10^6 psi). If the material is crystalline, a small drop in modulus is generally observed at T_g , while a large drop is seen at the melting temperature, T_m . The T_g is primarily associated with amorphous, rather than crystalline, resins or cross-linked thermosets. Resins that are partially crystalline have at least a 50% amorphous region, which is the region that has a T_g . If a material is amorphous, a single decrease is usually seen at temperatures near T_g . At even higher temperatures, there is another similar drop in modulus, and the plastic flows easily as a high-viscosity liquid. At this condition, the plastic can be processed by extrusion or molding.

Mechanical properties are also affected by molecular weight. Most material manufacturers provide grades with different molecular weights. High-molecular-weight materials have high-melt viscosities and low-melt indexes. For a commercial product, a melt index is generally an inverse indicator of molecular weight.

When molecular weight is low, the applied mechanical stress tends to slide molecules over each other and separate them. The solid, with very little mechanical strength, has negligible structural value. With a continuing increase in molecular weight, the molecules become entangled, the attractive force between them becomes greater, and mechanical strength begins to improve.

It is generally desirable for material manufacturers to make plastics with sufficiently high-molecular weights to obtain good mechanical properties. For polystyrene, this molecular weight is 100,000 and for polyethylene this value is 20,000. It is not desirable to increase molecular weight further because melt viscosity will increase rapidly, although there are occasional exceptions to this rule. The yield strength of polypropylene decreases when molecular weight increases. High molecular weight and branching reduce crystallinity. Polymers with high intermolecular interaction, such as hydrogen bonding, do not require high molecular weight to achieve good mechanical properties. With low molecular weight, viscosity is very low, which is commonly observed for polyamides.

Typical T_g temperatures and some general thermal properties of selected plastics are listed in Tables 1, 2, and 3. It should also be understood that glass transition temperatures are not distinct transition temperatures like phase transformations, because the transition occurs over a range of temperatures. In a thermoplastic polymer such as polystyrene, the change that occurs gradually over the T_g region eventually leads to a complete loss of

dimensional stability. In a thermoset (network) polymer such as epoxy, the change is less severe, but nonetheless produces significant softening and loss of mechanical properties. The value of T_g may also depend upon the method of measuring viscoelastic transition. Thus, T_g for a polymer represents roughly the center of the transition region.

Table 1 Transition and continuous-use temperatures of general purpose plastics

Plastic	Glass transition temperature (T_g)		Melting temperature (T_m)		Continuous use temperature	
	°C	°F	°C	°F	°C	°F
Polystyrene (PS) Atactic (amorphous)	100–105	212–220	(a)	(a)	45	110

(a) Dry

Glass transition temperatures are also influenced by moisture absorption and the intentional addition of plasticizers. Absorbed moisture invariably lowers the T_g , and the more moisture is absorbed, the lower the transition temperature. This is consistent with the role of water as a plasticizer, which is why absorbed moisture can reduce the strength of plastics. Plasticizers are low-molecular-weight additives that lower strength and T_g . The lowering of transition temperatures by plasticizers can be quantitatively described by various mixing formulas (Ref 3, 4), which can be quite useful for predicting the loss of properties due to absorbed moisture.

Mechanical Testing of Polymers and Ceramics

Mechanical Testing of Plastics

Engineering plastics are either thermoplastic resins (which can be repeatedly reheated and remelted) or thermoset (network) resins (which are cured resins with cross links that depolymerize upon exposure to elevated temperatures above T_g). Typical mechanical properties of various thermoplastic and thermoset resins are briefly summarized in Tables 4 and 5. Engineering plastics are not as strong as metals, but due to the lower density of plastics, the specific strengths of structural plastics are higher than those of metallic materials. This is shown in Table 6, which compares the range of mechanical properties of plastics with those of other engineering materials. These data show that glass-filled plastics have strength-to-weight ratios that are twice those of steel and cast aluminum. In addition to glass fillers, other types of additives (such as plasticizers, flame retardants, stabilizers, and impact modifiers) can also modify the mechanical properties of plastics.

Table 4 Room-temperature mechanical properties of selected thermoplastics with glass filler

The testing of plastics includes a wide variety of chemical, thermal, and mechanical tests (Table 7). The following sections briefly describe the test methods and comparative data for the mechanical property tests listed in Table 7. In addition, creep testing and dynamic mechanical analyses of viscoelastic plastics are also briefly described. For more detailed descriptions of these test methods and the other test methods listed in Table 7, readers are referred to Ref 5 and an extensive one-volume collection of ISO and European standards for plastic testing (Ref 6).

Table 7 ASTM and ISO mechanical test standards for plastics

ASTM standard	ISO standard	Topic area of standard
Specimen preparation		
D 618	291	Methods of specimen conditioning
D 955	294-4	Measuring shrinkage from mold dimensions of molded thermoplastics
D 3419	10724	In-line screw-injection molding of test specimens from thermosetting compounds
D 3641	294-1,2,3	Injection molding test specimens of thermoplastic molding and extrusion materials
D4703	293	Compression molding thermoplastic materials into test specimens, plaques, or sheets
D 524	95	Compression molding test specimens of thermosetting molding compounds
D 6289	2577	Measuring shrinkage from mold dimensions of molded thermosetting plastics
Mechanical properties		

D 256	180	Determining the pendulum impact resistance of notched specimens of plastics
D 638	527-1,2	Tensile properties of plastics
D 695	604	Compressive properties of rigid plastics
D 785	2039-2	Rockwell hardness of plastics and electrical insulating materials
D 790	178	Flexural properties of unreinforced and reinforced plastics and insulating materials
D 882	527-3	Tensile properties of thin plastic sheeting
D 1043	458-1	Stiffness properties of plastics as a function of temperature by means of a torsion test
D 1044	9352	Resistance of transparent plastics to surface abrasion
D 1708	6239	Tensile properties of plastics by use of microtensile specimens
D 1822	8256	Tensile-impact energy to break plastics and electrical insulating materials
D 1894	6601	Static and kinetic coefficients of friction of plastic film and sheeting
D 1922	6383-2	Propagation tear resistance of plastic film and thin sheeting by pendulum method
D 1938	6383-1	Tear propagation resistance of plastic film and thin sheeting by a single tear method
D 2990	899-1,2	Tensile, compressive, and flexural creep and creep-rupture of plastics
D 3763	6603-2	High-speed puncture properties of plastics using load and displacement sensors
D 4065	6721-1	Determining and reporting dynamic mechanical properties of plastics
D 4092	6721	Dynamic mechanical measurements on plastics
D 4440	6721-10	Rheological measurement of polymer melts using dynamic mechanical procedures
D 5023	6721-3	Measuring the dynamic mechanical properties of plastics using three-point bending
D 5026	6721-5	Measuring the dynamic mechanical properties of plastics in tension
D 5045	572	Plane-strain fracture toughness and strain energy release rate of plastic materials
D 5083	3268	Tensile properties of reinforced thermosetting plastics using straight-sided specimens
D 5279	6721	Measuring the dynamic mechanical properties of plastics in torsion

Tensile Properties

The chemical composition and the long-chain nature of polymers lead to some important differences with metals. These differences include significantly lower stiffnesses, much higher elastic limits or recoverable strains, a wider range of Poisson's ratios, and time-dependent deformation from viscoelasticity. Thermoplastics also exhibit a unique variety of post-yield phenomena. For example, Fig. 4 is a typical stress-strain plot for aluminum and polyethylene. The aluminum sample necks and extends to 50% strain. The polyethylene sample necks and extends to 350% strain as a consequence of the long-chain nature of polymers. The polyethylene also shows a stiffening due to chain alignment at the highest strains. This postyield stiffening involves shear deformation as described in Ref 6.

Fig. 4 Typical stress-strain curves for polycrystalline aluminum and semicrystalline polyethylene. Both materials neck. In polyethylene, chain alignment results in stiffening just before failure. Source: Ref 7

The ultimate tensile strengths of most unreinforced structural plastics range from 50 to 80 MPa (7–12 ksi) with elongation to final fracture much higher than metals (Fig. 5). It is very common to see large differences between metals and plastics in the amount of recoverable elastic strain. In metals, the amount of recoverable elastic strain is determined by the amount of strain that can be put into one of the metallic bonds before breaking. This amount of strain is typically less than 1%. In elastomers, the amount of recoverable strain can be 500% or more.

Fig. 5 Tensile stress-strain curves for copper, steel, and several thermoplastic resins. Source: Ref 8

When recoverable strain is this large, the individual polymer chains must be prevented from flowing past each other during deformation. This is easily accomplished by cross links tying the chains together (Ref 9). Even in glassy polymers, in which internal energy effects are evident in the elasticity, the recoverable strain is limited by the strain required to break the weaker and longer-range van der Waals bonds. Because these bonds can be

stretched farther than metallic bonds, it is possible to have a recoverable strain in glassy polymers of 5% or more. At such large strains, it is possible for the assumptions of small-strain elasticity to break down. Any standard test procedures based on small-strain elasticity may have to be modified to account for large elastic strains.

The mechanical behavior of polymers is also time dependent, or viscoelastic. Therefore, data based on short-term tests have the possibility of misrepresenting the tested polymer in a design application that involves long-term loading. The magnitude of the time dependence of polymers is very temperature dependent. Well below the T_g , glassy or semicrystalline polymers are only very weakly viscoelastic. For these polymers, test data based on a time-independent analysis will probably be adequate. As the temperature is increased, either by the environment or by heat given off during deformation, the time dependence of the mechanical response will increase.

Under viscoelastic conditions, one method useful for obtaining long-term design data is the time-temperature superposition principle. This principle states that the mechanical response at long times at some particular temperature is equivalent to the mechanical response at short times but at some higher temperature (Ref 8). By determining shift factors, it is possible to determine which temperature to use in obtaining long-term data from short-term tests. This is essentially true for linear viscoelastic behavior in the absence of a phase change.

The short-term tensile test (ASTM D 638 and ISO 517) is one of the most widely used mechanical tests of plastics for determining mechanical properties such as tensile strength, yield strength, yield point, and elongation. The stress-strain curve from tension testing is also a convenient way to classify plastics (Fig. 6). A soft and weak material, such as PTFE, is characterized by low modulus, low yield stress, and moderate elongation at break point. A soft but tough material such as polyethylene shows low modulus and low yield stress but very high elongation at break. A hard and brittle material such as general-purpose phenolic is characterized by high modulus and low elongation. It may or may not yield before break. A hard and strong material such as polyacetal has high modulus, high yield stress, high ultimate strength (usually), and low elongation. A hard and tough material such as polycarbonate is characterized by high modulus, high yield stress, high elongation at break, and high ultimate strength.

Fig. 6 Tensile stress-strain curves for several categories of plastic materials

Because of the diversity of mechanical behavior, the tension testing of plastics is subject to potential misapplication or misinterpretation of test results. This is particularly true for thermoplastics, which have some important differences with thermoset plastics. Compared to thermoset resins, thermoplastics exhibit more disruption or changes in the secondary bonding between the molecular chains during tension testing. This leads to a variety of postyield phenomena, such as the stiffening observed in polyethylene (Fig. 4). Another example is shown in Fig. 7. At the yield point the average axis of molecular orientation in thermoplastics may begin to conform increasingly with the direction of the stress. The term *draw* is sometimes used to describe this behavior. There is usually a break in the stress-strain curve as it begins to flatten out, and more strain is observed with a given increased stress. The result is that the giant molecules begin to align and team up in their resistance to the implied stress. Frequently, there is a final increase in the slope of the curve just before ultimate failure (Fig. 7). The extent to which this orientation takes place varies from one linear thermoplastic to the next, but the effect can be quite significant. Even the smallest amount of the teaming-up effect imparts greatly improved impact resistance and damage tolerance. In thermoplastics, there is much more area under the stress-

strain curve than in conventional thermosets, which are more rigid networks with much less area under the stress-strain curve.

Fig. 7 Thermoset versus thermoplastic stress-strain behavior

Because the deformation of thermoplastics is time-dependent, careful control of test duration and strain rate is important. A slower test (i.e., one at a low strain rate) allows more time for deformation and thus alters the stress-strain curve and lowers the tensile strength. This effect is shown in Fig. 8 for polycarbonate.

Fig. 8 Stress-strain curves for rubber-modified polycarbonate at room temperature as a function of strain rate

Short-term tensile properties are usually measured at a constant rate of 0.5 cm/min (0.2 in./min). It is recommended by the American Society for Testing and Materials (ASTM) that the speed of testing be such that rupture occurs in 0.5 to 5 min. Test coupons are either injection molded or compression molded and cut into a standard shape. In practice, injection-molded coupons are usually used.

The history of the plastic sample has some influence on tensile properties. A tensile bar prepared by injection molding with a high pressure tends to have higher tensile strength. A material that has been oriented in one direction tends to have a higher tensile strength and a lower elongation at break in the direction of orientation. In the direction perpendicular to the orientation, tensile strength is consistently lower. In a crystallizable material, stretching usually increases crystallinity.

Because the mechanical properties are sensitive to temperature and absorbed moisture, conditioning procedures for test specimens have been developed. These procedures are defined in ASTM D 618 and ISO 291.

Tensile Modulus. Because plastics are viscoelastic materials, stress-strain relationships are nonlinear and curved (usually convex upward). The curvature arises from two causes. First, the deflection axis is

simultaneously a time axis, and during the test, molecular relaxation processes continuously reduce the stress required to maintain any particular strain. Second, as the strain increases, the molecular resistance to further deformation decreases; that is, the effective modulus falls.

The degree of curvature depends on the material and the test conditions. At high strain rates and/or low temperatures, the stress-strain relationship usually approximates to a straight line. However, if the curvature is pronounced, the stress-strain ratio must be either a tangent modulus or a secant modulus. The tangent modulus is the instantaneous slope at any point on the stress-strain curve, while the secant modulus is the slope of a line drawn from the origin to any point on a nonlinear stress-strain curve. These moduli may be conservative or nonconservative, relative to one another and depending on the location on the curve.

The accuracy of modulus data derivable from a stress-strain test may be limited, mainly because axially loading is difficult to achieve and because the specimen bends initially rather than stretches. In addition, the origin of the force-deflection curve is often ill defined, and the curvature there is erroneous, to the particular detriment of the accuracy of the tangent modulus at the origin and, to a lesser degree, that of the secant moduli. Under the very best experimental conditions, the coefficient of variation for the modulus data derivable from tensile tests can be 0.03 or lower, but more typically it is 0.10 (Ref 10). If the strain is derived from the relative movement of the clamps rather than from an extensometer, the error in the calculated value of the tangent modulus at the origin can be 100% (Ref 9).

Yield stresses of plastics depend on a variety of molecular mechanisms, which vary among polymer classes and may not be strictly comparable. However, regardless of the underlying mechanisms, yield stress data have a low coefficient of variation, typically 0.03 (Ref 10). Brittle fracture strengths are much more variable, reflecting the distributions of defects that one might expect. The scatter due to the inherent defects in the materials is exacerbated when elongations at fracture are small because poor and variable alignment of the specimens induces apparently low strengths if the theoretical stresses are not corrected for the extraneous bending in the specimens (Ref 10).

Long-term uniaxial tensile creep testing of plastics is covered in ASTM D 2990 and ISO 899. ASTM D 2990 also addresses flexural and compressive creep testing. For the uniaxial tensile creep test in D 2990, the test specimen is either a standard type I or II bar, per ASTM D 638, that is preconditioned to ASTM D 618 specifications. The test apparatus is designed to ensure that the applied load does not vary with time and is uniaxial to the specimen. As with other tests, the test specimen must not slip in or creep from the grips. The load must be applied to the specimen in a smooth, rapid fashion in 1 to 5 s. If the test is run to specimen failure, the individual test cells must be isolated to eliminate shock loading from failure in adjacent test cells. Several types of tensile creep test systems are shown in Fig. 9.

Fig. 9 Various equipment designs for the measurement of tensile creep in plastics

Creep curves generally exhibit three distinct phases. First-stage creep deformation is characterized by a rapid deformation rate that decreases slowly to a constant value. The four-parameter model was proposed to describe long-term creep. In this model, the first-stage creep deformation was called retarded elastic strain. Second-stage creep deformation is characterized by a relative constant, low-deformation rate. In the four-parameter model, this was called equilibrium viscous flow. The final or third-stage creep deformation is creep rupture, fracture, or breakage.

The generalized uniaxial tensile creep behavior of plastics under constant load, isothermal temperature, and a given environment can be illustrated as ductile creep behavior (Fig. 10a) or as brittle creep behavior (Fig. 10b). At very low stress levels, both types of plastics exhibit similar first-stage and second-stage creep deformation. The onset of creep rupture may not occur within the service life of the product (let alone the test). As the stress level increases, first-stage and second-stage creep deformation rates remain relatively the same for these types, but the time of failure is of course considerably reduced. In addition, third-stage creep deformation characteristics now differ considerably. The ductile plastic exhibits typical ductile yielding or irreversible plastic deformation prior to fracture. The brittle plastic, on the other hand, exhibits no observable gross plastic deformation and only abrupt failure.

Fig. 10 Typical creep and creep rupture curves for polymers. (a) Ductile polymers. (b) Brittle polymers

Macroscopic yielding and fracture may not always be appropriate criteria for longtime duration material failure. For some plastics, stress crazing, stress cracking, or stress whitening may signal product failure and may therefore become a design limitation.

Creep strain is usually plotted against time on either semilog plots or log-log plots (Fig. 11). Extrapolation to times beyond the data can be difficult on the semilog plot (Fig. 11a). Replotting on log-log paper may allow easier extrapolation under one decade. Creep curves should not be extrapolated more than one decade, because some curvature still remains in the log-log plot. For small strains, the curves can be considered linear. These curves can usually be used to compare polymers at the same loading levels. Creep test data are also analyzed in various forms, as described further in the section “Creep Data Analysis” in this article.

Fig. 11 Tensile creep strain of polypropylene copolymer. (a) Semilog plot. (b) Log-log plot

Other Strength/Modulus Tests

Compressive Strength Test (ASTM D 695 and ISO 604). Stress-strain properties are also measured for the behavior of a material under a uniform compressive load. The procedure and nomenclature for compression tests are similar to those for the tensile test. Universal testing machines can be used, and, like tension testing, specimens should be preconditioned according to ASTM D 618 or ISO 291.

The standard test specimen in ASTM D 695 is a cylinder 12.7 mm (1/2 in.) in diameter and 25.4 mm (1 in.) in height. The force of the compressive tool is increased by the downward thrust of the tool at a rate of 1.3 mm/min (0.05 in./min). The compressive strength is calculated by dividing the maximum compressive load by the original cross section of the test specimen.

For plastics that do not fail by shattering fracture, the compressive strength is an arbitrary value and not a fundamental property of the material tested. When there is no brittle failure, compressive strength is reported at

a particular deformation level such as 1 or 10%. Compressive strength of plastics may be useful in comparing materials, but it is especially significant in the evaluation of cellular or foamed plastics. Compression testing of cellular plastics is addressed in ISO Standards 1856 and 3386-1.

Typical compressive strengths for various plastics are compared in Fig. 12. Generally, the compressive modulus and strength are higher than the corresponding tensile values for a given material.

Fig. 12 **Compressive strength of engineering plastics. PA, polyamide; PET, polyethylene terephthalate; PBT, polybutylene terephthalate; PPO, polyphenylene oxide; PC, polycarbonate; ABS, acrylonitrile-butadiene-styrene**

Compressive creep testing of plastic is addressed in ASTM D 2990. Normally creep information is given for tension loading.

Flexural Strength Test (ASTM D 790 and ISO 178). Flexural strength or cross-breaking strength is the maximum stress developed when a bar-shaped test piece, acting as a simple beam, is subjected to a bending force. Two methods are used: three-point bending (Fig. 13) and four-point bending (Fig. 14). Four-point bending is useful in testing materials that do not fail at the point of maximum stress in three-point bending (Ref 12).

Fig. 13 Flexural test with three-point loading. Source: Ref 11

Fig. 14 Flexural test with four-point loading

For three-point bending, an acceptable test specimen is one at least 3.2 mm (0.125 in.) thick, 12.7 mm (0.5 in.) wide, and long enough to overhang the supports (but with overhang less than 6.4 mm (0.25 in.) on each end). The load should be applied at a specified crosshead rate, and the test should be terminated when the specimen bends or is deflected by 0.05 mm/min (0.002 in./min). The flexural stress (S) at the outer fibers at mid-span in three-point bending is calculated from the following expression:

$$S = 3PL/2bd^2$$

in which P is the force at a given point on the deflection curve, L is the support span, b is the width of the bar, and d is the depth of the beam.

Because most plastics do not break from deflection, the flexural strength is measured when 5% strain occurs for most thermoplastics and elastomers. Fracture strength under flexural load may be more suitable for thermosets. To obtain the strain, r , of the specimen under three-point test, the following expression applies:

$$r = 6Dd/L^2$$

in which D is the deflection to obtain the maximum strain (r) of the specimen under test. To obtain data for flexural modulus, which is a measure of stiffness, flexural stress is plotted versus strain, r , during the test; the slope of the curve obtained is the flexural modulus. Flexural moduli for various plastics are compared in Fig. 15.

Fig. 15 Flexural modulus retention of engineering plastics at elevated temperatures. PET, polyethylene terephthalate; PBT, polybutylene terephthalate; ABS, acrylonitrile-butadiene-styrene; PA, polyamide; PSU, polysulfone

Flexural creep tests (ISO 899-2) are done with standard flexural test methods where the deflection is measured as a function of time. The flexural creep modulus at time, t , (E_t) for three-point bending (Fig. 13) is calculated as:

$$E_t = \frac{L^3 \cdot P}{4b \cdot d^3 \cdot s_t}$$

where s_t is the deflection at time, t .

Deflection Temperature under Load (ASTM D 648). Another measure of plastic rigidity under load is the deflection temperature under load (DTUL) test, also known as the heat deflection temperature (HDT) test. In the standard ASTM test (D 648), the heat deflection temperature is the temperature at which a 125 mm (5 in.) bar deflects 0.25 mm (0.010 in.) when a load is placed in the center. It is typically reported at both 460 and 1820 kPa (65 and 265 psi) stresses. The specimen is placed in an oil bath under a load of 460 or 1820 kPa (65 or 265 psi) in the apparatus shown in Fig. 16, and the temperature is raised at a rate of 2 °C/min. The temperature is recorded when the specimen deflects by 0.25 mm (0.01 in.). Because crystalline polymers, such as nylon 6/6, have a low heat deflection temperature value when measured under a load of 1820 kPa (265 psi), this test is often run at 460 kPa (65 psi).

Fig. 16 Apparatus used in test for heat deflection temperature under load (460 or 1820 kPa, or 65 or 265 psi)

The heat deflection temperature is an often misused characteristic and must be used with caution. The established deflection is extremely small, and in some instances may be, at least in part, a measure of warpage or stress relief. The maximum resistance to continuous heat is an arbitrary value for useful temperatures, which are always below the DTUL value. The DTUL value is also influenced by glass reinforcement.

The heat deflection temperature is more an indicator of general short-term temperature resistance. For long-term temperature resistance, one of the most common measures is the thermal index determined by the Underwriters' Laboratory (UL) (Ref 13). In this test, standard test specimens are exposed to different temperatures and tested at varying intervals. Failure is said to occur when property values drop to 50% of their initial value. The property criterion for determining the long-term use temperature depends on the application. Table 8 lists typical HDT values and the UL temperature index for various plastics.

Table 8 Heat-deflection and Underwriters' Laboratories index temperatures for selected plastics

Material	Heat-deflection temperature at 1.82 MPa (0.264 ksi)		UL index	
	°C	°F	°C	°F
Acrylonitrile-butadiene-styrene (ABS)	99	210	60	140

Shear Strength Test (ASTM D 732). The specimen proscribed in ASTM D 732 is a disc or a plate with an 11 mm ($\frac{7}{16}$ in.) hole drilled through the center of the specimen. Testing can be done with a special fixture like the one shown in Fig. 17. Shear strength is defined as the force for separation during loading divided by the area of the sheared edge. Shear strength is often estimated as $\frac{1}{2}$ the tensile strength of a material. When a value for creep shear modulus is needed, it is reasonable to divide the creep tensile modulus by 2.8.

Fig. 17 Example of set for shear-strength testing of plastics

Creep Data Analysis

Mechanical tests under tensile, compressive, flexural, and shear loading can be performed as either short-term tests or long-term tests of creep deformation. Data for the long-term tests are typically recorded as time dependent displacement values at various levels of constant stress (Fig. 18a). This type of data, however, can be displayed and analyzed in several forms as shown in Fig. 18. There is no universal method of graphically displaying tensile creep or, in fact, creep for compressive, shear, or flexural loading.

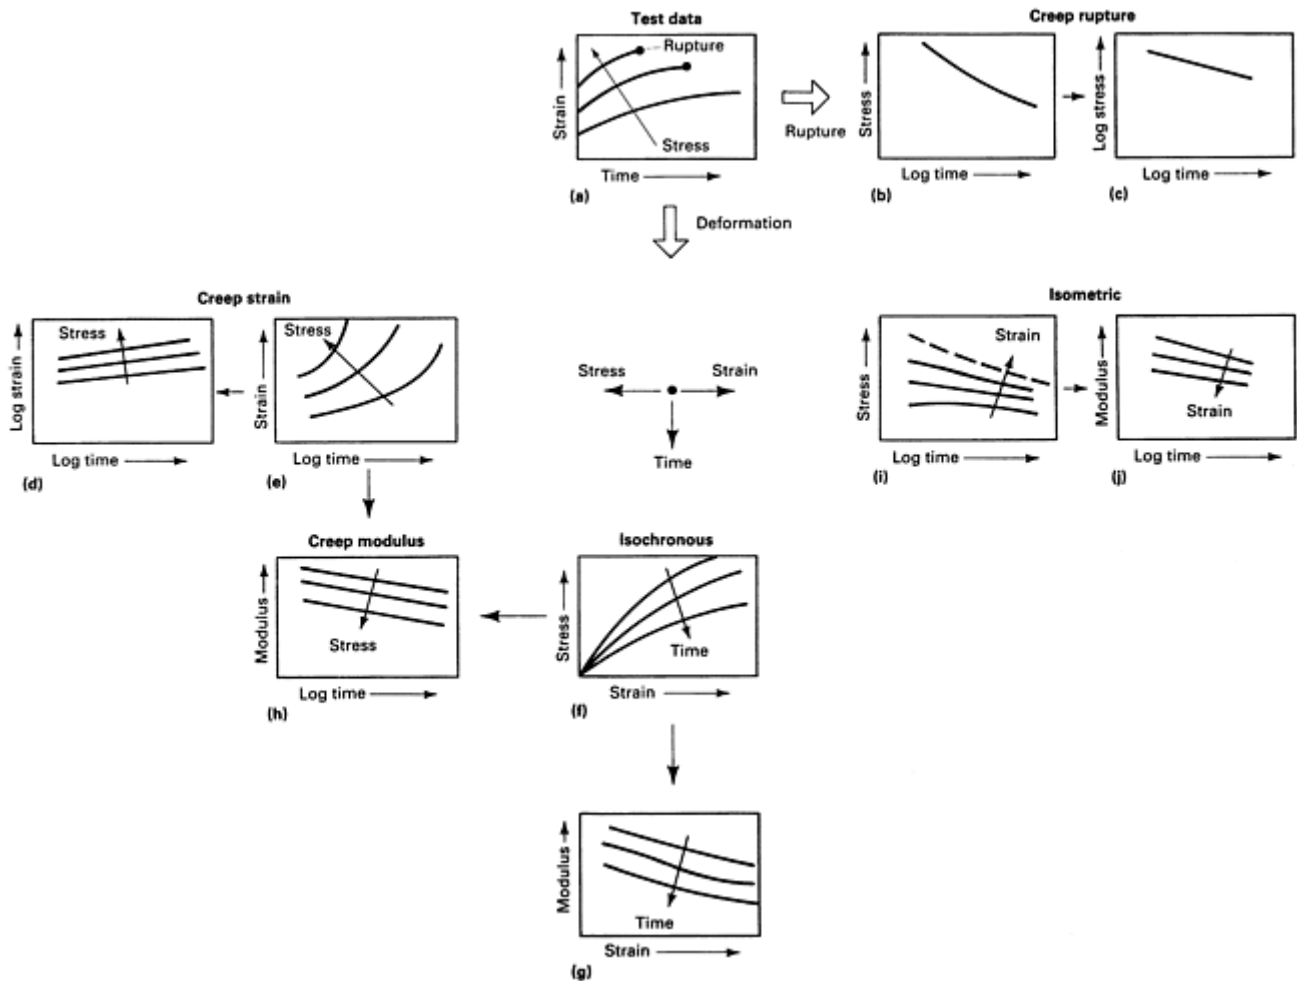

Fig. 18 Graphic representation of creep data showing various ways to plot time-dependent strain in response to time-dependent stress. See text for discussion.

Creep Modulus. In addition to stress-strain plots versus time, creep behavior is also expressed as a creep modulus, $E(t)$, where

$$E(t) = \sigma/\epsilon(t)$$

where σ is the applied stress and $\epsilon(t)$ is the creep strain as a function of time. The creep modulus is a measure of rigidity that can be applied for tensile, shear, compressive, or flexural load conditions. However, the creep modulus $E(t)$ is neither a design property nor a material constant. It is a time-dependent variable that is also a function of temperature and environment. The use of creep modulus data requires definition of intended design life and test conditions that accurately reflect the intended application.

Creep Rupture. Like the creep modulus, creep rupture data depend strongly on temperature. Creep rupture, in many respects, is a more important parameter because it represents the ultimate lifetime of a given material. Two types of graphic representation can be constructed for the creep rupture envelope, as shown in Fig. 18(b) and 18(c). Figure 18(b) shows a semilog plot of creep rupture stress as a function of failure time. For most plastic candidates for long-term performance, the design life can be quite long—months or years. As a result, the log-log coordinate system (Fig. 18c) has greater utility. Furthermore, creep rupture data tend to display linearly on this coordinate scheme.

Creep strain data plots can be done in various forms. Figure 18 shows three methods of analyzing these data. Each method holds one variable (stress, strain, or time) to be constant. For constant stress, Fig. 18(d) and 18(e) apply. The data can be displayed either as a set of (usually near-linear) linear lines on log-log paper (Fig. 18d) or as curvilinear lines on semilog paper (Fig. 18e). The parallel straight lines on log-log coordinates are called a creep strain plot (Fig. 18d).

Isochronous Creep Data. If the time parameter is held constant, a set of isochronous (or constant time) stress-strain curves results (Fig. 18f). A linear coordinate system is used to display these results. The slopes of these isochronous creep curves produce the isochronous modulus graph (Fig. 18g). If the slopes of the semilog curves

Polysulfone	B	B	B	B	B	B	B	B

(a) A, brittle even when unnotched; B, brittle, in the presence of a notch; C, tough

Although a number of standard impact tests are used to survey the performance of plastics exposed to different environmental and loading conditions, none of these tests provides real, geometry-independent material data that can be applied in design. Instead, they are only useful in application to quality control and initial material comparisons. Even in this latter role, different tests will often rank materials in a different order. As a result, proper test choice and interpretation require that the engineer have a very clear understanding of the test and its relationship to specific design requirements.

Because of differing engineering requirements, a wide variety of impact test methods have been developed. There is no one ideal method. The general classes of impact tests are shown in Fig. 19. However, this section briefly describes three of the most commonly used tests for impact performance: the Izod notched-beam test, the Charpy notched-beam test, and the dart penetration test.

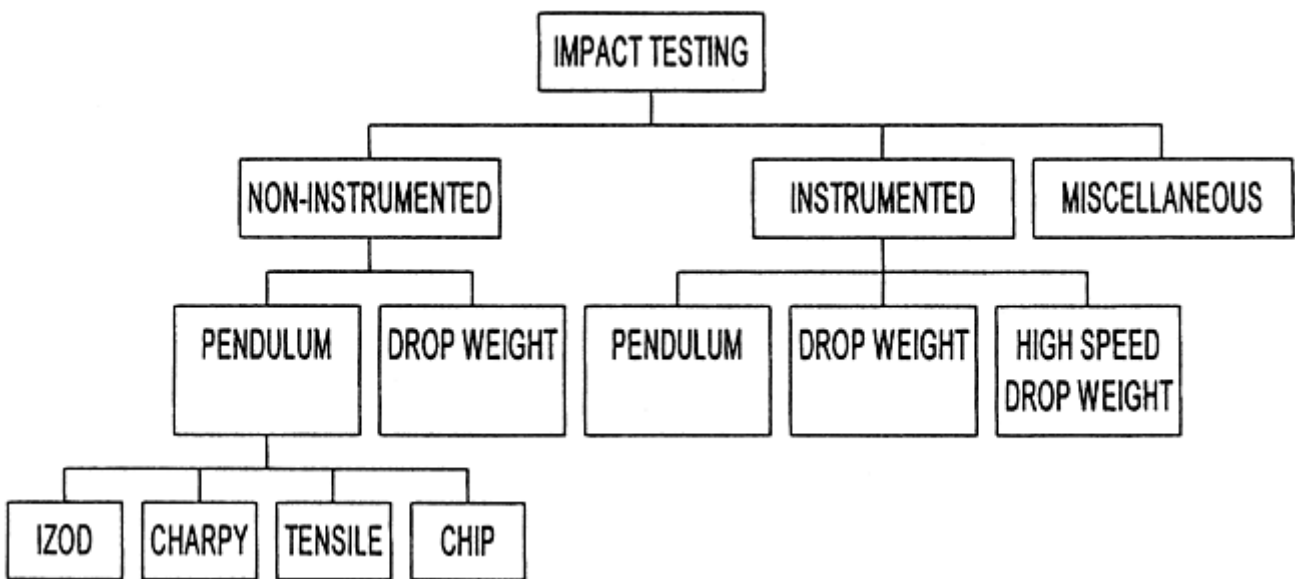

Fig. 19 Categories of impact test methods used in testing of plastics. Source: Ref 4

Charpy Impact Test (ASTM D 256 and ISO 179). The Charpy geometry consists of a simply supported beam with a centrally applied load on the reverse side of the beam from the notch (Fig. 20a). The notch serves to create a stress concentration and to produce a constrained multiaxial state of tension a small distance below the bottom of the notch. The load is applied dynamically by a free-falling pendulum of known initial potential energy. The important dimensions of interest for these tests include the notch angle, the notch depth, the notch tip radius, the depth of the beam, and the width of the beam. All these quantities, as well as more detailed information specifying loading geometry and conditions, are described in ASTM D 256 and ISO 179.

Fig. 20 Specimen types and test configurations for pendulum impact toughness tests. (a) Charpy method. (b) Izod method

Izod Impact Test (ASTM D 256 and ISO 180). Like the Charpy test, the Izod test involves a pendulum impact, but the Izod geometry consists of a cantilever beam with the notch located on the same side as the impact point (Fig. 20b). Because the pendulum hits the unnotched side of the sample in the Charpy test, Charpy values may be much higher impact strength values than Izod test values. However, the two measurements can be correlated (Ref 14). The Izod test is usually done on 3.2 mm ($\frac{1}{8}$ in.) thick samples. Materials such as polycarbonate exhibit thickness-dependent impact properties. Below 6.4 mm ($\frac{1}{4}$ in.), this material is ductile with a very high value, but above this thickness, the material has a much lower value.

Unnotched impact toughness tests in ASTM D 4812 and D 3029 (dart penetration test) have been replaced by ASTM D 5420. Impact values with unnotched samples are often considered a more definitive measure of impact strength, while the Izod test indicates notch sensitivity.

Dart Penetration (Puncture) Test. Another impact test that is often reported is the dart penetration (puncture) test. This test (Fig. 21) is different from the Izod and Charpy tests in a number of aspects. First, the stress state is two-dimensional in nature because the specimen is a plate rather than a beam. Second, the thin, platelike specimen does not contain any notches or other stress concentrations.

Fig. 21 Schematic puncture test geometry

The geometry and test conditions often applied using this specimen were described in ASTM D 3029 (now replaced by ASTM D 5420). The quantity most often quoted with respect to this test is the energy required for failure. Of course, these energy levels are very different from the notched beam energies-to-failure, but they also do not represent any fundamental material property. A marked transition in mode of failure can also be observed with this specimen as the rate is increased or the temperature is decreased. However, this transition temperature is quite different from that measured in the notched beam tests. Usually it displays a transition from ductile to brittle behavior at much lower temperatures than the notched specimens.

The dart penetration test is often performed with different specimens and indenter geometries. Linear elastic, small-displacement, thin-plate theory has occasionally been used to analyze test results in an effort to compare the performance of different materials tested with different specimen geometries. In all but the most brittle materials, this is an inappropriate simplification of the test. A number of very nonlinear events can take place during this test, including a growing indenter contact area, yielding, and large-displacement and large-strain deformation. References 15, 16, 17 provide more details on these events and their effects on the test data.

Fracture Mechanics. Another way to evaluate the toughness of materials is by fracture toughness testing, where the value of the critical stress-intensity factor for a material can be measured by testing standard cracked specimens, such as the compact-tension specimen. Standard test methods and specimen geometries are defined for measuring the critical stress-intensity factors for metals (ASTM E 399), but similar standards have yet to be officially defined for plastics. It appears that many of the recommendations of the ASTM E 399 test procedure for metals are equally worthwhile for plastics, although the ductile nature and low yield strength of plastics pose problems of specimen size.

In fracture toughness testing, the sample size can be reduced as long as all dimensions of the laboratory specimen are much larger than the plastic zone size. In fracture testing, according to ASTM E 399, the thickness, B , must be:

$$B \geq 2.5 \left(\frac{K_{Ic}}{\sigma_y} \right)^2 \approx 16r_p$$

where K_{Ic} is the plane-strain fracture toughness, σ_y is the yield stress, and r_p is the radius of the plastic zone, which is given by:

$$r_p = \frac{1}{2\pi} \left(\frac{K_{Ic}}{\sigma_y} \right)^2$$

By ensuring that the thickness is much larger than the yield zone size (at least 16 times larger), the laboratory specimen will be in the state of plane strain. Because of the hydrostatic stresses that develop at crack tips under plane-strain conditions, yielding is suppressed, and a minimum value for fracture toughness is obtained. The plane-strain fracture toughness can be used with confidence in designing large components.

Similar arguments hold for polymer fracture testing. To design large polymer components or to design for polymer applications in which yielding is suppressed, it is important to measure fracture properties under conditions of plane strain. However, typical engineering plastics have fracture toughnesses in the range of 2 to 4 MPa \sqrt{m} (1.8–3.6 ksi $\sqrt{in.}$) and yield strengths in the range of 50 to 80 MPa (7.3–11.6 ksi) (Ref 18). Plane-strain testing conditions would require sample thicknesses in the range of 1.6 to 16 mm (0.06–0.63 in.). The low-end range is a common size range, but the high end is more questionable. Engineering components designed with polymers almost never use polymers as thick as 16 mm (0.63 in.). Therefore, it is not clear that the plane-strain fracture toughness is the appropriate design data for engineering components in which the polymers will experience only plane-stress conditions. More importantly, fabricating thick polymer samples for plane-strain testing presents significant difficulties. Engineering plastics with fracture toughnesses in the range of 2 to 4 MPa \sqrt{m} (1.8–3.6 ksi $\sqrt{in.}$) are not particularly tough. Rubber-toughened polymers can have much higher toughness. Also, because the yield strength of rubber-toughened polymers is usually lower, the thickness requirements for plane-strain fracture testing are such that potential laboratory specimens cannot be prepared. Some of these toughened polymers can be tested with J integral techniques adapted from the J integral metals standard (Ref 19, 20). Another technique known as the essential work of fracture technique has been

considered. It has the potential to provide both plane-stress and plane-strain fracture toughness results for polymers. The essential work of fracture data can be obtained on thin polymers having thicknesses similar to those of typical polymer components (Ref 21).

Hardness Tests

Typical hardness values of common plastics are listed in Table 10. Rockwell testing and the durometer test method are the most common, although another type of hardness test for plastics is the Barcol method. A rough comparison of hardness scales for these methods is in Fig. 22, but it must be understood that any conversions from Fig. 22 are only rough estimates that vary depending on the materials. Hardness conversions are complicated by several material factors such as elastic recovery and, for plastics, the time-dependent effects from creep behavior. More information on the hardness testing of plastics is also given in the article “Selection and Industrial Applications of Hardness Tests” in this Volume.

Table 10 Typical hardness values of selected plastics

Plastic material	Rockwell		Durometer, Shore D	Barcol
	HRM	HRR		
Thermoplastic				
Acrylonitrile-butadiene-styrene	...	75–115
Acetal	94	120
Acrylic	85–105
Cellulosics	...	30–125
Polyphenylene oxide	80	120
Nylon	...	108–120
Polycarbonate	72	118
High-density polyethylene	60–70	...
Low-density polyethylene	40–50	...
Polypropylene	75–85	...
Polystyrene	68–70
Polyvinyl chloride (PVC)(rigid)	...	115
Polysulfone	70	120
Thermosets				
Phenolic (with cellulose)	100–110
Phenolic (mineral filler)	105–115
Unsaturated polyester (clear cast)	34–40
Polyurethane (high-density integral skin foam)	36–63	...
Polyurethane (solid reaction injection molded elastomer)	39–83	...
Epoxy (fiberglass reinforced)	106–108

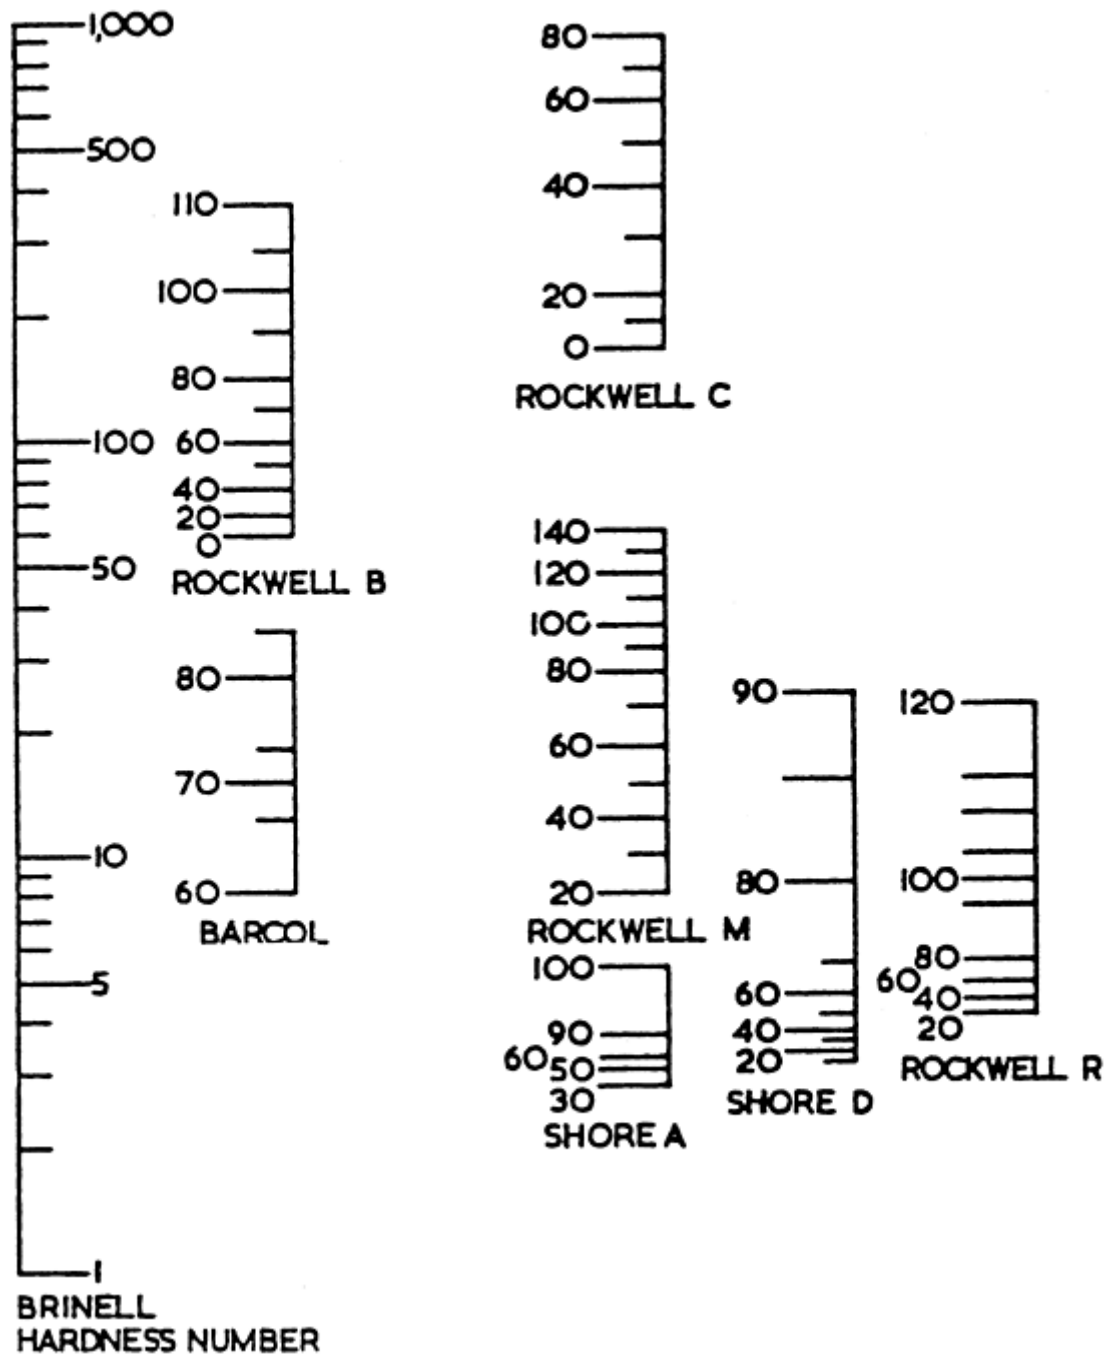

Fig. 22 Approximate relations among hardness scale for plastics

Rockwell hardness tests of plastics (ASTM D 785 and ISO 2039) are ball-indentation methods, where hardness is related to the net increase in the depth of an indentation after application of a minor load and a major load. The ball diameter and the loads are specified for each of the Rockwell scales, which are R, L, M, E, and K in order of increasing hardness. The Rockwell test is used for relatively hard plastics such as thermosets and structural thermoplastics such as nylons, polystyrene, acetals, and acrylics. Typical Rockwell values are shown in Fig. 23.

Fig. 23 Rockwell hardness of engineering plastics. PET, polyethylene terephthalate; PA, polyamide; PPO, polyphenylene oxide; PBT, polybutylene terephthalate; PC, polycarbonate; ABS, acrylonitrile-butadienestyrene

The durometer (or Shore hardness) method (ASTM D 2240 and ISO 868) registers the amount of indentation caused by a spring-loaded pointed indenter. This method is used for softer plastics and rubbers, and 100 is the highest hardness rating of this scale. Two types of durometers are used: type A and type D, as described further in the article “Selection and Industrial Applications of Hardness Tests” in this Volume.

The Barcol hardness test (ASTM D 2583) is mainly used for measuring the hardness of reinforced and unreinforced rigid plastics. A hardness value is obtained by measuring the resistance to penetration of a sharp steel point under a spring load. The instrument, called the Barcol impressor, gives a direct reading on a 0 to 100 scale. The hardness value is often used as a measure of the degree of cure of a plastic.

International Rubber Hardness Degrees (IRHD) Testing. The IRHD hardness test is very similar to durometer testing with some important differences. Durometer testers apply a load to the sample using a calibrated spring and a pointed or blunt shaped indenter. The load therefore will vary according to the depth of the indentation, because of the spring gradient. The IRHD tester uses a minor-major load system of constant load and a ball indenter to determine the hardness of the sample. This method is described further in the article “Miscellaneous Hardness Tests” in this Volume.

Fatigue Testing

Compared to testing of metals, the testing of plastics is a relatively recent pursuit. Because engineers and designers always use knowledge gained from previous experience, the methods used to test plastics in fatigue are largely based on methods developed for metals, with accommodations to account for the more obvious differences between the two materials.

For example, as previously noted in the section “Dynamic Mechanical Properties,” the role of high hysteresis losses in the repeated stressing of plastics is very important. Unlike metals, plastics deform in a largely nonelastic manner, resulting in part of the mechanical energy being converted into heat within the material. The gradual buildup of heat may be sufficient to cause a loss in strength and rigidity. This effect is further aggravated by the low thermal conductivity of plastics and a general increase in hysteresis losses with an

increase in temperature. Hysteresis losses are also a function of the loading rate (frequency), the type of load (bending, tension, or torsion), and the volume of material under stress. The hysteresis losses increase with loading rate and the volume of material under stress.

This also can be further extended to include the effects of different loading waveforms (sinusoid, saw tooth, or square) on the fatigue strength of viscoelastic materials. In addition, absorbed water and environmental variables also influence the fatigue strength of plastics. These and other factors are described in more detail in the article “Fatigue Testing and Behavior of Plastics” in this Volume.

Mechanical Testing of Polymers and Ceramics

Elastomers and Fibers

As previously noted, polymers can exhibit a range of mechanical behaviors that characterize their various classifications as elastomers, plastics, and fibers (Fig. 1). The following discussions briefly describe tension testing of elastomers and fibers.

Tension Testing of Elastomers

Elastomers have the ability to undergo high levels of reversible elongation that, in some cases, can reach up to 1000%. This high degree of reversible elongation allows stretching and recovery like that of a rubber band. Over 20 different types of polymers can be used as bases for elastomeric compounds, and each type can have a significant number of contrasting subtypes within it. Properties of different polymers can be markedly different: for instance, urethanes seldom have tensile strengths below 20.7 MPa (3.0 ksi), whereas silicones rarely exceed

8.3 MPa (1.2 ksi). Natural rubber is known for high elongation, 500 to 800%, whereas fluoroelastomers typically have elongation values ranging from 100 to 250%.

Literally hundreds of compounding ingredients are also available, including major classes such as powders (carbon black, clays, silicas), plasticizers (petroleum-base, vegetable, synthetic), and curatives (reactive chemicals that change the gummy mixture into a firm, stable elastomer). A rubber formulation can contain from four or five ingredients to 20 or more. The number, type, and level of ingredients can be used to change dramatically the properties of the resulting compound, even if the polymer base remains exactly the same.

ASTM D 412 is the U.S. Standard for tension testing of elastomers. It specifies two principal varieties of specimens: the more commonly used dumbbell-type, die cut from a standard test slab 150 mm by 150 mm by 20 mm (6 in. by 6 in. by 0.8 in.), and actual molded rings of rubber. The second type was standardized for use by the O-ring industry. For both varieties, several possible sizes are permitted, although, again, more tests are run on one of the dumbbell specimens (cut using the Die C shape) than on all other types combined. Straight specimens are also permitted, but their use is discouraged because of a pronounced tendency to break at the grip points, which makes the results less reliable.

The power-driven equipment used for testing is described, including details such as the jaws used to grip the specimen, temperature-controlled test chambers when needed, and the crosshead speed of 500 mm/min (20 in./min). The testing machine must be capable of measuring the applied force within 2%, and a calibration procedure is described. Various other details, such as die-cutting procedures and descriptions of fixtures, are also provided.

The method for determining actual elongation can be visual, mechanical, or optical, but the method must be accurate within 10% increments. In the original visual technique, the machine operator simply held a scale behind or alongside the specimen as it was being stretched and noted the progressive change in the distance between two lines marked on the center length of the dogbone shape. The degree of precision that could be attained using a handheld ruler behind a piece of rubber being stretched at a rate of over 75 mm/s (3 in./s) was always open to question, with 10% being an optimistic estimate.

More recent technology employs extensometers, which are comprised of pairs of very light grips that are clamped onto the specimen and whose motion is then measured to determine actual material elongation. The newest technology involves optical methods, in which highly contrasting marks on the specimen are tracked by scanning devices, with the material elongation again being determined by the relative changes in the reference marks.

Normal procedure calls for three specimens to be tested from each compound, with the median figure being reported. Provision is also made for use of five specimens on some occasions, with the median again being used.

Techniques for calculating the tensile stress, tensile strength, and elongation are described for the different types of test specimens. The common practice of using the unstressed cross-sectional area for calculation of tensile strength is used for elastomers, as it is for many other materials. It is interesting to note that if the actual cross-sectional area at fracture is used to calculate true tensile strength of an elastomer, values that are higher by orders of magnitude are obtained.

In recent years, attention has been given to estimating the precision and reproducibility of the data generated in this type of testing. Interlaboratory test comparisons involving up to ten different facilities have been run, and the later versions of ASTM D 412 contain the information gathered.

Variability of the data for any given compound is to some degree related to that particular formulation. When testing was performed on three different compounds of very divergent types and property levels, the pooled value for repeatability of tensile-strength determinations within labs was about 6%, whereas reproducibility between labs was much less precise, at about 18%. Comparable figures for ultimate elongation were approximately 9% (intralab) and 14% (interlab).

Similar comparisons of the 100% modulus (defined in "Modulus of the Compound" later in this section) have shown even less precision, with intralab variation of almost 20% and interlab variation of over 31%. This runs counter to the premise that modulus should be more narrowly distributed than tensile strength, because tensile strength and ultimate elongation are failure properties, and as such are profoundly affected by details of specimen preparation. Because the data do not support such a premise, some other factor must be at work. Possibly that factor is the lack of precision with which the 100% strain point is observed, but, in any case, it is important to determine the actual relationship between the precision levels of the different property measurements.

Significance and Use of Tensile-Testing Data for Elastomers. It is important to note that the tensile properties of elastomers are determined by a single application of progressive strain to a previously unstressed specimen to the point of rupture, which results in a stress-strain curve of some particular shape. The degree of nonlinearity and in fact complexity of that curve will vary substantially from compound to compound. Tensile properties of elastomers also have different significance than those of structural materials.

Tensile Strength of Elastomers. Because elastomers as a class of materials contain a substantial number of different polymers, the tensile strength of elastomers can range from as low as 3.5 MPa (500 psi) to as high as 55.2 MPa (8.0 ksi); however, the tensile strengths of the great majority of common elastomers tend to fall in the range from 6.9 to 20.7 MPa (1.0–3.0 ksi).

It should also be noted that successive strains to points just short of rupture for any given compound will yield a series of progressively different stress-strain curves; therefore, the tensile-strength rating of a compound would certainly change depending on how it was flexed prior to final fracture. Thus, the real meaning of elastomer tensile strength may be open to some question. However, some minimum level of tensile strength is often used as a criterion of basic compound quality, because the excessive use of inexpensive ingredients to fill out a formulation and lower the cost of the compound will dilute the polymer to the point that tensile strength decreases noticeably.

The meaning of tensile strength of elastomers must not be confused with the meaning of tensile strength of other materials, such as metals. Whereas tensile strength of a metal may be validly and directly used for a variety of design purposes, this is not true for tensile strength of elastomers. As stated early in ASTM D 412, “Tensile properties may or may not be directly related to the end-use performance of the product because of the wide range of performance requirements in actual use.” In fact, very seldom if ever can a given high level of tensile strength of a compound be used as evidence that the compound is fit for some particular application.

Elongation of Elastomers. Ultimate elongation is the property that defines elastomeric materials. Any material that can be reversibly elongated to twice its unstressed length falls within the formal ASTM definition of an elastomer. The upper end of the range for rubber compounds is about 800%, and although the lower end is supposed to be 100% (a 100% increase of the unstressed reference dimension), some special compounds with limits that fall slightly below 100% elongation still are accepted as elastomers.

Just as with tensile strength, certain minimum levels of ultimate elongation are often called out in specifications for elastomers. The particular elongation required will relate to the type of polymer being used and the stiffness of the compound. For example, a comparatively hard (80 durometer) fluoroelastomer might have a requirement of only 125% elongation, whereas a soft (30 durometer) natural rubber might have a minimum required elongation of at least 400%.

However, ultimate elongation still does not provide a precise indication of serviceability, because service conditions normally do not require the rubber to stretch to any significant fraction of its ultimate elongative capacity. Nonetheless, elongation is a key material selection factor that is more applicable as an end-use criterion for elastomers than is tensile strength.

Modulus of the Compound. Another characteristic of interest is referred to in the rubber industry as the modulus of the compound. Specific designations such as 100% modulus or 300% modulus are used. This is due to the fact that the number generated is not an engineering modulus in the normal sense of the term, but, rather, is the stress required to obtain a given strain. Therefore, the *100% modulus*, also referred to as M-100, is simply the stress required to elongate the rubber to twice its reference length.

Tensile modulus, better described as the stress required to achieve a defined strain, is a measurement of the stiffness of a compound. When the stress-strain curve of an elastomer is drawn, it can be seen that the tensile modulus is actually a secant modulus—that is, a line drawn from the origin of the graph straight to the point of the specific strain. However, an engineer needing to understand the forces that will be required to deform the elastomer in a small region about that strain would be better off drawing a line tangent to the curve at the specific level of strain and using the slope of that line to determine the approximate ratio of stress to strain in that region. This technique can be utilized in regard to actual elastomeric components as well as lab specimens.

Tension Set. A final characteristic that can be measured but that is used less often than the other three is called *tension set*. Often, when an elastomer or rubber is stretched to final rupture, the recovery in length of the two sections resulting from the break is less than complete. It is possible to measure the total length of the original reference dimension and calculate how much longer the total length of the two separate sections is. This is expressed as a percentage. Some elastomers will exhibit almost total recovery, whereas others may display

tension set as high as 10% or more. Tension set may also be measured on specimens stretched to less than breaking elongation.

The property of tension set is used as a rough measurement of the tolerance of high strain of the compound. This property is not tested very often, but, for some particular applications, such a test is considered useful. It could also be used as a quality-control measure or compound development tool, but most of the types of changes it will detect in a compound will also show up in tests of tensile strength, elongation, and other properties, and so its use remains infrequent.

Tensile-Test Curves. Figure 24 is a plot of tensile-test curves from five very different compounds, covering a range of base polymer types and hardnesses. The contrasts in properties are clearly visible, such as the high elongation (>700%) of the soft natural rubber compound compared with the much lower (about 275%) elongation of a soft fluorosilicone compound. Tensile strengths as low as 2.4 MPa (350 psi) and as high as 15.5 MPa (2.25 ksi) are observed. Different shapes in the curves can be seen, most noticeably in the pronounced curvature of the natural rubber compound.

Fig. 24 Tensile-test curves for five different elastomer compounds

Figure 25 demonstrates that, even within a single elastomer type, contrasting tensile-property responses will exist. All four of the compounds tested were based on polychloroprene, covering a reasonably broad range of hardnesses, 40 to 70 Shore A durometer. Contrasts are again seen, but more in elongation levels than in final tensile strength. Two of the compounds are at the same durometer level and still display a noticeable difference between their respective stress-strain curves. This shows how the use of differing ingredients in similar formulas can result in some properties being the same or nearly the same whereas others vary substantially.

Fig. 25 Tensile-test curves for four polychloroprene compounds

Tests for Determining the Tensile Strength of Fibers

Mechanical properties of fibers are very dependent on test method. Two basic methods are the single-filament tension test and the tow tensile test of a group or strand of fibers.

Single-filament tensile strength (ASTM D 3379) is determined using a random selection of single filaments made from the material to be tested. Filaments are centerline-mounted on special slotted tabs. The tabs are gripped so that the test specimen is aligned axially in the jaws of a constant-speed movable-crosshead test machine. The filaments are then stressed to failure at a constant strain rate. For this test method, filament cross-sectional areas are determined by planimeter measurements of a representative number of filament cross sections as displayed on highly magnified micrographs. Alternative methods of area determination use optical gages, an image-splitting microscope, a linear weight-density method, and others.

Tensile strength and Young's modulus of elasticity are calculated from the load elongation records and the cross-sectional area measurements.

The specimen setup is shown in Fig. 26. Note that a system compliance adjustment may be necessary for single-filament tensile modulus.

Fig. 26 Schematic showing typical specimen-mounting method for the single-filament fiber tension test (ASTM D 3379)

Tow Tensile Test (ASTM D 4018). The strength of fibers is rarely determined by testing single filaments and obtaining a numerical average of their strength values. Usually, a bundle or yarn of such fibers is impregnated with a polymer and loaded to failure. The average fiber strength is then defined by the maximum load divided by the cross-sectional area of the fibers alone.

Using ASTM D 4018 or an equivalent is recommended. This is summarized as finding the tensile properties of continuous filament carbon and graphite yarns, strands, rovings, and tows by the tensile loading to failure of the resin-impregnated fiber forms. This technique loses accuracy as the filament count increases. Strain and Young's modulus are measured by extensometer.

The purpose of using impregnating resin is to provide the fiber forms, when cured, with enough mechanical strength to produce a rigid test specimen capable of sustaining uniform loading of the individual filaments in the specimen.

To minimize the effect of the impregnating resin on the tensile properties of the fiber forms, the resin should be compatible with the fiber, the resin content in the cured specimen should be limited to the minimum amount required to produce a useful test specimen, the individual filaments of the fiber forms should be well collimated, and the strain capability of the resin should be significantly greater than the strain capability of the filaments.

ASTM D 4018 Method I test specimens require a special cast-resin end tab and grip design to prevent grip slippage under high loads. Alternative methods of specimen mounting to end tabs are acceptable, provided that test specimens maintain axial alignment on the test machine centerline and that they do not slip in the grips at high loads. ASTM D 4018 Method II test specimens require no special gripping mechanisms. Standard rubber-faced jaws should be adequate.

Mechanical Testing of Polymers and Ceramics

Mechanical Testing of Ceramics

Ceramic materials have been used in a variety of engineering applications that utilize their wear resistance, refractoriness, hardness, and high compression strength. Traditionally, they have not been used in tensile-loaded structures because they are brittle and experience catastrophic failure before permanent deformation. Nevertheless, their extreme refractoriness, chemical inertness, and favorable optical, electrical, and thermal properties are inducements to use ceramics in certain tensile load-bearing applications. Typical mechanical properties of common ceramics are listed in Table 11, and applicable ASTM standards for mechanical testing are listed in Table 12. More current information on mechanical testing of ceramics is provided in Ref 22.

Table 11 Typical mechanical properties of common ceramic materials

Material	Young's modulus		Flexural strength		Compressive strength	
	GPa	10 ⁶ psi	MPa	ksi	MPa	ksi
Brick	5–20	0.7–2.9	5–10	0.7–1.5	10–25	1.5–3.6
Roof tile	5–20	0.7–2.9	8–15	1.2–2.2	10–25	1.5–3.6
Steatite	1–3	0.1–0.4	140–160	20–23	850–1000	123–145
Silica refractories, 96–97% SiO ₂	8–14	1.2–2.0	30–80	4.4–11.6
Fireclay refractories, 10–44% Al ₂ O ₃	20–45	2.9–6.5	5–15	0.7–2.2	10–80	1.5–11.6
Corundum refractories, 75–90% Al ₂ O ₃	30–120	4.4–17.4	10–150	1.5–22	40–200	5.8–30.7
Forsterite refractories	25–30	3.6–4.4	5–10	0.7–1.5	20–40	2.9–5.8
Magnesia refractories	30–35	4.4–5.1	8–200	1.2–29	40–100	5.8–14.5
Zircon refractories	35–40	5.1–5.8	80–200	12–29	30–60	4.4–8.7

Whiteware	10–20	1.5–2.9	20–25	2.9–3.6	30–40	4.4–5.8
Stoneware	30–70	4.4–10.2	20–40	2.9–5.8	40–100	5.8–14.5
Electrical porcelain	55–100	8.0–14.5	90–145	13–21	55–100	8.0–14.5
Capacitor ceramics	90–160	13–23	300–1000	44–145

Room-Temperature Strength Tests

Uniaxial Tensile Strength. The nonductile nature of monolithic ceramics and their high sensitivity to stress concentrators has meant that conventional direct tensile testing is difficult and expensive. Gripping with jaws, screw threads, or other conventional devices causes invalid test results because of specimen breakage at the grips. The high stiffness (elastic modulus) of many ceramics means that a misalignment of only a few thousandths of a centimeter can lead to bending stresses with errors of 10% or more. Specimen preparation to exacting tolerances with minimal machining damage and careful tapers to avoid stress concentrators has been an expensive proposition. Considerable work has focused on improving tensile test methods for ceramics, with the result that tensile testing is becoming more routine. Commercial equipment is readily available, and specimen costs are falling. It will, however, always be more difficult to conduct direct tensile tests for ceramics than for metals.

The experimental difficulties, coupled with the problems of fabricating sufficiently large specimens, have prompted ceramists to use alternative test methods. The most common is flexure testing, in either the so-called three-point or four-point configuration. The latter is usually further specified by a description of the distance from the outer support points and the inner points, such as $\frac{1}{4}$ or $\frac{1}{3}$ four-point loading. The small size, low cost, and easy preparation of a flexure specimen account for its popularity, but there are distinct drawbacks. The bending creates a stress gradient in the specimen, and only a small volume is exposed to high tensile stress. The specimens are very sensitive to edge or surface machining damage. The test appears easy to set up and conduct, but misalignments and experimental errors can easily ruin it. Standard test methods are now available that permit accurate strength measurements for standard sizes and shapes, as shown in Fig. 27.

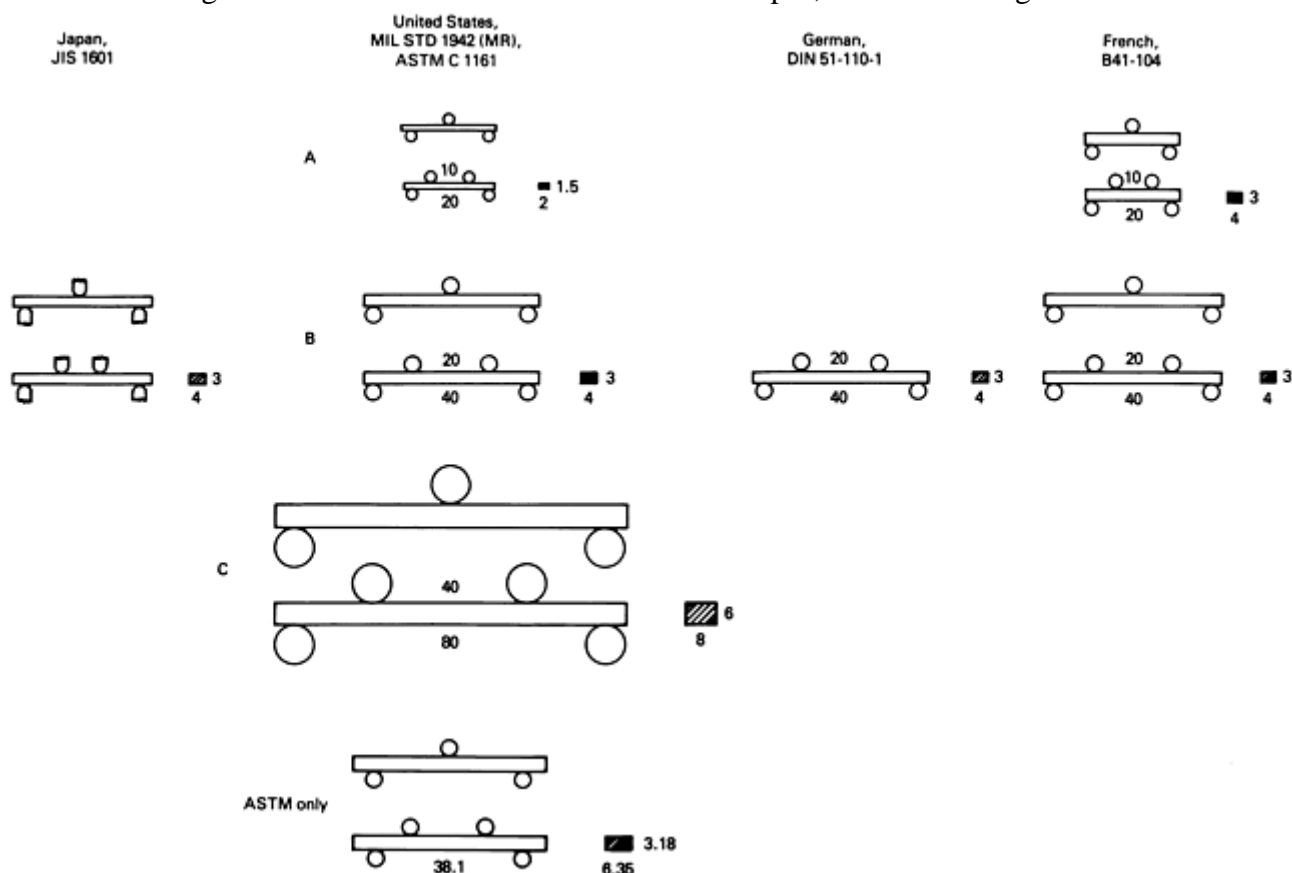

Fig. 27 Flexure strength standard test methods; all dimensions in mm

Nevertheless, it is still preferable to perform direct tension testing. Current testing systems are designed with self-aligning features that limit the imposed bending stresses to approximately 1%. There is usually less

extrapolation of the strength data from test specimen to component size. Tensile specimens are still expensive, however, because of costly fabrication and machining. They are inconveniently large, as well, because most systems are designed for high-temperature test rigs that use cold grips. Until recently, only a few laboratories had the ability to test or to even afford direct tensile experiments. A new emphasis on attaining accurate, quality data in support of ceramics in heat engine programs has led to rapid improvements in the field, and commercial test systems are now readily available. Different tensile specimen geometries that are being used are shown in Fig. 28 (Ref 23, 24, 25, 26, 27, 28).

Fig. 28 Tension specimens used for monolithic ceramics (each is in correct proportion to the others); all dimensions in mm. Upper row for round specimens; lower row for flat specimens. Adapted from Ref 26

Another occasionally cited test for engineering ceramics is the so-called diametral compression test, or Brazilian disk test, wherein a circular cylinder is loaded at its ends (Ref 29, 30). The test is actually biaxial, because in addition to the tensile stresses that tend to laterally split the specimen, compressive stresses that are three times as great act axially through the specimen. However, compressive stresses of this magnitude are not likely to affect uniaxial strength, an effect peculiar to monolithic ceramics. The specimen loading is between two platens with pads of compliant material (such as a metallic shim or paper) to avoid high shearing stresses. Careful machining of the end faces of the specimen is essential, once again to avoid damage that compromises the test. This point is often overlooked. This test is occasionally employed by ceramics processors for ceramics fabricated in cylindrical shapes.

Many ceramic materials have strengths that are specific to the shaping process being used, such as injection-molded turbocharger rotors or extruded heat-exchanger tubes. In such cases, it is not practical to cut tensile specimens from the part, but separately cast tensile specimens may not have the same microstructure or defects as the component and, therefore, are irrelevant (Ref 31, 32, 33). It is optimal to test components in as close a configuration to the final component shape as possible. Thus, in the case of a tube, a ring can be cut from the

tube and pressurized to obtain a uniaxial hoop-stress-testing configuration (Ref 34, 35). Contrary to expectations, such a test can be conducted at high temperatures. Indeed, one of the highest recorded strength test temperatures for a ceramic (2180 °C, or 3955 °F) was on a pressurized tube (Ref 36). Extreme care must be taken to ensure that the edges are not chipped and do not have excessive machining damage, lest the test merely become a measure of machining damage.

There is no simple answer to the question of what specimen is best for measuring strength data. The best practice is to test a configuration that most resembles the actual component in its service conditions and to ensure that the test material accurately represents the component material. It is likely that the first available data will be flexure-strength data, which are typically higher (10–50%) than tensile specimen data because of the dependency of strength on test specimen size. Nevertheless, considering the tradeoffs in cost, quantity of results, and difficulty in testing, it is likely that future engineering databases will feature complementary flexure and tensile data. Indeed, it will be beneficial to have strength data from different sizes and shapes to permit an assessment of material consistency, flaw uniformity, and the veracity of strength-size scaling models.

Elastic Modulus. Several methods are used to evaluate the elastic moduli of monolithic or fine-scaled, isotropic composites. The most common are deflection measurements in flexural strength tests (with proper consideration of the test machine compliance) or strain gage experiments in flexure or direct tension. Dynamic measurements are also quite common, with either sonic excitation of prismatic specimens at their resonant frequency or time-of-flight measurements of ultrasonic waves.

Interpretation of Uniaxial Strength. The scatter in uniaxial strengths is well modeled by Weibull statistics. Weibull observed that the strength of brittle materials is controlled by the presence of randomly distributed defects and that failure is controlled by the largest, most severely stressed defect. Fracture occurs when a defect in one particular element of the body reaches a critical loading. This analysis is colloquially known as the weakest-link model, in direct analogy to the strength of a chain.

The Weibull modulus, m , has no units and is the factor that determines the scatter in strength. High values are optimum. Traditional ceramics, such as whitewares and brick, may have values from 3 to 5. A good material has a value that exceeds 10. A ceramic with an m value ≥ 30 has very consistent strengths and could be practically considered to have a deterministic value of strength over a range of several orders of magnitude volume.

Not only does strength scale with specimen size, but the magnitude of the change strongly depends on whether the defects are surface or volume. Obviously, it is essential to know whether flaws are of one or the other category if the laboratory strength data are going to be size-scaled to predict component performance.

A Weibull graph is a convenient means to report strength data. The graph usually has special axes chosen to linearize the data. This is done in the same fashion that probability paper can be used to linearize data for a Gaussian distribution.

The Weibull analysis is adequate for multiaxially, tensilely loaded ceramics, provided that the second or third principal stresses are significantly less than the principal tensile stress. If this is not the case, then it is appropriate to use more sophisticated analyses that take into account the effect of multiaxial tensile stresses on defects. The Weibull analysis also has limitations if the defects are likely to grow subcritically during a test. A newly recognized phenomenon that could occasionally pose problems in strength analysis is *latent* defect caused by localized surface impact or contact stresses. Concentrated microdamage can occur that can lead to a larger microcrack popping in after an incubation period (Ref 37, 38).

Strength values by themselves are only half the picture. The types of defects are equally important because each flaw type has its own Weibull distribution, and because multiple flaw populations are common in ceramics. Therefore, it is essential that the defects be as clearly associated with the strength values as possible.

Uniaxial Compression Strength. The high compressive strength of ceramics is a consequence of the resistance of the material to plastic flow and the insensitivity of defects to compressive stress. Ancient structural applications of ceramics were columns and walls that capitalized on high compressive strength. The fact that ceramics fail at all in compression is a result of the distortion of the stress field in the immediate vicinity of the tip of a defect. This distortion causes a localized tensile stress concentration that, for defects at the worst orientation (-30° to the axial stress) is about $\frac{1}{8}$ of the concentration if the specimen is loaded in tension. Thus, a Griffith-type criterion for failure would predict that the compression specimen will fail at about 30° to the specimen axial direction when the compressive stress is eight times the tension strength, but this is an oversimplification.

The tensile stresses in the immediate vicinity of a defect will cause a crack to propagate stably for a slight distance (Ref 39, 40). The crack then aligns itself with the compression stress and is arrested. Progressively more defects grow until the damage that has accumulated in the specimen reaches some limit, and the specimen virulently disintegrates into powder (often with a triboluminescent emission) (Ref 41, 42). Compression strength thus depends not on the largest, worst-oriented, highest-stressed defect, but on the entire defect population. The high compressive stresses can nucleate cracks due to twinning or dislocation activity, as well (Ref 43, 44). Compression strength may have a dependence on the square root of grain size, because the size of defects may scale with the average grain size or because of microplasticity in the grains. Weibull statistics are irrelevant, and compression strengths often have very low scatter (Ref 41, 42).

The compression test appears deceptively easy to conduct. However, it is extremely difficult to accurately measure compression strength, because slight misalignments can create bending stresses, and end loading effects can cause parasitic tensile stresses that cause fracture. Mismatches of the elastic properties of the platens and test specimen can cause tensile stresses or frictional constraints. Buckling can occur if specimens are too long. Because the stresses being applied to a compression specimen are extremely high, the alignment errors may be greater than they would be for an equivalent tensile test specimen. True compression tests may be as difficult to conduct as direct tensile tests. Refined compression strength tests have been developed, as shown in Fig. 29.

Fig. 29 Compression test specimens. P , applied load. Source: Ref 41 and 45

Fiber-Reinforced Ceramic Composites. Test methods for ceramic-matrix composites are typically quite different than for monolithics, and they borrow heavily from organic-matrix and carbon-carbon test procedures. Uniaxial tensile strength testing is most commonly done in direct tension or flexure loadings. Flexure testing is not preferred, because the failure mechanism can be tensile, compressive, or interlaminar shear, depending on the composite components, the reinforcement architecture, and the loading geometry. Flexure testing is acceptable for measuring the matrix microcracking stress, the shear strength of one-dimensionally reinforced

composites (with the fibers perpendicular to the maximum stress), the effects of exposure or heat treatments, or certain high-temperature properties.

Direct tensile loading is much easier to conduct for composites than for monolithics, because the former are more tolerant of slight misalignments. Flat specimens with glued tabs (to avoid gripping damage) are quite adequate with commercial test machine grips. Ordinary clip extensometers or strain gages are suitable for measuring strain. At high temperatures, glued tabs are not adequate, and specimens with holes or tapered-wedge shoulders are necessary. However, the low shear strength of unidirectionally reinforced composites can make testing of pin-loaded specimens difficult or impossible, because the pins shear through the specimen. It is actually easier to test two-dimensionally fiber-reinforced composites for this reason.

Mechanical Testing of Polymers and Ceramics

High-Temperature Strength Tests

Fast Fracture. The overwhelming majority of high-temperature strength tests of isotropic ceramics have been done in four-point loading. Standards are being developed that are extensions of the low-temperature procedures. A variety of furnaces and environments can be used, with temperatures typically up to 1600 °C (2910 °F) in air and with some vacuum and inert gas systems at temperatures up to 2000 °C (3630 °F). The test fixtures themselves must be dense ceramics, usually fairly pure forms of silicon carbide, although occasionally alumina fixtures are used at lower temperatures, and graphite fixtures are used in inert atmospheres.

The upsurge in tensile testing has been driven in large part by new programs to use ceramics at high temperatures in heat engines. As a result, most tensile test systems have been designed with high temperatures in mind (Ref 23, 24, 25, 26). The gripping schemes must be not only elaborate enough to avoid stress concentrators and to align very precisely, but also capable of being used in conjunction with furnaces. Most tension systems use cold grips with relatively long (for ceramics) specimens of 150 mm (6 in.). Such systems are commercially available, and extensive testing is underway in the United States, Japan, and Germany.

Multiaxial strength tests are extremely rare at high temperatures and usually based on ring-on-ring loaded disks. The limited results for these experiments suggest that the high-temperature equibiaxial strength is 15 to 30% less than uniaxial strengths (Ref 46, 47).

Creep and Stress Rupture. Direct tension tests of long duration are becoming more common, but most test systems are complicated and expensive. They typically are derivatives of the fast-fracture systems, using cold grips and long specimens (Ref 24, 25, 26, 27). Most experiments are limited to a 1000 h duration. An economical alternative test system with hot grips and a “flat dog bone” specimen configuration has been developed and is optimized for long-duration, low-stress creep experiments (Ref 23). A short tapered specimen for similar experiments has been successfully used (Ref 26).

Strains must be measured with specialized extensometers, because ceramic strains are extremely small and resolutions of 1 μm (0.04 mil) must be recorded over the course of hours. The extensometers in use today are either delicate mechanical units (Ref 26) or lasers that monitor distance between flags (Ref 23) or diffract when passed through a narrow slit between two flags (Ref 27).

Most investigators have at some time resorted to using flexure testing, which is much less expensive and allows strains to be readily measured from the curvature in the specimen. In a sense, the bend specimen acts as a deflection magnifier, because the deflection associated with the integrated curvature is larger and easier to measure than the extension of a tension specimen. The drawback of the method is that a stress gradient in the specimen changes dramatically as the material creeps. Flexural creep testing is not a constant stress test. The strain is measured from the curvature, but this too must be adjusted for the proper constitutive equation.

In recent years, it has become painfully evident that flexural creep data can be misleading or even erroneous, a consequence of the stress gradient, the relaxation of such gradient, and the complicated constitutive equations that apply to ceramics. Analytical attempts to deconvolute the tensile and compressive creep behavior are usually tainted or compromised by the assumptions that have to be made about the constitutive equations. It is far more rational to conduct direct tension or compression experiments for careful creep work. Flexure tests can be used for qualitative assessments of conditions for the onset of creep.

Stress-rupture data require extremely long-duration experiments. Some static-fatigue phenomena occur in the absence of bulk creep deformation, and flexure testing may be eminently suitable in these cases.

Proof Testing

Ceramic users ultimately must have confidence that components will have a reliable minimum strength or performance level. The object of using nondestructive evaluation methods is to be able to discern defects to permit the culling of unacceptable components, but the state of the art is inadequate at the moment. Proof testing is a viable means of weeding out unacceptable parts in monolithic, brittle ceramics (Ref 48, 49, 50).

Proof testing entails stressing all components to a proof stress, σ_p , in order to cause fracture in the parts that are weaker than σ_p .

There are, however, severe restrictions on the utility of this method. Proof testing is only effective if the test precisely simulates the actual service conditions. Any deviation incurs risk. A further problem occurs if the material is susceptible to slow crack growth during the proof test. For a proof test to be effective in narrowing a strength distribution, it can be shown that the slow-crack-growth exponent n must meet the criterion $(n - 2)/m > 1.0$ (Ref 50). Ideally, n should be high under the conditions of the proof test. In the worst case, if unloading rates are low, it is even possible for some specimens to be weaker than σ_p after the test.

Proof tests are typically done to stress levels commensurate with or somewhat higher than the stresses expected in service. If slow crack growth is anticipated in the service conditions, it may be necessary to apply proof stresses much higher than the service levels. Analytical procedures exist that permit integration of the slow crack growth and statistical analyses, which allow the estimation of minimum lifetimes (Ref 48, 51), usually in the form of strength-probability-time diagrams (Ref 51).

The proof test only culls out specimens with defects at the time of the proof test. If new flaws subsequently develop (e.g., during high-temperature exposure or service loadings), the proof test may be negated.

Fracture Toughness

Fracture toughness values are used extensively to characterize the fracture resistance of ceramics and other brittle materials. Numerous techniques are available, and the choice of technique is determined by the type of information needed and type of flaws.

Fracture toughness values obtained through different techniques cannot be directly compared. Although much effort has been focused on this subject, it appears that a complementary number of techniques may have to be used to generate K_{Ic} values under different testing conditions.

To successfully standardize test measurements, careful attention and consideration must be given to testing details (both operators and machine), sample preparation, and prehistory in terms of microstructure, thermomechanical processing, and composition.

Both indentation crack length (fracture) and indentation strength methods can be successfully used to measure K_{Ic} only at ambient temperature in ceramic materials where neither significant slow crack growth nor R -curve behavior is observed. Simple sample preparation and small sample size are needed for such techniques.

Double torsion is applicable at high temperatures when enough material is available and under conditions where notch/crack geometry is established to allow for nearly uniform K_I value at the crack front.

Various double-cantilever techniques are advantageous because they use a small amount of material. Analytical solutions are available for accurately computing K_I values from double-cantilever configurations. However, loading fixtures and details are difficult and cumbersome, especially for high-temperature use. In ceramic multilayer electronic capacitors, miniaturization of the double-cantilever beam has proven to be useful.

The Japanese Industrial Standards (JIS) Association committee on the standardization of fine ceramics adopted the use of both indentation crack length/fracture and single-edge precracked beam techniques as standards in JIS R 1607 in 1989. However, these and other techniques still need to resolve the meaning of average resistance to crack growth and the undesirably high cost of machining, sample preparation, and fixturing.

The following sections briefly describe some common methods of fracture toughness testing. More information is also provided in the article "Fracture Resistance Testing of Brittle Solids" in this Volume.

Double Torsion Technique. This type of specimen test is popular and allows the use of a variety of specimen geometries. Basically, the specimen is a thin plate of about 75 mm by 25 mm by 2 mm (3 in. by 1 in. by 0.08 in.). A variety of specimen width-to-length ratios can be used. The specimen sometimes has a side groove, which is usually cut along its length to guide the crack. Best results are obtained without a groove, provided that there is good alignment. The specimen is best loaded and supported by ball bearings. It can be studied in terms of crack-growth behavior as well as fast fracture toughness measurements.

The double torsion technique requires a large amount (volume) of material, which may not always be available. The technique also suffers from the fact that the crack front is curved, which means that it is not under a uniform stress intensity. However, the technique is useful at high temperatures and severe environments and requires no particular fixtures (simple loading conditions).

A rigid machine is essential to conduct either precracking work or experiments where crack velocity is related to specimen compliance (during constant deflection or deflection rate trials). Some strain energy is stored in the test machine because of its finite compliance.

Indentation Fracture. Interest in this technique stems from its simplicity and the small volume of material required to conduct K_{Ic} measurements. A Vickers indentation is implanted onto a flat ceramic surface, and cracks develop around the indentation in inverse proportion to the toughness of the material. By measuring crack lengths, it is possible to estimate K_{Ic} . The crack morphology formed during the elastic-plastic contact between a sharp indenter and a brittle medium consists of both median and lateral vent cracks. It must be noted that under small indentation loads, only small, shallow cracks form. The median vent cracks are used for fracture toughness computations.

Crack dependence on sample preparation is well known for shallow cracks. The preparation of the sample surface, using effective polishing to achieve a stress state representative of the bulk, is recommended in order to achieve maximum crack length. Annealing also can be used. Ratios of crack length to indent radius of about 23 or more are recommended in order to achieve consistent results. In addition, the crack length must be measured immediately after the indentation to minimize possible post-indentation slow crack growth, especially in glasses, glass-ceramics, and ceramics that have a glassy grain boundary.

Chevron Notch Method. This method is gaining popularity because it uses a relatively small amount of material. The fracture toughness calculations are dependent on the maximum load and on both specimen and loading geometries. No material constants are needed for the calculations. The technique is also suitable for high-temperature testing, because flaw healing is not a concern. However, it requires a complex specimen shape that has an extra machining cost. A sawed notch is induced in a test bar that is usually 3 mm by 4 mm by 50 mm (0.12 in. by 0.16 in. by 2 in.). The notch angle varies from 30 to 50°. On subsequent testing of the specimen, a crack will develop at the chevron tip and extend stably as the load is increased, and later there is catastrophic fracture.

Double-Cantilever Beam Method. In this method, one of three different loading configurations can be applied (wedge load, applied load, or applied moment). A tapered double-cantilever double beam has also been suggested. Fracture toughness is derived from the notch length, specimen dimensions, and normal tensile load. This technique has a number of advantages over other fracture toughness tests. Stress intensity is independent of the crack length, in the case of the constant applied moment loading, and sample preparation and the testing procedure are both relatively simple. The specimen must be precracked (sharp cracks emanating from a blunt notch) to ensure that failure initiates from a sharp flaw of the correct geometry. Most of the time, a number of very small cracks emanate from a blunt notch with a tip radius of about 15 nm (0.6 $\mu\text{in.}$) or more. This usually results in crack growth away from the notch tip (uncontrolled geometry) and produces anomalously higher fracture toughness values than those obtained from specimens that have sharp cracks with the appropriate geometry.

Single-Edge Notched Beam. This method has been commonly used because of its simplicity (Fig. 30). The sharp crack requirement is replaced by a narrow notch, which is easier to introduce and can be measured more accurately. Fracture-toughness measurements are usually conducted using four-point bending apparatus. Unfortunately, it has been reported that the results of this test are very sensitive to the notch width and depth, and either a precracked single-edge notched beam or a single-edge precracked beam is preferred.

Fig. 30 Single-edge notched beam specimen

Single-Edge Precracked Beam. The main feature of the method is the loading fixture for precracking (Fig. 31), in which a beam-shaped specimen (flexure bend bar was also suggested) is compressively loaded against a centrally located groove in an anvil (Fig. 32). This generates a local tensile field of a Vickers indentation (or a straight notch), which is placed in the center of the tensile surface of the specimen. Then, on gradual loading, pop-in sound is detected, and a median crack is induced from the indent, extending both inward and sideways. Eventually, the crack front is arrested as a straight line through the thickness of the specimen.

Fig. 31 Loading fixture for precracking of the single-edge precracked beam specimen

Fig. 32 Loading anvil technique for generating a precrack in the single-edge precracked beam method

This technique is a refinement of the single-edge notched beam technique for introducing a precrack. It is necessary to carefully prepare (grind/polish) the beam surfaces and edges 0.08 μm (3 mils) or better to help eliminate undesirable crack starters. Careful parallelism and squareness of sample surfaces is essential for the success of precracking. The specimen is then loaded to failure in bend fixtures in the same fashion as a single-edge notched beam.

Compression Precracking. Suresh et al. (Ref 52) developed this procedure for measuring fracture toughness in either bending or tension after precracking notched specimens in uniaxial cyclic compression to produce a controlled and through-thickness fatigue flaw. After precracking, the specimen can be loaded in flexure in the single-edge notched beam configuration.

Mechanical Testing of Polymers and Ceramics

Hardness Testing

Hardness is defined in the conventional sense as a means of specifying the resistance of a material to deformation, scratching, and erosion. It is an important property for engineering applications that require good tribological resistance, such as seals, slurry pumps, rollers, and guides. Hardness tests are based on indenting the sample with a hard indenter, which may be spherical, conical, or pyramidal. There is a lack of experimental evidence to support the use of hardness for ceramics evaluation, because a combination of plastic flow, fragmentation, and cross-cracking leads to considerable scatter between indentations and to differences between observers.

Common techniques for measuring hardness in ceramics are Vickers (HV), Knoop (HK), and Rockwell superficial (HR). More detailed information is given in the article "Indentation Hardness Testing of Ceramics" in this Volume. The following guidelines should also be considered when conducting hardness measurements:

- Hardness tests can be used for engineering ceramics if it is recognized that errors (as high as 15%) and biases lead to high levels of uncertainty and increase with increasing hardness level.

- The indentation must be larger than the microstructural features. An adequate number of indentations must be used, preferably ten or more of good geometry.
- Badly damaged indentations must be ignored. Cracking from corners has to be accepted, but the impression of the corners must be undamaged.
- The machine-observer combination must have a means of calibration, preferably a high hardness test block.
- The geometry of the diamond indenter must be checked at intervals, especially in high-load tests.
- Hardness can vary with indentation load for small loads. Indentation loads greater than or equal to 9.8 N (2.2 lbf) are recommended for Knoop and Vickers indentations.

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Introduction

DESIGN is the ultimate function of engineering in the development of products and processes, and an integral aspect of design is the use of mechanical properties derived from mechanical testing. The basic objective of product design is to specify the materials and geometric details of a part, component, and assembly so that a system meets its performance requirements. For example, minimum performance of a mechanical system involves transmission of the required loads without failure for the prescribed product lifetime under anticipated environmental (thermal, chemical, electromagnetic, radiation, etc.) conditions. Optimum performance requirements may also include additional criteria such as minimum weight, minimum life cycle cost, environmental responsibility, human factors, and product safety and reliability.

This article introduces the basic concepts of mechanical design and its general relation with the properties derived from mechanical testing. Product design and the selection of materials are key applications of mechanical property data derived from testing. Although existing and feasible product shapes are of infinite variety and these shapes may be subjected to an endless array of complex load configurations, a few basic stress conditions describe the essential mechanical behavior features of each segment or component of the product. These stress conditions include the following:

- Axial tension or compression
- Bending, shear, and torsion
- Internal or external pressure
- Stress concentrations and localized contact loads

Mechanical testing under these basic stress conditions using the expected product load/time profile (static, impact, cyclic) and within the expected product environment (thermal, chemical, electromagnetic, radiation, etc.) provides the design data required for most applications.

In conducting mechanical tests, it is also very important to recognize that the material may contain flaws and that its microstructure (and properties) may be directional (as in composites) and heterogeneous or dependent on location (as in carburized steel). To provide accurate material characteristics for design, one must take care to ensure that the geometric relationships between the microstructure and the stresses in the test specimens are the same as those in the product to be designed.

It is also important to consider the complexity of materials selection for a combination of properties such as strength, toughness, weight, cost, and so on. This article briefly describes design criteria for some basic property combinations such as strength, weight, and costs. More detailed information on various performance indices in design, based on the methodology of Ashby, can be found in the article “Material Property Charts” in *Materials Selection and Design*, Volume 20 of *ASM Handbook*. The materials selection method developed by Ashby is also available as an interactive electronic product (Ref 1).

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Product Design

Design involves the application of physical principles and experience-based knowledge to develop a predictive model of the product. The model may be a prototype, a simplified mathematical model, or a complex finite element model. Regardless of the level of sophistication of the model, reaching the product design objectives of material and geometry specifications for successful product performance requires accurate material parameters (Ref 2).

Modern design methods help manage the complex interactions between product geometry, material microstructure, loading, and environment. In particular, engineering mechanics (from simple equilibrium equations to complex finite element methods) extrapolates the results of basic mechanical testing of simple shapes under representative environments to predict the behavior of actual product geometries under real service environments.

In the following sections, a simple tie bar is used to illustrate the application of mechanical property data to material selection and design and to highlight the general implications for mechanical testing. Material subjected to the basic stress conditions is considered in order to establish design approaches and mechanical test methods, first in static loading and then in dynamic loading and aggressive environments. More detailed reference books on mechanical design and engineering methods are also listed in the “Selected References” at the end of this article.

Tensile Loading

Design for Strength in Tension. Figure 1 shows an axial tensile load applied to a tie bar representing, for example, a boom crane support, cable, or bolt. For this elementary case, the stress in the bar is uniformly distributed over the cross section of the tie bar and is given by:

$$\sigma = F/A \quad (\text{Eq 1})$$

where F is the applied force and A is the cross-sectional area of the bar. To avoid failure of the bar, this stress must be less than the failure stress, or strength, of the material:

$$\sigma = F/A < \sigma_f \quad (\text{Eq 2})$$

where σ_f is the stress at failure. The failure stress, σ_f , can be the yield strength, σ_o , if permanent deformation is the criterion for failure, or the ultimate tensile strength, σ_u , if fracture is the criterion for failure. In a ductile metal or polymer, the ultimate tensile strength is defined as the stress at which necking begins, leading to fracture. In a brittle material, the ultimate strength is simply the stress at fracture. Typical values of yield and ultimate tensile strength for various materials are summarized in Tables 1, 2, and 3. These typical values are intended only for general comparisons; design values should be based on statistically based minimum values or on minimum values published in the purchase specifications of materials (such as ASTM standards).

Table 1 Typical room-temperature mechanical properties of ferrous alloys and superalloys

Fig. 1 Bar under axial tension

Equation 2 combines the performance of the part (load F) with the part geometry (cross-sectional area A) and the material characteristics (strength σ_f). The equation can be used several ways for design and material selection. If the material and its strength are specified, then, for a given load, the minimum cross-sectional area can be calculated; or, for a given cross-sectional area, the maximum load can be calculated. Conversely, if the force and area are specified, then materials with strengths satisfying Eq 2 can be selected.

Factor of Safety. Normally, designs involve the use of some type of a factor of safety. This factor, which is always greater than unity, is used in the design of components to ensure that the component can satisfactorily perform its intended purpose. The factor of safety is used to account for the uncertainties that exist in the real-world use of any component. Two main classifications of factors affect the factor of safety in a design, and they are these:

- Uncertainties associated with the material properties of the component itself, including the expected properties of the materials used to fabricate the component, as well as any uncertainties introduced by manufacturing and fabrication processing.
- Uncertainties associated with the level and type of loading the component will see, as well as the actual service conditions and any environmental conditions the component may experience.

The factor of safety is used to establish a target stress level for the design. This is sometimes referred to as the allowable stress, the maximum allowable stress, or simply, the design stress. In order to determine this allowable stress condition, the failure stress is simply divided by the safety factor. Safety factors ranging from 1.5 to 10 are typical. The lower the uncertainty is, the lower the safety factor.

Design for Strength, Weight, and Cost. If minimum weight or minimum cost criteria must also be satisfied, Eq 2 can be modified by introducing other material parameters. To illustrate, the area A in Eq 2 is related to density and mass by $A = M/\rho L$, where M is the mass of the bar, L is the length of the bar, and ρ is the material density. Solving Eq 2 for F and substituting for A :

$$F < \sigma_f A = (\sigma_f/\rho)(M/L) \quad (\text{Eq 3})$$

From Eq 3 it is clear that, to transmit a given load, F , the material mass will be minimized if the property ratio (σ_f/ρ) is maximized. The strength-to-weight ratio of a material is an important design and performance index; Fig. 2 is a plot developed by Ashby for comparison of materials by this design criterion. Similarly, material selection for minimum material cost can be obtained by maximizing the parameter $(\sigma_f/\rho c)$, or strength-to-cost ratio, where c represents the material cost per unit weight. These types of performance indices for design and the use of materials property charts like Fig. 2 are described in more detail in Ref 7 and in the articles “Material Property Charts” and “Performance Indices” in *Materials Selection and Design*, Volume 20 of *ASM Handbook*.

Fig. 2 Strength, σ_t , plotted against density, ρ , for various engineered materials. Strength is yield strength for metals and polymers, compressive strength for ceramic, tear strength for elastomers, and tensile strength for composites. Superimposing a line of constant σ_t/ρ enables identification of the optimum class of materials for strength at minimum weight.

Design for Stiffness in Tension. In addition to designing for strength, another important design criterion is often the stiffness or rigidity of a material. The elastic deflection of a component under load is governed by the stiffness of the material. For example, if a bridge or building is designed to avoid failure, it may still undergo motion under applied loads if it is not sufficiently rigid. As another example, if the tie bar in Fig. 1 were a bolt clamping a cap to a pressure vessel, excessive elastic change in length of the bolt under load might allow leakage through a gasket between the cap and vessel.

Elastic change in length occurs when an axial load is applied to the bar and is given by:

$$\Delta L = \epsilon L \quad (\text{Eq 4})$$

where ΔL is the change in length and ϵ is the strain in the bar. In the elastic range of deformation, axial stress is proportional to the strain:

$$\sigma = E\epsilon \quad (\text{Eq 5})$$

where the proportionality factor is E , the elastic modulus of the bar material.

The elastic modulus can be considered a physical property, because it is fundamentally related to the bond strength between the atoms or molecules in the material; that is, the stronger the bond, the higher the elastic modulus. Thus, the elastic modulus does not vary much in material with a given type of crystal structure or microstructure. For example, the elastic modulus of most steels is typically about 200 GPa (29×10^6 psi) for steels of various composition and strength levels (Fig. 3). However, the modulus can vary with direction if the material has an anisotropic structure. For example, Fig. 4 is a plot of the tensile and compressive modulus for type 301 austenitic stainless steel. Transverse and longitudinal values vary, as do values for tensile and compressive loads. At low stresses, the tension and compressive moduli are, by theory and experiment, identical. At higher stresses, however, differences in the compressive and tensile moduli can be observed due to the effects of deformation (e.g., elongation in tension). Typical values of elastic moduli are given in Table 4 for various alloys and metals.

Table 4 Elastic constants for polycrystalline metals at 20 °C

Metal	Elastic modulus (E)		Bulk modulus (K)		Shear modulus (G)		Poisson's ratio, ν

Equations 1 and 5 can be combined with Eq 4 to give the design equation:

$$\Delta L = FL/AE < \delta \quad (\text{Eq 6})$$

where δ is the design limit on change in length of the bar. Just as the strength, or load-carrying capacity, of the tie bar is related to geometry and material strength (Eq 2), the stiffness of the bar is related to geometry and the elastic modulus of the material. Again, part performance (force, F , and deflection, δ) is combined with part geometry (length, L , and cross-sectional area, A) and material characteristics (elastic modulus, E) in this design equation. To assure that the change in length is less than the allowable limit for a given force and material, the geometry parameters L and A can be calculated; or, for given dimensions, the maximum load can be calculated. Alternatively, for a given force and geometric parameters, materials can be selected whose elastic modulus, E , meets the design criterion given in Eq 6.

Similar to design for strength, additional criteria involving minimum weight or cost can be incorporated into design for stiffness. These criteria lead to the material selection parameters modulus-to-weight ratio (E/ρ) and modulus-to-cost ratio ($E/\rho c$), values that can be found in Ref 7 and *ASM Handbook*, Volume 20.

Mechanical Testing for Stress at Failure and Elastic Modulus. In Eq 2 and 6, the material properties σ_f and E play critical roles in design of the tie bar. These properties are determined from a simple tension test described in detail in the article “Uniaxial Tension Testing” in this Volume. The elastic modulus E is determined from the slope of the elastic part of the tensile stress strain curve, and the failure stress, σ_f , is determined from the tensile yield strength, σ_o , or the ultimate tensile strength, σ_u .

Tension-test specimens are cut from representative samples, as described in more detail in the article “Uniaxial Tension Testing.” in the example of the tie bar, test pieces would be cut from bar stock that has been processed similarly to the tie bar to be used in the product. In addition, the test piece should be machined such that its gage length is parallel to the axis of the bar. This ensures that any anisotropy of the microstructural features will affect performance of the tie bar in the same way that they influence the measurements in the tension test. For example, test pieces cut longitudinally and transverse to the rolling direction of hot rolled steel plates will exhibit the same elastic modulus and yield strength, but the tensile strength and ductility will be lower in the transverse direction because the stresses will be perpendicular to the alignment of inclusions caused by hot rolling (Ref 10).

During tension testing of a material to measure E and σ_f , in addition to the change in length due to the applied axial tensile loads, the material will undergo a decrease in diameter. This reflects another elastic property of materials, the Poisson ratio, given by:

$$\nu = -\epsilon_t/\epsilon_l \quad (\text{Eq 7})$$

where ε_t is the transverse strain and ε_l is the longitudinal strain measured during the elastic part of the tension test. Typical values of ν range from 0.25 to 0.40 for most structural materials, but ν approaches zero for structural foams and approaches 0.5 for materials undergoing plastic deformation. While the Poisson effect is of no consequence in the overall behavior of the tie bar (since the decrease in diameter has a negligible effect on the stress in the bar), the Poisson ratio is a very important material parameter in parts subjected to multiple stresses. The stress in one direction affects the stress in another direction via ν . Therefore, accurate measurements of the Poisson ratio are essential for reliable design analyses of the complex stresses in actual part geometries, as described later. Typical values of Poisson's ratio are given in Table 4.

Sonic methods also offer an alternative and more accurate measurement of elastic properties, because the velocity of an extensional sound wave (i.e., longitudinal wave speed, V_L) is directly related to the square root of the ratio of elastic modulus and density as follows:

$$V_L = (E/\rho)^{1/2} \quad (\text{Eq 8})$$

By striking a sample of material on one end and measuring the time for the pulse to travel to the other end, the velocity can be calculated. Combining this with independent measurement of the density, Eq 8 can be used to calculate the elastic modulus (Ref 8).

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Compressive Loading

If the bar in Fig. 1 were subjected to a compressive axial load, the same design criteria, Eq 2 and 7, would apply with appropriate material parameters. Measurement of the material parameters could be performed through compression tests; however, in anisotropic materials, the yield strength, σ_o , will be the same in compression and tension. The material ultimate strength, σ_u , will generally be different, however, because the fracture behavior of a material in compression is different from that in tension. Tests for failure in compression are covered in the article “Uniaxial Compression Testing” in this volume. In carrying out compression tests, the same precautions used in tension testing must be applied regarding orientation of the specimen and load relative to the material microstructure.

In compressive loading of materials, buckling may precede other forms of failure, particularly in long thin bars. The critical compressive stress for buckling of bars with simple pin-end supports is given by:

$$\sigma_b = F/A = \pi^2 EI/L^2A \quad (\text{Eq 9})$$

where I is the moment of inertia of the bar cross section. The only material parameter in Eq 9 is the elastic modulus, which is the same in tension and compression for most materials. Any convenient test for E , then, can be used to provide the material parameter required for buckling predictions.

Hardness Testing

When suitable samples for tension or compression test pieces are too difficult, costly, or time consuming to obtain, hardness testing can be a useful way to estimate the mechanical strength and characteristics of some materials. Hardness testing, therefore, is an indispensable tool for evaluating materials and estimating other mechanical properties from hardness (Ref 11, 12).

Correlation of hardness and strength has been examined for several materials as summarized in Ref 12. In hardness testing, a simple flat, spherical, or diamond-shaped indenter is forced under load into the surface of the material to be tested, causing plastic flow of material beneath the indenter as illustrated in Fig. 5. It would be expected, then, that the resistance to indentation or hardness is proportional to the yield strength of the material. Plasticity analysis (Ref 13) and empirical evidence (summarized in Ref 12) show that the pressure on the indenter is approximately three times the tensile yield strength of the material. However, correlation of hardness and yield strength is only straightforward when the strain-hardening coefficient varies directly with hardness. For carbon steels, the following relation has been developed to relate yield strength (YS) to Vickers hardness (HV) data (Ref 12):

$$\text{YS (in kgf/mm}^2\text{)} = \frac{1}{3}\text{HV (0.1)}^{m-2}$$

where m is Meyer's strain-hardening coefficient (see the article "Introduction to Hardness Testing" in this Volume). To convert kgf/mm^2 values to units of lb/in.^2 , multiply the former by 1422. This relation applies only to carbon steels. Correlation of yield strength and hardness depends on the strengthening mechanism of the material. With aluminum alloys, for example, aged alloys exhibit higher strain-hardening coefficients and lower yield strengths than cold worked alloys (Ref 12).

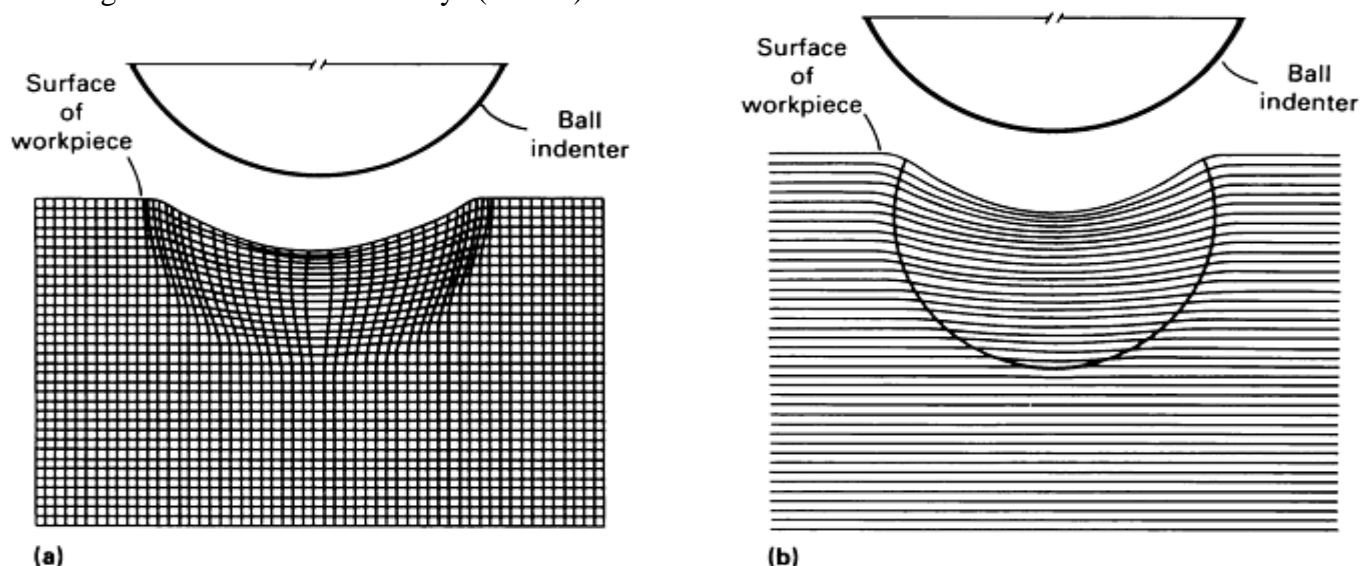

Fig. 5 Deformation beneath a hardness indenter. (a) Modeling clay. (b) Low-carbon steel

For many metals and alloys, there has been found to be a reasonably accurate correlation between hardness and tensile strength, σ_u (Ref 12). Several studies are cited and described in Ref 12, and Tables 5 and 6 summarize hardness-tensile strength multiplying factors for various materials. It must be emphasized, however, that these are empirically based relationships, and so testing may still be warranted to confirm a correlation of tensile strength and hardness for a particular material (and/or material condition). A correlation with hardness may not be evident. For example, magnesium alloy castings did not exhibit a hardness-strength correlation in a study by Taylor (Ref 11).

Table 5 Hardness-tensile strength conversions for steel

Material	Multiplying factor^(a)
Heat-treated alloy steel (250–400 HB)	470 HB
Heat-treated carbon and alloy steel (<250 HB)	482 HB
Medium carbon steel (as-rolled, normalized, or annealed)	493 HB

(a) Tensile strength (in psi) = multiplying factor \times HB.

Torsion and Bending

Instead of axial loads, the tie bar in Fig. 1 may be subjected to torsion moments about its axis on each end, as shown in Fig. 6. This represents the loading in drive shafts or torsion bar suspensions, for example. In other applications, the bar may be subjected to loads perpendicular to its axis resulting in a bending moment, as shown in Fig. 7. Typical examples include leaf springs and structural beams.

Fig. 6 Bar under torsion. M_t , applied torque. A , cross sectional area of the bar

Fig. 7 Bar under bending by a transverse load. F , applied force; L , length of the bar; M_b , bending moment

Shear Stress Distributions. In both torsion and bending, the shear strain (in torsion) and the longitudinal strain (in bending) are zero at the centerline, or neutral axis, and increase linearly to maximum values at the outer surfaces. As a result, the stress distributions are linear, as shown in Fig. 8 for torsion and Fig. 9 for bending. Note that, in bending, the stress is tensile on the convex side of the bar and compressive on the concave side.

Fig. 8 Linear distribution of shear stress in torsion of a round bar. M_t , applied torque

Fig. 9 Linear distribution of normal stress in bending. M_b , bending moment

The shear stress distribution in torsion is given by (Ref 15):

$$\tau = M_t r/J \quad (\text{Eq 10})$$

where τ is the shear stress, M_t is the applied torque, r is measured from the axis, and J is the polar moment of inertia (second moment about the axis of rotation) of the bar cross section. The influence of J in design is discussed later in “Shape Design” in this article. More detailed descriptions of rotational shear (i.e., torsion) are provided in the article “Fundamental Aspects of Torsional Loading” in this Volume.

The normal stress distribution in bending is given by (Ref 16):

$$\sigma = M_b z/I \quad (\text{Eq 11})$$

where σ is the longitudinal stress in the bar, M_b is the bending moment, z is measured from the neutral axis, and I is the moment of inertia (second moment about the bending axis) of the bar cross section. The role of I in design is also discussed later in “Shape Design.” More detailed descriptions of bending stress and strain behavior are provided in the article “Stress-Strain Behavior in Bending” in this Volume.

Design for Strength in Torsion or Bending. Design of bars under torsional or bending moments is based on preventing the maximum surface stresses from exceeding the failure limit of the material. For example, in torsion of a round bar, τ_{\max} occurs at $r = D/2$ (where D is the bar diameter) and must satisfy the design condition:

$$\tau_{\max} = M_t D/2J < \tau_f \quad (\text{Eq 12})$$

where τ_f is the failure shear strength of the material at failure. This value may be the shear yield strength, τ_o , or the ultimate shear strength, τ_u . Similarly, in bending, the maximum normal stress, σ_{\max} , occurs at $z = H/2$ (where H is the thickness of a symmetrical beam) and must satisfy the design condition:

$$\sigma_{\max} = M_b H/2I < \sigma_f \quad (\text{Eq 13})$$

where σ_f may be the tensile yield strength, σ_o , or the ultimate tensile strength, σ_u , for failure on the convex side of the bar. Compressive strengths apply to failure on the concave side of the bar.

In the same way that Eq 2 is used for design of bars under tensile loading, Eq 12 and 13 can be used to determine the maximum torque, M_t , or bending moment, M_b , that can be transmitted by a specific bar geometry (D and J , or H and I) and material (τ_f or σ_f). These equations can also be used to determine the geometric parameters required to transmit a specified torque or bending moment with a given bar material. Alternatively, Eq 12 and 13 can be used to select materials having the proper values of τ_f or σ_f to transmit a specified torque or bending moment in a bar of given geometry.

As with the case of simple tension, the design equations for torsion and bending can be modified to include the additional criteria of minimum weight or minimum cost. The material parameters for minimum weight or

minimum cost in this case depend on the geometric parameters that are fixed and those that are variable. For a beam with the width undefined, the design parameters are (σ_f/ρ) and $(\sigma_f/\rho c)$, while for beams in which the height is undefined, the design parameters are $(\sigma_f^{1/2}/\rho)$ and $(\sigma_f^{1/2}/c\rho)$ (Ref 1, 7).

Design for Stiffness in Torsion or Bending. Elastic deflection of a bar under bending moments and elastic twisting of the bar under torsion may lead to additional design limits. For example, in bending a simply supported beam (Fig. 7), the deflection at the center point is (Ref 16):

$$\delta = FL^3/48EI \quad (\text{Eq 14})$$

The beam stiffness is determined by the material parameter, E , and the geometry parameters, L and I . Beam design to meet deflection limitations can be accomplished by proper material specification or by geometric specifications.

Similarly, torsional rotation of a round bar is given by (Ref 15):

$$\theta = M_t L/GJ \quad (\text{Eq 15})$$

where M_t is the applied torque, L is the length of the bar, J is the polar moment of inertia, and G is the shear modulus of elasticity. Design for torsional stiffness involves selection of the bar dimensions as well as the material via its elastic property, G , which is related to other elastic properties by (Ref 15):

$$G = E/2(1 + \nu) \quad (\text{Eq 16})$$

Shape Design. Of particular interest in design of bars under torsion or beams under bending are the moments of inertia, J and I . Since the stress distributions in each case are linear and reach a maximum at the surface, as shown in Fig. 8 and 9, the best use of material is accomplished by distributing it near the surfaces rather than at the center. For example, the value of J for a solid circular cross section is:

$$J = \pi D^4/32 \quad (\text{Eq 17})$$

By removing material from the central region of the bar, which is under little stress, the torsional load carrying capacity is reduced slightly, but the area (and therefore weight) is reduced more significantly. Referring to Fig. 10, if one-half of the inner material is removed (i.e., inside diameter $D_i = D/\sqrt{2}$), the weight is reduced by 50%, but the value of J is reduced by just 25%.

Fig. 10 Comparison of polar moment of inertia, J , for (a) solid and (b) hollow round bars. A , cross-sectional area; D , diameter

Similarly, in bending, efficient material use is accomplished by placing material at the upper and lower surfaces, as in the shape of an I-beam. To illustrate this, consider that the moment of inertia for a rectangle is given by:

$$I = bH^3/12 \quad (\text{Eq 18})$$

where b is the width and H is the height of the rectangle. Obviously, increasing H has a much larger effect on I than increasing b . For example, as shown in Fig. 11, a rectangle that is 3 units thick and 9 units long has a value of I that is 9 times larger in the vertical orientation compared to the horizontal orientation. However, if the same amount of material is rearranged into an I-beam configuration, the value of I increases further by a factor of nearly 3. Thus, weight savings in design for torsion and bending can be accomplished not only by selecting

materials having high strength-to-weight ratios, but also by careful attention to the distribution of material in the component.

Fig. 11 Comparison of moment of inertia, I , for three different arrangements of the same amount of material

Mechanical Testing. Testing of materials for shear yield strength, τ_0 , to be used in Eq 12, or for tensile yield strength, σ_0 , for use in Eq 13, can be accomplished through a tension test. If the material is isotropic and homogeneous, the *shear yield strength* can also be calculated from the tensile yield strength (Ref 15):

$$\tau_0 = \sigma_0 / \sqrt{3} \quad (\text{Eq 19})$$

Fracture strengths, however, must be measured in torsion and bend tests because the mechanisms or modes of fracture may be different from those in tension testing.

Tensile yield strength, σ_o , and shear yield strength, τ_o , can also be derived directly from bending and torsion tests using Eq 12 and 13. Accuracy will be limited, however, because in both cases yielding occurs initially at the outside surfaces, so the effect on the measured loads is not as easily detectable as in the tension test, where yielding occurs simultaneously across the entire section.

Torsion and bend tests are particularly useful in evaluating materials that have been given surface treatments such as carburizing or shot peening to increase the strength of the surfaces and improve their resistance to the high stresses at the surface generated by torsional or bending moments. Generally, the metallurgical structures of such surfaces occur in a thin layer and cannot be produced easily in bulk form for measurement by tension testing. Then, Eq 12 can be used to determine the strength, τ_f , of the surface material in torsion, and Eq 13 can be used to determine the strength, σ_f , of surface material in bending. This approach is particularly useful for determining fracture strengths of the surface materials.

During bend or torsion testing of surface treated materials, however, certain precautions must be taken. First, the orientation of the bending and shear stresses in the test specimens must be in the same orientation with respect to the material microstructure as occurs in the actual components. Second, variations in material strength beneath the surface must be considered in comparison with the linear distributions of stress in bending and torsion shown in Fig. 8 and 9. Even though the surface material strength may be greater than the stress at the surface (such as in a case hardened part), away from the surface at the neutral axis of the bar the strength may decrease more rapidly than the applied stress, as illustrated in Fig. 12 (Ref 17). Then failure will occur beneath the surface where the stress exceeds the local strength of the material. Clearly, it is important to understand the strength distribution in a material in relation to the stress distribution acting on the material to ensure that the product design prevents such insidious failures. Details on torsion and bend testing are covered in separate articles in this Volume.

Fig. 12 Stress and strength distributions in a bar under torsion or bending. Failure occurs beneath the surface if the material strength decreases more rapidly than the stress in the material. Source: Ref 17

Equation 14 for deflection of a beam also suggests an alternative method for measuring the elastic modulus, E , of a material. For given geometry parameters, measured data pairs for force, F , and deflection, δ , lead to a calculation of E . Alternatively, resonant frequency methods can be used to measure E in the beam geometry shown in Fig. 7. The natural frequency of vibration of a beam is related to its geometry, density, and elastic modulus. To carry out the measurement, the beam is vibrated by a transducer connected to a frequency generator producing sinusoidal waves. By varying the frequency of the generator, the natural frequency is determined when resonance occurs. Then the elastic modulus can be calculated from (Ref 18):

$$E = Cf^2 \rho L^4 / H^2 \quad (\text{Eq 20})$$

where f is the resonant frequency, ρ is the material density, L is the beam length, H is the beam thickness, and C is a constant. The shear modulus, G , can also be measured by sonic and resonant frequency methods in torsion. Generally, resonant and sonic methods of measuring elastic properties are more accurate and easier to perform than direct measurement of stress and strain in a tension or torsion test.

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Shear Loading

The torsion test described above subjects material to shear stress in a rotational mode, but shear stresses also occur in a translational mode. Such modes can be found, for example, in the end connectors of tie bars.

Design Examples. In an actual tie bar, the loads at each end of the bar in Fig. 1 would be applied through a pin connector or a threaded coupling, for example, as shown in Fig. 13(a). If the tie bar were a composite material (which cannot be threaded or drilled), the loads would most likely be applied through an adhesive lap joint, as shown in Fig. 13(b).

Fig. 13 Methods of connecting loads. (a) A load is applied to the tie bar in Fig. 1 by a pin/eye connector and a threaded connector. (b) End loads are applied to a composite bar by adhesives.

In these and all other types of connectors, shear stresses occur in the transition from the connection to the straight section of the bar. For example, Fig. 14(a) shows a pin through the eye of the tie bar and the forces applied to the tie bar through a clevis. The pin, Fig. 14(b), is subjected to shear stresses along the dotted planes between the eye of the tie bar and the clevis. Shear failure may occur along these planes. On the face view of the eye on the tie bar, Fig. 14(c), shear also acts along the dotted planes from the hole to the end of the bar, potentially leading to tear out of the end of the conductor. On the threaded end of Fig. 13(a), transmission of load from a threaded connector to the tie bar also is carried by shear stresses at the root of the threads, shown by the dotted lines in Fig. 15. In the lap joint shown in Fig. 13(b), shear would occur along the adhesive interfaces. Concentrated shear stresses, similar to those shown in Fig. 14(b) and 14(c), also occur in many machine elements, such as keys and keyways in drive shafts, shear pins, and splined couplings. These applications are critical to the safe operation of machinery and require robust design methods using accurate material properties.

Fig. 14 Shear stresses in load end connectors. (a) A clevis and pin connected to the eye in Fig. 13(a). (b) Shear planes in the pin. (c) Shear planes in the eye

Fig. 15 Shear planes in a threaded end connector

In all of these examples, the average shear stress acting on the shear planes is:

$$\tau = F/A_s \quad (\text{Eq 21})$$

where F is the load transmitted and A_s is the total area of the shear planes. For design against failure, this shear stress must be less than the shear strength of the material.

Mechanical Testing. Measurement of the shear yield strength of the material can be extracted from a tension test by using Eq 19 if the material has an isotropic and homogeneous microstructure. The torsion test described previously also can be used to determine the shear strength of the material. However, the torsion test measures the shear strength of the material in rotational shear, but the applications shown in Fig. 13, 14, and 15 involve

linear shear along a plane through the material or along an interface. Linear shear behavior is affected significantly by anisotropy of the microstructure of the material, and specialized tests have been developed to determine the linear shear yield and fracture strength of materials. More details on torsion loading are in the article “Shear, Torsion, and Multiaxial Testing” in this Volume.

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Complex Stresses

The previous sections describe the relatively simple uniform and linear stress distributions occurring during tension, compression, torsion, bending, and shear. In all of these cases, one primary stress occurred. Nonelementary shapes, however, lead to nonuniform, nonlinear, and multiaxial stresses, and these complex stress states must be considered in a complete analysis for product design.

Constitutive Relations. To consider the effects of combined stresses in design, constitutive equations are required that give the relationships between multiple stresses and strains. A one-dimensional example of a constitutive relation is the combination of Eq 5 and 7, describing the elastic connection between uniaxial stress and strain. Extending this behavior to three dimensions, if σ_x is applied in the x -direction, the strain $\epsilon_x = \sigma_x/E$ occurs, and that same stress will generate transverse strains:

$$\epsilon_y = \epsilon_z = -\nu\epsilon_x = -\nu\sigma_x / E \quad (\text{Eq 22})$$

This leads to the complete three-dimensional expressions relating elastic stresses and strains (Ref 15):

$$\epsilon_x = (\sigma_x - \nu\sigma_y - \nu\sigma_z)/E \quad (\text{Eq 23a})$$

$$\epsilon_y = (\sigma_y - \nu\sigma_z - \nu\sigma_x)/E \quad (\text{Eq 23b})$$

$$\epsilon_z = (\sigma_z - \nu\sigma_x - \nu\sigma_y)/E \quad (\text{Eq 23c})$$

A complete description of material behavior requires a description of yielding under multiaxial stresses. Equations 2, 12, 13, and 21 express the conditions for yielding under the action of a single tensile or shear stress. For three-dimensional stresses, a commonly used criterion that includes the effect of all stresses acting at a point in a material is:

$$\begin{aligned} & [(\sigma_x - \sigma_y)^2 + (\sigma_y - \sigma_z)^2 + (\sigma_z - \sigma_x)^2 + 6\tau_{xy}^2 \\ & + 6\tau_{yz}^2 + 6\tau_{zx}^2]^{1/2} / \sqrt{2} = \sigma_o \end{aligned} \quad (\text{Eq 24})$$

where σ_o is the yield strength of the material in simple tension. Equation 24, known as the von Mises yield criterion (Ref 19), relates all of the stresses acting in a material to its yield strength. Note that, in a torsion test where normal stresses are zero and only one shear stress is applied, Eq 24 reduces to Eq 19, which enables shear yield strength values for design to be determined from a simple tension test.

Equations 23a, 23b, 23c, and 24 are the constitutive relations for elastic deformation and yielding of an isotropic material. More complex constitutive relations have been developed for anisotropic materials, composites, and rate dependent materials. For failure by fracture, no simple criterion, such as Eq 24, exists to express the effects of multiaxial stresses on failure.

Qualitative results from Eq 23a, 23b, 23c, and 24 lead to insights on the relationships between combined stresses and strains. For example, in a plane-strain tension test (Fig. 16), a groove across the face of the specimen will lead to stress $\sigma_x = F/tW$ where F is the applied load, t is the groove thickness, and W is the specimen width. Under the action of this stress, the material in the groove will tend to contract in the thickness direction, z , and in the width direction, y . There is no constraint preventing the material from contracting in the thickness, so $\sigma_z = 0$. In the width direction, however, the bulk material (thickness, T , much greater than t) on each side of the reduced section prevents material from contracting. That is, $\epsilon_y = 0$. Then, from Eq 23a, 23b, and 23c:

$$\epsilon_y = 0 = (\sigma_y - \nu\sigma_x)/E \quad (\text{Eq 25a})$$

or

$$\sigma_y = \nu\sigma_x \quad (\text{Eq 25b})$$

That is, a stress is generated in the y-direction because the natural tendency for the material to contract is constrained. The strain in the thickness direction will be:

$$\epsilon_z = -\nu(\sigma_x + \sigma_y)/E = -\nu(1 + \nu)\sigma_x/E \quad (\text{Eq 26})$$

which is slightly larger than the strain that would have occurred with no constraint in the y-direction. More complex interactions occur between three-dimensional stresses and strains in more complex geometries, and these interactions are influenced strongly by the Poisson ratio, ν .

Fig. 16 Plane strain tension test specimen, showing the strains and stresses in the gage section

The multiaxial stresses in this example have an effect on yielding. The applied stress, σ_x , combined with the constraint of transverse strain in the y-direction, generates a stress in the y-direction given by Eq 25a and 25b. The applied stress σ_x required to cause failure by yielding can be found by substituting the stresses $\sigma_y = \nu\sigma_x$ and $\sigma_z = 0$ into Eq 24, giving:

$$(\sigma_x - \nu\sigma_x)^2 + (\nu\sigma_x)^2 + (-\sigma_x)^2 = 2\sigma_o^2 \quad (\text{Eq 27a})$$

or

$$\sigma_x = \sigma_o/(1 - \nu + \nu^2)^{1/2} \quad (\text{Eq 27b})$$

Substituting the value of $\nu = 0.5$ for material undergoing plastic deformation, $\sigma_x = 1.15 \sigma_o$; that is, because of the constraint to contraction in the y-direction of the geometry shown in Fig. 16, the stress required to yield the material is 15% higher than the axial stress required to yield the material if it were in simple tension.

Following are further examples of basic design stress conditions that involve nonlinear stress distributions and multiaxial stresses.

Stress Concentrations. In the transition from the pin connector to the uniform cylindrical part of the tie bar (Fig. 13a), the irregular geometry leads to concentrations of stress around the hole in the tie bar. The load applied by the pin is distributed as a nonuniform stress across the eye cross section, as shown in Fig. 17. Although the average stress on the cross section equals the load divided by the area, peak values of the stress occur at the inside of the eye.

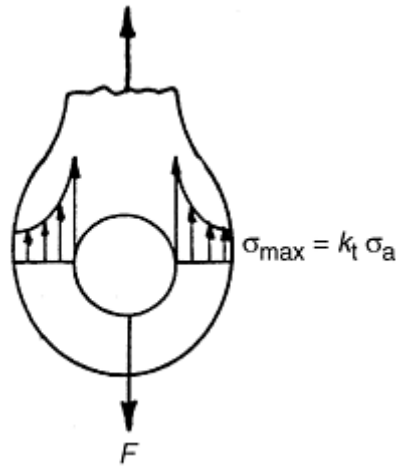

Fig. 17 Stress distribution on a cross section through the eye shown in Fig. 13(a)

Such concentrations of stress occur in all geometric irregularities such as fillet radii, notches, and holes. A simplistic but useful expression for the stress concentration is given by (Ref 19):

$$\sigma_{\max} = k_t \sigma_a \approx (1 + 2a/b) \sigma_a \quad (\text{Eq 28})$$

where k_t is the stress concentration factor, σ_a is the average stress, a is the dimension of the geometric irregularity perpendicular to the applied load, and b is the dimension parallel to the load (Fig. 18). In Fig. 17, for example, $a = b$, so the stress concentration factor is 3. For very small cracks perpendicular to the load, a is much greater than b so the stress concentration becomes $2 a/b$. Stress concentration factors for a wide range of practical geometries have been developed through extensive experimentation and analysis (Ref 16, 20). Failures usually initiate at these points of stress concentration and must be considered in all product designs.

Fig. 18 Stress concentration around a flaw. Source: Ref 19

Pressure Vessels. Multiaxial stresses occur in shells subjected to internal or external pressure. Examples include tanks containing fluids, vessels containing a high-pressure and high-temperature chemical reaction (such as in petroleum refining), dirigibles, and submarine pressure hulls. Proper design of such pressure vessels must account for the multiaxial stresses.

A spherical shell containing pressure, for example, has equal stresses in any two perpendicular directions tangent to the sphere (Fig. 19), given by (Ref 22):

$$\sigma_{\theta} = \sigma_{\phi} = pD/4t \quad (\text{Eq 29})$$

where p is the internal pressure, D is the spherical diameter, and t is the wall thickness. Note that for D much greater than t , these stresses are much larger than the pressure, and stress through the thickness $\sigma_t \approx 0$.

Fig. 19 Stresses in the wall of a spherical pressure vessel

A cylindrical pressure vessel wall will have a stress in the circumferential, or hoop, direction (Fig. 20), given by (Ref 16):

$$\sigma_{\theta} = pD/2t \quad (\text{Eq 30a})$$

and a stress in the axial direction given by:

$$\sigma_z = pD/4t \quad (\text{Eq 30b})$$

Fig. 20 Stresses in the wall of a cylindrical pressure vessel

Failure by yielding of a spherical pressure vessel can be found by substituting Eq 29 into Eq 24, giving:

$$p_{\max} = 4\sigma_o t/D \quad (\text{Eq 31})$$

For the cylindrical pressure vessel, substituting Eq 30a and 30b into Eq 24 gives:

$$p_{\max} = (4 / \sqrt{3})\sigma_o t/D \quad (\text{Eq 32})$$

In all pressure vessel applications, the stresses in the wall, given by Eq 29, 30a, and 30b, may be further complicated by stress concentrations due to holes for inlet and outlet piping.

In cases where the wall thickness is much less than the diameter, the stresses given by Eq 29, 30a, and 30b are nearly uniform through the thickness. For pressure containment where the wall thickness is a significant fraction of the diameter, such as in metalworking dies, the stress distribution is nonuniform with peak values at the inner surface (Ref 16). In these cases as well, Eq 24 is used to evaluate the initiation of failure by yielding.

Bearing Loads. Close examination of the pin end connector in Fig. 13(a) shows that the pin rests in a circular hole at the end of the tie bar. For ease of attachment to the connector, the pin diameter is smaller than the hole

diameter. As a result, the load transmitted from the pin to the inside surface of the hole occurs over a small area of contact, leading to high local pressures, as shown in Fig. 21. The pressure distribution in bearing contacts of this type is generally elliptical because the greatest elastic deformation occurs at the center of the contact zone. Figure 22 shows this more clearly in the contact pressure between a flat plate and a cylinder. Similar types of bearing loads and the accompanying elliptical pressure distributions occur in journal bearings, ball and roller bearings, gear tooth contacts, and railroad wheel/rail contacts. The nature of the contact pressure distributions and the internal distribution of stresses resulting from these loads have special implications regarding material testing and selection.

Fig. 21 Contact stresses between a pin and eye

Fig. 22 Flattening and contact pressure distribution between a roller and flat plate

In roller-on-roller contacts, the elliptical pressure distributions in Fig. 21 and 22 have peak pressures given by (Ref 21):

$$p_{\max} = \sqrt{2P/\pi\Delta} \quad (\text{Eq 33a})$$

where P is the load per unit length of contact and

$$\Delta \equiv [1/(1/D_1 + 1/D_2)] [(1 - \nu_1^2)/E_1 + (1 - \nu_2^2)/E_2] \quad (\text{Eq 33b})$$

where D_1 and D_2 are the diameters of the rollers, and ν and E are the elastic properties of the materials in contact. The width, w , of the contact zone between the rollers is given by:

$$w = \sqrt{8P\Delta/\pi} \quad (\text{Eq 34})$$

In addition to the normal contact pressure shown as σ_z in Fig. 22, elastic deformation in the contact zone also generates σ_x parallel to the surface and σ_y parallel to the axes of the rollers (perpendicular to the view in Fig. 21). In this case, σ_x has the same magnitude and elliptical distribution as σ_z . Beneath the surface in Fig. 22, all of the stresses decrease because the contact load is spread over a larger area. Stress analysis leads to the stress distributions (Ref 21):

$$\sigma_z = -w/2\Delta\zeta \quad (\text{Eq 35a})$$

$$\sigma_x = -(\zeta - z')^2 w/2\Delta\zeta \quad (\text{Eq 35b})$$

$$\sigma_y = -\nu(\zeta - z') w/\Delta\zeta \quad (\text{Eq 35c})$$

where z is the distance beneath the contact surface, $z' = 2z/w$, and $\zeta = \sqrt{1+z'^2}$. These stresses are plotted in Fig. 23, which shows that σ_x decreases more rapidly than σ_z . The von Mises stress σ_{vm} is also plotted, which shows a maximum at a distance $0.4w$ beneath the surface (where w is the contact width calculated from Eq 34). Subsurface failure as a result of these stresses is common in rolling contact configurations such as Fig. 22.

Fig. 23 Stresses beneath the contact zone in Fig. 22

Finite Element Analysis. For complex stress problems that are not easily solved using the basic loading situations (or their combinations) described previously, finite element analysis is commonly used. Over the past four decades, the finite element method has evolved from a structural analysis tool to a set of refined commercial programs that are invaluable aids in modern design. Much of this utility is a result of the availability of more rapid and powerful computers, improved numerical methods for solving the equations, and enhanced computer graphics for display of the results.

Finite element analysis reduces the infinite number of points in a prescribed product geometry to a finite number of elements bound by a finite number of points. The behavior of each element in a finite-element grid is governed by the same principles of equilibrium as in the tensile, compressive, torsional, and bend loadings described previously in this article, and by the material behavior described through constitutive equations (Eq 23a, 23b, 23c, and 24).

The beauty of finite element analysis for design is that it allows consideration of complicated geometries and any type of material for which the properties are known. Finite element analysis methods thus assist in the specification of geometry and material, which are the two primary objectives of design for mechanical applications. Evaluating small changes in geometry or variations in material properties via finite element modeling permits design optimization.

In the application of finite element analysis (Ref 22, 23), first the product geometry is described by a collection of two-dimensional or three-dimensional elements, such as those shown in Fig. 24. The choice of element type depends on the problem geometry and loading. From displacements of the nodal points in each element, the deformations and strains in the element are defined. Then the material constitutive equations (e.g., Eq 23a, 23b,

and 23c) relate these strains to the stresses in each element. Each node is connected to two or more elements, so there is interdependence between neighboring elements.

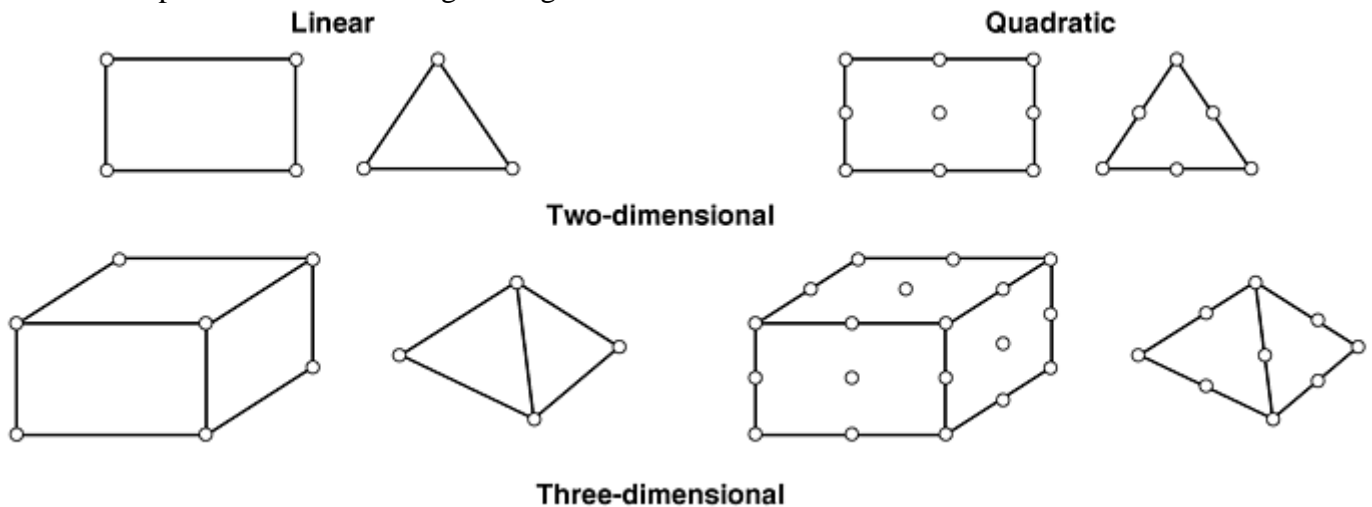

Fig. 24 Examples of element geometries used for finite element models

The next step is to define the boundary conditions (externally applied loads at the appropriate nodes) and constraints (identification of the nodes that are constrained from moving in at least one direction). This is a very important key to development of an accurate model and is based on mechanical insight of the person doing the modeling.

Energy methods are used to determine the interdependent nodal displacements (and stresses and strains) that minimize the total energy of the system. The resulting myriad of linear algebraic equations are then solved for all of the nodal displacements such that the stresses and deformations are compatible from element to element and are consistent with the externally applied loads and nodal constraints.

As an example, Fig. 25 shows a strip under tension and containing a hole, which was shown previously to cause a concentration of stress. The elements used for the analysis are quadrilateral to conform to the overall geometry of the part (Ref 24). In the vicinity of the hole, the elements are distorted to conform to the shape of the hole. In addition, the number of elements per unit area is increased in the vicinity of the hole because the stresses change rapidly. Taking advantage of symmetry, one-quarter of the geometry is considered to reduce the number of elements, nodes, and equations to be solved.

Fig. 25 Finite element model of a strip under tension and containing a hole. Source: Ref 24

Along the vertical line of symmetry, each nodal point is permitted to move vertically but not laterally. Along the horizontal line of symmetry, each node is permitted to move laterally but not vertically. These constitute the constraints on the problem.

At each of the nodal points along the upper surface, equal loads are applied that add up to the total applied load. Alternatively, uniform small displacements in the vertical direction can be applied to each node along the upper surface. This constitutes the loading for the problem. The material behavior is represented by elastic modulus, E , and Poisson ratio, ν , in the constitutive equations, Eq 23a, 23b, and 23c.

Results of solution of the simultaneous equations for all elements are shown in Fig. 26. Note that the axial stress, σ_y , along the horizontal plane through the hole has a peak value at the edge of the hole. Also, a small lateral stress distribution, σ_x , occurs along the horizontal plane of symmetry. Note that, along the vertical centerline, the axial stress is zero at the hole and then increases to the applied stress, while the lateral stress is compressive.

Fig. 26 Stress distributions calculated for the model shown in Fig. 25. Source: Ref 24

To evaluate failure by yielding, the stresses in each element of the model can be substituted into Eq 24. The resulting stress magnitude is called the von Mises stress and can be compared to the material yield strength, σ_o , to determine if yielding will occur. For example, Fig. 27 shows a contour plot of the von Mises stress for the problem shown in Fig. 25. Note that yielding would occur first at the inside of the hole and propagate along a 45° plane, illustrated by the band of high von Mises stress.

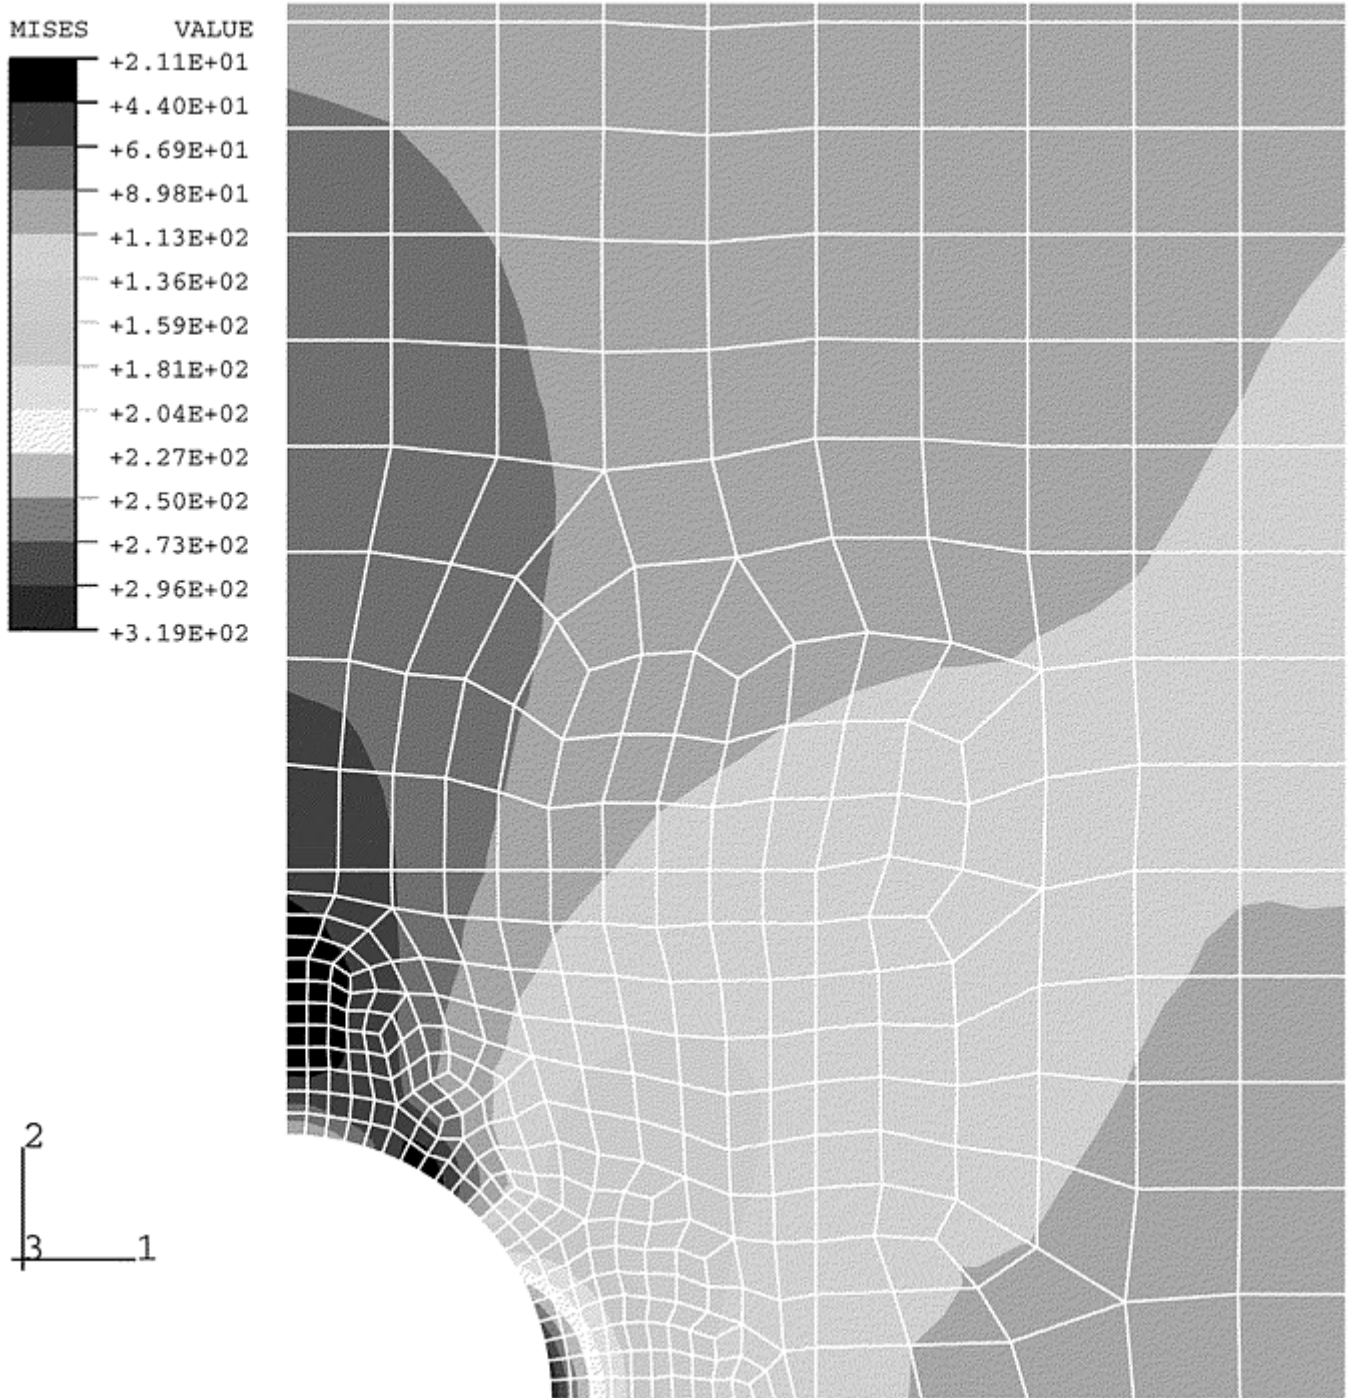

Fig. 27 Contour plot of von Mises stress for the model in Fig. 25. Source: Ref 24

As another example, a finite element analysis of the contact bearing load, described previously in Fig. 22, is shown in Fig. 28 (Ref 24). A contour plot of the calculated von Mises stress (Fig. 29) shows a potential subsurface failure point, as described previously by classical stress analysis (Fig. 22).

Fig. 28 Finite element model for contact stresses between a roller and flat plate, as in Fig. 22. Source: Ref 24

Fig. 29 Contour plot of von Mises stress beneath the zone of contact

These examples illustrate that finite element analysis tools provide deep insight into the mechanical behavior of materials for product design, but physical validity of the analytical results is a prime concern for designers who make decisions based on these results. Valid results depend on proper definition of the problem in terms of the meshing (element shape and size), loading (boundary conditions and constraints), and material characteristics

(constitutive relations). Setting up a valid problem and evaluating the results are greatly enhanced by knowledge of the stress, strain, and mechanical behavior of materials under the basic loading conditions presented in the previous paragraphs. Often, the cost and time for finite element analysis can be precluded by learned application of the knowledge of the basic modes of loading. This is the basis for the Cambridge Engineering Selector (Ref 1). On the other hand, some problems are so complex that only finite element analysis can provide the necessary information for design decisions. Analysts' and designers' skill and experience are the bases for judgment on the level of sophistication required for a given design problem.

Additional information on finite element methods is provided in the article, "Finite Element Analysis" in *Materials Selection and Design* Volume 20 of *ASM Handbook*.

Material Testing for Complex Stresses. In all of the cases given above for complex stresses, the tensile yield strength and the elastic properties, E and ν , are the key material parameters required for accurate design analyses. The yield criterion, using the tensile yield strength, σ_0 , is used to predict failure by yielding. All of these material parameters can be determined by tension testing.

The prediction of failure by yielding is also useful for prediction of the sites for fracture since localized yielding usually precedes fracture. Final failure by fracture, however, cannot be related to any single criterion or simple test. The following paragraphs describe approaches to material evaluation for various forms of failure by fracture.

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Fracture

The design approaches given in preceding sections of this article were based on prevention of failure by yielding or excessive elastic deflection. While the yield strength for ductile materials is below their tensile strength, it is well known that failure by fracture can occur even when the applied global stresses are less than the yield strength. Fractures initiate at localized inhomogenities, or defects, in the material, such as inclusions, microcracks, and voids. Previously it was shown that geometric inhomogenities in a part lead to

concentrations of stress (Fig. 18 and Eq 28). Material defects, generally having a sharp geometry (a much greater than b) lead to very high localized stresses.

Considering such defects in design against fracture requires looking beyond stress and elastic deformation to the combination of stress and strain, or energy per unit volume. Defects are commonplace in the microstructures of real materials and are generated both by materials processing and by service loads and environments. Under certain conditions, these defects can grow, unsteadily, leading to rapid and catastrophic fracture. This condition was first described by Griffith (Ref 25), who noted that a defect would grow when the elastic energy released by the growth of the defect exceeded the energy required to form the crack surfaces. The excess energy in the system, then, continuously feeds the fracture phenomenon, leading to unstable propagation. The driving energy from defect growth is a function of the applied stresses (loading, part, and defect size geometry), and the energy for crack surface formation is a function of the material microstructure. Details of the development can be found in Ref 19 and 27 and the Section “Impact Toughness Testing and Fracture Mechanics” in this Volume.

Design Approach. For design and materials selection to avoid fast fracture, the net result of these considerations is the basic design equation for stable crack growth (Ref 19):

$$K = Y\sigma\sqrt{\pi a} < K_c \quad (\text{Eq 36})$$

where K is the stress intensity factor, Y is a factor depending on the geometry of the crack relative to the geometry of the part, σ is the applied stress, a is the defect size or crack length, and K_c is a critical value of stress intensity. K must be less than K_c for stable crack growth.

The stress intensity K represents the effect of the stress field ahead of the crack tip and is related to the energy released as the crack grows. For example, Fig. 30 shows the results of finite element analysis of the stresses in the vicinity of a crack growing from a hole. The high level and distribution of stresses ahead of the crack tip all contribute to the stress intensity factor. When the stress intensity exceeds a critical value, K_c , the energy released exceeds the ability of the material to absorb that energy in forming new fracture surfaces, and crack growth becomes unstable. This critical value of the stress intensity is known as the fracture toughness of the material.

Fig. 30 Finite element calculation of stresses in the vicinity of a crack at the edge of a hole in a strip under axial tension

Equation 36 can be viewed in the same way as Eq 2 for tensile loading and Eq 12 and 13 for bending and torsion. The stress intensity factor, K , in Eq 36 is equivalent to stress, σ in Eq 2, 12, or 13. While the stress is

defined for each case by the applied load and geometry of the part, stress intensity is defined by the applied stress (load and part geometry) and the geometry of the crack relative to the geometry of the part, which is expressed by the factor Y . The important difference is that more information is given in the stress intensity factor since it involves the defect or crack size, which becomes an additional design parameter. Values of Y can be found in Ref 19 and 26, among others, for some common part geometries and crack configurations. Alternatively, finite element analysis can be used to determine K . The fracture toughness of the material, K_c , on the right side of Eq 36 is equivalent from a design perspective to the material strength, σ_f , in Eq 2, 12, and 13. In applying Eq 36, if the material is specified and the stress is known from the loading requirements, then the maximum flaw size that can be tolerated is $a_{\max} = K_c^2 / \sigma^2 \pi f^2$ (or $a_{\max} = Y^2 K_c^2 / \sigma^2 \pi$). This gives a clear objective for nondestructive inspection of flaws in the product. Alternatively, if the material is specified and a maximum flaw size is specified that can be easily seen by visual inspection, then the maximum stress that can be applied is $\sigma_{\max} = Y K_c / \sqrt{\pi a}$. On the other hand, if the stress and maximum flaw size are known, Eq 36 defines the value of K_c required to prevent fracture and is used for material selection from tables of fracture toughness. One application of the fracture criterion in Eq 36 is the design of pressure vessels, using a leak-before-break philosophy. If the pressure vessel contains a flaw that grows to extend through the pressure vessel wall without causing unstable fracture, then the internal pressurized fluid will leak out. On the other hand, if the flaw size in the pressure vessel is above the critical flaw size yet less than the wall thickness of the vessel, fracture will occur catastrophically. In Fig. 31, a flaw is shown having grown through the pressure vessel wall (Ref 19). If the critical flaw size is taken as the thickness of the pressure vessel wall, then Eq 36 gives $\sigma_{\max} = Y K_c / \sqrt{\pi t}$, where t is the thickness of the wall. Equations 29, 30a, and 30b can be used to define the applied stress in the pressure vessel wall and its relation to the internal pressure. Then, for a given material and its fracture toughness, K_c , the maximum stress and internal pressure is determined. Conversely, for a given pressure (and stress in the wall), the required value of fracture toughness is given by $K_c = \sigma \sqrt{\pi t} / Y$.

Fig. 31 Flaw in a pressure vessel wall. Source: Ref 19

Mechanical Testing. The crack opening mode described in this example is known as mode I, or crack opening perpendicular to a tensile stress (Fig. 32), which is the most common mode of fracture. Mode I cracking occurs, for example, in the tensile loading of the tie bar shown in Fig. 1, in the stress concentration around the eye in the end connector (Fig. 16) and in bending (Fig. 7 and 9). In this case, the critical stress intensity of the material, or fracture toughness, is designated K_{Ic} . However, two other crack opening modes are possible, as shown in Fig. 32. Mode II occurs in linear shear, as depicted in Fig. 14 and 15, while mode III occurs in torsional shear (Fig. 6 and 8). The critical stress intensity for these modes are denoted by K_{IIc} and K_{IIIc} . The mode of potential fracture prescribes the test and approach used for measurement of the respective fracture toughness values.

Fig. 32 Three crack opening modes

The material property to be determined for design against fracture is the fracture toughness, K_{Ic} , to be used in Eq 36. The critical stress intensity, K_{Ic} , or fracture toughness in mode I, for example, can be measured by a compact tension test as well as other standardized test specimens and procedures, as described in the Section “Impact Toughness Testing and Fracture Mechanics” in this Volume. In addition, fracture toughness values can be correlated with Charpy test measurements of toughness for certain steel alloys (Ref 27).

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Fatigue

In the previous discussion, the various loads and the resulting stress distributions are defined for static conditions. In most design applications, however, parts and components are subjected to cyclic loads. In this case, the peak amplitude of a load cycle (σ_{max} in Fig. 33) is the maximum value of applied stress, which can be analyzed by the equations for static stress distributions (for example, from Eq 1, 12, 13, 21, and 27a 27b). However, materials under cyclic stress also undergo progressive damage, which lowers their resistance to fracture (even at stresses below the yield strength).

Fig. 33 Cyclic stress that may lead to fatigue failure

The occurrence of fatigue (paraphrasing from Ref 28) can be generally defined as the progressive, localized, and permanent structural change that occurs in a material subjected to repeated or fluctuating strains at nominal stresses that have maximum values less than (and often much less than) the static yield strength of the material. Fatigue damage is caused by the simultaneous action of cyclic stress, tensile stress, and plastic strain. If any one of these three is not present, a fatigue crack will not initiate and propagate. The plastic strain resulting from cyclic stress initiates the crack; the tensile stress promotes crack growth (propagation). Compressive stresses (typically) will not cause fatigue, although compressive loads may result in local tensile stresses.

During fatigue failure in a metal free of cracklike flaws, microcracks form, coalesce, or grow to macrocracks that propagate until the fracture toughness of the material is exceeded and final fracture occurs. Under usual loading conditions, fatigue cracks initiate near or at singularities that lie on or just below the surface, such as scratches, sharp changes in cross section, pits, inclusions, or embrittled grain boundaries (Ref 32).

The three major approaches of fatigue analysis and testing in current use are the stress-based (*S-N* curve) approach, the strain-based approach, and the fracture mechanics approach. Both the stress-based and strain-based approaches are based on cyclic loading of test coupons at a progressively larger number of cycles until the test piece fractures. In stress-based fatigue testing, steels and some other alloys may exhibit a fatigue endurance limit, which is the lower stress limit of the *S-N* curve for which fatigue fracture is not observed at testing above $\sim 10^7$ cycles (Fig. 34). The observation of a fatigue endurance limit does not occur for all alloys (e.g., aluminum alloy 7075 in Fig. 34), and the endurance limit can be reduced or eliminated by a number of environmental and material factors that introduce sites for initiation of fatigue cracks. For example, Fig. 35 shows the effect of different surface conditions on the fatigue endurance limit of steels, which in this case is approximately one-half of the tensile strength. Under these conditions, when the designs of components subjected to cyclic loading are expected to perform under $\sim 10^7$ cycles, design equations such as Eq 2 and 13 would be applicable where the fatigue limit, σ_e , of the material represents the failure stress, σ_f . For alloys without a fatigue endurance limit (such as aluminum alloy 7075 in Fig. 34), design stresses must be specified in terms of the specific number of cycles expected in the lifetime of the part.

Fig. 34 Fatigue curves for ferrous and nonferrous alloys

Fig. 35 Correlation between fatigue endurance limit and tensile strength for specimens tested under various environments

Strain-based fatigue is similar to stress-based fatigue, except that cycles to failure are measured and plotted versus strain instead of applied stress. This type of testing and analysis is extremely useful in determining conditions for initiation fatigue. Strain-based fatigue is used in many design cases when a major portion of total life is exhausted in the crack initiation phase of fatigue. Fundamental design methods for this type of fatigue analysis are described in more detail in Ref 29. Design aspects for variable amplitude and multiaxial conditions are also described in Ref 30 and 31. Testing methods for stress-based and strain-based fatigue are described in more detail in the article “Fatigue, Creep Fatigue, and Thermomechanical Fatigue Life Testing” in this Volume. Although design and analysis methods based on fatigue crack initiation are important, most parts have material flaws or geometric features that serve as sites for crack initiation. Therefore, fatigue crack growth is an integral part of fatigue life prediction analysis. This method is based on the concepts of fracture mechanics, where

fatigue crack growth rates are measured under conditions of a cyclic stress intensity (ΔK) at subcritical levels ($K < K_c$). Fatigue failures start at points of stress concentration and can be considered as flaws in the material. As these flaws grow during the fatigue process, they can reach the critical size and lead to catastrophic failure by rapid fracture. For this purpose, fatigue crack growth testing and analysis are used to determine the number of cycles to reach the critical flaw size for a given material (with a fracture toughness, K_c). These tests are described in more detail in the article “Fatigue Crack Growth Testing” in this Volume.

Overview of Mechanical Properties and Testing for Design

Howard A. Kuhn, Concurrent Technologies Corporation

Creep

Many design applications involve materials and components that are subjected for extended periods of time to high-temperature environments. For example, the tie bar shown in Fig. 1 could be part of a hanger supporting steel parts in a furnace for heat treatment. Other examples include turbine blades in jet engines and pressure vessels in high-temperature refinery operations. In these cases, failure of the material occurs by complex diffusion-controlled phenomena leading to cavitation, creep elongation, and eventual rupture of the material. Testing of materials in its simplest forms involves subjecting a tensile specimen to constant load or constant stress within a high-temperature environment and measuring the elongation with time. A typical curve of creep elongation versus time is shown in Fig. 36. After initial rapid growth in creep strain, the rate of creep strain reaches a steady state, followed again by rapid growth to rupture. Increasing stress on temperature increases the rate of creep strain and decreases the time to creep rupture. Figure 37(a) shows the influence of temperature and stress on the time to rupture. Figure 37(b) shows the temperature dependence of yield strength, tensile strength, and stress for creep rupture at 1,000 h and 100,000 h. Typically, the stresses for creep rupture are less than the yield strength of the material, even for relatively short rupture times.

Fig. 36 Typical result for creep strain as a function of time

(a)

Fig. 37(a)

(b)

Fig. 37(b)

Typical data used for designs where materials are exposed to high temperatures for extended periods. (a) Creep stress versus time to rupture for Astroloy. (b) Temperature dependence of yield strength, tensile strength, and creep rupture strength at two different times for a nickel-based superalloy

In design applications to avoid creep rupture, the stresses on the material can be calculated as in the case of static loads such as Eq 2, 12, and 13. The failure stress, σ_f , used in these equations, however, would be the rupture strength of the material determined from curves such as Fig. 37(a) at the operating temperature of the components in the design application. Depending on the expected life of the part, then, the operating temperature will determine the maximum stress that can be applied. Alternatively, for a given operating stress and expected lifetime, the maximum operating temperature can be determined from data such as Fig. 37(a) (Ref 32).

In design applications where creep occurs, elongation of the material often becomes the limiting failure parameter rather than creep rupture strength. A major example is the elongation of turbine blades during turbine engine operation. If the blades elongate too much, they contact the internal parts of the engine leading to catastrophic failure. In this case, elongation would be described by the creep strain profile in Fig. 36, for example, rather than the elastic deflection calculated in Eq 4. Thus, for a given operating temperature and load, the lifetime for successful operation of a component would be obtained from data such as that provided in Fig. 36 for the specified limit on elongation.

Because of the importance of creep failure in many applications, refined test procedures have been developed for accurate measurement of creep behavior under complex thermal and stress histories, as well as various corrosive environments as described in the Section "Creep and Stress-Relaxation Testing" in this Volume.

Environmental Effects on Mechanical Properties

The mechanical properties of metals can be adversely affected when the metal is exposed to a corrosive environment while being simultaneously stressed. Even in only mildly corrosive environments, the consequences can be unexpected and serious. These mechanisms that cause adverse affects are collectively known as environmentally assisted cracking and include some of the more common mechanisms by which metals actually fail in service. The most important of the phenomena are *stress corrosion*, *hydrogen embrittlement*, and *corrosion fatigue*.

Stress-corrosion cracking (SCC) of metals occurs in certain environments when cracks initiate and propagate under conditions where neither the stress nor the environment acting alone would have caused cracking. The propagation of SCC may eventually lead to structural failure or at least to ineffective performance of a component (due to problems such as leaks and distortion). Stress-corrosion cracks initiate only at a surface—and only at a surface that is exposed to the damaging environment. Once initiated, they propagate laterally into the section thickness, by either transgranular cracking (across grains, Fig. 38) or intergranular cracking (along grain boundaries, Fig. 39). Most of the surface of a stress-cracked metal is essentially unattacked. Stress cracking may occur at relatively low stress levels compared with stress needed for failure (tensile strength) and at relatively low concentrations of chemicals (such as Cl⁻ for austenitic stainless steels).

Fig. 38 Transgranular stress-corrosion cracking (SCC) in annealed 310 stainless steel after prolonged exposure in a chloride-containing environment. Electrolytic: 10% chromic acid etch. 150×

Fig. 39 Branched intergranular SCC in a lightly drawn tube of 12200 copper after exposure to an amine boiler-treatment compound. Potassium dichromate etch. (a) 100 \times . (b) 500 \times

Although the mechanism of stress corrosion is not completely understood, SCC appears to develop only when the stress (applied or residual) is tensile in nature and when its magnitude exceeds a threshold value (Fig. 40), a value that is near the yield strength of the metal. The rate of crack propagation thereafter increases rapidly with increasing stress. Once initiated, stress-corrosion cracks extend laterally and grow into the underlying section in a plane that is normal to the principal tensile stress. They tend to branch extensively in the process (Fig. 38 and 39), but there are occasional exceptions to this. Only a limited number of separate cracks are likely to initiate and then tend to be confined to a limited area of a component. This is in contrast to the more widespread and random nature of intercrystalline corrosion.

(a)

(b)

Fig. 40 Stress corrosion cracking threshold examples. (a) Stainless steels in boiling 42% magnesium chloride solution. (b) Comparison of K_{ISCC} of AISI 4340 steel (tensile yield strength, 1515 MPa, or 220 ksi) in methanol and salt water at room temperature

The environments that induce SCC are specific to particular metals, and only a limited range of environments can cause cracking in any one metal. Some examples of cracking environments are listed in Table 7, most of them being at worst only mildly corrosive in a general sense. The presence of oxygen is important in most of them. Many of these environments are also likely to be encountered in everyday usage, and some are virtually impossible to avoid. Moisture containing chlorides that will cause cracking of aluminum alloys is a case in point, because moisture and traces of chlorides are ubiquitous. Traces of ammonia that can cause cracking of brasses are also frequently present in the atmosphere due to the decomposition of organic matter and the presence of animal waste products (Ref 33).

Table 7 Alloy/environment systems exhibiting stress-corrosion cracking

Alloy	Environment
Carbon steel	Hot nitrate, hydroxide, anhydrous ammonia, and carbonate/bicarbonate solutions
High-strength steels	Aqueous electrolytes, particularly when containing H_2S
Austenitic stainless	Hot, concentrated chloride solutions; caustics, saline solution, and chloride-

steels	contaminated steam
High-nickel alloys	High-purity steam, hot caustics
Aluminum alloys	Aqueous Cl⁻, Br⁻, and I⁻ solutions, including contaminated water vapor
Titanium alloys	Aqueous Cl⁻, Br⁻, and I⁻ solutions; methanol organic liquids; N₂O₄; hydrochloric acid
Magnesium alloys	Aqueous Cl⁻ solutions
Zirconium alloys	Aqueous Cl⁻ solutions; organic liquids; I₂ at 350 °C (660 °F)
Copper alloys	Ammonia and amines for high-zinc brasses; ammoniacal solutions for α brass; range of solutions for other specific alloys
Gold alloys^(a)	Chlorides, particularly ferric chloride; ammonium hydroxide; nitric acid

(a) Alloys containing less than 67% gold

Prevention of SCC. Stress cracking may be reduced or prevented by the following practices:

- Decreasing the stress level by annealing, design, and so forth
- Avoiding the environment that leads to stress cracking
- Changing the metal if the environment cannot be changed
- Adding inhibitors or applying cathodic protection to reduce the rate of corrosion

In principal, the easiest way to prevent SCC is to specify the load and geometry for a given measured or assumed initial flaw size such that $K < K_{ISCC}$ (where K_{ISCC} is the critical stress intensity for stress-corrosion cracking). For some alloys, however, the value of K_{ISCC} may be so low that impossible initial flaw sizes or impractically low stresses must be specified. Alternatively, attention may be focused on the use of coatings, alternate materials, or other means of corrosion protection. It is also important to understand the nature of crack growth and avoid the conditions leading to fast fracture; that is, the stress intensity factor due to flaws developed by corrosion must be kept below K_c , the fracture toughness of the material, by limiting the stress or time of exposure so that cracks do not grow to the critical size.

Measuring and testing of SCC behavior is a complex subject, but one approach is to subject a material specimen containing a prescribed defect to stress in the chemical environment (Fig. 41) (Ref 19). The increase in K (usually resulting from increase in crack length a) is then measured as a function of time. As a increases, the applied stress, σ , may change, and the factor Y in Eq 37 may also change. Their combined effects contribute to the increase in K . Figure 42 shows a typical result (Ref 19). For each initial stress intensity value, K_i , the stress intensity increases until it reaches K_I , and fast fracture occurs. Below a certain value of K_i , crack growth does not occur; this level of K_i is denoted K_{ISCC} , or the critical stress intensity for stress corrosion cracking in the environment under which the test was conducted. For example, in saltwater, K_{ISCC} for heat treated 2000 and 7000 series aluminum alloys are approximately 80% of their K_I values. For heat treated 4340 and 300M steels, K_{ISCC} is about one-third of the K_I values, and for titanium alloys, K_{ISCC} varies widely from 25 to 40% of their K_I values (Ref 19).

Fig. 41 Modified compact tension specimen for environmentally assisted cracking measurement.

Fig. 42 Stress intensity growth with time in a corrosive environment

Hydrogen Embrittlement and Cracking. Hydrogen embrittlement is another form of environmentally assisted crack growth. Only a comparatively few metals are susceptible to this phenomenon, but prominent among them are the high-strength steels, that is, steels having tensile strengths above about 1000 MPa (145 ksi). In some aspects, hydrogen embrittlement is similar to stress-corrosion cracking. Hydrogen-induced cracking (HIC) has been proposed as the SCC mechanism for carbon and high-strength ferritic steels, nickel-base alloys, titanium alloys, and aluminum alloys (Ref 34).

Cracking resistance of steels is a major concern in refining and petrochemical industries where aqueous H₂S is present. The generally accepted theory of the mechanism for hydrogen damage in wet H₂S environments is that monatomic hydrogen is charged into steel as a result of sulfide corrosion reactions that take place on the material surface. The primary source of atomic hydrogen available at internal surfaces of pipeline and vessel steels is generally the oxygen-accelerated dissociation of the H₂S gas molecule in the presence of water. The basic reaction is:

The FeS formed on the surface of the steel is readily permeated by atomic hydrogen, which diffuses further into the steel.

This diffusion of atomic hydrogen into steel is associated with three distinct forms of cracking:

- Hydrogen-induced cracking
- Stress-oriented hydrogen-induced cracking
- Hydrogen stress cracking (also known as sulfide stress cracking and sulfide stress-corrosion cracking)

Hydrogen-induced cracking (HIC) and stress oriented hydrogen-induced cracking (SOHIC) are both caused by the formation of hydrogen gas (H₂) blisters in steel. Hydrogen-induced cracking, also called stepwise cracking or blister cracking, is primarily found in lower-strength steels, typically with tensile strengths less than about 550 MPa (80 ksi). It is primarily found in line pipe steels.

In contrast, hydrogen stress cracking does not involve blister formation, but it does involve cracking from the simultaneous presence of high stress and hydrogen embrittlement of the steel. Hydrogen stress cracking occurs in higher-strength steels or at localized hard spots associated with welds or steel treatment. As a general rule of thumb, hydrogen stress cracking can be expected to occur in process streams containing in excess of 50 ppm H₂S (although cracking has been found to occur at lower concentrations).

The basic factors of these cracking modes include temperature, pH, pressure, chemical species and their concentration, steel composition and condition, and welding or the condition of the weld heat-affect zone. These types of cracking and important variables for failure control are described in more detail in Ref 35 and 36.

Corrosion Fatigue. As previously noted and shown in Fig. 35, fatigue is affected seriously in the presence of a corrosive environment. Another consequence is that even those alloys that have definite fatigue endurance limits no longer do so. The presence of a particular environment is not required for the deterioration in properties, as it is for SCC. The sole requirement is that the environment be sufficiently corrosive, although there is not necessarily a direct correlation between general corrosiveness and effect on corrosion fatigue.

For steels, the corrosion endurance limit ranges from about 50 to 10% of the limit in air. The corrosion endurance limit also is independent of metallurgical structure and thus shows little correlation with strength. Therefore, the endurance limit of steels, even under mildly corrosive conditions, is much less than that in air and does not increase with an increase in the tensile strength of the steel (Ref 33). The combination of corrosion with a cycling stress eliminates the benefits of all efforts made to improve the strength of steels as assessed by static mechanical tests.

Shock Loading

Another nonstatic loading condition often found in machine parts involves shock, or impact forces. This condition occurs if the time duration of the load is less than the natural period of vibration of the part or structure. Failure of a part under shock loading, as with other types of loading, depends on material parameters and geometric factors.

To illustrate this condition, consider the tie bar (Fig. 1) under *impact* tensile loading. If the bar is used to stop the motion of another part, then the kinetic energy of the moving part is absorbed by elongation of the tie bar and converted into elastic strain energy in the bar. Then, the maximum stress in the bar will be:

$$\sigma = V\sqrt{Em/AL} \quad (\text{Eq 37})$$

where V is the velocity of the mass, m , when it impacts the bar; A and L are the cross-sectional area and length of the bar, respectively; and E is the elastic modulus of the bar material.

To prevent failure under a shock load, the stress in Eq 37 must be less than the strength of the material, σ_f . Then, the parameters in Eq 37 can be regrouped into:

$$V\sqrt{m} < (\sigma_f / \sqrt{E})(\sqrt{AL}) \quad (\text{Eq 38})$$

which shows that the combination of impact velocity and mass that can be tolerated depends not only on the material strength but also on its elastic modulus. In other words, selecting a material that maximizes the parameter σ_f^2/E will maximize the impact energy that can be absorbed. Equation 38 also shows that increasing the volume of material in the bar, AL , increases its shock resistance. For example, increasing the length of the bar does not affect its ability to carry static axial load but does increase its ability to resist an impact load.

The description of shock resistance of a tie bar can be extended to other forms of loading, such as bending. For example, for a beam subjected to a lateral impact load (Fig. 6), the kinetic energy of a mass that is stopped by the beam is converted into strain energy in the beam. Then, the maximum stress that is in the beam is given by:

$$\sigma = V\sqrt{3mE/LI_H} \quad (\text{Eq 39})$$

where V is the velocity of mass m when it impacts the beam; L and H are the beam length and height, respectively; I is the moment of inertia of the beam cross section; and E is the elastic modulus of the beam material. Again, σ must be less than the strength of the material, σ_f , and Eq 39 can be rearranged to:

$$V\sqrt{m} < (\sigma_f/\sqrt{E})(\sqrt{LI/3H^2}) \quad (\text{Eq 40})$$

As with the bar under axial impact loading, the material parameter that maximizes shock resistance is σ_f^2/E , but the geometry parameter is now LI/H^2 . In the case of rectangular beam, from Eq 18, $I = bH^3/12$. Then, the geometry parameter becomes $LbH/12$. Since bH is the cross-sectional area of the beam, the geometry parameter becomes $AL/12$, so the impact resistance of the beam is increased by increasing the beam volume, similar to the case of the bar under tensile impact. A longer beam, for example, will not carry as much static load as a shorter beam, but the longer beam will be more resistant to failure by impact loading.

More complicated geometries can be analyzed through finite element models, which give the distribution of stresses due to impact loads throughout the part. In these cases the same general effects of the material parameter (σ_f^2/E) and geometry parameter (volume) on shock resistance apply.

Mechanical Testing for Metalworking Processes

Serope Kalpakjian, Illinois Institute of Technology

Introduction

AN IMPORTANT ACTIVITY in metalworking facilities is the testing of incoming raw materials for characteristics that ensure the integrity and quality of the products made. Several traditional as well as specialized tests are now available to assess the quality of materials, in bulk or sheet form, in order to predict their behavior in metalworking operations.

Because of the generally complex nature of the processes involved, the identification and quantification of appropriate parameters to predict performance and failure during processing continue to be challenging tasks. The metalworking industry has, by and large, depended on cumulative and long practical experience rather than on the continuous reporting of research findings in the technical literature. A notable exception is the automotive industry, particularly in sheet metal forming.

While such practical experience has been indispensable to the successful production of quality products, major efforts and investigations continue to be made to arrive at a comprehensive understanding of the underlying principles of the behavior of metals in deformation processing. The necessity for such an approach is self-evident, even though it is clear that there are, as yet, no simple criteria fully responsive to all metals and alloys, operations, and processing conditions.

This article generally reviews the state of knowledge in this subject. A more detailed discussion of various aspects related to specific topics and processes are given in *ASM Handbook*, Volume 14, *Forming and Forging*, and the other references cited in this article.

Mechanical Testing for Metalworking Processes

Serope Kalpakjian, Illinois Institute of Technology

Workability and Formability

A simple definition of *workability* is “the maximum amount of deformation a metal can withstand in a particular process without failure” (Ref 1). The term is generally applied to bulk deformation processes, such as forging, rolling, extrusion, and drawing, in which the forces applied are predominantly compressive in nature. In contrast, *formability* is usually applied to sheet-metal forming processes, in which the forces applied are primarily tensile. These definitions can also include undesirable conditions such as poor surface finish, sheet wrinkling, or lack of die fill in forging.

Although some definitions include the relative ease with which a metal can be shaped, the general definition of workability does not include forces or energies involved in processing. The reason is that forces and energies are related primarily to the strength of the workpiece material, tribological factors (friction, lubrication, and wear), and the size and capacity of the metalworking equipment.

The maximum amount of deformation has a different meaning depending on the particular metalworking process. For example, in bending, it is the minimum bend radius; in deep drawing, it is the maximum ratio of blank-to-punch diameters. In power spinning of tubular or curvilinear shapes, maximum deformation is the reduction in thickness per pass.

It is generally recognized that there are two basic types of failure in metalworking processes:

- Local or total separation of the metal: Surface cracking in upsetting or open-die forging, internal cracking in extrusion or drawing, and necking and subsequent tearing of sheet metals during forming
- Buckling: Upsetting of slender workpieces and wrinkling in sheet-metal forming operations

As a general guide to workability, some suppliers of metals have prepared tables or charts showing the relative workability or formability ratings (using letters, numbers, or terms such as excellent, good, fair, and poor). While such ratings are based on cumulative and proven experience on the plant floor and can indeed be useful, their application is somewhat limited due to the fact that ratings generally do not apply to specific processes and conditions and are not quantitative.

The behavior of a metal in an actual forming operation may be predicted from mechanical test results. Test specimens are cut from the same blank and, as much as possible, subjected to the same conditions (such as state of stress, temperature, and strain rate) as in the particular metalworking operation. Few metalworking processes can be simulated by such simple testing, however. Consequently, much effort has been expended toward the design of new test methods to simulate actual processing conditions. The alternative is, of course, to perform the actual process itself at a smaller scale, in a laboratory environment.

Mechanical Testing for Metalworking Processes

Serope Kalpakjian, Illinois Institute of Technology

Mechanical Behavior of Metals Influencing Workability

This section presents a brief review of the common material parameters that can have a direct or indirect influence on workability and product quality. The parameters described in this section are most commonly obtained in tension tests (Ref 2, 3, 4). All discussions pertain to metals and their alloys.

Strength. The strength of a metal is defined in terms of quantities such as yield stress, ultimate tensile strength, and breaking stress. Although easily determined from normal stress-normal strain curves (including shear stress-shear strain curves) or obtained from published literature and handbooks, these quantities basically influence the stresses, forces, energies, and temperature rise during processing.

Although strength is not directly relevant to workability, it can indirectly indicate some measure of workability. For ductile metals, for example, observing the difference between the yield and tensile strengths can indirectly indicate a measure of workability. The closer the magnitude of these two stresses, the more work hardened the metal is, and, hence, the lower its ductility, that is, the narrower the stress-strain curve. The dependence of strength on orientation in a bulk workpiece or sheet metal can, of course, also influence material behavior (as discussed in subsequent sections). A common example is the formation of ears in deep-drawn cups due to the planar anisotropy of the sheet.

Ductility. Two traditional and common measures of ductility have been the tensile elongation and the tensile reduction of area, quantities that are readily available in handbooks and from material suppliers. However, these quantities depend on gage length and cross-sectional area of the specimen. Total elongation and tensile reduction of area both increase with increasing cross-sectional area of the specimen. Also, because necking is a local phenomenon, total percent elongation depends on gage length; as expected, percent elongation decreases with increasing gage length.

Relationships between specimen length and cross section have been established and standardized in different countries. In the United States and according to ASTM standards, for example, the gage length-to-diameter ratio is 4.0 for round and 4.5 for sheet specimens.

Hardness can be defined as resistance to permanent indentation. The influence of hardness may be summarized as follows:

- It can be related to the strength of the metal and, thus, indirectly, to its ductility (i.e., the higher the hardness, the stronger the metal is and, generally, the lower its ductility is).
- The type of indentation profile is a measure of strain hardening, (i.e., the sharper the profile and its raised ridge around the indentation, the more strain hardened the metal is). Hardness is, thus, an indirect measure of the capacity of the metal for plastic deformation in metalworking.
- It affects the frictional and wear characteristics in forming operations.

The strain-hardening exponent, also called the work-hardening exponent, is a measure of how rapidly the metal becomes stronger and harder as it is strained (worked). This exponent is typically obtained from the true stress-true strain curve of the metal (often derived from engineering stress-engineering strain curves) and is expressed as a power law:

$$\sigma = K\varepsilon^n \quad (\text{Eq 1})$$

where σ is the true stress, K is the strength coefficient, ε is the true strain, and n is the strain-hardening exponent.

At room temperature, for magnitude of K typically ranges from about 200 MPa for soft aluminum to about 2000 MPa for superalloys; it decreases as the temperature increases. Depending on the metal and its condition, the values of n typically range from 0.05 to 0.5 (Table 1).

Table 1 Typical values for strength coefficient, K , and strain-hardening exponent, n , (Eq 1) at room temperature

Material	K		n
	MPa	ksi	
Aluminum 1100-O	180	26	0.20
2024-T4	690	100	0.16
5052-O	210	30	0.13

410 stainless, annealed	960	139	0.10

Source: Ref 3

It can be shown that the exponent n also gives a direct indication of the uniform elongation of the metal; that is, the extent to which the metal can be stretched before it begins to neck (plastic instability). The relationship is given by the following:

$$\epsilon_{\text{necking}} = n \quad (\text{Eq 2})$$

for simple tension. For example, in sheet-metal stretching, if the sheet is 1 m long and $n = 0.2$, the sheet, thus, can be stretched uniaxially to a true strain of 0.2 (to 1.22 m) before it begins to neck.

The magnitude of the strain-hardening exponent also has an effect on the maximum reduction per pass in rod and wire drawing. The higher the value of n is, the higher the strength of the metal exiting the die and, hence, the smaller is the final cross-sectional area to which the metal can be reduced by drawing.

Strain-Rate Effects. The strength exhibited by a metal also depends on the rate at which it is being deformed. For simple tension, this relationship is given by the following:

$$\sigma = C\dot{\epsilon}^m \quad (\text{Eq 3})$$

where C is the strength coefficient, $\dot{\epsilon}$ is the true strain rate, and m is the strain-rate sensitivity exponent. The magnitude of C at room temperature typically ranges from as low as approximately 10 MPa for aluminum to about 1000 MPa for titanium (Table 2); it decreases with increasing temperature.

Table 2 Approximate range of values for the strength coefficient, C , and strain-rate sensitivity exponent, m (Eq 3)

Material	Temperature, °C	C		m
		MPa	ksi	
Aluminum	200–500	82–14	12–2	0.07–0.23
Aluminum alloys	200–500	310–35	45–5	0–0.20
Copper	300–900	240–20	35–3	0.06–0.17
Copper alloys (brasses)	200–800	415–14	60–2	0.02–0.3
Lead	100–300	11–2	1.6–0.3	0.1–0.2
Magnesium	200–400	140–14	20–2	0.07–0.43
Steel	900–1200	165–48	24–7	0.08–0.22
Low-carbon				
Medium-carbon	900–1200	160–48	23–7	0.07–0.24
Stainless	600–1200	415–35	60–5	0.02–0.4
Titanium	200–1000	930–14	135–2	0.04–0.3
Titanium alloys	200–1000	900–35	130–5	0.02–0.3
Ti-6Al-4V ^(a)	815–930	65–11	9.5–1.6	0.05–0.80
Zirconium	200–1000	830–27	120–4	0.04–0.4

As temperature increases, C decreases and m increases. As strain increases, C increases, and m may increase or decrease. Also, m may become negative within certain ranges of temperature and strain.

(a) At a strain rate of $2 \times 10^{-4} \text{ s}^{-1}$.

Source: Ref 3

The magnitude of the exponent m depends not only on the particular material but depends also with great sensitivity on temperature. The higher the temperature, the higher the magnitude of the exponent m is. At room temperature, m can approach zero, and at elevated temperatures, it can approach unity. Consequently, strain-rate and temperature effects in metals are generally studied and reported simultaneously.

Strain-rate sensitivity is an important parameter in the elongation and ductility of metals. As m increases, total elongation increases and the post-uniform elongation (elongation after the onset of necking) also increases (Fig. 1 and 2). This behavior is typically exhibited by certain very fine grained alloys (10 to 15 μm) where total

elongations up to 2000% at strain rates on the order of 10^{-4} to 10^{-2} s^{-1} are obtained at certain temperature ranges. This phenomenon is known as superplasticity.

Fig. 1 The effect of the strain-rate sensitivity exponent, m , on the total elongation for various metals and alloys. Source: Ref 3

Fig. 2 The effect of strain-rate sensitivity exponent, m , on the post-uniform elongation for various metals and alloys. Source: Ref 3

Typical superplastic metals are zinc-aluminum, titanium, some aluminum alloys, nickel alloys, and iron-base superalloys. Superplastic forming has become important in fabricating sheet metal structures and various other components, particularly for aerospace applications.

Temperature effects generally are to decrease strength and increase workability. However, due to factors such as weakening of the grain boundaries (hot shortness), increased temperature can adversely influence workability and product quality.

Other related effects of temperature include (a) the blue brittleness range in steels, (b) surface oxidation, and (c) lubricant behavior, which, because it affects the tribological behavior at die-workpiece interfaces, can influence metal flow in dies (die filling, laps, defect formation).

State of stress in plastic deformation can have a major influence on workability. For example, even a very ductile metal can behave in a brittle manner when subjected to high levels of triaxial (hydrostatic) tensile stresses. Center-burst (chevron) cracking of solid rods in drawing and extrusion, plane-strain drawing of sheet or plate, and tube drawing or spinning are due to the high hydrostatic tensile stress component at the centerline of the workpiece during plastic deformation.

Another example of the importance of the state of stress is the favorable influence that normal compressive stress has on the maximum shear strain before fracture. Note (Fig. 3) that for torsion testing on steels, the shear strain to fracture rapidly increases as the compressive stress (normal to the cross section of the specimen) increases.

Fig. 3 The effect of axial compressive stress on the shear strain at fracture in torsion for various steels. Source: Ref 3

Effects of Hydrostatic Pressure. A highly beneficial state of stress is the environmental hydrostatic pressure; it has a major influence on the ductility of metals in metalworking operations. An otherwise brittle material can become ductile when plastically deformed under a state of high hydrostatic pressure, as has been observed in tension tests performed in highly pressurized chambers (Fig. 4).

Fig. 4 The effect of hydrostatic pressure on the tensile ductility for various metals. Source: Ref 3

While with most metals ductility increases gradually with hydrostatic pressure, in others, such as zinc and its alloys (hcp structure) very ductile behavior occurs abruptly with a rapid transition from brittle behavior over a narrow pressure range. Hydrostatic extrusion is the most common example of the beneficial use of hydrostatic pressure.

Mechanical Testing for Metalworking Processes

Serope Kalpakjian, Illinois Institute of Technology

Mechanical Testing Methods and Sample Preparation

The material behavior characteristics already outlined in this article are typically determined by mechanical testing methods that are described in detail in other Sections of this Volume. Those aspects of testing that are particularly relevant to workability and quality control for metalworking processes are described later in this article (Ref 1, 2, 4, 5, 6).

Tension Test. Partly because of its relative simplicity, the tension test has been and continues to be the most common mechanical testing method. From the test results, true stress-true strain curves are constructed, with a correction made for necking of the specimen (Bridgman correction factor due to triaxial tensile state of stress in the necked region) (Ref 2, 3, 4). From these curves most of the material behavior characteristics can be determined easily.

The shape of the specimens may be round, sheet, or plate, and they are prepared and tested according to various international and national standards specifications (such as ASTM, ISO, JIS, and DIN). As described earlier, reporting of test results must specify specimen shape and dimensions, as well as parameters such as strain rate and temperature.

Plane-Strain Tension Test. A modification of the simple uniaxial tension test is the plane-strain tension test, in which the specimen has two deep grooves across its width (Fig. 5). This geometry restricts the deformation to length and thickness of the specimen, but not to its width (hence the term plane strain).

Fig. 5 Schematic of a plane-strain tension test specimen. Source: Ref 1

Compared to the simple tension test, in the plane-strain tension test the same metal exhibits a lower fracture strain. The plane-strain tension test attempts to simulate metalworking processes in which the workpiece (in whole or in part) is subjected to plane-strain conditions, typically in sheet metal forming operations. (See the section “Plane-Strain Compression Test” that follows.)

Compression Test. Unlike tension tests, the compression (upsetting) test has significant difficulties because of the friction at the platen-specimen interfaces, the surface characteristics of the contacting bodies, and the nature of lubrication. When conducted with care, reliable true stress-true strain curves can be obtained. It has been shown that for ductile metals, the true stress-true strain curves in tension and compression are the same (Ref 3). Barreling is an inevitable phenomenon in compression tests, although it can be minimized by effective lubrication and use of ultrasonic vibration of the platens. For specimens with high length-to-diameter ratio, there is a tendency for double barreling, near each end of the specimen.

The extent of deformation of the workpiece in compression tests (using either round or square specimens) indicates some measure of ductility in bulk deformation processes, particularly in forging and for metals with limited ductility. A crack usually develops on the cylindrical surface of the specimen, due to what are known as secondary tensile stresses. Depending on the state of stress and lubrication conditions, the direction of the crack may be at 45° to the long axis of the specimen, but it can be longitudinal as well, particularly if seams (a defect developed during prior processing) are present on the cylindrical surfaces of the specimen.

Compression tests at elevated temperature can be difficult to perform because of the heat loss to the dies. However, compression testing is commonly used as a simple measure of workability of metal, particularly in forging and similar bulk deformation processes.

Although test specimens for compression are typically prepared with relatively smooth surfaces, longitudinal notches are sometimes machined on the cylindrical or square surfaces (notched bar upsetting test). The purpose

of these notches is to cause regions of stress concentrations and, thus, to better simulate actual processing conditions, particularly for metals with limited forgeability.

Plane-Strain Compression Test. The purpose of this test is basically to determine the yield stress of the material under plane-strain conditions. The results are used to calculate the forces required in processes such as rolling of wide sheet and some regions of the workpiece in forging operations.

Partial-width indentation tests (Fig. 6) involve partial indentation of a simple wrought or as-cast rectangular slab. As a result, the overhangs (ribs) are subjected to secondary tensile stresses. The reduction in rib height (h_f) is a measure of the ductility of the metal. This test can be performed cold or hot.

Fig. 6 Schematic of the partial-width-indentation test. $L \approx h$; $b = h/2$; $w_a = 2L$; $l = 4L$. Source: Ref 1

Torsion tests are generally performed on tubular specimens with reduced midsections in order to localize and control strains. Unlike in tension testing the specimen does not undergo necking (there is no plastic instability), and unlike in compression testing, there is no friction.

From test results, shear stress-shear strain curves are constructed. However, these curves are applicable to a limited number of processes, such as shearing (cropping) and power spinning of conical workpieces. Torsion tests at elevated temperatures (hot-twist tests) have long been found to be somewhat more suitable (as a measure of forgeability) than upsetting tests, particularly for alloy steels.

Sample Size and Aspect Ratio. As stated earlier, it has long been established that sample size and aspect ratio (length-to-cross section) have significant effects on mechanical test results, particularly ductility. These effects can be summarized as follows. In tension tests, the total percent elongation increases with increasing cross-sectional area and decreases with increasing gage length. For compression tests, the higher the aspect ratio, the higher is the tendency for buckling of the specimen and for double barreling.

Sample Location. Sample location as well as sample size can be important in applications where there are significant variations or gradients in the chemistry and defects present. Variations are, hence, present also in the mechanical properties of the workpiece material.

Even in seemingly simple metalworking operations (such as open-die forging, direct extrusion, and bending of thick plates), deformation of the metal is usually complex. There can be severe localized plastic deformation, therefore, property gradients within the workpiece. One example is the presence of shear bands (Fig. 7), developed during high deformation-rate processes and with metals whose strength decreases rapidly within a narrow temperature range. This phenomenon is similar to the formation of segmented or serrated chips in metal cutting, particularly in machining titanium.

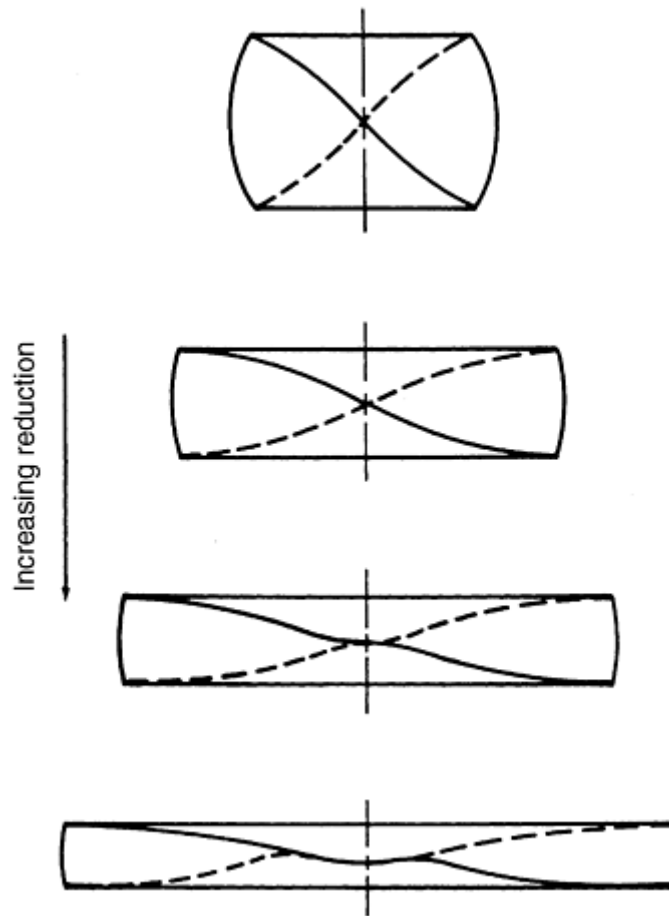

Fig. 7 Schematic of the mechanism of shear-band formation in upsetting. Source: Ref 1

Sample Orientation. Few metalworking processes involve simple, uniaxial deformation of the workpiece. Depending on the nature of the process, the metal is usually deformed in various directions. For example, in extrusion and rod drawing, the deformation is usually axisymmetric. Most forgings are typically multidirectional, and rolling of sheet is usually under plane-strain conditions, with the deformation principally in the direction of rolling. Because of the resulting anisotropy of the cold rolled metal, sample orientation can therefore be very significant, particularly in regard to subsequent processing such as bending or stamping.

In sheet metals, anisotropy is also important in springback behavior; this is because the amount of springback depends on the yield stress. All other variables being the same, the springback increases with increasing yield stress. (Note, for example, how helical or leaf springs are heat treated to increase their yield stress and, thus, attain full springback.) Control of springback is an important consideration in most sheet forming operations.

There are two basic types of anisotropy: preferred orientation and mechanical fibering. Preferred orientation (also called crystallographic anisotropy) arises from the alignment of grains in the general direction of material flow during deformation. (This type of anisotropy can be eliminated or minimized by annealing.) Mechanical fibering is due to the alignment of impurities, inclusions (stringers), and voids in the material during deformation processing. This phenomenon is typically observed in metals and alloys with poor quality.

An important beneficial effect of anisotropy is in deep drawing of sheet metals whereby the deep drawability increases with increasing normal anisotropy. On the other hand, planar anisotropy causes earing of the drawn cup (discussed in the section "Deep Drawing" in "Factors Influencing Formability in Sheet Metal Forming" in this article).

Quality Control

In addition to the various factors and parameters described so far, other considerations outlined in this section can have a direct and significant influence on workpiece quality.

Surface integrity includes both purely geometric features of a surface (such as roughness and lay) and its properties (such as the presence of cracks, discontinuities, and surface and subsurface defects). Because of the often large strains to which workpiece surfaces are subjected during processing, surface integrity can be of major importance.

For example, workpiece materials that are sensitive to surface scratches (notch sensitivity and lack of fracture toughness) can develop major flaws in the product, either in bulk or sheet form. Likewise, sheet blanks with poor edge conditions (roughness and severe strain and hardness gradients) have poor bendability due to premature cracking.

Structural Integrity. Depending on its processing history, a workpiece to be subjected to further metalworking operations may contain significant structural defects such as voids (microporosity), impurities, inclusions, inhomogeneities, internal cracks (chevron), and second-phase particles. These defects can have a major adverse effect on the ductility and workability of the metal (Fig. 8). Furthermore, the defects may or may not be distributed uniformly throughout the workpiece.

Fig. 8 The effect of volume fraction of second-phase particles on tensile ductility of steels. Source: Ref 1

Depending on the state of stress during deformation, these flaws can lead to major defects in the final product. For example, voids can form, coalesce, and open; external or internal cracks can propagate throughout the material. High shear bands can develop in certain regions, possibly leading to failure during the service life of the product.

In elevated temperature metalworking, minute amounts of impurities, small changes in composition, and phase changes throughout the workpiece (such as in bulk deformation of titanium alloys) can cause a major reduction in ductility. Embrittlement of grain boundaries (hot shortness) due to the presence of low-melting-point impurities can be a severe problem (liquid-metal or solid-metal embrittlement).

Residual Stresses. These internal stresses result typically from nonuniform deformation of the metal during metalworking and heat treatment and from thermal gradients. Residual stresses can have beneficial effects (improved fatigue life, if compressive on the surface) as well as adverse effects, such as stress cracking and distortion after subsequent processing (removing a layer of material, drilling a hole, or blanking). Stress relieving is commonly used to reduce the adverse effects.

Tribological Considerations. Equally important in product quality are tribological factors, namely friction, lubrication, and wear (Ref 3, 4, 6). Friction at tool, die, and workpiece interfaces can have a major effect on material flow (e.g., die filling in forging or the distribution of stresses in sheet forming), external and internal defect formation (e.g., poor surface finish, severe surface shear stresses, or excessive temperature rise during processing), and force and energy requirements in processing, because of the frictional energy involved.

Consequently, proper lubrication to control friction as well as to reduce tool and die wear are major concerns. These considerations are, in themselves, complex phenomena, and it is essential to select and apply appropriate lubricants, which are now largely water-based for environmental concerns.

Because the wear of tools and dies is inevitable, identification of the specific mechanisms of wear (adhesive, abrasive, corrosive, fatigue, and impact) is important. This helps determine the proper action to take in order to minimize or reduce the rate of wear, thereby improving the dimensional accuracy and surface finish of the products, as well as the overall economy of production.

Mechanical Testing for Metalworking Processes

Serope Kalpakjian, Illinois Institute of Technology

Factors Influencing Workability in Bulk Deformation Processes

Forging is a basic bulk deformation process typically involving a variety of processes such as open-die, impression-die, and closed-die forging (Ref 1, 3, 4, 6, 7, 8, 9, 10, 11). It is generally agreed that forgeability involves three basic parameters: flow stress, ductility, and the coefficient of friction, with temperature and speed being additional variables. Although no standard forgeability test has yet been devised, nearly all conventional mechanical tests have been utilized such as compression, tension, bend, torsion (twist), and impact tests.

Upsetting a solid cylindrical blank (pancaking) has been studied most extensively since it incorporates all the major factors involved. Typically, a solid cylindrical specimen is upset between flat dies (platens), and the cylindrical surfaces are inspected for the initiation of cracks. The original surface condition of the specimen is important in that the presence of defects (such as seams) can cause premature crack initiation.

In cold upsetting tests, linear relationships have been observed between the total surface strains at fracture, and the fracture loci have been established (Fig. 9). These plots consist of tensile strains versus compressive strains on the surface of the specimen (typically with a slope of -0.5), and they represent material limits to plastic deformation.

Fig. 9 Comparison of strain paths and fracture locus lines in cold upsetting. Source: Ref 1

A tapered, wedge-shaped test specimen has also been used (Fig. 10) whereby, as the upper flat die descends, the specimen undergoes varying degrees of deformation throughout its length. The onset of surface cracking can then be observed and related to the reduction in height at that particular location.

Fig. 10 Schematic illustration of a wedge-test specimen showing deformation after upsetting. Source: Ref 1

Forging of solid round blanks in the diametral direction in a manner similar to the disk test has also been investigated. In upsetting a round blank with flat dies, an internal lateral tensile stress develops at the center of the blank, leading to a vertical crack (Fig. 11). Although such a crack would normally be considered a defect, this phenomenon is the principle of the Mannesmann process for the production of seamless tubing and pipe.

Fig. 11 Effect of contact area between dies and workpiece in forging a solid round billet. Source: Ref 1

Note in Fig. 11 that as the contact area between the dies and the billet surface increases, the lateral tensile stress decreases and becomes compressive. Consequently, the tendency for internal crack formation is eliminated with increasing contact area.

Another test (hot twist) has been shown to be a good indicator of forgeability. A solid round bar with specific length (typically 10 to 50 mm) and diameter (typically 8 to 25 mm) is heated and twisted continuously until it fractures. Round tubular specimens can also be used for this test. In addition to temperature as a parameter, rotational (twisting) speeds are varied, particularly because of the greater sensitivity of the metal to higher strain rates at elevated temperatures. The torque and shear strains (which can then be converted to normal strains and effective strains) are monitored as an indication of the strength and ductility of the metal at various temperatures.

Rolling. One of the most important primary metalworking processes (performed either hot or cold), rolling involves several parameters. Control of these parameters is essential to avoiding defects such as alligating, edge cracking, and surface damage (Ref 1, 2, 3, 4, 6). In cold rolling, the quality and surface condition of the billet, slab, or plate to be rolled is as important as they are in all metalworking operations.

Deformation of the metal in the roll gap can be complex, because inhomogeneities usually exist throughout the thickness of the stock being rolled, depending primarily on the interrelationship between roll radius, R , and roll-strip contact length, L . These inhomogeneities also lead to residual stresses in cold rolled products. These stresses can be important because of the possibility of distortion and warping in subsequent processing of the rolled product (when it is cut into individual blanks), as well as the possibility of affecting springback and stress-corrosion cracking.

Alligating has been attributed to inhomogeneous deformation during rolling and the presence of defects such as piping in the original ingot. Barreling (or double barreling) in rolling can cause edge cracking. This tendency can be minimized by using edge-restraint rolling (Ref 4) and controlling the quality of the original edges of the sheet or plate. Surface damage in rolling can be controlled primarily by effective lubrication.

Extrusion. Although the extrusion process has been studied extensively, there is as yet no criterion or coined term (like *forgeability* or *machinability*) for establishing the capability of a material to be extruded (Ref 2, 3, 4, 6, 8, 11, 12).

Internal defects in extrusion, known variously as chevron or centerburst cracking, have been studied extensively. It has been established that these internal cracks are due to a high hydrostatic tensile stress component at the centerline in the deformation zone during extrusion.

These stresses can be reduced or eliminated by (a) increasing the extrusion ratio (i.e., the ratio of billet-to-extrusion cross-sectional areas), (b) decreasing the die angle, and (c) ensuring that the billet does not contain significant amounts of inclusions, voids, or impurities, which otherwise act as stress raisers, particularly if they are concentrated along the center-line of the billet.

Although not commercially practiced to a significant extent, hydrostatic extrusion can be employed to enhance the ductility of the metal. Further increase in ductility can be obtained by extruding the material into a second chamber of pressurized fluid (fluid-to-fluid extrusion).

Rod and wire drawing is a process in which the force and energy required for deformation is applied through the product (rod or wire) itself. Drawability is usually defined in terms of the maximum reduction in cross-sectional area per pass. The analysis is based on the condition that it is the tensile stress that causes failure (breakage of rod or wire), and that this stress must be below the flow stress of the metal at the die exit. Thus, strain hardening, die angle, and friction are important parameters (Ref 2, 3, 4, 6, 11, 12).

In the analysis of maximum reduction per pass, there are the underlying assumptions that the metal is sufficiently ductile to undergo the strains involved in this process without fracture, and that the magnitude of the tensile stress in the exiting material causes failure. For round bars or wire, the maximum reduction per pass is shown theoretically to be 63% in the absence of friction, redundant work, and strain hardening. As expected, friction and redundant work decrease this reduction. For plane-strain drawing of sheet and plate under the same conditions, the maximum reduction per pass is 57%.

The effect of strain hardening of the material is to increase the maximum reduction per pass from the theoretical limits. This is because of the higher strength of the exiting rod or wire as compared to the average strength that the material exhibits in the die gap. In practice, however, reductions per pass are much lower than these theoretical limits, typically being on the order of 10 to 45% to ensure successful drawing.

The possibility of chevron or centerburst cracking also exists in rod and wire drawing. The relevant parameters are the same as in extrusion, namely reduction per pass, die angle, and the quality of the material entering the die, particularly along its centerline where the hydrostatic tensile stress component is highest. As in forgeability, hot-twist tests have been shown to give some qualitative measure of the workability of metals in drawing.

In addition to internal defects, external defects such as circumferential surface cracks (fir-tree cracking and bamboo defects), crow's feet cracking (approximately at 45°), and splitting of the product in the longitudinal direction may also develop in drawing. In addition to the inherent ductility of the metal, other important parameters are the states of stress and strain and frictional behavior.

Spinning. Power spinning studies have been conducted to predict spinnability (maximum reduction in thickness per pass before failure) from the mechanical properties of the material. It has been shown, both experimentally and analytically, that the maximum reduction per pass can be predicted from the tensile reduction of area of the material, both for conical and tube spinning (Ref 3).

From the experimental data shown (Fig. 12), a maximum spinning reduction per pass of about 80% is possible when the metal possesses a tensile reduction of area of about 50%. Beyond this tensile reduction, there is no further increase in spinnability. Increased ductility beyond 50% thus, has no additional benefit. For metals with a reduction in area of less than this critical value, spinnability depends on the ductility. It is interesting to note that in bending of sheet metal, maximum bendability is achieved again at a tensile reduction of area of about 50%.

Fig. 12 Experimental data showing the relationship between maximum spinning reduction per pass and the tensile reduction of area of the material. Source: Ref 3

Factors Influencing Formability in Sheet-Metal Forming

Sheet-metal forming operations consist of a large family of processes, ranging from simple bending to stamping and deep drawing of complex shapes (Ref 2, 3, 4, 5, 6, 8, 11, 12). Formability of a sheet metal depends greatly on the nature of the forming operation. In simple stretching operations, for example, the forming limit is determined by the uniform elongation of the metal as it is related to the strain-hardening exponent, n .

Because most sheet forming operations usually involve stretching and some shallow drawing (see the “Deep Drawing” section in this article), the product of the strain hardening exponent, n , and the normal anisotropy, R , of the sheet has been shown to be a significant parameter. Normal anisotropy is the ratio of width to thickness strains in a simple tension test (also called strain ratio or plastic anisotropy).

The factors influencing formability for major classes of sheet forming are reviewed in the following sections.

Bending. Bending is a common metalworking operation in which bendability is defined as the minimum bend radius, R (measured to the inner surface of the bent part), to which a sheet metal can be bent without cracking of its outer surface. It is usually given as the minimum R/T ratio, where T is the sheet thickness.

The most consistent indication of bendability has been shown to be the tensile reduction of the area of the sheet metal, as obtained from a tension test specimen and cut in the direction of bending. Because of planar anisotropy of cold rolled sheets (with higher ductility in the rolling direction than in the transverse direction), it is important to prepare the specimens accordingly.

A theoretical relationship for bendability has been obtained:

$$\text{Minimum } R/T = (50/RA) - 1 \tag{Eq 4}$$

where RA is the tensile reduction of area of the sheet. This equation has been derived by equating the true strain at which the outer fiber in bending begins to crack to the true fracture strain of the sheet specimen in simple tension.

Experimental results are in reasonably good agreement with this expression, with a curve-fitting modification made by increasing the numerator in the equation from 50 to 60 (Fig. 13). Thus, a sheet with a tensile reduction of area of 60% can be bent completely over itself (hemming) without cracking, much like folding a piece of paper. Note that in the preceding section, “Spinning,” it was indicated that maximum spinnability is also obtained at a tensile reduction of area of about 50%.

Fig. 13 Experimental data showing the relationship between bend radius-to-sheet thickness ratio and the tensile reduction of area for various sheet metals. Source: Ref 3

It has also been shown that as the sheet width-to-thickness ratio increases (thus changing the deformation condition from one of plane stress to plane strain), bendability decreases (Fig. 14). Edge condition of the sheet

is also significant; the rougher the edge, the greater is the tendency for edge cracking. Bendability, thus, decreases.

Fig. 14 The effect of length of bend (strip width) and sheared-edge condition on bend radius-to-sheet thickness ratio for 7075 aluminum. Source: Ref 3

The effects of notch sensitivity, surface finish of the sheet metal and its lay, and rate of deformation are factors that should be taken into consideration. Note that bending is one of the metalworking processes in which formability depends not only on the property of the metal but also on the state of stress (geometric factors) and edge quality.

The beneficial effect of hydrostatic pressure has also been observed in bending. Although specimen size is limited, bending of metals with limited ductility has been carried out successfully in a pressurized chamber, and major increases in bendability have been observed.

Forming-Limit Diagrams (FLD). Cupping tests commonly used in the past have been Erichsen and Olsen tests (which involve stretching of the sheet by a steel ball) and Swift and Fukui tests (which principally involve the drawing of the sheet into a cavity and some stretching). Although easy to perform and providing some general and relative indication of formability, these tests rarely represent the biaxial state of stress typically encountered by the sheet metal during actual forming operations.

A major development in establishing sheet metal formability under biaxial stresses is the construction of forming limit diagrams (Ref 1, 2, 3, 4, 5, 12). In this test, sheets of different widths are marked with a grid pattern of circles, using chemical etching or photoprinting techniques. The specimens are then clamped over a fixture using draw beads (to prevent the sheet from being drawn in) and are stretched with a punch until fracture (tearing) is observed.

The narrower the specimen is, the closer the state of stress becomes to one of simple stretching. In contrast, a square specimen undergoes biaxial stretching. By observing and recording the deformation of the original grid patterns (along the cracked or torn region) from circular to elliptical (Fig. 15), the major and minor strains (generally engineering strains) can be calculated as percentages. For improved accuracy, the circle diameters and the thickness of the lines should be as small and thin as practicable in order to locate more accurately the region of maximum deformation (which would eventually lead to thinning and tearing).

Fig. 15 Deformation of circles into ellipses, showing major and minor strains in forming-limit diagrams

The major and minor strains observed are then plotted as shown in Fig. 16, in which the regions above the boundaries indicate the failure zone and the regions below the boundaries indicate the safe zone. The measurement of the grid distortions and the continuous plotting of data are now automated, using computer software and controls. It can be seen in Fig. 16 that the minor strains may be positive or negative, but the major strains are always positive. This is because a sheet forming operation always involves stretching the sheet (hence positive strain) in at least one direction.

Fig. 16 Forming-limit diagram for various sheet metals. Source: Ref 3

Note that the broken straight lines show the states of strain (Fig. 16). The pure shear line indicates that the tensile and compressive strains on the sheet are equal (therefore, the negative 45° slope). The simple tension line indicates a slope which relates to Poisson's ratio in plastic deformation (i.e., 0.5). The vertical line shows the plane-strain condition, where there is no width change (minor strain is zero) as the sheet is stretched over the punch. Finally, the 45° line on the right-hand side of the diagram indicates equal biaxial tension, meaning the major and the minor strains are both tensile and equal.

Because of volume constancy in plastic deformation, the thickness change in a particular location can also be calculated by comparing the surface areas of the original and distorted circles. If the area of the ellipse is larger than the area of the original circle, the sheet has undergone thinning. If the areas are the same, there is no thickness change. It is thus possible to predict thinning and tearing of the sheet by observing the shape changes of the original circles during forming.

As expected, friction between the punch and the sheet affects the test results; hence, lubrication of the punch-sheet interface is an important parameter. As for the effect of sheet thickness, experimental results indicate that the boundaries in Fig. 16 rise with increasing sheet thickness; that is, the safe zone is expanded.

Also note that the left-hand side of the FLD has a larger safe zone than the right-hand side, indicating the desirability of encouraging the development of a compressive strain during the forming of the sheet. This phenomenon has been utilized successfully in practice, such as in bulging of tubular workpieces or bending of tubes by applying a compressive force through the axis of the tube (Fig. 17).

Fig. 17 A method of forming a tube with sharp bends, using axial compressive forces. Source: Ref 3

A similar observation can be made with regard to bending, a process that is usually carried out in V-dies or by air bending with punch between two supports. It can be seen readily that the bending of less ductile metals can be performed by applying through-thickness compressive forces and pushing the piece into, for example, a 90° inner corner. In this way, the tensile stresses on the outer fibers, hence the tendency for fracture, are reduced or eliminated.

Limiting Dome Height (LDH). In this test, the sheet specimens with varying widths are prepared in a manner similar to that for the FLD test, but instead of measuring the strains on the distorted grid patterns, the height of the dome at the onset of failure is measured (or when the punch force reaches a maximum). Thus, the test result is a measure of the stretchability of the sheet, and the test can be used as a tool for quality control.

The data are plotted in a manner similar to FLDs, except that the ordinate is the ratio of LDH/punch radius. It has been shown that high LDH values for a sheet metal are related to such properties as high n and high m values, as well as high total elongation of the sheet metal in uniaxial tension.

Deep drawing of sheet metals has been studied extensively, and the term limiting drawing ratio (LDR, the ratio of maximum blank diameter to punch diameter) is used to define deep drawability. Several parameters are involved in deep drawing, and their control is important in avoiding tearing of the cup being drawn, wrinkling of the flange, or other defects.

After numerous investigations attempting to establish a relationship between the LDR and some mechanical property of the sheet metal, it has been shown that for pure drawing (as contrasted to pure stretching as in the FLD or LDH tests), the important parameter in deep drawability is the normal anisotropy of the sheet, R . This parameter is the ratio of width strain to longitudinal strain in simple tension, and it is generally measured at an elongation of 15 to 20% of the sheet specimen.

Because cold rolled sheet metals generally develop planar anisotropy (which causes earing during drawing), the tension-test specimens are cut at 0° , 45° , and 90° , respectively, to the rolling direction. The average normal anisotropy (or strain ratio), \bar{R} , is then given by the expression:

$$\bar{R} = (R_0 + 2R_{45} + R_{90})/4 \quad (\text{Eq 5})$$

When the results of LDR and \bar{R} are plotted on a log-log paper, it can be seen that there is a straight linear relationship between the two parameters (Fig. 18). Consequently, \bar{R} is a reliable and consistent indicator of deep drawability. In addition to the type of sheet metal and its processing history, the magnitude of the average normal anisotropy also depends on grain size. It increases as grain size increases (or as the ASTM number decreases).

Fig. 18 Relationship between limiting drawing ratio, LDR, and the average normal anisotropy (or strain ratio), \bar{R} , for a variety of sheet metals. Source: Ref 1

Earing can also be predicted from the expression for planar anisotropy, ΔR :

$$\Delta R = (R_0 - 2R_{45} + R_{90})/2 \quad (\text{Eq 6})$$

When ΔR is zero, there is no earing. Deep drawability is thus enhanced by high values and low ΔR values.

Although \bar{R} can be obtained from tensile tests on the sheet metal, another method is based on the observation that, especially for steels, there is a relationship between the modulus of elasticity, E , and the \bar{R} value of the sheet. The modulus of elasticity can be determined from the natural frequency of a vibrating beam (which is directly proportional to E). Based on this relationship, the modul-r drawability system (developed at U.S. Steel and licensed to different manufacturers such as Control Products, NASH International, Inc., and Tinius Olsen) is available that directly gives the R value when a simple strip of metal is inserted in the unit and vibrated automatically; results are displayed digitally.

Mechanical Testing for Metalworking Processes

Serope Kalpakjian, Illinois Institute of Technology

Conclusions

This brief review shows that product quality and control in metalworking facilities depend on a large number of material and process variables. Important parameters are the material properties, such as the inherent ductility of the material and its prior history, the state of stress and strain, the presence and location of external and internal defects in the original material, the strain hardening exponent and strain-rate sensitivity exponent, planar and normal anisotropy, temperature, surface roughness and integrity, workpiece-die contact geometry, and tribological factors.

Considerable success has been obtained in specific metalworking processes, particularly in sheet metal forming operations. Even then, such factors as workpiece size, shape, complexity, temperature, deformation rate, and tribological behavior encountered in actual practice continue to be difficult to simulate accurately in laboratory environments. The establishment of reliable quantitative relationships among the wide range of parameters involved (that are also applicable to a wide variety of processes and conditions) remains a challenging task.

Testing Machines and Strain Sensors

Joel W. House, Air Force Research Laboratory; Peter P. Gillis, University of Kentucky

Introduction

MECHANICAL TESTING MACHINES have been commercially available since 1886 (Ref 1) and have evolved from purely mechanical machines (like the popular “Little Giant” hand-cranked tensile tester of Tinius Olsen, circa 1900, shown in Fig. 1) to more sophisticated electromechanical and servohydraulic machines with advanced electronics and microcomputers. Electronic circuitry and microprocessors have increased the reliability of experimental data, while reducing the time to analyze information. This transition has made it possible to determine rapidly and with great precision ultimate tensile strength and elongation, yield strength, modulus of elasticity, and other mechanical properties. Current equipment manufacturers also offer workstation configurations that automate mechanical testing.

Fig. 1 “Little-Giant” hand-cranked tensile tester of Tinius Olsen, circa 1900

Conventional test machines for measuring mechanical properties include tension testers, compression testers, or the more versatile universal testing machine (UTM) (Ref 2). UTMs have the capability to test material in tension, compression, or bending. The word *universal* refers to the variety of stress states that can be studied. UTMs can load material with a single, continuous (monotonic) pulse or in a cyclic manner. Other conventional test machines may be limited to either tensile loading or compressive loading, but not both. These machines have less versatility than UTM equipment, but are less expensive to purchase and maintain. The basic aspects of UTM equipment and testing generally apply to tension or compression testing machines as well.

This article reviews the current technology and examines force application systems, force measurement, strain measurement, important instrument considerations, gripping of test specimens, test diagnostics, and the use of computers for gathering and reducing data. Emphasis is placed on UTMs with some separate discussions of equipment factors for tensile testing and compression testing. The influence of the machine stiffness on the test results is also described, along with a general assessment of test accuracy, precision, and repeatability of modern equipment.

Testing Machines and Strain Sensors

Joel W. House, Air Force Research Laboratory; Peter P. Gillis, University of Kentucky

Testing Machines

Although there are many types of test systems in current use, the most common are universal testing machines, which are designed to test specimens in tension, compression, or bending. The testing machines are designed to apply a force to a material to determine its strength and resistance to deformation. Regardless of the method of force application, testing machines are designed to drive a crosshead or platen at a controlled rate, thus applying a tensile or compressive load to a specimen. Such testing machines measure and indicate the applied force in pound-force (lbf), kilogram-force (kgf), or newtons (N). These customary force units are related by the

following: 1 lbf = 4.448222 N; 1 kgf = 9.80665 N. All current testing machines are capable of indicating the applied force in either lbf or N (the use of kgf is not recommended).

The load-applying mechanism may be a hydraulic piston and cylinder with an associated hydraulic power supply, or the load may be administered via precision-cut machine screws driven by the necessary gears, reducers, and motor to provide a suitable travel speed. In some light-capacity machines (only a few hundred pounds maximum), the force is applied by an air piston and cylinder. Gear-driven systems obtain load capacities up to approximately 600 kN (1.35×10^5 lbf), while hydraulic systems can obtain forces up to approximately 4500 kN (1×10^6 lbf).

Whether the machine is a gear-driven system or hydraulic system, at some point the test machine reaches a maximum speed for loading the specimen. Gear driven test machines have a maximum crosshead speed limited by the speed of the electric motor in combination with the design of the gear box transmission. Crosshead speed of hydraulic machines is limited to the capacity of the hydraulic pump to deliver a steady pressure on the piston of the actuator or crosshead. Servohydraulic test machines offer a wider range of crosshead speeds; however, there are continuing advances in the speed control of screw-driven machines, which can be just as versatile as, or perhaps more versatile than, servohydraulic machines.

Conventional gear-driven systems are generally designed for speeds of about 0.001 to 500 mm/min (4×10^{-6} to 20 in./min), which is suitable for quasi-static testing. Servohydraulic systems are generally designed over a wider range of test speeds, such as:

- 1 $\mu\text{m}/\text{h}$ test speeds for creep-fatigue, stress-corrosion, and stress-rupture testing
- 1 $\mu\text{m}/\text{min}$ test speeds for fracture testing of brittle materials
- 10 m/s (400 in./s) test speeds for dynamic testing of components like bumpers or seat belts

Servohydraulic UTM systems may also be designed for cycle rates from 1 cycle/day to over 200 cycles/s. Gear-driven systems typically allow cycle rates between 1 cycle/h and 1 cycle/s.

Gear-driven (or screw-driven) machines are electromechanical devices that use a large actuator screw threaded through a moving crosshead (Fig. 2). The screw is turned in either direction by an electric motor through a gear reduction system. The screws are rotated by a variable-control motor and drive the moveable crosshead up or down. This motion can load the specimen in either tension or compression, depending on how the specimen is to be held and tested.

Fig. 2 Components of an electromechanical (screw-driven) testing machine. For the configuration shown, moving the lower (intermediate) head upward produces tension in the lower space between the crosshead and the base

Screw-driven testing machines currently used are of either a one-, two-, or four-screw design. To eliminate twist in the specimen from the rotation of the screws in multiple-screw systems, one screw has a right-hand thread, and the other has a left-hand thread. For alignment and lateral stability, the screws are supported in

bearings on each end. In some machines, loading crossheads are guided by columns or guideways to achieve alignment.

A range of crosshead speeds can be achieved by varying the speed of the electric motor and by changing the gear ratio. A closed-loop servodrive system ensures that the crosshead moves at a constant speed. The desired or user-selected speed and direction information is compared with a known reference signal, and the servomechanism provides positional control of the moving crosshead to reduce any error or difference. State-of-the-art systems use precision optical encoders mounted directly on preloaded twin ball screws. These types of systems are capable of measuring crosshead displacement to an accuracy of 0.125% or better with a resolution of 0.6 μm .

As noted above, typical screw-driven machines are designed for speeds of 1 to 20 mm/min (0.0394–0.788 in./min) for quasi-static test applications; however, machines can be designed to obtain higher speeds, although the useful force available for application to the specimen decreases as the speed of the cross-head motion increases. Modern high-speed systems generally are useful in ranges up to 500 mm/min (20 in./min) (Ref 3). Nonetheless, top crosshead speeds of 1250 mm/min (50 in./min) can be attained in screw-driven machines, and servohydraulic machines can be driven up to 2.5×10^5 mm/min (10^4 in./min) or higher.

Due to the high forces involved, bearings and gears require particular attention to reduce friction and wear. Backlash, which is the free movement between the mechanical drive components, is particularly undesirable. Many instruments incorporate antibacklash preloading so that forces are translated evenly through the lead screw and crosshead. However, when the crosshead direction is constantly in one direction, antibacklash devices may be unnecessary.

Servohydraulic machines use a hydraulic pump and servohydraulic valves that move an actuator piston (Fig. 3). The actuator piston is attached to one end of the specimen. The motion of the actuator piston can be controlled in both directions to conduct tension, compression, or cyclic loading tests.

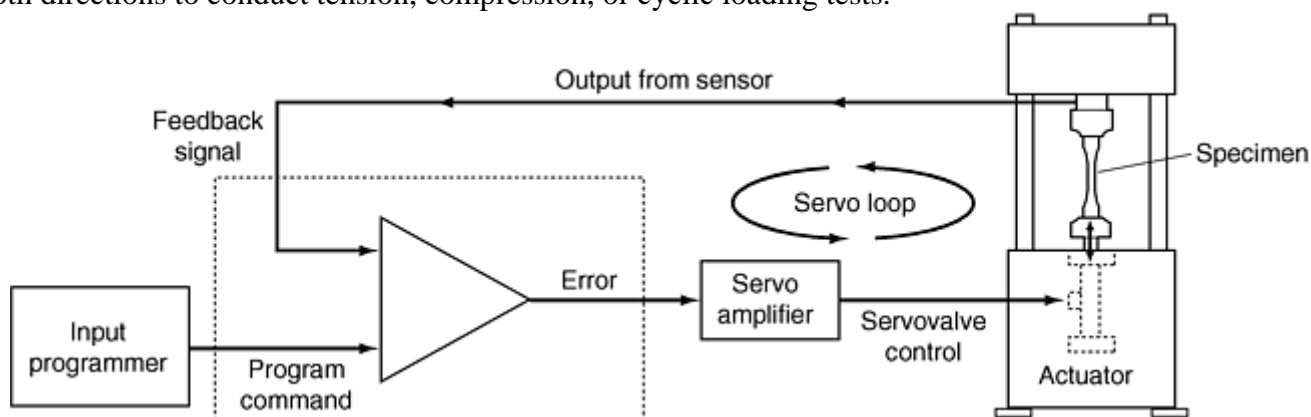

Fig. 3 Schematic of a basic servohydraulic, closed-loop testing machine

Servohydraulic test systems have the capability of testing at rates from as low as 45×10^{-11} m/s (1.8×10^{-9} in./s) to 30 m/s (1200 in./s) or more. The actual useful rate for any particular system depends on the size of the actuator, the flow rating of the servovalve, and the noise level present in the system electronics. A typical servohydraulic UTM system is shown in Fig. 4.

Fig. 4 Servohydraulic testing machine and load frame with a dedicated microprocessor-based controller

Hydraulic actuators are available in a wide variety of force ranges. They are unique in their ability to economically provide forces of 4450 kN (1,000,000 lbf) or more. Screw-driven machines are limited in their ability to provide high forces due to problems associated with low machine stiffness and large and expensive loading screws, which are increasingly more difficult to produce as the force rating goes up.

Microprocessors for Testing and Data Reduction. Contemporary UTMs are controlled by microprocessor-based electronics. One class of controller is based on dedicated microprocessors for test machines (Fig. 4). Dedicated microprocessors are designed to perform specific tasks and have displays and input functions that are limited to those tasks. The dedicated microprocessor sends signals to the experimental apparatus and receives information from various sensors. The data received from sensors can be passed to oscilloscopes or computers for display and storage. The experimental results consist of time and voltage information that must be further reduced to analyze material behavior. Analysis of the data requires the conversion of test results, such as voltage, to specific quantities, such as displacement and load, based on known conversion factors.

The second class of controller is the personal computer (PC) designed with an electronic interface to the experimental apparatus, and the appropriate application software. The software takes the description of the test to be performed, including specimen geometry data, and establishes the requisite electronic signals. Once the test is underway, the computer controls the tests and collects, reduces, displays, and stores the data. The obvious advantage of the PC-based controller is reduced time to generate graphic results, or reports. The other advantage is the elimination of some procedural errors, or the reduction of the interfacing details between the operator and the experimental apparatus. Some systems are designed with both types of controllers. Having both types of controllers provides maximum flexibility in data gathering with a minimal amount of time required for reducing data when conducting standard experiments.

Testing Machines and Strain Sensors

Joel W. House, Air Force Research Laboratory; Peter P. Gillis, University of Kentucky

Principles of Operation

The operation of a universal testing machine can be understood in terms of the main elements for any stress analysis, which include material response, specimen geometry, and load or boundary condition.

Material response, or material characterization, is studied by adopting standards for the other two elements. Specimen geometries, which are specific for tension, compression, or bending tests, are described in separate sections at the end of this article. This section briefly describes load condition factors, such as strain rate, machine rigidity, and various testing modes by load control, speed control, strain control, and strain-rate control.

Strain rate, or the rate at which a specimen is deformed, is a key test variable that is controlled within prescribed limits, depending on the type of test being performed. Table 1 summarizes the general strain-rate ranges that are required for various types of property tests. Creep tests require low strain rates, while conventional (quasi-static) tension and compression tests require strain rates between 10^{-5} and 10^{-1} s^{-1} .

Table 1 Strain rate ranges for different tests

Type of test	Strain rate range, s^{-1}
Creep tests	10^{-8} to 10^{-5}
Pseudostatic tension or compression tests	10^{-5} to 10^{-1}
Dynamic tension or compression tests	10^{-1} to 10^2
Impact bar tests involving wave propagation effects	10^2 to 10^4

Source: Ref 4

A typical mechanical test on metallic materials is performed at a strain rate of approximately 10^{-3} s^{-1} , which yields a strain of 0.5 in 500 s. Conventional equipment and techniques generally can be extended to strain rates as high as 0.1 s^{-1} without difficulty. Tests at higher strain rates necessitate additional considerations of machine stiffness and strain measurement techniques. In terms of machine capability, servohydraulic load frames equipped with high-capacity valves can be used to generate strain rates as high as 200 s^{-1} . These tests are complicated by load and strain measurement and data acquisition.

If the crosshead speed is too high, inertia effects can become important in the analysis of the specimen stress state. Under conditions of high crosshead speed, errors in the load cell output and crosshead position data may become unacceptably large. A potential exists to damage load cells and extensometers under rapid loading. The damage occurs when the specimen fractures and the load is instantaneously removed from the specimen and the load frame.

At strain rates greater than 200 s^{-1} , the required crosshead speeds exceed the speeds easily obtained with screw-driven or hydraulic machines. Specialized high strain rate methods are discussed in more detail in the Section “High Strain Rate Testing” in this Volume.

Determination of Strain Rates for Quasi-Static Tension Tests. Strength properties for most materials tend to increase at higher rates of deformation. In order to quantify the effect of deformation rate on strength and other properties, a specific definition of strain rate is required. During a conventional (quasi-static) tension test, for example, ASTM E 8 “Tension Testing of Metallic Materials” prescribes an upper limit of deformation rate as determined quantitatively during the test by one of the following methods (listed in decreasing order of precision):

- Rate of straining
- Rate of stressing (when loading is below the proportional limit)
- Rate of crosshead separation during the tests
- Elapsed time
- Free-running crosshead speed

For some materials, the free-running crosshead speed, which is the least accurate, may be adequate, while for other materials, one of the remaining methods with higher precision may be necessary in order to obtain test values within acceptable limits. When loading is below the proportional limit, the deformation rate can be specified by the “loading rate” units of stress per unit of time such that:

$$\dot{\sigma} = E\dot{\epsilon}$$

where, according to Hooke's law, $\dot{\sigma}$ is stress, E is the modulus of elasticity, $\dot{\epsilon}$ is strain, and the superposed dots denote time derivatives.

ASTM E 8 specifies that the test speed must be low enough to permit accurate determination of loads and strains. When the rate of stressing is stipulated, ASTM E 8 requires that it not exceed 690 MPa/min (100 ksi/min). This corresponds to an elastic strain rate of about $5 \times 10^{-5} \text{ s}^{-1}$ for steel or $15 \times 10^{-5} \text{ s}^{-1}$ for aluminum. When the rate of straining is stipulated, ASTM E 8 prescribes that after the yield point has been passed, the rate can be increased to about $1000 \times 10^{-5} \text{ s}^{-1}$; presumably, the stress rate limitation must be applied until the yield point is passed. Lower limits are also given in ASTM E 8.

In ASTM standard E 345, "Tension Testing of Metallic Foil," the same upper limit on the rate of stressing is recommended. In addition, a lower limit of 7 MPa/min (1 ksi/min) is given. ASTM E 345 further specifies that when the yield strength is to be determined, the strain rate must be in the range from approximately 3×10^{-5} to $15 \times 10^{-5} \text{ s}^{-1}$.

Inertia Effects. A fundamental difference between a high strain rate tension test and a quasi-static tension test is that inertia and wave propagation effects are present at high rates. An analysis of results from a high strain rate test thus requires consideration of the effect of stress wave propagation along the length of the test specimen in order to determine how fast a uniaxial test can be run to obtain valid stress-strain data.

For high loading rates, the strain in the specimen may not be uniform. Figure 5 illustrates an elemental length dx_0 of a tension test specimen whose initial cross-sectional area is A_0 and whose initial location is prescribed by the coordinate x . Neglecting gravity, no forces act on this element in its initial configuration. After the test has begun, the element is shown displaced by a distance u , deformed to new dimensions dx and A , and subjected to forces F and $F + dF$. The difference, dF , between these end-face forces causes the motion of the element that is manifested by the displacement, u . This motion is governed by Newton's second law, force equals mass times acceleration:

$$dF = \rho_0 A_0 dx_0 \left(\frac{d^2 u}{dt^2} \right) \quad (\text{Eq 1})$$

where $\rho_0 A_0 dx_0$ is the mass of the element, $A_0 dx_0$ is the volume, ρ is the density of the material, and $(d^2 u/dt^2)$ is its acceleration. Tests that are conducted very slowly involve extremely small accelerations. Thus, Eq 1 shows that the variation of force dF along the specimen length is negligible.

Fig. 5 The deformation of an elemental length, dx_0 , of a tension test specimen of initial cross-sectional area, A_0 , by a stress wave. The displacement of the element is u ; the differential length of the element as a function of time is dx ; the forces acting on the faces of the element are given by F and $F + dF$.

However, for tests of increasingly shorter durations, the acceleration term on the right side of Eq 1 becomes increasingly significant. This produces an increasing variation of axial force along the length of the specimen. As the force becomes more nonuniform, so must the stress. Consequently, the strain and strain rate will also vary with axial position in the specimen. When these effects become pronounced, the concept of average values of stress, strain, and strain rate become meaningless, and the test results must be analyzed in terms of the propagation of waves through the specimen. This is shown in Table 1 as beginning near strain rates of 10^2 s^{-1} . In an intermediate range of strain rates (denoted as dynamic tests in Table 1), an effect known as "ringing" of the load-measuring device obscures the interpretation of test data. An example of this condition is shown in Fig.

6, which is a tracing of load cell force versus time during a dynamic tension test of a 2024-T4 aluminum specimen. Calculation showed that the oscillations apparent in the figure are consistent with vibrations at the approximate natural frequency of the load cell used for this test (Ref 5, 6).

Fig. 6 Oscilloscope record of load cell force versus time during a dynamic tension test depicting the phenomenon of ringing. The uncontrolled oscillations result when the loading rate is near the resonant frequency of the load cell. The scales are arbitrary. Source: Ref 5

In many machines currently available for dynamic testing, electronic signal processing is used to filter out such vibrations, thus making the instrumentation records appear much smoother than the actual load cell signal. However, there is still a great deal of uncertainty in the interpretation of dynamic test data. Consequently, the average value of the high-frequency vibrations associated with the load cell can be expected to differ from the force in the specimen. This difference is caused by vibrations near the natural frequency of the testing machine, which are so low that the entire test can occur in less than $\frac{1}{10}$ of a cycle. Hence, these low-frequency vibrations usually are impossible to detect in a test record, but can produce significant errors in the analysis of test results. The ringing frequency for typical load cells ranges from 2400 to 3600 Hz.

Machine Stiffness. The most common misconception relating to strain rate effects is that the testing machine is much stiffer than the specimen. Such an assumption leads to the concept of deformation of the specimen by an essentially rigid machine. However, for most tests the opposite is true: the conventional tensile specimen is much stiffer than most testing machines. As shown in Fig. 7, for example, if crosshead displacement is defined as the relative displacement, Δ , that would occur under conditions of zero load, then with a specimen gripped in a testing machine and the driving mechanism engaged, the crosshead displacement equals the deformation in the gage length of the specimen plus elastic deflections in components such as the machine frame, load cell, grips, and specimen ends. Before yielding, the gage length deformation is a small fraction of the crosshead displacement.

Fig. 7 Schematic illustrating crosshead displacement and elastic deflection in a tension testing machine. Δ is the displacement of the crosshead relative to the zero load displacement; L_0 is the initial gage length of the specimen; K is the composite stiffness of the grips, loading frame, load cell, specimen ends, etc.; F is the force acting on the specimen. The development of Eq 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12 describes the effects of testing machine stiffness on tensile properties. Source: Ref 7

After the onset of gross plastic yielding of the specimen, conditions change. During this phase of deformation, the load varies slowly as the material strain hardens. Thus, the elastic deflections in the machine change slowly, and most of the relative crosshead displacement produces plastic deformation in the specimen. Qualitatively, in a test at approximately constant crosshead speed, the initial elastic strain rate in the specimen will be small, but the specimen strain rate will increase when plastic flow occurs.

Quantitatively, this effect can be estimated as follows. Consider a specimen having an initial cross-sectional area A_0 and modulus of elasticity E gripped in a testing machine so that its axially stressed gage length initially is L_0 . (This discussion is limited to the range of testing speeds where wave propagation effects are negligible. This restriction implies that the load is uniform throughout the gage length of the specimen.) Denote the stiffness of the machine, grips, and so on, by K and the crosshead displacement rate (nominal crosshead speed) by S . The ratio S/L_0 is sometimes called the nominal rate of strain, but because it is often substantially different from the rate of strain in the specimen, the term specific crosshead rate is preferred (Ref 8).

Let loading begin at time t equal to zero. At any moment thereafter, the displacement of the crosshead must equal the elastic deflection of the machine plus the elastic and plastic deflections of the specimen. Letting s denote the engineering stress in the specimen, the machine deflection is then sA_0/K . It is reasonable to assume that Hooke's law adequately describes the elastic deformation of the specimen at ordinary stress levels. Thus, the elastic strain e_e is s/E .

Denoting the average plastic strain in the specimen by e_p , the above displacement balance can be expressed as:

$$\int_0^t S dt = s \left(\frac{A_0}{K} + \frac{L_0}{E} \right) + e_p L_0 \quad (\text{Eq 2})$$

Differentiating Eq 2 with respect to time and dividing by L_0 gives:

$$\frac{S}{L_0} = \left(\frac{\dot{s}}{E} \right) \left(\frac{A_0 E}{K L_0} + 1 \right) + \dot{e}_p \quad (\text{Eq 3})$$

The strain rate in the specimen is the sum of the elastic and plastic strain rates:

$$\dot{e} = \dot{e}_e + \dot{e}_p = \left(\frac{\dot{s}}{E} \right) + \dot{e}_p \quad (\text{Eq 4})$$

Using Eq 3 to eliminate the stress rate from Eq 4 yields:

$$\dot{e} = \frac{\left(\frac{SK}{A_0 E} + \dot{e}_p \right)}{\left(\frac{K L_0}{A_0 E} + 1 \right)} \quad (\text{Eq 5})$$

Thus, it is seen that the specimen strain rate usually will differ from the specific crosshead rate by an amount dependent on the rate of plastic deformation and the relative stiffnesses of the specimen ($A_0 E/L_0$) and the machine, K .

Accounting for Testing Machine Stiffness. Machine stiffness is the amount of deflection in the load frame and the grips for each unit of load applied to the specimen. This deflection not only encompasses elastic deflection of the load frame, but includes any motion in the grip mechanism, or at any interface (threads, etc.) in the system. These deflections are substantial during the initial loading of the specimen, that is, through the elastic regime. This means that the initial crosshead speed (specified by the operator) is not an accurate measure of specimen displacement (strain). If the strain in the elastic regime is not accurately known, then extremely large errors may result in the calculation of Young's modulus (E , the ratio of stress versus strain in the elastic regime). In the analysis by Hockett and Gillis (Ref 9), the machine stiffness K is accounted for in the following equation:

$$K = \left(\frac{S}{\dot{P}_0} - \frac{L_0}{A_0 E} \right)^{-1} \quad (\text{Eq 6})$$

where L_0 is initial specimen gage length, S is crosshead speed of the testing machine, A_0 is initial cross-sectional area of the specimen, \dot{P}_0 is specimen load rate ($dF/dt = A_0\dot{S}$), and E is Young's modulus of the specimen material.

Research in this area showed that a significant amount of scatter was found in the measurement of machine stiffness. This variability can be attributed to relatively small differences in test conditions. For characterization of the elastic response of a material and for a precise measure of yield point, the influence of machine stiffness requires that an extensometer, or a bonded strain gage, be used. After yielding of the specimen material, the change of machine deflection is very small because the load changes slowly. If the purpose of the experiment is to study large strain behavior, then the error associated with the use of the crosshead displacement is small relative to other forms of experimental uncertainties.

Control Modes. During a test, control circuits and servomechanisms monitor and control the key experimental conditions, such as force, specimen deformation, and the position of the moveable crosshead. These are the key boundary conditions, which are analyzed to provide mechanical property data. These boundary conditions on the specimen can also be controlled in different ways, such as constant load control, constant strain control, and constant crosshead speed control. Constant crosshead speed is the most common method for tension tests.

Constant Load Rate Testing. With appropriate modules on a UTM system, a constant load rate test can be accomplished easily. In this configuration, a load-control module allows the machine with the constant rate of extension to function as a constant load rate device. This is accomplished by a feedback signal from a load cell, which generates a signal that automatically adjusts to the motion controller of the crosshead. Usually, the servomechanism system response is particularly critical when materials are loaded through the yield point.

Constant Strain Rate Testing. Commercial systems have been developed to control the experiment based on a constant rate of straining in the specimen. These systems rely on extensometers measuring the change in gage length to provide data on strain as a function of time. The resulting signal is processed to determine the current strain rate and is used to adjust the crosshead displacement rate throughout the test. Again, servomechanism response time is particularly critical when materials are taken through yield.

To maintain a constant average strain rate during a test, the crosshead speed must be adjusted as plastic flow occurs so that the sum $(SK/A_0E + e_p)$ remains constant. For most metallic materials at the beginning of a test, the plastic strain rate is ostensibly zero, and from Eq 5 the initial strain rate is:

$$\dot{e}_0 = \frac{\left(\frac{S_0}{L_0}\right)}{1 + \left(\frac{A_0E}{KL_0}\right)} \quad (\text{Eq 7})$$

where S_0 is the crosshead speed at the beginning of the test. For materials that have a definite yield, $\dot{S} = 0$ at the yield point. Therefore, from Eq 3 and 4, the yield point strain rate is:

$$\dot{e}_1 = \left(\frac{S_1}{L_0}\right) \quad (\text{Eq 8})$$

where S_1 is the crosshead speed at the yield point. Equating these two values of strain rate shows that the crosshead speed must be reduced from its initial value to its yield-point value by a factor of:

$$\frac{S_0}{S_1} = \left(1 + \frac{A_0E}{KL_0}\right) \quad (\text{Eq 9})$$

For particular measured values of machine stiffness given in Table 2, this factor for a standard 12.8 mm (0.505 in.) diameter steel specimen is typically greater than 20 and can be as high as 100. Only for specially designed machines will the relative stiffness of the machine exceed that of the specimen. Even for wire-like specimens, the correspondingly delicate gripping arrangement will ensure that the machine stiffness is less than that of the specimen. Thus, large changes in crosshead speed usually are required to maintain a constant strain rate from the beginning of the test through the yield point.

Table 2 Experimental values of testing machine stiffness

Machine stiffness		Source
kg/mm	lb/in.	
740	41,500	Ref 10
460	26,000	Ref 11
1800	100,000	Ref 12
1390–2970	77,900–166,500	Ref 13

Furthermore, for many materials, the onset of yielding is quite rapid, so that this large change in speed must be accomplished quickly. Making the necessary changes in speed generally requires not only special strain-sensing equipment, but also a driving unit that is capable of extremely fast response. The need for fast response in the driving system eliminates the use of screw-driven machines for constant strain-rate testing. Servohydraulic machines may be capable of conducting tests at constant strain rate through the yield point of a material.

Equation 9 indicates the magnitude of speed changes required only for tests in which there is no yield drop. For materials having upper and lower yield points, the direction of crosshead motion may have to be reversed after initial yielding to maintain a constant strain rate. This reversal may be necessary, because plastic strains beyond the upper yield point can be imposed at a strain rate greater than the desired rate by recovery of elastic deflections of the machine as the load decreases. For a description of yield point phenomena, see the article “Mechanical Behavior under Tensile and Compressive Loads” in this Volume.

Another important test feature related to the speed change capability of the testing machine is the rate at which the crosshead can accelerate from zero to the prescribed test speed at the beginning of the test. For a slow test this may not be critical, but for a high-speed test, the yield point could be passed before the crosshead achieves full testing speed. Thus, the crosshead may still be accelerating when it should be decelerating, and accurate information concerning the strain rate will not be obtained. With the advent of closed-loop servohydraulic machines and electromagnetic shakers, the speed at which the ram (crosshead) responds is two orders of magnitude greater than for screw-driven machines.

Tests at Constant Crosshead Speeds. Machines with a constant rate of extension are the most common type of screw-driven testers and are characterized by a constant rate of crosshead travel regardless of applied loads. They permit testing without speed variations that might alter test results; this is particularly important when testing rate-sensitive materials such as polymers, which exhibit different ultimate strengths and elongations when tested at different speeds.

For a gear-driven system, applying the boundary condition is as simple as engaging the electric motor with a gear box transmission. At this point, the crosshead displacement will be whatever speed and direction was selected. More sophisticated systems use a command signal that is compared with a feedback signal from a transducer monitoring the position of the crosshead. Using this feedback circuit, the desired boundary condition can be achieved.

Tension tests usually can be carried out at a constant crosshead speed on a conventional testing machine, provided the machine has an adequate speed controller and the driving mechanism is sufficiently powerful to be insensitive to changes in the loading rate. Because special accessory equipment is not required, such tests are relatively simple to perform. Also, constant crosshead speed tests typically provide as good a comparison among materials and as adequate a measure of strain-rate sensitivity as constant strain-rate tests.

Two of the most significant test quantities—yield strength and ultimate tensile strength—frequently can be correlated with initial strain rate and specific crosshead rate, respectively. The strain rate up to the proportional limit equals the initial strain rate. Thus, for materials that yield sharply, the time-average strain rate from the beginning of the test to yield is only slightly greater than the initial strain rate:

$$\dot{\epsilon}_0 = \left(\frac{\frac{S}{L_0}}{1 + \frac{A_0 E}{KL_0}} \right) \quad (\text{Eq 10})$$

even though the instantaneous strain rate at yield is the specific crosshead rate:

$$\dot{\epsilon}_1 = \left(\frac{S}{L_0} \right) \quad (\text{Eq 11})$$

However, beyond the yield point, the stress rate is small so that the strain rate remains close to the specific crosshead rate (Eq 11). Thus, ductile materials, for which a rather long time will elapse before reaching ultimate strength, have a time-average strain rate from the beginning of the test to ultimate that is only slightly less than the specific crosshead rate. Also, because the load rate is zero at ultimate as well as at yield, the instantaneous strain rate at ultimate equals the specific crosshead rate.

During a test at constant crosshead speed, the variation of strain rate from initial to yield-point values is precisely the inverse of the crosshead speed change required to maintain a constant strain rate (Eq 9):

$$\frac{\dot{\epsilon}_1}{\dot{\epsilon}_0} = \left(1 + \frac{A_0 E}{KL_0} \right) \quad (\text{Eq 12})$$

Consequently, in an ordinary tension test, the yield strength and ultimate tensile strength may be determined at two different strain rates, which can vary by a factor of 20 to 100, depending on machine stiffness. If a yield drop occurs, elastic recovery of machine deflections will impose a strain rate even greater than the specific crosshead rate given by Eq 12.

A point of interest from the analysis involves testing of different sized specimens at about the same initial strain rate. Assuming that these tests are to be made on one machine under conditions for which K remains substantially constant, the crosshead speed must be adjusted to ensure that specimens of different lengths, diameters, or materials will experience the same initial strain rate. In the typical case where the specimen is much stiffer than the machine, $(1 + A_0 E / KL_0)$ in Eq 10 can be approximated simply by $(A_0 E / KL_0)$, so that the initial strain rate is approximately $\dot{\epsilon}_0 = SK / A_0 E$. Thus, specimens of various lengths, tested at the same crosshead speed, will generally experience nearly the same initial strain rate. However, changing either the specimen cross section or material necessitates a corresponding change in crosshead speed to obtain the same initial rate.

A change in specimen length has substantially the same effect on both the specific crosshead rate (S/L_0) and the stiffness ratio of specimen to machine ($A_0 E / KL_0$) and, therefore, has no net effect. For example, an increase in specimen length tends to decrease the strain rate by distributing the crosshead displacement over the longer length; however, at the same time, the increase in length reduces the stiffness of the specimen so that more of the crosshead displacement goes into deformation of the specimen and less into deflection of the machine. These two effects are almost exactly equal in magnitude. Thus, no change in initial strain rate is expected for specimens of different lengths tested at the same crosshead speed.

Measuring Load

Prior to the development of load cells, testing machine manufacturers used several types of devices for the measurement of force. Early systems, some of which are still in use, employ a graduated balanced beam similar to platform-scale weighing systems. Subsequent systems have used Bourdon tube hydraulic test gages, Bourdon tubes with various support and assist devices, and load cells of several types. One of the most common load-measuring systems, prior to the development of load cells, was the displacement pendulum, which measured load by the movement of the balance displacement pendulum. The pendulum measuring system was used widely, because it is applicable to both hydraulic and screw-driven machines and has a high degree of reliability and stability. Many machines of this design are still in use, and they are still manufactured in Europe, India, South America, and Asia. Another widely used testing system was the Emery-Tate oil-pneumatic system, which accurately senses the hydraulic pressure in a closed, flat capsule.

Load Cells. Current testing machines use strain-gage load cells and pressure transducers. In a load cell, strain gages are mounted on precision-machined alloy-steel elements, hermetically sealed in a case with the necessary electrical outlets, and arranged for tensile and/or compressive loading. The load cell can be mounted so that the specimen is in direct contact, or the cell can be indirectly loaded through the machine crosshead, table, or columns of the load frame. The load cell and the load cell circuit are calibrated to provide a specific voltage as an output signal when a certain force is detected. In pressure transducers, which are variations of strain-gage load cells, the strain-gaged member is activated by the hydraulic pressure of the system.

Strain gages, strain-gage load cells, and pressure transducers are manufactured to several degrees of accuracy; however, when used as the load-measuring mechanism of a testing machine, the mechanisms must conform to ASTM E 4, as well as to the manufacturer's quality standards. Load cells are rated by the maximum force in their operating range, and the deflection of the load cell must be maintained within the elastic regime of the material from which the load cell was constructed. Because the load cell operates within its elastic range, both tensile and compressive forces can be monitored.

Electronics provide a wide range of signal processing capability to optimize the resolution of the output signal from the load cell. Temperature-compensating gages reduce measurement errors from changes in ambient temperature. A prior knowledge of the mechanical properties of the material being studied is also useful to obtain full optimization of these signals.

Within individual load cells, mechanical stops can be incorporated to minimize possible damage that could be caused by accidental overloads. Also, guidance and supports can be included to prevent the deleterious effects of side loading and to give desired rigidity and ruggedness. This is important in tension testing of metals because of the elastic recoil that can occur when a stiff specimen fails.

Calibration of Load-Measuring Devices. Calibration of load-measuring devices refers to the procedure of determining the magnitude of error in the indicated loads. Only load-indicating mechanisms that comply with standard calibration methods (e.g., ASTM E 74) should be used for the load calibration and verification of universal testing machines (see the section "Force Verification of Universal Testing Machines" in this article).

Calibration of load-measuring devices for mechanical test machines is covered in specifications of several standards organizations such as:

Specification number	Specification title
ASTM E 74	Standard Practice for Calibration of Force-Measuring Instruments for Verifying the Force Indication of Testing Machines
EN 10002-3	Part 3: Calibration of Force-Proving Instruments Used for the Verification of Testing Machines
ISO 376	Metallic Materials—Calibration of Force-Proving Instruments Used for the Verification of Testing Machines
BS EN 10002-3	Calibration of Force-Proving Instruments Used for the Verification of Uniaxial Testing Machines

To ensure valid load verification, calibration procedures should be performed by skilled personnel who are knowledgeable about testing machines and related instruments and the proper use of calibration standards. Load verification of load-weighing systems can be accomplished using methods based on the use of standard weights, standard weights and lever balances, and elastic calibration devices. Of these calibration methods, elastic calibration devices have the fewest inherent problems and are widely used. The two main types of elastic load-calibration devices are elastic proving rings and strain-gage load cells, as briefly described below. The elastic proving ring (Fig. 8a, b) is a flawless forged steel ring that is precisely machined to a fine finish and closely maintained tolerances. This device has a uniform and repeatable deflection throughout its loaded range. Elastic proving rings usually are designed to be used only in compression, but special rings are designed to be used in tension or compression.

Fig. 8 Proving rings. (a) Elastic proving ring with precision micrometer for deflection/load readout. (b) Load calibration of 120,000 lbf screw-driven testing machine with a proving ring

As the term “elastic device” implies, the ring is used well within its elastic range, and the deflection is read by a precise micrometer. Proving rings are available with capacities ranging from 4.5 to over 5000 kN (1000 to 1.2×10^6 lbf). Their usable range is from 10 to 100% of load capacity, based on compliance with the ASTM E 74 verification procedure.

Proving rings vary in weight from about 2 kg (5 lb) to hundreds of kilograms (or several hundred pounds). They are portable and easy to use. After initial certification, they should be recalibrated and recertified at intervals not exceeding 2 years.

Proving rings are not load rings. Although the two devices are of similar design and construction, only proving rings that use a precise micrometer for measuring deflection can be used for calibration. Load rings employ a dial indicator to measure deflection and usually do not comply with the requirements of ASTM E 74.

Calibration strain-gage load cells are precisely machined high-alloy steel elements designed to have a positive and predetermined uniform deflection under load. The steel load cell element contains one or more reduced sections, onto which wire or foil strain gages are attached to form a balanced circuit containing a temperature-compensating element.

Strain-gage load cells used for calibration purposes are either compression or tension-compression types and have built-in capacities ranging from about 0.4 to 4000 kN (100 to 1,000,000 lbf). Their usable range is typically from 5 to 100% of capacity load, and their accuracy is $\pm 0.05\%$, based on compliance with applicable

calibration procedures, such as ASTM E 74. Figure 9 illustrates a load cell system used to calibrate a UTM. This particular system incorporates a digital load indicator unit.

Fig. 9 Load cell and digital load indicator used to calibrate a 200,000 lbf hydraulic testing machine

Comparison of Elastic Calibration Devices. The deflection of a proving ring is measured in divisions that are assigned a value in lbf, kgf, or N. The force is then calculated in the desired units. Although the deflection of a load cell is given numerically and a force value can be assigned with a load cell reading, electric circuits can provide direct readout in lbf, kgf, or N. Thus, certified load cells are more practical and convenient to use and minimize errors in calculation.

In small capacities (5 to 20 kN, or 1000 to 5000 lbf), proving rings and load cells are of similar size and weight (2 to 5 kg, or 4 to 10 lb). In large capacities (2000 to 2700 kN, or 400,000 to 600,000 lbf), load cells are about one half the size and weight of proving rings. Proving rings are a single-piece, self-contained unit. A load cell calibration kit consists of two parts: the load cell and the display indicator (Fig. 9). Although the display indicator is designed to be used with a load cell of any capacity, it can only be used with load cells that have been verified with it as a system.

Although both proving rings and load cells are portable, the lighter weight and smaller size of high-capacity load cells enhance their suitability for general use. Load cells and their display indicators require a longer setup time; however, their direct readout feature reduces the overall calibration and reporting time. After initial certification, the load cell should be recalibrated after one year and thereafter at intervals not exceeding two years.

Both types of calibration devices are certified in accordance with the provisions of calibration standards. In the United States, devices are certified in accordance with ASTM E 74 and the verification values determined by the National Institute of Standards and Technology (NIST). NIST maintains a 1,000,000 lbf deadweight calibrator that is kept in a temperature- and humidity-controlled environment. This force-calibrating machine incorporates twenty 50,000 lb stainless steel weights, each accurate to within ± 0.25 lb. This machine, and six others of smaller capacities, are used to calibrate elastic calibrating devices, which in turn are employed to accurately calibrate other testing equipment.

Elastic calibrating devices for verification of testing machines are calibrated to primary standards, which are weights. The masses of the weights used are determined to 0.005% of their values.

Strain Measurement

Deformation of the specimen can be measured in several ways, depending on the size of specimen, environmental conditions, and measurement requirements for accuracy and precision of anticipated strain levels. A simple method is to use the velocity of the crosshead while tracking the load as a function of time. For the load and time data pair, the stress in the specimen and the amount of deformation, or strain, can be calculated. When the displacement of the platen is assumed to be equal to the specimen displacement, an error is introduced by the fact that the entire load frame has been deflected under the stress state. This effect is related to the concept of machine stiffness, as previously discussed.

Extensometry. The elongation of a specimen during load application can be measured directly with various types of devices, such as clip-on extensometers (Fig. 10), directly-mounted strain gages (Fig. 11), and various optical devices. These devices are used extensively and can provide a high degree of deformation- (strain-) measurement accuracy. Other more advanced instrumentations, such as laser interferometry and video extensometers, are also available.

Fig. 10 Test specimen with an extensometer attached to measure specimen deformation. Courtesy of Epsilon Technology Corporation

Fig. 11 Strain gages mounted directly to a specimen

Various types of extensometers and strain gages are described below. Selection of a device for strain measurement depends on various factors:

- The useable range and accuracy of the gage
- Techniques for mounting the gage
- Specimen size
- Environmental test conditions
- Electronic circuit configuration and analysis for signal processing

The last item should include the calibration of the extensometer device over its full operating range. In addition, one challenge of working with clip-on extensometers is to ensure proper attachment to the specimen. If the extensometer slips as the specimen deforms, the resulting signal will give a false reading.

Clip-on extensometers can be attached to a test specimen to measure elongation or strain as the load is applied. This is particularly important for metals and similar materials that exhibit high stiffness. Typical extensometers have fixed gage lengths such as 25 or 50 mm (1 or 2 in.). They are also classified by maximum percent elongation so that a typical 25 mm (1 in.) gage length unit would have different models for 10, 50, or 100% maximum strain. Extensometers are used to measure axial strain in specimens. There also are transverse strain-measuring devices that indicate the reduction in width or diameter as the specimen is tested.

The two basic types of clip-on extensometers are linear variable differential transformer (LVDT) devices and strain-gage devices. These two types are described along with a description of earlier dial-type extensometers.

Early extensometers were held to the specimen with center points matching the specimen gage-length punch marks, and elongation was indicated between the points by a dial indicator. Because of mechanical problems associated with these early devices, most dial extensometers use knife edges and leaf-spring pressure for specimen attachment. An extensometer using a dial indicator to measure elongation is shown in Fig. 12. The dial indicator usually is marked off in 0.0025 mm (0.0001 in.) increments and measures the total extension between the gage points. This value divided by the gage length gives strain in mm/mm, or in./in.

Fig. 12 Dial-type extensometer, 50 mm (2 in.) gage length

LVDT extensometers employ an LVDT with a core, which moves from specimen deformation and produces an electrical signal proportional to amount of core movement (Fig. 13). LVDT extensometers are small, light weight, and easy to use. Knife edges provide an exact point of contact and are mechanically set to the exact gage length. Unless the test report specifies total elongation, center punch marks or scribed lines are not required to define the gage length. They are available with gage lengths ranging from 10 to 2500 mm (0.4 to 100 in.) and can be fitted with breakaway features (Fig. 14), sheet metal clamps, low-pressure clamping arrangements (film clamps, as shown in Fig. 15), and other devices. Thus, they can be used on small specimens—such as thread, yarn, and foil—and on large test specimens—such as reinforcing bars, heavy steel plate, and tubing up to 75 mm (3 in.) in diameter.

Fig. 13 Averaging LVDT extensometer (50 mm, or 2 in. gage length) mounted on a threaded tension specimen

Fig. 14 Breakaway-type LVDT extensometer (50 mm, or 2 in. gage length) that can remain on the specimen through rupture

Fig. 15 Averaging LVDT extensometer (50 mm, or 2 in. gage length) mounted on a 0.127 mm (0.005 in.) wire specimen. The extensometer is fitted with a low-pressure clamping arrangement (film clamps) and is supported by a counterbalance device.

Modifications of the LVDT extensometer also permit linear measurements at temperatures ranging from -75 to 1205 °C (-75 to 2200 °F). Accurate measurements can also be made in a vacuum. For standard instruments, the working temperature range is approximately -75 to 120 °C (-100 to 250 °F). However, by substituting an elevated-temperature transformer coil, the usable range of the instrument can be extended to -130 to 260 °C (-200 to 500 °F).

Strain-gage extensometers, which use strain gages rather than LVDTs, are also common and are lighter in weight and smaller in size, but strain gages are somewhat more fragile than LVDTs. The strain gage usually is mounted on a pivoting beam, which is an integral part of the extensometer. The beam is deflected by the movement of the extensometer knife edge when the specimen is stressed. The strain gage attached to the beam is an electrically conductive small-sized grid that changes its resistance when deformed in tension, compression, bending, or torsion. Thus, strain gages can be used to supply the information necessary to calculate strain, stress, angular torsion, and pressure.

Strain gages have been improved and refined, and their use has become widespread. Basic types include wire gages, foil gages, and capacitive gages. Wire and foil bonded resistance strain gages are used for measuring stress and strain and for calibration of load cells, pressure transducers, and extensometers. These gages typically measure 9.5 to 13 mm ($\frac{3}{8}$ to $\frac{1}{2}$ in.) in width and 13 to 19 mm ($\frac{1}{2}$ to $\frac{3}{4}$ in.) in length and are adhesively bonded to a metal element (Fig. 16).

Fig. 16 Fatigue test specimen with bonded resistance strain gages and a 25 mm (1 in.) gage length extensometer mounted on the reduced section

Operation of strain-gage extensometers is based on gages that are bonded to a metallic element and connected to a bridge circuit. Deflection of the element, due to specimen strain, changes the gage's resistance that produces an output signal from a bridge circuit. This signal is amplified and processed by signal conditioners before being displayed on a digital readout, chart recorder, or computer. The circuitry in the strain-measuring system allows multiple ranges of sensitivity, so one transducer can be used over broad ranges. The magnification ratio, which is the ratio of output to extensometer deflection, can be as high as 10,000 to 1.

Strain Gages Mounted Directly to the Test Specimen. For some strain measurements, strain gages are mounted on the part being tested (Fig. 11). When used in this manner, they differ from extensometers in that they measure average unit elongation over nominal gage length rather than total elongation between definite gage points. For some testing applications, strain gages are used in conjunction with extensometers (Fig. 16).

In conventional use, wire or foil strain gages, when mounted on structures and parts for stress analysis, are discarded with the tested item. Thus, strain gages are seldom used in production testing of standard tension specimens. Foil strain gages currently are the most widely used, due to the ease of their attachment.

Averaging Extensometers. Typically extensometers are either nonaveraging or averaging types. A nonaveraging extensometer has one fixed nonmovable knife edge or center point and one movable knife edge or center point on the same side of the specimen. This arrangement results in extension measurements that are

taken on one side of the specimen only; such measurements do not take into account that elongation may be slightly different on the other side.

For most specimens, notably those with machined rounds or reduced gage length flats, there is no significant difference in elongation between the two sides. However, for as-cast specimens, high-modulus materials, some forged parts, and specimens made from tubing, a difference in elongation sometimes exists on opposite sides of the specimen when subjected to a tensile load. This is due to part configuration and/or internal stress. Misalignment of grips also contributes to elongation measurement variations in the specimen. For these situations, averaging extensometers are used. Averaging extensometers use dual-measuring elements that measure elongation on both sides of a sample; the measurements are then averaged to obtain a mean strain.

Optical Systems. Lasers and other systems can also be used to obtain linear strain measurements. Optical extensometers are particularly useful with materials such as rubber, thin films, plastics, and other materials where the weight of a conventional extensometer would distort the workpiece and affect the readings obtained. In the past, such strain-measuring systems were expensive, and their principal use has been primarily in research and development work. However, these optical techniques are becoming more accessible for commercial testing machines. For example, bench-top UTM systems with a laser extensometer are available (Fig. 17). This laser extensometer allows accurate measurement of strain in thin films, which would not otherwise be practical by mechanical attachment of extensometer devices. Optical systems also allow non-contact measurement from environmental test chambers.

Fig. 17 Bench-top UTM with laser extensometer. Courtesy of Tinius Olsen Testing Machine Company, Inc.

Calibration, Classification, and Verification of Extensometers. All types of extensometers for materials testing must be verified, classified, and calibrated in accordance with applicable standards. Calibration of extensometers refers to the procedure of determining the magnitude of error in strain measurements. Verification is a calibration to ascertain whether the errors are within a predetermined range. Verification also implies certification that an extensometer meets stated accuracy requirements, which are defined by classifications such as those in ASTM E 83 (Table 3).

Table 3 Classification of extensometer systems

Error of strain not to exceed the greater of ^(a) :			Error of gage length not to exceed the greater of:	
Classification	Fixed error, in./in.	Variable error, % of strain	Fixed error, in.	Variable error, % of gage length
Class A	0.00002	±0.1	±0.001	±0.01
Class B-1	0.0001	±0.5	±0.0025	±0.25
Class B-2	0.0002	±0.5	±0.005	±0.5
Class C	0.001	±1	±0.01	±1
Class D	0.01	±1	±0.01	±1
Class E	0.1	±1	±0.01	±1

(a) Strain of extensometer system—ratio of applied extension to the gage length.

Source: ASTM E 83

Several calibration devices can be used, including an interferometer, calibrated standard gage blocks and an indicator, and a micrometer screw. Applicable standards for extensometer calibration or verification include:

Specification number	Specification title
DIN EN 10002-4	Part 4: Verification of Extensometers Used in Uniaxial Testing, Tensile
ISO 9513	Metallic Materials—Verification of Extensometers Used in Uniaxial Testing
BS EN 10002-4	Verification of Extensometers Used in Uniaxial Testing
ASTM E 83	Standard Practice for Verification and Classification of Extensometers
BS 3846	Methods for Calibration and Grading of Extensometers for Testing of Materials

Verification and classification of extensometers are applicable to instruments of both the averaging and nonaveraging type.

Procedures for the verification and classification of extensometers can be found in ASTM E 83. It establishes six classes of extensometers (Table 3), which are based on allowable error deviations, as discussed later in this article. This standard also establishes a verification procedure to ascertain compliance of an instrument to a particular classification. In addition, it stipulates that a certified calibration apparatus must be used for all applied displacements and that the accuracy of the apparatus must be five times more precise than allowable classification errors. Ten displacement readings are required for verification of a classification.

Class A extensometers, if available, would be used for determining precise values of the modulus of elasticity and for precise measurements of permanent set or very slight deviations from Hooke's law. Currently, however, there are no commercially available extensometers manufactured that are certified to comply with class A requirements.

Class B-1 extensometers are frequently used to determine values of the modulus of elasticity and to measure permanent set or deviations from Hooke's law. They are also used for determining values such as the yield strength of metallic materials.

Class B-2 extensometers are used for determining the yield strength of metallic materials.

All LVDT and strain-gage extensometers can comply with class B-1 or class B-2 requirements if their measuring ranges do not exceed 0.5 mm (0.02 in.). Instruments with measuring ranges of over 0.5 mm (0.02 in.) can be class C instruments.

Most electrical differential transformer extensometers of 500-strain magnification and higher can conform to class B-1 requirements throughout their measuring range. Extensometers of less than 500-strain magnification can comply only with class B-1 requirements in their lower (40%) measuring range and are basically class B-2 instruments.

Dial Extensometers. Although all dial instruments usually are considered class C instruments, the majority (up to a gage length of 200 mm, or 8 in.) are class B-1 and class B-2 in their initial 40% measuring range, and class C throughout the remainder of the range. Dial instruments are used universally for determining yield strength by the extension-under-load method and yield strength of 0.1% offset and greater.

Class C and D Extensometers. Extensometers with a gage length of 610 mm (24 in.) begin in class C, although their overall measuring range must be considered as class D.

Testing Machines and Strain Sensors

Gripping Techniques

The use of proper grips and faces for testing materials in tension is critical in obtaining meaningful results. Trial and error often will solve a particular gripping problem. Tension testing of most flat or round specimens can be accommodated with wedge-type grips (Fig. 18). Wire and other forms may require different grips, such as capstan or snubber types. The load capacities of grips range from under 4.5 kgf (10 lbf) to 45,000 kgf (100,000 lbf) or more. ASTM E 8 describes the various types of gripping devices used to transmit the measured load applied by the test machine to the tension test specimen.

Fig. 18 Test setup using wedge grips on (a) a flat specimen with axial extensometer and (b) a round specimen with diametral extensometer

Screw-action grips, or mechanical grips, are low in cost and are available with load capacities of up to 450 kgf (1000 lbf). This type of grip, which is normally used for testing flat specimens, can be equipped with interchangeable grip faces that have a variety of surfaces. Faces are adjustable to compensate for different specimen thicknesses.

Wedge-type grips (Fig. 18) are self-tightening and are built with capacities of up to 45,000 kgf (100,000 lbf) or more. Some units can be tightened without altering the vertical position of the faces, making it possible to preselect the exact point at which the specimen will be held. The wedge-action design works well on hard-to-hold specimens and prevents the introduction of large compressive forces that cause specimen buckling.

Pneumatic-action grips are available in various designs with capacities of up to 90 kgf (200 lbf). This type of grip clamps the specimen by lever arms that are actuated by compressed air cylinders built into the grip bodies. A constant force maintained on the specimen compensates for decrease of force due to creep of the specimen in the grip. Another advantage of this design is the ability to optimize gripping force by adjusting the air pressure, which makes it possible to minimize specimen breaks at the grip faces.

Buttonhead grips enable the rapid insertion of threaded-end or mechanical-end specimens. They can be manually or pneumatically operated, as required by the type of material or test conditions.

Alignment. Whether the specimen is threaded into the crossheads, held by grips, or is in direct contact with platens, the specimen must be well aligned with the load cell. Any misalignment will cause a deviation from uniaxial stress in the material studied.

Testing Machines and Strain Sensors

Force Verification of Universal Testing Machines

The calibration and verification of UTM systems refer to two different methods that are not synonymous. Calibration of testing machines refers to the procedure of determining the magnitude of error in the indicated loads. Verification is a calibration to ascertain whether the errors are within a predetermined range. Verification also implies certification that a machine meets stated accuracy requirements. Valid verification requires device calibration by skilled personnel who are knowledgeable about testing machines, related instruments, and the proper use of device calibration standards (such as ASTM E 74 for load indicators and ASTM E 83 for extensometer devices). After verification is performed, the calibrator or agency must issue reports and certificates attesting to compliance of the equipment with the verification requirements, including the loading range(s) for which the system may be used.

Force Verification. For the load verification to be valid, the weighing system(s) and associated instrumentation and data systems must be verified annually. In no case should the time interval between verifications exceed 18 months. Testing systems and their loading ranges should be verified immediately after relocation of equipment, after repairs or parts replacement (mechanical or electric/electronic) that could affect the accuracy of the load-measuring system(s), or whenever the accuracy of indicated loads is suspect, regardless of when the last verification was made.

Force verification standards for mechanical testing machines include specifications from various standards organizations such as:

Specification number	Specification title
EN 10002-2	Metallic Materials—Tensile Testing—Part 2: Verification of the Force Measurements
DIN EN 10002-2	Part 2: Verification of the Force-Measuring System of Tensile Testing Machines
BS 1610	Materials Testing Machines and Force Verification Equipment
BS EN 10002-2	Verification of the Force Measuring System of the Tensile Testing Machine
ASTM E 4	Standard Practices for Force Verification of Testing Machines

To comply with ASTM E 4, one or a combination of the three allowable verification methods must be used in the determination of the loading range or multiple loading ranges of the testing system. These methods are based on the use of:

- Standard weights
- Standard weights and lever balances
- Elastic calibration devices

For each loading range, at least five (preferably more) verification load levels must be selected. The difference between any two successive test loads must not be larger than one third of the difference between the maximum and minimum test loads. The maximum can be the full capacity of an individual range. For example, acceptable test load levels could be 10, 25, 50, 75, and 100%, or 10, 20, 40, 70, and 100%, of the stated machine range.

Regardless of the load verification method used at each of the test levels, the values indicated by the load-measuring system(s) of the testing machine must be accurate to within $\pm 1\%$ of the loads indicated by the calibration standard. If all five or more of the successive test load deviations are within the $\pm 1\%$ required in ASTM E 4, the loading ranges may be established and reported to include all of the values. If any deviations are

larger than $\pm 1\%$, the system should be corrected or repaired immediately. For determining accuracy of values at various test loads (or the deviation from the indicated load of the standard), ASTM E 74 specifies the required calibration accuracy tolerances of the three allowable types of verification methods.

For determining material properties, the testing machine loads should be as accurate as possible. In addition, deformations resulting from load applications should be measured as precisely as possible. This is particularly important because the relationship of load to deformation, which may be, for example, extension or compression, is the main factor in determining material properties.

As described previously, load accuracy may be ensured by following the ASTM E 4 procedure. In a similar manner, the methods contained in ASTM E 83, if followed precisely, will ensure that the devices or instruments used for deformation (strain) measurements will operate satisfactorily.

Manufacturers of testing machines calibrate before shipping and certify conformation to the manufacturer's guarantee of accuracy and any applicable standards, such as ASTM E 4. Subsequent calibrations can be made by the manufacturer or another organization with recognized equipment that is properly maintained and recertified periodically.

Example: Calibrating a 60,000 lbf Capacity Testing Machine. A 60,000 lbf capacity dial-type UTM of either hydraulic or screw-driven design will have the following typical scale ranges:

- 0 to 60,000 lbf reading by 50 lbf divisions
- 0 to 30,000 lbf reading by 25 lbf divisions
- 0 to 12,000 lbf reading by 10 lbf divisions
- 0 to 1200 lbf reading by 1 lbf divisions

As discussed previously, the ASTM required accuracy is $\pm 1\%$ of the indicated load above 10% of each scale range. Most manufacturers produce equipment to an accuracy of $\pm 0.5\%$ of the indicated load or \pm one division, whichever is greater.

According to ASTM specifications, the 60,000 lbf scale range must be within 1% at 60,000 lbf (± 600 lbf) and at 6000 lbf (± 60 lbf). In both cases, the increment division is 50 lbf. Although the initial calibration by the manufacturer is to closer tolerance than ASTM E 4, subsequent recalibrations are usually to the $\pm 1\%$ requirement. In the low range, the machine must be accurate ($\pm 1\%$) from 120 to 1200 lbf. Thus, the machine must be verified from 120 to 60,000 lbf.

If proving rings are used in calibration, a 60,000 lbf capacity proving ring is usable down to a 6000 lbf load level. A 6000 lbf capacity proving ring is usable down to a 600 lbf load level, and a 1000 lbf capacity proving ring is usable down to a 100 lbf load level.

If calibrating load cells are used, a 60,000 lbf capacity load cell is usable down to a 3000 lbf load level, a 6000 lbf capacity load cell is usable to a 300 lbf load level, and a 600 lbf capacity load cell is usable down to a 120 lbf load level.

Before use, proving rings and load cells must be removed from their cases and allowed to stabilize to ambient (surrounding) temperature. Upon stabilization, either type of unit is placed on the table of the testing machine. At this stage, proving rings are ready to operate, but load cells must be connected to an appropriate power source and again be allowed to stabilize, generally for 5 to 15 min.

Each system is set to zero, loaded to the full capacity of the machine or elastic device, then unloaded to zero for checking. Loading to full capacity and unloading must be repeated until a stable zero is obtained, after which the load verification readings are made at the selected test load levels.

For the highest load range of 60,000 lbf, loads are applied to the calibrating device from its minimum lower limit (6000 lbf for proving rings and 3000 lbf for load cells) to its maximum 60,000 lbf in a minimum of five steps, or test load levels, as discussed in the section "Force Verification" in this article. In the verification loading procedure for proving rings, a "set-the-load" method usually is used. The test load is determined, and the nominal load is preset on the proving ring. The machine load readout is read when the nominal load on the proving ring is achieved. For load cells, a "follow-the-load" method can be used, wherein the load on the display indicator is followed until the load reaches the nominal load, which is the preselected load level on the readout of the testing machine.

In both methods, the load of the testing machine and the load of the calibration device are recorded. The error, E , and the percent error, E_p , can be calculated as:

$$E = A - B$$

$$E_p = \frac{(A - B)}{B} \times 100$$

(Eq 13)

where A is the load indicated by the machine being verified in lbf, kgf, or N, and B is the correct value of the applied load (lbf, kgf, or N), as determined by the calibration device.

This procedure is repeated until each scale range of the testing machine has been calibrated from minimum to maximum capacity. The necessary reports and certificates are then prepared, with the loading range(s) indicated clearly as required by ASTM E 4. Figures 8(b) and 9 illustrate UTMs being calibrated with elastic proving rings and calibration load cells.

Tensile Testing

Tensile testing requirements are specified in various standards for a wide variety of different materials and products. Table 4 lists various tensile testing specifications from several standards organizations. These specifications define requirements for the test apparatus, test specimens, and test procedures.

Table 4 Tension testing standards for various materials and product forms

Specification number	Specification title
ASTM A 770	Standard Specification for Through-Thickness Tension Testing of Steel Plates for Special Applications
ASTM A 931	Standard Test Method for Tension of Wire Ropes and Strand
ASTM B 557	Standard Test Methods of Tension Testing Wrought and Cast Aluminum- and Magnesium-Alloy Products
ASTM B 557M	Standard Test Methods of Tension Testing Wrought and Cast Aluminum- and Magnesium-Alloy products [Metric]
ASTM C 565	Standard Test Methods for Tension Testing of Carbon and Graphite Mechanical Materials
ASTM C 1275	Standard Test Method for Monotonic Tensile Strength Testing of Continuous Fiber-Reinforced Advanced Ceramics with Solid Rectangular Cross-Section Specimens at Ambient Temperature
ASTM C 1359	Standard Test Method for Monotonic Tensile Strength Testing of Continuous Fiber-Reinforced Advance Ceramics with Solid Rectangular Cross-Section Specimens at Elevated Temperatures
ASTM D 76	Standard Specification for Tensile Testing Machines for Textiles
ASTM E 8	Standard Test Methods for Tension Testing of Metallic Materials
ASTM E 8M	Standard Test Methods for Tension Testing of Metallic Materials [Metric]
ASTM E 338	Standard Test Method of Sharp-Notch Tension Testing of High-Strength Sheet Materials
ASTM E 345	Standard Test Methods of Tension Testing of Metallic Foil
ASTM E 602	Standard Method for Sharp-Notch Tension Testing with Cylindrical Specimens
ASTM E 740	Standard Practice for Fracture Testing with Surface-Crack Tension Specimens
ASTM E 1450	Standard Test Method for Tension Testing of Structural Alloys in Liquid Helium
ASTM F 1501	Standard Test Method for Tension Testing of Calcium Phosphate Coatings

ASTM F 152	Standard Test Methods for Tension Testing of Nonmetallic Gasket Materials
ASTM F 19	Standard Test Method for Tension and Vacuum Testing Metallized Ceramic Seals
ASTM F 1147	Standard Test Method for Tension Testing of Porous Metal Coatings
BS EN 10002	Tensile Testing of Metallic Materials
BS 18	Method for Tensile Testing of Materials (Including Aerospace Materials)
BS 4759	Method for Determination of K-Values of a Tensile Testing System
BS 3688-1	Tensile Testing
BS 3500-6	Tensile Stress Relaxation Testing
BS 3500-3	Tensile Creep Testing
BS 3500-1	Tensile Rupture Testing
BS 1687	Medium-Sensitivity Tensile Creep Testing
BS 1686	Long-Period, High-Sensitivity, Tensile Creep Testing
DIN 53455	Tensile Testing: Testing of Plastics
DIN 53328	Testing of Leather, Tensile Test
DIN 50149	Tensile Test, Testing of Malleable Cast Iron
EN 10002-1	Metallic Materials—Tensile Testing—Part 1: Method of test at Ambient Temperature
ISO 204	Metallic Materials—Uninterrupted Uniaxial Creep Testing Intension—Method of Test
ISO 783	Metallic Materials—Tensile Testing at Elevated Temperature
ISO 6892	Metallic Materials—Tensile Testing at Ambient Temperature
JIS B 7721	Tensile Testing Machines
JIS K 7113	Testing Methods for Tensile Properties of Plastics (English Version)

Standard tensile tests are conducted using a threaded tensile specimen geometry, like the standard ASTM geometry (Fig. 19) of ASTM E 8. To load the specimen in tension, the threaded specimen is screwed into grips attached to each crosshead. The boundary condition, or load, is applied by moving the crossheads away from one another.

Abbreviation	Dimension	Measurement	
		in.	mm
G	Gage length	2.4606	62.5 ±0.1
D	Diameter	0.4920 ±0.2	12.5 ± 0.2
R	Radius of fillet	0.3937	10.0
A	Length of reduced section	2.953	75
L	Approximate overall length	5.7086	145.0
B	Length of end section	1.378	35.0
C	Diameter of end section	0.787	20

Fig. 19 Standard ASTM geometry for threaded tensile specimens. Dimensions for the specimen are taken from ASTM 8M (metric units), or ASTM E 8 (English units).

For a variety of reasons, it is not always possible to fabricate a specimen as shown in Fig. 19. For thin plate or sheet materials, a flat, or dog-bone, specimen geometry is used. The dog-bone specimen is held in place by wedge shaped grips. The holding capacity of the grips provides a practical limit to the strength of material that a machine can test. Other specimen geometries can be tested, with certain cautions, and formulas for critical dimensions are given in ASTM E 8.

Accuracy, Repeatability, and Precision of Tension Tests. Accuracy and precision of test results can only be quantified when known quantities are measured. One difficulty of assessing data is that no agreed-upon “material standard” exists as reference material with known properties for strength and elongation. Tests of the “standard material” would reveal the system accuracy, and repeated experiments would quantify its precision and repeatability.

A variety of factors influence accuracy, precision, and repeatability of test results. Sources for errors in tension testing are mentioned in the appendix of ASTM E 8. Errors can be grouped into three broad categories:

- *Instrumental errors:* These can involve machine stiffness, accuracy and resolution of the load cell output, alignment of the specimen, gripping of the specimen, and accuracy of the extensometer.
- *Testing errors:* These can involve initial measurement of specimen geometry, electronic zeroing, and establishing a preload stress level in the specimen.
- *Material factors:* These describe the relationship between the material intended to be studied and that being tested. For example, does the material in the specimen represent the parent material, and is it homogenous? Other material factors would include specimen preparation, specimen geometry, and material strain-rate sensitivity.

The ASTM committee for tensile testing reported on a round robin set of experiments to assess repeatability and to judge precision of standard quantities. In this series (see appendix of ASTM E 8) six specimens of six materials were tested at six different laboratories. The comparison of measurements within a laboratory and between laboratories is given in Table 5. The data show the highest level of reproducibility in the strength measurements; the lowest reproducibility is found in elongation and reduction of area. Within-laboratory results were always more reproducible than those between laboratories.

Table 5 Results of round-robin testing

Property	Coefficient of variation, %	
	Within laboratory	Between laboratory
Tensile strength	0.91	1.30
0.02% yield strength	2.67	4.46
0.2% yield strength	1.35	2.32
Elongation in <i>5D</i>	2.97	6.36
Reduction in area	2.80	4.59

Compression Testing

Compression tests are conducted to provide engineering data on compressive strength and compressive failure. These data can differ substantially from tensile properties. Data on the response of materials to compression are needed for engineering design, such as loading concrete structures, or in metal fabrication, such as forging and rolling. One advantage of compression testing is the elimination of necking instability found in tensile testing of ductile metals. However, the geometry of compression specimens can cause buckling instabilities and failure, and frictional effects between the specimen and the platens can cause barreling. From a practical point of view, compression testing can reach the capacity of some machines because the force requirement increases with material hardening and with the increase in cross-sectional area of the specimen. This increase in area contributes to the frictional effects as well.

When testing high-strength brittle materials to failure, there exists a potential hazard from fragments of the specimen being ejected at high velocity. Personnel and equipment should be appropriately shielded. General Procedures. Various standards for compression testing are listed in Table 6 along with ASTM E 9. The most common specimen geometry for compression testing is a right circular cylinder with flat planar ends. ASTM E 9 identifies three sizes of specimens grouped as small, medium, and long. These samples differ in the ratio of length to diameter. Other shapes can be tested, but to avoid geometric buckling, special fixtures are required.

Table 6 Compression testing standards for various materials and products forms

Specification number	Specification title
ASTM A 256	Standard Method of Compression Testing of Cast Iron (discontinued)
ASTM B 485	Standard Method for Diametral Compression Testing of Cemented Carbides (discontinued)
ASTM C 1358	Standard Test Method for Monotonic Compressive Strength Testing of Continuous Fiber-Reinforced Advanced Ceramics with Solid Rectangular Cross-Section Specimens at Ambient Temperature
ASTM E 9	Standard Test Methods of Compression Testing of Metallic Materials at Room Temperature
BS 1881-115	Specification for Compression Testing Machines for Concrete
DIN 18554-1	Testing of Masonry, Determination of Compressive Strength and of Elastic Modulus
DIN 52185	Testing of Wood; Compression Test Parallel to Grain
DIN 52192	Testing of Wood; Compression Test Perpendicular to Grain
DIN 53517	Testing of Rubber and Elastomers
ISO 3132	Wood—Testing in Compression Perpendicular to Grain
ISO 4385	Plain Bearings—Compression Testing of Metallic Bearing Materials
JIS Z 0234	Testing Methods of Static Compression for Package Cushioning Materials
JIS Z 0235	Testing Methods of Dynamic Compression for Package Cushioning Materials

To load the standard specimen (right circular cylinder) a pair of platens attached to the crossheads make contact with the specimen. These platens must be flat, smooth, and parallel to one another. To avoid frictional effects, the specimen and platen interface is lubricated with silicon grease. In the case of compression testing, the crossheads move toward one another.

Compression tests can be performed using UTM equipment with or without a subpress, or with a unit specifically designed for compression testing. The unit specifically designed for compression testing may be portable for such purposes as in-the-field measurement of concrete compressive-failure strength. Figure 20 shows a diagram of a subpress. This unit is inserted between the crosshead platens of a conventional UTM machine. The subpress eliminates any lateral loads when aligned in the UTM.

Fig. 20 Subpress used during compression testing. Source: ASTM E 9

The boundary condition for compression testing can be established by load rate or with crosshead speed, such that the specimen deforms at a strain rate of 0.005/min as given in ASTM E 9. The analysis of deformation should be limited to the region of the test where deformation occurs homogeneously. The test should also be halted if the load reaches the capacity of the load cell as a result of increased cross-sectional area of the specimen.

Specimen Geometry. As previously noted, a right circular cylinder is the standard specimen defined in ASTM E 9. Most common in compression testing is a right circular cylinder with a length-to-diameter ratio in the range of 1 to 3. Longer specimens can be tested but failure from buckling instability will occur.

Measuring loads that cause a column of material to buckle can be the purpose of the experiment. Sheet or thin plate material can be tested to some extent. Specimens must be held in fixtures that constrain the material motion to the load plane, preventing buckling. This type of test configuration can provide useful engineering data for in-service conditions; it cannot measure material properties beyond a few percent strain.

Specimens of cylindrical shape will barrel as the deformation becomes large. Barreling is the influence of frictional effects, between the platens and the specimen, that changes the stress state in the material. When barreling occurs, the assumption of homogenous stress state throughout the sample is no longer valid. Lubricants and Teflon sheet material placed at the interfaces have been found to reduce this effect. At large strains, the stress at the interface will squeeze the lubrication from between the platens and the specimen.

Short specimen length makes it difficult to use an extensometer on the sample. The short specimen length means the gap between the platen faces (through which the arms of an extensometer must extend) is narrow at the beginning of the test and will decrease throughout the experiment. Unless the specimen has a length-to-diameter ratio of 3 to 1 or higher, most of the deformation data is taken indirectly from the actuator position. As mentioned above, machine stiffness effects can produce errors in such data.

Testing Machines and Strain Sensors

Joel W. House, Air Force Research Laboratory; Peter P. Gillis, University of Kentucky

Bending Tests

Bending tests require a different specimen geometry and a different configuration for applying the load. The typical specimen geometry is a beam with uniform cross section. In three-point bending, the load is applied at

the mid-span of a simply supported beam. In four-point bending, equal loads are applied at equal distances from the simple supports to create a shear-free central region. Various specifications are listed in Table 7.

Table 7 Bend testing standards for various materials and product forms

Specification number	Specification title
ASTM B 593	Standard Test Method for Bending Fatigue Testing for Copper-Alloy Spring Materials
ASTM E 290	Standard Test Method for Semi-Guided Bend Test for Ductility of Metallic Materials
ASTM E 855	Standard Test Methods for Bend Testing of Metallic Flat Materials for Spring Applications Involving Static Loading
ASTM F 1659	Bending and Shear Fatigue Testing of Calcium Phosphate Coatings on Solid Metallic Substrates
ASTM F 383	Standard Test Method for Static Bend and Torsion Testing of Intramedullary Rods, Standard Recommended Practice
ASTM F 384	Standard Practice for Static Bend Testing of Nail Plates
BS 1639	Methods for Bend Testing of Metals

Accreditation of Mechanical Testing Laboratories

Roxanne M. Robinson, American Association for Laboratory Accreditation

Introduction

ACCREDITATION is a “procedure by which an authoritative body gives formal recognition that a body or person is competent to carry out specific tasks” (Ref 1). The basic purpose of accreditation is to have the means to evaluate and assure high-quality results from suppliers of products or services without incurring the costs associated with auditing each supplier. This also applies to the accreditation of testing laboratories. The final product of a laboratory is test data, and confidence in test data is paramount to product acceptance. Laboratory accreditation, therefore, is gaining favor as an effective means to evaluate and improve product quality.

This article describes laboratory accreditation based on the general requirements of International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) Guide 25, “General Requirements for the Competence of Calibration and Testing Laboratories” (Ref 2). The ISO/IEC Guide 25 is an international standard that is generally recognized as the criteria for laboratory accreditation. This standard not only requires a quality system and manual in the laboratory but also requires that the laboratory be found competent to perform specific tests and types of tests. In 1990, Guide 25 was revised to reflect the content of ISO 9002, “Quality Systems—Model for Quality Assurance in Production, Installation, and Servicing.” Guide 25 is also presently undergoing another revision. When the latest revision is finalized, it will be published as standard, ISO/IEC 17025.

This article is also written to describe an accreditation process that would enhance the international acceptance of test data for mechanical testing laboratories. Laboratory accreditation is a valuable tool to enhance the international acceptance of test data in a more global economy. It also eliminates the need for multiple assessments. Thus, laboratory accreditation allows manufacturers to test products once with the results accepted in multiple markets on an international scale.

Accreditation Bodies

The accreditation process is typically carried out by third-party entities, which are capable of acting as an authoritative body to perform ISO/IEC Guide 25 assessments. These third-party entities gain the status as an authoritative body with peer accrediting organizations through a mutual recognition agreement (MRA) process. The MRA process allows accreditation to be recognized by international parties and allows testing of products once with the results accepted in other countries. In the United States, for example, the American Association for Laboratory Accreditation (A2LA) and the National Voluntary Laboratory Accreditation Program (NVLAP) have well-established programs that have been recognized through the MRA process to accredit mechanical testing laboratories. The goal is to provide a comprehensive national laboratory accreditation system that establishes widespread recognition of the competence of accredited laboratories. Elimination of the unnecessary multiple assessment of laboratories is also a goal.

The operations of an accreditation body must be designed to meet the requirements of ISO/IEC Guide 58 (Ref 3). Accrediting bodies may offer accreditation for a very narrow area of testing specific to a certain industry group or may offer a very broad-based program to meet needs across different materials, products, and testing procedures. For the purposes of this article, the accreditation process is described for mechanical testing laboratories.

Assessors may be employees or persons contracted on an as-needed basis to perform the laboratory assessments. They may be drawn from the ranks of the recently retired, consultants, industry, academia, government agencies, and the laboratory community. Candidates must have several years of direct laboratory experience in order to qualify as assessors. Auditing experience is a plus. They must be technically very knowledgeable in the mechanical testing area in which they assess. They must also be knowledgeable about the accreditation criteria and the policies and processes of the accrediting body.

Most accrediting bodies follow a similar process for qualifying assessor candidates to work for them. A background check is performed, and then new assessors may be evaluated as technical assessors on a team assessment and/or as the leader of an assessment team. Criteria based on Part 2 of ISO 10011-2 (Ref 4) are used to evaluate assessors. All new assessors and those needing refresher training should participate in available training courses, and approved assessors must be reevaluated at appropriate intervals. The assessors are also evaluated through their written reports, and laboratories may be given the opportunity to evaluate the assessor(s) who assessed the laboratory. Assessors are sometimes paid; other accrediting bodies use volunteer assessors.

Advisory Committees. Often accrediting bodies set up advisory committees for certain fields of testing or program areas if advice is needed beyond that which can be obtained from existing consensus standards writing organizations or industry committees, such as ASTM. Each advisory committee provides advice on the development of program requirements and the interpretation and/or amplification of ISO/IEC Guide 25 requirements for a particular field of testing.

Accreditation versus ISO 9000 Certification

The purposes of laboratory accreditation as stated in ISO/IEC Guide 25 (Ref 2) and quality system certifications such as ISO 9002 (Ref 5) are different, and, thus, examination against them gives different levels of assurance. The ISO 9000 series of standards provides a generic system for quality management of an organization, irrespective of the product or service it provides. In contrast, the ISO/IEC Guide 25 is a document developed specifically to provide minimum requirements to laboratories on both quality management in a laboratory environment and technical requirements for the proper operation of a laboratory. To the extent that both documents address quality management, Guide 25 can be considered as a complementary document to ISO 9002, which is written in terms most understandable by laboratory managers.

Some have expressed the view that the application of ISO 9002 alone is sufficient to ensure the effective operation of a laboratory and the validity of test data. Several significant differences, however, exist between laboratory accreditation using ISO/IEC Guide 25 and quality system certifications such as ISO 9002 (Ref 5). One key difference is that ISO/IEC Guide 25 is intended to ensure the validity of test data, while technical credibility is not addressed in quality management requirements of standards such as ISO 9002. From the point of view of the user of test data, quality management systems (ISO 9000) are deficient in that they do not necessarily provide any assessment of the technical competence of personnel engaged in what can only be described as a very technical activity, nor do quality management systems necessarily address the specific requirements of particular products or measurements. The better method of achieving these two objectives is through laboratory accreditation bodies operating according to an international practice, where laboratories adopt best practices by working with assessors who are expert in the specific tests in which the customer is interested.

It is also important to examine the differences in skill and emphasis of assessors involved in quality system certification and laboratory accreditation assessments. For quality system certification, emphasis is traditionally placed on the qualifications of the assessor to perform assessment against the systems standard. The systems assessor (often referred to as the lead assessor) is expected to have a thorough knowledge of the requirements of the standard. In current practice internationally, a quality system assessment team may or may not include personnel who have specific technical backgrounds or process familiarity relevant to the organizations being assessed.

For laboratory accreditation, the assessment team always involves a combination of personnel who have expert technical knowledge of the test or measurement methodology being evaluated for recognition in a specific laboratory, together with personnel who have specific knowledge of the policies and practices of the accreditation body and the general systems applicable to all accredited laboratories. The laboratory accreditation assessment, thus, includes a technical peer review component plus a systems compliance component.

Unlike quality system assessment, laboratory accreditation involves appraisal of the competence of personnel as well as systems. Part of the evaluation of a laboratory includes evaluation of supervisory personnel, in many cases leading to recognition of specific individuals as part of the laboratory accreditation. The technical competence and performance of laboratory operators may also be witnessed as part of the assessment process. The loss of key personnel may affect the continuing accreditation of the laboratory by the accrediting body; for

example, loss of key staff whose absence reduces the technical competence of the laboratory may prompt a reassessment before it would be normally scheduled.

Quality system certification, on the other hand, is not normally linked to nominated key personnel. The technical competence of managers and process operators is not a defined activity for quality system assessment teams. It is through the documented policies, job descriptions, procedures, work instructions, and training requirements of organizations and through objective evidence of their implementation that quality system certifiers appraise the personnel component of a system. Staff turnover is not an issue in maintaining certification.

The final product of a laboratory is test data. In many cases, laboratory accreditation assessments also include some practical testing of the laboratory through various forms of proficiency testing (interlaboratory comparisons or reference materials testing). This is another way that accreditation differs from quality system certification.

Accreditation of Mechanical Testing Laboratories

Roxanne M. Robinson, American Association for Laboratory Accreditation

Requirements of ISO/IEC Guide 25 (1990)

For international acceptance, accredited laboratories are required to comply with ISO/IEC Guide 25 (Ref 2). In this guide, attention is paid to the activities of both calibration and testing laboratories, and account is taken of other requirements for laboratory competence such as those of the Organization of Economic Cooperation and Development (OECD) *Code of Good Laboratory Practice* (GLP) (Ref 6) and the ISO 9000 series of quality assurance standards. Additional program requirements (specific criteria) for specific fields of testing (e.g., mechanical) or product requirements (e.g., fastener quality) (Ref 7) may also complement general requirements in particular areas.

ISO Guide 25 is recognized on an international level as the appropriate standard for determining the competency of a laboratory to perform specific tests or types of tests, or calibrations. Guide 25 is a balanced standard that addresses quality system requirements of ISO 9000 and the technical requirements needed to perform testing or calibration. The following criteria are included in ISO Guide 25:

- Organization and management
- Quality system, audit, and review
- Personnel
- Accommodation and environment
- Equipment and reference materials
- Measurement traceability and calibration
- Calibration and test methods
- Handling calibration and test items
- Records
- Certificates and reports
- Subcontracting calibration or testing
- Outside support and services

- Complaints

The mechanical testing accreditation program offered by accrediting bodies may differ in the breadth of testing each program covers. By the same token, a mechanical testing laboratory can request to be accredited for only a portion of, or the entire, testing capability of the laboratory. The scope of accreditation is based on the information provided by the laboratory to describe in detail the kinds of products tested, the test technologies used, and the specific test methods performed.

Accreditation of Mechanical Testing Laboratories

Roxanne M. Robinson, American Association for Laboratory Accreditation

Accreditation Process

Application. A laboratory applies for accreditation by obtaining the application package from the accrediting body headquarters and completing appropriate application sheets. All applicants may have to agree to the set of conditions for accreditation, pay the appropriate fees, and provide detailed supporting information on the following:

- Scope of testing in terms of field(s) of testing, testing technologies, test methods, and relevant standards (Table 1)
- Organization structure
- Proficiency testing

Table 1 Examples of items that can be specified in the scope of accreditation for a mechanical testing laboratory

Category	Examples
Products tested	Abrasives; adhesives and sealants; aircraft and automotive components; ceramics; coatings; fasteners; films; packaging; furniture; gaskets; glass and glass products; gypsum and gypsum products; leather; metals and alloys; packaging and containers; paper, paperboard, and pulp; plastic and polymers; pipes, hoses, valves, and fittings; pressure vessels; rubber and rubber products; safety tests on motor vehicles, toys, helmets; textiles; tools; windows and doors; and wood and wood products
Testing technologies used	Mechanical testing, including tensile, compression, hardness, shear, torsion, ductility, stress rupture; fracture (Charpy, Izod, etc.) and fatigue testing
	Metallography, including preparation, microstructure, inclusion content, grain size, hydrogen embrittlement, macroetching and microetching, depth of decarburization, and case depth
	Environmental simulation, including acceleration, altitude, durability, explosion,

	fungus, high/low temperature, high pressure, humidity, radioactivity, salt spray, sea water immersion, shock, and sun exposure simulation
	Dimensional inspection^(a)
Applicable standards or test methods	Consensus methods such as those issued by standards organizations such as ASTM, SAE^(b), and ISO^(c), or by companies such as General Motors Corp. and Ford Motor Co.^(d)
	In-house test methods^(e)

(a) Additional information concerning the range of measurement for each parameter and best measurement capability may have to be determined and included in the scope of accreditation.

(b) SAE, Society of Automotive Engineers.

(c) ISO, International Organization for Standardization.

(d) Usually, the laboratory must identify standard methods by designation and short title (e.g., ASTM B 117 Salt Spray).

(e) Accredited in-house methods are nonproprietary and must be made available to public persons with a valid reason to make such a request.

Applicants may also need to provide their quality manual or quality manual references, which address the documentation requirements of ISO/IEC Guide 25 and provide a matrix of the technical training of their laboratory personnel.

On-Site Assessment. Once the application information is completed and the appropriate fees are paid, headquarters staff identifies and tentatively assigns one or more assessors to conduct an on-site assessment. The laboratory has the right to ask for another assessor if it objects to the original assignment. Assessments may last from one to several days.

Assessors are given an assessor guide and checklists to follow in performing an assessment. These documents are intended to ensure that assessments are conducted as uniformly and completely as possible among the assessors and from laboratory to laboratory.

Before the assessment is conducted, the assessor team requests copies of the quality manual and related documentation (i.e., standard operating procedures related to Guide 25 requirements) in order to prepare for the assessment. The quality manual and related documentation must be reviewed by the assessor team before the on-site assessment can begin. Ideally, this review is done before the assessment is scheduled. Upon review of submitted documentation, the assessor(s) may ask the laboratory to implement corrective action to fill any documentation gaps required by Guide 25 before scheduling the assessment. A preassessment visit may be requested by the laboratory as an option at this point to enhance the success of the full assessment. Prior to scheduling the full assessment, the assessor reviews the scope of the draft to determine the tests to possibly witness and checks on the availability of the technical personnel who perform the tests. The assessor provides an assessment agenda.

The full assessment generally involves the following activities:

- An entry briefing with laboratory management
- Audit of the quality system to verify that it is fully operational and that it conforms to all sections of ISO/IEC Guide 25, including documentation
- Interviews with technical staff
- Demonstration of selected tests including, as applicable, tests done at representative field locations
- Examination of equipment and calibration records
- A written report of assessor findings
- An exit briefing including the specific written identification of any deficiencies

The objective of an assessment is to establish whether or not a laboratory complies with the requirements for accreditation and can competently perform the types of mechanical tests for which accreditation is sought. However, when accreditation is required to demonstrate compliance with additional criteria that may be imposed by other authorities, such as in the case of the *Fastener Quality Act*, the assessment will include such additional criteria. Assessors may also provide advice, based on observations or in response to questions, in order to help the laboratory improve its performance.

Deficiencies. During the assessment, assessors may observe deficiencies. A deficiency is any nonconformity to accreditation requirements including the following:

- The inability of a laboratory to perform a test or type of test for which the laboratory seeks accreditation.
- The nonconformance of a laboratory quality system to a clause or section of ISO/IEC Guide 25, inadequate documentation of a quality system, or a quality system that is not completely operational
- The nonconformance of a laboratory to any additional requirements of the accrediting body or specific fields of testing or programs necessary to meet particular needs

At the conclusion of an assessment, the assessor prepares a report of findings identifying deficiencies that, in the assessor's judgment, the laboratory must resolve in order to be accredited. The assessor holds an exit briefing with top management of the laboratory. The assessor goes over the findings and presents the list of deficiencies (deficiency report). The authorized representative of the laboratory (or designee) is asked to sign the deficiency report to attest that the deficiency report has been reviewed with the assessor. The signature does not imply that the laboratory representative concurs that the individual item(s) constitute a deficiency. The laboratory is requested to respond promptly after the date of the exit briefing, detailing either its corrective action or why it does not believe that a deficiency exists. The corrective action response should include a copy of any objective evidence (e.g., calibration certificates, lab procedures, paid invoices, packaging slips, and training records) to indicate that the corrective actions have been implemented/completed.

It is entirely possible that the laboratory will disagree with the findings that one or more items are deficiencies. In that case, the laboratory is requested to explain in its response why it disagrees with the assessor.

If the laboratory fails to respond in the agreed time frame, it may be treated as a new applicant subject to new fees and reassessment should it wish to pursue accreditation after that time.

Proficiency testing is a process for checking actual laboratory testing performance, usually by means of interlaboratory test data comparisons. For many test methods, results from proficiency testing are very good indicators of testing competence. Proficiency testing programs may take many forms, and standards for satisfactory performance can vary depending on the field. An accredited laboratory must participate in method-specific proficiency testing related to its field(s) of accreditation if such programs are available. There are commercially available proficiency testing programs that cover a wide array of mechanical testing procedures. Proficiency testing is available for plastics, rubber, textiles, paper, metals, and fasteners. Where proficiency testing programs are not available or suitable to the accredited testing, the laboratories often devise their own round-robin testing with a limited number of similar laboratories. Data from these round-robin studies are acceptable alternatives to proficiency testing program participation. When neither proficiency testing nor round-robin testing is available, internal performance-based data can substitute.

Accreditation Decisions. Before an accreditation decision ballot is sent to the person or group making the accreditation decision, the laboratory staff may review the deficiency response, including objective evidence of completed corrective action, for adequacy and completeness. If there is any doubt about the adequacy or completeness of any part of the deficiency response, the response may be submitted to the assessor(s) for additional review. The laboratory may then be asked to respond further to ensure a successful accreditation decision. The accreditation body then reviews the assessment record and any corrective action response to render a decision. Any concerns or negative decisions are relayed back to the laboratory for further response until the issue is resolved in a satisfactory way for final accreditation of the laboratory.

When accreditation is granted, the laboratory is issued a certificate and scope of accreditation for the mechanical field of testing and any special testing program. The laboratory should keep its scope of accreditation available to show clients or potential clients the testing technologies and test methods for which it is accredited. The scopes of accreditation are also used by the accrediting body to respond to inquiries and to prepare the directory of accredited laboratories.

Annual Review. Accreditation is generally established for a certain period of time before a reassessment is required. However, at set intervals between this established accreditation period, each laboratory would likely pay annual fees and undergo some type of surveillance activity that could include a one-day surveillance visit by an assessor. This surveillance visit is performed to confirm that the quality system of a laboratory and technical capabilities remain in compliance with the accreditation requirements. Other possible surveillance activities may include submission of updating information by the laboratory on its organization, facilities, and key personnel, and the results of any proficiency testing. Objective evidence of completion of the internal audit and management review may also be required. If the laboratory does not promptly provide complete annual

review documentation, or significant changes to the facility or organization have occurred, a one-day surveillance visit and payment of the associated assessor fees may be required.

Reassessment and Renewal of Accreditation. Full on-site reassessments of all accredited laboratories are conducted at intervals determined by the period of accreditation. Reassessments are also conducted when evaluations and submissions from the laboratory or its clients indicate significant technical changes in the capability of the laboratory have occurred.

The accredited laboratory is sent some type of renewal prompt, well in advance of the expiration date of its accreditation, to allow sufficient time to complete the renewal process. A successful on-site reassessment must be completed before accreditation is extended.

If deficiencies are noted during the renewal assessment, the laboratory is asked to respond in a timely fashion with a corrective action. All deficiencies must be resolved before accreditation is renewed.

Accreditation of Mechanical Testing Laboratories

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Introduction

THE MECHANICAL BEHAVIOR OF MATERIALS is described by their deformation and fracture characteristics under applied tensile, compressive, or multiaxial stresses. Determination of this mechanical behavior is influenced by several factors that include metallurgical/material variables, test methods, and the nature of the applied stresses.

This article focuses on mechanical behavior under conditions of uniaxial tension and compression. The main emphasis is on mechanical behavior during the engineering tension test, which is widely used to provide basic design information on the strength of materials and as an acceptance test for the specification of materials. In this test procedure, a specimen is subjected to a continually increasing uniaxial load (force), while simultaneous observations are made of the elongation of the specimen. In this article, emphasis is placed on the interpretation of these observations rather than on the procedures for conducting the tests. The article “Uniaxial Tensile Testing” in this Volume discusses the influence of test procedure variables.

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Engineering Stress-Strain Curve

In the conventional engineering tension test, an engineering stress-strain curve is constructed from the load-elongation measurements made on the test specimen (Fig. 1). The engineering stress (s) used in this stress-strain curve is the average longitudinal stress in the tensile specimen. It is obtained by dividing the load (P) by the original area of the cross section of the specimen (A_0):

$$s = \frac{P}{A_0} \quad (\text{Eq 1})$$

Fig. 1 Engineering stress-strain curve. Intersection of the dashed line with the curve determines the offset yield strength. See also Fig. 2 and corresponding text.

The strain, e , used for the engineering stress-strain curve is the average linear strain, which is obtained by dividing the elongation of the gage length of the specimen (δ) by its original length (L_0):

$$e = \frac{\delta}{L_0} = \frac{\Delta L}{L_0} = \frac{L - L_0}{L_0} \quad (\text{Eq 2})$$

Because both the stress and the strain are obtained by dividing the load and elongation by constant factors, the load-elongation curve has the same shape as the engineering stress-strain curve. The two curves frequently are used interchangeably.

The shape and magnitude of the stress-strain curve of a metal depend on its composition, heat treatment, prior history of plastic deformation, and the strain rate, temperature, and state of stress imposed during the testing. The parameters that are used to describe the stress-strain curve of a metal are the tensile strength, yield strength or yield point, percent elongation, and reduction in area. The first two are strength parameters; the last two indicate ductility.

The general shape of the engineering stress-strain curve (Fig. 1) requires further explanation. In the elastic region, stress is linearly proportional to strain. When the stress exceeds a value corresponding to the yield strength, the specimen undergoes gross plastic deformation. If the load is subsequently reduced to zero, the specimen will remain permanently deformed. The stress required to produce continued plastic deformation increases with increasing plastic strain; that is, the metal strain hardens. The volume of the specimen (area \times length) remains constant during plastic deformation, $AL = A_0L_0$, and as the specimen elongates, its cross-sectional area decreases uniformly along the gage length.

Initially, the strain hardening more than compensates for this decrease in area, and the engineering stress (proportional to load P) continues to rise with increasing strain. Eventually, a point is reached where the decrease in specimen cross-sectional area is greater than the increase in deformation load arising from strain hardening. This condition will be reached first at some point in the specimen that is slightly weaker than the rest. All further plastic deformation is concentrated in this region, and the specimen begins to neck or thin down locally. Because the cross-sectional area now is decreasing far more rapidly than the deformation load is increased by strain hardening, the actual load required to deform the specimen falls off, and the engineering stress defined in Eq 1 continues to decrease until fracture occurs.

The tensile strength, or ultimate tensile strength (s_u) is the maximum load divided by the original cross-sectional area of the specimen:

$$s_u = \frac{P_{\max}}{A_0} \quad (\text{Eq 3})$$

The tensile strength is the value most frequently quoted from the results of a tension test. Actually, however, it is a value of little fundamental significance with regard to the strength of a metal. For ductile metals, the tensile strength should be regarded as a measure of the maximum load that a metal can withstand under the very restrictive conditions of uniaxial loading. This value bears little relation to the useful strength of the metal under the more complex conditions of stress that usually are encountered.

For many years, it was customary to base the strength of members on the tensile strength, suitably reduced by a factor of safety. The current trend is to use the more rational approach of basing the static design of ductile metals on the yield strength. However, due to the long practice of using the tensile strength to describe the strength of materials, it has become a familiar property, and as such, it is a useful identification of a material in the same sense that the chemical composition serves to identify a metal or alloy. Furthermore, because the tensile strength is easy to determine and is a reproducible property, it is useful for the purposes of specification and for quality control of a product. Extensive empirical correlations between tensile strength and properties such as hardness and fatigue strength are often useful. For brittle materials, the tensile strength is a valid design criterion.

Measures of Yielding. The stress at which plastic deformation or yielding is observed to begin depends on the sensitivity of the strain measurements. With most materials, there is a gradual transition from elastic to plastic behavior, and the point at which plastic deformation begins is difficult to define with precision. In tests of materials under uniaxial loading, three criteria for the initiation of yielding have been used: the elastic limit, the proportional limit, and the yield strength.

Elastic limit, shown at point A in Fig. 2, is the greatest stress the material can withstand without any measurable permanent strain remaining after the complete release of load. With increasing sensitivity of strain measurement, the value of the elastic limit is decreased until it equals the true elastic limit determined from microstrain measurements. With the sensitivity of strain typically used in engineering studies (10^{-4} in./in.), the elastic limit is greater than the proportional limit. Determination of the elastic limit requires a tedious incremental loading-unloading test procedure. For this reason, it is often replaced by the proportional limit.

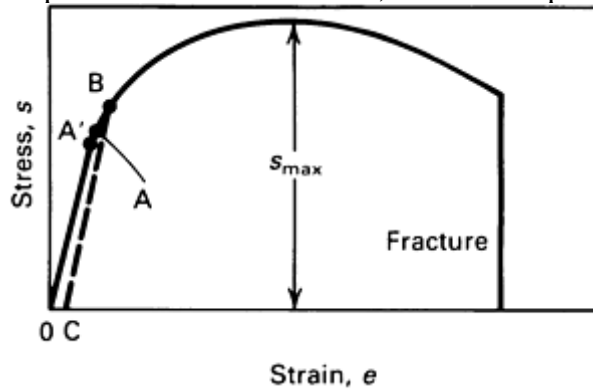

Fig. 2 Typical tension stress-strain curve for ductile metal indicating yielding criteria. Point A, elastic limit; point A', proportional limits; point B, yield strength or offset (0 to C) yield strength; 0, intersection of the stress-strain curve with the strain axis

Proportional limit, shown at point A' in Fig. 2, is the highest stress at which stress is directly proportional to strain. It is obtained by observing the deviation from the straight-line portion of the stress-strain curve.

The yield strength, shown at point B in Fig. 2, is the stress required to produce a small specified amount of plastic deformation. The usual definition of this property is the offset yield strength determined by the stress corresponding to the intersection of the stress-strain curve offset by a specified strain (see Fig. 1 and 2). In the United States, the offset is usually specified as a strain of 0.2 or 0.1% ($e = 0.002$ or 0.001):

$$s_0 = \frac{P_{(\text{strain offset}=0.002)}}{A_0} \quad (\text{Eq 4})$$

Offset yield strength determination requires a specimen that has been loaded to its 0.2% offset yield strength and unloaded so that it is 0.2% longer than before the test. The offset yield strength is often referred to in Great Britain as the proof stress, where offset values are either 0.1 or 0.5%. The yield strength obtained by an offset method is commonly used for design and specification purposes, because it avoids the practical difficulties of measuring the elastic limit or proportional limit.

Some materials have essentially no linear portion to their stress-strain curve, for example, soft copper, gray cast iron, and many polymers. For these materials, the offset method cannot be used, and the usual practice is to define the yield strength as the stress to produce some total strain, for example, $e = 0.005$.

Some metals, particularly annealed low-carbon steel, show a localized, heterogeneous type of transition from elastic to plastic deformation that produces a yield point in the stress-strain curve. Rather than having a flow curve with a gradual transition from elastic to plastic behavior, such as Fig. 1 and 2, metals with a yield point produce a flow curve or a load-elongation diagram similar to Fig. 3. The load increases steadily with elastic strain, drops suddenly, fluctuates about some approximately constant value of load, and then rises with further strain.

Fig. 3 Typical yield-point behavior of low-carbon steel. The slope of the initial linear portion of the stress-strain curve, designated by E , is the modulus of elasticity.

The load at which the sudden drop occurs is called the upper yield point. The constant load is called the lower yield point, and the elongation that occurs at constant load is called the yield-point elongation. The deformation occurring throughout the yield-point elongation is heterogeneous. At the upper yield point, a discrete band of deformed metal, often readily visible, appears at a stress concentration, such as a fillet. Coincident with the formation of the band, the load drops to the lower yield point. The band then propagates along the length of the specimen, causing the yield-point elongation. A similar behavior occurs with some polymers and superplastic metal alloys, where a neck forms but grows in a stable manner, with material being fed into the necked region from the thicker adjacent regions. This type of deformation in polymers is called “drawing”.

In typical cases, several bands form at several points of stress concentration. These bands are generally at approximately 45° to the tensile axis. They are usually called Lüders bands or stretcher strains, and this type of deformation is sometimes referred to as the Piobert effect. When several Lüders bands are formed, the flow curve during the yield-point elongation is irregular, each jog corresponding to the formation of a new Lüders band. After the Lüders bands have propagated to cover the entire length of the specimen test section, the flow will increase with strain in the typical manner. This marks the end of the yield-point elongation. Lüders bands formed on a rimmed 1008 steel are shown in Fig. 4.

Fig. 4 Rimmed 1008 steel with Lüders bands on the surface as a result of stretching the sheet just beyond the yield point during forming

Measures of Ductility. Currently, ductility is considered a qualitative, subjective property of a material. In general, measurements of ductility are of interest in three respects (Ref 1):

- To indicate the extent to which a metal can be deformed without fracture in metalworking operations, such as rolling and extrusion
- To indicate to the designer the ability of the metal to flow plastically before fracture. A high ductility indicates that the material is “forgiving” and likely to deform locally without fracture should the designer err in the stress calculation or the prediction of severe loads.
- To serve as an indicator of changes in impurity level or processing conditions. Ductility measurements may be specified to assess material quality, even though no direct relationship exists between the ductility measurement and performance in service.

The conventional measures of ductility that are obtained from the tension test are the engineering strain at fracture (e_f) (usually called the elongation) and the reduction in area at fracture (q). Elongation and reduction in area usually are expressed as a percentage. Both of these properties are obtained after fracture by putting the specimen back together and taking measurements of the final length, L_f , and final specimen cross section, A_f :

$$e_f = \frac{L_f - L_0}{L_0} \quad (\text{Eq 5})$$

$$q = \frac{A_0 - A_f}{A_0} \quad (\text{Eq 6})$$

Because an appreciable fraction of the plastic deformation will be concentrated in the necked region of the tension specimen, the value of e_f will depend on the gage length (L_0) over which the measurement was taken (see the section of this article on ductility measurement in tension testing). The smaller the gage length, the greater the contribution to the overall elongation from the necked region and the higher the value of e_f . Therefore, when reporting values of percentage elongation, the gage length should always be given.

Reduction in area does not suffer from this difficulty. These values can be converted into an equivalent zero-gage-length elongation (e_0). From the constancy of volume relationship for plastic deformation, $AL = A_0L_0$:

$$\frac{L}{L_0} = \frac{A_0}{A} = \frac{1}{1-q}$$

(Eq 7)

$$e_0 = \frac{L - L_0}{L_0} = \frac{A_0}{A} - 1 = \frac{1}{1-q} - 1 = \frac{q}{1-q}$$

This represents the elongation based on a very short gage length near the fracture.

Another way to avoid the complications resulting from necking is to base the percentage elongation on the uniform strain out to the point at which necking begins. The uniform elongation (e_u), correlates well with stretch-forming operations. Because the engineering stress-strain curve often is quite flat in the vicinity of necking, it may be difficult to establish the strain at maximum load without ambiguity. In this case, the method suggested in Ref 2 is useful.

Modulus of Elasticity. The slope of the initial linear portion of the stress-strain curve is the modulus of elasticity, or Young's modulus, as shown in Fig. 3. The modulus of elasticity (E) is a measure of the stiffness of the material. The greater the modulus, the smaller the elastic strain resulting from the application of a given stress. Because the modulus of elasticity is needed for computing deflections of beams and other members, it is an important design value.

The modulus of elasticity is determined by the binding forces between atoms. Because these forces cannot be changed without changing the basic nature of the material, the modulus of elasticity is one of the most structure-insensitive of the mechanical properties. Generally, it is only slightly affected by alloying additions, heat treatment, or cold work (Ref 3). However, increasing the temperature decreases the modulus of elasticity. At elevated temperatures, the modulus is often measured by a dynamic method (Ref 4). Typical values of the modulus of elasticity for common engineering metals at different temperatures are given in Table 1.

Table 1 Typical values of modulus of elasticity at different temperature

Material	Modulus of elasticity GPa (10^6 psi), at:				
	Room temperature	250 °C (400 °F)	425 °C (800 °F)	540 °C (1000 °F)	650 °C (1200 °F)
Carbon steel	207 (30.0)	186 (27.0)	155 (22.5)	134 (19.5)	124 (18.0)
Austenitic stainless steel	193 (28.0)	176 (25.5)	159 (23.0)	155 (22.5)	145 (21.0)
Titanium alloys	114 (16.5)	96.5 (14.0)	74 (10.7)	70 (10.0)	...
Aluminum alloys	72 (10.5)	65.5 (9.5)	54 (7.8)

Resilience. The ability of a material to absorb energy when deformed elastically and to return it when unloaded is called resilience. This property usually is measured by the modulus of resilience, which is the strain energy per unit volume (U_0) required to stress the material from zero stress to the yield stress (σ_0). The strain energy per unit volume for uniaxial tension is:

$$U_0 = \frac{1}{2} \sigma_x e_x \quad (\text{Eq 8})$$

From the above definition, the modulus of resilience (U_R) is:

$$U_R = \frac{1}{2} s_0 e_0 = \frac{1}{2} s_0 \frac{s_0}{E} = \frac{s_0^2}{2E} \quad (\text{Eq 9})$$

This equation indicates that the ideal material for resisting energy loads in applications where the material must not undergo permanent distortion, such as in mechanical springs, is one having a high yield stress and a low modulus of elasticity.

For various grades of steel, the modulus of resilience ranges from 100 to 4500 kJ/m³ (14.5–650 lbf · in./in.³), with the higher values representing steels with higher carbon or alloy contents (Ref 5). The cross-hatched regions in Fig. 5 indicate the modulus of resilience for two steels. Due to its higher yield strength, the high-carbon spring steel has the greater resilience.

Fig. 5 Comparison of stress-strain curves for high- and low-toughness steels. Cross-hatched regions in this curve represent the modulus of resilience (U_R) of the two materials. The U_R is determined by measuring the area under the stress-strain curve up to the elastic limit of the material. Point A represents the elastic limit of the spring steel; point B represents that of the structural steel.

The toughness of a material is its ability to absorb energy in the plastic range. The ability to withstand occasional stresses above the yield stress without fracturing is particularly desirable in parts such as freight-car couplings, gears, chains, and crane hooks. Toughness is a commonly used concept that is difficult to precisely define. Toughness may be considered to be the total area under the stress-strain curve. This area, which is referred to as the modulus of toughness (U_T) is an indication of the amount of work per unit volume that can be done on the material without causing it to rupture.

Figure 5 shows the stress-strain curves for high- and low-toughness materials. The high-carbon spring steel has a higher yield strength and tensile strength than the medium-carbon structural steel. However, the structural steel is more ductile and has a greater total elongation. The total area under the stress-strain curve is greater for the structural steel; therefore, it is a tougher material. This illustrates that toughness is a parameter that comprises both strength and ductility.

Several mathematical approximations for the area under the stress-strain curve have been suggested. For ductile metals that have a stress-strain curve like that of the structural steel, the area under the curve can be approximated by:

$$U_T \approx s_u e_f \quad (\text{Eq 10})$$

or

$$U_T \approx \frac{s_0 + s_u}{2} e_f \quad (\text{Eq 11})$$

For brittle materials, the stress-strain curve is sometimes assumed to be a parabola, and the area under the curve is given by:

$$U_T \approx \frac{2}{3} s_u e_f \quad (\text{Eq 12})$$

Typical Stress-Strain Curves. Figure 6 compares the engineering stress-strain curves in tension for three materials. The 0.8% carbon eutectoid steel is representative of a material with low ductility. The annealed 0.2% carbon mild steel shows a pronounced upper and lower yield point. The polycarbonate engineered polymer has no well-defined linear modulus, and a large strain to fracture. Note the pronounced difference in stress level at which yielding is defined, as well as the quite different shape of the stress-strain curves.

Fig. 6 Typical engineering stress-strain curves

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

True Stress-True Strain Curve

The engineering stress-strain curve does not give a true indication of the deformation characteristics of a metal because it is based entirely on the original dimensions of the specimen, and these dimensions change continuously during the test. Also, ductile metal that is pulled in tension becomes unstable and necks down during the course of the test. Because the cross-sectional area of the specimen is decreasing rapidly at this stage in the test, the load required to continue deformation falls off.

The average stress based on the original area likewise decreases, and this produces the fall-off in the engineering stress-strain curve beyond the point of maximum load. Actually, the metal continues to strain harden to fracture, so that the stress required to produce further deformation should also increase. If the true

stress, based on the actual cross-sectional area of the specimen, is used, the stress-strain curve increases continuously to fracture. If the strain measurement is also based on instantaneous measurement, the curve that is obtained is known as true stress-true strain curve. This is also known as a flow curve because it represents the basic plastic-flow characteristics of the material.

Any point on the flow curve can be considered the yield stress for a metal strained in tension by the amount shown on the curve. Thus, if the load is removed at this point and then reapplied, the material will behave elastically throughout the entire range of reloading.

The true stress (σ) is expressed in terms of engineering stress (s) by:

$$\sigma = \frac{P}{A_0}(e + 1) = s(e + 1) \quad (\text{Eq 13})$$

The derivation of Eq 13 assumes both constancy of volume and a homogeneous distribution of strain along the gage length of the tension specimen. Thus, Eq 13 should be used only until the onset of necking. Beyond the maximum load, the true stress should be determined from actual measurements of load and cross-sectional area.

$$\sigma = \frac{P}{A} \quad (\text{Eq 14})$$

The true strain, ϵ , may be determined from the engineering or conventional strain (e) by:

$$\epsilon = \ln(e + 1) = \ln \frac{L}{L_0} \quad (\text{Eq 15})$$

This equation is applicable only to the onset of necking for the reasons discussed above. Beyond maximum load, the true strain should be based on actual area or diameter (D) measurements:

$$\epsilon = \ln \frac{A_0}{A} = \ln \frac{\left(\frac{\pi}{4}\right)D_0^2}{\left(\frac{\pi}{4}\right)D^2} = 2 \ln \frac{D_0}{D} \quad (\text{Eq 16})$$

Figure 7 compares the true stress-true strain curve with its corresponding engineering stress-strain curve. Note that because of the relatively large plastic strains, the elastic region has been compressed into the y-axis. In agreement with Eq 13 and 15, the true stress-true strain curve is always to the left of the engineering curve until the maximum load is reached.

Fig. 7 Comparison of engineering and true stress-true strain curves

However, beyond maximum load, the high, localized strains in the necked region that are used in Eq 16 far exceed the engineering strain calculated from Eq 2. Frequently, the flow curve is linear from maximum load to fracture, while in other cases its slope continuously decreases to fracture. The formation of a necked region or mild notch introduces triaxial stresses that make it difficult to determine accurately the longitudinal tensile stress from the onset of necking until fracture occurs. This concept is discussed in greater detail in the section of

this article on instability in tension. The following parameters usually are determined from the true stress-true strain curve.

The true stress at maximum load corresponds to the true tensile strength. For most materials, necking begins at maximum load at a value of strain where the true stress equals the slope of the flow curve. Let σ_u and ϵ_u denote the true stress and true strain at maximum load when the cross-sectional area of the specimen is A_u . The ultimate tensile strength can be defined as:

$$s_u = \frac{P_{\max}}{A_0} \quad (\text{Eq 17})$$

and

$$\sigma_u = \frac{P_{\max}}{A_u} \quad (\text{Eq 18})$$

Eliminating P_{\max} yields:

$$\sigma_u = s_u \frac{A_0}{A_u} \quad (\text{Eq 19})$$

and

$$\sigma_u = s_u e^{\epsilon} \quad (\text{Eq 20})$$

The true fracture stress is the load at fracture divided by the cross-sectional area at fracture. This stress should be corrected for the triaxial state of stress existing in the tensile specimen at fracture. Because the data required for this correction frequently are not available, true fracture stress values are frequently in error.

The true fracture strain, ϵ_f , is the true strain based on the original area (A_0) and the area after fracture (A_f):

$$\epsilon_f = \ln \frac{A_0}{A_f} \quad (\text{Eq 21})$$

This parameter represents the maximum true strain that the material can withstand before fracture and is analogous to the total strain to fracture of the engineering stress-strain curve. Because Eq 15 is not valid beyond the onset of necking, it is not possible to calculate ϵ_f from measured values of e_f . However, for cylindrical tensile specimens, the reduction in area (q) is related to the true fracture strain by:

$$\epsilon_f = \ln \frac{1}{1 - q} \quad (\text{Eq 22})$$

The true uniform strain ϵ_u , is the true strain based only on the strain up to maximum load. It may be calculated from either the specimen cross-sectional area (A_u) or the gage length (L_u) at maximum load. Equation 15 may be used to convert conventional uniform strain to true uniform strain. The uniform strain frequently is useful in estimating the formability of metals from the results of a tension test:

$$\epsilon_u = \ln \frac{A_0}{A_u} \quad (\text{Eq 23})$$

The true local necking strain (ϵ_n) is the strain required to deform the specimen from maximum load to fracture:

$$\epsilon_n = \ln \frac{A_u}{A_f} \quad (\text{Eq 24})$$

Mathematical Expressions for the Flow Curve

The flow curve of many metals in the region of uniform plastic deformation can be expressed by the simple power curve relation:

$$\sigma = K\epsilon^n \tag{Eq 25}$$

where n is the strain-hardening exponent, and K is the strength coefficient. A log-log plot of true stress and true strain up to maximum load will result in a straight line if Eq 25 is satisfied by the data (Fig. 8).

Fig. 8 Log-log plot of true stress-true strain curve n is the strain-hardening exponent; K is the strength coefficient.

The linear slope of this line is n , and K is the true stress at $\epsilon = 1.0$ (corresponds to $q = 0.63$). As shown in Fig. 9, the strain-hardening exponent may have values from $n = 0$ (perfectly plastic solid) to $n = 1$ (elastic solid). For most metals, n has values between 0.10 and 0.50 (see Table 2).

Table 2 Values for n and K for metals at room temperature

Metals	Condition	n	K		Ref
			MPa	ksi	
0.05% carbon steel	Annealed	0.26	530	77	6
SAE 4340 steel	Annealed	0.15	641	93	6
0.6% carbon steel	Quenched and tempered at 540 °C (1000 °F)	0.10	1572	228	7
0.6% carbon steel	Quenched and tempered at 705 °C (1300 °F)	0.19	1227	178	7
Copper	Annealed	0.54	320	46.4	6
70/30 brass	Annealed	0.49	896	130	7

Fig. 9 Various forms of power curve $\sigma = K\varepsilon^n$

The rate of strain hardening $d\sigma/d\varepsilon$ is not identical to the strain-hardening exponent. From the definition of n :

$$n = \frac{d(\log \sigma)}{d(\log \varepsilon)} = \frac{d(\ln \sigma)}{d(\ln \varepsilon)} = \frac{\varepsilon}{\sigma} \frac{d\sigma}{d\varepsilon}$$

or

$$\frac{d\sigma}{d\varepsilon} = n \frac{\sigma}{\varepsilon} \quad (\text{Eq 26})$$

Deviations from Eq 25 frequently are observed, often at low strains (10^{-3}) or high strains ($\varepsilon \approx 1.0$). One common type of deviation is for a log-log plot of Eq 25 to result in two straight lines with different slopes. Sometimes data that do not plot according to Eq 25 will yield a straight line according to the relationship:

$$\sigma = K(\varepsilon_0 + \varepsilon)^n \quad (\text{Eq 27})$$

ε_0 can be considered to be the amount of strain that the material received prior to the tension test (Ref 8). Another common variation on Eq 25 is the Ludwik equation:

$$\sigma = \sigma_0 + K\varepsilon^n \quad (\text{Eq 28})$$

where σ_0 is the yield stress, and K and n are the same constants as in Eq 25. This equation may be more satisfying than Eq 25, because the latter implies that at zero true strain the stress is zero. It has been shown that σ_0 can be obtained from the intercept of the strain-hardening portion of the stress-strain curve and the elastic modulus line by (Ref 9):

$$\sigma_0 = \left(\frac{K}{E^n} \right)^{\frac{1}{1-n}} \quad (\text{Eq 29})$$

The true stress-true strain curve of metals such as austenitic stainless steel, which deviate markedly from Eq 25 at low strains (Ref 10), can be expressed by:

$$\sigma = K\varepsilon^n + e^{K_1} + e^{K_1} e^{n_1 \varepsilon} \quad (\text{Eq 30})$$

where e^{K_1} is approximately equal to the proportional limit, and n_1 is the slope of the deviation of stress from Eq 25 plotted against ε . Other expressions for the flow curve are available (Ref 11, 12). The true strain term in Eq 25 26 27 28 properly should be the plastic strain, $\varepsilon_p = \varepsilon_{\text{total}} - \varepsilon_E = \varepsilon_{\text{total}} - \sigma/E$, where ε_E represents elastic strain.

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Effect of Strain Rate and Temperature

The rate at which strain is applied to the tension specimen has an important influence on the stress-strain curve. Strain rate is defined as $\dot{\epsilon} = d\epsilon/dt$. It is expressed in units of s^{-1} . The range of strain rates encompassed by various tests is shown in Table 3.

Table 3 Range of strain rates in common mechanical property tests

Range of strain rate	Type of test
10^{-8} to $10^{-5} s^{-1}$	Creep test at constant load or stress
10^{-5} to $10^{-1} s^{-1}$	Tension test with hydraulic or screw driven machines
10^{-1} to $10^2 s^{-1}$	Dynamic tension or compression tests
10^2 to $10^4 s^{-1}$	High-speed testing using impact bars
10^4 to $10^8 s^{-1}$	Hypervelocity impact using gas guns or explosively driven projectiles

Increasing strain rate increases the flow stress. Moreover, the strain-rate dependence of strength increases with increasing temperature. The yield stress and the flow stress at lower values of plastic strain are more affected by strain rate than the tensile strength.

If the crosshead velocity of the testing machine is $v = dL/dt$, then the strain rate expressed in terms of conventional engineering strain is:

$$\dot{\epsilon} = \frac{de}{dt} = \frac{d(L - L_0) / L_0}{dt} = \frac{1}{L_0} \frac{dL}{dt} = \frac{v}{L_0} \tag{Eq 31}$$

The engineering strain rate is proportional to the crosshead velocity. In a modern testing machine, in which the crosshead velocity can be set accurately and controlled, it is a simple matter to carry out tension tests at a constant engineering strain rate.

The true strain rate is given by:

$$\dot{\epsilon} = \frac{d\epsilon}{dt} = \frac{d[\ln(L / L_0)]}{dt} = \frac{1}{L} \frac{dL}{dt} = \frac{v}{L} \tag{Eq 32}$$

Equation 32 shows that for a constant crosshead velocity the true strain rate will decrease as the specimen elongates or cross-sectional area shrinks. To run tension tests at a constant true strain rate requires monitoring the instantaneous cross section of the deforming region, with closed-loop control feed back to increase the crosshead velocity as the area decreases. The true strain rate is related to the engineering strain rate by the following equation:

$$\dot{\epsilon} = \frac{v}{L} = \frac{L_0}{L} \frac{de}{dt} = \frac{1}{1 + e} \frac{de}{dt} = \frac{\dot{\epsilon}}{1 + e} \tag{Eq 33}$$

The strain-rate dependence of flow stress at constant strain and temperature is given by:

$$\sigma = C (\dot{\epsilon})^m |_{\epsilon, T} \tag{Eq 34}$$

The exponent in Eq 34, m , is known as the strain-rate sensitivity, and C is the strain hardening coefficient. It can be obtained from the slope of a plot of $\log \sigma$ versus $\log \dot{\epsilon}$. However, a more sensitive way to determine m is with a rate-change test (Fig. 10). A tensile test is carried out at strain rate $\dot{\epsilon}_1$ and at a certain flow stress, σ_1 , the strain rate is suddenly increased to $\dot{\epsilon}_2$. The flow stress quickly increases to σ_2 . The strain-rate sensitivity, at constant strain and temperature, can be determined from:

$$m = \left(\frac{\partial \ln \sigma}{\partial \ln \dot{\epsilon}} \right)_{\epsilon, T} = \frac{\dot{\epsilon}}{\sigma} \left(\frac{\partial \sigma}{\partial \dot{\epsilon}} \right) = \frac{\Delta \log \sigma}{\Delta \log \dot{\epsilon}} \quad (\text{Eq 35})$$

$$= \frac{\log \sigma_2 - \log \sigma_1}{\log \dot{\epsilon}_2 - \log \dot{\epsilon}_1} = \frac{\log(\sigma_2 / \sigma_1)}{\log(\dot{\epsilon}_2 / \dot{\epsilon}_1)}$$

The strain-rate sensitivity of metals is quite low (<0.1) at room temperature, but m increases with temperature. At hot-working temperatures, $T/T_m > 0.5$, m values of 0.1 to 0.2 are common in metals. Polymers have much higher values of m , and may approach $m = 1$ in room-temperature tests for some polymers.

Fig. 10 Strain-rate change test, used to determine strain-rate sensitivity, m . See text for discussion

The temperature dependence of flow stress can be represented by:

$$\sigma = C_2 e^{Q/RT} \Big|_{\epsilon, \dot{\epsilon}} \quad (\text{Eq 36})$$

where Q is an activation energy for plastic flow, cal/g · mol; R is universal gas constant, 1.987 cal/K · mol; and T is testing temperature in kelvin. From Eq 36, a plot of $\ln \sigma$ versus $1/T$ will give a straight line with a slope Q/R .

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Instability in Tension

Necking generally begins at maximum load during the tensile deformation of a ductile metal. An exception to this is the behavior of cold-rolled zirconium tested at 200 to 370 °C (390–700 °F), where necking occurs at a strain of twice the strain at maximum load (Ref 13). An ideal plastic material in which no strain hardening occurs would become unstable in tension and begin to neck as soon as yielding occurred. However, an actual metal undergoes strain hardening, which tends to increase the load-carrying capacity of the specimen as deformation increases.

This effect is opposed by the gradual decrease in the cross-sectional area of the specimen as it elongates. Necking or localized deformation begins at maximum load, where the increase in stress due to decrease in the cross-sectional area of the specimen becomes greater than the increase in the load-carrying ability of the metal due to strain hardening. This condition of instability leading to localized deformation is defined by the condition $dP = 0$:

$$P = \sigma A \quad (\text{Eq 37})$$

$$dP = \sigma dA + A d\sigma = 0 \quad (\text{Eq 38})$$

From the constancy-of-volume relationship:

$$\frac{dL}{L} = -\frac{dA}{A} = d\epsilon \quad (\text{Eq 39})$$

and from the instability condition, Eq 38:

$$-\frac{dA}{A} = \frac{d\sigma}{\sigma} \quad (\text{Eq 40})$$

so that at a point of tensile instability:

$$\frac{d\sigma}{d\epsilon} = \sigma \quad (\text{Eq 41})$$

Therefore, the point of necking at maximum load can be obtained from the true stress-true strain curve by finding the point on the curve having a subtangent of unity (Fig. 11a), or the point where the rate of strain hardening equals the stress (Fig. 11b). The necking criterion can be expressed more explicitly if engineering strain is used. Starting with Eq 41:

$$\frac{d\sigma}{de} = \frac{d\sigma}{d\epsilon} \frac{de}{d\epsilon} = \frac{d\sigma}{d\epsilon} \frac{L_0}{L} = \frac{d\sigma}{d\epsilon} \frac{L}{L_0} = \frac{d\sigma}{d\epsilon} (1 + e) = \sigma \quad (\text{Eq 42})$$

$$\frac{d\sigma}{de} = \frac{\sigma}{1 + e}$$

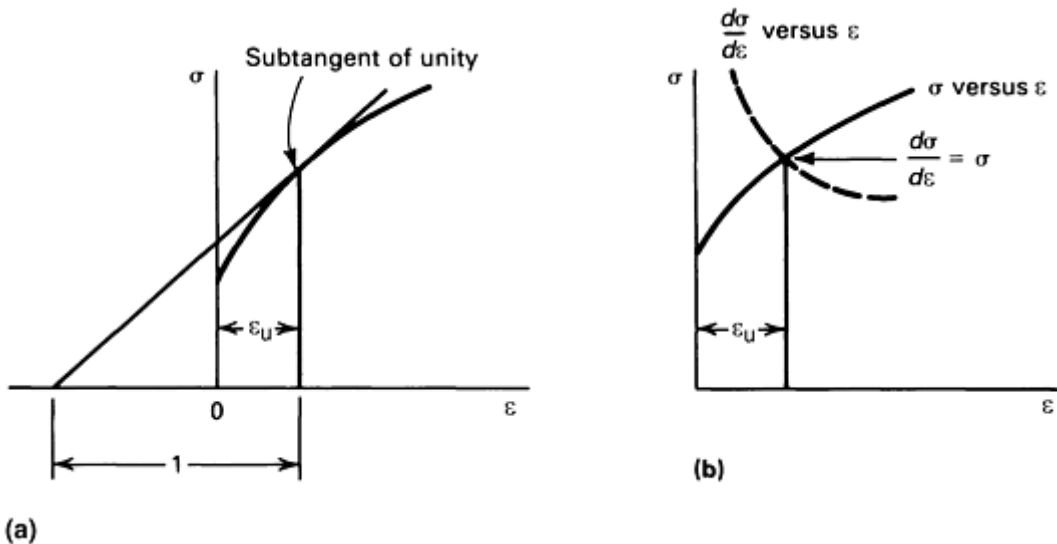

Fig. 11 Graphical interpretation of necking criterion. The point of necking at maximum load can be obtained from the true stress-true strain curve by finding (a) the point on the curve having a subtangent of unity or (b) the point where $d\sigma/d\epsilon = \sigma$.

Equation 42 permits an interesting geometrical construction for the determination of the point of maximum load (Ref 14). In Fig. 12, the stress-strain curve is plotted in terms of true stress against engineering strain. Let point A represent a negative strain of 1.0. A line drawn from point A, which is tangent to the stress-strain curve, will establish the point of maximum load because, according to Eq 42, the slope at this point is $\sigma/(1 + e)$.

Fig. 12 Considérés construction for the determination of the point of maximum load.
Source: Ref 14

By substituting the necking criterion given in Eq 41 into Eq 26, a simple relationship for the strain at which necking occurs is obtained:

$$\epsilon_u = n \quad (\text{Eq 43})$$

Although Eq 26 is based on the assumption that the flow curve is given by Eq 25, it has been shown that $\epsilon_u = n$ does not depend on this power law behavior (Ref 15).

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Stress Distribution at the Neck

The formation of a neck in the tensile specimen introduces a complex triaxial state of stress in that region. The necked region is in effect a mild notch. A notch under tension produces radial stress (σ_r) and transverse stress (σ_t) which raise the value of longitudinal stress required to cause the plastic flow. Therefore, the average true stress at the neck, which is determined by dividing the axial tensile load by the minimum cross-sectional area of the specimen at the neck, is higher than the stress that would be required to cause flow if simple tension prevailed.

Figure 13 illustrates the geometry at the necked region and the stresses developed by this localized deformation. R is the radius of curvature of the neck, which can be measured either by projecting the contour of the necked region on a screen or by using a tapered, conical radius gage.

Fig. 13 Stress distribution at the neck of a tensile specimen. (a) Geometry of necked region. R is the radius of curvature of the neck; a is the minimum radius at the neck. (b) Stresses acting on element at point O. σ_x is the stress in the axial direction; σ_r is the radial stress; σ_t is the transverse stress.

Bridgman made a mathematical analysis that provides a correction to the average axial stress to compensate for the introduction of transverse stresses (Ref 16). This analysis was based on the following assumptions:

- The contour of the neck is approximated by the arc of a circle.
- The cross section of the necked region remains circular throughout the test.
- The von Mises criterion for yielding applies.
- The strains are constant over the cross section of the neck.

According to this analysis, the uniaxial flow stress corresponding to that which would exist in the tension test if necking had not introduced triaxial stresses is:

$$\sigma = \frac{(\sigma_x)_{\text{avg}}}{\left(\frac{1+2R}{a}\right) \left[\ln \left(1 + \frac{a}{2R} \right) \right]} \quad (\text{Eq 44})$$

where $(\sigma_x)_{\text{avg}}$ is the measured stress in the axial direction (load divided by minimum cross section) and a is the minimum radius at the neck. Figure 7 shows how the application of the Bridgman correction changes the true stress-true strain curve. A correction for the triaxial stresses in the neck of a flat tensile specimen has been considered (Ref 17). The values of a/R needed for the analysis can be obtained either by straining a specimen a given amount beyond necking and unloading to measure a and R directly, or by measuring these parameters continuously past necking using photography or a tapered ring gage (Ref 18).

To avoid these measurements, Bridgman presented an empirical relation between a/R and the true strain in the neck. Figure 14 shows that this gives close agreement for steel specimens, but not for other metals with widely different necking strains. A much better correlation is obtained between the Bridgman correction and the true strain in the neck minus the true strain at necking, ϵ_u (Ref 20).

Fig. 14 Relationship between Bridgman correction factor $\sigma/(\sigma_x)_{avg}$ and true tensile strain.
Source: Ref 19

Dowling (Ref 21) has shown that the Bridgman correction factor B can be estimated from:

$$B = 0.83 - 0.186 \log \epsilon \quad (0.15 \leq \epsilon \leq 3) \quad (\text{Eq 45})$$

where $B = \sigma/(\sigma_x)_{avg}$.

Ductility Measurement in Tension Testing

The measured elongation from a tension specimen depends on the gage length of the specimen, or the dimensions of its cross section. This is because the total extension consists of two components: the uniform extension up to necking and the localized extension once necking begins. The extent of uniform extension depends on the metallurgical condition of the material (through n) and the effect of specimen size and shape on the development of the neck.

Figure 15 illustrates the variation of the local elongation, as defined in Eq 7, along the gage length of a prominently necked tensile specimen. The shorter the gage length, the greater the influence of localized deformation at the neck on the total elongation of the gage length. The extension of a specimen at fracture can be expressed by:

$$L_f - L_0 = \alpha + e_u L_0 \quad (\text{Eq 46})$$

where α is the local necking extension, and $e_u L_0$ is the uniform extension. The tensile elongation is then:

$$e_f = \frac{L_f - L_0}{L_0} = \frac{\alpha}{L_0} + e_u \quad (\text{Eq 47})$$

This clearly indicates that the total elongation is a function of the specimen gage length. The shorter the gage length, the greater the percent elongation.

Fig. 15 Variation of local elongation with position along gage length of tensile specimen

Numerous attempts have been made to rationalize the strain distribution in the tension test. Perhaps the most general conclusion that can be drawn is that geometrically similar specimens develop geometrically similar necked regions. According to Barba's law (Ref 22), $\alpha = \beta \sqrt{A_0}$, and the elongation equation becomes:

$$e_f = \beta \frac{\sqrt{A_0}}{L_0} + e_u \quad (\text{Eq 48})$$

where β is a coefficient of proportionality.

To compare elongation measurements of different sized specimens, the specimens must be geometrically similar. Equation 48 shows that the critical geometrical factor for which similitude must be maintained is $L_0/\sqrt{A_0}$ for sheet specimens, or L_0/D_0 for round bars. In the United States, the standard round tensile specimen has a 12.8 mm (0.505 in.) diameter and a 50 mm (2 in.) gage length. Subsize specimens have the following respective diameter and gage length: 9.06 and 35.6 mm (0.357 and 1.4 in.), 6.4 and 25 mm (0.252 and 1.0 in.), and 4.06 and 16.1 mm (0.160 and 0.634 in.). Different values of $L_0/\sqrt{A_0}$ are specified for sheet specimens by the standardizing agencies in different countries. In the United States, ASTM recommends a $L_0/\sqrt{A_0}$ value of 4.5 for sheet specimens and a L_0/D_0 value of 4.0 for round specimens.

Generally, a given elongation will be produced in a material if $\sqrt{A_0}/L_0$ is maintained constant as predicted by Eq 48. Thus, at a constant value of elongation $\sqrt{A_1}/L_1 = \sqrt{A_2}/L_2$, where A and L are the areas and gage lengths of two different specimens, 1 and 2, of the same metal. To predict elongation using gage length L_2 on a specimen with area A_2 by means of measurements on a specimen with area A_1 , it only is necessary to adjust the

gage length of specimen 1 to conform with $L_1 = L_2 \sqrt{A_1/A_2}$. For example, suppose that a 3.2 mm (0.125 in.) thick sheet is available, and one wishes to predict the elongation with a 50 mm (2 in.) gage length for the identical material but in 2.0 mm (0.080 in.) thickness. Using 12.7 mm (0.5 in.) wide sheet specimens, a test specimen with a gage length $L = 50 \text{ mm} (3.2 \text{ mm}/2.0 \text{ mm})^{1/2} = 63 \text{ mm}$, or 2 in. $(0.125 \text{ in.}/0.080 \text{ in.})^{1/2} = 2.5 \text{ in.}$, made from the 3.2 mm (0.125 in.) sheet would be predicted to give the same elongation as a 50 mm (2 in.) gage length in 2.0 mm (0.080 in.) thick sheet. Experimental verification for this procedure has been shown in Ref 23.

The occurrence of necking in the tension test, however, makes any quantitative conversion between elongation and reduction in area impossible. Although elongation and reduction in area usually vary in the same way—for example, as a function of test temperature, tempering temperature, or alloy content—this is not always the case. Generally, elongation and reduction in area measure different types of material behavior. Provided the gage length is not too short, percent elongation is primarily influenced by uniform elongation, and thus it is dependent on the strain-hardening capacity of the material.

Reduction in area is more a measure of the deformation required to produce fracture, and its chief contribution results from the necking process. Because of the complicated stress state in the neck, values of reduction in area are dependent on specimen geometry and deformation behavior, and they should not be taken as true material properties. However, reduction in area is the most structure-sensitive ductility parameter, and as such, it is useful in detecting quality changes in the material.

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Notch Tensile Test

Ductility measurements on standard smooth tensile specimens do not always reveal metallurgical or environmental changes that lead to reduced local ductility. The tendency for reduced ductility in the presence of a triaxial stress field and steep stress gradients (such as occur at a notch) is called notch sensitivity. A common way of evaluating notch sensitivity is a tension test using a notched specimen.

The notch tensile test has been used extensively for investigating the properties of high-strength steels, for studying hydrogen embrittlement in steels and titanium, and for investigating the notch sensitivity of high-temperature alloys. More recently, notched tension specimens have been used for fracture mechanics measurements (see the Section “Impact Toughness Testing and Fracture Mechanics” in this Volume). Notch sensitivity can also be investigated with the notched-impact test.

The most common notch tensile specimen uses a 60° notch with a root radius 0.025 mm (0.001 in.) or less introduced into a round (circumferential notch) or flat (double-edge notch) tensile specimen. Usually, the depth of the notch is such that the cross-sectional area at the root of the notch is one half of the area in the unnotched section. The specimen is aligned carefully and loaded in tension until fracture occurs. The notch strength is

defined as the maximum load divided by the original cross-sectional area at the notch. Because of the plastic constraint at the notch, this value will be higher than the tensile strength of an unnotched specimen if the material possesses some ductility. Therefore, the common way of detecting notch brittleness (or high notch sensitivity) is by determining the notch-strength ratio, NSR:

$$NSR = \frac{s_{net}(\text{for notched specimen at maximum load})}{s_u(\text{tensile strength for unnotched specimen})} \quad (\text{Eq 49})$$

If the NSR is less than unity, the material is notch brittle. The other property that is measured in the notch tensile test is the reduction in area at the notch.

As strength, hardness, or some metallurgical variable restricting plastic flow increases, the metal at the root of the notch is less able to flow, and fracture becomes more likely. Notch brittleness may be considered to begin at the strength level where the notch strength begins to fall or, more conventionally, at the strength level where the NSR becomes less than unity.

The sensitivity of notch strength for detecting metallurgical embrittlement is illustrated in Fig. 16. Note that the conventional elongation measured on a smooth specimen was unable to detect the fall in notch strength produced by tempering in the 330 to 480 °C (600–900 °F) range. For a more detailed review of notch tensile testing, see Ref 25.

Mechanical Behavior Under Tensile and Compressive Loads*

George E. Dieter, University of Maryland

Compression Test

The compression test consists of deforming a cylindrical specimen to produce a thinner cylinder of larger diameter (upsetting). The compression test is a convenient method for determining the stress-strain response of materials at large strains ($\epsilon > 0.5$) because the test is not subject to the instability of necking that occurs in a tension test. Also, it may be convenient to use the compression test because the specimen is relatively easy to make, and it does not require a large amount of material. The compression test is frequently used in conjunction with evaluating the workability of materials, especially at elevated temperature, because most deformation processes, like forging, have a high component of compressive stress. The test is also used with brittle materials, for which it is extremely difficult to machine a specimen and tensile test it in perfect alignment.

There are two inherent difficulties with the compression test that must be overcome by the test technique: buckling of the specimen and barreling of the specimen. Both conditions cause nonuniform stress and strain distributions in the specimen that make it difficult to analyze the results.

Buckling is a mode of failure characterized by an unstable lateral material deflection caused by compressive stresses. Buckling is controlled by selecting a specimen geometry with a low length-to-diameter ratio. L/D should be less than 2, and a compression specimen with $L/D = 1$ is often used. It also is important to have a very well aligned load train and to ensure that the end faces of the specimen are parallel and perpendicular to the load axis (Ref 26). Often a special alignment fixture is used with the testing machine to ensure an accurate load path (Ref 27).

Barreling is the generation of a convex surface on the exterior of a cylinder that is deformed in compression. The cross section of such a specimen is barrel shaped. Barreling is caused by the friction between the end faces of the compression specimen and the anvils that apply the load. As the cylinder decreases in height (h) it wants to increase in diameter (D) because of the volume of an incompressible material must remain constant. As

$$\frac{\pi}{4} D_1^2 h_1 = \frac{\pi}{4} D_2^2 h_2 \tag{Eq 50}$$

As the material spreads outward over the anvils, it is restrained by the friction at this interface. The material near the mid-height position is less restrained by friction and spreads laterally to the greatest extent. The material next to the anvil surfaces is restrained from spreading the most; hence, the creation of a barreled profile. This deformation pattern also leads to the development of a region of relatively undeformed materials under the anvil surfaces.

This deformation behavior clearly means that the stress state is not uniform axial compression. In addition to the axial compressive stress, a circumferential tensile stress develops as the specimen barrels (Ref 28). Because barreling increases with the specimen ratio D/h , the force to deform a compression cylinder increases with D/h (Fig. 17).

Fig. 17 Load-deformation curves for compression tests with specimens having different initial values of D/h

Calculation of Stress and Strain. The calculation of stress and strain for the compression test is based on developing a test condition that minimizes friction (and barreling) and assumes the stress state is axial compression. When friction can be neglected, the uniaxial compressive stress (flow stress) is related to the deformation force P by:

$$\sigma_f = \frac{P}{A} = \frac{4P}{\pi D^2} = \frac{4Ph_2}{\pi D_1^2 h_1} \quad (\text{Eq 51})$$

where the last term is obtained by substituting from Eq 50. In Eq 51 state 1 refers to the initial values of D and h , while state 2 refers to conditions at some subsequent value of specimen height, h . Equation 51 shows that the flow stress can be obtained directly from the load P and the instantaneous height (h_2), provided that friction can be neglected.

The true strain in the compression test is given by:

$$\epsilon = \ln\left(\frac{h_1}{h_2}\right) = 2 \ln\left(\frac{D_2}{D_1}\right) \quad (\text{Eq 52})$$

where either the displacement of the anvil or the diameter of the specimen can be used, whichever is more convenient.

Minimizing barreling of the compression specimen means minimizing friction on the ends of the specimen that are in contact with the anvils. This is done by using an effective lubricant and machining concentric rings on the end of the specimen to retain the lubricant and keep it from being squeezed out. An extensive series of tests have shown what works best (Ref 29).

Figure 18 shows the true stress-true strain curve (flow curve) for an annealed Al-2%Mg alloy. Stress and strain were calculated as described in the previous section. Note how the flow curve in compression agrees with that determined in a tensile test, and how the compressive curves extend to much larger strains because there is no specimen necking. Figure 19 extends the strain over double the range of Fig. 18. Note that once beyond $\epsilon > 0.5$ the curves begin to diverge depending on the effectiveness of the lubrication. The highest curve (greatest deviation from uniaxial stress) is for grooved anvils (platens) that dig in and prevent sidewise flow. The least friction is for the condition where a Teflon (E.I. Du Pont de Nemours & Co., Inc., Wilmington, DE) film sprayed with Molykote (Dow Corning Corporation, Midland, MI) is placed between the anvil and the specimen.

Fig. 18 Comparison of true stress-true strain curves in tension and compression (various lubricant conditions) for Al-2%Mg alloy. Curve 2, Molykote spray; curve 4, boron nitride + alcohol; curve 5, Teflon + Molykote spray; curve 8, tensile test. Source: Ref 29

Fig. 19 Flow curves for Al-2%Mg alloy tested in compression for various lubricant conditions out to $\epsilon \approx 1.0$. Curve 1, molygrease; curve 2, Molykote spray; curve 3, boron-nitride spray; curve 4, boron-nitride and alcohol; curve 5, Teflon and Molykote spray; curve 6, polished dry anvils; curve 7, grooved anvils. Source: Ref 29

Essentially no barreling occurs in room-temperature compression tests when Teflon film is placed between the anvil and the end of the specimen. Because the film will eventually tear, it is necessary to run the test incrementally, and replace the film when an electrical signal indicates that there is no longer a continuous film. Obviously, the need to run the test incrementally is inconvenient. A series of single-increment compression tests on a range of materials with strain-hardening exponents from $n = 0.08$ to 0.49 showed that lubricant conditions do not become significant until $\epsilon > 0.5$ so long as $n > 0.15$. For strains out to $\epsilon = 1.0$, a grooved specimen with molybdenum disulfide (MoS_2) grease lubricant gave consistently good results. Nearly as good results are achieved with smooth anvils and a spray coat of MoS_2 (Ref 29).

For additional details on compression testing, see the article “Uniaxial Compression Testing” in this Volume. For information on hot compression testing and other forms of the compression test, see the article “Hot Tension and Compression Testing” in this Volume.

Stress-Strain Behavior in Bending

P. Dadras, Wright State University (retired)

Introduction

A CHARACTERISTIC FEATURE of bending is the inhomogeneous (nonuniform) nature of the deformation. Therefore, in a bent specimen the strain and stress at a given point are dependent on the location of the point with respect to the neutral axis of the cross-sectional area of the specimen. In cases where the applied bending moment varies along the length of the specimen (as in three-point bending), the strains and stresses become dependent on axial location as well. Because of these inhomogeneities, a full appreciation of stress and strain distributions is of utmost importance in bending analyses and computations. Stress-strain relationships, strain curvature, and stress-moment equations are discussed in this article. The formulations are for elastic, elastic-plastic, and fully plastic bending conditions.

Stress-Strain Behavior in Bending

P. Dadras, Wright State University (retired)

Elastic Bending

Elastic analysis of bending deformation can be performed by simple-beam theory (Ref 1), elasticity solutions, and numerical methods such as the finite-difference and finite-element methods (Ref 2). Generally, numerical methods are suitable for bending of specimens that are subjected to complex loading patterns and that have irregular and/or varying cross-sectional areas. Elasticity solutions are useful when accuracies better than ~5% are desired. Simple-beam theory is used in most testing applications in which plates, strips, bars, and rods are bent in three-point or four-point bending modes. The basic assumptions of the simple-beam theory for pure elastic bending (shear force = 0) are: (a) all sections that are initially plane and perpendicular to the axis of the beam remain plane and perpendicular to it after bending; (b) all longitudinal elements (fibers) bend into concentric circular arcs (hence, cylindrical bending); and (c) a one-dimensional stress state is assumed, and the same stress-strain relationship is used for tension and compression.

The first assumption implies a linear distribution for fiber elongations and contractions, as shown in Fig. 1(a). The resulting strain distributions (Fig. 1b, c) are given by (engineering bending strain):

$$\epsilon_x = -\frac{y}{R_n} \quad (\text{Eq 1})$$

and (true bending strain):

$$\epsilon_x = \ln\left(1 - \frac{y}{R_n}\right) \quad (\text{Eq 2})$$

where R_n is the radius of curvature of the neutral axis. For $\epsilon_x \leq 0.1$, the difference between these two strain definitions is $\leq 5\%$. Therefore, for most elastic bendings, the engineering strain definition is sufficiently accurate and more convenient. As shown in Fig. 1, the true strain description indicates a nonlinear strain distribution and a maximum compressive strain in the concave inner fiber that is greater than the maximum tensile strain in the outermost fiber.

Fig. 1 Distribution of strain determined by the simple-beam theory. (a) Linear distribution for fiber elongations and contractions. (b) Distribution of engineering strain. (c) Distribution of true strain. R_n = radius of neutral axis; R_i = inner radius; R_o = outer radius

For a linear elastic material:

$$\epsilon_x = \frac{1}{E}[\sigma_x - \nu(\sigma_y + \sigma_z)] \quad (\text{Eq 3})$$

where E is the modulus of elasticity for axial loading (Young's modulus), and ν is Poisson's ratio. From the third assumption, $\sigma_y = \sigma_z = 0$. Therefore:

$$\sigma_x = -E \frac{y}{R_n} \quad (\text{Eq 4})$$

When expressions similar to Eq 3 are written for ϵ_z and ϵ_y , the following results are obtained:

$$\epsilon_z = \epsilon_y = \nu \frac{y}{R_n} \quad (\text{Eq 5})$$

Also:

$$\epsilon_{xy} = \epsilon_{yz} = \epsilon_{xz} = 0 \quad (\text{Eq 6})$$

Figure 2 illustrates grid deformations in the longitudinal and cross directions. A transverse curvature, called anticlastic curvature (Ref 3) develops with a radius of curvature equal to (R_n/ν) . Experimental evidence indicates that the actual radius of anticlastic curvature depends on $(b^2/2R_nh)$, where b is the width and $2h$ is the thickness of the beam. For $(b^2/2R_nh) \leq 1$ (i.e., narrow beams), the R_n/ν estimate is sufficiently accurate. For plates and wide beams ($b^2/2R_nh > 20$), the anticlastic deformation is primarily concentrated at the edges.

Fig. 2 Grid deformations in the longitudinal and cross directions of a beam

The location of the neutral axis, which is the line of zero fiber stress in any given section of a member subject to bending, is determined from the condition of zero axial forces acting on the beam. Therefore:

$$\int_A \sigma_x dA = -\frac{E}{R_n} \int_A y dA = 0 \quad (\text{Eq 7})$$

where A is the cross-sectional area. This equation indicates that the first moment of the cross-sectional area about the neutral axis is zero, which implies that the neutral and the central (centroidal) axes are coincident.

The moment-curvature and moment-stress relationships are found by equating the externally applied bending moment to the internal bending moment at any cross section:

$$M = -\int_A (\sigma_x dA) y \quad (\text{Eq 8})$$

where M is the bending moment.

For the linear stress distribution shown in Fig. 3, the results are:

$$R_n = \frac{E}{M} I_z \quad (\text{Eq 9})$$

and

$$\sigma_x = -\frac{My}{I_z} \quad (\text{Eq 10})$$

where I_z is the area moment of inertia of the cross section about the z axis, which is coincident on the centroidal axis.

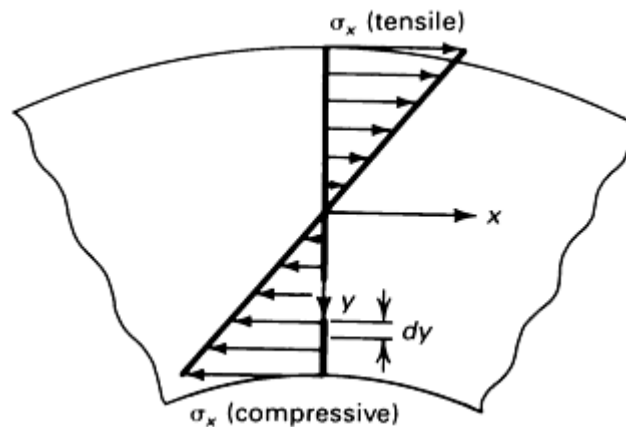

Fig. 3 Linear stress distributions in a beam

The sign (positive or negative) of the bending moment is found from the following relationship: (sign of the bending moment) = (sign of the moment vector) \times (sign of the outward normal to the section). For example, the bending moment acting on section $ABCD$ in Fig. 4 is positive, because the moment vector, \vec{M} , is in the positive z -direction (right-hand rule) and outward normal of the plane, \vec{n} , is also in the positive x -direction.

Fig. 4 Sign convention for the bending moment

Noncylindrical Bending

In the previous section it was stated that the simple beam theory considers the effect of bending moments alone (shear force = 0) and assumes a bent configuration consisting of concentric circular arcs (cylindrical bending). For cylindrical bending to occur, these conditions must be met:

- Bending must occur under the action of bending moments alone, which implies zero applied shear force.
- The cross-sectional area of the beam must possess at least one axis of symmetry.
- The vector of the applied bending moment must be in the direction of an axis of symmetry.

For asymmetrical beams such as Z-sections and unequal L-sections, the second and third conditions for cylindrical bending are not satisfied; for unsymmetrical bending of symmetrical beams, the third condition is not met. These cases are significant in structural design and will not be considered here. Information on unsymmetrical loading of straight beams can be found in Ref 2.

In a majority of testing applications such as three-point bending, roll bending, and press-brake forming, the applied bending moment varies along the length of the specimen. Because shear force $V = (dM/dx)$, such variations in the bending moment imply a nonzero shear force. Therefore, condition 1 for cylindrical bending is not met. The resulting shear-stress, τ_{xy} , which is determined from the equilibrium considerations at a typical section $m-n$ (Fig. 5a), is:

$$\text{(Eq 11)}$$

where

$$Q = \int_{A_s} y dA \quad \text{(Eq 12)}$$

is the first moment of the shaded area (A_s) with respect to the neutral axis (Fig. 5b). The first moment of the unshaded area with respect to the neutral axis gives the same Q . The distribution of τ_{xy} for a rectangular cross section is shown in Fig. 5(c).

Fig. 5 Distribution of shear stress, τ_{xy} , for a rectangular specimen. See text for details.

Stress-Strain Behavior in Bending

P. Dadras, Wright State University (retired)

Elastic-Plastic Bending

The limit for elastic bending, which is the onset of elastic-plastic bending, is reached when the maximum fiber strain $(\epsilon_x)_{\max} = (h/R_n)$ becomes equal to $9 (\sigma_y/E)$, where σ_y is the yield strength and E is Young's modulus of the material. For bending beyond this limit, the beam consists of a central elastic core and two plastically deforming zones remote from the neutral axis. For accurate analysis of elastic-plastic bending, factors such as the shift of the neutral axis from the centroidal axis and the effect of radial (transverse) stresses must be considered. Elastic-perfect plastic (Ref 4) and elastic-linear hardening (Ref 5) analyses are available. However, in view of analytical and computational difficulties, an approximate method, which is an extension of the simple-beam theory, is commonly employed. Therefore, the three assumptions stated for elastic bending will be enforced. The location of the neutral axis is assumed to be fixed at the centroidal axis, as it is for elastic bending.

For a beam with the stress-strain curve shown in Fig. 6(a), the development of longitudinal strain and stress at different stages of deformation is shown in Fig. 6(b) and 6(c), respectively. In Fig. 6(b), a linear strain distribution given by $\epsilon_x = (-y/R_n)$ was used. When the strain at the outermost fiber exceeds 0.1, it is suggested that the true strain distribution (Eq 2) be used. For bending to a radius of curvature equal to R_n , the strain distribution and the subsequent stress distribution (from the $\sigma - \epsilon$ curve or from a known constitutive equation for the $\sigma - \epsilon$ dependence) can be found. The moment, M , required to produce R_n is:

$$M = - \int_A (\sigma_x dA) y \quad (\text{Eq 13})$$

Fig. 6 Stress-strain distributions in a beam. (a) Stress-strain curve. (b) Strain distribution. (c) Stress distribution. (d) Stress distribution for elastic-perfect plastic material

The thickness of the elastic core, C (Fig. 6c), is:

$$C = 2R_n \left(\frac{\sigma_y}{E} \right) \quad (\text{Eq 14})$$

Therefore, in bending plates of the same material to the same radius of curvature R_n , the fractional thickness of the elastic core $C/2h$ becomes smaller as the thickness increases.

For elastic-plastic bending, a general equation for the relationship between R_n and M (analogous to Eq 9 for the elastic case) does not exist. For the simple case of an elastic-perfect plastic material (Fig. 6d), the following equation is obtained:

$$R_n = \frac{E}{\sigma_y} \left[3 \left(\frac{\sigma_y b h^2 - M}{b \sigma_y} \right) \right]^{1/2} \quad (\text{Eq 15})$$

The predictions of this equation at large plastic deformations ($C/2h \leq 0.02$) are not reliable.

Pure Plastic Bending

The fractional thickness of the elastic core decreases as the ratio $R_n/2h$ decreases. For $R_n/2h \leq 10$, the thickness of the elastic core in a hot rolled strip of AISI 1020 steel is $\leq 3.2\%$. In such cases it is possible to ignore the elastic core altogether and use the analysis for pure plastic bending.

Most plastic bending analyses are for sheet-type specimens in which b is much greater than $2h$. The width strain is small for such a geometry and plane-strain bending deformation ($\epsilon_z = 0$) is commonly assumed. Also, the first two assumptions of the simple-beam theory are still applied. However, the radial (transverse) stresses and strains induced by higher curvatures are considered, and a plane-in state, rather than a one-dimensional stress state (the third assumption of the simple-beam theory), is assumed. Also, the neutral axis is not fixed at the centroid, and thickness variations due to bending sometimes are incorporated into the solution. Figure 7 shows the geometry of deformation and the strain and stress states at different zones.

Fig. 7 Pure plastic bending of strip specimen. (a) Geometry of deformation. R_i = inner radius of curvature; R_o = outer radius of curvature; R_n = radius of curvature of the neutral axis; R_u = radius of currently unstretched fiber; R_c = current radius of curvature of original center fiber. (b) Strain and stress states in different zones.---, deformed state. $\epsilon_\theta = \ln r/R_n$ is the circumferential strain. (c) Stress-strain curves and stress-strain states at various locations. N = stress-strain state at R_n ; U = stress-strain state at R_u ; C = stress-strain state at R_c .

At the onset of the assumed full plastic condition, $R_c = R_n = R_u$. In the current state, the fiber with radius of curvature equal to R_n is being overtaken by the neutral axis and is experiencing unloading from a compressive tangential stress field. Accordingly, all fibers below the neutral axis $r \leq R_n$ have been progressively compressed, while those situated above R_c have been consistently stretched during deformation. All fibers in the interval R_n

$\leq r < R_c$ have been overtaken by the neutral axis. Fibers between $R_u < r < R_c$ have now been stretched beyond their original length due to reverse loading, while those located in $R_n \leq r \leq R_u$ have yet to recover their original undeformed length.

As expected, a comprehensive analysis accounting for the described fiber movements is very complicated (Ref 6). A compromise solution (Ref 7), which ignores thickness variations and assumes rigid-perfect plastic material behavior, provides useful approximations for the stress-strain distributions in plastic bending.

When a rigid-perfect plastic material model is used (Fig. 7c), the same stress-strain relationship applies to all fibers with $r \geq R_n$. As a result, the distinction among R_n , R_u , and R_c becomes inconsequential. This eliminates the complicated task of describing the behavior of fibers in reversed loading and the Bauschinger effect.

The state of stress acting on a typical element is shown in Fig. 8, where σ_θ is the circumferential (tangential) stress, and σ_r is the radial (transverse) stress. The equilibrium equation for plane strain deformation is:

$$\frac{d\sigma_r}{dr} = \frac{\sigma_\theta - \sigma_r}{r} \quad (\text{Eq 16})$$

Fig. 8 State of stress acting on a typical element in plane-strain bending

The effective or significant stress, $\bar{\sigma}$, and strain, $\bar{\epsilon}$, for plane strain deformation, using von Mises criterion, are, respectively:

$$\bar{\sigma} = \pm \frac{\sqrt{3}}{2} (\sigma_\theta - \sigma_r) \quad \begin{array}{l} (+) \text{ for } R_o \geq r \geq R_n \\ (-) \text{ for } R_n > r > R_i \end{array} \quad (\text{Eq 17})$$

and

$$\bar{\epsilon} = \frac{2}{\sqrt{3}} |\epsilon_\theta| \quad (\text{Eq 18})$$

where $\epsilon_\theta = \ln r/R_n$. Substituting $(\sigma_\theta - \sigma_r)$ from Eq 16 into Eq 15 and putting $\sigma_r = 0$ at $r = R_o$ and $r = R_i$, these equations for the distribution of σ_r are obtained:

$$\sigma_r = - \left(\frac{2\bar{\sigma}}{\sqrt{3}} \right) \ln \left(\frac{R_o}{r} \right) \quad \text{for } R_n \leq r \leq R_o \quad (\text{Eq 19})$$

$$\sigma_r = - \left(\frac{2\bar{\sigma}}{\sqrt{3}} \right) \ln \left(\frac{r}{R_i} \right) \quad \text{for } R_i \leq r \leq R_n \quad (\text{Eq 20})$$

From the expressions for σ_r and Eq 16, the following expressions for σ_θ are determined:

$$\sigma_\theta = - \left(\frac{2\bar{\sigma}}{\sqrt{3}} \right) \left[1 - \ln \left(\frac{R_o}{r} \right) \right] \quad \text{for } R_n \leq r \leq R_o \quad (\text{Eq 21})$$

$$\sigma_{\theta} = -\left(\frac{2\bar{\sigma}}{\sqrt{3}}\right)\left[1 + \ln\left(\frac{r}{R_i}\right)\right] \quad \text{for } R_i \leq r \leq R_n \quad (\text{Eq 22})$$

Because of equilibrium considerations, the radial stress must be continuous at $r = R_n$. Applying this condition to Eq 19 and 20, the location of the neutral axis can be found:

$$R_n = \sqrt{R_i R_o} \quad (\text{Eq 23})$$

Figure 9 is a schematic of the distributions of σ_r and σ_{θ} . In the figure, σ_r is continuous and compressive throughout the plate thickness, while σ_{θ} changes from tension to compression at the neutral axis. The bending moment, which according to this solution is independent of R_n , becomes:

$$M = \int_{R_i}^{R_o} (\sigma_{\theta} b dr) r = \left(\frac{2}{\sqrt{3}}\right) \bar{\sigma} b h^2 \quad (\text{Eq 24})$$

where h is half thickness, and b is the plate width.

Fig. 9 Schematic of circumferential, σ_{θ} , and radial, σ_r , stresses in a plate during bending. Source: Ref 7

The maximum radial stress occurs at the neutral axis. Its magnitude from Eq 19 and 23 is:

$$(\sigma_r)_{\max} = -\left(\frac{\bar{\sigma}}{\sqrt{3}}\right) \ln\left(\frac{R_o}{R_i}\right) \quad (\text{Eq 25})$$

The ratio between $(\sigma_r)_{\max}$ and the tangential stress at $r = R_o$ for four plates of different thicknesses, all bent to an inside radius of $R_i = 25$ mm (1 in.), is given in Table 1. This table shows that for plastic bending to $(R_n/2h) > 10$, the magnitude of $(\sigma_r)_{\max}$ becomes very small. In such cases, the effect of σ_r can be neglected in the analysis and the elastic-plastic bending solution based on the simple-beam theory can be used.

Table 1 Ratio between maximum radial stress and tangential stress for plate of various thicknesses

R_i	Thickness		$R_n / 2h$	$\sigma_r \max /$	
mm	in.	mm	in.	$(\sigma_{\theta} \text{ at } r = R_n)$	
25	1	1.59	0.0625	16.49	0.030
25	1	3.17	0.125	8.48	0.059
25	1	6.35	0.25	4.47	0.112
25	1	12.7	0.5	2.45	0.203

See text for explanation of symbols

More elaborate analyses of plastic bending (Ref 6 and 8) commonly involve complicated numerical computations. Hence, no equations can be given. A comparison between the results of the analysis in Ref 7 and a solution for rigid work-hardening material behavior (Ref 6) is shown in Fig. 10. In this case, the result from Ref 6 is for a model material with a high rate of strain hardening.

$$\bar{\sigma} = 70 + 300\bar{\epsilon}^{0.5} \text{ MPa} \quad (\text{Eq 26})$$

In using the analysis from Ref 6, $\bar{\sigma} = 120 \text{ MPa}$ (17.4 ksi), which is the approximate average flow stress for bending to $\bar{\epsilon} = 0.11$, and $\bar{\sigma} = 169.5 \text{ MPa}$ (24.6 ksi), as shown in Fig. 10(b), have been assumed. As expected, some differences in the predicted stress distributions are observed.

Fig. 10 Comparison of results for determining plastic bending in a plate. (a) Distribution of tangential and radial stresses for a 25 mm (1 in.) thick plate bent to $R_i = 100 \text{ mm}$ (4 in.). (b) Stress-strain diagrams used in the analyses for (a)

However, by using $\bar{\sigma} = 169.5 \text{ MPa}$ (24.6 ksi) in the solution from Ref 6, a close agreement (percent different < 6) between the estimates for the fiber stresses at $r = R_i$ and $r = R_o$ is obtained. Because the prediction of maximum fiber stress and strain is of special interest, the following procedure based on the solution in Ref 6 is suggested. First, find the maximum fiber strain:

$$\epsilon_o = -\epsilon_i = \ln \sqrt{\frac{R_o}{R_i}} \quad (\text{Eq 27})$$

where ϵ_o and ϵ_i represent the maximum fiber strain at the outer and inner radii, respectively. Using the stress-strain equation or stress-strain curve for the material, determine $\bar{\sigma}$ as the flow stress at ϵ_o . The maximum fiber stress is $2\bar{\sigma}/\sqrt{3}$.

Residual Stress and Springback

When a specimen that has been bent beyond the elastic limit is unloaded, the applied moment M becomes zero, and the radius of curvature increases from R_n to R'_n . For a fiber at distance y from the neutral axis, this produces a strain difference:

$$\Delta\varepsilon_x = y\left(\frac{1}{R_n} - \frac{1}{R'_n}\right) \quad (\text{Eq 28})$$

The removal of the bending moment, which is an unloading event, is assumed to be elastic. Therefore:

$$\Delta\sigma_x = E\Delta\varepsilon_x = Ey\left(\frac{1}{R_n} - \frac{1}{R'_n}\right) \quad (\text{Eq 29})$$

The change in bending moment for complete unloading is $\Delta M = M$, where M is the applied bending moment prior to unloading. Therefore:

$$\int_A \left[Ey\left(\frac{1}{R_n} - \frac{1}{R'_n}\right) dA \right] y = - \int_A (\sigma_x dA) y \quad (\text{Eq 30})$$

which reduces to

$$\frac{1}{R_n} - \frac{1}{R'_n} = - \frac{\int_A \sigma_x y dA}{EI_z} \quad (\text{Eq 31})$$

The distribution of the residual stresses can be found from either of the following equations:

$$\sigma'_x = \sigma_x + \Delta\sigma_x = \sigma_x - \left(\frac{y}{I_z}\right) \int_A \sigma_x y dA \quad (\text{Eq 32})$$

$$\sigma'_x = \sigma_x + yE\left(\frac{1}{R_n} - \frac{1}{R'_n}\right) \quad (\text{Eq 32a})$$

It is important that the correct signs for σ_x and y be used when applying these equations.

As an example, the springback and the residual stress distribution of a strip of annealed 1095 steel was examined (Ref 9). For this material, yield strength is $\sigma_y = 308$ MPa (44.7 ksi), Poisson's ratio is $\nu = 0.28$, and the approximate constitutive equation for σ in metric units of measure is:

$$\bar{\sigma} = (2 \times 10^5 \text{ MPa})\varepsilon \text{ for } \varepsilon \leq 0.00154 \quad (\text{Eq 33})$$

$$\bar{\sigma} = (896 \text{ MPa})\varepsilon^{0.16} \text{ for } \varepsilon \geq 0.00154 \quad (\text{Eq 34})$$

In English units of measure, σ is:

$$\bar{\sigma} = (29 \times 10^6 \text{ psi})\varepsilon \text{ for } \varepsilon \leq 0.00154$$

$$\bar{\sigma} = (126 \text{ ksi})\varepsilon^{0.16} \text{ for } \varepsilon \geq 0.00154$$

The width of the strip, b , is 50 mm (2 in.), and its thickness, $2h$, is 5 mm (0.2 in.). It is assumed that the strip is bent to $R_n = 100$ mm (4 in.). Because $(b/2h) = 10$, plane-strain deformation prevails. Because of this, the elastic modulus in plane-strain

$$E' = \frac{E}{1 - \nu^2} \quad (\text{Eq 35})$$

is employed, and the plastic flow stresses (Eq 34) are multiplied by $(2 / \sqrt{3})$. These approximate plane-strain adjustments are considered adequate when the simplified elastic-plastic analysis, which was discussed earlier in this article, is used. The thickness of the elastic core in metric units of measure is:

$$C = \frac{2R_n\sigma_y}{E'} = 2(100) \frac{(2 \times 308)/\sqrt{3}}{2.17 \times 10^5} \quad (\text{Eq 36})$$

$$C = 0.33 \text{ mm}$$

In English units of measure, the thickness of the elastic core is:

$$C = \frac{2R_n\sigma_y}{E'} = \frac{2(3.937) \left(2 \times \frac{44.7}{\sqrt{3}} \right)}{(31465)}$$

$$C = 0.013 \text{ in.}$$

which is 6.6% of the total plate thickness. The final radius of curvature in metric units of measure after springback is found from Eq 31:

$$\begin{aligned} \frac{1}{100} - \frac{1}{R'_n} = & - \frac{2}{El_z} \\ & \times \left[\int_0^{C/2} -2.17 \times 10^5 \left(\frac{y}{100} \right) b \, dy \right. \\ & \left. + \int_{C/2}^h - \left(\frac{2}{\sqrt{3}} \right) 869 \left(\frac{y}{100} \right)^{0.16} b y \, dy \right] \end{aligned} \quad (\text{Eq 37})$$

which results in $R'_n = 116.9 \text{ mm}$ (4.60 in.). A more elaborate analysis of springback (Ref 9) for this case predicts $R'_n/2h = 23.41$ (or $R'_n = 117.05 \text{ mm}$, or 4.608 in.). Also, for bending the same strip to $R_n = 40 \text{ mm}$ (1.6 in.) and $R_n = 500 \text{ mm}$ (19.7 in.), the final radii of curvature from Eq 31 are 42.8 mm (1.68 in.) and 1150 mm (45.3 in.), respectively. The corresponding results from Ref 9 are 42.9 mm (1.69 in.) and 1075 mm (42.3 in.). The distribution of residual stresses after bending to $R_n = 100 \text{ mm}$ (3.937 in.) is obtained from Eq 32a(a). Therefore, in this case, in metric units:

$$\sigma'_x = \sigma_x + yE(0.0014457) \quad (\text{Eq 38})$$

In English units:

$$\sigma'_x = \sigma_x + yE(0.03672)$$

At $R = R_i$, $y = h = 2.5 \text{ mm}$ (0.098 in.):

$$\varepsilon_x = -0.025$$

and

$$\sigma_x = - \left(\frac{2}{\sqrt{3}} \right) (869) (0.025)^{0.16} = -556 \text{ MPa}$$

or

$$\sigma_x = - \left(\frac{2}{\sqrt{3}} \right) (126) (0.025)^{0.16} = -80.63 \text{ ksi}$$

For this location:

$$\begin{aligned} \sigma'_x = & -556 + 2.5(2.17 \times 10^5) \\ & \times (0.0014457) = +228 \text{ MPa} \end{aligned}$$

or

$$\sigma'_x = -80.63 + 0.098 (31465)(0.03672) = +32.6 \text{ ksi}$$

Similarly, the magnitude of σ_x for other values of y can be determined. Figure 11 shows the distribution of applied and residual stresses.

Fundamental Aspects of Torsional Loading

John A. Bailey, North Carolina State University; Jamal Y. Sheikh-Ahmad, Wichita State University

Introduction

TORSION TESTS can be carried out on most materials, using standards specimens, to determine mechanical properties such as modulus of elasticity in shear, yield shear strength, ultimate shear strength, modulus of rupture in shear, and ductility. Torsion tests can also be carried out on full-size parts (shafts, axles, and twist drills) and structures (beams and frames) to determine their response to torsional loading. In torsion testing, unlike tension testing and compression testing, large strains can be applied before plastic instability occurs, and complications due to friction between the test specimen and dies do not arise.

Torsion tests are most frequently carried out on prismatic bars of circular cross section by applying a torsional moment about the longitudinal axis. The shear stress versus shear strain curve can be determined from simultaneous measurements of the torque and angle of twist of the test specimen over a predetermined gage length.

Certain shear properties of materials can also be determined by single or double direct shear tests. In these types, of tests loads are applied to bars, usually of circular section, in such a way as to produce failure (shear) on either one (single) or two (double) transverse planes perpendicular to the axis of the bar. The shear strength of the bar is determined by dividing the shear load by the cross-sectional area of the bar. Such tests provide little fundamental information on the shear properties of materials and are primarily used in the design of rivets, bolts keyway systems, and so forth, that are subjected to shearing loads in service (Ref 1) (see also the article "Shear, Torsion, and Multiaxial Testing" in this Volume).

The following sections discuss the torsional deformation of prismatic bars of circular cross section. Discussion of the torsional response of prismatic bars of noncircular cross section (rectangular, elliptical, triangular) in the elastic range can be found in Ref 2.

Fundamental Aspects of Torsional Loading

John A. Bailey, North Carolina State University; Jamal Y. Sheikh-Ahmad, Wichita State University

Prismatic Bars of Circular Cross Section

Elastic Deformation (Solid Bars). In torsional testing of prismatic bars of circular cross section it is assumed that:

- Bar material is homogeneous and isotropic.
- Twist per unit length along the bar is constant.
- Sections that are originally plane to the torsional axis remain plane after deformation.

- Initially straight radii remain straight after deformation.

Figure 1 shows the torsional deformation of a long, straight, isotropic prismatic bar of circular section. Assuming the above-mentioned constraints, the displacements are given by:

$$\begin{aligned} u_r &= 0 \\ u_z &= 0 \\ u_\theta &= rz \left(\frac{d\theta}{dz} \right) \end{aligned} \quad (\text{Eq 1})$$

where $d\theta/dz$ is the angle of twist per unit length (θ/L) and L is the gage length of the test specimen. The strains are given by:

$$\begin{aligned} \epsilon_{zz} &= 0 \\ \epsilon_{rr} &= 0 \\ \epsilon_{\theta\theta} &= 0 \\ \gamma_{zr} &= 0 \\ \gamma_{r\theta} &= 0 \\ \gamma_{z\theta} &= \frac{rd\theta}{dz} \end{aligned} \quad (\text{Eq 2})$$

For an isotropic material that obeys Hooke's law, the corresponding stress state is given by:

$$\begin{aligned} \sigma_{zz} &= 0 \\ \sigma_{rr} &= 0 \\ \sigma_{\theta\theta} &= 0 \\ \tau_{zr} &= 0 \\ \tau_{r\theta} &= 0 \\ \tau_{z\theta} &= G\gamma_{z\theta} \end{aligned} \quad (\text{Eq 3})$$

where G is the shear modulus that is related to Young's modulus (E) and Poisson's ratio (ν) by:

$$G = \frac{E}{2(1 + \nu)} \quad (\text{Eq 4})$$

The stress distribution across a prismatic bar of circular cross section is given by:

$$\tau_{z\theta} = \frac{Gr\theta}{L} \quad (\text{Eq 5})$$

Thus, the shear stress is zero at the center of the bar ($r = 0$) and increases linearly with radius. The maximum value of the shear stress occurs at the surface of the bar ($r = a$) and is given by:

$$\tau_{z\theta \text{ max}} = \frac{Ga\theta}{L} \quad (\text{Eq 6})$$

Fig. 1 Torsion of a solid circular prismatic section

The torque (T) transmitted by the elemental section shown in Fig. 1 is given by:

$$dT = (\tau_{z\theta} r) dA \quad (\text{Eq 7})$$

or

$$T = \int_0^a \tau_{z\theta} 2\pi r^2 dr \quad (\text{Eq 8})$$

Combining Eq 5 and 8 gives:

$$T = \frac{G\theta}{L} \int_0^a 2\pi r^3 dr \quad (\text{Eq 9})$$

Integration gives:

$$T = \frac{\pi a^4 G\theta}{2L} \quad (\text{Eq 10})$$

or on rearrangement:

$$\theta = \frac{TL}{GJ} \quad (\text{Eq 11})$$

where $J = \pi a^4/2$ is the polar moment of inertia of a prismatic bar of circular section about its axis of symmetry. Thus, the angle of twist can be calculated from knowledge of the applied torsional load, shear modulus, and bar geometry. Combining Eq 6 and 10 gives:

$$(\tau_{z\theta})_{\max} = \frac{2T}{\pi a^3} \quad (\text{Eq 12})$$

or

$$(\tau_{z\theta})_{\max} = \frac{Ta}{J} \quad (\text{Eq 13})$$

Thus, the maximum shear stress can be calculated from knowledge of the torsional loading and bar geometry. Plastic Deformation (Solid Bars) of Non-Work-Hardening Material. When the surface shear stress $(\tau_{z\theta})_{\max}$ of a solid bar during torsional loading reaches the yield shear stress (k) of the test material, plastic deformation (flow) occurs. The deformation zone begins at the surface of the bar and advances inward as an annulus surrounding an elastic core. The stress distributions are shown schematically in Fig. 2 for a non-work-hardening and a work-hardening material.

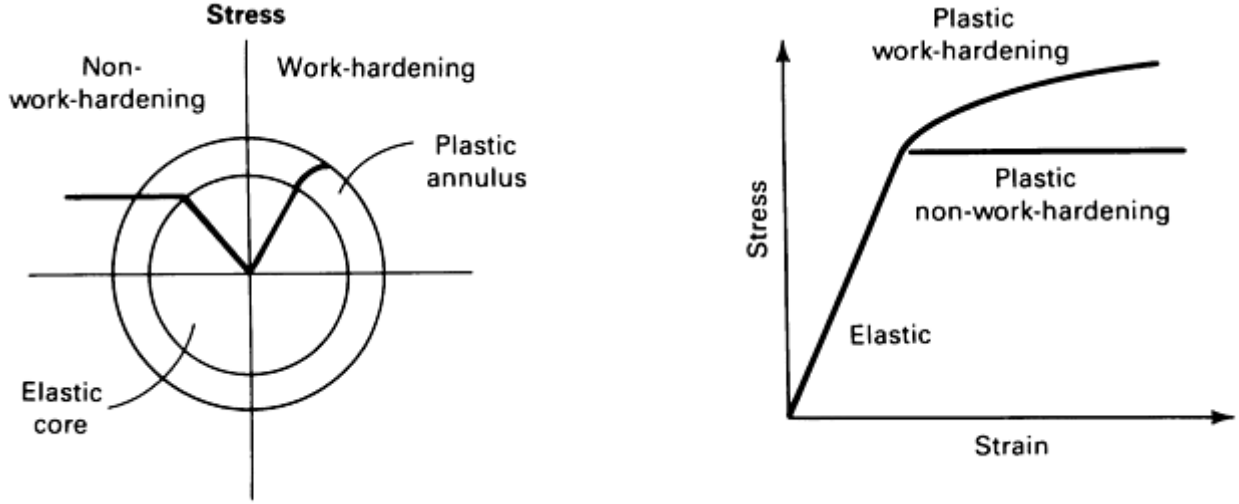

Fig. 2 Section through prismatic bar of circular section

For a non-work-hardening material, the total torque transmitted by the bar, according to Ref 3, is given by:

$$T = \int_{r=0}^{r=r_p} \tau_{z\theta} 2\pi r^2 dr + \int_{r=r_p}^{r=a} k 2\pi r^2 dr \quad (\text{Eq 14})$$

The first term on the right side of Eq 14 is the torque transmitted by the elastic core, where the shear stress varies linearly with r . The second term on the right side of Eq 14 is the torque transmitted by the plastic annulus, where the shear stress is constant and independent of r . The elastic-plastic boundary occurs at $r = r_p$. Integration of Eq 14 gives:

$$T = \frac{\pi r_p^4 G\theta}{2L} + \frac{2\pi a^3 k}{3} - \frac{2\pi r_p^3 k}{3} \quad (\text{Eq 15})$$

Compatibility at the elastic-plastic boundary requires that:

$$k = \frac{G\theta r_p}{L} \quad (\text{Eq 16})$$

Combining Eq 15 and 16 and rearranging gives:

$$T = \frac{2\pi a^3 k}{3} \left\{ 1 - \frac{1}{4} \left(\frac{r_p}{a} \right)^3 \right\} \quad (\text{Eq 17})$$

or

$$T = \frac{2\pi a^3 k}{3} \left\{ 1 - \frac{1}{4} \left(\frac{\theta_y}{\theta} \right)^3 \right\} \quad (\text{Eq 18})$$

where θ_y is the angle of twist at which yielding begins. When θ is very large compared to θ_y , then:

$$T_p = \frac{2\pi a^3 k}{3} \quad (\text{Eq 19})$$

where T_p is the torque required for fully plastic flow. Equation 18 can now be rewritten as:

$$T = T_p \left\{ 1 - \frac{1}{4} \left(\frac{\theta_y}{\theta} \right)^3 \right\} \quad (\text{Eq 20})$$

When the bar becomes fully plastic, the torque becomes independent of the angle of twist. In the elastic regime, the shear stress at the surface of the bar is given by Eq 6. In the elastic-plastic and fully plastic regimes, the shear stress at the surface of the bar is k . The shear strain at the surface of the bar is:

$$\gamma = \frac{a\theta}{L} \quad (\text{Eq 21})$$

for all regimes.

Plastic Deformation (Solid Bars) of Work-Hardening Material. In practice, most materials work harden when tested at temperatures below $0.5 T_H$, where T_H is the homologous temperature and is given by $T_H = T_T/T_M$ (where T_T is the testing temperature and T_M is the melting point temperature of the material). The result is that the torque continues to increase up to fracture.

The shear stress versus shear strain curve in the plastic range can be computed from the torque-twist curve using the procedure given below. It is important to note that the computed values of stress and strain are those that occur at the surface of the bar and that the material is insensitive to the rate of deformation.

The torque, according to Ref 3 and 4, is given by:

$$T = \int_0^a \tau 2\pi r^2 dr \quad (\text{Eq 22})$$

where the subscripts on the shear stress are dropped. Changing the variable from r to γ gives:

$$T = \int_0^{\gamma_a} \frac{\tau 2\pi\gamma^2 d\gamma}{\theta_1^3} \quad (\text{Eq 23})$$

where θ_1 is the twist per unit length. In general, the shear stress versus shear strain curve can be written as:

$$\tau = f(\gamma) \quad (\text{Eq 24})$$

Thus, Eq 24 becomes:

$$T = \int_0^{\gamma_a} \frac{2\pi f(\gamma)\gamma^2 d\gamma}{\theta_1^3} \quad (\text{Eq 25})$$

Differentiating Eq 25 with respect to θ_1 gives:

$$d(T\theta_1^3) = 2\pi f(\gamma_a) \gamma_a^2 d\gamma_a \quad (\text{Eq 26})$$

At the specimen surface:

$$\tau_a = f(\gamma_a) \quad (\text{Eq 27})$$

and

$$\gamma_a = a\theta_1 \quad (\text{Eq 28})$$

Substituting Eq 27 and 28 into Eq 26 gives:

$$d(T\theta_1^3) = 2\pi\tau_a a^3 \theta_1^2 d\theta_1$$

or

$$\frac{d(T\theta_1^3)}{d\theta_1} = 2\pi\tau_a^3 \theta_1^2 a^3 \quad (\text{Eq 29})$$

Expanding Eq 29 gives:

$$\frac{dT}{d\theta_1} \theta_1^3 + 3T\theta_1^2 = 2\pi\tau_a a^3 \theta_1^2$$

or

$$\tau_a = \frac{1}{2 \pi a^3} \left[3T + \theta_1 \frac{dT}{d\theta_1} \right] \quad (\text{Eq 30})$$

The first term on the right side of Eq 30 is the torque due to the maximum yield shear stress of τ_a in a fully plastic non-strain-hardening material, whereas the second term is a correction for strain hardening. These terms can be readily derived from the torque-twist curve shown in Fig. 3, where:

$$\begin{aligned} \frac{dT}{d\theta_1} &= \frac{BC}{CD} \\ \theta_1 &= CD \\ \theta_1 \frac{dT}{d\theta_1} &= BC \end{aligned}$$

so that:

$$\tau_a = \frac{1}{2 \pi a^3} \{ 3BA + BC \} \quad (\text{Eq 31})$$

The shear strain at the surface is given by Eq 28. Thus, the shear stress versus shear strain curve can be deduced by drawing tangents to the torque versus the angle of twist per unit length curve.

Fig. 3 Torque-twist curves

In experimental work, it has often been found that the torque (T) is related to the angle of twist per unit length by the expression:

$$T = T_0 \theta_1^n \quad (\text{Eq 32})$$

where T_0 is the torque at unit angle of twist, and n is the exponent. A graph of the logarithm of the torque (T) versus the logarithm of the angle of twist per unit length (θ_1) at constant rate of twist ($\dot{\theta}_1$) is linear and of slope n . Differentiating Eq 32 gives:

$$\left(\frac{dT}{d\theta_1} \right)_{\dot{\theta}_1} = \frac{nT}{\theta_1} \quad (\text{Eq 33})$$

Combining Eq 30 and 33 gives:

$$\tau_a = \frac{T}{2\pi a^3} [3 + n] \quad (\text{Eq 34})$$

This expression has been derived in Ref 3.

Shear stress versus shear strain curves may also be derived by the method of differential testing, where tests are carried out on two specimens of slightly different radii, a_1 and a_2 . The shear stress and shear strain are given by:

$$\tau = \frac{3(T_1 - T_2)}{2\pi(a_1^3 - a_2^3)} \quad (\text{Eq 35})$$

and

$$\gamma = \frac{(a_1 + a_2)\theta_1}{2} \quad (\text{Eq 36})$$

respectively. An excellent critical review of existing methods for converting torque to shear stress is given in Ref 5.

The stress gradient across the diameter of a solid bar allows the less highly stressed inner fibers to restrain the surface fibers from yielding. Thus, the onset of yielding is generally not apparent. This effect can be minimized by the use of thin-walled tubes, in which the stress across the tube wall can be assumed to be constant. For a thin-walled tube, the shear stress and shear strain are given by:

$$\tau = \frac{T}{2\pi a^2 t} \quad (\text{Eq 37})$$

and

$$\gamma = \frac{a\theta}{L} \quad (\text{Eq 38})$$

respectively, where a is now the mean radius of the tube, t is the thickness of the tube wall, θ is the angle of twist, and L is the specimen gage length. Thus, from measurements of the torque (T) and angle of twist (θ), it is possible to construct the shear stress (τ) versus shear strain (γ) curve directly. The dimensions of the tube must be chosen carefully to avoid buckling.

Effect of Strain Rate on Plastic Deformation. In the analysis presented in the previous section, it is inherently assumed that the shear stress is independent of strain rate. The assumption is approximately valid at low homologous temperatures, but is not valid at high homologous temperatures, where the strain-rate sensitivity of materials is usually large. A graphical procedure for accounting for strain-rate effects is presented in Ref 3 and 6.

If it is assumed that the torque is a function of both the angle of twist and the twisting rate, that is, $T = f(\theta, \dot{\theta})$, then the change in torque with respect to a change in the angle of twist is given by:

$$\frac{dT}{d\theta_1} = \left(\frac{dT}{d\theta_1} \right)_{\dot{\theta}_1} + \left(\frac{dT}{d\dot{\theta}_1} \right)_{\theta_1} \frac{\dot{\theta}_1}{\theta_1} \quad (\text{Eq 39})$$

The first term on the right-hand side of this equation has been evaluated (Eq 33). The second term can be evaluated from the experimental observation that a logarithmic graph of torque (T) versus the rate of twist ($\dot{\theta}_1$) at a constant angle of twist per unit length (θ_1) is often linear. The slope of the graph corresponds to the twist-rate sensitivity (m). Strain hardening predominates at low temperatures, whereas twist-rate sensitivity predominates at elevated temperatures.

If the effect of twist rate on torque can be expressed by:

$$T = T_1 \dot{\theta}_1^m \quad (\text{Eq 40})$$

then, at constant strain:

$$\left(\frac{dT}{d\dot{\theta}_1} \right)_{\theta_1} = \frac{mT}{\dot{\theta}_1} \quad (\text{Eq 41})$$

Substitution of Eq 33 and 41 into Eq 39 gives:

$$\frac{dT}{d\dot{\theta}_1} = \frac{T}{\theta_1} (m + n) \quad (\text{Eq 42})$$

Combining Eq 30 and 42 gives:

$$\tau_a = \frac{T}{2\pi a^3} (3 + m + n) \quad (\text{Eq 43})$$

The shear strain is again given by:

$$\gamma = a\theta_1 \quad (\text{Eq 44})$$

Equations 43 and 44 can be used to plot graphs of shear stress versus shear strain for all temperatures and strain rates up to the point of torsional instability.

A new method of converting torque to surface shear stress (Ref 5) is based on the assumption that the shear stress at radius r is affected only by the history of this particular location. The torque is given by:

$$T = \int_0^a 2\pi r \tau r^2 dr \quad (\text{Eq 45})$$

The derivative of this integral at a given angle of twist and strain rate is:

$$\frac{dT}{dr} = 2\pi \tau_a r_a^2 \quad (\text{Eq 46})$$

In this method, torque versus angle of twist curves are determined on specimens of increasing radii from which the torque versus radii relationship can be determined at a given strain (twist) and strain rate (twist rate). The slope of this curve at any given radius can be substituted into Eq 46 to determine the current shear stress at this radius. This method appears to reduce significantly the errors inherent in previous methods.

Effective Stresses and Strains

It is often helpful to convert data derived under one state of stress to another state of stress. This can be accomplished by the use of so-called effective or tensile equivalent stresses and strains. The form of the relationships from shear stresses and strains to effective stresses and strains depends on the particular yield criterion used (Ref 7).

For the distortional energy (von Mises) criterion, the effective stress and strain are given by:

$$\bar{\sigma} = C_1 [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \quad (\text{Eq 47})$$

and

$$d\bar{\epsilon} = C_2 [(d\epsilon_1 - d\epsilon_2)^2 + (d\epsilon_2 - d\epsilon_3)^2 + (d\epsilon_3 - d\epsilon_1)^2]^{1/2} \quad (\text{Eq 48})$$

respectively, where the variables have their usual significance (Ref 7). The constants C_1 and C_2 are now chosen so that the effective stresses and strains are identical to the stresses and strains in uniaxial tension (or compression). For uniaxial tension:

$$\begin{aligned} \sigma_1 &= \sigma_0 & d\epsilon_1 &= d\epsilon_1 \\ \sigma_2 &= 0 & d\epsilon_2 &= \frac{-d\epsilon_1}{2} \\ \sigma_3 &= 0 & d\epsilon_3 &= \frac{-d\epsilon_1}{2} \end{aligned} \quad (\text{Eq 49})$$

Substituting Eq 49 into Eq 47 and 48 gives:

$$C_1 = \frac{1}{\sqrt{2}}$$

and

$$C_2 = \frac{\sqrt{2}}{3}$$

Thus, the effective stresses and strains become:

$$\bar{\sigma} = \frac{1}{\sqrt{2}} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]^{1/2} \quad (\text{Eq 50})$$

and

$$d\bar{\epsilon} = \frac{\sqrt{2}}{3} [(d\epsilon_1 - d\epsilon_2)^2 + (d\epsilon_2 - d\epsilon_1)^2 + (d\epsilon_3 - d\epsilon_1)^2]^{1/2} \quad (\text{Eq 51})$$

respectively. For the state of pure shear (torsion):

$$\begin{aligned} \sigma_1 &= k & d\epsilon_1 &= \frac{d\gamma}{2} \\ \sigma_2 &= 0 & d\epsilon_2 &= 0 \\ \sigma_3 &= -k & d\epsilon_3 &= -\frac{d\gamma}{2} \end{aligned} \quad (\text{Eq 52})$$

Substitution of Eq 52 into 50 and 51 gives:

$$\bar{\sigma} = \sqrt{3}k$$

$$d\bar{\epsilon} = \frac{2}{\sqrt{3}} d\epsilon_1$$

or

$$d\bar{\epsilon} = \frac{1}{\sqrt{3}} d\gamma$$

Thus, the effective stresses and strains are related to the shear stresses and strains by the factors $\sqrt{3}$ and $1/\sqrt{3}$, respectively; that is, the shear stress versus shear strain curve can be converted to a true (tensile) stress versus strain curve by using:

$$\bar{\sigma} = \sqrt{3}\tau$$

$$\bar{\epsilon} = \frac{\gamma}{\sqrt{3}}$$

For the Tresca (maximum shear stress) criterion, the effective stresses and strains are given by:

$$\bar{\sigma} = C_3(\sigma_1 - \sigma_3) \quad (\text{Eq 53})$$

and

$$d\bar{\epsilon} = C_4(d\epsilon_1 - d\epsilon_3) \quad (\text{Eq 54})$$

respectively (Ref 7). The constants C_3 and C_4 are again chosen so that the effective stresses and strains are identical to the stresses and strains in uniaxial tension (or compression). Using the conditions defined by Eq 49 gives:

$$C_3 = 1$$

and

$$C_4 = \frac{2}{3}$$

Thus, the effective stresses and strains become:

$$\bar{\sigma} = (\sigma_1 - \sigma_3) \quad (\text{Eq 55})$$

and

$$d\bar{\epsilon} = \frac{2}{3}(d\epsilon_1 - d\epsilon_3) \quad (\text{Eq 56})$$

Substitution of Eq 52 into Eq 55 and 56 gives:

$$\bar{\sigma} = 2k$$

and

$$d\bar{\epsilon} = \frac{4}{3} d\epsilon_1$$

or

$$d\bar{\epsilon} = \frac{2}{3} d\gamma$$

Thus, the effective stresses and strains are related to the shear stresses and shear strains by the factors 2 and $\frac{2}{3}$, respectively; that is, the shear stress versus shear strain curve can be converted to a true (tensile) stress versus strain curve by using:

$$\sigma = 2\tau \quad (\text{Eq 57})$$

and

$$\bar{\epsilon} = \frac{2}{3} \gamma \quad (\text{Eq 58})$$

The work of deformation per unit volume in terms of the effective stresses is given by:

$$u = \int \bar{\sigma} d\bar{\epsilon} \quad (\text{Eq 59})$$

The work of deformation in torsion can be calculated from the expressions:

$$\bar{\sigma} = 2\tau \quad (\text{Eq 60})$$

$$d\bar{\epsilon} = \frac{2}{3} d\gamma$$

and

$$\bar{\sigma} = \sqrt{3}\tau \quad (\text{Eq 61})$$

$$d\bar{\epsilon} = \frac{d\gamma}{\sqrt{3}}$$

for the Tresca (maximum shear stress) criterion and distortional energy criterion, respectively. For the Tresca criterion, substitution of Eq 60 into Eq 59 gives:

$$u = \int 2\tau \cdot \frac{2}{3} d\gamma \quad (\text{Eq 62})$$

$$u = \int \frac{4}{3} \tau d\gamma$$

For the distortional energy criterion, substitution of Eq 61 into Eq 59 gives:

$$u = \int \sqrt{3} \tau \cdot \frac{1}{\sqrt{3}} d\gamma \quad (\text{Eq 63})$$

$$u = \int \tau d\gamma$$

It is evident that the work obtained by the Tresca criterion is too high and that the distortional energy criterion gives the correct result.

Constitutive Relationships

Application to Metalworking Analyses. In the past, numerous techniques were developed for the analysis of metalworking processes including slip-line field theory, upper and lower bound approaches, slab/disk/tube approaches, viscoplasticity theory, and the method of weighted residuals (Ref 8). These techniques are usually based on various simplifying assumptions that often severely restrict their usefulness. However, recent advances in the development of numerical methods (e.g., finite element analysis) and computational techniques have led to the evolution of new tools for the analysis and design of metalworking processes. A key feature of such tools should be their ability to calculate the influence of processing variables on forming loads, torques,

and power requirement as well as capturing a quantitative description of workpiece deformation. Inherent in performing such calculations is knowledge of the effects of strain, strain rate, and temperature on the flow stress of the work material. Such effects are described by a constitutive model that represents material behavior. Effects of Strain, Strain Rate, and Temperature on Flow Stress. There is much evidence suggesting that the torsion of hollow tubes of the appropriate dimensions (Ref 9) may be one of the better ways to obtain information on the effect of strain, strain rate, and temperature on the flow stress of materials over the range of these variables usually encountered in metalworking processes. Tests can be carried out to large strains over a wide range of temperature and at constant true strain rates. In addition, the occurrence of frictional effects (compression) and instability (tension) are absent.

The preceding sections present methods for obtaining the shear stress and shear strain from measures of the torque and angle of twist. It is also shown that the shear stresses and shear strains could be readily converted into effective stresses and strains. This section includes some simple relationships that relate the effective stress to the effective strain, effective strain rate, and temperature.

The effective stress is often related to the effective strain by the expression:

$$\bar{\sigma} = K(\bar{\epsilon})^n \quad (\text{Eq 64})$$

at constant strain rate and temperature, where K is a strength coefficient and n is the strain-hardening exponent. A plot of $\log \bar{\sigma}$ against $\log \bar{\epsilon}$ is usually linear and of slope n . The strength coefficient K is the value of the effective stress at an effective strain of unity.

The effective stress is often related to the effective strain rate by the expression:

$$\bar{\sigma} = C_1 (\dot{\bar{\epsilon}})^m \quad (\text{Eq 65})$$

at constant strain and temperature where C_1 is a strength coefficient and m is the strain-rate sensitivity. A plot of $\log \bar{\sigma}$ against $\log \dot{\bar{\epsilon}}$ is usually linear and of slope m . The strength coefficient is the value of the effective stress at an effective strain rate of unity. The combined effect of strain and strain rate on the effective stress can often be described by the expression:

$$\bar{\sigma} = A(\bar{\epsilon})^n (\dot{\bar{\epsilon}})^m \quad (\text{Eq 66})$$

at constant temperature where A is a strength coefficient. Graphical procedures based on experimental results can be used to solve for the unknown constants.

The effective stress is often related to temperature by the expression:

$$\bar{\sigma} = C_2 \exp(Q/RT) \quad (\text{Eq 67})$$

at constant strain and strain rate where C_2 is a strength coefficient, Q is the activation energy for plastic deformation, and R is the universal gas constant. A plot of $\log \bar{\sigma}$ against $1/T$ is often linear and of slope Q/R , from which Q can be calculated. The value of the flow stress depends on the dislocation structure at the time at which the flow stress is measured. However, dislocation structure may change with strain, strain rate, and temperature. One way to minimize this effect is to evaluate Q using a temperature change test. Such tests are carried out at constant strain rate and at a desired value of the plastic strain the temperature is changed from, say, T_1 to T_2 , and the new stress ($\bar{\sigma}_2$) is measured (Ref 10).

The activation energy is then given by the expression:

$$Q = R \log \left(\frac{\bar{\sigma}_1}{\bar{\sigma}_2} \right) \cdot \frac{T_1 T_2}{T_2 - T_1} \quad (\text{Eq 68})$$

The combined effect of strain rate and temperature on flow stress can often be described by the expression:

$$\bar{\sigma} = f(Z) \quad (\text{Eq 69})$$

at constant strain where Z is the Zener-Hollomon parameter and is given by the expression:

$$Z = \dot{\bar{\epsilon}} \exp(\Delta H/RT) \quad (\text{Eq 70})$$

where ΔH is an activation energy that is related to Q by the expression:

$$Q = m \Delta H \quad (\text{Eq 71})$$

In the past, Eq 69 was considered to be a mechanical equation of state. However, this is no longer regarded as being valid (Ref 10).

In torsion tests and plane strain compression tests that are carried out to large strains, it is often found that deformation occurs under steady-state conditions, and the flow stress attains a constant value, independent of further straining. Such a condition is often encountered in many hot metalworking processes. It is then found that stress, strain rate, and temperature are related by the well-known creep equation (Ref 11 and 12) that also applies to steady-state deformation:

$$\dot{\bar{\epsilon}} = A(\sinh \alpha \bar{\sigma})^{n'} \exp(-Q/RT) \quad (\text{Eq 72})$$

where α , n' , and A are constants and the remaining symbols have their usual significance. At low stress (high temperature) and high stress (low temperature), Eq 72 reduces to a power law:

$$\dot{\bar{\epsilon}} = A_1 \bar{\sigma}^{n'} \exp(-Q/RT) \quad (\text{Eq 73})$$

and an exponential law:

$$\dot{\bar{\epsilon}} = A_2 \exp(\beta \bar{\sigma}) \exp(-Q/RT) \quad (\text{Eq 74})$$

respectively. It is found for many materials that linear relationships exist between $\log_e \dot{\bar{\epsilon}}$ and $\log_e [\sinh \alpha \bar{\sigma}]$ at constant temperature and between $\log_e \dot{\bar{\epsilon}}$ and $1/T$ at constant $\sinh \alpha \bar{\sigma}$. The latter relationship enables the value of Q to be determined. An alternative and simpler method for calculating Q is to recognize that Eq 72 can be written in the form:

$$Q = 2.3R \left(\frac{\partial \log \dot{\bar{\epsilon}}}{\partial \log [\sinh \alpha \bar{\sigma}]} \right)_T \times \left(\frac{\partial \log [\sinh \alpha \bar{\sigma}]}{\partial 1/T} \right)_{\dot{\bar{\epsilon}}} \quad (\text{Eq 75})$$

or

$$Q = 2.3R(n')_T(n'')_{\dot{\bar{\epsilon}}} \quad (\text{Eq 76})$$

Linear relationships usually exist between $\log_e \dot{\bar{\epsilon}}$ and $\log_e [\sinh \alpha \bar{\sigma}]$ and between $\log_e [\sinh \alpha \bar{\sigma}]$ and $1/T$ at constant temperature and strain rate, respectively. Data over a wide range of temperature in the hot-working regime can be reduced to a single linear relationship by plotting $\log_e [\dot{\bar{\epsilon}} \exp Q/RT]$ versus $\log_e [\sinh \alpha \bar{\sigma}]$ (Ref 13).

In some practical metalworking operations, steady-state deformation may not be achieved because temperatures and plastic strains may be too low. Flow stress then depends upon strain, strain rate, and temperature. In these situations, a general constitutive relation of the form:

$$\bar{\sigma} [B \bar{\epsilon}^n] [1 + C \log_c \dot{\bar{\epsilon}} / \dot{\bar{\epsilon}}_0] f(\bar{T}) \quad (\text{Eq 77})$$

where B , n , and C are material constants has been found to be very useful (Ref 14, 15, 16). The quantity \bar{T} (dimensionless temperature) is given by the expression:

$$\bar{T} = (T_m - T) / (T_m - T_0) \quad (\text{Eq 78})$$

where T_m is the melting point temperature of the material, and $\dot{\bar{\epsilon}}_0$ and T_0 are reference strain rates and temperatures, respectively.

The first term in Eq 77 accounts for strain-hardening effects, the second term accounts for strain-rate effects, and the third term accounts for temperature effects. Linear, bilinear, and exponential forms (Ref 16) of the term $f(\bar{T})$ have been used by many investigators. The advantage of the above constitutive relationship (model) is that the effects of strain, strain rate, and temperature are uncoupled, which greatly simplifies the evaluation of the constants from experimental data.

Fundamental Aspects of Torsional Loading

John A. Bailey, North Carolina State University; Jamal Y. Sheikh-Ahmad, Wichita State University

Anisotropy in Plastic Torsion

Marked dimensional changes can occur during the torsional straining of solid bars and hollow cylinders of circular cross section (Ref 7, 9, and 17). These changes may produce either an increase or a decrease in the length of test specimens. Changes in length produced in hollow cylinders are considerably greater than those produced in solid bars because of the constraining effect of the solid core with the latter geometry. If changes in length are suppressed, then large axial stresses may be produced.

Dimensional changes have been attributed to the development of crystallographic anisotropy that arises because of a continuous change in the orientation of individual grains. This produces preferred orientation, where the yield stresses and macroscopic stress versus strain relationships vary with direction. The general observation is that the torsional deformation of solid bars and tubes produces axial extension at ambient temperatures and contraction that is often preceded by an initial period of lengthening, at elevated temperatures. Specific results, however, depend on the initial state (anisotropy) of the test material.

Theory of Anisotropy. A general phenomenological theory of anisotropy (Ref 17) proposes that the criterion describing the yield direction for anisotropic and orthotropic materials be quadratic in stress components and of the form:

$$\begin{aligned}
 2f(\sigma_{ij}) = & F(\sigma_y - \sigma_z)^2 + G(\sigma_z - \sigma_x)^2 \\
 & + H(\sigma_x - \sigma_y)^2 + 2L\tau_{yz} + 2M\tau_{zx} \\
 & + 2N\tau_{xy}
 \end{aligned}
 \tag{Eq 79}$$

where F , G , H , L , M , and N are six parameters describing the current state of anisotropy, $f(\sigma)_{ij}$ is the plastic potential, and the remaining symbols have their usual significance. The set of axes used in this criterion is assumed to be coincident with the principal axes of anisotropy. For an orthotropic material, the plastic properties at a given point are symmetric with respect to three orthogonal planes whose intersection defines the principal axes of anisotropy. It is clear that any practical application of this criterion requires prior knowledge of the principal axes of anisotropy and the numerical values of F , G , H , L , M , and N .

The basic theory of anisotropy (Ref 17) has been applied to the torsional straining of a thin-walled cylinder in an attempt to describe the changes in dimensions that occur. For a thin-walled cylinder, the radius is large compared with the wall thickness, and thus anisotropy can be considered to be uniformly distributed throughout

the volume of the material deformed. It was also assumed that the axes of anisotropy along the surface of an initially anisotropic cylinder were coincident with the directions of greatest accumulated tensile and compressive strain. These axes were also assumed to be mutually perpendicular and oriented at an angle ϕ to the transverse axis of the cylinder. This geometry is shown in Fig. 4. For an initially isotropic cylinder, the angle ϕ is a function of the shear strain (γ) and increases from $\pi/4$, approaching $\pi/2$ at large strains. This rotation is confined to the (x,y) plane about the z -axis that is perpendicular to the surface of the cylinder.

Fig. 4 Geometry of deformation for the plastic straining of a hollow cylinder. γ , shear strain; L , initial length of cylinder; OC , initial direction of greatest compression; OC' , final direction of greatest compression; OE , initial direction of greatest extension; OE' , final direction of greatest extension

From an analysis of the deformation, it was shown that the change in axial strain with shear strain is given by:

$$\frac{d\epsilon_a}{d\gamma} = \frac{(N - G - 2H) \sin \phi \sin 2\phi}{2N + (F + G + 4H - 2N) \sin^2 2\phi} - \frac{(N - F - 2H) \cos^2 \phi \sin 2\phi}{2N + (F + G + 4H - 2N) \sin^2 2\phi} \quad (\text{Eq 80})$$

It is clear from Eq 80 that measurement of the change in axial strain with shear strain is insufficient to determine the anisotropic parameters and yield stresses along the anisotropic axes and thereby insufficient to describe quantitatively the state of anisotropy. Simple expressions for the variation of the anisotropic parameters and yield stresses along the anisotropic axes with shear strain have been developed in terms of the changes in axial strain, tangential strain, principal yield shear stress, and through thickness yield stress of the hollow cylinder (Ref 18), all of which can be determined easily by experiment. It was found that the anisotropic parameters decrease and that the yield stresses along the anisotropic axes increase with an increase in strain, eventually becoming independent of strain when the test material is fully work hardened.

Montheillet and his coworkers (Ref 19, 20) modified Hill's theory of anisotropy by aligning the principal axes of anisotropy with the $\langle 100 \rangle$ directions of the ideal orientation prevailing in a polycrystal. Following the alignment, an optimization process was carried out such that the modified yield surface gives a good fit to the crystallographic yield surface of the single crystal representing the ideal orientation. The anisotropic parameters can then be determined. A direct relationship between the axial forces generated (positive, negative, zero) and the crystallographic texture developed for several materials was proposed. The sign and approximate magnitude of the effects was predicted from knowledge of the ideal orientation.

Utilizing the rate-sensitive theory of crystal plasticity based on glide modeling, a number of researchers have succeeded in developing computer models that are capable of predicting and explaining the evolution of texture and the subsequent lengthening and axial compressive stresses that develop during free-end and fixed-end twisting, respectively. A brief review of this work is given in Ref 21. Glide-modeling methods alone, however, are not capable of predicting and explaining the shortening behavior noted at elevated temperatures. A more plausible explanation of this phenomenon was provided by taking into account the occurrence of dynamic recrystallization (DRX) at elevated temperatures. In a series of recent studies (Ref 22, 23, and 24), Toth, Jonas, and coworkers were able to characterize and model the texture developed during the free-end hot torsion of

copper bars under DRX conditions. A computational method based on both glide and DRX modeling was developed. In this method, the texture is first determined by glide modeling until a critical strain is reached, at which DRX sets in. It was shown that the principal effects of DRX on texture development and the resulting free-end effect (shortening) can be predicted reasonably accurately.

The changes in length of a twisted bar during straining result in a continuous change in the specimen cross-sectional area. Thus, if the true shear stress versus shear strain curve is required, then instantaneous values of specimen dimensions must be used in computing shear stress and shear strain from the measured torque and angle of twist. Since the shear stress is proportional to r^{-3} and the shear strain is proportional to r/ℓ (Eq 12, 21), the use of initial values of r and ℓ in calculating the shear stress and shear strain curve will generate an error of 15 and 6%, respectively, if a length change of 10% took place (Ref 25). On the other hand, if the length of the specimen is held constant the developed axial stresses will range from 2 to 20% of the developed shear stress. In this case, the ratio ($\bar{\sigma}_{fx}/\bar{\sigma}$) of the effective stress in the fixed-end condition to that in the free-end condition is in the range from 1.0 to 1.01 for face-centered cubic metals, and in the range from 1.0 to 1.08 for body-centered cubic metals (Ref 19, 20).

Fundamental Aspects of Torsional Loading

John A. Bailey, North Carolina State University; Jamal Y. Sheikh-Ahmad, Wichita State University

Testing Equipment

A typical torsion testing machine consists of a drive system, a test section, torque and rotational displacement transducers, and a rigid frame. A rigid frame that is capable of allowing accurate alignment of the various torsion machine components is necessary for twisting the torsion specimen accurately around its axis with no

superimposed flexural loading. For this purpose, Culver (Ref 26) and Kobayashi (Ref 27), among others, used a lathe bed for constructing their torsion testing machine because of its high rigidity and precision-machined slides. In addition to the components mentioned above, a heating chamber with vacuum or inert gas environment is required when tests are conducted at high temperatures. A variety of torsion testing machines have been designed and built, and an excellent review of some of these machines is given in Ref 27 and 28. More information on torsion testing is also provided in the article “Shear, Torsion, and Multiaxial Testing” in this Volume.

Drive Systems. Most of the differences between existing torsion testing machines lie in the type of drive system used. The drive system is required to provide sufficient power to twist the test specimen at a constant rotational speed. Electric drive systems were used in most of the early torsion testing machines, such as the one shown in Fig. 5 (Ref 9). The electric drive system consists of an electric motor, gearbox or hydraulic reducers, a flywheel, and a clutch and brake system. The torsion machine shown here uses a 2.2 kW induction motor and a drive train consisting of two planetary gear reducers and three gear pairs and is capable of providing 24 different rotational speeds in the range from 0.0115 to 1745 rpm. A flywheel is required in this system in order to maintain approximately constant rotational speed at clutch engagement and during specimen twisting. A pneumatic disk clutch that is activated by a three-way solenoid provides quick transmission of torque from the flywheel to the test section. An inherent problem in this type of drive system is the lack of positive engagement between the drive system and the test section, which causes loss of rotational speed because of slippage, especially at high rates of twisting. This problem can be avoided to some extent by using a positive engagement mechanical “dog or ramp” clutch (Ref 26, 27) or an electromagnetic clutch (Ref 29) that allows shear strain rates of the order to 300 and 1000 s^{-1} , respectively, to be achieved.

Fig. 5 Torsion testing machine. (a) Drive section. C, coupling; F, flywheel; M electric motor; O, output shaft; P, pillow block; AG, gear pair; GP, interchangeable gear pair; PR, planetary reducer; TB, timing belt drive. (b) Test section. The use of a hydraulic drive system abolishes the need for a drive train and clutch and brake system, thus eliminating the inherent problems associated with these components. A typical hydraulic drive system consists of a hydraulic motor (Ref 30) or a hydraulic rotary actuator (Ref 31), a source of hydraulic power in the form of pressurized oil, and servocontrollers for controlling the flow of oil by means of servovalves. The torque in the

hydraulic drive system is provided by the pressurized oil as it pushes against a set of rotary vanes. The advantage of this system is that it can be accurately controlled in a closed-loop arrangement so that the prescribed loading history can be obtained. Because angular displacement in a rotary actuator system is limited to a fraction of a revolution, special torsion specimen designs with a short gage length and a large gage diameter are required to achieve high values of shear strain and strain rate.

The test section in most torsion testing machines consists of a pair of grips for attaching both ends of the specimen to the torsion machine and a furnace for heating the specimen. One end of the test specimen is attached to the output side of the loading train. The other end of the specimen is rigidly mounted to the torque and axial force transducers. Grips are usually designed in such a way as to eliminate the relative motion between the test specimen and the testing machine. The grips shown in Fig. 6 utilize a chuck-type design with three moving jaws. When the test is conducted at elevated temperatures, special care must be taken to reduce the conduction of heat from the specimen to the drive train and the load cells. This is usually done by constructing a cooling water jacket around the grips. In addition, the grip design shown in Fig. 6 uses a thick ceramic disk as a thermal insulator.

Fig. 6 Detailed view of a torsion test specimen holder with a three-jaw chuck

It is known that torsional straining of metals induces axial stresses when the testing is conducted under fixed-end conditions (i.e., specimen ends are constrained axially). Similarly, when testing is conducted under free-end conditions (i.e., one end of the specimen is allowed to move axially), the specimen undergoes lengthening or shortening depending on the workpiece material and testing temperature. These axial effects are inherent in torsion testing because they are associated with texture development and evolution in the workpiece material, as discussed in the previous section. Therefore, it is necessary when conducting a torsion test to monitor these changes and account for their effects when determining the effective stress-strain relationships from experimental data. Conducting a test under free-end conditions is more difficult than under fixed-end conditions because of the difficulties in designing grips or fixtures that allow both a rigid reaction to the torsional load applied and a true free movement axially. In the torsion machine discussed previously, a linear bearing mechanism was used to ensure free-end movement of the specimen. This mechanism is shown in Fig. 7. It consists of three case-hardened steel shafts press fitted 120° apart in the free end of the specimen holder. The three shafts slide freely inside three pairs of linear bearings press fitted 120° apart in the fixed end of the holder. A linear differential transformer is used to continuously monitor the relative motion between the free end and fixed end of the linear bearing mechanism.

Fig. 7 Detailed view of a linear bearing mechanism used to ensure free-end movement of the specimen in torsion testing

Load and Displacement Transducers. It was shown previously that knowledge of the applied torque and rotational displacement are sufficient to calculate the state of shear stress and shear strain based on specimen geometry. It is of interest, therefore, to measure both the applied torque and rotation continuously during the torsion test. It is also necessary to monitor the axial force induced by fixed-end testing or the change in specimen length induced in free-end testing. The measurement of axial and torsional loads are performed using various types of reaction-load transducers that utilize foil strain gages as the load-sensing element. These load cells are conveniently mounted at the fixed end of the torsion machine. Rotational displacement is measured electrically using a variable resistor or a differential capacitor or optically using photoelectric devices in combination with a perforated disk or an optically encoded shaft. The torsion machine uses a perforated disk with 120 holes equally spaced around its circumference. A photo transistor detects the holes and sends an electric pulse to the control panel for conditioning and amplification. The output signal is recorded simultaneously with the torque signal generated by the load cell using a chart recorder or a storage oscilloscope.

Torsion Specimens. A wide range of specimen sizes and geometries have been used in the past, and a standard size or geometry has not been agreed upon. A good survey of various specimen designs used in torsion testing is given in Ref 27. A typical torsion specimen is composed of a uniform cylindrical gage section, two shoulders for clamping into the machine grips, and two fillets to connect the gage section to the shoulders. Solid and hollow gage sections have been used. Thin-walled specimens that have a hollow gage section and a wall thickness that is a small fraction of the radius of the section offer the possibility of homogeneous stress and strain states in the gage section. However, because of their tendency toward torsional buckling, solid specimens are preferred over hollow specimens for large deformation studies. The problem of torsional buckling in thin-walled specimens can be suppressed, to some extent, by shortening the gage length. The range of ratios of gage length to gage radius (l/r) for specimens reported in the literature varies from 0.67 to 8 (Ref 28). A small length-to-radius ratio is preferred because it provides an increase in the maximum shear strain and shear strain rate for a given rotational displacement and rotational speed, respectively.

In torsion specimen design, care must be taken to maintain uniform plastic deformation throughout the gage section. This can be achieved by maintaining a truly uniform cross section, proper polishing of the outside surface to eliminate stress raisers such as scratches, and by providing properly sized fillets. In addition, bulky shoulders as compared with the gage section will help to constrain the plastic deformation in the gage section. White (Ref 32) performed an analysis of the plastic deformation in a thin-walled specimen using the finite element method. He reported that plastic deformation extends into the transition region between the gage section and the grips. The fraction of the total torsional displacement that is experienced by the gage section was determined. Knowledge of this factor allows for the correct evaluation of shear strain in the gage section. Khoddam and coworkers (Ref 33) studied the effect of plastic deformation outside the gage section on the analysis of shear stress and shear strain. They suggested that an effective gage length be used in the calculation

of stress and strain, instead of the actual length. For a power law constitutive equation, the effective length was found to be a function of specimen geometry and the coefficients in the constitutive equation.

Another factor that may affect the uniformity of deformation during twisting is the temperature rise in the gage section that is caused by plastic deformation. At high rates of deformation, and especially for materials with low thermal conductivity, the temperature rise may lead to localized flow and shear banding (Ref 34, 35, and 36). The temperature distribution in torsion specimens can be determined numerically as described in previous work. Once the temperature distribution in the gage section is known, the effect of temperature on flow stress can be determined (Ref 36). Zhou and Clode (Ref 37) used the finite element method to study the effect of specimen design on temperature rise in the gage section of an aluminum specimen. Their work showed the effect of temperature rise can be minimized by proper specimen design, but it cannot be totally eliminated.

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Introduction

THE TENSION TEST is one of the most commonly used tests for evaluating materials. In its simplest form, the tension test is accomplished by gripping opposite ends of a test item within the load frame of a test machine. A tensile force is applied by the machine, resulting in the gradual elongation and eventual fracture of the test item. During this process, force-extension data, a quantitative measure of how the test item deforms under the applied tensile force, usually are monitored and recorded. When properly conducted, the tension test provides force-extension data that can quantify several important mechanical properties of a material. These mechanical properties determined from tension tests include, but are not limited to, the following:

- Elastic deformation properties, such as the modulus of elasticity (Young's modulus) and Poisson's ratio
- Yield strength and ultimate tensile strength
- Ductility properties, such as elongation and reduction in area
- Strain-hardening characteristics

These material characteristics from tension tests are used for quality control in production, for ranking performance of structural materials, for evaluation of newly developed alloys, and for dealing with the static-strength requirements of design.

The basic principle of the tension test is quite simple, but numerous variables affect results. General sources of variation in mechanical-test results include several factors involving materials, namely, methodology, human factors, equipment, and ambient conditions, as shown in the "fish-bone" diagram in Fig. 1. This article

discusses the methodology of the tension test and the effect of some of the variables on the tensile properties determined. The following methodology and variables are discussed:

- Shape of the item being tested
- Method of gripping the item
- Method of applying the force
- Determination of strength properties other than the maximum force required to fracture the test item
- Ductility properties to be determined
- Speed of force application or speed of elongation (e.g., control of stress rate or strain rate)
- Test temperature

The main focus of this article is on the methodology of tension tests as it applies to metallic materials. Factors associated with test machines and their method of force application are described in more detail in the article “Testing Machines and Strain Sensors” in this Volume.

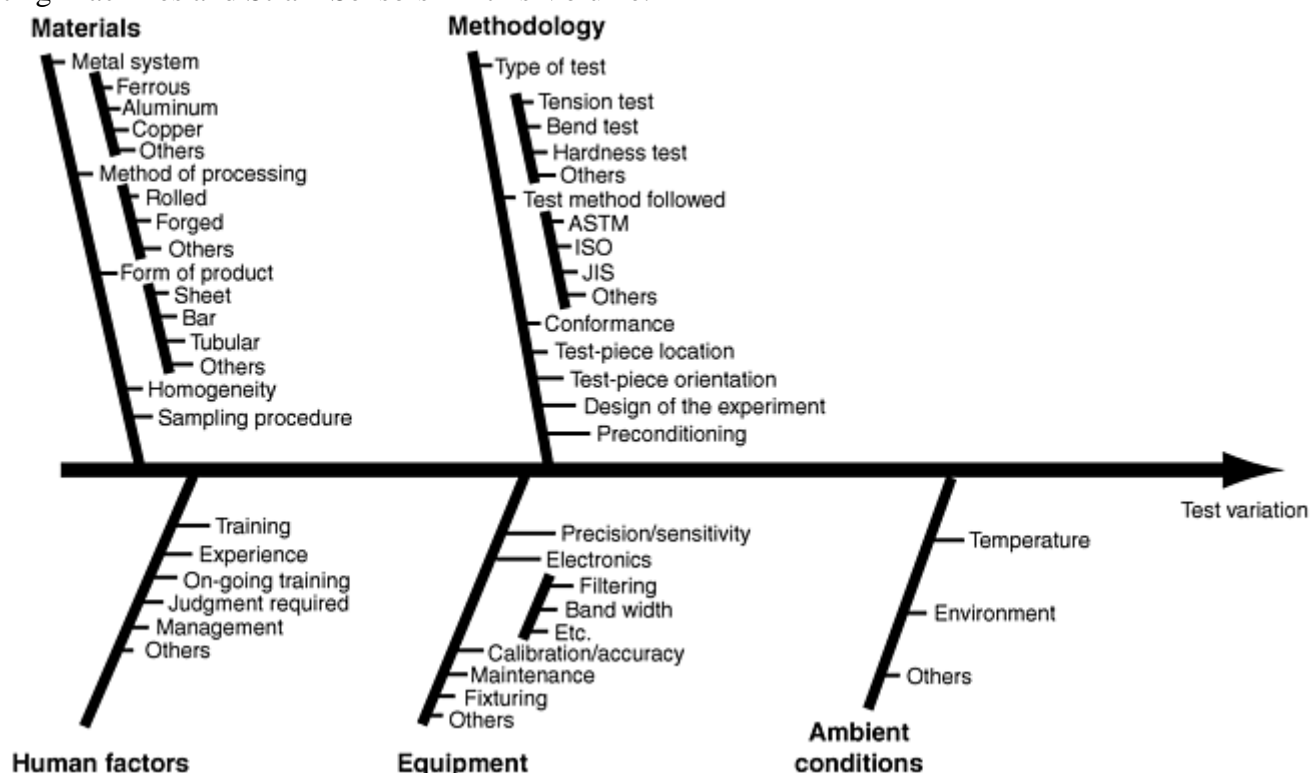

Fig. 1 “Fish-bone” diagram of sources of variability in mechanical-test results

This article does not address the tension testing of nonmetallic materials, such as plastics, elastomers, or ceramics. Although uniaxial tension testing is used in the mechanical evaluation of these materials, other test methods often are used for mechanical-property evaluation. The general concept of tensile properties is very similar for these nonmetallic materials, but there are also some very important differences in their behavior and the required test procedures for these materials:

- *Tension-test results for plastics* depend more strongly on the strain rate because plastics are viscoelastic materials that exhibit time-dependent deformation (i.e., creep) during force application. Plastics are also more sensitive to temperature than metals. Thus, control of strain rates and temperature are more critical with plastics, and sometimes tension tests are run at more than one strain and/or temperature. The ASTM standard for tension testing of plastics is D 638.
- *Tension testing of ceramics* requires more attention to alignment and gripping of the test piece* in the test machine because ceramics are brittle materials that are extremely sensitive to bending strains and because the hard surface of ceramics reduces the effectiveness of frictional gripping devices. The need for a large gripping areas thus requires the use of larger test pieces (Ref 1). The ASTM standard for tension testing of monolithic ceramics at room temperature is C 1275. The standard for continuous fiber-reinforced advanced ceramics at ambient temperatures is C 1273.

- *Tension testing of elastomers* is described in ASTM D 412 with specific instructions about test-piece preparation, equipment, and test conditions. Tensile properties of elastomers vary widely, depending on the particular formulation, and scatter both within and between laboratories is appreciable compared with the scatter of tensile-test results of metals (Ref 2). The use of tensile-test results of elastomers is limited principally to comparison of compound formulations.

Footnote

* The term “test piece” is used in this article for what is often called a “specimen” (see “The Test Piece” in this article).

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Definitions and Terminology

The basic results of a tension test and other mechanical tests are quantities of stress and strain that are measured. These basic terms and their units are briefly defined here, along with discussions of basic stress-strain behavior and the differences between related terms, such as stress and force and strain and elongation.

Load (or force) typically refers to the force acting on a body. However, there is currently an effort within the technical community to replace the word load with the more precise term *force*, which has a distinct meaning for any type of force applied to a body. Load applies, in a strict sense, only to the gravitational force that acts on a mass. Nonetheless, the two terms are often used interchangeably.

Force is usually expressed in units of pounds-force, lbf, in the English system. In the metric system, force is expressed in units of newtons (N), where one newton is the force required to give a 1 kg mass an acceleration of 1 m/s^2 ($1 \text{ N} = 1 \text{ kgm/s}^2$). Although newtons are the preferred metric unit, force is also expressed as kilogram force, kgf, which is the gravitational force on a 1 kg mass on the surface of the earth. The numerical conversions between the various units of force are as follows:

- $1 \text{ lbf} = 4.448222 \text{ N}$ or $1 \text{ N} = 0.2248089 \text{ lbf}$
- $1 \text{ kgf} = 9.80665 \text{ N}$

In some engineering disciplines, such as civil engineering, the quantity of 1000 lbf is also expressed in units of kip, such that $1 \text{ kip} = 1000 \text{ lbf}$.

Stress is simply the amount of force that acts over a given cross-sectional area. Thus, stress is expressed in units of force per area units and is obtained by dividing the applied force by the cross-sectional area over which it acts. Stress is an important quantity because it allows strength comparison between tests conducted using test pieces of different sizes and/or shapes. When discussing strength values in terms of force, the load (force) carrying capacity of a test piece is a function of the size of the test piece. However, when material strength is defined in terms of stress, the size or shape of the test piece has little or no influence on stress measurements of strength (provided the cross section contains at least 10 to 15 metallurgical grains).

Stress is typically denoted by either the Greek symbol sigma, σ , or by s , unless a distinction is being made between true stress and nominal (engineering) stress as discussed in this article. The units of stress are typically lbf/in.² (psi) or thousands of psi (ksi) in the English system and a pascal (Pa) in the metric system. Engineering stresses in metric units are also expressed in terms of newtons per area (i.e., N/m² or N/mm²) or as kilopascals (kPa) and megapascals (MPa). Conversions between these various units of stress are as follows:

- 1 Pa = 1.45×10^{-4} psi
- 1 Pa = 1 N/m²
- 1 kPa = 10³ Pa or 1 kPa = 0.145 psi
- 1 MPa = 10⁶ Pa or 1 MPa = 0.145 ksi
- 1 N/mm² = 1 MPa

Strain and elongation are similar terms that define the amount of deformation from a given amount of applied stress. In general terms, strain is defined (by ASTM E 28) as “the change per unit length due to force in an original linear dimension.” The phrase *change per unit length* means that a change in length, ΔL , is expressed as a ratio of the original length, L_0 . This change in length can be expressed in general terms as a strain or as elongation of gage length, as described subsequently in the context of a tension test.

Strain is a general term that can be expressed mathematically, either as engineering strain or as true strain. Nominal (or engineering) strain is often represented by the letter e , and logarithmic (or true) strain is often represented by the Greek letter ε . The equation for engineering strain, e , is based on the nominal change in length, (ΔL) where:

$$e = \Delta L/L_0 = (L - L_0)/L_0$$

The equation for true strain, ε , is based on the instantaneous change in length (dl) where:

$$\varepsilon = \int_{L_0}^L \frac{dl}{l} = \ln\left(\frac{L}{L_0}\right)$$

These two basic expressions for strain are interrelated, such that:

$$\varepsilon = \ln(1 + e)$$

In a tension test, the typical measure of strain is engineering strain, e , and the units are inches per inch (or millimeter per millimeter and so on). Often, however, no units are shown because strain is the ratio of length in a given measuring system.

This article refers to only engineering strain unless otherwise specified. In a tension test, true strain is based on the change in the cross-sectional area of the test piece as it is loaded. It is not further discussed herein, but a detailed discussion is found in the article “Mechanical Behavior under Tensile and Compressive Loads” in this Volume.

Elongation is a term that describes the amount that the test-piece stretches during a tension test. This stretching or elongation can be defined either as the total amount of stretch, ΔL , that a part undergoes or the increase in gage length per the initial gage length, L_0 .

The latter definition is synonymous with the meaning of engineering strain, $\Delta L/L_0$, while the first definition is the total amount of extension. Because two definitions are possible, it is imperative that the exact meaning of elongation be understood each time it is used.

This article uses the term elongation, e , to mean nominal or engineering strain (i.e., $e = \Delta L/L_0$). The amount of stretch is expressed as extension, or the symbol ΔL . In many cases, elongation, e , is also reported as a percentage change in gage length as a measure of ductility (i.e., percent elongation), $(\Delta L/L_0) \times 100$.

Engineering Stress and True Stress. Along with the previous descriptions of engineering strain and true strain, it is also possible to define stress in two different ways as engineering stress and true stress. As is intuitive, when a tensile force stretches a test piece, the cross-sectional area must decrease (because the overall volume of the test piece remains essentially constant). Hence, because the cross section of the test piece becomes smaller during a test, the value of stress depends on whether it is calculated based on the area of the unloaded test piece (the initial area) or on the area resulting from that applied force (the instantaneous area). Thus, in this context, there are two ways to define stress:

- *Engineering stress, s* : The force at any time during the test divided by the initial area of the test piece; $s = F/A_0$ where F is the force, and A_0 is the initial cross section of a test piece.
- *True stress, σ* : The force at any time divided by the instantaneous area of the test piece; $\sigma = F/A_i$ where F is the force, and A_i is the instantaneous cross section of a test piece.

Because an increasing force stretches a test piece, thus decreasing its cross-sectional area, the value of true stress will always be greater than the nominal, or engineering, stress.

These two definitions of stress are further related to one another in terms of the strain that occurs when the deformation is assumed to occur at a constant volume (as it frequently is). As previously noted, strain can be expressed as either engineering strain (e) or true strain, where the two expressions of strain are related as $\epsilon = \ln(1 + e)$. When the test-piece volume is constant during deformation (i.e., $A_i L_i = A_0 L_0$), then the instantaneous cross section, A_i , is related to the initial cross section, A_0 , where

$$A = A_0 \exp \{-\epsilon\}$$

$$= A_0 / (1 + e)$$

If these expressions for instantaneous and initial cross sections are divided into the applied force to obtain values of true stress (at the instantaneous cross section, A_i) and engineering stress (at the initial cross section, A_0), then:

$$\sigma = s \exp \{\epsilon\} = s (1 + e)$$

Typically, engineering stress is more commonly considered during uniaxial tension tests. All discussions in this article are based on nominal engineering stress and strain unless otherwise noted. More detailed discussions on true stress and true strain are in the article “Mechanical Behavior under Tensile and Compressive Loads” in this Volume.

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Stress-Strain Behavior

During a tension test, the force applied to the test piece and the amount of elongation of the test piece are measured simultaneously. The applied force is measured by the test machine or by accessory force-measuring devices. The amount of stretching (or extension) can be measured with an extensometer. An extensometer is a device used to measure the amount of stretch that occurs in a test piece. Because the amount of elastic stretch is quite small at or around the onset of yielding (in the order of 0.5% or less for steels), some manner of magnifying the stretch is required. An extensometer may be a mechanical device, in which case the magnification occurs by mechanical means. An extensometer may also be an electrical device, in which case the magnification may occur by mechanical means, electrical means, or by a combination of both. Extensometers generally have fixed gage lengths. If an extensometer is used only to obtain a portion of the stress-strain curve sufficient to determine the yield properties, the gage length of the extensometer may be shorter than the gage length required for the elongation-at-fracture measurement. It may also be longer, but in general, the extensometer gage length should not exceed approximately 85 to 90% of the length of the reduced section or of the distance between the grips for test pieces without reduced sections. This ratio for some of the most common test configurations with a 2 in. gage length and $2\frac{1}{4}$ in. reduced section is 0.875%.

The applied force, F , and the extension, ΔL , are measured and recorded simultaneously at regular intervals, and the data pairs can be converted into a stress-strain diagram as shown in Fig. 2. The conversion from force-extension data to stress-strain properties is shown schematically in Fig. 2(a). Engineering stress, s , is obtained by dividing the applied force by the original cross-sectional area, A_0 , of the test piece, and strain, e , is obtained by dividing the amount of extension, ΔL , by the original gage length, L . The basic result is a stress-strain curve

(Fig. 2b) with regions of elastic deformation and permanent (plastic) deformation at stresses greater than those of the elastic limit (EL in Fig. 2b).

Fig. 2 Stress-strain behavior in the region of the elastic limit. (a) Definition of σ and ϵ in terms of initial test piece length, L , and cross-sectional area, A_0 , before application of a tensile force, F . (b) Stress-strain curve for small strains near the elastic limit (EL)

Typical stress-strain curves for three types of steels, aluminum alloys, and plastics are shown in Fig. 3 (Ref 3). Stress-strain curves for some structural steels are shown in Fig. 4(a) (Ref 4) for elastic conditions and for small amounts of plastic deformation. The general shape of the stress-strain curves can be described for deformation in this region. However, as plastic deformation occurs, it is more difficult to generalize about the shape of the stress-strain curve. Figure 4(b) shows the curves of Fig. 4(a) continued to fracture.

Elastic deformation occurs in the initial portion of a stress-strain curve, where the stress-strain relationship is initially linear. In this region, the stress is proportional to strain. Mechanical behavior in this region of stress-strain curve is defined by a basic physical property called the modulus of elasticity (often abbreviated as E). The modulus of elasticity is the slope of the stress-strain line in this linear region, and it is a basic physical property of all materials. It essentially represents the spring constant of a material.

The modulus of elasticity is also called Hooke's modulus or Young's modulus after the scientists who discovered and extensively studied the elastic behavior of materials. The behavior was first discovered in the late 1600s by the English scientist Robert Hooke. He observed that a given force would always cause a repeatable, elastic deformation in all materials. He further discovered that there was a force above which the deformation was no longer elastic; that is, the material would not return to its original length after release of the force. This limiting force is called the elastic limit (EL in Fig. 2b). Later, in the early 1800s, Thomas Young, an English physicist, further investigated and described this elastic phenomenon, and so his name is associated with it.

The proportional limit (PL) is a point in the elastic region where the linear relationship between stress and strain begins to break down. At some point in the stress-strain curve (PL in Fig. 2b), linearity ceases, and small increase in stress causes a proportionally larger increase in strain. This point is referred to as the proportional limit (PL) because up to this point, the stress and strain are proportional. If an applied force below the PL point

is removed, the trace of the stress and strain points returns along the original line. If the force is reapplied, the trace of the stress and strain points increases along the original line. (When an exception to this linearity is observed, it usually is due to mechanical hysteresis in the extensometer, the force indicating system, the recording system, or a combination of all three.)

The elastic limit (EL) is a very important property when performing a tension test. If the applied stresses are below the elastic limit, then the test can be stopped, the test piece unloaded, and the test restarted without damaging the test piece or adversely affecting the test results. For example, if it is observed that the extensometer is not recording, the force-elongation curve shows an increasing force, but no elongation. If the force has not exceeded the elastic limit, the test piece can be unloaded, adjustments made, and the test restarted without affecting the results of the test. However, if the test piece has been stressed above the EL, plastic deformation (set) will have occurred (Fig. 2b), and there will be a permanent change in the stress-strain behavior of the test piece in subsequent tension (or compression) tests.

The PL and the EL are considered identical in most practical instances. In theory, however, the EL is considered to be slightly higher than the PL, as illustrated in Fig. 2b. The measured values of EL or PL are highly dependent on the magnification and sensitivity of the extensometer used to measure the extension of the test piece. In addition, the measurement of PL and EL also highly depends on the care with which a test is performed.

Plastic Deformation (Set) from Stresses above the Elastic Limit. If a test piece is stressed (or loaded) and then unloaded, any retest proceeds along the unloading path whether or not the elastic limit was exceeded. For example, if the initial stress is less than the elastic limit, the load-unload-reload paths are identical. However, if a test piece is stressed in tension beyond the elastic limit, then the unload path is offset and parallel to the original loading path (Fig. 2b). Moreover, any subsequent tension measurements will follow the previous unload path parallel to the original stress-strain line. Thus, the application and removal of stresses above the elastic limit affect all subsequent stress-strain measurements.

The term *set* refers to the permanent deformation that occurs when stresses exceed the elastic limit (Fig. 2b). ASTM E 6 defines set as the strain remaining after the complete release of a load-producing deformation. Because set is permanent deformation, it affects subsequent stress-strain measurements whether the reloading occurs in tension or compression. Likewise, permanent set also affects all subsequent tests if the initial loading exceeds the elastic limit in compression. Discussions of these two situations follow.

Reloading after Exceeding the Elastic Limit in Tension. If a test piece is initially loaded in tension beyond the elastic limit and then unloaded, the unload path is parallel to the initial load path but offset by the set; on reloading in tension, the unloading path will be followed. Figure 5 illustrates a series of stress-strain curves obtained using a machined round test piece of steel. (The strain axis is not to scale.) In this figure, the test piece was loaded first to Point A and unloaded. The area of the test piece was again determined (A_2) and reloaded to Point B and unloaded. The area of the test piece was determined for a third time (A_3) and reloaded until fracture occurred. Because during each loading the stresses at Points A and B were in excess of the elastic limit, plastic deformation occurred. As the test piece is elongated in this series of tests, the cross-sectional area must decrease because the volume of the test piece must remain constant. Therefore, $A_1 > A_2 > A_3$.

Fig. 5 Effects of prior tensile loading on tensile stress-strain behavior. Solid line, stress-strain curve based on dimensions of unstrained test piece (unloaded and reloaded twice); dotted line, stress-strain curve based on dimensions of test piece after first unloading; dashed line, stress-strain curve based on dimensions of test piece after second unloading. Note: Graph is not to scale.

The curve with a solid line in Fig. 5 is obtained for engineering stresses calculated using the applied forces divided by the original cross-sectional area. The curve with a dotted line is obtained from stresses calculated using the applied forces divided by the cross-sectional area, A_2 , with the origin of this stress-strain curve located on the abscissa at the end point of the first unloading line. The curve represented by the dashed line is obtained from the stresses calculated using the applied forces divided by the cross-sectional area, A_3 , with the origin of this stress-strain curve located on the abscissa at the end point of the second unloading line. This figure illustrates what happens if a test is stopped, unloaded, and restarted. It also illustrates one of the problems that can occur when testing pieces from material that has been formed into a part (or otherwise plastically strained before testing). An example is a test piece that was machined from a failed structure to determine the tensile properties. If the test piece is from a location that was subjected to tensile deformation during the failure, the properties obtained are probably not representative of the original properties of the material.

Bauschinger Effect. The other loading condition occurs when the test piece is initially loaded in compression beyond the elastic limit and then unloaded. The unload path is parallel to the initial load path but offset by the set; on reloading in tension, the elastic limit is much lower, and the shape of the stress-strain curve is significantly different. The same phenomenon occurs if the initial loading is in tension and the subsequent loading is in compression. This condition is called the Bauschinger effect, named for the German scientist who first described it around 1860. Again, the significance of this phenomenon is that if a test piece is machined from a location that has been subjected to plastic deformation, the stress-strain properties will be significantly different than if the material had not been so strained. This occurrence is illustrated in Fig. 6, where a machined round steel test piece was first loaded in tension to about 1% strain, unloaded, loaded in compression to about 1% strain, unloaded, and reloaded in tension. For this steel, the initial portion of tension and compression stress-strain curves are essentially identical.

Fig. 6 Example of the Bauschinger effect and hysteresis loop in tension-compression-tension loading. This example shows initial tension loading to 1% strain, followed by compression loading to 1% strain, and then a second tension loading to 1% strain.

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Properties from Test Results

A number of tensile properties can be determined from the stress-strain diagram. Two of these properties, the tensile strength and the yield strength, are described in the next section of this article, “Strength Properties.” In addition, total elongation (ASTM E 6), yield-point elongation (ASTM E 6), Young's modulus (ASTM E 111), and the strain-hardening exponent (ASTM E 646) are sometimes determined from the stress-strain diagram. Other tensile properties include the following:

- Poisson's ratio (ASTM E 132)
- Plastic-strain ratio (ASTM E 517)
- Elongation by manual methods (ASTM E 8)

- Reduction of area

These properties require more information than just the data pairs generating a stress-strain curve. None of these four properties can be determined from a stress-strain diagram.

Strength Properties

Tensile strength and yield strength are the most common strength properties determined in a tension test. According to ASTM E 6, tensile strength is calculated from the maximum force during a tension test that is carried to rupture divided by the original cross-sectional area of the test piece. By this definition, it is a stress value, although some product specifications define the tensile strength as the force (load) sustaining ability of the product without consideration of the cross-sectional area. Fastener specifications, for example, often refer to tensile strength as the applied force (load-carrying) capacity of a part with specific dimensions.

The yield strength refers to the stress at which a small, but measurable, amount of inelastic or plastic deformation occurs. There are three common definitions of yield strength:

- Offset yield strength
- Extension-under-load (EUL) yield strength
- Upper yield strength (or upper yield point)

An upper yield strength (upper yield point) (Fig. 7a) usually occurs with low-carbon steels and some other metal systems to a limited degree. Often, the pronounced peak of the upper yield is suppressed due to slow testing speed or nonaxial loading (i.e., bending of the test piece), metallurgical factors, or a combination of these; in this case, a curve of the type shown in Fig. 7(b) is obtained. The other two definitions of yield strength, EUL and offset, were developed for materials that do not exhibit the yield-point behavior shown in Fig. 7. Stress-strain curves without a yield point are illustrated in Fig. 4(a) for USS Con-Pac 80 and USS T-1 steels. To determine either the EUL or the offset yield strength, the stress-strain curve must be determined during the test. In computer-controlled testing systems, this curve is often stored in memory and may not be charted or displayed.

(a)

(b)

Fig. 7 Examples of stress-strain curves exhibiting pronounced yield-point behavior. Pronounced yielding, of the type shown, is usually called yield-point elongation (YPE). (a) Classic example of upper-yield-strength (UYS) behavior typically observed in low-carbon steels with a very pronounced upper yield strength. (b) General example of pronounced yielding without an upper yield strength. LYS, lower yield strength

Upper yield strength (or upper yield point) can be defined as the stress at which measurable strain occurs without an increase in the stress; that is, there is a horizontal region of the stress-strain curve (Fig. 7) where discontinuous yielding occurs. Before the onset of discontinuous yielding, a peak of maximum stress for yielding is typically observed (Fig. 7a). This pronounced yielding, of the type shown, is usually called yield-point elongation (YPE). This elongation is a diffusion-related phenomenon, where under certain combinations of strain rate and temperature as the material deforms, interstitial atoms are dragged along with dislocations, or dislocations can alternately break away and be repinned, with little or no increase in stress. Either or both of these actions cause serrations or discontinuous changes in a stress-strain curve, which are usually limited to the onset of yielding. This type of yield point is sometimes referred to as the upper yield strength or upper yield point. This type of yield point is usually associated with low-carbon steels, although other metal systems may exhibit yield points to some degree. For example, the stress-strain curves for A36 and USS Tri-Ten steels shown in Fig. 4(a) exhibit this behavior.

The yield point is easy to measure because the increase in strain that occurs without an increase in stress is visually apparent during the conduct of the test by observing the force-indicating system. As shown in Fig. 7,

the yield point is usually quite obvious and thus can easily be determined by observation during a tension test. It can be determined from a stress-strain curve or by the halt of the dial when the test is performed on machines that use a dial to indicate the applied force. However, when watching the movement of the dial, sometimes a minimum value, recorded during discontinuous yielding, is noted. This value is sometimes referred to as the lower yield point. When the value is ascertained without instrumentation readouts, it is often referred to as the halt-of-dial or the drop-of-beam yield point (as an average usually results from eye readings). It is almost always the upper yield point that is determined from instrument readouts.

Extension-under-load (EUL) yield strength is the stress at which a specified amount of stretch has taken place in the test piece. The EUL is determined by the use of one of the following types of apparatus:

- Autographic devices that secure stress-strain data, followed by an analysis of this data (graphically or using automated methods) to determine the stress at the specified value of extension
- Devices that indicate when the specified extension occurs so that the stress at that point may be ascertained

Graphical determination is illustrated in Fig. 8. On the stress-strain curve, the specified amount of extension, $0-m$, is measured along the strain axis from the origin of the curve and a vertical line, $m-n$, is raised to intersect the stress-strain curve. The point of intersection, r , is the EUL yield strength, and the value R is read from the stress axis. Typically, for many materials, the extension specified is 0.5%; however, other values may be specified. Therefore, when reporting the EUL, the extension also must be reported. For example, yield strength (EUL = 0.5%) = 52,500 psi is a correct way to report an EUL yield strength. The value determined by the EUL method may also be termed a yield point.

Fig. 8 Method of determining yield strength by the extension-under-load method (EUL) (adaptation of Fig. 22 in ASTM E 8)

Offset yield strength is the stress that causes a specified amount of set to occur; that is, at this stress, the test piece exhibits plastic deformation (set) equal to a specific amount. To determine the offset yield strength, it is necessary to secure data (autographic or numerical) from which a stress-strain diagram may be constructed graphically or in computer memory. Figure 9 shows how to use these data; the amount of the specified offset $0-m$ is laid out on the strain axis. A line, $m-n$, parallel to the modulus of elasticity line, $0-A$, is drawn to intersect the stress-strain curve. The point of intersection, r , is the offset yield strength, and the value, R , is read from the stress axis. Typically, for many materials, the offset specified is 0.2%; however, other values may be specified. Therefore, when reporting the offset yield strength, the amount of the offset also must be reported; for example,

“0.2 % offset yield strength = 52.8 ksi” or “yield strength (0.2% offset) = 52.8 ksi” are common formats used in reporting this information.

Fig. 9 Method of determining yield strength by the offset method (adaptation of Fig. 21 in ASTM E 8)

In Fig. 8 and 9, the initial portion of the stress-strain curve is shown in ideal terms as a straight line. Unfortunately, the initial portion of the stress-strain curve sometimes does not begin as a straight line but rather has either a concave or a convex foot (Fig. 10) (Ref 5). The shape of the initial portion of a stress-strain curve may be influenced by numerous factors such as, but not limited to, the following:

- Seating of the test piece in the grips
- Straightening of a test piece that is initially bent by residual stresses or bent by coil set
- Initial speed of testing

Generally, the aberrations in this portion of the curve should be ignored when fitting a modulus line, such as that used to determine the origin of the curve. As shown in Fig. 10, a “foot correction” may be determined by fitting a line, whether by eye or by using a computer program, to the linear portion and then extending this line back to the abscissa, which becomes point 0 in Fig. 8 and 9. As a rule of thumb, Point *D* in Fig. 10 should be less than one-half the specified yield point or yield strength.

Fig. 10 Examples of stress-strain curves requiring foot correction. Point *D* is the point where the extension of the straight (elastic) part diverges from the stress-strain curve. Source: Ref 5

Tangent or Chord Moduli. For materials that do not have a linear relationship between stress and strain, even at very low stresses, the offset yield is meaningless without defining how to determine the modulus of elasticity. Often, a chord modulus or a tangent modulus is specified. A chord modulus is the slope of a chord between any two specified points on the stress-strain curve, usually below the elastic limit. A tangent modulus is the slope of the stress-strain curve at a specified value of stress or of strain. Chord and tangent moduli are illustrated in Fig. 11. Another technique that has been used is sketched in Fig. 12. The test piece is stressed to approximately the yield strength, unloaded to about 10% of this value, and reloaded. As previously discussed, the unloading line will be parallel to what would have been the initial modulus line, and the reloading line will coincide with the unloading line (assuming no hysteresis in any of the system components). The slope of this line is transferred to the initial loading line, and the offset is determined as before. The stress or strain at which the test piece is unloaded usually is not important. This technique is specified in the ISO standard for the tension test of metallic materials, ISO 6892.

Fig. 11 Stress-strain curves showing straight lines corresponding to (a) Young's modulus between stress, *P*, below proportional limit and *R*, or preload; (b) tangent modulus at any stress, *R*; and (c) chord modulus between any two stresses, *P* and *R*. Source: Ref 6

Fig. 12 Alternate technique for establishing Young's modulus for a material without an initial linear portion

Yield-strength-property values generally depend on the definition being used. As shown in Fig. 4(a) for the USS Con-Pac steel, the EUL yield is greater than the offset yield, but for the USS T-1 steel (Fig. 4a), the opposite is true. The amount of the difference between the two values is dependent upon the slope of the stress-

strain curve between the two intersections. When the stress-strain data pairs are sampled by a computer, and a yield spike or peak of the type shown in Fig. 7(a) occurs, the EUL and the offset yield strength will probably be less than the upper yield point and will probably differ because the m - n lines of Fig. 8 and 9 will intersect at different points in the region of discontinuous yielding.

Ductility

Ductility is the ability of a material to deform plastically without fracturing. Figure 13 is a sketch of a test piece with a circular cross section that has been pulled to fracture. As indicated in this sketch, the test piece elongates during the tension test and correspondingly reduces in cross-sectional area. The two measures of the ductility of a material are the amount of elongation and reduction in area that occurs during a tension test.

Fig. 13 Sketch of fractured, round tension test piece. Dashed lines show original shape. Strain = elongation/gage length

Elongation, as previously noted, is defined in ASTM E 6 as the increase in the gage length of a test piece subjected to a tension force, divided by the original gage length on the test piece. Elongation usually is expressed as a percentage of the original gage length. ASTM E 6 further indicates the following:

- The increase in gage length may be determined either at or after fracture, as specified for the material under test.
- The gage length shall be stated when reporting values of elongation.
- Elongation is affected by test-piece geometry (gage length, width, and thickness of the gage section and of adjacent regions) and test procedure variables, such as alignment and speed of pulling.

The manual measurement of elongation on a tension test piece can be done with the aid of gage marks applied to the unstrained reduced section. After the test, the amount of stretch between gage marks is measured with an appropriate device. The use of the term elongation in this instance refers to the total amount of stretch or extension. Elongation, in the sense of nominal engineering strain, e , is the value of gage extension divided by the original distance between the gage marks. Strain elongation is usually expressed as a percentage, where the nominal engineering strain is multiplied by 100 to obtain a percent value; that is:

$$e, \% = \left[\frac{(\text{final gage length} - \text{original gage length})}{\text{original gage length}} \right] \times 100$$

The final gage length at the completion of the test may be determined in two ways. Historically, it was determined manually by carefully fitting the two ends of the fractured test piece together (Fig. 13) and measuring the distance between the gage marks. However, some modern computer-controlled testing systems obtain data from an extensometer that is left on the test piece through fracture. In this case, the computer may

be programmed to report the elongation as the last strain value obtained prior to some event, perhaps the point at which the applied force drops to 90% of the maximum value recorded. There has been no general agreement about what event should be the trigger, and users and machine manufacturers find that different events may be appropriate for different materials (although some consensus has been reached, see ASTM E 8-99). The elongation values determined by these two methods are not the same; in general, the result obtained by the manual method is a couple of percent larger and is more variable because the test-piece ends do not fit together perfectly. It is strongly recommended that when disagreements arise about elongation results, agreement should be reached on which method will be used prior to any further testing.

Test methods often specify special conditions that must be followed when a product specification specifies elongation values that are small, or when the expected elongation values are small. For example, ASTM E 8 defines small as 3% or less.

Effect of Gage Length and Necking. Figure 14 (Ref 7) shows the effect of gage length on elongation values. Gage length is very important; however, as the gage length becomes quite large, the elongation tends to be independent of the gage length. The gage length must be specified prior to the test, and it must be shown in the data record for the test.

Fig. 14 Effect of gage length on the percent elongation. (a) Elongation, %, as a function of gage length for a fractured tension test piece. (b) Distribution of elongation along a fractured tension test piece. Original spacing between gage marks, 12.5 mm (0.5 in.). Source: Ref 7

Figures 13 and 14 also illustrate considerable localized deformation in the vicinity of the fracture. This region of local deformation is often called a neck, and the occurrence of this deformation is termed necking. Necking occurs as the force begins to drop after the maximum force has been reached on the stress-strain curve. Up to the point at which the maximum force occurs, the strain is uniform along the gage length; that is, the strain is independent of the gage length. However, once necking begins, the gage length becomes very important. When the gage length is short, this localized deformation becomes the principal portion of measured elongation. For long gage lengths, the localized deformation is a much smaller portion of the total. For this reason, when elongation values are reported, the gage length must also be reported, for example, elongation = 25% (50 mm, or 2.00 in., gage length).

Effect of Test-Piece Dimensions. Test-piece dimensions also have a significant effect on elongation measurements. Experimental work has verified the general applicability of the following equation:

$$e = e_0(L/A)^{1/2} - a$$

where e_0 is the specific elongation constant; $L/A^{1/2}$ the slimmness ratio, K , of gage length, L , and cross-sectional areas, A ; and a is another material constant. This equation is known as the Bertella-Oliver equation, and it may be transformed into logarithmic form and plotted as shown in Fig. 15. In one study, quadruplet sets of machined

circular test pieces (four different diameters ranging from 0.125 to 0.750 in.) and rectangular test pieces ($\frac{1}{2}$ in. wide with three thicknesses and $1\frac{1}{2}$ in. wide with three thicknesses) were machined from a single plate. Multiple gage lengths were scribed on each test piece to produce a total of 40 slinness ratios. The results of this study, for one of the grades of steel tested, are shown in Fig. 16.

Fig. 15 Graphical form of the Bertella-Oliver equation.

Fig. 16 Graphical form of the Bertella-Oliver equation showing actual data

In order to compare elongation values of test pieces with different slinness ratios, it is necessary only to determine the value of the material constant, a . This calculation can be made by testing the same material with two different geometries (or the same geometry with different gage lengths) with different slinness ratios, K_1 and K_2 , where

$$e_0 = e_1 / K_1^{-a} = e_2 / K_2^{-a}$$

solving for a , then:

$$(K_2/K_1)^{-a} = e_2/e_1$$

or:

$$-a = \frac{\ln(e_2/e_1)}{\ln(K_2/K_1)} \tag{Eq 1}$$

$$-a = \frac{\ln(e_2) - \ln(e_1)}{\ln(K_2) - \ln(K_1)} \quad (\text{Eq 2})$$

The values of the e_0 and a parameters depend on the material composition, the strength, and the material condition and are determined empirically with a best-fit line plot around data points. Reference 8 specifies “value $a = 0.4$ for carbon, carbon-manganese, molybdenum, and chromium-molybdenum steels within the tensile strength range of 275 to 585 MPa (40 to 85 ksi) and in the hot-rolled, in the hot-rolled and normalized, or in the annealed condition, with or without tempering. Materials that have been cold reduced require the use of a different value for a , and an appropriate value is not suggested.” Reference 8 uses a value of $a = 0.127$ for annealed, austenitic stainless steels. However, Ref 8 states that “these conversions shall not be used where the width-to-thickness ratio, w/t , of the test piece exceeds 20.” ISO 2566/1 (Ref 9) contains similar statements. In addition to the limit of $(w/t) < 20$, Ref 9 also specifies that the slimmness ratio shall be less than 25.

Some tension-test specifications do not contain standard test-piece geometries but require that the slimmness ratio be either 5.65 or 11.3. For a round test piece, a slimmness ratio of 5.65 produces a 5-to-1 relation between the diameter and the gage length, and a slimmness ratio of 4.51 produces a 4-to-1 relation between the diameter and gage length (which is that of the test piece in ASTM E 8).

Reduction of area is another measure of the ductility of metal. As a test piece is stretched, the cross-sectional area decreases, and as long as the stretch is uniform, the reduction of area is proportional to the amount of stretch or extension. However, once necking begins to occur, proportionality is no longer valid.

According to ASTM E 6, reduction of area is defined as “the difference between the original cross-sectional area of a tension test piece and the area of its smallest cross section.” Reduction of area is usually expressed as a percentage of the original cross-sectional area of the test piece. The smallest final cross section may be measured at or after fracture as specified for the material under test. The reduction of area (RA) is almost always expressed as a percentage:

$$\text{Ra, \%} = \left[\frac{(\text{original area} - \text{final area})}{\text{original area}} \right] \times 100$$

Reduction of area is customarily measured only on test pieces with an initial circular cross section because the shape of the reduced area remains circular or nearly circular throughout the test for such test pieces. With rectangular test pieces, in contrast, the corners prevent uniform flow from occurring, and consequently, after fracture, the shape of the reduced area is not rectangular (Fig. 17). Although a number of expressions have been used in an attempt to describe the way to determine the reduced area, none has received general agreement. Thus, if a test specification requires the measurement of the reduction of area of a test piece that is not circular, the method of determining the reduced area should be agreed prior to performing the test.

Fig. 17 Sketch of end view of rectangular test piece after fracture showing constraint at corners indicating the difficulty of determining reduced area

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

General Procedures

Numerous groups have developed standard methods for conducting the tension test. In the United States, standards published by ASTM are commonly used to define tension-test procedures and parameters. Of the various ASTM standards related to tension tests (for example, those listed in "Selected References" at the end of this article), the most common method for tension testing of metallic materials is ASTM E 8 "Standard Test Methods for Tension Testing of Metallic Materials" (or the version using metric units, ASTM E 8M). Standard methods for conducting the tension test are also available from other standards organizations, such as the Japanese Industrial Standards (JIS), the Deutsche Institut für Normung (DIN), and the International Organization for Standardization (ISO). Other domestic technical groups in the United States have developed standards, but in general, these are based on ASTM E 8.

With the increasing internationalization of trade, methods developed by other national standards organizations (such as JIS, DIN, or ISO standards) are increasingly being used in the United States. Although most tension-test standards address the same concerns, they differ in the values assigned to variables. Thus, a tension test performed in accordance with ASTM E 8 will not necessarily have been conducted in accordance with ISO 6892 or JIS Z2241, and so on, and vice versa. Therefore, it is necessary to specify the applicable testing standard for any test results or mechanical property data.

Unless specifically indicated otherwise, the values of all variables discussed hereafter are those related to ASTM E 8 "Standard Test Methods for Tension Testing of Metallic Materials." A flow diagram of the steps involved when a tension test is conducted in accordance with ASTM E 8 is shown in Fig. 18. The test consists of three distinct parts:

- Test-piece preparation, geometry, and material condition
- Test setup and equipment
- Test

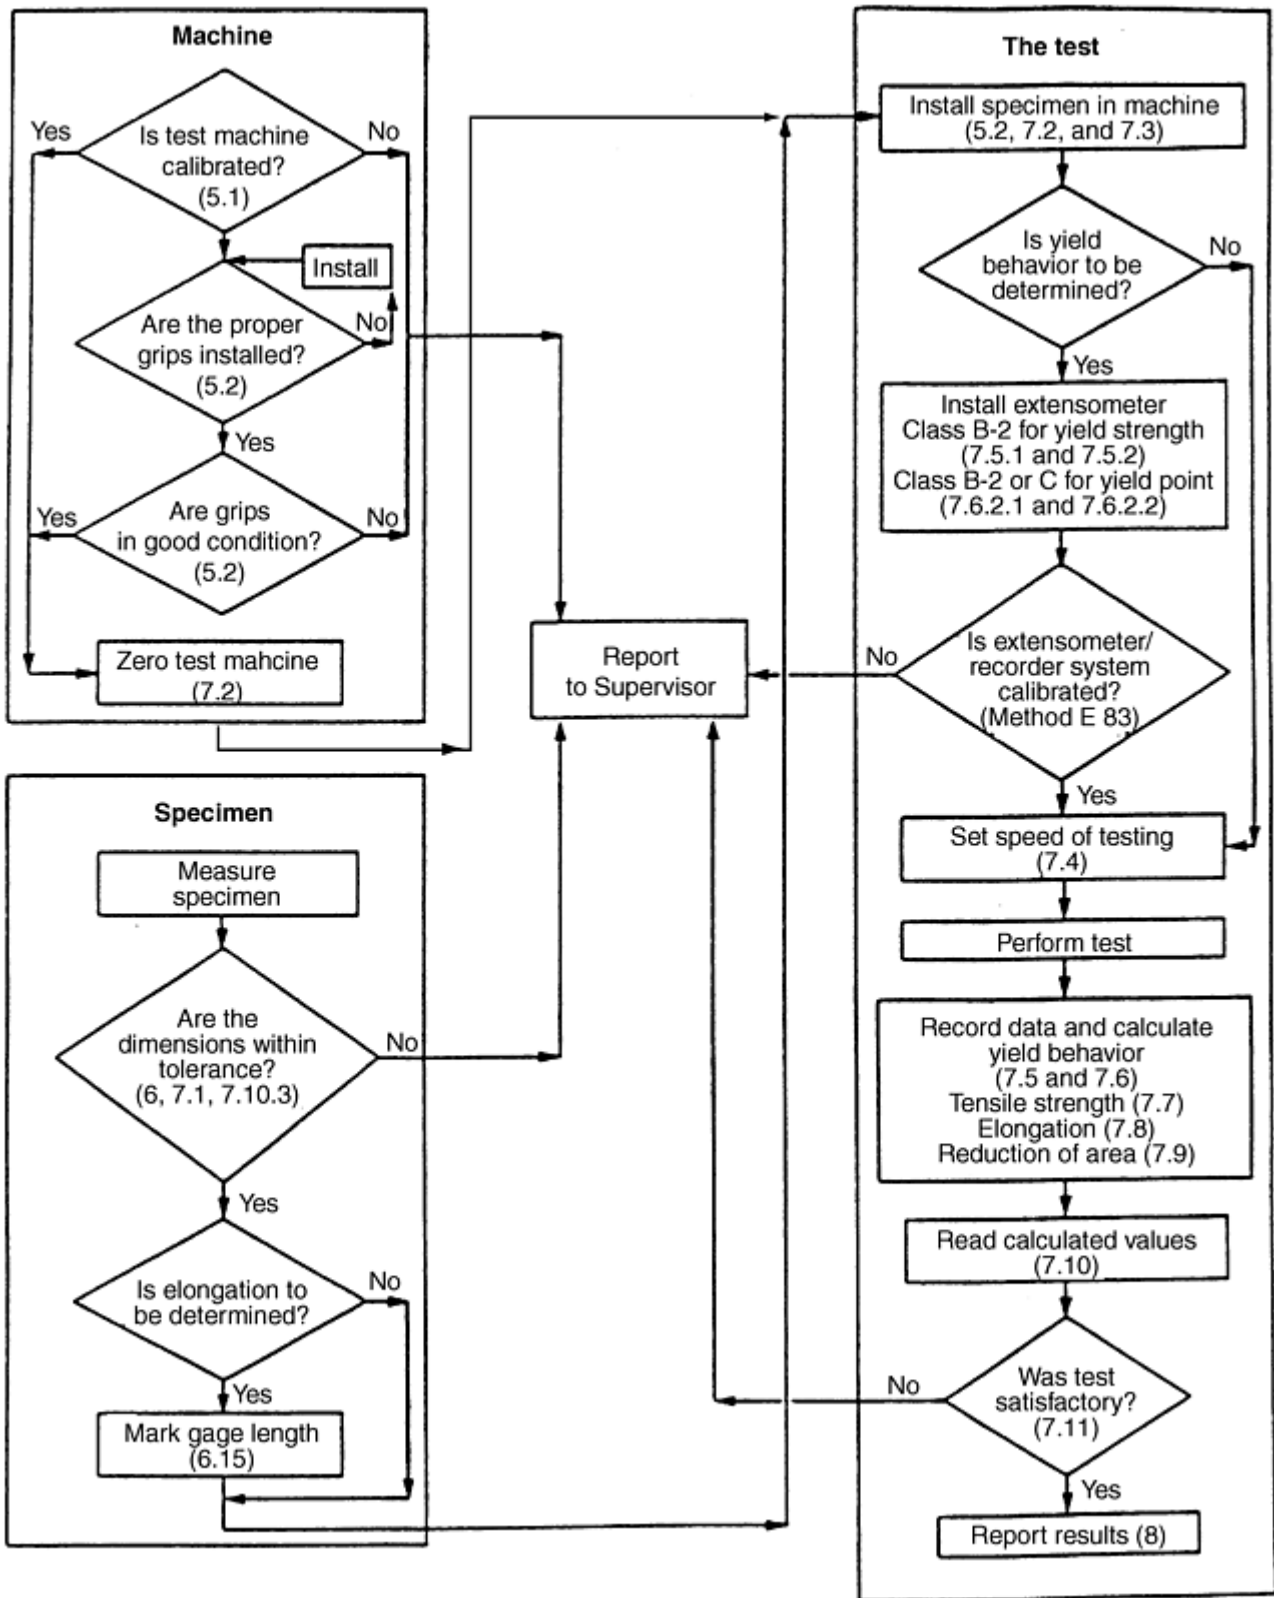

Fig. 18 General flow chart of the tension test per procedures in ASTM E 8. Relevant paragraph numbers from ASTM E 8 are shown in parentheses.

The Test Piece

The test piece is one of two basic types. Either it is a full cross section of the product form, or it is a small portion that has been machined to specific dimensions. Full-section test pieces consist of a part of the test unit as it is fabricated. Examples of full-section test pieces include bars, wires, and hot-rolled or extruded angles cut to a suitable length and then gripped at the ends and tested. In contrast, a machined test piece is a representative sample, such as one of the following:

- Test piece machined from a rough specimen taken from a coil or plate
- Test piece machined from a bar with dimensions that preclude testing a full-section test piece because a full-section test piece exceeds the capacity of the grips or the force capacity of the available testing machine or both
- Test piece machined from material of great monetary or technical value

In these cases, representative samples of the material must be obtained for testing. The descriptions of the tension test in this article proceed from the point that a rough specimen (Fig. 19) has been obtained. That is, the rough specimen has been selected based on some criteria, usually a material specification or a test order issued for a specific reason.

Fig. 19 Illustration of ISO terminology used to differentiate between sample, specimen, and test piece (see text for definitions of test unit, sample product, sample, rough specimen, and test piece). As an example, a test unit may be a 250-ton heat of steel that has been rolled into a single thickness of plate. The sample product is thus one plate from which a single test piece is obtained.

In this article, the term *test piece* is used for what is often called a specimen. This terminology is based on the convention established by ISO Technical Committee 17, Steel in ISO 377-1, “Selection and Preparation of Samples and Test Pieces of Wrought Steel,” where terms for a test unit, a sample product, sample, rough specimen, and test piece are defined as follows:

- *Test unit*: The quantity specified in an order that requires testing (for example, 10 tons of $\frac{3}{4}$ in. bars in random lengths)

- *Sample product*: Item (in the previous example, a single bar) selected from a test unit for the purpose of obtaining the test pieces
- *Sample*: A sufficient quantity of material taken from the sample product for the purpose of producing one or more test pieces. In some cases, the sample may be the sample product itself (i.e., a 2 ft length of the sample product).
- *Rough specimen*: Part of the sample having undergone mechanical treatment, followed by heat treatment where appropriate, for the purpose of producing test pieces; in the example, the sample is the rough specimen.
- *Test piece*: Part of the sample or rough specimen, with specified dimensions, machined or unmachined, brought to the required condition for submission to a given test. If a testing machine with sufficient force capacity is available, the test piece may be the rough specimen; if sufficient capacity is not available, or for another reason, the test piece may be machined from the rough specimen to dimensions specified by a standard.

These terms are shown graphically in Fig. 19. As can be seen, the test piece, or what is commonly called a specimen, is a very small part of the entire test unit.

Description of Test Material

Test-Piece Orientation . Orientation and location of a test material from a product can influence measured tensile properties. Although modern metal-working practices, such as cross rolling, have tended to reduce the magnitude of the variations in the tensile properties, it must not be neglected when locating the test piece within the specimen or the sample.

Because most materials are not isotropic, test-piece orientation is defined with respect to a set of axes as shown in Fig. 20. These terms for the orientation of the test-piece axes in Fig. 20 are based on the convention used by ASTM E 8 "Fatigue and Fracture." This scheme is identical to that used by the ISO Technical Committee 164 "Mechanical Testing," although the *L*, *T*, and *S* axes are referred to as the *X*, *Y*, and *Z* axes, respectively, in the ISO documents.

Fig. 20 System for identifying the axes of test-piece orientation in various product forms. (a) Flat-rolled products. (b) Cylindrical sections. (c) Tubular products

When a test is being performed to determine conformance to a product standard, the product standard must state the proper orientation of the test piece with regard to the axis of prior working, (e.g., the rolling direction of a flat product). Because alloy systems behave differently, no general rule of thumb can be stated on how prior working may affect the directionality of properties. As can be seen in Table 1, the longitudinal strengths of steel are generally somewhat less than the transverse strength. However, for aluminum alloys, the opposite is generally true.

Table 1 Effect of test-piece orientation on tensile properties

Orientation	Yield strength, ksi	Tensile strength, ksi	Elongation in 50 mm (2 in.), %	Reduction of area, %
ASTM A 572, Grade 50 (3/4in. thick plate, low sulfur level)				
Longitudinal	58.8	84.0	27.0	70.2
Transverse	59.8	85.2	28.0	69.0
ASTM A 656, Grade 80 (3/4in. thick plate, low sulfur level + controlled rolled)				
Longitudinal	81.0	102.3	25.8	71.2
Transverse	86.9	107.9	24.5	67.1
ASTM A 5414 (3/4in. thick plate, low sulfur level)				
Longitudinal	114.6	121.1	19.8	70.6
Transverse	116.3	122.2	19.5	69.9

Many standards, such as ASTM A 370, E 8, and B 557, provide guidance in the selection of test-piece orientation relative to the rolling direction of the plate or the major forming axes of other types of products and in the selection of specimen and test-piece location relative to the surface of the product. Orientation is also important when characterizing the directionality of properties that often develops in the microstructure of materials during processing. For example, some causes of directionality include the fibering of inclusions in steels, the formation of crystallographic textures in most metals and alloys, and the alignment of molecular chains in polymers.

The location from which a test material is taken from the initial product form is important because the manner in which a material is processed influences the uniformity of microstructure along the length of the product as well as through its thickness properties. For example, the properties of metal cut from castings are influenced by the rate of cooling and by shrinkage stresses at changes in section. Generally, test pieces taken from near the surface of iron castings are stronger. To standardize test results relative to location, ASTM A 370 recommends that tension test pieces be taken from midway between the surface and the center of round, square, hexagon, or octagonal bars. ASTM E 8 recommends that test pieces be taken from the thickest part of a forging from which a test coupon can be obtained, from a prolongation of the forging, or in some cases, from separately forged coupons representative of the forging.

Test-Piece Geometry

As previously noted, the item being tested may be either the full cross section of the item or a portion of the item that has been machined to specific dimensions. This article focuses on tension testing with test pieces that are machined from rough samples. Component testing is discussed in more detail in the article “Mechanical Testing of Fiber Reinforced Composites” in this Volume.

Test-piece geometry is often influenced by product form. For example, only test pieces with rectangular cross sections can be obtained from sheet products. Test pieces taken from thick plate may have either flat (plate-type) or round cross sections. Most tension-test specifications show machined test pieces with either circular cross sections or rectangular cross sections. Nomenclature for the various sections of a machined test piece are shown in Fig. 21. Most tension-test specifications present a set of dimensions, for each cross-section type, that are standard, as well as additional sets of dimensions for alternative test pieces. In general, the standard dimensions published by ASTM, ISO, JIS, and DIN are similar, but they are not identical.

Fig. 21 Nomenclature for a typical tension test piece

Gage lengths and standard dimensions for machined test pieces specified in ASTM E 8 are shown in Fig. 22 for rectangular and round test pieces. From this figure, it can be seen that the gage length is proportionally four times (4 to 1) the diameter (or width) of the test piece for the standard machined round test pieces and the sheet-type, rectangular test pieces. The length of the reduced section is also a *minimum* of $4\frac{1}{2}$ times the diameter (or width) of these test-piece types. These relationships do not apply to plate-type rectangular test pieces.

(a)

	Standard specimens, in.		Subsize specimen, 1/4 in. wide, in.
	Plate type, 1 1/2 in. wide	Sheet type, 1/2 in. wide	
G, gage length^{(a)(b)}	8.00 ± 0.01	2.00 ± 0.005	1.000 ± 0.003
W, width^{(c)(d)}	1 1/2 + 1/8 - 1/4	0.500 ± 0.010	0.250 ± 0.005
T, thickness^(e)	3/16	0.005 ≤ T ≤ 3/4	0.005 ≤ T ≤ 1/4
R, radius of fillet, min^(f)	1	1/2	1/4
L, overall length, min^{(b)(g)}	18	8	4
A, length of reduced section, min	9	2 1/4	1 1/4
B, length of grip section, min^(h)	3	2	1 1/4
C, width of grip section, approximate^{(d)(i)}	2	3/4	3/8

Note:

(a) For the 1 1/2 in. wide specimen, punch marks for measuring elongation after fracture shall be made on the flat or on the edge of the specimen and within the reduced section. Either a set of nine or more punch marks 1 in. apart or one or more pairs of punch marks 8 in. apart may be used.

(b) When elongation measurements of 1 1/2 in. wide specimens are not required, a minimum length of reduced section (A) of 2 1/4 in. may be used with all other dimensions similar to those of the plate-type specimen.

(c) For the three sizes of specimens, the ends of the reduced section shall not differ in width by more than 0.004, 0.002, or 0.001 in., respectively. Also, there may be a gradual decrease in width from the ends to the center, but the width at each end shall not be more than 0.015, 0.005, or 0.003 in., respectively, larger than the width at the center.

(d) For each of the three sizes of specimens, narrower widths (W and C) may be used when necessary. In such cases the width of the reduced section should be as large as the width of the material being tested permits; however, unless stated specifically, the requirements for elongation in a product specification shall not apply when these narrower specimens are used.

(e) The dimension T is the thickness of the test specimen as provided for in the applicable material specifications. Minimum thickness of 1 1/2 in. wide specimens shall be 3/16 in. Maximum thickness of 1/2 in. and 1/4 in. wide specimens shall be 3/4 in. and 1/4 in., respectively.

(f) For the 1 1/2 in. wide specimen, a 1/2 in. minimum radius at the ends of the reduced section is permitted for steel specimens under 100,000 psi in tensile strength when a profile cutter is used to machine the reduced section.

(g) To aid in obtaining axial force application during testing of 1/4 in. wide specimens, the overall length should be as large as the material will permit, up to 8.00 in.

(h) It is desirable, if possible, to make the length of the grip section large enough to allow the specimen to extend into the grips a distance equal to two-thirds or more of the length of the grips. If the thickness of 1/2 in. wide specimens is over 3/8 in., longer grips and correspondingly longer grip sections of the specimen may be necessary to prevent failure in the grip section.

(i) For the three sizes of specimens, the ends of the specimen shall be symmetrical in width with the center line of the reduced section within 0.10, 0.05, and 0.005 in., respectively. However, for referee testing and when required by product specifications, the ends of the 1/2 in. wide specimen shall be symmetrical within 0.01 in.

Fig. 22 Examples of tension test pieces per ASTM E 8. (a) Rectangular (flat) test pieces. (b) Round test-piece

	Standard specimen, in., at nominal diameter:		Small-size specimens proportional to standard, in., at nominal diameter:				
	0.500	0.350	0.250	0.160	0.113		
G, gage length	2.000	± 1.400	± 1.000	± 0.640	± 0.450	±	±
	0.005	0.005	0.005	0.005	0.005		
D, diameter^(a)	0.500	± 0.350	± 0.250	± 0.160	± 0.113	±	±
	0.010	0.007	0.005	0.003	0.002		
R, radius of fillet, min	$\frac{3}{8}$	$\frac{1}{4}$	$\frac{3}{16}$	$\frac{5}{32}$	$\frac{3}{32}$		
A, length of reduced section, min^(b)	$2\frac{1}{4}$	$1\frac{3}{4}$	$1\frac{1}{4}$	$\frac{3}{4}$	$\frac{5}{8}$		

Note:
 (a) The reduced section may have a gradual taper from the ends toward the center, with the ends not more than 1% larger in diameter than the center (controlling dimension).
 (b) If desired, the length of the reduced section may be increased to accommodate an extensometer of any convenient gage length. Reference marks for the measurement of elongation should, nevertheless, be spaced at the indicated gage length.

Fig. 22

Many specifications outside the United States require that the gage length of a test piece be a fixed ratio of the square root of the cross-sectional area, that is:

$$\text{Gage length} = \text{constant} \times (\text{cross-sectional area})^{1/2}$$

The value of this constant is often specified as 5.65 or 11.3 and applies to both round and rectangular test pieces. For machined round test pieces, a value of 5.65 results in a 5-to-1 relationship between the gage length and the diameter.

Many tension-test specifications permit a slight taper toward the center of the reduced section of machined test pieces so that the minimum cross section occurs at the center of the gage length and thereby tends to cause fracture to occur at the middle of the gage length. ASTM E 8-99 specifies that this taper cannot exceed 1% and requires that the taper is the same on both sides of the midlength.

When test pieces are machined, it is important that the longitudinal centerline of the reduced section be coincident with the longitudinal centerlines of the grip ends. In addition, for the rectangular test pieces, it is essential that the centers of the transition radii at each end of the reduced section are on common lines that are perpendicular to the longitudinal centerline. If any of these requirements is violated, bending will occur, which may affect test results.

The transition radii between the reduced section and the grip ends can be critical for test pieces from materials with very high strength or with very little ductility or both. This is discussed more fully in the section “Effect of Strain Concentrations” in this article.

Measurement of Initial Test-Piece Dimensions. Machined test pieces are expected to meet size specifications, but to ensure dimensional accuracy, each test piece should be measured prior to testing. Gage length, fillet radius, and cross-sectional dimensions are measured easily. Cylindrical test pieces should be measured for concentricity. Maintaining acceptable concentricity is extremely important in minimizing unintended bending stresses on materials in a brittle state.

Measurement of Cross-Sectional Dimensions. The test pieces must be measured to determine whether they meet the requirements of the test method. Test-piece measurements must also determine the initial cross-sectional area when it is compared against the final cross section after testing as a measure of ductility.

The precision with which these measurements are made is based on the requirements of the test method, or if none are given, on good engineering judgment. Specified requirements of ASTM E 8 are summarized as follows:

- For referee testing of test pieces under $\frac{3}{16}$ in. in their least dimension, the dimensions should be measured where the least cross-sectional area is found.

- For cross sectional dimensions of 0.200 in. or more, cross-sectional dimensions should be measured and recorded to the nearest 0.001 in.
- For cross sectional dimensions from 0.100 in. but less than 0.200 in., cross-sectional dimensions should be measured and recorded to the nearest 0.0005 in.
- For cross sectional dimensions from 0.020 in. but less than 0.100 in., cross-sectional dimensions should be measured and recorded to the nearest 0.0001 in.
- When practical, for cross-sectional dimensions less than 0.020 in., cross-sectional dimensions should be measured to the nearest 1%, but in all cases, to at least the nearest 0.0001 in.

ASTM E 8 goes on to state how to determine the cross-sectional area of a test piece that has a nonsymmetrical cross section using the weight and density. When measuring dimensions of the test piece, ASTM E 8 makes no distinction between the shape of the cross section for standard test pieces.

Measurement of the Initial Gage Length. ASTM E 8 assumes that the initial gage length is within specified tolerance; therefore, it is necessary only to verify that the gage length of the test piece is within the tolerance.

Marking Gage Length. As shown in the flow diagram in Fig. 18, measurement of elongation requires marking the gage length of the test piece. The gage marks should be placed on the test piece in a manner so that when fracture occurs, the fracture will be located within the center one-third of the gage length (or within the center one-third of one of several sets of gage-length marks). For a test piece machined with a reduced-section length that is the minimum specified by ASTM E 8 and with a gage length equal to the maximum allowed for that geometry, a single set of marks is usually sufficient. However, multiple sets of gage lengths must be applied to the test piece to ensure that one set spans the fracture under any of the following conditions:

- Testing full-section test pieces
- Testing pieces with reduced sections significantly longer than the minimum
- Test requirements specify a gage length that is significantly shorter than the reduced section

For example, some product specifications require that the elongation be measured over a 2 in. gage length using the machined plate-type test piece with a 9 in. reduced section (Fig. 22a). In this case, it is recommended that a staggered series of marks (either in increments of 1 in. when testing to ASTM E 8 or in increments of 25.0 mm when testing to ASTM E 8M) be placed on the test piece such that, after fracture, the elongation can be measured using the set that best meets the center-third criteria. Many tension-test methods permit a retest when the elongation is less than the minimum specified by a product specification if the fracture occurred outside the center third of the gage length. When testing full-section test pieces and determining elongation, it is important that the distance between the grips be greater than the specified gage length unless otherwise specified. As a rule of thumb, the distance between grips should be equal to at least the gage length plus twice the minimum dimension of the cross section.

The gage marks may be marks made with a center punch, or may be lines scribed using a sharp, pointed tool, such as a machinist's scribe (or any other means that will establish the gage length within the tolerance permitted by the test method). If scribed lines are used, a broad line or band may first be drawn along the length of the test piece using machinist's layout ink (or a similar substance), and the gage marks are made on this line. This practice is especially helpful to improve visibility of scribed gage marks after fracture. If punched marks are used, a circle around each mark or other indication made by ink may help improve visibility after fracture. Care must be taken to ensure that the gage marks, especially those made using a punch, are not deep enough to become stress raisers, which could cause the fracture to occur through them. This precaution is especially important when testing materials with high strength and low ductility.

Notched Test Pieces. Tension test pieces are sometimes intentionally notched in the center of the gage length (Fig. 23). ASTM E 338 and E 602 describe procedures for testing notched test pieces. Results obtained using notched test pieces are useful for evaluating the response of a material to a localized stress concentration. Detailed information on the notch tensile test and a discussion of the related material characteristics (notch sensitivity and notch strength) can be found in the article "Mechanical Behavior Under Tensile and Compressive Loads" in this Volume. The effect of stress (or strain) concentrations is also discussed in the section "Effect of Strain Concentrations" in this article.

*This dimension is 56 mm (2.25 in.) for the substandard length specimen.

Fig. 23 Example of notched tension-test test piece per ASTM E 338 “Standard Test Method of Sharp-Notch Tension Testing of High-Strength Sheet Materials”

Surface Finish and Condition. The finish of machined surfaces usually is not specified in generic test methods (that is, a method that is not written for a specific item or material) because the effect of finish differs for different materials. For example, test pieces from materials that are not high strength or that are ductile are usually insensitive to surface finish effects. However, if surface finish in the gage length of a tensile test piece is extremely poor (with machine tool marks deep enough to act as stress-concentrating notches, for example), test results may exhibit a tendency toward decreased and variable strength and ductility.

It is good practice to examine the test piece surface for deep scratches, gouges, edge tears, or shear burrs. These discontinuities may sometimes be minimized or removed by polishing or, if necessary, by further machining; however, dimensional requirements often may no longer be met after additional machining or polishing. In all cases, the reduced sections of machined test pieces must be free of detrimental characteristics, such as cold work, chatter marks, grooves, gouges, burrs, and so on. Unless one or more of these characteristics is typical of the product being tested, an unmachined test piece must also be free of these characteristics in the portion of the test piece that is between the gripping devices. When rectangular test pieces are prepared from thin-gage sheet material by shearing (punching) using a die the shape of the test piece, ASTM E 8 states that the sides of the reduced section may need to be further machined to remove the cold work and shear burrs that occur when the test piece is sheared from the rough specimen. This method is impractical for material less than 0.38 mm (0.015 in.) thick. Burrs on test pieces can be virtually eliminated if punch-to-die clearances are minimized.

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Test Setup

The setup of a tensile test involves the installation of a test piece in the load frame of a suitable test machine. Force capacity is the most important factor of a test machine. Other test machine factors, such as calibration and load-frame rigidity, are discussed in more detail in the article “Testing Machines and Strain Sensors” in this Volume. The other aspects of the test setup include proper gripping and alignment of the test piece, and the

installation of extensometers or strain sensors when plastic deformation (yield behavior) of the piece is being measured, as described below.

Gripping Devices. The grips must furnish an axial connection between the test piece and the testing machine; that is, the grips must not cause bending in the test piece during loading. The choice of grip is primarily dependent on the geometry of the test piece and, to a lesser degree, on the preference of the test laboratory. That is, rarely do tension-test methods or requirements specify the method of gripping the test pieces.

Figure 24 shows several of the many grips that are in common use, but many other designs are also used. As can be seen, the gripping devices can be classified into several distinct types, wedges, threaded, button, and snubbing. Wedge grips can be used for almost any test-piece geometry; however, the wedge blocks must be designed and installed in the machine to ensure axial loading. Threaded grips and button grips are used only for machined round test pieces. Snubbing grips are used for wire (as shown) or for thin, rectangular test pieces, such as those made from foil.

Fig. 24 Examples of gripping methods for tension test pieces. (a) Round specimen with threaded grips. (b) Gripping with serrated wedges with hatched region showing bad practice of wedges extending below the outer holding ring. (c) Butt-end specimen constrained by a split collar. (d) Sheet specimen with pin constraints. (e) Sheet specimen with serrated-wedge grip with hatched region showing the bad practice of wedges extended below the outer holding ring. (f) Gripping device for threaded-end specimen. (g) Gripping device for sheet and wire. (h) Snubbing device for testing wire. Sources: Adapted from Ref 1 and ASTM E 8

As shown in Fig. 22, the dimensions of the grip ends for machined round test pieces are usually not specified, and only approximate dimensions are given for the rectangular test pieces. Thus, each test lab must prepare/machine grip ends appropriate for its testing machine. For machined-round test pieces, the grip end is often threaded, but many laboratories prefer either a plain end, which is gripped with the wedges in the same manner as a rectangular test piece, or with a button end that is gripped in a mating female grip. Because the principal disadvantage of a threaded grip is that the pitch of the threads tend to cause a bending moment, a fine-series thread is often used.

Bending stresses are normally not critical with test pieces from ductile materials. However, for test pieces from materials with limited ductility, bending stresses can be important, better alignment may be required. Button grips are often used, but adequate alignment is usually achieved with threaded test pieces. ASTM E 8 also recommends threaded gripping for brittle materials. The principal disadvantage of the button-end grip is that the diameter of the button or the base of the cone is usually at least twice the diameter of the reduced section, which necessitates a larger, rough specimen and more metal removal during machining.

Alignment of the Test Piece. The force-application axis of the gripping device must coincide with the longitudinal axis of symmetry of the test piece. If these axes do not coincide, the test piece will be subjected to a combination of axial loading and bending. The stress acting on the different locations in the cross section of the test piece then varies, from the sum of the axial and bending stresses on one side of the test piece, to the difference between the two stresses on the other side. Obviously, yielding will begin on the side where the stresses are additive and at a lower apparent stress than would be the case if only the axial stress were present. For this reason, the yield stress may be lowered, and the upper yield stress would appear suppressed in test pieces that normally exhibit an upper yield point. For ductile materials, the effect of bending is minimal, other than the suppression of the upper yield stress. However, if the material has little ductility, the increased strain due to bending may cause fracture to occur at a lower stress than if there were no bending.

Similarly, if the test piece is initially bent, for example, coil set in a machined-rectangular cross section or a piece of rod being tested in a full section, bending will occur as the test piece straightens, and the problems exist.

Methods for verification of alignment are described in ASTM E 1012.

Extensometers. When the tension test requires the measurement of strain behavior (i.e., the amount of elastic and/or plastic deformation occurring during loading), extensometers must be attached to the test piece. The amount of strain can be quite small (e.g., approximately 0.5% or less for elastic strain in steels), and extensometers and other strain-sensing systems are designed to magnify strain measurement into a meaningful signal for data processing.

Several types of extensometers are available, as described in more detail in the article “Testing Machines and Strain Sensors” in this Volume. Extensometers generally have fixed gage lengths. If an extensometer is used only to obtain a portion of the stress-strain curve sufficient to determine the yield properties, the gage length of the extensometer may be shorter than the gage length required for the elongation-at-fracture measurement. It may also be longer, but in general, the extensometer gage length should not exceed approximately 85% of the length of the reduced section or the distance between the grips for test pieces without reduced sections. National and international standardization groups have prepared practices for the classification of extensometers, as described in the article “Testing Machines and Strain Sensors” extensometer classifications usually are based on error limits of a device, as in ASTM E 83 “Standard Practice for Verification and Classification of Extensometers.”

Temperature Control. Tension testing is sometimes performed at temperatures other than room temperature. ASTM E 21 describes standard procedures for elevated-temperature tension testing of metallic materials, which is described further in the article “Hot Tension and Compression Testing” in this Volume. Currently, there is no

ASTM standard procedure for cryogenic testing; further information is contained in the article “Tension and Compression Testing at Low Temperatures” in this Volume.

Temperature gradients may occur in temperature-controlled systems, and gradients must be kept within tolerable limits. It is not uncommon to use more than one temperature-sensing device (e.g., thermocouples) when testing at other than room temperature. Besides the temperature-sensing device used in the control loop, auxiliary sensing devices may be used to determine whether temperature gradients are present along the gage length of the test piece.

Temperature control is also a factor during room-temperature tests because deformation of the test piece causes generation of heat within it. Test results have shown that the heating that occurs during the straining of a test piece can be sufficient to significantly change the properties that are determined because material strength typically decreases with an increase in the test temperature. When performing a test to duplicate the results of others, it is important to know the test speed and whether any special procedures were taken to remove the heat generated by straining the test piece.

Test Procedures

After the test piece has been properly prepared and measured and the test setup established, conducting the test is fairly routine. The test piece is installed properly in the grips, and if required, extensometers or other strain-measuring devices are fastened to the test piece for measurement and recording of extension data. Data acquisition systems also should be checked. In addition, it is sometimes useful to repetitively apply small initial loads and vibrate the load train (a metallographic engraving tool is a suitable vibrator) to overcome friction in various couplings, as shown in Fig. 25(a). A check can also be run to ensure that the test will run at the proper testing speed and temperature. The test is then begun by initiating force application.

(a)

(b)

Speed of Testing

The speed of testing is extremely important because mechanical properties are a function of strain rate, as discussed in the section “Effect of Strain Rate” in this article. It is, therefore, imperative that the speed of testing be specified in either the tension-test method or the product specification.

In general, a slow speed results in lower strength values and larger ductility values than a fast speed; this tendency is more pronounced for lower-strength materials than for higher-strength materials and is the reason that a tension test must be conducted within a narrow test-speed range.

In order to quantify the effect of deformation rate on strength and other properties, a specific definition of testing speed is required. A conventional (quasi-static) tension test, for example, ASTM E 8, prescribes upper and lower limits on the deformation rate, as determined by one of the following methods during the test:

- Strain rate
- Stress rate (when loading is below the proportional limit)
- Cross-head separation rate (or free-running cross-head speed) during the test
- Elapsed time

These methods are listed in order of decreasing precision, except during the occurrence of upper-yield-strength behavior and yield point elongation (YPE) (where the strain rate may not necessarily be the most precise method). For some materials, elapsed time may be adequate, while for other materials, one of the remaining methods with higher precision may be necessary in order to obtain test values within acceptable limits. ASTM E 8 specifies that the test speed must be slow enough to permit accurate determination of forces and strains. Although the speeds specified by various test methods may differ somewhat, the test speeds for these methods are roughly equivalent in commercial testing.

Strain rate is expressed as the change in strain per unit time, typically expressed in units of min^{-1} or s^{-1} because strain is a dimension-less value expressed as a ratio of change in length per unit length. The strain rate can usually be dialed, or programmed, into the control settings of a computer-controlled system or paced or timed for other systems.

Stress rate is expressed as the change in stress per unit of time. When the stress rate is stipulated, ASTM E 8 requires that it not exceed 100 ksi/ min. This number corresponds to an elastic strain rate of about $5 \times 10^{-5} \text{ s}^{-1}$ for steel or $15 \times 10^{-5} \text{ s}^{-1}$ for aluminum. As with strain rate, stress rate usually can be dialed or programmed into the control settings of computer-controlled test systems. However, because most older systems indicate force being applied, and not stress, the operator must convert stress to force and control this quantity. Many machines are equipped with pacing or indicating devices for the measurement and control of the stress rate, but in the absence of such a device, the average stress rate can be determined with a timing device by observing the time required to apply a known increment of stress. For example, for a test piece with a cross section of 0.500 in. by 0.250 in. and a specified stress rate of 100,000 psi/min, the maximum force application rate would be 12,500 lbf/min (force = stress rate \times area = 100,000 psi/min \times (0.500 in. \times 0.250 in.)). A minimum rate of $\frac{1}{10}$ of the maximum rate is usually specified.

Comparison between Strain-Rate and Stress-Rate Methods. Figure 26 compares strain-rate control with stress-rate control for describing the speed of testing. Below the elastic limit, the two methods are identical. However, as shown in Fig. 26, once the elastic limit is exceeded, the strain rate increases when a constant stress rate is applied. Alternatively, the stress rate decreases when a constant strain rate is specified. For a material with discontinuous yielding and a pronounced upper yield spike (Fig. 7a), it is a physical impossibility for the stress rate to be maintained in that region because, by definition, there is not a sustained increase in stress in this region. For these reasons, the test methods usually specify that the rate (whether stress rate or strain rate) is set prior to the elastic limit (EL), and the crosshead speed is not adjusted thereafter. Stress rate is not applicable beyond the elastic limit of the material. Test methods that specify rate of straining expect the rate to be controlled during yield; this minimizes effects on the test due to testing machine stiffness.

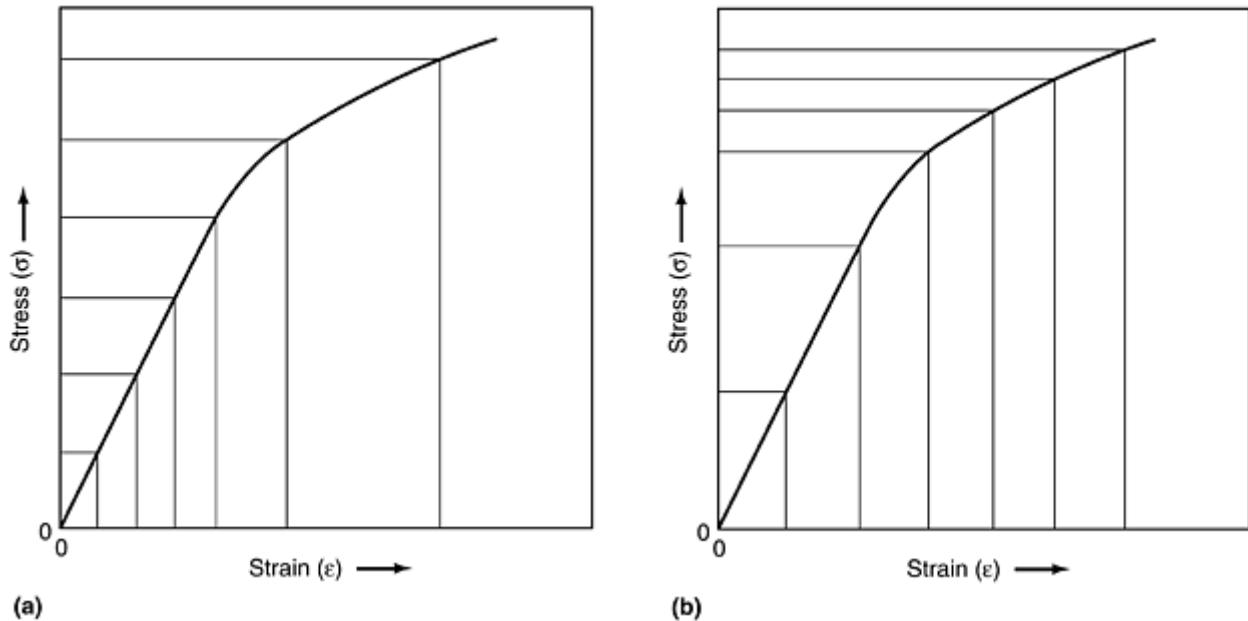

Fig. 26 Illustration of the differences between constant stress increments and constant strain increments. (a) Equal stress increments (increasing strain increments). (b) Equal strain increments (decreasing stress increments)

The rate of separation of the grips (or rate of separation of the cross heads or the cross-head speed) is a commonly used method of specifying the speed of testing. In ASTM A 370, for example, the specification of test speed is that “through the yield, the maximum speed shall not exceed $\frac{1}{16}$ in. per inch of reduced section per minute; beyond yield or when determining tensile strength alone, the maximum speed shall not exceed $\frac{1}{2}$ in. per inch of reduced section per minute. For both cases, the minimum speed shall be greater than $\frac{1}{10}$ of this amount.” This means that for a machined round test piece with a $2\frac{1}{4}$ in. reduced section, the rate prior to yielding can range from a maximum of $\frac{9}{64}$ in./min (i.e., $2\frac{1}{4}$ in. reduced-section length $\times \frac{1}{16}$ in./min) down to $\frac{9}{640}$ in./min (i.e., $2\frac{1}{4}$ in. reduced-section length $\times \frac{1}{160}$ in./min).

The elapsed time to reach some event, such as the onset of yielding or the tensile strength, or the elapsed time to complete the test, is sometimes specified. In this case, multiple test pieces are usually required so that the correct test speed can be determined by trial and error.

Many test methods permit any speed of testing below some percentage of the specified yield or tensile strength to allow time to adjust the force application mechanism, ensure that the extensometer is working, and so on. Values of 50 and 25%, respectively, are often used.

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Post-Test Measurements

After the test has been completed, it is often required that the cross-sectional dimensions again be measured to obtain measures of ductility. ASTM E 8 states that measurements made after the test shall be to the same accuracy as the initial measurements.

Method E 8 also states that upon completion of the test, gage lengths 2 in. and under are to be measured to the nearest 0.01 in., and gage lengths over 2 in. are to be measured to the nearest 0.5%. The document goes on to state that a percentage scale reading to 0.5 % of the gage length may be used. However, if the tension test is

being performed as part of a product specification, and the elongation is specified to meet a value of 3% or less, special techniques, which are described, are to be used to measure the final gage length. These measurements are discussed in a previous section, "Elongation," in this article.

Uniaxial Tension Testing

John M. (Tim) Holt, Alpha Consultants and Engineering

Variability of Tensile Properties

Even carefully performed tests will exhibit variability because of the nonhomogenous nature of metallic materials. Figure 27 (Ref 10) shows the three-sigma distribution of the offset yield strength and tensile strength values that were obtained from multiple tests on a single aluminum alloy. Distribution curves are presented for the results from multiple tests of a single sheet and for the results from tests on a number of sheets from a number of lots of the same alloy. Because these data are plotted with the minus three-sigma value as zero, it appears there is a difference between the mean values; however, this appearance is due only to the way the data are presented. Figures 28(a) and (b) show lines of constant offset yield strength and constant tensile strength, respectively, for a 1 in. thick, quenched and tempered plate of an alloy steel. In this case, rectangular test pieces 1½ in. wide were taken along the transverse direction (*T* orientation in Fig. 20) every 3 in. along each of the four test-piece centerlines shown. These data indicate that the yield and tensile strengths vary greatly within this relatively small sample and that the shape and location of the yield strength contour lines are not the same as the shape and location of the tensile strength lines.

Effect of Strain Concentrations. During testing, strain concentrations (often called stress concentrations) occur in the test piece where there is a change in the geometry. In particular, the transition radii between the reduced section and the grip ends are important, as previously noted in the section on test-piece geometry. Most test

methods specify a minimum value for these radii. However, because there is a change in geometry, there is still a strain concentration at the point of tangency between the radii and the reduced section. Figure 29(a) (Ref 11) shows a test piece of rubber with an abrupt change of section, which is a model of a tension test piece in the transition region. Prior to applying the force at the ends of the model, a rectangular grid was placed on the test piece. When force is applied, it can be seen that the grid is severely distorted at the point of tangency but to a much lesser degree at the center of the model. The distortion is a visual measure of strain. The strain distribution across section $n-n$ is plotted in Fig. 29(b). From the stress-strain curve for the material (Fig. 29c), the stresses on this section can be determined. It is apparent that the test piece will yield at the point of tangency prior to general yielding in the reduced section. The ratio between the nominal strain and actual, maximum strain is often referred to as the strain-concentration factor, or the stress-concentration factor if the actual stress is less than the elastic limit. This ratio is often abbreviated as k_t . Studies have shown that k_t is about 1.25 when the radii are $\frac{1}{2}$ in., the width (or diameter) of the reduced section is 0.500 in., and the width (or diameter) of the grip end is $\frac{3}{4}$ in. That is, the actual strain or the actual elastic stress at the transition (if less than the yield of the material) is 25% greater than would be expected without consideration of the strain or stress concentration. The value of k_t decreases as the radii increase such that, for the above example, if the radii are 1.0 in., and k_t decreases to about 1.15.

Fig. 29 Effect of strain concentrations on section $n-n$. (a) Strain distribution caused by an abrupt change in cross section (grid on sheet of rubber) (Ref 11). (b) Schematic of strain distribution on cross section (Ref 11). (c) Calculation of stresses at abrupt change in cross section $n-n$ by graphical means

Various techniques have been tried to minimize k_t , including the use of spirals instead of radii, but there will always be strain concentration in the transition region. This indicates that the yielding of the test piece will always initiate at this point of tangency and proceed toward midlength. For these reasons, it is extremely important that the radii be as large as feasible when testing materials with low ductility.

Strain concentrations can be caused by notches deliberately machined in the test piece, nicks from accidental causes, or shear burrs, machining marks, or gouges that occur during the preparation of the test piece or from many other causes.

Effect of Strain Rate. Although the mechanical response of different materials varies, the strength properties of most materials tend to increase at higher strain rates. For example, the variability in yield strength of ASTM A 36 structural steel over a limited range of strain rates is shown in Fig. 30 (Ref 12). A “zero-strain-rate” stress-strain curve (Fig. 31) is generated by applying forces to a test piece to obtain a small plastic strain and then maintaining that strain until the force ceases to decrease (Point A). Force is reapplied to the test piece to obtain another increment of plastic strain, which is maintained until the force ceases to decrease (Point B). This

procedure is continued for several more cycles. The smooth curve fitted through Points A, B, and so on is the “zero-strain-rate” stress-strain curve, and the yield value is determined from this curve.

Fig. 30 Effect of strain rate on the ratio of dynamic yield-stress and static yield-stress level of A36 structural steel. Source: Ref 12

Fig. 31 Stress-strain curves for tests conducted at “normal” and “zero” strain rates

The effect of strain rate on strength depends on the material and the test temperature. Figure 32 (Ref 13) shows graphs of tensile strength and yield strength for a common heat-resistant low-alloy steel ($\frac{1}{4}$ Cr-1 Mo) over a wide range of temperatures and strain rates. In this figure, the strain rates were generally faster than those prescribed in ASTM E 8.

Fig. 32 Effect of temperature and strain rate on (a) tensile strength and yield strength of $2\frac{1}{4}$ Cr-1 Mo Steel. Note: Stain-rate range permitted by ASTM Method E8 when determining yield strength at room temperature is indicated. Source: Ref 13

Another example of strain effects on strength is shown in Fig. 33 (Ref 14). This figure illustrates true yield stress at various strains for a low-carbon steel at room temperature. Between strain rates of 10^{-6} s^{-1} and 10^{-3} s^{-1} (a thousandfold increase), yield stress increases only by 10%. Above 1 s^{-1} , however, an equivalent rate increase doubles the yield stress. For the data in Fig. 33, at every level of strain the yield stress increases with increasing strain rate. However, a decrease in strain-hardening rate is exhibited at the higher deformation rates. For a low-carbon steel tested at elevated temperatures, the effects of strain rate on strength can become more complicated by various metallurgical factors such as dynamic strain aging in the “blue brittleness” region of some mild steels (Ref 14).

Fig. 33 True stresses at various strains vs. strain rate for a low-carbon steel at room temperature. The top line in the graph is tensile strength, and the other lines are yield points for the indicated level of strain. Source: Ref 14

Structural aluminum is less strain-rate sensitive than steels. Figure 34 (Ref 15) shows data obtained for 1060-O aluminum. Between strain rates of 10^{-3} s^{-1} and 10^3 s^{-1} (a millionfold increase), the stress at 2% plastic strain increases by less than 20%.

Uniaxial Compression Testing

Howard A. Kuhn, Concurrent Technologies Corporation

Introduction

COMPRESSION LOADS occur in a wide variety of material applications, such as steel building structures and concrete bridge supports, as well as in material processing, such as during the rolling and forging of a billet. Characterizing the material response to these loads requires tests that measure the compressive behavior of the materials. Results of these tests provide accurate input parameters for product-or process-design computations. Under certain circumstances, compression testing may also have advantages over other testing methods. Tension testing is by far the most extensively developed and widely used test for material behavior, and it can be used to determine all aspects of the mechanical behavior of a material under tensile loads, including its elastic, yield, and plastic deformation and its fracture properties. However, the extent of deformation in tension testing is limited by necking. To understand the behavior of materials under the large plastic strains during deformation processing, measurements must be made beyond the tensile necking limit. Compression tests and torsion tests are alternative approaches that overcome this limitation.

Furthermore, compression-test specimens are simpler in shape, do not require threads or enlarged ends for gripping, and use less material than tension-test specimens. Therefore, compression tests are often useful for subscale testing and for component testing where tension-test specimens would be difficult to produce. Examples of these applications include through-thickness property measurements in plates and forgings (Ref 1), weld heat-affected zones, and precious metals (Ref 2) where small amounts of material are available.

In addition, characterizing the mechanical behavior of anisotropic materials often requires compression testing. For isotropic polycrystalline materials, compressive behavior is correctly assumed to be identical to tensile behavior in terms of elastic and plastic deformation. However, in highly textured materials that deform by twinning, as opposed to dislocation slip, compressive and tensile deformation characteristics differ widely (Ref 3). Likewise, the failure of unidirectionally reinforced composite materials, particularly along the direction of reinforcement, is much different in compression than in tension.

In this article, the characteristics of deformation during axial compression testing are described, including the deformation modes, compressive properties, and compression-test deformation mechanics. Procedures are described for the use of compression testing for measurement of the deformation properties and fracture properties of materials.

Uniaxial Compression Testing

Howard A. Kuhn, Concurrent Technologies Corporation

Deformation Modes in Axial Compression

Compression tests can provide considerable useful information on plastic deformation and failure, but certain precautions must be taken to assure a valid test of material behavior. Figure 1 illustrates the modes of deformation that can occur in compression testing. The buckling mode shown in Fig. 1(a) occurs when the length-to-width ratio of the test specimen is very large, and can be treated by classical analyses of elastic and plastic buckling (Ref 4). These analyses predict that cylindrical specimens having length-to-diameter ratios, L/D , less than 5.0 are safe from buckling and can be used for compression testing of brittle and ductile materials. Practical experience with ductile materials, on the other hand, shows that even L/D ratios as low as 2.5 lead to unsatisfactory deformation responses. For these geometries, even slightly eccentric loading or nonparallel compression plates will lead to shear distortion, as shown in Fig. 1(b). Therefore, L/D ratios less than 2.0 are normally used to avoid buckling and provide accurate measurements of the plastic deformation behavior of materials in compression.

Fig. 1 Modes of deformation in compression. (a) Buckling, when $L/D > 5$. (b) Shearing, when $L/D > 2.5$. (c) Double barreling, when $L/D > 2.0$ and friction is present at the contact surfaces. (d) Barreling, when $L/D < 2.0$ and friction is present at the contact surfaces. (e) Homogenous compression, when $L/D < 2.0$ and no friction is present at the contact surfaces. (f) Compressive instability due to work-softening material

Friction is another source of anomalous deformation in compression testing of ductile materials. Friction between the ends of the test specimen and the compression platens constrains lateral flow at the contact surfaces, which leads to barreling or bulging of the cylindrical surface. Under these circumstances, for L/D ratios on the order of 2.0, a double barrel forms, as shown in Fig. 1(c), smaller L/D ratios lead to a single barrel, as in Fig. 1(d). Barreling indicates that the deformation is nonuniform (i.e., the stress and strain vary throughout the test specimen), and such tests are not valid for measurement of the bulk elastic and plastic properties of a material. Barreling, however, can be beneficial for the measurement of the localized fracture properties of a material, as described in the section “Instability in Compression” of this article.

If the compression test can be carried out without friction between the specimen and compression platens, barreling does not occur, as shown in Fig. 1(e), and the deformation is uniform (homogenous). For measurement of the bulk deformation properties of materials in compression, this configuration must be achieved.

A final form of irregular deformation in axial compression is an instability that is the antithesis of necking in tension. In this case, the instability occurs due to work softening of the material and takes the form of rapid, localized expansion, as shown in Fig. 1(f).

Uniaxial Compression Testing

Howard A. Kuhn, Concurrent Technologies Corporation

Compressive Properties

The bulk elastic and plastic deformation characteristics of polycrystalline materials are generally the same in compression and tension. As a result, the elastic-modulus, yield-strength, and work-hardening curves will be the same in compression and tension tests. Fracture strength, ultimate strength, and ductility, on the other hand, depend on localized mechanisms of deformation and fracture, and are generally different in tension and compression testing. Anisotropic materials, such as composite materials and highly textured polycrystalline materials, also exhibit considerable differences between tensile and compressive behaviors beyond initial elastic response.

Measurements of bulk elastic modulus and yield strength require accurate measurements of the axial strain of the material under compression testing. This is accomplished by attaching to the specimen an extensometer, which uses a differential transformer or strain gages to provide an electronic signal that is proportional to the displacement of gage marks on the specimen. Extensometers are most easily used in tension testing because tension test specimens are long and provide ample space for attachment of the extensometer clips. Due to the limitations noted in the previous section (Fig. 1a and b), compression-test specimens are considerably smaller in length and make attachment of the extensometer clips difficult. Alternatively, a differential transformer can be used to measure the displacement between the compression platen surfaces. Because the measurement is not made directly on the specimen, however, elastic distortion and slight rotations of the platens during testing will give false displacement readings.

Measurement of the work-hardening, or plastic-flow, curve of a material is best carried out by compression testing, particularly if the application, such as bulk metalworking, requires knowledge of the flow behavior at large plastic strains beyond the necking limit in tension testing. In this case, the strains are many orders of magnitude larger than the elastic strains, and indirect measurement of the axial strain by monitoring the motion of the compression platens is sufficiently accurate. Any systematic errors caused by elastic deformation of the platens or test equipment are insignificant compared to the large plastic displacements of the compression specimen.

The fracture strength of a material is much different in tension and compression. In tension, the fracture strength of a ductile material is determined by its necking behavior, which concentrates the plastic deformation in a small region, generates a triaxial stress state in the neck region, and propagates ductile fracture from voids that initiate at the center of the neck region. The fracture strength of a brittle material in tension, on the other hand, is limited by its cleavage stress.

In compression of a ductile material, necking does not occur, so the void generation and growth mechanism that leads to complete separation in the tension test does not terminate the compression test. Ductile fractures can form, however, on the barreled surface of a compression specimen with friction. These fractures generally grow slowly and do not lead to complete separation of the specimen, so the load-carrying capacity of the material is not limited. As a result, there is no definition of fracture strength in compression of ductile materials. Surface cracks that may form on the barreled surface of compression tests with friction depend not only on the material,

but also on the amount of friction and the L/D ratios of the specimen, as described in the section “Compression Testing for Ductile Fracture” in this article.

In compression of a brittle or low-ductility material, however, fracture occurs catastrophically by shear. The failure either occurs along one large shear plane, leading to complete separation, or at several sites around the specimen, leading to crushing of the material. In either case, the load-carrying capacity of the material comes to an abrupt halt, and the fracture strength of the material is easily defined as the load at that point divided by the cross-sectional area.

The ultimate strength of a material in tension is easily defined as the maximum load-bearing capacity. In a ductile material, this occurs at the initiation of necking. In a brittle material, it occurs at fracture. Because necking does not occur in compression testing, there is no ultimate compressive strength in ductile materials, and in brittle materials the ultimate compressive strength occurs at fracture. The only exception to this is in materials that exhibit severe work softening, in which case, plastic instability (Fig. 1f) leads to an upper limit in load-carrying capacity, which defines the ultimate strength of the material, as described in the section "Instability in Compression" in this article.

Plasticity Mechanics

Further understanding of the axial compression test can be obtained by examining the interactions between the plastic flow and forces acting during the test. The essential features of this interaction can be developed by considering a thin, vertical slab of material in a compression-test specimen (Fig. 2a). Pressure, P , from the compression platens acts on the top and bottom of the slab. Because this slab is to the right of the centerline, the slab moves to the right as the compression test progresses. Motion of the slab to the right, coupled with the pressure from the platens, causes friction, f , on the top and bottom surfaces of the slab. The direction of friction on the slab is to the left, opposing the motion of the slab.

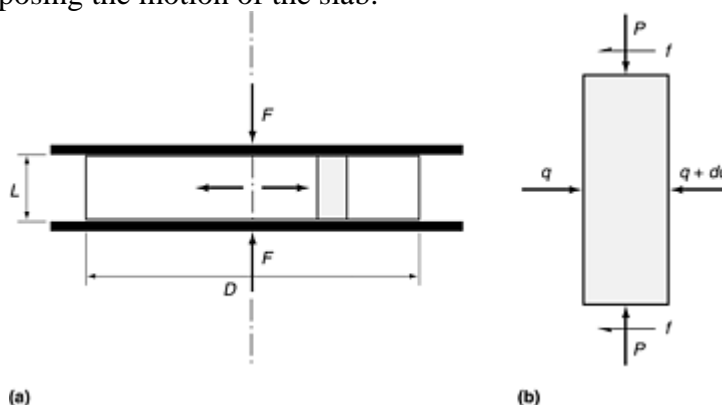

Fig. 2 Interactions between plastic flow and forces acting during compression testing. (a) Schematic of a compression test showing applied force F , radial expansion away from the centerline, and a slab element of material in a compression test. (b) Forces acting on the slab. P , pressure from the compression platens; f , friction at the contact surfaces, acting opposite to motion of the slab; q , internal radial pressure in the test specimen

Extracting the slab from the compression test, shown in Fig. 2(b), it is clear that the friction forces on the top and bottom of the slab cause an imbalance of forces in the horizontal direction. This implies that there must be internal horizontal forces acting on the vertical faces of the slab to maintain force equilibrium (forces due to acceleration are negligible). As shown in Fig. 2(b), the resulting horizontal pressure, q , acting on opposite sides of the slab must differ by some amount, dq , to achieve equilibrium.

Applying the principle of equilibrium to the slab in the horizontal direction gives a simple differential equation for the horizontal pressure q :

$$dq/dr = -2f/L \quad (\text{Eq 1})$$

where L is the thickness of the compression-test specimen. At the outside edge of the test specimen ($r = D/2$), the horizontal pressure must be zero (free surface); therefore, Eq 1 shows that q increases from zero at the edge to positive values inside the test specimen. Furthermore, Eq 1 shows that the rate of increase of q toward the centerline is larger for high values of friction and low values of specimen thickness. If f is constant, the internal pressure distribution is:

$$q = f(D/L)(1 - 2r/D) \quad (\text{Eq 2})$$

which has a peak value at $r = 0$.

Finally, the vertical pressure, P , is related to the internal pressure, q , by the yield criterion for plastic deformation:

$$P = q + \sigma_0 \quad (\text{Eq 3})$$

where σ_0 is the yield strength of the material. Therefore, P has the same distribution as the radial stress, q , plus the material yield strength. Integrating this pressure distribution over the contact area gives the total force, F .

Schematic plots of the pressure distribution, P , in axial compression are given in Fig. 3. Note that even though the deformation is uniform at every point, the compressive stress is not uniform, but reaches peak values at the centerline. The values of this peak pressure increase as friction increases and as the test specimen aspect ratio, L/D , decreases. More importantly, if friction is zero, Eq 2 shows that internal pressure, q , is zero throughout the test specimen. Then, from Eq 3, P is uniform and equal to σ_0 . Frictionless conditions, therefore, must be used to measure the plastic deformation response of a material, as described in the next section. More detailed analysis of the plasticity mechanics of axial compression are given in Ref 5.

Fig. 3 Schematic of pressure distributions, P , in a compression test. When friction is zero, P is uniform and equal to the material flow stress, σ_0 , but increasing friction and decreasing L/D with friction lead to increasingly nonuniform pressure distributions with peak values at the centerline.

The analysis given above is strictly valid only for specimens having very low aspect ratios. However, the essential roles of friction and geometry are valid qualitatively for test specimens having large aspect ratios; for these test specimens, the deformation patterns are very complex and vary in the thickness direction, as well as in the lateral direction. A macrograph of a compression test cross section, shown in Fig. 4(a), reveals the nonuniformity of internal deformation patterns due to friction at the contact surfaces. In general, the internal deformation depicted in Fig. 4(b) can be described as three zones (Ref 6): (a) nearly undeformed wedges at the top and bottom (referred to as dead-metal zones), (b) crisscrossing regions of intense shear deformation, and (c) moderately deformed regions near the barrel surfaces. The severity of barreling and the differences in degree of deformation between the three regions increase as friction at the contact surfaces increases.

Uniaxial Compression Testing

Howard A. Kuhn, Concurrent Technologies Corporation

Homogenous Compression for Plastic Deformation Behavior

Under homogenous-compression conditions (frictionless compression), height reduction and the resulting radial and circumferential expansion are uniform throughout the test specimen. Furthermore, under these conditions, radial and circumferential stresses are zero, and the only stress acting is the uniform compressive stress in the axial direction, as described in the previous section.

Homogenous compression is accomplished by eliminating friction at the contact surfaces, which obviously requires the use of lubricants. Polishing the ends of the compression-test specimens as well as the die platens provides smooth surfaces, and lubricants applied to the contact surfaces form a low-friction layer between these surfaces. However, during compression of high-strength materials, the interface pressure between the test specimen and die platens becomes extremely high, and the lubricant squeezes out, leaving metal-on-metal contact, resulting in high friction.

One approach to retaining lubricants at the contact surface involves machining concentric circular grooves into the end faces of the test specimen (Fig. 5a) (Ref 7). Another approach was pioneered by Rastegaev and refined by Herberthz and Wiegels (Ref 8), in which the entire end face is machined away except for a small rim, as shown in Fig. 5(b). This traps a small volume of lubricant in the cavity, forming a hydrostatic cushion with nearly zero friction. This approach was modified by machining a tapered recess, as shown in Fig. 5(c), which reduces the amount of material removed and diminishes the strain measurement error. Furthermore this lubricant recess provides greater lubrication at the rim where material movement is greatest. During compression testing, radial displacement of the test material is zero at the center and increases linearly to the

outer rim. Evaluations of lubrication practice for high-temperature testing have shown that the tapered lubricant reservoir shown in Fig. 5(c) leads to the greatest reproducibility (Ref 9).

Fig. 5 Compression-test end profiles for lubricant entrapment. (a) Concentric grooves. Source: Ref 7. (b) Rastegaev reservoir. Source: Ref 8. (c) Modified Rastegaev reservoir. Source: Ref 9

Several high-pressure lubricants are available for room-temperature compression tests, including mineral oil, palm oil, stearates, and molybdenum disulfide. Teflon (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) in the form of spray or sheet is also widely used at room temperature and can be used at temperatures up to 500 °C (930 °F). For high-temperature testing of steels, titanium, and superalloys, one can use emulsions of graphite, molybdenum disulfide, and various glasses. It is important to match the grade of glass and resulting viscosity with the test temperature.

In homogenous compression tests, the plastic stress-strain curve can be easily calculated by measurement of the load, cross-sectional area, and height of the specimen throughout the test. The test can be conducted incrementally at room temperature wherein the specimen height and lateral dimensions are measured after each increment of deformation. For high-temperature deformation or continuous testing, the test-equipment load cell and crosshead displacement can be used to determine the load and dimensional changes of the specimen. In the latter measurement, it is necessary to remove systematic errors by first carrying out the compression test with no test specimen in place. This provides a load-stroke curve for the test-machine load train and measures the compliance of the various elements in the loaded column. Subtracting this compliance from the measured crosshead stroke during a compression test then provides a more accurate measurement of the specimen deformation. In any event, if constancy of volume can be assumed for the material being tested, then the cross-sectional area can be readily calculated from the specimen height at any point throughout the test.

Compression Testing for Ductile Fracture

When friction exists at the die contact surfaces, material at the contact surfaces is retarded from moving outward while the material at the midplane is not constrained. As a result, barreling occurs, as shown in Fig. 1(c) and 1(d). Under these conditions, for a given axial compressive strain, the bulge profile provides circumferential strain at the equator that is greater than the strain that occurs during homogenous compression. At the same time, due to the bulge profile, the local compressive strain at the equator is less than the strain that would have occurred during homogenous compression for the same overall height strain. These surface strain deviations from homogenous compression increase as bulging increases; the severity of the bulge, in turn, is controlled by the magnitude of friction and the L/D ratio of the specimen. Figure 6 illustrates the progressive change in strain at the bulge surface for different lubrication and L/D ratios (Ref 10).

Fig. 6 Progressive change in strain at the bulge surface in compression testing. (a) Strains at the bulge surface of a compression test. (b) Variation of the strains during a compression test without friction (homogenous compression) and with progressively higher levels of friction and decreasing aspect ratio L/D (shown as h/d)

These strain combinations lead to tensile stress around the circumference and reduced compressive stress at the bulge equator. Therefore, compression tests with friction, and consequent bulging, can be used as tests for fracture. Figure 7 shows compression-test specimens with and without friction. Note that the compression test with the bulge surface, that is, with friction at the contact surfaces, has a crack caused by the tensile stress in the circumferential direction at the bulge surface. The homogenous compression specimen, even after greater height compression, has not bulged; therefore, there is no tensile stress in the circumferential direction, and the specimen has not cracked.

Fig. 7 Compression tests on 2024-T35 aluminum alloy. Left, undeformed specimen; center, compression with friction (cracked); right, compression without friction (no cracks)

The stress and strain environment at the bulge surface of upset cylinders suggests that axial compression tests can be used for workability measurements by carrying out the tests under a variety of conditions regarding interface friction and L/D ratios. By plotting the surface strains at fracture for each condition, a fracture strain locus can be generated representing the workability of the material. Figure 8 illustrates such a fracture locus. Modifications of the cylindrical compression-test specimen geometry have been used to enhance the range of strains over which fracture can be measured (Ref 11).

Instability in Compression

In tension testing, the onset of necking indicates unstable flow, characterized by a rapid decrease in diameter localized to the neck region. Up to this point, as the test specimen elongates, work hardening of the material compensates for the decrease in cross-sectional area; therefore, the material is able to carry an increasing load. However, as the work-hardening rate decreases, the flow stress acting across the decreasing cross-sectional area is no longer able to support the applied axial load. At this point, necking begins and the rate of decrease of cross-sectional area exceeds the rate of increase of work hardening, leading to instability and a rapidly falling tensile load as the neck progresses toward fracture.

In compression testing, a similar phenomenon occurs when work softening is prevalent (Ref 12). That is, during compression, the cross-sectional area of the specimen increases, which increases the load-carrying capability of the material. However, if work softening occurs, its load-carrying capability is decreased. When the rate of decrease in strength of the material due to work softening exceeds the rate of increase in the area of the specimen, an unstable mode of deformation occurs in which the material rapidly spreads in a localized region, as shown in Fig. 1(f).

Instability in tension and compression can be described through the Considère construction. Instability occurs when the slope of the load-elongation curve becomes zero, that is:

$$dF = d(\sigma A) = \sigma dA + Ad\sigma = 0$$

or

$$d\sigma/\sigma = -dA/A = d\varepsilon = de/(1 + e)$$

and

$$d\sigma/de = \sigma/(1 + e) \tag{Eq 4}$$

where σ is true stress, ε is true strain, e is engineering strain, F is force, and A is area.

Equation 4 indicates that instability occurs when the slope of the true stress-engineering strain curve equals the ratio of true stress to one plus the engineering strain. This leads to the Considère construction for instability (Fig. 9). The upper part of Fig. 9 shows the Considère construction for a tension test. When the work hardening stress-strain curve reaches point C , necking begins and unstable deformation continues through to complete separation or fracture. This defines the ultimate strength of the material in tension. In the lower part of Fig. 9, the Considère construction for the compression test shows that, for a work softening material, unstable flow commences at point C' , leading to a configuration as shown in Fig. 1(f). Thus, the ultimate strength of the material in compression in this case can be defined as the stress at this point.

Fig. 9 Considère construction showing instability conditions in tension testing (due to decreasing work-hardening rate) and in compression testing (due to work softening)

Materials that undergo severe work softening are prone to compressive instabilities. While useful in itself, this precludes measurement of the bulk plastic deformation behavior of the material, just as the necking instability in tension testing prevents measurement of plastic deformation behavior at large strains. Several metallurgical conditions can lead to such work softening. These include dynamic recovery and dynamic recrystallization where substructure rearrangements and dislocation reductions lead to a rapid decrease in flow stress. Morphological changes in second phases, such as the rapid spheroidization of pearlite at elevated temperatures, the coarsening of small spherical precipitates, and the coarsening of martensitic substructures, are another source of work softening. Further examples of work softening include incipient melting of eutectic phases and localized shear-band formation, seen commonly in titanium alloys.

Uniaxial Compression Testing

Howard A. Kuhn, Concurrent Technologies Corporation

Test Methods

Axial compression testing is a useful procedure for measuring the plastic flow behavior and ductile fracture limits of a material. Measuring the plastic flow behavior requires frictionless (homogenous compression) test conditions, while measuring ductile fracture limits takes advantage of the barrel formation and controlled stress and strain conditions at the equator of the barreled surface when compression is carried out with friction. Axial compression testing is also useful for measurement of elastic and compressive fracture properties of brittle materials or low-ductility materials. In any case, the use of specimens having large L/D ratios should be avoided to prevent buckling and shearing modes of deformation.

Axial compression tests for determining the stress-strain behavior of metallic materials are conducted by techniques described in test standards, such as:

- ASTM E 9, “Compression Testing of Metallic Materials at Room Temperature”
- DIN 50106, “Compression Test, Testing of Metallic Materials”
- ASTM E 209, “Compression Tests of Metallic Materials at Elevated Temperatures with Conventional or Rapid Heating Rates and Strain Rates”

This section briefly reviews the factors that influence the generation of valid test data for tests conducted in accordance with ASTM E 9 and the capabilities of conventional universal testing machines (UTMs) for compression testing.

Specimen Buckling

As previously noted, errors in compressive stress-strain data can occur by the nonuniform stress and strain distributions from specimen buckling and barreling. Buckling can be prevented by avoiding the use of specimens with large length-to-diameter ratios, L/D . In addition, the risk of specimen buckling can be reduced by careful attention to alignment of the loading train and by careful manufacture of the specimen according to the specifications of flatness, parallelism, and perpendicularity given in ASTM E 9. However, even with well-made specimens tested in a carefully aligned loading train, buckling may still occur. Conditions that typically induce buckling are discussed in the following sections.

Alignment. The loading train, including the loading faces, must maintain initial alignment throughout the entire loading process. Alignment, parallelism, and perpendicularity tests should be conducted at maximum load conditions of the testing apparatus.

Specimen Tolerances. The tolerances given in ASTM E 9 for specimen end-flatness, end-parallelism, and end-perpendicularity should be considered as upper limits. This is also true for concentricity of outer surfaces in cylindrical specimens and uniformity of dimensions in rectangular sheet specimens. If tolerances are reduced from these values, the risk of premature buckling is also reduced.

Inelastic Buckling. Only elastic buckling is discussed in ASTM E 9. This may be somewhat unrealistic, because for the most slender specimen recommended, the calculated elastic buckling stresses are higher than can be achieved in a test. This specimen has a length-to-diameter ratio of 10. An approximate calculation using the elastic Euler equation for a steel specimen with flat ends on a flat surface (assumed value of end-fixity coefficient is 3.5) yields a buckling stress in excess of 4100 MPa (600 ksi); the comparable value for an aluminum specimen would be 1380 MPa (200 ksi). These values, however, are not realistic.

Buckling stress in the above example should not be calculated by an elastic formula but by an inelastic buckling relation. In terms of inelastic buckling it has been concluded that the following relation appropriately calculates inelastic buckling stresses (Ref 13):

$$S_{cr} = C\pi^2 \left[\frac{E_t}{(L/\rho)^2} \right] \quad (\text{Eq 5})$$

where S_{cr} is the buckling stress in MPa (ksi); C is the end-fixity coefficient; E_t is the tangent modulus of the stress-strain curve in MPa (ksi); L is the specimen length in mm (in.); and r is the radius of gyration of specimen cross section in mm (in.). Equation 1 reduces to the Euler equation if E , the modulus of elasticity, is substituted for E_t .

Rearranging Eq 5 to combine the stress-related factors results in:

$$\left(\frac{1}{C\pi^2} \right) \left(\frac{L}{\rho} \right)^2 = \frac{E_t}{S_{cr}} \quad (\text{Eq 6})$$

Note that the value of the right side of Eq 6 decreases as stress increases in a stress-strain curve. In a material with an elastic-pure-plastic response, the right side of Eq 6 vanishes, because E_t becomes zero, and buckling will always occur at the yield stress. When the material exhibits strain hardening, calculations using Eq 6 will yield the appropriate specimen dimensions to resist buckling for given values of stress.

Side Slip. Figure 10 illustrates one form of buckling of cylindrical specimens that can result from misalignment of the loading train under load or from loose tolerances on specimen dimensions. The ends of the specimen undergo sideslip, resulting in a sigmoidal central axis. This form of buckling could be described by Eq 5 and 6, provided an appropriate value of the end-fixity coefficient can be assigned.

Fig. 10 Schematic diagram of side-slip buckling. The original position of the specimen centerline is indicated by the dashed line.

Thin-Sheet Specimens. In testing thin sheet in a compression jig, approximately 2% of the specimen length protrudes from the jig. Buckling of this unsupported length can occur if there is misalignment of the loading train such that it does not remain coaxial with the specimen throughout the test (Ref 14). A typical compression jig and contact-point compressometer are shown in Fig. 11(a) and (b) respectively.

Fig. 11 Compression testing of thin-sheet specimens. (a) Sheet compression jig suitable for room-temperature or elevated-temperature testing. (b) Contact-point compressometer installed on specimen removed from jig. Contact points fit in predrilled shallow holes in the edge of the specimen.

Barreling of Cylindrical Specimens

When a cylindrical specimen is compressed, Poisson expansion occurs. If this expansion is restrained by friction at the loading faces of the specimen, nonuniform states of stress and strain occur as the specimen acquires a barreled shape (Fig. 12). The effect on the stress and strain distributions is of consequence only when the deformations are on the order of 10% or more.

Fig. 12 Barreling during a test when the friction coefficient is 1.00 at the specimen loading face. Note that as the deformation increase, points *A*, *B*, and *C* originally on the specimen sides, move to the loading face.

Friction on the loading face causes rollover. As shown in Fig. 12, points originally on the sides of the specimen are ultimately located on the specimen end face. Use of a high-pressure lubricant at the loading surface of the specimen reduces friction. One such material commonly used is 0.1 mm (0.004 in.) thick Teflon sheet. The action of the lubricant may be enhanced if the bearing surfaces that apply the load are hard and highly polished. The use of tungsten-carbide bearing blocks is recommended for all materials undergoing compression testing. Other techniques have been used to reduce nonuniformity of stress and strain distributions along the gage length (Ref 15, 16).

The contact area between the lateral faces of the specimen and the lateral support guides of the testing jig must be well lubricated. Personnel engaged in sheet compression testing should become familiar with the literature on the subject. A selected bibliography on this subject is given in ASTM E 9.

Testing Machine Capacity

In a compression test performed to large strains (e.g., to obtain fracture data), a large load capacity may be required. For example, consider four medium-length cylindrical specimens suggested in ASTM E 9, where specimens are specified with diameters that range from 12.7 to 28.4 mm (0.50 to 1.12 in.) and with length-to-diameter ratios of 3. Using these specimen sizes, consider the testing of a material with a yield stress of 1380 MPa (200 ksi) and a compression strain-hardening exponent of 0.05. Figure 13 illustrates the load-capacity requirements to reach a height reduction of 60% for each of the four cylinders recommended in ASTM E 9. The maximum required load is approximately 3.5 times the load at yield. The required capacity for testing the same specimens to failure at 60% strain in tension would be no more than 1.5 times the yield loads.

Fig. 13 Load requirements for compressing specimens of various diameters made of a material with a yield stress of 1380 MPa (200 ksi) and a strain-hardening exponent of 0.05. Diameters: A = 28.4 mm (1.12 in.), B = 25.4 mm (1.00 in.), C = 20.3 mm (0.80 in.), D = 12.7 mm (0.50 in.). Length-to-diameter ratio (L/D) = 3

Medium-Strain-Rate Testing

Medium-strain-rate compression testing with conventional load frames is very similar to low-strain-rate compression testing. For medium-rate testing, the load frames require the capability to generate higher crosshead or ram velocities. An important consideration is the stiffness of the machine, as discussed in more detail in the article “Testing Machines and Strain Sensors” in this Volume. For tests at a uniform strain rate, a high machine stiffness is desired; techniques to increase the stiffness of a hydraulic machine are described in Ref 17. This section describes some of the techniques used to obtain medium strain rates with conventional test frames and additional experimental factors for measurement of load and strain at medium rates.

Grip design for compression testing at medium strain rates requires the same considerations that apply to grip design for low strain rates. The compression specimen typically is sandwiched between two hard, polished platens that are placed in a subpress designed to maintain parallel faces during deformation. A typical grip assembly is shown in Fig. 14, in which a compression specimen (5.1 mm, or 0.2 in., long by 5.1 mm, or 0.2 in., diam) is in place and ready for testing. The ram is shown in position and is separated from the subpress by approximately 20 mm (0.8 in.). This gap allows time (approximately 2 ms at the highest ram velocity) for the ram to accelerate to the specified velocity. In this test, the stroke of the ram must be set accurately to ensure the desired deformation.

Fig. 14 Subpress assembly for medium strain-rate testing with conventional load frame. The specimen, which is 5.1 mm (0.2 in.) diam by 5.1 mm (0.2 in.) long, is sandwiched between two highly polished platens. A quartz load washer is shown positioned above the subpress assembly.

Measurement of Load and Displacement. As the strain rate increases, the measurement of load and displacement becomes increasingly more difficult. The requirement for adequate frequency response in the signal conditioners and the problems associated with load-cell ringing were discussed in the introduction to this article. In this section, the measurement of load and displacement at medium strain rates is described in more detail.

Measurement of Load. A typical load cell determines load by measuring displacement in an elastic member, such as a diaphragm or cylinder. The displacements are measured with bonded strain gages; this gives the load cell sufficient intrinsic frequency response for testing at medium strain rates. However, a problem often arises due to ringing in the load cell. The load cell has a natural frequency of vibration determined by geometry and physical properties, such as density and elastic modulus. Typical load cells have a natural frequency in the range of 500 to 5000 Hz. In effect, the natural frequency of vibration sets the bandwidth of the load-measuring system.

By this criterion alone, load cells should be sufficient for compression testing at strain rates as high as 100 s^{-1} . However, the transient response of the load cell in practice limits the measurement to much lower strain rates. When a constant-strain-rate test is desired, deformation must be initiated by an impact due to the acceleration time required by the ram. This impact can excite the natural vibrational mode of the load cell, which will produce oscillations in the output signal that can mask the actual load measurement. Unless the impact is dampened by some means, load measurement at strain rates greater than about 1 s^{-1} can be subject to load-cell ringing.

Ringing of the load cell can be minimized by selecting a load cell with a high vibrational frequency. If the natural frequency is sufficiently high, the vibrational mode may not be excited by the impact, or if excited, it may be possible to remove it from the signal with a low pass filter. Another method to reduce ringing is to dampen the impact that initiates deformation within the specimen. Often, a thin layer of deformable material placed between the impacting surfaces is sufficient to remove the higher frequencies generated by the impact that can excite the natural frequency of the load cell. For example, in the configuration shown in Fig. 14, a single loop, approximately 50 mm (2 in.) in diameter, of 0.51 mm (0.02 in.) diameter lead-tin solder wire

placed on the impacting face of the hydraulic ram was found to be effective in minimizing load-cell ringing. Such layers, however, may complicate measurement of displacement within the specimen.

At strain rates close to 100 s^{-1} , the standard load cell either may not possess the necessary frequency response, or it may ring excessively. These characteristics can make the load cell inadequate for load measurement. Under these conditions, a quartz piezoelectric device, such as a load washer (Fig. 14), is useful. The load washer is convenient because it is easily adapted to a compression test; it also has excellent intrinsic frequency response and a high fundamental vibrational frequency. However, these devices require special signal conditioning and low-capacitance cables.

Measurement of Strain. The direct measurement of strain at medium strain rates presents a challenge. Many of the devices typically used for low-strain-rate testing are inappropriate at medium strain rates. Extensometers, for example, may have the necessary response characteristics for medium-strain-rate testing. However, it is difficult to ensure that the rapid and large displacement in small compression specimens will not damage the fragile extensometer.

Many hydraulic test frames use a linear variable differential transformer (LVDT) to control the motion of the hydraulic ram. This LVDT signal is comprised of displacements within the specimen as well as elastic displacements throughout the test frame. To relate this signal to displacements within the specimen, the latter contribution must be subtracted; this problem also is encountered at low strain rates. If a deformable material is placed between the impact surfaces to dampen the impact, the displacements within this layer also must be subtracted from the LVDT signal.

A common practice is to mount the LVDT at an off-axis position adjacent to the specimen. The benefit of this configuration is that a displacement measurement is possible between two points that are quite close to the specimen; this measurement includes less of the elastic deformation in the load frame. When a measurement is made at an off-axis position, it is important to verify that the measurement truly represents displacements within the sample. Often, two LVDT units are mounted at diametrically opposite positions, and their outputs are processed to eliminate the effects of nonplanar motion. The LVDT suffers from an intrinsic frequency-response limitation determined by the excitation frequency. Standard excitation frequencies are in the range of 1 to 5 kHz, which limits the frequency response to around 100 to 500 Hz.

Velocity transducers, which have good intrinsic frequency response, have been used to measure the motion of the specimen and grip assembly (Ref 17). Their output can be integrated electronically or by computer to obtain the displacement. Generally, these also require mounting at off-axis locations.

Strain measurement by noncontact methods is becoming more common with optical extensometers or laser interferometers. Laser interferometers, which are capable of operating at high sampling rates, can be used to measure strain at strain rates exceeding 10^3 s^{-1} .

Types of Compressive Fracture

For all but the most ductile materials, cylindrical specimens develop cracks when they are compressed. The cracks generally initiate on the outer surface of the compressed specimen. As the specimen is further deformed, the initiated cracks propagate, and new cracks form. Some different modes of compression fracture are described in Ref 18 and some examples are described in the following sections.

Orange Peel Cracking. In many materials, roughening or wrinkling of the surface (orange peel effect) occurs prior to compressive cracking. This effect is particularly prominent in some aluminum alloys. An extreme example is illustrated for an aluminum alloy 7075-T6 specimen in Fig. 15. The specimen is shown after 72% deformation. Wrinkling first appeared at 10 to 15% compressive deformation, and macrocracking occurred after 50 to 60% deformation. Microscopic examination revealed many microcracks in the valleys of the wrinkles, with greatest concentration in the equatorial region of the specimen. Defining a compression strength or a strain criterion of fracture would be difficult for this material.

Fig. 15 Two views of a 72% compressed specimen of aluminum alloy 7075-T6 displaying orange peel effect. The loading axis is vertical. Extensive macrocracking is evident in the severely wrinkled surface. Microscopic examination of the surface revealed extensive microcracking in the valleys of the wrinkles. Source: Ref 16

Macrocracks in Steel. A case in which macrocracks form without apparent precursor microcracks is shown in Fig. 16. The material is AISI-SAE 4340 steel tempered at 204 °C (400 °F), yielding a hardness of 52 HRC. The cracks initiated one at a time and extended across the surface of the specimen almost instantaneously. The first cracks appeared when the compressive deformation reached 30%, and other cracks continued to initiate until the test was concluded at 72% deformation, which is the condition shown in Fig. 16. The specimen was still intact, and subsequent sectioning revealed that the cracks penetrated inward a distance of diameter.

Fig. 16 Shear cracks in a 72% compressed specimen of AISI-SAE 4340 steel. The cracks initiated one at a time, starting when the deformation was 30%. Source: Ref 16

Microcrack to Macrocrack Coalescence. In some tungsten alloys, the first visible evidence of fracture is a shear macrocrack that appears at the equator of the specimen after 45 to 50% compressive deformation. However, using fluorescent-dye penetrant methods, microcrack initiation was detected at 25% deformation (Ref 18). For this material, if crack initiation is the criterion of failure, it is necessary to state the method of crack detection with the selected parameter for strength.

Hot Tension and Compression Testing

Dan Zhao, Johnson Controls, Inc.; Steve Lampman, ASM International

Introduction

HIGH-TEMPERATURE MECHANICAL PROPERTIES of metals are determined by three basic methods:

- Short-term tests at elevated temperatures
- Long-term tests of creep deformation at elevated temperatures
- Short-term and long-term tests following long-term exposure to elevated temperatures

This article focuses on short-term tension and compression testing at high temperatures. The basic methods and specimens are similar to room-temperature testing, although the specimen heating, test setup, and material behavior at higher temperatures do introduce some additional complexities and special issues for high-temperature testing.

Two types of long-term testing for high-temperature applications are not discussed in this article. The first type is long-term exposure testing, where materials are exposed to high temperatures prior to mechanical testing at either ambient or elevated temperatures. This type of testing is needed for the evaluation of metallurgical changes that can occur during exposure to high temperatures. The second type of long-term test for many high-temperature structural applications is the creep test. When the application temperature, T , of a stressed metallic or ceramic material is in the range of about $0.3 T_M < T < 0.6 T_M$ (where T_M is the melting point of the material in Kelvin), the stressed material undergoes a continuous accumulation of plastic strain (i.e., creep) over time. The continuous accumulation of creep strain can occur even when the material is stressed below its elastic limit; therefore many high-temperature structural applications require creep testing. This type of testing is discussed in more detail in the Section “Creep and Stress-Relaxation Testing” in this Volume. For metals and ceramics, creep occurs in the temperature range of about $0.3 T_M$ to $0.6 T_M$. For polymers, creep deformation is a factor at temperatures above the glass transition temperature, T_g , of a polymer.

Hot Tension and Compression Testing

Dan Zhao, Johnson Controls, Inc.; Steve Lampman, ASM International

Effects of Temperature

In general terms, the effects of temperature on the mechanical behavior of metals can be classified into three basic ranges based on the application temperature, T , relative to the melting point, T_M , of a metal as follows:

- Cold working applications, $T < 0.3 T_M$
- Warm working applications, $0.3 T_M < T < 0.6 T_M$
- Hot working applications, $T > 0.6 T_M$

These general temperature ranges are based on the underlying physical processes that influence mechanical behavior at different temperatures. For example, the warm working temperature range ($0.3 T_M < T < 0.6 T_M$) is the region of creep deformation. It is also the region of recovery and recrystallization. This includes high-temperature applications of structural materials (such as those listed in Table 1) and room-temperature testing of metals with low melting points.

Table 1 Typical elevated temperatures in engineering applications

Application	Typical materials	Typical temperatures , K	Homologous temperatures , T/T_{ME}
Rotors and piping for steam turbines	Cr-Mo-V steels	825–975	0.45–0.50
Pressure vessels and piping in nuclear reactors	316 stainless steel	650–750	0.35–0.40
Reactor skirts in nuclear reactors	316 stainless steel	850–950	0.45–0.55
Gas turbine blades	Nickel-base superalloys	775–925	0.45–0.60
Burner cans for gas turbine engines	Oxide dispersion-strengthened nickel-base alloys	1350–1400	0.55–0.65

Source: Ref 1

In general, strength is reduced at high temperatures, and materials become softer and more ductile as temperature increases. However, the rate and direction of property changes can vary widely for the yield strength and elongation of various alloys as function of temperature, as shown in Fig. 1. These changes are due to various metallurgical factors. For example, there is a significant drop in the ductility of 304 stainless steel in the temperature range of 425 to 870 °C (800–1000 °F). This ductility drop is from the embrittling effect of carbide precipitation in the grain boundaries.

Fig. 1 Effect of temperature on strength and ductility of various materials. (a) 0.2 offset yield strength. (b) Tensile elongation. Source: Ref 2

Other factors, which often cannot be easily predicted, can also affect mechanical behavior at high temperatures. For example, resolutioning, precipitation, and aging (diffusion-controlled particle growth) can occur in two-phase alloys, both during heating prior to testing and during testing itself. These processes can produce a wide variety of responses in mechanical behavior depending on the material. For example, Fig. 2 shows the effect of exposure time on the high-temperature yield strength and elongation of a precipitation-hardening aluminum alloy.

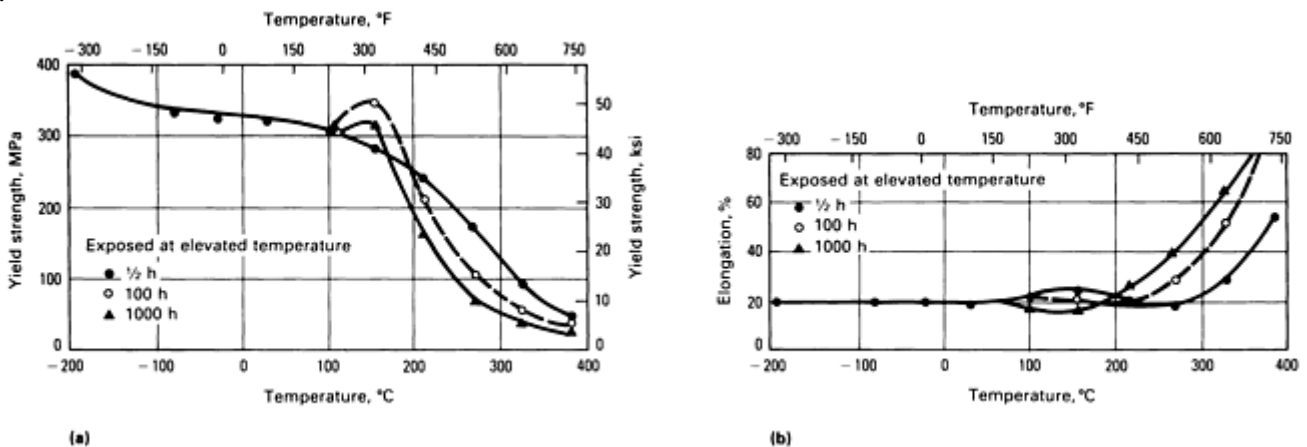

Fig. 2 Effect of exposure time on (a) yield strength and (b) elongation at testing temperature for an aluminum alloy 2024. Source: Ref 2

Effect of Temperature on Deformation and Strain Hardening. As temperature increases, the strength of a material usually decreases and the ductility increases. The general reduction in strength and increase in ductility of metals at high temperatures can be related to the effect of temperature on deformation of the material. At room temperature, plastic deformation occurs when dislocations in the material slip. The dislocations also intersect and build up in the material as they slip. This build-up of dislocations restricts the slip, and, thus, increases the forces necessary for continued deformation. This process is known as strain hardening or work hardening.

At elevated temperatures, dislocation climb comes into play as another deformation mechanism. Further, the build-up of strain energy from strain hardening can be relieved at high temperatures when crystal imperfections are rearranged or eliminated into new configurations. This process is known as recovery. A much more rapid restoration process is recrystallization, in which new, dislocation-free crystals nucleate and grow at the expense of original grains. The restoration processes can be greatly enhanced by the increase in the thermal activity and mobility of atoms at higher temperatures. As a result, lower stress is required for deformation, as shown in the stress-strain diagrams of several materials at elevated temperatures (Fig. 3 4 5 6 7).

Deformation under tensile conditions is also governed to some extent by crystal structure. Face-centered cubic (fcc) materials generally exhibit a gradual change in strength and ductility as a function of temperature. Such a change in the strength of 304 austenitic stainless steel is illustrated in Fig. 1. Some body-centered cubic (bcc) alloys, however, exhibit an abrupt change at the ductile-to-brittle transition temperature (~ 200 °C, or 390 °F, for tungsten in Fig. 1), below which there is little plastic flow. In hexagonal close-packed (hcp) and bcc materials, mechanical twinning can also occur during testing. However, twinning by itself contributes little to the overall elongation; its primary role is to reorient previously unfavorable slip systems to positions in which they can be activated.

There are exceptions to these generalizations, particularly at elevated temperatures. For example, at sufficiently high temperatures, the grain boundaries in polycrystalline materials are weaker than the grain interiors, and intergranular fracture occurs at relatively low elongation. In complex alloys, hot shortness, in which a liquid phase forms at grain boundaries, or grain boundary precipitation can lead to low strength and/or ductility.

Diffusion processes are also involved in yield-point and strain-aging phenomena. Under certain combinations of strain rate and temperature, interstitial atoms can be dragged along with dislocations, or dislocations can alternately break away and be repinned, producing serrations in the stress-strain curves. This produces effects such as discontinuous yielding and upper yield-strength behavior, which are a common occurrence in the tension testing of low-carbon steels (see the article "Uniaxial Tension Testing" in this Volume).

Another effect that can be accelerated during high-temperature testing is strain aging. In strain aging, cold-worked steels (especially rimmed or capped steels) undergo a loss in ductility while stored at room temperature. This loss in ductility is typically attributed to precipitation and diffusion-controlled particle growth along the slip planes. The precipitation occurs along slip lines because plastic deformation presumably causes local areas of supersaturation along the slip lines (Ref 7). Strain aging is more pronounced in rimmed and capped steels than in killed steels. Steels that are drastically deoxidized with aluminum or aluminum and titanium are essentially nonaging (Ref 8).

Strain aging also causes a ductility drop (and a corresponding increase in hardness and strength) during high-temperature tension testing of some steels. This effect on tensile strength is shown in Fig. 8 for a mild steel and a stabilized (nonaging) steel. The increase in strength at elevated temperature is attributed to the acceleration of precipitation in the grain boundaries, and at high temperature, the influence of strain on precipitation can be the actual deformation occurring during the hot tension test (Ref 4). This effect is known as strain-age embrittlement.

Fig. 8 Effect of testing temperature on tensile strength of ordinary mild steel and of nonaging steel. The nonaging steel gives almost no indication of the “blue heat” phenomenon. The ductility in a tension test of the nonaging steel in the “blue heat” region is considerably higher than the ductility of ordinary aging mild steel sheet. Source: Ref 7

Hot tension testing is one of the simplest ways to distinguish aging steels from nonaging steels. This is shown in Fig. 8 and 9. Aging steels develop an increase in strength and a decrease in ductility within the temperature range of about 230 to 370 °C (450–700 °F). This strain-aging effect is also known as blue brittleness, because the effect occurs in the blue-heat region. Tension testing in the blue-heat region is thus one way to identify aging steels. Blue brittleness affects tensile strength and elongation values (Fig. 10a and b) but not yield strength (Fig. 10c). Although the effect is more pronounced in rimmed or capped steels, strain aging is also observed in killed steels (Fig. 11). Drastically killed steels are nonaging.

Fig. 9 Stress-strain curves of ordinary mild steel sheet and nonaging sheet tested at various temperatures. The higher tensile strength and the “stepped” or “saw-toothed”

stress-strain curve of the ordinary sheet in the “blue heat” region are characteristic. These features are absent in the nonaging sheet. Source: Ref 7

High-Temperature Creep in Structural Alloys. At higher temperatures (between $0.3 T_M$ and $0.6 T_M$), metals and ceramics are subject to thermally activated processes that can produce continuous plastic deformation (creep) with the application of a constant stress. For metals, various mechanisms are used to explain creep deformation, but all the mechanisms can fall into two basic categories: diffusional creep and dislocation creep (Ref 10).

In diffusional creep, diffusion of single atoms or ions, either by bulk transport (Nabarro-Herring creep) or by grain-boundary transport (Coble creep) leads to Newtonian viscous flow. In this type of creep, steady-state creep rates vary linearly. At low stresses, diffusional creep is seen only at very high temperatures in the hot working region ($T > 0.6 T_M$) and, thus, is not a factor in typical high-temperature structural applications.

For high-temperature structural applications (such as the examples in Table 1), dislocation creep mechanisms are operative at intermediate and high stresses. These mechanisms include thermally activated processes, such as multiple slip and cross slip, allowing stress relaxation and reductions in strength. In this temperature region, creep rates are typically a nonlinear function of stress. They are either a power function or an exponential function of stress (Ref 7).

Mechanical Testing for High-Temperature Structural Alloys. Maximum-use temperatures of structural materials can depend on different design criteria, such as strength or graphitization/oxidation in steels (Table 2) or creep rate and rupture strength (Table 3). When mechanical testing is performed for high-temperature structural applications, the testing generally includes a combination of both short-term testing for tensile properties and long-term testing of creep rate and rupture strength.

Table 2 Temperature limits of superheater tube materials covered in ASME Boiler Codes

Material	Maximum-use temperature			
	Oxidation/graphitization criteria, metal surface ^(a)		Strength criteria, metal midsection	
	°C	°F	°C	°F
SA-106 carbon steel	400–500	750–930	425	795
Ferritic alloy steels	550	1020	510	950
0.5Cr-0.5Mo				
1.2Cr-0.5Mo	565	1050	560	1040
2.25Cr-1Mo	580	1075	595	1105
9Cr-1Mo	650	1200	650	1200
Austenitic stainless steel, Type 304H	760	1400	815	1500

(a) In the fired section, tube surface temperatures are typically 20–30 °C (35–55 °F) higher than the tube midwall temperature. In a typical U.S. utility boiler, the maximum metal surface temperature is approximately 625 °C (1155 °F).

Table 3 Suggested maximum temperatures in petrochemical operations for continuous service based on creep or rupture data

Material	Maximum temperature based on creep rate		Maximum temperature based on rupture	
	°C	°F	°C	°F
Carbon steel	450	850	540	1000
C-0.5Mo steel	510	950	595	1100
2¼Cr-1Mo steel	540	1000	650	1200
Type 304 stainless steel	595	1100	815	1500
Alloy-C-276 nickel-base alloy	650	1200	1040	1900

The test temperatures for short-term properties depend on the alloy and its typical maximum-use temperature for application. For example, Fig. 12 is a summary of short-term and long-term properties of various low-alloy steels with short-term properties up to about 540 °C (1000 °F). In contrast, short-term strength for austenitic stainless steels (Fig. 13), martensitic stainless steels (Fig. 14), and superalloys (Fig. 15) are tested at higher temperatures. Other examples of short-term strength at high temperatures are shown for nonferrous alloys (Fig. 16) and precipitation-hardening (PH) stainless steels (Fig. 17). The PH stainless steels have lower maximum-use temperatures than other stainless steels due to a rapid drop in strength at about 425 °C (800 °F) (Fig. 18).

AM 350	Solution annealed at 1038–1066 °C (1900–1950 °F), reheated to 932 °C (1710 °F), cooled in air, treated at -73 °C (-100 °F), aged at 454 °C (850 °F)

Fig. 17 Short-time tensile, rupture, and creep properties of precipitation-hardening stainless steels

Fig. 18 General comparison of the hot-strength characteristics of austenitic, martensitic, and ferritic stainless steels with those of low-carbon unalloyed steel and semiaustenitic precipitation and transformation-hardening steels

When short-term tests are considered at high-temperature, the effect of testing time must be considered. Because creep occurs continuously over time, a longer test in the creep region results in lower strength values. This is shown in Fig. 19 for various mechanical properties of H11 die steel. Testing at higher temperatures also increases strain-rate effects because slower strain rates allow more time for creep to occur (Fig. 4).

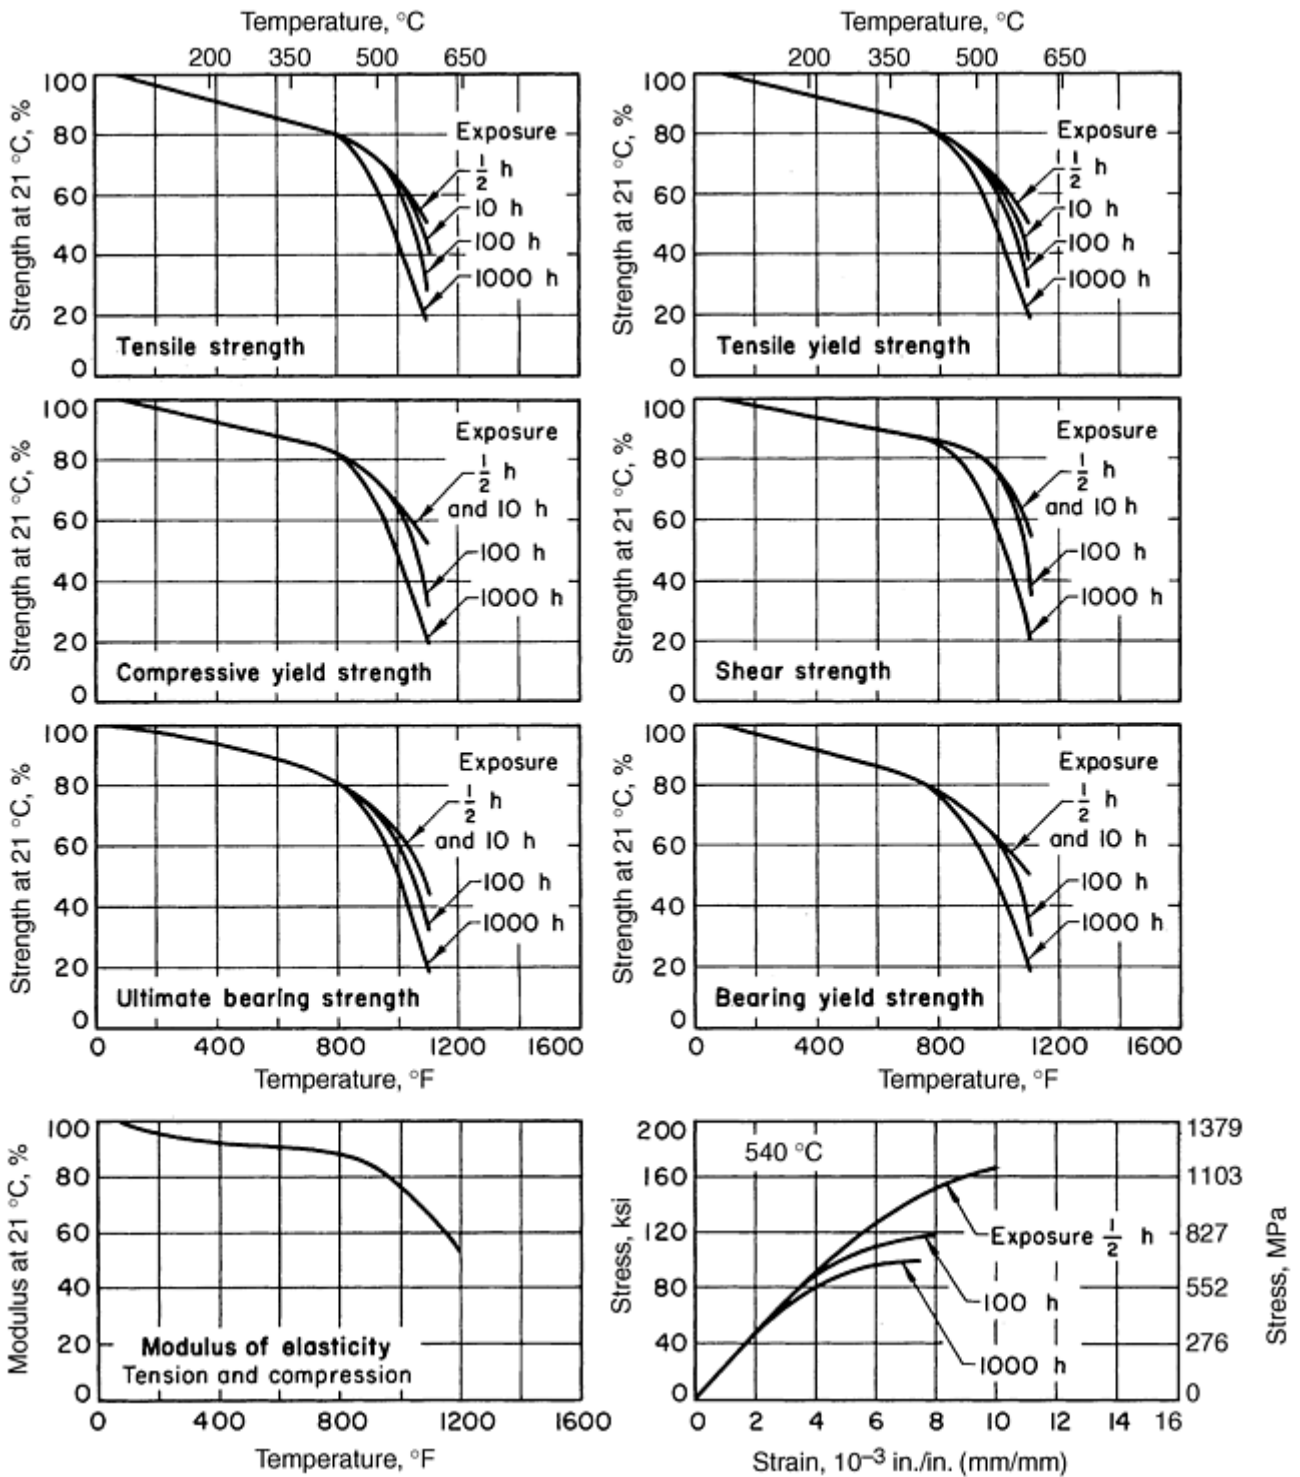

Fig. 19 Effect of time on high-temperature mechanical properties of H11 die steel

The time-dependent properties of high-temperature structural alloys are determined by a variety of methods, as discussed in more detail in the Section “Creep and Stress-Relaxation Testing” in this Volume. Many of these test methods in the creep region involve long-term testing. However, short-term tension tests on universal testing machines (UTMs) can also be used in the evaluation of creep deformation or stress relaxation. (See the article “Stress-Relaxation Testing” in this Volume.)

Hot Working Range. At higher temperatures in the hot working range ($T > 0.6 T_M$), mechanical behavior is different from plastic deformation at cold and warm working temperatures (where the change in microstructure is largely a distortion in the grains). In the hot working regime, creep and work softening can occur from self-diffusion (diffusion creep), dynamic recovery, and dynamic recrystallization. These high-temperature mechanisms are only briefly described here as a general reference on the overall effects of temperature on mechanical properties. More detailed coverage appears in the Section “Testing for Deformation Processes” in this Volume.

Static Recrystallization. When work-hardened alloys are heated, at some point a temperature level is reached where the atoms rearrange to form an entirely new set of crystals. This process, where the stored energy (produced by previous working at cold or warm temperatures) is released by migration of the grain boundaries, is known as recrystallization. The process is distinct from recovery, and the starting temperature for recrystallization depends on the amount of prior plastic deformation. At higher levels of working, more strain energy is stored in the crystal structure; therefore, a lower temperature initiates recrystallization.

Dynamic Recovery. In some cases, increased plastic strain results in a decrease in the necessary stress for continued deformation. This effect, known as work softening, occurs in the hot working range, as shown schematically in Fig. 20. The two main mechanisms of work softening in the hot working regime are dynamic recovery and dynamic recrystallization.

Fig. 20 Typical flow curves for metals deformed at cold working temperatures (A, low strain rate; B, high strain rate) and at hot working temperatures (C, D). Strain hardening persists to large strains for curve A. The flow stress maximum and flow softening in curve B arise from deformation heating. The steady-state flow stress exhibited by curve C is typical of metals that dynamically recover. The flow stress maximum and flow softening in curve D may result from a number of metallurgical processes. Source: Ref 11

In dynamic recovery, the dislocations obtained during previous working become unstable upon further working. The relative amount of softening depends on the ratio of the yield strength to the applied stress and the ratio of strength from previous work hardening to the yield strength (Ref 11). For example, as noted in Ref 11, the bcc and hcp metals have relatively high yield strengths in the annealed condition, so the amount of strain hardening is typically a smaller percentage of overall strength than for fcc metals. Thus, the amount of strain softening for fcc metals tends to be greater than that for hcp or bcc metals (Ref 11).

Dynamic Recrystallization. In contrast to dynamic recovery, dynamic recrystallization involves the motion of grain boundaries and annihilation of large numbers of dislocations in a single event, thereby producing new strain-free grains. Dynamic recrystallization is also distinct from static recrystallization (Ref 12). In dynamic recrystallization, the process occurs during the deformation process, thus facilitating working. In contrast, static recrystallization is a purely kinetic process where a fixed amount of stored energy (dependent on cold work) is released by thermally activated dislocation recovery and migration of the grain boundaries.

Dynamic recrystallization is largely limited to the fcc metals (Ref 11). For example, Fig. 21 shows true stress-strain curves for HY-100 steel tested in compression at 1000 °C (1832 °F) and different strain rates (Ref 13). There is a peak on the curves at strain rates of 0.01 s⁻¹ and above, which is usually an indication of dynamic recrystallization. The amount of strain required to trigger recrystallization during deformation varies with temperatures and strain rates.

Hot Tension and Compression Testing

Dan Zhao, Johnson Controls, Inc.; Steve Lampman, ASM International

Hot Tension Testing

Tension testing is a very common mechanical test for the evaluation of service properties. Most materials laboratories have tensile-testing machines. When compression-testing equipment is not available, or when a metalworking process involves mainly tensile stresses, the tension test can also be used for processing properties. More information on typical tension testing at room temperature is provided in the article “Uniaxial Tension Testing” in this Volume.

At high temperatures, the procedures and specimens of the tension test are basically the same as room-temperature testing. The key differences are the heating apparatus, accurate measurement of specimen temperature, and suitable instruments for measuring strain at high temperature. ASTM E 21 is the prevailing U.S. standard for high-temperature tensile testing (Ref 14).

General Characteristics. A typical high-temperature mechanical test setup is shown in Fig. 22. The system is the same as that used at room temperature, except for the high-temperature capabilities, including the furnace, cooling system, grips, and extensometer. In this system, the grips are inside the chamber but partly protected by refractory from heating elements. Heating elements are positioned around a tensile specimen. Thermocouple and extensometer edges touch the specimen.

Fig. 22 A typical high-temperature mechanical testing system

Most tensile specimens are cylindrical. Specimens with rectangular cross sections can also be used. The specimen ends can be machined into smooth cylindrical or screw heads. The cylindrical head is usually used with split-ring types of grips, which provide for quick removal of the specimen if quenching outside the furnace immediately after testing is specified.

Universal joints are necessary to align the loading train. In any case, the maximum bending strain should not exceed 10% of the axial strain. Strain gages can be used to examine bending strains of the gage length. If the maximum (or minimum) bending strain is within the limit at room temperature, the alignment should be fine at elevated temperatures. Care must be taken to ensure that the alignment of the loading train is maintained when attaching the furnace and its accessories. The alignment needs to be tested periodically.

Heating methods for high-temperature mechanical testing include vacuum or environmental furnaces, induction heating, and resistance heating of the specimen. Vacuum furnaces are expensive and have high maintenance costs. The furnace has to be mounted on the machine permanently, making it inconvenient if another type of heating device is to be used. The heating element is expensive and oxidizes easily. The furnace can only be

opened at relatively lower temperatures to avoid oxidation. Quenching has to be performed with an inert gas, such as helium.

Environmental chambers are less expensive (Fig. 23). An environmental chamber has a circulation system to maintain uniform temperature inside the furnace. Inert gas can flow through the chamber to keep the specimen from oxidizing. Temperature inside the chamber can be kept to ± 1 °C (2 °F), about the nominal testing temperature. However, the maximum temperature of an environmental chamber is usually 550 °C (1000 °F), while that of a vacuum furnace can be as high as 2500 °C (4500 °F). The chamber can either be mounted on the machine or rolled in and out on a cart.

Fig. 23 Environmental chamber for elevated-temperature mechanical testing

A split furnace is also cost effective and easy to use (Fig. 24). When not in use, it can be swung to the side. The split furnace shown in Fig. 24 has only one heating zone. More sophisticated split furnance have three heating zones for better temperature control. Heating rate is also programmable.

Fig. 24 Split furnace for high-temperature mechanical testing

Induction-heating systems allow fast heating rates (Fig. 25). Specimens can reach testing temperatures within seconds. Induction heating heats up the outer layer of the specimen first. Furnaces with a lower frequency have better penetration capability. Coupling of the heating coil and the specimen also plays an important role in heating efficiency. The interior of the specimen is heated through conduction. With the rapid heating rate, the temperature is often overshoot and nonuniform heating often occurs.

Fig. 25 Induction-heating furnace for high-temperature mechanical testing

Direct resistant heating is used in Gleeble machines with electric current going through the specimen (Ref 15). Advanced Gleeble testing systems, as shown in Fig. 26, are capable of rapid heating rates up to 10,000 °C/s (20,000 °F/s) (Ref 16). Grips with high thermal conductivity also allow rapid cooling rates up to 10,000°C/s (20,000°F/s) at the specimen surface.

Fig. 26 A Gleeble 3800 testing system. Source: Ref 12

Temperature Measurement. Thermocouples are the most common method for temperature measurement in hot tension tests. Because tensile specimens usually have longer gage length than compression specimens, more than one thermocouple may be needed to monitor the temperature along the gage length of the specimen. It is necessary to shield the thermocouple unless the difference in indicated temperature from an unshielded bead and a bead inserted in a hole in the specimen has been shown to be less than one half the variation listed below (Ref 14):

Temperature	Variation
Up to including 1800 °F (1000 °C)	± 5 °F (3 °C)
Above 1800 °F (1000 °C)	± 10 °F (6 °C)

Thermocouples need to be calibrated as specified in Ref 10. Thermocouple wire exposed to a hot zone should be cut off after each test, and a new bead should be formed for subsequent tests. During the entire test, temperature variation should not exceed the ranges indicated previously for the entire test, temperature variation should not exceed the ranges indicated previously for the entire gage length.

When testing with high heating rates, a thermocouple welded on the test specimen can provide a more accurate temperature reading (Ref 15). A thermocouple touching the specimen surface usually takes more time to reach the same reading as a thermocouple welded on the specimen. However, welding produces a heating affected zone and must be conducted carefully to minimize this effect. Drilling a hole in the gage length of a specimen for insertion of a thermocouple is not recommended, especially for specimens with small diameters. The hole may cause premature necking and failure, and lower the ultimate tensile strength.

Strain-Measurement. The simplest method for strain measurement is to take the crosshead displacement as the deformation of the specimen reduced section. However, this assumes that the rest of the loading train does not deform during testing and introduce error only at large plastic strains. Young's modulus cannot be determined in this way, and 0.2% offset yield strength would not be accurate. To accurately measure strains, strain gages or extensometers must be employed.

Strain gages can be used up to 600 °C (1112 °F) (Ref 2). Several extensometers are commercially available for strain measurement at high temperature: clip-on, water cooled, air cooled, and noncontact extensometers. Clip-on extensometers can be used up to 200 °C (392 °F); they are simple easy to use, and provide accurate readings. Water-cooled (Fig. 27) and air-cooled (Fig. 28) extensometers can be used at higher temperatures, up to 500 °C (930 °F) and 2500 °C (4500 °F), respectively.

Fig. 27 Water-cooled extensometer used up to 500 °C (932 °F)

Fig. 28 Air-cooled extensometer used at temperatures up to 2500 °C (4532 °F)

Water- and air-cooled extensometers are contact extensometers that use rods touching the specimen; the rods transmit the relative motion of the specimen to a sensing device, usually a linear variable differential transformer (LVDT). Some capacitive extensometers have high resolution and extremely low contact force. The contact rods are made of various materials, ranging from nickel-base superalloys to ceramics, for different temperature ranges.

The extensometer should be attached very carefully because it may affect alignment (Ref 17). Attaching extensometers on opposite sides and averaging the reading may reduce the error. Some of the commercial extensometers are designed to attach to both sides of the specimen. Whenever feasible, extensometers should be attached directly to the reduced section (Ref 14). Stress-strain data may not be useful beyond the maximum-load point due to necking.

Noncontact extensometers include laser interferometers, optical extensometers, and video extensometers. These methods use more sophisticated instrumentation and are more expensive, but they are becoming more common. Laser extensometers, which allow faster sampling rates than optical extensometers, are used for measuring

strain rates in excess of 10^3 s^{-1} . Video extensometers, where a camera records the displacement of marks on a specimen through a glass window, can also be used with temperature chambers.

Hot Tension and Compression Testing

Dan Zhao, Johnson Controls, Inc.; Steve Lampman, ASM International

Hot Compression Testing

Hot compression testing is also relatively easy to perform because of its simple specimen geometry (e.g., a cylinder). Testing machines and accessories are similar to those for hot tensile testing except the pull bars and grips are replaced by pushing anvils and platens. The anvils and platens can be made of stainless steel, tungsten carbide, TZM (Ti-Zr-Mo alloy), ceramics, or carbon.

Details on the applicable temperature ranges of anvils and platens are provided in the article "Testing for Deformation Modeling" in this Volume. The flat and parallel of platens should be within 0.0051 mm (0.0002 in.) (Ref 18). To improve parallelism, adjustable platens (bearing blocks) can be used. A drawing of such blocks can be found in Ref 19. Using a subpress, as suggested in the ASTM standards (Ref 18, 20), is very difficult with the limited space inside the furnace.

Specimen. The simplest specimen geometry is a cylinder. The aspect ratio (height to diameter) is usually between 1 and 2. An aspect ratio that is too high can cause the specimen to buckle, while one that is too low can increase friction even if lubricant is applied (see the article "Uniaxial Compression Testing" in this Volume). Typical specimen diameter is 10 to 15 mm (0.394–0.591 in.), depending on microstructure. For a cast alloy with coarse grains, large specimens are necessary. Subscale specimens can also be used for fine grain structure. In general, the specimen size must be representative of the material being tested. Other types of specimens, such as those with square or rectangular cross sections, can also be used, depending on the purpose of the tests. For example, a plane-strain compression specimen can have a rectangular cross section (Ref 19).

Lubrication. For testing at elevated temperatures, water-base graphite, graphite sheet, boron nitride solution, glass-base lubricant, and molybdenum disulfide may be used (Ref 13, 21). The lubricants can be applied to the

top and bottom ends of the specimen. They can also be applied to the platens at the same time to increase the effectiveness of lubrication. To retain the lubricant, grooves can be machined into the ends. Detailed specimen and groove dimensions can be found in the article “Testing for Deformation Modeling” in this Volume.

Temperature Control. As mentioned for hot tensile testing, a thermocouple that just touches the specimen does not provide an accurate temperature measurement unless the specimen is soaked at the nominal testing temperature for some time. To accurately measure the temperature of a specimen, thermocouples can either be welded to the specimen or inserted into a small hole drilled into the specimen. Compression-testing specimens are usually larger in diameter than tensile specimens, so a small hole drilled into the specimen to insert thermocouples may have little impact on the stress-strain curves. However, a hole may induce false cracking in a workability test, especially for brittle materials such as intermetallic compounds.

To determine the uniformity of temperature within the specimen, three thermocouples may be used to measure the top, bottom, and center temperatures of a dummy specimen as a function of time. If the temperatures are identical, only one thermocouple is necessary during testing. If it takes some time for the entire specimen to reach the set temperature, this procedure can also be used to determine the necessary soaking time.

To ensure the correct microstructure or specimen condition right before the compression testing commences, a specimen soaked at the testing temperature for the specified soaking time should be quenched and examined to determine the starting microstructure. It is essential that the platens be at the same temperature as the specimen. A temperature difference between the platens and the specimen results in a deformation gradient and, therefore, barreling of the deformed specimen (Ref 22).

Data Reduction and Temperature Correction. Load and displacement data are acquired from testing. To reduce the data into true stress and true strain, deformation is assumed homogeneous. Correction for the elastic deflection of the machine needs to be taken into account. True stress is simply the load divided by instantaneous cross-sectional area, which can be calculated by assuming constant volume in the specimen. For a cylindrical specimen, true stress, σ , is calculated as (Ref 19):

$$\sigma = \frac{P}{A} = \frac{4P}{\pi D^2} = \frac{4Ph}{\pi D_0^2 h_0} \quad (\text{Eq 1})$$

where P is load, A is cross-sectional area, D and D_0 are the instantaneous and initial diameter of the specimen, respectively, and h and h_0 are the instantaneous and initial height of the specimen, respectively. If friction is significant, the average pressure, \bar{P} , required to deform the specimen is greater than the flow stress of the material, σ :

$$\frac{\bar{P}}{\sigma} = \left(\frac{h}{2\mu D} \right)^2 \left[\exp\left(\frac{\mu}{h} \right) - \frac{\mu}{h} - 1 \right] \quad (\text{Eq 2})$$

where μ is the Coulomb coefficient of friction. The true strain, ϵ is given by:

$$\epsilon = \ln \frac{h_0}{h} \quad (\text{Eq 3})$$

Deformation heating occurs inevitably during testing, especially at high strain rates. Because isothermal stress-strain curves are desired for analysis, correction for deformation heating is necessary. The procedure for the correction can be found in the article “Testing for Deformation Modeling” in this Volume.

Tension and Compression Testing at Low Temperatures

Robert P. Walsh, National High Magnetic Field Laboratory, Florida State University

Introduction

THE SUCCESSFUL USE of engineering materials at low temperatures requires that knowledge of material properties be available. Numerous applications exist where the service temperature changes or is extreme. Therefore, the engineer must be concerned with materials properties at different temperatures. Some of the typical materials properties of concern are strength, elastic modulus, ductility, fracture toughness, thermal conductivity, and thermal expansion. The lack of low temperature engineering data, as well as the use of less common engineering materials at low temperatures, results in the need for low-temperature testing.

The terms "high temperature" and "low temperature" are typically defined in terms of the homologous temperature (T/T_M), (where T is the exposure temperature, and T_M is the melting point of a material (both given on the absolute temperature scale, K). The homologous temperature is used to define the range of application temperatures in terms of the thermally activated metallurgical processes that influence mechanical behavior.

The term "low temperature" is typically defined in terms of boundaries where metallurgical processes change. One general definition of "low-temperature" is $T < 0.5 T_M$. For many structural metals, another definition of low temperature is $T < 0.3 T_M$, where recovery processes are not possible in metals and where the number of slip systems is restricted. For these definitions, room temperature (293 K) is almost always considered a low

temperature for a metal with a few exceptions, such as metals that have melting temperatures below 700 °C (indium and mercury). In a structural engineering sense, low temperature may be one caused by extreme cold weather. A well-known example of this is the brittle fracture of ship hulls during WWII that occurred in the cold seas of the North Atlantic (Ref 1). For many applications, low temperature refers to the cryogenic temperatures associated with liquid gases. Gas liquefaction, aerospace applications, and superconducting machinery are examples of areas in engineering that require the use of materials at very low temperatures. The term cryogenic typically refers to temperatures below 150 K. Service conditions in superconducting magnets that use liquid helium for cooling are in the 1.8 to 10 K range.

The mechanical properties of materials are usually temperature dependent. The most common way to characterize the temperature dependence of mechanical properties is to conduct tensile or compressive tests at low temperatures. Depending on the data needed, a test program can range from a full characterization of the response of a material over a temperature range, to a few specific tests at one temperature to verify a material performance. Many of the rules for conducting low temperature tests are the same as for room temperature tests. Low-temperature test procedures and equipment are detailed in this article. The role that temperature plays on the properties of typical engineering materials is discussed also. Important safety concerns associated with low-temperature testing are reviewed.

Tension and Compression Testing at Low Temperatures

Robert P. Walsh, National High Magnetic Field Laboratory, Florida State University

Mechanical Properties at Low Temperatures

In general, lowering the temperature of a solid increases its flow strength and fracture strength. The effect that lowering the temperature of a solid has on the mechanical properties of a material is summarized below for three principal groups of engineering materials: metals, ceramics, and polymers (including fiber-reinforced polymer, or FRP composites). An excellent source for an in-depth coverage of material properties at low temperatures is Ref 2.

Metals. Most metals are polycrystalline and have one of three relatively simple structures: face-centered cubic (fcc), body-centered cubic (bcc), and close-packed hexagonal (hcp). The temperature dependence of the mechanical properties of the fcc materials are quite distinct from those of the bcc materials. The properties of hcp materials are usually somewhere in between fcc and bcc materials. The general aspects of temperature-dependent mechanical behavior may be discussed using the deformation behavior maps shown in Fig. 1(a) and 1(b). The axes of these graphs are normalized for temperature and stress. Temperature is normalized to the melting temperature, while stress is normalized to the room temperature shear modulus, G (Ref 2).

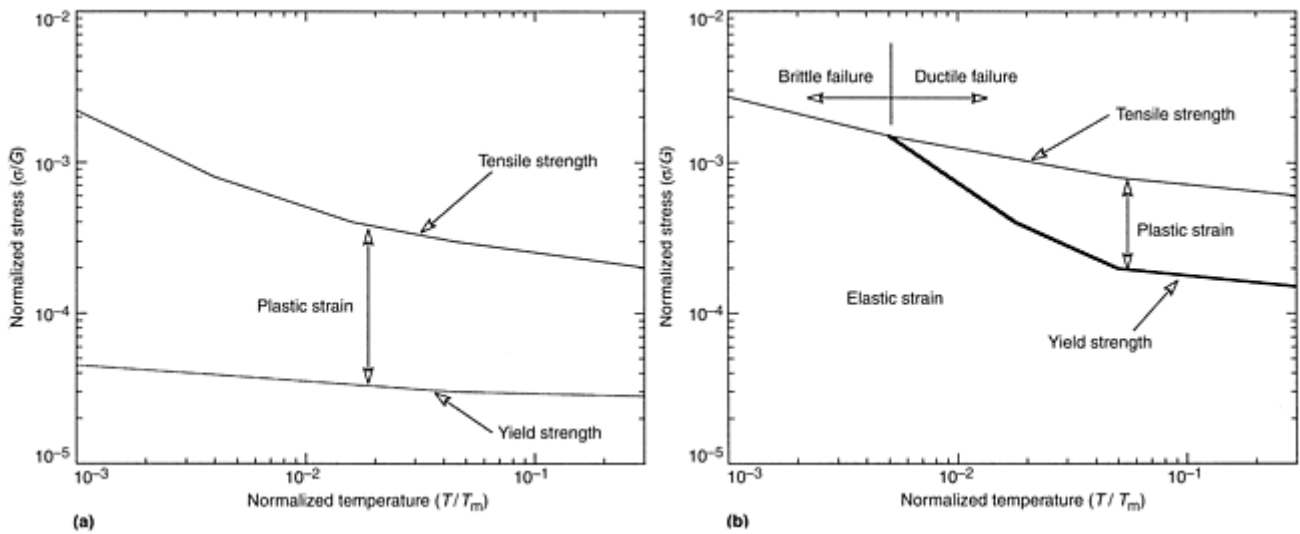

Fig. 1 Simplified deformation behavior (Ashby) maps (a) for face-centered cubic metals and (b) for body-centered cubic metals. Source: Ref 2

The behavior characteristic of a pure, annealed fcc material is shown in Fig. 1(a). The small increase of yield strength that occurs upon cooling is characteristic of the fcc behavior. The ultimate strength, which is shown as the ductile failure line, increases much more than the yield strength on cooling. The large increase in ultimate strength coupled with the relatively small increase in yield strength in fcc materials results from ductile, rather than brittle, failure (Ref 2).

Figure 1(b) illustrates the classic bcc behavior. The large temperature dependence of the yield strength, the smaller temperature dependence of the ultimate strength, and a region where the specimen fails before any significant plastic deformation occurs should be noted (Ref 2).

The previous discussion is for pure annealed metals. Engineering alloys may behave somewhat differently, but the trends are relatively consistent. Solid solution strengthening typically increases yield and ultimate strengths of the fcc alloys while giving the yield strength an increased temperature dependence. The temperature dependence of the ultimate strength is still greater than that of the yield strength, allowing the alloy to maintain its ductile behavior. The ultimate tensile strengths of the fcc metals have stronger temperature dependence than those of bcc metals. Austenitic stainless steels have fcc structures and are used extensively at cryogenic temperatures because of their ductility, toughness, and other attractive properties. Some austenitic steels are susceptible to martensitic transformation (bcc structure) and low-temperature embrittlement. Plain carbon and low alloy steels having bcc structures are almost never used at cryogenic temperatures because of their extreme brittleness. Cases of anomalous strength behavior have been reported where a maximum strength is reached at temperatures above 0 K. These cases are unique and usually involve single crystal research materials or very soft materials, although yield strengths of commercial brass alloys are reported to be higher at 20 K than at 4 K (Ref 2).

Ceramics. Ceramics are inorganic materials held together by strong covalent or ionic bonds. The strong bonds give them the desirable properties of good thermal and electrical resistance and high strength but also make them very brittle. Graphite, glass, and alumina are ceramics used at low temperature usually in the form of fibers that reinforce polymer-matrix composite materials. The high temperature (~77 K) superconducting compounds are ceramics that pose challenging problems with respect to using brittle materials at low temperatures.

Polymers and Fiber-Reinforced Polymer (FRP) Composites. Polymers are rather complex materials having many classifications and a wide range of properties. Two important properties of polymers are the melting temperature, T_m , and the glass transition temperature, T_g , both of which indicate the occurrence of a phase change. The glass transition temperature, the most important material characteristic related to the mechanical properties of polymer, is influenced by degree of polymerization. The T_g is the temperature, upon cooling, at which the amorphous or crystalline polymer changes phase to a glassy polymer. For most polymers at temperatures below T_g , the stress-strain relationship becomes linear-elastic, and brittle behavior is common. Some ductile or tough polymers exhibit plastic yielding at temperatures below T_g . The T_g represents the temperature below which mass molecular motion (such as chain sliding) ceases to exist, and ductility is

primarily due to localized strains. Suppression of T_g helps to produce tougher polymers. The strong temperature dependence of the modulus is a distinguishing feature of polymers compared to metals or ceramics.

Fiber-reinforced polymer composites are used extensively at low temperatures because of their high strength-to-weight ratio and their thermal and electrical insulating characteristics. The FRPs tend to have excellent tensile and compression strength that increases with decreasing temperature. Reinforcing fibers commonly used in high-performance composites for low-temperature applications are alumina, aramid, carbon, and glass. Typical product forms are high-pressure molded laminates (such as cotton/ phenolics and G-10) and filament-wound or pultruded tubes, straps, and structures. Although the FRP composites have desirable tensile and compressive strengths, other mechanical properties such as fatigue and interlaminar shear strength are sometimes questionable. Two good sources of properties of structural composites at low temperature are Ref 4 and 5.

Tension and Compression Testing at Low Temperatures

Robert P. Walsh, National High Magnetic Field Laboratory, Florida State University

Test Selection Factors

Tensile and compression tests produce engineering data but also facilitate study of fundamental mechanical-metallurgical behavior of a material, such as deformation and fracture processes. If obtaining engineering data is the objective and the materials application is at low temperature, the designer must be sure that mechanical properties are stable at the desired temperatures. One important factor related to low-temperature testing is that the low temperature may cause unstable brittle fracture behavior that tensile or compression tests may fail to reveal. The cooling of materials, especially bcc metals and polymers, can cause the materials to undergo a ductile-to-brittle transition. This behavior is not unique to steel but has its counterpart in many other materials. Brittle fracture occurs in the presence of a triaxial stress state to which a simple tensile or compression test will not subject the material. Brittle fracture is caused by high tensile stress, while ductile behavior is related to shear stress. A metal that flows at low stress and fractures at high stress will always be ductile. If, however, the same material is retreated so that its yield strength approaches its fracture strength, its behavior may become altered, and brittleness may ensue (Ref 1). If the materials application is at low temperature, the designer must be sure that mechanical properties are stable, because the possibility of brittle fracture requires modification of the design approach.

If the material in question is a new material or a material for which little or no low-temperature data exist, screening tests that can assess susceptibility to brittle fracture are advisable. Two such screening tests are Charpy impact tests and notch tensile tests. Conducting Charpy or notch tensile tests at various temperatures can detect a ductile-to-brittle transition over a temperature range. Ultimately, if the fracture toughness of the material is an issue, fracture toughness testing should be performed.

The intended service condition for the material should influence the test temperature and the decision to perform tensile or compressive tests. It is good practice to determine the properties while simulating the service

conditions. Of course, life is not always this simple, and actual service conditions may not be easily achieved with an axial stress test at a given temperature.

Tensile testing is the most common test of mechanical properties and is usually easier than compression testing to conduct properly at any temperature. The compressive and tensile Young's moduli of most materials are identical. Fracture of a material is caused by tensile stress that causes crack propagation. Tensile tests lend themselves well to low-temperature test methods because the use of environmental chambers necessitates longer than normal load trains. Pin connections and spherical alignment nuts can be used to take advantage of the increased length for self-alignment purposes. For most homogeneous materials, stress-strain curves obtained in tension are almost identical to those obtained in compression (Ref 6). Exceptions exist where there is disagreement between the stress-strain curves in tension and compression. This effect, termed "strength differential effect," is especially noticeable in high-strength steels (Ref 7).

There are times when compression testing is required such as when the service-condition stress is compressive or when the strength of an extremely brittle material is required. The second case is true for almost all polymers at cryogenic temperatures as they become extremely brittle, glassy materials. The fillet radius of a reduced-section tensile-test sample can create enough of a stress riser that the material fails prematurely. Stress concentrations, flaws, and submicroscopic cracks largely determine the tensile properties of brittle materials. Flaws and cracks do not play such an important role in compression tests because the stress tends to close the cracks rather than open them. The compression tests are probably a better measure of the bulk material behavior because they are not as sensitive to factors that influence brittle fracture (Ref 3). A brittle material will be nearly linear-elastic to failure, providing a well-defined ultimate compressive strength. The following table lists competing factors that influence the test method choice, many of which are generic while some are specific to conditions associated with low-temperature testing.

The temperature at which to run the test can be a simple determination such as when mechanical properties data for a material at the

Tension	Compression
Advantages	
Common	Good for modulus and yield strength
Self-aligning	
Well-defined gage section	No grips
Good for modulus, yield, ultimate, and ductility parameters	No stress concentration in sample design
	Good for ultimate strength of brittle materials
	Easy sample installation
	Inexpensive sample cost
Disadvantages	
Sensitive to specimen design	End effects (friction/constraint)
Difficult to test brittle materials and composites where machining reduced section is not plausible	Sensitive to alignment
	Not always good for ultimate strength
	Need containment for fractured material

proposed service temperature are not available. Other cases are not so straightforward, and the temperature choice should be based on cost and the ability to provide conservative results. Sometimes, a material is to be used at a cold temperature, but testing it at room temperature will yield conservative data that are sufficient for the application. For many 4 K applications, conservative properties can be measured at 77 K in a simpler, more economical test. The degree of strengthening that will occur upon cooling from 77 to 4 K is much less than that which occurs from 295 to 77 K. When there is doubt about the applicability of data from tests at a temperature other than the service temperature, testing should be done at the service temperature. Good practice is to test above, below, and at the service temperature for a more complete understanding of the material behavior.

The relative costs and difficulty of the tests are important. Tests conducted in liquid media are simpler to perform, in general, than intermediate temperature tests that require temperature control. Below is a list of testing media and their associated temperatures (Ref 2).

Substance	Temperature, K	Bath type
Ice water	273	Slush
Isobutane	263	Liquid at BP
Carbon tetrachloride	250	Slush
Propane	231	Liquid at BP
Trichloroethylene	200	Slush
Carbon dioxide	195	Solid
Methanol	175	Slush
n-pentane	142	Slush
Iso-pentane	113	Slush
Methane	112	Liquid at BP
Oxygen	90.1	Liquid at BP
Nitrogen	77.3	Liquid at BP
Neon	27.2	Liquid at BP
Hydrogen	20.4	Liquid at BP
Helium (He₄)	4.2	Liquid at BP
Helium (He₃)	3.2	Liquid at BP

All temperatures given at 0.1 MPa (1 atm). BP, boiling point

Some of these substances are more common, cheaper, or easier to handle than others. The most commonly used substances in mechanical tests are ice water, CO₂/methanol slush, liquid-nitrogen (LN₂) cooled methanol, LN₂, and liquid helium (LHe). Obvious hazards are associated with the use of oxygen and hydrogen, and they should be avoided if possible. Safety issues concerning the use of cooled methanol, LN₂, and LHe are discussed subsequently in this section. Cost of the cryogenic medium is also an issue. Since LN₂ is common and readily available, its cost is relatively low. LHe, on the other hand, is about a factor of ten times as expensive as LN₂. Liquid neon is sometimes used because it is easy to handle and its liquid boiling point temperature is relatively close to that of liquid hydrogen, but it can be 20 to 40 times as expensive as LHe. The sublimation temperature of dry ice (CO₂) is 195 K, and it can be used to cool a methanol or propanol bath with relative ease. Many of these bath cooling techniques are tried and true methods that require some practice to perfect but are usually inexpensive and simple ways to control test sample temperature. Low-temperature control can also be accomplished with electronic temperature control systems that utilize heaters and a cooling medium. Electronic temperature control systems are described in the following section.

Equipment

Low-temperature tensile and compression tests can be performed on electromechanical or servo-hydraulic test machines with capacities of approximately 50 to 100 kN. The 100 kN machine is preferable for high strength materials such as steels or composites but of course larger or smaller capacities can be used as necessary. Direct tension and compression tests usually require a simple ramp function that is possible on the more economical electromechanical (screw-drive) test machine. Computer controlled servo-hydraulic test systems are versatile and can perform a variety of tasks as well as direct tension and compression tests.

To facilitate the low-temperature requirement, the test machine must be equipped with a temperature-controlled environmental chamber. One consideration for the suitability of the machine for low-temperature tests is the ease with which a low-temperature environmental chamber can be implemented. The physical characteristics of the test machine come into play, such as the maximum distance between crossheads and load columns.

A major factor to consider for cryogenic tests is the cryostat. "Cryostat" is a general term for an environmental chamber designed for cryogenic temperatures and can be as simple as a container (dewar) to hold a liquid cryogen. Cryostats designed for mechanical testing have the added requirement of providing structural support to react to tensile or compressive forces that are applied to the test material. Typically, a load frame is designed as an insert to a dewar. Since a dewar is a vacuum-insulated bucket to hold liquid, it is not advisable to have a hole in the bottom for pull-rod penetration because it introduces a leak potential for liquid, vacuum, and heat. The closed-bottom feature of a cryostat necessitates that the applied load and reacted load be introduced from the top. Cryostats are described further in the section "Environmental Chambers" below.

The simplest method to introduce the load path from the top on a servo-hydraulic machine is to use a machine that has the hydraulic actuator mounted on top of the upper crosshead. Hydraulic machines with this configuration are available, and the arrangement does not restrict normal use of the machine. Figure 2 shows a servo-hydraulic test machine equipped with a mechanical test cryostat. The screw-drive type test machine is usually accommodating and should have a movable lower crosshead with a through hole for the load train. References 8 and 9 give details of the design of cryostats for mechanical test machines.

Fig. 2 A 100 kN capacity test machine equipped with cryostat for low-temperature testing

If the machine is not configured as described in the preceding paragraphs, the machine is relatively incompatible for cryogenic tests. Cryogenic tests on an incompatible machine require specially designed cryostats or an external frame system both of which are usually expensive and cumbersome alternatives. Figure 3 shows a schematic of a simple test chamber (canister) for immersion bath tests above liquid nitrogen temperature. This fixture provides an inexpensive method for conducting tests on conventional machines down to approximately 100 K.

Fig. 3 Schematic of simple tensile canister from a standard-configuration machine for low-temperature testing

Environmental Chambers. For low temperature tests, an environmental chamber is a thermal chamber that contains a gaseous or liquid bath media used to control the low temperature of a test. Sub-room-temperature environments are obtained with three basic chamber designs: a conventional refrigeration chamber; a thermally insulated box-container, or a cryostat designed for cryogenic temperatures with vacuum insulation; and thermal radiation shielding.

Conventional refrigeration covers the temperature range from +10 to -100 °C and could be employed for tests in this range, much the same as furnaces are used on test machines to achieve elevated temperatures. Although mechanical refrigeration seems like a logical choice to cool environmental chambers, it is rarely used. This is probably because of the capital expense and the relative simplicity of other methods.

Commercial environmental chambers designed for use with test machines are available for controlling temperatures from approximately 800 K down to 80 K. Such chambers use electrical heaters for elevated temperatures and cold nitrogen gas cooling for sub-room-temperature. The cold nitrogen gas is supplied from a liquid nitrogen storage dewar. The flow of cold gas determines the cooling power and is controlled at the inlet with a variable flow valve that is regulated by the temperature controller. These systems are versatile in that a wide range of test temperature is possible with a single system. Some of the disadvantages are bulkiness, which can make setup difficult, and that the tests can be time consuming with respect to attaining equilibrated test temperatures.

Cryogenic temperature tests are conducted in an environmental chamber called a cryostat. Cryostat is a general description of a low-temperature environmental chamber and can be as simple as a container (dewar) to hold a liquid cryogen. Reference 10 is an excellent historical perspective on low-temperature mechanical tests that details a number of cryostat designs, many of which use conventional machines with standard load path configurations. As mentioned previously, pull-rod penetration through the bottom of a cryostat introduces a

leak potential for liquid, vacuum, and heat and is not recommended for liquid bath-cooled tests. Modern mechanical test cryostats are typically a combination of a custom designed structural load frame fit into a commercial open-mouth bucket dewar. Some of the design details of a tensile test cryostat are shown in the schematic in Fig. 4 and photograph in Fig. 5. The design of the cryostat load frame is driven by engineering design factors such as cost, strength, stiffness, thermal efficiency, and ease of use. A good design philosophy is to produce a versatile fixture that can test a variety of specimens over a range of temperatures. The effect of lowering the temperature on the properties of a material can be evaluated by comparing the baseline room temperature properties. It is advisable to have the test apparatus capable of testing the material at both room temperature and cold temperatures. Construction materials used are austenitic stainless steels, titanium alloys, maraging steels, and FRP composites. For tensile tests, the cryostat frame reacts to the load in compression. The frame can be thermally isolated with low-thermal conductivity, FRP composite standoffs. For compression tests, the reaction frame is in tension and is not as easily thermally isolated. The cryostat shown here is easily converted between the more thermally efficient tensile cryostat and the more robust compressive cryostat (Fig. 6).

Fig. 4 Schematic of a tensile test cryostat

Fig. 5 Tensile test cryostat. The force-reaction posts have fiber-reinforced polymer composite stand-offs.

Fig. 6 Compression test cryostat, including heavier force-reaction posts and a tubular push rod designed to withstand buckling

Cryogen Liquid Transfer Equipment. The supply and delivery of cryogenic fluids require special equipment. The equipment described here pertains to the use of the two most common cryogen test media, liquid nitrogen and liquid helium. Both liquid helium and nitrogen can be purchased from suppliers (usually welding supply distributors) in various quantities that are delivered in roll-around storage dewars. Liquid nitrogen can be transferred out of the storage dewar into the test dewar with simple or common tubing materials. Its thermal properties and inexpensive price allow its flow through uninsulated tubes. For example, butyl rubber hose can be attached to the storage dewar, and the hose will freeze as the liquid passes through. Liquid helium, on the other hand, is more difficult to handle, and it requires special vacuum-insulated transfer lines. Liquid helium transfer lines are usually flexible stainless steel lines with end fittings to match the inlet ports of the test cryostat and the supply cryostat. For both liquid nitrogen and helium, the storage tank is pressurized to enable transfer of the liquid.

Instrumentation. The minimum instrumentation requirement in any tensile or compression test is that for force measurement. Typically, forces are measured with the test machine force transducer (load cell) in the same manner as for forces measured in room temperature tests. During low-temperature tests, precautions should be taken to ensure the load cell remains at ambient room temperature.

Strain measurements may require temperature dependent calibration. Common strain measurement methods used are test machine displacement, bondable resistance strain gages, and clip-on extensometers or compressometers. Also applicable to low-temperature strain measurements but less commonly used are capacitive transducer methods (Ref 11), noncontact laser extensometers, and linear variable differential transformers (LVDT) with extension rods to transmit displacements outside of the environmental chamber to the LVDT-sensing device.

Test machine displacement (stroke or crosshead movement) is a simple, low-accuracy method of estimating specimen strain. The inaccuracy comes because the displacement includes deflection of the test fixturing plus the test specimen gage section. Compensating for test fixturing compliance improves accuracy.

Bondable resistance strain gages are for sensitive measurements such as modulus and yield strength determination. The strain gage manufacturer supplies strain gage bonding procedures for use at cryogenic temperatures. The overall range of strain gages at cryogenic temperatures is limited to about 2% strain. Applicable strain gages recommended by strain gage manufacturers have temperature dependent calibration data down to 77 K. Interest in their use down to 4 K has resulted in strain gage research verifying their performance to 4 K (Ref 12). A typical gage factor (GF) is 2 for NiCr alloy foil gages and it increases approximately 2 to 3% on cooling from 295 to 4 K. Thermal output strain signals are a large source of error that must be compensated for. Compensation is usually accomplished using the bridge balance of the strain circuit where zero strain can be adjusted to coincide with zero stress. If this is not possible, other steps must be taken to electrically or mathematically correct the thermal output strain.

Extensometers and compressometers applicable to low-temperature tests utilize strain gages mounted to a bending beam element. The temperature sensitivity can be determined by calibrating with a precision calibration fixture that enables calibration at various temperatures. Depending on the accuracy desired, it is possible to use one or two calibration factors over a large temperature range. A typical strain-gage extensometer-calibration factor changes about $\pm 1\%$ over the temperature range from 295 to 4 K.

Temperature measurement is done with an assortment of temperature sensors. Reference 2 has a section devoted to temperature measurement at low temperatures. The most common method of temperature measurement is to use a thermocouple. Type E thermocouples (Chromel versus Constantan) and Type K (Chromel versus Alumel) cover a wide range of temperature and can be used at 4 K when carefully calibrated. A better choice of thermocouple, designed to have higher sensitivity at cryogenic temperatures, is a AuFe alloy versus Chromel thermocouple. Electronic temperature sensors (diodes and resistance devices) are available with readout devices that have higher precision than thermocouples. Silicon diodes, gallium-aluminum-arsenide diode, carbon glass resistor, platinum resistor, and germanium resistor are some of the more commonly used types of sensors.

Cryogenic temperature controllers that work with the types of temperature sensors named above are available. The majority of temperature controllers vary heating power and require that the test chamber environment is slightly cooler than the set-point temperature. The test engineer is responsible for the environmental chamber and cooling medium of the system. The controllers use the temperature sensors as the feedback sensor to operate a control loop and supply power for resistive heaters.

Additional Equipment Considerations. Teflon-insulated (E.I. DuPont de Nemours & Co., Inc., Wilmington, DE) lead wires are advisable at very low temperatures because the insulation will be less likely to crack and cause problems. Electronic noise reduction can be an issue in low-temperature tests because lead wires tend to be long. Standard methods of noise-reduction are shielding and grounding. Self-heating and thermocouple effects are important issues at low temperatures. Precautions should be taken to ensure that thermal effects do not mask the test data. Strain gage excitation voltages should be kept low. Reference 10 gives the parameters in terms of power density for calculating excitation voltage to be used for strain gages at 4 K.

Tension and Compression Testing at Low Temperatures

Robert P. Walsh, National High Magnetic Field Laboratory, Florida State University

Tension Testing

As at room temperature, tensile tests at low temperature are for determining engineering design data as well as for studying fundamental mechanical-metallurgical behaviors of a material such as deformation and fracture processes. The usual engineering data from tensile tests are yield strength, ultimate tensile strength, elastic modulus, elongation to failure, and reduction of area. The effects of material flaws (inclusions, voids, scratches, etc.) are amplified in low-temperature testing, as materials become more brittle and sensitive to stress concentrations. Data scatter tends to increase, and the quantity of tests to characterize a material is usually greater than that used for room temperature testing. The test engineer must judge when sufficient testing has been done to provide representative data on a material.

Test fixture alignment is important at low temperatures because of necessarily long load trains. Self-alignment in tensile tests can be accomplished through the use of universal joints, spherical bearings, and pin connections. The alignment should meet specifications detailed in ASTM E 1012, “Standard Practice for Verification of Specimen Alignment Under Tensile Loading.” Strain measurement should be done using an averaging technique that can reduce errors associated with misalignment or bending stress. Strain measurement equipment is detailed above in the instrumentation section.

Metals. The standard tensile test method for metals, ASTM E 8, covers the temperature range from 50 to 100 °F and is used as a guideline for lower temperature tests. The need for engineering data in the design of superconducting magnets has resulted in the adoption of the tensile test standard ASTM E 1450 for tests of structural alloys in liquid helium at 4.2 K.

The strain rate sensitivity of the flow stress in metals decreases as temperature is reduced. Typical strain rates in standard tensile tests are on the order of 10^{-5} s^{-1} to 10^{-2} s^{-1} and do not have a pronounced effect on the material flow stress. The strain rate becomes important in cryogenic temperature tests because of a tendency for specimen heating causing discontinuous yielding in displacement control tests. Discontinuous yielding is a subject of low-temperature research of alloys, well described in ASTM E 1450. The localized strain/heating phenomenon typically initiates after the onset of plastic strain and results in a serrated stress-strain curve. ASTM test standard E 1450 prescribes a maximum strain rate of 10^{-3} s^{-1} and notes that lower rates may be necessary. The strain required to initiate discontinuous yielding increases with decreasing strain rate. If discontinuous yielding starts before the 0.2% offset yield strength is reached, the associated load drop affects the estimation of the yield strength. It may be possible to slow the strain rate to postpone the serrated curve

until after the 0.2% offset yield strength is reached and then to increase the rate, not to exceed 10^{-3} s^{-1} . Reference 13 reports research on the effect of strain rate in tensile tests at 4 K.

Test specimen sizes are preferably small for low-temperature tests. The common 0.5 in. round, ASTM-standard tensile specimen is rarely used at low temperature. Tensile specimens should be small due to size constraints placed by the environmental test chamber, which is designed for thermal efficiency. Standard capacity test machines (100 and 50 kN) favor small specimens due to high tensile strengths encountered at low temperatures. A subscale version of the 0.5 in. round that meets ASTM specifications and works well at cryogenic temperature is shown in Fig. 7(a). A 100 kN force capacity test machine can generate about 3.5 GPa stress on a 6 mm diameter gage section. Figure 7(b) shows a flat, subscale tensile specimen that is also commonly used at cryogenic temperatures.

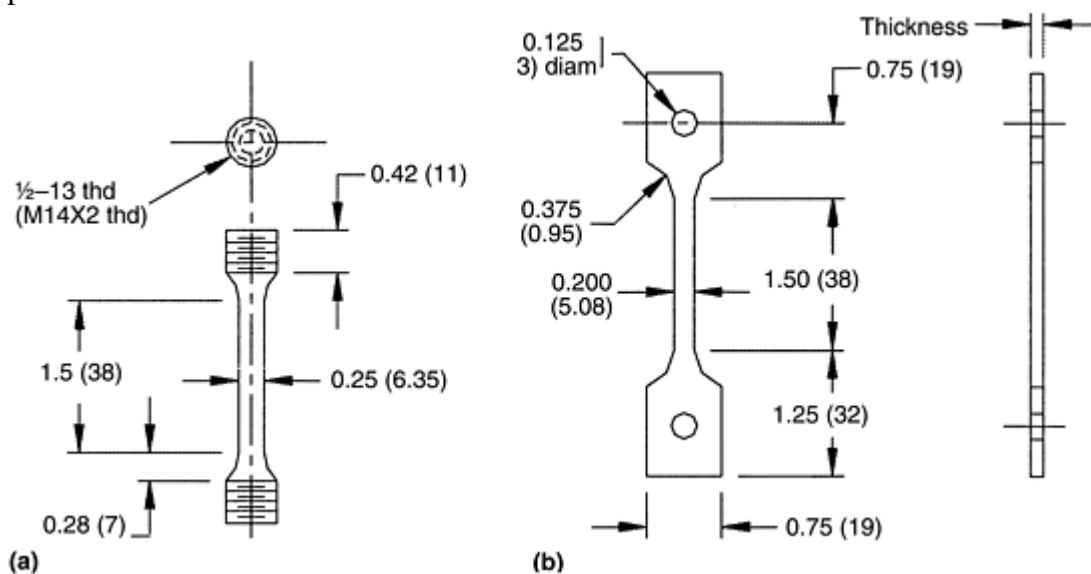

Fig. 7 Schematics of tensile specimen commonly used at low temperature. (a) Round. (b) Flat. Dimensions are in inches (millimeters.) thd, threaded

Polymers and Fiber-Reinforced Polymer (FRP) Composites. Tension tests of FRP composites are governed in test procedure ASTM D 3039, while polymers and low modulus ($<20 \text{ GPa}$) composites are tested using the guidelines established in ASTM D 638. Neither have specific temperature ranges or limitations.

The problem with testing polymers at low temperatures is the tendency for polymers to be extremely brittle materials. Test temperatures below room temperature are usually well below the glass transition temperature, T_g , of the polymer. The test specimen designs in ASTM D 638 are susceptible to grip failures once the material is brittle. Traditional strain measurement techniques must be performed carefully. Clip-on extensometers must mechanically attach to the material, usually producing some sort of stress concentration that may initiate failure. Strain gages locally reinforce low-modulus material, and the associated error and correction method is explained in Ref 14. Most tensile tests of polymers show an increase in tensile strength upon cooling from 295 to 77 K and a decrease or constant level of strength with continued cooling to 4 K (Ref 15). One would expect the strength to continue to increase with decreasing temperature. This anomalous behavior is probably an artifact of the tensile testing of an extremely brittle material.

Tensile tests of FRP composites at low temperatures are simpler than tests of neat polymers because of the more rugged sample. One challenge is the gripping of high-strength, unidirectionally reinforced composites. The convenience of hydraulic wedge grips is not usually an option in low-temperature tests. An example of a low-temperature tension and compression test program to characterize a unidirectionally reinforced epoxy composite from 295 to 4 K is described in Ref 16.

Tension and Compression Testing at Low Temperatures

Robert P. Walsh, National High Magnetic Field Laboratory, Florida State University

Compression Testing

Compressive properties are of interest to the design and analysis of structures subjected to compressive or bending stress. Compressive properties include modulus of elasticity, yield stress, deformation beyond yield point, and compressive strength (assuming that the material does not just flatten).

Compression testing of metals is conducted using the guidelines established in test procedure ASTM E 9, “Standard Test Methods of Compression Testing of Metallic Materials at Room Temperature.” An application of low-temperature compression tests is to determine if there is a strength differential effect for a particular metal. Another case for compression tests is to measure the yield strength of a brittle metal that tends to fail in tension before the 0.2% offset yield strength is reached.

Polymers are compression tested at low temperatures using ASTM D 695, “Standard Test Method for Compressive Properties of Rigid Plastics” for guidance. This standard states that it is applicable to tests of unreinforced and reinforced rigid plastics, including high-modulus composites. Research comparing results for different compressive test methods on high-modulus composites has shown that ASTM D 695 is acceptable for modulus determination but not a good method for strength measurement (Ref 17). This direct compression test method is excellent for determining the strength and modulus of brittle polymers at low temperatures. A compressive test fixture used for testing polymers and composites at low temperatures is shown in Fig. 6. The fixture uses a spherical bearing seat on the lower stationary compression platen (dry graphite powder is used as a lubricant) to adjust platen parallelism. Applying a nominal load with the upper platen aligns the lower platen, which is then locked into place with three clamps. Figure 8 shows some data from recent low-temperature tests on a high-strength polymer (Ref 18). The results graphically show the difference between the tension (ASTM D 638) and compression (ASTM D 695) tests of these relatively brittle materials.

Fig. 8 A comparison of the effect of temperature on tensile and compressive properties of some high strength polymers. A, polyphenylene; B, modified polyphenylene; BF, chopped fiber-reinforced polyphenylene; and BP, polyphenylene with plasticizer

Compression tests of FRP composites are governed by ASTM D 3410, “Standard Test Method for Compressive Properties of Polymer Matrix Composite Materials with Unsupported Gage Section by Shear Loading.” This standard is for high-modulus composites where the elastic modulus of the composite is greater than 21 GPa. The test standard has three test procedures within it. Procedure A uses a compression test fixture commonly called the Celanese compression fixture. This test fixture has been applied to low-temperature tests described in Ref 16. Test procedure B is similar but uses a different test fixture, commonly called the IITRI (Illinois Institute of Technology Research Institute) fixture. Test procedure C is a sandwich beam test where the beam is loaded in four-point bending. All three-test procedures are rather compact and well suited for low-temperature testing. The Celanese and IITRI fixtures are rather heavy and take some time to heat and cool. This is a consideration when repetitive testing is to be done at low temperature. These two fixtures also have alignment sleeves or pins that may have a tendency to freeze at low temperatures due to differential thermal contractions and/or due to ice. The sandwich beam test specimen is rather small and may be well suited for low-temperature tests.

Tension and Compression Testing at Low Temperatures

Robert P. Walsh, National High Magnetic Field Laboratory, Florida State University

Temperature Control

Test temperature is controlled by a bath temperature or by controlling the temperature of a gaseous environment. The temperature of the test specimen should be maintained ± 1 K for the duration of the test. For bath-cooled tests, the temperature of the bath and the specimen should be the same. A potential source for error is the conduction path or heat sink that the load train provides, possibly causing the specimen to be warmer than the bath. For tests at temperatures below 77 K (typically 4 K tests), the test cryostat is precooled with liquid nitrogen as an economical time-saving step.

The temperature of the specimen is usually monitored for tests using gaseous environment temperature control. The temperature should be measured at the gage section and at the gripped ends to ensure that the temperature across the length of the specimen is constant. For temperatures above 80 K, the cooling can be a static method, such as a pool of liquid nitrogen in the dewar below the test fixturing. Test temperatures below the liquid nitrogen bath temperature are best accomplished through the use of cold helium gas for cooling power. This can be accomplished with a flow cryostat, where cooling power is regulated by throttling the flow of the cold gas or liquid. Between the manual regulation of the cooling medium and the regulated heater power, one can obtain constant test temperatures between 77 and 4 K. Variations of cryogenic temperature control exist such as cryogenic refrigerators, which can be applied to the temperature control of mechanical tests. Cryocoolers and other mechanical refrigeration techniques are not commonly used in mechanical tests, due to the initial capital expense and the relative simplicity of other cooling methods.

Tension and Compression Testing at Low Temperatures

Safety

Safety in a laboratory or industrial setting is always a concern. Some of the safety issues with respect to low-temperature testing are common sense issues, while some others are not so obvious. Table 1 describes the most common safety issues and appropriate solutions for each. Safety issues associated with the use of liquid hydrogen or liquid oxygen are not dealt with in this article and can be found in Ref 10. In addition to the issues listed in Table 1, personnel should consider general safety issues related to tension and compression testing at all temperature ranges.

Table 1 Safety issues associated with the use of liquid cryogens for low-temperature testing

Safety issue	Solution
Liquid cryogens can spill or splash onto the body and cause freezing of human tissue.	Personnel should wear appropriate clothing and avoid direct contact with cold parts.
Helium, nitrogen, or carbon dioxide can displace air in a confined area.	Cryogens should be used only in well-ventilated areas.
Volumetric expansion is extremely high (typically 700–1000 times) when a liquid cryogen vaporizes. Such expansion is dangerous when it occurs in closed containers or fixture components with potential for trapped gas/liquid volumes.	Cryostats must include safety pressure-relief capabilities; redundancy is necessary because mechanical relief valves may freeze or malfunction. Component parts such as tubes or threaded connections that can trap liquids or gases should be identified, and

	solutions (such as weep holes) included in the design. If there is potential for liquid to get into a space, provide exit relief rather than trying to seal the liquid out.
Oxygen-rich (flammable) condensation can form on chilled surfaces (surfaces that are chilled to temperatures below 90 K and then exposed to air; common on uninsulated liquid nitrogen transfer lines and inside open-mouth dewars containing liquid nitrogen or helium residue).	Inform personnel of potential fire hazard, and take appropriate precautions.
Low temperatures may cause embrittlement of the material, causing it to fail at lower-than-expected loads.	Test personnel must be aware of the potential and prepare for brittle fracture of structural components.

Bend Testing

Eugene Shapiro, Olin Corporation

Introduction

BEND TESTS are conducted to determine the ductility or strength of a material. The tests typically used are discussed in this article with details on test methods, apparatuses, procedures, specimen preparation, and interpretation and reporting of results. The section “Bending Ductility Tests” also includes representative test data for many metals.

Bend tests for ductility differ fundamentally from other mechanical tests in that most mechanical tests are designed to give a quantitative result and have an objective endpoint. In contrast, bending ductility tests give a pass/fail result with a subjective endpoint; the test operator judges whether a surface has undergone cracking.

The bending ductility test developed as a shop-floor material inspection test because of its pass/fail qualities and the simplicity and low cost of the required tooling. As a consequence, the development of bending ductility test methods and apparatuses has been carried out by users rather than by mechanical-test equipment manufacturers.

Test procedures and specimen preparation methods have evolved without close attention to detail. Therefore, despite the value of the test and its long history of use, there has been minimal standardization. There are, however, two ASTM standards—ASTM E 190, “Standard Test Method for Guided Bend Test for Ductility of Welds” (Ref 1), and ASTM E 290, “Standard Test Method for Semi-Guided Bend Test for Ductility of Metallic Materials” (Ref 2)—which provide guidelines for testing strip, sheet, plate, and weldments.

Tests for determining the bending strength of metals have not been used widely, although the information from such tests is clearly useful. ASTM E 855, “Standard Methods of Bend Testing of Metallic Flat Materials for Spring Applications” (Ref 3), discusses the techniques for determining the bending strength of metal. These testing methodologies are described extensively in this article with greater emphasis on interpretation and analysis. Also included are descriptions of methods used in Europe and Japan. Finally, a section on computerized testing is included.

Bending tests that have been developed for brittle materials, coatings, construction (girder and beam) sections, and other specific product forms are not covered in this article. However, descriptions of these test methods can be found in the ASTM standards.

Bend Testing

Eugene Shapiro, Olin Corporation

Bending Ductility Tests

Frank N. Mandigo, Olin Corporation

Bending ductility tests determine the smallest radius around which a specimen can be bent without cracks being observed in the outer fiber (tension) surface. This forming limit commonly is called the minimum bend radius and is expressed in multiples of specimen thickness, t . A material with a minimum bend radius of $3t$ can be bent without cracking through a radius equal to three times the specimen thickness. It thus follows that a material with a minimum bend radius of $1t$ has greater ductility than a material with minimum bend radius of $5t$. Alternatively, the bend radius can be fixed, and the angle of bend at which fracture occurs noted. Figure 1 illustrates bend radius, angle of bend, and other concepts associated with bending tests.

Fig. 1 Terms used in bend testing

This article describes apparatuses, specimen, preparation, and test procedures used in bending ductility testing. Bending tests are usually performed on strip, sheet, or plate; however, the same methods and apparatuses can be

used to evaluate the bending ductility of other product forms (drawn or extruded rounds, squares, or polygonal shapes) and of weldments.

Evaluating and reporting results of bending tests are also discussed. This discussion includes a description of failure criteria, strain distribution, directionality, and factors that affect bend ductility. Finally, a compilation of bend data for select engineering materials is presented.

Bend Testing

Eugene Shapiro, Olin Corporation

Apparatuses

Bending test apparatuses include wrap, wipe, V-block, and soft tooling devices that may have interchangeable die radii and are able to bend test specimens to several preset angles. The pins, mandrels, rollers, radiused flats, and clamping devices must be longer than the specimen width, and they must be strong and rigid enough to resist deformation and wear. Descriptions of basic types of bending devices follow.

Wrap bending devices (Fig. 2) grip the test specimen at one end; a mandrel, reaction pin, or block with the desired bend radius is positioned at midlength. A roller that sweeps concentrically around the bend radius applies the bending force. The distance from the mandrel to the loading roller generally is equal to the thickness or diameter of the test piece, plus clearance. The clearance is adjusted to allow the test specimen to bend to the desired radius or angle without scuffing, smearing, or galling of strip and die surfaces.

Fig. 2 Wrap bending device. Bending force is applied by a roller that sweeps concentrically around the bend radius.

Wipe bending devices (Fig. 3) are similar to wrap bending devices, except that the bending force is applied by a mandrel or roller that moves perpendicular to the clamped specimen.

Fig. 3 Wipe bending devices. (a) Mandrel type with force applied near free end. (b) Die type with force applied near free end

V-block bending devices consist of a mandrel and a bottom block (Fig. 4a) or specimen supports (Fig. 4b). The sample rests on supports or on the bottom block and is not clamped during the test. The distance between supports is selected to force the specimen to conform to the mandrel radius without excessive interference. This clearance is often the mandrel diameter, d , plus three times the specimen thickness, t . Bending force is applied at the center of the specimen. The bottom block normally is a V or U shape. Bends made with conforming bottom block radii are bottoming or closed-die bends (Fig. 4a); those without conforming bottom block radii are air or free bends (Fig. 4b).

Fig. 4 V-block bending devices. (a) Closed V-block. (b) Open V-block

Soft tool bending, or rubber pad bending, is similar to V-block bending, except that the bottom block is replaced by highly compressible materials such as polyurethane. Figure 5 illustrates various setups for soft tool bending.

Fig. 5 Setups for soft tool (rubber pad) bending of sheet metal. (a) Simple 90° V-bend. Air space below die pad permits deep penetration. (b) Simple U-bend or channel. Spacers enable U-bends of varying widths to be formed in the same die-pad retainer. Deflector bars help provide uniform distribution of punch pressure. (c) Modified U-bend with partial air bending. (d) Acute-angle U-bend. High side pressures are obtained by using a conforming rubber die pad and deflector bars.

Bend Testing

Eugene Shapiro, Olin Corporation

Specimen Preparation

Sheet and plate specimens normally are full thickness and are prepared by shearing or sawing. Narrow strip and bar sections can be tested with specimens cut to length. For polygonal shapes, it is sometimes necessary to machine or grind a flat, with the unmachined surface to be placed on the tension side of the bend. The rough edges of cut samples can be removed by processes such as belt sanding and filing. The edges of rectangular-section test pieces can be rounded to a radius up to one tenth of the sample thickness. Edge preparation is not required for specimens with width-to-thickness ratios (w/t) greater than 8 to 1, unless cracking initiates from the edge during bending.

A specimen can be machined to fit if it is too thick for the bending device or if the required bending forces exceed the capacity of the bending device. The unmachined surface is placed on the tension side. If reduced thickness samples are used, the specimen dimensions must be held constant during testing and noted in the test report.

Specimens must be long enough to be clamped securely to prevent slippage in wrap and wipe tests. Specimens for V-block and soft tool bending can be of any length greater than the distance between specimen supports (Fig. 4b).

Test specimens usually are cut parallel or perpendicular to the direction of rolling, drawing, or extrusion. However, any orientation in the plane of the product width and length can be tested. Specimen dimensions should be the same for any test orientation. Figure 6 shows the orientation of a bending test specimen with the rolling direction for a longitudinal orientation and a transverse orientation. The transverse orientation generally

produces lower ductility because the tensile bending stresses are oriented perpendicular to the fiber structure developed by the rolling procedure used to produce sheet and plate products.

Fig. 6 Relative orientation of longitudinal and transverse bending tests

Cold rolling oils or other protective coatings usually are left on specimens to serve as a lubricating film during bending tests. Other lubricants can be used if they reflect field conditions.

The principal stress and strain directions developed during bending are defined in Fig. 7(a). The specimen width-to-thickness ratio (w/t) determines the respective stress and strain states. At $w/t > 8$, bending occurs under plane-strain conditions ($\epsilon_2 = 0$ and $\sigma_2/\sigma_1 = 0.5$) and bend ductility is independent of the exact width-to-thickness ratio (Fig. 7b). At $w/t < 8$, bending occurs under plane-stress conditions ($\sigma_2/\sigma_1 < 0.5$) with plastic deformation in all principal strain directions, and the measured bend ductility is strongly dependent on the width-to-thickness ratio (Fig. 7b). Therefore, bending tests are conducted at width-to-thickness ratios greater than 8 to 1 whenever possible to eliminate geometric effects on the test results. Although specimens with width-to-thickness ratios less than 8 to 1 can be tested, the entire test lot must have the same width-to-thickness ratio.

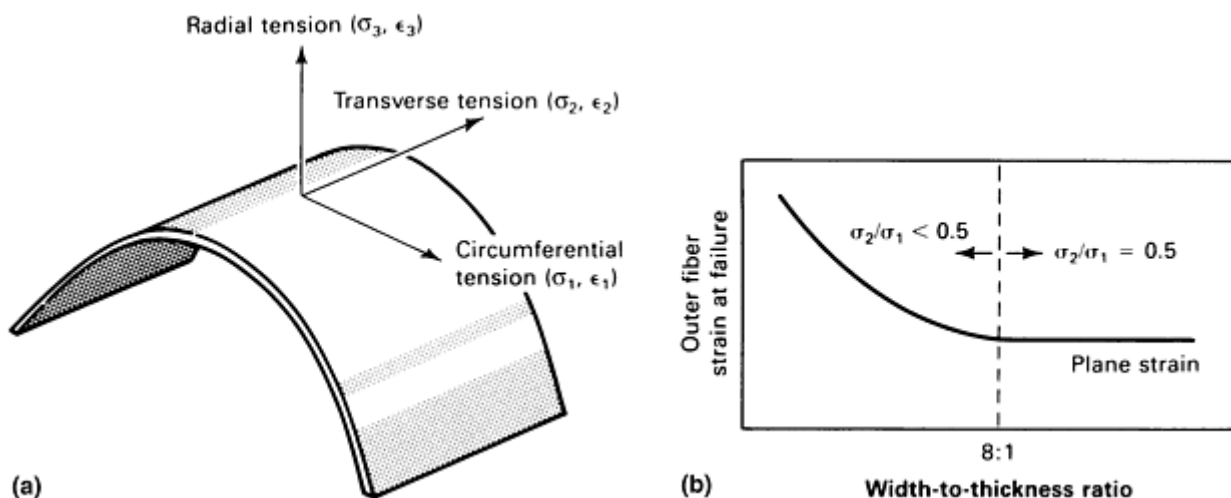

Fig. 7 Stress and strain in bending. (a) Schematic of the bend region defining the direction of principal stresses and strains. (b) Outer fiber strain at fracture versus width-to-thickness ratio

Bend Testing

Eugene Shapiro, Olin Corporation

Test Method

Specimens and apparatuses should be carefully inspected. Specimens with scuff marks, scratches, excessive curvature, twisting, or other surface defects should be discarded. Bend radii, mandrels, and support blocks must be free of scuff marks or other visible damage.

In bending tests, specimens are bent around progressively tighter radii, or to large bend angles, until failure or cracking occurs on the convex surface. If wipe or wrap bending apparatus is used, the clearance must be adjusted for each radius. Any method can be used to force the specimen to obtain the desired radius or angle; however, it must be applied slowly and steadily without significant lateral motion. Bend angles of 180° are obtained by pressing bent specimens between platens (Fig. 8), maintaining the bend radius with a spacer block twice as thick as the radius between the legs of the specimen.

Fig. 8 Methods used to develop 180° bend angles. (a) Bend sample from wipe or V-block placed between platens. (b) Sharp (180°) bend. (c) Bend with radius equal to one-half the spacer-block thickness

During bending, the specimen can be removed to inspect the convex surface for cracks. The test is complete when product specifications have been achieved.

Bend Testing

Eugene Shapiro, Olin Corporation

Interpretation

Specimens are examined for cracking at the apex of the bend with magnifications of up to $20\times$. A specimen is acceptable if there are no visible cracks on its outside surface. Surface rumples and orange peeling are not considered fracture sites. If cracking occurs at the edges of the bent sample when the specimen width-to-thickness ratio is 8 to 1 or greater, the edges of the sample should be polished or ground and the specimen retested. At width-to-thickness ratios less than 8 to 1, edge preparation may be required to obtain reproducible measurements of minimum bend radii.

The bending method can influence the strain distribution on the surface of the specimen (Fig. 9). V-block bending (Fig. 9b) develops a nonuniform strain distribution, while wrap or wipe bending produces strain that increases progressively with the bend angle until saturation. Circumferential strain becomes uniform only after the bend angle exceeds certain minimum values (Fig. 10 and 11). For wipe or wrap bending, these values are a 90° bend angle and a $1t$ radius.

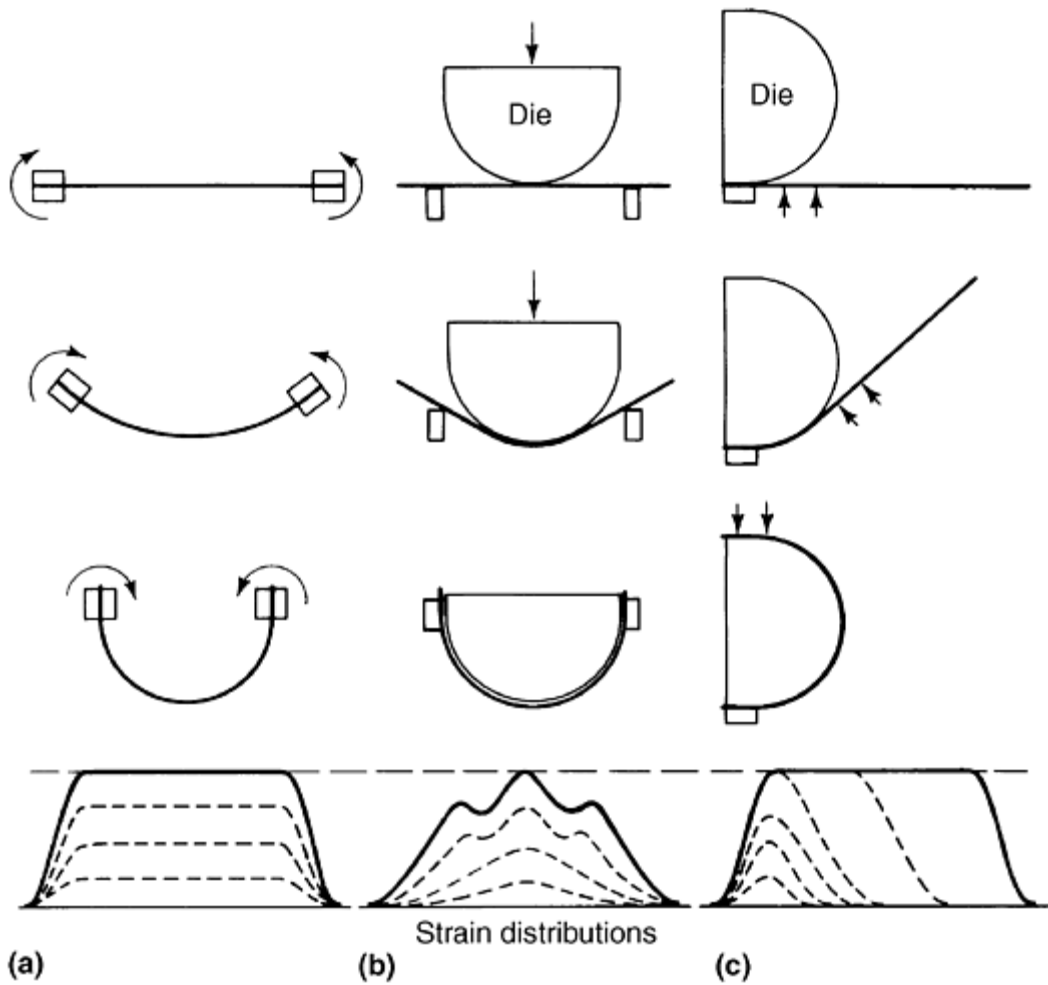

Fig. 9 Comparison of strain distributions produced by different bending methods. (a) Application of a pure bending moment (not achievable in commercial bending devices). (b) V-block bending. (c) Wipe bending

Fig. 10 Effect of bend angle on strain distribution along the circumference of bends for tempered aluminum alloy 2024 sheet. (a) 3.2 mm (0.125 in.) thick sheet, $R/t = 0.7$. (b) 6.4 mm (0.25 in.) thick sheet, $R/t = 2.5$

Fig. 11 Dependence of measured circumferential strain on bend angle for tempered aluminum alloy 2024 sheet. Radius expressed in terms of thickness, t

Minimum bend radii reported are subjective measurements, not intrinsic material properties. This subjectivity is due to visual assessment of pass/fail criteria and the incremental steps of the available bend radii. The problems associated with visual assessment include reproducibility by one tester over time and the difficulty of two or more testers agreeing on the definition of a visible crack. The problems associated with the incremental steps of the bend radii can be minimized by using closely spaced bend radii.

A number of characteristics can be expected when performing bending tests on metallic materials. The minimum bend radius is dependent on alloy composition. The minimum bend radius increases as strip or bar temper increases. Annealed strips generally have isotropic bend characteristics in the plane of the sheet (the minimum bend radii are similar both parallel or perpendicular to the process direction). Strips in highly cold-rolled tempers usually have better bend properties when bends are made perpendicular to the rolling direction. For a given alloy and temper, the minimum bend radius usually is directly proportional to strip thickness, as indicated in the following equation:

$$\frac{\text{Minimum bend radius}}{\text{Strip thickness}} = \text{Constant}$$

Because of these characteristics, caution should be used in choosing a bending test method or using tabulated data. The best practice is to use the same test method, specimen dimensions, bend angle, and bend radii that are used during part fabrication. Representative data for aluminum and ferrous sheet are provided in Tables 1, 2, 3, and 4.

Table 1 Recommended minimum bend radii for 90° cold forming of aluminum alloy sheet and plate

Introduction to Hardness Testing

Gopal Revankar, Deere & Company

Introduction

THE TERM HARDNESS, as it is used in industry, may be defined as the ability of a material to resist permanent indentation or deformation when in contact with an indenter under load. Generally a hardness test consists of pressing an indenter of known geometry and mechanical properties into the test material. The hardness of the material is quantified using one of a variety of scales that directly or indirectly indicate the contact pressure involved in deforming the test surface. Since the indenter is pressed into the material during testing, hardness is also viewed as the ability of a material to resist compressive loads. The indenter may be spherical (Brinell test), pyramidal (Vickers and Knoop tests), or conical (Rockwell test). In the Brinell, Vickers, and Knoop tests, hardness value is the load supported by unit area of the indentation, expressed in kilograms per square millimeter (kgf/mm^2). In the Rockwell tests, the depth of indentation at a prescribed load is determined and converted to a hardness number (without measurement units), which is inversely related to the depth.

Hardness tests are no longer limited to metals, and the currently available tools and procedures cover a vast range of materials including polymers, elastomers, thin films, semiconductors, and ceramics. Hardness measurements as applied to specific classes of materials convey different fundamental aspects of the material. Thus, for metals, hardness is directly proportional to the uniaxial yield stress at the strain imposed by the indentation. This statement, however, may not apply in the case of polymers, since their yield stress is ill defined. Yet hardness measurement may be a useful characterization technique for different properties of polymers, such as storage and loss modulus. Similarly, the measured hardness of ceramics and glasses may relate to their fracture toughness, and there appears to be some correlation between microhardness and compressive strength (Ref 1).

The consequence of material hardness also depends on its application in industry. For example, a fracture mechanics engineer may consider a hard material as brittle and less reliable under impact loads; a tribologist may consider high hardness as desirable to reduce plastic deformation and wear in bearing applications. A metallurgist would like to have lower hardness for cold rolling of metals, and a manufacturing engineer would prefer less hard materials for easy and faster machining and increased production. These considerations lead, during component design, to the selection of different types of materials and manufacturing processes to obtain the required material properties of the final product, which are, in many cases, estimated by measuring the hardness of the material.

Hardness, though apparently simple in concept, is a property that represents an effect of complex elastic and plastic stress fields set up in the material being tested. The microscopic events such as dislocation movements and phase transformations that may occur in a material under the indenter should not be expected to exactly repeat themselves for every indentation, even under identical test conditions. Yet experience has shown that the indentations produced under the same test conditions are macroscopically nearly identical, and measurements of their dimensions yield fairly repeatable hardness numbers for a given material. This observation by James A. Brinell in the case of a spherical indenter led to the introduction of the Brinell hardness test (Ref 2). This was followed by other tests (already mentioned) with unique advantages over the Brinell indenter, as described in the various articles of this Section.

Hardness testing is perhaps the simplest and the least expensive method of mechanically characterizing a material since it does not require an elaborate specimen preparation, involves rather inexpensive testing equipment, and is relatively quick. The theoretical and empirical investigations have resulted in fairly accurate quantitative relationships between hardness and other mechanical properties of materials such as ultimate tensile strength, yield strength and strain hardening coefficient (Ref 3, 4), and fatigue strength and creep (Ref 5). These relationships help measure these properties with an accuracy sufficient for quality control during the intermediate and final stages of manufacturing. Many times hardness testing is the only nondestructive test alternative available to qualify and release finished components for end application.

Introduction to Hardness Testing

Gopal Revankar, Deere & Company

Principles of Hardness Testing (Ref 6)

Brinell versus Meyer Hardness. In the Brinell hardness test, a hard spherical indenter is pressed under a fixed normal load onto the smooth surface of a material. When the equilibrium is reached, the load and the indenter are withdrawn, and the diameter of the indentation formed on the surface is measured using a microscope with a built-in millimeter scale. The Brinell hardness is expressed as the ratio of the indenter load W to the area of the concave (i.e., contact) surface of the spherical indentation that is assumed to support the load and is given as Brinell hardness number (BHN) denoted by HB. Thus:

$$HB = 2W / \pi D^2 \left[1 - \sqrt{1 - (d / D)^2} \right] \quad (\text{Eq 1})$$

where W is the load in kilograms, and d and D are the diameters of the indentation and the indenter, respectively, in millimeters.

However, BHN, though widely and universally accepted in manufacturing practice, is not considered a satisfactory concept, since it does not represent the mean pressure over the curved area (see the following discussion). Consideration of equilibrium of the indenter (sphere) under load would show (Ref 6) that the mean pressure over the indentation spherical area is given by load *divided* by the projected area of indentation, or:

$$P = W / (\pi d^2 / 4) \quad (\text{Eq 2})$$

where P is the Meyer hardness (Ref 7), also expressed in kilograms per square millimeter (kgf/mm^2). A more fundamental relationship between the load and the indentation diameter is given by Meyer's law, which states that:

$$W = cd^n \quad (\text{Eq 3})$$

where c and n are constants for a given material. The value of n generally varies between 2 and 2.5; it is approximately 2.6 for fully annealed metals and approximately 2.0 for fully cold worked metals. It may be mentioned here that fully annealed metals tend to work harden whereas the highly cold worked metals have a near ideal plastic behavior; that is, they do not work harden.

If D_1, D_2, D_3, \dots are the diameters of the indenters producing indentations of diameters d_1, d_2, d_3, \dots produced by the same load, then Meyer's law states that:

$$W = c_1 d_1^{n_1} = c_2 d_2^{n_2} = c_3 d_3^{n_3} = \dots \quad (\text{Eq 4})$$

Meyer determined experimentally that, for a given material, the value of n is almost independent of D , and that c and D are inversely related such that:

$$A = c_1 D_1^{n-2} = c_2 D_2^{n-2} = c_3 D_3^{n-2} \dots = \text{constant}$$

Equation 4 then becomes:

$$W = Ad_1^n/D_1^n = Ad_2^n/D_2^n \quad (\text{Eq 5})$$

$$= Ad_3^n/D_3^n \dots$$

This relationship may be expressed in two useful forms:

$$W/d^2 = A(d/D)^{n-2} \quad (\text{Eq 6})$$

and

$$W/D^2 = A (d/D)^n \quad (\text{Eq 7})$$

where A is a constant.

Equation 6 shows that, for geometrically similar indentations (see Fig. 1) for which d/D is fixed, the ratio W/d^2 , and, hence, Meyer hardness, which is proportional to this ratio, will be constant. Similarly, the Brinell hardness values, which are related to Meyer hardness through a constant, will also be constant. According to Eq 7, the indentations produced by using different values of W and D will be geometrically similar (i.e., $d/D = \text{a constant}$) and will give the same hardness values if the ratio W/D^2 is held constant. This concept is used in practical hardness measurements when the load, and, hence, D , need to be varied depending on the type of material and the shape and size of the component. Thus hardness values obtained using a 3000 kg load and 10 mm diameter ball would be practically the same as when a 750 kg load and a 5 mm diameter ball are used, since $W/D^2 = 30$ in both cases.

Fig. 1 Geometrically similar indentations produced by spherical indenters of different diameters. Note that the solid angle ϕ and the ratio d/D are the same for both the indentations

In the case of highly cold worked metals, it is experimentally observed that Meyer hardness is independent of the applied load; that is, the mean pressure resisting deformation is approximately constant. Brinell hardness, however, is nearly constant at smaller loads but decreases as the load is increased, indicating incorrectly that the materials soften at higher indentation loads. Similarly, for fully annealed metals (which undergo work hardening during the indentation process), Meyer hardness is found to increase steadily with load, suggesting the presence of work hardening. Brinell hardness would, however, rise at first and then fall as the load increases, again suggesting material softening. Meyer hardness, which is an expression of the mean yield pressure, is therefore considered a more appropriate and satisfactory measure of resistance to indentation (see also further discussion that follows and “Summary” in this article).

Plastic Deformation of Ideal Plastic Metals under an Indenter. The complex stresses set up in a material due to indentation and immediately next to the indenter can be resolved into three principal stresses, p_1 , p_2 , and p_3 , and it has been shown empirically that, for the onset of plastic deformation:

$$\frac{1}{3}[(p_1 - p_2)^2 + (p_2 - p_3)^2 + (p_3 - p_1)^2] = \text{constant} \quad (\text{Eq 8})$$

For uniaxial stresses as in a tensile test, $p_2 = p_3 = 0$ and $p_1 = Y$ at the onset of yielding, where Y is the yield stress. Equation 8 gives:

$$\frac{1}{3}(2 Y^2) = \frac{1}{3}(2 Y^2) = \text{constant}$$

This leads to the equation:

$$(p_1 - p_2)^2 + (p_2 - p_3)^2 + (p_3 - p_1)^2 = 2Y^2 \quad (\text{Eq 9})$$

which is the Huber-Mises criterion for the onset of plasticity.

An alternative criterion, due to Tresca and Mohr, is based on the assumption that plastic deformation occurs under the action of three principle stresses, $p_1 > p_2 > p_3$, when the maximum shear stress, $\frac{1}{2}(p_1 - p_3)$, exceeds a critical value. The value of this stress can be obtained, again, by considering uniaxial loading with $p_2 = p_3 = 0$, when the maximum shear stress is $\frac{1}{2}p_1$. Since $p_1 = Y$ at yielding:

$$\frac{1}{2}(p_1 - p_3) = \frac{1}{2}Y \text{ or}$$

$$p_1 - p_3 = Y, \text{ when } p_1 > p_2 > p_3 \quad (\text{Eq 10})$$

It may be shown for a two dimensional plastic flow, that is, under plane strain conditions of deformation, that $p_2 = \frac{1}{2}(p_1 + p_3)$, with zero strain in the direction of p_2 . Substituting this in Eq 9 yields:

$$p_1 - p_3 = (2/\sqrt{3})Y \quad (\text{Eq 11})$$

Thus, according to the Huber-Mises criterion, the plasticity under the indenter occurs when $(p_1 - p_3)$ reaches the value $(2/\sqrt{3})Y$ (or $1.15 Y$), which is 15% higher than that for Tresca or Mohr criterion.

When plastic strain occurs in a plane (plane strain), the system of stresses can be represented by the sum of a hydrostatic pressure, p , and a maximum shear stress, k , where $2k = 1.15 Y$ or Y (depending on the criterion chosen) at every point in the plastically deformed region of the material. Since the hydrostatic component does not produce deformation, only the shear stress may be considered responsible for the plastic strain. The stress field in the deformed material volume may therefore be represented by the maximum shear stresses in the form of slip lines (see Fig. 2). These lines should not be confused with the slip lines associated with dislocation movements under the action of stresses, which appear on the metal surface, or the dislocation images observed as lines in transmission electron microscopy.

Fig. 2 Slip-line field solutions for a flat-ended, two-dimensional punch having a width $2a$. (a) Prandtl's flow pattern. Flow in the center area is downward and to the left and right, as indicated by arrows in the adjoining areas. (b) Hill's flow pattern. Flow is to left and right in directions indicated by arrows in (a), but is separated. The dashed line AFE has been added to 3(a) to approximately suggest areas of elastic-plastic and elastic strain regions. Strain between ABCDE and AFE is partly plastic and partly elastic, and that below AFE is mostly elastic. Source: Ref 6

Deformation of an Ideal Plastic Metal by a Flat Punch (Two Dimensional Deformation). The rigorous solutions for the problem of plastic indentation have been possible only for the case of a two-dimensional deformation. When a load is first applied to an infinitely long and rigid punch with uniform width and negligible thickness, the shear stresses in an ideal plastic metal at the punch edges *A* and *B* (Fig. 3) will be very high, and these points will reach a plasticity state much earlier than the rest of the contact length. As the load is increased, the plasticity region expands outward from these edges until it covers the whole width of the punch. The pressure on the punch face at this state of plastic deformation was first derived by Prandtl (Ref 8) and later by Hill (Ref 9) through the slip line analysis already mentioned, and the corresponding slip line patterns are shown in Fig. 2.

Fig. 3 Two-dimensional deformation (plain strain) of an ideal plastic semi-infinite metal by a rigid flat punch of width $2a$. The onset of plasticity occurs at the edges *A* and *B*. Source: Ref 6

The slip line analysis of plastic deformation shows that the mean normal pressure, P_m , on the punch is given by:

$$P_m = 2k(1 + \frac{1}{2}\pi) \quad (\text{Eq 12})$$

where k is the magnitude of maximum shear stress, equal to $Y/2$ if Tresca or Mohr criterion is used and $(1.15Y)/2$ if Huber-Mises criterion is used. The Tresca or Mohr criterion holds for fully annealed mild steel, whereas the Huber-Mises criterion is applicable to most other metals. The mean pressure on the punch, therefore, would be between $2.6Y$ and $3.0Y$. The shaded region in Fig. 2(b) represents the volume of plastic deformation where elastic strains may be neglected, and the region between *ABCDE* and *AFE* may be considered to have both plastic and elastic deformation. The volume below *AFE* may be considered a region of totally elastic strain.

An approximate extension of the above analysis for a two-dimensional flat punch to the case of a three-dimensional circular punch has shown that the pressure is not uniform over the area of the circular punch (as it is slightly higher at the center than at the edges) and that the mean pressure, P_m , over the face of the punch when the material under the punch is plastically deformed is still given by the same relationship, $P_m \approx 3Y$. Note that P_m is a quantity similar to Meyer hardness discussed previously.

Deformation of Ideal Plastic Metal by Spherical Indenters. The preceding analysis of plastic deformation under the flat and circular punches may now be used to understand the stress field under a spherical indenter pressed into the surface of an ideal plastic metal.

Based on Tresca or Huber-Mises criterion, Timoshenko (Ref 10) showed that when a sphere is pressed into a metal under load, the maximum shear stress and, hence, the plastic deformation starts at a depth equal to $0.5a$ where $2a$ is the indentation diameter, as at *X* in Fig. 4. The maximum shear stress at this point has been shown to be $0.47 P_m$ where P_m is the mean pressure on the indenter. From Tresca-Mohr criterion, it is obvious, the plastic transformation would start at *X* when $0.47 P_m = \frac{1}{2}Y$, or $P_m = 1.1Y$. Figure 4 also shows contours (Ref 11) of shear stress expressed in terms of P_m as a function of the distance from *X*.

Fig. 4 Elastic deformation of a flat surface on an elastic semi-finite body under a frictionless load, by a rigid sphere of a large radius, showing the location of maximum shear stress in the bulk material below the deformed surface. The maximum shear stress occurs at X , $0.5a$ below the center of the circle of contact and has a value of about $0.47 P_m$ where P_m is the mean pressure. The contours represent lines of constant shear stress in the deformed material. Source: Ref 6

If the load is reduced or removed before P_m reaches the value $1.1Y$ at X , there will be no permanent deformation or indentation; that is, there will be a complete elastic recovery. If, however, P_m exceeds the value $1.1Y$, plastic deformation begins at X , and the plastic region would grow in size at the expense of the elastic-plastic and elastic regions underlying the indenter. This process will continue until the mean pressure in the plastic volume reaches a value $\approx 3Y$. If the load is now increased, the indenter penetrates the metal further, and the plastic zone would expand until the value of P_m in the newly formed plastic volume again equals $\approx 3Y$. When the equilibrium is reached between the indenter and the material during indentation, and the plastic flow has stopped, the indenter load is supported by the elastic stresses in the material. If the load is removed, therefore, there will be an elastic recovery with a corresponding change in shape of the plastically deformed volume and, hence, that of the indentation.

The spherical indentation process may be visualized through an experimental trace of pressure-load for indentations formed in work hardened mild steel by a spherical indenter. In Fig. 5, point L represents the onset of plastic deformation at a mean pressure corresponding to $1.1Y$. The interval $L-M$ represents a gradual increase in the plastic stress, which ultimately reaches a value $\approx 3Y$ corresponding to $M-N$ section of the curve when full plasticity is attained.

Fig. 5 Experimental pressure-load characteristic of indentations formed in work-hardened mild steel by a hard spherical indenter. Yield stress of steel, $Y = 77 \text{ kg/mm}^2$. Ball diameter is 10 mm. The broken line is the theoretical result for elastic deformation. OL, elastic region; LM, elastic-plastic region; and MN, fully plastic region. Source: Ref 6

Fully Cold Worked versus Fully Annealed Metals. The above discussion has considered ideal plastic metals, which, by definition, do not work harden during deformation and show a constant yield stress when the linear strain is increased as in a tensile or compressive test. Metals that have been sufficiently cold worked would behave in approximately this manner. However, fully annealed, and, in reality, most metals will have a tendency to work harden during deformation and will be characterized by a continuously increasing yield stress with increasing strain. The relation $P_m = CY$ ($C \approx 3$), which applies to fully cold worked metals, also holds for fully annealed metals provided Y denotes the yield stress corresponding to the strain produced during testing, which is higher than the initial yield stress. The value of C has the same approximate value of 3 as for ideal plastic metals. Also, P_m is found to be a function of d/D for fully annealed metals, and therefore, geometrically similar indentations would give identical hardness values, as for ideal plastic metals. It may be noted here that the value of $C \approx 3$ obtained through slip line analysis as already mentioned has also been recently confirmed through finite element analysis (Ref 12, 13).

Tabor (Ref 6) showed that the strain, ϵ , in the plastic region of an indentation is proportional to the ratio d/D and empirically determined the proportionality constant to be approximately 20 for many metals, thus arriving at the relation, $\epsilon = 20d/D$. Combining this equation with the relationship $Y = b\epsilon^x$, where b and x are constants for a given metal and x is the strain hardening coefficient, Tabor has shown that $W = c_1d_1^n = c_2d_2^n = c_3d_3^n$ and so on for indentations made with indenters of different diameters $D_1, D_2, D_3 \dots$. This is Meyer's law, mentioned earlier and first derived by Meyer empirically. This relation has been shown to hold fairly well for many materials. The value of n in the Meyer equation is roughly related to the strain hardening coefficient x by the relation $n = x + 2$.

Conical and Pyramidal Indenters (Ref 6). Shortly after the introduction of Brinell hardness testing, Ludwik (Ref 14) proposed hardness testing using a conical indenter and defined the hardness as the mean pressure over the surface of the indentation. Thus, for an indent with an included angle of 90° , the Ludwik hardness number is given by:

$$HL = 4W / \sqrt{2\pi d^2} \quad (\text{Eq 13})$$

where d is the diameter of the impression. This concept is similar to that of Brinell and therefore has no real physical significance. The true pressure, P , between the indenter and the indentation is given by the ratio of load to projected area, that is, $4W/\pi d^2$ (similar to Meyer's concept for a spherical indenter), which means that the Ludwik hardness number is $1/\sqrt{2}$ times the mean yield pressure P . Experiments have shown that Ludwik hardness is practically independent of the load for a given indenter, though it depends on the cone angle. It is observed that the yield pressure increases as the cone semi-angle decreases, and the effect may be partially explained as due to friction between the indenter and the indentation (Ref 15).

The diamond pyramidal indenter was first introduced by Smith and Sandland (Ref 16) and was later developed by Vickers-Armstrong, Ltd. The indenter is in the form of a square pyramid with opposite faces making an included angle of 136° with each other. The origin of this value of the angle is traced to the Brinell hardness testing practice. It is customary in Brinell hardness testing to select loads so that the indentation diameter lies between $0.25D$ and $0.5D$ where D is the indenter diameter. Thus, an average of the two diameters, $0.375D$, was chosen for the indentation diameter as shown in Fig. 6, which also shows the origin of the included angle 136° of the Vickers indenter. The geometry of the indenter is such that projected area of the indentation is 0.927 times the area of the contact surface. Since Vickers hardness, HV, is defined as the load divided by the surface area of the indentation, the yield pressure, P , is related to the Vickers hardness number by the relation $HV = 0.927P$.

Fig. 6 Relationship between the 136° included angle between the opposite faces of a Vickers indenter and the spherical Brinell indenter of diameter D

During Vickers hardness tests, the lengths of the two diagonals of the indentation are measured, and their mean value, d , is calculated. If the indentation is square, the projected area of the indentation is $d^2/2$, so that the yield pressure is $2W/d^2$ and $HV = 0.927 (2W/d^2)$. As in the case of the conical indenter, experiments have shown that the Vickers hardness number is independent of the size of the indentation, and hence, of the load. It is interesting to note that the Brinell hardness values, obtained by using a 10 mm steel ball loaded to give an indentation diameter equal to $0.375D$, have been shown to closely match the Vickers hardness numbers (Ref 17), thus giving some justification to the selection of 136° as the included angle.

The Knoop diamond indenter is a variation of the Vickers indenter. It is a pyramid in which the included angles are 172° 30' and 130°, and the indentation has the shape of a parallelogram with the longer diagonal about seven times as long as the shorter diagonal. The Knoop hardness is defined as the load, W , divided by the *projected* area A of the indentation. Thus $HK = W/A$, which gives the yield pressure. The hardness values obtained by the Knoop method are, as would be expected, nearly independent of the load and are almost identical with HV numbers.

The elastic and plastic deformation processes that occur in the case of conical and pyramidal indenters are similar to those described for a spherical indenter.

Again, as in the case of a flat punch already described, slip line analysis has been done (Ref 18) for the plastic deformation under a two-dimensional conical and pyramidal indenter in the form of a wedge. The slip line pattern in Fig. 7 shows that the analysis allows for metal flow past the indenter surface to form a ridge. The pressure normal to the indenter surface is given by (Ref 6):

$$P = 2k(1 + \theta) \quad (\text{Eq 14})$$

where θ is the angle as shown in Fig. 6, and is related to α , the semi-angle of the wedge, by the equation:

$$\text{Cos}(2\alpha - \theta) = \text{cos}\theta / (1 + \sin\theta) \quad (\text{Eq 15})$$

Since $2k = 1.15Y$ for Huber-Mises criterion:

$$P = 1.15Y(1 + \theta) \quad (\text{Eq 16})$$

As seen from Fig. 7, when the semi-angle $\alpha = 90^\circ$, $\theta = 90^\circ$. The wedge forms flat punch, as discussed. Equation 15 becomes:

$$P = 1.15Y(1 + \frac{1}{2}\pi) \quad (\text{Eq 17a})$$

or

$$P = 2.96Y \quad (\text{Eq 17b})$$

Fig. 7 Slip-line pattern for a two-dimensional wedge penetrating an ideally plastic material (Ref 18). The pressure across the face of the indenter is uniform and has the value $P = 2k(1 + \theta)$, where θ is the angle HBK in radians. This analysis allows for the displacement of the deformed material as can be seen in the figure. Source: Ref 6

Equation 17a 17b is the same as Eq 12 derived for a flat punch and shows the yield pressure is again about three times the yield stress. The two-dimensional analysis and the expression for yield pressure ($P = CY$) for a wedge are expected to apply to the case of solid pyramidal and conical indenters just as the flat punch analysis was found to hold fairly well for a flat circular punch. In fact, it has been shown experimentally that it is true. However, the value of C for these solid indenters is found in practice to be slightly higher than for a spherical indenter (3.2 versus 3.0), and this is considered to be probably due to the higher friction between the indenter and the material.

The pyramidal and conical indenters may be considered to have a spherical indentation point with an extremely small radius. The plastic deformation therefore starts immediately after the indenter comes in contact with the material surface, even at very small loads. As the load is increased, the indentation increases in size and depth, but its shape and the flow pattern remain unchanged whatever its depth. This implies that the indentations produced by these indenters are geometrically similar for all indentation loads, and hence, the hardness values measured by these indenters are, for all practical purposes, independent of the indentation load (compare this with the case of the Brinell test where the requirement is that the d/D ratio should be constant to obtain identical hardness values).

The preceding discussion is true for the commonly used microhardness and macrohardness tests with indentations above a certain size where the hardness is independent of their depth. However, recent investigations have shown that for indentations of extremely small depths (50 nm), the hardness can vary inversely with depth due to the probable influence of several surface factors such as dislocation image forces, contamination layers, and electric fields (Ref 19).

Rockwell Hardness Test with a Conical Indenter. In the Rockwell test, a load of 10 kg is first applied to the material surface, and the depth of penetration is considered as zero for further depth measurements. A load of 90 or 140 kg is then applied and removed, leaving the minor load in place, and the additional depth of penetration is measured directly on a dial gage, which gives the hardness value that may be correlated with Vickers or Brinell values. In the Rockwell test, a spherical indenter is used for softer materials (Rockwell B scale), and a conical indenter is used for hard materials (Rockwell C scale). Other scales of Rockwell test are omitted from this discussion but are described in the article "Indentation Hardness Testing of Metals and Alloys" in this Section.

Rockwell testing has two important advantages as compared to other tests previously discussed:

- Application and retention of the minor load during the test prepares the surface upon which the incremental penetration depth due to the major load is measured.
- The hardness value is read directly on the dial gage without the necessity for measuring the indentation dimensions, as in other hardness testing methods. This expedites the testing process—an important advantage in manufacturing and quality control.

However, there may be appreciable elastic recovery of the material when the major load is removed, and the recovered indentation depth will be less than the depth before removing the load. The hardness value deduced from the depth of recovered indentation may, therefore, be in error. This error may not be serious if the instrument is calibrated for materials having approximately the same elastic modulus, a requirement that is generally satisfied in industry where the most common materials used in manufacturing are ferrous and have approximately the same elastic modulus.

If the above effect is neglected and the plastic deformation is large compared to the elastic recovery, then it is relatively simple to obtain a relationship between the hardness values obtained from depth measurements and those from diameter measurements of the spherical indentation. Thus, assuming that the penetration depth, t , is small as compared to the ball diameter, D , one can obtain from simple geometry considerations that $t = d^2/4D$ where d is the diameter of the indentation. Since the mean pressure P across the indentation, which is equivalent to the Meyer hardness, is given by $P = 4W/\pi d^2$:

$$t = (W/P)(1/\pi D) \quad (\text{Eq 18})$$

Thus, if the load is kept constant as in a Rockwell test, Eq 18 shows depth of penetration t is inversely proportional to P ; that is, the depth of penetration increases with decreasing hardness. This fact is reflected in the dial gage readings, which do not give the actual depth of penetration but, rather, give a quantity, R , given by 100 scale divisions minus the depth penetrated. Thus:

$$R = \text{constant} - t$$

or

$$R = C_1 - C_2 / P \quad (\text{Eq 19})$$

where C_1 and C_2 are constants.

This type of relation is approximately obeyed if a spherical indenter is employed. However, a different relation is obtained if a conical indenter is used. Thus if α is the semi-angle of the cone and the depth of penetration is $t = a \cot \alpha$ where $2a$ is the indentation diameter, then:

$$t = \sqrt{(W/\pi P)} \cot \alpha \quad (\text{Eq 20})$$

where P , the mean pressure, is again given by $P = W/\pi a^2$. Since t is inversely proportional to P for a given value of α , the Rockwell number may be expressed by the relationship:

$$R = C_3 - C_4 / \sqrt{P} \quad (\text{Eq 21})$$

where C_3 and C_4 are constants. If Rockwell hardness values R_c , obtained using a spherically tipped conical indenter, are plotted against Brinell hardness numbers, B , it is found that the curve can be approximately represented by the relationship:

$$R_c = C_5 - C_6 / \sqrt{B} \quad (\text{Eq 22})$$

where C_5 and C_6 are constants.

Equation 22 is similar to Eq 21 with P replaced by B . Since it is reasonable to assume Meyer hardness P is not widely different from B , it may be concluded that the theoretical relation between R_c and B (Eq 21) is substantiated by the empirical observations (Eq 22), and this provides a degree of validity to the concept of measurement of hardness from depth measurements.

Summary. The indentation hardness values are essentially a measure of the elastic limit or yield stress of the material being tested. For most types of indenters in use, the yield pressure under conditions of appreciable plastic flow is approximately three times the yield stress of the material. The elastic recovery of the indentation when the load and the indenter are removed seems to affect mostly the depth of the indentation rather than the projected area of the indentation. Consequently the yield pressure or the hardness as measured from the indentation dimensions are nearly the same as would be obtained if measurements were made before the load and the indenter were removed.

The yield pressure is mostly dependent on the plastic properties of the material and only to a secondary extent on the elastic properties. If the hardness measurements are made based on the depth measurements, then the elastic recovery may affect the calculated yield pressure, which may be in error when compared with the actual values that may be obtained during indentation. However, this error may be small when the instrument is calibrated for materials with similar elastic moduli.

With conical and pyramidal indenters, the indentations are geometrically similar (whatever the indentation size), and, therefore, the mean pressure to produce the plastic flow is almost independent of the indentation size. Consequently the hardness value is fairly constant over a wide range of loads. This means it is not necessary in practice to specify the load.

With spherical indenters, the shape of the indentation varies with its size so that the amount of work hardening, the elastic limit, and, as a result, the yield pressure in general increase with the size of the indentation and hence with the load. It is therefore necessary in Brinell hardness measurements to specify the load and the diameter of the indenter. With spherical indenters the ratio W/D^2 must be maintained constant to produce geometrically similar indentations and nearly identical hardness numbers.

In Brinell testing, the increase in the yield pressure with the size of indentation provides useful information about the yield stress of the material and about the way in which the yield stress increases with the amount of deformation. In fact, the hardness measurements made using a spherical indenter can be used in conjunction with the Meyer analysis and Meyer's index, n , to determine the work hardening coefficient, x , using the relationship $n = x + 2$.

Introduction to Hardness Testing

Gopal Revankar, Deere & Company

Classification of Hardness Tests

The hardness tests may be classified using various criteria, including type of measurement, magnitude of indentation load, and nature of the test (i.e., static, dynamic, or scratch).

Type of Measurement. Hardness tests may be classified into two types: one, involving measurement of dimensions of the indentation (Brinell, Vickers, Knoop) and the other, measuring the depth of indentation (Rockwell, nanoindentation). They may also be classified as the traditional tests, which measure one contact area or penetration depth at a prescribed load (Brinell, Vickers, Knoop, Rockwell), and the recent instrumented-indentation tests, which allow for a continuous measurement of load and displacement.

Magnitude of Indentation Load. Hardness tests may be classified based on the magnitudes of indentation loads. There are, thus, macrohardness, microhardness, and the relatively new nanohardness tests. For macrohardness tests, indentation loads are 1 kgf or greater: Vickers testing may use loads from 1 to 120 kgf. Rockwell test loads vary from 15 to 150 kgf, depending on the type of indenter and the Rockwell scale of measurement. Brinell tests involve 500 and 3000 kgf loads though intermediate loads. Loads as low as 6.25 kgf are occasionally used.

The microhardness tests (Vickers and Knoop) use smaller loads ranging from 1 gf to 1 kgf, the most common being 100 to 500 gf and suited for material layers that are thicker than about 3 μm . The nanoindentation test, also called the instrumented indentation test, depends on the simultaneous measurement of the load and depth of indentation produced by loads that may be as small as 0.1 mN, with depth measurements in the 20 nm range.

Static, Dynamic, or Scratch Types. All of the above mentioned tests are of the static type. In the dynamic tests, the indenter, usually spherical or conical, is allowed to bounce off the surface of the material to be tested, and the rebound height of the indenter is used as a measure of hardness. The scleroscope is the most popular test of this type. In the scratch test, a material of known hardness is used to scratch the surface of material of unknown hardness to determine if the latter is more or less hard than the reference material.

Eddy current hardness testing, which does not fall into any of the above categories, is a noncontact method and does not use an indenter. The method depends on the measurement of eddy current permeability of the material surface layer, which is determined by its microstructure and hence hardness.

These and various other test methods are discussed in greater detail in the subsequent articles of this Section.

Macroindentation Hardness Testing

Edward L. Tobolski, Wilson Instruments Division, Instron Corporation; Andrew Fee, Consultant

Introduction

ALMOST ALL indentation hardness testing is done with Brinell, Rockwell, Vickers, and Knoop indenters. These modern methods of indentation testing began with the Brinell test, which was developed around 1900 when the manufacturing of ball bearings prompted J.A. Brinell in Sweden to use them as indenters. The Brinell test was quickly adopted as an industrial test method soon after its introduction, but several limitations also became apparent. Basic limitations included test duration, the large size of the impressions from the indent, and the fact that high-hardness steels could not be tested with the Brinell method of the early 1900s.

The limitations of the indentation test developed by Brinell prompted the development of other macroindentation hardness tests, such as the Vickers test introduced by R. Smith and G. Sandland in 1925, and the Rockwell test invented by Stanley P. Rockwell in 1919. The Vickers hardness test follows the same

principle of the Brinell test—that is, an indenter of definite shape is pressed into the material to be tested, the load removed, the diagonals of the resulting indentation measured, and the hardness number calculated by dividing the load by the surface area of indentation. The principal difference is that the Vickers test uses a pyramid-shaped diamond indenter that allows testing of harder materials, such as high-strength steels.

The Rockwell hardness test differs from Brinell hardness testing in that the hardness is determined by the depth of indentation made by a constant load impressed upon an indenter. Rockwell hardness testing is the most widely used method for determining hardness, primarily because the Rockwell test is fast, simple to perform, and does not require highly skilled operators. By use of different loads (force) and indenters, Rockwell hardness testing can determine the hardness of most metals and alloys, ranging from the softest bearing materials to the hardest steels.

This article describes the principal methods for macroindentation hardness testings by the Brinell, Vickers, and Rockwell methods. Microindentation hardness tests with the Knoop and Vickers indenters are described further in the next article “Microindentation Hardness Testing.” An overall discussion on the applications and selection of these test methods is provided in the article “Selection and Industrial Applications of Hardness Tests” in this Volume.

Macroindentation Hardness Testing

Edward L. Tobolski, Wilson Instruments Division, Instron Corporation; Andrew Fee, Consultant

Rockwell Hardness Testing

The Rockwell hardness test is defined in ASTM E 18 and several other standards (Table 1). Rockwell hardness testing differs from Brinell testing in that the Rockwell hardness number is based on the difference of indenter depth from two load applications (Fig. 1). Initially a minor load is applied, and a zero datum is established. A major load is then applied for a specified period of time, causing an additional penetration depth beyond the zero datum point previously established by the minor load. After the specified dwell time for the major load, it is removed while still keeping the minor load applied. The resulting Rockwell number represents the difference in depth from the zero datum position as a result of the application of the major load. The entire procedure requires only 5 to 10 s.

Table 1 Selected Rockwell hardness test standards for metals and hardmetals

Standard No.	Title
ASTM B 294	Standard Test Method for Hardness Testing of Cemented Carbides
ASTM E 18	Test Methods for Hardness and Rockwell Superficial Hardness of Metallic Materials
ASTM E 1842	Test Method for Macro-Rockwell Hardness Testing of Metallic Materials
BS 5600-4.5	Powder Metallurgical Materials and Products—Methods of Testing and Chemical Analysis of Hardmetals—Rockwell Hardness Test (Scale A)
BS EN ISO 6508-1	Metallic Materials—Rockwell Hardness Test—Part 1: Test Method (Scales A, B, C, D, E, F, G, H, K, N, T)
BS EN ISO 6508-2	Metallic Materials—Rockwell Hardness Test—Part 2: Verification and Calibration of Testing Machines (Scales A, B, C, D, E, F, G, H, K, N, T)
BS EN ISO 6508-3	Metallic Materials—Rockwell Hardness Test—Part 3: Calibration of Reference Blocks (Scales A, B, C, D, E, F, G, H, K, N, T)
ISO 3738-1	Hardmetals—Rockwell Hardness Test (Scale A)—Part 1: Test Method
ISO 3738-2	Hardmetals—Rockwell Hardness Test (Scale A)—Part 2: Preparation and Calibration of Standard Test Blocks
JIS B 7726	Rockwell Hardness Test—Verification of Testing Machines
JIS B 7730	Rockwell Hardness Test—Calibration of Reference Blocks

Fig. 1 Principle of the Rockwell test. Although a diamond indenter is illustrated, the same principle applies for steel ball indenters and other loads.

Use of a minor load greatly increases the accuracy of this type of test, because it eliminates the effect of backlash in the measuring system and causes the indenter to break through slight surface roughness. The basic principle involving minor and major loads is shown in Fig. 1. Although the principle is illustrated with a diamond indenter, the same principle applies for hardened steel ball indenters and other loads.

Test Types and Indenters

There are two types of Rockwell tests: Rockwell and superficial Rockwell. In Rockwell testing, the minor load is 10 kgf, and the major load is 60, 100, or 150 kgf. In superficial Rockwell testing, the minor load is 3 kgf, and major loads are 15, 30, or 45 kgf. In both tests, the indenter may be either a diamond cone or a hardened ball depending principally on the characteristics of the material being tested.

Hardened ball indenters with diameters of $\frac{1}{16}$, $\frac{1}{8}$, $\frac{1}{4}$ and, $\frac{1}{2}$ in. (1.588, 3.175, 6.35, and 12.7 mm) are used for testing softer materials such as fully annealed steels, softer grades of cast irons, and a wide variety of nonferrous metals. Hardened steel balls have traditionally been used for Rockwell testing. However, a changeover to tungsten carbide is in process. All future testing will be done with carbide balls. This will improve the durability of the balls significantly, but a slight change in hardness results may occur.

Rockwell diamond indenters are used mainly for testing hard materials such as hardened steels and cemented carbides. “Hard materials” are those with hardness greater than 100 HRB and greater than 83.1 HR30T (see the section “Rockwell Scales” in this article for further explanation).

The Rockwell diamond indenter is a spheroconical shape with a 120° cone and a spherical tip radius of 200 μm (Fig. 2a). Older standard indenters in the United States had a nominal radius closer to 192 μm, which was within ASTM specifications ($200 \pm 10 \mu\text{m}$); standard indenters in the rest of the world have been closer to 200 μm. While not out of tolerance, the old U.S. standard indenter is at the low end of the specification. This led to a change in tip radius closer to 200 μm used in the rest of the world.

Fig. 2 Rockwell indenter. (a) Diamond-cone Brale indenter (shown at about 2×). (b) Comparison of old and new U.S. diamond indenters. The angle of the new indenter remains at 120°, but has a larger radius closer to the average ASTM specified value of 200 μm; the old indenter has a radius of 192 μm. The indenter with the larger radius has a greater resistance to penetration of the surface.

A comparison of the old (192 μm) U.S. standard diamond indenter and the current (200 μm tip) U.S. indenter is shown in Fig. 2(b). The larger radius increases the resistance of the indenter to penetration into the surface of the testpiece. At higher Rockwell C hardness, most of the indenter travel is along the radius; whereas at the lower hardnesses, more indenter travel is along the angle. This is why the hardness shift from old to new has been most significant in the 63 HRC range and not the 25 HRC range.

Rockwell Scales

Rockwell hardness values are expressed as a combination of hardness number and a scale symbol representing the indenter and the minor and major loads. The Rockwell hardness is expressed by the symbol HR and the scale designation. For example, 64.0 HRC represents the Rockwell hardness number of 64.0 on the Rockwell C scale; 81.3 HR30N represents the Rockwell superficial hardness number of 81.3 on the Rockwell 30N scale. Because of the changeover to carbide balls, the designation for the ball scales will require the use of an S or W to indicate the ball used. For example, a HRB scale reading of 80.0 obtained using a steel ball would be labeled 80.0 HRBS, while the same result using a carbide ball would be designated 80.0 HRBW.

There are 30 different scales, defined by the combination of the indenter and the minor and major loads (Tables 2 and 3). In many instances, Rockwell hardness tolerances are specified or are indicated on drawings. At times, however, the Rockwell scale must be selected to suit a given set of circumstances.

Table 2 Rockwell standard hardness

Scale symbol	Indenter	Major load, kgf	Typical applications
A	Diamond (two scales—carbide and steel)	60	Cemented carbides, thin steel, and shallow case-hardened steel
B	$\frac{1}{16}$ in. (1.588 mm) ball	100	Copper alloys, soft steels, aluminum alloys, malleable iron
C	Diamond	150	Steel, hard cast irons, pearlitic malleable iron, titanium, deep case-hardened steel, and other materials harder than 100 HRB
D	Diamond	100	Thin steel and medium case-hardened steel and pearlitic malleable iron
E	$\frac{1}{8}$ in. (3.175 mm) ball	100	Cast iron, aluminum and magnesium alloys, bearing metals
F	$\frac{1}{16}$ in. (1.588 mm) ball	60	Annealed copper alloys, thin soft sheet metals
G	$\frac{1}{16}$ in. (1.588 mm) ball	150	Phosphor bronze, beryllium copper, malleable irons. Upper limit 92 HRG to avoid possible flattening of ball
H	$\frac{1}{8}$ in. (3.175 mm) ball	60	Aluminum, zinc, lead
K	$\frac{1}{8}$ in. (3.175 mm) ball	150	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.
L	$\frac{1}{4}$ in. (6.350 mm) ball	60	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.
M	$\frac{1}{4}$ in. (6.350 mm) ball	100	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.
P	$\frac{1}{4}$ in. (6.350 mm) ball	150	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.
R	$\frac{1}{2}$ in. (12.70 mm) ball	60	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.
S	$\frac{1}{2}$ in. (12.70 mm) ball	100	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.
V	$\frac{1}{2}$ in. (12.70 mm) ball	150	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not produce anvil effect.

Table 3 Rockwell superficial hardness scales

Scale symbol	Indenter	Major load, kgf
15N	Diamond	15
30N	Diamond	30
45N	Diamond	45
15T	$\frac{1}{16}$ in. (1.588 mm) ball	15
30T	$\frac{1}{16}$ in. (1.588 mm) ball	30
45T	$\frac{1}{16}$ in. (1.588 mm) ball	45
15W	$\frac{1}{8}$ in. (3.175 mm) ball	15
30W	$\frac{1}{8}$ in. (3.175 mm) ball	30
45W	$\frac{1}{8}$ in. (3.175 mm) ball	45
15X	$\frac{1}{4}$ in. (6.350 mm) ball	15
30X	$\frac{1}{4}$ in. (6.350 mm) ball	30
45X	$\frac{1}{4}$ in. (6.350 mm) ball	45
15Y	$\frac{1}{2}$ in. (12.70 mm) ball	15
30Y	$\frac{1}{2}$ in. (12.70 mm) ball	30
45Y	$\frac{1}{2}$ in. (12.70 mm) ball	45

Note: The Rockwell N scales of a superficial hardness tester are used for materials similar to those tested on the Rockwell C, A, and D scales, but of thinner gage or case depth. The Rockwell T scales are used for materials similar to those tested on the Rockwell B, F, and G scales, but of thinner gage. When minute indentations are required, a superficial hardness tester should be used. The Rockwell W, X, and Y scales are used for very soft materials. The letter N designates the use of the diamond indenter; the letters T, W, X, and Y designate steel ball indenters. Superficial Rockwell hardness values are always expressed by the number suffixed by a number and a letter that show the load and indenter combination. For example, 80 HR30N indicates a reading of 80 on the superficial Rockwell scale using a diamond indenter and a major load of 30 kgf

The majority of applications for testing steel, brass, and other materials are covered by the Rockwell C and B scales. However, the increasing use of materials other than steel and brass as well as thin materials necessitates a basic knowledge of the factors that must be considered in choosing the correct scale to ensure an accurate Rockwell test. The choice is not only between the regular hardness test and superficial hardness test, with three different major loads for each, but also between the diamond indenter and the $\frac{1}{16}$, $\frac{1}{8}$, $\frac{1}{4}$, and $\frac{1}{2}$ in. (1.588, 3.175, 6.35, and 12.7 mm) diam ball indenters.

If no specification exists or there is doubt about the suitability of the specified scale, an analysis should be made of the following factors that control scale selection:

- Type of material
- Specimen thickness or the thickness of a hardened layer on the surface of the part
- Test location
- Scale limitations

In general, the best results are obtained using the highest loads that the specimen will allow.

Selection of Scale Based on Material Type. Standard Rockwell scales and typical materials for which these scales are applicable are listed in Table 2. For example, when a hard material such as steel or tungsten carbide is tested, a diamond indenter would be used. This automatically limits the choice of scale to one of six: Rockwell C, A, D, 45N, 30N, or 15N. The next step is to determine which scale will provide the best accuracy, sensitivity, and repeatability. Typically, as the thickness of the sample decreases the major load should also decrease.

Effect of Specimen Thickness. The material immediately surrounding a Rockwell indentation is cold worked. The extent of the cold-worked area depends on the type of material and previous work hardening of the test specimen. The depth of material affected has been found by extensive experimentation to be on the order of 10 to 15 times the depth of the indentation. Therefore, unless the thickness of the material being tested is at least

10 times the depth of the indentation, an accurate Rockwell test cannot be ensured. This “minimum thickness ratio” of 10 to 1 should be regarded only as an approximation.

The depth of the indentation can be determined as follows. One Rockwell number is equal to 0.002 mm (0.00008 in.). When the reading is taken with a diamond indenter, the Rockwell hardness number obtained on the sample is subtracted from 100, and the result multiplied by 0.002 mm. Therefore, a reading of 60 HRC indicates an indentation depth from minor to major load of:

$$(100 - 60) \times 0.002 \text{ mm} = 0.08 \text{ mm}$$

$$\text{Depth} = 0.08 \text{ mm (0.003 in.)}$$

When a ball indenter is used, the hardness number is subtracted from 130; therefore, for a dial reading of 90 HRB, the depth is determined by:

$$(130 - 80) \times 0.002 \text{ mm} = 0.10 \text{ mm}$$

$$\text{Depth} = 0.10 \text{ mm (0.004 in.)}$$

In Rockwell superficial tests, regardless of the type of indenter used, one number represents an indentation of 0.001 mm (0.00004 in.). Therefore, a reading of 80 HR30N indicates a depth of indentation from minor to major load of:

$$(100 - 80) \times 0.001 \text{ mm} = 0.02 \text{ mm}$$

$$\text{Depth} = 0.02 \text{ mm (0.0008 in.)}$$

As indicated above, computation of the depth of penetration for any Rockwell test requires only simple arithmetic. However, in actual practice, computation is not necessary because minimum thickness values have been established (Table 4). These minimum thickness values generally follow the 10-to-1 ratio, but they are based on experimental data accumulated for varying thickness of low-carbon steels and of hardened-and-tempered strip steel.

Table 4 Minimum work metal hardness values for testing various thicknesses of metals with standard and superficial Rockwell hardness testers

Metal thickness		Minimum hardness for standard hardness testing						Minimum hardness for superficial hardness testing					
		Diamond indenter			Ball indenter, $\frac{1}{16}$ in. (1.588 mm)			Diamond indenter			Ball indenter, $\frac{1}{16}$ in. (1.588 mm)		
mm	in.	A (60 kgf)	D (100 kgf)	C (150 kgf)	F (60 kgf)	B (100 kgf)	G (150 kgf)	15 N (15 kgf)	30 N (30 kgf)	45 N (45 kgf)	15 T (15 kgf)	30 T (30 kgf)	45 T (45 kgf)
0.127	0.005	93

0.508	0.020	82	77	...	100	^(a)	57	63	^(a)	55	53
0.559	0.022	78	75	69	^(a)	47	58	...	45	43
0.610	0.024	76	72	67	98	94	94	^(a)	^(a)	51	...	34	31
0.635	0.025	^(a)	^(a)	...	^(a)	^(a)	...
0.660	0.026	71	68	65	91	87	87	^(a)	^(a)	37	18

0.711	0.028	67	63	62	85	...	76	(a)	(a)	20	4
0.762	0.030	60	58	57	77	71	68	(a)	(a)	(a)	(a)	(a)	(a)
0.813	0.032	(a)	51	52	69	62	59	(a)	(a)	(a)
0.864	0.034	(a)	43	45	...	52	50	(a)	(a)	(a)
0.889	0.035	(a)	(a)	(a)	(a)	(a)	(a)	(a)
0.914	0.036	(a)	(a)	37	...	40	42	(a)	(a)	(a)
0.965	0.038	(a)	(a)	28	...	28	31	(a)	(a)	(a)
1.016	0.040	(a)	(a)	20	(a)	...	22	(a)	(a)	(a)	(a)	(a)	(a)

Note: These values are approximate only and are intended primarily as a guide; see text for example of use. Material thinner than shown should be tested with a microhardness tester. The thickness of the workpiece should be at least 1.5 times the diagonal of the indentation when using a Vickers indenter, and at least one-half times the long diagonal when using a Knoop indenter.

(a) No minimum hardness for metal of equal or greater thickness.

Consider a requirement to check the hardness of a strip of steel 0.36 mm (0.014 in.) thick with an approximate hardness of 63 HRC. According to the established minimum thickness values, material in the 63 HRC range must be approximately 0.71 mm (0.028 in.) thick for an accurate Rockwell C scale test. Therefore, 63 HRC must be converted to an approximate equivalent hardness on other Rockwell scales. These values, taken from a conversion table, are 73 HRD, 82.8 HRA, 69.9 HR45N, 80.1 HR30N, and 91.4 HR15N. Hardness conversion tables are provided in the article “Hardness Conversions for Steels” in this Volume.

Referring to Table 4, there are only three appropriate Rockwell scales—45N, 30N, and 15N—for hardened 0.356 mm (0.014 in.) thick material. The 45N scale is not suitable because the material should be at least 74 HR45N. The 30N scale requires the material to be at least 80 HR30N; on the 15N scale, the material must be at least 76 HR15N. Therefore, either the 30N or 15N scale can be used.

If a choice remains after all criteria have been applied, then the scale applying the heavier load should be used. A heavier load produces a larger indentation covering a greater portion of the material, as well as a Rockwell hardness number more representative of the material as a whole. In addition, the heavier the load, the greater the sensitivity of the scale.

In the example under consideration, a conversion chart will indicate that, in the hard steel range, a difference in hardness of one point on the Rockwell 30N scale represents a difference of only 0.5 points on the Rockwell 15N scale. Therefore, smaller differences in hardness can be detected when using the 30N scale. This approach also applies when selecting a scale to accurately measure hardness when approximate case depth and hardness are known.

Minimum thickness charts and the 10-to-1 ratio serve only as guides. After determining which Rockwell scale should be used based on minimum thickness values, an actual test should be performed, and the side directly beneath the indentation should be examined to determine whether the material was disturbed or a bulge exists. If so, the material is not sufficiently thick for the applied load. This results in a condition known as “anvil effect.” When anvil effect or flow exists, the Rockwell hardness number obtained may not be a true value. The Rockwell scale applying the next lighter load should then be used.

Use of several specimens, one on top of the other, is not allowed. Slippage between the contact surfaces of the specimens makes a true value impossible to obtain. The only exception is in the testing of plastics; use of several thicknesses for elastomeric materials when anvil effect is present is recommended in ASTM D 785, “Standard Test Method for Rockwell Hardness of Plastics and Electrical Insulating Materials.” Testing performed on soft plastics may not have an adverse effect when the test specimen is composed of a stack of several pieces of the same thickness, provided that the surfaces of the pieces are in total contact and not held apart by sink marks, buffs from saw cuts, or other protrusions.

When testing specimens for which the anvil effect results, the condition of the supporting surface of the anvil must be observed carefully. After several tests, this surface may become marred, or a small indentation may be produced. Either condition affects the Rockwell test, because under the major load the test material will sink into the indentation in the anvil and a lower reading will result. If a specimen is found to have been too thin during testing, the anvil surface should be inspected; if damaged, it should be relapped or replaced.

When using a ball indenter and a superficial scale load of 15 kgf on a specimen in which anvil effect or material flow is present, a diamond spot anvil can be used in place of the standard steel anvil. Under these conditions, the hard diamond surface is not likely to be damaged when testing thin materials. Furthermore, with materials

that flow under load, the hard polished diamond provides a somewhat standardized frictional condition with the underside of the specimen, which improves repeatability of readings.

Additional information is provided in the section “Anvil Effect” in the article “Selection and Industrial Application of Hardness Tests” in this Volume.

Test Location

If an indentation is placed too close to the edge of a specimen, the workpiece edge may bulge, causing the Rockwell hardness number to decrease accordingly. To ensure an accurate test, the distance from the center of the indentation to the edge of the specimen must be at least 2.5 times the diameter of the indent. Therefore, when testing in a narrow area, the width of this area must be at least five diameters when the indentation is placed in the center. The appropriate scale must be selected for this minimum width. Although the diameter of the indentation can be calculated, for practical purposes the minimum distance can be determined visually.

An indentation hardness test cold works the surrounding material. If another indentation is placed within this cold-worked area, the reading usually will be higher than that obtained had it been placed outside this area. Generally, the softer the material, the more critical the spacing of indentations. However, a distance three diameters from the center of one indentation to another is sufficient for most materials.

Scale Limitations

Because diamond indenters are not calibrated below values of 20, they should not be used when readings fall below this level. If used on softer materials, results may not agree when the indenters are replaced, and another scale—for example, the Rockwell B scale—should be used.

There is no upper limit to the hardness of a material that can be tested with a diamond indenter. However, the Rockwell C scale should not be used on tungsten carbide because the material will fracture or the diamond life will be reduced considerably. The Rockwell A scale is the accepted scale in the carbide products industry. Due to the unique requirements for the Rockwell testing of carbide materials, a separate ASTM test method has been developed. That test method, ASTM B 294, defines the tighter requirements necessary when testing carbide. The carbide hardness levels have been established and are maintained by the Cemented Carbide Producers Association (CCPA). Standard test blocks and indenters traceable to the CCPA standards are available. The user should note that diamond indenters for carbide testing are different than normal HRA scale testing indenters and should not be mixed. Because of the high stress on the tip of the indenter, the life of carbide indenters is normally much shorter than other Rockwell indenters.

Although scales that use a ball indenter (for example, the Rockwell B scale) range to 130, readings above 100 are not recommended, except under special circumstances. Between approximately 100 and 130, only the tip of the ball is used. Because of the relatively blunt shape in that part of the indenter, the sensitivity of most scales is poor in this region.

Also, with smaller diameter indenters, flattening of the ball is possible because of the high stress developed at the tip. However, because there is a loss of sensitivity as the size of the ball increases, the smallest possible ball should be used. If values above 100 are obtained, the next heavier load, or next smaller indenter, should be used. If readings below 0 are obtained, the next lighter load, or next larger indenter, should be used. Readings below 0 are not recommended on any Rockwell scale, because misinterpretation may result when negative values are used. On nonhomogeneous materials, a scale should be selected that gives relatively consistent readings. If the ball indenter is too small in diameter or the load is too light, the resulting indentation will not cover an area sufficiently representative of the material to yield consistent hardness readings.

Rockwell Testing Machines

Many different types of Rockwell testers are currently produced. Test loads can be applied in a number of ways; most utilize deadweight, springs, or closed-loop load-cell systems. Many testers use a dial (analog) measuring device. However, digital-readout testers are becoming the norm because of improved readability and accuracy. Some testers use microprocessors to control the test process, and such testers can be used to interface with computers. These testers can have significantly greater capabilities such as automatic conversions,

correction factors, and tolerance limits. Most digital units now have outputs to interface with a host computer or printer.

Various methods for performing the function of a Rockwell test have been developed by manufacturers. Generally, different machines are used to make standard Rockwell and superficial Rockwell tests. However, there are combination (twin) machines available that can perform both types of tests. The principal components of a deadweight type Rockwell tester are shown in Fig. 3.

Fig. 3 Schematic of Rockwell testing machine

Bench-Type Testing Machines. Routine testing is commonly performed with bench-type machines (Fig. 4), which are available with vertical capacities of up to 400 mm (16 in.). A machine of this type can accommodate a wide variety of part shapes by capitalizing on standard as well as special anvil designs. The usefulness of this standard type of machine can be greatly extended by the use of various accessories, such as:

- Outboard or counterweighted anvil adapters for testing unwieldy workpieces such as long shafts
- Clamps that apply pressure on the part, which are particularly suited for testing parts that have a large overhang or long parts such as shafts
- Gooseneck anvil adapters for testing inner and outer surfaces of cylindrical objects

Fig. 4 Bench-type Rockwell tester

Production Testing Machines. When large quantities of similar workpieces must be tested, conventional manually operated machines may not be adequate. With a motorized tester, hourly production can be increased by up to 30%.

To achieve still greater production rates, high-speed testers (5) are used. High-speed testers can be automated to include automatic feeding, testing, and tolerance sorting. Upper and lower tolerance limits can be set from an operator control panel. These testers allow test loads to be applied at high speed with short dwell times. Up to 1000 parts per hour can be tested. These testers are normally dedicated to specific hardness ranges.

Fig. 5 Production Rockwell testers. (a) High-speed Rockwell tester. (b) Automated Rockwell tester for high-rate testing, such as the setup shown for Jominy end-quench hardenability testing

Computerized Testing Systems. With the use of microprocessors in digital testers, the ability to add computer control is possible. The computer can be programmed to perform a series of tests such as a case-depth study or a Jominy test. Using a motorized stage, any combination of test patterns can be performed with little operator effort. Automatic test reports and data storage are normally part of the program.

Portable Testing Machines. For hardness testing of large workpieces that cannot be moved, portable units are available in most regular and superficial scales and in a wide range of capacities (up to about a 355 mm, or 14 in., opening between anvil and indenter). Most portable hardness testers follow the Rockwell principle of minor and major loads, with the Rockwell hardness number indicated directly on the measuring device. Both digital and analog models are available. In Fig. 6(a), the workpiece is clamped in a C-clamp arrangement, and the indenter is recessed into a ring-type holder that is part of the clamp. The test principle is identical to that of bench-type models. The workpiece is held by the clamp between what is normally the anvil and the holder (which, in effect, serves as an upper anvil). The indenter is lowered to the workpiece through the holder. Other types of portable units (Fig. 6b) use the near-Rockwell method, where the diamond indenter is a truncated cone.

Fig. 6 Portable Rockwell testers. (a) C-clamp setup with a portable tester. (b) Portable near-Rockwell hardness tester

Calibration

If a Rockwell testing system is in constant use, a calibration check should be performed daily. Testers not used regularly should be checked before use. This check uses standardized test blocks to determine whether the tester and its indenter are in calibration.

Rockwell test blocks are made from high-quality materials for uniformity of test results. To maintain the integrity of the test block, only the calibrated surface can be used. Regrinding of this surface is not recommended due to the high possibility of hardness variations between the new and original surfaces.

If a tester is used throughout a given hardness scale, the recommended practice is to check it at the high, middle, and low ranges of the scale. For example, to check the complete Rockwell C scale, the tester should be checked at values such as 63, 45, and 25 HRC. On the other hand, if only one or two ranges are used, test blocks should be chosen that fall within 5 hardness numbers of the testing range on any scale using a diamond indenter and within 10 numbers on any scale using a ball indenter.

A minimum of five tests should be made on the standardized surface of the block. The tester is in calibration if the average of these tests falls within the tolerances indicated on the side of the test block. For best results, a pedestal spot anvil should be used for all calibration work.

If the average of the five readings falls outside the Rockwell test block limits, the ball in the ball indenter should be inspected visually; in the case of a diamond indenter, the point should be examined using at least a 10× magnifier. If there is any indication of damage, the damaged component must be replaced.

Rockwell Hardness Level National Standards. For more than 75 years, the producers of test blocks held the Rockwell hardness standards. While this worked well when there was only one manufacturer, the situation changed as more and more companies produced test blocks. To make matters worse, the U.S. standard did not match that used in the rest of the world and could not be traced to a government agency. In general, HRC hardness results with the old U.S. indenter appeared slightly softer (Fig. 2).

With involvement of the National Institute of Standards and Technology (NIST), a new U.S. Rockwell hardness standard was created. As expected, the level is very close to the other standardizing laboratories around the world. As soon as NIST released the new standard, many of the manufacturers started to calibrate their test blocks to the new standard. At the same time, ASTM Subcommittee E-28.06 started working on revisions to

ASTM E 18 to require the use of NIST traceable test blocks in the calibration of the blocks and testers. NIST initially released the Rockwell C scale, but they will eventually maintain standards for most of the commonly used scales (HRB, HRA, HR30N, HR30T, HR15N, and HR15T).

The impact of the new Rockwell C scale standards is that scales are shifted up slightly. The shift is greater in the high ranges (Fig. 2). For example, a piece of hardened steel that was determined to be 63.0 HRC under the old standard is now 63.6 HRC. This shift will impact some users more than others. The shift at the low end of the C scale is much less and will not be a problem to most users. The benefit to the new standard is that testers in the United States now have traceability, and results are comparable to those in the rest of the world.

Gage Repeatability and Reproducibility (GRR) Studies. Computerized statistical process control (SPC) techniques are used more and more by industry to control the manufacturing process. Gage repeatability and reproducibility studies are commonly used to evaluate the performance of gages.

Because hardness testers can be considered as gages, there have been some efforts by manufacturers and users of hardness testers to use GRR studies to determine what percent of the part tolerance is being used up by tester variations (see the article “Gage Repeatability and Reproducibility in Hardness Testing” in this Volume). The major problem associated with doing this type of study on any material testing instrument is that the material being tested can contribute significantly to the final results. This is due to unavoidable variations inherent in the material being tested. It is also not possible to test the exact same spot, and no material has completely uniform hardness. To obtain reasonable GRR results of hardness testing, material variability must be addressed. Test blocks that have known good uniformity should be used. Normally, blocks in the 63 HRC range with a reasonable tolerance will work. Using 63 HRC test blocks with low variations and a tolerance of ± 3 HRC points, it is possible to achieve GRR results in the 10% range or better. Good basic techniques must also be used to eliminate any other factors that could affect the results.

Testing Methodology

Although the Rockwell test is simple to perform, accurate results depend greatly on proper testing methods.

Indenters. The mating surfaces of the indenter and plunger rod should be clean and free of dirt, machined chips, and oil, which prevent proper seating and can cause erroneous test results. After replacing an indenter, a ball in a steel ball indenter, or an anvil, several tests should be performed to seat these parts before a hardness reading is taken. Indenters should be visually inspected to determine whether any obvious physical damage is present that may affect results.

Anvils should be selected to minimize contact area of the workpiece while maintaining stability. Figure 7 illustrates several common types of anvils that can accommodate a broad range of workpiece shapes. An anvil with a large flat surface (Fig. 7b) should be used to support flat-bottom workpieces of thick section. Anvils with a surface diameter greater than about 75 mm (3 in.) should be attached to the elevating screw by a threaded section, rather than inserted in the anvil hole in the elevating screw.

Fig. 7 Typical anvils for Rockwell hardness testing. (a) Standard spot, flat, and V anvils. (b) Testing table for large workpieces. (c) Cylinder anvil. (d) Diamond spot anvil. (e) Eyeball anvil

Sheet metal and small workpieces that have flat undersurfaces are best tested on a spot anvil with a small, elevated, flat bearing surface (Fig. 7a). Workpieces that are not flat should have the convex side down on the bearing surface. Round workpieces should be supported in a V-slot anvil (Fig. 7a and c). Diamond spot anvils (Fig. 7d) are used only for testing very thin sheet metal samples in the HR15T and HR30T scales.

Other anvil designs are available for a wide range of odd-shaped parts, such as the eyeball anvil (Fig. 7e) that is used for tapered parts. Special anvils to accommodate specific workpiece configurations can be fabricated. Regardless of anvil design, rigidity of the part to prevent movement during the test is absolutely essential for accurate results, as is cleanliness of the mating faces of the anvil and its supporting surface.

Specimen Surface Preparation. The degree of workpiece surface roughness that can be tolerated depends on the Rockwell scale being used. As a rule, for a load of 150 kgf on a diamond indenter, or 100 kgf on a ball indenter, a finish ground surface is sufficient to provide accurate readings. As loads become lighter, surface requirements become more rigorous. For a 15 kgf load, a polished or lapped surface usually is required.

Surfaces that are visibly ridged due to rough grinding or coarse machining offer unequal support to the indenter. Loose or flaking scale on the specimen at the point of indenter contact may chip and cause a false test. Scale should be removed by grinding or filing. Decarburized surface metal must also be removed to permit the indenter to test the true metal beneath.

Workpiece Mounting. An anvil must solidly support the test specimen. The movement of the plunger rod holding the indenter measures the depth of indentation when the major load is applied; any slippage or movement of the workpiece will be followed by the plunger rod. The motion will be transferred to the measuring system. Errors of this type always produce softer hardness values. Because one point of hardness represents a depth of only 0.002 mm (0.00008 in.), a movement of only 0.025 mm (0.001 in.) could cause an error of more than 10 Rockwell points.

Integral Clamping Systems. Some testers are designed with a clamping surface that surrounds the indenter either built into the test head or as a removable assembly (Fig. 8). These clamps can be helpful if a rapid test cycle is desired or the test point is on the end of a long overhung part. The anviling surface on the part is less critical; however, any movement of the part during the test will cause errors in the test results.

Fig. 8 Rockwell tester with removable clamping assembly

Angle of Test Surface. The test surface should be perpendicular to the indenter axis. Extensive experimentation has found errors of 0.1 to 1.5 HRC, depending on the hardness range being tested, with a 3° angle deviation. Such errors produce softer hardness values.

Load Application. The minor load should be applied to the test specimen in a controlled manner, without inducing impact or vibration. With manually operated testing machines, the measuring device must then be set to zero datum, or set point, position. The major load is then applied in a controlled fashion.

During the test cycle on a manually operated tester, the operator should not force the crank handle because inaccuracies and damage to the tester may result. When the large pointer comes to rest or slows appreciably, the full major load has been applied and should dwell for up to 2 s. The load is then removed by returning the crank handle to the latched position. The hardness value can then be read directly from the measuring device. Semiautomatic digital testers perform most of these steps automatically.

Homogeneity. A Rockwell tester measures the hardness of a specimen at the point of indentation, but the reading is also influenced by the hardness of the material under and around the indentation. The effects of indentation extend about 10 times the depth of the indentation. If a softer layer is located in this depth, the impression will be deeper, and the apparent hardness will be less.

The factor must be taken into account when testing material with a superficial hardness such as case-hardened work. To obtain the average hardness of materials such as cast iron with relatively large graphite particles, or nonferrous metals with crystalline aggregates that are greater than the area of the indenter, a larger indenter must be used. In many instances, a Brinell test may be more valid for this type of material.

Spacing of indentations is very important. The distance from the center of one indentation to another must be at least three indentation diameters, and the distance to the edge should be a minimum of 2.5 diameters. Readings from any indentation spaced closer should be disregarded. These guidelines apply for all materials.

Configuration Adjustments

When performing a Rockwell test, specimen size and configuration may require that modifications in the test setup be made. For example, large specimens and thin-wall rings and tubing may need additional support equipment, and test results obtained from curved surfaces may require a correction factor.

Large Specimens. Many specially designed Rockwell hardness testers that have been developed to accommodate the testing of large specimens cannot conveniently be brought to or placed in a bench-type tester. For large and heavy workpieces, or workpieces of peculiar shape that must rest in cradles or on blocks, use of a large testing table is recommended.

Long Specimens. Work supports are available for long workpieces that cannot be firmly held on an anvil by the minor load. Because manual support is not practical, a jack-rest should be provided at the overhang end to prevent pressure between the specimen and the penetrator. Figure 9 illustrates methods for testing long, heavy workpieces.

Fig. 9 Rockwell test setups for long testpieces. (a) Jack setup. (b) Variable rest setup

Workpieces with Curved Surfaces. When an indenter is forced into a convex surface, there is less lateral support supplied for the indenting force; consequently, the indenter will sink farther into the metal than it would into a flat surface of the same hardness. Therefore, for convex surfaces, low readings will result. On the other hand, when testing a concave surface, opposite conditions prevail; that is, additional lateral support is provided, and the readings will be higher than when testing the same metal with a flat surface.

Results from tests on a curved surface may be in error and should not be reported without stating the radius of curvature. For diameters of more than 25 mm (1 in.), the difference is negligible. For diameters of less than 25 mm (1 in.), particularly for softer materials that involve larger indentation, the curvature, whether concave or convex, must be taken into account if a comparison is to be made with different diameters or with a flat surface. Correction factors should be applied when workpieces are expected to meet a specified value. Typical correction factors for regular and superficial hardness values are presented in the article "Selection and Industrial Applications of Hardness Tests" in this Volume (see Table 4 in that article). The corrections are added to the hardness value when testing on convex surfaces and subtracted when testing on concave surfaces.

On cylinders with diameters as small as 6.35 mm (0.25 in.), standard Rockwell scales can be used; for the superficial Rockwell test, correction factors for diameters as small as 3.175 mm (0.125 in.) are given in the article "Selection and Industrial Applications of Hardness Tests" in this Volume (see Table 4 in that article). Diameters smaller than 3.175 mm (0.125 in.) should be tested by microindentation methods (see the article "Microindentation Hardness Testing" in this Section).

When testing cylindrical pieces such as rods, the shallow V or standard V anvil should be used, and the indenter should be applied over the axis of the rod. Care should be taken that the specimen lies flat, supported by the sides of the V. 10 Figure 10 illustrates correct and incorrect methods of supporting cylindrical work while testing.

Fig. 10 Anvil support for cylindrical workpieces. (a) Correct method places the specimen centrally under indenter and prevents movement of the specimen under testing loads. (b) Incorrect method of supporting cylindrical work on spot anvil. The testpiece is not firmly secured, and rolling of the specimen can cause damage to the indenter or erroneous readings.

Inner Surfaces. The most basic approach to Rockwell hardness testing of inner surfaces is to use a gooseneck adapter for the indenter, as illustrated in Fig. 12. This adapter can be used for testing in holes or recesses as small as 11.11 mm (0.4375 in.) in diameter or height. Some testers are designed with an extended indenter holder to allow easier internal testing.

Fig. 11 Setup for Rockwell hardness testing of inner surfaces of cylindrical workpieces, using a gooseneck adapter

Thin-Wall Rings and Tubes. When testing pieces such as thin-wall rings and tubing that may deform permanently under load, a test should be conducted in the usual manner to see if the specimen becomes permanently deformed. If it has been permanently deformed either an internal mandrel on a gooseneck anvil or a lighter test load should be used.

Excessive deformation of tubing (either permanent or temporary) can also affect the application of the major load. If through deformation the indenter travels to its full extent, complete application of the major load will be prevented, and inaccurately high readings will result.

Gears and other complex shapes often require the use of relatively complex anvils in conjunction with holding fixtures. When hardness testing workpieces that have complex shapes—for example, the pitch lines of gear teeth—it is sometimes necessary to design and manufacture special anvils and fixtures; specially designed hardness testers may be required to accommodate these special fixtures.

Testing at Elevated Temperatures

Several methods have been devised to determine hardness at elevated temperatures, but a modified Rockwell test is used most often. Elevated-temperature testing typically consists of a Rockwell tester with a small furnace mounted on it. The furnace has a controlled atmosphere, usually argon, although a vacuum furnace may be used. Testing up to 760°C (1400°F) is possible; however, diamond indenters have a very limited life at high temperatures.

High-temperature test setups may also feature an indexing fixture that makes it possible to bring any area of the specimen under the indenter without contaminating the atmosphere or disturbing the temperature equilibrium. This arrangement permits several tests to be made on a single specimen while maintaining temperature and atmosphere.

In addition to modified Rockwell testers, hot hardness testers using a Vickers sapphire indenter with provisions for testing in either vacuum or inert atmospheres have also been described (Ref 1, 2). An extensive review of hardness data at elevated temperatures is presented in Ref 3. The development and design of hot hardness testing furnaces is described in Ref 4.

Rockwell Testing of Specific Materials

Most homogeneous metals or alloys, including steels of all product forms and heat treatment conditions and the various wrought and cast nonferrous alloys, can be accurately tested by one or more of the 30 indenter-load combinations listed in Tables 2 and 3. However, some nonhomogeneous materials and case-hardened materials present problems and therefore require special consideration.

Cast irons, because of graphite inclusions, usually show indentation values that are below the matrix value. For small castings or restricted areas in which a Brinell test is not feasible, tests may be made with either the Rockwell B or C scale. If the hardness range permits, however, the Rockwell E or K scale is preferred, because the 3.175 mm ($\frac{1}{8}$ in.) diam ball provides a better average reading.

Powder metallurgy (P/M) parts usually are tested on the Rockwell F, H, or B scale. Where possible, the Rockwell B scale should be used. In all instances, the result is apparent hardness because of the voids present in the P/M parts. Therefore, indentation testing does not provide accurate results of matrix hardness, although it serves well as a quality-control tool.

Cemented carbides are usually tested with the Rockwell A scale. If voids exist, the result is apparent hardness, and matrix evaluations are possible only by microhardness testing.

Case-Hardened Parts. For accuracy in testing case-hardened workpieces, the effective case depth should be at least 10 times the indentation depth. Generally, cases are quite hard and require the use of a diamond indenter; thus, a choice of six scales exists, and the scale should be selected in accordance with the case depth.

If the case depth is not known, a skilled operator can, by using several different (sometimes only two) scales and making comparisons on a conversion table, determine certain case characteristics. For example, if a part shows a reading of 91 HR15N and 62 HRC, this indicates a case that is hard at the surface, as well as at an appreciable depth, because the equivalent of 62 HRC is 91 HR15N. However, if the reading shows 91 HR15N and only 55 HRC, this indicates that the indenter has broken through a relatively thin case.

Decarburization can be detected by the indentation hardness test, essentially by reversing the technique described above for obtaining an indication of case depth. Two indentation tests—one with the Rockwell 15N scale and another with the Rockwell C scale—should be performed. If the equivalent hardness is not obtained in converting from the Rockwell 15N to the Rockwell C scale, a decarburized layer is indicated. This technique is most effective for determining very thick layers of decarburization, 0.1 mm (0.004 in.) or less. When decarburization is present, other methods such as microindentation hardness testing should be used to determine the extent.

Macroindentation Hardness Testing

Brinell Hardness Testing

The Brinell test is a simple indentation test for determining the hardness of a wide variety of materials. The test consists of applying a constant load (force), usually between 500 and 3000 kgf, for a specified time (10 to 30 s) using a 5 or 10 mm (0.2 or 0.4 in.) diam tungsten carbide ball on the flat surface of a workpiece (Fig. 12a). The

load time period is required to ensure that plastic flow of the metal has ceased. After removal of the load, the resultant recovered round impression is measured in millimeters using a low-power microscope (Fig. 12b).

Fig. 12 Brinell indentation process. (a) Schematic of the principle of the Brinell indentation process. (b) Brinell indentation with measuring scale in millimeters

Hardness is determined by taking the mean diameter of the indentation (two readings at right angles to each other) and calculating the Brinell hardness number (HB) by dividing the applied load by the surface area of the indentation according to the following formula:

$$HB = \frac{2P}{\pi D (D - \sqrt{D^2 - d^2})}$$

where P is load (in kgf), D is ball diameter (in mm), and d is diameter of the indentation (in mm).

It is not necessary to make the above calculation for each test. Calculations have already been made and are available in tabular form for various combinations of diameters of impressions and load. Table 5 lists Brinell hardness numbers for indentation diameters of 2.00 to 6.45 mm for 500, 1000, 1500, 2000, 2500, and 3000 kgf loads.

Table 5 Brinell hardness numbers

6.40	13.7	27.4	41.2	54.8	68.8	82.5
6.45	13.5	27.0	40.5	54.0	67.5	81.0

Before using the Brinell test, several points must be considered. The size and shape of the workpiece must be capable of accommodating the relatively large indentation and heavy test loads. Because of the large indentation, some workpieces may not be usable after testing and others may require further machining. In addition, the maximum range of Brinell hardness values is 16 HB for very soft aluminum to 627 HB for hardened steels (approximately 60 HRC).

Several standards specify requirements for Brinell hardness testing. Table 6 is a partial list of several Brinell standards, which should be compared in detail if equivalency is being considered.

Indenter Selection and Geometry

The standard ball for Brinell hardness testing is 10.0 mm (0.39 in) in diameter. ASTM E 10, “Standard Test Method for Brinell Hardness of Metallic Materials,” specifies that the 10 mm ball indenter shall not deviate more than ± 0.005 mm in any diameter. When balls smaller than 10 mm in diameter are used, both the test load and ball size should be specifically stated in the test report. The tolerance for balls differing in size from the standard 10 mm ball should conform to standard limits, such as those in Table 7 from ASTM E 10. When using a different size ball, more comparable results can be obtained if the load to diameter squared ratios are similar.

Table 7 Tolerances for Brinell indenter balls other than standard

Ball diameter, mm	Tolerance^(a), mm
1–3, inclusive	± 0.0035
More than 3–6, inclusive	± 0.004
More than 6–10, inclusive	± 0.0045

(a) Balls for ball bearings normally satisfy these tolerances.

Source: ASTM E 10

Hardened steel balls have been used in the past for testing material up to 444 HB (2.90 mm diam indentation). Testing at higher hardness with steel balls may cause appreciable error due to the possible flattening and permanent deformation of the ball. Therefore, the latest ASTM standards require the use of only tungsten carbide balls with a minimum hardness of 1500 HV10. Tungsten carbide ball indenters are usable up to 627 HB (2.40 mm diam indentation). The user is cautioned that slightly higher hardness values result when using carbide balls instead of steel balls because of the difference in elastic properties between these materials. To avoid any confusion, whenever a steel ball is used, the hardness is reported as HBS, and when a carbide ball is used the HBW designation is required.

Load Selection and Impression Size

While theoretically any load can be used, the loads considered standard are 500, 1000, 1500, 2000, 2500, and 3000 kgf. The test load used is dependent mainly on size of impression, specimen thickness, and test surface. The 500 kgf load is usually used for testing relatively soft metals such as copper and aluminum alloys. The 3000 kgf load is most often used for testing harder materials such as steels and cast irons.

It is recommended that the test load be of such magnitude that the diameter of the impression be in the range 2.40 to 6.00 mm (24.0–60.0% of ball diameter). Upper and lower limits of impression diameters are necessary because the sensitivity of the test is reduced as impression size exceeds the limits specified above. In addition, the upper limit may be influenced by limitations of the travel of the indenter in certain types of testers. Other nonstandard lighter loads can be used as required on softer or thinner materials.

Indentation Measurement

The diameter of the indentation is frequently measured to the nearest 0.01 mm by means of a specially designed microscope having a built-in millimeter scale. To eliminate error in the measurements due to slightly out-of-round impressions, two diameter measurements should be taken at 90° to each other. The Brinell hardness

number is based on the average of these two measurements. Table 5 provides a simple way to convert the indentation diameter to the Brinell hardness number.

The indentations produced in Brinell hardness tests may exhibit different surface characteristics. In some instances there is a ridge around the indentation that extends above the surface of the workpiece. In other instances the edge of the indentation is below the original surface. Sometimes there is no difference at all. The first phenomenon, called “ridging,” is illustrated in Fig. 13(a). The second phenomenon, called “sinking,” is illustrated in Fig. 13(b). An example of no difference is shown in Fig. 13(c). Cold-worked metals and decarburized steels are those most likely to exhibit ridging. Fully annealed metals and light case-hardened steels more often show sinking around the indentation.

Fig. 13 Sectional views of Brinell indentations. (a) Ridging-type Brinell impression. (b) Sinking-type Brinell impression. (c) Flat-type Brinell impression

The Brinell hardness number is related to the surface area of the indentation. This is obtained by measuring the diameter of the indentation, based on the assumption that it is the diameter with which the indenter was in actual contact. However, when either ridging or sinking is encountered there is always some doubt as to the exact part of the visible indentation with which the actual contact was made. When ridging is present, the apparent diameter of the indentation is greater than the true value, whereas the reverse is true when sinking occurs.

Because of the above conditions, measurements of indentation diameters require experience and some judgment on the part of the operator. Experience can be gained by measuring calibration indents in the standardized test block.

Even when all precautions and limitations are observed, the Brinell indentations for some materials vary in shape. For example, materials that have been subjected to unidirectional cold working often exhibit extreme elliptical indentations. In such cases, where best possible accuracy is required, the indentation is measured in four directions approximately 45° apart, and the average of these four readings is used to determine the Brinell hardness number. Other techniques such as Rockwell-type depth measurements are often used with high-production equipment.

Semiautomatic Indent Measurements. In an effort to reduce measurement errors, image analysis systems are available for the measurement of the indent area. The systems normally consist of a solid-state camera mounted on a flexible probe, which is typically manually placed over the indent (Fig. 14). A computer program then analyzes the indent and calculates the size and Brinell number. The advantage of these systems is that they can reduce the errors associated with the optical measurements done by an operator. The surface finish requirements are frequently higher as the computer can have difficulty measuring noncircular indents or jagged edges for which an experienced operator could make judgments and correct as needed.

Fig. 14 Computerized Brinell hardness testing optical scanning system

General Precautions and Limitations

To avoid misapplication and errors in Brinell hardness testing, the fundamentals and limitations of the test must be thoroughly understood. The following precautions should be observed before testing.

Thickness of the testpiece should be such that no bulge or other marking showing the effect of the load appears on the side of the piece opposite the impression. The thickness of the specimen should be at least ten times the depth of the indentation. Depth of indentation may be calculated from the formula:

$$\text{Depth (mm)} = \frac{P}{\pi D \times (\text{HB})}$$

where P is load in kgf, D is ball diameter in mm, and HB is Brinell hardness number. For example, a reading of 300 HB indicates:

$$\begin{aligned} \text{Depth} &= \frac{3000}{\pi D \times 300} \\ \text{Depth} &= \frac{1}{\pi} = 0.32 \text{ mm} \end{aligned}$$

Therefore, the minimum thickness of the workpiece is 10×0.32 or 3.2 mm (0.125 in.). Table 8 gives minimum thickness requirements.

Table 8 Minimum thickness requirements for Brinell hardness tests

Minimum thickness of specimen		Minimum hardness for which the Brinell test may be made safely		
mm	in.	3000 kgf load	1500 kgf load	500 kgf load
1.6	0.0625	602	301	100
3.2	0.125	301	150	50

4.8	0.1875	201	100	33
6.4	0.250	150	75	25
8.0	0.3125	120	60	20
9.6	0.375	100	50	17

Test surfaces that are flat give best results. Curved test surfaces of less than 25 mm (1 in.) radius should not be tested.

Spacing of Indentations. For accurate results, indentations must not be made near the edge of the workpiece. Lack of sufficient supporting material on one side will result in abnormally large, unsymmetrical indentations. In most instances the error in Brinell hardness number will not be significant if the distance from the center of the indentation to any edge of the workpiece is more than three times the diameter of the indentation.

Similarly, Brinell indentations must not be made too close to one another. The first indentation may cause cold working of the surrounding area that could affect the subsequent test if made within this affected region. It is generally agreed that the distance between centers of adjacent indentations should be at least three times the diameter of the indentation to eliminate significant errors.

Anvilting. The part must be anvilged properly to minimize workpiece movement during the test and to position the test surface perpendicular to the test force within 2°.

Surface Finish. The degree of accuracy attainable by the Brinell test can be greatly influenced by the surface finish of the workpiece. The surface of the workpiece should be milled, ground, or polished so that the indentation is defined clearly enough to permit accurate measurement. Care should be taken to avoid overheating or cold working the surface, as that may affect the hardness of the material. In addition, for accurate results, the workpiece surface must be representative of the material. Decarburization or any form of surface hardening must be removed prior to testing.

Testing Machines

Various kinds of Brinell testers are available for laboratory, production, automatic, and portable testing. These testers commonly use deadweight, hydraulic, pneumatic, elastic members (i.e., springs), or a closed-loop load-cell system to apply the test loads. All testers must have a rigid frame to maintain the load and a means of controlling the rate of load application to avoid errors due to impact (500 kgf/s maximum). The loads must be consistently applied within 1.0% as indicated in ASTM E 10. In addition, the load must be applied so that the direction of load is perpendicular to the workpiece surface within 2° for best results.

Bench units for laboratory testing are available with deadweight loading and/or pneumatic loading. Because of their high degree of accuracy, deadweight testers are most commonly used in laboratories and shops that do low- to medium-rate production. These units are constructed with weights connected mechanically to the Brinell ball indenter. Minimum maintenance is required because there are few moving parts. Figure 15(a) is an example of a motorized deadweight tester.

Fig. 15 Bench-type Brinell testers. (a) Motorized tester with deadweight loading. Courtesy of Wilson Instruments. (b) Brinell tester with combined deadweight loading and pneumatic operation. Courtesy of NewAge Industries

Bench units are also available with pneumatic load application or a combination of deadweight/pneumatic loading. Figure 15(b) shows an example of the latter, where the load can be applied by release of deadweights or by pneumatic actuation.

In both deadweight and pneumatic bench units, the testpiece is placed on the anvil, which is raised by an elevating screw until the testpiece nearly touches the indenter ball. Operator controls initiate the load, which is applied at a controlled rate and time duration by the test machine. The testpiece is then removed from the anvil, and the indentation width is measured with a Brinell scope, typically at 20× power. Testing with this type of apparatus is relatively slow and prone to operator influence on the test results.

Machines for Production Testing. Hydraulic testers were developed to reduce testing time and operator fatigue in production operations. Advantages of hydraulic testers include operating economy, simplicity of controls, and dependable accuracy. The controls prevent the operator from applying the load too quickly and thus overloading. The load is applied by a hydraulic cylinder and monitored by a pressure gage. Normally the pressure can be adjusted to apply any load between 500 and 3000 kgf. Hydraulic machines for production are available as bench-top or floor units (Fig. 16).

Fig. 16 Hydraulic Brinell tester. Courtesy of Wilson Instruments

Automatic Testers. Many types of automatic Brinell testers are currently available. Most of these testers (such as the one shown in Fig. 17) use a depth-measurement system to eliminate the time-consuming and operator-biased measurement of the diameters. All of these testers use a preliminary load (similar to the Rockwell principle) in conjunction with the standard Brinell loads. Simple versions of this technique provide only comparative “go/no-go” hardness indications; more sophisticated models offer a microprocessor-controlled digital readout to convert the depth measurement to Brinell numbers. Conversion from depth to diameter frequently varies for different materials and may require correlation studies to establish the proper relationship.

Fig. 17 Automatic Brinell hardness tester with digital readout. Courtesy of NewAge Industries

These units can be fully automated to obtain production rates up to 600 tests per hour and can be incorporated into in-line production equipment. The high-speed automatic testers typically comply with ASTM E 103, “Standard Method of Rapid Indentation Hardness Testing of Metallic Materials.”

Portable Testing Machines. The use of conventional hardness testers may occasionally be limited because the work must be brought to the machine and because the workpieces must be placed between the anvil and the indenter. Portable Brinell testers that circumvent these limitations are available. A typical portable instrument is shown in Fig. 18. This type of tester weighs only about 11.4 kg (25 lb), so it can be easily transported to the workpieces. Portable testers can accommodate a wider variety of workpieces than can the stationary types. The tester attaches to the workpiece as would a C-clamp with the anvil on one side of the workpiece and the indenter on the other. For very large parts, an encircling chain is used to hold the tester in place as pressure is applied.

Fig. 18 Hydraulic, manually operated portable Brinell hardness tester

Portable testers generally apply the load hydraulically, employing a spring-loaded relief valve. The load is applied by operating the hydraulic pump until the relief valve opens momentarily. With this type of tester, the hydraulic pressure should be applied three times when testing steel with a 3000 kgf load. This is equivalent to a holding time of 15 s, as required by the more conventional method. For other materials and loads, comparison tests should be made to determine the number of load applications required to give results equivalent to the conventional method.

A comparison-type tester that uses a calibrated shear pin is shown in 19Fig. 19. In this method, a small pin of a known shear load is placed in the indenter assembly against the indenter (Fig. 19b). Through hammer impact or static clamping load, the indenter is forced into the material only as far as it takes to shear the pin. Excessive force is absorbed after shear by upward movement of the indenter into an empty cavity. The resulting impression is measured by the conventional Brinell method. This method does not comply with ASTM E 10.

Fig. 19 Pin Brinell hardness tester. (a) Clamp loading tester. (b) Schematic of pin Brinell principle

Equipment Maintenance. To maintain accurate results from Brinell testing, equipment must be calibrated and serviced regularly, especially when machines are exposed to shop environments. The frequency of servicing depends on whether the testers are used in a production line or for making an occasional test. However, it is important that they be serviced and calibrated on a regular basis. Regular checking of the ball indenter for deformation is particularly important. Indenters are susceptible to wear as well as to damage. When an indenter becomes worn or damaged so that indentations no longer meet the standards, it must be replaced. Under no circumstances should attempts be made to compensate for a worn or damaged indenter.

Verification of Loads, Indenters, and Microscopes. As with any procedure that is dependent on several components, the accuracy of each must be verified to determine the accuracy of the result. In the case of Brinell hardness testing, load, indenter, and microscope accuracies must lie within a specified tolerance to ensure accurate results.

Load Verification. ASTM E 10 specifies that a Brinell hardness tester is acceptable for use over a load range within which the load error does not exceed $\pm 1\%$. Test loads should be checked by periodic calibration with a proving ring or load cell, the accuracy of which is traceable to the National Institute of Standards and Technology (NIST). Proving rings (see Fig. 20) are an elastic calibration device that is placed on the anvil of the tester. The deflection of the ring under the applied load is measured either by a micrometer screw and a vibrating reed or a reading dial gage. The amount of elastic deflection is then converted into load in kilograms and compared with required accuracies.

Fig. 20 Proving rings used for calibrating Brinell hardness testers

Ball Indenter Verification. The ball indenter must be accurate within ± 0.0005 mm of its nominal diameter. It is very difficult for the user to measure the ball in enough locations to guarantee the correct shape. Therefore, a close visual inspection is normally done, and any sign of damage will require replacement. A performance test (indirect verification) using test blocks is the best way to verify the ball. When in doubt, the ball should be replaced with a new ball certified by the manufacturer to meet all of the requirements in ASTM E 10.

Microscope Verification. The measuring microscope or other device used for measuring the diameter of the impression should be verified at five intervals over the working range by the use of a scale of known accuracy such as a stage micrometer. The adjustment of the micrometer microscope should be such that, throughout the range covered, the difference between the scale divisions of the microscope and of the calibrating scale does not exceed 0.01 mm.

Verification by Test Block (Indirect Verification). Standardized Brinell test blocks are available so that the accuracy of the Brinell hardness tester can be indirectly verified at the hardness level of the work being tested. Commonly available hardnesses are:

Test block material	Hardness, HB
Steel	500, 400, 350, 300, 250, 200
Brass	90
Aluminum	140

Good practice is to verify the tester throughout the hardness range encountered. This ensures that all test parameters are within tolerance.

Application for Specific Materials

As is true for other indentation methods of testing hardness, the most accurate results are obtained when testing homogeneous materials, regardless of the hardness range.

Steels. Virtually all hardened-and-tempered or annealed steels within the range of hardness mentioned provide accurate results with the Brinell test. However, as a rule, case-hardened steels are totally unsuitable for Brinell testing. In most instances, the surface hardness is above the practical range and is rarely thick enough to provide the required support for a Brinell test. Thus, “cave in” results, and grossly inaccurate readings are obtained.

Cast Irons. The large area of the test serves to average out the hardness difference between the iron and graphite particles present in most cast iron. This averaging effect allows the Brinell test to serve as an excellent quality-control tool.

Nonferrous metals (especially the wrought types) are generally amenable to Brinell testing, usually with the 500 kgf load, but occasionally with the 1500 kgf load. Some high-strength alloys such as titanium- and nickel-base alloys that are phase-transformation- or age-hardened can utilize the 3000 kgf load. In this situation, practical limits must be observed and some testing may be required to establish the optimal technique for testing a specific metal or alloy.

There are certain multiphase cast nonferrous alloys that are simply too soft for accurate Brinell testing. Microhardness testing is then employed. The lower limit of 16 HB with a 500 kgf load must always be observed.

Powder Metallurgy Parts. Testing of P/M parts with a Brinell tester (or any sort of macro-hardness tester) involves the same problem as encountered with cast iron. Instead of a soft graphite phase (some P/M parts also contain free graphite), P/M parts contain voids that may vary widely in size and number. Light-load Brinell testing is sometimes used successfully for testing of P/M parts, but its only real value is as a quality-control tool in measuring the apparent hardness of P/M parts (see the article “Selection and Industrial Applications of Hardness Tests” for more information on P/M hardness testing.)

Macroindentation Hardness Testing

Edward L. Tobolski, Wilson Instruments Division, Instron Corporation; Andrew Fee, Consultant

Vickers Hardness Testing

The Vickers hardness was first introduced in England in 1925 by R. Smith and G. Sandland (Ref 5). It was originally known as the 136° diamond pyramid hardness test because of the shape of the indenter. The manufacture of the first tester was a company known as Vickers-Armstrong Limited, of Crayford, Kent, England. As the test and the tester gained popularity, the name Vickers became the recognized designation for the test.

The Vickers test method is similar to the Brinell principle in that a defined shaped indenter is pressed into a material, the indenting force is removed, the resulting indentation diagonals are measured, and the hardness number is calculated by dividing the force by the surface area of the indentation. Vickers testing is divided into two distinct types of hardness tests: macroindentation and microindentation tests. These two types of tests are

defined by the forces. Microindentation Vickers (ASTM E 384) is from 1 to 1000 gf and is covered in detail in the article “Microindentation Hardness Testing.” this section focuses on the macroindentation range with test forces from 1 to 120 kgf as defined in ASTM E 92. Selected international standards for Vickers hardness testing are listed in Table 9.

Table 9 Selected Vickers hardness testing standards

Test Method

As mentioned previously, the principle of the Vickers test is similar to the Brinell test, but the Vickers test is performed with different forces and indenters. The square-base pyramidal diamond indenter is forced under a predetermined load ranging from 1 to 120 kgf into the material to be tested. After the forces have reached a static or equilibrium condition and further penetration ceases, the force remains applied for a specific time (10 to 15 s for normal test times) and is then removed. The resulting unrecovered indentation diagonals are measured and averaged to give a value in millimeters. These length measurements are used to calculate the Vickers hardness number (HV).

The Vickers hardness number (formerly known as DPH for diamond pyramid hardness) is a number related to the applied force and the surface area of the measured unrecovered indentation produced by a square-base pyramidal diamond indenter. The Vickers indenter has included face angles of 136° (Fig. 21), and the Vickers hardness number (HV) is computer from the following equation:

$$HV = \frac{2P \sin(136/2)}{d^2} = \frac{1.8544P}{d^2}$$

where P is the indentation load in kgf, and d is the mean diagonal of indentation, in mm. This calculation of Vickers hardness can be done directly from this formula or from Table 10 (lookup table in ASTM E 92). This table contains calculated Vickers numbers for a 1 kgf load, so that it is not necessary to calculate every test result. For example, if the average measured diagonal length, d , is 0.0753 mm with a 1 kgf load, then the Vickers number is:

$$HV = \frac{1.8544 (1 \text{ kgf})}{(0.0753)^2}$$

$$HV = 327$$

This value can be obtained directly from the lookup table. For obtaining hardness numbers when other loads are used, simply multiply the number from the lookup table by the test load.

Table 10 Vickers hardness numbers

Diamond indenter, 136° face angle, load of 1 kgf

Diagonal of impression, nm	Vickers hardness number for diagonal measured to 0.0001 mm

Source: ASTM E 92

Fig. 21 **Diamond pyramid indenter used for the Vickers test and resulting indentation in the workpiece. d , mean diagonal of the indentation in millimeters**

Quite often the length of indentations are larger than the values given in most lookup tables. Calculation of larger indentations is best shown by the following example: with a test load of 50 kgf, the averaged diagonal length is measured at 0.753 mm. This length is beyond the range of the lookup table; however, the table can be extended by looking up the hardness number for a 0.0753 mm indent diagonal, which has a Vickers hardness of 327 for a 1 kgf load (Table 10). Therefore, for a 0.753 mm diagonal, the table (if extended) would read 3.27 HV at 1 kgf. With a 50 kgf load, then:

$$\text{HV} = 3.27 \times 50 = 163.5$$

The Vickers hardness number is followed by the symbol “HV” with a suffix number denoting the force and a second suffix number indicating the dwell time, if different from 10 to 15 s, which is normal dwell time. For example:

6. A value of 440 HV30 represents Vickers hardness of 440 made with a force of 30 kgf applied for 10 to 15 s.
7. 440 HV30/20 represents Vickers hardness of 440 made with a force of 30 kgf applied for 20 s.

Macroindentation Vickers Test Loads. The forces of 5, 10, 20, 30, 50, 100, and 120 kgf are the most commonly used in industry today for Vickers macroindentation hardness testing. The 30 kgf force seems to be the most desirable and is used for most standardizing and calibration work. This is not to imply that the other forces cannot be used for calibrating the testers by the indirect or test block method. The applied forces normally are checked by using a calibrated electronic load cell. A Vickers hardness tester should be verified at a minimum of three forces including the forces specified for testing. The tester is considered force calibrated if the error is not greater than 1%. These forces should be applied in a smooth and gradual manner so that impact or overloading is avoided. The loading should be such that it does not cause any movement of the specimen while under test.

The Vickers indenter is a highly polished, pointed square-base pyramidal diamond (Fig. 21) with opposite face angles of $136 \pm 5^\circ$ that produces edge angles of $148^\circ 06' 43''$. All four faces are equally inclined to the vertical axis of the indenter to within $\pm 30'$ and meet at a common point so as not to produce an offset greater than 0.001 mm in length. The indenter should be periodically examined by making an indentation in a polished steel block and observing the indent formed under high magnification (500 \times). The indentation edges and point should be examined for rounding and chipping or other damage to the diamond. A wider and brighter image at the point or diagonal edges will indicate excessive wear. If chipping occurs, it will be indicated by a bright spot that usually occurs on the angle edges (diagonals). Any noticeable damage or wear would indicate that the indenter should be replaced.

The measuring microscope or measuring device must be capable of determining the length of the indentation diagonals to ± 0.0005 mm ($0.5 \mu\text{m}$) or $\pm 0.5\%$ of length, whichever is larger, in accordance to ASTM E 92, "Standard Test Method for Vickers Hardness of Metallic Materials." The most common measuring system is either a basic vertical light microscope or an optical projection screen (Fig. 22). The magnification range is usually from 4 to 500 \times , depending on the size of the indentation to be measured. The optical measuring device generally uses a Fililar micrometer eyepiece, a graduated incremental scale, or a sliding vernier attachment. The measuring microscope or other device for measuring the diagonals of the indentation is calibrated with a precision stage micrometer. As per ASTM E 92 the error of the spacing of the lines of the stage micrometer shall not exceed $0.05 \mu\text{m}$ or 0.05% of any interval. The measuring device is calibrated throughout its range of use, and a calibration factor is utilized so that an error shall not exceed $\pm 0.5\%$.

Fig. 22 **Optical projection screen and caliper for diagonal measurement in Vickers hardness testing**

Determining the calibration factor is critical for accurate diagonal measurements and should be done with care and precision. Multiple verifications should be made at several micron lengths representing the full range of measurements normally used. The averaged values should be used to calculate the calibration factor.

Video Measuring Systems and Image Processors. Newer measurement techniques successfully use image processing and analysis. This technique utilizes a scanning device, usually a microscope equipped with a solid-state video camera with a photodiode array lens that is sensitized to gray shading of the field of view. The digital image is sent to a computer that processes the photo-array output and sends a signal that projects an image on a television screen. This technique, due to the limitations of the pixel arrays in the cameras, does not have the accuracy of a trained operator using a high-quality conventional microscope. However, the method can improve the level of repeatability, especially when multiple operators are involved. The accuracy is being improved as the pixel arrays are reduced in size; however, measurements below $0.05\mu\text{m}$ are not possible with existing equipment. Another use of a solid-state video camera is commonly called a video Fililar, or Vilar, system (Fig. 23). With this type of system the operator still has to locate the indent diagonals using a joystick or

mouse; however, observing the image on the television screen is easier and less tiring than a microscope, resulting in more consistent results.

Fig. 23 Vilar system for digital image processing of Vickers indents

Application Factors

Test Specimen. The Vickers hardness test is adaptable to most test specimens ranging from large bars and rolled stock to small pieces in metallographic mounts. The surface should be flat, polished, and supported rigidly normal to the axis of the indenter. The distance from the center of the indentation to other indents or from the specimen edge should be at least 2.5 times the diagonal length. The thickness of the test specimen should be such that no bulge or marking appear on the underside surface directly opposite the indentation, and it is recommended that the thickness of the testpiece be equal to 1.5 times the length of the diagonal of the indentation. As the depth of the Vickers test is approximately $\frac{1}{7}$ of the diagonal, the rule of thumb is that the thickness of the testpiece should be 10 times the depth of the indentation.

The finish of the specimen must be smooth enough to permit the ends of the diagonals to be clearly defined so the length can be measured with a precision of 0.0005 mm or 0.5% of the length of the diagonals, whichever is larger. It is necessary that sample preparation be carefully controlled to ensure that changes to the hardness of the material are avoided. The test surface of the specimen should be presented normal to the axis of the indenter within $\pm 1^\circ$.

Testing of Cylindrical and Spherical Rounds. When testing specimens with radius of curvature, a factor is required to correct the readings as though the testing was done on a flat surface. A method for correcting Vickers hardness values taken on spherical and cylindrical surfaces has been standardized as ISO 6507-1. The correction factors are tabulated in terms of the ratio of the mean diagonal d of the indentation to the diameter D of the sphere or cylinder. Tables listing correction factors for convex and concave spherical surfaces and for cylindrical surfaces are provided in the article "Selection and Industrial Applications of Hardness Tests" in this Volume.

The rationale for this manner of correcting Vickers values on spheres and cylinders is that when testing a convex cylinder the indentation will have shorter diagonals in the curve region (90° to the longitudinal axis) compared to diagonals parallel to the long axis. This results in a shorter mean diagonal length (and a higher hardness number) than if tested on a flat surface. The correction for a convex surface therefore must be less than 1.0 to reduce the higher hardness value caused by the convex surface. The reverse is true for concave radii; the correction ratios are greater than 1.0, which increases the hardness value. The corrections for similar d/D ratios are the largest for the spherical surfaces.

Following is an example of hardness correction for a spherical surface. Similar examples for cylindrical surfaces are given in the article “Selection and Industrial Applications of Hardness Tests” in this Volume. For cylinders, correction factors depend on whether the diagonal is parallel or perpendicular to the longitudinal axis of the cylinder. In general, correction factors for cylinders are smallest when the measured diagonal is parallel to the longitudinal axis of a cylinder.

Example 1: Hardness Correction for a Convex Sphere. The test conditions are:

Force, kgf	10
Diameter of sphere (D), mm	10
Mean diagonal of indentation (d), mm	0.150
d/D	$0.150/10 = 0.015$

From the Vickers hardness table (Table 10) and adjusted for 10 kgf load, hardness for a flat surface would be 824 HV10. From the correction table (see Table 5 in the article “Selection and Industrial Application of Hardness Tests” in this Volume), the correction factor (by interpolation) is 0.983. Thus, the corrected hardness of the sphere is $824 \times 0.983 = 810$ HV 10.

Advantages and Disadvantages. One advantage of the Vickers test is that in theory constant hardness values can be obtained from homogeneous material irrespective of the test force. This generally works for force levels above 5 kg. The other advantage is that one hardness scale can be used from the softest to the hardest metals including carbides. As a result of these advantages and the relative simplicity of the test process, the Vickers scale may be useful for maintaining stable hardness standards.

In summary, advantages of the Vickers test are:

8. Vickers hardness, in general, is independent of force when determined on homogeneous material, except possibly at forces below 5 kgf.
9. The edge or ends of the diagonals are usually well defined for measurement.
10. The indentations are geometrically similar, irrespective of size.
11. One continuous scale is used for a given force, from lowest to highest values.
12. Indenter deformation is negligible on hard material.

Disadvantages of the Vickers test are:

13. Test is slow and not well adapted for routine testing. Typical test and measurement times are in the one-minute range.
14. Careful surface preparation of the specimen is necessary, especially for shallow indentations.
15. Measurement of diagonals is operator dependent, with possible eyestrain and fatigue adding to test errors.

Comparison with Brinell Testing. Because of the geometric similarity of the indentations, Vickers hardness values are independent of the applied force. That is to say that on homogeneous material the hardness value obtained with a 10 kgf load should be the same as that obtained with a 50 kgf load. When the Vickers test was first introduced, Vickers hardness values were practically constant under different forces for different materials, whereas values from Brinell testing were not. The angle of 136° was chosen by Smith and Sandland (Ref 5) to represent the most desirable ratio of indentation diameter to the ball diameter in the Brinell test.

Due to the fact that the Brinell test does not always yield constant hardness values with varying forces, and in order to minimize this variable, it is generally advisable to restrict the indentations to 25 to 50% of the diameter of the ball. Therefore the ideal size of the ball indentation lies midway between these ratios or at $0.375D$. This was the reasoning of Smith and Sandland so that some method of comparison between their test and Brinell testing could be done. The tangential angle of indentation corresponding with 0.375 times the ball diameter is 136° .

Studies have shown that hardness values obtained with Vickers testing are almost identical to those done with the Brinell test when the force has been such to produce an indentation in the range of 0.375 times the ball diameter. This similarity only holds true in the softer hardness ranges from approximately 100 to 300 HB. At approximately 350 HB the Brinell test has a slight tendency to yield lower readings than does the Vickers test, and this tendency becomes more pronounced as the hardness increases. It should be noted that some studies

have indicated a decrease in hardness values as the forces are increased when testing mild steels and soft coppers.

Effect of Elastic Recovery. As noted in the article “Selection and Industrial Applications of Hardness Tests,” the elastic response of a material can cause a change in the indent shape after unloading. A perfect pyramid indentation (area A_2 in Fig. 24) does not always remain after unloading. This is caused by “ridging” and “sinking” at the surface of the material being tested. Ridging during Vickers does not occur in a concentric ridge, as found in the Brinell test, but rather the material extrudes upward along the face of the diamond leaving the material at the corners of the indentation near the original level. This bulging effect on the sides of the indentation (A_3 in Fig. 24) is called “convexity” and indicates the material has been cold worked. Indents with a sinking-in appearance (A_1 in Fig. 24) show a downward curvature of the material along the face of the diamond called “concavity.”

Fig. 24 Vickers indentations with equal diameters but different areas

Because Vickers hardness is related to the surface area of the indentation, these effects influence hardness readings. When ridging occurs, the diagonal measurement gives a low value for the true contact area and therefore a higher hardness value ($A_2 < A_3$ in Fig. 24). The exact opposite occurs with the sinking type and causes high values of the area and low hardness numbers ($A_1 < A_2$ in Fig. 24). It has been shown that errors as high as 10% in hardness numbers using the conventional formula may occur on different metals due to these effects. Generally, cold-worked alloys and decarburized steels will demonstrate the ridging type, while annealed and softer metals are prone to the sinking type.

Anisotropy. When testing anisotropic or heavily rolled materials, it is recommended that the test specimen be oriented to have both diagonals approximately the same length. This would necessitate reorienting the testpiece so that its direction of rolling is at a 45° angle to the diagonals direction, thus equalizing the lengths. Distortion of the indentation, due to crystallographic or microstructural texture, influences diagonal lengths and the validity of the hardness value. A Vickers indentation that has one-half of either diagonal 5% longer than the other half of the diagonal will produce an error of approximately 2.5% in hardness values. Therefore it is recommended, whenever possible, that only symmetrical indentations be used to obtain hardness values.

If the diagonal legs are unequal, the specimen should be rotated 90° and another indent made. If the nonsymmetrical aspect of the indent has rotated, this indicates that the specimen surface is not perpendicular to the indenter axis. If the nonsymmetrical nature remains in the same orientation, the indenter is misaligned or damaged.

Vickers testers should be designed to apply the force smoothly and friction free without impact. The error of the indenting force must not exceed 1%, and the measuring device shall be capable of measuring accuracies within ± 0.0005 mm or $\pm 0.5\%$, whichever is larger. Many of the testers available today apply force by means of deadweights and lever combinations, usually with a dashpot control to impede overshoot.

Recently, motorized closed-loop, load-cell force application testers (Fig. 25) have been developed. They have the advantage of allowing a nearly limitless selection of test forces. Manual measuring devices that require operator calculation of the Vickers number are still produced; however, most testers have full digital systems that automatically do the calculations. Digital testers also have the ability to download test results to a printer or host computer.

Fig. 25 Closed-loop servo controlled Vickers hardness testing unit

Calibrations. Vickers testers are typically indirectly verified for performance by doing periodic tests on certified test blocks. A wide variety of test blocks are available in different hardness ranges calibrated with different test forces. It is recommended that each test force used be verified using at least two test blocks of different hardnesses.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Introduction

IN MICROINDENTATION HARDNESS TESTING (MHT), a diamond indenter of specific geometry is impressed into the surface of the test specimen using a known applied force (commonly called a "load" or "test load") of 1 to 1000 gf. Historically, the term "microhardness" has been used to describe such tests. This term, taken at face value, suggests that measurements of very low hardness values are being made, rather than measurements of very small indents. Although the term "microhardness" is well established and is generally interpreted properly by test users, it is best to use the more correct term, microindentation hardness testing.

There is some disagreement over the applied force range for MHT. ASTM E 384 states that the range is 1 to 1000 gf, and this is the commonly accepted range in the United States. Europeans tend to call the range of 200 to 3000 gf the "low-load" range. They do this because forces smaller than 200 gf generally produce hardness numbers that are different from those determined from tests conducted with forces ≥ 200 gf. This problem is discussed later in this article.

The hardness number is based on measurements made of the indent formed in the surface of the test specimen. It is assumed that recovery does not occur upon removal of the test force and indenter, but this is rarely the case. The Knoop test is claimed to eliminate recovery, but again, this is not true for tests of metallic materials. For the Vickers test, both diagonals are measured and the average value is used to compute the Vickers hardness (HV). The hardness number is actually based on the surface area of the indent itself divided by the applied force, giving hardness units of kgf/mm^2 . In the Knoop test, only the long diagonal is measured, and the Knoop hardness (HK) is calculated based on the projected area of the indent divided by the applied force, also giving test units of kgf/mm^2 . In practice, the test units kgf/mm^2 (or $\text{gf}/\mu\text{m}^2$) are not reported with the hardness value.

Microindentation Hardness Testing

Vickers Hardness Test

In 1925, Smith and Sandland of the United Kingdom developed an indentation test that employs a square-based pyramidal-shaped indenter made from diamond (Fig. 1a). Figure 1(b) shows examples of Vickers indents to illustrate the influence of test force on indent size. The test was developed because the Brinell test, using a spherical hardened steel indenter, could not test hard steels. They chose the pyramidal shape with an angle of 136° between opposite faces in order to obtain hardness numbers that would be as close as possible to Brinell hardness numbers for the same specimens. This made the Vickers test easy to adopt, and it rapidly gained acceptance. Unlike Rockwell tests, the Vickers test has the great advantage of using one hardness scale to test all materials.

Fig. 1 Vickers hardness test. (a) Schematic of the square-based diamond pyramidal indenter used for the Vickers test and an example of the indentation it produces. (b) Vickers indents made in ferrite in a ferritic-martensitic high-carbon version of 430 stainless steel using (left to right) 500, 300, 100, 50, and 10 gf test forces (differential interference contrast illumination, aqueous 60% nitric acid, 1.5 V dc). 250×

In this test, the force is applied smoothly, without impact, and held in contact for 10 to 15 s. The force must be known precisely (refer to ASTM E 384 for tolerances). After the force is removed, both diagonals are measured and the average is used to calculate the HV according to:

$$HV = \frac{2000P \sin(\alpha/2)}{d^2} = \frac{1854.4P}{d^2} \quad (\text{Eq 1})$$

where d is the mean diagonal in μm , P is the applied load in gf, and α is the face angle (136°).

The hardness can be computed with the formula and a pocket calculator, or using a spreadsheet program. Most modern MHT units have the calculation capability built in and display the hardness value along with the measured diagonals. A book of tables of HV as a function of d and P also accompanies most testers, and ASTM E 384 includes such tables.

The macro-Vickers test (ASTM E 92) operates over a range of applied forces from 1 to 120 kgf, although many testers cover a range of only 1 to 50 kgf, which is usually adequate. The use of forces below 1 kgf with the Vickers test was first evaluated in 1932 at the National Physical Laboratory in the United Kingdom. Four years later, Lips and Sack constructed the first Vickers tester designed for low applied forces.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Knoop Hardness Test

In 1939, Frederick Knoop and his associates at the former National Bureau of Standards developed an alternate indenter based on a rhombohedral-shaped diamond with the long diagonal approximately seven times as long as the short diagonal (Fig. 2a). Figure 2(b) shows examples of Knoop indents to illustrate the influence of applied load on indent size. The Knoop indenter is used in the same machine as the Vickers indenter, and the test is conducted in exactly the same manner, except that the Knoop hardness (HK) is calculated based on the measurement of the long diagonal only and calculation of the projected area of the indent rather than the surface area of the indent:

$$HK = \frac{1000P}{C_p d^2} = \frac{14229P}{d^2} \quad (\text{Eq 2})$$

where C_p is the indenter constant, which permits calculation of the projected area of the indent from the long diagonal squared.

Fig. 2 Knoop hardness test. (a) Schematic of the rhombohedral-shaped diamond indenter used for the Knoop test and an example of the indentation it produces. (b) Knoop indents made in ferrite in a ferritic-martensitic high-carbon version of 430 stainless steel using (left to right) 500, 300, 100, 50, and 10 gf test forces (differential interference contrast illumination, aqueous 60% nitric acid, 1.5 V dc). 300×

The Knoop indenter has a polished rhombohedral shape with an included longitudinal angle of $172^{\circ} 30'$ and an included transverse angle of $130^{\circ} 0'$. The narrowness of the indenter makes it ideal for testing specimens with steep hardness gradients. In such specimens, it may be impossible to get valid Vickers indents as the change in hardness may produce a substantial difference in length of the two halves of the indent parallel to the hardness gradient. With the Knoop test, the long diagonal is set perpendicular to the hardness gradient and the short diagonal is in the direction of the hardness gradient.

For the same test force, Knoop indents can be more closely spaced than Vickers indents, making hardness traverses easier to perform. The Knoop indenter is a better choice for hard brittle materials where indentation cracking would be more extensive using the Vickers indenter at the same load. The Knoop indent is shallower (depth is approximately $\frac{1}{30}$ the long diagonal) than the Vickers indent (depth is approximately $\frac{1}{7}$ the average diagonal). Hence, the Knoop test is better suited for testing thin coatings. On the negative side, the Knoop hardness varies with test load and results are more difficult to convert to other test scales.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Expression of Test Results

Historically, the official way in which Vickers and Knoop hardness numbers have been presented has varied with time, although many users seem to be unaware of the preferred style. The acronyms VHN and KHN were introduced many years ago and stand for Vickers hardness number and Knoop hardness number. DPN, for diamond-pyramid hardness number, was introduced at approximately the same time. While some have claimed the DPN and VHN are not the same, this is not true. In the early 1960s, ASTM initiated a more modern, systematic approach for all hardness tests and adopted the acronyms HV and HK for the two tests, yet the former acronyms are still widely used (as are many other obsolete acronyms, like BHN and R_C instead of HB and HRC). Style guides for many publications do not seem to track these changes carefully.

For stating the actual hardness results, ASTM advocates the following approach. ASTM E 384 recommends expressing a mean hardness of 425 in the Vickers test using a 100 gf applied force as 425 HV₁₀₀, while by ISO rules, it would be expressed as 425 HV_{0.1} (because 100 gf would be expressed as 0.1 kgf). ASTM Committee E-4 is currently recommending adoption of a slightly different approach: 425 HV 100 gf. While it has proven difficult to get people to adopt a unified expression style, it is important that the stated results indicate the mean value, the test used, and the test force as a minimum.

Microindentation Hardness-Testing Equipment

A variety of microindentation test machines are produced, ranging from relatively simple, low-priced units (Fig. 3) to semiautomated systems (Fig. 4a) and fully automated systems (Fig. 4b). In most cases, either a Knoop or a Vickers indenter can be used with the same machine, and it is a relatively simple matter to exchange indenters. The force is applied either directly as a dead weight or indirectly by a lever and lighter weights. New testers using a closed-loop load-cell system (Fig. 5) are also available. The magnitude of the weights and force application must be controlled precisely (refer to ASTM E 384).

Fig. 3 Example of a simple, low-cost manual microindentation hardness-testing unit with a Filar micrometer for measurements but no automation

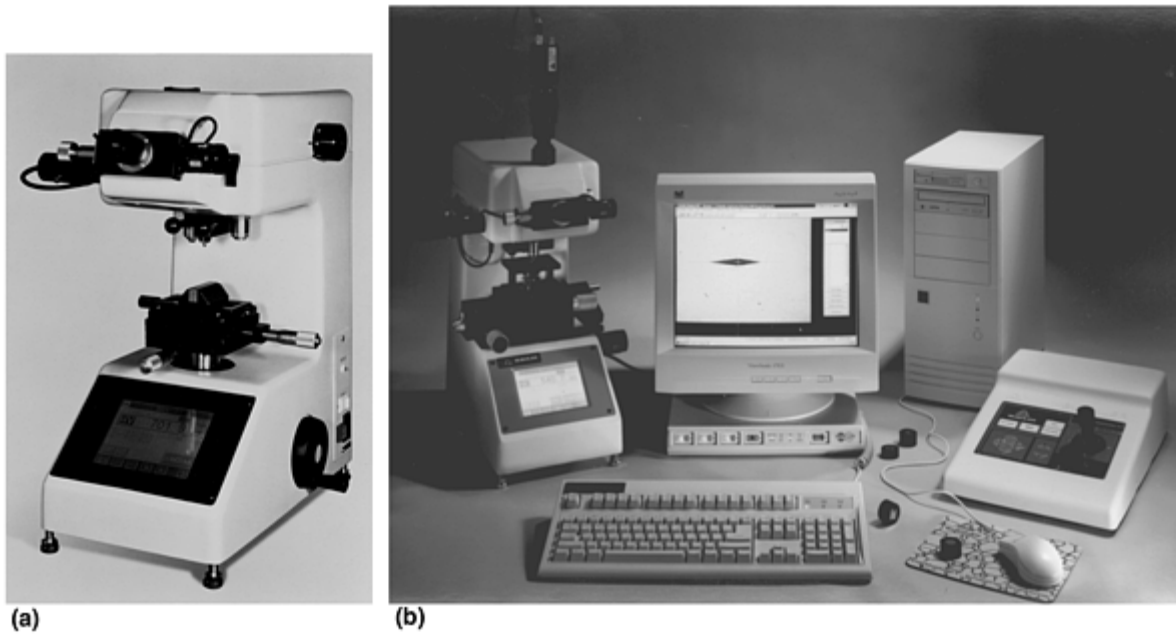

Fig. 4 Semiautomated and fully automated microindentation hardness testers. (a) Semiautomated tester with a Filar micrometer for measurements, automated readout of the test results with its equivalent hardness in another selected scale. (b) Fully automated tester interfaced to an image analyzer to control indenting, measurement, and data manipulation

Fig. 5 Closed-loop load-cell microindentation hardness tester

Most tester systems use an automated test cycle of loading, applying the load for the desired time, and unloading to ensure reproducibility in the test. Vibrations must be carefully controlled, and this becomes even more important as the applied force decreases. Manual application and removal of the applied force is not recommended due to the difficulty in preventing vibrations that will enlarge the indent size.

The indenter must be perpendicular to the test piece. An error of as little as 2° from perpendicular will distort the indentation shape and introduce errors. A larger tilt angle may cause the specimen to move under the applied force. To aid in controlling this problem, most testers come with a device that can be firmly attached to

the stage (Fig. 6). The mounted specimen, or a bulk unmounted specimen of the proper size, can be placed within this device and the plane-of-polish is automatically indexed perpendicularly to the indenter. Historically, it has been a common practice to simply place a specimen on the stage and proceed with indentation, but if the plane-of-polish is not parallel to the back side of the specimen, it will not be perpendicular to the indenter, introducing tilt errors.

Fig. 6 Examples of fixtures for holding test pieces for microindentation hardness testing

The stage is an important part of the tester. The stage must be movable and movement is usually controlled in the x and y directions by micrometers. Once the specimen is placed in the top-indexed holder, the operator must move the stage micrometers to select the desired location for indenting. If a traverse of several hardness readings is desired at inward intervals from a side surface of the specimen (as in case-depth measurements), then the surface of interest should be oriented in the holder so that it is perpendicular to either the x or y direction of the traverse. If the Knoop indenter is chosen, its long diagonal must also be parallel to the surface of interest. For example, if the Knoop long axis is in the direction going from the front to the back of the tester, then the surface of interest must also be aligned in the same direction. Accordingly, the x -axis (left to right) micrometer is used to select the desired indentation positions. The micrometers are ruled in either inches or millimeters and are capable of making very precise movement control.

Because the diagonals must be measured after the force has been removed, the tester is equipped with at least two metallurgical objectives (i.e., reflected light), usually $10\times$ and $40\times$. Some systems may have a third or fourth objective on the turret. For measurement of small indents ($<20\ \mu\text{m}$ in diagonal length), a higher-power objective ($60\times$, $80\times$, or $100\times$) can be used in place of the $40\times$ objective if the tester has places for only two objectives. The objectives should have a reasonably high numerical aperture for their magnifications to give the best resolution. The $10\times$ objective is usually used as a spotter, that is, simply to find the desired test location. The measuring eyepiece is generally $10\times$. Naturally, the optical system must be carefully calibrated using a stage micrometer. In general, indents are measured to the nearest $0.1\ \mu\text{m}$ with an accuracy of no more than $\pm 0.5\ \mu\text{m}$ in length. A proper Köhler illumination system is necessary to fully illuminate the specimen. In general, a magnification that makes the diagonal between 25% and less than 75% of the field width is ideal; however, it is not always possible to follow this rule.

Calculation of the hardness is based on the length of the diagonals. The major problem is defining where the indent tips are located. This requires proper illumination, adjustment of the optics for best resolution and contrast, and careful focusing. Every laboratory should have a regular schedule for cleaning the optical components of their MHT apparatuses, as well as for verifying their calibration. A Filar micrometer is used for the diagonal measurement. The micrometer lines have a finite thickness, which requires use of a systematic measurement scheme. Several indent measurement approaches can be used. One popular approach is to bring the two Filar lines just into contact and then zero the micrometer. The interior sides of the Filar lines are then adjusted so that the indent tips just touch the inside of each line.

In recent years, the MHT system has been automated by coupling it to an image analyzer (Fig. 4b). The image-analysis system software is used to control all of the functions regarding indent location, indent spacing, number of indents, indenting, measurement of the indents, calculation of hardness values, and data plotting. For those who perform a substantial number of hardness traverses, this equipment is very useful because the test work is automated, allowing the metallographer to do other tasks.

Hardness Conversions

Sometimes it is desirable to know the equivalent hardness in a scale other than the Vickers or Knoop. It is not uncommon for product specifications to define the hardness for a case depth in the Rockwell C scale, which, of course, is a bulk test scale unsuitable for case depth determination. Although this seems (and is) illogical, it is widely practiced, probably because designers are not familiar with the Vickers or Knoop scales. Hardness conversions are developed empirically, and there is a degree of error associated with all conversions. The primary source for hardness conversions is ASTM E 140, which lists the conversions in tabular form and also contains equations based on the tabular data. Some MHT units have these tables or the equations built in and will list an equivalent hardness of your choice with each measurement. The most common conversion is from a Vickers or Knoop scale to a Rockwell C scale. In general, these conversions are most commonly available for steels, aluminum alloys, and nickel alloys. Conversions between various scales may be material sensitive.

Conversion of Vickers data to other scales is more straightforward than converting Knoop data to other scales. Basically, the ASTM E 140 conversions between Vickers and other scales can be used for any test force greater than 100 gf. Conversions of Knoop to other scales are problematic because Knoop hardness varies more with load. If the published conversion is for a 500 gf applied load, then this conversion is best for that load and reasonably accurate for loads slightly lower and generally adequate for greater loads, as the Knoop hardness is reasonably constant for loads of 500 gf and above. Aside from the E 140 conversions, two published conversion charts are worth noting. First, Emond (Ref 1) published a correlation chart of Vickers hardness (10 kgf load) to Knoop hardness at loads of 10, 25, 50, 100, 200, and 500 gf (Fig. 7). Second, Batchelder (Ref 2) published conversions from Knoop hardness, with loads of 15, 25, 50, 100, 200, 300, 500, and 1000 gf, to Rockwell C (Fig. 8). Before using these conversions, it is a good practice to test your material with both scales to see how well the conversion chart agrees with your bulk test specimens before utilizing the conversions.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Specimen Preparation

Specimen preparation for microindentation hardness testing is not a trivial matter and becomes more critical as the applied force decreases. Further, if testing is to be done near an edge, then edge preservation (i.e., flatness out to the edge) is also required. For relatively high test forces, for example, 300 to 1000 gf, a perfectly prepared specimen is not required. However, this does not mean that sectioning and grinding damage need not be removed. Rather, the normal preparation procedure could be stopped after grinding and polishing down to a 6, 3, or 1 μm diamond finish. For lower loads, it is advisable to completely prepare the specimen to a damage-

free condition. Excessive residual damage from sectioning and grinding will influence test results and produce erroneous hardness values. Depending on the nature of the specimen, preparation damage can cause either an increase or a decrease in the apparent hardness relative to the true hardness. Guidelines for preparing metallographic test specimens are given in ASTM E 3 and in standard textbooks (Ref 3) and handbooks (Ref 4, 5).

Microindentation hardness testing near the edge of a specimen is used frequently to determine the hardness of coatings or to evaluate the extent of the increase in surface hardness due to treatments such as induction hardening, carburizing, or nitriding, or due to the loss in hardness because of decarburization. A variety of procedures have been developed to provide good edge retention. Today, with a good thermosetting epoxy resin (for best results, cool back to ambient temperature under pressure during mounting), automated preparation equipment, and modern consumable products (use napless cloths for best results), adequate edge retention is readily achievable without requiring protective surface platings (e.g., electroless nickel). It is also possible to prepare unmounted bulk specimens with adequate edge retention using automated equipment and consumables.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Important Test Considerations

All tests require both properly operating equipment and knowledge of how to use it. To obtain precise, unbiased hardness data, a properly prepared specimen must be tested in the correct manner using a properly operating, calibrated tester. ASTM E 384 provides guidance on operating variables developed both theoretically and empirically over a long period of time. Conservative application of these rules is advisable.

Indent Size. In general, the larger the indent is, the better the precision will be. Due to the mathematical approach to defining the Vickers and Knoop hardnesses (Eq 1 and 2, where the denominator is d^2), the curves of diagonal length versus HV or HK get steeper as the test force decreases, as shown in Fig. 9 and 10. Note that as the test force decreases, smaller and smaller variations in diagonal length correlate to larger and larger variations in hardness.

Fig. 9 Relationships between the mean diagonal length and the Vickers hardness for loads of 10-1000 gf

Fig. 10 Relationships between the long diagonal length and the Knoop hardness for loads of 10-1000 gf

Experience has shown that a single operator typically exhibits a $\pm 0.5 \mu\text{m}$ variation when measuring the same indent over a period of time, while multiple operators exhibit approximately a $\pm 1.0 \mu\text{m}$ variation over time. Larger variations have also been observed (Ref 6, 7). A $\pm 0.5 \mu\text{m}$ variation in the measured diagonal has a greater influence on hardness as the test load decreases, that is, as the diagonal size decreases.

As an example, Fig. 11 shows the change in Vickers hardness when $0.5 \mu\text{m}$ is either added to, or subtracted from, the diagonal measurement for diagonals $\leq 40 \mu\text{m}$ in length. Note that subtracting $0.5 \mu\text{m}$ has a greater effect on the calculated HV than adding $0.5 \mu\text{m}$. This is again due to the d^2 divisor in Eq 1. The graph shows

that for a Vickers indent with a 10 μm average diagonal, a $\pm 0.5 \mu\text{m}$ measurement variation can produce approximately a 10% rise or drop in the hardness. If the hardness is low, this is not too much of a problem, but for high-hardness specimens, a $\pm 10\%$ variation is substantial.

Fig. 11 Influence of a measurement error of $\pm 0.5 \mu\text{m}$ on the calculated Vickers hardness as a function of diagonal length

ASTM E 384 recommends that the operator should try to keep indents larger than 20 μm in d . Figure 11 demonstrates the reason for this recommendation. A similar graph could be constructed for the Knoop test. In general, determining the location of the tips of the Knoop indent to measure the long diagonal is more difficult than with a Vickers indent because the contrast at the Knoop indent tips is not as strong. The $\pm 0.5 \mu\text{m}$ measurement variability for the same person as a function of time may be a bit conservative for the Knoop test. If the operator has a rough idea of the hardness of the test piece, then a good estimate can be made of the appropriate test load to choose. The harder the specimen, the greater the test load needed to keep d greater than 20 μm . Figures 9 and 10 can be used as a guide. For example, assume that a hardness traverse is to be made on an induction-hardened specimen that is expected to vary in hardness from approximately 750 HV at the surface to 250 HV in the core. Figure 9 says that an applied force of 200 gf will produce approximately a 22 μm diagonal indent for a 750 HV steel and close to a 40 μm diagonal indent for a 250 HV steel. For a 100 gf applied force, the diagonal for 750 HV is less than 16 μm , so it would be best to use a higher load. A 300 gf applied force produces approximately a 27 μm diagonal for 750 HV and approximately a 47 μm diagonal at 250 HV, and it may be a better choice than a 200 gf or 100 gf load. If the hardened case is rather shallow, it may be necessary to space indents along several different parallel traces at different depths so that the gradient can be assessed satisfactorily without tight indent spacing adversely influencing the test data.

The opposite problem, that of an excessively large ($d > 75\%$ of the field width) indent is less common, but may arise depending on test conditions. In general, MHT is performed in an effort to measure spatial variations in hardness or the hardness of small regions. But sometimes it is used as a convenient substitute for a bulk hardness test on a small specimen of homogenous nature at the same time as the structure is examined. In that case, the indent size is not too critical as long as a $\pm 0.5 \mu\text{m}$ measurement variation has only a small influence on

the calculated HV. With a very soft material, the indent should be small enough that it can be kept entirely in the field of view of the optics.

Indent Spacing. In general, the same guidelines used in bulk hardness tests are used for MHT. Indenting creates both elastic and plastic deformation and a substantial strain field around the indent. If a second indent is made too close to a prior indent, its shape will be distorted on the side toward the first indent. This produces erroneous test results.

In general, the spacing between indents should be at least 2.5 times the d length for the Vickers test and at least twice the length of the short diagonal for the Knoop test. The minimum spacing between the edge of a specimen and the center of an indent should be $2.5d$, although values as low as $1.8d$ have been demonstrated to be acceptable.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Hardness versus Applied Test Force

For the Vickers test, especially in the macro applied force range, it is commonly stated that the hardness is constant as the load is changed. For microindentation tests, the Vickers hardness is not constant over the entire range of test forces. For Vickers tests with an applied force of 100 to 1000 gf, the measured hardnesses are usually equivalent within statistical precision. The Vickers indent produces a geometrically similar indent shape at all loads, and a log-log plot of applied force (load) versus diagonal length should exhibit a constant slope, n , of 2 for the full range of applied force (Kick's Law); however, this usually does not occur at forces under 100 gf.

Reference 6 shows four trends for force (load) and Vickers MHT data:

- *Trend 1:* HV increases as force decreases ($n < 2.0$).
- *Trend 2:* HV decreases as force decreases ($n > 2.0$).
- *Trend 3:* HV essentially constant as force varies ($n = 2.0$).
- *Trend 4:* HV increases, then decreases with decreasing force.

Trends 1, 2, and 4 are more easily detected in hard specimens than on soft specimens where trend 3 is observed. Many publications, particularly those reporting trends 1 and 2, have attributed these trends to material characteristics.

The Knoop indenter does not produce geometrically similar indents, so the hardness should increase with decreasing test force. Due to the poor image contrast at the Knoop indent tips (long diagonal), it is far more likely that d will be undersized, leading to a higher hardness number. Consequently, the Knoop hardness increases with decreasing test force, and the magnitude of the increase rises with increasing hardness. However, a few studies reported a variation in this trend: HK increased with decreasing force and then decreased at the lowest applied force.

It is widely claimed in the literature that the Vickers hardness is constant with test force in the macro force range (≥ 1 kgf). However, a search in the literature for data to prove this point yielded very little evidence. Reference 3 gives measurements made on five polished HRC test blocks, with hardnesses ranging from 22.9 to 63.2 HRC, using six test forces from 1 to 50 kgf. At each force, six impressions were made, and the mean results are in Fig. 12. The Filar micrometer used a magnification of 100 \times . Note that the HV is essentially constant for forces of 10 kgf and greater. For each test block, the hardness decreased for test forces less than 10 kgf. The degree of decrease increased with increasing hardness. Thus, for this macro Vickers tester, HV was not constant but exhibited trend 2, the most commonly observed trend for studies of MHT and HV force.

Fig. 12 Measured Vickers macrohardness for five steel test blocks using test forces from 1-50 kgf. Source: Ref 3

The exact same steel test blocks were also subjected to Vickers microindentation hardness tests using nine different forces from 5 to 500 gf (Ref 3). Again, six impressions were made at each test force, and the mean values are plotted in Fig. 13. These impressions were measured at 500 \times . Again, the same basic trend is observed. In most cases, HV is essentially constant at forces down to 100 gf, then the hardness decreases. The magnitude of this decrease again increases with increasing specimen hardness. For several of the data, the hardness appears to rise slightly as the force drops below 100 gf, and then it decreases (trend 4). Thus, for the work detailing MHT in HV versus the test forces, both trends 2 and 4 were obtained.

Fig. 13 Measured Vickers microindentation hardness for five steel test blocks using test forces from 5-500 gf. Source: Ref 3

These results, using the same set of five specimens with a wide range of hardnesses and tests with both micro- and macro-Vickers units, revealed basically the same trend. At small indent sizes for both testers, measurements yielded lower hardness (indents being oversized) than they should. This can only be due to visual perception problems in sizing small indents at the tester magnifications employed (100× for the macro system and 500× for the micro system). No material characteristic can possibly explain this problem.

To further demonstrate that the observed trends of HV versus test force (load) are due to measurement difficulties, the results of an ASTM Committee E-4 interlaboratory round-robin test program is cited (Ref 6, 7). In this study, one person indented three ferrous and four nonferrous specimens at test forces of 25, 50, 100, 200, 500, and 1000 gf (five times at each force). Then, twenty-four people measured the indents: thirteen measured all of the Knoop and Vickers indents in the ferrous specimens (fourteen actually measured specimen F1), and eleven measured the Knoop and Vickers indents in the nonferrous specimens. Agreement was best for the low hardness specimens, as would be expected, because they had the largest indents and the effect of small measurement errors is minimal. The Vickers hardness, in most cases, decreased with forces below 100 gf, but all four possible trends reported in the literature can be seen in the measurement data for the same indents.

As an example, Fig. 14 shows the data for nine of the fourteen people who measured the Vickers indents in the hardest ferrous specimen (specimen F1). The overall trend for the data is trend 2. However, examination of the data shows that test lab 8 followed trend number 1, lab 1 followed trend 3, and lab 3 followed trend 4. Statistical analysis of all of the test data suggested that these nine people obtained essentially the same test results while some or all of the data from the other five people represented “outlier” conditions. Figure 15 shows the data for the five outlier labs for the F1 specimen (where lab F was defined as an outlier lab based on results for other specimens—their results for specimen F1 were marginal). The “good max” and “good min” lines in Fig. 15 encompass the range of “good” data shown in Fig. 14. Again, several HV-versus-force trends are observed: labs E, H, and J follow trend 1, and labs F and M follow trend 2. Because exactly the same indents were measured, these variations in test results come only from measurement inconsistencies. This study reveals that the most commonly obtained trend was trend 2, decreasing HV with decreasing test force, and this is the most commonly reported trend in the literature. Thus, it is more likely for an operator to oversize small Vickers indents than to undersize them or to measure their true size.

Fig. 14 ASTM E-4 round-robin interlaboratory Vickers microindentation hardness-testing data for the hardest (F1) test specimen and nine people (measuring the same indents) who produced “good” data for test loads from 25-1000 gf. Source: Ref 6, 7

Fig. 15 Data shown in Fig. 14 (all points fall within the two lines) plus the individual data from four “outlier” raters. Source: Ref 6, 7

Measurements of the Knoop indents also reveal substantial variations in the data. In most cases, the HK rose as the test force decreased, with most of the increase occurring at forces less than 200 gf. In general, HK results were statistically identical for each specimen at forces from 200 to 1000 gf. For the nonferrous specimens, one rater consistently obtained the very unusual trend of decreasing HK with forces less than 200 gf. One other rater obtained a similar, but less pronounced, decrease in HK with decreasing test forces; but this was only for the hardest nonferrous specimen (mean hardness, approximately 330 HK).

The visibility of the tips of the long diagonal on the Knoop indent is poorer than for Vickers indents. Thus, for Knoop indents, undersizing the indent is far more likely than oversizing. However, it is clear that one of the eleven people who measured the Knoop indents in this study consistently oversized the Knoop indents. At test forces above 200 gf, this person's results agreed with the mean results in two cases, were below the mean in one case, and were above the mean in another case. A calibration error would produce a consistent bias in all of the data; however, this could not be the case for this person's test results. Interestingly, this person was an experienced metallographer, not a novice.

There are times when the hardness tester can be the source of a variation in the load-hardness relationship. Before using a new MHT unit, it is a good practice to select a specimen with a homogeneous microstructure and a known hardness and then perform a series of tests using the full range of applied test forces available for the unit. To obtain good statistics, make a number of impressions at each load. As an illustration of this problem, two testers were evaluated over their full ranges using a hardened specimen of type 440C martensitic stainless steel. For tester A, six indents were made at each available test load, while for tester B, only three indents were made at each load due to time limitations with the unit. The mean results are plotted in Fig. 16. While tester A produced virtually identical results over the full load range, it is clear that tester B was applying excessively high test forces at all loads under 1000 gf. Clearly this was a machine problem because the same person performed both sets of measurements on the same specimen. Verification of the instrument using properly calibrated test blocks should help identify this type of problem.

Fig. 16 Curves showing load versus Vickers hardness for two testers (with the same operator) evaluating the hardness of the same type 440C martensitic stainless steel specimen (62.7 HRC)

Repeatability and Reproducibility

Appendix X2 of ASTM E 384, along with Ref 6 and 7, describes the results of an ASTM interlaboratory round-robin program used to determine the precision of measuring Knoop and Vickers indents and the repeatability and reproducibility of such measurements. Repeatability is a measure of how well an individual operator can replicate results on different days with the same specimen and the same equipment. Reproducibility measures the ability of different operators, in different laboratories, to obtain the same results, within statistical limits. Repeatability and reproducibility were best for low-hardness specimens and got poorer as the hardness increased; that is, as the indent size decreased. Repeatability was always somewhat better than reproducibility, as might be expected. For a material with a hardness of 900 HV, repeatability for a 25 gf load was approximately ± 170 HV, and for a 1000 gf load it was approximately ± 25 HV, while reproducibility for a 25 gf load was approximately ± 220 HV, and for a 1000 gf load it was approximately ± 40 HV. For a material with a hardness of 900 HK, repeatability for a 25 gf load was approximately ± 75 HK, and for a 1000 gf load it was approximately ± 25 HK, while reproducibility for a 25 gf load was approximately ± 105 HK, and for a 1000 gf load it was approximately ± 40 HK. This shows that the repeatability and reproducibility values at the highest loads were similar for both types of indents, but as the test load decreased, the longer Knoop indent (at each load) yielded better repeatability and reproducibility than the smaller Vickers indent at the same load. These trends again highlight the importance of trying to use the greatest possible load for any test.

Microindentation Hardness Testing

George F. Vander Voort, Buehler Ltd.

Applications

Because hardness tests are a quick and convenient way to evaluate the quality or characteristics of a material, hardness testing is widely used in quality-control studies of heat treatment, fabrication, and materials processing. It is also a key test used in failure analysis work.

Microindentation hardness testing provides the same benefit as bulk hardness testing, but with a much smaller indent. Because the indents are small, MHT can be used for many parts or material forms that are too small or too thin to test with bulk test procedures. Likewise, MHT allows hardness measurements of microstructural constituents. For example, the determination of hardness of specific types of carbides, nitrides, borides, sulfides, or oxides in metals has been widely performed, particularly in wear and in machinability research.

There is a long list of applications where MHT is indispensable. A few examples are described in this section. The examples are just a few of the many that could be chosen to demonstrate the value of MHT. To a large extent, MHT can be considered as simply an extension of bulk hardness testing, in that it can be used for all the same purposes as bulk hardness tests. However, due to the very small size of the indent, MHT has a host of applications that cannot be performed with bulk tests. It can also be considered as a strength microprobe and, thus, an extension of tensile testing. When properly used, MHT is a great asset in any laboratory.

Hardness Testing of Thin Products

Foil or wire product forms depend on MHT in quality-control programs. In general, the indent depth should be no more than 10% of the thickness or diameter of the products. Figure 17 shows the relationship among the minimum foil thickness that can be tested, the applied force, and the Knoop hardness. As this figure shows, for thicknesses less than 0.010 in. (254 μm), test-force selection becomes more critical as the thickness decreases and the hardness decreases. For example, for a foil 0.002 in. thick (51 μm) with high hardness (e.g., greater than 500 HK), test forces up to 800 gf can be used. However, if the hardness is not known, and a 500 gf load indicates a hardness of approximately 200 HK, then it would be advisable to retest the foil using a force of, at most, 300 gf because the test at 500 gf may not be valid.

Fig. 17 Minimum thickness of test specimens for the Knoop test as a function of applied force (load) and Knoop hardness

Hardness tests of thin materials and thin coatings often require very low applied forces (loads). As already demonstrated, it is quite difficult to measure very small indents. MHT units are readily available for making impressions at forces down to 1 gf, and special testers are available that can indent at even lower forces. (These devices are not discussed in this article, however.) In the case of MHT systems using indenting forces less than 25 gf and indents between 1 and 25 μm , it may be advisable to place the tester on an antivibration platform and to use at least 60 \times objectives with a high numerical aperture for measurements. Oil-immersion objectives may be required, particularly for materials with poor light reflectivity.

Case Hardness Measurement

Perhaps the classic application of MHT is the assessment of changes in surface hardness: usually increases due to surface treatments, such as carburizing, nitriding, or localized surface-hardening processes, are analyzed, but decreases in hardness due to local chemistry changes (decarburization) or localized heating are also examined. While these changes are usually detectable by eye on a properly prepared metallographic cross-section, hardness traverses define the magnitude and extent of such changes with greater precision and detail. It is not uncommon for quality-control tests to require determination of the depth to a specific hardness for a carburized or nitrided part.

Figure 18 demonstrates the measurement of case depth by a series of indentations that traverse a cross-section from a flame-hardened SAE 8660 specimen. The hardness traverses used a Vickers tester with the fully automated device (Fig. 4b) and a 300 gf load. The surface hardness is approximately 830 HV, and the hardness drops steadily until, at 2.5 mm depth, the core hardness (~200 HV) is reached. The effective case depth (the depth to 550 HV) occurs at a depth of 1.95 mm.

Fig. 18 Vickers traverse showing the hardness profile results from a flame-hardened SAE 8660 gear using a fully automated microindentation hardness-testing system

Figure 19 shows the hardness profile for an induction-hardened SAE 1053 carbon-steel gear using the fully automated system and a 300 gf load. Note that the surface hardness increased slowly from the surface to a depth of 4.1 mm. In this specimen, the microstructure contained at the surface substantial retained austenite, which decreased until it was undetectable at a depth of approximately 3 mm. The prior-austenitic grain size was coarse at the surface and decreased in size through the hardened case. These trends are caused by the temperature profile from induction heating. The hardness drops rapidly in the depth range of 4 to 4.6 mm, and the microstructure changes from predominantly martensite to ferrite and pearlite with a hardness of approximately 230 HV.

Fig. 19 Vickers traverse showing the hardness profile results from an induction-hardened SAE 1053 gear using a fully automated microindentation hardness-testing system

When manual MHT systems are used to determine the effective case depth, it is quite common to etch the specimen and find the depth where the microstructure changes from hardened to unhardened. Then, the operator places a few indents in this region and interpolates the depth to the desired hardness, most often 500 or 550 HV, depending on the carbon content. Of course, the very interesting rise in hardness (Fig. 19) from the surface to 4.1 mm would not be detected. This may have an adverse effect on the wear behavior and presents a dilemma for the analyst because the surface hardness is less than the hardness criteria for the effective case depth. Note that the surface does not exceed 550 HV until a depth of approximately 1.5 mm. Then, the hardness raises to approximately 680 HV at approximately 4 mm depth. The hardness falls again to 550 HV at approximately 4.5 mm depth. The detailed variation of hardness with depth can be observed more easily with automated traverse hardness tests.

Figure 20 shows a hardness traverse for a carburized SAE 8620 mold that exhibited substantial retained austenite in the hardened case. Again, the specimen was evaluated with the fully automated system in Fig. 5 with a 300 gf load. Note that the hardness is somewhat erratic in the fully hardened surface layer (surface to approximately 1.8 mm depth). This is due to the presence of retained austenite in this zone, which is substantially lower in hardness than plate martensite. If a lower test force were used, the scatter would be greater. Very low test forces, producing very small indents, might produce a hardness variation of several hundred HV in the case. The effective case depth (depth to 550 HV) is at 2.1 mm, and the core is reached at approximately 2.5 mm (~400 HV). Again, if testing were performed manually and only in the transition zone, the metallographer would not have observed the variability in hardness in the fully hardened zone.

Fig. 20 Vickers traverse showing the hardness profile results from a carburized and hardened SAE 8620 mold using a fully automated microindentation hardness-testing system

Alloy Phase Hardness Measurements

Microindentation hardness testing has been widely used in alloy development research, particularly in multiphase alloy studies. Because hardness can be correlated to strength, MHT can be used to determine the properties of phases or constituents. Some such examples are described here.

Example 1: Hardness Measurement on Ferrite and Austenite Grains in Dual Phase Steel. Microindentation testing was performed on the ferrite and austenite grains in a specimen of hot-rolled dual-phase stainless steel. The specimen was prepared so that a plane parallel to the hot-working direction could be observed. Because the phases were elongated rather than equiaxed, the Knoop indenter was used (with a 50 gf load). The specimen was lightly etched electrolytically with 20% nitric acid, which colors the ferrite grains. Indents were made in a number of grains (six or more indents per constituent type, as a rule) to calculate the mean, standard deviation, and the 95% confidence interval. The ferrite had a hardness of $263.5 \pm 5 \text{ HK}_{50}$ (mean $\pm 95\%$ confidence interval), while the austenite had a hardness of $361.8 \pm 18.6 \text{ HK}_{50}$. This difference was significant at the 99.9% confidence level. Figure 21 shows the microstructure of this specimen along with a number of Knoop indents.

Fig. 21 Knoop indents in ferrite (dark) and austenite (white) grains in a dual-phase stainless steel (differential interference contrast illumination, aqueous 20% nitric acid, 3 V dc). 500×

Example 2: Hardness Measurement on Alpha and Beta Phases in Naval Brass. Microindentation testing with a Knoop indenter was performed on the alpha and beta phases in a specimen of naval brass (C 46400). A longitudinally oriented test plane was evaluated, and the Knoop indenter was used due to the elongated shape of the grains. A test load of 50 gf was used to keep the indents within the grains. The specimen was tint etched with Klemm's I, which colors the beta phase. Again, indents were made on a number of grains of each phase. The alpha phase had a hardness of $178.1 \pm 8.8 \text{ HK}_{50}$, while the beta phase had a hardness of $185.4 \pm 13.7 \text{ HK}_{50}$. The difference in hardness between alpha and beta phases was not statistically significant. Figure 22 shows the microstructure of this specimen and several of the Knoop indents.

Fig. 22 Knoop indents (50 gf) in alpha (white) and beta (dark) grains in naval brass (C 46400) (differential interference contrast illumination, Klemm's I reagent). 500×

Example 3: Microindentation Hardness of Phases in 430 Stainless Steel. Similar tests were performed on a dual-phase, ferrite and martensite, high-carbon, type 430 stainless-steel specimen. It was possible to test with a 100 gf load using the Vickers indenter. The ferrite had an average hardness of $152.3 \pm 5.7 \text{ HV}_{100}$ while the martensite had a mean hardness of $473 \pm 41.5 \text{ HV}_{100}$. Again, at least six impressions were made in each constituent. The specimen, shown in Fig. 23, was electrolytically etched with aqueous 60% nitric acid at 1.5 V dc. The difference in hardness between the alpha phase and martensite was statistically significant at the 99.9% confidence level.

Fig. 23 Vickers indents (100 gf) in alpha (white) and martensite (dark) grains in a high-carbon version of 430 stainless steel (differential interference contrast illumination, aqueous 60% nitric acid, 1.5 V dc). 500×

Example 4: Hardness of Phases in As-Cast Beryllium Copper. MHT can be used to study effects of heat treatment and segregation on the hardness of the phases in as-cast beryllium copper (C 82500) that has been solution treated at 871 °C, hot enough to cause incipient melting. One specimen was age hardened and one was not. Because the phases were essentially equiaxed in shape, the Vickers indenter was used. In the unaged specimen, a 50 gf test force was used, while in the harder, aged specimen, 100 gf could be used. Again, a number of indents, at least six, were made in each phase. For the unaged specimen, shown in Fig. 24, the alpha matrix had a hardness of $107.6 \pm 4.8 \text{ HV}_{50}$, while the intergranular beta had a hardness of $401.0 \pm 63.0 \text{ HV}_{50}$. For the aged specimen, shown in Fig. 25, the alpha matrix exhibited light and dark crosshatched etched areas suggesting chemical segregation. The light etching alpha had a hardness of $316.1 \pm 38.3 \text{ HV}_{100}$, while the dark etching alpha had a hardness of $416.6 \pm 8.6 \text{ HV}_{100}$. This difference in hardness was statistically significant at the 99.9% confidence level. The intergranular beta phase also exhibited a crosshatched etched appearance and had a hardness of $521.6 \pm 31.9 \text{ HV}_{100}$. The difference in hardness of the intergranular beta phase in the aged versus unaged condition was statistically significant at the 99.9% confidence level. The specimens were etched with aqueous 3% ammonium persulfate-1% ammonium hydroxide. It is best to use the same applied force for each phase or constituent when doing such comparisons, rather than the highest possible applied force in each phase or constituent.

Fig. 24 Vickers indents (50 gf) in the matrix (dark) and in the intergranular beta (white) phase in as-cast beryllium copper (C 82500) that was burnt in solution annealing (differential interference contrast illumination, aqueous 3% ammonium persulfate and 1% ammonium hydroxide). 500×

Fig. 25 Vickers indents (100 gf) in the matrix (dark) and in the intergranular beta (white) phase in an age-hardened as-cast beryllium copper (C 82500) that was burnt in solution annealing (differential interference contrast illumination, aqueous 3% ammonium persulfate and 1% ammonium hydroxide). 500×

Instrumented Indentation Testing

J.L. Hay, MTS Systems Corporation; G.M. Pharr, The University of Tennessee and Oak Ridge National Laboratory

Introduction

INSTRUMENTED INDENTATION TESTING (IIT), also known as depth-sensing indentation, continuous-recording indentation, ultra-low-load indentation, and nanoindentation, is a relatively new form of mechanical testing that significantly expands on the capabilities of traditional hardness testing. Developed largely over the past two decades, IIT employs high-resolution instrumentation to continuously control and monitor the loads and displacements of an indenter as it is driven into and withdrawn from a material (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13). Depending on the details of the specific testing system, loads as small as 1 nN can be applied, and displacements of 0.1 nm (1 Å) can be measured. Mechanical properties are derived from the indentation load-displacement data obtained in simple tests.

The advantages of IIT are numerous, as indentation load-displacement data contain a wealth of information, and techniques have been developed for characterizing a variety of mechanical properties. The technique most frequently employed measures the hardness, but it also gives the elastic modulus (Young's modulus) from the same data (Ref 8, 11). Although not as well-developed, methods have also been devised for evaluating the yield stress and strain-hardening characteristic of metals (Ref 14, 15, 16); parameters characteristic of damping and internal friction in polymers, such as the storage and loss modulus (Ref 17, 18); and the activation energy and stress exponent for creep (Ref 19, 20, 21, 22, 23, 24, 25). IIT has even been used to estimate the fracture toughness of brittle materials using optical measurement of the lengths of cracks that have formed at the corners of hardness impressions made with special sharp indenters (Ref 13, 26, 27). In fact, almost any material property that can be measured in a uniaxial tension or compression test can conceivably be measured, or at least estimated, using IIT.

An equally important advantage of IIT results because load-displacement data can be used to determine mechanical properties without having to image the hardness impressions. This facilitates property measurement at very small scales. Mechanical properties are routinely measured from submicron indentations, and with careful technique, properties have even been determined from indentations only a few nanometers deep. Because of this, IIT has become a primary tool for examining thin films, coatings, and materials with surfaces modified by techniques such as ion implantation and laser heat treatment.

Many IIT testing systems are equipped with automated specimen manipulation stages. In these systems, the spatial distribution of the near-surface mechanical properties can be mapped on a point-to-point basis along the surface in a fully automated way. Lateral spatial resolutions of about a micron have been achieved. An example of small indentations located at specific points in an electronic microcircuit is shown in Fig. 1.

Fig. 1 Small Berkovich indentations located at specific positions in an electronic microcircuit

The purpose of this article is to provide a practical reference guide for instrumented indentation testing. Emphasis is placed on the better-developed measurement techniques and the procedures and calibrations required to obtain accurate and meaningful measurements.

Instrumented Indentation Testing

J.L. Hay, MTS Systems Corporation; G.M. Pharr, The University of Tennessee and Oak Ridge National Laboratory

Testing Equipment

As shown schematically in Fig. 2, equipment for performing instrumented indentation tests consists of three basic components: (a) an indenter of specific geometry usually mounted to a rigid column through which the force is transmitted, (b) an actuator for applying the force, and (c) a sensor for measuring the indenter displacements. Because these are also the basic components used in tensile testing, a standard commercial tensile-testing machine can be adapted for IIT testing. However, to date, most IIT development has been performed using instruments specifically designed for small-scale work. Advances in instrumentation have been driven by technologies that demand accurate mechanical properties at the micron and submicron levels, such as the microelectronic and magnetic storage industries. Thus, while the principles and techniques described in this article were developed primarily using instruments designed for small-scale work, there is no inherent reason that they could not be applied at larger scales using equipment available in most mechanical-testing laboratories.

Fig. 2 Schematic representation of the basic components of an instrumented indentation testing system

Several small-scale IIT testing systems are commercially available. They differ primarily in the ways the force is applied and the displacement is measured. Small forces can be conveniently generated (a) electromagnetically with a coil and magnet assembly, (b) electrostatically using a capacitor with fixed and moving plates, and (c) with piezoelectric actuators. The magnitudes of the forces are usually inferred from the voltages or currents applied to the actuator, although in piezoelectrically driven instruments, a separate load cell is often included to provide a direct measurement of the force. Displacements are measured by a variety of means, including capacitive sensors, linear variable differential transformers (LVDTs), and laser interferometers. The range and resolution of the instrument are determined by the specific devices employed.

It is important to realize that as in a commercial tensile-testing machine, the displacements measured in an IIT system include a component from the compliance of the machine itself. Under certain circumstances, the machine compliance can contribute significantly to the total measured displacement, so it must be carefully calibrated and removed from the load-displacement data in a manner analogous to tension and compression testing. Specific procedures for determining the machine compliance in IIT testing are outlined in this article.

A variety of indenters made from a variety of materials are used in IIT testing. Diamond is probably the most frequently used material because its high hardness and elastic modulus minimize the contribution to the measured displacement from the indenter itself. Indenters can be made of other less-stiff materials, such as sapphire, tungsten carbide, or hardened steel, but as in the case of the machine compliance, the elastic displacements of the indenter must be accounted for when analyzing the load-displacement data.

Pyramidal Indenters. The most frequently used indenter in IIT testing is the Berkovich indenter, a three-sided pyramid with the same depth-to-area relation as the four-sided Vickers pyramid used commonly in microhardness work. The Berkovich geometry is preferred to the Vickers because a three-sided pyramid can be ground to a point, thus maintaining its self-similar geometry to very small scales. A four-sided pyramid, on the other hand, terminates at a “chisel edge” rather than at a point, causing its small-scale geometry to differ from that at larger scales; even for the best Vickers indenters, the chisel-edge defect has a length of about a micron. Although Vickers indenters could conceivably be used at larger scales, their use in IIT has been limited because most work has focused on small-scale testing.

Spherical Indenters. Another important indenter geometry in IIT testing is the sphere. Spherical contact differs from the “sharp” contact of the Berkovich or Vickers indenters in the way in which the stresses develop during indentation. For spherical indenters, the contact stresses are initially small and produce only elastic deformation. As the spherical indenter is driven into the surface, a transition from elastic to plastic deformation occurs, which can theoretically be used to examine yielding and work hardening, and to recreate the entire uniaxial stress-strain curve from data obtained in a single test (Ref 14, 15). IIT with spheres has been most successfully employed with larger-diameter indenters. At the micron scale, the use of spherical indenters has been impeded by difficulties in obtaining high-quality spheres made from hard, rigid materials. This is one reason the Berkovich indenter has been the indenter of choice for most small-scale testing, even though it cannot be used to investigate the elastic-plastic transition.

Cube-Corner Indenters. Another indenter used occasionally in IIT testing is the cube—corner indenter, a three-sided pyramid with mutually perpendicular faces arranged in a geometry like the corner of a cube. The centerline-to-face angle for this indenter is 34.3° , whereas for the Berkovich indenter it is 65.3° . The sharper cube corner produces much higher stresses and strains in the vicinity of the contact, which is useful, for example, in producing very small, well-defined cracks around hardness impressions in brittle materials; such cracks can be used to estimate the fracture toughness at relatively small scales (Ref 13, 26, 27).

Conical Indenters. A final indenter geometry worth mentioning is the cone. Like the Berkovich, the cone has a sharp, self-similar geometry, but its simple cylindrical symmetry makes it attractive from a modeling standpoint. In fact, many modeling efforts used to support IIT are based on conical indentation contact (Ref 28, 29, 30, 31, 32, 33, 34, and 35). The cone is also attractive because the complications associated with the stress concentrations at the sharp edges of the indenter are absent. Curiously, however, very little IIT testing has been conducted with cones. The primary reason is that it is difficult to manufacture conical diamonds with sharp tips, making them of little use in the small-scale work around which most of IIT has developed (Ref 36). This problem does not apply at larger scales, where much could be learned by using conical indenters in IIT experimentation.

A summary of the indenters used in IIT testing and parameters describing their geometries is given in Table 1.

Table 1 Summary of nominal geometric relationships for several indenters used in IIT

Parameter	Vickers	Berkovich	Cube-corner	Cone (angle ψ)	Sphere (radius R)
Centerline-to-face angle, α	68°	65.3°	35.2644°
Area (projected), $A(d)$	24.504 d^2	24.56 d^2	2.5981 d^2	πa^2	πa^2
Volume-depth relation, $V(d)$	8.1681 d^3	8.1873 d^3	0.8657 d^3
Projected area/face area, A/A_f	0.927	0.908	0.5774
Equivalent cone angle, ψ	70.2996°	70.32°	42.28°	ψ	...
Contact radius, a	$d \tan \psi$	$(2Rd - d^2)^{1/2}$

Testing Equipment

As shown schematically in Fig. 2, equipment for performing instrumented indentation tests consists of three basic components: (a) an indenter of specific geometry usually mounted to a rigid column through which the force is transmitted, (b) an actuator for applying the force, and (c) a sensor for measuring the indenter displacements. Because these are also the basic components used in tensile testing, a standard commercial tensile-testing machine can be adapted for IIT testing. However, to date, most IIT development has been performed using instruments specifically designed for small-scale work. Advances in instrumentation have been driven by technologies that demand accurate mechanical properties at the micron and submicron levels, such as the microelectronic and magnetic storage industries. Thus, while the principles and techniques described in this article were developed primarily using instruments designed for small-scale work, there is no inherent reason that they could not be applied at larger scales using equipment available in most mechanical-testing laboratories.

Fig. 2 Schematic representation of the basic components of an instrumented indentation testing system

Several small-scale IIT testing systems are commercially available. They differ primarily in the ways the force is applied and the displacement is measured. Small forces can be conveniently generated (a) electromagnetically with a coil and magnet assembly, (b) electrostatically using a capacitor with fixed and moving plates, and (c) with piezoelectric actuators. The magnitudes of the forces are usually inferred from the voltages or currents applied to the actuator, although in piezoelectrically driven instruments, a separate load cell is often included to provide a direct measurement of the force. Displacements are measured by a variety of means, including capacitive sensors, linear variable differential transformers (LVDTs), and laser interferometers. The range and resolution of the instrument are determined by the specific devices employed.

It is important to realize that as in a commercial tensile-testing machine, the displacements measured in an IIT system include a component from the compliance of the machine itself. Under certain circumstances, the machine compliance can contribute significantly to the total measured displacement, so it must be carefully calibrated and removed from the load-displacement data in a manner analogous to tension and compression testing. Specific procedures for determining the machine compliance in IIT testing are outlined in this article.

A variety of indenters made from a variety of materials are used in IIT testing. Diamond is probably the most frequently used material because its high hardness and elastic modulus minimize the contribution to the measured displacement from the indenter itself. Indenters can be made of other less-stiff materials, such as sapphire, tungsten carbide, or hardened steel, but as in the case of the machine compliance, the elastic displacements of the indenter must be accounted for when analyzing the load-displacement data.

Pyramidal Indenters. The most frequently used indenter in IIT testing is the Berkovich indenter, a three-sided pyramid with the same depth-to-area relation as the four-sided Vickers pyramid used commonly in microhardness work. The Berkovich geometry is preferred to the Vickers because a three-sided pyramid can be ground to a point, thus maintaining its self-similar geometry to very small scales. A four-sided pyramid, on the other hand, terminates at a “chisel edge” rather than at a point, causing its small-scale geometry to differ from that at larger scales; even for the best Vickers indenters, the chisel-edge defect has a length of about a micron. Although Vickers indenters could conceivably be used at larger scales, their use in IIT has been limited because most work has focused on small-scale testing.

Spherical Indenters. Another important indenter geometry in IIT testing is the sphere. Spherical contact differs from the “sharp” contact of the Berkovich or Vickers indenters in the way in which the stresses develop during indentation. For spherical indenters, the contact stresses are initially small and produce only elastic deformation. As the spherical indenter is driven into the surface, a transition from elastic to plastic deformation occurs, which can theoretically be used to examine yielding and work hardening, and to recreate the entire uniaxial stress-strain curve from data obtained in a single test (Ref 14, 15). IIT with spheres has been most successfully employed with larger-diameter indenters. At the micron scale, the use of spherical indenters has been impeded by difficulties in obtaining high-quality spheres made from hard, rigid materials. This is one reason the Berkovich indenter has been the indenter of choice for most small-scale testing, even though it cannot be used to investigate the elastic-plastic transition.

Cube-Corner Indenters. Another indenter used occasionally in IIT testing is the cube—corner indenter, a three-sided pyramid with mutually perpendicular faces arranged in a geometry like the corner of a cube. The centerline-to-face angle for this indenter is 34.3° , whereas for the Berkovich indenter it is 65.3° . The sharper cube corner produces much higher stresses and strains in the vicinity of the contact, which is useful, for example, in producing very small, well-defined cracks around hardness impressions in brittle materials; such cracks can be used to estimate the fracture toughness at relatively small scales (Ref 13, 26, 27).

Conical Indenters. A final indenter geometry worth mentioning is the cone. Like the Berkovich, the cone has a sharp, self-similar geometry, but its simple cylindrical symmetry makes it attractive from a modeling standpoint. In fact, many modeling efforts used to support IIT are based on conical indentation contact (Ref 28, 29, 30, 31, 32, 33, 34, and 35). The cone is also attractive because the complications associated with the stress concentrations at the sharp edges of the indenter are absent. Curiously, however, very little IIT testing has been conducted with cones. The primary reason is that it is difficult to manufacture conical diamonds with sharp tips, making them of little use in the small-scale work around which most of IIT has developed (Ref 36). This problem does not apply at larger scales, where much could be learned by using conical indenters in IIT experimentation.

A summary of the indenters used in IIT testing and parameters describing their geometries is given in Table 1.

Table 1 Summary of nominal geometric relationships for several indenters used in IIT

Instrumented Indentation Testing

J.L. Hay, MTS Systems Corporation; G.M. Pharr, The University of Tennessee and Oak Ridge National Laboratory

Time-Dependent Materials and Properties

All of the discussion so far has assumed that the material response to indentation contact is instantaneous, or nearly so, as is the case for most metals and ceramics tested at room temperature. In general, however, indentation deformation can be time-dependent, with the extent and nature of the time dependence strongly influenced by temperature. Time dependence is the rule rather than the exception in polymers—the viscoelastic behavior of polymers at room temperature is well known—and time-dependent creep is an important phenomenon in metals and ceramics at elevated temperatures. Methods for probing and characterizing the time-dependent phenomena, although not nearly as well developed as methods for measuring H and E , are now examined.

Influences on the Measurement of H and E . One important aspect of time-dependent behavior is an experimental complication arising in the measurements of hardness and modulus. Time-dependent creep and/or viscoelastic deformation can cause the indentation displacement to increase even as the indenter is unloaded, giving abnormally high contact stiffnesses that adversely affect the measurement of hardness and modulus. This is commonly encountered, for example, when testing soft metals, such as aluminum, with sharp indenters like the Berkovich. In some cases, the time-dependent portion of the displacement can be large enough to produce an unloading curve with a negative slope. When creep is observed or suspected, holding the load constant for a period of time prior to unloading, which allows the creep displacements to dissipate, can help alleviate the problem, at least in materials with short-lived creep responses.

Measurement of Creep Parameters. For materials in which the creep response is dominant, IIT can be used to characterize and quantify important creep parameters. For conventional creep tests conducted in uniaxial tension, the temperature and stress dependence of the steady state creep rate ($\dot{\epsilon}$) are often described by the relation:

$$\dot{\epsilon} = \alpha \sigma^n \exp(-Q_c/RT) \quad (\text{Eq 10})$$

where α is a material constant, σ is stress, n is the stress exponent for creep, Q_c is the activation energy, R is the gas constant, and T is temperature. Values of n ranging from 3 to 5 are typical for many metals. By analogy, an equivalent expression can be developed for indentation creep conducted, for example, by applying a constant load to the indenter and monitoring its displacement as a function of time. The expression follows by defining an indentation strain rate as $\dot{\epsilon}_i = h/\dot{h}$, that is, the normalized rate of indentation displacement (Ref 19, 24, 25). This definition is appropriate for cones and pyramids (Ref 9, 68). Noting that the equivalent of stress in an indentation test is the mean contact pressure $H = P/A$, the analog of Eq 10 for an indentation creep test is:

$$\dot{\epsilon}_i = \alpha_i H^n \exp(-Q_c/RT) \quad (\text{Eq 11})$$

where α_i is a material constant.

Equation 11 has been found to adequately describe creep behavior of some but not all materials (Ref 19, 21, 22, 23, 24, 25, 68, 69). When it does, a log-log plot of the indentation strain rate versus hardness produces a straight line with a slope that gives the stress exponent, n . Interestingly, such a plot can often be constructed from data obtained in a single indentation test. As an example, consider the indentation creep data in Fig. 9 for indium, a material that creeps at room temperature by virtue of its relatively low melting point (Ref 25). The data were obtained by loading a Berkovich indenter at a fixed rate of loading and then holding at a maximum load while monitoring the indenter displacement as a function of time. As the indenter penetrates, the contact area increases (thereby reducing the contact pressure), and the rate of displacement decreases correspondingly. In a

test like this, it is not unusual to obtain creep data over several orders of magnitude in $\dot{\epsilon}_i$. The stress exponent deduced from the data, $n = 6$, is very close to the value derived using conventional creep testing techniques.

Fig. 9 Room-temperature indentation creep data for indium obtained by loading the indenter at a constant rate (10 mN/s) to a peak load and holding for an extended period of time. Source: Ref 25

To date, indentation creep tests have been limited largely to the low-melting metals that exhibit creep at room temperature. In some cases, the stress exponent measured by indentation techniques has been close to that determined in conventional tests, but in others it has not. One important reason for the difference concerns the influence of transients on the creep response. For an indentation creep test, the stresses in the vicinity of the contact vary with time and position as the indenter penetrates the specimen. Thus, transient effects (primary creep) and stress-induced changes in microstructure can influence the behavior in a manner that is not observed in uniaxial creep testing, for which the stress is relatively uniform and invariant with time. Carefully conducted indentation creep tests have shown that when $\dot{\epsilon}_i$ varies significantly during the test, transient effects do indeed affect the results and are particularly important at high strain rates (Ref 25). It has been suggested that better results can be obtained by performing a series of tests over a range of $\dot{\epsilon}_i$ in which the indentation strain rate in any one test is held constant. This is easily achieved in a displacement-controlled machine by maintaining \dot{h}/h constant. Under conditions for which the deformation is predominantly steady state, a constant indentation strain rate can be obtained in a load-controlled system by holding the normalized loading rate (\dot{P}/P) constant (Ref 25).

The effect of temperature on creep, as quantified by the activation energy (Q_c) has been investigated only to a very limited extent (Ref 23, 25, 68, 69). Such tests are challenging due to inherent difficulties in measuring small displacements at elevated temperatures. When the specimen and/or testing apparatus are heated, the measured displacements are often dominated by thermal expansions and contractions of the machine, which are difficult to separate from the data.

Viscoelasticity. In addition to creep, indentation techniques have also been developed to characterize the time-dependent properties of viscoelastic materials like polymers. Dynamic stiffness measurement techniques offer distinct advantages here. Using the amplitude and phase of the force and displacement oscillations, the storage modulus (E'), characteristic of elasticity, and the loss modulus (E''), characteristic of internal friction and damping, can both be measured (Ref 17, 18). In its simplest form, the analysis follows by modeling the contact as a spring of stiffness S in parallel with a dashpot with damping coefficient $C\omega$, where ω is the angular frequency of the dynamic oscillation. Provided the dynamic response of the testing system is well known, S and $C\omega$ can be measured from the amplitude and phase of the load and displacement oscillations. The storage modulus is related to S by Eq 2; that is:

$$E' = \frac{\sqrt{\pi} S}{2\beta \sqrt{A}} \quad (\text{Eq 12})$$

and by analogy to this equation, it has been suggested that the loss modulus is related to $C\omega$ through:

$$E'' = \frac{\sqrt{\pi} C\omega}{2\beta \sqrt{A}} \quad (\text{Eq 13})$$

Other models for the dynamic response of the specimen-indenter contact can be used to give similar results. Although quite promising, the technique has yet to be rigorously tested on a variety of materials. Thus far, only materials with exceptionally high damping, like natural rubber, have been examined.

Good Experimental Practice

As in any experimental work, accurate measurements can be obtained only with good experimental technique and practice. A discussion of some of the factors that should be considered in making high-quality measurements follows. Emphasis is placed on those that are common to many measurement procedures and independent of the specific apparatus used to make them.

Choosing an appropriate indenter requires consideration of a number of factors. One consideration is the strain the tip imposes on the test material. Although the indentation process produces a complex strain field beneath the indenter, it has proven useful to quantify the field with a single quantity, often termed the characteristic strain (ϵ) (Ref 70, 71). Empirical studies in metals have shown that the characteristic strain can be used to correlate the hardness to the flow stress in a uniaxial compression test (Ref 70). For sharp indenters, such as self-similar cones and pyramids, the characteristic strain is constant regardless of the load or displacement, and is given by:

$$\epsilon = 0.2 \cot(\psi) \quad (\text{Eq 14})$$

where ψ is the half-included angle of the indenter for cones; for pyramids, ψ is the half-included angle of the cone having the same area-to-depth relationship (Ref 70, 71). Thus, the sharper the cone or pyramid, the larger the characteristic strain. For the two most commonly used pyramidal indenters, the Berkovich and Vickers, the characteristic strain is about 8%, and the measured hardness is about 2.8 times the stress measured at 8% strain in a uniaxial compression test.

The use of sharper pyramidal indenters (smaller centerline-to-face angles), such as the cube-corner, is required when one wishes to produce larger strains. For example, cube-corner indenters are preferred to Berkovich indenters when investigating fracture toughness at small scales by indentation-cracking methods because the larger strain induces cracking at much smaller loads (Ref 13, 26, 27). There are problems, however, in obtaining accurate measurements of hardness and elastic modulus with cube-corner indenters (Ref 43, 44, 45). Although not entirely understood, the problems appear to have two separate origins. First, as the angle of the indenter decreases, friction in the specimen-indenter interface and its influence on the contact mechanics becomes increasingly important. Second, as mentioned earlier, recent analytical work has shown that Eq 2 is not an entirely adequate description of the relation among the contact stiffness, contact area, and reduced elastic modulus (Ref 42, 43, 44, 45). Corrections are required, and the magnitude of the correction factor depends on angle of the indenter. The correction is relatively small for the Berkovich indenter, but much greater for the cube-corner indenter. Future measurement of H and E with cube-corner indenters will require methods for dealing with these complications (Ref 45).

For spherical indenters, the characteristic strain changes continuously as the indenter penetrates the material, as given by:

$$\epsilon = 0.2a/R \quad (\text{Eq 15})$$

where a is the radius of contact and R is the radius of the indenter (Ref 71). Thus, spheres can be used when one wishes to take advantage of the continuously changing strain. In principle, one can determine the elastic modulus, yield stress, and strain-hardening behavior of a material all in one test. However, because plasticity commences well below the surface (Ref 70, 71, 72, 73), the point of initial yielding can be difficult to detect experimentally. Specific methods for exploring the stress-strain curve with spherical indenters are described elsewhere (Ref 14, 15, 16, 70).

It is important to note that in order to measure a value for the hardness that is consistent with the traditional definition—that is, the indentation load normalized by the area of the *residual* hardness impression—the contact must be fully plastic. For spherical indenters, full plasticity is achieved in elastic-perfectly-plastic materials when $E_r a / \sigma_y R > 30$ (Ref 71). Thus, the contact radius (a) and, therefore, the penetration depth at which full plasticity is achieved are smaller for spherical indenters with smaller radii (R). This is one important reason that sharp pyramids, such as the Berkovich, are often preferred to spheres for small depth testing. The tip

radii on precision-ground Berkovich indenters are usually no greater than 100 nm—often better—implying that fully plastic contact is achieved at very small depths. Table 1 provides useful information on indenter geometries commonly used in IIT testing.

Environmental Control. To take full advantage of the fine displacement resolution available in most IIT testing systems, several precautions must be taken in choosing and preparing the testing environment. Uncertainties and errors in measured displacements arise from two separate environmental sources: vibration and variations in temperature that cause thermal expansion and contraction of the sample and testing system.

To minimize vibration, testing systems should be located on quiet, solid foundations (ground floors) and mounted on vibration-isolation systems. Thermal stability can be provided by enclosing the testing apparatus in an insulated cabinet to thermally buffer it from its surroundings and by controlling room temperature to within ± 0.5 °C. If the material is thermally stable (i.e., not time dependent), one can account for small thermal displacements using procedures described later. However, for time-dependent materials, extra care must be taken in providing thermal stability, because separation of the thermal displacements from the specimen displacements is virtually impossible and, therefore, introduces large uncertainties into the displacement data.

Surface Preparation. Surface roughness is extremely important in instrumented indentation testing because the contact areas from which mechanical properties are deduced (for instance, using Eq 5, 6, and 7) are calculated from the contact depth and area function *on the presumption that the surface is flat*. Thus, the allowable surface roughness depends on the anticipated magnitude of the measured displacements and the tolerance for uncertainty in the contact area. The greatest problems are encountered when the characteristic wavelength of the roughness is comparable to the contact diameter. In this case, the contact area determined from the load-displacement data underestimates the true contact area for indentations residing in “valleys” and overestimates it for indentations on “peaks.” The magnitude of the error depends on the wavelength and amplitude of the roughness relative to the contact dimensions. Thus, one should strive to prepare the specimen so that the amplitude of the roughness at wavelengths near the contact dimension is minimized. For metallographic specimens, a good guide for surface preparation is ASTM E 380 (Ref 74). One can normally determine whether roughness is an issue by performing multiple tests in an area and examining the scatter in measured properties. For a homogeneous material with minimal roughness, scatter of less than a few percent can be expected with a good testing system and technique.

Testing Procedure. To avoid interference, successive indentations should be separated by at least 20 to 30 times the maximum depth when using a Berkovich or Vickers indenter. For other geometries, the rule is 7 to 10 times the maximum contact radius. The importance of frequently testing a standard material cannot be overemphasized. For reasons explained in the calibration section, fused quartz is a good choice for such a standard. It is good practice to routinely perform 5 to 10 indents on the standard; when the measured properties of the standard appear to change, the user is immediately alerted to problems in the testing equipment and/or procedures.

Detecting the Surface. One very important part of any good IIT testing procedure is accurate identification of the location of the surface of the specimen. This is especially important for very small contacts, for which small errors in surface location can produce relatively large errors in penetration depth that percolate through the calculation procedures to all those properties derived from the load-displacement data (Ref 75). Schemes for detecting the surface are frequently based on the change in a contact-sensitive parameter that is measured continuously as the indenter approaches the surface. For hard and stiff materials, such as hardened metals and ceramics, the load and/or contact stiffness, both of which increase upon contact, are often used. However, for soft, compliant materials, like polymers and biological tissues, the rate of increase in load and contact stiffness is often too small to allow for accurate surface identification. In these situations, a better method is sometimes offered by dynamic stiffness measurement, for which the phase shift between the load and displacement oscillations can potentially provide a more sensitive indication of contact, depending on the dynamics of the testing apparatus and the properties of the material (Ref 48, 49).

Calibrations

The accurate measurement of mechanical properties by IIT requires well-calibrated testing equipment. While load and displacement calibrations are usually provided by the manufacturer using procedures specific to the machine, a number of calibrations must be routinely performed by the user. These calibrations are discussed in an order that roughly reflects the frequency of their necessity; that is, thermal-drift calibration is performed most often. With minor modifications, the procedures are essentially those developed by Oliver and Pharr (Ref 11).

Many of the calibrations require that a calibration material be indented during the procedure. One material commonly used for this purpose is fused quartz. This relatively inexpensive material is readily available in a highly polished form that gives repeatable results with very little scatter. Due to its amorphous nature, it is highly isotropic, and its relatively low elastic modulus, ($E = 72$ GPa) and high hardness ($H = 9$ GPa), facilitate calibrations that are best served by a large elastic recovery during unloading, such as area-function calibrations. Pile-up is not observed in fused quartz, and because it is not subject to oxidation, its near-surface properties are similar to those of the bulk and do not depend to a large degree on the depth of penetration. Fused quartz also exhibits essentially no time dependence when indented at room temperature, so there are no complications in separating thermal drift from time-dependent deformation effects.

Thermal-Drift Calibration. Thermal drift calibration seeks to adjust the measured displacements to account for small amounts of thermal expansion or contraction in the test material and/or indentation equipment. Good technique requires that it be performed individually for each indentation because the drift rate can vary in relatively short time spans. In fact, the calibration is best achieved by incorporation directly into the indentation test procedure itself. A procedure that works well for materials exhibiting little or no time-dependent deformation behavior (metals and ceramics tested at room temperature) is based on the notion that displacements observed when the indenter is pressed against the sample surface at a small, fixed load must arise from thermal drift. This can be implemented in an indentation experiment by including a period near the end of the test during which the load is held constant for a fixed period of time (about 100 seconds is usually sufficient) while the displacements are monitored to measure the thermal-drift rate. A small load is preferred to minimize the possibility of creep in the specimen; a good guideline for this load is 10% of the maximum indentation load. Displacement changes measured during this period are attributed to thermal expansion or contraction in the test material and/or indentation equipment, and a drift rate is calculated from the data. All displacements measured during the indentation test are then corrected according to the time at which they were acquired. For example, if the measured thermal drift rate is $+0.05$ nm/s, then a displacement acquired 10 s into the experiment must be corrected by -0.5 nm.

Figure 10 shows displacement-versus-time data acquired during a constant load period near the end of a test in fused quartz. In this case, the drift rate was fairly high, about 0.31 nm/s. Figure 11 shows the effect of applying this correction to the indentation load-displacement data. The shift in the corrected load-displacement curves has important consequences for the calculated contact area by affecting the maximum depth of penetration and the contact depth. Although not quite as obvious, the thermal drift also affects the contact stiffness determined from the slope of the unloading curve.

Fig. 10 Indenter displacement versus time during a period of constant load showing thermal drift in a fused quartz specimen. The measured drift rate, 0.31 nm/s, is used to correct the load-displacement data shown in Fig. 11.

Fig. 11 Load-displacement data for fused quartz showing correction for thermal drift

If the test material exhibits significant time-dependent deformation, as might be the case for polymers or metals tested at a significant fraction of their melting point, thermal drift correction should not be used because it is not possible to distinguish the thermal displacements from time-dependent deformation in the specimen. Under

such circumstances, thermal drift should be minimized by precisely controlling the temperature of the testing environment and allowing samples to thermally equilibrate for long periods of time prior to testing.

Machine Compliance (Stiffness) Calibration. Determination of the machine compliance (C_m) or equivalently, the machine stiffness ($K_m = 1/C_m$) allows one to determine that part of the total measured displacement (h_t) that occurs in the test equipment and correct the indentation data for it. If C_m or K_m is known, then the displacement in the machine at any load (P) is simply $h_m = C_m P = P/K_m$, and the true displacement in the specimen is given by:

$$h = h_t - C_m P = h_t - P/K_m \quad (\text{Eq 16})$$

To determine C_m or K_m , the machine and contact are modeled as springs in series whose compliances are additive. Thus, the total measured compliance (C_t) is given by:

$$C_t = C_s + C_m \quad (\text{Eq 17})$$

where C_s is the elastic compliance of the indenter-specimen contact. Because C_t is just the inverse of the total measured stiffness (S_t), and C_s is the inverse of the elastic contact stiffness (S), Eq 2 and 17 combine to yield:

$$C_t = \frac{\sqrt{\pi}}{2\beta E_r \sqrt{A}} + C_m \quad (\text{Eq 18})$$

Thus, the intercept of a plot of C_t versus $A^{-1/2}$ gives the machine compliance (C_m) and the slope of the plot is related to the reduced modulus (E_r). Because extrapolation of the data to $A^{-1/2} = 0$ is required, the best measures of C_m are obtained when the first term on the right is small, that is, for large contacts.

A convenient procedure for determining C_m is based on the assumption that the area function of the indenter at large depths is well described by the ideal area function, that is, the area function under the assumption that the indenter has no deviations from its perfect geometric shape. For pyramidal and conical indenters, the ideal area function is given by:

$$A = F_1 d^2 \quad (\text{Eq 19})$$

where the constant F_1 follows from geometry. Values of F_1 for several important indenters are included in Table 1. For spherical indenters, the ideal area function depends on the diameter of the sphere (D) through:

$$A = \pi d(D - d) = -\pi d^2 + \pi Dd \quad (\text{Eq 20})$$

which, for small penetration depths relative to the sphere diameter ($d < D$), simplifies to:

$$A = \pi Dd = F_2 d \quad (\text{Eq 21})$$

where $F_2 = \pi D$.

The specific calibration procedure used to determine the machine compliance is an iterative one that uses data from a calibration material such as fused quartz. Indentations are made at several large depths for which the ideal area function is expected to apply. Assuming first that $C_m = 0$, the load-displacement data are corrected for the machine compliance according to Eq 16 and analyzed according to Eq 4, 5, 6, and 7 to determine the contact area at each depth. The intercept of a plot of C_t versus $A^{-1/2}$ then gives a new estimate of C_m . After correcting the load-displacement data for the new C_m , which affects the values of $A^{-1/2}$, the procedure is iteratively repeated until adequate convergence in C_m is obtained. As a check on the procedure, the slope of the final C_t versus $A^{-1/2}$ plot should be within a few percent of $\sqrt{\pi}/(2\beta E_r)$, as indicated in Eq 18. If not, one must question whether the assumed ideal geometry is correct and carefully inspect the indenter to check on it.

Accurately knowing C_m and K_m becomes increasingly important as the contact stiffness (S) approaches the machine stiffness (K_m). Because S increases with \sqrt{A} , machine stiffness corrections are most important for larger contacts. For example, Fig. 12 shows the effect of K_m on load-displacement data for relatively small and large indentations in fused quartz obtained with a Berkovich indenter. In each plot, the data have been reduced in two ways: (a) using $K_m = 1 \times 10^{30}$ N/m, that is, an essentially infinite machine stiffness; (b) using the correct value, $K_m = 6.8 \times 10^6$ N/m. The data in Fig. 12(a) are largely unaffected by the machine stiffness correction because the small load ($P_{\max} = 7$ mN) is associated with a small contact stiffness; in this case, the contact stiffness is less than 1% of K_m . In Fig. 12(b), however, the machine stiffness correction is much more important because the contact stiffness at the larger peak load, 600 mN, is approximately 10% of the machine stiffness. One sure symptom of an incorrect K_m is a steady change in E with depth in a sample that should have depth-

independent properties. Assuming all else is correct, if one uses a value of K_m that is too large, E will be correct at small depths, but will steadily decrease at larger depths; the converse is also true.

Fig. 12 Load-displacement data for fused quartz showing machine stiffness corrections at two peak loads: (a) 7 mN and (b) 600 mN. The correct machine stiffness is 6.8×10^6 N/m, while the value $K_m = 1 \times 10^{30}$ is used to represent an infinite stiffness. The plots illustrate the insensitivity of the load-displacement data to machine stiffness corrections for small contacts, but the stiffness correction is more important when the contact is large.

Area-Function Calibration. Although the ideal area function sometimes provides an accurate description of the contact geometry, especially at larger contact depths, deviations from geometrical perfection near the indenter tip, even when subtle, must be properly taken into account when measurements are to be made at small scales. For pyramidal indenters and cones, variations from the ideal self-similar geometry are produced by tip blunting. For spherical indenters, knowledge of the precise tip shape is important because small deviations from perfect spherical geometry can have large effects on the measured contact area. There may also be circumstances for which the ideal area function is not known, as in the case of a pyramidal indenter not ground precisely to the appropriate face angles. In each of these situations, the area function must be determined by an independent method. A general procedure for calibrating area functions without having to image the indenter or contact impressions follows.

The area function is determined by making a series of indentations at various depths in a calibration material of well-known elastic properties. The data can also be acquired using dynamic stiffness measurement, which has the advantage of being able to obtain all the necessary data in a few tests. The basic assumption is that the elastic modulus is independent of depth, so it is imperative that a calibration material be chosen that is free of oxides and other surface contaminants that may alter the near-surface elastic properties. It is also imperative that there be no pile-up, because the procedure is based on Eq 4, 5, 6, and 7, which do not account for the influences of pile-up on the contact depth. For these reasons, fused quartz is a good choice, although because of its relatively high hardness ($H = 9$ GPa), the upper limit on the achievable depth is somewhat restricted. For the specific procedure outlined here, the machine compliance must also be known from the procedures outlined in the previous section. In cases for which this is not possible, as when the ideal area function is not known or suspected to be inaccurate, an alternative procedure must be adopted in which the machine compliance and the area function are determined simultaneously in a coupled, iterative process. This procedure, which is considerably more complex, is described in detail elsewhere (Ref 11).

To implement the area-function calibration, a series of indentations is made at depths spanning the range of interest, usually from as small as possible to as large as possible, so that the area function is established over a wide range. Correcting for machine compliance, the load-displacement data are reduced and used to obtain the contact stiffnesses (S) and the contact depths (h_c) by means of Eq 5 and 6. From these quantities and the known elastic properties of the calibration material, the contact areas are determined by rewriting Eq 2 as:

$$A = \frac{\pi}{4} \left(\frac{S}{\beta E_r} \right)^2 \quad (\text{Eq 22})$$

When fused quartz is used as the calibration material ($E = 72$ GPa; $\nu = 0.17$) and the indenter is diamond ($E = 1141$ GPa; $\nu = 0.07$), the reduced modulus in the above expression is $E_r = 69.6$ GPa. A plot of A versus h_c then

gives a graphical representation of the area function, which can be curve fit according to any of a number of functional forms. A general form that is often used is:

$$A = C_1d^2 + C_2d + C_3d^{1/2} + C_4d^{1/4} + C_5d^{1/8} + \dots \quad (\text{Eq 23})$$

where the number of terms is chosen to provide a good fit over the entire range of depths as assessed by comparing a log-log plot of the fit with the data. Because data are often obtained over more than one order of magnitude in depth, a weighted fitting procedure should be used to assure that data from all depths have equal importance. Note that the first term in the expression represents the ideal area function for a pyramidal or conical indenter provided $C_1 = F_1$ in Eq 19. Thus, for pyramidal and conical indenters for which the ideal area function is known, it is often convenient to fix $C_1 = F_1$. Similarly, inspection of Eq 20 shows that for spherical indenters of known diameter D , one may wish to set $C_1 = -\pi$ and $C_2 = \pi D$. Fixing the values of these constants is particularly important when areas greater than those achievable in the calibration material are to be determined by extrapolating the area function to larger depths. Such extrapolations should be used with caution and only when there is confidence that the ideal area function applies at large depths. At depths greater than those included in the calibration, it is usually best to use the ideal area function of the indenter.

Figure 13 shows area functions determined with these procedures for three separate diamond indenters: Berkovich, Vickers, and a 70.3° cone (Ref 36). All three have nominally the same ideal area function, $A = 24.5d^2$, and tend to this function at large depths. However, the data show that there is indeed tip blunting for all three indenters, the conical diamond having the most and the Berkovich the least. The data corroborate the claim that the sharpest diamonds are those with the Berkovich geometry.

Fig. 13 Calibrated area functions for three indenters. Although the ideal area function, $A = 24.5d^2$, is nominally the same for each, the area functions differ due to different degrees of tip rounding. Source: Ref 36

Future Trends

Instrumented indentation testing is a dynamic, growing field for which many new developments can be expected in the near future. From an equipment standpoint, one can expect that conventional microhardness testing equipment will be adapted to expand its capabilities in the manners afforded by IIT. This will lead to a new generation of relatively inexpensive IIT testing systems that operate primarily in the microhardness regime. Integration of atomic force microscopy with IIT will become increasingly more commonplace, allowing one to obtain three-dimensional images of small indentations to confirm contact areas and to examine pile-up phenomena. New displacement measurement methods based on laser interferometry can be expected to improve displacement measurement resolution and reduce the influences of machine compliance and thermal drift on measured properties. Laser interferometry will also facilitate testing at nonambient temperatures.

One can also expect new developments in techniques for measurement and analysis. Finite-element simulation may become an integral part of property measurement, accounting for the influences of pile-up and aiding the separation of film properties from substrate influences. Finite-element techniques may also prove useful in establishing tensile stress-strain behavior from experimental data obtained with spherical indenters. New methods and analyses based on dynamic measurement techniques can be expected to expand the characterization of the viscoelastic behavior of polymers over a wide range of frequency.

One of the great challenges in IIT is to develop equipment and techniques for measuring the properties of ultra-thin films, such as the hard protective overcoats used in magnetic disk storage, some of which are only 5 nm thick. At these scales, surface contaminants and surface forces due to absorbed liquid films severely complicate contact phenomena and analyses. New methods for obtaining and analyzing such data will be required.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Introduction

HARDNESS is a key attribute of ceramics. One would suppose that measuring and interpreting ceramic hardness is routine, but there are pitfalls, controversies, new developments, and sometimes even surprises. Although commonly measured for a ceramic, hardness is usually evaluated for different purposes than for metallic materials. Ceramists are more concerned with evaluating the generic ceramic hardness rather than verifying that a correct heat treatment or surface treatment has been applied to a body. Hardness of ceramics is important for characterizing ceramic cutting tools, wear and abrasion resistant parts, prosthetic hip joint balls and sockets, optical lens glasses (for scratch resistance), ballistic armor, molds and dies, and valves and seals. Typically, ceramic material specifications may have minimum hardness requirements. For example, a zirconia specification for surgical implants, ASTM F 1873-98 (Ref 1), states that Vickers hardness (HV) shall be no less than 11.8 GPa (1200 kgf/mm²) at 9.8 N (1 kgf) load.

Hardness characterizes the resistance of the ceramic to deformation, densification, displacement, and fracture. Densification often is important because it relates to the microporosity that is often present in sintered ceramics. Densification may also occur in some glasses. Microfracture and shear fracture under an indentation are also important deformation components. The complexity of the deformation, displacement, and fracture processes is beautifully illustrated in Ref 2.

Hardness is usually measured with conventional microindentation hardness machines using Knoop or Vickers diamond indenters. Figures 1 and 2 show some typical well-formed indentations, whose diagonal length is measured with an attached optical microscope. For research purposes, Vickers, Knoop, and Berkovich (triangular pyramid) indenters are used. Rockwell and Brinell indenters are rarely used for ceramics research. In engineering and characterization applications, approximately 60% of worldwide published ceramic hardness values are Vickers, with loads typically in the range of a few Newtons to 9.8 N (>100 gf-1 kgf) with occasional data for soft or high toughness ceramics at loads as high as 98 N (10 kgf). About 35% are Knoop with loads from as low as 0.98 up to 19.6 N (0.10–2 kgf). Knoop hardness is more frequently cited in the United States than in the rest of the world, presumably due to the existence of ASTM standards C 730 for glass (Ref 3), C 849 for ceramic whitewares (Ref 4), and C 1326 for advanced ceramics (Ref 5). Knoop testing is frequently used to study the hardness of ceramic single crystals (Ref 6), because orientation effects may be studied by varying the diagonal axis orientation. Cracking problems are also less severe than with Vickers indentations.

Fig. 1 Scanning electron micrographs, entire indentation and closeup of one tip, of Knoop indentation (19.6 N, or 2 kgf) in a silicon nitride.

Fig. 2 Light micrograph of Vickers indentation (98 N, or 10 kgf) in a silicon nitride. Specimen is tilted to show the three-dimensional form of the indentation.

About another 5% of published hardness values are Rockwell, usually the HRA or superficial HR45N scales. Another scale for measuring ceramic hardness is the traditional Moh's scale from a scratch hardness test, which ranks various minerals from gypsum (hardness of 1) to corundum (9) and diamond (10). Although popular in mineralogy and geology, the Mohs scale is rarely used for engineering purposes.

The indentation size effect in ceramics wherein hardness decreases with increasing indentation load (Fig. 3) occurs for both conventional Knoop and Vickers hardness but with slightly different trends. The Meyer-law exponent, n (see Eq 6), is less than 2. A constant hardness is reached at loads from 5 to 100 N (0.5–10.2 kgf) depending on the ceramic. The Knoop hardness often is greater at small loads, but then decreases to a plateau load that is somewhat less (~10%) than the Vickers hardness at large loads. The differences in hardness are due to different relative amounts of deformation, densification, displacement, and fracture in the material beneath the Knoop and Vickers indenters.

Fig. 3 Effect of indentation size on the measured hardness of ceramics

Ideally, one should measure the entire hardness-load curve, but in practice testers often chose one reference or standard load to allow comparisons between materials. It is preferable to make the indentations as large as possible to reduce measurement uncertainties, yet not so large as to induce excessive cracking that interferes with the measurement or destroys the indentation altogether. The preferred indentation loads that are specified in world standards are listed in the following sections. Indentation load should always be reported with the hardness outcome. Many contemporary structural ceramics have hardnesses in the 10 to 30 GPa (1020–3060 kgf/mm²) range. For the latter hardness, Vickers indentations made at 9.8 N (1 kgf) load are 25 μ m long and Knoop indentations are 68 μ m long.

The preponderance of published Vickers and Knoop hardness values in the ceramics technical literature and in many company product brochures are reported with *units of GPa*. Thus, the hardness of dense silicon nitride is of the order of 15 GPa. Some values are published either with older units of kgf/mm², or as dimensionless hardness with kgf/mm² implied (e.g., 1500 kgf/mm² or 1500). ISO 14705 for hardness of fine ceramics (advanced ceramics) (Ref 7) recommends the use of GPa, but allows the dimensionless values as an alternative.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Microindentation Hardness

Metrology Issues of Knoop and Vickers Hardness. At small indentation loads (<9.8 N, or 1 kgf) problems arise from the significant load dependence of hardness and measurement uncertainty due to the small indentation size. At higher loads (>49 N, or 5 kgf), cracking and spalling can be a problem and may make measurement impossible. The difficulties in obtaining accurate and precise hardness readings are not fully appreciated. Figure 4 shows some of the common, serious issues with hardness measurements in ceramics. The slightest bump to a hardness machine or the table on which it sits while the indenter is in contact with the specimen can create an appreciable error. Hardness is proportional to the square of the diagonal length of the indentation, and so any error in length measurement has the effect of doubling the error in hardness measurement. It is crucial that the diagonal length be measured carefully, especially for ceramics where the indentation size is small and the percentage error is larger. Many ceramics and glasses are often transparent or translucent and require careful microscopic examination. A Versailles Advanced Materials and Standards (VAMAS) round-robin project with two alumina ceramics showed that the reproducibility (between-laboratory) uncertainty in reported mean hardness was 10 to 15%, and in some instances, much greater (Ref 8, 9).

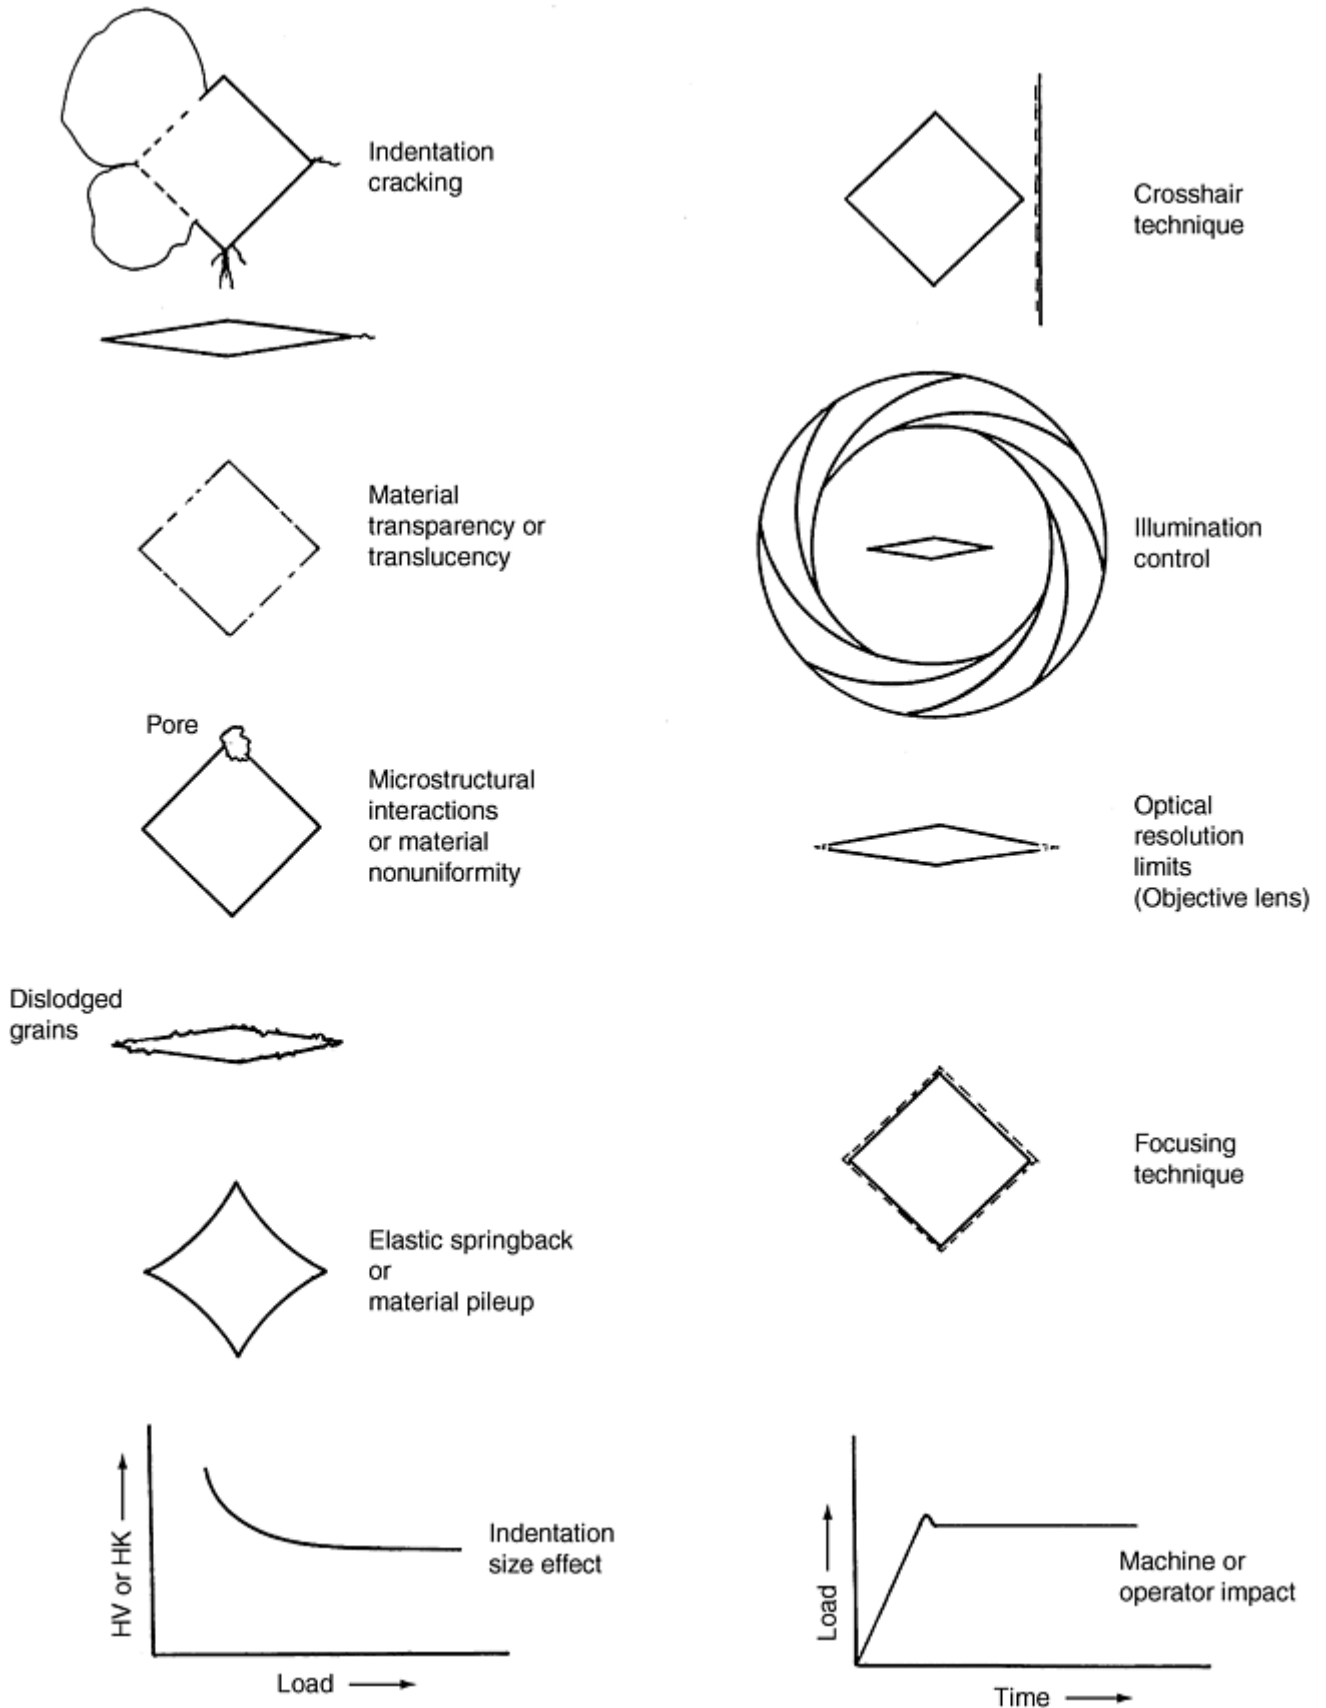

Fig. 4 Common problems in ceramic hardness testing

Indentations in ceramics and glasses are often very small, and microindentation hardness machines should have a microscope with a magnification capability of *no less than 400*×. Optical microscopy technique is crucial. Reasonable skill, experience, and careful experimental technique are necessary to accurately and precisely measure diagonal lengths. This skill level is readily achievable through practice and use of reference hardness blocks. The early microindentation hardness literature (e.g., Ref 10, 11, 12) has numerous discussions of

objective lens quality and design, optical resolution limits, crosshair technique, and information on the use of field and aperture diaphragms to control contrast and brightness. The latter are especially important for translucent or transparent ceramics and glasses. Much of the difference in interpretation of indentation tip location between observers can be traced to illumination and contrast control.

Although many machines have digital readouts to 0.1 μm (4 μm in.), users should recognize this is less than the wavelength of light and does not represent the true machine accuracy or machine precision, which are probably several times larger. In practice, the resolution of the indentation tips and the subjectivity of the viewer usually leads to a between-observer variability of 0.5 to 1.0 μm in diagonal size. In light of the importance of optical technique, it is amazing and regrettable that some contemporary commercial hardness machines have no aperture diaphragm. Some have neither an aperture nor a field diaphragm. Optimum indentation illumination on ceramics and glasses cannot be achieved with such equipment. The emphasis with some contemporary machines seems to be on capturing the indentation image with a video camera and projecting the image onto a monitor and interpreting results with a computer. Computer analysis and controls cannot overcome basic optical limitations of an instrument. In many instances, a single monitor pixel can represent as much as 0.5 μm and is a significant fraction of the size of a small ceramic indentation. Of course, whatever system is used to measure diagonal lengths, it should be verified by use of a calibrated stage micrometer or other magnification verification device. Ceramic hardness reference blocks with certified indentation sizes may be used to verify length measurements as well.

With some care and practice, an operator should be able to measure a well-formed $\sim 50 \mu\text{m}$ Vickers indentation diagonal size to within 0.5 μm and to within 1.0 μm for a 50 to 100 μm Knoop indentation with 400 to 500 \times optical magnification. As previously noted, different observers using the same equipment and viewing the same indentations typically agree within 0.5 and 1.0 μm (20 and 40 $\mu\text{in.}$) for Vickers and Knoop indentations, respectively. Practice with reference blocks can improve this precision considerably.

Knoop Hardness of Ceramics and Glasses. Frederick Knoop developed his elongated pyramidal indenter as an alternative to the square base pyramidal Vickers indenter, in large part to overcome the cracking observed in brittle materials (Ref 13, 14). Knoop indentations are far less apt to manifest severe cracking than Vickers indentations. Several key standards for Knoop hardness of ceramics or glasses are listed in Table 1. The European Community standard CEN ENV 843-4 has Knoop as well as Vickers and Rockwell A and N hardness methods. The new ISO 14705 standard from Technical Committee TC 206, Fine Ceramics, includes both Knoop and Vickers hardness.

Table 1 Knoop hardness standard test methods for ceramics and glasses

Standard	Materials covered	Preferred test load		Alternate test load		Ref
		N	kgf	N	kgf	
ASTM C 730	Glass	0.98	0.1	3
ASTM C 849	Ceramic whitewares	9.8	1	4
ASTM C 1326	Advanced ceramics	19.6	2	9.8	1	5
CEN 843-4	Advanced technical ceramics	9.8	1	16
DIN 52333	Glass and glass ceramics	0.98	0.1 ^(a)	17
ISO 14705	Fine (advanced, advanced technical) ceramics	19.6	2	9.8	1	7
ISO 9385	Glass and glass-ceramics	0.98	0.1 ^(a)	18

(a) At least two other test loads that are not likely to cause excessive fracture shall also be used.

The preferred loads for testing are all within the range of most microindentation hardness testing machines. The standards usually include provisions for alternative (usually smaller) loads if cracking is a problem. The three ASTM standards all refer back to the master standard E 384 (Ref 15), "Microindentation Hardness of Materials," but each have specific conditions and requirements for ceramics or glasses. For example, the indenter displacement rate is much slower in C 730 than for the other standards, which reflects some concern about loading rate effects. In addition, C 730 and C 849 include an important correction factor for optical resolution limitations. Figure 5 shows acceptable and unacceptable indentations according to ASTM C 1326 and ISO 14705. The glass standards all recommend 0.98 N (100 gf) as the standard test force. This small load is

used because glasses have low hardness, and so a small test load will produce a moderate-sized indentation. The small load also avoids cracking. The ceramic standards all prescribe 19.6 or 9.8 N (2 or 1 kgf). The larger 19.6 N (2 kgf) force is advantageous since the larger indentation produces more precise readings, as is discussed below. The 9.8 or 19.6 N forces may not be sufficiently large to ensure that hardness has reached the plateau, however. These forces were chosen because they are within the load capacity of most commercial microindentation hardness machines.

Fig. 5 Acceptable and unacceptable Knoop indentations in ceramics

As noted earlier, it is essential that the test force be reported along with any ceramic hardness number. ISO 14705 requires the use of one of two methods of reporting Knoop hardness. The preferred scheme is SI compatible and has the symbol HK preceded by the hardness value and supplemented by a number representing the test force:

15.0 GPa HK 9.807 N

which denotes a Knoop hardness of 15.0 GPa determined with a test force of 9.807 N (1 kgf). Alternately:

1500 HK 1

denotes a Knoop hardness of 1500 (dimensionless) determined with a test force of 9.807 N (1 kgf).

Fortunately, all world standards and the entire ceramics community use the traditional definition of Knoop hardness based upon test force divided by projected surface area:

$$HK = 14.229 \frac{W}{d^2} \quad (\text{Eq 1})$$

where W is the indenter force and d is the long diagonal length.

Knoop indentations are 2.8× longer than Vickers indentations made at the same load. The longer indentations in principle should make an easier-to-read indentation, but in practice the length advantage is offset by the greater difficulty in determining where the tapered tip ends. A major advantage of the Knoop indentation over Vickers for ceramics is that larger indentation loads may be used without cracking. Even if the sides of the indentation are displaced or cracked, a credible diagonal length reading and hardness estimate may be made. The tip uncertainty is often of the order of 0.5 to 1.0 μm, irrespective of the indentation size, and consequently the percentage error is minimized with long indentations. In addition, it is easier to measure hardness in the constant-hardness region of the indentation size effect curve. Knoop hardness is not fully utilized or appreciated by the ceramics community.

Optical microscope resolution limitations are a problem for Knoop indentations due to the slender tapered tip (Fig. 6). The error in underestimating the true tip location has been estimated as $7\lambda/2(\text{NA})$ where λ is the wavelength of light and NA is the objective lens numerical aperture (Ref 12). For a typical microscope having a 40×, 0.65 NA objective lens, the calculated correction for green light ($\lambda = 0.55 \mu\text{m}$) is thus 3.0 μm, a significant number. A correction for this is incorporated in the two older ASTM Knoop standards; C 730 for glass and C 849 for ceramic whitewares, but is not used either in the master microindentation hardness of materials standard E 384 or in the advanced ceramic standard, C 1326. The confusion about whether to add this correction factor reached the point where a major glass manufacturer at one time included both uncorrected and corrected numbers for Knoop hardness numbers in their product data handbook.

Fig. 6 Resolution limits of light microscopy when measuring the long, slender tips of Knoop indents. λ , wavelength of light; NA, numerical aperture of objective lens

To determine whether the $7\lambda/2(\text{NA})$ correction is appropriate, the National Institute of Standards and Technology (NIST) compared calibrated scanning electron microscope (SEM) diagonal length measurements to optical microscope measurements on a Knoop impression in a silicon nitride reference block (Ref 19, 20). The indentation was measured optically by four skilled operators. Three used the optical system on a conventional microindentation hardness machine, and the fourth used a metallograph used to certify metallic microindentation hardness standard reference materials (SRMs). The length was measured using several lenses with different numerical apertures, all calibrated using the same NIST-certified stage micrometer. Five or ten repetitions were made by each observer. The SEM measurements benefited from higher magnification photographs (1500×, 5000×), which aided the interpretation of the exact tip location. The mean SEM length measurement was 146.8 μm (standard deviation ±0.2 μm). The mean optical diagonal lengths were 0.4 to 2.1 μm shorter than the SEM readings. These differences are less than the full $7\lambda/2(\text{NA}) = 3.0 \mu\text{m}$ correction probably because the optical observers did discern the tip as a faint black line, albeit not as two distinguishable tip lines as shown in Fig. 6. Later, as part of an eleven-laboratory international round-robin, three certification laboratories using their normal optical microscopes obtained average diagonal length readings (10 indentations) that were within 0.4 to 1.2 μm of the NIST SEM readings. This is better than 1% agreement on 142 μm long indentations and underscores how the percentage error may be kept small by utilizing large Knoop indentation

sizes. In conclusion, with careful optical microscopy the diagonal length readings for this opaque reference material were close to the calibrated SEM values, and the $7\lambda/2(\text{NA})$ correction factor is excessive.

Knoop indenters sometimes are used to create a controlled surface microflaw in ceramic fracture specimens for fracture toughness determination by the surface crack in flexure method. The indentation and the residual stress damage zone underneath it are removed by polishing or hand grinding. The specimen is fractured and fracture toughness evaluated from the fracture load and the precrack dimensions. This approach has been adopted in ASTM and ISO standards. Indentation loads are usually 19.6 to 49.0 N (2–5 kgf), which cause no damage to the diamond indenter (see the article “Fracture Toughness of Ceramics and Ceramic Matrix Composites” in this Volume).

Vickers Hardness of Ceramics. The square pyramidal Vickers indenter creates smaller, deeper impressions than Knoop indentations at the same load. Vickers indentations are more apt to crack. There are no Vickers standard test methods for glasses, undoubtedly due to cracking problems. Table 2 shows some of the current key world standards and preferred test loads. All standards have settled on a reference test force of 9.8 N (1 kgf), which is within the capacity of nearly all microindentation hardness testing machines, but probably is not on the hardness plateau for a hardness versus load curve for many ceramics. Japanese Industrial Standard (JIS) R 1610 and ISO 14705 also allow 98.0 N (10 kgf), but these large loads cause extreme fracturing in ceramics such as silicon carbide and boron carbide.

Table 2 Vickers hardness standard test methods for ceramics

Standard	Materials covered	Preferred test load		Alternative test load		Ref
		N	kgf	N	kgf	
ASTM C 1327	Advanced ceramics	9.8	1	21
CEN 843-4	Advanced technical ceramics	9.8	1	16
JIS R 1610	Fine ceramics	9.8	1	98.0	10	22
ISO 14705	Fine (advanced, advanced technical) ceramics	9.8	1	98.0	10	7

The late 1970s and early 1980s saw the advent of indentation fracture studies wherein Vickers indentations were used to study fracture behavior and, in particular, to estimate fracture toughness. In this approach, a Vickers indentation is made into a polished surface, and the lengths of the four long cracks that emanate from the indentation corners are measured. Many workers began to try to measure hardness and fracture toughness at the same time on the same indentations. Indentation loads were varied in order to adjust the crack sizes. This frequently led to the use of very large indentation loads, much greater than the 9.8 N (1 kgf) or even the 98 N (10 kgf) forces recommended in the hardness standards. Often the hardness data were of poor quality. Mangled indentations and mangled diamond indenters often resulted. Diamond indenters may be damaged by edge cracking or loss of the meticulously prepared tips, rendering them useless for quality hardness measurements in the microhardness range.

The optical resolution limits are estimated to be only $1.0\lambda/2(\text{NA})$ or $\sim 0.4 \mu\text{m}$ for Vickers indentations (Ref 12) with a 40 \times , 0.65 NA objective lens. Correction factors are rarely applied to the length measurements and are not incorporated into any Vickers standard. Figure 2 shows a typical well-formed indentation in a silicon nitride specimen and illustrates the three-dimensional nature of the indentation as well as a modest amount of tip cracking. There is considerable uplift to the indentation sides. Although the indentation tips are “blunter” and easier to judge than the slender, tapered Knoop indentations, the Vickers indentation lengths are much shorter. Consequently, any error in measuring the diagonal size of a Vickers indentation is a larger fraction of the diagonal size. The hardness uncertainty is similar to or greater than that for Knoop hardness measurements at the same load. The cracks at the Vickers indentation corners typically are wider and more pronounced and may interfere with the interpretation of the tip location. In the limit, cracking can be so extensive that portions of the indentation spall off as shown in Fig. 7, making measurements imprudent or impossible. Figure 8 illustrates acceptable and unacceptable Vickers indentations according to ASTM C 1327 and ISO 14705.

Fig. 7 Badly spalled and fractured Vickers indentation in boron carbide at indentation loads of (a) 9.8 N (1 kgf) and (b) 98.0 N (10 kgf)

Fig. 8 Acceptable and unacceptable Vickers indentations in ceramics

It is essential that the test force be reported along with any ceramic hardness number. ISO 14705 requires the use of one of two methods of reporting Vickers hardness. The preferred scheme is to use the symbol HV preceded by the hardness value and supplemented by a number representing the test force:

$$15.0 \text{ GPa HV } 9.807 \text{ N}$$

which denotes a Vickers hardness of 15.0 GPa determined with a test force of 9.807 N (1 kgf). Alternately:

$$1500 \text{ HV } 1$$

denotes a Vickers hardness of 1500 (dimensionless) determined with a test force of 9.807 N (1 kgf).

All world standards and most of the ceramics community use the traditional definition of conventional Vickers hardness based upon test force divided by contact area:

$$\text{HV} = 1.8544 \frac{W}{d^2} \quad (\text{Eq 2})$$

where W is the indenter force and d is the long diagonal length. This is the preferred, consensus world standard formulation for conventional Vickers hardness. Unfortunately, some practitioners in the ceramics community (those who use Vickers indentations to study fracture, or those who use instrumented or load and depth-sensing methods) use a formula for hardness (H) based upon test force divided by *projected surface area*:

$$H = 2.0 \frac{W}{d^2} \quad (\text{Eq 3})$$

which is sometimes expressed alternately as

$$H = 2.0 \frac{W}{(2a)^2} = 0.5 \frac{W}{a^2} \quad (\text{Eq 4})$$

where a is the indentation half diagonal size. Many papers or reports do not state which equation was used to compute a conventional Vickers hardness value or even the indentation load. Hardness values in such cases should be discounted because they are almost worthless. If the symbol HV is used in reporting hardness, the odds are very good that the data were generated by a sound test method and hardness calculated by Eq 2.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Hardness and Microstructure

Ceramic hardness is strongly dependent on the microstructure of the material. Grain size, grain morphology, porosity, and secondary phases (even in trace amounts), all affect measured hardnesses (Ref 6, 23). The porosity dependence of hardness may be expressed as:

$$H = H_0 \exp^{-bP} \quad (\text{Eq 5})$$

where H_0 is the hardness with zero porosity, P is the volume fraction of porosity, and b is a constant. Values for b , which range from 3 to 11 depending upon the ceramic, attest to the significant influence of porosity on hardness. Hardness usually increases with decreasing grain size in accordance with a Hall-Petch relationship,

wherein hardness varies with the inverse square root of grain size (Ref 23, 24, 25, 26). At very large grain sizes, the trend may change and hardness may increase with increasing grain size and approach single-crystal hardness values (Ref 23). Examples of the effect of grain size on Vickers hardness are shown by Rice et al. (Ref 23), Clinton and Morrell (Ref 24), and Krell and Blank (Ref 25), and for Knoop hardness by Skrovanek and Bradt (Ref 26). Just as one cannot generalize and attribute a value of hardness to “steel,” one should not generalize and assign a value to “alumina.” The more specific one can be about the ceramic (i.e., its code designation, grain size, and porosity) the better.

Ceramic Hardness Reference Materials

The poor results from a 1988–1989 VAMAS round-robin study (Ref 8, 9) with Knoop, Vickers, and Rockwell tests on alumina ceramics underscored the need for standard reference materials (SRMs). In response to this need, NIST subsequently prepared for Knoop hardness NIST SRM 2830, which is a hot isopressed silicon nitride disk that was prepared from a ceramic bearing ball (Ref 19, 20). It has a high-quality polish with five well-defined indentations and has a nominal hardness of 14.0 GPa (1400 kgf/mm²). A typical 19.6 N (2 kgf) impression is shown in Fig. 1. The average diagonal length (~142.0 μm, or 5590 μin.) for each block is listed and certified to within 0.6 μm (24 μin.) (0.4%) at a 95% confidence interval. The 19.6 N (2 kgf) load is used to exploit the advantage that long Knoop indentations can reduce the percentage error to such remarkably small levels. Hardness is certified to within 0.9% or within 0.12 GPa (12 kgf/mm²). A calibrated scanning electron microscope was used to make all length measurements. An eleven-laboratory international round-robin verified that operators with conventional optical microscopes obtained readings in excellent agreement with the SEM readings. This was especially true for the three participating certification labs: NIST's Metallurgy Division, Wilson Division of Instron, and the Materials Testing Institute, Nordrhein-Westfalen, Germany. The Fraunhofer Institute for Ceramic Technologies and Sintered Material (IKTS), Dresden, also has prepared ceramic Knoop hardness reference blocks to support EN 843-4.

NIST SRM 2831 for Vickers hardness was still in preparation as of 2000. It is a tungsten carbide with cobalt binder with five indentations made at a load of 9.8 N (1 kgf) (Ref 19, 20). A tungsten carbide was chosen since it is an opaque ceramic (hardmetal) that does not crack at the tips.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Cracking from Vickers Indentations

Hardness testing usually seeks to avoid the cracking that interferes with the hardness measurement. On the other hand, the ceramics community has contrived a simple method to estimate fracture toughness (K_{Ic}) from Vickers indentation cracking. The indentation crack length or "indentation fracture" method is based on measurement of the crack lengths emanating from the corners of Vickers hardness indentations on polished surfaces (Ref 27, 28). The lengths of the cracks and the indentation half diagonal size are related to the hardness, elastic modulus, and fracture toughness of the material by a semiempirical analytical expression. The expression inevitably has a calibration constant with considerable uncertainty. The early work on this methodology claimed that K_{Ic} calculations were accurate to within 30 to 40%. Despite this uncertainty, the method is popular because of its seeming simplicity, the need for only one small piece, and the potential to make repeat measurements.

The mediocre success of the early equations prompted the ceramics community to spawn a plethora of alternative expressions, to the point that massive confusion now reigns in the ceramics community (Ref 6, 29) (see, for example, the chapter "Cracked Indents—Friend or Foe" in Ref 6). The failure of a single equation to apply and the large uncertainty in the calibration constants originate in the complicated, material-specific deformation-crack patterns and residual stress fields underneath a hardness indentation. The method also suffers from the drawback that toughness depends on the measured crack length raised to the 1.5 power. The substantial uncertainties in measuring the crack size (far worse than measuring indentation size) are thus magnified. Data consistency among laboratories is usually poor due to variations in the interpretation of the crack length arising from microscopy limitations as well as operator experience or subjectivity. A VAMAS round-robin demonstrated variability of almost a factor of 2 in reported toughness (Ref 30, 31). The requirement to obtain cracks lengths that are sufficiently long ($>2.0\times$ the half diagonal size) has led some to use enormous loads (sometimes up to 500 N, or 50 kgf) that cause severe shattering, prompting one skeptical group to remark that indentations in some materials might resemble "nuclear bomb craters" (Ref 32). This method may have some utility within a laboratory for research purposes, but experience belies its suitability for producing accurate fracture toughness results that can be compared between laboratories.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Instrumented Hardness Testing

Instrumented hardness testing, wherein displacement is monitored during load application, is an important emerging technology. Load displacements typically appear as shown in Fig. 9, but test cycles with partial unloading and reloading are often used. Vickers or Berkovich (triangular pyramid) indenters may be used. The Berkovich indenter avoids the flat, or “chisel tip” that inevitably exists in Vickers pyramids in which four surfaces or edges meet almost (but not quite) at a point. Tip shape is crucial in instrumented hardness tests at low loads. Various indices of hardness may be deduced from the load and depth of penetration of the indenter, and, if it is assumed that the diamond indenter does not change shape, it is even possible to compute a conventional HV hardness. An enormous advantage of this methodology is that it obviates the need for microscopy for measuring the indentation size, thereby eliminating operator skill or subjectivity and microscopy limitations. On the other hand, complications arise because of the need to make assumptions about the analytical form of the load-displacement curves. Unloading curves may be analyzed to determine the elastic modulus, but again assumptions about the indenter shape and penetration geometries must be made. There is no consensus on the interpretation of these curves. For example, one commercial apparatus that is widely used in Europe to measure a so-called “universal hardness” actually measures a hardness defined as the load divided by assumed contact area while the load is still applied. Consequently, this universal hardness includes both plastic and elastic deformation components. Another problem common to all instrumented hardness testers is the uncertainty associated with determining the exact initial contact point.

Fig. 9 A typical load-displacement trace for instrumented hardness testing

Sometimes ordinary microindentation hardness machines may be retrofitted with displacement transducers, but care must be taken to measure displacement as close to the indenter-specimen contact point as possible. Frame compliance is an important source of error with retrofitted machines. Severe variability (up to a factor of 2) in instrumented hardness results were recently demonstrated in a VAMAS round-robin exercise with a borosilicate crown glass and NIST SRM 2830 silicon nitride blocks (Ref 33, 34). Dedicated low-load instrumented hardness or even extremely low-load nanohardness machines are now commercially available. This emerging technology has great promise, but consensus on the analyses, standard procedures, and reference materials are sorely needed.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Hardness and Brittleness

Much of the ceramics literature has thus far emphasized the effect of load and hardness on fracture processes and fracture toughness. It has not considered in detail the reverse effect of fracture on hardness. This article notes that the hardness of a brittle material is a measure of the resistance of the material to deformation, densification, displacement, and fracture. Local fracture around and under an indentation can affect the impression size and can be considered an intrinsic part of the indentation process. The degree of fracture at

ceramic indentations is load dependent. Deformation is predominant at low loads, while fracture is more evident at high loads. The Meyer law is:

$$W = cd^n \quad (\text{Eq 6})$$

where W is the load, c is a constant, and n is the Meyer or logarithmic index. As noted previously, for ceramics and glasses, $n < 2$ and hardness decreases with increasing load. The hardness-load curves for many ceramics deviate somewhat from the empirical Meyer law. This has prompted alternative attempts to achieve improved curve fits to hardness-load or hardness-indentation size data. Bückle (Ref 35) and later Mitsche (Ref 36) suggested a power series expansion that was later simplified to only two terms:

$$W = a_1d + a_2d^2 \quad (\text{Eq 7})$$

where a_1 and a_2 are constants. This equation alternatively may be expressed as an energy balance by multiplying both sides by d :

$$Wd = a_1d^2 + a_2d^3 \quad (\text{Eq 8})$$

The term Wd is proportional to the external work done by the indenter, $W\ell$, where ℓ is the indenter penetration depth, which is proportional to d for self-similar indentations. A number of investigators have attempted to correlate surface energy processes to the a_1d^2 term (Ref 37, 38, 39, 40), while Li et al. (Ref 41, 42) have related this term to frictional and elastic contributions in their “proportional specimen resistance” model. The a_2d^3 term, on the other hand, is considered to be the “work of permanent deformation” (Ref 39) or the “volume energy of deformation” (Ref 42).

Close examination of experimental ceramic Vickers hardness-load curves (on either HV versus load or HV versus diagonal size graphs) suggests a discrete transition point may exist where hardness changes from being load dependent to load independent as shown in Fig. 10 (Ref 43). The Meyer relationship and energy models (Eq 2 3 4) do not predict a specific transition point to constant hardness. The transition point, which is usually overlooked, appears to be associated with the onset of extensive cracking around and underneath the indentation. Cracking, an integral response of the ceramic to indentation even at small loads, may either be localized or, at higher loads, massive to the extent that crushing occurs. Yurkov and Bradt (Ref 44) detected significant acoustic emission activity at the indentation load where the constant hardness plateaus were reached for five sialon ceramics. Knoop hardness does not exhibit an abrupt transition to a constant hardness plateau, presumably because there is less cracking. The Vickers hardness transition point is related to a new index of ceramic brittleness defined as (Ref 43):

$$B = \frac{HV_c \cdot E}{K_{Ic}^2} \quad (\text{Eq 9})$$

where HV_c is Vickers hardness at the plateau, E is the elastic modulus, and K_{Ic} is the fracture toughness.

Fig. 10 Vickers hardness versus load (indentation size effect) curve for ceramics, showing a distinct transition to a plateau hardness, H_c , at W_c

B may also be expressed as:

$$B \propto \frac{HV_c}{2\gamma_f}$$

(Eq 10)

where γ_f is the fracture surface energy. B is the ratio of hardness to the fracture surface energy. Hardness has units of work per unit volume and may be considered the work to create unit deformed volume, whereas γ_f is the work to create unit surface area. In other words, B is a ratio of volume deformation energy to surface fracture energy. Figure 11 shows some hardness versus indentation load data for three ceramics of varying brittleness. The transition point is easy to detect in brittle ceramics such as silicon carbide but may require very careful measurements in less brittle materials.

Fig. 11 Hardness versus load for three ceramics. The silicon carbide is the most brittle of the three.

Indentation Hardness Testing of Ceramics

G.D. Quinn, Ceramics Division, National Institute of Standards and Technology

Summary

Hardness testing of ceramics, while conceptually simple, has many pitfalls. Sound metrological practices using quality equipment (microscopes and optical controls with aperture and diaphragm stops) coupled with the use of ceramic reference blocks will dramatically improve the quality of conventional test data. High-quality ceramic or glass standard test methods that have been backed by major international round-robins are on the books. New schemes for designating conventional hardness will rationalize the reporting of results. Hardness in SI units is widely used and is codified in several world standards. The indentation load should always be reported with the hardness data. New interpretations of conventional tests (such as brittleness, or fracture toughness) and emerging new instrumented hardness technologies hold great promise for the future.

Miscellaneous Hardness Tests

Edward L. Tobolski, Wilson Instrument Division, Instron Corporation

Introduction

MISCELLANEOUS HARDNESS TESTS encompass, for the purpose of this article, a number of test methods that have been developed for specific applications. These include dynamic, or “rebound,” hardness tests using a Leeb tester or a Scleroscope, static indentation tests on rubber or plastic products using the durometer or IRHD testers, scratch hardness tests, and ultrasonic microindentation testing. This article reviews the procedures, equipment, and applications associated with these alternate hardness test methods.

Miscellaneous Hardness Tests

Edward L. Tobolski, Wilson Instrument Division, Instron Corporation

Dynamic (Rebound) Test Methods

Hardness can be empirically related to either the elastic response of a material or the plastic deformation of a material. Indentation hardness tests determine hardness in terms of plastic behavior, while dynamic test methods relate hardness to the elastic response of a material.

A number of dynamic hardness test methods have been developed, but only a few have common use. The two most common methods of dynamic hardness testing are the Shore Scleroscope and the Leeb tester. These two methods are rebound-type tests and are described further here. Other dynamic hardness tests include a pendulum test method and dynamic indentation hardness testing using a Hopkinson-bar technique (the article “Dynamic Indentation Testing” in this Volume contains details).

Scleroscope Hardness Testing

The Scleroscope (Instron Corporation, Canton, MA) dynamic hardness tester was invented by Albert F. Shore in 1907 and was the first commercially available metallurgical hardness tester produced in the United States. While Scleroscopes are not currently manufactured in the United States, the unit is still used frequently for testing very large specimens such as forged steel or wrought alloy steel rolls. In this procedure, a diamond-tipped hammer is dropped from a fixed height onto the surface of the material being tested. The height of rebound of the hammer is a measure of the hardness of the metal.

The Scleroscope scale consists of units determined by dividing into 100 units the average rebound of a hammer from a quenched (to maximum hardness) and untempered water-hardened tool steel. The scale is continued above 100 units to permit testing of materials with hardnesses greater than that of fully hardened tool steel.

Testers. Two types of Scleroscope hardness testers were manufactured. The model C Scleroscope (Fig. 1) consists of vertically disposed barrel containing a precision-bore glass tube. A scale, graduated from 0 to 140, is set behind the tube and is visible through it. Hardness is read from the vertical scale, usually with the aid of a reading glass attached to the tester. A pneumatic actuating head, affixed to the top of the barrel, is manually operated by use of a rubber bulb and tube. The hammer drops and rebounds within the glass tube.

Fig. 1 Model C Scleroscope hardness testers mounted in stands

The model D Scleroscope hardness tester (Fig. 2) may have either analog (dial) or digital readouts. The tester consists of a vertically disposed barrel that contains a clutch to arrest the hammer at the maximum height of rebound. This is possible because of the short rebound height. The hammer is longer and heavier than the hammer used in the model C Scleroscope, developing the same striking energy even through dropping a shorter distance.

Fig. 2 Model D Scleroscope hardness testers mounted in stands

Models C, D, and D digital Scleroscopes were available in two calibrations: standard and roll. Standard calibration, which conforms to ASTM E-448, "Standard Practice for Scleroscope Hardness Testing of Metallic Materials," has a direct correlation to Rockwell C, Brinell, and Vickers hardness values (Table 1). Roll calibration conforms to ASTM A 427, "Standard Specification for Wrought Alloy Steel Rolls for Cold and Hot Reduction," and is used to determine hardness values of homogeneous wrought hardened alloy steel rolls for use in reduction of flat-rolled products. This calibration is symbolized by HFRSc or HFRSd. The model C Scleroscope can also be calibrated in accordance with ASTM C 886, "Standard Test Method for Scleroscope Hardness Testing of Fine-Grained Carbon and Graphite Materials." This is referred to as model C carbon calibration.

Table 1 Approximate hardness conversion numbers for nonaustenitic steels

Scleroscope hardness	Rockwell C hardness number, HRC	Vickers hardness number, HV	Brinell hardness number, HB	
			10 mm standard ball, 3000 kgf load	10 mm carbide ball, 3000 kgf load

35.5	22	248	237	237
34.8	21	243	231	231
34.2	20	238	226	226

Note: These Scleroscope hardness conversions are based on Vickers/Scleroscope hardness relationships developed from Vickers hardness data provided by the National Bureau of Standards for 13 steel reference blocks. Scleroscope hardness values obtained on these blocks by the Shore Instrument and Mfg. Co. Inc., the Roll Manufacturers Institute, and members of this institute, and also on hardness conversions previously published by the American Society for Metals and the Roll Manufacturers Institute.

Source: Ref 1

Both models of Scleroscopes can be mounted on various types of bases, although the model C Scleroscope is commonly used unmounted when testing large workpieces with a minimum weight of 2.3 kg (5 lb). Due to its critical vertical alignment, the model D Scleroscope should not be used unmounted, as erroneous readings may result.

Workpiece Surface Finish. In Scleroscope-hardness testing, certain workpiece surface finish requirements must be met in order to obtain accurate, consistent readings. An excessively coarse surface finish will yield erratic readings; when necessary, the surface of the workpiece should be filed, machined, ground, or polished.

Care should be taken to avoid overheating or excessively cold working the surface. The surface finish required to obtain reproducible results varies with the hardness of the workpiece. In proceeding from soft metals to hardened steel, the required surface finish ranges from a minimum finish, as produced by a No. 2 file, to a finely ground or polished finish.

Limitations on Workpiece and Case Thickness. Case-hardened steel with cases as thin as 0.25 mm (0.010 in.) can be accurately hardness tested provided the core hardness is no less than 30 Scleroscope. Softer cores require a minimum case thickness of 0.38 mm (0.015 in.) for accurate results.

Thin strip or sheet may be tested, with some limitations, but only when the Scleroscope hardness tester is mounted in a clamping stand. Ideally, the sheet should be flat and without undulation. If the sheet material is bowed, the concave side should be placed upwards to preclude any possibility of erroneous readings due to spring effect. The minimum thicknesses of sheet in various categories that may be hardness tested with a Scleroscope are as follows:

Metal	Minimum thickness	
	mm	in.
Hardened steel	0.13	(0.005)
Cold-finished steel strip	0.25	(0.010)
Annealed brass strip	0.38	(0.015)
Half-hard brass strip	0.25	(0.010)

Test Procedure. To perform a hardness test with either the model C or the model D Scleroscope, the tester should be held or set in a vertical position, with the bottom of the barrel in firm contact with the workpiece. The hammer is elevated and then allowed to fall and strike the surface of the workpiece. The height of rebound is then measured, which indicates the hardness.

When using the model C Scleroscope, the hammer is elevated by squeezing a pneumatic bulb. The hammer is released by again squeezing the bulb. When using the model D Scleroscope, the hammer is elevated by turning a knurled control knob clockwise until a definite stop is reached. The hammer strikes the workpiece when the control knob is released, and the reading is recorded on a dial. Hard steel tests about 100, medium-hard about 50, and soft metals 10 to 15.

Vertical Alignment. To minimize error, the hardness tester must be set or held in a vertical position, using the plumb rod or level on the machine to determine vertical alignment. The most accurate readings are obtained with the Scleroscope hardness tester mounted in a C-frame base that rests on three points, two of which are adjustable to facilitate leveling of the anvil and to ensure vertical alignment of the barrel. When using a

mounted tester, the opposite sides of the workpiece must be parallel to each other. Vibration impedes the free fall of the hammer, thereby producing low readings, and must be avoided.

Spacing of Indentations. Indentations should be singly spaced at least 0.50 mm (0.020 in.) apart. Flat workpieces with parallel surfaces may be hardness tested within 6 mm (0.25 in.) of the edge when properly clamped.

Taking the Readings. Experience is necessary to interpret readings accurately on a model C Scleroscope hardness tester. Thin materials, or those weighing less than 2.3 kg (5 lb), must be securely clamped to absorb the inertia of the hammer. The sound of the impact is an indication of the effectiveness of the clamping; a dull thud indicates that the workpiece has been clamped solidly, whereas a hollow ringing sound indicates that the workpiece is not tightly clamped or is warped and not properly supported. Five hardness determinations should be made, and their average taken as representative of the hardness of a particular workpiece.

Calibration. Scleroscope hardness testers are supplied with reference bars (or test blocks) of known hardness. The reference bars can be used correctly only with the Scleroscope mounted in a clamping stand, because they do not have sufficient mass to produce a full rebound of the hammer unless firmly clamped. If actual Scleroscope readings do not correspond to the values of the reference bars, the instrument should be returned to the manufacturer for service.

Advantages. The Scleroscope hardness test has several advantages. Tests can be made very rapidly; over 1000 tests per hour are possible. Operation is simple and does not require highly skilled technicians.

The model C Scleroscope is portable and can be used unmounted for testing workpieces of unlimited size (rolls and large dies). The Scleroscope hardness test is considered a nonmarring test; no obvious crater is left and only in the most unusual instances would the tiny hammer mark be objectionable on a finished workpiece. Additionally, a single scale covers the entire hardness range from the softest to the hardest metals.

Limitations of the Scleroscope hardness test include the necessity of keeping the test instrument in a vertical position so that the hammer can fall freely. Scleroscope hardness tests are more sensitive to variations in surface conditions than other hardness tests are. Because readings taken with the model C Scleroscope are indicated by the maximum rebound of the hammer on the first bounce, even the most experienced operators may disagree by one or two points. Also, the mass or configuration of the part can affect the accuracy of readings.

Leeb Scale (Equotip) Hardness Testing

Leeb testers (Fig. 3) are portable hardness testers that operate on a dynamic rebound principal similar to the Scleroscope. An impact device is propelled into the sample using a spring for the initial energy. The impact device travels a short distance until it contacts the sample. A small indent is formed, and the impact device rebounds away from the test surface according to the hardness and elasticity of the material. An electronic induction coil measures the velocity of the impact device before and after it contacts the sample. The Leeb hardness number is defined as the following:

$$L = \frac{\text{Rebound velocity}}{\text{Impact velocity}} \times 1000$$

The Leeb hardness number is followed by “HL,” with one or more suffix characters representing the impact device (Table 2). Leeb hardness is also known as Equotip hardness (for example, in ASTM A 956 “Standard Test Method for Equotip Hardness Testing of Steel Products”). (Equotip is the trademark of PROCEQ SA, Zurich, Switzerland.)

Table 2 Application guidelines for Leeb hardness testers

Impact device	Maximum hardness, HRC	Minimum sample size		Description and use guidelines
		kg	lb	
D	68	5	11	The basic impact device used for most testing of forged and cast steels, aluminum alloys, copper alloys, and cast irons
DC	68	5	11	A special impact device designed to make hardness measurements in very confined spaces such as bores. Material applications are the

				same as those for the D device.
D + 15	68	5	11	A special impact device, very slim with the measuring coil set back for access to small holes and grooves. Material applications are the same as those for the D device.
G	60	15	33	A special impact device, larger in size and impact energy than the other devices, for use on large, heavy test pieces. For testing of steel forgings, cast iron, and cast steel
C	68	1.5	3.3	A special impact device with low impact energy that can be used for testing of surface-hardened components, coatings, and thin-walled components of steel
E	70	5	11	A special impact device, with a synthetic diamond test tip that can be used for testing of steel forgings or castings with extremely high hardness

Fig. 3 Handheld Leeb hardness tester

Testers. By definition, all Leeb testers are electronic; therefore, they display the hardness result digitally. There are several different types available to test a variety of different size and shape samples (Table 2). The D model is the most common and suits a wide variety of materials. All models use either a tungsten carbide ball or diamond as the indenter part of the impact device. Since the Leeb hardness value is not recognized universally, most of the testers provide a built-in conversion to the other more common hardness scales (Rockwell, Brinell, Vickers, and Scleroscope). The problem with these conversions is that they are very material dependent, usually a function of the elastic modulus of the material. Therefore, most units include separate conversion data for several different classes of materials. Steels, cast iron, aluminum, and brass are some of the materials normally included internal to the tester.

Operation of the Tester. The Leeb testers are very simple to use. First, it is necessary to compress the impact device against the spring and lock it in place. Then the unit is positioned carefully over the test point, making sure that it is perpendicular to the surface. The release button is then pressed, allowing the impact device to be propelled into the sample. As soon as the impact is felt, the result is indicated on the digital display.

Applications. Table 2 shows the normal applications for the various types. Since the test uses a rebound principle, the mass of the sample is critical to the test result. Table 2 shows the desired minimum mass of the sample for the different types. Smaller masses can be tested by carefully coupling the sample to a larger mass. The Leeb testers also normally have the ability to test at various angles. Correction factors are frequently built into the tester or provided as a table. The table provides a value to be subtracted from the result to account for the effect of gravity on the velocity of the impact device when testing in any position other than vertical.

Like all hardness tests, the surface finish of the test point is important to the accuracy of the results. Rougher surfaces will normally give softer results. Concave or convex surfaces can be tested with a Leeb tester if the radius of curvature is greater than 30 mm (1.18 in.) for all units except the G type, which requires a radius of 50 mm (2 in.). Most testers can be purchased with a variety of adapters to facilitate the testing of various round and odd surfaces.

Calibration. The only method to verify the calibration of Leeb testers is by using standardized test blocks. The procedure is to make ten readings on the test surface of the blocks and average the readings. If the average is within 13 numbers of the calibration certificate, the unit is considered calibrated. A limited number of hardness ranges are available from the manufacturers.

Miscellaneous Hardness Tests

Edward L. Tobolski, Wilson Instrument Division, Instron Corporation

Durometer Hardness Testing

The durometer is a hand-sized instrument that measures the indentation hardness of rubber and plastic products. It is manually applied to the test specimen, and the reading is observed on a dial or digital indicator. Laboratory accuracy can also be obtained by mounting the durometer on one of several types of operating stands. Durometer hardness is the resistance of the material being tested to the penetration of the indenter as the result of a variable force applied to the indenter by a spring. An infinitely hard material would yield a durometer hardness of 100, because there would be zero penetration.

Durometer selection depends on the material being tested. Several types of durometers are available, as shown in Table 3. All of these conform to ASTM D 2240, "Standard Test Method for Rubber Property—Durometer Hardness."

Table 3 Specifications of durometers

Durometer type	Main spring	Indenter	Applications
A (conforms to ASTM D 2240)	822 g	Frustum cone	Soft vulcanized rubber and all elastomeric materials, natural rubber, GR-S, GR-I, neoprene, nitrile rubbers, Thiokol, flexible polyester cast resins, polyacrylic esters, wax, felt, leather, etc.
B	822 g	Sharp 30° included angle	Moderately hard rubber such as typewriter rollers, platens, etc.
C	4.54 kg (10 lb)	Frustum cone	Medium-hard rubber and plastics
D (conforms to)	4.54 kg	Sharp 30°	Hard rubber and the harder grades of plastics such as rigid

ASTM D 2240)	(10 lb)	included angle	thermoplastic sheet, Plexiglas (AtoHaas Americas, Inc., Philadelphia, PA), polystyrene, vinyl sheet, cellulose acetate and thermosetting laminates such as formica (Formica Corp., Cincinnati, OH), paper-filled calendar rolls, calendar bowls, etc.
D0	4.54 kg (10 lb)	2.38 mm ($\frac{3}{32}$ in.) sphere	Very dense textile windings, slasher beams, etc.
0	822 g	2.38 mm ($\frac{3}{32}$ in.) sphere	Soft printer rollers, Artgum, medium-density textile windings of rayon, orlon, nylon, etc.
00	113 g (4 oz)	2.38 mm ($\frac{3}{32}$ in.) sphere	Sponge rubber and plastics, low-density textile windings; not for use on foamed latex
000 (available with round dial only)	113 g (4 oz)	12.7 mm ($\frac{1}{2}$ in.) diam spherical	Ultrasoft sponge rubber and plastic
T	822 g	2.38 mm ($\frac{3}{32}$ in.) sphere	Medium-density textile windings on spools and bobbins with a maximum diameter of 100 mm (4 in.); types T and T-2 have a concave bottom plate to facilitate centering on cylindrical specimens

With the exceptions of types 00 and M, all durometer types are variations of the ASTM types A and D specifications by changing the indenters and/or load springs. Durometers are available with either a round or quadrant style face (Fig. 4) or with a digital display (Fig. 5). The M style is not available in the quadrant design. Pencil-style durometers are also available, but only in the A scale (Fig. 6).

Fig. 4 Round- and quadrant-style durometer hardness testers

Fig. 5 Digital durometer with stand

Fig. 6 Pencil durometer hardness tester

The total measurement range is from 0 to 100 points. This represents a total travel of the indenter of 2.5 mm (0.10 in.) for all scales except the M scale, which is 1.25 mm (0.05 in.). The hardness numbers are typically displayed in increments that vary from five points for the quadrant and pencil styles, to one point for the round, and in tenths of a point on digital units.

The M scale is relatively new and was developed to test O-rings. Testing small round sections down to 1.25 mm (0.05 in.) is possible with the M scale. This is possible because of a smaller spring load and shorter depth of penetration. Because of the increased sensitivity, M scale units can only be used in a stand. Normally, the stand is equipped with an alignment fixture to properly align the round samples with the indenter. Proper alignment is critical to obtain accurate results.

Testing Procedure. Test specimens should have a minimum thickness of at least 6 mm (0.2 in.) (1.25 mm, or 0.05 in., for the M scale), unless it is known that identical results are obtained on thinner specimens. Thinner specimens may be stacked to obtain an indicative reading.

Readings should not be taken on an uneven, irregular, or coarsely grained surface. Round or cylindrical surfaces, such as rubber rollers, can be tested by “rocking” the durometer on the convex surface and observing the maximum reading that is attained when the indenter is aligned with the axis of the roller.

Application pressure should be sufficient to ensure firm contact between the flat bottom of the durometer and the test specimen; the reading should be taken within 1 s after firm contact has been established. However, after attaining an initially high reading, the dial hand may gradually recede on specimens exhibiting cold flow or creep characteristics (such as nitrile rubber stock). In such instances, both the instantaneous, or maximum, reading and the reading after a specified time interval—for example, 10 or 15 s—should be recorded.

Testing Results. Durometer hardness numbers, although arbitrary, have an inverse relationship to indentation by the indenter. For example, a reading of 30 on the type A durometer on a soft rubber roller indicates an indenter indentation of 1.8 mm (0.07 in.). Similarly, a reading of 90 on a neoprene faucet washer indicates an indenter indentation of 0.25 mm (0.01 in.). The use of the durometer at the extreme ends of the scale (below 20 and above 90) is not recommended. Materials reading above 90 on the type A scale should be tested with the type D durometer. Materials reading below 20 on the type D scale should be tested with a type A durometer.

One of the most common causes of disagreement in readings among operators is variation in the speed with which the durometer is applied to the elastomer. For example, in testing a high-creep nitrile rubber, if the durometer is applied too rapidly to the test specimen, an erroneously high reading is initially attained, with the dial hand dropping as the durometer is held in contact. At the other extreme, the durometer may be applied too slowly, causing a significant percentage of indenter penetration to occur before the presser foot of the durometer is in flush contact with the test specimen, resulting in an inaccurately low reading.

Disagreement can also occur when an insufficient number of tests have been made. Reporting the average of five readings gives the best results. Tests on a particular material should all be run at the same temperature. Proper spacing must be allowed between the test point and the edge of the sample.

Scale Relationships. It should be noted that there is no fixed relationship between the test results from the different scales. A hardness reading of 50 on the A scale is not the same hardness as a 50 reading on the M or any other scale.

Durometer Calibration. Durometers frequently are equipped with a metal or rubber test block, which enables the user to ascertain whether the durometer is operating properly at one point on the scale (usually 60 durometer). The metal test block consists of a flat piece of metal with a blind hole on its top surface. When the presser foot is held against the top surface with the indenter in the blind hole, the durometer reading should agree with the hardness number stamped on the side of the block, within plus or minus one point. Rubber test blocks are simply tested like a sample and the result compared to the certificate.

A correct reading on the test block does not mean that the durometer is in calibration. The only way to accurately verify the durometer is to directly measure the loads applied over the full range for a given indicating device, indenter extension, and indenter shape. Calibrations of this type are recommended annually.

A durometer calibrating device is also available. This mechanism has limited capabilities and is recommended for end users who have several durometers to monitor. The durometer may be returned to the manufacturer for periodic inspection and calibration.

Auxiliary Equipment. The operating stand (Fig. 7) is designed to enable absolutely flush application of the durometer to the test specimen, thus eliminating errors in readings due to out-of-perpendicular contact. The stand is intended primarily for testing specimens with parallel opposite sides (except for the M-scale stands that provide a means to align O-rings). Additional weights are frequently applied to the top of the stands (see the

tester setup on the right side of Fig. 7). The higher load on the presser foot can greatly improve the repeatability of the results. Operating stands normally provide some means to ensure constant velocity and constant load applications. This helps to eliminate user error due to too rapid or too slow an application, as discussed earlier.

Fig. 7 Durometer hardness testers mounted in operating stands

Miscellaneous Hardness Tests

Edward L. Tobolski, Wilson Instrument Division, Instron Corporation

IRHD Rubber Hardness Testing

International rubber hardness degrees (IRHD) testing is very similar to durometer testing with some important differences. Durometer testers apply a load to the sample using a calibrated spring and a pointed or blunt-shaped indenter. The load, therefore, will vary according to the depth of the indentation because of the spring gradient. The IRHD tester uses a minor-major load system of constant load and a ball indenter to determine the hardness of the sample. In the procedure, the minor load is applied to the sample through the ball indenter. After 5 s, the depth-measuring system is set to zero. The higher major load is then applied. After 30 s, the IRHD hardness number is read from the depth-measuring indicator.

Testers. The instruments used for IRHD testing look very similar to the durometer testers described in the previous section. The IRHD tester cannot be used as a handheld instrument due to the requirements to apply the minor and major loads accurately. Therefore, all IRHD units have a built-in stand to hold the indicator and loading mechanism. The presser foot size and load applied to it during the test are critical to the final results.

Applications. IRHD testers come in two different versions, standard and micro (see Table 4) and are capable of testing a range of soft elastomers. The standard units are intended to test flat parallel samples thicker than 4 mm

(0.16 in.). Microtesters can test parts as thin as 1 mm (0.04 in.) and are used to test O-rings or other curved samples. A maximum of two layers of material may be used to reach the minimum thickness requirements. The test spacing and edge-clearance requirements for IRHD testing are similar to those of durometer testing.

Table 4 Comparison of standard and micro IRHD hardness testers

Parameter	Standard testers	Microtesters
Diam of ball, mm	2.50 ± 0.01	0.395 ± 0.005
Minor force on ball, N	0.29 ± 0.02	0.0083 ± 0.0005
Major force on ball, N	5.4 ± 0.01	0.1455 ± 0.0005
Total force on ball, N	5.7 ± 0.03	0.153 ± 0.001
Outside diam of foot, mm	6 ± 1	1.00 ± 0.15
Force on foot, N	8.3 ± 1.5	0.235 ± 0.03

Miscellaneous Hardness Tests

Edward L. Tobolski, Wilson Instrument Division, Instron Corporation

Scratch Hardness Tests

Scratch hardness tests represent the oldest type of hardness evaluation procedures. The two most common techniques for measuring scratch hardness are the Mohs scale, which is used for testing minerals, and the file hardness test, which is used for testing steels.

A third type of scratch hardness test sometimes referred to as the “plowing test” is not discussed in detail in this article. This test measures the width of a scratch made by drawing a diamond indenter across the surface under a definite load. Loads on the indenter of 1, 2, 5, 10, and 25 g are commonly used. This is a useful tool for studying the relative hardness of microconstituents, but it does not lend itself to high reproducibility or extreme accuracy. For more information, see the article “Scratch Testing” in this Volume.

The Mohs scale of hardness was devised in 1822 by German mineralogist Friedrich Mohs. The Mohs scale consists of ten minerals arranged in order from 1 (softest) to 10 (hardest). Each mineral in the scale will scratch all those below it:

Mineral	Hardness index
Diamond	10
Corundum	9
Topaz	8
Quartz	7
Orthoclase (feldspar)	6
Apatite	5
Fluorite	4
Calcite	3
Gypsum	2
Talc	1

The steps between numbers on the scale are not of equal value; for example, the difference in hardness between 9 and 10 is much greater than between 1 and 2. To determine the hardness of a mineral, it must be determined which of the standard materials the unknown will scratch. The hardness will lie between two points on the scale, the point between the mineral, which may be scratched, and the next one harder.

Materials engineers and metallurgists find little use for the Mohs scale due to its nonquantitative nature. However, the hardness of iron with 0.1% carbon maximum is between 3 and 4 on the Mohs scale, and copper is between 2 and 3. Fully hardened high-carbon tool steel is between 7 and 8.

The file hardness test was one of the first scratch tests used for evaluating the hardness of metallic materials. The file test is useful in estimating the hardness of steels in the high hardness ranges. It provides information on soft spots and decarburization quickly and easily and is readily adaptable to odd shapes and sizes that are difficult to test by other methods.

Standard test files are heat treated to approximately 67 to 70 HRC. The flat face of the file is pressed firmly against, and slowly drawn across, the surface to be tested. If the file does not bite, the material is designated as file hard. A number of factors, such as pressure, speed, angle of contact, and surface roughness, influence the results of the test. Consequently, its ability to give reproducible hardness values is rather limited, and reasonable accuracy is obtained only at the highest hardness levels.

Ultrasonic Microhardness Testing

Ultrasonic microhardness testing offers an alternative to the more conventional methods based on visual (microscopic) evaluation of an indentation after the load has been removed. Ultrasonic testing uses a maximum indentation load of approximately 800 gf. Therefore, as in other microhardness techniques, the indentation depth is relatively small (from 4 to 18 μm). In the vast majority of instances, the workpiece surface is unharmed, thus classifying this test as nondestructive. Measured values in either the Vickers or Rockwell C scale are displayed on a digital readout display directly after penetration of the test piece. This feature renders the method suitable for automated on-line testing. Up to 1200 parts/h can be tested.

In ultrasonic microhardness testing, a Vickers diamond is attached to one end of a magnetostrictive metal rod. The diamond-tipped rod is excited to its natural frequency by a piezoelectric converter. The resonant frequency of the rod changes as the free end of the rod is brought into contact with the surface of a solid body. Once the device is calibrated for the known modulus of elasticity of the tested material, the area of contact between the diamond tip and the tested surface can be derived from the measured resonant frequency. The area of contact is inversely proportional to the hardness of the tested material, provided the force pressing the surface is constant. Consequently, the measured frequency value can be converted into the corresponding hardness number.

Components of an ultrasonic hardness tester are shown schematically in Fig. 8. The hardness number is displayed on a digital readout, while the oscillating rod is retracted to protect it until the next reading. The entire process generally takes less than 15 s. This type of instrument is quite small and can be battery powered for portability. The automatic probe allows hardness measurements to be made in any orientation, further enhancing its usefulness. By means of a probe and suitably designed fixtures for holding the probe, the possibilities are virtually unlimited. For example, Fig. 9 shows the test point, fixture, and actual testing of fillet radii on an engine crankshaft. In this instance, it was possible to take ten readings/min.

Various types of probes are available, but one popular type has a round, flat end and can be handheld. This type of instrument is most frequently used on flat workpieces. In one specific instance, a die casting plant was experiencing problems with heat checking dies. The dies were made from H13 tool steel, quenched and tempered. On-site hardness tests with an ultrasonic instrument proved that the superficial surface was quite soft as a result of decarburization, even though Rockwell C readings (actual) were acceptable. The decarburized layer was thus the cause of heat checking, and corrective measures were applied to the heat treating procedure.

Capabilities of Ultrasonic Microhardness Testing. There are several advantages of the ultrasonic hardness testing system. With ultrasonic hardness testing, one advantage is the ability to measure the area of indentation during loading. This differs from conventional microhardness tests, where the indent area is determined after loading. This conventional method can lead to erroneous hardness values due to elastic recovery on unloading (see Fig. 1 in the article "Selection and Industrial Applications of Hardness Tests" in this Volume).

As in conventional Vickers and Brinell hardness testing, a single loading force is used. Thus, in ultrasonic hardness testing, no time is lost in consecutive load application as in Rockwell testing. Because only one test load is used in ultrasonic testing, sensitive displacement-measuring instruments are not necessary, and rigid machine frames are not required. In many instances, it is possible to perform the hardness measurement with ultrasonic testing without clamping or rigidly supporting the test material, which simplifies design and handling.

Because the sensitivity and resolving power of the ultrasonic instrument can be increased to high levels, it is possible to measure even the smallest indentation. Hardness profile curves can be obtained by untrained personnel automatically in a fraction of the time previously required. The digital display virtually eliminates operator interpretation errors. A memory feature, which will hold the last reading displayed for up to 3 min or until another reading is taken, facilitates any manual recording of data that is necessary.

A one-point calibration procedure allows the instrument to be set up quickly and easily. The few controls and adjustments that are required, coupled with a motor-driven probe, facilitate repeatable test results. The portability of ultrasonic microhardness testers allows hardness evaluations to be taken not only in a laboratory environment but also on site, in the field, and in any specimen orientation. Inspection of large parts and on-line, in-process inspection hardness testing is possible.

Typical applications of ultrasonic microhardness testing are in the automotive, nuclear, petrochemical, aerospace, and machinery manufacturing industries, including finished goods with hardened surfaces, thin case-hardened parts, thin sheet, strip, coils, platings, and coatings. Often, 100% inspection is possible on critically stressed components. Small components and difficult-to-access parts can also be tested by the ultrasonic microhardness method, either in a handheld or a fixtured mode.

Portability is one of the important advantages of ultrasonic microhardness testers. The entire assembly fits into a convenient carrying case so that it can be easily hand carried. It is, by far, the most portable microhardness tester and exceeds the Scleroscope in degree of portability. While it is preferable to hold the element in a fixture and test on a flat surface, there are numerous other positions in which it can be used with a wide variety of fixtures, or by hand with the probe. Thus, this type of instrument is not only a laboratory instrument but can also be used as an on-site inspection tool.

Limitations of Ultrasonic Microhardness Testing. The principal disadvantage of the ultrasonic technique is the lack of an optical system, a characteristic that is, in many cases, an advantage. Reading the indentations by an optical system is slow and tedious, but it does permit precise location of the indenter in relation to locations on the test metal. With the ultrasonic system, obtaining readings on microconstituents becomes difficult, because there is no way to precisely spot the indenter.

This characteristic of ultrasonic testing is, in many instances, a drawback in making hardness traverses on case-hardened steels. With the conventional Vickers or Knoop systems, common practice is to position the test piece so that the first indentation is made at some prescribed distance from the edge, such as 0.05 or 0.10 mm (0.002 or 0.004 in.), for example, and then make a series of indentations at established intervals for the distance required to determine the depth of hard case. With ultrasonic instruments, however, positioning the indenter to obtain a near-the-edge reading is very difficult. This difficulty can be overcome by taking the first reading at an appreciable distance from the edge (beyond the point at which the case exists), then working outward at prescribed intervals toward the edge until a very soft reading occurs, thus indicating that the indenter has reached the softer mounting material.

Surface Finish Requirements. Regardless of other variations, ultrasonic testing actually constitutes microhardness testing, and as such, the surface finish of the test material must be taken into account. To accurately measure any Vickers (diamond pyramid) indentation, it must be clearly defined. Therefore, requirements for surface finish are stringent. These requirements become increasingly stringent as the load decreases. Therefore, to accommodate the force used in ultrasonic testing, a metallographic finish is required. When grinding or polishing, or when both operations are necessary for specimen preparation, care should be taken to minimize heating and distortion of the specimen surface. Polishing should be performed according to the procedures outlined in ASTM E 3, "Standard Practice for Preparation of Metallographic Specimens." When

the specimen to be tested for microhardness will also be used for metallographic examination, mounting (usually in plastic) and polishing are justified. In other instances, only polishing is required.

When mounting is not necessary, fixtures may be used for holding the specimens or workpieces. Most workpieces can be adapted to any one of the commonly used fixture types. The fixture must maintain a rigid surface perpendicular to the indenter. A holding and polishing vise can reduce preparation time because the specimen can be polished and tested without removing it from the vise. A turntable vise fixture is convenient for holding mounted specimens.

When ultrasonic readings are taken in the shop on actual workpieces, some means of obtaining a good surface finish must be used. This goal usually can be accomplished by metallographic emery papers. As a rule, it is desirable to avoid stock removal on actual parts that are scheduled to undergo hardness testing.

Selection and Industrial Applications of Hardness Tests

Andrew Fee, Consultant

Introduction

HARDNESS TESTING includes a variety of techniques that can be generally classified into the following categories (Ref 1):

- Indentation tests (such as Brinell, Rockwell, Vickers, Knoop, and ultrasonic testing)
- Scratch tests (such as the Mohs test)
- Dynamic tests (such as the Shore test and Hopkinson pressure bar methods)
- Abrasion tests
- Erosion tests

The more common types of hardness tests are the indentation methods, described in previous articles in this Section. These tests use a variety of indentation loads ranging from 1 gf (microindentation) to 3000 kgf (Brinell). Low- and high-powered microscopes (Brinell, Vickers, and microindentation) also help measure the resulting indentation diagonals from which a hardness number is calculated using a formula. In the Rockwell test, the depth of indentation is measured and converted to a hardness number, which is inversely related to the depth. Another type of indentation test is ultrasonic hardness testing, which is described further in the article “Miscellaneous Hardness Tests” in this Volume.

A general comparison of indentation hardness testing methods, including ultrasonic, is given in Table 1. This article focuses principally on the selection and application of Brinell, Rockwell, Vickers, and Knoop methods. However, ultrasonic hardness testing is also an important method, because the area of indentation is measured *during* the application of load. This is an important feature that is not affected by elastic recovery. For example, a perfect indentation made with a perfect Vickers indenter would be a square (Fig. 1a). However, anomalies may be observed with a pyramid indenter. The pincushion indentation (Fig. 1b) can occur from the inward sinking of the metal around the flat faces of the pyramid. This condition is observed with annealed metals and results in an overestimate of the diagonal length. The barrel-shaped indentation in Fig. 1(c) is found in cold-worked metals. It results from ridging or piling up of the metal around the faces of the indenter. The diagonal measurement in this case produces a low value of the contact area so that the hardness numbers are erroneously high. These types of anomalies can be prevented in ultrasonic testing, which is based on measurement of the indentation area under load.

Table 1 Comparison of indentation hardness tests

The minimum material thickness for a test is usually taken to be 10 times the indentation depth.

Test	Indenter(s)	Indent		Load(s)	Method of measurement	Surface preparation	Tests per hour	Applications	Remarks
		Diagonal or diameter	Depth						
Brinell	Ball indenter, 10 mm (0.4 in.) or 2.5 mm (0.1 in.) in diameter	1–7 mm (0.04–0.28 in.)	Up to 0.3 mm (0.01 in.) and 1 mm (0.04 in.), respectively, with 2.5 mm (0.1 in.) and 10 mm (0.4 in.) diam balls	3000 kgf for ferrous materials down to 100 kgf for soft metals	Measure diameter of indentation under microscope; read hardness from tables	Specially ground area for measurements of diameter	50 with diameter measurements	Large forged and cast parts	Damage to specimen minimized by use of lightly loaded ball indenter. Indent then less than Rockwell
Rockwell	120° diamond cone, 1.6–13 mm ($\frac{1}{16}$ to $\frac{1}{2}$ in.) diam ball	0.1–1.5 mm (0.004–0.06 in.)	25–375 µm (0.1–1.48 µin.)	Major 60–150 kgf Minor 10 kgf	Read hardness directly from meter or digital display	No preparation necessary on many surfaces	300 manually 900 automatically	Forgings, castings, roughly machined parts	Measure depth of penetration, not diameter
Rockwell superficial	As for Rockwell	0.1–0.7 mm (0.004–0.03 in.)	10–110 µm (0.04–0.43 µin.)	Major 15–45 kgf Minor 3 kgf	As for Rockwell	Machined surface, ground	As for Rockwell	Critical surfaces of finished parts	A surface test of case hardening and annealing
Vickers	136° diamond pyramid	Measure diagonal, not diameter	30–100 µm (0.12–0.4 µin.)	1–120 kgf	Measure indent with low-power microscope; read hardness from tables	Smooth clean surface, symmetrical if not flat	Up to 180	Fine finished surfaces, thin specimens	Small indent but high local stresses
Microhardness	136° diamond	40 µm (0.16	1–4 µm (0.004–0.016	1 gf-1 kgf	Measure indentation	Polished surface	Up to 60	Surface layers, thin	Laboratory test used on brittle

	indenter or a Knoop indenter	μin.)	μin.)		with low-power microscope; read hardness from tables			stock, down to 200 μm	materials or microstructural constituents
Ultrasonic	136° diamond pyramid	15–50 μm (0.06–0.2 μin.)	4–18 μm (0.016–0.07 μin.)	800 gf	Direct readout onto meter or digital display	Surface better than 1.2 μm (0.004 μin.) for accurate work. Otherwise, up to 3 μm (0.012 μin.)	1200 (limited by speed at which operator can read display)	Thin stock and finished surfaces in any position	Calibration for Young's modulus necessary, 100% testing of finished parts. Completely nondestructive

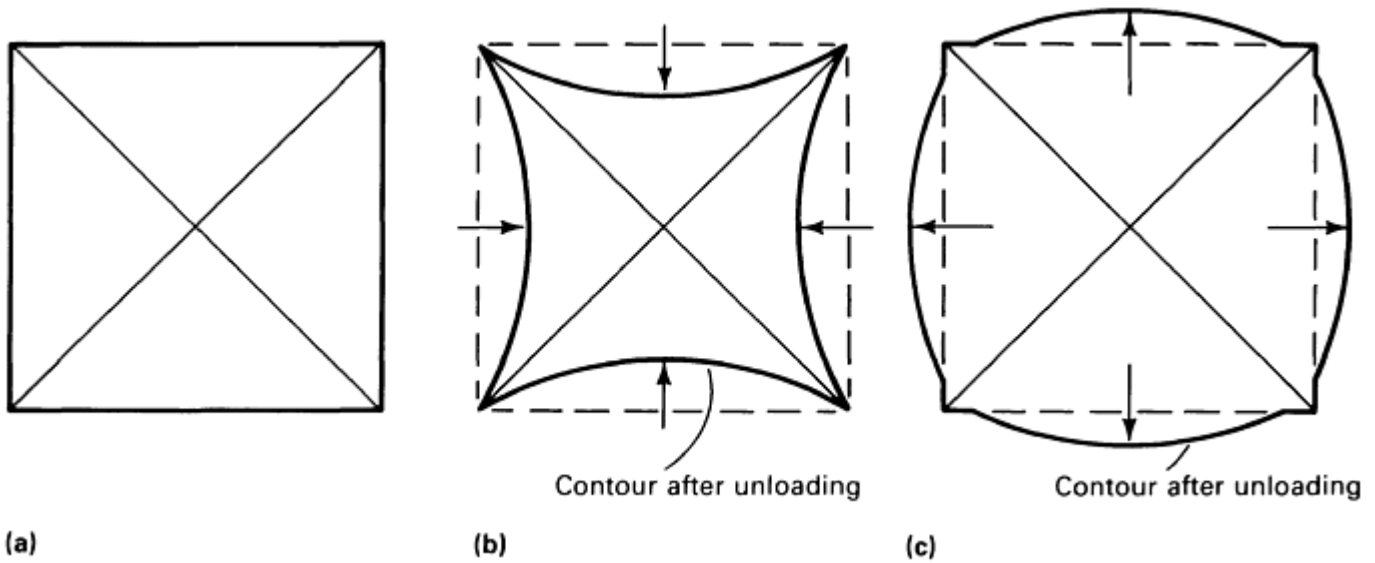

Fig. 1 Distortion of diamond pyramid indentations due to elastic effects. (a) Perfect indentation. (b) Pincushion indentation due to material sinking in and around the flat faces of the pyramid. (c) Barreled indentation due to ridging of the material around the faces of the indenter

Selection and Industrial Applications of Hardness Tests

Andrew Fee, Consultant

General Factors

Selection of a hardness test is relatively straightforward if tests are conducted on simple, flat pieces with a minimum thickness of about 3 mm (0.125 in.) and a homogeneous composition or microstructure. However, in actual applications there are a number of factors that can have a significant effect on the method selected and the interpretation of test results. General factors (not necessarily in order of importance) that influence the selection of hardness include:

- Hardness level (and scale limitations)
- Specimen thickness
- Size and shape of the workpiece
- Specimen surface flatness and surface condition
- Indent location
- Production rates
- Type of material being tested

The first six factors in this list are reviewed in this section; the remaining sections focus on selection for specific types of materials and industrial applications of hardness tests.

Hardness Level and Scale Limitations

It is essential to select a suitable hardness scale for good repeatability of test results. Selection of an appropriate hardness scale depends on the expected hardness range of the material being tested (which can be determined from its general composition and processing history or some trial-and-error tests) and on the type of indenter.

Diamond Indenters. There is no upper hardness limit when using the diamond indenters for Rockwell, Vickers, and Knoop scales. The only limitations are:

- Because Rockwell diamond indenters are not calibrated below 20 HRC, they should not be used when readings fall below this level.
- When performing Vickers testing, hardness must be high enough so that only the diamond portion of the penetrator is in contact with the material and not the mounting material.

Brinell Ball Indenters. For hard test materials, the ball indenter of the Brinell tester may undergo deformation. The standard Brinell ball has been changed from steel to carbide to minimize permanent ball deformation when testing very hard materials. Even when using a tungsten carbide ball, some elastic or temporary deformation will occur, but the extent of this is small and will have only a negligible effect on the final results. For the Brinell test, it is recommended that the test force be of such magnitude that it produces an indentation of 25 to 60% of the ball diameter; that is, the ideal indentation for a 10 mm (0.4 in.) ball should range from 2.5 to 6.0 mm (0.10 to 0.24 in.) in diameter. The reading error of the small diameters becomes very critical and the test becomes supersensitive as small changes in hardness create large diameter changes. For indentation diameters greater than 6.0 mm (0.24 in.) the test becomes insensitive. Recommended hardness ranges for various forces to produce the above range of indentation diameters (using a 10 mm, or 0.4 in., diam ball) are:

Rockwell Ball Indenters. Rockwell scales using the ball indenters (e.g., Rockwell B) range from 0 to 130 points; however, readings above 100 should be avoided, except under special circumstances. The ball indenter can be easily damaged when testing material above 100; therefore it is necessary to change the ball

Load, kgf	Recommended hardness range, HB
3000	96–600
1500	48–300
500	16–100

frequently to avoid errors.

Between 100 and 130, the extreme tip of the ball is used. Because of the blunt shape of the ball at this location, the sensitivity of most scales is poor. It should be realized that as the diameter of the ball is increased the sensitivity of the test decreases. Therefore, it is recommended that the smallest diameter ball should always be used. On the other hand, if Rockwell B readings are below 50, the indenter may be sinking too deeply for accurate readings, and the load should be decreased or the size of the indenter should be increased. This also applies to the Rockwell E and F scales.

Specimen Thickness

The material immediately surrounding indentations is cold worked due to the flow of the material caused by the indenting process. The extent of this cold-work area depends on the material and any previous work hardening of the test specimen. The depth of material affected also extends down below the indentation. Studies and experiments indicate that the affected zone is approximately 10 times the indentation depth. Therefore, as a rule it is recommended that the thickness of the specimen be at least 10 times the depth of indentation with diamond indenters and 15 times with ball indenters. There should not be any deformation or mark visible on the opposite side of the test specimen after testing, although not all such markings are indicative of a bad test. Any bulging or marking on the underside of the specimen is commonly referred to as “anvil effect,” (see the section “Anvil Effect” in this article).

Depth of the Brinell indentation can be calculated from:

$$\text{Depth of indentation (in mm)} = \frac{F}{D \times (HB)(\pi)}$$

where F is the force (in kgf), D is the ball diameter (in mm), and (HB) is the Brinell hardness number. Table 2 is a summary of minimum thickness requirements for Brinell tests done at 500, 1500, and 3000 kgf with a 10 mm (0.4 in.) ball; other forces and ball sizes can be calculated using the above formula.

Table 2 Minimum thickness requirements for Brinell hardness tests using a 10 mm (0.4 in.) ball indenter

Minimum thickness of specimen		Minimum hardness for which the Brinell test may safely be made at indicated load		
mm	in.	3000 kgf	1500 kgf	500 kgf
1.6	$\frac{1}{16}$	602	301	100

Minimum thickness of specimen		Minimum hardness for which the Brinell test may safely be made at indicated load		
mm	in.	3000 kgf	1500 kgf	500 kgf
3.2	$\frac{1}{8}$	301	150	50
4.8	$\frac{3}{16}$	201	100	33
6.4	$\frac{1}{4}$	150	75	25
8.0	$\frac{5}{16}$	120	60	20
9.6	$\frac{3}{8}$	100	50	17

Microindentation hardness tests are routinely done on thin sheet metals and other small parts of 0.025 mm (0.001 in.) or less thickness. The Vickers indenter makes an indentation with a depth of one-seventh of the length of the mean diagonals. The Knoop indenter makes an indentation depth of one-thirtieth of the long diagonal. Generally, the same ratio (10:1) of depth of indent to thickness follows the same criteria as the other tests. The following examples show this calculation.

Because the depth of the Vickers test is one-seventh of the diagonal length, the depth calculation is simply as follows:

$$\text{Indentation depth} = \frac{\text{Mean diagonal length}}{7}$$

For example, if the Vickers indentation mean diagonal is measured at 0.074 mm, then the corresponding depth would be 0.0106 mm = 0.074 mm/7. The minimum thickness of the specimen thus should be 0.106 mm = 0.0106 mm × 10.

The depth of the Knoop indenter is one-thirtieth the longitudinal diagonal, and depth is calculated as follows: if the long diagonal of a Knoop indentation is measured at 136.4 μm, then the indentation depth is 4.55 μm = 136.4 μm/30. The minimum thickness of the specimen thus should be at minimum 46 μm = 4.55 μm × 10.

Depth of the Rockwell Test Indentations. When using the C, A, or D scales, the Rockwell number is subtracted from 100 and the result is multiplied by 0.002 mm. Therefore, a reading of 60 HRC indicates an indentation increase in depth from preliminary to total force:

$$\text{Depth} = (100 - 60) \times 0.002 \text{ mm} = 0.08 \text{ mm}$$

When the 1.59 mm ($\frac{1}{16}$ in.) ball indenter with the B, F, or G scale is used, the hardness number is subtracted from 130; therefore, for a reading of 80 HRB the depth is determined by:

$$\text{Depth} = (130 - 80) \times 0.002 \text{ mm} = 0.10 \text{ mm}$$

In Rockwell superficial testing, regardless of the type of indenter used, one number represents an indentation of 0.001 mm (0.00004 in.). Therefore, a reading of 80 HR30N indicates an increase in depth of indentation from preliminary to total force of:

$$\text{Depth} = (100 - 80) \times 0.001 = 0.02 \text{ mm}$$

Generally, depth computation is not necessary because minimum thickness values have been calculated (Table 3). These minimum thickness values follow the 10-to-1 ratio for scales using the diamond indenter and 15-to-1 using the ball indenters. It should also be noted that the initial indentation from the preliminary force is not included in these calculations.

Table 3 Minimum work metal hardness values for testing various thicknesses of metals with standard and superficial Rockwell hardness testers

Metal thickness		Minimum hardness for standard testers at indicated scale and load (in kgf)						Minimum hardness for superficial testers at indicated scale and load (in. kgf)					
		Diamond indenter			Ball indenter (1.59 mm, or $\frac{1}{16}$ in., diam)			Diamond indenter			Ball indenter (1.59 mm, or $\frac{1}{16}$ in., diam)		
mm	in.	A (60)	D (100)	C (150)	F (60)	B (100)	G (150)	15N (15)	30N (30)	45N (45)	15T (15)	30T (30)	45T (45)
0.152	0.006	92	92
0.203	0.008	90	90
0.254	0.010	88	91
0.305	0.012	83	82	77	86
0.356	0.014	76	78.5	74	81	80	...
0.406	0.016	86	68	74	72	75	72	71
0.457	0.018	84	66	68	68	64	62

Metal thickness		Minimum hardness for standard testers at indicated scale and load (in kgf)						Minimum hardness for superficial testers at indicated scale and load (in. kgf)					
		Diamond indenter			Ball indenter (1.59 mm, or $\frac{1}{16}$ in., diam)			Diamond indenter			Ball indenter (1.59 mm, or $\frac{1}{16}$ in., diam)		
mm	in.	A (60)	D (100)	C (150)	F (60)	B (100)	G (150)	15N (15)	30N (30)	45N (45)	15T (15)	30T (30)	45T (45)
2.032	0.080
2.083	0.082
2.134	0.084
2.184	0.086
2.235	0.088
2.286	0.090
2.337	0.092
2.388	0.094
2.438	0.096
2.489	0.098
2.540	0.100

Note: These values are approximate only and are intended primarily as a guide. Material thinner than shown should be tested with a microindentation hardness tester. The thickness of the workpiece should be at least 1.5 times the diagonal of the indentation when using a Vickers indenter, and at least 0.5 times the long diagonal when using a Knoop indenter.

(a) No minimum hardness for metal of equal or greater thickness

Example: Scale Selection for Thin Steel Strip. Consider a requirement to check the hardness of 0.36 mm (0.014 in.) thick steel strip with a suspected hardness of 63 HRC. According to Table 3, material in this hardness range must be approximately 0.71 mm (0.028 in.) thick for an accurate Rockwell C test. Therefore, 63 HRC must be converted to an approximate equivalent hardness on other Rockwell scales. These hardness values taken from a conversion table are 82.8 HRA, 73 HRD, 69.9 HR45N, 80.1 HR30N, and 91.4 HR15N. (See the article “Hardness Conversions for Steels” in this Volume.)

Referring to Table 3, only three Rockwell scales—45N, 30N, and 15N—are appropriate for testing this hardened 0.36 mm (0.014 in.) thick material. The 45N scale is unsuitable because the material should be at least 72 HR45N. The 30N scale requires the material to be 64 HR30N; on the 15N scale, the material must be at least 70 HR15N. Therefore, either the 30N or 15N scale should be used.

If a choice remains after all the criteria have been applied, then the scale applying the heaviest force should be used. A heavier force produces a larger indentation covering a greater portion of the material and a better representation of the material as a whole. In addition, the heavier the force, the greater the sensitivity of the scale. In this example, a conversion chart indicates that, in the hard steel range, a difference in hardness of one Rockwell number in the 30N scale represents just one-half of a point on the 15N scale. Therefore, smaller differences can be detected when using the 30N scale. This approach also applies when selecting a scale to accurately measure hardness when approximate case depth and hardness are known.

Anvil Effect. Minimum thickness charts and the 10-to-1 ratio serve only as guides. After determining which Rockwell scale should be used based on minimum thickness values, an actual test should be performed, and the specimen side opposite the indentation should be examined for any marking, bulging, or disturbed material; these indicate that the material is not thick enough for the applied force. This condition is known as “anvil effect.” When anvil effect or material flow restriction is encountered, the Rockwell value may not be correct and should be considered an invalid test. The Rockwell scale applying the lower force should be used.

Use of several specimens or stacking is not recommended. Slippage between the contact surfaces of the specimens makes a valid test impossible to obtain. The only exception is when testing plastics. The use of several thicknesses for elastomeric materials when anvil effect is present is considered in ASTM D 785 (Ref 2). Testing performed on soft plastics does not have an adverse effect when the test specimen is composed of a stack of several pieces of the same thickness, provided that the surfaces are in total contact and not held apart by sink marks, burrs from saw cuts, or any protrusions that would permit an air gap between the pieces.

When testing specimens from which the anvil effect results, the condition of the supporting surface of the anvil should be inspected. After several tests, this surface can become marred or indented. Either condition will have adverse results with Rockwell testing, because under the total force, the test material will sink into the indentation in the anvil and a lower reading will result. If the anvil surface shows any damage it should be replaced or relapped.

When using a ball indenter and a superficial scale of 15 kgf on a specimen in which anvil effect or material flow is present, a diamond spot anvil is used in place of the hardened steel anvil. Under these conditions, the diamond surface is not likely to be damaged when testing thin materials. Furthermore, with materials that flow under load, the hard polished diamond surface provides a more uniform frictional condition with the underside of the specimen, which improves repeatability of readings. These results should be used in a comparative manner inasmuch as they may not be the same as those obtained with a steel anvil.

Workpiece Size and Shape

Specimen size and configuration may require modification in the test setup for some indentation-type testing. For example, large specimens and thin-wall rings or tubing may need additional support equipment as well as correction factors for curved surfaces. A few examples and illustrations are provided here.

Workpiece Size. For large workpieces that are not easily transported to the stationary testers, the logical procedure is to take the testers to the workpiece. Portable machines often are used for onsite testing of workpieces that are too large and/or unwieldy to transport to the tester. In many applications where on-site testing is required, the Scleroscope can be a great advantage. Likewise, ultrasonic instruments can be used for on-site testing. When using either Scleroscope or ultrasonic testing, however, surface condition is critical to obtaining accurate results. Neither method is well suited for testing cast irons.

Many specially designed Rockwell hardness testers also have been developed to accommodate the testing of unusually large specimens, such as railroad car wheels and large turbine blades that cannot be conveniently brought to or placed in a bench-type tester. Figure 2 shows an example of a Rockwell tester for large parts. For large and heavy workpieces or workpieces of peculiar shape, a large support table may be required.

Fig. 2 Rockwell tester for large parts

Shape of the Workpiece. The ideal shape for hardness testing is a square block of sufficient size to permit making any kind of indentation required. Such ideal conditions seldom exist, and arrangements must be made to accommodate a variety of shapes.

The first step in dealing with different shapes is to have a variety of anvils for either Rockwell or Brinell testing. Several options exist for dealing with unwieldy parts (long shafts, for instance). The use of outboard supports or counter-weights are two possibilities. Another approach is to use a type of tester that firmly clamps the workpiece before the load is applied.

Cylindrical Shapes. Round ringlike parts often are tested by using special adapters or specially designed instruments. Cylindrical parts can be tested accurately by either the Brinell or Rockwell method with the use of correction factors. In Brinell testing of cylindrical surfaces an oval indentation results, but this can be corrected to a reasonable degree by obtaining the average of four optical readings taken at 45° apart.

When testing cylindrical pieces, such as rods, the shallow V or standard V anvil should be used, and the test should be applied over the axis of the rod. Care should be taken that the specimen lies flat, supported by the sides of the V anvil. Figure 3 illustrates correct and incorrect methods of supporting cylindrical work for testing.

Fig. 3 Anvil support for cylindrical workpieces. (a) Correct method places the specimen centrally under indenter and prevents movement of the specimen under testing loads. (b) Incorrect method of supporting cylindrical work on spot anvil. The testpiece is not firmly secured, and rolling of the specimen can cause damage to the indenter or erroneous readings

Inner Surfaces. The most common approach to Rockwell testing of inner surfaces is to use a gooseneck adapter for the indenter (Fig. 4). This method can be used to test inner surfaces as small as 11.11 mm (0.4375 in.) in diameter or height. Many of the smaller gooseneck adapters can be used with any tester; larger units may require a special gooseneck tester.

Fig. 4 Setup for hardness testing of inner surfaces of cylindrical workpieces using a gooseneck adapter

Thin-Wall Rings or Tubes. When testing thin-wall rings or tubing that may not support the applied force and therefore deform permanently, a test should be made to determine if this condition exists. If the specimen is permanently deformed, either an internal mandril on a gooseneck anvil and/or a lighter force should be used. Excessive deformation of tubing (either permanent or temporary) can affect the application of the total force. If through deformation the indenter travels to its full extent, complete application of the applied force may not be achieved and an inaccurately high reading will result.

Gears and other complex shapes often require the use of relatively complex anvils and related holding fixtures. When testing workpieces that have complex shapes, for example testing on the pitch line of gear teeth, a specially designed anvil or fixture usually is required. In some cases a specially designed tester may be required. Portable testers may work well for testing large, odd-shaped parts.

Long Specimens. When a workpiece has excessive overhang because of its configuration and cannot be firmly held by the application of the preliminary force, additional support must be used to ensure that the surface to be tested is perpendicular to the indenter axis and that the workpiece will not move during testing. Because manual support is not

practical, a jack-rest should be provided at the overhang end for adequate support. Figure 5 illustrates the correct and incorrect methods for testing long, heavy workpieces.

Fig. 5 Method for mounting and testing long, heavy workpieces. (a) Correct method requires a support of the extended end of the piece to prevent any pressure of specimen against indenter. The jack-rest support is available as an accessory. (b) Incorrect method causes damage to indenter and, through leverage action, causes drag and jamming of plunger rod, producing inaccurate readings. When testing, the specimen must be pressed rigidly on the anvil by the pressure of the minor load. Because of this, only short or lightweight material may be permitted much overhang.

Correction Factors for Workpieces with Curved Surfaces. When an indenter is forced into a convex surface, there is less lateral support supplied for the indenting force; consequently, the indenter will sink deeper into the material than it would into a flat surface of the same hardness. Therefore, for convex surfaces, lower hardness values will result. The opposite is true for concave surfaces because additional lateral support is provided, resulting in higher hardness values than when testing the same hardness material with a flat surface.

Results from tests made on a curved surface may be in error and should not be reported without stating the radius of curvature. For Brinell testing, the radius of curvature of the surface shall be greater than 2.5 times the diameter of the indenter. For Rockwell testing diameters of more than 25 mm (1 in.), the difference is negligible. For diameters less than 25 mm (1 in.), particularly for softer materials that involve larger indentations, the curvature, whether convex or concave, must be taken into account if a comparison is to be made with different diameters or with a flat surface.

Correction factors should be applied when workpieces are expected to meet specified values. Typical correction factors for regular and superficial Rockwell hardness values are given in Table 4. The correction values are added to the hardness value when testing convex surfaces and subtracted when testing concave surfaces. On cylinders with diameters as small as 6.35 mm (0.25 in.) regular Rockwell scales may be used; for superficial Rockwell testing, correction factors as small as 3.175 mm (0.125 in.) are given in Table 4.

Table 4 Correction factors for cylindrical workpieces tested with standard and superficial Rockwell hardness testers

Observed reading	Correction factor for workpiece with diameter of:

Note: These correction factors are added to the dial-gage reading when hardness testing on the outer (convex) surface and subtracted when testing on the inner (concave) surface. The values are approximate only and represent the averages, to the nearest half Rockwell number, of numerous actual observations by different investigators, as well as mathematical analyses of the same problem. The accuracy of tests on cylindrical workpieces will be seriously affected by alignment of elevating screw, V-anvil, and indenters, and by surface finish and straightness of the cylinders.

The method recommended by the International Organization for Standardization for correcting Vickers hardness values taken on spherical or cylindrical surfaces is given in Tables 5, 6, and 7. These tables give correction factors to be applied to Vickers hardness values when testing on curved surfaces. The correction factors are tabulated in terms of the ratio of the mean diagonal d of the indentation to the diameter D of the sphere or cylinder.

D, diameter of cylinder in millimeters; *d*, mean diagonal of impression in millimeters.

Source: ASTM E 92 (Ref 3)

Example: Correction Factors for Vickers Hardness of a Convex Sphere. The test conditions are:

Diameter of sphere (<i>D</i>), mm	10
Vickers test load, kgf	10
Mean diagonal of indentation (<i>d</i>), mm	0.150
<i>d/D</i>	0.015 (i.e., 0.150/10)

With a mean diagonal of 150 μm and a test load of 10 kgf, the Vickers hardness number for a flat surface is 824 (per ASTM E 92, Ref 3). From Table 5, the correction factor (by interpolation) for a convex surface is 0.983. The corrected hardness of the sphere is thus $824 \times 0.983 = 810 \text{ HV10}$.

Example: Correction Factors for Vickers Hardness of a Concave Cylinder (One Diagonal Parallel to Axis). The test conditions are:

Diameter of cylinder (D), mm	5
Vickers test load, kgf	30
Mean diagonal of indentation (d), mm	0.415
d/D	0.083 (i.e., 0.415/5)

With a mean diagonal of 415 μm and a test load of 30 kgf, the Vickers hardness number for a flat surface is 323 (per ASTM E 92, Ref 3). From Table 7, the correction factor is 1.075 when $d/D = 0.083$. Thus, the hardness of the cylinder after correction is $323 \times 1.075 = 347 \text{ HV}_{30}$.

Degree of Flatness. An absolutely flat surface is the ideal condition for hardness testing, and some methods are more sensitive to this condition than are others. To obtain accurate readings from Brinell, Rockwell, Scleroscope, and conventional microhardness testers, the surface being tested should be at least within 2 or 3° of flatness—that is, close to 90° of the direction of travel of the indenter. For example, when odd-shaped workpieces do not have any surfaces parallel to the surface to be tested, it is often possible to provide adjustable fixtures, which can be tilted as required to allow a flat surface for testing. This accommodation often is made with either the Brinell or the Rockwell tester.

In microhardness testing, securing and holding devices are used to attain a test surface that is sufficiently flat. Similar approaches have been used for Brinell and Rockwell testing; frequently, devices are designed for specific workpieces. Ultrasonic microhardness tests can be performed on surfaces that are not flat, however, because different principles are involved.

Surface Condition

Surface condition is a term covering two different conditions, surface finish and surface composition, both of which can affect the selection of the optimal method and/or testing technique.

Surface Finish. In general, the degree of surface smoothness required for accurate results is related directly to the size of the indenter. Although the smoother finishes are highly desirable for any testing method, the Brinell test, which involves a large indenter, can be made and read with a reasonable degree of accuracy when the finish is comparable to finished-machined or rough-ground types. In Rockwell testing, a finished ground surface is generally the minimum requirement, but polished surfaces are preferred. In Vickers testing through microhardness testing (including Scleroscope), finish requirements are far more stringent. By comparison, in microhardness testing with very light loads (less than 100 gf), the workpiece or specimen requires a surface finish equal to that used for microscopic examination at high magnification. It is obvious that the degree of smoothness that can be obtained can have a profound effect on which test method is selected.

Surface Composition. The other surface condition that can affect the selection of the hardness test method is surface composition (generally unique to steels). Decarburization, retained austenite, carburization, or other composition changes that result in a hard case are likely to influence selection. In many instances, differences in surface conditions require the use of more than one method or scale.

Indent Location and Effects

Location. If an indentation is placed too close to the edge of a specimen the testpiece edge may bulge, causing a lower hardness value because of improper support in the test area. To ensure an accurate test, the distance from the center of the indentation to the edge of the testpiece shall be at least 2.5 times the diameter of the indentation. Therefore, when testing in a narrow area, the width of the test area must be at least five diameters when the indentation is made in the center. The appropriate scale or test force must be selected for this minimum width. Although the diameter of the indentation can be calculated, for practical purposes the minimum distance can be determined visually.

Effect of Indentation Marks. An indentation hardness test cold works and/or work hardens the surrounding area. If another indentation is made too close to this work-hardened area, the reading is usually higher in value than if placed outside the hardened area. Generally, the softer the material, the more critical the spacing of the indentations. A distance between the center of two adjacent indentations of at least three times the diameter of the indentations should be sufficient for most materials.

The presence (or absence) of test marks on a part can also be a factor in selecting a test procedure. In most instances, the presence of Brinell impressions on workpieces such as forgings and castings is not objectionable. On a finished part, however, a mark as large as a Brinell impression might be undesirable from an appearance standpoint, or in some instances, can interfere with its function. There are notable cases where analysis of a service failure proved that a fracture was nucleated by a Brinell impression.

Rockwell indentation marks also can have a deleterious effect, although because the indentations are much smaller, the likelihood of damage is usually less than that caused by Brinell marks. Generally, diamond indenter marks are not sufficient to impair the function of a part, except in the case of precision parts used for purposes such as in fuel control systems. Rarely are marks left by Scleroscope or microhardness testers objectionable.

Production Rates

The number of identical or similar parts being tested can also be a selection factor. The Scleroscope lends itself to very rapid testing, when specific conditions exist, and is used frequently for high-production testing. Likewise, under certain conditions, the ultrasonic hardness test can be used for microhardness testing of many identical parts.

As a rule, however, mass-production hardness testing is done with either the Brinell or the Rockwell tester. Either instrument is available in partly or completely automated setups in which rejects are automatically separated.

Accuracy and Frequency of Calibration

Although the indentation-type test is a comparatively simple test to perform, reliable results depend a great deal on the accuracy of the equipment and the proper test method. It is recommended the tester be checked each day that hardness tests are to be made and whenever the indenter, anvil, or test force is changed.

Standardized test blocks should be used to monitor the performance of the tester daily. At least two test blocks should be used with hardness levels that bracket below and above the range of hardness levels that are normally tested. Prior to doing any testing, it is good practice to ensure that the tester is operating according to manufacturer requirements and that the anvil and indenter are seated properly. At least three hardness measurements should be made on any uniform specimen having a high hardness level in the scale to be verified. The measurements should be continued until there is no trend (increasing or decreasing hardness) in the measurement values. This technique implies that the tester's repeatability is consistent and that the indenter and anvil are seated adequately. These results need not be recorded.

After the trial tests, at least three uniformly spaced hardness measurements should be made on each of the standardized test blocks. If the average of the hardness measurements are within the tolerance marked on the blocks, the tester may be regarded as performing satisfactorily. If not, an indirect verification should be performed. In monitoring the tester in this manner it is recommended that these hardness measurements be recorded using acceptable statistical process control techniques, such as X-bar charts (measurement averages), *R*-charts (measurement ranges), gage repeatability and reproducibility (GRR) studies, and histograms (see the article “Gage Repeatability and Reproducibility in Hardness Testing” in this Volume).

Most indentation-type testing should be carried out at a temperature within the limits of 10 to 35 °C (50–95 °F). If there is a possibility of hardness variation within these test-temperature limits, users may choose to control temperatures within a tighter range. A range of 18 to 23 °C (64–81 °F) is recommended. Tests performed outside this temperature range should be considered suspect.

NIST-Traceable Test Blocks. Due to the empirical nature of hardness testing, the need for standardization of hardness values is an area of continued attention. In many countries of Europe and Asia, for example, nationally traceable hardness standards have been around for many years. Traceable standards can help resolve or reduce differences in test results between vendors and customers, who each rely on their test block for machine verification.

In 1990, after several meetings between the American Society for Testing and Materials (ASTM) and standards groups from Europe and Asia, the U.S. government agreed to provide hardness standards for U.S. manufacturers. The reason for the change is that hardness, though based on traceable parameters, has had no absolute numbers. For example, the loads on a tester can be verified with a traceable load cell, but the hardness values themselves are empirical; that is, hardness would not be directly traceable to any standard, national or otherwise.

In order to evaluate the magnitude of variation, commercially available test blocks were evaluated by the National Institute of Standards and Technology (NIST). A variation of 1.0 HRC was found to exist among test blocks supplied by domestic manufacturers. A shift of almost 1.0 HRC also was realized versus standards from other countries. This finding reinforced the need for standardization.

The hardness program at NIST involves traceable Standard Reference Material (SRM) blocks—or what industry refers to as “NIST-traceable test blocks.” The SRMs are calibrated at NIST by means of a dead-weight tester. Only two of these machines exist in the world. Other primary machines exist in other countries, but the only exact duplicate of the NIST machine is located at IMGIC, which is the NIST equivalent in Italy.

NIST-traceable test blocks are available for three nominal ranges in the Rockwell C scale:

- SRM 2810, “Rockwell C Scale Hardness—Low Range” (25 HRC nominal)
- SRM 2811, “Rockwell C Scale Hardness—Mid Range” (45 HRC nominal)
- SRM 2812, “Rockwell C Scale Hardness—High Range” (63 HRC nominal)

The new NIST-traceable blocks, at a nominal size of 60 mm (2.36 in.) diameter and 15 mm (0.6 in.) thick, are larger than the typical Rockwell hardness test blocks. They are made of steel in the appropriate Rockwell C range and have a polished mirrorlike surface. Although most ASTM-type Rockwell C test blocks are labeled ± 0.5 HRC on the high end (60 HRC range), the NIST blocks have much tighter tolerances (down to 0.1). Test locations are indicated on the block; associated hardness numbers and statistical information are listed on the certificate, enabling the user to find more than just the arithmetic mean of the hardness.

Secondary traceable standards are available from commercial test block manufacturers. NIST standardized test blocks are based on methods (especially on the diamond indenter) that are more closely aligned with those of the national laboratories of other nations than with the values that were being used in North America. The most dramatic change is tighter specification of indenter radius closer to the average ASTM-specified value of 200 μm . This is slightly larger than previous standard indenter radius of 192 μm . This change in indenter radius shifts values at the upper end of the Rockwell C scale (59–63 HRC), where values shifted upward by 0.5 to 0.8 points HRC. From 46 to 58 HRC the shift was from 0.2 to 0.49 points, while the shift was insignificant below 46 HRC.

Selection and Industrial Applications of Hardness Tests

Andrew Fee, Consultant

Hardness Test Selection for Specific Materials

Generally, the scale to be used for a specified material is indicated on engineering design drawings or in the test specifications. However, at times the scale must be determined and selected to suit a given set of circumstances. In general, the scale using a diamond indenter (Rockwell and Vickers) are used for testing hardened steels and alloys, while the ball indenters (Brinell and Rockwell) are used on more malleable materials.

Table 8 is a general guide relating materials and scales for regular Rockwell testing. As noted in Table 8, the Rockwell superficial scales (N and T) are used for testing similar material that may be too thin to accommodate the regular scales. In microindentation hardness testing, the Knoop and Vickers diamond indenters are used for all testing. Additional details about these indentation hardness test methods are given in separate articles in this Section of the Handbook.

Table 8 Typical applications of regular Rockwell hardness scales

Scale ^(a)	Typical applications
B	Copper alloys, soft steels, aluminum alloys, malleable iron
C	Steel, hard cast irons, pearlitic malleable iron, titanium, deep case-hardened steel, and other materials harder than 100 HRB
A	Cemented carbides, thin steel, and shallow case-hardened steel
D	Thin steel and medium case-hardened steel and pearlitic malleable iron
E	Cast iron, aluminum and magnesium alloys, bearing metals
F	Annealed copper alloys, thin soft sheet metals
G	Phosphor bronze, beryllium copper, malleable irons. Upper limit is 92 HRG to avoid flattening of ball.
H	Aluminum, zinc, lead
K, L, M, P, R, S, V	Bearing metals and other very soft or thin materials. Use smallest ball and heaviest load that do not give anvil effect.

(a) The N scales of a superficial hardness tester are used for materials similar to those tested on the Rockwell C, A, and D scales but of thinner gage or case depth. The T scales are used for materials similar to those tested on the Rockwell B, F, and G scales but of thinner gage. When minute indentations are required, a superficial hardness tester should be used. The W, X, and Y scales are used for very soft materials

Conversion from one hardness scale to another also depends on the material being tested. Therefore, this section provides some hardness conversion data for materials other than steel. Hardness conversion tables for steel are included in the article “Hardness Conversions for Steels.”

Steels

Forgings, Castings, and Plate Products. Annealed, hot-rolled, cold-finished, forged, or cast carbon and alloy steels usually are tested by the Brinell or Rockwell B method. Because of the nature of forgings and most iron and steel castings, the Brinell test is the preferred test method; the larger Brinell indentation gives a better average value of the local surface and thus a truer homogenic hardness than would be expected with the Rockwell test.

Rockwell testing is used on specimens with fine grain composition or those that lack sufficient area to accommodate a Brinell test. Although the Rockwell B scale (1.59 mm, or $\frac{1}{16}$ in., ball indenter) is used sometimes, the Rockwell E and K scales (3.175 mm, or $\frac{1}{8}$ in., ball indenter) are preferred because the larger indenter gives a better average reading. The surface that is to be tested should be prepared, if needed, to allow for a well-defined indentation for accurate measurement. Care should be taken to ensure that any surface preparation will not influence the condition of the surface by overheating and cold working. To better correlate between Rockwell and Brinell values, it is suggested that three to five Rockwell tests be made and averaged to give a more representative hardness value because of the possible variations within the cast part. Hard white iron castings and chilled rolls are usually tested using the Rockwell C and Vickers scales.

Hardened and Tempered Steels. The hardness of quenched-and-tempered carbon, alloy, tool, and stainless steels is typically tested with a diamond indenter by Rockwell, Vickers, or microindentation techniques. The Rockwell C test generally is used when conditions permit. Rockwell C readings of less than 20 (or its equivalent in other scales) should not be considered valid, and some inaccuracy can be expected as the value drops below 30 HRC. For hardenability testing, the Rockwell C scale is preferred (see the section “Hardenability Testing” in this article).

Steel Sheet. Depending on the thickness of the sheet, hardness specifications are usually given in the Rockwell B scale or a superficial Rockwell scale (HR30T or sometimes HR15T). Sheet metal is usually tested and controlled for its drawing and stamping capabilities with the Rockwell test.

A common industry description of the various sheet steel tempers is:

Temper	Hardness, HRB
No. 1 Hard	90 ± 5
No. 2 Half-hard	80 ± 5
No. 3 Quarter-hard	70 ± 5
No. 4 Soft	60 ± 5
No. 5 Dead-soft	45 ± 5

The verbal descriptions of the tempers involve wide tolerances, and a specification in the actual Rockwell hardness gives a more precise and defined tolerance for control of the end product.

Powder Metallurgy (P/M) Steels. Because the density of P/M steels may vary from less than 7 g/cm³ (0.25 lb/in.³) to a density approaching that of wrought steel (about 7.8 g/cm³, or 0.28 lb/in.³), the variation in hardness can vary widely. Besides porosity, sintered P/M steels may also have inhomogeneous microstructures from graphite. At least five consistent readings should be taken, in addition to any obviously high or low readings, which should be discarded. The remaining five readings should be averaged.

Because of the variety of compositions and densities encountered in P/M materials, the recommendation for suitable test methods may require preliminary trials. Generally, the Rockwell test, with its variety of scales, is the usual choice. The Rockwell F, H, B, and the superficial T scales are generally used for hardness testing of P/M materials. Heat treated P/M steels are sometimes tested in the Rockwell C scale (Table 9). Although not widely used, the Rockwell B scale may be combined with a carbide ball for testing hardened parts. Data scattering is minimized with a Rockwell B 1.59 mm ($\frac{1}{16}$ in.) diameter ball, and it is useful up to 120 HRB.

Table 9 Common hardness scales used for P/M parts

Material	Sintered hardness scale	Heat treated hardness scale
Iron	HRH, HRB	HRB, HRC
Iron-carbon	HRB	HRB, HRC
Iron-nickel-carbon	HRB	HRC
Prealloyed steel	HRB	HRC
Bronze	HRH	...
Brass	HRH	...

Apparent Hardness. In powder metallurgy there are generally two types of hardness specified—apparent hardness (macrohardness) and microhardness. The microhardness is the hardness of each particle of material, and the apparent hardness is the hardness of the surface—bridging across many particles and the porosity, too. Apparent hardness is typically measured according to Metal Powder Industries Federation (MPIF) Standard 43 (Ref 4). The procedure is relatively straightforward and quick. The basics are:

1. Obtain a sample part of adequate thickness and parallel configuration (or, for cylindrical parts, a correction factor may be used).
2. The sample must be large enough so that the indenter marks from the hardness tester are at least three indenter diameters from any edge or previous impression.
3. Sand each face of the sample so that no burrs are present (burrs will cause erroneous readings), or be sure to use a holding fixture that avoids the burrs.
4. Take readings with a properly calibrated hardness tester.
5. Reject obvious outliers and report the average of at least five nonoutliers.

Typically, the outliers are on the low side. The cause of these occasional low readings is a chance happening that the hardness indenter falls right into a pore.

Microhardness is usually measured according to MPIF Standard 51 (Ref 5). The determination of microhardness is significantly more difficult than measuring apparent hardness and requires specialized equipment that many P/M users do not have on-site. The procedure involves:

1. Sectioning the part and making a polished mount for the evaluation.
2. Placing the mount in a special microhardness testing machine.
3. Under magnification, orienting the mount and making a diamond indenter mark precisely over a particle of the material.
4. Measuring the length of the penetration on the particle and converting this length to a hardness reading.

Microindentation hardness tests of porous materials can best be measured with Knoop or diamond pyramid hardness indenters at loads of 100 gf or greater. In atomized irons, particles exhibit minimal porosity; consequently, the Knoop indenter is suitable because it makes a very shallow indentation and is not frequently disturbed by entering undisclosed pores. Care should be taken in preparing the sample surface. The diamond pyramid indenter is particularly well suited to irons that contain numerous fine internal pores. Because of its greater depth of penetration, the diamond pyramid indenter frequently encounters hidden pores. Microhardness testing and the measurement of effective case depth are covered by MPIF standard 51 (Ref 6).

Cast Irons

Accurate hardness values often are difficult to attain when the material has an inhomogeneous structure and composition. This applies to the complex metal-carbon structure of cast irons. Conventional hardness measurements of cast irons thus tend to be lower values than the hardness of the metal portion. This discrepancy, which is more pronounced in gray iron than in ductile and malleable irons, occurs because conventional hardness readings are composite values that reflect the hardnesses of both the matrix metal and

soft graphite. Greater variations in hardness results may also occur from the inhomogeneous structure. Therefore, a Brinell hardness test, by virtue of its indenter size, is preferred to provide more consistent average hardness values. However, sometimes other scales may be required. For example, when determining the hardness of small castings, it is often impossible to use a Brinell tester; a Rockwell tester must be used. Fine grain structure, hard white-iron castings, and chilled rolls may also require the use of other scales, as previously noted in the section “Forgings, Castings, and Plate Products” in this article.

Conversions between different hardness scales have been developed for some types of cast irons. For example, Fig. 6 shows conversions from Brinell to Rockwell B and G scales for malleable and pearlitic malleable irons, respectively. Figure 6(b) shows Rockwell C equivalents for Brinell values of pearlitic malleable iron. These conversions generally are accepted by producers of malleable iron. Reliable hardness conversion for other types of cast irons, especially gray irons, is more difficult due to the variations in metallurgical conditions. For example, Fig. 7 shows the relationship between observed Rockwell C readings and those converted from microhardness values for five gray irons of different carbon equivalents. The wide variation illustrates the need to know the carbon equivalent of the iron being tested before a conversion chart can be developed. For white iron, conversions are shown in Table 10.

Nonferrous Alloys

To a great extent, the same general guidelines apply to both nonferrous and ferrous materials. Indentation spacing, proximity to edges, thickness of testing material, and the selection of indenter and load combinations are all factors that influence hardness readings.

With very few exceptions, nonferrous metals are generally softer than steels and cast irons. Brinell testing and Rockwell testing with ball indenters under a variety of test loads are most often used. Many of the higher strength or higher hardness nonferrous metals can be accurately tested with the Brinell test method when the workpiece is of sufficient thickness and size.

The Brinell test is the preferred test for wrought aluminum alloys and large nonferrous castings, which are usually tested with the 500 kgf load. Some high-strength alloys such as titanium-base alloys that are phase transformation or age hardened can be tested with the 3000 kgf load. Diamond indenters are sometimes used—notably, the Rockwell A scale. Some multiphased cast nonferrous alloys that are too soft for Brinell testing will require the Rockwell or Vickers test methods. Typical Rockwell scales used for a wide variety of nonferrous metals and other materials are listed in Table 8. Very small nonferrous metal parts made of extremely thin sheet, strip, or foil are tested by microindentation methods.

Aluminum and aluminum alloys are tested frequently for hardness to distinguish between annealed, cold-worked, and heat treated grades. The Rockwell B scale (100 kgf load with a 1.58 mm, or $\frac{1}{16}$ in., steel ball indenter) generally is suitable in testing grades that have been precipitation hardened to relatively high strength levels. For softer grades and commercially pure aluminum, hardness testing usually is done with the Rockwell F, E, and H scales. For hardness testing of thin gages of aluminum, the 15T and 30T scales of the Rockwell superficial tester are recommended. Approximate hardness conversions for wrought aluminum are listed in Table 11.

Copper and Copper Alloys. Because copper alloys vary so widely in hardness, a wide range of indenters and loads may apply to this family of alloys. Beginning at the top of the range, the precipitation-hardenable alloys (such as C17000, C17200, and C17300) may be regarded as essentially the same as steel in their hardened condition because they are generally within the range of 36 to 45 HRC. Therefore, these alloys can be tested satisfactorily with the Rockwell C scale. For thinner gages, the 15H or 30H scale is used. The Brinell test, using 1500 to 3000 kgf loads, is also appropriate for testing the harder copper alloys. When these alloys are in the annealed or cold-worked condition, the Rockwell B scale is recommended, or the 15T or 30T scale for very thin sections. When the indenter is penetrating the test material too deeply with the B scale, a lighter load or larger ball, such as that used for Rockwell E or F scale, must be used. Approximate hardness conversions for wrought copper alloys and cartridge brass are listed in Tables 12 and 13, respectively.

Source: ASTM E 140 (Ref 6)

Magnesium and magnesium alloys are tested by applying the Rockwell B scale, but when the alloys are softer (annealed), the indenter size is increased to 3.175 mm ($\frac{1}{8}$ in.) using the Rockwell E scale. As with other metals and alloys, thin sections of magnesium alloys must be tested with the 15T or 30T scale to avoid the anvil effect. Titanium. The Rockwell A scale is best suited for testing titanium. The 60 kgf load tends to increase the life of the diamond penetrator because there is an affinity between diamond and titanium, which usually shortens diamond life. Titanium tends to adhere to the tip of the diamond penetrator and can readily be removed with 3/0 grade emery paper when the penetrator is rotated in a lathe. Maintaining a clean diamond will give more reliable results.

Zinc and lead alloys are typically tested using the Rockwell method. They exhibit extensive time-dependent plasticity characteristics and therefore require longer dwell time of load application to obtain accurate and repeatable results. For materials that show some time-dependent plasticity, the dwell time of indent load should be 5 to 6 s using a diamond indenter. For materials that show considerable time-dependent plasticity, dwell time should be 20 to 25 s using any indenter. One method for determining the magnitude of time-dependent plasticity is to do a series of tests at progressively longer dwell times. As the dwell increases the hardness

values will decrease significantly. When the rate of change decreases significantly the proper dwell time has been reached.

Zinc. The Rockwell E scale is used for zinc sheets down to 3.2 mm (0.125 in.) and the Rockwell H scale for sheets down to 1.25 mm (0.050 in.) gage. These values are for zinc in the soft condition, thinner sheets may be tested if the zinc is relatively hard. For thinner sheet, the 15T or 30T scale of the Rockwell superficial tester should be used.

Lead. Most testing on lead is done on thicker specimens with the Rockwell E and H scales.

Tin plate is tested on the Rockwell superficial HR15T, HR30T, and HR45T scales along with a diamond spot anvil in accordance with the following criteria:

Thickness		Scale
mm	in.	
<0.212	<0.0083	HR15T
0.213–0.547	0.0084–0.0215	HR30T
0.548–0.770	0.0216–0.0303	HR45T

Since most results are reported in the HR30T scales, all test results in the other scales are converted using the standard conversion chart found in ASTM E 140 (Ref 6).

Cemented carbides are tested primarily with the Rockwell A scale as designated in ASTM B 294 (Ref 7). Using the Rockwell C scale has resulted in poor diamond longevity due to breakage. Because of the extremely high stress placed on the diamond point, only indenters designated for carbide testing should be used. It should be noted that the carbide Rockwell A scale hardness levels are not the same as the steel Rockwell A scale levels because of the use of diamond indenters. Interchanging indenters will give incorrect results. See the section on Rockwell hardness testing in the article “Macroindentation Hardness Testing” for more information about the differences.

Cemented carbides are P/M products produced by sintering and thus may also contain tiny voids. However, the amount of void area on the surface usually is not large enough to complicate hardness testing. Cemented carbides are also composite materials made of hard carbides with a cobalt binder. The soft cobalt binder occupies approximately 20% of the area, whereas the remaining 80% consists of hard carbide particles that have hardness values of 9 on Mohs scale (diamond is 10) or 1500 HV and above. Obviously, the macroindentation hardness is an average value for this composite material. The carbide content is the principal contributor to the hardness.

Hardness Testing of Plastics

Hardness testing of plastics presents many variables that do not relate to the testing of metals. For example, plastics are much more sensitive to humidity and temperature than metals. The deformation of plastics is also very time dependent, and plastics may exhibit excessive flow characteristics during force applications. Because of these extenuating factors special procedures are given in ASTM D 785 (Ref 2) for Rockwell testing of plastics. These include:

5. Conditioning of the test specimen at a controlled temperature and relative humidity level
6. Requirements for the application and dwell time of the preliminary force
7. Application of the additional force within 10 s of applying the preliminary force
8. Removing the additional force, after the extended dwell time (usually 15 s) or until further penetration has apparently stopped, as indicated with the depth indicator (gage)
9. Extending the read time to 15 s after the removal of the additional force

It should be noted that some of these same conditions also apply to Vickers or Knoop hardness testing of plastics.

In the Rockwell test (ASTM D 785) (Ref 2), penetrators generally are balls 3.18, 6.35, and 12.7 mm (0.125, 0.25, and 0.50 in.) diameter at major loads of 60, 100, and 150 kg. Because of the creep and recovery characteristics of plastics, dwell times are carefully controlled, and specimens should be conditioned for temperature and humidity. Hardness tests on plastics are an indication of cure of some thermosetting materials and an indication of punching quality of laminated sheet stock.

For metals, excluding shapes such as tubes, the movement of the dial gage caused by the elasticity of the metal being tested is small and not considered to be a problem. Elasticity may reach considerable proportions with plastics. In addition to the spring of the tester frame, elasticity may prevent full application of the major load because of limitations in the design of the tester.

The limitation of the standard model Rockwell tester is considered to be 150 dial gage divisions under a 150 kgf load. This figure represents the number of divisions of travel on the dial gage, when the major load is applied, due to penetration into the material under tests, spring of the frame, penetrator, plunger rod system, and elasticity of the material under test. Special Rockwell testers, designated as “PL” models, increase this limitation to 250 divisions under a load of 150 kgf.

To determine whether the machine limitation is being exceeded and the major load is being fully applied, the major load can be tested in the following manner. With the major load still applied, an additional load can be applied by manually exerting pressure on the weights on the machine; the dial gage needle then should indicate additional penetration. If not, the full major load might not be acting (due to reaching limit of depth of indentation), and faulty readings can result. In this instance, the manufacturer should be contacted.

Use of the Alpha Scale. A variation of the standard Rockwell test is often used for testing plastics. It is referred to as the alpha Rockwell hardness number in Procedure B of ASTM D 785 (Ref 2). The advantage of the alpha scale is that it covers the range of plastics.

The standard Rockwell tester is used with a major load of 60 kgf and 12.7 mm (½ in.) ball penetrator. The test is made by applying the minor load in the usual manner, setting the dial to “set,” and applying the 60 kgf major load for 15 s. With the major load applied, the number of divisions the penetrator has traveled from “set” is read on the dial gage. From this reading, the spring of the tester is subtracted, determined under the major load of 60 kgf, and the remainder is subtracted from 150.

The spring of the machine, known as the “spring constant,” is determined as follows:

- Place a soft copper block of sufficient thickness and with plane parallel surfaces on the anvil in the normal testing position.
- Raise the sample and the anvil by the capstan screw until the large pointer is at the set position.
- Apply the major load by tripping the load release lever.

The dial gage then will indicate the vertical distance of indentation, the spring of the machine frame, and any other elastic compressible deformation of the plunger rod system and penetrator. This operation should be repeated several times without moving the block. However, the dial must be reset after each test while under minor load until the deflection of the dial gage becomes constant—that is, until no further indentation takes place, and only the spring of the instrument remains. This value, in terms of dial divisions, is the spring constant.

Durometer Testing. The durometer is a well-known and widely used instrument for measuring hardness of virtually all types of plastics, rubbers, and various rubberlike materials. The durometer measures hardness by means of an indentation much like that used in hardness testing of metals. The indenters used in durometers, however, are spring loaded rather than forced by weights. Nonmetallic materials, similar to metals, vary greatly in hardness, thus requiring a variety of test instruments. Several types of durometers accommodate the full range of hardness, and special instruments are available for testing O-rings and extremely thin materials. The various types available are listed in the left column of Table 14; however, only two (A and D) are covered in ASTM D 2240 (Ref 8).

Table 14 Specifications of durometers

Durometer type	Main spring	Indenter	Applications
A (conforms to ASTM D 2240)	822 g	Frustum cone	Soft vulcanized rubber and all elastomeric materials, natural rubber, GR-S, GR-1, neoprene, nitrile rubbers, Thiokol, flexible polyester cast resins, polyacrylic esters, wax, felt, and leather
B	822 g	Sharp included angle	30° Moderately hard rubber such as typewriter rollers and platens
C	20 lb	Frustum cone	Medium-hard rubber and plastics
D (conforms to ASTM D 2240)	10 lb	Sharp included angle	30° Hard rubber and the harder grades of plastics such as rigid thermoplastic sheet. Plexiglas (AtoHaas Americas Inc.), polystyrene, vinyl sheet, cellulose acetate and thermosetting laminates such as Formica (Formica Corp., Cincinnati, OH), paper-filled calendar rolls, and calendar bowls
D0	10 lb	2.4 mm (3/32 in.) sphere	Very dense textile windings and slasher beams
0	822 g	2.4 mm (3/32 in.) sphere	Soft printer rollers, Artgum, medium-density textile windings of rayon, orlon, and nylon
00	4 oz	2.4 mm (3/32 in.) sphere	Sponge rubber and plastics, low-density textile windings; not for use on foamed latex
000 (available with round dial only)	4 oz	13 mm (1/2 in.) diam spherical	Ultrasoft sponge rubber and plastic
T	822 g	2.4 mm (3/32 in.) sphere	Medium-density textile windings on spools and bobbins with a maximum diam of 100 mm (4 in.); types T and T-2 have a concave bottom plate to facilitate centering on cylindrical specimens

Durometers are used for measuring hardness of plastics and rubbers ranging from ultrasoft sponge rubbers to hard plastics. A list of test materials correlated with the specific type of durometer, main spring data, and type of indenter is presented in Table 15. In some instances, durometer test results can be converted to another scale. A partial conversion chart is shown in Fig. 8. The types of durometers range from simple handheld devices (Fig. 9) to laboratory instruments with digital readout for accurate and reproducible readings. Materials that are too thin for hardness measurement by conventional instruments can be measured with durometers for thin and microthin samples.

Table 15 Taylor's equations for estimating the tensile strength from hardness data

Material	Tensile strength (MPa)	Tensile strength (ksi)
Heat treated carbon and alloy steels	(3.24–3.55) HB	(0.470–0.515) HB
Annealed carbon steels	(3.55–3.86) HB	(0.515–0.560) HB
All steels	(3.09–3.55) HB	(0.448–0.515) HV

Selection and Industrial Applications of Hardness Tests

Andrew Fee, Consultant

Applications of Hardness Testing

Hardness testing has many applications in quality control, materials evaluation, and the prediction of properties. Because hardness testing is nondestructive and quick, it is a very useful tool for manufacturing and process control. For example, the most common application of the Rockwell test is testing steels that have been hardened and tempered. If a hardened-and-quenched steel piece is tempered by reheating at a controlled and relatively low temperature and then cooled at a control rate and time, it is possible to produce a wide range of desired hardness levels. By using a hardness test to monitor the end results, the operator is able to determine and control the ideal temperatures and times so that a specified hardness may be obtained.

Quality Control

Decarburization. In general, decarburization is an unwanted condition that results in a softer surface (or skin) on the metal. This is caused by the loss of carbon from the surface of the material during a heat treatment process. Unless it is removed, the part may not have the properties necessary to perform its function. A Rockwell test, because it is done on the surface of the part, will frequently indicate this soft condition. An example of the most commonly used method to determine if decarburization exists is to make Rockwell 15N and C scale tests in the same area of the part. When the converted values are compared, if the Rockwell 15N value, converted to C, is significantly lower than the unconverted Rockwell C value, a soft, decarburized layer is most likely present. Removing the layer and retesting will confirm the diagnosis.

Statistical Process Control (SPC). When large populations of materials make testing each workpiece impractical and a tighter control is demanded for a product, SPC is usually incorporated. This means of statistical control can enable continual product manufacturing with minimum testing and a high level of quality. Because many hardness tests are done rapidly, they are well suited for use with SPC techniques. Users are cautioned that the proper testing procedures must be followed to ensure the high degree of accuracy necessary when using SPC.

Measurement of Case Depth

The surface layer of case-hardened steels is generally characterized in terms of:

- Case hardness
- Effective case depth (typically defined as the depth where hardness has a value of 50 HRC, unless otherwise specified)
- Total case depth (which is the depth at which no difference in chemical or physical properties can be distinguished between the case and the core)

In testing case-hardened material it is essential that the depth of case be sufficient to support the test being conducted. The rule that the case be at least 10 times thicker than the depth of indentation should be followed. This 10-to-1 ratio is based on the flow characteristics of most steels; if, however, the material being tested has flow characteristics unlike most steels a greater ratio may be required.

The most accurate and repeatable method of determining effective or total case depth is by means of some type of hardness traverse. A hardness traverse indicates the precise hardness characteristics from the edge to the core. Hardness depths may be studied by either taper or step grinding as illustrated in Fig. 10. When the case is very thin, but quite hard, as usually found in materials that have been nitrided, a more qualitative method for determining case depth is done by making a microindentation hardness traverse on a cross section of a prepared specimen. Surface hardness can be determined on cases as thin as 10 μm (0.0005 in.) with this method. The cross-section method, while time consuming, is the most common process used to determine case depth.

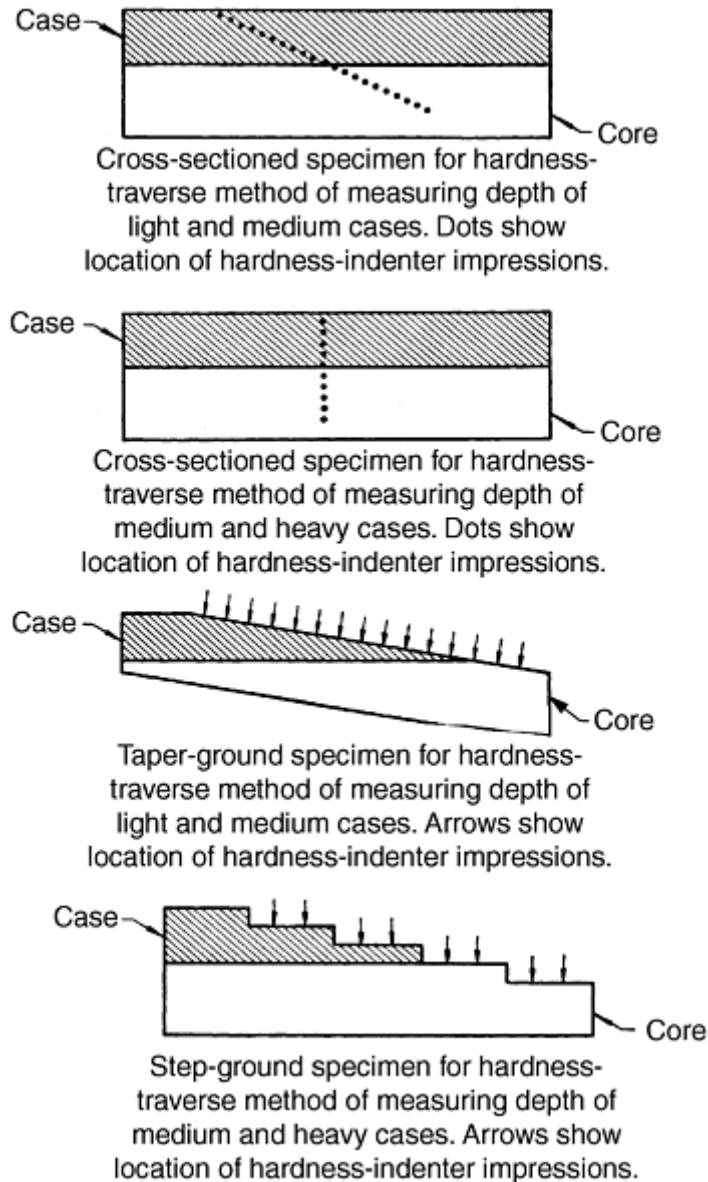

Fig. 10 Hardness traverse methods for case-hardness profiling

Hardenability Testing

One of the important properties of alloyed steels is their ability to be hardened to a much greater depth than plain-carbon steels. In many cases, they can be hardened throughout their entire thickness. The degree of depth hardening is not the same for all alloying elements. Therefore, hardenability testing is used to evaluate the hardening of steels.

A number of hardenability tests have been devised (principally by means of the Rockwell C scale), but the Jominy end-quenching hardness test has proved to be the method with the highest degree of reproducibility. It has been almost universally adopted in evaluating virtually all standard alloy steels and for some grades of carbon steels. The test is relatively simple to perform and can produce much useful information for the designer, as well as for the fabricator.

Jominy End-Quenching Hardness Test. Although variations are sometimes made to accommodate specific requirements, the test bars for the end-quench test are normally 25 mm (1 in.) in diameter by 100 mm (4 in.) long. The specimen has a collar on one end to hold it in a quenching jig (Fig. 11).

Fig. 11 Standard end-quench (Jominy) test specimen and method of quenching in quenching jig

In this test, the water flow is controlled by a suitable valve so that the amount striking the end of the specimen (Fig. 11) is constant in volume and velocity. The water impinges on the end of the specimen only and drains away. By this means, cooling rates vary from about the fastest possible on the quenched end to very slow, essentially equal to cooling in still air, on the opposite end. This results in a wide range of hardnesses along the length of the bar.

After the test bar has been quenched, two opposite and flat parallel surfaces are ground along the length of the bar to a depth of 0.381 mm (0.015 in.). Rockwell C hardness determinations then are made every 1.59 mm (0.0625 in.). A specimen-holding indexing fixture is helpful for this operation for convenience, as well as for accuracy. Such fixtures are available as accessory attachments for conventional Rockwell testers.

The next step is to record the readings and plot them on graph paper to develop a curve (Fig. 12). By comparing the curves resulting from end-quench tests of different grades of steel (Fig. 13), relative hardenability can be established. Steels with higher hardenability will be harder at a given distance from the quenched end of the specimen than steels with lower hardenability. Thus, the flatter the curve is, the greater the hardenability will be. On the end-quench curves, hardness usually is not measured beyond approximately 50 mm (2 in.) because hardness measurements beyond this distance are seldom of any significance. At approximately 50 mm (2 in.) from the quenched end, the effect of water on the quenched end has deteriorated, and the effect of cooling from the surrounding air has become significant. An absolutely flat curve demonstrates conditions of very high hardenability, which characterize an air-hardening steel, such as some highly alloyed steels.

Fig. 12 Method of developing end-quench curve by plotting hardness versus distance from quenched end. Hardness plotted every 6.4 mm ($\frac{1}{4}$ in.), although Rockwell C readings were taken in increments of 1.59 mm ($\frac{1}{16}$ in.), as shown on top of illustration.

Fig. 13 Plot of end-quench test results for five different steels

Additional information about Jominy end-quench hardenability is provided in the article “Quantitative Prediction of Transformation Hardening in Steels” in *Heat Treating*, Volume 4 of *ASM Handbook*.

Introduction to Adhesion, Friction, and Wear Testing

Peter J. Blau, Oak Ridge National Laboratory

Introduction

THE SURFACES OF SOLIDS play many different and important roles in technology. Their functions range from imparting a pleasing appearance to protecting the underlying material from wear and corrosion, and from bearing contact loads to serving as the substrates for coatings. The properties of free surfaces differ from those of bulk materials. A variety of specialized testing methods, therefore, have been developed specifically for characterizing the mechanical behavior of surfaces and the treatments and coatings applied to them.

In some engineering applications, like the bonding or fastening of parts, surfaces are placed in intimate contact with the intention that they will not move relative to one another. In other cases, as in bearings, gears, brakes, and rotating face seals, adjacent surfaces are intended to move relative to one another in a smooth and stable fashion, while at the same time supporting a normal load. Sometimes, as in the attachment of protective coatings to a surface, strong adhesion is desirable, but in other instances, as in the seizure and galling of sliding bearings, strong adhesion is not desirable. Likewise, low friction might be desirable for a face seal but undesirable for a brake pad. A high rate of abrasive wear for a paper mill slitter-knife blade is to be avoided, yet the high abrasive wear rate associated with grinding prepares the surfaces of castings for mating with other parts. Consequently, adhesion, friction, and wear are neither inherently good nor bad. Rather, they are important to both the cosmetic and engineering functions of parts and must, therefore, be measured and controlled.

Under some conditions, adhesion, friction, and wear are directly related, but under other conditions they are not. For example, when clean metals rub against one another, adhesion can occur, raising the friction and promoting the deformation and fracture of the softer material. The more extensive these processes are, the more the wear. By contrast, there are cases in which the sliding friction of an interface can be relatively high (disc brake pads against rotors), but the wear of the materials involved is relatively low. While appearing contrary to intuition, the high-friction/low-wear situation becomes understandable when friction is viewed as the energy available to do work on a material, and wear is but one of the possible ways in which a system can dissipate that energy—conversion into heat being another. Thus, two sliding couples can possess nearly the same friction coefficients but greatly different wear rates.

In this Section, tests designed specifically to evaluate the adhesion, friction, and wear behavior of various material systems are described. Included within the wear category are other forms of surface damage, like galling and scuffing. Unlike other mechanical properties, such as the elastic constants or shear strength, properties of adhesion, friction, and wear depend strongly upon the surface conditions of the solid and not exclusively upon its bulk structure. The selection of appropriate test methods to meet engineering requirements for adhesion, friction, and wear, therefore, is somewhat complicated. Each functional requirement must be analyzed on a case-by-case basis, and no one test is universally the best for measuring either adhesion, friction, or wear.

Introduction to Adhesion, Friction, and Wear Testing

Peter J. Blau, Oak Ridge National Laboratory

Adhesion Testing

The article “Adhesion Testing” in this Section describes many different techniques and test methods that have been devised for measuring the adhesion between solids. There is little standardization in this field, although some investigators tend to favor one method over another. Most adhesion test methods are designed to assess the ability of two materials to remain connected to one another despite the application of external or internal body forces in various directions with respect to the interface. For example, different types of adhesion tests have been designed to measure resistance to peeling, shearing, and delamination. In a few instances, adhesion tests are used in the study of frictional phenomena that occur at a fine scale between protuberances on mating surfaces. The article on adhesion testing contains a more complete discussion of these test methods and a bibliography.

Introduction to Adhesion, Friction, and Wear Testing

Peter J. Blau, Oak Ridge National Laboratory

Friction Testing

Friction and wear are not basic properties of materials but rather represent the response of a material pair in a certain environment to imposed forces, which tend to produce relative motion between the paired materials. Friction and wear behavior is, therefore, subject to the considerations of testing geometry, the characteristics of the relative motion, the contact pressure between the surfaces, the temperature, the stiffness and vibrational properties of the supporting structures, the presence or absence of third bodies, the duration of contact, and the chemistry of the environment in and around the interface. Tables of friction coefficients should not be trusted to provide applicable numerical values unless the conditions used to develop the data closely mimic those of the application for which the data are intended. Since frictional interactions occur under a wide variety of contact conditions and size scales, selecting test methods for screening materials or lubricants for frictional behavior should be done with care.

The article “Testing Methods for Solid Friction” describes a variety of methods that have proven useful in measuring friction coefficients, both under static and kinetic conditions. Since frictional response is sometimes sensitive to the preparation and cleaning of surfaces, these factors should be addressed when developing friction testing procedures. Other testing variables, some of them rather subtle (like the fixture stiffness or thermal conductivity), can affect friction test results in some cases. Frictional transitions, like running-in, are common in engineering systems (Ref 1), so they should be considered when deciding on the type of data collection method.

Standard test methods, like those produced by ASTM, can be useful not only as guides to friction testing procedures but also as a source of information on which test variables should be controlled. Published standards, like friction test methods in general, do not address all possible needs for friction measurement, and thus, the engineer might need to devise his or her own tests to fit the situation.

Introduction to Adhesion, Friction, and Wear Testing

Peter J. Blau, Oak Ridge National Laboratory

Scratch Testing

Scratch tests are used for two main purposes:(a) to measure the adhesion of a coating or film to a surface, or (b) to measure the resistance of a surface to damage from a harder opposing body. Scratch testing methods for the former purpose are described in the article “Adhesion Testing.” Scratch tests used for the latter purpose are described in the article “Scratch Testing” in this Volume. The use of scratch tests has a relatively long history, having been introduced by the German mineralogist Friedrich Mohs in 1822 for identifying different mineral species. The ability of a mineral to scratch or be scratched by another mineral is an important clue to its identification, and use of the Mohs test persists to this day.

During recent years, scratch tests have been instrumented using force and acoustic emission sensors to provide additional information for materials and coatings characterization. Diamond is the material of choice for most scratch testing indenters, but diamond is not the only material used in scratch tests. Hardened steel files, for example, are used for scratch testing under certain circumstances. New testing parameters, such as the critical load for coating failure and the scratching coefficient (i.e., the normal force divided by the tangential force that resists scratching), have been introduced to measure other surface properties. Scratch tests can be useful for obtaining numerical rankings of the resistance of a material to single-point abrasion and for assessing the mechanisms of material removal under abrasive conditions.

Introduction to Adhesion, Friction, and Wear Testing

Peter J. Blau, Oak Ridge National Laboratory

Testing for Wear and Surface Damage of Various Kinds

Because wear and surface damage take on many different forms, several articles on wear and surface damage testing have been included in this Volume. Wear is a form of mechanically induced surface damage that results in the progressive removal of material from a surface. Galling, chipping, or scratching can occur with one contact event, and not being progressive, these phenomena are not strictly forms of wear. However, they still fall under the category of surface damage. Because a great many types of surface damage occur in machinery, different types of tests have been developed. The chapters in this Section describe quite a few of them, but it is possible that a specialized method must be developed to effect a simulation of specific conditions or to isolate a certain form of wear for detailed study.

Selection of the right type of test becomes critically important in order to achieve engineering relevance. In fact, materials and surface treatments can rank in opposite order when tested for resistance to different forms of wear (Ref 2). More than one type of wear can attack the same part, like both sliding and impact wear in printing presses, and both erosive and abrasive wear on plastic extrusion machine screws. Sometimes wear can operate in the presence of corrosive or chemically active environments, and synergistic chemomechanical effects are possible. The selection of an appropriate wear testing method begins with an assessment of the type of wear involved as well as the mechanical conditions and the environment that produced it.

Having a structured classification of wear types can make test selection easier. Different classification schemes for wear have been developed because those who developed them have come from different backgrounds with different experiences with wear. No one scheme is universally accepted, but most systems have similar features. For example, mechanical wear can be classified by the type of relative motion: (a) tangential motion (sliding), (b) impact, and (c) rolling (Ref 3). An abbreviated summary of the common wear and surface damage types, categorized in this way, is given in Table 1. Formal definitions for the important types of wear are provided in the *ASM Handbook*, Vol 18, *Friction, Lubrication and Wear Technology* (Ref 4). That Volume also contains reviews of each major form of wear and comprehensive discussions of wear mechanisms, the wear of different types of materials, and application-specific methods for wear control.

Table 1 Common types of wear and mechanical surface damage

Category	Characteristics
Sliding wear	Tangential motion and traction between surfaces
2 body abrasive wear	Wear by fixed hard particles moving along a surface
3 body abrasive wear	Wear by hard particles passing between opposing bodies
Adhesive wear	Wear arising from the localized adhesion of one surface to another, which results in plastic deformation and fracture with the transfer of detached material to the opposing surface
Fretting wear	Wear arising from short-amplitude oscillations or tangential contact vibrations
Fatigue wear	Wear involving the nucleation and propagation of surface and/or subsurface cracks under cyclic tangential forces arising from sliding contact
Polishing wear	Fine-scale wear by the action of hard particles, chemomechanical processes, or both
Impact wear	Normal forces acting cyclically on surfaces
Single-body impact wear	Wear from the repeated impact of a second body
Multibody impact wear	Wear from the repeated impact of particles, bubbles, droplets, or energy discharges. Examples include particle impingement erosion, cavitation erosion (wear by imploding bubbles), slurry erosion, and spark erosion.
Rolling contact wear	Wear from the accumulation of surface damage during the cyclic stressing of one body rolling over or along another
Surface damage other than wear (examples)	Loss or displacement of material from a surface owing to mechanical contact in some form
Chipping	Removal of material from a surface, generally involving brittle crack propagation and the production of shell-like features. Chipping commonly occurs at sharp corners or edges of brittle contact surfaces.
Scuffing	Plastic deformation of surface material by rubbing, which generally produces a smooth appearance and is often localized in certain areas of the surface. Scuffing is sometimes referred to as <i>incipient galling</i> .
Scratching	Production of one or more shallow grooves in a surface by a hard counter body moving tangentially along the surface
Galling	A severe form of surface material displacement involving plastic deformation and the loss of fit between counter surfaces
Gouging	A severe form of localized plastic deformation in which relatively deep, localized troughs are produced
Scoring	Production of one or more deep scratches in a body generally involving plowing by a hard particle or protuberance on an opposing body
False Brinelling	Production of clusters of craters similar in appearance to hardness indentations with a spherical indenter
Frosting	The production of a dull appearance, typically on a bearing surface, due to a random pattern of fine scratches or gouges

The descriptions given in the “Characteristics” column of Table 1 suggest that the use of wear terminology is not without ambiguities. It is therefore important, when discussing or reporting on wear problems, to describe the phenomena sufficiently well so that terminology ambiguities are avoided. Wear problems can be further complicated by environmental interactions, such as oxidation or other surface chemical reactions, which occur along with wear. In fact, some wear classification schemes list oxidational or chemical wear as major forms of wear. Tests for most of the important forms of wear listed in Table 1 are described in this section. Sources for information regarding impact wear, polishing wear, and other types not covered here are listed in the bibliography.

Abrasive wear is one of the most economically important types of wear. The cost of damaged equipment, down time, and materials loss attributable to abrasive wear in the mining and agriculture industries alone is staggering. Several types of two-body and three-body abrasive wear tests are described. As with other types of

wear, more than one kind of test can be needed to establish the suitability of a given material, coating, or surface treatment for complex abrasive environments.

Erosive wear, as indicated in Table 1, can involve removal of material by impinging solids, liquids, liquid-entrained or gas-entrained solids, bubbles (cavitation erosion), or sparks. Like abrasive wear, erosive wear is a costly form of wear in industry. It attacks piping, pumping equipment, turbomachinery, and conveyor systems. Loose particles from erosive wear can also travel to other parts of a machine, creating secondary damage and loss of function. The variables associated with different types of erosive wear tests commonly include impingement angle, impingement velocity, screening by rebounding particles, and the shapes and sizes of the erodent particles.

Sliding contact, like galling or scuffing, can produce surface damage with only one contact event, or it can be a progressive form of wear like fretting or other repetitive contact types of wear. The article “Testing for Sliding Contact Damage” in this Section describes several forms of sliding contact damage and the methods commonly used to evaluate the resistance of materials to these damages.

Just as machines and their parts exist in a spectrum of sizes, friction and wear phenomena can also occur in various size scales. Obviously, the fine-scale interfacial contact processes involved in nanoscale coatings on hard disks require a different testing approach than the macroscale wear that occurs on the digger teeth of mining equipment and on the bows of icebreakers. Therefore, not only are there different types of wear, like abrasive wear, erosive wear, and so on, but there are also different size-scales of wear phenomena.

Introduction to Adhesion, Friction, and Wear Testing

Peter J. Blau, Oak Ridge National Laboratory

Adhesion, Friction, and Wear Testing Devices

Literally hundreds of devices for measuring adhesion, friction, and wear have been developed. Some of these are commercially manufactured but most of them probably have been custom-designed for specific purposes. This situation makes it difficult to compare the results from one study with those of another study unless the appropriate correlation has been established. There is no simple answer to the problems arising from the

proliferation of different testing machines for adhesion, friction, and wear. The use of established voluntary standards can help, but only if the standard applies directly to the problem of current concern. In the absence of widespread, commonly used test methods, it is necessary to analyze the applied conditions associated with each set of results carefully to determine the extent to which they can be compared to other work.

As with mechanical testing in general, commercial adhesion, friction, and wear testing machines are becoming increasingly computer automated. While automation has obvious advantages, it also necessitates conscientious calibration to ensure that the sensors and control mechanisms provide accurate readings to the computer.

In adhesion, friction, and wear testing, as in other forms of mechanical testing, the four most important requirements are (a) understanding the characteristics of the test method being applied, (b) expecting differing degrees of repeatability from different material types, (c) selecting the right testing tool for the job, and (d) coupling measurements with physical observations of contact surfaces to ascertain the causes for the measured behavior.

Adhesion Testing

Introduction

ADHESION refers to the interfacial bond strength between two materials in close proximity with one another. Adhesive bond strength can be described in several ways, depending on the nature of the interface. In physical chemistry, for example, adhesion is a fundamental term that refers to the attractive force between a solid surface and a second phase in either liquid or solid form. In this context, adhesion is a manifestation of the innate interatomic and intermolecular bonds that occur between the surfaces of two materials.

Other meanings of adhesion also arise in different disciplines related to mechanical engineering and the evaluation of coatings and films. In railway engineering, for example, adhesion often means friction (Ref 1) or the sliding resistance between two materials. In this context, the term adhesion refers to mechanical adhesion, which is defined as the adhesion produced by the interlocking of protuberances on the surfaces in an interface (Ref 1).

Adhesion also has important practical meaning in the evaluation of coatings, adhesives, and composite materials. Thin films ($<1\ \mu\text{m}$, or 0.04 mil), thick films ($>1\ \mu\text{m}$), and bulk coatings ($>25\ \mu\text{m}$, or 98 mils) all depend on adhesion, which can be evaluated and measured in a variety of ways, depending on the product configuration and application requirements. Therefore, it is not surprising that many methods are used to measure adhesion for films, coatings, and adhesive-bonded joints. Indeed, there are so many variations on adhesion measurements in coatings, surface films, and adhesives (Ref 2, 3, 4, 5, 6) that it would be impossible to describe them fully here.

Therefore, the purpose of this article is to describe briefly common adhesion measurement techniques for the three basic types of adhesion outlined by Mittal (Ref 2 and 6):

1. Fundamental (or basic) adhesion
2. Thermodynamic adhesion
3. Practical adhesion

Common measurement methods for each type of adhesion are briefly discussed, with the main focus on practical adhesion testing of coatings and thin films. However, to illustrate the use of adhesion testing in materials research, this article also includes a section on the use of adhesion tests in the evaluation of stress-corrosion cracking (SCC) within bimaterial interfaces.

Fundamental Adhesion

Fundamental adhesion refers to the basic intermolecular forces that occur whenever two materials are in close proximity. These intermolecular forces that act between the surfaces of bodies are called surface forces (Ref 7, 8), and adhesion is one manifestation of the existence of surface forces.

Surface Forces

Fundamental adhesion arises from innate surface forces, which have their origins in well-understood interatomic and intermolecular forces (Ref 7). Such forces are always present, and they can be described by the summation of individual bond strengths over a unit area or by the energy required to break chemical bonds at the weakest plane or loci of points within an interface (Ref 2).

It is sometimes convenient to classify surface forces as either short-range or long-range surface forces. Short-range surface forces are those that act between atoms and molecules that are essentially in contact, say within 0.1 or 0.2 nm of each other. Examples of this are covalent and hydrogen bonding, as well as Born repulsions. Long-range surface forces act between surfaces that are farther apart, which in this context means on the order of a few nanometers. Examples of long-range surface forces include van der Waals and electrostatic forces. However, some short-range surface forces also produce effects over a longer range. An example of this is steric repulsion. In this case, surfactant molecules adsorbed on a solid surface (via short-range bonding) can prevent a second surface from approaching the first. Boundary lubricants operate in this way to keep solid surfaces separated.

In general, short-range forces are stronger than long-range forces and make the most important contributions to adhesion. Unfortunately, long-range forces are easier to both measure and model. Therefore, knowledge of surface forces, from both a theoretical and experimental standpoint, is much sounder for long-range effects. This is why an understanding of fundamental adhesion based on short-range surface forces has proven to be difficult (Ref 9).

Measurement of Surface Forces

“Long-range” surface forces act over surface separations from 1 to 100 nm and cause forces levels in the range of about 10^{-7} to 10^{-4} N. Measuring these forces is not a trivial matter. The magnitude of the forces increases with surface area (or, as shown below, with the radius of curved surfaces). Thus, in order to have measurable forces, it is desirable to have extended areas of surface. At the same time, to make sensible measurements of surface separation on a nanometer scale, it is necessary for the surfaces to be extremely smooth. A method of detecting small forces is required, as are methods of controlling and measuring very small surface separations.

Although surface force measurements have been made for several decades, the inherent difficulties of surface preparation and cleanliness limited the number of materials studied and the amount of data to a small level, until about 1970. The most popular technique has been the crossed-cylinder apparatus devised by Tabor (Ref 10) and further developed by Israelachvili (Ref 11). This technique uses a surface force apparatus (SFA), which is commercially available. A review of the field up until 1982 is also provided in Ref 12.

The SFA consists of a closed stainless steel chamber designed to enclose a variety of liquid or vapor media and is usually operated at ambient temperature and pressure. Force is measured between two cylindrical surfaces, with the axes of the cylinders at right angles to each other (Fig. 1). The reason for choosing this geometry is for purposes of practicality. If two planar surfaces were to be used (as one might have supposed), then there would be extreme difficulties in forming surfaces of sufficient flatness, mounting them exactly parallel, maintaining parallelism while moving the surfaces together or apart, and avoiding edge effects, all while working on a nanometer scale. As shown in the next section, “The Derjaguin Approximation,” it turns out that there is no difficulty interpreting the forces measured in this odd geometry because there is a simple relationship between the force measured between crossed cylinders and the energy of interaction between flat surfaces.

Fig. 1 Surface force apparatus, in which two thin solid substrates are mounted as cross cylinders, with one of them supported by a cantilever spring whose deflection measures the force. An optical interferometric technique is used to measure the distance between the surfaces.

In order to measure surface separation, the SFA employs an optical interference technique (Ref 11, 13, 14). Under optimal conditions, this gives a resolution of 0.1 nm or better. Of course, one drawback is that it places a limitation on the solid materials that can be investigated; namely, that at least one of the pair whose surfaces approach contact must be transparent and rather thin (ideally, a few nm). Most of the measurements made with this apparatus have been made with thin foils of mica bent around and glued to cylindrical glass lenses.

To implement the optical method, a 95% reflecting silver layer is coated on the outer (that is, remote) surface of each solid substrate. Collimated white light is shone through the two substrates and whatever medium separates them (Fig. 1). Multiple-beam interference between the two silver layers selects only certain wavelengths of light, which are passed by the interferometer. All other wavelengths interfere destructively and are not transmitted. The transmitted light is collected and directed to a grating spectrometer, which spreads it according to wavelength, so that discrete wavelengths appear at the exit port of the spectrometer as spatially separated fringes of equal chromatic order.

The wavelengths depend on the thicknesses and refractive indices of the materials that are included in the interferometer: usually, the two transparent substrates and whatever fluid medium is between them. Measurement and analysis of the wavelengths allow computation of these thicknesses (Ref 13, 14). Because the two solids are of fixed thickness, those values can be subtracted from the total to give the thickness of the intervening medium, that is, the separation, D , between the inner (adjacent) surfaces of the solids at their closest point of approach.

The surface force that one solid substrate exerts on the others is measured by a simple spring-deflection method. One solid is mounted on a cantilever spring, the remote end of which is moved up or down using a three-stage drive mechanism. The first stage is a micrometer that allows coarse positioning of the surfaces from a separation of a few mm to a few μm . The second stage is a micrometer that acts through a differential spring mechanism, which reduces the motion a thousand-fold, allowing positioning to approximately 1 nm. Finally, voltage applied to a piezoelectric tube expander gives positioning to a fraction of 1 nm.

After calibrating the drive mechanisms, it is straightforward to monitor any differences between a movement of the remote end of the spring and the distance moved by the end that bears one of the solids. This difference corresponds to a deflection of the spring. Multiplying it by the spring stiffness (typically 100 N/m, or 7 lbf/ft) gives the increment in force resulting from the movement. Because both the calibration and the movement of the solid are measured with a resolution of ~ 0.1 nm, it is possible to measure very small force changes (10^{-7} to 10^{-8} N) using this technique.

The Derjaguin Approximation. The force, F_c , between two gently curved surfaces is proportional to the interaction energy per unit area, E_f , between two flat ones at the same separation. This relationship, known as the Derjaguin approximation, allows straightforward interpretations to be made of surface force measurements between crossed cylinders (or between one sphere and another or between a sphere and a flat plate). It is also helpful in certain adhesion measurements, as described below.

The Derjaguin approximation is derived (see Ref 7, for example) by considering the force between each element of one curved surface and each element of the other, and then integrating over the two surfaces to obtain the total force. As long as the radius of curvature is much larger than the range of the surface force, this is approximately equivalent to integrating the force per unit area, F_f , between flat surfaces, from the minimum separation of the curved surfaces, D , to an effectively infinite upper limit, with some geometrical factors to account for the shape of the surfaces. The integral simply gives the interaction energy between flats, $E_f(D)$, which is the work done against the surface forces in moving the flat surfaces from infinity to D . For two spheres of radius R_1 and R_2 , the geometrical factor is a constant, giving:

$$F_c(D) = 2\pi R E_f(D)$$

where $1/R = 1/R_1 + 1/R_2$. It can be shown that the geometry of crossed cylinders of equal radii, R_c , is equivalent to a sphere of radius R_c approaching a flat plate, or to two spheres of radius $2R_c$ approaching each other.

Substrate Materials. The original and still most common solid material used in surface force measurements is mica, chosen because it satisfies the requirements (thin and transparent) of the optical interference technique used in the SFA and because it is easy to prepare large areas of molecularly smooth surface by cleavage. Experiments have been conducted on mica surfaces immersed in many different liquid and vapor environments (Ref 8).

Recently, there has been some success in extending these measurements to a wider range of surfaces. One approach is to coat mica surfaces by various techniques, including Langmuir-Blodgett deposition, surfactant or polymer adsorption from solution, plasma modification, and evaporative coating of thin metal, carbon, and metal-oxide films. An alternative approach is to find a means of preparing other transparent materials as micron-thick foils with very smooth surfaces. This has been done for sapphire, silica, pyrex glass, and certain polymers. It is reasonable to expect that the range of materials studied will continue to increase in the near future.

Currently, the best way to prepare metal surfaces for SFA appears to be thin-film evaporation onto mica or another smooth substrate. Because the optical technique requires some light to pass through the two films, their thicknesses cannot be more than a few tens of nanometers. It is possible to use the metal films themselves as one or both optical interferometer mirrors, but the fringes of equal chromatic order would disappear from the visible spectrum if the two metal surfaces were brought closer together than about $1\ \mu\text{m}$ ($40\ \mu\text{in.}$). In that case, an alternative method of measuring separation, such as capacitance, would be required.

Environments. Tests with the surface force apparatus can be conducted in many different liquids or vapors, as long as they are compatible with the materials of the SFA system (namely, stainless steel, silica, Kel-F, and Teflon). There is a provision to heat the chamber to around $100\ \text{°C}$ ($212\ \text{°F}$). Use of an appropriate heating jacket could extend the temperature range from, perhaps, -50 to $150\ \text{°C}$ (-60 to $300\ \text{°F}$). At about $150\ \text{°C}$ ($300\ \text{°F}$), the silver layers used for interferometer mirrors degrade. This limit might be raised by using other optical coatings. The next limitation of the current design would be the maximum operating temperature of the Teflon seals, which is $250\ \text{°C}$ ($480\ \text{°F}$). In principle, the same or comparable techniques could be extended to operate at several hundred degrees, but in practice this would require a major redesign of the apparatus.

At present, the SFA is intended only to operate at or near ambient pressure. With some modifications to the seals, it could be made to hold moderate vacuum, say 10^{-4} Pa (10^{-6} torr). A total redesign would be required to build a device for making comparable measurements in ultrahigh vacuum (UHV) conditions.

Preparation of Surfaces and Fluids. Any solid to be investigated by the SFA method should be smooth, compared to the range of forces under examination. Because the adhesion between surfaces is often dominated by very short-range forces, atomically smooth surfaces would be required to make fundamental and reproducible measurements of these. However, rough surfaces still adhere, and so measurements can be made without insisting on atomic smoothness. The drawback, in that case, is that it would be more difficult to obtain a straightforward interpretation of the results.

Because SFA measurements involve extremely small surface separations, there are stringent requirements for cleanliness. One speck of dust in the wrong place can spoil the entire test. The relative importance of surface cleanliness is again related to the range of force under investigation. For very short-range forces, even a

monolayer of adsorbed vapor will dramatically influence results. Considerable care must also be taken in preparing any liquid or vapor environment. Vapors must be free of dust, and liquids must be free of both particulate and molecular (for example, polymer or surfactant) contamination that can easily adsorb to solid surfaces and affect the results.

Other Measurements with SFA. The SFA method can be used to measure other properties of thin liquid or vapor films and solids at or near contact. These properties include the thickness of an adsorbed layer, the refractive index of very thin liquid films or adsorbed layers (Ref 13), the viscosity of ultrathin liquid films (Ref 15, 16), and the friction between two molecularly smooth solids (Ref 17).

Adhesion Testing

Thermodynamic Adhesion

Thermodynamic adhesion refers to the change in free energy when an interface is formed or separated. This concept of adhesion is defined in terms of surface energy, interfacial energy, and the work of adhesion.

Surface energy (γ_s) is the work required to create a unit area of new surface from bulk material. It is commonly defined as half the reversible work (W_c) required to first divide a monolithic solid into two new surfaces and then to pull the two surfaces far apart in a vacuum (where far apart means beyond the range of the applicable surface forces). The term W_c is also called the work of cohesion.

In general, the creation of a new surface from a separation of materials involves the breaking of interatomic bonds, whose number (and possibly strength) depend on crystallographic orientation. Therefore, surface energy varies from one crystal face to another (Ref 18). The act of creating two surfaces requires work to be done against the attractive surface forces, and thus the integration of surface force, as a function of separation from 0 to ∞ , gives a quantity:

$$W_{SF} = - \int_0^{\infty} F_f(D) dD \quad (\text{Eq 1})$$

where $F_f(D)$ is the surface force between flat solids at a separation, D , using the convention that $F < 0$ for an attractive force. The subscript SF indicates that this is the contribution to W_c from the surface forces.

Sometimes W_{SF} is equated to twice the surface energy, but this is not generally correct because other energetic processes are likely to occur during the creation of new surfaces. In particular, the new surfaces are likely to reconstruct. Atoms near the new surface rearrange their positions to a configuration that is more favorable near a surface than was their original configuration in the bulk of the solid. Furthermore, there is the delicate issue of assigning the energy associated with breaking strong, short-ranged atomic bonds when the original solid is “magically” cleaved. This is certainly a contribution (probably the major one) to W_c , but it is unclear whether or not it should be included in the definition of W_{SF} .

Interfacial Energy. When a solid is not in vacuum but is in contact with a liquid or vapor, it is considered in terms of interfacial energy, γ_{SL} or γ_{SV} , respectively, rather than surface energy. If the above process is carried out in either a liquid or vapor environment, the work of cohesion equals twice the interfacial (solid-liquid or solid-vapor) energy. The same remarks about reversibility and reconstruction still apply. Furthermore, in this situation there is also the likelihood that molecules of the liquid or vapor will adsorb to the new solid surface (which could be thought of as “reconstruction” of the fluid at the interface). Adsorption reduces the interfacial energy.

Note that the reconstruction of both solid and fluid depends on which materials are involved. For example, a given solid material may reconstruct differently in water than in a hydrocarbon liquid. The details of the interfacial structure are also likely to depend on the distance between one interface and the other. Careful consideration also must be given to the question of reversibility. If the adsorption is irreversible, then bringing the two solids back together after they have been separated will not remove the adsorbate, and the surfaces will never return to their original intimate contact and will not reform the original atomic bonding that existed in the monolithic solid.

The interfacial energy, γ_{LV} , between a liquid and its own vapor is also called the surface energy, or, more commonly, the surface tension of that liquid. The term “tension” comes from a real force that resists any attempt to increase the surface area of a given volume of liquid. Surface tension of a liquid can be measured directly. Determining either the surface or interfacial energy of a solid is much more problematic. Solid-liquid and solid-vapor surface energies are related to the liquid surface tension and the contact angle, θ , made by the liquid on the solid through Young's equation:

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta \quad (\text{Eq 2})$$

Work of adhesion (W_A) refers to the energetic cost of creating new interfaces of each solid material in contact with the environment, γ_{1E} and γ_{2E} , where the subscript E could be liquid or vapor, as appropriate, less the energetic gain from removing the original solid-solid interface. The energy associated with the solid-solid interface is also termed an interfacial energy, γ_{12} , which is defined by the Dupré equation:

$$W_A = \gamma_{1E} + \gamma_{2E} - \gamma_{12} \quad (\text{Eq 3})$$

Adhesion is sometimes used to mean work of adhesion. In a similar way, one could define the work of adhesion between two pieces of the same solid material. This would differ from the work of cohesion if the two pieces were brought together in an environment so that adsorbate remained at the interface or if they were formed with their crystal orientations misaligned, giving a grain boundary at the interface. In that case, the quantity γ_{12} would be nonzero and would correspond to a grain-boundary energy, with or without extrinsic molecules

present. Because grain-boundary energy depends on grain-boundary angle, the adhesion between two crystals of the same material depends on their relative orientation.

Note that there is another effect that can make the above definition of work of adhesion problematic. When two solids are pulled apart, it is quite possible, and often observed in practice, that separation does not occur precisely between the two materials. Many solids diffuse into one another when in contact, particularly at high temperature. This makes it almost impossible to separate them in the ideal way that the simple thought experiment would imply. Even without diffusion, it is frequently found that joints break parallel to, but not precisely at, the interface. Many experimentalists have detected at least one of the materials on both sides of the division following separation (Ref 18).

When the environment includes a condensable vapor, an additional contribution to the adhesion between two solids occurs from an effect known as capillary condensation. Liquid condenses (as long as the contact angle is less than 90°) to form a bridge wherever the gap between the solids is small. Curvature of the liquid-vapor meniscus results in a negative Laplace pressure in the liquid, which acts as a cohesive force that holds the solids together. The magnitude of this force depends on the relative vapor pressure of the liquid and on the geometry of the solids (Ref 7 and 19). In some situations, this is the predominant factor in adhesion.

Adhesion Testing

Practical Adhesion

There are many types of adhesion tests for specific geometries and modes of separation for coatings, films, and adhesive joints (Ref 2, 3, 4, 5, 6). A number of them are either empirical or semiempirical. Others give only a comparative test of adhesion, such as whether the adhesion between a thin film and a substrate is greater or less than the adhesion between the film and some reference material.

In general, practical adhesion tests involve the application of a known stress to a joint or interface to determine when it fails. However, the force required to separate two bodies with mating surfaces depends very much on the manner in which they are separated. For example, two microscope slides held together by a thin film of moisture are extremely difficult to separate in simple tension or even by wedging them apart, whereas they separate easily in shear. The reason for this lies partly in the fact that the work of adhesion can be done by applying a large force over a small distance (uniform tension) or a small force over a large distance (as in peeling or sliding). In a similar way, the fracture threshold also depends on the mode of separation, such as tension versus shear. Therefore, an adhesion test carried out in one mode might reveal little about failure in another.

Adhesive Joints. Various arrangements that can be employed in adhesion tests are illustrated in Fig. 2. For large pieces (as opposed to films or coatings), the most obvious arrangement is the butt joint (Fig. 2a). Although it may look simple, the ease of fracture or failure can depend strongly on the presence of flaws in the joint and on how and whether a crack/separation is initiated at the edges of the sample. A lap joint (Fig. 2b) is appropriate to test shear strength, for example, in laminates. Care must be taken to avoid excessive bending of the beams during the test, because that introduces some tensile component. The ring shear, or “napkin ring,” test (Fig. 2c) applies a more uniform shear stress to the joint, whereas the peg topple test (Fig. 2d) is closer to ideal tension, but not straightforward to analyze.

Fig. 2 Various arrangements for adhesion tests

The double-cantilever-beam geometry (Fig. 2e) provides an excellent fracture-mechanics type of test if suitable samples can be prepared. A clever variation on this is to profile the beams in such a way that the fracture

threshold is independent of the length of the crack (Ref 20), making the analysis very simple. These types of practical adhesion tests are most commonly applied to adhesive-joint testing, which is described in more detail in the article “Testing of Adhesive Joints” in this Volume.

Films and Coatings. When thin films, thick films, or coatings are involved, there is another set of test geometries that can be used. The peel test is very common, with the force applied at various angles, not just the 90° angle shown in Fig. 2(g). Blister and delamination tests (Fig. 2f and h) can be very well controlled and properly analyzed in terms of fracture mechanics (Ref 2 and 21). The scratch test (Fig. 2i) is much more difficult to analyze, but it at least has the merit of being the only one of these configurations that tests adhesion under dynamic sliding conditions. More detailed coverage of the various methods is contained in Ref 2 and 6. Mechanical testing and indentation testing of thin films are also covered in the article “Evaluation of Mechanical Properties of Thin Films” in the *ASM Handbook*, Volume 5, *Surface Engineering* (p 642–646).

Adhesion Testing

Adhesion and Interfacial Degradation

Natalia Tymiak and W. Gerberich, University of Minnesota

Gaining an insight into mechanisms of environmentally induced interfacial degradation requires an understanding of the fundamental aspects of adhesion between two dissimilar materials. For any application involving multilayers, fiber/matrix, or film/substrate systems, strength of bonding between two materials is one of the critical reliability issues. Environmental exposure is also a key factor in the interfacial degradation of various bond interfaces of metal/polymer (Ref 22, 23), ceramic/polymer (Ref 24), metal/ceramic (Ref 25, 26), and so forth. For interfaces involving metals, the possibility of hydrogen-induced interfacial degradation exists under exposure to gaseous hydrogen (Ref 27) or during cathodic hydrogen discharge (Ref 28). The latter may

result from an appropriate combination of local galvanic electrocoupling and moisture environment that is quite common for microelectronics applications.

Adhesion Testing

Fundamental Aspects of Bimaterial Interfacial Adhesion

The practical work of adhesion, W_{prac} , refers to the total energy necessary for separation along an interface between two materials as affected by several energy absorption mechanisms. In terms of the critical strain energy release rate, G_{crit} , that is, elastic energy released per unit of fracture area:

$$W_{\text{prac}} = G_{\text{crit}} = \Gamma_0 + \Gamma_p + \text{other forms of dissipation} \quad (\text{Eq 4})$$

Here, Γ_0 is the work consumed by the fracture process per unit area of new surfaces. Interfacial fracture energy, Γ_0 , accounts for both the thermodynamic work of adhesion, W_a , and microstructural effects in the fracture process zone such as crack bridging (Ref 29), interdiffusion, mechanical interlocking (Ref 30), and/or existing defects along an interface. The thermodynamic work of adhesion is determined mainly by attractive interatomic or intermolecular forces. The most common interfacial attractive forces result from van der Waals and Lewis acid-base interactions (Ref 31). A contribution of electrostatic forces should also be considered (Ref 32).

The magnitude of W_a is determined by the Dupré equation (Eq 3) (Ref 33) and is defined as:

$$W_a = \gamma_1 + \gamma_2 - \gamma_{12}$$

where γ_1 , γ_2 , and γ_{12} are surface energies of materials along an interface and of the interface respectively. The term Γ_p in Eq 4 accounts for plastic energy dissipation rate at the interfacial crack tip. For interfaces involving polymers, viscoelastic-plastic deformation may result in additional dissipational losses, Γ_v . The stronger the interface (higher Γ_0), the more energy is dissipated through plastic and/or viscoelastic deformation (as well as through any other dissipation process). Other factors affecting Γ_p and Γ_v are viscoelastic-plastic properties of two materials forming an interface and geometry of a system. The latter implies crack configuration and

volumes of materials involved. For example, experimental results for ductile films on brittle substrates such as copper on SiO₂ suggest plastic energy dissipation scaling with the copper film thickness (Ref 34). As a result, the practical work of adhesion can increase by orders of magnitude when film thickness increases from the nanometer to the micron scale. Among other mechanical properties determining Γ_p , yield stress appears to be of a critical concern due to its high sensitivity to microstructure, chemistry, and gradient constraints. Frictional losses may be significant for rough interfaces with the effect increasing with the decreasing film thickness (Ref 35). For strong interfaces, additional dissipation mechanisms may be present. These include void nucleation (Ref 36), second-phase debonding, microcracking, and shear band formation (Ref 37, 38).

Measurements of the practical work of adhesion can also be strongly dependent on the mode mixity or a relative fraction of mode I and mode II. Mode mixity is determined by sample/applied load geometry and can be defined as (Ref 39):

$$\Psi = \arctan\left(\frac{K_{II}}{K_I}\right) + \text{elastic mismatch term} \quad (\text{Eq 5})$$

Generally, G_{crit} increases as the crack tip becomes increasingly heavy under mode II conditions (Ref 40). Possible mechanisms responsible for this trend include frictional losses (Ref 35) and/or plastic energy dissipation rates (Ref 41, 42), which increase with increasing mode II contribution.

It is clear that even in the absence of an environment there is no single value of adhesion for a bimaterial couple. The reasoning is that the practical work of adhesion depends on the volumes of materials involved as well as the loading modes and the microstructural characteristics determined by a particular processing route.

Adhesion Testing

Environment-Interface Interactions

An environmentally induced reduction in interfacial fracture energy may result from the following:

- Change in the thermodynamic work of adhesion
- Microstructural degradation such as microcracking
- Yield stress and/or viscoelastic property changes affecting dissipation losses
- Chemical or electrochemical reactions along an interface or in one or both materials, for example, hydride formation

Depending on the bimaterial couple and the environment, any of the above may be prevalent.

Similarly, as in the case of bulk solids, environments may be considered as chemically reactive if their reaction with either materials at the interface leads to dissolution or compound formation. Nonreactive environments include media that influence mechanical behavior of one or both joining materials. The other part of nonreactive media regarded as “inert” comprises environments that only may induce changes in surface energies of joining materials (γ_1 and γ_2) and that of an interface (γ_{12}). Note that specific interfacial crack-tip conditions may change environment/material interactions. Thus, any experimental results for a bulk material/environment may not be directly applicable to the same material along an interfacial crack. For example, varying ionic species concentrations unique to the crack tip region may adversely affect either side of an interface. This could involve oxygen reduction along a metal/polymer interface leading to polymer degradation. Another example is hydrogen evolution leading to metal embrittlement. It is also necessary to emphasize that diffusion along an interface may be much higher than in any of the two joining materials. Thus, after the same time of environmental exposure, the effect may be much stronger for a fracture along an interface compared to fracture in bulk materials.

Adhesion Testing

Polymer/Inorganic Interfaces

Factors Determining Polymer/Inorganic Material Adhesion. The thermodynamic work of adhesion for polymers is determined mainly by intermolecular bonds and Lewis acid-base (donor-acceptor) interactions (Ref 31). With a significant difference between acidities of joining materials, donor-acceptor bonds would be prevalent compared to intermolecular bonds (Ref 43). There is experimental evidence of adhesion strength decreasing with decreasing difference in acidities of joining surfaces (Ref 31). Environmental exposure resulting in change of surface acidity may affect adhesion strength. A so-called weak boundary layer may exist in some cases determining strength of an interface (Ref 44). It should be cautioned that bonding may be distinctively different

for metal-on-polymer compared to polymer-on-metal for a given couple. This would imply different response to environment/deformation exposure.

Environmental Effects on Different Contributions of Interfacial Toughness. The considerations for fracture in bulk polymers are relevant for interfaces involving polymers as well.

Special attention should be given to:

- Specific interactions between a polymer and an environment within a specific highly stressed near-crack-tip region
- Liquid transport toward a crack tip
- Temperature effects
- Rate dependence (loading and/or crack growth)

Environment/inorganic material interactions should be accounted for with specific attention to the environmentally induced surface modification. These may range from change in surface acidity to formation of a reaction product with the chemical and/or mechanical properties distinctively different from those of the original material.

For a particular system, environmental effects on the dominant contribution of adhesion strength would probably be most apparent. Depending on the structure of an interface and viscoelastic-plastic properties of joining materials, the thermodynamic work of adhesion may be small compared to dissipation and microstructural contributions. For several polymer-on-metal systems, adhesion strength is governed by mechanical/microstructural factors. On the other hand, viscoelastic-plastic dissipation may be dominant for strong interfaces involving polymers that exhibit viscoelastic flow. In some cases, it is possible to identify and evaluate environmental effects on a specific mechanism of adhesion, as discussed in the next sections.

Thermodynamic Work of Adhesion. With the peel test, Carre and Shultz (Ref 22) were able to evaluate environmentally induced relative change in the thermodynamic work of adhesion for rubber films on aluminum tested in various alcohols. These results agree very well with the theoretical calculations.

Microstructural/Mechanical Effects. The strongest effects may be expected here from exposure to “reactive” environments causing structural and/or chemical changes in one or both components of an interface. For interfaces where a dominant fraction of adhesion strength comes from a mechanical interlocking between a polymer and underlying metal oxide, environmentally induced changes in the chemistry and morphology of an oxide may be critical. Examples include aluminum oxide conversion to a hydroxide that is less strong and adheres poorly to the underlying metal (Ref 23). Similarly, adhesion to Ti/TiO₂ substrate may deteriorate with titanium oxide undergoing a polymorphic transformation to anatase (Ref 23). Such a transformation is highly temperature and moisture dependent. In other systems, such as epoxy-coated phosphated steel, exposure to humid environments results in formation of a porous, moisture-retaining metal oxide layer (Ref 45). This facilitates adhesion strength losses. It should be noted that reactions between a solid and an environment may be strongly affected by the presence of a joining material. For example, galvanic coupling between an exposed metal and an adjacent polymer-coated surface results in oxygen reduction along an intact interface (Ref 46). This leads to the transformation of a near-interface layer of polymer into a gel-like structure with subsequent gradual interface deterioration. In many cases involving degradation of a near-interface region in one of the joining materials, a cohesive rather than adhesive fracture occurs.

Dissipation Losses. Environmental exposure may result in both *direct* and *indirect* effects on plastic/viscoplastic dissipation. First, environmentally induced changes in viscoelastic plastic behavior would influence dissipation *directly*. Second, degradation of the thermodynamic work of adhesion and/or microstructural component of adhesion strength may result in lower dissipation contributions. Moisture-affected viscoplastic deformation may be regarded as a major source of humidity-induced interfacial strength degradation for a glass/pressure sensitive adhesive (PSA) interface (Ref 47). There was no apparent difference between exposed and nonexposed samples prior to the “yield point” corresponding to fibril formation. In contrast, the capacity for viscoplastic deformation associated with interfacial fracture appeared greatly deteriorated in the presence of a humid environment. This resulted from local moisture absorption in the vicinity of the crack tip rather than humidity-induced changes in the bulk viscoelastic behavior of the polymer. Sometimes, moisture effects are complicated by the possible change of mechanisms at different humidity levels. In general, moisture has been shown to decrease interfacial toughness for polyimide films on glass substrates. For low humidity levels, adhesion strength decreased with the increasing moisture content.

However, for moisture content levels above 60%, adhesion strength increased with the further humidity increase as shown in Fig. 3 (Ref 48). Here, formation of a boundary layer along an interface has been suggested as the possible mechanism responsible for adhesion strength increase at relative humidities above 60%.

Adhesion Testing

Interfaces between Inorganic Materials

As of the late 1990s, there appears to be only limited experimental data available on environmental degradation of inorganic interfaces. As for polymer/inorganic interfaces, environment could affect the thermodynamic work of adhesion as well as deteriorate an interfacial bond via reaction with one or both joining materials. *Direct* environmental effects on the dissipation losses would not be considered here, except possibly for interfaces where one material is susceptible to environmentally induced changes (e.g., via hydrogen charging) in plastic behavior. In contrast, *indirect* changes in dissipation losses are possible via environmental effects on the thermodynamic work of adhesion and/or microstructure.

Metal Films on Ceramic Substrates. As of the late 1990s, environmental effects for metal films on ceramic substrates have only been evaluated for very few metal/ceramic systems. All of these studies examined humidity or hydrogen effects on interfaces between metallic films and ceramic substrates. From these studies, the condition of a ceramic surface appeared to be very important in determining susceptibility to environmental cracking as shown by the Al/Si₃N₄ (Ref 49) system tested in water. Presence of a damaged near-surface region in Si₃N₄ seemed to increase propensity for SCC. With such a layer, a crack propagated through this layer rather than along an interface. Removal of the damaged material yielded interfacial strength approaching that for bulk Si₃N₄.

In contrast, with the deliberately patterned SiO₂ surface, Cu/SiO₂ interfaces exhibit much higher toughness in both dry and humid environments (Ref 26) as shown in Fig. 4. The effect was attributed to crack bridging. Indicating similarity of mechanisms, the form of velocity-energy release rate (*V-G*) dependencies was essentially the same for smooth and patterned interfaces. Likewise for bulk materials, the kinetic curves for interfacial crack growth exhibit three characteristic regions. The strong environmental effect on both threshold (~20% reduction) and crack growth rates (more than 3 orders of magnitude increase) is evident from comparison of *V-G* curves in wet and dry nitrogen. Enhanced crack growth rates in humid environments were attributed to absorbed-water-induced weakening of interfacial bonds, which limits the extent of plastic stretching of the bridging segments of copper film. Namely, indirect changes in plastic energy dissipation were present there. It should be noted that observed interfacial crack velocities exhibited higher sensitivity to stress intensity and were more than 3 orders of magnitude greater than crack velocities for bulk soda lime glass in water vapor (Ref 50).

Fig. 4 Crack growth rates along plain and patterned glass/copper interfaces in wet and dry gaseous nitrogen environments

Experimental results for gold films on Al_2O_3 substrates tested in laboratory air and dry nitrogen indicate a moisture-induced reduction in adhesion strength (Ref 25). Examination of fracture surfaces indicated separation along an interface with no crack kinking into joining materials. With no apparent changes in any joining material, observed adhesion strength reduction would be attributed to the environmental effects on the interfacial fracture energy. Similarly, as in the previous example, a decrease of the interfacial bond strength resulted in less plastic deformation of the metal.

Hydrogen effects have been examined for thin 200 to 1000 nm copper film on oxidized silicon with 10 nm titanium interlayers between copper and SiO_2 (Ref 51). For both charged and noncharged films, the practical work of adhesion (W_{prac}) increased with the increasing film thickness, as shown in Fig. 5. Based on previous studies (Ref 52), this trend was attributed to plastic energy dissipation scaling with the film thickness. Hydrogen charging induced degradation of the practical work of adhesion. The possibility of a direct decrease in Γ_p has been eliminated as there was no change in the copper film yield stress following hydrogen charging. Based on the W_{prac} values and a theoretical model (Ref 53), a hydrogen-induced decrease of Γ_0 from 4 to 2 J/m^2 , independent of film thickness, had been determined. An additional investigation would be required to determine whether this change is attributed to the decreased thermodynamic work of adhesion, microstructural effects, or both. Examination of chemical composition and topography of fracture surfaces would clearly be necessary here. Also, to eliminate the possibility of a contribution from humidity, charging with gaseous hydrogen could be utilized.

Fig. 5 Hydrogen effects on strain energy release rates for Cu/Ti/SiO₂ interfaces

Ceramic Films on Metallic Substrates. Studies of environmental stability of ceramic coatings on metallic substrates have shown interfacial strength degradation during long-term aging without applied stress. For example, a substantial adhesion loss was observed for flame sprayed Al₂O₃ coatings on 316L stainless steel aged in aerated Ringers solution (Ref 54). Ferber and Brown (Ref 55) evaluated alumina coatings on 316L stainless steel and titanium alloy Ti-6Al-4V in distilled water under applied four-point bending. With the lower “inert” strength, alumina/stainless-steel interface exhibited higher susceptibility to environmental stress cracking. For both systems, the extent of slow crack growth was much greater than that reported for porous alumina (Ref 56). With increasing temperature, adhesion strength degradation increased for both types of coatings. Reaction between water and strained crack-tip bonds was suggested as a governing mechanism for environmentally assisted interfacial crack growth. At ambient temperature, fracture was always 100% adhesive for the alumina/stainless-steel interface. In contrast, for the alumina/titanium-alloy interface, fraction of adhesive fracture decreased with increasing fatigue life. This indicated that slow crack growth in a coating became the dominant mechanism at lower stress levels where longer environmental exposure was involved. For alumina/stainless steel, an observed environmental effect may be attributed to interfacial strength degradation. The situation is more complex for the alumina/titanium-alloy interface. Here, cohesive energy reduction for alumina becomes more significant with increasing time and, eventually, becomes less than the adhesive energy. For the weaker alumina/stainless-steel interface, the cohesive energy still exceeds the adhesive energy of an interface.

Ceramic-Ceramic Interfaces. Similarly, as for metal/ceramic interfaces, only very few systems have been evaluated. Only humidity or hydrogen effects have been investigated in these studies. Several studies (Ref 57, 58) address subcritical crack growth along SiO₂/TiN interfaces exposed to aqueous environments. Here environmental effects were evaluated both ex situ and in situ. For the ex situ experiments, crack growth velocities have been found to be highly sensitive to humidity exposure time (Ref 57). With the above, it was suggested that subcritical crack growth involved the diffusion of environmental species along the interface ahead of a crack. In fact, ion mass spectroscopy (SIMS) measurements (Ref 59) revealed that moisture diffusion along an interface was about 10⁴ times faster than diffusion in the bulk SiO₂. In situ experiments (Ref 58) were conducted under controlled humidity (40% RH) and temperature. It was suggested that mechanisms responsible for SCC in bulk glasses may also be involved in the environmentally assisted interfacial fracture (Ref 58).

Moody et al. (Ref 60) evaluated deuterium effects on adhesion between 600 nm thick tantalum nitride films and sapphire. As revealed by a microscratch test, deuterium exposure resulted in an interfacial toughness decrease from 24.5 to 9.1 MPa√m. At the same time, indentation testing indicated no changes in the mechanical properties of TaN films. Thus, direct deuterium effects on plastic energy dissipation could be eliminated. Therefore, decreasing interfacial toughness was attributed to an interfacial fracture energy decrease. Available experimental evidence supported hydrogen-induced decohesion. However, deuterium could also affect adhesion

strength by affecting the interfacial microstructure. Thus, the necessity of a more precise microstructural evaluation was suggested.

Testing Methods

Testing techniques for in situ environmental testing of thin-film adhesion are briefly reviewed. The focus is on quantitative methods where a characteristic of interfacial toughness is extracted from experimental results utilizing an appropriate model. In most cases, modeling is based on elasticity solutions. It is necessary to emphasize that these are applicable only under small-scale-yielding crack-tip conditions with the remaining material being elastic. However, extensive plastic deformation or even general yielding may develop in a ductile counterpart of an interface. Lai and Dillard (Ref 61) determined general yielding conditions for the most common test configurations and suggest appropriate types of test and sample dimensions for interfaces with different elastic mismatch and residual stresses. Even under conditions where general yielding is not expected, the local crack-tip region may experience extensive plastic deformation and associated dissipation losses. Several studies evaluate plastic energy dissipation associated with interfacial fracture (Ref 62, 63, 64). Results of these studies may be applied to practical specimen configurations that approximate situations treated in the above analyses. As for specific testing methods, either finite element analysis (FEM) analysis (Ref 65) or analytical approximation may be available (Ref 66) in some cases.

Methods suitable for in situ environmental testing of thin-film adhesion are briefly described below and are summarized in Tables 1 and 2 (Ref 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95). For ease of evaluation and to obtain useful quantitative data, the following criteria are suggested for these tests:

- Simple sample preparation with no or minimum effect on the properties of interfaces and/or joining materials
- A simple testing procedure with a possibility for in situ environmental exposure and/or testing shortly after an environmental exposure
- Precision and reliability in measurements of loading and crack growth characteristics
- Availability of an adequate model for a *quantitative* analysis. Ideally, not only a characteristic value of interfacial toughness should be determined, but also corresponding mode mixity and possible contributions of various dissipation processes
- Close approximation of service conditions (geometry and environment)

Examination of fracture surfaces may also provide useful information.

Table 1 Summary of adhesion testing methods

Test	Driving force for delamination	Sample preparation	Analysis	Mode mixity	Applicability	Requirements	Advantages	Disadvantages
Sandwich (Ref 65, 67, 68, 69)	External load	Diffusion bonding	Relatively simple, analytical solutions available	Between 0 and 90°, depending on a particular sample geometry	All types of interfaces	Film thickness small with any in-plane dimension	In situ testing; film residual stresses not required.	Sample preparation may change interfacial properties.
Peel test (Ref 70, 71, 72, 73)	External load	Simple partial delamination needs to be introduced.	A variety of dissipational processes to account for	...	Thick films; relatively weak adhesion	Mode mixity range out of practical interest range; not directly applicable to very brittle and/or very thin films
Blister (Ref 74, 75, 76, 77, 78)	Pressurization-environmental effects may be evaluated by pressurization with the media of interest.	Complex removing a “window” of a substrate (direct) or a fil (invert)	...	-60° to -30°	Challenging sample preparation; a direct method is not suitable for brittle films.

Table 2 Summary of indentation (contact mechanics) methods for adhesion testing

Test	Driving force for delamination	Sample preparation	Analysis	Mode mixity	Applicability	Requirements	Advantages	Disadvantages
Axisymmetric indentation (Ref 81, 82, 83)	Film residual stress plus stress due to indentation-induced plastic deformation in a film	None	Analytical	...	Plastically deforming films on harder substrates	More accurate for indentation depth smaller than film thickness	Simple sample preparation, procedure, and analysis	In general, not applicable for very ductile films and/or strong adhesion. Residual stress measurements are required.

Microwedge indentation (Ref 84, 85)	Indentation-induced plastic deformation in a film; or indentation-induced plastic deformation in a substrate	May involve microlithography	Analytical	-37° to -53°	Fine lines of ductile material on a brittle substrate and brittle films on ductile substrates	...	Directly applicable for microelectronic structures	...
Superlayer and axisymmetric indentation (Ref 86, 87, 88)	Same as above plus an additional driving force from a superlayer	None	Numerical	...	Ductile films on brittle substrates	...	Simple procedure; may be applied for very ductile film and/or strong interfaces	Challenges in analysis. Residual stress measurements are required.
Axisymmetric indentation (Ref 89, 90)	Indentation-induced plastic deformation of a substrate	None	Analytical approximation utilizing fem results	Pure mode II assumed	Brittle films on ductile substrates	Indentation depth much smaller than film thickness	Simple procedure	Not applicable for very strongly adherent films where very large penetration depth with the associated pileup are required. Here, film might experience out of plane bending
Microwedge scratch (Ref 84)	...	Microlithography or may be applied directly to fin lines	Analytical	...	Same as above	Same as above	Simple procedure	...
Scratch (Ref 91, 92, 93, 94)	...	None	Crude analytical approximations	Close to mode II	...	Thin films	Simple procedure may be applied to films on very ductile substrates	Very challenging analysis

Sandwich Specimen Testing. A thin film is sandwiched between two halves of a different material to make a fracture specimen tested either in tension or flexural bending. With the crack growing along an interface of interest, fracture toughness can be determined (Ref 65, 67, 68, 69).

Peel Test. A film is detached from a substrate under a fixed angle (Ref 70, 71). Elastic-plastic dissipation losses for a fixed-arm peel test have been analyzed by Kinloch et al. (Ref 72). The symmetrical double-peel arrangement for peel testing at variable angle and constant rate has been described in Ref 73.

Blister Test. A window in a substrate (direct method) (Ref 74, 75, 76, 77) or in a film (invert method) (Ref 78) is removed, and a remaining counterpart is pressurized by a liquid or a gas. An environmental effect may be evaluated by pressurization with the media of interest. With the electrolytic hydrogen charging of a thin metallic film, spontaneous blisters may form. Interfacial toughness may be estimated in this case, providing hydrogen fugacity is known.

Shear test under uniform plane stress loading along an interface (Ref 79, 80).

Contact Mechanics Testing. In this test, an indenter is driven into film/substrate system in order to induce film debonding. The driving force for delamination in contact mechanics methods is indenter-induced deformation. Little or no sample preparation is required (Table 2) and so there are no interfacial property changes from sample preparation. Based on the load and delamination dimensions, adhesion strength may be evaluated (Ref 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95).

Adhesion Testing

Surface and Adhesive Energies

Surface energies of fracture surfaces for environmentally exposed and nonexposed interfaces can be evaluated with the contact angle method (Ref 96, 97). Measured values may be compared to these for corresponding bulk material (Ref 98). Contact mechanics approaches provide an alternative measure of adhesive strength between flat and spherical surfaces (Ref 99, 100). Swadener et al. (Ref 98) measured adherence of an epoxy sphere to both pure glass surface and that obtained after fracture along an interface with epoxy. Similarly, environmental effects on interfacial fracture surfaces may be evaluated. Finally, an alternative way to measure adhesion strength using fracture surface examination was proposed by Sharma and coworkers (Ref 101). The method is based on digital image processing. A special sample preparation involving microlithography is required here.

Testing Methods for Solid Friction

K.G. Budinski, Eastman Kodak Company; P.J. Blau, Oak Ridge National Laboratory

Introduction

IN MACHINERY WITH MOVING PARTS, friction control can make the difference between acceptable operation and catastrophic failure. Friction in moving parts also reduces the energy-efficiency of machines, making them more costly to operate than if friction were reduced. Therefore, the measurement of friction force and the calculation of the coefficient of friction is warranted for many kinds of machines. In machine design, friction characteristics must be known for friction drives, for sizing motors, for determining work forces, for braking, for rotary seals, and for designing any part of the machine in which changes in forces between sliding members could affect operation. There is a close parallel between the history of friction science and the development of transportation systems, because friction problem solving has enabled the development of all kinds of engines, motor bearings, brakes, transmissions, seals, tires, and other vehicle components (Ref 1). To emphasize the importance of friction in machine design, it has been estimated that one-third to one-half the energy production of the world is wasted through friction (Ref 2).

Friction is not a measure of wear or the tendency to wear; therefore, it does not determine service life. Frictional heating sometimes causes a part to fail, but this usually occurs when circumstances cause abnormal friction effects. Articles describing a variety of measurement methods for different types of wear can be found in other articles in this Section of the Handbook and in *Friction, Lubrication, and Wear Technology*, Vol 18, *ASM Handbook*.

This article describes techniques for measuring friction. Emphasis is on solid/solid sliding friction, but in several instances, lubricated testing methods are described. Many different methods have been developed to measure friction because frictional behavior is dependent not only on the properties of the materials involved, but also on the manner in which they come together and interact (Ref 4). The objective of this article, therefore, is to provide enough information so that a person who has never conducted a friction test can do so. Depending on the method of measurement and the way in which the data are to be used, friction data can be obtained in various forms. The last section of this article therefore, describes how to report friction data and how these data can be entered into a database.

Testing Methods for Solid Friction

K.G. Budinski, Eastman Kodak Company; P.J. Blau, Oak Ridge National Laboratory

Definition of the Friction Coefficient

The static friction force, F_s , is that force which is just sufficient to resist the onset of relative motion between two bodies in contact under an applied normal force, N . The kinetic friction force, F_k , is that force which must

be overcome to allow the continuance of motion between two bodies. F_s and F_k act along or tangent to contact surface or interface in a direction so as to directly oppose relative motion. Thus, the static friction coefficient, μ_s , and the kinetic friction coefficient, μ_k , can be defined as a dimensionless ratio of forces as follows:

$$\mu_s = \frac{F_s}{N} \quad (\text{Eq 1})$$

and

$$\mu_k = \frac{F_k}{N} \quad (\text{Eq 2})$$

Elsewhere in this article, if there is no subscript for μ and it is not otherwise stated, it should be assumed that μ_k is implied.

In Eq 1 and 2, both N and F are expressed in units of force. For example, a 1 kg mass resting on a plane exerts a downward force of 9.81 newtons. Strictly speaking, the applied “load” is only equivalent to the normal force if it is applied downward. Thus, it is appropriate to say a load of 9.8 newtons was applied only if the weight acts downward, as in deadweight loading. If, as in a horizontally loaded component, the N acts in a direction other than parallel to the gravitational force, the expression “normal force,” not “load,” must be used. In practice, it is always better to use the general term “normal force” to avoid having to make this distinction.

Testing Methods for Solid Friction

Methods for Measuring Friction

Surface Preparation. Before one conducts any kind of friction test, surfaces of the test pieces should be properly prepared, and their method of preparation should be documented. Since frictional behavior reflects the condition of the contact surfaces and the interface conditions between them, it can be affected by the initial cleanliness of surfaces as well as the method used to produce those surfaces (i.e., machining conditions, polishing methods, etc.). The degree to which the cleanliness and other initial preparation factors will affect the results depends to some extent on the applied test conditions. For example, lightly loaded contacts tend to be more sensitive to surface cleanliness than heavily loaded surfaces in which the onset of sliding quickly wipes films away and can even alter the surface roughness and the subsurface microstructure.

In preparing surfaces for application-oriented testing, including lubricated testing, the conditions of the tribosystem should be simulated as closely as possible. For example, if brake rotor surfaces become rusty during long idle periods in a parking lot, then rusty surfaces should be used for brake rotor friction testing to simulate this condition. Absorbed films from the atmosphere can be another source of contamination. In tests of ultrahigh-molecular weight polyethylene used for conveyor tracks, for example, it was found that if the material sat unused for 48 h or more, as over a weekend, the starting friction was unacceptably high due to the formation of a film on the material. Thus, the laboratory test conditions should mimic such practical operating considerations.

The effects of specimen surface preparation and handling are not further discussed here, but the reader can consult Ref 2 and 3 for additional details. The next sections describe friction testing geometries and the major considerations implicit in their use.

Inclined-Plane Method. Most commonly used friction coefficient measuring methods require the measurement of both the friction force and the normal force, but not all friction coefficient measuring methods do. For example, the inclined-plane static friction coefficient measurement method depicted in Fig. 1 and dating back over 400 years to Leonardo da Vinci's notebooks, requires only a block of material resting on a flat surface, which can be tilted gradually. The weight of the block need not be known, only the angle of tilt. In this case, μ_s is obtained from the following expression:

$$\mu_s = \tan \theta \quad (\text{Eq 3})$$

The specimen is placed on the plane in a horizontal position, and the plane is gradually raised. At some angle, θ , movement of the specimen begins, and the static friction coefficient can be determined. This simple and straightforward test lends itself to standardization. The ease of repetition allows many measurements to be made to obtain an average and standard deviation for μ_s . If the static friction coefficient is relatively low (less than 0.09, $\theta = \sim 5^\circ$), additional precautions in leveling and measuring the tilt angle are required. In fact, alternative means for friction measurement should be considered if such low values are to be accurately measured.

Fig. 1 Inclined plane measurement of the static coefficient of friction (μ_s)

Inclined-plane tests form the basis for ASTM D 3248 (for measuring cardboard friction) and D 3334 (for measuring the friction of woven fabrics), but they can be used for a wide variety of other solid materials. This method does not require the weight of slider block to be known, but research on metals has shown that the results are not independent of the normal force, especially at light loads (Ref 5). The problem with this technique is that it does not simulate many real-life tribosystems. Machine designers do not design systems that involve only inclined planes, and friction is not dependent on just the materials making up the couple. Therefore, more complex machines that simulate the frictional contact of the specific applications can be required. The same argument holds true for simple pulley and weight methods described in the next section.

Friction Test Methods Using Weights and Pulleys. The friction coefficient can be calculated for simple geometries using arrangements of weights and pulleys. Some typical arrangements for measuring static friction coefficients are shown in Fig. 2. Mass is added until the block or cylinder of known weight just begins to move. Equation 1 can then be used.

Fig. 2 Schematics of friction-measuring devices based on early work of Leonardo da Vinci

Like the inclined plane method, the problem with block and pulley methods is that the precision and repeatability of the measurement tends to be not very high. One has to account for such things as the stretching of the connecting wires or cords, the friction in the pulleys, pulling any knots tight before motion begins, and more. It is thus, desirable when possible to use force sensors. With force sensors and smooth motor drives, sled-type, block-on-plane methods can be used to measure not only the static but the kinetic friction coefficient as well.

Pulling a block on a flat surface with a load sensor yields the friction force, F in the basic friction equation, $F = \mu N$, where N is the normal force. This is probably the most common method of measuring friction force. Although there are countless variations of this test, most devices use a force sensor that is essentially a calibrated spring. This spring has a spring constant that determines the sensitivity of the system; there is probably some damping associated with the system. A free-body diagram of a sled friction tester is shown in Fig. 3.

Fig. 3 Free-body diagram of a sled friction tester. N , normal force

Certain system parameters can affect the results of a friction study. All that is measured is the friction force, F , by means of an electrical signal or a mechanical device. Both types of sensors have elastic and damping characteristics that can affect the measurement. The major concern is static friction. If the pulling system shown in Fig. 3 were replaced by a steel rod, which would have much smaller time-dependent strain behavior, the system model could be simplified as shown in Fig. 4. The measured force would still involve the elastic properties of the steel rod (spring a), but any time-dependent component of the friction force would come from the system under study, that is, the elasticity, a , and viscous behavior, b , of the surface contacts.

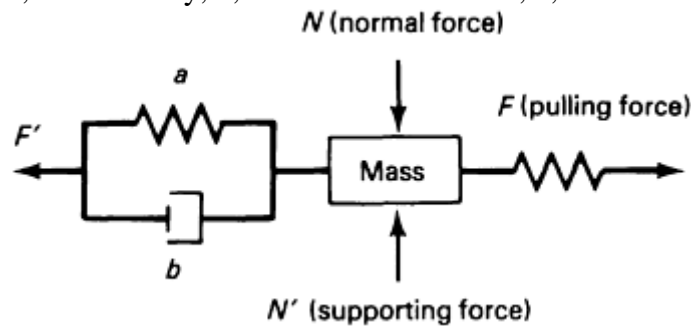

Fig. 4 Free-body diagram of a sled friction tester with a nonelastic driver.

Friction Tests of Shafts and Capstans. The friction of shafts turning in journal bearings and of flexible materials sliding over curved surfaces represents two important classes of practical frictional problems. In each case, the plane of interaction is not flat, and the resistance to rotation is of interest. The directions of the friction force represent a family of vectors of tangency to the curved surface acting along the contact zone.

Figure 5 shows a diagram of a journal bearing. The Petrov equation, developed in the late 19th century, can be used to calculate the friction coefficients as follows:

$$\mu_k = \left(\frac{4\pi^2 l}{c} \right) \left(\frac{\eta \omega}{N} \right) \quad (\text{Eq 4})$$

where r is shaft radius, l is bushing length, c is lubricant film thickness, η is lubricant viscosity, ω is shaft velocity, and N is normal force.

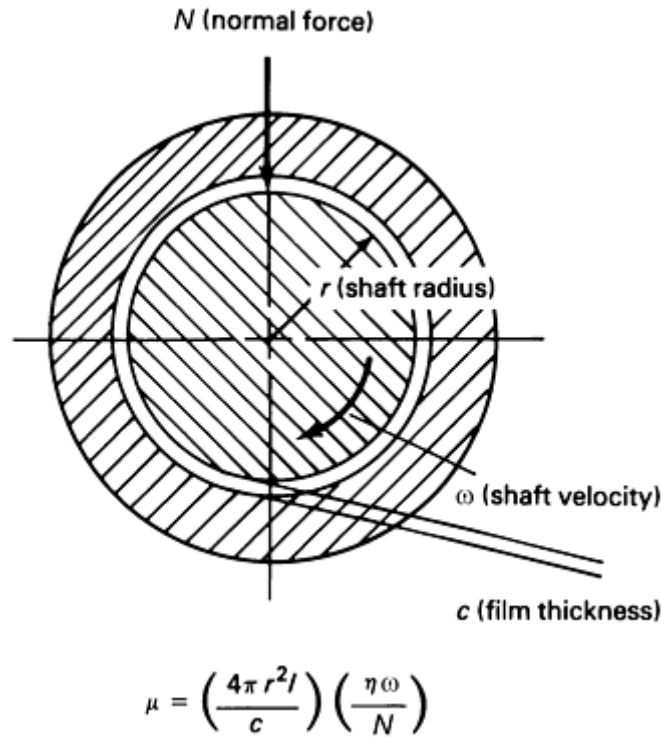

Fig. 5 Petrov equation for the coefficient of friction of a lubricated tribosystem. See text for details.

The friction of a journal bearing or rotating bushing can be measured using an arrangement such as that shown in Fig. 6. The use of a calibrated spring of some kind (as in Fig. 4) is probably the most common method of measuring friction force. The spring has a spring constant that determines the sensitivity of the system, but as shown in Fig. 3 and 4, there is probably some damping associated with this kind of system as well.

Fig. 6 Use of load cells for measurement of friction force

In another case of non-flat sliding contact, a flexible web is wrapped around a capstan. Figure 7 shows this geometry. The tension T_1 , which can be measured by a force sensor, is given by the following:

$$T_1 = We^{\mu b} \tag{Eq 5}$$

where W is the weight (or another tension force), μ is the friction coefficient (either static or kinetic depending on the use for the test), b is the wrap angle around the capstan or shaft (in radians), and e is the base of natural logarithms (2.7183). Solving for μ as a function of the measured tension, applied tension or weight, and the wrap angle in radians is possible, as follows:

$$\mu = b \ln \frac{T_1}{W} \tag{Eq 6}$$

The capstan test has become a standard ASTM test method ASTM G 143. When using multiple wraps, as in ASTM D 3412, the value of b is adjusted accordingly to equal the number of wraps, or wraps plus fractions of complete wraps, times 2 radians.

Fig. 7 Schematics of friction-measuring concept for non-flat sliding contact

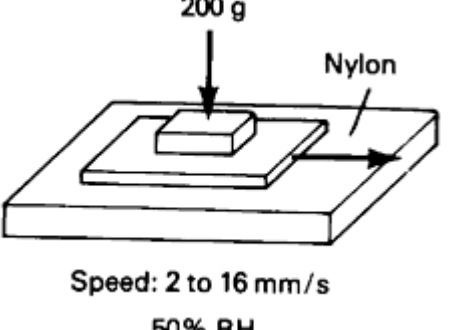

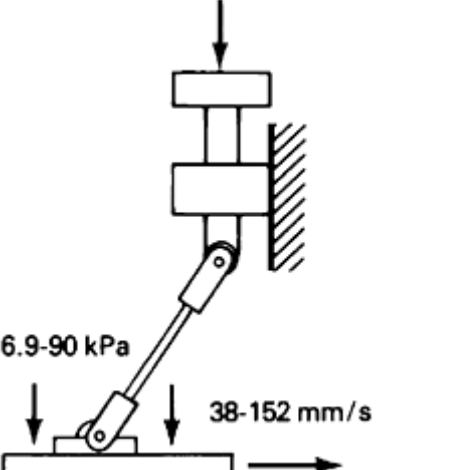

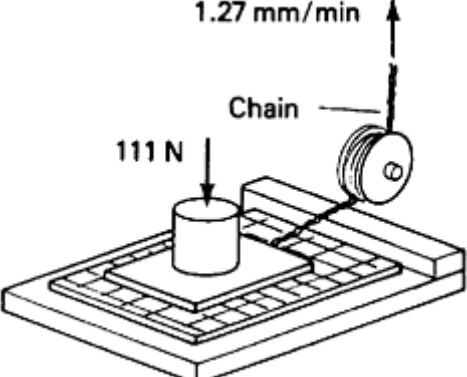

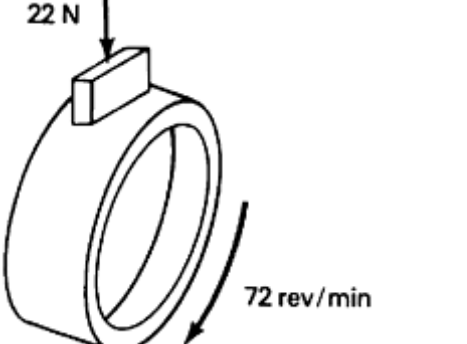

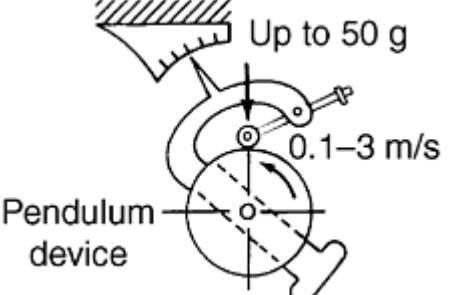

Other Types of Friction Tests, Including Standards. As mentioned, earlier, there are many types of friction tests because there are many reasons for obtaining friction data. In some cases, one might wish to simulate a certain tribosystem. In other cases, one might wish to screen new materials, lubricants, or coatings in a more generic sense and without a specific application in mind. Sometimes, the fine-scale frictional interaction of surfaces is studied purely for scientific purposes.

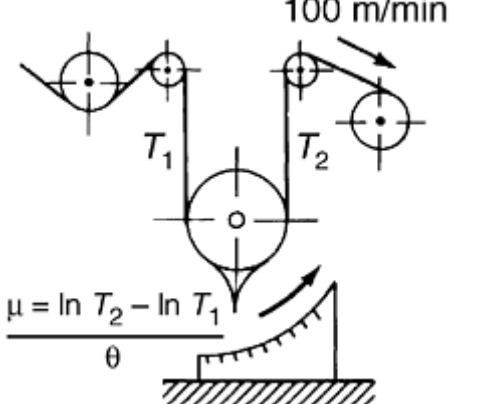

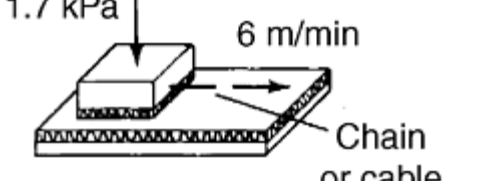

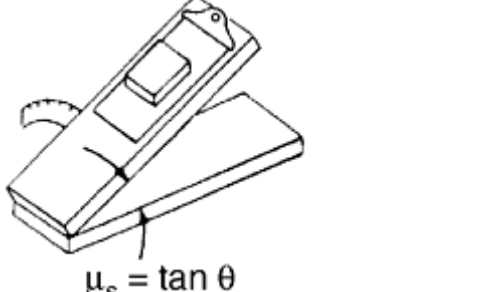

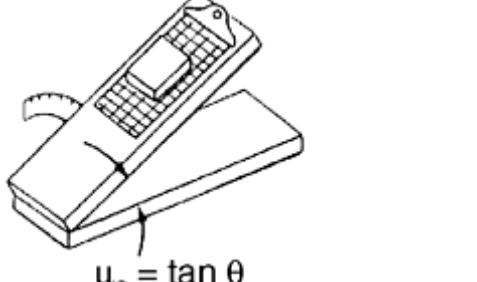

Sometimes, only a limited quantity of a new or experimental material or lubricant is available, and it is necessary to use small, easy-to-fabricate test specimens. A variety of commercial friction testing machines is available for friction testing using simple test geometries, like block-on-ring and pin-on-disk.

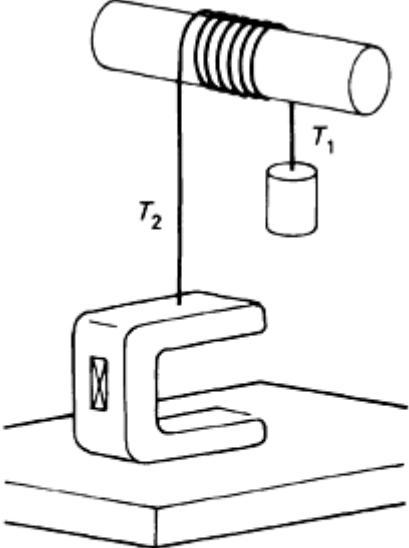

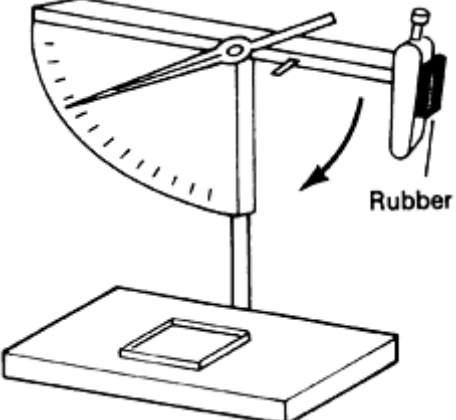

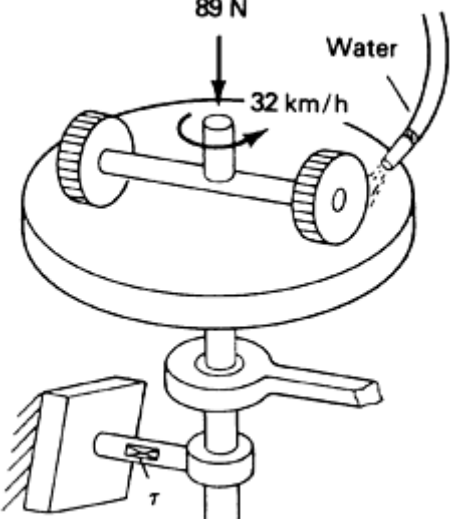

Table 1 shows ASTM friction test methods. Standards documents generally describe the characteristics of a method, as well as its applicability, precision, and accuracy.

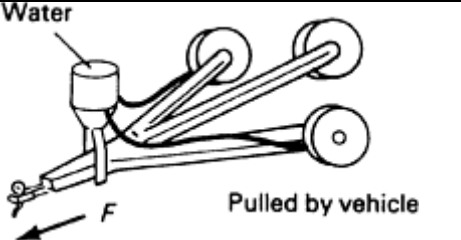

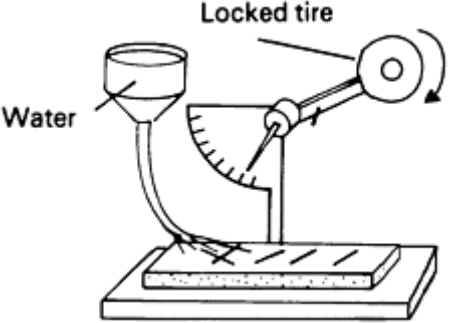

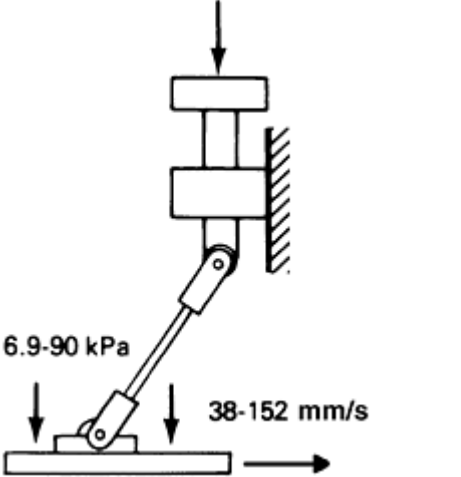

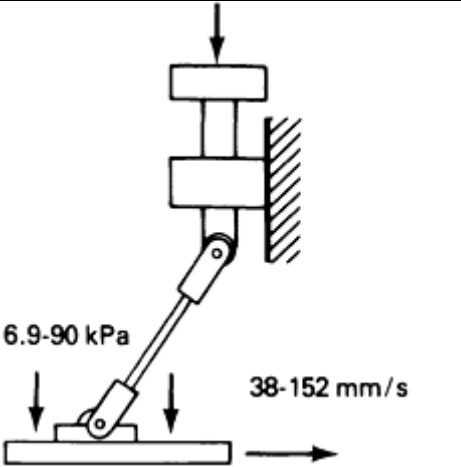

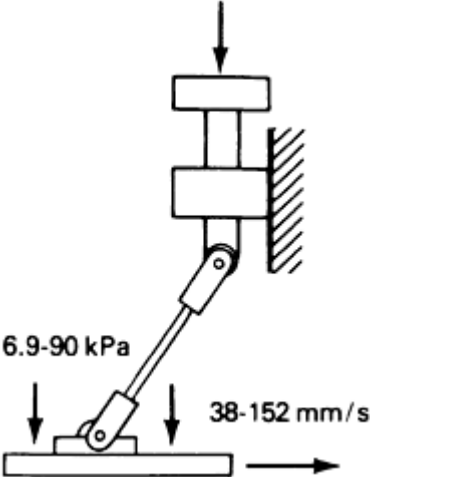

Table 1 Selected solid friction tests per ASTM standards

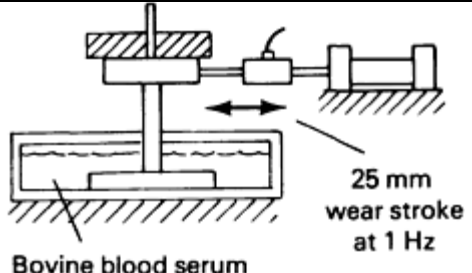

Standard (committee), title	Material couple (measured parameters)	Test configuration
B 460 (B-9 on metal powders), Dynamic Coefficient on Friction and Wear of Sintered Metal Friction Materials under Dry conditions	Friction materials versus metal (μ_k versus temperature)	
B 461 (B-9 on metal powders), Frictional Characteristics of Sintered Metal Friction Materials Run in Lubricants	Friction materials versus metal (μ_k versus number of engagements) (μ_k versus velocity)	
B 526 (B-9 metal powders), Coefficient of Friction and Wear of Sintered Metal	Friction materials versus gray case iron (μ_s and μ_k)

Microscale Friction Tests. In recent years, the ability to perform friction-type tests at scales approaching the atomic level has been developed in research laboratories. This field has been called “microtribology” or “nanotribology.” Microscale tests address a special class of friction and adhesion problems. The results can fail to directly agree with test results on similar materials conducted at more macroscales of contact, such as those described in Table 1. Fine-scale friction test results can relate to such applications as thin films on computer hard disks, read-write heads, and microelectromechanical systems (MEMS). They can provide information on the behavior of monolayers of lubricating films, but they tend not to be able to address issues such as particulate contamination and embedment effects, microstructural inhomogeneity, thick film behavior, and surfaces with the scales of roughness typical of many present-day engineering components. Therefore, it is important to conduct such fine-scale tests with a full understanding of the implications and limitations of the results.

In conducting microscale friction tests, the typical apparatus contains an elastic beam of some kind on which a needlelike probe is affixed. A full range of materials is not generally available in the form of these tiny slider tips, so the ability to examine many different material combinations is limited. There are various sensing modes, some of which reflect a laser beam off the back side of the elastic beam and measure its deflection to infer the bending force produced by frictional drag. In other cases, capacitive sensors or piezoelectric sensors are used. Providing details on these specialized, largely basic-research oriented test methods is beyond the scope of this article. The reader is referred instead to Ref 6 and the article by R.G. Horn in Ref 3 for more details.

Friction Testing under Well-Lubricated Conditions. If sliding members are fully separated by a film of lubricant (oil, water, gas, and so forth), the friction coefficient of the system is essentially the friction coefficient of the fluid. When boundary lubrication exists, the surfaces are partially in contact, and the coefficient of friction of the system is a function of the combined properties of the fluid and surfaces. When dry-film lubricants are used, the friction coefficient of the system can be related to the properties of the dry-film lubricant slipping on itself or to those of an uncoated solid on the lubricant film. Lubrication with graphite, molybdenum disulfide, or fluorocarbons is an example of this.

With fluid separation, the friction coefficients can be several orders of magnitude lower than they are for systems that involve solid contact. The Stribeck-Hersey curve shown in Fig. 8 allows calculation of the coefficient of friction from lubricant properties ($\eta N/P$), where η is the viscosity, N is the velocity, and P is the pressure (load). Empirical measurement of friction in film-separated systems is complicated by the need to maintain the fluid separation. With oils and greases, it usually involves testing at high velocities. If circumstances allow, the use of a friction coefficient calculated from the fluid parameters is much easier.

Fig. 8 Plot of friction coefficient, μ , versus $[(\text{viscosity})(\text{velocity})]/\text{load}$, $(\eta_0 U)/P$, to show range of the three regimes of lubrication. Regime 1, boundary lubrication; regime 2, thin-film lubrication; regime 3, thick-film lubrication

A number of test methods, like the lubricated block-on-ring test (ASTM D 2714) and the four-ball test, are used for determining the effects of lubricant additives on frictional behavior. A pin-in-Vee block test is used for assessing load carrying capacity and seizure. Additional information on lubricant friction testing is available in, for example, the ASTM standards developed by committee D-2 and in Ref 7.

Testing Methods for Solid Friction

K.G. Budinski, Eastman Kodak Company; P.J. Blau, Oak Ridge National Laboratory

Performing a Valid Test

The procedural considerations that should be addressed to ensure that valid data are derived from a friction test are discussed in this section. Investigators often run a friction test that is convenient to use but that has no resemblance to the system under study. Friction is a system property, and systems must be modeled carefully (same materials, same surface treatments, and so forth). Other factors that can affect the validity of a friction test include sample preparation, method of friction measurement, and interpretation of data.

System Modeling. Essentially three types of geometries prevail in systems where friction is a concern. These include:

- Hertzian contact
- Flat-on-flat
- Conforming surfaces (belt on a drum, plain bearings, and so forth)

These systems are illustrated in Fig. 9. It could be argued that when wear occurs, all surfaces become conforming. This is true for all systems except those where the triboelements remain Hertzian in contact. For example, railroad wheels wear significantly in service, but they still contact the track in a Hertzian manner by line or point contact. With regard to wear of the sliding surfaces, this can be the most important aspect of modeling a tribosystem. If the system under study will wear, and it is the desired goal of the study to determine the friction characteristics under conditions of steady-wear, friction should be measured in a wear test. If the system of concern will not change with time, a friction test that does not involve wear can be conducted. Figure 10 shows how wear can affect friction forces. Figure 10(a) illustrates the friction force variation with time for a system that does not experience any wear or changes in behavior when wear occurs. If, for example, paper is conveyed over a fixed roller with a smooth finish, it is highly likely that the friction force will remain the same as the roller wears by polishing abrasion, and the friction force will be constant with time, as will the nature of the tribosystem. The roller constantly wears, but the surface is always polished. The wear debris is carried away with the product, and nothing in the system changes. This statement must be qualified by noting that the environment (humidity, temperature, and so forth) can cause friction to change with time. Environmental effects are discussed later in this article.

Fig. 9 Friction test specimen configuration options

Fig. 10 Effect of system wear on friction force. (a) System that does not experience any wear or changes in behavior when wear occurs. (b) System where friction force increases with time until reaching a steady-state conditions. (c) System where friction force varies with each event in the wear process

Figure 10(b) illustrates a tribosystem where the friction force increases with time and then reaches steady state. This type of behavior might occur in a system experiencing severe wear. Friction is low when both members have their original surfaces. When the original surfaces start to wear, friction increases, and from that point on, the worn surfaces remain the same. It is comparable to a machining operation in that material is constantly being removed, but the cutting forces remain constant.

Figure 10(c) illustrates a system where the friction force varies with events in the wear process. This type of behavior often occurs in a tribosystem where wear debris remains in the system. Depending on how it separates the surfaces, wear debris can have lubricating or nonlubricating effect on the system. The friction will be constant when the triboelements have their original surfaces; when they wear, there will be a friction event followed by another when both surfaces become coated and are separated by wear debris. Because wear is a statistical process, some other event can take place to remove the separating wear debris, and still another cycle or friction event will occur. This phenomenon is seen in many machines. The machine can run quietly for a year, but then a squeal occurs that lasts for two weeks and then stops. The noise can come back in two months, or it might never return. It is quite possible that significant fluctuations in friction force with time are the result of environmental events. For example, it is well documented that the friction characteristics of photographic films are significantly affected by relative humidity. Photographic emulsions are gelatin based. Many gelatins have mechanical properties that are directly proportional to their water content. Mechanical properties vary with humidity, and these property changes in turn affect friction characteristics. Temperature has a similar influence on many materials, particularly plastics.

The illustrations shown in Fig. 10 are presented in order to emphasize that it is important to closely model the system under consideration. The test should simulate the mode of contact and the environment, and the length of time that the system is tested should be typical for the intended service. If new materials are being screened for friction characteristics, short-term and long-term tests should be conducted to explore friction events that change with time. If a service problem is being studied, the test should simulate the important aspects of the service, the environment, the type of contact, and the materials. It is not necessary to exactly duplicate the sliding speed and load unless they are likely to change some properties of the test materials (temperature, chemical environment, and so forth).

Material Documentation. Problems concerning repeatability of a friction test with time can be related to subtle or major changes in the nature of one of the tribocomponents. For this reason, it is important to provide adequate documentation of the materials in a tribosystem where friction measurement is the goal. As shown in Table 2, the necessary documentation varies with the type of material (metal, plastic, ceramic, or composite).

Table 2 Material parameters that should be documented to ensure repeatability when testing tribosystems

Metals

- **Chemical composition**
- **Manufacturer name and address**
- **Manufacturing process [wrought (cold finished or hot finished), cast, extruded, etc.]**
- **Generic designation**
- **Trade name (if applicable)**
- **ASTM or similar designation**
- **Condition of heat treatment**
- **Surface finish**
- **Surface treatments**
- **Grain direction**
- **Microstructure**

Plastics

- **Polymer species (If a blend, state ratio of blended polymers)**
- **Fillers, lubricants, and so forth (percentage)**
- **Manufacturing process (injection molded, extruded, cast)**
- **Generic name**
- **Applicable specifications (MIL, ASTM, and so on)**
- **Trade name and manufacturer number**
- **Manufacturer name and address**
- **Process used to generate wear surfaces, orientation of wear surfaces to original shape (wear surfaces flatwise on as-molded flatwise plate, wear surfaces end grain in extruded shape, and so on)**
- **Lubricants on the surface or in the material**
- **Surface texture of wear surface or in the material**
- **Surface texture of wear surfaces (R_a , lay, waviness)**
- **Heat treatments applied**

Composites

- **Detailed description of composite components (filament winding details, number of plies, components in laminate)**
- **Generic name and applicable specifications on composite components**
- **Trade names of components**
- **Manufacturer name and address**
- **Method of manufacture**
- **How wear surfaces were generated**
- **Orientation of wear surfaces to reinforcement**
- **Heat treatments**
- **Surface texture (R_a , lay, waviness)**
- **Surface treatments, lubricants, mold releases, and so forth**

Ceramics

- **Basic type and composition**
- **Percent theoretical density**
- **Manufacturer name and address**
- **Trade name**

- Manufacturing process (HIP, vacuum sintering, chemical vapor deposition, and so on)
- Method used to generate wear surfaces (grinding, polishing, and so on)
- Texture of wear surfaces (R_a , lay, waviness)
- Heat treatment
- Surface treatments
- Grain size
- Microstructure
- Morphology (degree of crystallinity, phases present, crystal structure)
- Lubricants/impregnants

R_a , surface roughness in terms of arithmetic average

More items undoubtedly could be added to Table 2, but the point to be made is that all of the variables that have been mentioned thus far could affect sliding friction. If the surfaces are lubricated, the tester must add related details of the type of lubricant and its distribution on the sliding surfaces. It is imperative that documentation on all members in the tribosystem be included. It is quite easy to cite examples where each of the factors listed in Table 2 has affected friction results in laboratory tests; more importantly, these factors influence friction properties in service. Heat treatment, structure, and so forth can affect mechanical properties. Surface films affect sliding forces; surface texture affects early friction. A cast polyester has different mechanical properties than a tentered and drafted polyester web, and a hot isostatically pressed silicon carbide has different mechanical properties than pressed and sintered material. The tester should be meticulous about material documentation.

Surface Condition. Few tribologists will argue with the statement that friction can be affected by surface condition. If the loads are light enough, only the outer one or two mono-layers on the surface might take part in sliding interactions. In lubricated systems, surface roughness plays a role in determining whether the surfaces are separated. Full-film separation will not occur unless the film thickness is greater than the composite surface roughness. Even with hydrodynamic lubrication, there are some investigators who claim that the system friction is affected by the surface roughness and lay (Fig. 11). In the normal range of roughness on rolling-element bearings and plain metal bearings (0.1 to 1 $\mu m R_a$), it is likely that the surface features do not significantly affect lubricated sliding. In nonlubricated sliding, the effect of roughness can be negligible to significant, depending on the system (Ref 8). With normal machined surfaces with a roughness less than about 1.5 μm , the effect will be slight. Roughness becomes a meaningful factor when the roughness interactions result in mechanical locking effects. This usually happens only with very rough surfaces. Sometimes, very smooth surfaces cause adhesion—for example, gage blocks or plastic webs on smooth surfaces. Conversely, in some applications such as high-speed sliding of yarns and filaments over stationary guide pins, the friction coefficient is low when the pin surfaces are rough (0.5 to 2 $\mu m R_a$) and becomes very high when the pins become polished from wear.

Fig. 11 Effect of surface roughness on the friction coefficient of a lubricated sliding system. Adapted from Ref 8

A valid wear test considers the effect of surface texture. For many systems, the effect is not significant. If, however, surface texture is considered a variable for a given wear study, a few quick tests using the high and

low of the expected range of surface texture will determine whether this is a parameter to be pursued in a friction study.

Surface films are important in most tribosystems, especially unlubricated systems. The recommended practice in friction testing is to leave the films in place if they are likely to occur in the tribosystem of interest. If they are not part of the system of interest, they should be removed by cleaning. Valid wear results require that a cleaning procedure be used that will remove contaminants and not leave another contaminating film. The cleanest surface is the as-machined or as-ground surface (without coolants and the like). These types of surfaces prevent cleaning-solution contamination problems. If metal surfaces must be cleaned of contaminating films, then a refluxed solvent system should be used. Plastics are difficult to clean with solvents because of the risk of chemical alteration of the surface. Commercial glass-cleaning solutions have been employed to clean plastic test surfaces with favorable results. Ceramics can also be cleaned by these solutions. Sometimes even water-based cleaners can chemically alter a ceramic surface. The safest technique for removing contaminants on ceramics is dry lapping or similar abrasive finishing.

Absorbed films from the atmosphere can be another source of contamination. To cite an example, many plastics were tested in a comprehensive laboratory program as a track material for conveyance of plastic parts. Test results indicated that an ultrahigh-molecular-weight poly-ethylene had the lowest friction. Hundreds of feet of this track were installed in the manufacturing plant, but within a month the track was pulled out and replaced because of an environmental factor that had not been considered during laboratory testing. Although there were no problems with the track during the week when there was a three-shift operation, after the weekend, parts would stick to the track with great frequency. Only after several hours of downtime and frequent “nudging” of the parts would the system begin working properly. Further study indicated that when the track material was allowed to sit idle for a period of 48 h, some type of film formed that deleteriously altered the friction characteristics.

This example points out the importance of carefully duplicating the system environment, even to the extent of allowing surfaces to sit idle in production environments. Many manufacturing plants have an atmosphere that can leave a condensate on a surface. If this is likely to occur in a tribosystem under study, then it should be made part of the friction testing.

Testing Methods for Solid Friction

K.G. Budinski, Eastman Kodak Company; P.J. Blau, Oak Ridge National Laboratory

Test Parameters

Friction test parameters, such as speed and load, should be as close as possible to actual conditions. Sometimes, however, it is difficult to simulate these parameters in a laboratory environment. The speeds and loads can be out of the range of the lab equipment, or testing at actual conditions might take too long. A valid friction test does not require that speeds and loads be exactly duplicated. Friction coefficients are relatively insensitive to speed and loads up to the point where these parameters affect the properties of the test surfaces. Speed will affect friction results on most metals when it is sufficiently high to soften the surface and alter mechanical properties. With plastics, this temperature can be only a few hundred degrees Fahrenheit. With metals, the critical temperature is close to the stress-relief temperature for a given alloy.

Sliding speed for a friction test can range from 10 mm/s (0.4 in./s) for an inclined plane test to 100 m/s (325 ft/s) for high-speed yarn friction tests. For optimum results, test equipment should yield a wide range of sliding speeds. If the actual operating speed is unusually high or low, unique friction conditions can be produced that

can be simulated only by test speeds in the range of concern. For example, a laboratory study was conducted on plastic and competitive plain bearings for a compact-disk drive scanner that had to slide (bushings versus hardened steel shafts) in a linear motion at a speed of $1.6 \mu\text{m/s}$ (0.00006 in./s). The slow speed caused many materials to display stick-slip behavior. When higher speeds were used, this did not occur. Under such conditions, the speed of the tribosystem should be duplicated as closely as possible.

The same type of reasoning should be applied to test loads. If a system under study uses loads of only a few grams, this should be duplicated. If the system under study is subject to extreme forces, such as those that occur in threaded fasteners, there is little recourse other than to use these very high forces. When studying bolt friction, most investigators use actual bolts and nuts and a washer equipped with a strain gage for measurement of bolt tension. This is because of the difficulty in obtaining a bench-top friction tester that can apply a 45 kN ($10,000 \text{ lbf}$) normal force.

As a rule of thumb, if it is not possible to simulate the service load, then the highest load that does not exceed the compressive strength of either member in the test couple should be used. This is particularly applicable to Hertzian loading situations. If the compressive strength of the material is exceeded, the friction test only yields the forces to plastically deform the surfaces. Test speeds and loads that produce significant wear should be avoided unless that is part of the tribosystem under study.

As previously mentioned, friction force might not be constant throughout a test, and questions can arise as to the value that should be reported. The most meaningful data are the minimum, the maximum, the mean, and the standard deviations. These allow the use of statistical analysis to determine whether friction coefficients for various systems are really different. Erratic systems such as that described in Fig. 10(c) will be treated with statistics. In friction tests where the goal is to find a couple with the smoothest motion, a suitable test parameter for ranking materials is the standard deviation of the friction force. This shows the variability of the friction forces for the various systems. In fact, for all friction tests it is recommended that statistical tests be used. The simplest test of differences is illustrated in Fig. 12. If the mean of test data is plotted with error bars coinciding with plus or minus two standard deviations, a visual test of differences can be made. If the error bars overlap, the test results are not statistically different. In Fig. 12, couples B, C, and D have the same frictional characteristics; only couple A differs.

Fig. 12 Graphical use of statistics to show differences in friction coefficients between various material couples

Sample size must also be considered in statistic tests. There are a number of ways to calculate sample size, but most statisticians prefer a large number (for example, 40) of replicate tests. Because most friction tests are very repeatable within a laboratory, this number may be a bit high. Most studies using a bench-top friction tester can have statistical accuracy with as few as 10 replicates per system.

Friction Measurements

A number of precautions must be observed during friction measurements, and most have to do with the measuring equipment. Some of the more commonly used force-measuring systems are illustrated in Fig. 13. Probably the most important consideration with regard to instruments for measuring friction forces is selection of a force-measuring system that is suitably sized for the task. If the tribosystem being tested will produce friction forces of about 4.5 N (1 lbf), it is recommended that a force-measuring system with a capacity of only about 45 N (10 lbf) be used. In other words, a sensor with a capacity not more than 10 times the force to be measured should generally be selected for a given application.

Fig. 13 Friction force sensors. (a) Strain ring with strain gages. (b) Strain gage load cell. (c) Mechanical force gage. (d) Inclined plane. (e) Web tension tester (tension is measured by the position of the weighted sheaves)

The strain ring illustrated in Fig. 13(a) is assembled in the laboratory and features four strain gages adhesively bonded to the ring to form a Wheatstone bridge strain rosette. This type of system can be very accurate, because

the ring can be made as heavy or as light as desired. The disadvantages are that such gages are more fragile than purchased gages, and humidity and temperature can affect the adhesion of the gages. This system also requires assembly by a person with some expertise in strain gages.

The commercially available strain-gage load cells shown in Fig. 13(b) are quite durable. Most have some type of internal diaphragm that is instrumented with strain gages. However, these devices can be destroyed by a momentary load greater than its capacity, necessitating expensive replacement. Many companies offer these gages with mechanical stops to prevent overload damage.

Mechanical force gages (Fig. 13c) work much like strain gages, except that force measurements are made by a spring and sliding system arrangement. The greatest disadvantage of such devices is that they have no recording capability. They are also prone to inaccurate readings by operators.

Friction coefficients measured on inclined planes (Fig. 13d) require only the measurement of the angle at which motion of the test block occurs. The most common technique for measuring this angle is the simple incorporation of a protractor scale in the device. A more accurate system uses an electronic level on the inclined plane. These devices have digital readout capability and are much more accurate than visual assessment of the angle of an inclined plane. One precaution in using this type of device is that the speed at which the plane is raised will affect the breakaway angle. The more reliable inclined plane rigs have a motorized raising device on the table.

The device illustrated in Fig. 13(e) is commonly used to measure the friction coefficient of a moving web over a stationary surface or over a roll where relative slip is occurring. The tension in the web on either side of the test roll will yield the coefficient of kinetic friction when the capstan formula is used. The tension-measuring roll, called a "dancer roll," moves up and down with changes in web tension. The disadvantage of these systems is that they are not very easy to gage electronically, and, thus, continuous recording can be difficult. Most dancer rolls are being replaced by cantilever rolls with strain gages incorporated in their mounting brackets.

Whichever force-measuring technique is used, it is most important that the device be sized correctly and that friction forces be recorded over a sufficient period of time to ensure that steady-state conditions exist.

Computerized data acquisition systems may be used for high-speed digital recording if the details of frictional behavior are needed. The digital data can be used to rapidly calculate average friction force, standard deviation, and other statistical parameters. Sometimes, however, high-speed friction recordings can produce hash in the signal, and a filtering algorithm must be used to reveal the general trends. The response of common chart recorders is usually slow enough to eliminate the hash problem, and, therefore, such chart recorders are still useful for recording trends in the overall friction behavior.

The final precaution that warrants consideration is the system stiffness. If a system is prone to stick-slip behavior or high static friction, a highly compliant force-measuring system should be used. From a practical standpoint, an elastic force-measuring system usually consists of nylon fishing line to pull member A along member B. If a stiff-movement system such as a screw drive is used to produce specimen motion, phenomena such as stick-slip behavior might not be produced. The decision as to whether a high-stiffness (steel) or low-stiffness (plastic) system should be used must be based on the intended application. If the tribosystem of interest is highly elastic, the plastic-movement system should be used. If the system is rigid, the screw-drive system (or a similar system) should be used.

Testing Methods for Solid Friction

Overall System Considerations

A proposed method for analyzing wear problems is to look at the tribosystem and tabulate all of the system inputs, outputs, and disturbances (Fig. 14). Friction is considered to be a system loss, but certain components of friction should be noted and recorded. From the aspect of system usability, sometimes these system losses are more important than the friction force. For example, in a study on the wear of various cemented carbide couples, it was learned that some carbide couples produced squealing. The friction coefficient was slightly

higher than comparable metal-to-metal couples (about 0.5 compared with 0.4) while the wear was very low, but this couple was deemed unacceptable for use because of the noise.

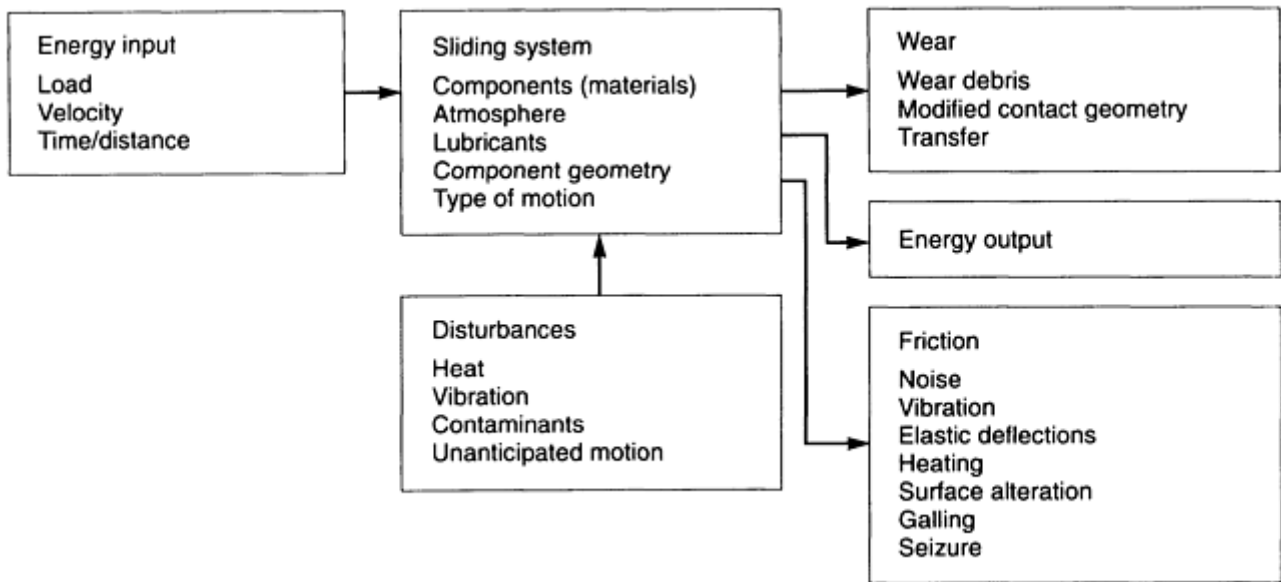

Fig. 14 Systems approach for analyzing friction and wear problems

In Fig. 14, important losses include vibration, elastic deflections, heating, surface alteration, galling, and even seizure. Vibration as an output of a sliding system often indicates that stick-slip behavior is prevalent. Noise is often the result of stick-slip behavior, but a system that exhibits such behavior does not necessarily emanate noise. Although vibration is not always apparent on friction force traces, it can show up on deflection or displacement transducers. This type of behavior from a sliding system is usually undesirable. Accurate measurement of vibration can require the use of accelerometers on one of the members of the sliding system. Likewise, elastic deflection, which can occur at a sliding interface, does not always show up on the friction force recording. This deflection can mean that the couple under study has unacceptable frictional characteristics. For example, when several elastomers that were undergoing friction tests were slid on a paper counterface, they bent over in the direction of motion; the contact geometry was changed from the point contact of a hemispherical rider to a line contact of a bent hemispherical-ended rod. The friction force was apparently high enough to cause this deflection.

Although heating is an obvious result of friction between sliding members, it is often not measured. The temperature rise is often significant, and it is easy to measure. The mechanical properties of plastics are susceptible to degradation by heating to relatively low temperatures. The temperature rise at a sliding interface is the result of the properties of the materials in contact in addition to the sliding conditions. It will be different for different couples that can have the same friction coefficient. Therefore, for sliding systems that can be affected by frictional heating of the interfaces, a valid friction test should record the temperature rise.

Surface alteration is another important aspect of many wear and friction tests. Whenever wear occurs in a sliding test, the friction coefficient is not that of the test couple alone, but it is the system that comprises the couple as well as wear debris in the interface. When wear testing couples that are not supposed to wear during friction testing, it is important to examine both surfaces for alterations. Damage often can be caused by polishing or scratching. When friction alters the prevailing surface texture, a wear test has been performed, not a friction test. The friction force measured and coefficient of friction must be reported for a worn surface.

Galling and seizing are the worst possible results of a friction test. Galling is characterized by the formation of microscopic cumulative material transfer during sliding, and seizure (stopping of motion) can be the net result. If a couple seizes, there will be no friction coefficient to report, but merely the fact that the couple seized. If galling occurs, the friction force will often decrease (Fig. 15), but the surfaces will be damaged. This can produce data that misleads a user, who may think that the couple works fairly well because the friction coefficient was low, when actually galling occurred and the material couple is not compatible.

Fig. 15 Typical friction coefficients derived from galling tests (various metal/metal couples)

Testing Methods for Solid Friction

Friction Databases

The first friction database was compiled by J.T. Desagulies around 1725 (as reported by Dowson in Ref 1). Desagulies tabulated the friction coefficients for the couples of interest at the time. Some current handbooks list friction coefficients for 50 or so materials, with limited documentation regarding test conditions. These tabulations are of little use if the application requires knowing a friction coefficient within an accuracy of ± 0.2 . Differences in the tribosystem used to make the measurements can, for example, produce a result of 0.1 for a couple on device No. 1 and a result of 0.3 for the same couple tested on device No. 2. It can be stated with a high degree of confidence that measuring techniques will have a significant effect on the friction coefficient of a particular couple in the unlubricated condition. Differences can exist in lubricated systems, but the coefficients will be much lower. An accuracy of $\pm 20\%$ results in a much smaller number. For example, well-lubricated steel couples can have a kinetic coefficient of friction of 0.05 ($\pm 20\%$ makes the number 0.04 to 0.06). In other words, existing friction databases have limited utility unless the test conditions used to develop the data are stated and the application conditions are similar.

In order to determine how friction databases should be formulated and used, ASTM Committee G-2 on wear and erosion developed a standard format for friction databases in 1987. Although this work is ongoing, progress has been made as to the type of data that should go into databases. The minimum results to be reported are the following:

- Test couple (member 1 and member 2)
- Static coefficient of friction
- Kinetic coefficient of friction

The minimum test condition information includes the following:

- Apparent pressure
- Normal force
- Velocity
- Temperatures (bulk) of samples
- Test atmosphere
- Lubricant

- Sliding distance (when μ was measured)

Other types of data would also be desirable, but even the ASTM-recommended list is difficult to deal with in database or spreadsheet types of software. The strategy is to have these data in a database so that selective data can be tabulated (see Table 3). The motivation for establishing friction databases is the elimination of repetitive tests. Even within a single laboratory, it is not uncommon to see the same couples brought in for study several times over a period of several years. Without a database, the tests are rerun each time. The long-range goal is to have published data that can be used by design engineers in the same way that designers use corrosion data generated by countless sources over many years.

Table 3 Friction and wear data of selected plastics tested against polycarbonate containing 12% polytetrafluoroethylene

Plastic ^(a)	Kinetic coefficient of friction, μ_k	Specific wear rate of selected plastic ^(b) , $K \times 10^{-6}$
PC	0.19	7.00
PC + PET	0.19	7.26
PCTG + 30% GF	0.36	9.00
PET + 30% GF	0.27	9.00
PET + 30% GF + mica	0.29	8.00
PC + 10% aramid	0.09	4.00
PA + 10% aramid	0.08	0.80
PA + 15% aramid + 10% TFE	0.70	0.50
LCP wear grade	0.10	2.00
LCP + mineral	0.07	0.60
PC + 40% aramid	0.18	9.00
PC/IPN + 2% aramid	0.15	2.00
PC + 20% aramid	0.20	7.00

(a) PC, polycarbonate; PET, polyethylene terephthalene; GF, glass fiber, PA, polyamide; LCP, liquid crystal polymer; IPN, interpenetrating networks; TPE, tetrafluoroethylene.

(b) Parameters; friction force, F , 9.86 N (2.20lbf); velocity, V , 0.208 m/s (0.682 ft/s); sliding distance, D , 732.0 m (2402 ft)

Scratch Testing

Vispi Homi Bulsara, Cummins Engine Company; Srinivasan Chandrasekar and Thomas N. Farris, Purdue University

Introduction

TO UNDERSTAND the basis and applications of scratch testing, it is useful first to consider it relative to indentation hardness testing (described in detail in the Section “Hardness Testing” in this Volume). It is well established that indentation hardness testing measures the resistance of a material to permanent, plastic deformation (Ref 1). Indentation hardness has a direct correlation with the yield strength of a solid, and for most materials the hardness is directly proportional to the yield strength. Thus, indentation hardness may be said to “measure” the plastic properties of a material. In a typical hardness test, a sharp (e.g., pyramid) or blunt (sphere) indenter is pressed into the material being tested, and the hardness is estimated as the load divided by the contact area of the indentation. The indentation hardness test is widely used both in academic laboratories and in industry as a tool for characterizing mechanical properties of a material and also as a quality control measure (Ref 2, 3).

In contrast to indentation hardness, scratch hardness is a parameter that is determined by sliding a hard indenter tip across the surface of the material (Ref 4). The scratch hardness is again obtained as the load over a load-bearing area, which is representative of the indenter track. Scratch hardness has some correlation with indentation hardness in that it also measures the response of a material to plastic deformation. Furthermore, since scratch formation is a form of controlled abrasive wear, it would seem reasonable to use the test as a means of ranking materials for their resistance to abrasion in service. This must, however, be done with some caution since the geometry of the indenter tip may be substantially different from that of the asperities present on a surface. In practice, scratch testing is typically used to determine the scratch hardness of materials, characterize the mechanisms of deformation and material removal, compare the abrasive wear resistance of materials, and measure the adhesion strength of coatings. An examination of its application in these areas indicates that it is used more as a quality control technique, and furthermore the measure obtained is more qualitative than quantitative.

This article reviews the origins and development of scratch tests, the experimental configurations used in these tests, and the application of the tests to characterize the mechanical response of materials.

Scratch Testing

Vispi Homi Bulsara, Cummins Engine Company; Srinivasan Chandrasekar and Thomas N. Farris, Purdue University

Origins of Scratch Testing and the Mohs Scale

Perhaps the earliest attempt to develop a scale of scratch hardness for different materials was made by Reaumur in 1722 (Ref 5), who measured the hardness of a substance as the point at which it started scratching a bar whose hardness decreased from one end to the other. A similar method was used by Werner (Ref 5), who developed the first real scale of hardness, which was further extended by Hauy (Ref 5). In Hauy's scale, there were four groups of hardness listed in order of their mutual scratchability.

The Austrian mineralogist Mohs is credited with developing the first semiquantitative measure for scratch hardness in 1822. This measure is expressed on a scale called the Mohs scale. The Mohs scale consists of 10 minerals, arranged in an order such that each mineral will scratch the one on the scale below it, but will not scratch any mineral that is above it on the scale. In measuring scratch hardness using the Mohs scale, the sharp corner of a material is rubbed against the flat surface of another, and the flat surface is checked for scratches. A material higher up on the Mohs scale would scratch all materials with a lower Mohs number. The Mohs hardness number for the material being tested is given by the number corresponding to the hardest of the 10 reference materials that does not scratch this material.

Since the scratching process and the indentation process are both determined by the plastic properties of the material, one may expect to find some correlation between Mohs hardness and the indentation hardness for minerals. Such a correlation does in fact exist, as shown in Fig. 1, which is based on Williams (Ref 6). Some of the indentation hardness measurements in this figure were made with the standard Vickers indenter, others with the Knoop indenter. Both of the indenters produce a pyramidal indentation and give roughly the same hardness values for materials.

Fig. 1 Variation of indentation hardness with Mohs number. The slope of the line indicates that a unit change in Mohs number corresponds to a factor of ~1.6 in the indentation hardness. The logarithm of hardness is plotted in the figure. Source: Ref 6

The gradient of the logarithmic plot of Fig. 1 indicates that each skip in the Mohs scale is equivalent to an increase in indentation hardness by a factor of ~1.6, with the exception of that between corundum (a form of aluminum oxide with a Mohs number of 9) and diamond (which has a Mohs number of 10). The uniformity of this scale in terms of the indentation hardness of the 10 minerals reflects the high quality of the experimental work of Mohs, who was himself also well aware of the much larger increase on the scale between the Mohs values of 9 and 10.

The relation between Mohs scale and indentation hardness embodied in Fig. 1 may be interpreted in terms of the following simple experiment performed by Tabor (Ref 7). By suitable heat treatment, a strip of metal is rendered soft at one end and hard at the other, with a fairly uniform increase in indentation hardness along its length. Another metal specimen of uniform intermediate hardness is prepared with a sharp point at one end, and the point is dragged over the strip from the soft to the hard end. It is found that under well-lubricated conditions, the friction is high over the soft portion, and a fine chip is produced during sliding. This behavior changes rather abruptly at a critical value of hardness, where the friction quickly drops to a low value (Fig. 2) and there is little material removal or surface damage. In terms of Fig. 2 it is seen that a point of Vickers hardness 930 kg/mm^2 just ceases to scratch the surface when the hardness of the mating surface exceeds about 830 kg/mm^2 . Based on such experiments, it has been generally accepted that for one material to scratch another the indenter material must be at least 20% harder than the damaged surface. Additional experiments carried out since this early work have shown that this difference depends on the shape of the indenter, varying between a few percent harder for a spherical indenter to about 60% harder for a much more angular indenter.

Fig. 2 Frictional force plotted as a function of surface hardness for a metal point of hardness $H_p = 930 \text{ kg/mm}^2$ traversing a steel surface (load 4.2 kg). Lubricated surfaces. Scratching ceases, and the friction falls to a low value if the hardness of the surface exceeds 830 kg/mm^2 . Source: Ref 7

The apparently linear variation of the logarithm of indentation hardness with Mohs number seen in Fig. 1 can be easily explained in light of the above results pertaining to scratching. If one assumes that scratching just begins when $H \geq kH_s$, where H is indentation hardness and H_s is scratch hardness, then we can construct a hardness scale in which every unit is k times as hard as the preceding one. The Mohs number (M) is then related to indentation hardness (H) by a relation of the form:

$$H = C(k)^M \quad (\text{Eq 1})$$

where C is a proportionality constant. Taking the logarithm of both sides of Eq 1 gives:

$$\log H = M \log k + \text{Constant} \quad (\text{Eq 2})$$

Thus a plot of $\log H$ against M should give a straight line. From experimental results reported earlier, k has a value slightly greater than one for a spherical indenter and ~ 1.6 for a much more angular indenter.

Equation 2 and Fig. 1 can be used to obtain an approximate estimate of indentation hardness of a material when its Mohs number is specified. Even though Mohs number is not very much used to specify hardness of a material, it has been the experience of the authors that, not infrequently, they have seen it arise in various contexts.

Scratch Testing

Vispi Homi Bulsara, Cummins Engine Company; Srinivasan Chandrasekar and Thomas N. Farris, Purdue University

Experimental Devices

Scratch tests can be classified into two categories—low speed and high speed—based on the velocity of the scratching element with respect to the material surface.

Low-Speed Devices. The scratch element (i.e., indenter) is usually mounted on a linear slide and moved along the material surface at speeds of no more than a few millimeters per second to generate a single-pass scratch. The element may be reciprocated against the sample to generate a multipass scratch. Another method used to generate a multipass scratch is to mount the sample on a rotating turntable and slide it against a stationary scratch element. These three configurations are shown in Fig. 3(a) to (c).

Fig. 3 Different scratch devices. (a) and (b) Linear. (c) Rotary. (d) Pendulum. (e) Grinding type. Source: Ref 4

High-Speed Devices. A high-speed, linear slide can be used to provide relative motion of the sample surface with respect to the scratch element. In this configuration, which is simple and easily instrumented, it is difficult to achieve speeds greater than about 3 m/s. Single-pass as well as multipass scratches can be generated with this device. Other high-speed scratching devices utilize a scratch element that is mounted on the end of a pendulum (Fig. 3d) or on the periphery of a rotating metal disk (Fig. 3e) to generate high speeds, while the sample is mounted on a slide, which may or may not be moving. Speeds much higher than 3 m/s can be easily achieved with the rotating-disk device; in fact by mounting the disk on the spindle of high-speed grinding machines it is feasible to achieve speeds as high as 90 m/s.

In-Situ Scratch Devices. There is a third category of scratching devices that are somewhat less often used. These may be termed as in situ scratching devices because scratch formation can be directly observed in these devices, in situ, using an optical or a scanning electron microscope (SEM). The indenter is stationary, and the sample is slid at a very low velocity by mounting it on a linear slide. In the device, which is mounted inside the chamber of an SEM, the electron beam is focused at the contact between the scratch element tip and the sample surface, thereby enabling scratch formation to be observed at high magnification, but at speeds of the order of a few microns per second. The ambient atmosphere within the chamber may also be varied between a vacuum ($\sim 10^{-7}$ torr) to low pressures of various gases. The authors have developed a simple, in situ device that utilizes an optical microscope to study scratch formation in optically transparent solids (Fig. 4). A high-magnification optical microscope with a large working distance objective is mounted behind the sample, enabling observation of the scratch interface through the sample. The sample is traversed against the scratch element using a high-pressure linear slide at speed between 25 nm/s and 200 mm/s. A high-speed camera may be attached to the microscope for high-speed observation. This has made possible a study of scratch mechanisms ranging from ductile scratching to brittle fracture during scratching of transparent brittle materials like glass, spinel, sapphire, and several oxide polycrystals, and observation of ductile chip formation during scratching of brittle materials. Indentation and scratch damage on coatings deposited over transparent substrates can also be studied using this device.

Test Parameters

When a scratch test is used to determine the scratch hardness of a material, the test has to be performed in a controlled or standard configuration. The important parameters of the test are highlighted and briefly described.

Indenter Material. For most tests, a diamond indenter is used to minimize the wear on the indenter and to reduce the influence of wear on the mechanism of scratching. Other hard materials, such as sapphire and tungsten carbide, may also be used as indenters provided they are much harder than the material being scratched. It should be noted that for wear tests—since wear properties of a pair of materials, that is, a material system, are usually studied—the scratch element is made of one material, not necessarily a hard material such as diamond, while the sample may be made of another material.

Indenter Shape. The shape of the indenter is usually spherical (or ball), conical with a sharp tip, a four-faced pyramid (Vickers, Knoop), or a triangular (Berkovich) pyramid. The radius of the indenter tip for a sharp indenter should not be larger than a prescribed amount, and it should be at least an order of magnitude less than the depth of the scratch. Typical indenter radius for a Vickers indenter is $<2\ \mu\text{m}$. It is important that the indenter tip shape is carefully characterized before testing. Conical or pyramid indenters are commonly used in scratch tests, since they can produce a plastic scratch even in brittle materials.

Orientation of the Indenter Relative to the Scratch Direction. In the case of a nonaxisymmetric indenter, such as a pyramid indenter, the diagonal of the indenter is aligned parallel to the scratch direction to reduce cracking in brittle materials and formation of a chip in ductile materials.

Indenter Angle of Attack. This is the angle made by the leading face of the indenter with the sample surface. Usually, the axis of the indenter is aligned perpendicular to the sample surface with the sharp tip (apex) digging in to the sample. However, in some scratch tests this is not necessarily the case. For example, in the Birnbaum scratch hardness test, the leading edge of the cubic indenter (formed by the corner of a cube) is at 35° to the sample surface, hence orienting the main diagonal at 80° to the sample surface.

Sample Preparation. The sample surface is usually polished to a micron or submicron arithmetic average roughness (R_a) to minimize the influence of roughness on the test results. The R_a of the surface should be an order of magnitude less than the depth of the scratch. By a suitable series of polishing steps, it is feasible to achieve R_a values as small as 10 nm fairly easily.

Scratch Velocity. The relative velocity between the indenter and the work surface is held constant during the test. In older scratch devices, the velocity was controlled by weights, attached to the slide (on which the work material or indenter is installed), which was passed over a pulley; by varying the weights it was possible to obtain different scratch velocities. In devices used at the time of publication, the slide is driven by a motor with precise velocity and position control.

Scratch Length or Duration. In order to avoid end effects associated with sample edges and obtain steady-state data, the length of the scratch should be at least 20 times greater than the depth or width of the scratch (whichever is larger).

Scratch Load or Depth. Either scratch load or the depth of indenter penetration can be set at a fixed amount throughout the test. It should be noted that for testing the strength of coatings, the depth of the scratch or the normal load on the indenter is increased at a fixed rate as the indenter is traversed across the sample. The scratch depth is controlled by aligning the scratch direction parallel to the surface of the test material. The scratch load is held constant by the use of deadweights to apply the load. Alternatively, load cells can be used to monitor the scratch load and a feedback mechanism used to move the indenter into or away from the sample surface to maintain constant load.

Number of Passes. This is the number of times the indenter passes over the same scratch track. In most scratch tests, only a single scratch track is made in the sample. Wear tests involve several passes of the scratch element over the same scratch track.

Determination of Scratch Width or Depth. If the scratch width and depth are determined visually using an optical microscope, the magnification, lighting, and grid/scale used should be standardized to enable

reproducibility of results. If the scratch cross-section profile is determined by contact (stylus)-based methods, parameters such as filter type, cutoff length, stylus travel velocity, and stylus tip radius have to be standardized. In the recent past, techniques such as scanning probe microscopy (atomic force microscopy and scanning tunneling microscopy), confocal microscopy, and light-interference-based profilometry have improved the accuracy and resolution of measurement of scratch width and depth. The techniques also provide information about the three-dimensional geometry of the scratch including material pileup, elastic recovery, and so forth (Fig. 5).

Application and Interpretation of Results

Before discussing the application of the scratch test to determine different parameters pertaining to the deformation and fracture of solids, it is instructive to briefly review the measurement of indentation hardness (which is discussed in more detail in the Section “Hardness Testing” in this Volume).

Overview of Indentation Hardness. The indentation hardness test has found widespread application in analyzing the mechanical properties of materials. The most common method of estimating indentation hardness of a solid is by slowly loading an indenter, sharp or blunt, into the surface and estimating the contact pressure applied by the indenter in producing a well-developed plastic zone. In practice, the contact dimensions of the indentation, that is, the contact circle diameter for a spherical indenter and the diagonal lengths for pyramidal indenters, are measured after the indenter is unloaded from the surface. The hardness is obtained most commonly as the load (P) divided by the surface area of the indentation. A better hardness value, referred to as true hardness, is obtained by dividing the load by the projected area of the indentation. This value can be directly identified with the mean pressure, p_m , applied by the indenter, if it is assumed, as is commonly done, that the projected area of the indentation is negligibly changed by the elastic recovery taking place during unloading of the indenter.

Applying these definitions to the case of quasistatic loading of a solid by a Vickers indenter, which produces a pyramid indentation, the Vickers indentation hardness (H_V) is obtained as:

$$H_V = \frac{P}{\text{Surface area of indentation}}$$

$$\approx \frac{P}{d^2} \times 1.854 \tag{Eq 3}$$

Here d is the diagonal length of the indentation and P is the maximum load applied by the indenter. A true value for the Vickers hardness, namely the true Vickers hardness (H_{TV}), is estimated as:

$$H_{TV} = \frac{P}{\text{Projected area of indentation}} = \frac{2P}{d^2} \quad (\text{Eq 4})$$

Note that $H_V = 0.927 H_{TV}$. For most materials, it is commonly assumed that $H_{TV} \approx 3\sigma_y$ where σ_y is the yield strength of the material.

It is most often the case that during indentation part of the displaced material is piled up in the form of a ridge surrounding the indentation. This is well illustrated by the atomic force microscopy image and associated line trace of a Vickers indentation shown in Fig. 5. When obtaining the contact area for Eq 3 and 4, it is assumed that the pileup of the material produced during indentation does not support any load. In practice, the piled-up material does, in fact, support a load.

Scratch Hardness Estimation. Now consider what happens to a Vickers indenter if it is moved along the sample surface, after a load, P , has been applied. This corresponds to a scratch test. For the purpose of discussion it shall be assumed, without loss of generality, that the pyramid indenter is being moved along the direction of one of the indentation diagonals. As the indenter is quasi-statically loaded and then slid against the surface, the indenter first sinks further into the surface due to loss of load-carrying capacity of the two rear faces. As sliding proceeds, the indenter will “climb up,” pushing a ridge of deforming material ahead of it. A steady state is soon reached in which the normal force, P , the tangential force, F , and the extent of plastic deformation as characterized by the width of the scratch track become constant. A schematic of a scratch track and an optical micrograph of the plan views of a track made by a Vickers indenter are shown in Fig. 6 and 7, respectively. Figure 8 is a schematic of the relevant load-bearing areas associated with the normal and tangential force, respectively, which enter into the calculation of scratch hardness.

Fig. 6 Parameters encountered in scratch testing. F_T , tangential friction force; F_N , normal load; v , scratching speed

Fig. 7 The load dependence of fracture and deformation about scratches made by a Vickers indenter in soda-lime glass. These photographs were taken in tests conducted in the Purdue scratch apparatus. (a) Scratch appears plastic until end of traverse. Load, 120 g. (b) Lateral and median cracks pop up around the scratch track, shown in (a), when the indenter is unloaded. (c) Lateral and median cracks after unloading. Load, 90 g. A, extent of median crack; B, extent of lateral crack. (d), (e), and (f), different parts of the same scratch track showing ductile chip formation at low loads. A, curly chip; B, spiral chip; C, chips attached to groove surface

Fig. 8 Effect on load-bearing area, A_{LB} , of scratching with a conical tool. (a) Pure cutting (no ridge formation). (b) A more realistic situation of ridge formation (that is, mixed microplowing and microcutting). w , groove width; b , groove height

The scratch hardness may also be defined with reference to Fig. 8. By analogy with quasi-static indentation, the scratch hardness H_S is defined as (Ref 6):

$$H_S = \frac{P}{A_{LB}} \quad (\text{Eq 5})$$

The projected load-bearing area, A_{LB} , is estimated from measurements of the scratch track width, w . In practice, if w is measured with an optical microscope, some part of the piled-up region along the lateral edges of the track will be included in the measurement. For a Vickers indenter, A_{LB} is obtained as:

$$A_{LB} = \frac{w^2}{4} \quad (\text{Eq 6})$$

Similar relations can be obtained easily for other indenter geometries. Note that A_{LB} for a Vickers indenter calculated using Eq 6 is independent of whether the indenter is moved edge first or face first.

It is reasonable to expect that the scratch hardness, H_S , is equal to the associated indentation hardness (Vickers, Knoop, Brinell), H , since both parameters are associated with the plastic response of a material. However, experimental results indicate otherwise. Table 1 is a comparison of indentation hardness (H) and scratch hardness, H_S , for a selection of materials. It is seen that the ratio H_S/H is not only different from a value of one, but also varies widely, depending on material type and properties. In order to understand these variations, it is necessary to analyze a detailed model of the plastic scratching process (Ref 6), but this is beyond the scope of this article. Suffice to say that H_S may be used in an analogous way to indentation hardness, but with considerable caution. From a measurement point of view, the measurement of scratch width, including the pileup region, is much easier and can be more accurately carried out than indentation diagonal measurement. For example, profilometry of the scratch track provides an accurate measurements of w .

Table 1 Comparison of indentation hardness H and scratch hardness H_S for a range of materials

Material	H		H_S		H_S/H
	MPa	ksi	MPa	ksi	
0.9% carbon steel	2,800	405	3,300	480	1.16

Plowing Hardness. When performing a scratch test, the tangential force (F) on the indenter is also measured. This leads to the definition of another hardness parameter that is based on the groove cross-sectional area, A_P , and the tangential force (see Fig. 8). This hardness parameter is usually referred to as plowing hardness (H_P) and is defined as (Ref 6):

$$H_P = \frac{F}{A_P} \quad (\text{Eq 7})$$

For a Vickers indenter, or more generally for scratching with a wedge indenter of wedge apex angle 2α ,

$$A_P = b^2 \tan \alpha \quad (\text{Eq 8})$$

where b is the depth of the scratch groove measured either from the original surface or from the peak of the piled-up region. The corresponding area A_P for this wedge indenter is $b^2 \tan^2 \alpha$. It must be noted that b cannot be estimated from track width, w , and the indenter angle 2α , because of elastic recovery of the scratch. Consequently, b has to be obtained from a measurement. The quantity H_P can be interpreted in more than one way. For example, it can be thought of as the energy expended in displacing a unit volume of material. It is also related to the minimum load required for a chip to be formed during scratching. However, the demarcation between the deformation regimes in which chip formation is the preferred mode rather than indentation is primarily dependent on the attack angle of the indenter, and to a lesser extent on indenter tip radius.

Specific Energy of Abrasive Machining. The scratch test, with a pyramid indenter or an abrasive particle, can be used to estimate the specific energy (u) in abrasive machining, that is, the energy required to remove unit volume of material by chip formation. The specific energy can be obtained as:

$$u = \frac{\text{Power}}{\text{Volume of material removed}} \quad (\text{Eq 9})$$

$$= \frac{Fv}{Vbw} = \frac{F}{bw}$$

where F is the tangential or cutting force on the particle, b is the depth of material removed, and w is the width of the scratch track.

The specific energy is an important parameter used to evaluate the efficiency of machining processes. It can also be a useful parameter in studying the cutting action of abrasive grits of different type, shape, and composition. The challenge in using this approach is that high-frequency dynamometers capable of measuring the force on a single indenter or particle that is imposed over a duration of a few tens of microseconds are not currently available. There are other approaches to estimating the energy consumed during cutting, but these are not sufficiently accurate, nor do they have high resolution.

Efficiency of Material Removal. The scratch test can be used to evaluate the efficiency of material removal by calculating a parameter that compares the amount of material removed by chip formation with the volume displaced by indentation. This parameter, sometimes called the removal coefficient, η , is defined as:

$$\eta = \frac{\text{Volume of material removed}}{\text{Volume of material displaced}} \quad (\text{Eq 10})$$

The challenge in estimating this parameter is quantifying the amount of material that is piled up (see earlier discussion).

Stress analysis of scratch testing is used to determine whether information more detailed than scratch hardness is available within the test. Analysis of the stress field induced by scratch testing is difficult due to the complicated geometry imposed by the contact problem and the inelastic behavior of the material in the presence of concentrated stresses. Stress analysis of scratch testing can be classified broadly into indentation of ductile or brittle materials by spherical or pyramidal indenters. The elastic stresses associated with a sliding spherical indenter are well characterized, for example, in Ref 8. However, detailed elastic stress fields for pyramid indenters are not available due to the singular nature of the stresses. These singularities require special care when using finite elements to resolve elastic-plastic stress fields for normal indentation (Ref 9). An accurate finite element solution for scratching using pyramid indenters is not available.

For spherical indenters, the finite-element method is capable of resolving the stresses associated with scratch testing of ductile materials (Ref 10). However, an assumed constitutive behavior that is capable of accurately predicting the ratcheting strain for repeated sliding of a range of materials eludes researchers (Ref 11). These elastic-plastic calculations yield much information that is difficult to present in a compact form that can be used to interpret experimental results over a range of loads. However, an approximate solution for ductile materials subjected to normal indentation based on the “expanding cavity” are available (Ref 8). This solution relies on an observation that strain fields are spherically symmetric. It provides a convenient classification of spherical indentations into elastic, elastic-plastic, and fully plastic regimes. This model has not been applied to scratching.

Sliding Indentation Fracture of Brittle Materials

The Blister Field. Recent interest in fracture induced by sliding indentation of brittle materials warrants special attention. When a sharp indenter is quasi-statically applied onto a surface of a brittle solid, the classical theory relating the hardness to the yield stress of metals (Ref 1) no longer applies since yielding no longer occurs at a constant maximum shear stress or at a constant volume (Ref 12). A large body of experimental observations have shown that in brittle materials the volume of material displaced by the penetration of the indenter is accommodated by compaction or shear deformation, or both, and this may occur either uniformly or irregularly. In silicate glasses, which have a relatively open structure, the displaced material is most readily accommodated by compaction within a zone underneath the indenter. However, in soda-lime glasses and in most ceramics shear deformation dominates, with some compaction also taking place underneath the indenter. The experimental model used by Yoffe (Ref 13) to describe the deformation underneath a sharp conical indenter in soda-lime glass is based on the work of Peter (Ref 14), among others, who showed that the mean contact pressure under a sharp indenter remains constant and relatively independent of the indenter geometry. This model assumes that as a conical indenter is applied to the solid surface, yielding initially occurs in a hemispherical bowl under the indenter and continues until the yielded zone attains its stable preferred state for that pressure. As the indenter is loaded further, no additional flow occurs within this bowl, but fresh yielding takes place in an adjoining thin hemispherical shell. This process continues, and “it is as if a set of nested hemispherical bowls separated by plastic filler were forced down in turn, one within the other” (Ref 13). The yielding process occurs through a combination of shear deformation and compaction within the yielded zone. Part of the material displaced by the indenter is accommodated by compaction within the yielded zone, while the remaining material is pushed into the surroundings. At the end of the indentation process, the elastic half-space is left with an overlarge hemispheroid fixed in a hemispherical cavity on its surface. This misfit leads to a residual stress in the region outside of the cavity. Consequently, as the material reacts to this residual stress, cracking may occur within the solid.

The “blister” field proposed by Yoffe (Ref 13) was for describing the development of cracks below a conical indenter acting on a brittle solid. The stress distribution in the surrounding elastic zone was obtained as the superposition of two stress fields—the Boussinesq field for the point force, which idealized the indentation pressure distribution, and a doublet force system, which idealized the localized inelastic deformation. The doublet force system for the blister field consisted of superposition of a point center of expansion in an infinite elastic solid with an additional doublet to satisfy the free surface normal stress boundary condition. Such a doublet force system leads to a volume increase of the inelastic deformation zone that must be taken up by compaction or elastic deformation of the remainder of the solid. The volume increase is a measure of the “strength” of the blister field. The strength of the blister field varies with the applied force; this variation is characterized by a material property that has thus far defied a precise estimation. Qualitatively, Yoffe's model has predicted the origin and growth of radial, median, and lateral crack systems quite well. In particular it is consistent with the observation that for a certain range of loads, the lateral crack forms and grows during

unloading. Its only disadvantage is from a quantitative point of view, as a procedure for determining the strength of the blister field for various indenter geometries is not yet available.

Models to describe the sliding indentation fracture process in ceramics have not yet evolved to a stage where the inelasticity under the indenter is accounted for completely (Ref 15, 16, 17). This is in large part due to the difficulty introduced by a lack of information concerning the constitutive behavior of ceramics in large hydrostatic compressive stress fields such as that existing underneath a microindentation. It seems that a reasonable first step for modeling the sliding indentation stress fields would be to extend Yoffe's work on static indentation to the sliding situation (Ref 18). This extension includes the load-history effects of inelastic deformation left behind by the sliding indenter and the elastic effects due to the frictional force.

Sliding Indentation Fracture Observations. The sliding indentation stress field (Ref 18) provides interpretation of observations of the microcracking about scratches in brittle solids (Ref 15, 16, 19, 20). Figure 9(a) shows a schematic view of the crack patterns that have emerged from the studies, most of which have been carried out at light loads in soda-lime glass, silicon, polycrystalline alumina, and nickel-zinc ferrite. The typically observed crack patterns are median, lateral, and chevron (radial) cracks. The load regimes at which the various cracks occur in soda-lime glass are summarized in Table 2, which is obtained based on observations of the fractured specimen.

Table 2 Classification of fracture patterns in soda-lime glass under a sliding Vickers indenter

Normal load (N)	Fracture pattern
~0–0.05	No crack
~0.05–0.8	Median cracking
~0.8–3	Median and lateral cracking with lateral crack growth to the surface at higher loads
~3–6	Median cracking and crushed scratch track

Source: Ref 19

Fig. 9 (a) Cracks induced by sliding microindentation of brittle solids. (b) Photograph of cross section

In situ observations indicate that these cracks initiate at or close to the boundary between the inelastic deformation zone and the surrounding elastic solid. The subsequent growth of these cracks occurs in the elastic region. Bulsara (Ref 20) observes that for most loads at which median and lateral cracks occur, the cracks propagate such that the crack front moves with the load. However, near loads of about 1 N applied with a Vickers indenter in soda-lime glass, the lateral crack does not appear until the indenter is lifted from the surface. Once the load is removed, the lateral crack forms beneath the end of the scratch and propagates rapidly along the entire length of the scratch and until the beginning of the scratch track, where it stops. Fracture and

deformation patterns about scratches in soda-lime glass, which is often used as a model brittle material, as shown in Fig. 7, which also shows ductile chips formed by scratching in glass.

The assumption that these cracks are initiated and propagated by tensile stresses that occur in the elastic material immediately adjoining the inelastic zone allows for predictions of crack formation and growth through a consideration of the stress fields. It has been shown that the present analytical model provides reasonably good descriptions of the crack patterns observed around sliding indentations in brittle materials. In particular, the analysis accounts for the occurrence of lateral cracking under sliding indenters above an experimentally observed threshold load (Ref 18).

The sliding blister field does not reveal any information about details of deformation in the inelastic zone near the indenter. Recently, investigators have been examining this issue using nanoscratch testing. However, the sliding blister field is a simple analytical tool that can be used to explain many interesting aspects of failure mechanisms in glass that occur near sliding microindentations.

Sliding Indentation Modeling of Polishing. A common method for making surfaces smooth is by rubbing them against a block with an abrasive slurry interspersed between them. This process is called polishing or, sometimes, lapping. The block is typically made of a metal, for example, cast iron or tin, or it consists of a soft, flexible material such as cloth, nylon, or leather attached to the surface of a metal block. The polishing slurry is composed of hard, abrasive particles (e.g., diamond, silicon carbide, alumina) suspended in a fluid medium such as deionized water, glycol, or viscous oil. A force is applied to the work surface by the polishing block; this force typically corresponds to a polishing pressure of 7 to 14 kPa (1–2 psi), where polishing pressure is the polishing force divided by the work surface area. The relative sliding velocity between the block and the work surface is usually less than 0.5 m/s and randomly oriented through the course of the process so as to produce a smooth surface devoid of directional scratches. This velocity is one to two orders of magnitude less than the relative velocity between an abrasive wheel and workpiece in grinding. An early, important application of polishing was lens making, and indeed it was for this purpose that the process was studied by Newton, Herschel, and Rayleigh (Ref 21). Since then, polishing has become a critical process in many applications ranging from the manufacture of precision mechanical components to electronic substrates and optical windows.

While the applied polishing force is low and in itself insufficient even to cause considerable elastic deformation of the work surface, this force is transmitted to the surface, not uniformly, but at the microscopic contacts between the abrasive particles and the work surface (Ref 22, 23). At these contacts the pressure imposed by a particle on the surface should be quite high, often comparable to the hardness of the work material. Consequently, the mechanism of material removal in polishing, which varies from brittle fracture to plastic microcutting, is not so much dictated by the applied polishing force as by the manner in which this force is transmitted locally by the particles to the work surface. This is consistent with microscopic observations of polished surfaces and polishing debris, which indicate that the abrasive particles act like single-point cutting tools or indenters (Ref 22, 24). The force applied by an abrasive particle also plays a major role in determining polishing temperatures (Ref 25) and the extent of plastically deformed layers and residual stresses on polished surfaces (Ref 22, 26, 27). Because of the critical importance of these forces to the mechanics of polishing, it is of interest to deduce the magnitude and distribution of these forces and their dependence on polishing parameters.

A model has been developed to determine the number and size of abrasive particles involved in material removal in polishing and the forces acting on these particles (Ref 28). This model assumes that each particle acts as a sliding microindentation. The effect of particle size on these parameters has been simulated for a range of particle sizes. It is shown that when polishing with abrasive powders having relatively broad size distributions, only a very small percentage of the particles are involved in material removal. Further, these particles comprise the larger particles occurring in the tail end of the particle size distribution. The average force on a particle is found to be in the range of 5 to 200 mN under typical polishing conditions, which is of the order of loads used in microindentation hardness testing. These predictions of the model are consistent with observations pertaining to polished surfaces and the polishing process.

Scratch Testing

Vispi Homi Bulsara, Cummins Engine Company; Srinivasan Chandrasekar and Thomas N. Farris, Purdue University

Summary

Scratch testing is useful and simple as a means of comparing the hardness of materials. The ubiquitous presence of the Mohs scale is testament to the usefulness of scratch testing. The scratch test also provides the basis for developing models of more complicated processes such as wear or polishing. However, it is not currently used to obtain more fundamental information, such as stress-strain curves, due to the lack of a robust model of the process.

Abrasive Wear Testing

Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Introduction

ABRASIVE WEAR is a major problem for the excavation, earth moving, mining, and minerals processing industries and occurs in a wide variety of equipment, such as bulldozer blades, excavator teeth, rock drill bits, crushers, slushers, ball mills and rod mills, chutes, slurry pumps, and cyclones. Figure 1 shows the extent of abrasion that can occur on a bulldozer blade. However, abrasive wear is not limited to these activities. Abrasion is a problem in most wear environments at one point or another, even though it may not be the primary wear mechanism initially. In any tribosystem where dust and wear debris are not controlled and excluded, abrasive

wear will be a problem. The wear of parts, the cost of repair and replacement of these parts, and the associated downtime related to these activities results in significant costs to many industries. As a result, some sort of preliminary indication of the wear resistance of these parts is desirable. For the most part, however, wear tests of specific machinery or parts are costly to perform, are very labor intensive, and require a long time to complete. In addition, the environmental variables change over the course of the test, making correlations between tests run at different times and in different places difficult. In order to reduce testing costs and speed up component development laboratory wear tests have been developed (Ref 1, 2, 3, 4). Many of these tests are company specific and consist of data collected over many years. These data are then used in conjunction with experience to design and select alloys for use as wear components within that company. However, these data are not usually available to other competitors or to the general public. Consequently, laboratory abrasive wear tests that are not specific to any particular tribological environment have also been developed over the years.

Fig. 1 Extent of abrasion on a bulldozer blade. Notice the width and depth of the wear scars.

In general, abrasive wear processes have typically been divided into two broad regimes: high-stress abrasion or low-stress abrasion. High-stress, or grinding abrasion, occurs when abrasive particles are compressed between two solid surfaces, as for example, between grinding rods or balls. The high-stress abrasion that occurs, for example, in grinding mills takes place over a very small contact region, where the ore particles are caught between the grinding balls or between the grinding balls and the mill liner. The high contact pressure produces indentations and scratching of the wearing surfaces and fractures and pulverizes the abrasive particles. Hard minerals such as quartz will indent and scratch martensitic steels having yield strengths of 2100 MPa (300 ksi). High-stress abrasion is often referred to as three-body abrasion, although two-body, high-stress conditions can also exist. High-stress abrasion implies that the abrasive particle is fractured and broken apart during the wear process. Exactly how these small abrasive particles affect the actual removal of the material is not well understood. It has been speculated that high-stress grinding abrasion facilitates material removal by a combination of cutting, plastic deformation, and surface fracture on a microscopic scale, as well as by tearing and fatigue or spalling on a macroscopic scale.

Low-stress, or scratching, abrasion occurs when lightly loaded abrasive particles impinge upon and move across the wearing surface, cutting and ploughing on a microscopic scale. In aqueous or other liquid environments, corrosion may also contribute to the overall wear rate, in which case erosion-corrosion is the operative wear mechanism. In both cases, low-stress abrasion is the primary mode of wear. The wear rates in

terms of metal thickness removed per day are quite low in low-stress abrasion, so a significant portion of the total wear is probably due to the abrasion of a continually reforming oxide film. This may be especially true in the handling of particulates in a wet environment, such as agricultural operations and the movement of slurries.

Abrasive Wear Testing

Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Parameters Influencing Wear

A variety of parameters influence all wear mechanisms and thus influence the abrasive wear behavior of materials. To a certain extent, abrasive wear tests have been designed to emphasize one or more of these parameters, especially the dominant one in an application. These parameters can be categorized as follows (Ref 5, 6):

- *Material parameters*: Material parameters of importance include composition, microstructure (e.g., grain size), mechanical properties (e.g., yield strength, elastic modulus, ductility), fracture toughness, thermal conductivity, degree of work hardening, hardness, and so on.
- *Design parameters*: Design parameters also influence the wear mechanisms, and some of the more important ones are shape, loading, force/impact level, type of motion (e.g., sliding/rolling), roughness, vibration, and cycle time.
- *Environmental parameters*: Of particular importance is the environment of the wear event and parameters such as temperature, humidity, atmosphere, wet/dry conditions, pH, contamination, and so on.
- *Lubrication parameters*: In certain nonabrasive applications, the type of lubricant, lubricant stability, type of fluid lubrication, and so on are all important.

In abrasive wear, the characteristics of the abrasive particle are also important. Some factors of influence are particle shape, particle size, hardness, yield strength, fracture properties, and concentration (Ref 7). These characteristics will influence the severity of the abrasion.

Abrasive Wear Testing

Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Elements of a Wear Test

The general elements of all laboratory wear tests are simulation, acceleration, specimen preparation, test control, wear measurement, and data reporting (Ref 5, 6). Simulation is the most important element of the wear test because it ensures that the behavior experienced in the laboratory test is the same as in the application. The ideal wear test will exactly duplicate the wear situation, but in most cases only an actual field test of the component will accomplish that. It is important, at the very least, that the laboratory wear test generate the same wear mechanisms as the application and that the primary wear mechanism in the application is the primary one in the laboratory test. Other factors of attention include test geometry, load range, surface conformity, break-in, and so on.

Acceleration of the wear test is important because it reduces the overall time and cost of the testing effort. Accelerating the wear test, however, can influence or change the material response. For example, if the load or the speed of the test is increased, one wear mechanism may be emphasized more than another or the wear regime may pass from mild to severe. Even so, all laboratory wear tests are accelerated to one degree or another, either through continuous operation, measurement of smaller quantities of wear, or by applying higher loads, speeds, or temperatures.

Attention to specimen preparation and test control are important in laboratory wear testing because they determine the degree of scatter in the data (i.e., they either improve or degrade precision and reproducibility). In any test method, it is important to reduce as much as possible the number of factors that can influence the result of that test. Ideally, the wear test should reflect differences in the material and not differences in the operation of the test. Specimen preparation is critical because each test should start with a specimen that is identical to the last in terms of geometry, surface finish, break-in, and so on. Therefore, it is important that each specimen is prepared for the test in exactly the same manner (i.e., cleaning, drying, storage, weighing, etc.). In addition, accurate control of wear test apparatus operating parameters such as load, speed, instrument construction, ambient environment, location and alignment, and supply of abrasive is critical to controlling the reproducibility of the test data. Of particular importance in a wear test is the use of a reference material. The use of a reference material allows the operation of the wear test apparatus to be checked periodically for conformance to the operating parameters, to test the skill of the operator, and to determine such factors as the influence of environment (Ref 6).

Determining the most efficient way to measure the extent of wear loss from a test depends primarily on the type of wear test and the amount of wear generated from the test. Common wear measuring techniques include the measurement of mass loss, volume loss or displacement, scar width or depth or some other geometrical measure, or other indirect measures, such as the time required to wear through a coating or the load required to cause severe wear or a change in surface reflectance (Ref 6). The way in which the degree of wear is measured is based on convenience, the nature of the wear specimen, and the available measuring techniques. In abrasive wear, large amounts of material are typically removed, and as a result, mass loss measurements are typically favored. In the case of microabrasion, where mass loss is minimal, geometrical methods are more effective. Material wear behavior in terms of the wear rate can be described by either producing a wear curve or by measuring wear at a single point in the test (Ref 6). Because wear is nonlinear, a wear curve generally provides more information and allows evaluation of more complex behavior than a single-point measurement (Ref 6).

However, once a wear curve has been established for a material or class of materials, the wear test can be designed so that a single-point measurement can be used.

Wear is a system response, and when reporting data, a complete description of the system is needed to put the data in context. Information that should be supplied includes the following where applicable (Ref 5, 6):

- Apparatus
- Geometry of contact
- Type of motion
- Load
- Speed
- Environmental conditions
- Conditions of wearing mediums
- Description of materials
- Description of lubricants and lubrication used
- Description of wear-in period, if appropriate
- Unusual observations (e.g., evidence of material transfer)
- Surface and materials preparations
- Sample surface roughness

The report should describe the material tested, the general nature of the test, conditions of the counterface, testing environment, and any other significant features.

Wear test data scatter can be significantly reduced by careful testing methods. The number of tests that should be conducted to provide accurate results depends on the type of wear test being conducted, but it is suggested that several tests, rather than one, should form the basis for conclusions. In general, a minimum of three tests is preferred, and the need for replication depends on the testing purpose, degree of control, and scatter (Ref 6).

Abrasive Wear Testing

Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Standardized Abrasive Wear Tests

Wear testing in general, and abrasion testing in particular, has few standardized tests with well-defined experimental procedures. In many cases, the standardized tests do not adequately represent the actual wear environment of interest, and as a result, many ad hoc wear tests have been developed over the years within specific industries and companies. The American Society for Testing and Materials (ASTM) has tried to standardize the most popular of these wear tests so that the tests can be performed in a like manner from one laboratory to the next with a reasonable degree of precision and bias.

The following abrasion and erosion test procedures are listed in the *Annual Book of ASTM Standards*, Volume 03.02 (Ref 8):

Standard No.	Description
G 56	Abrasiveness of Ink-Impregnated Fabric Printer Ribbons
G 76	Conducting Erosion Tests by Solid Particle Impingement Using Gas Jets
G 65	Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus
G 132	Pin Abrasion Testing
G 75	Slurry Abrasivity (Miller Number) and Slurry Abrasion Response of Materials (SAR No.)
G 105	Conducting Wet Sand/Rubber Wheel Abrasion Tests
G 81	Jaw Crusher Gouging Abrasion Test

The first six items in the table are all ASTM test methods, while the seventh is an ASTM practice. In the following sections, some of the test procedures and practices are described in more detail, while others are left for the reader to explore. Additional nonstandard ASTM abrasive wear tests are also described. For anyone wishing to do abrasive wear testing, it is useful to read the various ASTM standards and practices in order to gain an understanding of how to structure a wear test (abrasive or otherwise), calculate mass/volume losses and wear rates, and report the measures of precision and bias in the data.

Description of Tests and Equipment

In the following section, abrasive wear testing is broken up into the following general topics: scratch testing, dry abrasion against fixed particles, dry abrasion against loose particles, wet abrasion against fixed or loose particles, gouging-abrasion, small particle erosion, impact abrasion, slurry abrasion, and microabrasion. For these abrasion categories, the general test procedures are outlined, some in more detail than others, selected results are given, and the advantages and limitations of the tests are discussed.

Scratch Wear Testing

Scratch wear testing is a method of mechanically testing a specimen by moving a stylus or indenter over its surface (Ref 9). This wear test is important because it provides information on the micromechanics of material removal for the stylus-material tribosystem. Typically, a single abrasive particle, in the form of a well-defined and oriented stylus, is moved across the surface of a material in some controlled manner (load and velocity) generating a groove. By controlling the shape of the stylus and its orientation with the wear surface, information as to the volume of material removed and the wear mechanism controlling material removal can be obtained (i.e., cutting or plowing) (Ref 9, 10). The following simple expression has been used as a starting point for quantifying the volume of material removed from a surface during two-body abrasion by a single conical abrasive particle (Ref 11):

$$W_v = \left(\frac{2 \tan \alpha}{\pi} \right) \cdot \frac{s \cdot F_N}{H} \quad (\text{Eq 1})$$

where W_v is the volume of material lost to abrasive wear, s is the sliding distance, F_N is the normal load on the conical abrasive particle, H is the yield pressure or the hardness of the wearing surface, and α is the angle of attack of the abrasive particle. Equation 1 is more typically written as:

$$W_v = k_{ab} \frac{s \cdot F_N}{H} \quad (\text{Eq 2})$$

where k_{ab} is known as the wear coefficient for abrasion and replaces the first factor (i.e., a geometrical one) in Eq 1. Many preconditions exist for using Eq 2, the most important of which is that microcutting occurs during the abrasive process. As a consequence, Eq 2 provides an upper limit for the amount of material removed from a surface during abrasion. Values of k_{ab} fall between 10^{-2} and 10^{-4} for ductile materials, with the lower values of k_{ab} associated with three-body wear and the greater values with that of two-body wear (Ref 11).

Although diamond indenters are usually used in scratch testing because of their prevalence in hardness testing, any material can be used as the scratch stylus. Although details of scratch testing are not covered here (see the article "Scratch Testing" in this Volume), it is important to realize that scratch testing can aid in understanding the large-scale abrasive wear behavior of materials by fixed particles through understanding what occurs as one particle moves across the surface (Ref 12). Figure 2 shows the damage mechanisms that occur in a white cast iron as a result of a single scratch using a diamond stylus.

Fig. 2 Single scratch, using a 20 μm conical diamond stylus under a 100 g load, on a high-Cr white cast iron. Notice the matrix transformation to martensite and the cracking of the carbides. Source: Ref 12

Dry Abrasion against Fixed Particles

Dry abrasion against fixed particles is typically performed using a pin abrasion wear tester. Pin abrasion wear testing simulates high-stress, quasi-two-body abrasive wear. The wear test is high stress because the abrasive grains are frequently fractured during the test. It is quasi-two-body because at the onset of the test, the abrasive particles are fixed to the cloth backing with an adhesive. As the test progresses, fractured bits of the abrasive and wear debris become trapped in the interfacial region between the end of the pin and the abrasive cloth, thus adding a third body to the system.

Many different pin abrasion wear testers have been developed over the years (Table 1). All these devices have one thing in common; that is, they expose a specimen to an environment where the abrasive grains are initially fixed to a substrate. Table 1 also provides some of the pertinent operating conditions for various pin abrasion wear testers. ASTM G 132 provides a useful guide to the general features of pin abrasion wear testing (Ref 27). In the discussion that follows, details specific to the operation of the pin-on-drum are provided (Fig. 3) (Ref 23, 28), although these same conditions also hold for many of the other pin abrasion wear testers.

Selection of the Abrasive Media. Selecting the appropriate abrasive to use in the wear test is important. The most common abrasive in the earth's environment is silica (SiO_2), with a hardness of about 1000 HV. To more closely simulate the actual abrasion that occurs in a particular application, however, the same type of abrasive encountered should be used in the pin abrasion test. Commercially available abrasive cloths are produced with garnet (1300 HV), alumina (2000 HV), and silicon carbide (2500 HV) as the abrasives. Sometimes flint abrasives (common sandpaper) are used, although silicon carbide is probably the easiest abrasive particle to find in the variety of paper sizes needed to fit on the pin abrasion testers.

Another consideration in abrasive selection is the amount of abrasive wear desired during the course of the wear test, and this is a function of the abrasive used in the test, the sliding distance, and the hardness of the material being investigated. For "soft" metals and alloys such as aluminum and mild steel, garnet, alumina, and silicon carbide abrasive particles of the same size remove approximately the same mass of material during a test of the same duration. Any minor variations in material removed when using these abrasives is due to slight variations in the characteristics of the abrasive particles, such as their shape (angularity), their fracture characteristics (sharp or blunt fragments upon fracture), and their packing on the backing cloth during manufacture (different abrasive types pack differently on the cloth as a result of their shape). For "hard" materials such as tool steels and high-chromium white cast iron, some change in the relative wear ranking may occur when different abrasives are used (Ref 29). For hard-particle reinforced composites and ceramics, a harder abrasive such as alumina or silicon carbide should be used in order to give reasonable mass losses for reasonable sliding distance.

Pin Abrasion Test Procedures. During a pin abrasion test, a pin (of whatever diameter used for that particular machine) is first broken in by running it across the abrasive to be used in the actual wear test. This act accomplishes two purposes: it creates a uniform surface for testing and conforms the specimen surface to the counterface. The pin specimen is cleaned and then weighed (typically to an accuracy of 0.1 mg). The actual wear test is then performed, with the sliding distance being determined to give a reasonable amount of mass loss, usually on the order of 20 to 40 mg. (This way, measurement errors are kept low, that is, 1 part in 200–400.) Sometimes the sliding distance is determined by the physical constraints of the pin abrasion test apparatus (especially for the phonograph-style or table machines). Once an abrasion test is completed, the specimens are cleaned in some manner to remove any loosely adherent wear debris, rinsed in some manner to remove surface contamination, and then air dried or stored in a vacuum desiccator before weighing.

At some point in the analytical investigation of the wear properties of the material, the density of the material should be determined using standard techniques. The density can then be used to convert specimen mass loss to a volume loss. This allows the wear rates for different materials classes to be directly compared when determined under identical conditions.

In pin abrasion wear testing, a reference pin is also typically used so that variations in the abrasives can be accounted for and so that the relative abrasion rate of different classes of materials (e.g., steels, cast irons, ceramics, metal matrix composites, etc.) can be compared (Table 2). Typically, the reference material is an alloy that is easily obtainable so that it can be used by anyone with a pin abrasion tester in order to compare results with those of other researchers. Usually, the heat treated condition of the reference pin is given by a hardness value (e.g., ASTM A 514/A 514M, type B hardened to HB 269).

Table 2 Typical pin-on-drum wear data for ferrous alloys

Alloy and designation	Hardness, HB	Abrasive wear ^(a)	
		WF	mm ³ /m
Stainless steel, type 304	207	0.73	0.86
Low-alloy steel, ASTM A 514	256	0.98	1.11
Low-alloy steel, AISI 4340	540	0.73	0.95
Tool steel, type D2	698	0.42	0.49
High-chromium white cast iron	661	0.27	0.31
Carbon steel, AISI 1060	785	0.50	0.56

Note: Load, 66.7 N (15 lbf); pin diameter, 6.35 mm (0.25 in.).

(a) WF, relative wear factor

If a reference material is used in the pin abrasion test, a ratio of the volume loss of the specimen of interest and the reference pin can be calculated from the following relationship:

$$WF = \frac{V_x}{V_r} \quad (\text{Eq 3})$$

where WF is the relative wear factor for a given set of abrasive test conditions (i.e., load, sliding distance, and abrasive), and these conditions should always be stated. The term V_x is the volume of material lost to abrasion for the test specimen under the given test conditions, while V_r is the volume lost to abrasion for the reference specimen. In ASTM G 132, the normalized wear is calculated in the following manner (Ref 27):

$$\text{wear rate} = \frac{CW_x}{\rho S_x}, \text{ mm}^3/\text{Nm} \quad (\text{Eq 4})$$

where W_x is the mass loss of the specimen (in any units), S_x is the mass loss of the reference specimen (in the same units as W_x), ρ is the density of the test specimen (known or measured to three significant figures) in g/cm^3 or mg/mm^3 , and C is the reference constant equal to the mean mass loss (also in grams or milligrams) of the reference pin per unit track length (in meters) per unit load (in newtons) for the abrasive type and test parameters used. The ratio $C:S_x$ functions as a normalizing factor. (The value of C should be determined for each abrasive particle type and size used in a pin abrasion test. Using many rolls of abrasive over a number of years can cause large errors in the determination of C .)

As an alternative method for determining wear rate from the mass loss data, one of the many equations listed in the literature can be used (Ref 30). Typically, these equations represent the wear as either the specific wear rate

(mm³/Nm), a dimensionless wear coefficient, or as the volume wear (mm³/m). Wear rate can also be represented as the total volume of material lost (mm³) for a specific set of test conditions (i.e., abrasive size, abrasive type, applied load, and sliding distance). Table 3 lists some of the ways in which wear rate can be represented.

Table 3 General definitions of wear rate

Definition	Equation	Relationships between wear rates
Time-dependent wear rate	$\dot{W}_t = \frac{\Delta h}{t}$	$\dot{W}_t = \dot{W}_s p v$ $\dot{W}_t = \dot{W}_v$
Distance-dependent wear rate	$\dot{W}_L = \frac{\Delta h}{L}$	$\dot{W}_t = \dot{W}_L p^2 v$
Dimensionless wear rate	$\dot{W} = \frac{\Delta V}{LA}$	$\dot{W} = \dot{W}_L p^2$
Specific wear rate	$\dot{W}_s = \frac{\Delta V}{L F_n} = \frac{\Delta m}{L \rho F_n}$	$\dot{W}_s = \dot{W}_L p$

Note: Δh , height loss of specimen; t , time of operation; L , sliding distance; ΔV , volume loss; A , apparent contact area; F_n , normal load on specimen; Δm , specimen mass loss; ρ , density of specimen; p , pressure; v , velocity.

Source: Ref 30

Variation in test results for the pin-on-drum abrasion test at a single facility is consistently less than 5% for homogeneous metals, alloys, and ceramics, and in some cases, less than 1%. For composite materials and composite-type materials such as high-chromium white cast irons, the variance is typically between 5 and 10%, depending on the reinforcement and the strength of the interfacial bond between matrix and reinforcement (Ref 31, 32, 33).

In addition to ranking materials, the pin-on-drum abrasive wear test is very effective in discerning volume wear and wear mechanisms for a wide range of metals, alloys, composites, ceramics, and polymers. The surface area remains constant during the test, and consequently, different materials can be compared directly for volume loss and material-removal mechanisms.

Dry Abrasion against Loose Particles

Many cases of abrasive wear occur where the abrasive particles are not fixed but are free to slide and rotate. The dry sand, rubber wheel (DSRW) abrasion test apparatus simulates one such environment (i.e., low-stress, three-body abrasive wear) (Ref 34, 35). This type of wear occurs in the mining industry in linkages, pivot pins, and wire ropes, which suffer slow wear from the sliding and rolling action of abrasive fragments of rock and ore trapped between metal surfaces. It also occurs in agricultural tillage tools. Since this type of wear is slow, field trials alone are much too long to be effective in evaluating new materials. The DSRW abrasion test presents researchers with a quick and easy way to perform numerous tests, rank materials, and correlate the result with selected field tests. Even before the test became an ASTM standard (G65) in 1980, it had been used by a number of laboratories for many year. Since becoming an ASTM standard, it has become one of the most popular abrasive wear tests in the United States for ranking materials. As such, many companies have developed a qualitative understanding of how their materials perform in a particular wear environment relative to other materials.

DSRW Equipment and Specimen. The basic ASTM machine (Fig. 4) consists of a chlorobutyl rubber-rimmed steel wheel, 228 mm (9 in.) diam \times 12.7 mm (0.5 in.) wide; a sand hopper connected by a tube to a nozzle that allows 300 to 400 g/min sand flow; a revolution counter that stops the drive motor after a set number of revolutions; and a weighted lever arm that holds the specimen and produces a horizontal force against the wheel where the sand is flowing. The sand is 50/70 mesh Ottawa sand (although other rounded quartz sands may be used). The mesh size corresponds to a particle size range of 212 to 300 μ m. The hardness of the chlorobutyl rubber on the wheel must be durometer A - 60 \pm 2.

Fig. 4 Schematic diagram of the dry sand, rubber wheel wear apparatus. Source: Ref 35

A typical test specimen is a rectangle, 25 mm (1 in.) wide \times 75 mm (3 in.) long, that is 3 to 13 mm (0.1 to 0.5 in.) thick. The wear surface is ground flat with a surface finish of at least 0.8 μm . The density of the test material must be known in order to calculate the volume of material lost during the course of the test.

DSRW Test Procedure. The equipment has two test parameters: the sliding distance (i.e., the number of wheel revolutions) and the specimen load. ASTM recognizes five procedures using variations of these two test parameters (Table 4).

Table 4 Standard conditions for the dry sand, rubber wheel abrasion test

ASTM procedure	Force on specimen		Wheel revolutions	Distance abraded	
	N	lbf		m	ft
A	130	29	6,000	4,309	14,137
B	130	29	2,000	1,436	4,711
C	130	29	100	71.8	235.6
D	45	10	6,000	4,309	14,137
E	130	29	1,000	718	2,356

A test consists of the following eight steps:

1. Cleaning and weighing the specimen
2. Mounting the specimen in the lever arm fixture and loading the lever arm fixture
3. Starting the sand flow through the nozzle
4. Starting the rubber-wheel drive motor
5. Releasing the lever arm so that the specimen contacts the wheel, starting the revolution counter
6. Stopping the motor (automatic) and sand flow
7. Removing the test specimen
8. Cleaning and reweighing the test specimen to determine the mass loss during the course of the test.

From the mass loss and the density of the material, the volume loss is calculated. The test is repeated one or more times. The coefficient of variation between two or more tests for a material must not exceed 7% in order to meet ASTM specifications for a valid test. Wear-scar nonuniformity is another reason for invalidating test results. A nonuniform wear scar is an indication that the sample lever arm was misaligned or that the chlorobutyl rubber wheel has deteriorated and must be redressed.

Two points need to be kept in mind when performing DSRW tests. First, moisture in the sand may affect the flow rate of the sand through the nozzle (agglomeration of sand particles) and thus affect test results. In order to prevent this from occurring, it is good practice to dry the sand prior to use in some sort of oven at approximately 100 °C (210 °F), typically for more than 1 h. However, before using the sand in a test, it must be allowed to cool to room temperature. Reproducibility will also be improved if the sand is sieved prior to its use in the DSRW to remove foreign debris that may have inadvertently been included when the sand was bagged. Using a 40 mesh (425 µm) sieve will allow the sand to pass through while trapping agglomerations and other debris. A second factor that may adversely affect the results is softening of the chlorobutyl rubber wheel. After any test, the friction between the rubber wheel, sand, and specimen causes the rubber to heat up and soften. Consequently, the rubber must be allowed to cool to room temperature before another test is run. Typically, 1 h between tests is sufficient.

For most ferrous materials, testing is performed using a 130 N (29 lbf) load for 2000 revolutions of the rubber wheel (ASTM procedure B in Table 4), leading to volume losses ranging from 20 to 120 mm³. The reproducibility of the test is highest for volume losses in the range of 20 to 100 mm³.

Typically, in tests in which less than 20 mm³ is lost, any small material inhomogeneities are greatly magnified; therefore, a more severe test should be run by using either a greater sliding distance or higher load. Above 100 mm³ of material loss, the wear groove becomes so deep that it may contact the edge of the rubber wheel and cause erratic results. Therefore, a less severe procedure may be necessary. Using another procedure has a disadvantage in that test results cannot be directly compared among different procedures.

The DSRW test should be used only for the ranking of various materials, not for determining the absolute values of wear. For example, a material that wears half as much as another in this test probably will not last twice as long in the field because the test tends to exaggerate differences. Field factors such as the hardness and particle size of the abrading material will affect the absolute values of wear more than they affect the ranking. Typical wear data are presented in Table 5. In general, there is reasonable correlation between hardness and wear, with the amount of material removed decreasing as the hardness of the material increases.

Table 5 Typical dry sand, rubber wheel abrasive wear data

Alloy	Hardness, HV	Volume loss, mm ³	
		Procedure A	Procedure B
Stainless steel, type 304	207	408.0	170.8
Low-alloy steel, ASTM A 514	256	...	134.1
Low-alloy steel, AISI 4340	540	...	74.0
Tool steel, type D2	689	45.3	14.6
High-chromium white cast iron	661	31.5	12.7
Carbon steel, AISI 1060	785	...	32.1

One criticism of the DSRW test is that the area of contact changes as the test proceeds. That is, as the volume of material removed by abrasion increases, the surface area of contact between the rubber wheel and the DSRW sample increases. Thus, the effective contact area increases continually during the course of the test. This circumstance makes direct comparison of material loss between specimens impracticable, especially for those situations where material volume loss is greater than 20 mm³.

An advantage of DSRW testing over pin abrasion testing is that different types of abrasive particles can be used. Of course, doing this moves the test away from the ASTM standard 50/70 mesh Ottawa sand, but more realistic information can be obtained concerning the wear that occurs to a material as a result of a particular abrasive. The process of creating sand for use in the DSRW is straightforward. The ore of interest must be crushed, sized, washed, and dried. The sand should then be tested to determine whether the flow rate falls within the ASTM specifications (i.e., 300–400 g/min). If not, another nozzle should be fabricated that provides this flow rate. The wear test is then run as per the procedures specified in Table 4.

DSRW Test Variants. In order to obtain more information about the three-body abrasive wear process and to exert more control over test parameters, modifications to the standard DSRW test have been made (Ref 36, 37). Aside from a change in the position of the wear specimen (where it is placed in a horizontal configuration instead of the vertical one specified in G 65), major differences in operation include better control of particle feed rate (and the use of less abrasive during the course of the test), the ability to change wheel material (metal, polyurethane rimmed in addition to the usual rubber rimmed), the measurement of tangential traction forces (leading to calculation of the coefficient of friction), shorter duration tests, and the ability to use different abrasives. These configurations permit the load per particle and the packing density of the abrasive within the contact region to be determined. Research has shown that the steady state wear rate is reached at approximately 200 wheel revolutions, so tests of shorter duration can be run, with multiple tests run on the same specimen.

Wet Abrasion against Fixed or Loose Particles

Two significantly different test approaches have been developed to perform wet abrasive wear tests. One approach, similar to the DSRW, is defined in ASTM G 105, "Standard Test Method for Conducting Wet Sand/Rubber Wheel Abrasion Tests" (Ref 38). The other wet abrasion tests use the principles associated with the grinding, polishing, and lapping of materials (Ref 39). The former test can be roughly classified as a macroabrasion wear test, while the latter one is more of a microabrasion wear test.

Wet Sand/Rubber Wheel Abrasion Test. The wet sand, rubber wheel (WSRW) test is almost identical to the DSRW test. In this test (i.e., ASTM G 105) (Ref 38), a test specimen is abraded in a slurry containing abrasive grit of controlled size and composition. As in the DSRW test, the abrasive is introduced between the test specimen and a rotating neoprene rubber-rimmed wheel of specified hardness. Unlike the DSRW test, however, where the abrasive is directed between the specimen and the rubber-rimmed wheel using a gravity feed system, the wheel and specimen in the WSRW test sit in the slurry with stirring paddles agitating the mixture of sand and water. This constant agitation facilitates the movement of abrasive particles to the specimen rubber-rimmed wheel interface where they are caught and used to abrade the specimen in the direction of wheel rotation.

Figure 5 is a schematic diagram of the WSRW apparatus. The test apparatus consists of the following major parts: rubber-rimmed wheel with stirring paddles, slurry chamber, and specimen holder and loading assembly. The rubber-rimmed wheel and paddle assembly is nominally 178 mm (7 in.) in diameter (including the rubber rim) by 13 mm (0.5 in.) in width. Neoprene GW is used as the elastomer for the rubber rim with other constituents added to give the desired durometer A hardness (Ref 38). The slurry chamber must be large enough to hold the 0.940 kg of deionized water-1.5 kg rounded grain quartz sand (AFS 50/70) slurry. The slurry is typically only used once and then discarded because multiple use of the sand-water slurry may affect test comparisons.

Fig. 5 Schematic diagram of wet sand, rubber wheel wear apparatus. Source: Ref 38

For the DSRW test, only one rubber-rimmed wheel of specified hardness (Shore A durometer 60 ± 2) is used. In the case of the WSRW test, three rubber-rimmed wheels of different hardnesses (Shore A durometer 50, 60, and 70, all of ± 2 variance) are used to determine the wear rate. The WSRW test procedure is very straightforward. First, the test specimen (nominal dimensions: 57 mm, or 2.2 in., long \times 25 mm, or 1 in., wide \times 6.5 - 16 mm, or 0.26 - 0.63 in., thick) is placed in the specimen holder and immersed in the sand-water slurry. It is then loaded with a mass equivalent of 222 N (50 lbf) force and run in for 1000 revolutions of the wheel (total sliding distance of 558.6 m, or 1833 ft). The run-in eliminates the machined surface layer and exposes fresh

material that has not been affected by the surface preparation procedure. The test specimen is then removed, thoroughly cleaned, dried, and weighed (to the nearest 0.0001 g). The slurry chamber is drained and rinsed to remove any remnants of sand-water slurry from the run-in step.

The actual test begins at this point and is conducted in the run-in wear scar using either the same durometer 50 wheel used in the run-in or with another durometer 50 rubber-rimmed wheel. (Before each test is run, the durometer A hardness must be measured for the rubber-rimmed wheel at several points around the periphery.) The actual test follows the same procedure used to perform the run-in; that is, a 222 N (50 lbf) force is used to press the test specimen into the wheel in the presence of fresh sand-water slurry for an additional 1000 revolutions of the wheel. After the test, the sample is removed, cleaned, and weighed. The slurry is discarded and the chamber is rinsed out. Additional 1000 revolution tests are then performed using the durometer 60 and 70 wheels (in increasing order of hardness). From each of these tests, the normalized mass loss is calculated. The normalized mass loss for each durometer A hardness is then graphed on semilog coordinates as a function of the wheel hardness. The mass loss is plotted on the log scale while the wheel hardness is plotted on the linear scale. The reportable mass loss is obtained by fitting a least square line to the three data points and solving the equation for a hardness value of exactly durometer 60. The durometer 60 normalized mass loss can be converted to a volume loss by dividing by the density of the test material.

As with any wear test apparatus, the WSRW unit should be periodically checked to make sure it continues to operate within normal conditions. As with all ASTM tests, a reference specimen is used to establish and periodically verify machine variance. For a specific reference material, a minimum of five tests should be run to establish the machine operating parameters and precision. Subsequently, additional tests can be run with the reference specimens and these results compared against the baseline operating parameters. If the variation is greater than 7%, the machine should be considered out of control and steps taken to bring it back into compliance.

One advantage of the WSRW test is that variations in the hardness of the rubber-rimmed wheel, which plague the DSRW test, are lessened. For example, it has been observed that a difference in the durometer A hardness of 3 points produces a variation of 30% in the total mass loss (Ref 40). By using wheels of three different hardnesses, and normalizing the mass loss to the durometer 60 value on the least square line, more consistent values of wear rate are obtained. The linear nature of the lines on the semilog plot supports this approach. In addition to rubber-wheel hardness variations, the following variables also affect the reproducibility of the wear data: "loss of diameter" of the rubber wheel (accounted for by normalized mass loss calculations) (Ref 38), rubber wheel surface finish (a freshly dressed wheel holds abrasive grains better than a glazed wheel (Ref 40), rpm of the rubber wheel, specimen surface finish, pressure, slurry density, and slurry temperature. All of these variables, except slurry temperature, are addressed specifically in ASTM G 105.

For very wear-resistant materials, the number of wheel revolutions may need to be increased in order to obtain mass loss with the required statistical accuracy. If this is done, the procedure used is the same as just outlined.

Other abrasive-type slurry mixtures can be used in this test as needed to simulate applications. However, doing this makes the test nonstandard, and all operating parameters should be carefully controlled and noted so comparisons can be appropriately made. This wear test is not as widely used as the DSRW test because of the time and effort required to produce a valid result.

Metallographic Polishing Microabrasion Wear Tests. In order to determine the wear rate of a material, a metallographic polishing wheel can be used as the abrasive application device, where the sample can be abraded against alumina or silicon carbide paper, or against a diamond polishing disk, using water as a fluid lubricant for two-body abrasive wear conditions, and against a metal lapping wheel using a slurry of some composition for three-body abrasive wear conditions. The wear sample may be rigidly fixed relative to the wheel and abrasive (i.e., moving in the same wear track with the wear rate decreasing as a function of sliding distance, a result of the interstices between the abrasive particles becoming clogged with wear debris). Or, the sample may undergo a complicated movement relative to the wheel and abrasive (as in the case of an automatic polisher where the head rotates the samples so that they encounter fresh abrasive and so that the wear debris can be flushed from between the abrasive particles). A third type of wear tester that makes use of a modified pin-on-disk sliding wear tester and resin bonded grinding disks has been developed. The wet abrasion tests in this section are nonstandard, but they offer different ways to perform abrasion testing on materials.

In using metallographic grinding, polishing, or lapping equipment as the wear test apparatus, care must be taken to identify and monitor all operating conditions used, such as wheel velocity, sample holder velocity (if necessary), applied load, test duration, abrasive delivery system (i.e., abrasive size, particle loading, liquid

suspension, delivery rate), sample dimensions and configuration, and wear loss determination method. One technique, the Struers Micro Wear Test (Ref 39, 41), has standardized these operating features using the Struers Abrapol-2. In this test, three identical samples are abraded during one wear-test cycle.

Sample preparation is critical to the success of this test because a modified metallographic sample holder is used to hold the wear specimens. Typically, the wear samples are cut into cubes (e.g., $10 \times 10 \times 10 \text{ mm}^3$) and embedded into epoxy resin under controlled conditions using a special mounting device (Fig. 6a). In this way, a small thickness (~1 mm) of material protrudes from the mount so that abrasion occurs only to the specimen material and not the mounting resin. The samples are then lapped to a mirror finish using $3 \mu\text{m}$ diamonds (i.e., to make sure all samples start with a uniform and planar surface). They are then thoroughly cleaned, dried, and weighed before being mounted into the specimen holder. The specimens are separated from each other by 120° in the holder.

Fig. 6 Schematic diagram of (a) sample and (b) wear apparatus used for performing microabrasion wear tests. Source: Ref 41

The sample holder with specimens is then inserted in the polishing unit. As with most automatic metallographic polishing units, the sample holder is rotated at high speed (in this case, 150 rpm) relative to the rotating 300 mm (12 in.) diameter disk (Fig. 6b). In this way, the samples do not follow the same wear path on the disk but sweep the whole working area, thus encountering fresh abrasive as determined by the slurry handling system throughout the test. A cast iron disk (210 HV) is used with the slurry, and off-center concentric grooves are machined into its surface to hold slurry and wear debris. The load on the wear samples can be varied, from between 20 and 1200 N (4.5 and 270 lbf), depending on the sample cross-sectional area. Disk and specimen holder velocity is also variable, yielding specimen velocities of between 1.0 and 7.5 m/s . Test duration is

variable, but a typical test can last up to 2 minutes. However, the test time ultimately depends on the hardness of the material being tested and the type and size of abrasive particle being used. After the operating conditions have been determined, a test cycle is run on the three samples. After each test cycle, the samples are moved, ultrasonically cleaned in alcohol, and dried. Mass loss is determined for each sample, and the average value is used to calculate a wear rate from one of the equations in Table 3. If needed, a second, third, or additional wear cycle is run to achieve the precision and accuracy required.

In the case of the pin-on-abrasive disk (Ref 42), different fluids, either corrosive or noncorrosive in nature, can be used so that the effect of corrosion can be investigated while a sample is being abraded. Using ASTM G 119 (Ref 43), the effect of corrosion on wear and wear on corrosion can be determined for a given material. Figure 7 is a schematic representation of the corrosive-abrasive wear apparatus. Although the geometrical configuration is different from the pin-on-drum in that the pin is abraded against a flat disk of abrasive (in this case, a resin bonded grinding disk), the same general principles hold as with the pin-on-drum with one exception. In the pin-on-drum test, the sample is traversed in a helical fashion so that only fresh abrasive is encountered by the pin. In this test, the pin remains in the same position relative to the disk, but the disk deteriorates with time in such a manner as to constantly expose fresh abrasive grains for abrasion. The use of a circulating liquid facilitates the flushing of wear debris from the wear track on the disk. Thus, a wear curve can be generated that shows the typical linear increase in mass/volume loss with sliding distance (Fig. 8).

Fig. 7 Schematic diagram of pin-on-abrasive disk wear apparatus. I , current; V , potential; N_g , normal acceleration (up and down motion of pin specimen as a result of interaction with abrasive disk); f , frictional force of pin-abrasive disk couple; V_s , sliding speed of disk. Source: Ref 42

Fig. 8 Wear curve for ASTM A 514, type B low-alloy steel showing nonlinear and linear portions of volume loss versus sliding distance data. Normal force, 1.4 N (0.3 lbf); sliding speed, 0.1 m/s. Source: Ref 42

The general procedure for performing a wear test is exactly the same as with the other abrasion tests described so far. The sample is broken in, thoroughly cleaned, dried, and weighed before use. The pin is placed in a holder, then pressed against the surface of the grinding disk (either alumina or silicon carbide of different grit sizes), and the deionized circulating water is started. The sliding speed, distance to be traveled, and load are then selected. The test is run and the mass loss is measured. The wear rate is calculated in the normal way using one of the equations in Table 3. Research has shown that for any pin specimen-grinding disk couple, a curve of sliding distance versus cumulative mass/volume loss can be constructed. Typically, there is a nonlinear portion to the curve at short sliding distances where the pin is conforming to the disk surface. In essence, this test requires that both the pin and disk be conditioned before recording wear data. Once the nonlinear region has been identified for a material-disk couple under a specific set of operating conditions, then single-point wear tests can be subsequently run to determine the wear rate. The use of a deionized water lubricant usually does not introduce problems in determining the wear rate since the test is short enough (typically 2–3 hours), and the abrasive wear rate is large enough to obscure the effects of corrosion. However, if another lubricant, either more acidic or basic, is used, then the test becomes one of abrasion-corrosion. In this case, the component of corrosion is more significant.

Gouging-Abrasion Wear Testing

Gouging-abrasive wear is identified by the removal of a significant amount of material (a gouge) from the wear object during an encounter with an abrasive object in which the abrasive object also suffers damage. It is a type of high-stress wear that may be produced by either two-body or three-body conditions. The jaw crusher test gives high-stress, three-body abrasive wear. Jaw crusher wear tests were pioneered in the United States by Borik (Ref 44, 45) and used abroad by Sare and Hall (Ref 46). The jaws that crush the rock are taken as the test specimen. A number of investigators believe that the jaw crusher test gives the closest correlation to wear that occurs on earth-penetrating equipment, such as excavator teeth, power shovel buckets, scoops, and grader blades, as well as real jaw crusher wear.

Jaw Crusher Equipment and Specimen. One test plate and one reference plate are attached to the stationary jaw, and the other test and reference plates are attached to the movable jaw such that a test plate and a reference plate oppose each other. A rock hopper and rock chute are attached above the jaw crusher. The arrangement of the jaw crusher test equipment is shown in Fig. 9.

Fig. 9 Schematic diagram of jaw crusher wear apparatus. Source: Ref 47, 49

The test as used provides an average of the mass or volume loss of a pair of test plates, one from the stationary and the other from the movable jaw of the test machine. As specified by ASTM G 81 (Ref 47), jaw crusher data are presented as the ratio of the mass loss of the test specimen to that of a reference material. However, there is some disagreement (Ref 48) regarding the most efficient way to perform multiple tests and interpret the data. Complete details of the ASTM procedure can be found in Ref 47. The procedure described subsequently is an alternative test procedure that determines the absolute wear rate for a pair of jaw crusher specimens (Ref 49).

Jaw Crusher Procedure. In the nonstandard ASTM jaw crusher test, a set of four wear plates are cleaned and weighed and then clamped into the jaws of the jaw crusher (one set of specimens, A and B, in the stationary jaw, and another set of specimens, B and A, in the movable jaw). One specimen plate in the stationary jaw (A, for example) opposes that of another specimen (B) in the movable jaw. The minimum jaw opening is set (as per ASTM standard G 81), and rock is processed through the jaw crusher. The specimens are removed and cleaned thoroughly to remove any microscopic wear and/or crushed ore debris. The samples are rinsed in ethanol and then warm air dried. The mass loss is determined for each of the four jaw crusher plates. The samples are then reversed in the jaw assembly (i.e., the plates in the A position of the stationary jaw are now placed in the A position of the movable jaw), and the plates in the movable jaw are now placed in the stationary jaw, again in positions that oppose each other. The assembly is then placed back into the jaw crusher, the gap is reset, and a second run is made. The samples are once again removed, thoroughly cleaned, dried, and weighed. At this point, an average of the mass loss during the test is calculated for each of the two plates of the same material. This value is converted to a volume loss by dividing the mass loss by the density of the material. Table 6 shows data from both the ASTM method and the method just described.

Table 6 Typical jaw crusher wear data for ferrous alloys

Alloy and designation	Hardness ^(a) , HV	Volume loss ^(b) , mm ³ /kg
Stainless steel, type 304	207	27.7 ± 4.9
Austenitic steel, 13% Mn	230	13.2 ± 2.1
Low-alloy steel, ASTM A 514	256	23.9 ± 3.3
Low-alloy steel, AISI 4340	540	13.8 ± 1.4
Tool steel, type D2	698	15.9 ± 2.5
High-chromium white cast iron	661	15.6 ± 2.2

Tests conducted using high-silica quartzite ore.

(a) Hardness measurements were calculated from the average of ten readings from each wear face of the two jaw crusher specimens, for a total of 20 measurements.

(b) Volume loss is in cubic millimeters of material lost per kilogram of ore crushed.

In the ASTM procedure, a reference material is run with every test. Therefore, only one specimen material can be run at a time, and the ratio calculated refers to the wear of the specimen compared with the wear of the standard. By running the test with a standard material in all positions, the operation of the jaw crusher can be checked to see whether it still operates within performance limits. By using a nonstandard approach, data from

two sets of test specimens can be obtained during one test. Using reference materials mixed in with the other specimens will also provide information on whether the jaw crusher is performing within specified limits. An advantage in using the nonstandard method is that it allows the specimen materials to be matched according to their hardness so that the wear rates from both sets of materials will be similar in magnitude. Doing this eliminates the possibility of a softer material wearing at an accelerated rate, skewing the ratio with respect to the reference material. Another advantage of the jaw crusher is that the abrasive used for the test can be exactly matched to the field application. Table 7 gives some representative data for different ore types.

Table 7 Jaw crusher wear data for ferrous alloys using different ores

Alloy and designation	Volume loss, mm ³ /kg		
	Quartzite	Limestone	Granite
Stainless steel, type 304	27.7 ± 4.9	6.3 ± 0.1	6.3 ± 1.0
Low-alloy steel, ASTM A 514	23.9 ± 3.3	6.1 ± 1.0	6.9 ± 0.5
Low-alloy steel, REM 500	11.3 ± 1.5	1.2 ± 0.0(2)	0.8 ± 0.0(3)
Low-alloy steel, AISI 4340	13.8 ± 1.4	1.5 ± 0.2	0.9 ± 0.1

Erosion Testing

Solid particle erosion is the loss of material from repeated impacts by small, solid particles. Erosion by solid particles using gas jets is a standard ASTM test method, G 76 (Ref 50), which provides specific guidelines on erosion testing. This test is briefly discussed here because it is another example of an impact-abrasion process. When referring to solid particle erosion, it is implied that the erosive particle size is relatively small (tens to hundreds of micrometers), and particle velocities are relatively high (i.e., >1 m/s but usually in the range of ten to several hundred m/s).

Material removal via erosion is a complicated process, dependent upon the incident angle of impact. For example, at incident angles approaching 90°, material is lost in a sequential process of platelet formation and detachment. In this process, material is extruded from the impact crater in the form of a lip or platelet through plastic deformation. These lips or platelets are subsequently deformed by further impacts, leading eventually to detachment as a wear flake. At impact angles of less than 20°, the abrasive particles form shallow craters and grooves as they impact and move across the surface. Material removal is via a process of plastic deformation, extrusion, microplowing, and microcutting, where any extruded material from an impact or plowed groove is subsequently detached as a result of further particle impact (Ref 51, 52).

As in scratch testing, erosion testing using either single or multiple particles of controlled size and mass (e.g., 1 mm, or .04 in., diameter WC-Co spheres) provides information on the micromechanics of damage and mass loss mechanisms in homogeneous and complex materials. The degree of damage from single impacts can be determined using surface profilometry measurements and scanning electron microscopy. In multiple impact solid particle erosion using controlled particles, mass loss is determined by weighing. For the interested reader, the following references describe the procedure used in single- and multiple-impact particle erosion and the methods used to measure damage (Ref 53, 54). These tests require consistent specimen preparation of the samples in order to obtain representative mass loss measurements and to assess damage.

Contrasted with the controlled erosion tests just described are those tests that are related directly to applications such as erosion in coal combustion power plants and gas turbines in coal-fired combined cycle power generation (Ref 55, 56, 57). In these cases, the effects of environment, especially temperature and atmosphere, complicate the analysis process.

Impact Abrasion Wear Testing

Bond (Ref 58) developed a laboratory scale test to accurately simulate the wear conditions that exist in the impact crushing of ores (both soft and hard) by impact hammers and blow bars. The rationale for the development of the test apparatus was to be able to predict the wear, and hence the energy consumption, that occurred in the crushing and grinding of ore (Ref 59, 60). However, this test is applicable to any wear process in which impact occurs during the abrasion process. Impact-abrasion testing can be performed in an impeller-

in-drum apparatus, which is also a nonstandard wear test. Unlike solid particle erosion, where the size of the erosive particle is in the range of 10 to 100 μm , particle sizes using the impeller-in-drum are on the order of 25 to 30 mm (1.0 to 1.2 in.). Consequently, the size of the impact craters can be several hundred micrometers in diameter.

Impeller-in-Drum Apparatus and Test Specimens. The impeller-in-drum wear test apparatus uses an impeller-in-a- (rotating) drum arrangement (Fig. 10). The central impeller holds the three paddles, which impact the abrasive media at a high linear velocity. The impeller and abrasive particles reside inside a nominally closed and slowly rotating larger drum (a 3.0 mm, or 0.12 in., gap exists between the covering plate and the drum so that the smaller wear debris can escape the drum during operation). When operating, the drum and the impeller rotate in the same direction. The large drum, which is rubber lined (to both reduce noise and to provide some friction between the drum and the abrasive particles), rotates slowly at 45 rpm, lifting the abrasive particles until they overcome the frictional forces of the rubber lining and fall into the path of the rapidly rotating paddles. The impeller-in-drum wear test apparatus uses three metal paddles as wear test specimens instead of the one used in the Bond apparatus. These paddles are $75 \times 25 \times 12.5$ mm ($3 \times 1 \times 0.5$ in.). Approximately 38 mm (1.5 in.) of the length of the paddle extends from the impeller hub assembly and is available for particle impact. This translates into approximately 950 mm^2 of impact surface area. During operation, the paddles rotate at 620 ± 5 rpm (a velocity equal to about 6 m/s at the tip of the paddle), causing them to impact against particles of a hard abrasive mineral, for example, quartzite or granite or limestone. The abrasive particle-wear specimen collisions cause wear to occur on the broad faces of the paddles from a combination of impact-type events as well as from abrasion. The impeller-in-drum wear test provides quantitative information on the impact-abrasion wear rate of the three test specimens through measurements of the mass loss before and after the wear test schedule. Wear test variance is typically less than 10% for a duplicate set of specimens, although this test does have the potential for greater wear variance than either the dry sand, rubber wheel or the pin-on-drum. (Note: Certain safety precautions must also be exercised when using the impeller-in-drum wear test apparatus. Because the test can cause a large amount of very fine particulate matter, when working with high silica quartzite, ventilation through the use of a cyclone exhaust system, as well as through the use of a respirator or small particle dust mask, is required. The silica-rich dust will irritate the mucus membranes in the throat and nasal passages in the short term and can cause silicosis, a form of lung cancer, if exposed for longer times.)

Fig. 10 Schematic diagram of impeller-in-drum impact-abrasion wear apparatus. Source: Ref 61

Impeller-in-drum test procedures include a one hour procedure and a multihour procedure.

One Hour Test Procedure. The general test procedure for the impeller-in-drum starts with the sizing of abrasive particles in the range of -25 to +19 mm (-1 to +0.75 in.). After this step, 0.6 kg of abrasive is measured, and the number of particles that make up the charge is counted. Typically, for a 0.6 kg charge of high-silica quartzite, the number of particles range from 38 to 44. The 0.6 kg charge is then loaded into the impeller and the cover is bolted into place. An empty bag is positioned under the discharge chute to catch any abrasive debris that escapes from the drum during operation and is not vented by the cyclone exhaust system. Typically, 30 to 50 g

of fines will escape from the drum during a 15 min milling run. The cyclone exhaust system collects and traps the very finest dust. In this way, only the larger abrasive fragments are comminuted in the drum.

The drum and impeller are then set into motion. This marks the beginning of the first of two 1 h tests. The speed of the impeller is adjusted to 620 rpm for the first 15 min interval. After the first 15 min test interval has elapsed, the impeller and drum are stopped, the cover is removed, and the abrasive is collected. A fresh 0.6 kg charge of abrasive is placed in the drum, and the procedure is repeated for a second 15 min interval. This is done twice more, for a total running time of 1 h. During this time, the total amount of abrasive passed through the impeller-in-drum system is 2.4 kg. After the first four 15 min tests, the paddle samples are removed, thoroughly cleaned, and then hot-air dried. They are weighed to the nearest tenth of a milligram to determine the mass loss. The specimen face is then reversed, and a duplicate series of four 15 min tests are run. The results of these two series of tests are averaged and the standard deviation is calculated.

Multihour Test Procedure. In the multihour impeller-in-drum test, only one side of the sample is tested. In this case, four or five 1 h test segments are run on one side of the specimen paddle in the same manner as the single hour test. After each 1 h time period, the sample is removed, thoroughly cleaned, and weighed. It is then placed back into the impeller-in-drum and another hour of testing is performed. In each case, fresh abrasive is placed in the drum at 15 min intervals. For a 4 h test, 9.6 kg of abrasive is processed, while for the 5 h test, 12 kg of abrasive is comminuted.

The results of the multihour test are presented in graphical form (i.e., a wear curve) in terms of the cumulative mass or volume loss for the specimen as a function of time. In this way, the steady state wear impact-abrasion wear rate can be determined, if one exists, from the linear portion of the mass/volume loss versus time curve. Figure 11 shows examples of wear curves generated from impeller-in-drum wear tests.

Fig. 11 Wear curves of volume loss versus time for different materials worn against high silica quartzite. Source: Ref 61

Previous research has shown that the 1 h impact-abrasion wear test represents an upper limit as far as the wear rate is concerned (Ref 61). During the 1 h test, break-in is occurring during which the wear specimen conforms to the wear environment. In this case, the sharp edges are being rounded and the surface is work hardening. Development of the wear curves indicate that this process occurs during the first 1 to 2 h of the test, after which the material reaches a steady state in terms of mass loss. Table 8 shows the results for both the 1 h impact-abrasion test and the multiple hour test. Notice that the steady state wear rates are consistently lower than those of the average of the 1 h tests.

Table 8 Typical impeller-tumbler wear data for ferrous alloys

Alloy and designation	Hardness, HV	Wear rate, mm ³ /h		Difference ^(a) , %
		1 h test	5 h test	
304 stainless steel	207	112.2	102.3	-8.8
12% Mn steel	230	84.2	69.7	-17.2
ASTM A 514	256	101.3	96.7	-4.5

AISI 4340	540	96.2	76.6	-20.4
REM 500	505	93.7	81.0	-13.6
D2 tool steel	698	70.2	57.0	-18.8
High-chromium white cast iron	661	69.1	58.0	-16.1

(a) Comparison is made to the wear rate of that material after the first hour of testing.

Comparable to the jaw crusher test, the impeller-in-drum has the advantage of simulating more than one wear mechanism (i.e., both abrasion and impact). The test also can use many different ores as abrasive particles, thus matching the environment of the application more closely.

Slurry Abrasion Wear Testing

A slurry is a mixture of solid particles and a liquid (usually water) of a consistency that allows it to be pumped. This mixture is by nature abrasive and causes extensive damage to pump housings and impellers, tee junctions, elbows, and hydrocyclones. ASTM test method G 75 specifies a test for performing slurry abrasion tests (Ref 62). Other tests using slurries that allow different conditions from those in G 75 to be evaluated also have been developed. These tests include low-angle slurry pot (Ref 63, 64, 65), pipeline (Ref 66, 67), and jet impingement (Ref 68) type tests. All of these tests involve lowstress, two-body abrasive wear. One such device, illustrated in Fig. 12, consists of a slurry pot with an impeller that rotates the slurry past an array of specimens located around the inside of the pot (Ref 65, 69, 70, 71). In this apparatus, the impingement angle is low or nearly tangential.

Fig. 12 Schematic diagram for slurry wear apparatus. Source: Ref 65, 69, 70, 71

ASTM G 75, or the Miller number, is used to determine the abrasivity of slurries, based on the rate of metal loss from a standard 27% Cr white cast iron test block that reciprocates through any slurry, on a rubber lap, with an imposed load of 22.2 N (5.0 lbf) placed on the 27% Cr white cast iron test block. The higher the Miller number is, the more aggressive the slurry will be on the part. Although not specifically addressed in ASTM G 75, the effect of corrosion on the slurry abrasion process must be accounted for in the operation of any slurry-handling system (Ref 72). Information on equipment, the specifics of the test procedure, and factors affecting slurry abrasivity can be found in Ref 62.

A limitation on the Miller number is that it is based on a high-chromium white cast iron. Consequently, the slurry-abrasion response (SAR) was developed so that different materials could be tested against a standard slurry to see how they performed. In essence, the SAR is the determination of the Miller number in reverse, and it is based on the same Miller number procedure. This test tends to emphatically highlight the effects of corrosion on a material for a particular slurry.

A slurry wear test apparatus of a general nature comprises a slurry pot and the equipment to feed the slurry to the pot at a controlled rate. The feeding of slurry can be accomplished in one of two ways: flow-through mode where the slurry passes through the system once and is discarded, and recirculating mode where the slurry is passed through the system many times. In the recirculating mode of this slurry-pot apparatus, abrasive degradation and wear debris contamination influence the wear rate over time. Figure 13 shows what can happen when the slurry is recirculated, compared with when it passes through the system only one time. In general,

when the slurry passes through once, a linear volume loss-versus-time curve is generated. The wear rate will vary with slurry loading (i.e., the solids concentration in the slurry), size of abrasive particle, angularity of the abrasive particle, slurry flow rate, temperature, liquid composition and pH, and the material being tested. As in other wear tests, the inclusion of reference standards is important to maintaining proper operation of the equipment and normalizing the wear data between different material classes.

Fig. 13 Wear curves from slurry wear tests showing different wear rates when slurry is recirculated versus a once-through test. Source: Ref 65

Microabrasion Wear Testing

The tests described to this point are typically used to determine the abrasive wear response of materials on a macroscopic scale. Many advanced composites for abrasive wear applications consist of layered structures where the outermost material is meant to be wear resistant, or are materials that have a hard or soft outer coating. In these cases, a test is needed that can investigate the properties of the layer or coating without complicating the result with the effect of the underlying material. In some cases, information on the wear behavior of materials is needed where the abrasive interaction results from the contact of submicron to nanometer scale particles with a surface (e.g., as in the effects of flow of a nanometer size slurry used for polishing silicon wafers in the semiconductor industry).

Two different techniques for measuring microabrasion have been developed (Ref 73, 74, 75, 76, 77, 78, 79). Both techniques use a cratering approach where the rotation of some tool in the presence of a fine abrasive slurry results in the production of a circular depression. At some point during the test, the coating is worn through, and a “bull's-eye” depression is seen where the substrate shows through. Using geometrical relationships, the thickness of the coating can be determined. If the rotational speed of the tool, applied load, and number of rotations (i.e., sliding distance) of the tool are accurately monitored, the wear rate can be determined for the coating and underlying material. This is done by interrupting the test at different points in the process and making visual measurements of the wear scar using optical or scanning electron microscopy (SEM). Another way to measure the diameter and depth of the wear scar is to use a surface profilometer. Although these testing techniques are relatively new, their importance grows as a result of efforts to create new materials with wear-resistant hard surfaces for possible use as components in micron-scale machines.

By imposing a spherical geometry on the wear scar, the overall wear behavior can be described by a classical model for abrasive wear:

$$SN = \frac{V}{\kappa} \quad (\text{Eq 5})$$

where S is the total relative sliding distance between counterbody and specimen, N is the normal load on the contact area, and V is the wear volume. κ is the wear coefficient and represents the wear properties of the material.

The imposed geometrical condition means that the wear volume can be calculated from a single measurement of the wear scar diameter. The sliding distance is equal to the total number of revolutions of the spherical tool multiplied by the circumference of the tool. Thus, in terms of measured quantities, Eq 5 becomes:

$$SN \approx \left(\frac{\pi b^4}{64R} \right) \frac{1}{\kappa} \quad (\text{Eq 6})$$

where b is the diameter of the circular wear scar, and R is the radius of the rotating spherical tool. Note, however, that this equation is only valid for wear scar depths much less than R .

In one microabrasion test method (Ref 76, 77, 78, 79), a rotating steel sphere is pressed against the test specimen in the presence of a slurry of small abrasive particles (Fig. 14). The steel sphere can be any diameter but in these references is approximately 25 mm (1 in.). The abrasive slurry is typically an aqueous suspension of small abrasive particles (e.g., 4 μm silicon carbide abrasive particles with an initial concentration of 0.75 g/cm^3 , although silica, alumina, diamond, or any other abrasive can be used in any desired concentration). The sliding speed of the steel sphere can be varied from 30 to 150 rpm (i.e., 0.04 to 0.20 m/s for a 25 mm, or 1 in., steel sphere) to control the rate of wear, but a typical value is 0.05 m/s. The normal load can also be varied (0.05–5 N, or 0.01–1.1 lbf), but a value of 0.18 N (0.04 lbf) is typical. The normal load is monitored by a load cell. The wear coefficient can be calculated by measuring the progressive increase in the diameter of the wear scar with respect to total sliding distance. The gradient of the linear relationship between wear volume and the product of sliding distance and normal load yields the wear resistance of the material. Figure 15 shows one such calculation.

Abrasive Wear Testing

Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Summary and Conclusions

This discussion on abrasive wear testing attempts to show that both standard (ASTM) and nonstandard laboratory abrasive wear tests are available. All these wear tests have similarities in terms of application simulation, acceleration, specimen preparation, test control, wear measurement, and data reporting (Ref 5, 6). The most important fact to keep in mind is that in any laboratory wear test, application simulation of the wear mechanisms is of utmost importance. It is critical to run a test where the operative wear mechanisms in the laboratory are the ones observed in the field. It is also important to make sure that all equipment variables are noted and controlled so that any differences in the wear behavior of a suite of materials are due to the physical and mechanical differences in the materials and not to variations in the sample preparation, test procedures, or operation of the test equipment.

In running abrasive wear tests for the first time, or in the investigation of new classes of materials, it is important to perform multiple tests and generate wear curves of volume loss versus sliding distance. Doing this has several advantages. First, any nonlinearities will show up, thus providing a guide of how the test should be

run. Second, the steady state wear behavior will yield more accurate wear rates. In many cases, this procedure will subsequently verify the use of single test wear measurements for obtaining wear rates (as in the pin-on-drum).

Solid Particle Erosive Wear Testing

Ian M. Hutchings, University of Cambridge (England)

Introduction

EROSION is defined as “progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, or impinging liquid or solid particles” (Ref 1). Because of the broad scope of this term, it is usually qualified to indicate the relevant mechanism or context, for example, as cavitation erosion, liquid impingement erosion, slurry erosion, or solid particle erosion. This article addresses the topic of erosion by the impact of solid particles, which can be a serious cause of wear in

powder handling and transport systems, gas wells, chemical plant, and gas turbine engines. The particles responsible for erosion are typically between 5 and 500 μm in size, and impact velocities can range from less than 10 m/s up to supersonic speeds. Erosive particles are usually, but not inevitably, suspended in a flowing gas stream, although the particle velocity may differ significantly from that of the gas.

The amount of material removed from a surface by erosion generally increases with the time of exposure to the particle stream, as shown schematically in Fig. 1. Several methods can be used to express the dependence of erosion on exposure time. Because in erosion testing it is often most convenient, as well as most accurate, to determine material removal by periodically weighing the specimen, erosion is often quoted in terms of mass removed from the surface by unit mass of erodent particles striking it (e.g., in milligrams eroded per kilogram). This measure of erosion has the advantage that it is dimensionless, but for practical purposes, it is sometimes preferable to express it as volume removed per unit mass of erodent (e.g., mm^3 eroded per kilogram of erodent). In many applications the surface is exposed to a constant flux of erodent particles, and it is straightforward to convert a value of erosion expressed, for example, as mass removed per unit mass of particles striking the surface to depth removed in unit time. However the erosion is expressed, it is important to note that under some circumstances, the rate of material removal will not be constant and that a significant incubation period may occur after a fresh surface is exposed to the particle stream before the rate of erosion reaches a steady state (Fig. 1).

Fig. 1 Typical dependence of mass lost from a specimen on the total mass of erodent particles that have struck it. In many cases, the mass loss increases linearly with mass of erodent from the start of the test, but under some conditions there may be a significant incubation period when the specimen gains mass.

Important Variables in Erosion

Erosion, defined as mass removed from the surface per unit mass of impacting particles, depends strongly on the following:

- Particle impact velocity
- Particle impact angle
- Particle size, shape, and material
- Ambient temperature

as well as on the properties of the material being eroded. In a reproducible erosion test, all these factors should be well controlled and, if possible, measured.

The most important variable in erosion is the particle velocity because, under most conditions, it has a very strong influence on erosion rate. For many materials, once steady state conditions have been reached, the erosion, E (expressed as the mass removed by unit mass of erodent particles), can be expressed as a simple power function of particle impact velocity, V (Ref 2):

$$E = kV^n \quad (\text{Eq 1})$$

where the constant of proportionality, k , includes the effects of all the other variables. The value of n , the velocity exponent, is typically between 2 and 3, although much higher exponents are seen under some circumstances. A value of approximately 2.4 is commonly seen for the erosion of ductile metals. The value of n does not vary much with impact angle, although there is some suggestion that higher values of n are associated with steeper impact angles.

Erosion also depends markedly on impact angle, often in one of two distinctive ways. Ductile metals eroded by angular particles show maximum erosion (expressed as mass loss per unit mass of particles) at shallow angles of incidence. The impact angle in erosion is almost invariably defined as the angle between the direction of particle motion and the plane of the surface, so that normal incidence corresponds to an impact angle of 90° . Peak erosion for ductile metals occurs typically at an angle of 20 to 30° and is associated with impact under the most favorable conditions for the removal of material by ductile ploughing and cutting mechanisms. The erosion of a ductile metal at 90° incidence may be about $\frac{1}{2}$ to $\frac{1}{3}$ of the peak value. An example of this angular dependence is illustrated in Fig. 2.

Fig. 2 Typical dependence of erosion (defined as mass lost per unit mass of impinging particles) on impact angle (defined as the angle between the impact direction and the surface)

Materials that erode by the formation and intersection of brittle fractures, such as inorganic glasses impacted by hard angular particles that are large enough to cause local cracking, show peak erosion for normal incidence and a steady reduction in erosion as the impact angle falls. Figure 2 also shows this behavior. The two types of behavior are often referred to as *ductile* and *brittle*, respectively. However, it is not safe to deduce the mechanisms of material removal on the basis of the angular dependence of erosion, since in some systems ductile processes can lead to peak erosion at 90°, and transitions in fracture behavior can result in atypical angular dependence of erosion even in a “classically brittle” material. Intermediate behavior, with peak erosion at 45 to 60°, is not unknown.

The particles used in an erosion test must be well characterized. The size of the particles can influence the erosion rate in two important and distinct ways. Particles of different sizes, striking the surface at the same angle and velocity, will generally remove different amounts of material per unit mass of particles, although for particles larger than about 100 μm striking a ductile metal this variation may be small. This dependence of erosion on particle size represents a genuine size effect. In some erosion test methods, as discussed later, the impact velocity will itself vary with particle size, and since erosion is generally a strong function of velocity, this effect contributes to a further dependence of the measured erosion rate on particle size. For these reasons, it is clear that, wherever possible, the size range of the particles used in an erosion test should be known and should be as narrow as possible. Particles are often classified by sieving, and standard sources that discuss the principles and optimal procedures for this method are available (Ref 3, 4). Specification of the sieve sizes may be sufficient to define the range of particle size used in a test; however, laser granulometry is a readily available technique that can be used to provide a more accurate description of the particle size distribution.

The erodent particle material is an important factor, as illustrated in Fig. 3, that shows results for the erosion of a glass-bonded alumina (a common erosion-resistant ceramic), tested with silicon carbide, alumina, and silica particles, all of the same size (125–150 μm). The erosion caused by the silicon carbide particles was more than ten times that caused by the same mass of silica particles. A major factor responsible for this effect is the relative hardness of the erodent particles and the surface being eroded. In this example, both the silicon carbide and the alumina particles, which were commercial abrasives, were significantly harder than the alumina specimen. The silica, in contrast, had about the same hardness as the specimen:

Specimen or erodent	Vickers microhardness	
	GPa	10 ⁶ psi
Alumina specimen	12.7	1.84
Silicon carbide particles	33.4	4.84
Alumina particles	26.5	3.84
Silica particles	13.1	1.90

Fig. 3 Influence of particle material on erosion rate, for erosion of a sintered glass-bonded alumina ceramic by silica, alumina, and silicon carbide particles, 125–150 µm in diameter, at normal incidence. Adapted from Ref 5

Shape also plays a role in determining the relative erosivity of different particles (Ref 6) and is difficult to separate from other particle properties, since particle shape is often determined by the fracture processes by which the particles themselves are formed. As in the case of particle size, there is an intrinsic effect of shape on the erosion rate, which can lead to angular particles producing up to ten or more times the erosion caused by spherical particles of the same material. Measurement of particle shape is not straightforward because, although there are many possible methods of assessing shape, it is unclear which method is most appropriate in the context of erosive wear testing. Qualitative descriptors such as “rounded,” “subangular,” “angular,” and so on, are often used and may be adequate in conjunction with a more detailed specification of the material and source of the erodent particles.

For these reasons, it is important that if the purpose of erosion testing is to compare material behavior or obtain quantitative measurements of erosion rate in the context of a particular engineering application, appropriate erodent particles are used in the test. Not only should the particle size and shape be representative of the application in question, but the particle material should also provide a realistic simulation of the properties of the actual particles. Although the ready availability of reproducible commercial abrasive particles such as silicon carbide or alumina with well-defined size may suggest their use in erosion testing, it is important to appreciate that they are much harder than most naturally occurring erosive particles, which are often silica or silicate minerals. Not only may the absolute values of erosion rate measured with very hard particles be misleading, but the mechanisms of damage and even the ranking of erosion rates of materials may be different. Because damage is suffered by the erodent particles when they strike a surface, the properties of the particles after they have been used in an erosion test will differ, often significantly, from those of fresh particles. Even if gross fracture of the particles is avoided, subtle changes in shape can occur. If at all possible, erodent particles should, therefore, not be reused for erosion testing.

Solid Particle Erosive Wear Testing

Ian M. Hutchings, University of Cambridge (England)

Erosion Test Methods

Laboratory-scale erosion testing is performed for several reasons: to provide data on absolute or relative wear rates under specific conditions, to examine the validity of theoretical models, or to study the mechanisms of wear. The first of these objectives can include data on the relative behavior of different materials and provides information of direct value to the design engineer, while the others are of more value in improving understanding of erosive wear.

Methods used for laboratory erosion testing can be divided into those in which the particles are accelerated in a gas stream and those where circular motion is used to achieve the impact velocity. Four methods are shown schematically in Fig. 4 and are discussed in detail subsequently. Of these, the gas-blast test rig (Fig. 4a) and the centrifugal accelerator (Fig. 4b) are the most widely used methods.

Fig. 4 Schematic diagrams showing four classes of erosion test methods. (a) Gas-blast rig. (b) Centrifugal accelerator. (c) Wind tunnel. (d) Whirling arm tester

Gas-Blast Method. In the gas-blast or jet impingement test, particles are entrained into a gas stream and accelerated along a nozzle. The particles leave the end of the nozzle and then strike the test specimen, which is fixed at a known angle to the axis of the nozzle some distance from its end. The acceleration nozzle used in this test method is generally a plain cylindrical tube for ease of construction and replacement. There are national standards relating to this type of test method, but nonstandard designs are also commonly used.

In ASTM standard G 76 (Ref 7), the use of a nozzle 50 mm (2 in.) long with a bore of 1.50 mm (0.06 in.) is recommended. A former German standard (DIN 50332) suggested the use of a nozzle 120 mm (4.7 in.) long with an internal diameter of either 8 or 18 mm (0.3 or 0.7 in.), depending on the test conditions. Sheldon and coworkers (Ref 8) used a nozzle 305 mm (12 in.) long with an internal diameter of 4.95 mm (0.19 in.), and similar dimensions have been used in many other experimental programs. The aspect ratio (length:diameter) of this nozzle is 61.6, approximately twice that of the ASTM standard nozzle. Other investigators have used considerably longer nozzles. For example, Marshall and others (Ref 9) used a nozzle 3 m (9.8 ft) long with a bore of 9.5 mm (0.37 in.) (aspect ratio = 316), while Andrews and others (Ref 10) used nozzles 4 m (13.1 ft) long with 25 mm (1 in.) internal diameter (aspect ratio = 160), and 1 m (3.3 ft) long with an internal diameter of 10 mm (0.4 in.) (aspect ratio = 100). The ASTM standard suggests that a length:diameter ratio of at least 25 is desirable to achieve an acceptable particle velocity distribution in the stream.

The velocity with which the particles leave the nozzle and strike the specimen will depend on the velocity of the gas stream, on the drag forces acting on the particles, and on the distance over which the particles accelerate

along the nozzle. In long nozzles of large diameter, the particles may reach essentially the same speed as the gas stream, but in short or narrow nozzles, the particle velocity may be significantly lower than that of the gas. Accurate knowledge of the particle exit velocity is therefore essential unless the purpose of the test is simply to compare material behavior under constant, but unspecified, erosion conditions.

A long nozzle might be considered to be beneficial on the grounds that it might lead to a higher particle exit velocity for a given gas pressure. It might also be assumed that the divergence of the erodent particle stream on leaving the nozzle would be less, leading to less uncertainty in the angle with which the particles strike the target. A long nozzle might also have the advantage of reducing the spread in the velocities of particles where there is a distribution of particle sizes in the erodent supply. However, the assumption that longer nozzles give higher particle exit velocities is not necessarily correct. It is true that with a longer nozzle the particles reach a higher proportion of the gas exit velocity than in shorter nozzles, but on the other hand, for the same overall pressure drop, the gas velocity will be lower than with a shorter nozzle due to friction between the gas and the nozzle wall. A second important influence on particle exit velocity arises from the collision of the particles against the nozzle wall, which causes a retarding effect. The internal surface topography (i.e., roughness) of the nozzle wall therefore affects the particle exit velocity.

Particles can be fed into the gas stream in various ways. One simple method is to use a pressurized particle feeder in which particles are metered by the rotation of an electrically driven disk carrying a groove from which the powder is supplied through a pressurized tube to a mixing chamber at the high-pressure end of the nozzle. Powder feeders of this type are commercially available, for example, to supply plasma-spray guns. An alternative method of erodent feeding uses a rotating grooved disk at atmospheric pressure from which the powder is sucked through a feed tube into a constricted portion of the airstream in which a low pressure region is created. Screw feeders can also be used. However the erodent particles are metered, good control over the feed rate is desirable.

Figure 5 shows the layout of a typical laboratory-scale gas-blast erosion rig. Suction created in the ejector causes the erodent particles to be drawn into a feed tube from a groove in a slowly rotating turntable, which is fed by gravity from a hopper. The particles are then mixed into the main gas stream. By controlling the speed of rotation of the turntable, a constant particle feed rate can be accurately maintained. The acceleration nozzle is a stainless steel tube, typically 5 mm (0.2 in.) in internal diameter and 300 mm (11.8 in.) long. Since the nozzle wears progressively in use, the diameter should be regularly monitored to ensure constant test conditions. The test sample is clamped at an accurately known angle to the axis at a standoff distance of about 5 nozzle diameters from the end of the nozzle. Arrangements are made to collect the erodent particles and debris from the airstream before it is vented from the apparatus. Since the particle velocity is controlled by maintaining a fixed pressure drop between the ends of the nozzle, it is relatively straightforward to achieve reproducible and well-characterized conditions in such a rig.

Fig. 5 Typical small-scale laboratory gas-blast erosion rig. Eroder particles are accelerated in a gas stream along a cylindrical nozzle and strike a specimen fixed at the end of the nozzle. Source: Ref 11

A typical test procedure would involve mounting the specimen at the appropriate distance and angle from the end of the nozzle, filling the particle feeder with a weighed quantity of sieved erodent particles, setting the pressure at the nozzle entry to the level needed to achieve the desired particle velocity, starting the particle feeder at an appropriate rate, checking and adjusting the nozzle pressure if necessary, and running the test until all the particles have passed through the apparatus. The specimen is handled carefully, cleaned (to remove loose particles), and weighed before and after the test. The specimen is then replaced in the apparatus in the same position and orientation, and the test run is repeated to produce further erosion of the same region of the surface until sufficient data have been gathered (see the section “Data Analysis and Interpretation” in this article).

The use of preweighed quantities of erodent in each test, and running the test until the particles have all passed through the rig, is preferable to running the test for a set time at a preset feed rate because a constant feed rate cannot always be assured.

Computational models are available to predict particle velocities in gas-blast erosion testing, but in order to make accurate predictions they must take account not only of the size, density, and drag coefficient (which will depend on the shape) of the particles, but also of the nozzle wall friction and the effects of particle-wall and even particle-particle interactions. The plume of particles leaving the end of a cylindrical nozzle contains some particles that diverge quite markedly from the nozzle axis, showing that impacts between particles and the nozzle wall can be significant (Ref 11). Theoretical models for particle velocity are therefore no substitute for accurate measurements under realistic operating conditions performed by one of the methods discussed in the section “Measurement of Particle Velocity” in this article.

For some purposes, however, a simple empirical model has been found to be useful. The following equation provides a good fit to the dependence of particle velocity on air pressure for a cylindrical nozzle 4.9 mm (0.19

in.) in diameter and 308 mm (12.1 in.) long, with one end at atmospheric pressure, along which particles are accelerated in an airstream (Ref 12):

$$V^2 = \frac{kP}{d^{0.57}\rho^{1.08}} \quad (\text{Eq 2})$$

where V is the exit velocity of the particles (in m/s), P is the gage pressure at the high-pressure end of the nozzle (in kPa; 100 kPa = 1 bar), d is the diameter of the particles (in micrometers), and ρ is the density of the particles (in Mg/m³). For these conditions and with the data expressed in the units given, $k = 7900$. As shown in Fig. 6, this equation provides a good fit to measured particle velocities up to about 80 m/s. A linear variation of (particle velocity)² with gas pressure has also been demonstrated for cylindrical nozzles with other aspect ratios, and the functional dependence of velocity on particle size and density has been shown to be similar to that of Eq 2. It is likely that an empirical relationship similar to Eq 2 can be used, after suitable calibration, for many designs of gas-blast erosion rig.

Fig. 6 Empirical correlation between particle velocity and nozzle pressure drop, P ; mean particle diameter, d ; and particle material density, ρ , for erodent particles of a wide range of sizes and materials in an air-blast erosion rig with a nozzle 308 mm (12 in.) long and 4.90 mm (0.19 in.) internal diameter. The data are well fitted by Eq 2. Adapted from Ref 12

The stream of particles leaving the nozzle diverges significantly because of particle-wall collisions and particle-particle interactions. This divergence can be described by a simple function (Ref 11). The proportion of particles traveling at angles between θ and $\theta + d\theta$ to the nozzle axis, $p(\theta)d\theta$, is given by:

$$p(\theta) = \beta^2 \frac{\sin \theta}{\cos^3 \theta} \exp(-\beta \tan \theta) \quad (\text{Eq 3})$$

where β is a dimensionless quantity that describes the spreading of the plume and has been termed the *focus coefficient*. The value of β depends on the shape of the erodent particles and on the internal roughness of the nozzle wall, as well as on the impact velocity; typical values lie in the range of approximately 10 to 25, with a low value of β corresponding to a highly divergent stream. Because of this divergence, the area of the specimen exposed to the erodent stream must be significantly greater than the cross-sectional area of the end of the nozzle in order to ensure that most of the particles strike the specimen. For a typical nozzle diameter of 5 mm (0.2 in.) and a specimen mounted at a distance of 20 mm (0.8 in.) from the end of the nozzle, a specimen width of at least 25 mm (1 in.) is necessary to avoid significant error from this source.

Centrifugal Accelerator. In the centrifugal accelerator, illustrated by the apparatus shown in Fig. 7, the erodent particles are fed to the center of a rotating disk, usually with a screw or vibratory feeder, and then travel outwardly along radial slots or tubes in the disk. They leave the disk at the periphery with a tangential component of velocity equal to that of the disk itself and a radial velocity component that depends on their motion within the radial channels. Specimens are mounted at points surrounding the periphery of the disk and are exposed to a series of streams of erodent particles as the radial tubes sweep past. The use of a centrifugal

accelerator for erosion testing was specified in a national standard of the former Soviet Union (GOST 23.201.78), and examples of such apparatus have been described in Ref 13, 14, and 15.

Fig. 7 Typical centrifugal accelerator test rig. Erodent particles are fed into the center of a rotating disk and emerge through radial tubes to strike the specimens, which are arranged in a ring around the periphery of the disk. Source: Ref 13

The method has the advantage over the gas-blast method in that a large number of specimens can be subjected to the same erosion conditions simultaneously, and it is therefore well suited to performing screening tests on many different materials. The specimens are often mounted on a ring that rotates slowly around the rotating disk, to eliminate any possible bias associated with specific specimen locations. Maximum numbers of specimens per test have ranged up to 30 in different designs of rig, with rotating disk diameters between 200 and 600 mm (8 and 24 in.). The apparatus shown in Fig. 7 (Ref 13) has a disk 240 mm (9.4 in.) in diameter, containing six radial tubes, each with an internal bore diameter of 2.6 mm (0.10 in.). The particles are supplied to the center of the disk by a vibratory feeder at a constant rate, and care is taken in the design to ensure that the particle flow is split evenly between the six tubes. Typically, ten samples are placed symmetrically around the carrier ring; each specimen holder can be angled independently to achieve impact angles in the range of 5 to 90°. The specimens are all mounted in the vertical plane.

Constant particle impact velocity is achieved through control of the disk speed, which is readily measured. However, the velocity of the particles results from both radial and tangential motion; typical particle trajectories are illustrated in Fig. 8. Accurate determination of the impact velocity, and of the impact angle at the specimen surface, thus requires a knowledge of the ratio of the velocity components or the angle of motion relative to the radial direction. Probably the simplest method of determining these is to measure the direction of motion of the particles experimentally, by allowing them to pass through a slotted shield and noting the position of impact on a specimen surface fixed beyond the shield. The particle trajectory, defined by the line joining the centers of the erosion scar and the slot, allows the relative velocity components, as well as the true angle of impact on the specimens, to be calculated. For one particular design of centrifugal accelerator (Ref 15), the radial velocity component was found to be about 0.8 times the tangential component and independent of velocity and particle size. The particle trajectories were therefore at an angle of about 39° to the tangential direction.

Fig. 8 Single flash exposure showing streak images of particle trajectories for olivine sand particles, 150–250 μm in diameter, leaving an acceleration tube at the rim of the rotating disk in a centrifugal accelerator of the design shown in Fig. 7. The disk was rotating clockwise and the mean particle velocity was 7 m/s. Courtesy of T. Deng and M.S.A. Bradley, University of Greenwich, UK

Erosion at different impact angles can be achieved by varying the angles at which the specimens are mounted in the apparatus. Because of the pattern of motion of the particles in this test, the impingement angle and the particle flux vary in a complex but geometrically predictable way across the surface of a finite-sized specimen. These effects have been analyzed in detail (Ref 15). At least one edge of the specimen will also, in general, be exposed to the erodent stream, and it is common practice to mask both the leading and trailing edges of samples in order to prevent erosion occurring at unwanted angles of impingement. The total amount of erodent striking each specimen surface will be only a small fraction of the total fed into the rig and must be calculated from the specimen and rig dimensions. The erosion of each specimen can then be calculated, in terms of mass removed per unit mass of impinging erodent particles, from measurements of mass loss.

As in the gas-blast method discussed in the previous section, it is desirable to run the test to consume a preweighed total mass of erodent, rather than rely on maintaining and measuring a steady particle feed rate and running the test for a fixed time.

Wind-Tunnel Tests. Because of the large size and expense of the test rig, the wind-tunnel method shown schematically in Fig. 4(c) is used predominantly where information on the performance of shaped components such as turbine blades is required, rather than for studies of material response alone. For tests of the former type, the wind tunnel method, in which the test specimen is immersed in a rapidly flowing stream of air or other gas containing erodent particles, is invaluable. Figure 9 shows a typical wind tunnel test facility (Ref 17). The specimen is located in a rectangular section (dimensions 25.4×76.2 mm, or 1×3 in.) of the wind tunnel, following a long (approximately 4 m, or 13 ft) acceleration duct. With this length of acceleration tunnel, relatively large particles ($200 \mu\text{m}$) are accelerated to up to 85% and smaller particles ($20 \mu\text{m}$) to up to 98% of the air speed. In order to avoid disturbing the airflow too much, the specimen area in the test section is typically restricted to $<10\%$ of the total cross-sectional area of the flow. After impact with the specimen, the erodent particles, which have been supplied from a preweighed batch in the particle feeder, are separated from the main airstream by a cyclone separator and filter.

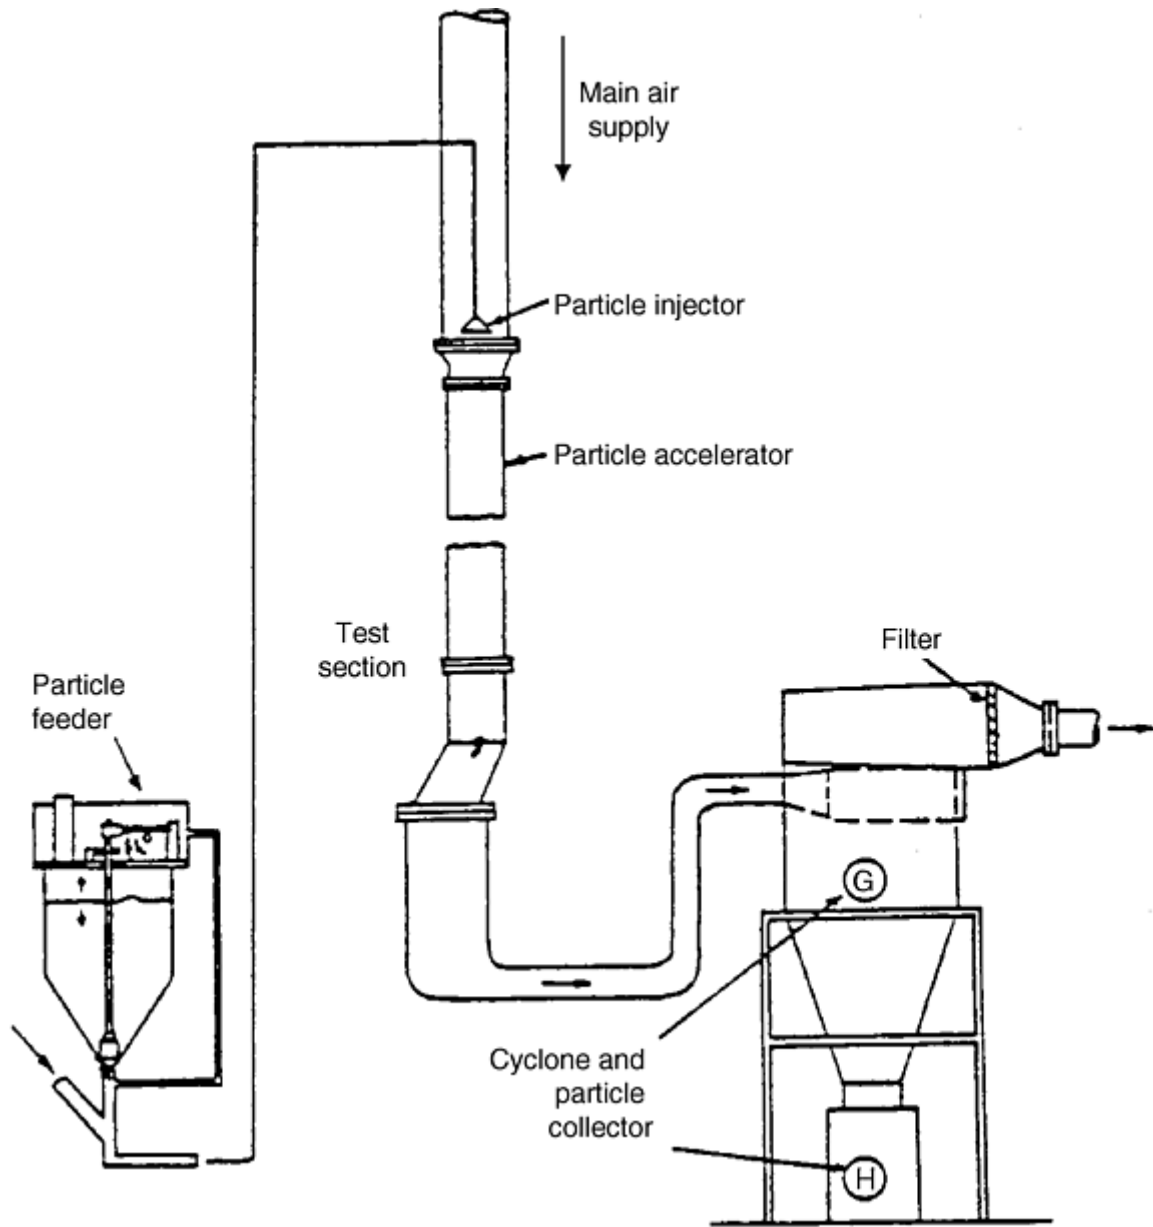

Fig. 9 Schematic diagram of wind tunnel test rig. Source: Ref 16

Whirling Arm Testers. Figure 10 shows an example of a whirling arm test rig in which impact occurs between a moving specimen and a slowly falling stream of erodent particles. In this approach, which is particularly useful in studying erosion at very high impact velocities, the specimens are carried at the ends of a rotating arm (Ref 14, 18). At high speeds, accurate balancing of both the arm and the specimens becomes important and introduces extra complexity to the process of specimen preparation. Specimen materials must have sufficient strength and ductility to withstand the high centrifugal stresses to which they are subjected during testing, and satisfactory methods must be used to attach the specimens to the rotor. In some designs, aerodynamic effects are eliminated by operating the rig in a vacuum or reduced air pressure, and this is essential if very high speeds are required. There are then engineering problems associated with the sealing of the vacuum against the rapidly rotating drive shaft, unless the method shown in Fig. 10 is adopted, where the motor casing itself provides the vacuum seal.

Fig. 10 Schematic diagram of whirling arm erosion rig, in which particles are dropped into the path of two specimens attached to the ends of a rapidly rotating arm. Adapted from Ref 18

Both electric motors and air turbines have been used to rotate the specimen arm, and specimen speeds up to at least 550 m/s have been achieved. The impact velocity can be accurately calculated from the rotor radius and the rotational speed, while the impact angle can be controlled by fixing the specimens to the rotor arm at an appropriate angle. This often involves the use of different rotors for different impact angles. The fate of erodent particles after striking the specimen must be considered since they will rebound and may cause secondary impacts, from intact particles or fragments, during subsequent rotation of the arm. Some method of capturing the particles after impact is required. The design described in Ref 18 used sheet metal traps coated with silicone oil to catch small dust fragments as well as whole particles.

The whirling arm method involves greater effort in specimen preparation and in conducting the test than other methods; the time taken to load and unload the specimens, and to pump the chamber down if it is an evacuated rig, may be significant. The specimens must be of accurate dimensions, form a dynamically balanced pair on the whirling arm, and be sufficiently strong and tough to withstand the high centrifugal stresses imposed during testing. These requirements have tended to restrict the method to metallic samples. Despite these considerations, the whirling arm method can achieve the highest particle velocities, and in order to obtain erosion data under such conditions, it has great value.

Solid Particle Erosive Wear Testing

Ian M. Hutchings, University of Cambridge (England)

Measurement of Particle Velocity

Since impact velocity is a very important variable in erosion, accurate measurement of impact velocity is essential in any quantitative erosion test.

Various methods of velocity measurement have been employed. Potentially, the most accurate is laser Doppler velocimetry (LDV), which can provide statistical information on particle speed and direction of motion at any selected point close to, or distant from, the specimen surface. Laser Doppler velocimetry has been applied to gas-blast, centrifugal accelerator, and wind tunnel tests (Ref 17, 19), but the apparatus can be bulky and expensive, and for many purposes simpler methods are adequate.

An early method, still valuable and widely used, is the rotating double-disk method (Ref 20) illustrated in Fig. 11. Two disks are rotated on a common shaft, and the stream of erodent particles is arranged to strike the upper disk, which has a thin radial slot cut in it. The lower disk is coated with a thin paint or dye film to show where particles strike it. Two erosion scars are formed: one with the disks stationary, with the particles passing through the slit in the upper disk, and the other with the disks rotating at a known speed. The angular displacement, θ , between the two scars is measured and can be used to calculate the time taken for the particles to travel the distance, L , between the disks, and hence their velocity, V . The velocity is given by:

$$V = \frac{L\omega}{\theta} \quad (\text{Eq 4})$$

where ω is the angular velocity of the rotating disks. In practical examples of this device, a high rotational speed is needed to achieve reasonable displacement of the scars and thus accuracy of measurement of the angle, θ . Values between 3000 and 10,000 revolutions per minute (rpm) are common, with a distance, L , of about 20 to 40 mm (0.8 to 1.6 in.). The method is well suited to use in an air-blast erosion test, since velocity calibration can be carried out under exactly the same conditions of particle feed rate and air pressure as used in the erosion test. Typically, the random error in measuring velocity in this way is $\pm 10\%$. There can also be a systematic error due to the aerodynamic influence of the rotating disks on particle stream, which may be 10% or even greater for very small particles of low density. A comparison of velocities measured by both the double-disk

method and LDV suggests that for a typical velocity in a gas-blast rig (45 m/s) and for rather small particles (50 μm silicon carbide or alumina), the double-disk method systematically underestimates the velocity by some 10%, although the error would be expected to be less for larger particles (Ref 19).

Fig. 11 Rotating disk method for measuring particle velocity. Adapted from Ref 20

Another relatively simple method, which is well suited to use with the gas-blast method, involves measuring the time of flight of the particles between two transverse light beams a short distance apart (Ref 11, 21). In one version of this method, illustrated in Fig. 12, the sensor contains a short glass tube that can be attached to the end of the nozzle; the small increase in length has been shown to have a negligible effect on the particle exit velocity (Ref 11). The timer uses infrared emitters and detectors, and the beams are collimated by two pairs of holes 1 mm (0.04 in.) in diameter, aligned perpendicularly to the axis of the nozzle. The electronic timing system contains a clock that is triggered by a decrease in light intensity of approximately 0.5%. The velocity is determined from the time taken for the particle to pass between the two beams. Inevitably, there will be some particles that will interrupt one beam but not the other, while in some cases, the particle that stops the clock may not be the one that started it. It can be shown by computer simulation of the system that even for a stream of particles all traveling with the same velocity, these effects will lead to a distribution of recorded flight times. However, in all cases, the peak in the distribution corresponds to the true flight time, from which the particle velocity can be calculated. The use of a low concentration of particles in the gas stream helps to provide a well-defined peak in the time distribution. Figure 13 shows typical data from this method, for spherical glass Ballotini particles, about 130 μm in diameter, accelerated along a straight nozzle at two different driving pressures. In this plot the times of flight have been converted into equivalent velocities over the timing distance.

Fig. 12 Optoelectronic method of determining particle velocity, by time-of-flight measurement. Source: Ref 11

Fig. 13 Typical data from the time-of-flight method shown in Fig. 12, for 125–150 μm glass Ballotini accelerated in a gas blast rig at nozzle pressure (P) of 0.2 and 0.5 bar. Source: Ref 11

High-speed multiple-flash photography has also been successfully used to measure particle velocities and can provide a more economical alternative to LDV. Specialist equipment is needed to produce flashes of sufficiently short duration to freeze the motion of rapidly moving particles, with accurately known interflash timing. To image the small particles used in erosion testing, a relatively small field of view is needed, with sharp focus and a small depth of field. Conventional stroboscopic light sources tend to be too slow to be useful and of insufficient brightness when used at the high speeds that are needed; a means of triggering separate short-duration flash sources at precise time intervals provides a better method. Although two flashes alone are sufficient in principle to determine a velocity, confusion can occur in identifying which images correspond to each particle if there are several images in the frame, and a sequence of several flashes can provide more reliable data. Figure 14 illustrates this method and shows images of olivine sand particles leaving a horizontal gas-blast nozzle at a mean speed of 30 m/s, produced with a four-flash sequence. The image was captured with a video camera and computer frame-grabber card synchronized with the flashes. This method provides very quick image acquisition, and since the image is already in digital form, particle velocity vectors can easily and quickly be determined by suitable image analysis software.

Fig. 14 Multiple flash image showing olivine sand particles leaving a horizontal gas-blast nozzle (at the left of the frame) and traveling to the right at a mean velocity of 30 ms. The particles were imaged with four short duration flashes at 0.2 ms intervals, and the frame was acquired with a video camera and computer image-grabber card. Courtesy of D.N. Allsopp and I.M. Hutchings, University of Cambridge, UK

Solid Particle Erosive Wear Testing

Ian M. Hutchings, University of Cambridge (England)

Data Analysis and Interpretation

Most erosion tests are performed to determine the rate of material removal, and the primary measurement of material loss is by weighing. Since the mass loss to be measured will usually be small, often less than 1 mg, it is very important that the balance used to weigh the specimen has adequate sensitivity and long-term stability. The latter point is important, since an erosion experiment may last for several hours or even days, and the measurement involves determining small changes in the mass of a specimen that has a much larger mass itself. The balance must be carefully zeroed before each weighing. Temperature control in the balance room may be necessary, and a “control” specimen similar in mass to the erosion specimen but not exposed to erosion may be useful to reduce random errors in weighing. A well-defined protocol must be adopted to clean the specimen (for example, with a clean, dry blast of compressed air) before each weighing. With such precautions, and by using a well-characterized erosion test operated under stable conditions, it is possible to achieve highly reproducible measurements of erosion rate. Figure 15(a)(a) shows data from a low carbon steel specimen eroded by three 100 g quantities of olivine sand in a gas-blast erosion test at 20 m/s and 30° impact angle. The plot is linear (with a regression coefficient of 0.9997), leading to high confidence in the measured erosion value, and in this case, a single test in which the specimen was exposed to 300 g of erodent would have yielded essentially the same erosion rate.

Fig. 15(a)

Fig. 15(b)

Typical erosion data from tests in a gas-blast rig with 300–425 μm olivine sand particles. (a) Mild steel specimen, 20 m/s, 30° impact angle. (b) Glass-bonded alumina ceramic specimen, 30 m/s, 90° impact angle. Courtesy of D.N. Allsopp and I.M. Hutchings, University of Cambridge, UK

In some circumstances, as just noted, materials may exhibit an incubation period of lower mass loss, or even mass gain, before steady state erosion occurs. Data showing this effect are illustrated in Fig. 15(b)(b) for a sintered alumina ceramic sample eroded at 30 m/s and 90 ° impact angle. Linear behavior was exhibited only after some 200 g of erodent had struck the specimen, but if a single measurement of mass loss had been made after exposure to, for example, 400 or even 800 g of erodent, the resulting value of mean erosion rate would not have accurately reflected the true steady state behavior of the sample. It is therefore essential that enough data are gathered from the sample to enable its steady state erosion behavior to be accurately assessed. This may involve preliminary testing to establish the exposure needed to achieve steady state conditions.

Although reproducibility within a single laboratory can be good, erosion test results obtained in different laboratories often show greater variability (Ref 22). The most important source of this is in the method and accuracy of measurement of particle velocity. Different methods of erosion testing may also introduce subtle, but important, differences in the particle motion. For example, there is evidence (Ref 23) that particle rotation plays an important role in explaining differences in erosion rate seen with gas-blast and rotating disk erosion testers (Ref 13).

Solid Particle Erosive Wear Testing

Ian M. Hutchings, University of Cambridge (England)

Data Analysis and Interpretation

Most erosion tests are performed to determine the rate of material removal, and the primary measurement of material loss is by weighing. Since the mass loss to be measured will usually be small, often less than 1 mg, it is very important that the balance used to weigh the specimen has adequate sensitivity and long-term stability. The latter point is important, since an erosion experiment may last for several hours or even days, and the measurement involves determining small changes in the mass of a specimen that has a much larger mass itself. The balance must be carefully zeroed before each weighing. Temperature control in the balance room may be necessary, and a “control” specimen similar in mass to the erosion specimen but not exposed to erosion may be useful to reduce random errors in weighing. A well-defined protocol must be adopted to clean the specimen (for example, with a clean, dry blast of compressed air) before each weighing. With such precautions, and by using a well-characterized erosion test operated under stable conditions, it is possible to achieve highly reproducible measurements of erosion rate. Figure 15(a)(a) shows data from a low carbon steel specimen eroded by three 100 g quantities of olivine sand in a gas-blast erosion test at 20 m/s and 30° impact angle. The plot is linear (with a regression coefficient of 0.9997), leading to high confidence in the measured erosion value, and in this case, a single test in which the specimen was exposed to 300 g of erodent would have yielded essentially the same erosion rate.

Fig. 15(a)

Sliding Contact Damage Testing

Introduction

SURFACE DAMAGE from sliding contact is related to the adhesion of the mating surfaces in contact. Adhesion is a major contributor to sliding resistance (friction) and can cause loss of material at the surface (i.e., wear) or surface damage without a loss of material at the surface (e.g., galling or scuffing). Adhesion is clearly demonstrated in sliding systems when a shaft seizes in a bearing.

The types of surface damage caused by sliding contact include adhesive wear, galling, and fretting. These three damage mechanisms are all influenced by adhesion of the mating surfaces, but these categories also reflect the nature of the surface damage and the type of sliding contact. For example, galling is considered a severe form of adhesive wear that occurs when two surfaces slide against each other at relatively low speeds and high loads. Fretting is also a special case of adhesive wear that occurs from oscillatory motion of relatively small amplitude.

The third damage type, adhesive wear, is a little more ambiguous. Often adhesive wear is defined by excluding other forms of wear. For example, if no abrasive substances are found, if the amplitude of sliding is greater than that in fretting, and if the rate of material loss is not governed by the principles of oxidation, adhesive wear is said to occur. In most cases, however, adhesive wear involves a transfer of material from one surface to another. Adhesive wear also occurs typically from the sliding contact of two surfaces, where interfaces in contact are made to slide and the locally adhered regions must separate, leaving transferred material. Breakout of this transferred material will form additional debris. This separation of material results in a wide range of wear rates, depending on the type of contact and the adhesion between the mating surfaces.

This article describes the methods for evaluation of surface damage caused by sliding contact. The first section, "Adhesive Wear," describes wear testing from long-distance sliding of nominally clean and dry (unlubricated) surfaces. This is followed by sections on test methods for galling and fretting wear, which are more unique forms of adhesive wear and surface damage. Additional information on sliding contact damage can be found in *Friction, Lubrication, and Wear Technology*, Volume 18 of *ASM Handbook*.

Sliding Contact Damage Testing

Adhesive Wear

W.A. Glaeser, Battelle

Adhesive wear typically occurs from sliding contact and is often manifested by a transfer of material between the contacting surfaces. As an example, Fig. 1 shows bronze transfer to a steel surface under sliding contact. Transfer can be minute and only visible in the microscope. Deformation wear, or plastic deformation of a thin surface layer during sliding contact, can also fall under the definition of adhesive wear. Adhesive wear can occur along with abrasive or chemical wear conditions. A transfer layer can build up on the harder surface of a sliding pair in the form of a mechanically mixed material (Ref 1). The transfer layer can also contain compacted wear debris. This layer will tend to break out and form wear debris.

Fig. 1 Bronze transfer to a steel surface after adhesive wear during sliding contact

Adhesive wear is a function of material combination, lubrication, and environment. For instance, austenitic stainless steels (AISI 304, 316, etc.) sliding against themselves are very likely to transfer and gall with severe surface damage. Other materials that are prone to adhesive wear include titanium, nickel, and zirconium. These materials make very poor unlubricated sliding pairs and can wear severely in adhesive mode even when lubricated. Other metals are apt to show adhesive wear when dry sliding contact occurs. Rubber tends to bond to smooth, dry surfaces (glass and polymers) by weak van der Waals forces and slide in a stick-slip mode that involves adhesion.

A gaseous environment is an important factor in promoting adhesive wear. The lack of oxygen and water vapor in a wear environment can aggravate adhesive wear. High vacuum conditions as found in outer space will make adhesive wear likely. Wear tests run in simulated space conditions (10^{-10}) torr reveal tendencies for various material combinations to develop adhesive wear in that environment (Ref 2).

Adhesive wear testing can be carried out with a variety of sliding contact systems. These include four-ball, block-on-ring, pin-on-disk, crossed cylinders, flat-on-flat, and disk machines. Examples are shown in Fig. 2.

Fig. 2 Diagrams of contact types for various test machines

Adhesive wear testing (sliding contact wear, no lubrication, slow motion, heavy load) may be chosen deliberately to investigate the resistance of a material to excessive wear and material transfer for a given application. Adhesive wear can also occur unexpectedly in a sliding contact test and should be recognized from the wear morphology. Typical wear scars associated with adhesive wear are shown in Fig. 3 and 4. Figure 4(a) shows a scanning electron microscope (SEM) micrograph of an embedded steel particle in an aluminum bearing surface; the particle is identified by the energy-dispersive x-ray spectrometry (EDX) pattern for iron shown in Fig. 4(b). The test can be designed to determine load capacity or effects of temperature on the onset of

adhesive wear. These data would then be used in the design of a bearing or gear system that could operate safely in the conditions simulated in the test.

Adhesive Wear Terms

Adhesive wear from sliding contact occurs from the transference of material from one surface to another due to a process of solid-phase welding (Ref 3). Particles that are removed from one surface are either permanently or temporarily attached to the other surface. There are also a number of other terms used to describe adhesive wear conditions, defined as follows.

Asperity refers to an isolated high spot in a given surface-roughness profile or a protuberance in the small-scale topographical irregularities of a solid surface.

Cold welding is the bonding of surface contact points after localized softening or melting caused by the frictional heating of contacting asperities during sliding.

Galling is a severe form of scuffing and is often associated with gross damage to the surfaces or failure. The usage of the term galling has different intents, and therefore its meaning must be ascertained from the specific context of the usage. Galling can be considered to be a severe form of adhesive wear, where cold welding of asperities causes heavy transfer of surface material.

Scuffing is the formation of severe scratches in the sliding direction. Also referred to as *scoring*, scuffing is considered a milder form of galling. It occurs when cold-welded junctions leave hardened protrusions, which tend to plow and scratch the softer mating surface much like abrasion.

Seizure is the stopping of relative motion as a result of interfacial friction or by gross surface welding. Seizure is an adhesive wear condition, where cold welding and material transfer result in loss of clearance between mating surfaces.

Wear coefficient is a nondimensional number that is typically defined as the proportionality k factor in the Archard wear formula (Ref 4):

$$W = kLD/H$$

where W is wear volume, L is normal load or force, D is distance of sliding, H is hardness, and k is wear coefficient.

This equation *assumes a linear process*; that is, wear is proportional to the applied load and distance, and inversely proportional to hardness. This equation is used extensively in developing data from wear tests. As an example, assume a pin-on-disk wear test is run using a copper pin. The operating conditions are as follows (a detailed description of the calculation and use of the wear coefficient can be found in Ref 5):

Normal load, N (kgf)	19.6 (2)
Disk speed, rpm	80
Track diameter, mm (in.)	32 (1.3)
Test duration, h	2
Pin weight loss, mg (grains)	23.1 (0.35)
Hardness of pin, HV	80
Density of copper, g/cm³ (lb/in.³)	8.9 (0.3)

The wear coefficient is calculated as follows:

$$W = 23.1 / 8.9 = 260 \text{ mm}^3$$

$$D = \pi \times 32 \times 80 \times 120 = 9.65 \times 10^5 \text{ mm}$$

$$k = 2.60 \times 80 / 9.65 \times 10^5 \times 2 = 1.08 \times 10^{-4}$$

Wear Life Determination. Assume a 10 mm diam copper pin electrode rides against a rotating steel surface running at 100 rpm and the allowable shortening of the pin due to wear is 10 mm. The pin load is 1 kg. The track diameter is 70 mm. What is the approximate life of the pin?

$$k = 1.08 \times 10^{-4}$$

$$\text{Pin wear volume} = \pi \times 100 \times 10 = kLD/H$$

$$D = (3.14 \times 10^3 \times 80) / 1.08 \times 10^{-4}$$

$$= 2.32 \times 10^9 \text{ mm}$$

$$D = \pi \times 70 \times 100 \times \text{time}$$

$$\text{Time} = 2.32 \times 10^9 / 2.2 \times 10^4$$

$$= 1.05 \times 10^5 \text{ min, or 1750 h}$$

Specific wear is similar to wear coefficient, except that the hardness factor is not included. This is often used when determining the wear properties of materials of similar hardness.

Sliding Contact Damage Testing

Selecting Standard Adhesive Wear Tests

Generally, adhesive wear testing involves sliding contact between unlubricated parts. For instance, such testing might help identify a material combination for a slow-moving brake or clutch system. Testing also could assist in operating a sleeve bearing in a high vacuum or oxygen and water-vapor-free environment. The purpose might be to estimate the wear life of such an operating system. The wear coefficient can be obtained from an appropriate wear test apparatus, and the maximum wear loss can be specified.

Simulation of Operating Conditions. In selecting a standard wear test, it is important that the test come close to simulating the prospective operating conditions of the mechanism of concern. The test should simulate the following conditions:

Contact
Point contact (ball-on-flat, ball-on-ball, crossed cylinders)
Line contact (roller-on-flat; roller-on-roller, axes parallel)
Flat-on-flat
Conforming (sleeve or journal bearing)
Velocity and load (high speed, low load; low speed, high load; low speed, low load)
Temperature
Vibration
Gaseous environment

Contact conditions can be selected from a number of wear test configurations as are shown in Fig. 2. These are taken from standard wear tests, and many can be found in ASTM specifications. The Amsler and Falex vee block represent line contact systems. Point contact is represented in pin-on-disk, crossed cylinders and four-ball tests, while flat-on-flat is shown in ring-on-ring, fretting bridge, and flat-on-flat configurations.

The following ASTM standards apply to the configurations shown in Fig. 2:

Test	ASTM No.	Title
Block-on-ring	G 77	Standard Test Method for Ranking Resistance of Materials to Sliding Wear, Using Block-on-Ring Test
Crossed cylinders	G 83	Standard Test Method for Wear Testing with a Crossed Cylinder Apparatus
Pin-on-disk	G 99	Standard Test Method for Wear Testing with a Pin-on-Disk Apparatus
Falex vee block	D 2670	Standard Test Method for Measuring Wear Properties of Fluid Lubricants (Falex Pin and Fee Block Method)
Four-ball	D 4172	Standard Test Method for Wear Preventive Characteristics of Lubrication Fluid (Four-Ball Method)

These standards are also available in Ref 6.

Temperature and Friction. Wear tests should have continuous measurement of both specimen temperature and friction. Temperature can be measured by a thermocouple inserted in the stationary specimen near the contact surface. A number of standard tests found in ASTM specifications have friction measuring devices included in the description of the apparatus.

Velocity and Load. Archard's equation, as a general model of wear, assumes that wear is proportional to the applied load and sliding distance. Distance and velocity are related, and so wear is also proportional to velocity by Archard's equation. Because it is desirable and economical to run wear tests as quickly as possible, both the load and the velocity can be increased to speed up a test. However, increasing these parameters will also increase the frictional heat generation and can lead to overheating. Overheating will change the wear mode (increasing galling and surface damage) and will result in misleading wear data. This is particularly important in wear testing of polymers. Polymers have low thermal conductivity and low melting and softening points compared to metals. Therefore, before embarking on a series of wear tests for statistical analysis, a set of preliminary tests should be run to establish the most efficient method, while keeping the wear mode as expected in the application.

Sliding Contact Damage Testing

Statistical Analysis of Wear Data

Data scatter is inherent in any testing, and using a statistical approach to the analysis of wear data is desirable. The method in ASTM G 83 (Ref 7) recommends sample sizes over 10. However, because 10 samples may not be possible owing to availability of samples and cost, ASTM G 83 does provide a method for analysis with sample sizes less than 10. The method uses the range of test results, where the range, R , is the difference between the highest and lowest test values for an initial set (2 to 10 samples) of measurements. For these small sample sizes, the standard deviation (s) can be calculated from the R value instead of from the root mean square value. For sample sizes from 2 to 10, the standard deviation is calculated from the range of the first few test results as follows:

$$s = R/d_2$$

where the values for d_2 are listed in Table 1 for different sample sizes.

Table 1 Factors for estimating standard deviation for sample sizes 10 and less

Sample size	d_2
2	1.128
3	1.693
4	2.059
5	2.326
6	2.534
7	2.704
8	2.847
9	2.970
10	3.078

Standard deviation $s = R/d_2$ for small sample size, where the range R is the difference between the highest and lowest test values for an initial set (2 to 10 samples) of measurements.

Source: Ref 7

Sample size (n) estimate can be derived from the relation:

$$n = 1.96 v/e^2$$

where v is the percent coefficient of variation = $(s/x) \times 100(\%)$, e is the sampling error, and x is the average for n tests. For example, if $s = 0.9$ mg and $x = 8$ mg, then the coefficient of variation is 11%. If an allowable sampling error (e) is selected as 10%, the sample size for 95% confidence limits should be $(1.9 \cdot 11/10)^2 = 5$.

The results of round-robin tests from several laboratories using block-on-ring test apparatus are reported in the appendix of ASTM G 77 (and also Ref 8). This reference shows the expected scatter in such wear tests.

Sliding Contact Damage Testing

Measuring Wear

A wear test should be run long enough to produce measurable wear. What constitutes measurable wear depends on the measuring method. The easiest way to determine measurable wear is to measure weight loss. This is also the coarsest method. Weight loss must be sufficient to be uninfluenced by condensed moisture, contaminants such as dust and oil, and minute transfer. Dimensional change is a more sensitive method. If a well-defined contact geometry is used such as ball-on-flat, ball-on-ball, or ring-on-flat, a scar length can be translated to volume loss. Equations for calculating wear volume from scar dimensions are shown in Fig. 5.

Fig. 5 Wear volume calculations for various shapes in contact with a flat surface. Source: Ref 9

Adhesive wear testing often involves some transfer from one surface to another. It is good practice to use two methods to measure wear: scar measurement and weight loss. The volumes determined from both methods can be compared, and effects of transfer, deformation, or pitting can be detected.

Galling

John H. Magee, Carpenter Specialty Alloys

Galling is a severe form of adhesive wear or surface damage that occurs when the surface of two components slide against each other at relatively low speeds and high loads. Lubricants or coatings, designed to reduce friction and prevent galling, are sometimes either ineffective or cannot be used due to product contamination concerns. Thus, gross surface damage occurs and is characterized by localized material transfer or removal. This gross surface damage is known as galling and can occur after just a few cycles of relative movement between the mating surfaces. Severe galling can cause seizure of these parts.

When galling takes place, mated surfaces typically show distinct junctions where severe plastic deformation has occurred (Fig. 6). These contact surfaces contain areas where asperities, or surface protrusions, from one surface have bonded together with those on the other surface. Under low stresses, these junctions are minute and break apart with movement resulting in adhesive wear debris. However, higher stresses produce much larger junctions and galling (Ref 11).

Fig. 6 Galling test button specimens, after testing. (a) No galling exhibited. (b) Severe galling. Source: Ref 10

Components that encounter galling conditions include threaded fasteners from a typical bolt/nut connection to large threaded tubular used in oil exploration. Valve parts have mating surfaces that are designed to encounter infrequent sliding movement. Galling damage on these surfaces affects valve performance, for example, leaking. The interface of a roller and side plate on a continuous chain-link conveyor belt can gall when lubrication is not used. This is an important design consideration for the conveyance of food and drug products because lubricants are prohibited due to contamination concerns (Ref 12).

The term galling has also been used to describe surface damage caused during metalworking. Metalworking processes include rolling, extrusion, wire drawing, deep drawing of sheet, and press-forming operations. Insufficient lubrication sometimes causes metal transfer and galling. In Japan, the term galling is used mainly to describe damage in sheet metalforming processes. Tests to characterize this gross surface damage usually involve production equipment or laboratory simulation of various plastic metalworking processes. Additional information can be found in Ref 13 and in *Friction, Lubrication, and Wear Technology*, Volume 18 of *ASM Handbook*.

This section describes in detail the ASTM G 98 button-on-block galling test. The purpose of this test is to rank material couples resistant to galling. Several variations of this test are also discussed that either increase the severity of the test or attempt to quantify the surface damage using profilometry. Data obtained from button-on-block testing are very useful in screening materials for prototype testing.

This section also describes prototype testing of threaded fasteners. Three threaded connection tests are discussed as examples of prototype tests designed to closely simulate field service for a specific application. This type of testing tends to be expensive, but vital before use in-service. Also, these tests can be used to solve a specific galling problem.

Sliding Contact Damage Testing

Button-on-Block Galling Test

In the 1950s, a simple button-on-block test was developed to evaluate the galling resistance of material couples (Ref 14). A specific version of this test is defined in ASTM G 98 (Ref 6, 15). This test is generally performed on bare metals; however, nonmetallics, coatings, solid lubricants, and surface-modified alloys can be tested as well.

The button-on-block test uses available laboratory equipment capable of maintaining a constant, compressive load between two flat surfaces. Both a Brinell hardness tester and a tension-test machine have been used to perform this test. Also, Falex Corporation, a designer and manufacturer of wear test equipment, has an apparatus specifically designed for button-on-block testing.

For bare metal evaluations, both galling specimens (button and block) are ground with abrasive paper or machine ground with an abrasive wheel. Both test surfaces should have a surface finish between 0.25 and 1.1 μm (10 and 45 $\mu\text{in.}$) for the arithmetic average surface roughness (R_a). Specimen flatness should be maintained at 0.33 mm/m (0.004 in./ft) to ensure 100% contact between the specimens during testing. The only critical dimension for either specimen is the button diameter that constitutes the contact area. The standard diameter is 13 mm (0.5 in.); however, other button diameters can be used. If a different diameter is used, then it should be reported since it can affect the test result. The block specimen must have sufficient area to accommodate at least one test; however, most users have found that a block length between 75 and 150 mm (3 and 6 in.) is ideal for this multiple sample test procedure. A reasonable block width is 19 mm (0.75 in.), and a minimum width of 17 mm (0.625 in.) is necessary for testing a 13 mm (0.5 in.) button. Thickness is not critical.

Immediately prior to testing, both galling specimens are cleaned to remove machinery oils and metallic particles. The following cleaning technique is suggested for metals in ASTM G 98. First, ultrasonically clean the button and block in trichloroethane. Then, use a methanol rinse to remove any traces of trichloroethane residue. Materials with open grains (powder metals or hardfaced alloys) must be dried to remove all traces of the cleaning solvent that may be entrapped in the material. Note that because the use of trichloroethane is being discouraged, any nonchlorinated, non-film-forming cleaning agent and solvent can be used as a substitute.

Once cleaned, the specimens are mounted in the loading device, and a light compressive load, for example, 110 N (25 lb), is applied to make sure the button is properly seated on the block. The button-on-block test setup is shown in Fig. 7. A selected compressive load is then placed on the button specimen. This results in a specific compressive stress for a 13 mm (0.5 in.) button sample. The selected load is dependent on educated judgment of the galling resistance of the mated couples, that is, light loads for poor galling resistance and heavy loads for excellent galling-resistant couples. Stress cannot exceed the compressive yield strength of the button material.

Fig. 7 Button-on-block galling test arrangement using a tension test machine. Source: Ref 16

Once loaded, the button is rotated slowly one revolution (360°) using either an open-end wrench, an adjustable wrench, or some other special tool for rotating by hand. A mechanized system may also be used to rotate one specimen relative to the other. The latter may allow torque measurement during testing. Actual sliding time should be between 3 and 20 s. Rotation direction, clockwise or counterclockwise, is not specified in ASTM G 98; however, it should be noted. The compressive load is then removed, and the mated surfaces are visually examined for galling. If specimens appear smooth and undamaged, to the unaided eye, the procedure is repeated at a higher load with an untested button specimen at a new location on the block sample. A burnished surface does not constitute a galled surface, nor does a scored surface. At least one of the contacting surfaces must exhibit torn metal. Galling has a distinct, macroscopic appearance with protrusions of metal above the original surface (Fig. 6).

If galling has occurred, testing is done at a lower load with a new button and block location to establish an interval between the highest nongalled stress and galled stress. This interval is used to define the threshold galling stress (TGS) and should be no greater than 34.5 MPa (5 ksi) for threshold stresses greater than 138 MPa (20 ksi) and no greater than 21 MPa (3 ksi) for threshold stresses of 138 MPa (20 ksi) or less. If galling is questionable or borderline, the test is repeated at a higher load to confirm the previous test result.

A typical series of galling tests is shown in Fig. 8. The reported TGS for the example is 34.5 MPa (4.5 ksi). Since the galling stress is based on the button diameter contact, the button impression on the block should be measured to determine if full contact occurred. At light loads, that may not be the case.

Fig. 8 Sequence of galling tests on block specimens. Source: Ref 17

Experience has shown that galling is most prevalent in sliding systems that are slow moving and operate intermittently. The movement of threaded components or the opening and closing of valve components are classic examples that this test method attempts to simulate. This test method has proved valuable in screening

materials for further prototypical testing that more closely simulates actual service conditions. The button and block material do not have to be the same material and hardness. When dissimilar, the selection of the button material should be the same as the sliding component being screened for the specific application. Table 2 lists threshold galling stress data for a variety of material couples using the button-on-block test. Additional data can be found in Ref 12. This test is most popular for galling-prone materials, such as stainless steels.

Multiple-Rotation Button-on-Block Testing. A modification of the standard single-rotation test is a multiple-rotation procedure. This change is designed to simulate the action of valve components. Also, repetitive sliding across the same surface results in galling at lower stress values. Thus, alloys or coatings with good-to-excellent galling resistance can be evaluated. This procedure is especially useful for screening materials for service conditions known to be severe. One example of this multiple procedure is the triple-rotation test where the button is turned counterclockwise (360°), clockwise (360°), and counterclockwise (360°). This modified button-on-block test has been used to evaluate stainless steels with improved galling resistance and for testing solid lubricants, such as molybdenum-disulfide. Table 3 compares various stainless steels using the single- and triple-rotation tests. Most stainless alloys tested have significantly lower TGS values using the triple-rotation tests. Those who use cobalt-base alloys, hardfaced materials, and metallic coatings, should consider a multiple-rotation type of test procedure.

Sliding Contact Damage Testing

Profilometry Evaluation of Galling Damage

Instead of a visual determination to assess galling damage, surface profilometry has been used. Several test procedures can be found in the literature (Ref 18, 19, 20). One example is a galling procedure that involves the twisting of a cylindrical 16 mm ($\frac{5}{8}$ in.) diameter pin against a block. Tests are performed at three selected loads. Cylindrical pins are slowly tested back and forth 10 times, through an arc of 120° at each load, using a new pin and block location per load. Scar profiles are measured using a profilometer. The difference in peak-to-valley amplitudes between the final roughness and the initial roughness (measured in microns) is plotted versus load. Resistance to galling is quantified by the degree of damage (measured in microns) as shown in Fig. 9. This 10-turn test is designed to evaluate excellent galling-resistant materials such as Stellite alloy No. 6, against other materials. Damage measured by this test typically does not reach the level of surface damage observed in the button-on-block test, that is, macroscopic protrusions of metal above the surface. Note that when stainless steels, such as type 304, 316, and 410, are evaluated self-mated using this procedure, severe damage occurs at relatively low loads with only one or two twists possible before total seizure.

Sliding Contact Damage Testing

Pin-on-Flat Galling Test

A second example of a procedure that uses surface profilometry to measure galling damage is the pin-on-flat test (Ref 21). In this test, a spherically tipped pin slides in a straight line against a flat surface (Fig. 10). Unlike the procedures previously discussed, there is no twisting action, nor is the button surface flat. A single pass with a distance of 40 mm (1.5 in.) is employed at a speed of 2 mm/s (0.8 in./s) and a load of 130 N (30 lb). Surface

finish of the specimens is produced by a 6 μm polish, and the pin diameter is 13 mm (0.5 in.). A pin tip radius of 25 mm (1 in.) is used. As with all galling evaluations discussed, specimens are thoroughly cleaned in an ultrasonic bath and then alcohol rinsed prior to testing.

Fig. 10 Pin-on-flat galling test configuration. Source: Ref 21

The topography of the damage is measured on the flat specimen by means of a stylus profilometer. A series of parallel traces at a spacing of approximately 0.3 mm (0.012 in.) is taken over the entire length of the track. The tracing direction is perpendicular to the sliding direction. Profile data are acquired in digital form, yielding a matrix of values that specify the elevation of points on the surface. A significant parameter, R_t , determined by these profilometry measurements, is the average maximum peak-to-valley distances (microns) for traces taken across the surface damage area. This parameter reflects the importance of the large protrusions and deep gouges that are characteristic of galling. Galling tendency of material is a function of the R_t value. Figure 11 plots damage severity (R_t) versus Knoop hardness for a wide variety of materials. The results show there is no overall correlation of damage severity with hardness. Aluminum-bronze, a known galling-resistant material, had no surface damage, while galling-prone alloys (such as type 410 stainless steel) had significant damage.

Sliding Contact Damage Testing

Threaded Connection Galling Tests

The galling tests described previously have been designed to rank material couples as a screening evaluation for prototype testing. Prototype tests tend to be more expensive and are designed for a specific application. Several threaded connections tests exemplify prototype testing (Ref 22, 23, 24). They are designed to determine if galling or seizure is a problem when inserting and removing threaded connections.

The first example involves evaluating a bolted joint design consisting of a socket head captive screw, a stainless flat washer, a helical lock washer, a stainless steel threaded insert, and a 19 mm ($\frac{3}{4}$ in.) thick drawer manifold to be bolted to the casting of a computer cabinet. In this test, each screw was inserted manually to minimize the chance of cross-threading, then torqued to a specified level, loosened, and removed completely. This sequence was repeated until galling or severe thread damage occurred. Variables evaluated were screw and insert material, molybdenum-disulfide lubricant, cadmium or nickel-plated screws, and thread type. The life-cycle design requirement was 900 cycles. Results of two of these tests can be found in Table 4.

Table 4 Sample results of two threaded connection galling tests

Test	Screw material	Insert material	Number of cycles to galling of threads
1	17-4 PH stainless steel, $\frac{3}{8}$ -24 in., UNF-3A, 41 HRC, nonlubricated	Type 303 stainless steel hole, $\frac{3}{8}$ -24 in., UNF-3B, 89 HRB	225
2	17-4 PH stainless steel, H1050, $\frac{3}{8}$-24 in., UNF-3A, 31 HRC, nonlubricated	Nitronic 60 hole, $\frac{3}{8}$-24 in., UNF-3B, 96 HRB	1000

Source: Ref 22

Other examples of prototype tests involve threaded tubular products for deep and gas wells. These connections are prone to galling due to the high torque applied in the makeup operation, that is, near the yield strength of some alloys. Prototype tests were developed to evaluate this condition especially to determine the effectiveness of lubricants or surface treatments. A bolt-nut test apparatus was designed to closely simulate a threaded tubular makeup (Fig. 12) (Ref 23). Lubricants were applied to bolts and nuts according to manufacturer directions, and the makeup torque was applied. The calculated surface stress on the threaded parts and bolt-to-washer mating parts corresponded to metal-to-metal seal parts in actual threads. The makeup speed was slow: 3 rpm. Torque and clamping force were measured. After each makeup and break operation, the threaded parts and bolt-to-washer mating parts were inspected for galling. The lubricant performance was evaluated principally by noting the number of makeup and break cycles until galling was first observed. Also, the variation of torque coefficient was monitored during the test. Typical results are shown in Table 5. Longer test times of 30 days in the fastened state prior to breakout have been evaluated by this method as have higher-temperature test conditions to simulate deep-well service.

Another oil-country threaded tubular test involves thick-walled, high-alloy products such as nonmagnetic drill collars. These 9 m (30 ft) long collars are prone to galling when their threaded box and pin connections are released after being joined with high makeup torques. These connections require an antigalling lubricant or surface treatment, such as ion implantation (Ref 25). To evaluate their effectiveness, make/break galling tests are performed. Full-size connections are machined with threads and lubricant/surface treatments are applied. A large torque machine then “makes” the connection at a specified torque, appropriate for the threaded tubular size, then breaks the connection. The breakout torque is recorded. This procedure is repeated several times (typically 5 to 10 times). Alignment of the box/pin connection is important to prevent galling. After testing, the threads and seal surfaces of the box and pin tubulars are examined for galling. Test results simply report whether or not galling occurred.

Sliding Contact Damage Testing

Prevention of Galling

Preventing galling damage is a critical part in applications where parts are sliding against each other under high loads and low speeds. It becomes a bigger issue when corrosion-resistant alloys, such as stainless steels, are required under nonlubrication conditions. Despite the best efforts of designers and users, occasions also arise when close clearances result in the contact and rubbing of components in rotating machinery. Of key importance in this case is the prevention of galling, because this can cause seizure and severe damage.

Galling can be resisted in several ways. For applications in which galling is of concern, the following guidelines should be considered:

- Lubricate where possible.
- Keep load, temperature, and speed as low as possible.
- Parts should be dimensionally tight with sufficient clearance.
- Use a surface finish between 0.25 and 1.75 μm (10 and 70 $\mu\text{in.}$) whenever possible (many stainless parts are electropolished, which can lead to galling and wear).
- Increase contact area, so that there is less stress on parts and less depth of wear.
- Carefully select alloys in unlubricated systems, or where insufficient lubrication may be present. Dissimilar-mated couples with high threshold galling stress values can be chosen or high work-hardening rate austenitic stainless alloys can be selected for improved adhesive and cavitation wear resistance and galling resistance.
- Use surface treatments, such as nitriding, carburizing, and hardface coating, or solid lubricant coatings (i.e., molybdenum disulfide or graphite).

Galling resistance can sometimes be aided by heat treating the opposing parts so that they have a hardness difference of at least 50 HB, which encourages wear of the softer material rather than adhesion and resultant part-to-part material transfer (Ref 26). Another method of discouraging galling is to machine grooves in one or both of the close-clearance components, so that as wear takes place the debris can collect somewhere other than at the close running clearance. This also promotes rapid heat transfer at rubbing interfaces, keeping parts cool and hard. Local surface temperatures can become very high even with grooving, because of the flash-temperature effect, but such temperatures decay in short distances and do not result in galling if surface heat removal is effective (Ref 27). Grooving the surfaces results in a design compromise, however. Although grooving reduces clearance leakage, it also reduces the beneficial shaft support provided by the Lomakin effect (Ref 28).

Finally, the test methods described in this article also provide a basis in the evaluation and prevention of galling. The general comparison of galling potential for different materials can be done by the measurement of the contact stress required for cold welding and subsequent material pullout for a material mated against itself. This is called threshold galling stress. A complete listing of threshold galling data for stainless steels can be found in Ref 12.

Sliding Contact Damage Testing

Fretting Wear

R.B. Waterhouse, University of Nottingham (United Kingdom)

Fretting refers to a special form of surface wear that occurs from small-amplitude tangential oscillations between two surfaces in contact. The amplitude (or magnitude) of the relative motion in fretting wear is what distinguishes it from other forms of wear during unidirectional and reciprocating sliding contact. In practical cases, fretting wear occurs from extremely small repetitive motion, usually less than 25 μ m peak-to-peak amplitude.

One immediate consequence of the fretting process in normal atmospheric conditions is the production of oxide debris; hence the terms “fretting wear” and “fretting corrosion” are used for this phenomenon. Surface damage from fretting begins with local adhesion between mating surfaces and progresses when adhered particles are removed from a surface. When adhered particles are removed from the surface, they may react with air or other corrosive environments. Affected surfaces show pits or grooves with surrounding corrosion products.

The movement is usually the result of external vibration, but movement also occurs from cyclic contact stresses (fatigue) between mated parts. This fact gives rise to another and usually more damaging aspect of fretting, namely the early initiation of fatigue cracks. This is termed *fretting fatigue* or *contact fatigue*. Fatigue cracks may also be initiated where the contacting surfaces are under a very heavy normal load or where there is a static tensile stress in one of the surfaces. There are cases where the movement is not simply tangential, but is complicated by the normal force also oscillating to the extent that the surfaces lose contact in each cycle. This leads to a hammering effect, which is termed *impact fatigue*. In this case, the phase relationship between the two motions can be an important factor. Fretting fatigue and the associated methods of testing are described in more detail in the article “Fretting Fatigue” in this Volume.

This section describes the testing and the special problems in the evaluation of fretting wear. For example, one important feature of fretting is that the debris or wear product remains between the surfaces and can play a role in the development of the process. This is particularly true where the surfaces are flat or conforming as in, for example, a hub on an axle. In many experimental investigations, the common type of geometry has been the sphere or cylinder on a flat.

Another problem in investigating fretting wear in the laboratory has been devising systems to produce controlled movement of extremely small amplitude and the ability to measure and monitor that amplitude in the very area of the contact. It follows, of course, that the amount of wear debris produced is also very small, which creates problems where quantitative measurements are required. This section describes how these problems have been overcome by investigators in the past.

Fretting Mechanism

In general, fretting occurs between two tight-fitting surfaces that are subjected to a cyclic, relative motion of extremely small amplitude. Although certain aspects of the mechanism of fretting are still not thoroughly understood, the fretting process is generally divided into the following three parts: initial conditions of surface adhesion, oscillation accompanied by the generation of debris, and fatigue and/or wear in the region of contact. Fretting wear occurs from repeated shear stresses that are generated by friction during small amplitude oscillatory motion or slip between two surfaces pressed together in intimate contact. In fretting, the term *slip* is used to denote small amplitude surface displacements, in contrast to *sliding*, which denotes macroscopic displacements. In many cases, slip only occurs over part of the contacting surfaces and is therefore referred to as partial slip. Fretting damage has been detected at amplitudes of less than 1 μm (Ref 29). As the amplitude is increased, the process resembles unidirectional or reciprocating sliding wear. The upper limit has been suggested as 75 μm (Ref 30), and Fig. 13 shows the volume of wear damage as a function of slip amplitude.

Fig. 13 Effect of slip amplitude on fretting damage of mild steel. Source: Ref 30

The severity of fretting damage is influenced by several factors including:

- *Contact Load*. As long as fretting amplitude is not reduced, fretting wear will increase linearly with increasing load.

- *Amplitude*. There appears to be no measurable amplitude below which fretting does not occur. However, if the contact conditions are such that deflection is only elastic, it is not likely that fretting damage will occur. Fretting wear loss increases with amplitude. The effect of amplitude can be linear, or there can be a threshold amplitude above which a rapid increase in wear occurs (Ref 30). The transition is not well established and probably depends on the geometry of the contact.
- *Frequency*. When fretting is measured in volume of material removed per unit sliding distance, there does not appear to be a frequency effect.
- *Number of Cycles*. An incubation period occurs during which fretting wear is negligible. After the incubation period, a steady-state wear rate is observed, and a more general surface roughening occurs as fretting continues.
- *Relative Humidity*. For materials that rust in air, fretting wear is higher in dry air than in saturated air.
- *Temperature*. The effect of elevated temperature on fretting depends on the oxidation characteristics of the material.

The effects of these factors are discussed in more detail in Ref 30 and 31. The article “Fretting Fatigue Testing” in this Volume also provides additional details on the effects of these test variables. The main focus of this section is on fretting test rigs and wear measurements.

Sliding Contact Damage Testing

Fretting Rigs

Experimental rigs for investigating fretting wear are either driven mechanically or by an electromagnetic vibrator. Figure 14 shows a mechanical rig driven by an electric motor with eccentric loading device. Other methods of producing small amplitude have been the use of rotating out-of-balance weights, but control here is much more difficult.

Fig. 14 Mechanical fretting wear rig. LVDT, linear variable differential transformer

A key factor in test rigs is the type of contact, because the ease with which debris can escape from the contact region influences the fretting process itself. For example, the escape of debris in the crossed-cylinder arrangement (Fig. 15) is greatly influenced by the direction of motion (Ref 32). The arrangement shown in Fig. 15(b) allows the debris to escape by being pushed out by the axial movement of the upper cylinder, leading to more frequent metal-to-metal contact and a higher wear rate than the arrangement shown in Fig. 15(a).

The original machine designed by Tomlinson (Fig. 16) comprised a long horizontal lever connected to an annular specimen in contact with a horizontal flat specimen with the load applied by a vertical rod through the center of the specimen passing through a hole in the flat specimen. By applying an oscillating circumferential motion to the end of the lever of, for example, 5 mm (0.2 in.), this would be reduced at the specimen to 5 μm (200 $\mu\text{in.}$) for a lever 1 m (3.28 ft) in length. More recent machines (e.g., Fig. 14) use an adjustable eccentric producing a horizontal movement that is transmitted via a sleeve bearing to the upper specimen, which can be a ball bearing, a spherical-ended slider, or a flat in contact with a fixed-flat specimen. The normal load can be

applied by a dead-weight system. It is advisable to have as few junctions as possible between the eccentric and the specimen since movement will be lost in them. The motor driving the eccentric should have sufficient power to force the movement, particularly as considerable changes in the coefficient of friction can occur during fretting. Amplitude is measured with a proximity or capacitance gage. Rotational movement can be measured with an optical lever.

In experimental investigations, the ease and cost of preparing specimens are significant factors, and the crossed-cylinder arrangement (Fig. 15) is one of the most convenient. However, as previously noted, the ease with which debris escapes can influence results. In this regard, Tomlinson's original design of an apparatus with torsional vibration of annulus on flat has much to commend it because no part of the contacting surfaces becomes exposed, and, for debris to escape, it must move at right angles to the direction of motion. A further slight advantage is that the amplitude of slip has a small variation from the inner to the outer edge and can therefore be used to investigate the effect of amplitude in one test. With flat contact surfaces, however, the initiation and development of areas of wear damage are sporadic no matter how carefully the surfaces are prepared and the alignment controlled. Contact pressure is usually expressed as the nominal value calculated from the apparent area of contact and the applied load.

Friction Monitoring. It is usually necessary to monitor the friction during a test. This can be accomplished by strain gaging the connecting rod to the specimen to measure the tangential force. Such an arrangement can be made more sensitive by using a tubular member. This arrangement can also provide cooling if the fretting couple is to be enclosed in a furnace.

Frequency is controlled by driving the device with a variable-speed dc motor. Using electromagnetic vibrators requires them to be of sufficient power for the purpose and has the same problems in transmitting the movement to the fretting specimens. For low frequencies of less than 5 Hz, mechanical machines have the advantage, but for higher frequencies even up to kHz, electromagnetic rigs (Fig. 14) are recommended. For very high frequencies and small fretting amplitude piezoelectric rigs have been used (Ref 33). Other methods of producing the small-amplitude movement have been to use rotating out-of-balance weights, but control here is much more difficult.

The environment is an important feature of fretting testing. Humidity can have a marked effect, particularly with reactive materials such as aluminum and titanium, and it should be controlled by enclosing the fretting couple in a suitable container. This can also be used to provide other environments such as argon or carbon dioxide. More specialized environments such as high temperature, low temperature, seawater or body fluids, and even vacuum require more complicated equipment, but have all been successfully accomplished and are documented in the literature. The author's most difficult task was to study fretting of stainless steels in an

atmosphere of carbon dioxide at 4050 kPa (40 atm) pressure and 600 °C (1110 °F). Descriptions of this rig and others can be found in Ref 29 and 30.

Sliding Contact Damage Testing

Measurement of Fretting Wear

The amount of material removed in fretting wear is extremely small, particularly in the partial slip regime, so determining it by loss in weight of the specimen is impractical. The minute amount of debris, usually an oxide, is difficult to remove for the purpose of weighing. The debris is often compacted. On steel, it is the α ferric oxide, which is red in color but, when compacted, is blackish gray. It is the mineral hematite, which is black in massive form but red when powdered.

It is much more satisfactory to attempt to measure the volume of material removed. One of the earliest methods was to measure the area of damage (A) and then to find the depth by carefully machining the surface until the last trace of damage had just disappeared and to estimate the depth (d) from the weight of material machined off. The product Ad was thus a measure of the volume of material lost as wear. Nowadays computerized profilometers are available that can survey the scar and produce a view of it as in Fig. 17. The computer can also provide information on the volume below the datum of the original surface as well as material above the datum, since often there is local plastic deformation arising from the fretting action. It is usual to express the wear as the difference between these two figures.
